Chapter 1

Structural Health Monitoring—An Introduction and Definitions

Christian Boller

Saarland University & Fraunhofer Institute for Non-Destructive Testing, Saarbrücken, Germany (and formerly of The University of Sheffield, Sheffield, UK)

1 BACKGROUND

Structural health monitoring (SHM) is a combination of words that has emerged around the late 1980s. It is very much associated with what we are accustomed with in the classical medical and health sector, combines it possibly with what we are accustomed to in control (monitoring) and links it to what we are truly considering here: engineering structures. SHM (although not expressed like this at the time) possibly dates back much earlier than the 1980s when the combination of words was created. Indeed, it may date back to the origins of structural engineering.

Engineering structures are designed to be safe. The difficulty one trading in this regard is the desire to construct something for a specific purpose out of a material of which one can never know enough in terms of the material's properties as well as the environment the structure is going to operate in. We are happy with the knowledge we can gain in this regard and all we do not know needs to be covered by a safety factor that we have to assume at best guess. The less we know about the operational conditions of a structure and the performance of materials and structures, the higher the safety factor will have to be. This is the risk and dilemma structural engineering is in.

Engineering structures are designed to withstand loads. These loads can be mechanical loads of a static and/or dynamic nature. Loads can, however, also be of an environmental nature such as temperature, humidity or chemical, and again the structure can be exposed to these loads in either a static or even very short term and thus dynamic condition such as a thermo shock. Knowledge of loads applied to a structure has to come from experience. This experience has been either gathered on similar structures in the past or from assumptions. The safest

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

way to design a structure is to design it against an ultimate design limit load, which is the maximum load ever experienced with such a structure added by a safety margin. Designing a structure against this load, however, makes the structure heavy. Often, the maximum load of a structure may just occur once in the structure's life, if ever at all. In that case one may start to question the extreme safety built in, specifically if the maximum load applied would not result in any observable damage.

Loads applied to a structure are the reason for structural deterioration and hence resulting damage. This damage may be generated at a microscopic level and may gradually progress until it becomes observable and critical. Trading with this observability and criticality is the art of damage tolerant design, which has allowed structures to become lighter weight. The way the damage accumulates is of a fairly random nature, and scatter of a factor of 2 in operational life is absolutely normal. This requires a careful means and procedure of inspection at well-defined intervals.

The booming development of sensing technology in terms of sensors decreasing in size and cost, and the combination with microprocessors with increasing power and enhanced materials design and manufacturing in terms of functional materials or even electronic textiles have opened avenues in merging structural design and maintenance with those advanced sensing, signal processing, and materials manufacturing technologies. Taking advantage of this lateral integration is what SHM is about. The central set of questions in this field is therefore

Without compromising safety, could we make our structures

- better available
- lighter weight
- more cost efficient and
- more reliable

by making sensors (and possibly also actuators) to become an integral part of the structure?

What about

- looking at advanced cheap sensors, which are continuously becoming
  - smaller
  - lighter and
  - cheaper?
- making the sensors an integral part of the structural component?
- combining the sensors through
  - advanced microelectronics and possibly
  - wireless technology with
  - advanced microprocessors and
  - advanced signal processing?

If one would try to give an answer to all these, the answer could somehow result in SHM, and a definition for SHM could possibly be the following.

SHM is the integration of sensing and possibly also actuation devices to allow the loading and damaging conditions of a structure to be recorded, analyzed, localized, and predicted in a way that nondestructive testing (NDT) becomes an integral part of the structure and a material.

As a consequence, SHM requires to look at loads as well as damage monitoring with respect to their sensing and assessment algorithms and needs to get those merged in a holistic process such that the health of a structure can be accompanied during the complete life cycle process of the structure considered. How this has emerged and could be further achieved is described as the holistic process in the following articles with further details to be found throughout the wide range of articles being provided throughout this encyclopedia.

2 LOADS MONITORING

Design of engineering structures is at least based on static strength. This is the way structures have been designed since the past mainly by applying a test load that exceeds the maximum operational load by a safety factor to be defined or by designing the structure against the expected maximum load times the safety factor, or possibly both. The problem of fatigue in structures became apparent with the upcoming railway industry in the second half of the nineteenth century. August Wöhler [1] was possibly the first to determine that components—and in his case railway axles—would fracture at loads much lower than the ultimate tensile load if the components were exposed to a repetitive loading. Wöhler furthermore determined that the number of cycles to fracture is related to the level of the repetitive load being applied. This resulted in the effect of materials fatigue to be established and has been mainly described in the form of a fatigue–life curve also often denominated as S–N or Wöhler curve. S–N curves were

and are therefore used to determine the allowable loads of railway axles compared to static loads, which were now named fatigue loads. This principle is well applicable because fatigue loads on railway axles are fairly constant over the life cycle and hence can be considered constant amplitude. Wöhler's principle was shortly expanded to other railway applications such as frames or boogies of railway engines and carriages as well as even railway steel bridges.

Constant amplitude loading is not the way structures are conventionally loaded while operating in service. Most of them are more loaded in accordance to a randomized nature where small loads follow a high load or vice versa such as the different time domain signals shown in Figure 1. Ernst Gaßner [2] was possibly the first to recognize in the 1930s that service loading of structures had to be treated different from constant amplitude loading or in other words constant amplitude loading to be a specific condition within the frame of in-service loading. Fatigue–life curves for in-service loading were therefore defined in terms of the maximum load applied in the in-service spectrum versus the number of loading cycles sustained until fracture. Palmgren [3] from Sweden published his damage accumulation rule (published later in English by Miner [4]) seeming initially trivial for constant amplitude loading, which however became not only more attractive to be applied for randomized in-service loading but also an issue for wide scientific discussion until even today.

Parallel to fatigue analysis, the other wide area of fracture mechanics was initiated during the early twentieth century, mainly driven by people such as Griffith [5] initially. Fracture mechanics was further developed since that time and specifically during WW2, which led to an enhanced understanding of the fatigue process. Furthermore, the combination of fatigue loading and fracture mechanics allowed the new principle of damage tolerant design to be established. Damage tolerant design as opposed to safe life design, which is shown in Figure 2, is a principle that allows damages such as cracks to be present in a structure as long as the overall integrity of the structure is not compromised. This is achieved by either monitoring slow crack growth through well-defined inspection intervals or building in load redundancy in a way such that when a component is due to fracture another component is still able to take over the load without compromising the overall structure itself. Considering damage tolerance in structures has allowed those structures to become much more lighter weight when compared to the traditional safe life design. Damage tolerant design has therefore become mainly the standard for designing civil aviation metallic structures nowadays, with military and even jet engine structures to gradually move towards those design principles as well. However, there are also other areas that have taken advantage of the damage tolerance principle such as marine and offshore structures.

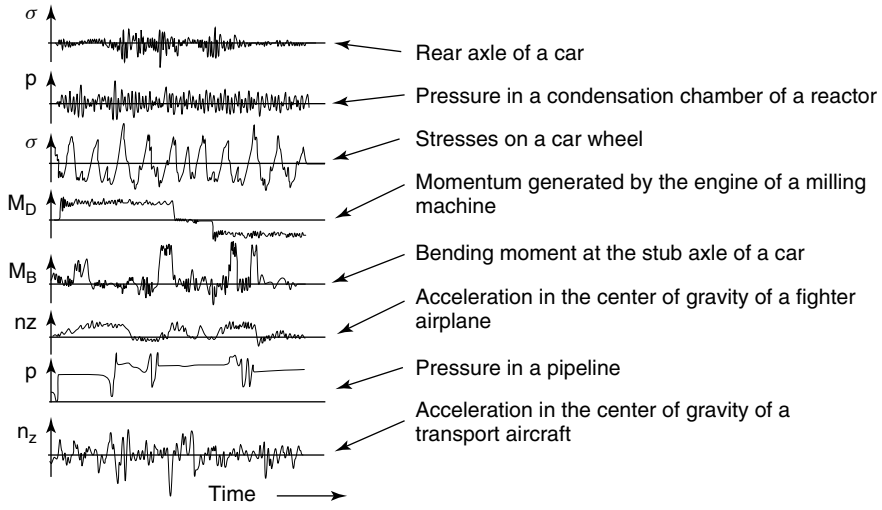

Figure 1. Time domain signals for different in-service random loads.

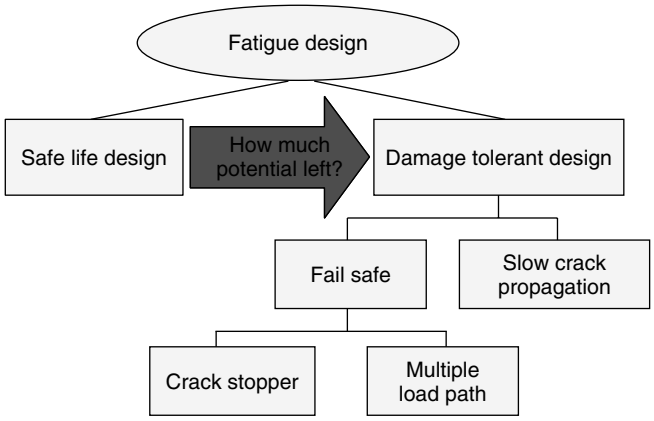

Figure 2. Principles in engineering structural design.

Aircraft structures are hence designed to be either safe life or damage tolerant for a service loading spectrum to be defined during the design of the aircraft. Safe life means that the structure is not allowed to fracture for the loading spectrum defined and up to a given service life. Irrespective of its condition, the component will have to be replaced by a new component after its service life achievement. Damage tolerance is however the alternative to safe life design where a crack is allowed to grow in the structure over a significantly long period of time such that it can be detected during that period safely and does not lead to a critical hazard.

The first aircraft to possibly ever seriously consider damage tolerant design was the De Havilland Comet designed and built in the early 1950s, which was first flown in 1952. This aircraft was possibly the ever most challenging aircraft built in civil aviation history. The design did not just include damage tolerance but also a pressurized fuselage as well as jet engines integrated into the wing. This extreme innovation push however led to some serious crashes in 1953/1954, which resulted from a crack having generated from one of the corner of the windows where the crack had initiated due to underestimation of the window corners' notch combined with the continuous pressurization cycles during each flight. The consequences of this accident were immediate and led to

- the shape of the windows being near to rectangular at the time to be changed to the more ovoid shape we have nowadays;
- the major airframe fatigue test (MAFT) to be introduced where a full-scale aircraft structure is tested under in-service loading conditions on the ground and this being ahead of the so-called fleet leader (the aircraft in a fleet having the most flight cycles accumulated) in terms of flight cycles; and
- operational loads monitoring devices to be considered for aircraft in general.

While the former two consequences can be attributed to structural design, the latter can be clearly attributed to SHM. Although nobody was using the expression of SHM at the time, it was clearly shown that a more precise knowledge of operational loads would be highly essential. This led to the UK Royal Air Force to design a mechanical device that was integrated around the center of gravity of fighter airplanes in the late 1950s and was based on a set of accelerometers being set at different acceleration thresholds (Figure 3). Whenever the aircraft would exceed one of the thresholds, the counter would count those as a measure of exceedances. Hence the numbers being recorded by the different accelerometers would represent the actual load spectrum of the aircraft at the time of recording. The following formula for calculating a flight (or better fatigue) index was introduced

$$\begin{aligned}\text{Flight index } (FI) = K_2 \times S_1 \times (&2.31A + 0.03B \\ &+ 0.001C + 0.001D + 0.28E \\ &+ 3.43F + 10.36G + 18.63H \\ &+ 1.16WL) \end{aligned} \quad (1)$$

Figure 3. Acceleration exceedance monitoring system introduced in the Royal Air Force in the 1950s.

where K_2, S_1, and WL denote the mission coefficient, stores configuration coefficient and landing coefficient, respectively, while A to H represents the readings from the different accelerometers.

Gaßner, who had introduced the eight-step block program sequence as a first step in in-service load sequence analysis [6], continued to determine in-service load sequences for automobiles where a load cycle counting system was developed as shown in Figure 4. Tests performed with this system on various types of roads resulted in a variety of load spectra as shown in Figure 5. This further led to the development of a variety of standard load sequences such as the Gauß and linear distribution spectrum for random loading [7].

Further development was ongoing into a variety of random load sequences such as for transport aircraft (Transport WIng STandard (TWIST)) [9], fighter aircraft (FALSTAFF) [10], helicopters (HELIX FELIX) [11], wind energy structures (WISPER) [12], and possibly much more. Figure 6 shows the TWIST random load sequence for the wing attachment of a transport aircraft as an example. It can be seen that this load sequence is not just composed of a randomization of loads but also of a randomization of different flight types.

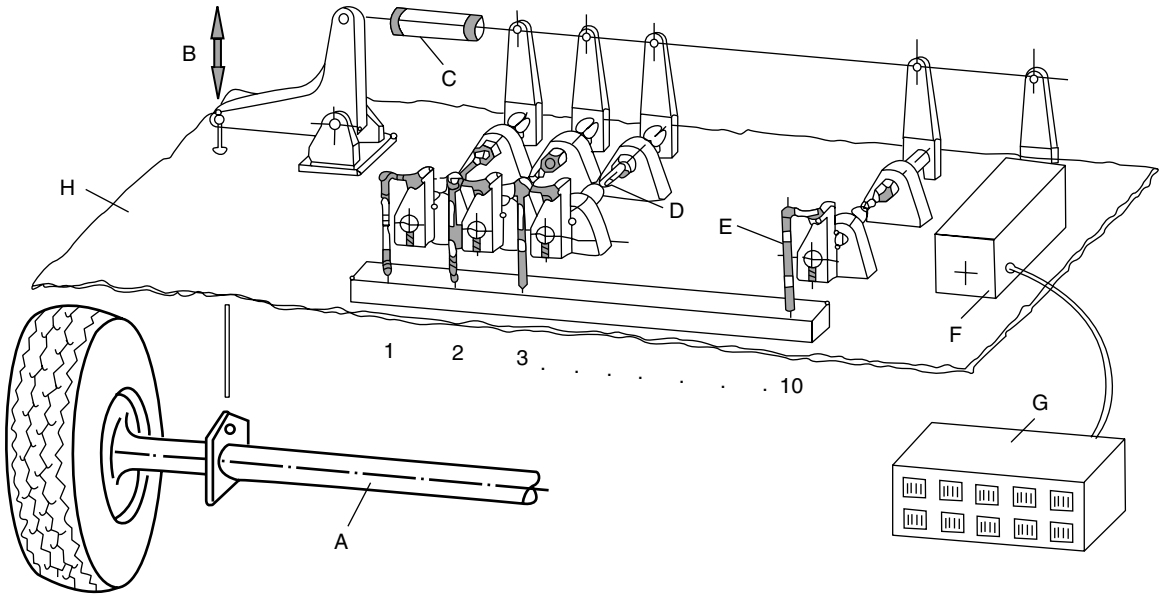

Figure 4. Gaßner's loads monitoring system used in the late 1950s and early 1960s for monitoring road transport load sequences [8].

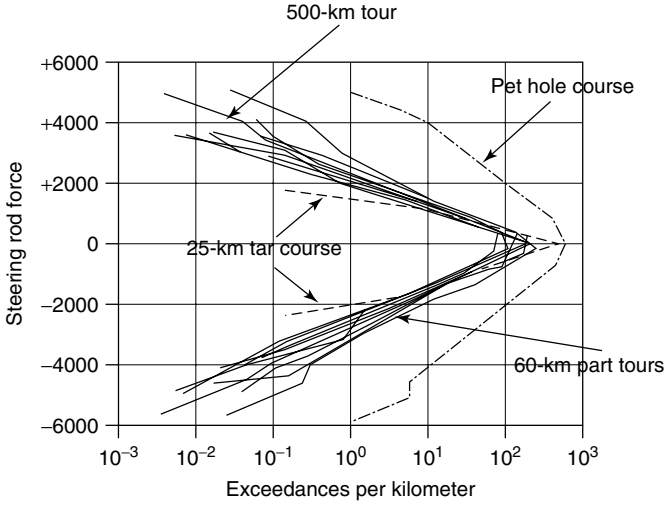

Figure 5. Different road transport load sequences for different road conditions [7].

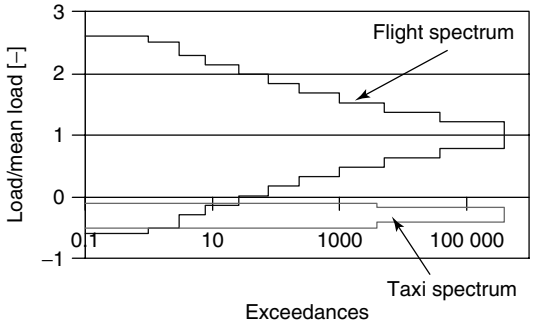

Flight type	Number of flights	Cycles per step										Cycles per flight
		I	II	III	IV	V	VI	VII	VIII	IX	X	
A	1	1	1	1	4	8	18	64	112	391	900	1500

Figure 6. TWIST random load spectrum [9].

What can be concluded from that development in the 1930s to 1980s is that the need for better understanding the true operational loads has been essential. Besides developing standard load sequences, this has been gradually achieved through implementing load monitoring sensors into structures. Aviation has been again a driver in getting those loads monitoring systems integrated. Besides the Royal Air Force (RAF) accelerometer system mentioned above, the Panavia Tornado fighter airplane was possibly one of the first ones getting an Operational Loads Monitoring System called *OLMOS* onboard [13] (*see also*

Usage Management of Military Aircraft Structures). To minimize the number of additional sensors to be implemented, this system was mainly based on monitoring flight parameters only and constructing the operational loads sequence from these with a few strain gauges to be implemented for verification. The system allows overloads to be well detected as well as the usage of the different aircraft in a fleet in general. However, it lacks in allowing the load sequence detected to be used for any further more detailed fatigue analysis. A lot of discussion centered around the question if either flight parameters or strain gauge based monitoring would be the better solution for operational loads monitoring. The Canadian Air Force introduced a strain gauge based system in some of their CF-18 [14], which was then explored by others as well. This discussion culminated in the operational loads monitoring system used on the Eurofighter Typhoon where a flight parameter as well as a strain gauge based operational loads monitoring system has been implemented [15]. This is currently possibly the most advanced operational loads monitoring system being available on an aircraft in general. Similar activities were ongoing on the civil aviation side with an Airbus A320 [16], which never matured due to lack of clarity regarding the operational benefits to be achieved. However, with aircraft nowadays increasingly flying into smaller airports with partially severe weather conditions and possibly associated with fairly short runways and full payload has led to an enhanced probability of hard landings, which resulted in the development of hard landing monitoring devices as described in **Video Landing Parameter Surveys**; **Landing Gear**.

What can be summarized from all this is that all aircraft structures are designed such that they are able to withstand damage resulting from fatigue and static loads as long as the loads do not exceed the design loads. This has been and is validated by numeric analysis and possibly also by destructive materials and component testing, the latter even exceeding to a full-scale fatigue test. As for mechanical loading, a similar design philosophy also applies with regard to impact or environmental damage (i.e., corrosion). In this case, the operational loads would have to be determined in terms of distributions of possible impact loads or sequences of temperature or humidity at different locations around the structure, which is indeed done in the context of monitoring civil engineering structures (*see* **The Influence of Environmental Factors**), electronic systems (*see* **Health Monitoring, Diagnostics, and Prognostics of Avionic Systems**), or mechanical systems such as jet engines (*see* **Monitoring of Aircraft Engines**).

The big advantage of monitoring mechanical loads or even loads in general is not just limited to detecting loads exceeding the design limits but also to feed the information recorded back into the different models of structural assessment being used. Since most of the recent structures are designed on the basis of a digital model using Computer Aided Design (CAD), Finite Element Method (FEM), and Computer Aided Manufacturing (CAM) or Computer Aided Engineering (CAE) in general, where a wide gallery of software tools is provided, it becomes more and more easy to simulate the behavior of structures mainly online. This simulation allows to predict where damage might be most likely to accumulate and finally to occur in form of a crack, corrosion, a delamination or any other sort of deterioration. This is therefore the transition from loads to damage or from new to aged as one may express this in structural terms. A new structure is by definition designed to be damage free as long as no unpredictable accident occurs and will have to face damage once the structure ages. Since structures are designed for a finite life damage is likely to occur beyond that life, which is a consequence of the randomness of damage initiation and the resulting scatter, and can lead to damage to occur twice as late than initially predicted. This is the reason why a large number of structures is still used far beyond their design life.

A good example with regard to aging structures is aircraft. Aircraft are normally considered as aging when they are 15 years old or more. Damage resulting from aging of an aircraft does not necessarily have to result at the locations where this has been expected to happen, which is a consequence of a certain randomness of the damaging process and the scatter in materials' properties. This randomness is also the reason why structural inspections are scheduled at least half of an expected residual life or even less.

Many of the aircraft designed and built in the past or today are conceived to be still used for many decades in the future. Although their design life is definite, they are often used much longer and possibly even more extensive than this was initially planned. Figure 7 gives an overview of some

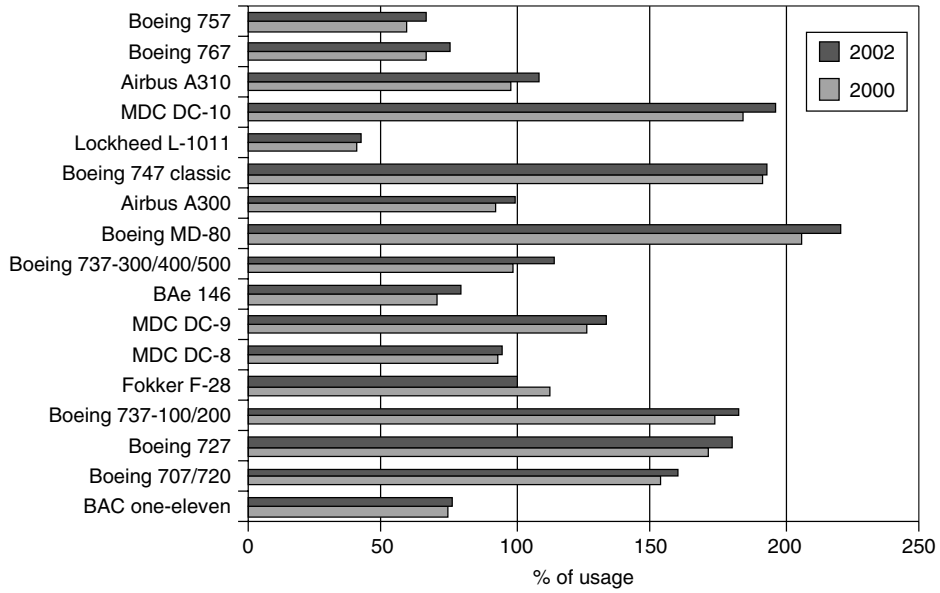

Figure 7. Change of usage of fleet leaders between 2000 and 2002 for different western built aircraft.

typical aircraft types built in the western world and the usage of their fleet leader (the aircraft having been flown most within the fleet) recorded in two different years. It can be observed that for many of the aircraft types the original design life has been exceeded and that there seems to be a trend in continuously expanding the usage of these aircraft in case the demand for aircraft and, thus, air transportation increases. Another extreme example is the US Air Force B-52 bomber, which was designed and built just after WW2 and of which the US Air Force does not plan to take out of service before the year 2045. A set of further examples from the defense environment can be found in Figure 8.

Aircraft operational lives of around a century can hardly avoid a structure to be deteriorated by environmental hazards or threats, nor to be used in a way different from the one it was originally designed for. Examples include conversions from passenger to cargo aircraft or different weapon loads due to different flight missions of a fighter airplane. In any of the cases, additional information is required that will allow the operational conditions such as the loads that the structure has been exposed to and the resulting damage to be known. Since the structure may have been designed quite far in the past where design tools were significantly different from those used today, a conversion into design tools of the twenty-first century may be required as well, such that the structure's integrity can be managed. Looking therefore at the management of the structural integrity of old engineering structures in terms of keeping them "ageless" poses a variety of questions as follows:

- How to handle structures designed in the past in terms of digital modeling?
- What are the load spectra the structure is currently exposed to?
- How to know the degree of damage of an aging structure?
- Where is damage likely to occur on the structure?
- When and where will it be useful to implement sensors on the structure?

An answer to these different questions is given in a first approach below and in further details within various articles of this encyclopedia.

2.1 Digital modeling

In the light of a younger generation taking over in designing engineering structures, the availability of CAD and finite element (FE) models becomes a must. This infrastructure does not exist per se for aircraft, trains, ships, automobiles, buildings, or

Aircraft type	First service flight	Total in service	Average age

Figure 8. Aging military aircraft overview.

bridges having been designed 20 years or more in the past. This infrastructure therefore needs to be generated. Means in that regard have been provided in doing such a conversion from solid-state hardware to a digital model by using a laser scanning device. A laser-based projector produces a light stripe on an object where the light stripe is then recorded by a camera and converted into a digital point cloud that can be recorded as an initial digital information. This point cloud is then further converted into a polygon mesh, from there into Non-Uniform Rational B-Spline (NURBS) patches and finally into the desired CAD model. Scanning can be either done manually or automatically by using a robot arm. The digital model up to a coarse-meshed FE model is thus obtained.

2.2 Operational loads

Monitoring operational loads can become a highly complex subject. It results from the multitude of different loads that can apply and the reactions they can have with respect to their variation in height and occurrence. An additional problem in simulation exists with respect to the correct simulation of the reaction forces, i.e., can the structure be rigidly clamped or will a spring and possibly even damper reaction be more appropriate? To find this out requires an iteration process between loads simulation and experimental verification to be initiated. Analysis of the loading influence on the structure can now be done for each of the loads individually with the resulting stress distribution for the load case being obtained from superposition and the resulting figure showing the distribution of stresses and strains. The stress and strain distribution calculated will allow in a first instance to identify the locations where sensors may be placed best to identify loads applied to the structure. Since loading of a structure is however often not solely composed of a single set of loads only but is rather the result of an accumulation of different loads, the analysis done for a single load needs to be performed for all the loads applied on the structure followed by a superposition of the stress analysis results of all these single loading cases, which finally results in the complete picture of the stress distribution for one of the structure's specific loading combinations. This procedure demonstrates the complexity of the loads monitoring and simulation problem and requires a clear strategic approach to be determined when considering the application of loads monitoring for structures of higher complexity such as aircraft.

To experimentally verify the stress distribution simulated requires a loads monitoring system that can be equipped to the structure considered. The

Figure 9. 4-channel loads monitoring system MATCH-II-4 by SWIFT GmbH based on electrical strain gauge monitoring.

system must be relatively small, light weight, robust, and service proven. Examples of such systems being commercially available could be the MATCH-II-4 box from SWIFT GmbH in Germany [17], which is a 4-channel digital data recorder shown in Figure 9. It is designed as a small solid box of 400 g in mass that can be attached to a structure easily and contains a power supply, a CPU with external digital I/O, and a communication interface. The CPU has a 16-bit microprocessor and a Flash-ROM 256 kB memory, which can be reprogramed and stores data up to 864 kB. The I/O can communicate with a standard PC via a RS232C interface. Different types of these boxes can be linked to a network that allows for a multichannel recording of structures of higher complexity. A remote link is further provided as an option. There are larger systems of this kind with airworthiness certification made available for helicopter monitoring where further details can be found in [17].

Different options of strain measurement exist where electrical strain gauges are devices that are very well established for loads measurement. However, each of the sensors has to be connected by individual wires, which make the situation highly complex in case a variety of sensors is involved. A much more elegant and thus smarter solution would exist with the application of optical fiber Bragg grating sensors where virtually tens and hundreds of sensors could be attached to in accordance to the locations worth to be monitored on the structure considered. All sensors could be virtually connected with one single fiber and could be recorded individually by one single piece of equipment. However, such a type of loads monitoring equipment of adequate size and of required cost currently does not exist but may be certainly considerable for larger structures with a high asset value such as aircraft where either cost and/or size of the SHM system may not have such a dominant impact.

2.3 Damage accumulation

The ability to monitor loads also allows load sequences to be monitored, which is the sequence of loads over time and is mainly characterized by peaks and troughs. As shown in Figure 10, each loading cycle can be characterized in terms of load amplitude and mean load in accordance to the rainflow cycle counting method, and the number of cycles with a specific mean load versus load amplitude characteristic is stored in a rainflow matrix. A rainflow matrix can therefore be used to characterize a specific maneuver or mission such as the flight mission of a specific aircraft. The rainflow matrix shown in the lower left part of Figure 10 is an output from the software provided with the SWIFT MATCH-II-4 box.

The availability of an FE loads model and a load spectrum in terms of a rainflow matrix now allows a fatigue–life evaluation analysis to be performed. Knowing the stress distribution through the FE analysis enables fatigue damage accumulation to be calculated at virtually any location of the structure considered. FE fatigue from nCode [18] is a tool that reads the model and results from an FE code, and writes the fatigue results to a postprocessor. Measured or synthesized load data from a rainflow matrix is imported. A database of around 200 standard material fatigue properties or the provision of own fatigue data allows a fatigue analysis to be performed for each loading cycle of the spectrum and for each single element of the structure. Either stress–life or strain–life methods can be used. Damage for each loading cycle and element is accumulated over the load spectrum and finally leads to a picture shown on the lower right-hand side of Figure 10.

The damage distribution figure can so far only be considered as a qualitative one should the component to be analyzed be an aging component where only limited knowledge of the past would be available. The information being available includes the material type, the material properties, the current load distribution, and the current load spectrum. From this knowledge, an experimental quantification could now

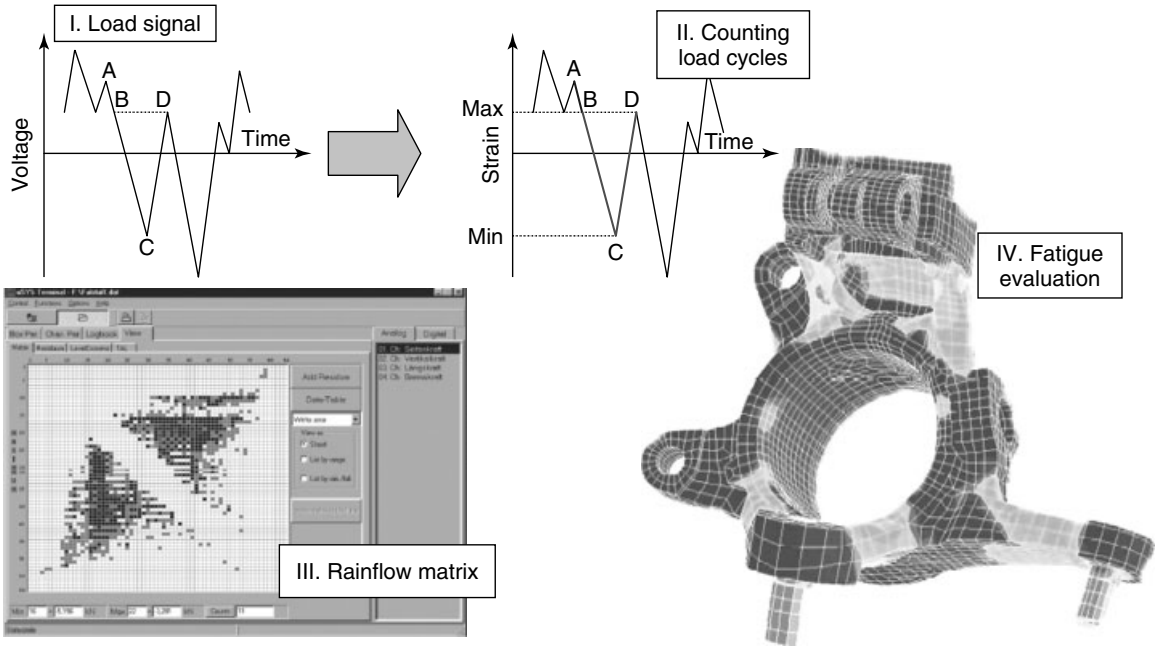

Figure 10. Damage accumulation calculation based on loads monitoring and an FE model.

be made in accordance to the procedure schematically sketched in Figure 11 by cutting off material from the component considered and exposing this material to a fatigue test. The fatigue–life obtained from these tests is the residual fatigue–life of the component at the location where the material was taken from. The amount of damage could therefore be determined as the ratio $(N_f - N_r)N_f$, where N_f is the number of cycles to failure for the pristine material that can be obtained from handbooks and N_r is the number of cycles determined in the experiment. To further prove this concept, more material specimens could be taken for fatigue testing from other locations of the component where the amount of damage has been estimated to be higher.

3 DAMAGE MONITORING

All what has been discussed so far could be solved with loads monitoring only. The other major element of SHM is damage monitoring where different other disciplines come into play. One of them is structural dynamics where the area of condition monitoring has

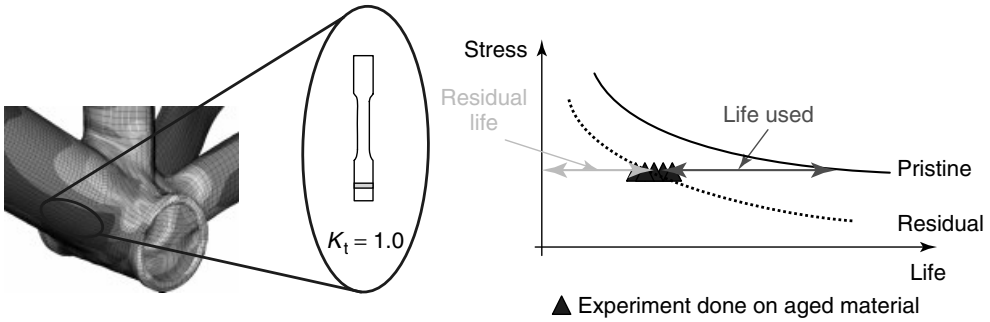

Figure 11. Experimental estimation of aged material's residual life.

a long tradition. Dynamically loaded structures such as rotating machinery are usually loaded at relatively high frequencies with a loading spectrum that can often be determined to be constant amplitude. Hence, if a frequency such as an eigenfrequency (a mode) has turned out to be relevant, it has to be filtered out of a highly randomized and thus possibly noisy signal. The characteristics of these signals may therefore change upon the change of a structure's condition. Hence a crack in a rotating shaft or a gear or a change in a gear's or bearing's surface condition might be easily recognized through the change in the frequency characteristics. Owing to the complexity of the signals, structural dynamics has provided a multitude of signal processing algorithms of which a large number is presented in Section 3 of this encyclopedia.

Besides using vibrations for monitoring damage in materials and structures, there is a multitude of other physical parameters and principles for monitoring damage as well. Those principles include acoustics, temperature, electrical or magnetic fields to just name a few and they are all covered in the wide area of NDT. NDT has provided not only the physical damage monitoring principles discussed in Section 2 but also the variety of sensors to be applied, which are widely described in Section 5. NDT is therefore one of the other major elements contributing to SHM.

Coming back to the structural assessment made so far in terms of loads monitoring and fatigue–life evaluation, the damage accumulation plot shown in the lower right of Figure 10 is an indication regarding where damage accumulates most and is thus most likely to occur. It is related to the loading configuration set and may change if the loading configuration changes as well. However a structure usually follows a specific loading pattern (spectrum) that can be described analytically.

A next question of relevance with respect to damage assessment is related to the incident when damage is likely to occur. As mentioned before fatigue–life can easily vary by a factor of 2 or even more. Hence, the incident of crack initiation can only be determined by continuous inspection where NDT and specific sensing technologies come into play. This can be done, in terms of SHM, by integrating sensing elements around the areas of the structure where damage is most likely to occur first.

Figure 12 shows how the principle can be applied by using acousto-ultrasonics as the monitoring technique. In this case a burst acoustic signal is sent under a Hanning window through some piezoelectric element actuators into the structure and the signals

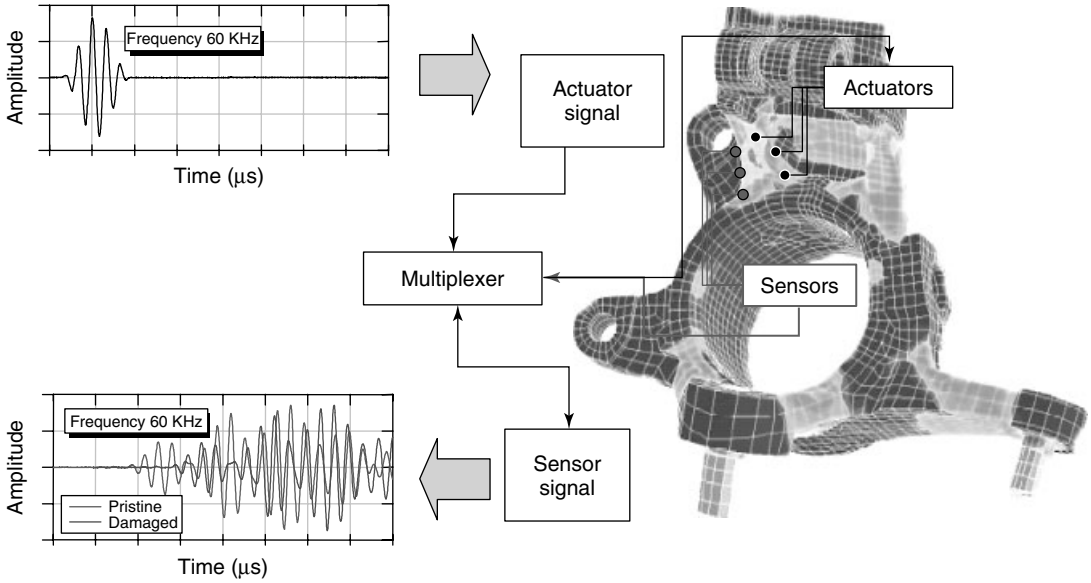

Figure 12. Acousto-ultrasonics damage monitoring principle applied damage critical areas of components.

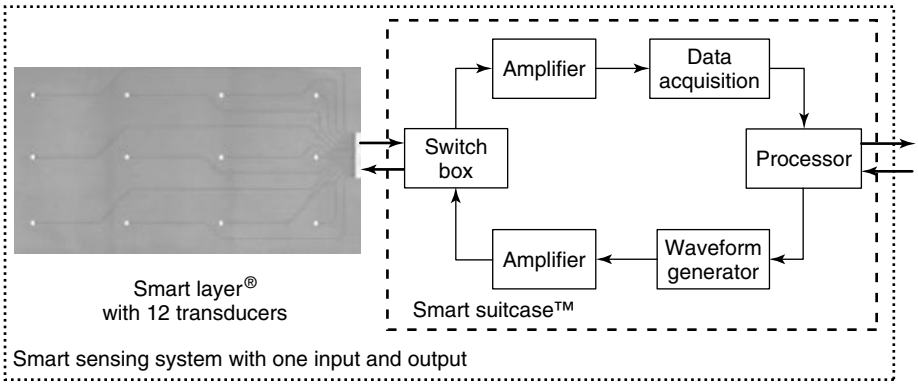

Figure 13. Logic for a sensing system within SHM.

are recorded again by another set of piezoelectric elements acting as sensors. Differences in the signal received will then indicate when damage has been initiated and repair or replacement of the component is required.

4 SENSOR SYSTEM IMPLEMENTATION STRATEGIES

4.1 Sensor or sensor system?

There is a general reluctance in implementing sensors into engineering structures. The reasons for this are understandable since there is no sensor where 100% reliability can be guaranteed for. Hence, the overall reliability of a system may decrease with an increasing number of sensors if the sensors do not provide a significantly additional amount of reliability for the overall engineering structure considered. Consequently, copying the principle of nature such as the human body, where billions of sensors continuously monitor the body itself, may be worth revisiting. As an overriding principle, the number of sensors in an engineering structure is therefore mainly minimized. Minimization of sensors also means that sensors should only be used—and thus possibly also just be implemented—when they are truly required.

However, the number of transducers becomes irrelevant when the complete signal generation and processing unit becomes a part of a sensor system, in practical terms when becoming a sensing system as shown in Figure 13. This system now only has a single interface between the remaining engineering system, such as an aircraft, for which the requirements in terms of input and output as well as reliability can be clearly defined and controlled. Hence, whatever is inside the sensing system is not relevant as long as the system meets the requirements set at the interface to the engineering structure or system. Problems of reliability and redundancy are therefore transferred to the SHM system supplier similar to the approach applied for any avionic or engine system in aviation. Virtually, the biological analogy would be indeed applicable under these conditions, provided the sensing system would meet the requirements accordingly.

Besides the system shown in Figure 13, there is a multitude of other systems being proposed, which are widely described in Section 6. What a holistic SHM system might have idealistically to consist of would be loads monitoring on the one side and damage monitoring on the other. How this might be achievable would require some further strategic considerations, which are subject of the following sections in this article.

4.2 Structural damage classification by MSG-3 process

There is a variety of ways SHM might be implemented in an engineering structure. This very much depends on the way the structure has been designed, the way it can be inspected, and a variety of other

regulations being associated to the structure's operational environment and life cycle. Each area of application has its specifics. One of them to be described here again comes from civil aviation where more examples and specifics are provided in Section 7.

As regards the structural integrity of aircraft structures, a clear route has been identified through the Maintenance Steering Group (MSG), which consists of representatives from the aircraft manufacturers, operators, maintenance, repair and overhaul (MRO) organizations, and the airworthiness authorities. A procedure known as *MSG-3* [18] is now widely applied, whose 'backbone' is shown in Figure 14.

The MSG-3 procedure mainly tries to find out if a component has to be considered as a structure significant item (SSI) or not. If this is the case, then damage can be either introduced to the component through accident, environment, or fatigue. Figure 15 shows the logic of this process combined with the steps where SHM could virtually play a role.

4.3 SHM implementation decision

Accidental damage is something that is unpredictable and can thus occur from day 1 of an aircraft's life. Environmental damage is partially accounted for by design but difficult to handle. Hence environmental damage may be considered from day 1 of an aircraft's life in cases where a large variation in damage initiation can be expected and a corrosion prevention and protection plan may not exist. Fatigue damage is however covered through damage tolerance and is not due to occur before half of the aircraft's design

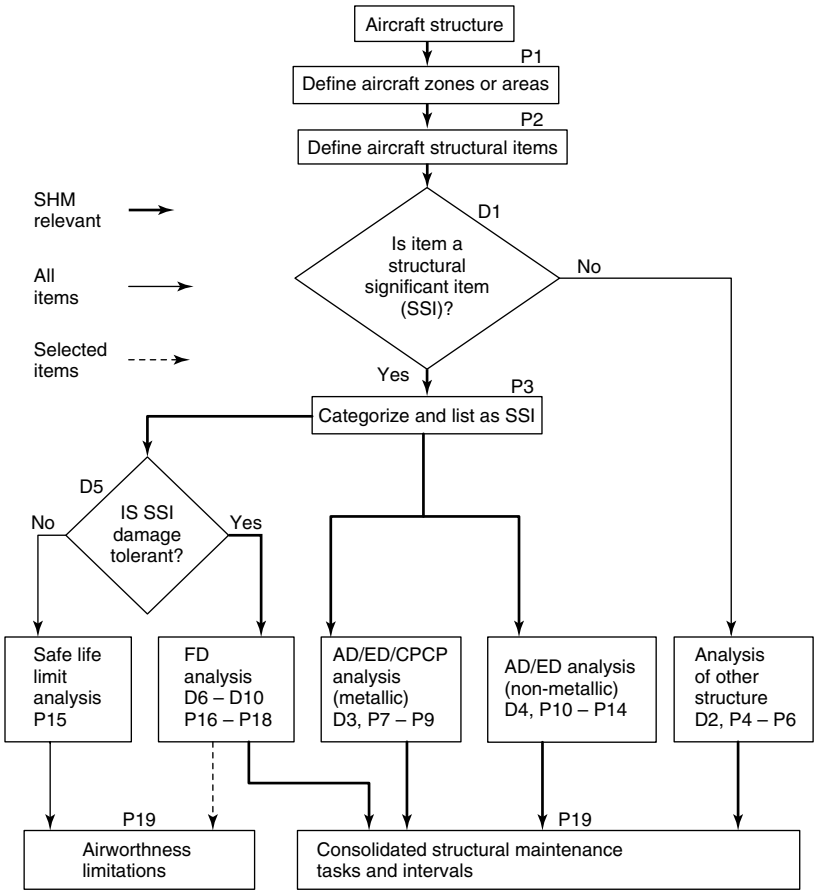

Figure 14. Selection of damage critical aircraft components in accordance to MSG-3 [18].

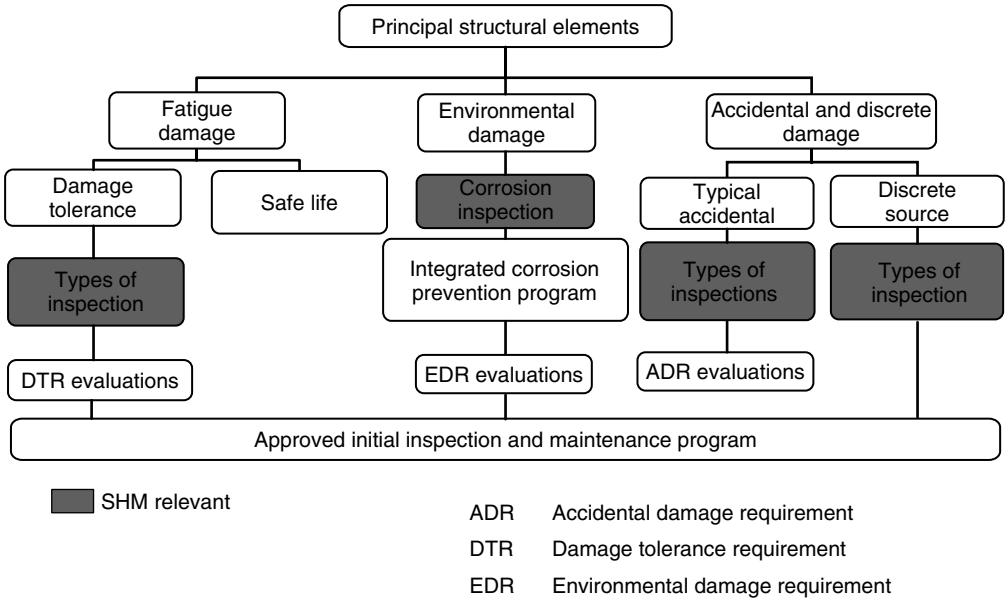

Figure 15. MSG-3 classification of structural damage [18].

life. Fatigue damage monitoring sensors are therefore not due to be implemented before midlife of the aircraft. Consequently, the aircraft manufacturers are following a strategy by looking at sensing accidental and critical environmental damage first which might result in damage monitoring locations as shown in Figure 16. Here, specifically, the locations around passenger and cargo doors are critical where uncontrolled collisions with ground vehicles are likely. Other environmentally critical areas are floor beams and frames close to galleys and lavatories where water spillage combined with corrosion is most likely.

As discussed earlier, loads monitoring using advanced sensing and combining this with a digital model for assessing damage accumulation is the other useful SHM option to be implemented into an aircraft from day 1.

All components being prone to fatigue damage are most likely not to be equipped with SHM systems from the very beginning of an aircraft's operational life since current design rules have been established such that any critical fatigue damage is avoided until the end of the next structural inspection interval defined. Introducing an SHM system would only make sense in case an inspection could be postponed beyond the end of the next inspection interval and this would lead to significant cost savings in terms of the aircraft's life cycle cost (LCC). This however needs to be proven before the SHM system is implemented.

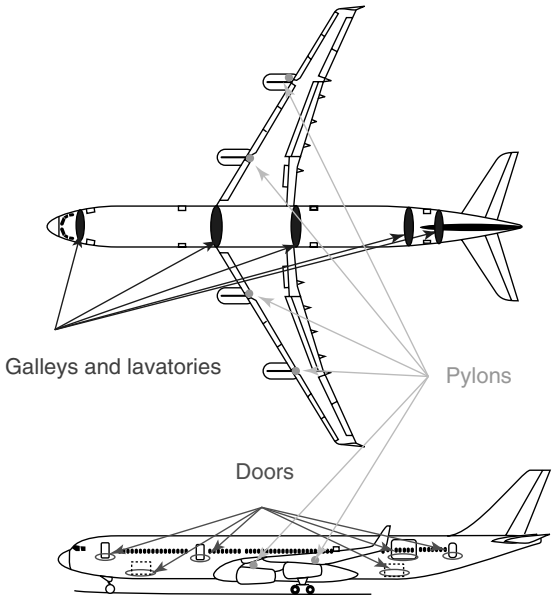

Figure 16. Potential locations for initial damage monitoring on aircraft.

The randomness of fatigue damage otherwise will not make prediction of the damage locations and

specifically their incident easy. Determining these locations and incidents therefore requires a close link to analyzing inspection protocols and here specifically those of the fleet leaders, being the aircraft having accumulated the highest number of flight cycles in a specific fleet. Once these locations and components have been determined, the economic potentials of implementing SHM have to be evaluated for which a procedure is described further below.

5 SHM POTENTIAL DETERMINATION

5.1 Background

A major issue of SHM for aircraft applications is the monitoring of a structure's condition by automation. SHM systems have progressively matured but the question of where to implement those onboard an aircraft to harvest the economic benefits resulting from automated inspection has still to be addressed. Schmidt *et al.* [19] proposed four different areas where SHM could be implemented based on potential fatigue-prone areas over a typical airframe fuselage. Areas identified were stringers, frames, and skins to identify cracks. Schmidt *et al.* also assessed the trade-off relationship that exists between structural weight and frequency of inspections. With increased inspection opportunities gained with SHM, additional damage characteristics could be incorporated into the aircraft design stage, increasing allowable design stresses on components that could result in a reduction in weight. Alternatively, the increased information gained could provide for an extension in the inspection interval, i.e., how frequent the component is inspected.

Schmidt's approach is definitely well applicable with regard to the design of future aircraft. However, with the fleet of existing aircraft, the benefits gained from SHM have to be seen within the frame of automating the inspection process. Inspection automation is, however, only beneficial if it shortens the time of inspection and enhances the availability of the aircraft to be inspected. Hence, what needs to be identified are the structural components along the critical path of the maintenance process and what implications the implementation of SHM would have in shortening the inspection and thus the maintenance process.

A major source along the MSG-3 process where the maintenance process is documented for each aircraft type and where structural inspection tasks are found is the Maintenance Planning Document (MPD). Assigned to each task is a description of the structural location and the nature of inspection (a special detailed inspection (SDI) or a general visual inspection (GVI)), the threshold of the inspection (when the initial inspection could be undertaken) along with the inspection interval (frequency of the inspection), and the estimated time to carry out the task. Optimization and simulation of maintenance processes based on the MPD allowing time critical tasks to be highlighted that may have the potential of being replaced by SHM in terms of maintenance time reduction is therefore what is addressed here. This is demonstrated along with a generic example.

5.2 Structure of maintenance process and problem definition

A maintenance process can be described by depicting the operational life of the aircraft as shown in Figure 17. An aircraft can be in service (white area) or out of service within a maintenance phase (shaded area). The maintenance process can be considered as the entire maintenance undertaken over the aircraft's life and is segmented into maintenance phases, tasks, and jobs, respectively.

Two types of maintenance phases exist: scheduled and unscheduled maintenance. Tasks that belong to scheduled maintenance phases are specified within the MPD and are those to be analyzed. A maintenance task is an action that specifies the action in general providing a description of the area involved, i.e., "inspection of frame 47 for cracks". Maintenance tasks can be segmented further into jobs. Maintenance jobs are more specific actions that make up a maintenance task. However, they have to be undertaken in a particular order. Maintenance jobs include the following: preparation, access gain, removal, inspection, reporting, and reassembly.

With the MPD only specifying the maintenance interval and threshold inspection, commercial airline operators have the freedom to allocate maintenance

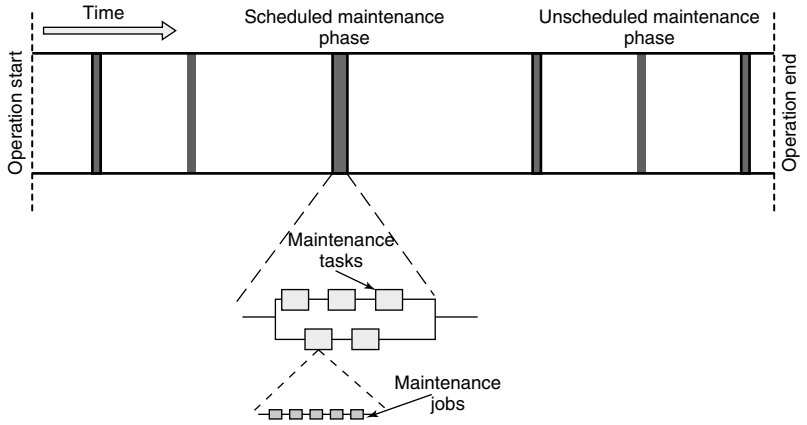

Figure 17. Maintenance process in its entirety and its components.

tasks to a phase in accordance to the allowable maintenance intervals. This results in different inspection tasks in different maintenance phases, which ultimately influences the critical path.

Also with changes to how maintenance is executed (i.e., number of laborers on site and the sequence of tasks executed) changes in the critical path is imminent. Additionally, critical path changes can occur due to changes in times that exist for a maintenance job. In reality, the duration time of a job is even often unlikely to be deterministic. With more complex maintenance phases, there may be a tendency for changes in the critical path with changes in job times. This nondeterministic situation requires optimization procedures that allow for effective maintenance planning as well as reliable identification of structural components being those most likely to positively affect the inspection and maintenance process through integration of SHM. It has to be noted in that regard that any component being identified for SHM may lead to a change in the critical path of the maintenance process, hence also leading to a sequential iteration process. How such an optimization could be achieved is therefore explained in the following paragraphs.

5.3 An integrated methodology for effective maintenance planning

For simulation of the maintenance processes, a commercial software named Arena© has been used [20], which has been successfully applied in post-depot maintenance of helicopters before [21]. Arena is a discrete event process simulation software that has the ability to analyze and predict process performance. A process is modeled in blocks in accordance to a flow chart. Each of the blocks contains the necessary data that describes the discrete event in terms of a process element, a decision, or something else. A process element is analogous to a maintenance action along the process.

Once the process is defined, described, and validated, a simulation run can be initiated. A simulation is based on entities that pass through discrete events (i.e., process blocks, etc.). For the purpose of the study, an entity is allocated as the aircraft to be maintained. The aircraft to which attributes are assigned, virtually moves along the flow chart. The number of entities, i.e., aircraft, can be increased, which allows maintenance in an aircraft hangar to be simulated and thus the maximum of aircraft maintained to be determined under the constraints of the maintenance process. These constraints mainly include the number of workers, tools and maintenance space, and the organization of the maintenance process itself. The constraints such as the number of workers and tools required can be optimized as well. Finally, the process is optimized in its sequence such that a maximum of aircraft is put through the maintenance process at a minimum of time. This simulation will therefore help to determine the maximum of aircraft operability gained from enhancing the aircraft maintenance process just from a logistical perspective. To obtain the complete picture simulation, runs are done over the complete life cycle of an aircraft.

For optimizing a maintenance process in accordance to the objectives set before, the following five steps can be defined:

1. Formation of inspection phases and consolidation of tasks from MPD based on airliner's operation
Following the inspection phases defined by the operator in accordance to the operational conditions, the different maintenance phases mentioned in the MPD are allocated with regard to MSG-3 [18], which is different when compared to the traditional letter checks [22].

2. Optimization (minimization) of maintenance tasks at each inspection phase
To provide a consistent benchmark against SHM and avoid changes in the critical path via different approaches, maintenance tasks in a phase are rearranged in an optimal fashion to a set number of maintenance staff. Scheduling jobs to laborers to minimize maintenance phase times allows time critical tasks to be determined with fixed times (i.e., those that lie on the critical path). The need to schedule inspection tasks to a set number of laborers fits very closely to the flexible job shop problem (FJSP), which is of current interest in the manufacturing sector. A number of approaches have been applied to the FJSP. Gao *et al.* [23] have developed a genetic algorithm (GA) approach that has been used to successfully solve the FJSP in the manufacturing industry, which has been remodified here for optimizing maintenance downtime in a maintenance phase.

3. Identification of critical maintenance tasks
Once each maintenance phase has been optimized in terms of downtime, a critical path analysis is undertaken at each maintenance phase. Uncertainties in duration of each task are addressed through statistical variations in job times and the effect it has on the critical path, using the discrete event simulation option with Arena©.

4. Analysis to suitability of SHM
Highlight tasks being related to the integrity of structural components and that lie on a maintenance phase's critical path, which may be suitable for SHM. Assess if a suitable SHM solution can be achieved for the component.

5. Remodeling of maintenance phases with the inclusion of SHM
Remodel the complete maintenance process with the SHM solutions included. This requires going back to step 2 (or possibly even step 1) and redoing the complete process again. It may lead to new critical paths with new components to be identified where SHM might be applied. This remodeling is repeated until no further potentials can be identified. Comparison of the existing maintenance method to a SHM scenario will finally demonstrate the potential gained.

The method has also been summarized in Figure 18.

5.4 Case study

To demonstrate the method described, assume the maintenance phase to consist of inspection of Gantries (task 1) and Frame 47 (task 2) both depicted in Figure 19. Gantries and Frame 47 are highly loaded structures in an aircraft's center fuselage section that serve as load carriers for fuselage bending and twisting forces mainly, partially superimposed by passenger payload and cabin pressure. Their loading is therefore complex and they are prone to cracking over lifetime. Hence they require inspections at certain time intervals specified in the maintenance document such as an MPD.

To highlight optimization of the maintenance phase, an initial inspection phase interval of 5000 FH was taken, which only consisted of the two maintenance tasks mentioned in more detail below. The objective was to arrange maintenance jobs with a given number of laborers to minimize the makespan of the maintenance phase (the makespan is defined as the difference between end time of the last remaining job and start time of the first job, i.e., the maintenance phase duration). For each task, the three maintenance jobs were removal, inspection, and reinstallation. It was assumed that four labor pairs existed L_1, L_2, L_3, and L_4. L_1, and L_2 were labor pairs that could only undertake access and removal jobs. Labor pairs L_3 and L_4 were only designated to undertake inspections. Figure 20 highlights the problem domain.

Job times (p_{tjl}) related to inspections were gathered from the MPD. Times associated to access were

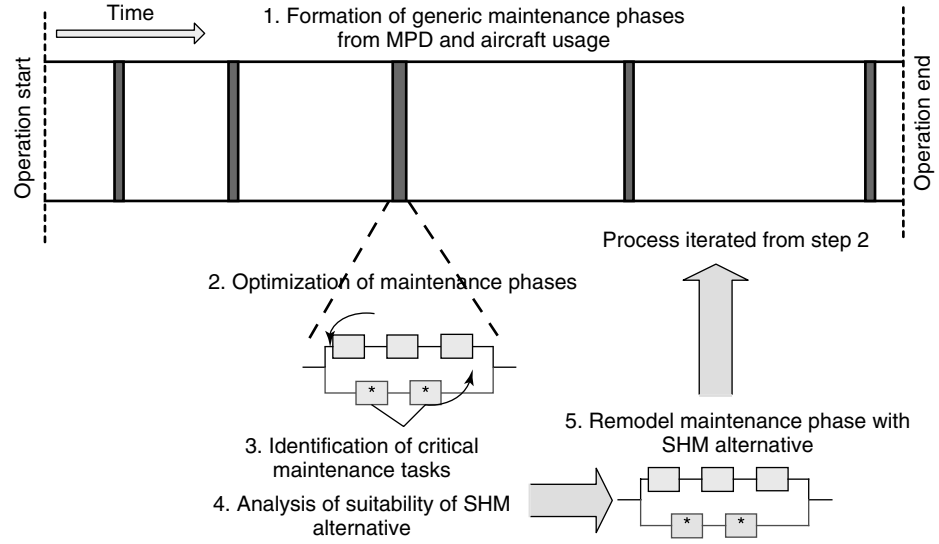

Figure 18. Overview of method for the determination of SHM potentials.

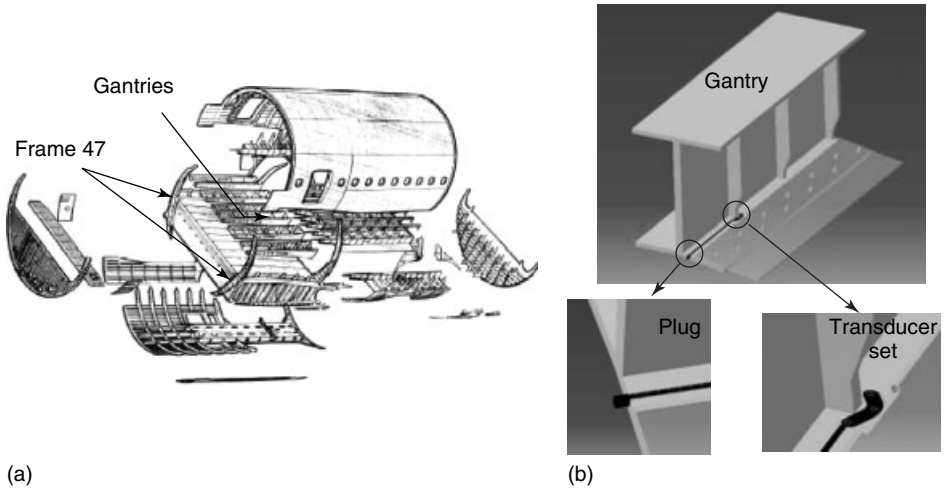

Figure 19. Components considered for case study (a) and proposed SHM solution (b).

assumed based on indications given by maintainers and documentation. Table 1 shows the assumed labor times for each job.

The GA procedure was then used to determine the optimal sequence of maintenance jobs to laborers that provides the minimum makespan, i.e., downtime of the maintenance phase. GAs are an optimization method that are based on an initial random population, which is manipulated through evolutionary mechanisms (selection, crossover, mutation, etc.) to provide better solutions after each generation governed by an objective function. The problem required a suitable permutation representation, which was adopted from Gao *et al.* [23] who were successful in solving similar type problems in manufacturing. The GA developed in Matlab was run and each solution was decoded to a schedule where it was evaluated by the objective function (total duration time). The GA converged to a minimum makespan of 6.3 h for a solution shown in Figure 21, which

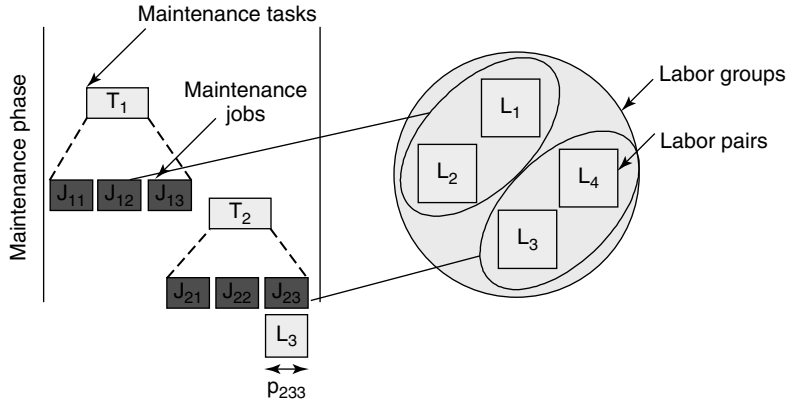

Figure 20. Illustration of the problem domain for 5000 FH maintenance phase.

resulted to around 120 h for the aircraft's complete life cycle.

The critical path could be established from the minimum schedule, which is the one related to task 1. Uncertainties of a standard deviation of 10% of the mean duration times could further be considered in the Arena simulation. However, this did not make a change in the path criticality of the case considered here. The model in Arena© is shown in Figure 22.

A SHM solution was developed as shown in Figure 19(b). Feeding this one back into the optimization process allowed task 1 duration to shrink by roughly a factor of 6 over the life cycle, leading to a saving of around 100 h of aircraft availability and let task 2 now to be on the critical path with around 36 h over the life cycle. Implementing an SHM solution to Frame 47 allowed the total inspection time to be reduced to 22 h, hence enhancement of 100 h in aircraft availability could be made by implementing SHM on both the Gantries and Frame 47.

Table 1. Maintenance tasks in 5000 FH phase

Description	Job	L1	L2	L3	L4
Access task A	J_{11}	2.1	2.1	–	–

6 CONCLUSIONS

SHM is a topic that has gained a significant high attention in the meantime. The reason is that it integrates a variety of classical disciplines on a lateral basis. This does not only include materials science, fracture, fatigue, strength, NDT, structural dynamics, or design but also include areas such as maintenance logistics, economics, and possibly others. SHM as a result is therefore not just sensors, electronics, or signal processing but rather a system. Such a system must result into something that is shown for a rail axle system in Figure 23. It must consist of a sensor or sensor network, some onboard electronics and a data transmitter possibly in the form of an antenna that does allow to link into the maintenance logistics.

SHM is not just limited to monitoring damage only. It also needs to encompass monitoring of operational loads, which in combination with the various prognostic simulation tools being available today will allow the locations of damage to be predicted in accordance to the operational needs. This will only allow current design and maintenance principles to be included, which is a major necessity should SHM find some promising application. SHM might further change design principles in a way that it could extend the damage tolerance design principle, so far applied with success in civil aviation and also in other areas as well. This however requires SHM systems operating at highest reliability, which is an area where still a lot of effort needs to be invested.

Although the examples being described here have been mainly related to aviation, SHM is by far being limited to this only. The same logic can be principally applied into any other field in engineering such as automotive, naval, railway, civil engineering, the processing, or the heavy machinery industry. Many of those are addressed in the various articles of this encyclopedia.

A big need with SHM is also that whatever will be developed is well integrated into the maintenance concept of the engineering system considered. With

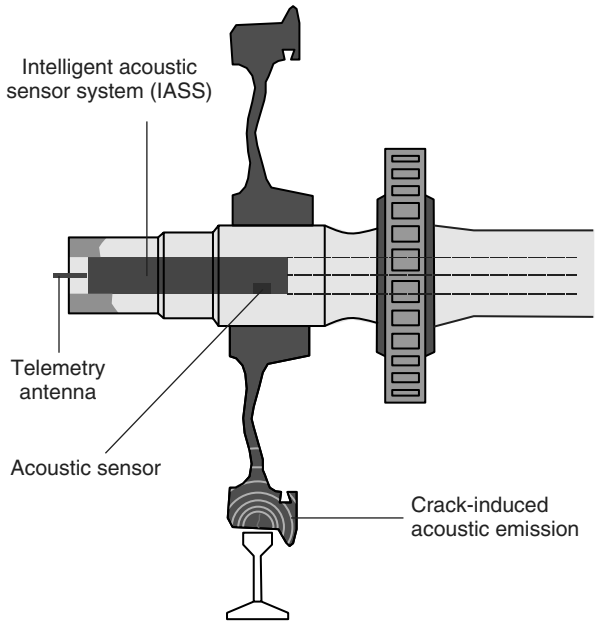

Figure 23. SHM system for train wheel monitoring [24].

regard to aircraft, this requires to follow maintenance principles used for avionics or engines since those are possibly further ahead when compared to structures so far. This also includes the way prognostic maintenance will be done and presented to the operator and maintainer specifically.

A major discussion centers around the question of when SHM should be implemented best along the life cycle of an engineering structure. Implementation at Day 1 makes sense for monitoring operational loads in general and components being prone to accidental damage. Monitoring environmental or fatigue damage from Day 1 will only make sense if an inspection interval can be significantly postponed and this results in a remarkable LCC benefit. These LCC benefits have to be determined in advance before those SHM systems are implemented into an engineering system such as an aircraft. A procedure on how to determine those potentials has been described. For fatigue and environmental damage, monitoring locations have to be determined from ongoing inspection records and here specifically from the fleet leaders of a fleet of engineering structures. Learning from experience will still be the major postulation. The question is only how this experience will be gathered and stored in the future when SHM will be in application.

Chapter 2
Free and Forced Vibration Models

Muhammad Haroon
Purdue University, West Lafayette, IN, USA

1 INTRODUCTION

Vibrations-based structural health monitoring (SHM) is the process of identifying the health of mechanical systems and structures based on changes in the dynamic behavior caused by damage. The process includes loads identification, damage detection, location, characterization, quantification, and life prediction. Vibrations-based methods are a natural choice because the vibration signature of mechanical systems is a known function of the system's physical parameters. In addition, the data-acquisition process and associated technology are well developed for system identification and relatively easy to apply. The global nature of vibration data also offers advantages in structural damage identification, as demonstrated later in this section. Modal information (natural frequencies and mode shapes), including properties derived from modal information (modal curvature, model strain energy, etc.), has long been used for damage identification. Changes in natural frequencies were among the earliest avenues of investigation and considerable work has been done in this regard; Salawu [1] provides a review of work in this area.

In studying the vibrations-based dynamic behavior of systems, modal properties are the obvious choice for system health analysis because these properties are directly affected by changes in a system's physical parameters (mass, stiffness, and damping) and are straightforward to estimate once models have been developed. Thus, model identification or system identification plays a role in SHM, especially when modal properties are used. A model for the system has to be assumed along with the assumptions about structural behavior, e.g., linear, time invariant, etc. Mechanical damage (e.g., cracks, delamination, and loose bolts) can be related to changes in stiffness and/or damping, which directly affect the system modal properties. Modal parameter–based methods, such as those using natural frequency shifts, are sometimes insensitive to damage and often corrupted by measurement variability, which hinder their general applicability. Many other categories of features can be estimated from vibration data that cover the whole

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

range of possible damage scenarios, operating conditions, structure types, and applications. The subcategories of vibrations-based SHM techniques include those exploiting linear or nonlinear changes and methods utilizing features in the time or frequency domain. The diversity in the available data, information, and features from vibrations-based system interrogation points to the power and versatility of this class of SHM methodologies. Doebling *et al.* [2] and Sohn *et al.* [3] have provided thorough reviews of vibrations-based SHM research.

The aim of vibrations-based SHM is to combine experimental vibration data, e.g., acceleration, with vibration models for damage identification (detection, location, characterization, and quantification) and ultimately develop damage models for prediction. The models can range from simplistic lumped parameter models to complex finite element (FE) or numerical models. Therefore, model development, validation, updating, and uncertainty quantification are important steps in the process.

In the next section, the framework for general vibrations-based SHM is provided followed by a discussion of a number of vibrations-based data interrogation techniques applied to numerical and experimental data. A number of practical examples are presented that step through the four stages of SHM as outlined by Rytter [4]: detection, location, quantification, and damage models for prediction.

2 FRAMEWORK OF VIBRATIONS-BASED SHM (NEWTON'S LAW)

Vibrations-based SHM has its basis in Newton's second law of motion for a constant mass, $\Sigma F = ma$. This simple equation provides the framework for damage identification, including parameters, loads, damage indicators, and various types of vibrations-based SHM techniques. It is used to derive the equations of motion for a lumped parameter system,

$$[M]\underline{\ddot{X}} + [C]\underline{\dot{X}} + [K]\underline{X} + N[\underline{X}(t), \underline{\dot{X}}(t)] = \underline{F} \quad (1)$$

where M is the mass, C is the damping, K is the stiffness, $\underline{\ddot{X}}$, $\underline{\dot{X}}$, $\underline{X}$, and $\underline{F}$ are the acceleration, velocity, displacement, and force vectors respectively, and $N[\underline{x}(t), \underline{\dot{x}}(t)]$ represents nonlinearities in the structural system.

This single equation, or set of equations, provides all of the information for the numerous diverse techniques and approaches for vibrations-based SHM.

Equation (1) contains the kinematic quantities that can be measured in order to interrogate the health of a mechanical system.

Acceleration measurements are the most convenient to make and commercial piezoelectric accelerometers are commonly used to measure dynamic response. Acceleration can be integrated to obtain velocity and displacement, as long as care is exercised in the integration, and then used directly for various SHM techniques [5–7].

The relative motion between structural elements changes with damage and load redistribution accompanying damage and, hence, relative displacements can be monitored to examine the integrity of structures (e.g., this is the primary damage-sensitive feature of interest for buildings subjected to earthquake damage referred to as *interstory drift* [8]). Displacement can be obtained from acceleration measurements via time- and frequency-domain integration but there are drawbacks to this approach [9] including loss of the dc component, which can contain important information for SHM; for example, quadratic nonlinearities cause dc components to appear in the system response. Laser Doppler vibrometry (LDV), a noncontact method, has been used to directly measure displacements [10, 11], including continuously scanning laser Doppler vibrometers (CSLDVs) [12]. Lead zirconate titanate (PZT) transducers are extensively used to measure structural displacement. Martin *et al.* [13] provide a comparison of different types of piezoelectric transducers for measuring structural displacement.

Strain measurements are also often used for SHM, especially in civil applications such as bridge and building health monitoring. The strains can be correlated with deformation and loads on structures in operation [14]. Fiber-optic strain gauges [15, 16], fiber Bragg grating (FBG) sensors [17, 18], and even electromagnetic sensors [19] have been used to monitor strain on structures. Because strain is a localized measurement, a large number of sensors need to be mounted to monitor possible defect locations on structures. Low-cost thin-film piezoelectric

(polyvinyldene fluoride (PVDF)) patches have been proposed to measure strain [20].

External loads need to be measured or estimated for many vibrations-based SHM techniques, for example, frequency response function (FRF)-based damage-identification algorithms [21–23]. In many realistic mechanical systems, inputs are not readily measured, as in automotive road vehicle data, for which the input to the tire patch of the tires from the road is neither measurable nor easy to estimate. For example, consider the equation of motion of a single degree-of-freedom (SDOF) system with base excitation,

$$M\ddot{x} + C\dot{x} + Kx = C\dot{x}_{\mathrm{b}} + Kx_{\mathrm{b}} \tag{2}$$

where x_{b} is the base excitation. In this case, the input is a function of the base motions and system parameters. In such cases, passive methods, which are those relying on output measurements only, need to be utilized for SHM.

The unmeasured external inputs to a system can be modeled, for example, as a stationary stochastic process [24]. Considerable work has been done on indirect estimation of the input forces, including the use of Markov parameters [25, 26], the sum of weighted acceleration technique [27], and the inverse-FRF approach [28, 29]. The inverse-FRF approach suffers from the problem of ill-conditioning. Stites [30] used an overdetermined inverse problem to overcome the ill-conditioning issue for estimating impact loads on mechanical structures. Seydel and Chang [31, 32] developed a real-time technique for determination of force location and time history using piezoceramic sensors and modeling of the system response. Wheel force transducers have been used for wheel force estimation [33]. Considerable work has been done on estimating moving vehicle loads on structures such as bridges. A number of approaches have been taken that involve some form of modeling of the bridge deck [34–36]. Stites [30] provides a survey of the latest developments in indirect force estimation.

Time- and frequency-domain analyses of equation (1) define the modal properties that can be used for damage identification such as natural frequencies, FRFs, antiresonances, modal vectors, dynamic flexibility, Ritz vectors, etc. [2, 3]. It is also the basis of most other vibrations-based SHM techniques. This equation can be rearranged as follows to more clearly illuminate the classes of vibration-based SHM approaches that are possible:

$$[M]\underline{\ddot{X}} = -[C]\underline{\dot{X}} - [K]\underline{X} - N\left[\underline{X}(t), \underline{\dot{X}}(t)\right] + \underline{F} \tag{3}$$

Convenient measurement; Linear or nonlinear; Active or passive; Internal loads

2.1 Internal loads

The displacement- and velocity-dependent terms in equation (3) represent the internal loads with which a mechanical system or component resists the inertial motion caused by excitation forces. The damage causes changes in the system parameters (linear and nonlinear), and these changes alter the internal loading of the components of mechanical systems. It is important to track such changes for reliable diagnosis and prognosis in these structural systems. The magnitude and directionality of the internal loads dictates the rate at which the damage progresses, and if and when the structure will fail. Consequently, the damage and internal loads together determine how damage progresses in mechanical systems (Figure 1).

Although every SHM method works to identify features that are influenced by changes in the system dynamics, including internal loads, a limited amount of work has been done on identifying the actual internal loads in mechanical systems. Neural networks and regression models have been used to identify operating loads on helicopter components [37–40]. Uhl and Pieczara [41] presented a method for identification of operational loading forces for mechanical structures. The method has two major requirements that impose limitations on its practical applicability in an industrial setting:

1. A known and verified finite element model of the structure is available.
2. Responses of the structure to any load vector can be simulated.

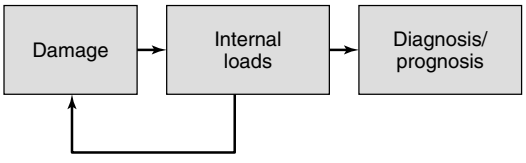

Figure 1. Diagnostic/prognostic methodology.

Haroon and Adams [42, 43] presented a time-domain technique for loads identification that uses system acceleration operating response data. Force-state maps are used to characterize the internal loading (linear and nonlinear) on components of vehicle suspension systems and to track changes in the loads with damage for damage identification. Force-state maps, which represent the displacement- and velocity-dependent internal forces with which a system resists inertial motions, have their origin in the work of Masri *et al.* [44–47] on nonparametric identification of nonlinear systems. Restoring force curves are projections of the force-state maps onto the force-velocity or the force-displacement plane and represent the load characteristics of a system/component as a function of its mechanical state [48]. The force–velocity curves represent the damping loads and the force–displacement curves represent the stiffness loads of a system. These curves allow visualization of the internal loads. An example of a restoring force curve is shown in Figure 2. It is a plot of the displacement versus the acceleration (which is the force scaled by the mass, $F = ma$) of an SDOF system with linear and nonlinear cubic stiffness. The nonlinearity can be characterized by its distinct restoring force curve. Individual nonlinearities have particular restoring forces; therefore, the nonlinear nature of the internal forces can also be characterized by the restoring forces within a system. The area entrained by a restoring force curve is proportional to the magnitude of the internal load and can be estimated to quantify the loads.

2.2 Linear or nonlinear

Damage often causes changes in the nonlinear characteristics of mechanical systems or causes a structure that responds in a linear manner to exhibit nonlinear response characteristics (e.g., loose connections and cracks). Consequently, nonlinear identification can provide useful information for SHM (Brandon [49, 50]). In the past few years, considerable work has been done to identify damage by identifying the nonlinear effects accompanying damage, such as cracks, using frequency harmonics [51] and nonlinear output frequency response functions (NOFRFs) [52]. Nonlinear frequency correlations are also useful for detecting the appearance and propagation of damage. Higher order spectra, specifically bispectra, are useful for crack detection and machine condition monitoring because the nonlinear changes can lead to changes in nonlinear frequency correlations [53–56]. Adams and Farrar [57] developed frequency-domain autoregressive exogenous (ARX) models by considering nonlinearities as internal feedback forces, which contribute to the forced

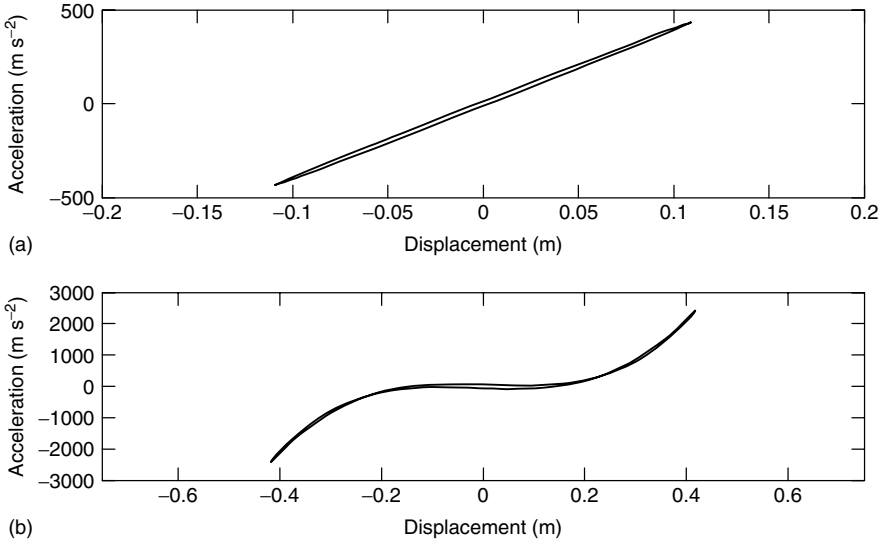

Figure 2. Single degree-of-freedom displacement-restoring force curve; (a) linear stiffness and (b) cubic stiffness.

response of the system. The nonlinear components change with damage and can be used for damage identification. The nonlinear changes in restoring forces can also be used for nonlinear damage detection [58]. Along the same lines of regression of one state variable in terms of another state variable, global phase-space representations of the dynamics of systems have also been used for damage identification. Nonlinear time-series analysis was used to analyze chaotic attractor properties and damage metrics were developed [59–61], which are sensitive to subtle changes in systems and robust to operational variability. In an example of linear phase-plane analysis, Stites *et al.* [62] used phase-plane maps to detect and quantify damage in gas turbine wire harness connectors under harmonic excitation. Other linear health-monitoring techniques include methods based on modal properties [1–3] and methods based on linear FRFs [21–23], including experimental sensitivity functions [21], which detect and quantify damage by comparing the sensitivity of FRFs to system parameters to measured changes in the FRFs. Ackers *et al.* [63] used linear FRF analysis to detect cracks in a metal spindle housed deep within a vehicle end assembly. It is prudent to mention here that the sensitivity of damage features, such as those based on FRFs, to environmental and operational variability is an important consideration for SHM. Cornwell *et al.* [64] discussed the variability in modal properties of a bridge with environmental and operational conditions. Kess and Adams [65] presented a study of the effects of environmental and operational variability on FRFs and transmissibility functions, and showed that frequency bands can be identified where variability is minimum and the possibility of getting false-positive/-negative indications is minimized.

2.3 Active or passive

In cases where the external inputs cannot be measured or estimated accurately, passive methods, which use only measurements of the structural response to external (operational) forces for damage identification, are employed for health monitoring. Transmissibility functions [66, 67], restoring forces [43], phase-plane methods [59–62], and output-only modal parameter estimation techniques [68] are examples of methods that utilize only response measurements to identify damage. Such methods work well in cases where the inputs are difficult to measure, for example in bridge health monitoring, or where restrictions on space and cost hinder the use of actuators to excite structures, but passive methods have the following limitations:

1. There is no guarantee that the excitations are persistent enough or at the frequency required to accentuate the damage, and as such small defects may be difficult to detect.
2. Variability in the unmeasured excitation forces makes the interpretation of the damage features more challenging.
3. Damage cannot be quantified in a physically meaningful way.

A variety of methods are used to excite the structure in active SHM, including shakers, modal impacts, and piezoelectric transducers. Specifically, piezoelectric transducers (Figure 3) are part of a rich and highly active research area for active SHM. Piezoactuators are used to excite structures at high frequencies, where the dynamic response is often more sensitive to local changes within a structure. Electromechanical impedance (EMI) techniques rely on the electromechanical coupling between the electric impedance of piezoelectric materials and the local mechanical impedance of the structure and use the PZT materials to both actuate and sense [69–71]. A number of techniques have been developed that use piezoelectric actuators/sensors to interrogate the health of structures [72–74], with the view to develop embedded sensor technologies. White *et al.* [75, 76] have used piezoactuator/sensor pairs (Figure 4) in the development of the virtual forces technique for SHM.

2.4 Time- and frequency-domain analysis

Vibration-based SHM techniques can also be classified according to the domain of analysis, time or frequency. Restoring force curves and autoregressive moving average (ARMA) models are examples of time-domain techniques. In ARMA modeling, response time histories of structural response are fit and the coefficients and residual errors are the damage-sensitive features [77–79]. In addition, time–frequency analysis can be used to analyze any nonstationary events localized in the time domain [3]. Spectrograms (short-term Fourier transform), wavelet analysis, and the Hilbert–Huang transform [80] are examples of time-series analysis techniques. Wavelet transforms have been extensively used for damage identification, especially in rotating structures [81–85].

2.5 Excitation frequency content

Vibrations-based SHM techniques can also be classified on the basis of frequency content of the excitation. Broadband techniques require frequency content over a broad range. Modal parameter estimation techniques [1, 2] and methods requiring spectra of measurements, for example, those based on FRFs [21–23], bispectra [53–56], and frequency-domain ARX models [57], come under this classification. On the flip side, methods that require a narrow frequency range in the input include restoring forces [42, 43] and phase-plane methods [62], which require harmonic excitation.

3 DAMAGE IDENTIFICATION

In this section, numerical and experimental examples of the process of damage identification are presented. Internal loads identification, damage detection, location, and quantification using the classes of vibrations-based damage identification discussed in the previous section are covered, leading up to the development of vibration-based damage prognosis models for prediction of growth of fatigue damage to failure. It is shown that vibration loads and damage information can be combined to develop damage prognosis models.

3.1 Internal loads identification

The internal loads, the forces with which a system resists inertial motion, are a function of the linear and nonlinear parameters of the system. Consequently, the internal loads change with the onset and progression of damage and can be estimated for damage identification. Restoring force curves can be used to identify internal system loads [42, 43]. Response acceleration measurements from two response locations are required to estimate the internal loads between the two locations. A two degree-of-freedom quarter car model (Figure 5) has been used to identify the internal loads in the strut of a passenger vehicle [86]. Acceleration measurements at the spindle and strut-body mount from full-vehicle two-post shaker tests (Figure 6) were used to estimate the restoring forces in the strut. The equation for the sprung mass, M_2, can be written using Newton's Law as

$$M_2\ddot{x}_2 = -C_2(\dot{x}_2 - \dot{x}_1) - K_2(x_2 - x_1) - K_3x_2 + N_1[x_1(t), x_2(t), \dot{x}_1(t), \dot{x}_2(t)] \quad (4)$$

where $x_k(t)$ are the displacements of the unsprung and sprung masses, M_k, C_2 is the suspension viscous damping coefficient, K_k are the stiffness elements in

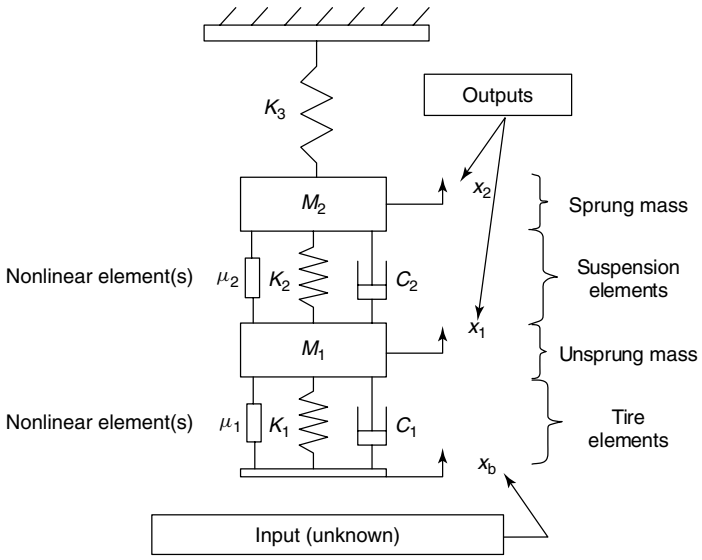

Figure 5. Two degree-of-freedom quarter car model.

the suspension and vehicle body, and $N_1[x_1(t), x_2(t), \dot{x}_1(t)\dot{x}_2(t)]$ denotes the nonlinear forces in the suspension. Because restoring force curves need to be generated at discrete frequencies, slow sine sweep (narrow-band) tests were run and the acceleration signals were numerically integrated to obtain the velocities and displacements. The relative velocity and relative displacement across the suspension were plotted against the acceleration of the sprung mass to generate the restoring force curves and identify the internal loads. Figure 7 shows the frequency characteristic of the velocity-dependent internal loads and Figure 8 shows the same result for the displacement-dependent internal loads.

The velocity-dependent force (Figure 7) initially exhibits primarily hysteresis, but as the frequency increases the force takes on the shape of a Coulomb friction curve, then a piecewise linear characteristic (typical of vehicle shocks), and finally it becomes primarily linear with some hysteresis. The displacement-dependent force (Figure 8) shows primarily hysteresis with backlash at certain frequencies. As an example of comparison of models with experiments, the same restoring forces were also generated from simulations of a full-vehicle numerical model. The ADAMS model with linear stiffness and nonlinear shock damping is shown in Figure 9. As with the experimental results, the displacement-dependent curves show hysteresis with backlash and the velocity-dependent curves show a piecewise linear characteristic.

The internal loads of a sway bar link while subjected to tension–tension fatigue tests were also estimated by measuring the axial acceleration at the two ends (Figure 10). The measurements at the two ends were used to estimate the internal loads. The velocity-dependent internal load has hysteresis and the displacement-dependent load is linear (Figure 11). This example is used throughout the following section to demonstrate the process of damage identification, leading up to the development of a prognostic model.

3.2 Damage detection

A wide variety of vibrations-based methods can be used for damage identification, depending on the available data, the system, and the damage [2, 3]. Shifts in resonant frequencies are the most basic means of detecting damage. Consider a four degree-of-freedom lumped parameter model (Figure 12) simulated in Matlab Simulink®. Damage is introduced in the system in the form of a reduction in stiffness between degrees of freedom 2 and 3. The estimated FRFs for the damaged and undamaged cases are shown in Figure 13. There are clear shifts downward in the second and fourth resonance

Figure 6. Two-post shaker setup and accelerometer locations.

peaks, which represent the change in system modal properties with damage (- - - -). Similarly, damage in realistic structural systems affects the system parameters, which can be detected with the changes in structural natural frequencies [1].

The antiresonances of an FRF are more sensitive to local dynamics and, hence, can provide a better indication of damage in certain cases. For example, modal impact testing of a helicopter blade (Figure 14) with localized damage (change in stiffness) in the form of a gradually tightened strap, which modified the chord stiffness, showed that the antiresonances are more sensitive to a change in system dynamic properties in this case because the damage is more localized (Figure 15).

Damage can also cause nonlinear changes in mechanical systems, in which case nonlinear methods can be used to detect damage. Bolt loosening leads to nonlinear changes associated with Coulomb friction. This damage mechanism was simulated in a building model [57] and identified using frequency-domain ARX models. Consider the two degree-of-freedom quarter car model (Figure 5) with cubic stiffness nonlinearity between the sprung and unsprung mass. A first-order linear ARX model can be used,

$$Y(k) = B(k)U(k) + \sum_{j=-1\neq 0}^{1} A_j(k)Y(k-j) \quad (5)$$

where the response is considered to be caused by the input at the driving frequency and feedback correlation with one frequency above and one frequency below the input frequency. A damage index can be

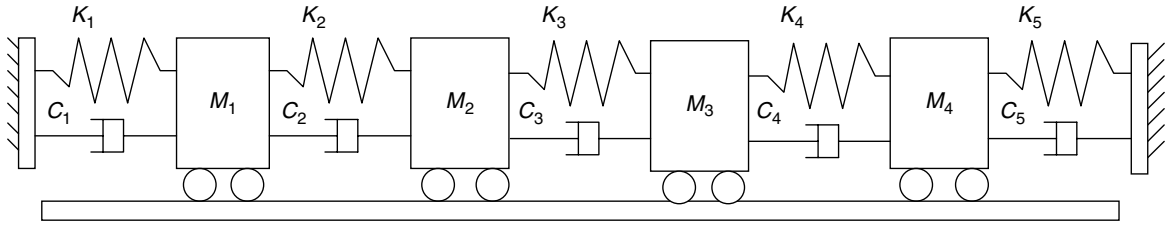

Figure 12. Four degree-of-freedom system.

developed using the nonlinear autoregressive coefficients, $A(k)$. If the damage is assumed to cause a change in the nonlinear parameter, the damage indicator can be used to detect that change. Figure 16 shows that the indicator captures the simulated increase in the nonlinearity with damage.

Similarly, damage simulated by gradual loosening of the lower ball joint in a vehicle suspension (Figure 17) was identified using these damage models [7, 86]. Figure 18 shows that as the bolt is loosened the nonlinear correlations increase owing to the increased friction between the bolt and the ball joint caused by relative motion (undamaged torque was 400 lb-in). The nonlinearity decreases when the bolt is removed because the source of the increased friction is no longer present.

Farrar *et al.* [87] provide a substantial set of examples of nonlinear feature extraction for damage detection, including linearity checks on bridge FRF measurements [88], waveform distortion in rotating machinery [86, 87], time-series analysis [89–93], and higher order spectra [94, 95].

Because the internal loads change with damage, they can also be used to detect damage. The internal loads across the path containing the bolt damage in the vehicle suspension were also estimated as the damage progressed (bolt loosening) (Figure 19). The damage causes a change in frequency characteristics

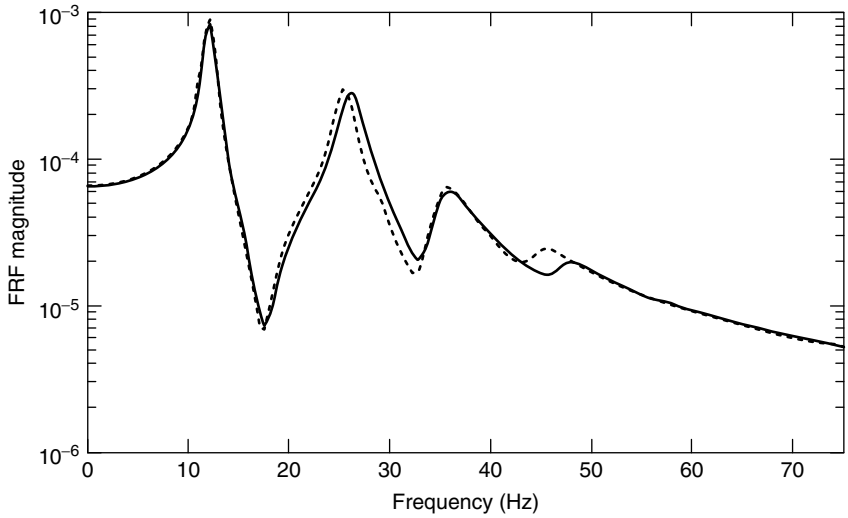

Figure 13. Change in resonant frequencies with damage represented by reduction in stiffness between degrees of freedom 2 and 3; undamaged (———) and damaged (- - - -).

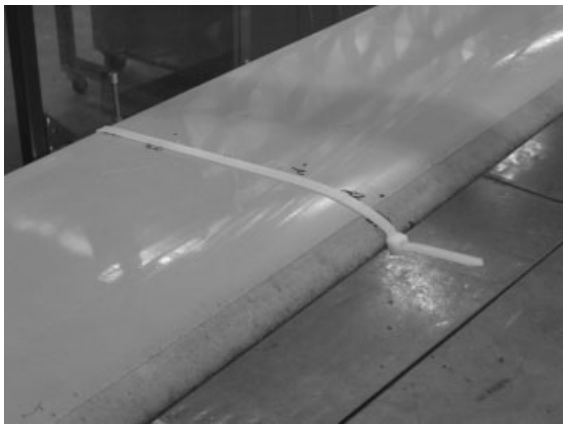

Figure 14. Strap to simulate damage, causing change in stiffness of helicopter blade.

of the velocity-dependent restoring force with the progression of damage. The system moves out of the hysteresis loop at different frequencies because of the damage. The intermediate cases (loosened bolts, 250 in-lb (· · ·) and 100 in-lb (- - - -)) change at higher frequencies (the frequency at which the restoring force corresponding to 100 in-lb bolt torque changes is the highest) compared to the undamaged case, and the most severe damage case (bolt removed) changes at a lower frequency compared to the undamaged case. This same behavior is observed for different input amplitudes. Thus, changes in the characteristic of the nonlinear internal loads can be used to detect damage.

The fatigue testing of the sway bar link in Figure 10 led to the appearance of a circumferential fatigue crack at the lower weld location (Figure 20). The transmissibility across the link and the internal load were used to detect the damage. The transmissibility shows a shift in the level and peak (Figure 21) and the internal loads show an increase in magnitude as the area of the velocity-dependent curve increases (Figure 22). The displacement-dependent internal load shows a decrease in slope, which represents a decrease in stiffness with damage as the link weakens.

3.3 Damage location

Damage localization requires the use of techniques that are sensitive to local changes in a system dynamic's properties, such as the transmissibility functions. Transmissibility functions are like FRFs in many ways, but they are ratios of the same variable (acceleration to acceleration, etc.). This nondimensional property tends to suppress global effects of damage and, thus, enhances the local effects because transmissibilities only contain the zeros, and not the

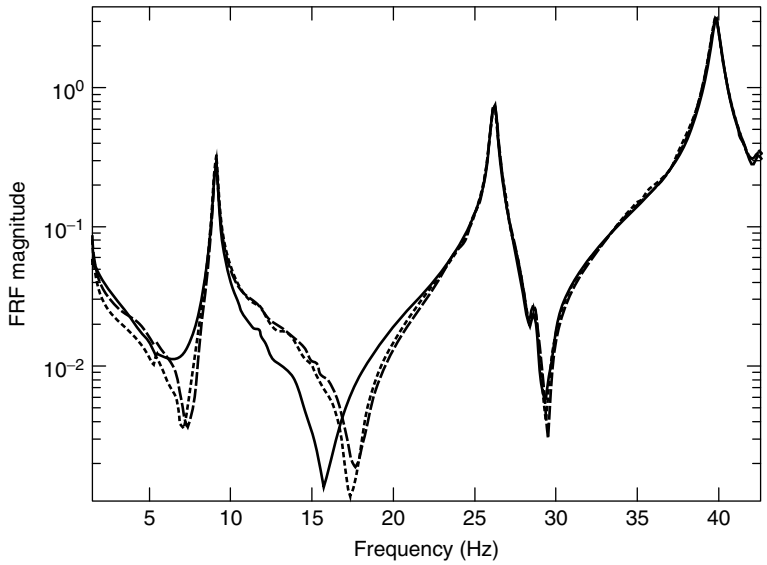

Figure 15. FRFs for helicopter blade damage showing greater sensitivity of antiresonances to localized damage; undamaged (———), damaged level 1 (- - - -), and damaged level 2 (· · · ·).

poles, of discrete FRFs, and therefore contain information about more localized regions of structures [67]. Consider once again the four degree-of-freedom system in Figure 12. Suppose damage is introduced in the form of a reduction in stiffness between masses 1 and 2. Transmissibility functions between different response pairs can be used to locate the damage (Figure 23). The transmissibility functions for the response pairs, which have the damage in the path between them (Figure 23a and d), clearly indicate the change in system dynamics with damage, while the response pairs that do not have the damage in the path between them (Figure 23b and c) show no significant change with damage.

Figure 17. Ball joint connecting lower control arm to the steering knuckle.

The bolt damage in Figure 16 can be located in a similar manner. The frequency-domain ARX model in equation (5) is an output-only formulation and, hence, is similar to transmissibility functions. Consequently, it is more sensitive to local changes in dynamic properties. The model in equation (5) was applied to data from locations that did not have the damage in their path. Figure 24 shows the estimated indicator $1 - |A_{j_d}/A_{j_{un}}|$ for the data from points that did not have the damage location in the path between them. It is clear that there are no significant changes in the nonlinear correlations in the path between these two points. This analysis located the damage at the lower ball joint.

A number of other techniques have been developed for damage location. These include methods based on active piezoactuation and sensing, which use traveling, guided waves to sense and locate damage in structures [74, 96], wavelets [97, 98], and strain energy–based methods [98, 99].

3.4 Damage quantification

Quantification is important for developing prognosis models to predict damage growth and failure. Damage indices based on the various damage-identification techniques can be used to track the growth of damage and thresholds can be defined to quantify damage. For example, the level of the index based on the frequency-domain ARX model (Figure 18) can be used, and similarly an index based on transmissibility functions can be developed [67]. However, quantification of damage in a manner that has physical engineering significance is more useful. For example, if it can be stated that a crack has caused a certain change in the stiffness of a structure, the affect of damage on the performance of the structure will be clearer.

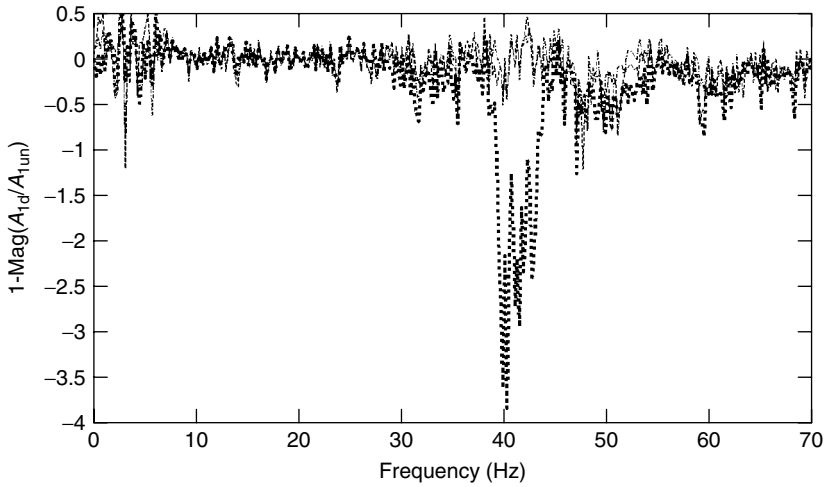

Figure 18. Nonlinear indicator 1-Mag$(A_{1d}(\omega)/A_{1un}(\omega))$ for bolt loosening damage; 250 in-lb torque (- - - -), 100 in-lb torque ($\cdot\cdot\cdot\cdot$) and no bolt (–.–.–).

Figure 20. Initial circumferential crack in sway bar link under cyclic loading.

Experimental sensitivity functions [21] provide a method that can be used to quantify damage in terms of discrete changes in mass, stiffness, or damping. This method requires a measure of the input force. Consider the two degree-of-freedom quarter car model in Figure 5. Suppose that damage causes a change in the stiffness, K_2, between the sprung and unsprung masses. Estimated or, in the experimental case, measured FRFs can be used to quantify the change in stiffness caused by the damage as

$$\Delta K_{12} \approx \frac{\Delta H_{11}(\omega)}{-[H_{11}(\omega) - H_{12}(\omega)][H_{11}(\omega) - H_{12}(\omega)]} \tag{6}$$

The subscript "12" describes the location of the damaged element. The denominator is called the sensitivity of the FRF to a change in the stiffness K_{12}, $\partial H_{11}(\omega)/\partial K_{12}$. Let us take an example of damage causing a 10% (2500 N m^{-1}) decrease in the stiffness. Using the estimated FRFs in equation (6) to estimate the change in stiffness gives the result in Figure 25. The frequency region between the two resonant frequencies provides an estimated change in stiffness of 2476 N m^{-1}, which is approximately the same as the actual change. Similarly, mechanical system damage can be related to a parametric

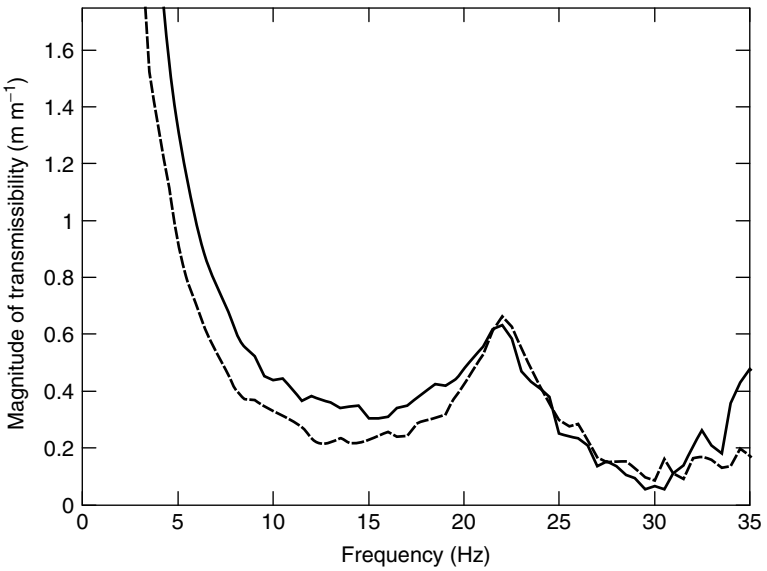

Figure 21. Change in transmissibility with the appearance of the initial circumferential crack in link; undamaged (———) and initial crack (- - - -).

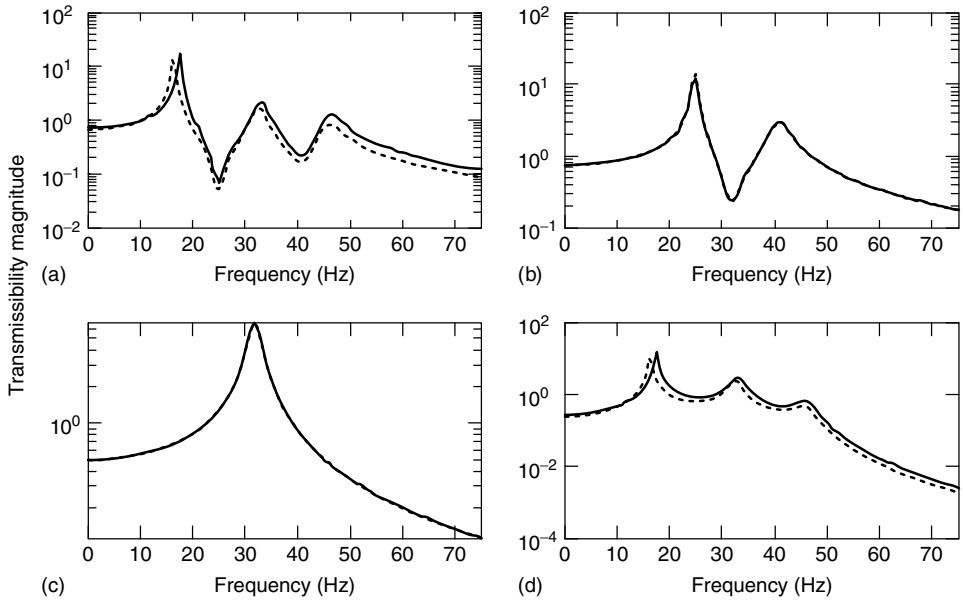

Figure 23. Transmissibility functions between different response location pairs for undamaged (———) and stiffness damage (- - - -) cases in four degree-of-freedom system: (a) x_1 and x_2, (b) x_2 and x_3, (c) x_3 and x_4, and (d) x_1 and x_4.

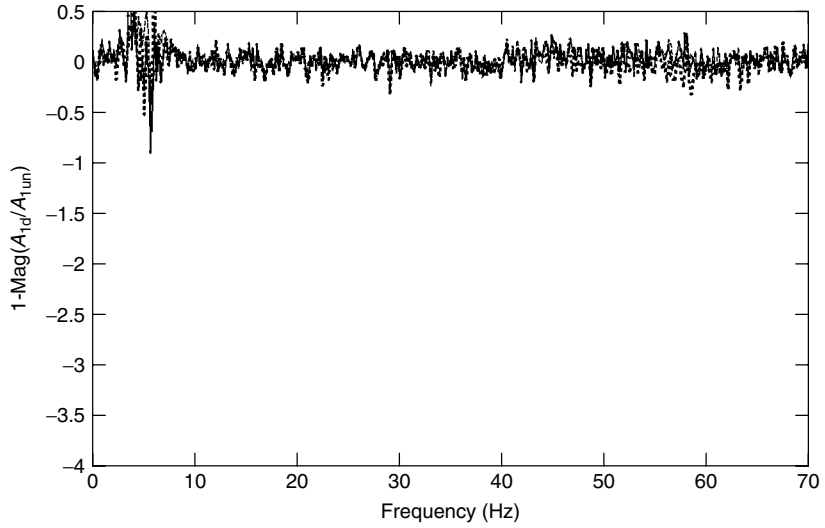

Figure 24. Nonlinear indicator 1-Mag($A_{1d}(\omega)/A_{1un}(\omega)$) for first-order linear ARX model applied to points with no damage in their path; 250 in-lb torque (- - - -), 100 in-lb torque (· · · ·), and no bolt (–.–.–).

change in the structure properties to attach a physical significance to the observed damage in the system.

Changes in the restoring force area, which is proportional to internal system load magnitude, can also be used to quantify damage. The progressive change in area of the velocity-dependent internal load of the sway bar link (Figure 10) as the circumferential crack grew to failure was estimated to quantify the change in internal load with damage (Figure 26 and Table 1). It is clear that the area of the curves, and

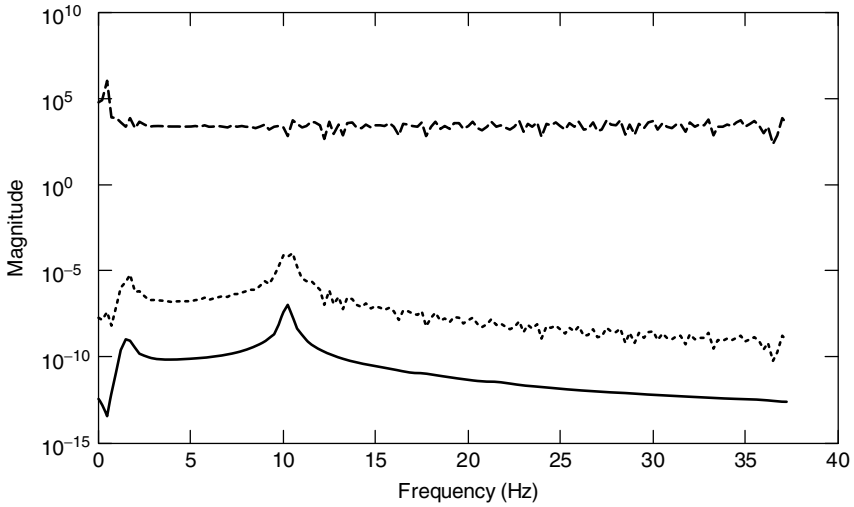

Figure 25. Estimated change in stiffness of the two degree-of-freedom system with damage; stiffness sensitivity $\partial H_{11}(\omega)/\partial K_{12}$ (———), change in FRF, ΔH_{11} (· · · ·), and change in stiffness, ΔK_{12} (- - - -).

Figure 26. the load, increases progressively with the damage. The velocity-dependent restoring force also shows an indication of the approaching failure. Immediately before complete failure, the restoring force becomes multiply connected (Figure 26 (–+–+–+)). The internal loads provide a quantifiable change with damage and an indication of impending failure.

Some of the other techniques developed for damage quantification include those based on elemental modal strain energy [100] and methods

Table 1. Changing velocity-dependent restoring force areas with the appearance and progress of circumferential crack in a sway bar link

	Undamaged	Undamaged 2	Crack visible 5000 cycles	Progression 1 10 000 cycles	Progression 2 12 500 cycles	Just before failure 15 000 cycles
Restoring force area ($mm^3\ s^{-2}$)	0.0074	0.0073	0.0088	0.0149	0.0246	0.0028

based on finite element model updating [101], which iteratively minimize the differences between measured and predicted parameters.

3.5 Prognosis

The ultimate aim of SHM is to combine load and damage models that can be used to predict the growth of damage and ultimately failure. And loads identification is an important component of the prognosis process (Figure 1). Information about the current status of damage (health monitoring) alone is not sufficient for accurate prediction of future trends; the nature of system loads (usage monitoring) is also needed for prognosis [102]. A vast amount of work has been done on fatigue and fracture analysis for prognosis, including extensive development of crack propagation laws. But these laws require localized information like geometry of the component, orientation of damage (cracks), and local loading. One of the goals of vibrations-based SHM is to utilize global vibration measurements to identify damage to the system without the need for localized information, which would make the data-acquisition process prohibitively complex, time consuming, and expensive. Prognosis of structural damage at the system level is not a well-developed area and basic research is being conducted. Having said that, damage-based prognostics in the helicopter industry is quite well developed with the advent of the health and usage monitoring system (HUMS) [103]. Risk assessment is another form of damage prognosis. Seismic probabilistic risk assessment (PRA) has been applied to commercial power plants. The annual probability of damage as a result of some future earthquake is obtained [104]. Preliminary work on the use of hidden Markov models for damage prognosis has also been presented [105]. Another example of initial work on damage prognosis is fatigue crack growth prediction using an energy method [106]. Inman *et al.* [107] provide an overview of the technology of prognosis.

Haroon [86] developed empirical mechanical damage growth models, which combine internal loads identification and damage diagnosis. Crack growth laws, which predict the growth of cracks based on the current length of crack and the stress distribution around it, are used as motivation. Damage information from a transmissibility function–based damage index and internal loads quantification from restoring force curve areas are combined to develop prognosis models of the form,

$$\frac{\mathrm{d}(D)}{\mathrm{d}N} = C|D|^m \times |\Delta L|^n \tag{7}$$

where D represents the damage, ΔL is the changing internal component load, and C, m, and n are empirical constants that depend on material properties, material geometry, boundary conditions, external loading, and damage mechanism. The models in equation (7) are used to predict the growth of fatigue cracks in the front sway bar link of a passenger vehicle under tension–tension cyclic fatigue loading (Figure 10). Loads (Figure 26) and damage (Figure 27) information are combined in this model to predict the growth of damage in terms of change in the transmissibility-based index, $D = \Delta T$ (Figure 28).

$$DI_k = \frac{\sum_{i=a}^{b} |\mathrm{Re}(\ln(T_k(\omega_i))) - \mathrm{Re}(\ln(T_{k-1}(\omega_i)))|}{N_f} \tag{8}$$

where T_k is the transmissibility at the kth measurement, T_{k-1} is the previous measurement, ln is the natural log, ω is the frequency, and i is the index that determines the range of frequencies (a to b) over

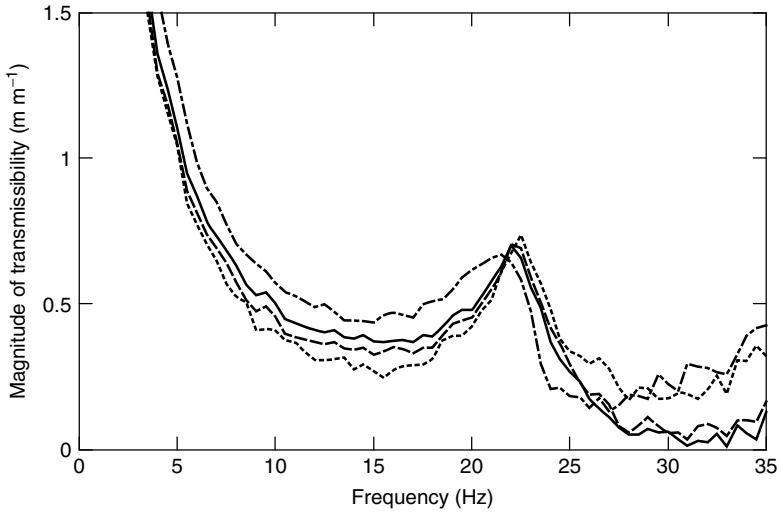

Figure 27. Change in transmissibility with progressive growth of fatigue crack to failure in sway bar link under tension–tension fatigue loading; initial crack (———), progression 1 (- - - -), progression 2 (· · · ·), and just before failure (–.–.–).

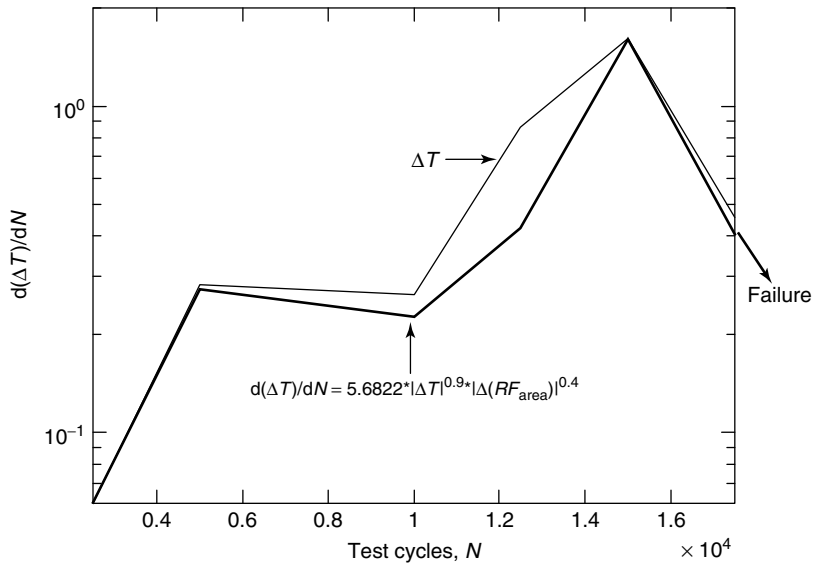

Figure 28. Empirical regression model relating estimated change in transmissibility to change in restoring force area for experimental circumferential crack damage in a sway bar link.

which the change is summed and N_f is the total number of frequencies.

In this case, $m = 0.9$, $n = 0.4$, and $C = 5.6822$. As Figure 28 shows, this model produces the same rate of change of the damage indicator (darker line) as the actual change in the damage indicator (lighter line). The empirical model follows the same trend as the damage indicator; hence, it predicts the growth of damage and the associated damage indicator.

In order to demonstrate that the models actually predict the growth of damage, tests were run on three links with the same material properties, geometries,

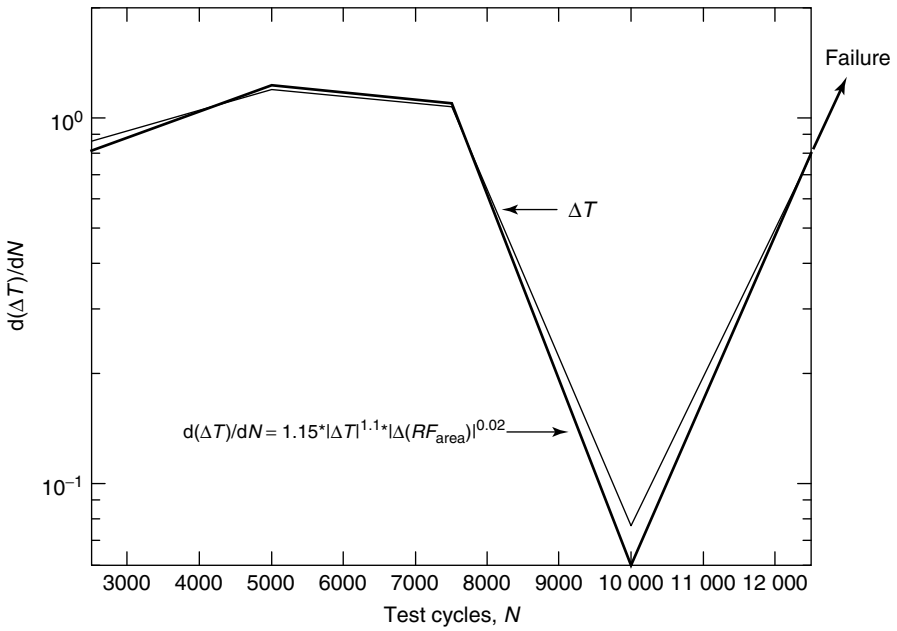

Figure 29. Empirical damage prognosis model for experimental fatigue crack damage in a sway bar link; $m = 1.1$, $n = 0.02$, and $C = 1.15$.

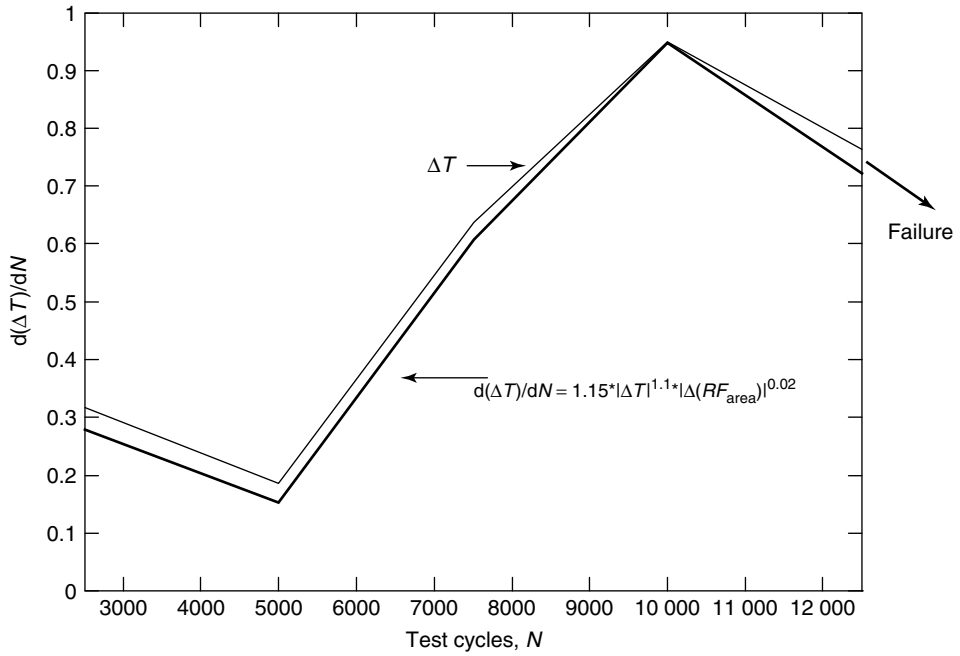

Figure 30. Prediction of growth of experimental fatigue crack damage in sway bar link to failure; Link 1.

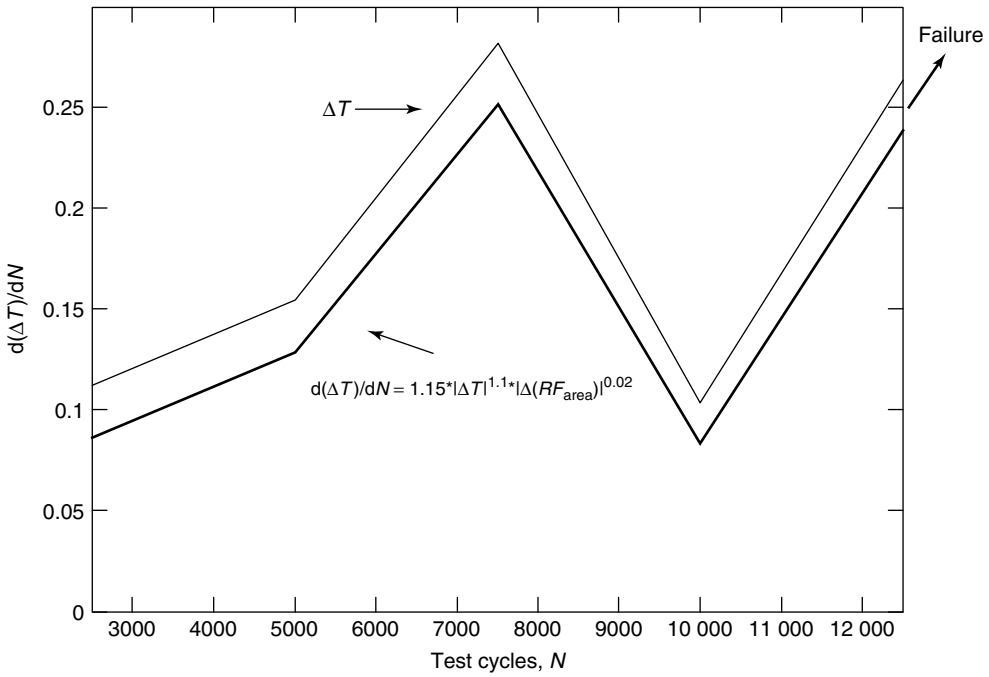

Figure 31. Prediction of growth of experimental fatigue crack damage in sway bar link to failure; Link 2.

loading, and crack mechanism. The model developed using the first link (Figure 29) was used to predict the growth of damage in the other two links (Figures 30 and 31). It is clear that for the same component, material, boundary conditions, loading, and damage mechanism, there exists an empirical relationship between load and damage that predicts the growth of damage to failure. The only error in the prognoses is offsets, which can be attributed to the variability in the placement of the links in the test fixture, variability in the loading, and the fact that all three links had different usage levels; the first two links were 14 years old and had been extensively tested in full-vehicle tests and the last link was new and had never been tested prior to the fatigue testing. This difference in usage is also the primary reason that the damage indicator (or damage) grows differently for the three links; but the same empirical model predicts the growth of damage once it has been initiated. It should be noted that the reason the damage indicator does not have a growing trend is that the change in the transmissibility has been considered rather than the absolute value. The important factor is the empirical model that fits the damage indicator behavior.

It is important to mention that the crack laws require localized information about the loading (stress) and damage (crack length), and it is not feasible to instrument every potential crack initiation region to collect this localized information. On the other hand, the vibrations-based damage prognosis models in [86] only require component-level vibration measurements and this global nature make them more practical for SHM.

4 SUMMARY

Vibrations-based SHM is a class of techniques that have their basis in Newton's Law. Global vibration measurements at the system or component level can be used to interrogate the health of structures. Quite diverse and wide-ranging techniques come under the umbrella of vibrations-based SHM based on the type of data, analysis domain, nature of systems, etc. This collection of techniques points to the power and versatility of this class of SHM methodologies. The available data ranges from acceleration and force to strain, with acceleration being the most convenient measurement, and the techniques can be

further classified according to linear or nonlinear nature of analysis, time-domain or frequency-domain techniques, and availability of input measurements and excitement of structures (active or passive).

Internal loads identification is an important part of the vibrations-based SHM process. The internal loads are a function of system parameters, change with damage, and affect the further growth of damage. As such they can be used to detect damage and develop prognosis models to predict the remaining useful life of structures. Vibrations-based techniques are available for all aspects and stages of SHM: loads ID, damage detection, location, quantification, and life prediction.

Damage prognosis is an area of vibrations-based SHM that is still in its infancy. The aim is to develop damage models to predict growth of damage and remaining useful life. Loads identification can be combined with damage information to develop empirical models to predict damage growth.

Chapter 3

Fundamentals of Guided Elastic Waves in Solids

Carlos E. S. Cesnik and Ajay Raghavan

Department of Aerospace Engineering, University of Michigan, Ann Arbor, MI, USA

1 INTRODUCTION

Unlike passive structural health monitoring (SHM) methods, active schemes are capable of exciting the structure, and in a repeatable, prescribed manner, they can quickly examine it for damage, where and when required. Guided-wave (GW) testing has emerged as a promising option among active schemes. It can offer an effective method to estimate the location, severity, and type of damage, and it is a well-established practice in the nondestructive evaluation and testing (NDE/NDT) industry. There, GWs are excited and received in a structure using hand-held transducers for scheduled, offline maintenance. They have also demonstrated suitability for SHM applications having an onboard, preferably built-in, sensor and actuator network to assess the state of a structure during operation. The actuator–sensor pair in GW testing has a large coverage area, resulting in fewer units distributed over the structure.

GWs can be defined as stress waves forced to follow a path defined by the material boundaries of the structure. For example, when a beam is excited at high frequency, stress waves travel in the beam along its axis away from the excitation source, i.e., the beam "guides" the waves along its axis. Similarly, in a plate, the two free surfaces of the plate "guide" the waves in the plane of the plate. In GW SHM, an actuator generating GWs is excited by some high-frequency pulse signal (typically a modulated sinusoidal toneburst of some limited number of cycles). In general, when a GW field is incident on a structural discontinuity, which has a size comparable to the GW wavelength, the wave scatters GWs in all directions. The structural discontinuity could be damage in the structure such as a crack or delamination; a structural feature (such as a stiffener); or a structural boundary. Therefore, to be able to distinguish between damage and structural features, one needs prior information about the structure in its undamaged state. This prior information is typically in the form of a baseline signal obtained for the "healthy state"

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

and is used as reference for comparison with the test case. There are two approaches commonly used in GW SHM: pulse echo and pitch–catch. In the former, after exciting the structure with a narrow bandwidth pulse, a sensor collocated with the actuator is used to "listen" for echoes of the pulse coming from discontinuities. Since the boundaries and the wave speed for a given center actuation frequency of the toneburst are known, the signals from the structural features can be filtered out (alternatively, one could subtract the test signal from the baseline signal). One is then left with signals from the defects (if present). From these signals, defects can be located using the wave speed. In the pitch–catch approach, a pulse signal is sent across the specimen under interrogation and a sensor at the other end of the specimen receives the signal. From various characteristics of the received signal, such as delay in time of transit, amplitude, frequency content, etc., information about the damage can be obtained. Thus, the pitch–catch approach cannot be used to locate the defect unless a dense network of transducers is used. In either approach, damage-sensitive features are extracted from the signal using some signal-processing algorithm (*see* **Signal Processing for Damage Detection**; **Wavelet Analysis**; **Damage Detection Using the Hilbert–Huang Transform**), and then a pattern-recognition technique (*see* **Statistical Pattern Recognition**; **Machine Learning Techniques**; **Artificial Neural Networks**) is required to classify the damage and estimate its severity. These steps involved in GW

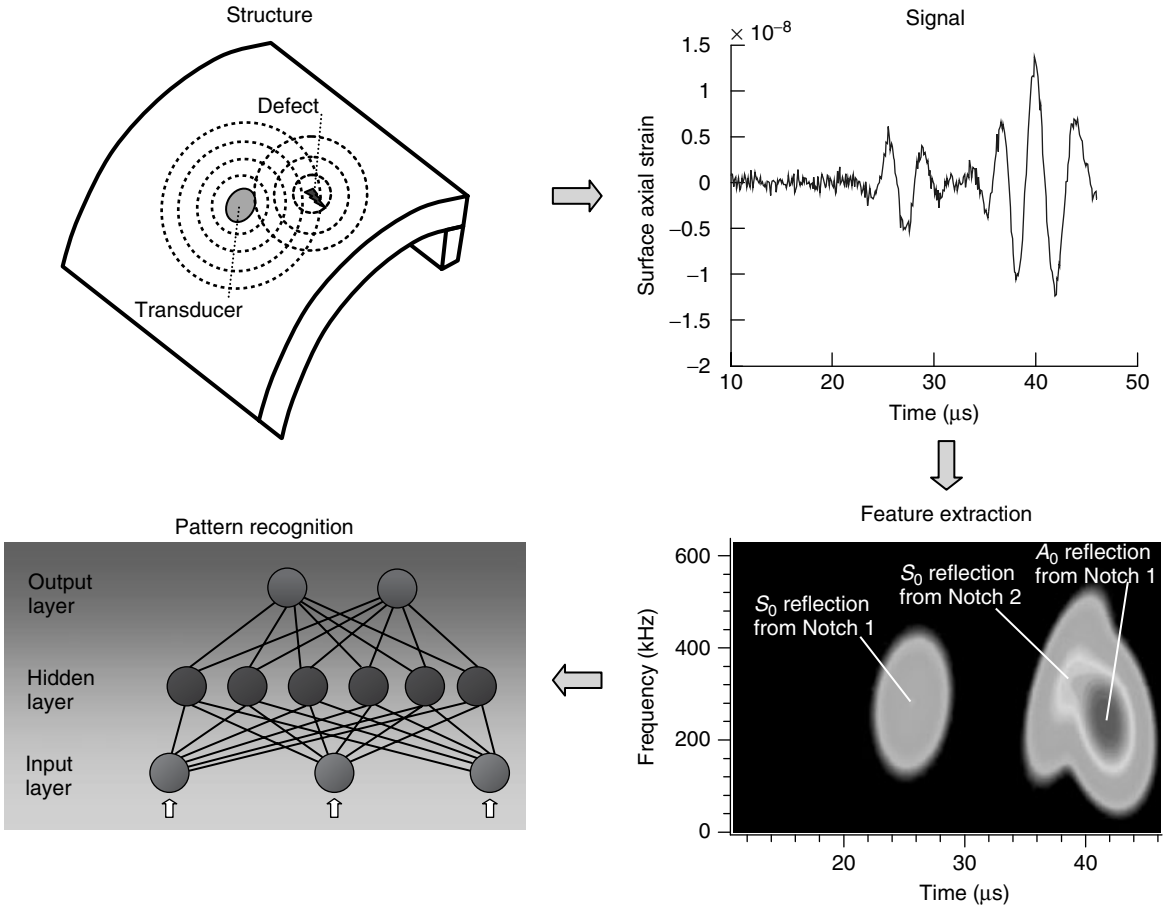

Figure 1. The four essential steps in GW SHM.

SHM are illustrated in Figure 1. Another crucial point to note is that GW SHM always involves the use of some threshold value to decide whether damage is present in the structure. The choice of the threshold is usually application dependent and typically relies on some false-positive probability estimation. A detailed survey paper on this technology, outlining efforts by various researchers in different aspects of this technology and application areas, is presented in [1].

There are several application areas for GWs in solids such as seismology, inspection, material characterization, electronic delay lines, etc., and consequently, they have been a subject of much study [2–5]. A very important class among these areas is that of Lamb waves, which can propagate in a solid plate (or shell) with free surfaces. Because of the abundance of plate- and shell-like structural configurations, this class of GWs has been the subject of much scrutiny. Another class of GW modes is also possible in plates, i.e., the horizontally polarized shear or SH modes. Other classes of GWs have also been examined in the literature. Among them is that of Rayleigh waves [6], which propagate close to the free surface of elastic solids. Other examples are Love [7], Stoneley [8], and Scholte [9] waves that travel at material interfaces. Lamb waves were first predicted mathematically and described by Horace Lamb [10]. Gazis [11] developed and analyzed the dispersion equations for GWs in hollow cylinders. However, neither was able to produce GWs experimentally. This was first done by Worlton [12], who was probably also the first person to recognize the potential of GWs for NDE.

GW testing can become complex owing to the multimodal and dispersive (dependence of wave speed on frequency) nature of these waves. In anisotropic structures, additionally, there can be significant dependence of wave speed on the direction of propagation and "steering" (the tendency of waves to move in a direction different from the launched direction). Hence, a fundamental understanding of wave propagation is essential for the successful application of this method. This understanding can also be very useful for better implementation of acoustic emission (which is a passive SHM method *see* **Acoustic Emission**), where sensors on the structure are tuned to sense GWs excited by damage initiation or growth.

2 FUNDAMENTALS OF ELASTIC WAVE PROPAGATION

The problem of wave propagation is presented below in three steps. First, one-dimensional (1D) wave propagation in a string under tension is introduced to establish some of the basic principles and nomenclature used in the field. This analysis is followed by a general 3D representation of an isotropic solid and analysis of free GWs in an infinite plate. GW excitation by finite-dimensional piezos in isotropic plates is covered next. Finally, wave propagation in transversely isotropic solids is analyzed and wave solutions are found for the GW modes in a multilayered laminated plate.

2.1 1D wave propagation

2.1.1 Introduction

To understand some basic concepts on wave propagation, consider the 1D wave propagation problem along the x direction. The problem of waves in a taut string serves as a good model problem for 1D wave propagation, as illustrated in Figure 2. Consider the following assumptions:

1. The restoring force in the string is due to the tension T.
2. The deflections w are small as are the angles of the string with respect to the horizontal at various points.
3. T is much larger in magnitude than the dynamic strain fluctuations.

From the equilibrium of an infinitesimal piece of the string, one obtains

$$T\frac{\partial^2 w}{\partial x^2} + q = \rho_L \frac{\partial^2 w}{\partial t^2} \tag{1}$$

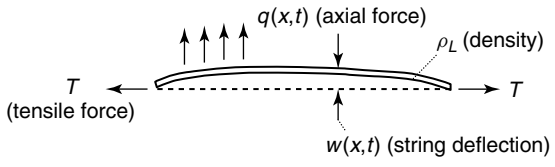

Figure 2. String under tension.

For the free vibrations case, $q = 0$ and equation (1) simplifies to

$$\frac{\partial^2 w}{\partial x^2} - \frac{1}{v^2}\frac{\partial^2 w}{\partial t^2} = 0; \quad v^2 = \frac{T}{\rho_L} \tag{2}$$

where v represents the square of the wave speed.

2.1.2 D'Alembert's solution for an infinite string

One can show that

$$w(x,t) = f(x - vt) + g(x + vt) \tag{3}$$

is a solution of equation (2), where f and g are arbitrary functions. This solution can be verified by direct substitution:

$$\frac{\partial^2 f(x - vt)}{\partial x^2} = f''; \quad \frac{\partial^2 f(x - vt)}{\partial t^2} = v^2 f'' \tag{4}$$

Therefore,

$$\text{LHS} = \frac{1}{v^2}(v^2 f'' + v^2 g'') = f'' + g'' = \text{RHS} \tag{5}$$

This solution for the 1D wave equation, known as *D'Alembert's solution*, can thus be used to solve initial value problems on infinite strings. For example, consider the following initial conditions:

$$w(x,0) = U(x); \quad \dot{w}(x,0) = V(x) \tag{6}$$

After inserting these conditions into D'Alembert's solution, equation (3) yields

$$w(x,t)|_{t=0} = f(x) + g(x) = U(x) \tag{7}$$

$$\dot{w}(x,t)|_{t=0} = v(-f'(x) + g'(x)) = V(x) \tag{8}$$

where $()'$ represents the derivative with respect to x. These two equations yield

$$w(x,t) = \frac{1}{2}[U(x - vt) + U(x + vt)] + \frac{1}{2v}\int_{x-vt}^{x+vt} V(s)\,\mathrm{d}s \tag{9}$$

To aid visualization, consider the simple case $V(x) = 0, U(x) = He(x - a) - He(x + a)$, where $He()$ is the Heaviside function. This case is illustrated in Figure 3.

2.1.3 Reflection from a fixed boundary

Consider a string fixed at one end and a wave pulse $f(x - vt)$ approaching the fixed end from $-\infty$. One can solve for the reflected wave from the fixed end at $x = 0$, which imposes the condition $w(0,t) = 0$, by creating an imaginary wave in the $+x$ axis. For this condition, as illustrated in Figure 4, imagine the string to be extended symmetrically to $+\infty$ and further consider a negative (of equal magnitude as the original pulse, but opposite in sign) wave pulse

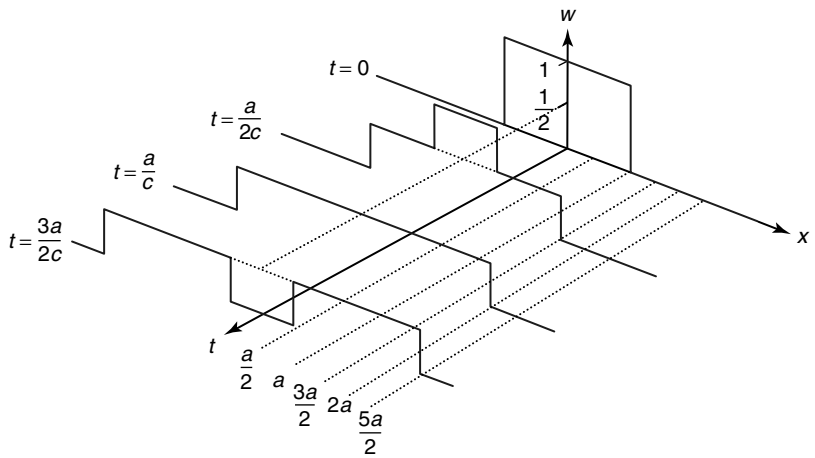

Figure 3. Simple example of transient wave propagation in a 1D string.

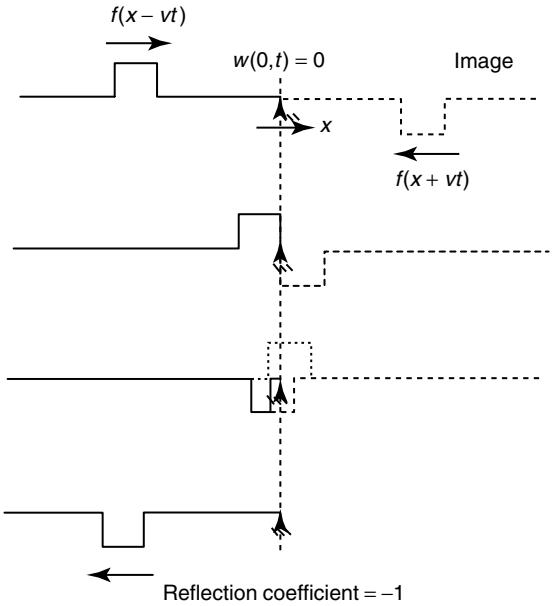

Figure 4. Reflection of a wave pulse in a string from a fixed boundary.

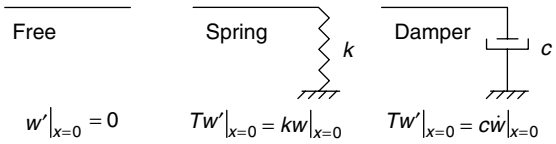

Figure 5. Other boundary conditions for the string problem.

approaching the fixed end simultaneous to the original pulse. As the two waves approach the fixed end, their superposition will ensure the satisfaction of the fixed boundary condition at that end. Since the superposition of the two waves is a feasible solution, by the uniqueness condition, it is indeed the solution. This solution is illustrated in Figure 4. As shown there, for a fixed end, the incident wave packet simply bounces off with its sign reversed. Other boundary conditions are described in Figure 5.

2.1.4 Reflection and buildup of standing waves in finite domains

Consider a finite string of length L with one end fixed and the other being harmonically excited, as shown in Figure 6. Thus, its boundary conditions are

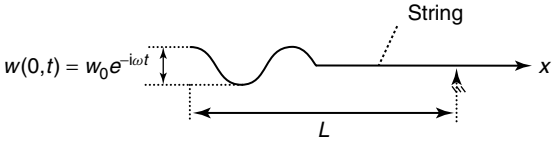

Figure 6. Buildup of waves in a finite string.

$$w(0,t) = w_0 \mathrm{e}^{-\mathrm{i}\omega t}; \quad w(L,t) = 0 \tag{10}$$

Before the rightward wave arrives at the fixed end, it propagates as if it were in an infinite string. Therefore, for the transient wave, D'Alembert's solution for an infinite string applies for this case for $t < L/v$.

The reflection coefficients γ_s at $x = 0$ and γ_e at $x = L$ are defined as follows:

$$\gamma_\mathrm{s} = \left.\frac{w_\mathrm{reflected}}{w_\mathrm{incident}}\right|_{x=0}; \quad \gamma_\mathrm{e} = \left.\frac{w_\mathrm{reflected}}{w_\mathrm{incident}}\right|_{x=L} \tag{11}$$

Since the boundary at $x = L$ is fixed, $\gamma_\mathrm{e} = -1$. Further, since only rightward propagating waves are sought,

$$w(x,t) = f(x - vt) \tag{12}$$

Now using the boundary condition at $x = 0$,

$$w(0,t) = f(-vt) = w_0 \mathrm{e}^{-\mathrm{i}\omega t} \tag{13}$$

One can identify the unknown function f as

$$f(\,) = w_0 \mathrm{e}^{\mathrm{i}\frac{\omega}{v}(\,)} \tag{14}$$

and, therefore, until $vt < L$,

$$\begin{aligned} w(x,t) &= w_0 \mathrm{e}^{\mathrm{i}(\xi x - \omega t)}; \quad \xi = \frac{\omega}{v} \quad \text{for } x < vt \\ &= 0 \qquad\qquad\qquad\quad \text{for } x > vt \end{aligned} \tag{15}$$

The symbols ω, ξ, and v introduced here are commonly encountered when analyzing harmonic waves in a medium. ω is called the *angular frequency*, and is related to the frequency of harmonic oscillations f by the relation

$$\omega = 2\pi f \tag{16}$$

ξ is the wavenumber and is related to the spatial wavelength λ_w of the wave by the following relation:

$$\xi = \frac{2\pi}{\lambda_w} \tag{17}$$

As can be seen from equation (17), the wavenumber is proportional to the number of wavelengths per unit distance. v (also denoted by v_{ph}) is called the *phase speed* and is the speed at which the harmonic wave propagates through the medium. Note that here the wave speed is independent of frequency. It is related to ω and ξ by the equation

$$\frac{\omega}{v} = \xi \tag{18}$$

When the disturbance reaches the fixed end at $x = L$ (at $t = L/v$) for the first time, the solution must be augmented by a leftward wave according to what was described in Section 2.1.4. Therefore, the total solution for $t > L/v$ is

$$w^1{}_{\text{total}} = (w_0 e^{i\xi x}) + (w_0 \gamma_e e^{i\xi L}\ e^{-i\xi(x-L)})e^{-i\omega t} \tag{19}$$

Rightward wave — Leftward wave

The first factor $e^{i\xi L}$ of the new second term appearing in the expression for w is needed to cancel out the first term (i.e., maintain $w = 0$ at $x = L$ as imposed by the boundary condition). The second factor of the second term $e^{-i\xi(x-L)}$ is the resultant leftward wave that has just started.

Once the wave travels all the way back to the left (length L), it will arrive at $x = 0$ at $t = 2L/v$. Again, to satisfy the boundary condition at this point, yet another wave is introduced, so that the new resultant wave is

$$w^2_{\text{total}} = w^1_{\text{total}} + \gamma_s \gamma_e w_0 e^{2i\xi L} e^{i(\xi x - \omega t)} \tag{20}$$

This goes on, and each time the wave hits one of the string boundaries, a new term is added. The terms of this expression are in geometric progression and can be written as

$$\begin{aligned} w(x,t) = w_0 \big(&e^{i\xi x} + \gamma_e e^{i\xi(2L-x)} + \gamma_s \gamma_e e^{i\xi(2L+x)} \\ &+ \gamma_s \gamma_e^2 e^{i\xi(4L-x)} \\ &+ \gamma_s^2 \gamma_e^2 e^{i\xi(4L+x)} + \cdots\big) e^{-i\omega t} \end{aligned} \tag{21}$$

For the steady-state solution, the sum of an infinite number of these terms is needed, and this can be expressed using the formula for geometric series yielding

$$w(x,t) = w_0 \left[\frac{e^{i\xi x} + \gamma_e e^{i\xi(2L-x)}}{1 - \gamma_e \gamma_s e^{2i\xi L}}\right] e^{-i\omega t} \tag{22}$$

Note that the same *steady-state* solution could have been reached by a much simpler approach. Assume a solution of the form

$$w(x,t) = \left(A e^{i\xi x} + B e^{-i\xi x}\right) e^{-i\omega t} \tag{23}$$

and impose $w(0,t) = w_0 e^{-i\omega t}$, $w(L,t) = 0$ to find the constants A and B. However, the earlier approach was adopted to provide an insight into how transients build up into the steady-state solution. A key lesson to learn from the above analysis is that *the solution for the infinite string holds for the finite string for analyzing the transient waves*. This will eventually prove useful in the analysis for GW testing, where essentially transient waves are used, particularly the transmitted pulse and first few echoes. Hence, an infinite plate wave solution can be used as part of the transient wave analysis in finite plates.

2.2 Wave propagation in isotropic solids

The equations governing wave propagation in isotropic plates are presented next. The 1D equations discussed above are first generalized to a 3D solid and then particularized for an infinite plate (or semi-infinite solid).

2.2.1 Isotropic linear elastic 3D solid

The general 3D equilibrium equations of motion for elastic solids are given by

$$\nabla \cdot \boldsymbol{\sigma} + \boldsymbol{f} = \rho \ddot{\boldsymbol{u}} \tag{24}$$

or equivalently by

$$\sigma_{ij,j} + f_i = \rho \ddot{u}_i \tag{25}$$

where the indices i, j, k can assume values 1–3, $\boldsymbol{\sigma}$ is the stress tensor, ρ is the density of the solid, $\boldsymbol{f}$ is the body force per unit volume and $\ddot{\boldsymbol{u}}$ is the acceleration vector. For simplicity, consider the case of a linear elastic isotropic medium. For this medium, the constitutive relations are given by

$$\sigma_{ij} = \lambda \varepsilon_{kk} \delta_{ij} + 2\mu \varepsilon_{ij} \tag{26}$$

where λ and μ are Lamé's constants for the isotropic medium, δ_{ij} is the Kronecker delta, and ε_{ij} are the components of the strain tensor. To complete the set of elasticity equations, the kinematical relations for the case of geometrically linear deformations are

$$\varepsilon_{ij} = \tfrac{1}{2}\left(u_{i,j} + u_{j,i}\right) \tag{27}$$

Combining these three sets of equations, one can reach the Navier's equation for a 3D isotropic body:

$$(\lambda + \mu)\nabla\nabla\cdot\boldsymbol{u} + \mu\nabla^2\boldsymbol{u} + \boldsymbol{f} = \rho\ddot{\boldsymbol{u}} \tag{28}$$

2.2.2 The Helmholtz decomposition for isotropic media

Consider a decomposition for the displacement vector $\boldsymbol{u}$ into a scalar potential ϕ and a vector $\mathbf{H}$. The physical meaning of these will become evident in due course. This decomposition eases the solution of the problem of wave propagation in a 3D elastic linear isotropic medium. Thus, let the displacement vector be expressed as follows:

$$\boldsymbol{u} = \nabla\phi + \nabla \times \mathbf{H} \tag{29}$$

Furthermore, for uniqueness of the solution, impose the divergence-free condition on $\mathbf{H}$:

$$\nabla\cdot\mathbf{H} = 0 \tag{30}$$

Such a decomposition is always possible and unique, since there are four equations and four unknowns (ϕ and the three components of $\mathbf{H}$) for a given displacement field. Again recalling Navier's elastodynamic equation of motion for zero body force, equation (28), we have

$$(\lambda + \mu)\nabla\nabla\cdot\boldsymbol{u} + \mu\nabla^2\boldsymbol{u} = \rho\ddot{\boldsymbol{u}} \tag{31}$$

The substitution of equations (29) and (30) into equation (31) yields

$$\begin{aligned}(\lambda + \mu)\nabla\left[\nabla\cdot(\nabla\phi + \nabla \times \mathbf{H})\right] \\ + \mu\nabla^2(\nabla\phi + \nabla \times \mathbf{H}) \\ = \rho\left(\nabla\ddot{\phi} + \nabla \times \ddot{\mathbf{H}}\right)\end{aligned} \tag{32}$$

This can be rewritten as

$$\nabla\left\{(\lambda + 2\mu)\nabla^2\phi - \rho\ddot{\phi}\right\} + \nabla \times \left\{\mu\nabla^2\mathbf{H} - \rho\ddot{\mathbf{H}}\right\} = 0 \tag{33}$$

Applying the operators $\nabla\cdot(\,)$ and $\nabla \times (\,)$ on equation (33), one gets

$$(\lambda + 2\mu)\nabla^2\phi - \rho\ddot{\phi} = 0; \quad \mu\nabla^2\mathbf{H} - \rho\ddot{\mathbf{H}} = 0 \tag{34}$$

or

$$\nabla^2\phi = \frac{1}{v_{\mathrm{p}}^2}\ddot{\phi}; \quad \nabla^2\mathbf{H} = \frac{1}{v_{\mathrm{s}}^2}\ddot{\mathbf{H}} \tag{35}$$

Therefore, the original elastodynamic vector equation, equation (31), is decomposed into a scalar wave equation for ϕ and a vector wave equation for $\mathbf{H}$. v_{p} and v_{s} are the wave speeds of the two possible bulk waves in an isotropic unbounded solid, viz., the longitudinal wave (a.k.a. "P" or "dilatational" wave; these are characterized by displacements normal to the propagation direction) and shear wave (a.k.a. "S" or "distortional" wave; these are characterized by displacements normal to the propagation direction).

2.2.3 Rayleigh–Lamb wave equation for an infinite plate

Consider an infinite plate of thickness $2b$, i.e., the domain D: $\{(x_1, x_2, x_3) = (-\infty, \infty) \times (-\infty, \infty) \times (-b, b)\}$ with free surfaces (Figure 7). Waves of interest are in the $x_1 - x_3$ plane, and there are no variations along x_2, i.e., $(\partial/\partial x_2) = 0$.

For this case, Helmholtz's decomposition yields

$$u_1 = \frac{\partial\phi}{\partial x_1} + \frac{\partial H_2}{\partial x_3}; \quad u_3 = \frac{\partial\phi}{\partial x_3} - \frac{\partial H_2}{\partial x_1} \tag{36}$$

$$u_2 = -\frac{\partial H_1}{\partial x_3} + \frac{\partial H_3}{\partial x_1}; \quad \frac{\partial H_1}{\partial x_1} + \frac{\partial H_3}{\partial x_3} = 0 \tag{37}$$

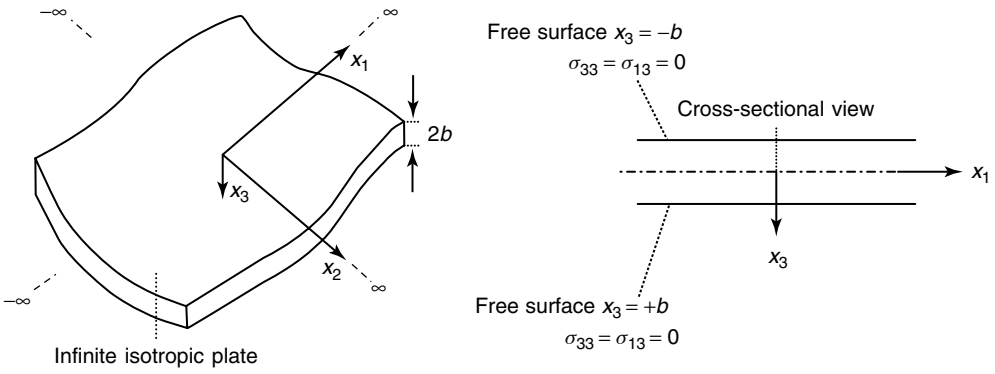

Figure 7. Infinite plate with free surfaces.

Since the boundaries $x_3 = +b$ and $x_3 = -b$ are stress-free, one has

$$\sigma_{33} = 0; \quad \sigma_{13} = \sigma_{31} = 0;$$
$$\sigma_{23} = \sigma_{32} = 0 \text{ at } x_3 = \pm b \tag{38}$$

Using equations (26), (27), and (36), these stress components can be written as

$$\sigma_{33} = (\lambda + 2\mu)\nabla^2\phi - 2\mu\left(\frac{\partial^2\phi}{\partial x_1^2} + \frac{\partial^2 H_2}{\partial x_1 \partial x_3}\right) \tag{39}$$

$$\sigma_{31} = \mu\left(2\frac{\partial^2\phi}{\partial x_1 \partial x_3} + \frac{\partial^2 H_2}{\partial x_3^2} - \frac{\partial^2 H_2}{\partial x_1^2}\right) \tag{40}$$

$$\sigma_{32} = \mu\left(-\frac{\partial^2 H_1}{\partial x_3^2} + \frac{\partial^2 H_3}{\partial x_1 \partial x_3}\right) \tag{41}$$

which will eventually be equated to zero at the plate's free surfaces to find the governing equations. It is interesting to note here that u_1, u_3, σ_{33}, and σ_{31} depend only on ϕ and H_2, while u_2 and σ_{32} depend only on H_1 and H_3. Thus, it suffices to consider the following two cases separately:

Case I

In this case $u_2 = 0$ and the governing equations are

$$\nabla^2\phi = \frac{1}{v_p^2}\ddot{\phi}; \quad \nabla^2 H_2 = \frac{1}{v_s^2}\ddot{H}_2 \tag{42}$$

The surface conditions are

$$\sigma_{33}|_{x_3=\pm b} = 0; \quad \sigma_{13}|_{x_3=\pm b} = 0 \tag{43}$$

Case II

In this case the governing equation is

$$\nabla^2 u_2 = \frac{1}{v_s^2}\ddot{u}_2 \tag{44}$$

The surface condition is

$$\sigma_{32}|_{x_2=\pm b} = 0 \tag{45}$$

As indicated by the previous equations, while the equations (42) are uncoupled, their solutions are coupled through the surface traction-free conditions. As a result, the combination of waves governed by equations (42) in a plate (known as *Lamb waves*) is always "dispersive," i.e., the wave velocity depends on the frequency of the traveling wave. On the other hand, for the waves governed by equation (44), called *SH* or *horizontal shear waves*, there exists a fundamental dispersionless mode at all frequencies.

To derive the equations for Lamb waves, consider first the governing equations in terms of the Helmholtz scalar and vector potentials, i.e., equations (42). Seeking plane wave solutions in the $x_1 - x_3$ plane for waves propagating along the $+x_1$ direction, assume solutions of the form

$$\phi = f\left(x_3\right)\mathrm{e}^{\mathrm{i}(\xi x_1 - \omega t)}; \quad H_2 = h_2\left(x_3\right)\mathrm{e}^{\mathrm{i}(\xi x_1 - \omega t)} \tag{46}$$

Using equations (46) and (42), one gets

$$\frac{\mathrm{d}^2 f}{\mathrm{d}x_3^2} + \left(\frac{\omega^2}{v_p^2} - \xi^2\right) f = 0;$$

$$\frac{\mathrm{d}^2 h_2}{\mathrm{d}x_3^2} + \left(\frac{\omega^2}{v_\mathrm{s}^2} - \xi^2\right) h_2 = 0 \tag{47}$$

Let

$$\frac{\omega^2}{v_\mathrm{p}^2} - \xi^2 \equiv \alpha^2; \quad \frac{\omega^2}{v_\mathrm{s}^2} - \xi^2 \equiv \beta^2 \tag{48}$$

The solutions to the differential equations in (47) are

$$\begin{aligned} f\left(x_3\right) &= A \sin \alpha x_3 + B \cos \alpha x_3; \\ h_2\left(x_3\right) &= C \sin \beta x_3 + D \cos \beta x_3 \end{aligned} \tag{49}$$

Substituting these solutions into equations (39), (40), and (46) and enforcing the conditions given by equations (43), two possible solutions result:

1. Symmetric modes

$$\begin{bmatrix} -\left(\xi^2 - \beta^2\right)\cos \alpha b & 2i\xi\beta \cos \beta b \\ -2i\xi\alpha \sin \alpha b & \left(\xi^2 - \beta^2\right)\sin \beta b \end{bmatrix} \times \begin{bmatrix} B \\ C \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \tag{50}$$

Nontrivial solutions for the constants B and C exist if and only if

$$\det \begin{bmatrix} -\left(\xi^2 - \beta^2\right)\cos \alpha b & 2i\xi\beta \cos \beta b \\ -2i\xi\alpha \sin \alpha b & \left(\xi^2 - \beta^2\right)\sin \beta b \end{bmatrix} = 0 \tag{51}$$

where "det[ ]" refers to the determinant of the matrix. This expression gives

$$\frac{\tan \beta b}{\tan \alpha b} = \frac{-4\alpha\beta\xi^2}{\left(\xi^2 - \beta^2\right)^2} \tag{52}$$

2. Antisymmetric modes

$$\begin{bmatrix} -\left(\xi^2 - \beta^2\right)\sin \alpha b & -2i\xi\beta \sin \beta b \\ 2i\xi\alpha \cos \alpha b & \left(\xi^2 - \beta^2\right)\cos \beta b \end{bmatrix} \times \begin{bmatrix} A \\ D \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \tag{53}$$

Nontrivial solutions for the constants A and D exist if and only if

$$\det \begin{bmatrix} -\left(\xi^2 - \beta^2\right)\sin \alpha b & -2i\xi\beta \sin \beta b \\ 2i\xi\alpha \cos \alpha b & \left(\xi^2 - \beta^2\right)\cos \beta b \end{bmatrix} = 0 \tag{54}$$

This gives

$$\frac{\tan \beta b}{\tan \alpha b} = \frac{-\left(\xi^2 - \beta^2\right)^2}{4\alpha\beta\xi^2} \tag{55}$$

Therefore, given a certain isotropic material, equations (52) and (55) can be solved numerically to find the relation between the driving angular frequency ω and the wavenumber ξ from which the corresponding phase speed v_{ph} can be found. This relation is plotted in Figure 8(a) for an aluminum alloy (material properties used: Young's modulus $E = 70\,\mathrm{GPa}$; Poisson's ratio $\nu = 0.33$; density $\rho = 2700\,\mathrm{kg\,m^{-3}}$). Consequently, a finite time-span pulse (which would have a Fourier transform with a certain spread in the frequency domain) will be distorted as it propagates owing to the different phase speeds of its individual frequency components. Another important characteristic is the group speed dispersion curve (Figure 8b). The magnitude of the group velocity for an isotropic medium (denoted by $\boldsymbol{v}_{\mathrm{gr}}$) is the derivative of the angular frequency with respect to the wavenumber ξ and its direction is coincident with that of the phase velocity. Its magnitude gives a very good approximation to the speed of the peak of the modulation envelope of a narrow frequency bandwidth pulse. This approximation improves in accuracy as the pulse moves further away from the source or if the GW mode becomes less dispersive. The procedure above, although for a simple structure, can be generalized to obtain dispersion curves for complex structures (*see* e.g., **Noncontact Rail Monitoring by Ultrasonic Guided Waves**; **Multiwire Strands**).

The resulting displacement components are given by

$$\begin{aligned} u_1 &= \left\{i\xi\left(A \sin \alpha x_3 + B \cos \alpha x_3\right)\right. \\ &\quad \left. + \beta\left(C \cos \beta x_3 - D \sin \beta x_3\right)\right\} \mathrm{e}^{\mathrm{i}(\xi x_1 - \omega t)} \\ u_3 &= \left\{\alpha\left(A \cos \alpha x_3 - B \sin \alpha x_3\right)\right. \\ &\quad \left. - i\xi\left(C \sin \beta x_3 + D \cos \beta x_3\right)\right\} \mathrm{e}^{\mathrm{i}(\xi x_1 - \omega t)} \end{aligned} \tag{56}$$

For $A = D = 0; B, C \neq 0$, one has symmetric Lamb modes, i.e., symmetric u_1 and antisymmetric u_3 about $x_3 = 0$. For $A, D \neq 0$; $B = C = 0$, one has antisymmetric Lamb modes, i.e., antisymmetric u_1 and symmetric u_3 about $x_3 = 0$. The discussion

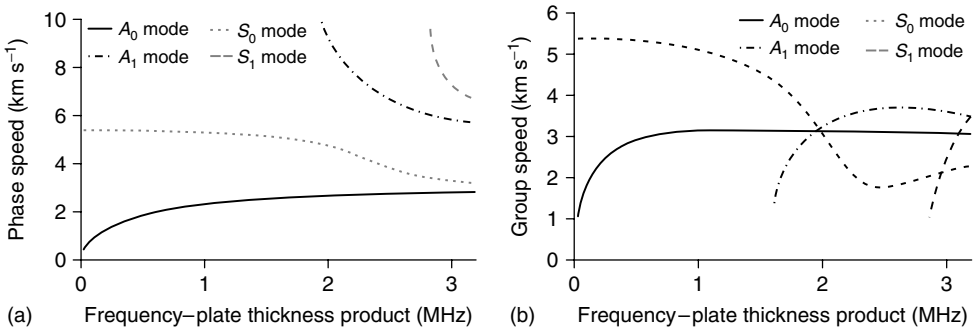

Figure 8. Dispersion curves for Lamb modes in an isotropic aluminum plate structure: (a) phase speed and (b) group speed.

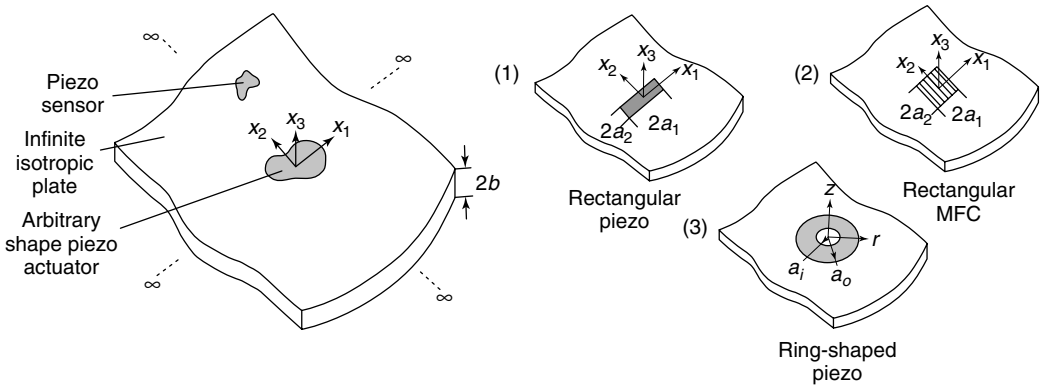

Figure 9. Infinite isotropic plate with arbitrary shape surface-bonded piezo actuator and piezo sensor and the three specific piezo shapes considered.

till this point has only covered free bulk waves and GWs. The next subsection covers GW excitation by piezoelectric wafer transducers (*see* **Piezoceramic Materials—Phenomena and Modeling**; **Piezoelectricity Principles and Materials**; **Piezoelectric Wafer Active Sensors**; **Integrated Sensor Durability and Reliability**), which are among the more commonly used GW SHM transducers.

2.2.4 GW excitation by finite-dimensional piezoelectric wafer transducers in plates

In this section, general expressions for the GW field excited by an arbitrary shape (finite-dimensional) piezoelectric wafer (called *piezo* here) actuator surface bonded on an infinite isotropic plate are presented. Consider an actuator bonded on the surface $x_3 = +b$, as illustrated in Figure 9. The origin is located midway through the plate thickness and the x_3 axis is normal to the plate surface. The starting point is the equations of elasticity in terms of the Helmholtz components, i.e., equations (35). However, for this problem, the 3D elasticity equations of motion cannot be simplified by ignoring variations along one direction in the plane of the plate.

Harmonic excitation at angular frequency ω is assumed. The response to any transient excitation signal can then be found by superimposing the individual responses to the harmonic components of that signal. The 2D spatial Fourier transform is applied to equations (35) in the spatial domain along x_1 and x_2. For a generic variable ψ, it is defined by (denoting the wavenumber components along x_1 and x_2 by ξ_1 and ξ_2, respectively)

$$\tilde{\psi}\left(\xi_1, \xi_2\right) = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \psi\left(x_1, x_2\right) \mathrm{e}^{\mathrm{i}(\xi_1 x_1 + \xi_2 x_2)}\, \mathrm{d}x_1\, \mathrm{d}x_2 \tag{57}$$

and the inverse transform is given by

$$\psi\left(x_1, x_2\right) = \frac{1}{4\pi^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\tilde{\psi}\left(\xi_1, \xi_2\right) \times \mathrm{e}^{-i(\xi_1 x_1 + \xi_2 x_2)}\,\mathrm{d}\xi_1\,\mathrm{d}\xi_2 \tag{58}$$

This yields the stresses and displacements in the Fourier wavenumber domain in terms of eight free constants. Similar to the analysis in the previous section, the problem can be decomposed into two independent problems involving four constants each corresponding to symmetric and antisymmetric GW modes. Then, one enforces the forcing condition due to the surface-bonded piezo actuator. This is modeled as causing shear traction normal to its free edge along its boundary on the free surface to which it is bonded. Thus, on the surface $x_3 = b$,

$$\sigma_{31} = \tau_0 \cdot F_1\left(x_1, x_2\right) \quad \sigma_{32} = \tau_0 \cdot F_2\left(x_1, x_2\right)$$
$$\sigma_{33} = 0 \tag{59}$$

where F_1 and F_2 are functions that are zero everywhere except around the edge of the piezo actuator and τ_0 is the magnitude of the shear traction (linearly proportional to the product of the piezo's piezoelectric constant d_{31} or d_{33} and in-plane Young's modulus). This assumes uncoupled dynamics between the actuator and plate. For example, for a rectangular actuator of dimensions $2a_1$ and $2a_2$ along the x_1 and x_2 axes, with its center aligned with the in-plane location of the origin of the coordinate system,

$$\begin{aligned} F_1 &= \left[\delta\left(x_1 - a_1\right) - \delta\left(x_1 + a_1\right)\right] \\ &\quad \times \left[He\left(x_2 + a_2\right) - He\left(x_2 - a_2\right)\right] \\ F_2 &= \left[He\left(x_1 + a_1\right) - He\left(x_1 - a_1\right)\right] \\ &\quad \times \left[\delta\left(x_2 - a_2\right) - \delta\left(x_2 + a_2\right)\right] \end{aligned} \tag{60}$$

where $\delta(\,)$ is the Kronecker delta function and $He(\,)$ is the Heaviside function. Equating the external forcing conditions would give three equations in four unknowns. The fourth equation results from the divergence condition on $\mathbf{H}$, applied on $x_3 = b$. Solving for the constants yields the following equation for out-of-plane displacement in the spatial domain:

$$\begin{aligned} u_3 = \frac{\tau_0}{4\pi^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} &\frac{-i.\mathrm{e}^{-\mathrm{i}(\xi_1 x_1 + \xi_2 x_2 - \omega t)}}{D_S(\xi)} \\ &\times \left[2\alpha\beta \sin\alpha b \cos\beta b + (\xi^2 - \beta^2)\sin\beta b \cos\alpha b\right] \\ &\times \left(\xi_1 \tilde{F}_1\left(\xi_1, \xi_2\right) + \xi_2 \tilde{F}_2\left(\xi_1, \xi_2\right)\right)\mathrm{d}\xi_1\,\mathrm{d}\xi_2 \end{aligned} \tag{61}$$

where

$$\xi^2 = \xi_1^2 + \xi_2^2; \quad \alpha^2 = \left(-\xi_1^2 - \xi_2^2\right) + \frac{\omega^2}{v_\mathrm{p}^2};$$

$$\beta^2 = \left(-\xi_1^2 - \xi_2^2\right) + \frac{\omega^2}{v_\mathrm{s}^2}$$

$$D_S(\xi) = \left(\xi^2 - \beta^2\right)^2 \cos\alpha b \sin\beta b + 4\xi^2\alpha\beta \sin\alpha b \cos\beta b$$

The integral form results from applying the inverse 2D Fourier transform in the wavenumber domain. This integrand is singular at the points corresponding to the real roots of $D_S = 0$. The integrands for u_1 or u_2 can also be singular at the roots of $\sin\beta b = 0$ depending on the actuator shape. The former corresponds to the wavenumbers, ξ^S, from the solutions of the Rayleigh–Lamb equation for symmetric modes at frequency ω, i.e., equation (52). The latter corresponds to the wavenumbers of SH waves. While in the above derivation only symmetric modes were considered, the contribution from antisymmetric modes can be found analogously and the complete solution would be a superposition of these two modal contributions.

To illustrate the inversion process in the integral expression for u_3, equations (60) and (61) can be rewritten as

$$\begin{aligned} u_3 = \frac{\tau_0}{\pi^2\mu}\mathrm{e}^{\mathrm{i}\omega t}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} &\frac{T_S(\xi)}{\xi \cdot D_S(\xi)} \\ &\times \frac{\sin\left(\xi a_1 \cos\gamma\right)\sin\left(\xi a_2 \sin\gamma\right)}{\sin\cos\gamma} \\ &\cdot \mathrm{e}^{-i\xi(x_1\cos\gamma + x_2\sin\gamma)}\,\mathrm{d}\gamma\,\mathrm{d}\xi \end{aligned} \tag{62}$$

with $T_S(\xi) = \xi^2(\beta^2 - \xi^2)\cos\alpha b \sin\beta b - 2\alpha\beta\xi^2 \cos\beta b \sin\alpha b$. Here the Cartesian wavenumbers ξ_1 and ξ_2 have been replaced by the polar wavenumber coordinates ξ and γ. To obtain the 2D spatial inverse

Fourier transform, residue calculus is used. For convenience, the integral in equation (62) is rewritten thus:

$$u_3 = \frac{-\tau_0}{4\pi^2\mu} e^{i\omega t} \int_0^{\infty} \int_0^{2\pi} \frac{T_S(\xi)}{\xi \cdot D_S(\xi)} \times \frac{\left(e^{i\xi a_1 \cos\gamma} - e^{-i\xi a_1 \cos\gamma}\right)\left(e^{i\xi a_2 \sin\gamma} - e^{-i\xi a_2 \sin\gamma}\right)}{\sin\gamma \cos\gamma} \times e^{-i\xi(x_1 \cos\gamma + x_2 \sin\gamma)} \, d\gamma \, d\xi = \frac{-\tau_0}{4\pi^2\mu} e^{i\omega t} \left(\int_0^{\infty} \int_0^{2\pi} \frac{T_S(\xi)}{\xi \cdot D_S(\xi)} \times \frac{e^{-i\hat{\xi}^S((x_1-a_1)\cos\gamma + (x_2-a_2)\sin\gamma - \omega t)}}{\sin\gamma \cos\gamma} \, d\gamma \, d\xi + \cdots \right) \tag{63}$$

The "..." indicates that there are three other similar integrals. Consider the first of the four integrals in the second line of equation (63), say I_1. It is further rewritten as follows:

$$I_1 = \int_{\gamma_1 - \pi/2}^{\gamma_1 + \pi/2} \int_{-\infty}^{\infty} \frac{T_S(\xi)}{\xi \cdot D_S(\xi)} \frac{e^{-i(\xi r_1 \cos(\gamma - \gamma_1) - \omega t)}}{\sin\gamma \cos\gamma} \, d\xi \, d\gamma \tag{64}$$

where $\gamma_1 = \tan^{-1}\left(x_2 - a_2 / x_1 - a_1\right)$ and $r_1 = \sqrt{((x_1 - a_1)^2 + (x_2 - a_2)^2)}$. This form ensures that the coefficient of ξ in the exponent remains positive over the domain of integration. The inner integral along the real ξ axis is solved by considering a contour integral in the lower half of the complex ξ plane, the semicircular portion C with radius $|\xi| = R \to \infty$. Using the residue theorem for the inner integral in equation (64) yields in this case (assuming I is the integrand in I_1)

$$\int_{-\infty}^{\infty} I \, d\xi + \int_C I \, d\xi = -\pi i \sum_{\hat{\xi}^S} \mathrm{Res}\left(\mathrm{I}\left(\hat{\xi}^S\right)\right) \tag{65}$$

where $\hat{\xi}^S$ are the roots of the Rayleigh–Lamb equation for symmetric modes ($D_S = 0$). It can be shown that the contribution over the semicircular portion C of the contour vanishes (see [13] for details). Therefore,

$$\int_C I \, d\xi = 0; \quad \int_{-\infty}^{\infty} I \, d\xi = -\pi i \sum_{\hat{\xi}} \mathrm{Res}\left(\mathrm{I}\left(\hat{\xi}^S\right)\right)$$

$$I_1 = \sum_{\hat{\xi}^S} \int_{\gamma_1 - \pi/2}^{\gamma_1 + \pi/2} \frac{T_S\left(\hat{\xi}^S\right)}{\hat{\xi}^S \cdot D_S'\left(\hat{\xi}^S\right)} \times \frac{e^{-i\left(\hat{\xi}^S r_1 \cos(\gamma - \gamma_1) - \omega t\right)}}{\sin\gamma \cos\gamma} \, d\gamma \tag{66}$$

where $(\,)'$ indicates a derivative with respect to ξ. A similar approach can be used to solve the other three integrals in equation (63), to finally yield the expression for u_3. Expressions for ring-shaped piezo actuators have also been derived in [14]. The GW field excited by anisotropic piezocomposites, such as macro fiber composite (MFC) actuators, consisting of piezo fibers in an epoxy matrix, has been derived for isotropic plates, hollow cylinders, and rectangular-sectional beams in [13, 15]. These have also been extensively validated by numerical and experimental results (see, e.g., Figure 10).

2.3 Wave propagation in anisotropic solids

Fiber-reinforced composite materials are becoming increasingly common in aerospace and other structures owing to their superior stiffness-to-mass ratio and corrosion resistance compared to metals (*see* **Lamb Wave-based SHM for Laminated Composite Structures**; **Commercial Fixed-wing Aircraft**). Therefore, it is useful to have a basic understanding of bulk elastic waves in transversely isotropic solids with uniform density, which serve as a useful model for unidirectional fiber-reinforced composites. This model is most effective if the wavelength is large compared to the fiber diameter and interfiber spacing. This is then used to build the solution for GWs in multilayered laminated plates (Figure 11).

2.3.1 Transversely isotropic elastic 3D solid

First, consider the general solution for bulk waves in a generic anisotropic medium with uniform density ρ. The equations of motion for the bulk medium are

$$\nabla \boldsymbol{c} \nabla^T \bar{\boldsymbol{u}} = \rho \ddot{\bar{\boldsymbol{u}}} \tag{67}$$

where $\bar{\boldsymbol{u}}$ is the local displacement vector (later the global displacement vector $\boldsymbol{u}$ will be introduced for

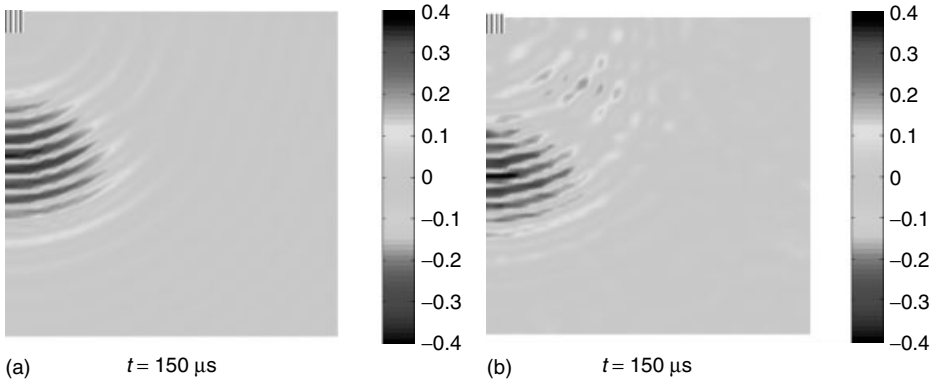

Figure 10. Surface plots showing out-of-plane velocity signals over a $20 \times 20\,\text{cm}^2$ quarter section of an aluminum plate excited by macro fiber composites (the striped portion in the upper left corner) in the A_0 mode using a 30 kHz, 3.5 cycle windowed toneburst: (a) Using the model from [13] and (b) experimental plot obtained using laser vibrometry. Both plots are normalized to the respective peak values over all time instants.

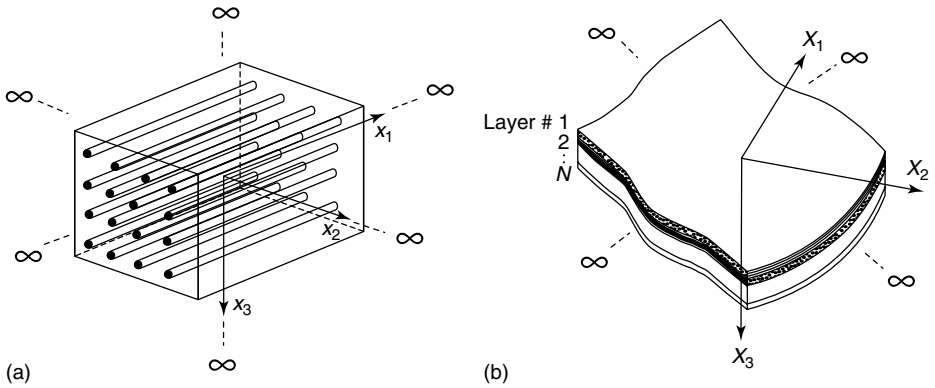

Figure 11. (a) Infinite transversely isotropic solid and (b) multilayered laminated composite plate.

the laminate), $\boldsymbol{c}$ is the stiffness matrix and the operator ∇ is defined as

$$\nabla \equiv \begin{bmatrix} \dfrac{\partial}{\partial x_1} & 0 & 0 & 0 & \dfrac{\partial}{\partial x_3} & \dfrac{\partial}{\partial x_2} \\ 0 & \dfrac{\partial}{\partial x_2} & 0 & \dfrac{\partial}{\partial x_3} & 0 & \dfrac{\partial}{\partial x_1} \\ 0 & 0 & \dfrac{\partial}{\partial x_3} & \dfrac{\partial}{\partial x_2} & \dfrac{\partial}{\partial x_1} & 0 \end{bmatrix} \tag{68}$$

For a unidirectional fiber-reinforced composite, if the fibers are oriented along the 1-direction in the local coordinate system (x_1, x_2, x_3) of the material, the stress–strain relation and the stiffness matrix $\boldsymbol{c}$ for the transversely isotropic material are

$$\begin{bmatrix} \bar{\sigma}_{11} \\ \bar{\sigma}_{22} \\ \bar{\sigma}_{33} \\ \bar{\sigma}_{23} \\ \bar{\sigma}_{31} \\ \bar{\sigma}_{12} \end{bmatrix} = \boldsymbol{c} \begin{bmatrix} \bar{u}_{1,1} \\ \bar{u}_{2,2} \\ \bar{u}_{3,3} \\ \bar{u}_{2,3} + \bar{u}_{3,2} \\ \bar{u}_{1,3} + \bar{u}_{3,1} \\ \bar{u}_{2,1} + \bar{u}_{1,2} \end{bmatrix};$$

$$\boldsymbol{c} = \begin{bmatrix} c_{11} & c_{12} & c_{12} & 0 & 0 & 0 \\ c_{12} & c_{22} & c_{23} & 0 & 0 & 0 \\ c_{12} & c_{23} & c_{22} & 0 & 0 & 0 \\ 0 & 0 & 0 & c_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & c_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{55} \end{bmatrix},$$

$$\text{with} \quad c_{44} = \frac{c_{22} - c_{23}}{2} \tag{69}$$

Here $\bar{\sigma}_{ij}$, with i and j taking integer values from 1 to 3, are the local stress components. Next, constants are introduced that correspond to the squares of bulk wave speeds possible along the principal directions:

$$
\begin{aligned}
a_1 &= \frac{c_{22}}{\rho} \text{ (longitudinal wave normal to the fiber direction)} \\
a_2 &= \frac{c_{11}}{\rho} \text{ (longitudinal wave along the fiber direction)} \\
a_3 &= \frac{\left(c_{12}+c_{55}\right)}{\rho} \text{ (shear wave in the plane of isotropy)} \\
a_4 &= \frac{\left(c_{22}-c_{23}\right)}{2\rho} = \frac{c_{44}}{\rho} \text{ (shear wave along the fiber direction)} \\
a_5 &= \frac{c_{55}}{\rho} \text{ (shear wave in the plane of isotropy)}
\end{aligned}
\tag{70}
$$

Viscoelastic damping can be modeled by the use of complex stiffness constants. Suppose the wavenumber components are ξ_1, ξ_2, and ζ along the 1-, 2-, and 3-local directions, respectively. Furthermore, without loss of generality, consider harmonic excitation at angular frequency ω. Then the wave field is of the form

$$
\bar{\boldsymbol{u}} = \bar{\boldsymbol{\Omega}} \mathrm{e}^{-\mathrm{i}\left(\xi_1 x_1 + \xi_2 x_2 + \zeta x_3 - \omega t\right)} \tag{71}
$$

where $\bar{\boldsymbol{\Omega}}$ is a linear superposition of the possible eigenvectors. Then, from equations (67–71), one obtains the Christoffel equation:

$$
\begin{bmatrix}
c_{11}\xi_1^2 + c_{55}\left(\xi_2^2+\zeta^2\right) & \left(c_{12}+c_{55}\right)\xi_1\xi_2 & \left(c_{12}+c_{55}\right)\xi_1\zeta \\
\left(c_{12}+c_{55}\right)\xi_1\xi_2 & c_{55}\xi_1^2 + c_{22}\xi_2^2 + c_{44}\zeta^2 & \left(c_{23}+c_{44}\right)\xi_2\zeta \\
\left(c_{12}+c_{55}\right)\xi_1\zeta & \left(c_{23}+c_{44}\right)\xi_2\zeta & c_{55}\xi_1^2 + c_{44}\xi_2^2 + c_{22}\zeta^2
\end{bmatrix}
\begin{bmatrix} \bar{\Omega}_1 \\ \bar{\Omega}_2 \\ \bar{\Omega}_3 \end{bmatrix}
= \rho\omega^2
\begin{bmatrix} \bar{\Omega}_1 \\ \bar{\Omega}_2 \\ \bar{\Omega}_3 \end{bmatrix}
\tag{72}
$$

For fixed values of ξ_1, ξ_2, and ω, there are six possible roots $\pm\zeta_i$, $i = 1$–3, of this equation. The first two pairs of roots correspond to pairs of "quasi-longitudinal" waves (characterized by displacements dominantly along the wave propagation direction but with small components normal to it) and "quasi-shear" waves (characterized by displacements dominantly normal to the wave propagation direction but with small components along it; see [3]). The wavenumbers in the thickness direction corresponding to these four roots are, respectively

$$
\begin{aligned}
&\zeta_1^2 = -\xi_2^2 + b_1; \quad \zeta_2^2 = -\xi_2^2 + b_2 \\
&b_1 = -\left(\frac{\beta}{2\alpha}\right) - \sqrt{\left(\frac{\beta}{2\alpha}\right)^2 - \frac{\gamma}{\alpha}}; \\
&b_2 = -\left(\frac{\beta}{2\alpha}\right) + \sqrt{\left(\frac{\beta}{2\alpha}\right)^2 - \frac{\gamma}{\alpha}} \\
&\alpha = a_1 a_5; \\
&\beta = \left(a_1 a_2 + a_5^2 - a_3^2\right)\xi_1^2 - \omega^2\left(a_1 + a_5\right); \\
&\gamma = \left(a_2\xi_1^2 - \omega^2\right)\left(a_5\xi_1^2 - \omega^2\right)
\end{aligned}
\tag{73}
$$

The third pair of roots corresponds to quasi-shear waves and their through-thickness wavenumbers are given by

$$
\zeta_3^2 = -\xi_2^2 + \frac{\left(\omega^2 - a_5\xi_1^2\right)}{a_4} \tag{74}
$$

The displacement eigenvectors resulting from equation (72) corresponding to these roots are

$$
\begin{aligned}
\boldsymbol{e}_1 &= \begin{bmatrix} i\xi_1 q_{11} & i\xi_2 q_{21} & i\zeta_1 q_{21} \end{bmatrix}^{\mathrm{T}}; \\
\boldsymbol{e}_2 &= \begin{bmatrix} i\xi_1 q_{12} & i\xi_2 q_{22} & i\zeta_2 q_{22} \end{bmatrix}^{\mathrm{T}}; \\
\boldsymbol{e}_3 &= \begin{bmatrix} 0 & i\zeta_3 & -i\xi_2 \end{bmatrix}^{\mathrm{T}}
\end{aligned}
\tag{75}
$$

where

$$
\begin{aligned}
q_{11} &= a_3 b_1; \quad q_{21} = \omega^2 - a_2\xi_1^2 - a_5 b_1; \\
q_{21} &= a_3 b_2; \quad q_{22} = \omega^2 - a_2\xi_1^2 - a_5 b_2
\end{aligned}
\tag{76}
$$

The other three eigenvectors $\boldsymbol{e}_4$, $\boldsymbol{e}_5$, and $\boldsymbol{e}_6$ are obtained by replacing ζ_i by $-\zeta_i (\zeta_i \geq 0)$. The general

solution for the displacement vector is then given by

$$\begin{aligned}\bar{\boldsymbol{u}} &= \left(C_{1+}\boldsymbol{e}_1 e^{i\zeta_1 x_3} + C_{2+}\boldsymbol{e}_2 e^{i\zeta_2 x_3} + C_{3+}\boldsymbol{e}_3 e^{i\zeta_3 x_3}\right.\\ &\quad + C_{1-}\boldsymbol{e}_4 e^{-i\zeta_1 x_3} + C_{2-}\boldsymbol{e}_5 e^{-i\zeta_2 x_3}\\ &\quad \left. + C_{3-}\boldsymbol{e}_6 e^{-i\zeta_3 x_3}\right) e^{-i(\xi_1 x_1 + \xi_2 x_2 - \omega t)}\\ &= \begin{bmatrix}\boldsymbol{Q}_{11} & \boldsymbol{Q}_{12}\end{bmatrix}\begin{bmatrix}\bar{\boldsymbol{E}}_+(x_3) & 0\\ 0 & \bar{\boldsymbol{E}}_-(x_3)\end{bmatrix}\\ &\quad \times \begin{bmatrix}\boldsymbol{C}_+\\ \boldsymbol{C}_-\end{bmatrix} e^{-i(\xi_1 x_1 + \xi_2 x_2 - \omega t)}\end{aligned} \tag{77}$$

where $C_{i\pm}$, $i = 1\text{–}3$, are free constants, and

$$\begin{aligned}&\boldsymbol{Q}_{11} = \begin{bmatrix}\boldsymbol{e}_1 & \boldsymbol{e}_2 & \boldsymbol{e}_3\end{bmatrix};\quad \boldsymbol{Q}_{12} = \begin{bmatrix}\boldsymbol{e}_4 & \boldsymbol{e}_5 & \boldsymbol{e}_6\end{bmatrix}\\ &\bar{\boldsymbol{E}}_+(x_3) = \mathrm{Diag}\left[e^{i\zeta_1 x_3}, e^{i\zeta_2 x_3}, e^{i\zeta_3 x_3}\right]\\ &\bar{\boldsymbol{E}}_-(x_3) = \mathrm{Diag}\left[e^{i\zeta_1 x_3}, e^{i\zeta_2 x_3}, e^{i\zeta_3 x_3}\right]\end{aligned} \tag{78}$$

2.3.2 GWs in multilayered laminated plates

With the general solution for the bulk medium in place, one can then solve for free GWs in multilayered laminated plates. The equations in this particular subsection are adapted from [16] and details can be found there. Each ply is a unidirectional fiber-reinforced composite whose fibers are in the plane of the plate.

Owing to the different orientations of the fibers in the different layers, it is useful to work with a global coordinate system (X_1, X_2, X_3) distinct from the local coordinate system, for which the x_1^m axis of the mth ply (m being between 1 and N) is aligned with the fiber direction. However, the X_3 and x_3^m axes are coincident and the two coordinate systems differ only in the plane of the plate. One can relate the displacement vector $\boldsymbol{u}$ in the global system and $\bar{u}^m$ in the local system using the transformation matrix $\boldsymbol{L}^m$ (with ϕ^m being the angle between the X_1 and x_1^m axes):

$$\begin{aligned}&\boldsymbol{u}^m = \boldsymbol{L}^m \bar{\boldsymbol{u}}^m\\ &\text{where}\quad \boldsymbol{L}^m = \begin{bmatrix}\cos\phi^m & -\sin\phi^m & 0\\ \sin\phi^m & \cos\phi^m & 0\\ 0 & 0 & 1\end{bmatrix}\end{aligned} \tag{79}$$

Using "global" wavenumbers K_1 and K_2 along the X_1 and X_2 directions, plane wave solutions of the following form are assumed:

$$\begin{aligned}\boldsymbol{u}^m &= \boldsymbol{U}^m(X_3)\, e^{i(K_1 X_1 + K_2 X_2 - \omega t)};\\ \boldsymbol{\sigma}^m &= \boldsymbol{\Sigma}^m(X_3)\, e^{i(K_1 X_1 + K_2 X_2 - \omega t)}\end{aligned} \tag{80}$$

The global wavenumbers K_1 and K_2 are related to the "local" wavenumbers ξ_1 and ξ_2 in each layer through the following relation:

$$\begin{bmatrix}\xi_1\\ \xi_2\end{bmatrix} = \begin{bmatrix}\cos(\phi^m) & \sin(\phi^m)\\ -\sin(\phi^m) & \cos(\phi^m)\end{bmatrix}\begin{bmatrix}K_1\\ K_2\end{bmatrix} \tag{81}$$

Traction and displacement continuity must be maintained across the interfaces between the different layers. Therefore, it is convenient to work with a "displacement–stress vector" $\boldsymbol{S}^m$ defined by

$$\boldsymbol{S}^m(X_3) = \left\{\boldsymbol{U}^m(X_3)\ \boldsymbol{\Sigma}_{i3}^m(X_3)\right\}^T \tag{82}$$

Then, from equations (69), (77), and (79)

$$\begin{aligned}\boldsymbol{S}^m(X_3) &= \begin{bmatrix}\boldsymbol{L}^m & \boldsymbol{0}\\ \boldsymbol{0} & \boldsymbol{L}^m\end{bmatrix}\begin{bmatrix}\boldsymbol{Q}_{11}^m & \boldsymbol{Q}_{12}^m\\ \boldsymbol{Q}_{21}^m & \boldsymbol{Q}_{22}^m\end{bmatrix}\\ &\quad \times \begin{bmatrix}\boldsymbol{E}_+^m(X_3) & \boldsymbol{0}\\ \boldsymbol{0} & \boldsymbol{E}_-^m(X_3)\end{bmatrix}\begin{Bmatrix}\boldsymbol{C}_+^m\\ \boldsymbol{C}_-^m\end{Bmatrix}\\ &\equiv \boldsymbol{Q}^m(X_3)\,\boldsymbol{C}^m\end{aligned} \tag{83}$$

where

$$\begin{aligned}\boldsymbol{Q}_{21}^m &= \begin{bmatrix}-\rho a_5\xi_1\zeta_1(q_{11}+q_{21}) & -\rho a_5\xi_1\zeta_2(q_{12}+q_{22}) & \rho a_5\xi_1\xi_2\\ -2\rho a_4\xi_2\zeta_1 q_{21} & -2\rho a_4\xi_2\zeta_2 q_{22} & \rho a_4(\xi_2^2-\zeta_3^2)\\ \mu_1 & \mu_2 & 2\rho a_4\xi_2\zeta_3\end{bmatrix}\\ \boldsymbol{Q}_{22}^m &= \begin{bmatrix}\rho a_5\xi_1\zeta_1(q_{11}+q_{21}) & \rho a_5\xi_1\zeta_2(q_{12}+q_{22}) & \rho a_5\xi_1\xi_2\\ 2\rho a_4\xi_2\zeta_1 q_{21} & 2\rho a_4\xi_2\zeta_2 q_{22} & \rho a_4(\xi_2^2-\zeta_3^2)\\ \mu_1 & \mu_2 & -2\rho a_4\xi_2\zeta_3\end{bmatrix}\end{aligned} \tag{84}$$

$$\mu_1 = \rho\left[\left(a_5 - a_3\right)\xi_1^2 q_{11} - \left(a_1 - 2a_4\right) \times \xi_2^2 q_{21} - a_1\zeta_1^2 q_{21}\right]$$

$$\mu_2 = \rho\left[\left(a_5 - a_3\right)\xi_1^2 q_{12} - \left(a_1 - 2a_4\right) \times \xi_2^2 q_{22} - a_1\zeta_1^2 q_{22}\right]$$

$$\boldsymbol{E}_+^m\left(X_3\right) = \mathrm{Diag}\left[\mathrm{e}^{\mathrm{i}\zeta_1\left(X_3 - X_3^{m-1}\right)}, \mathrm{e}^{\mathrm{i}\zeta_2\left(X_3 - X_3^{m-1}\right)}, \mathrm{e}^{\mathrm{i}\zeta_3\left(X_3 - X_3^{m-1}\right)}\right] \tag{85}$$

$$\boldsymbol{E}_-^m\left(X_3\right) = \mathrm{Diag}\left[\mathrm{e}^{\mathrm{i}\zeta_1\left(X_3^m - X_3\right)}, \mathrm{e}^{\mathrm{i}\zeta_2\left(X_3^m - X_3\right)}, \mathrm{e}^{\mathrm{i}\zeta_3\left(X_3^m - X_3\right)}\right]$$

$$\boldsymbol{C}^m = \left\{\boldsymbol{C}_+^m \quad \boldsymbol{C}_-^m\right\}$$

with X_3^m being the X_3 coordinate of the interface between layers m and $(m-1)$. $\boldsymbol{Q}_{21}^m$ and $\boldsymbol{Q}_{22}^m$ are matrices whose columns are the stress eigenvectors for the mth layer corresponding to wavenumbers along the 3-axis, ζ_i and $-\zeta_i$, respectively. These are obtained from the displacement eigenvectors using equation (68). The interface continuity conditions can then be expressed as

$$\boldsymbol{Q}_+^m \boldsymbol{C}^m = -\boldsymbol{Q}_-^{m+1}\boldsymbol{C}^{m+1}$$

where $\boldsymbol{Q}_+^m = \boldsymbol{Q}^m\left(X_3^{m+1}\right)$;

$$\boldsymbol{Q}_-^{m+1} = \boldsymbol{Q}^{m+1}\left(X_3^{m+1}\right) \tag{86}$$

These equations ensure continuity of all displacement and traction components at the interface across two layers. The surface traction-free conditions can be expressed as

$$\hat{\boldsymbol{Q}}_-^1 \boldsymbol{C}_-^1 = \boldsymbol{0}; \qquad \hat{\boldsymbol{Q}}_+^N \boldsymbol{C}_+^N = \boldsymbol{0}$$

where $\hat{\boldsymbol{Q}}_-^1 = \left[-\boldsymbol{L}^1\boldsymbol{Q}_{21}^1 \quad -\boldsymbol{L}^1\boldsymbol{Q}_{22}^1\boldsymbol{E}^1\right]$;

$$\hat{\boldsymbol{Q}}_+^N = \left[\boldsymbol{L}^N\boldsymbol{Q}_{21}^N\boldsymbol{E}^N \quad \boldsymbol{L}^N\boldsymbol{Q}_{22}^N\right] \tag{87}$$

The matrices $\hat{\boldsymbol{Q}}$ correspond to the lower half of $\boldsymbol{Q}$ relating to stress. The system of equations is then solved by assembling equations (86) and (87) together into a $6N \times 6N$ banded matrix (called the *global matrix*, say $\boldsymbol{G}$, which, for a given laminate, is a function of ω, K_1, and K_2):

$$\begin{bmatrix} \hat{\boldsymbol{Q}}_-^1 & \boldsymbol{0} & \cdots & & & & & & \\ \hat{\boldsymbol{Q}}_+^1 & \boldsymbol{Q}_-^2 & \boldsymbol{0} & \cdots & & & & & \\ & & \ddots & & & & & & \\ & \cdots & \boldsymbol{0} & \boldsymbol{Q}_+^{m-1} & \boldsymbol{Q}_-^m & \boldsymbol{0} & \cdots & & \\ & & \cdots & \boldsymbol{0} & \boldsymbol{Q}_+^m & \boldsymbol{Q}_-^{m+1} & \boldsymbol{0} & \cdots & \\ & & & & & & \ddots & & \\ & & & & & \cdots & \boldsymbol{0} & \boldsymbol{Q}_+^{N-1} & \boldsymbol{Q}_-^N \\ & & & & & & \cdots & \boldsymbol{0} & \hat{\boldsymbol{Q}}_+^N \end{bmatrix} \begin{bmatrix} \boldsymbol{C}^1 \\ \boldsymbol{C}^2 \\ \\ \vdots \\ \\ \boldsymbol{C}^N \end{bmatrix} = \begin{bmatrix} \boldsymbol{0} \\ \boldsymbol{0} \\ \\ \vdots \\ \\ \boldsymbol{0} \end{bmatrix} \tag{88}$$

Alternatively, if the layup is symmetric about the midplane of the plate, then the system can be solved for the symmetric and antisymmetric modes separately, thereby saving some computational time. Then, traction-free surface condition and continuity conditions up to the interface between layers $N/2$ and $(N/2)-1$ are enforced along with conditions of symmetry (u_3, σ_{32}, and σ_{31} being zero at the midplane) or antisymmetry (u_1, u_2, and σ_{33} being zero at the midplane). The problem is thus reduced to two systems, each of complexity $3N \times 3N$. Then, for nontrivial values of the constants,

$$\det \boldsymbol{G}\left(\omega, K_1, K_2\right) = 0 \tag{89}$$

For a given excitation angular frequency ω and angle $\Gamma\left(=\tan^{-1}\left(K_2/K_1\right)\right)$ between the global Cartesian wavenumbers, one can solve equation (89) for the radial wavenumber $K\left(=\left(K_1^2 + K_2^2\right)^{1/2}\right)$, which is related to the phase velocity along that direction ($K = \omega/v_{\mathrm{ph}}$). Thus, the phase velocity also depends on the direction of propagation along with excitation frequency. This directional dependence is usually presented in the form of a "slowness curve", which is a polar plot of the inverse of phase velocity versus propagation angle. This curve is shown in

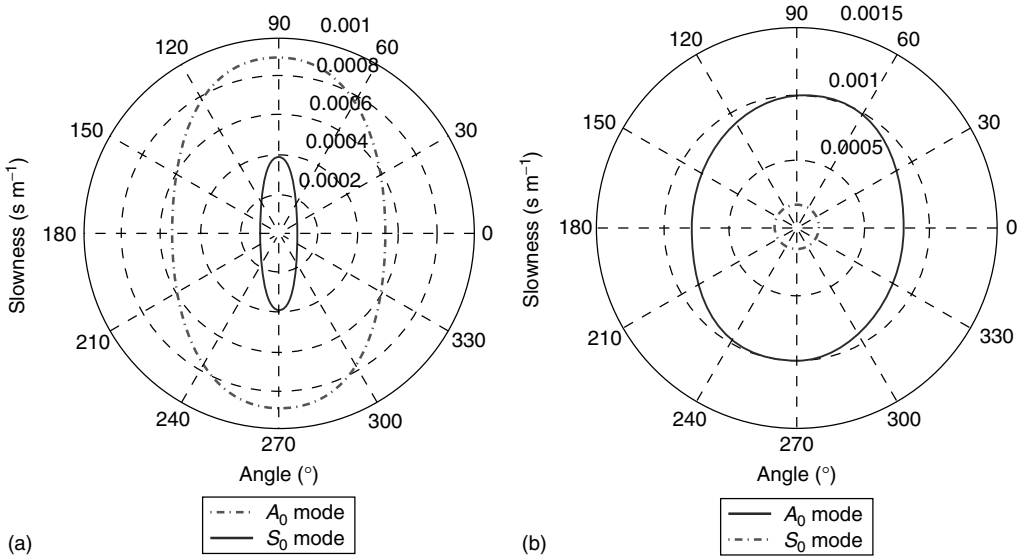

Figure 12. Slowness surfaces (plot of inverse of phase velocity versus direction) in (a) a 1-mm-thick unidirectional graphite–epoxy composite plate at 500 kHz (with graphite fibers along $0^\circ/180^\circ$) and (b) a quasi-isotropic $[0^\circ/45^\circ/-45^\circ/90^\circ]_s$ laminate with each ply being 0.11-mm thick at 200 kHz.

Figure 12(a) for a single-layered unidirectional fiber-reinforced composite and in Figure 12(b) for a quasi-isotropic layup. As seen there, in quasi-isotropic layups, the S_0 mode is approximately isotropic at low frequency-thickness products (up to around 700 kHz for a 1-mm laminate thickness). In composite plates, owing to the anisotropy of phase velocity, the modulation envelope of the GW is 2D and the group velocity is given by the expression

$$\boldsymbol{v}_{\mathrm{gr}} = \frac{\partial \omega}{\partial K_1}\hat{i} + \frac{\partial \omega}{\partial K_2}\hat{j} = -\frac{\nabla_K(\det \boldsymbol{G})}{\partial(\det \boldsymbol{G})/\partial \omega} \qquad (90)$$

where $\hat{i}$ and $\hat{j}$ are unit vectors along the X_1 and X_2 directions. The second form of the formula above is more useful, since the relation between ω, K_1, and K_2 is only available in implicit form of the global matrix determinant. This implies that the group velocity $\mathbf{v}_{\mathrm{gr}}$ is along the normal to the slowness curve (Figure 13a). Thus, the phase velocity and group velocity vectors are, in general, not coincident for anisotropic media. This implies that a plane GW is "steered" in a direction (along the group velocity) different from the direction along which it was launched by a source (which defines the phase velocity), as shown in Figure 13(b). This is explained in Auld [3] in more detail. Semi-analytical expressions for the GW field excited by finite-dimensional piezos in multilayered composite plates are also derived in [17].

3 CONCLUDING REMARKS

A brief introduction to active GW SHM methods was given. The discussion then delved into the rudimentary concepts of elastic waves using the example of 1D wave propagation in taut strings. This example was followed by the governing equations for elastic waves in 3D isotropic elastic solids and a discussion of the GW modes in isotropic plates. The equations for GW excitation by finite-dimensional piezos were then presented. Finally, the more generic governing equations for elastic waves in transversely isotropic solids were covered and this was used to solve for the GW modes in multilayered laminated composite plates. With this basic understanding of GW theory, one is in a much better position to explore other issues in active GW and acoustic emission SHM. In designing effective GW SHM systems, it is important to at least account for the caveats associated with GW propagation discussed, such as the presence

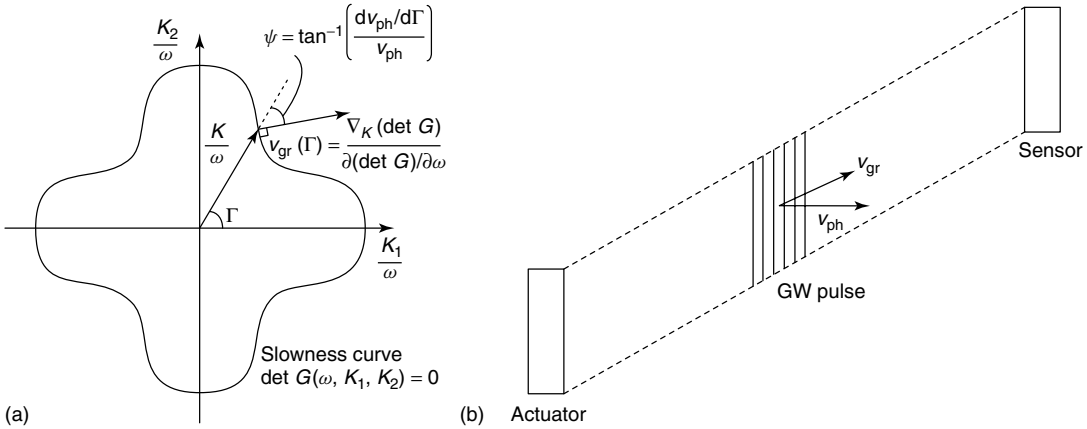

Figure 13. (a) Relation between group velocity and slowness curve and (b) "steering" in anisotropic media.

of multiple modes, dispersiveness, and steering in anisotropic materials.

Beyond these phenomena, depending on the application in question, there may be further challenges to tackle. Apart from the modeling and validation work for GW excitation by finite-dimensional piezos summarized here, the authors' efforts in the past have focused on a variety of research issues in active GW SHM for aerospace structures. An advanced signal processing using chirplet matching pursuits [18] and mode identification has also been developed, which can distinguish between and identify the modes of overlapping, multimodal GW reflections from multiple damage sites (Figure 14). Modeling the effects of elevated temperature (up to 150 °C) on GW SHM has been addressed in [19] (e.g., see Figure 15). This temperature is representative of the maximum limit seen in internal spacecraft structures. Present efforts are directed toward developing/manufacturing of anisotropic piezocomposite transducers and radar-scanning array configurations. As outlined in the review paper by Raghavan and Cesnik [1], much more work is still required before this technology sees widespread field deployment.

1 INTRODUCTION

Thin piezoelectric wafers have received considerable attention as active elements of structural health monitoring (SHM) systems [1]. Direct and converse piezoelectric effects (*see* **Piezoelectricity Principles and Materials**) intrinsic to the wafers' material enable a broad spectrum of SHM applications ranging from passive sensing to active generation of elastic waves [2]. To reflect the versatility of embeddable piezoelectrics, in this article, the term *piezoelectric wafer active sensors* (PWAS) is used (*see* **Piezoelectric Wafer Active Sensors**).

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

One distinct SHM methodology facilitated by PWAS is the electromechanical (EM) impedance method [3]. Electromechanical impedance (EMI) is a measure of opposition to the mechanical motion of an electrically excited piezoelectric element. The EMI of the embedded PWAS includes contributions of the piezoelectric element and a host structure. Consequently, the EMI method utilizes local structural dynamic characteristics obtained through impedance measurements for the assessment of structural condition (*see* **Piezoelectric Impedance Methods for Damage Detection and Sensor Validation**) in the immediate vicinity of the sensor [4]. In this respect, [5], the EMI methodology complements embedded ultrasonics, employing the same sensors for long-range inspection. The EMI method assesses the local structural response at relatively high frequencies, ranging from a few kilohertz to hundreds of kilohertz. This is in contrast to vibration methods that explore low-frequency structural responses involving global motion. Monitoring of the structural condition at such high frequencies yields several advantages. The high-frequency response is little affected by global conditions such as flight loads and ambient vibrations; compensation algorithms are employed to address variation of environmental parameters. In addition, because the wavelength of the interrogation signal at high

frequencies is relatively small, the EMI method allows for monitoring small-scale phenomena (i.e., cracks, delamination, disbonds), whose contribution to the global structural dynamics may not be noticeable or detectable by other methods.

It is important to note that the complexity of the EMI spectra depends on structural geometry and constitution. The admittance signatures reflect the resonance behavior and, for structures with simple geometry, yield well separated peaks in the low-frequency range. The impedance is inversely proportional to admittance and therefore indicates a frequency-dependent structural resistance to the applied excitation. An example of the impedance spectrum of a simple structural element, an aluminum circular plate, is shown in Figure 1. The evolution of the spectrum due to a circumferential crack introduced with a jet cutting tool at different distances from the sensor is also presented in the figure. The crack changes the structural condition in the area adjacent to the sensor and this is manifested in an increasing complexity of the impedance spectra. However, the intact (undamaged) structure reveals dynamic characteristics that can be modeled analytically using the principles of structural dynamics. To gain insights into the physical mechanisms governing the EMI method, theoretical underpinnings of the sensor and structural dynamic behavior need to be studied. This is the subject of the article.

2 PIEZOELECTRIC IMPEDANCE SENSORS

Piezoelectric wafer active sensors are typically fabricated from lead zirconate titanate (PZT) ceramic. For small changes in mechanical and electrical parameters, a linear theory of piezoelectricity [6] is applicable and the piezoelectric ceramic is described by the following pair of equations in tensor notation.

$$S_{ij} = s^{E}_{ijkl} T_{kl} + d_{kij} E_k$$
$$D_j = d_{jkl} T_{kl} + \varepsilon^{T}_{jk} E_k \qquad (1)$$

Equations (1) signify a relationship between mechanical strain, S_{ij}, mechanical stress, T_{kl}, electrical field, E_k, and electrical displacement D_j that are coupled through mechanical compliance measured at

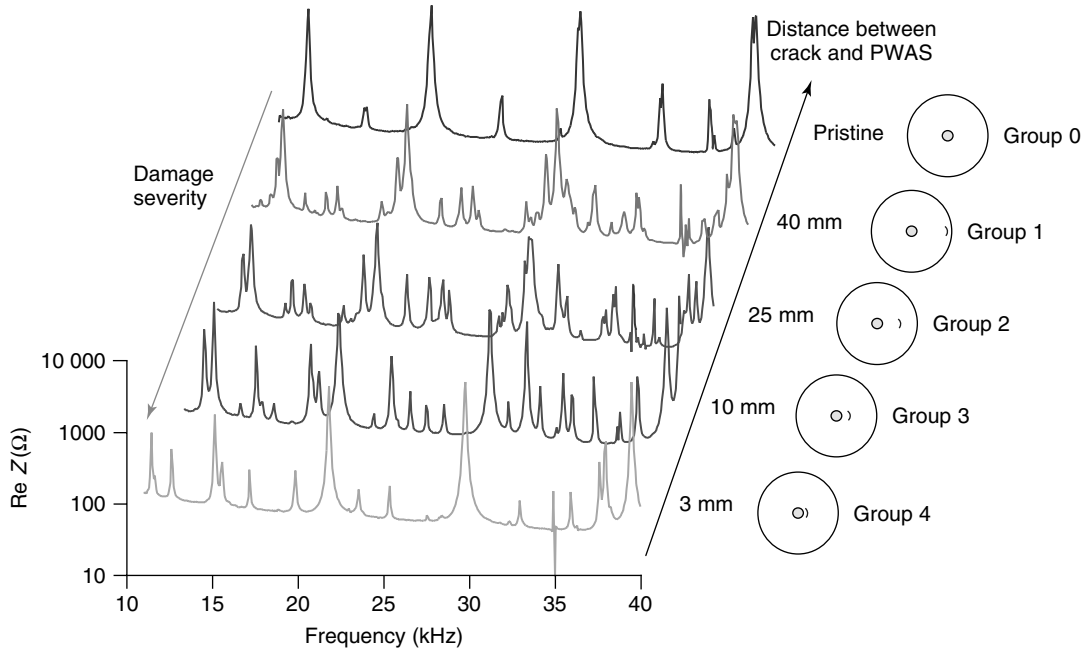

Figure 1. Dependence of the electromechanical impedance spectra on the location of damage.

zero electric field ($E = 0$), s^E_{ijkl}; dielectric permittivity measured at zero mechanical stress ($T = 0$), ε^T_{jk}; and the piezoelectric coefficient, d_{kij}. In general, the tensorial representation in equations (1) would result in nine equations corresponding to respective strain components and polarization directions. Simplification of the constitutive equations is achieved by considering particularities of the piezoelectric sensor configuration and its interaction with the host structure.

2.1 1D PWAS model

One of the most widely used sensor configurations is a thin piezoelectric strip, plate, or disk with the polarization vector parallel to the thickness direction. Effectively, this permits a separation of the sensor geometry into one-dimensional (1D) and two-dimensional (2D) classes. The discussion is provided on an analytical description of the 1D case as the most effective avenue for understanding the modeling aspects of the piezoelectric wafer EMI sensor.

Consider a thin piezoelectric strip with a length l_a, width b_a, and thickness t_a. Figure 2 indicates the sensor geometry, coordinate system, and poling direction E_3. The harmonic voltage $V(t) = \hat{V}e^{i\omega t}$ with amplitude $\hat{V}$ applied across continuous electrodes results in a spatially uniform ($\partial E/\partial x_1 = 0$) electric field $E = V/t_a$ inducing sensor displacements, u_1, u_2, u_3. A one-dimensional case is achieved when thickness and width dimensions are much smaller than the length of the sensor ($t_a \ll b_a \ll l_a$) and corresponding displacement components are practically decoupled. The indicated assumptions allow for reducing the number of equations participating in equations (1) and extensional (longitudinal) motion along the dominant dimension is described by the following system.

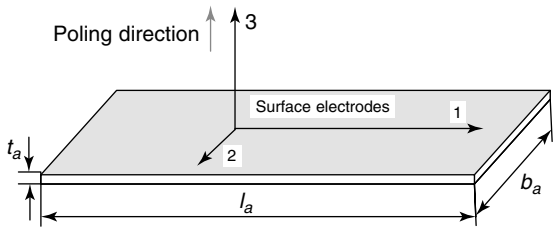

Figure 2. PWAS schematics.

$$S_1 = s^E_{11}T_1 + d_{31}E_3$$
$$D_3 = d_{31}T_1 + \varepsilon^T_{33}E_3 \tag{2}$$

Using Newton's law of motion, $T_1' = \rho\ddot{u}_1$, and the strain–displacement relation, $S_1 = u_1'$, the first of equations (2) yields the classical wave equation:

$$\ddot{u}_1 = c^2 u_1'' \tag{3}$$

where $(\dot{}) = \partial(\,)/\partial t$ and $(\,)' = \partial(\,)/\partial x$, while $c^2 = 1/\rho_a s^E_{11}$ is the wave speed and ρ_a is the density of piezoelectric material. The solution to the equation of motion (3), is separated into temporal and spatial components:

$$u_1(x,t) = \hat{u}_1(x)e^{i\omega t}$$

where

$$\hat{u}_1(x) = \left(C_1 \sin \gamma x + C_2 \cos \gamma x\right) \tag{4}$$

In equation (4), $\hat{u}_1(x)$ is the amplitude of the spatial solution presented in terms of harmonic functions, the wave number $\gamma = \omega/c$, and the constants C_1 and C_2 are dependent on the boundary conditions.

The classical set of boundary conditions includes free and clamped mechanical terminals. A reader may consult the work of Ikeda [7] for the derivation of solutions for classical boundary conditions. Practical applications of piezoelectric impedance sensors imply a more complex form of boundary conditions. The embedded or bonded sensors are essentially constrained by structural elements and, therefore, elastic boundary conditions must be considered. The elastically constrained case opens a path toward the analysis of the complete sensor–structure dynamics because it represents a generic scenario asymptotically approaching free–free and clamped sets as the constraint becomes vanishingly soft, or infinitely stiff [8].

In the 1D case, a bonded piezoelectric sensor is represented as a piezoelectric strip constrained by structural stiffness. The symmetry of the problem yields the constraints of $2k_{\text{str}}$ at each side of the sensor. Figure 3 provides a schematic of the elastically constrained sensor. A spring reaction force at the ends of the sensor is connected with internal stresses according to the following expressions.

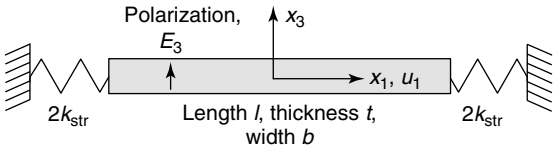

Figure 3. PWAS constrained by the structural stiffness.

$$T_1\left(\frac{l_a}{2}\right) b_a t_a = -2k_{str} u_1\left(\frac{l_a}{2}\right)$$
$$T_1\left(\frac{-l_a}{2}\right) b_a t_a = 2k_{str} u_1\left(\frac{-l_a}{2}\right) \tag{5}$$

Expressing the quasistatic stiffness of the impedance sensor as $k^b_{PWAS} = A_a/s^E_{11} l_a$ and introducing the dynamic stiffness ratio

$$r(\omega) = \frac{k_{str}(\omega)}{k^b_{PWAS}} \tag{6}$$

one obtains

$$u_1'\left(\frac{l_a}{2}\right) + \frac{r(\omega)}{\frac{l_a}{2}} u_1\left(\frac{l_a}{2}\right) = S_{ISA}$$
$$u_1'\left(\frac{-l_a}{2}\right) - \frac{r(\omega)}{\frac{l_a}{2}} u_1\left(\frac{-l_a}{2}\right) = S_{ISA} \tag{7}$$

where $S_{ISA} = d_{31} E_3 = u_{ISA}/l_a$ is the induced strain and u_{ISA} is the induced displacement with the amplitude $\hat{u}_{ISA} = d_{31}\hat{E}_3 \cdot l_a$.

Considering a general solution in the form of equation (4) and denoting $\varphi = \frac{1}{2}\gamma l_a$, one arrives at

$$\begin{aligned}&(\varphi\cos\varphi + r(\omega)\sin\varphi)\, C_1 \\ &\quad - (\varphi\sin\varphi - r(\omega)\cos\varphi)\, C_2 = \tfrac{1}{2}\hat{u}_{ISA} \\ &(\varphi\cos\varphi + r(\omega)\sin\varphi)\, C_1 \\ &\quad + (\varphi\sin\varphi - r(\omega)\cos\varphi)\, C_2 = \tfrac{1}{2}\hat{u}_{ISA}\end{aligned} \tag{8}$$

Constants C_1 and C_2 are obtained by subtracting the first of equations (8) from the second

$$-2\cdot(\varphi\sin\varphi - r(\omega)\cos\varphi) C_2 = 0 \tag{9}$$

which yields $C_2 = 0$, and on adding the two equations

$$2\cdot(\varphi\cos\varphi + r(\omega)\sin\varphi) C_1 = \hat{u}_{ISA} \tag{10}$$

Hence,

$$C_1 = \tfrac{1}{2}\hat{u}_{ISA}/(\varphi\cos\varphi + r(\omega)\sin\varphi) \tag{11}$$

The solution of the wave equation (4) is now expressed as

$$\hat{u}_1(x) = \tfrac{1}{2}\hat{u}_{ISA}\frac{\sin\gamma x}{(\varphi\cos\varphi + r(\omega)\sin\varphi)} \tag{12}$$

In EMI diagnostics, electrical measurements are conducted at the terminals of the sensor. The measured impedance reflects both the electrical and mechanical responses. Modeling of the EM transformation enabled by the sensor is achieved by utilizing the solution (equation 12) in conjunction with the second equation in the system (2). According to the first expression in equations (2), the stress function T_1 depends on the mechanical strain and the electric field:

$$T_1 = \frac{1}{s^E_{11}}\left(S_1 - d_{31}E_3\right) \tag{13}$$

This leads to electrical displacement

$$D_3 = \frac{d_{31}u_1'}{s^E_{11}} - \frac{d^2_{31}E_3}{s^E_{11}} + \varepsilon^T_{33}E_3 \tag{14}$$

When mechanical stress is applied to the piezoelement, it results in an electrical charge that can be obtained by integrating the electrical displacement (equation 14) over the electrode area

$$\begin{aligned}Q(\omega) &= \int_{-\frac{l_a}{2}}^{+\frac{l_a}{2}}\int_{-\frac{b_a}{2}}^{+\frac{b_a}{2}} D_3\,\mathrm{d}x\,\mathrm{d}y \\ &= \int_{-\frac{l_a}{2}}^{+\frac{l_a}{2}}\int_{-\frac{b_a}{2}}^{+\frac{b_a}{2}}\left[\varepsilon^T_{33}E_3 - \frac{d^2_{31}E_3}{s^E_{11}} + \frac{d_{31}u_1'}{s^E_{11}}\right]\mathrm{d}x\,\mathrm{d}y \\ &= \varepsilon^T_{33}E_3 b_a l_a - \frac{d^2_{31}E_3 b_a l_a}{s^E_{11}} + \frac{b_a d_{31}u_1}{s^E_{11}}\Bigg|_{-\frac{l_a}{2}}^{+\frac{l_a}{2}} \\ &= \varepsilon^T_{33}E_3 b_a l_a - \frac{d^2_{31}E_3 b_a l_a}{s^E_{11}} \\ &\quad + \frac{b_a d_{31}}{s^E_{11}}\frac{\hat{u}_{ISA}\cdot\sin\varphi\cdot\mathrm{e}^{i\omega t}}{(\varphi\cos\varphi + r(\omega)\sin\varphi)}\end{aligned} \tag{15}$$

where equation (12) was utilized to express displacement $u_1(x)$ and the argument of the harmonic

functions is $\varphi = \frac{1}{2}\gamma l_a$. Defining the resultant voltage $V(\omega) = \hat{E}_3 \cdot e^{i\omega t}/t_a$, capacitance at zero mechanical stress $C = \varepsilon_{33}^T b_a l_a / t_a$, the EM coupling coefficient $\kappa_{13} = d_{31}/\sqrt{s_{11}^E \varepsilon_{33}^T}$, and $\hat{u}_{\mathrm{ISA}} = d_{31}\hat{E}_3 \cdot l_a$, one arrives at

$$Q(\omega) = V(\omega) \cdot C\left(1 - \kappa_{31}^2\left(1 - \frac{1}{\varphi \cot \varphi + r(\omega)}\right)\right) \tag{16}$$

The time derivative of the charge (equation 16) yields an electric current contributing to expressions for EM admittance and impedance:

$$Y(\omega) = \frac{I(\omega)}{V(\omega)} = i\omega \cdot C\left(1 - \kappa_{31}^2\left(1 - \frac{1}{\varphi \cot \varphi + r(\omega)}\right)\right) \tag{17}$$

$$Z(\omega) = [Y(\omega)]^{-1} \tag{18}$$

Formulations (17) and (18) reveal that the electrical response of the impedance sensor is dominated by the capacitance, C. The mechanical response, reflected through the term containing the EM coupling coefficient κ_{13}, includes the sensor resonance term $\varphi\cot\varphi$ and the contribution of the host structure dynamics participating in the dynamic stiffness ratio $r(\omega)$. Therefore, the ratio $r(\omega)$ allows for the manifestation of structural resonances in the admittance spectrum of the bonded or embedded piezoelectric sensor.

The admittance and impedance formulations in equations (17) and (18) cover a complete frequency range and include the dynamics of both the sensor element and the host structure. Derivation of these expressions has been presented without consideration of the dissipative effects. Dissipation via structural damping can be introduced by utilizing a complex representation of sensor and structural material parameters, e.g., complex mechanical compliance $\bar{s}_{11}^E = s_{11}^E \cdot (1 + i \cdot \eta)$, where $i = \sqrt{-1}$ and η is the damping constant. It follows that

$$\bar{Y}(\omega) = i\omega \cdot \bar{C}\left(1 - \bar{\kappa}_{31}^2\left(1 - \frac{1}{\bar{\varphi} \cot \bar{\varphi} + \bar{r}(\omega)}\right)\right) \tag{19}$$

and

$$\bar{Z}(\omega) = \frac{1}{i\omega \cdot \bar{C}}\left(1 - \bar{\kappa}_{31}^2\left(1 - \frac{1}{\bar{\varphi} \cot \bar{\varphi} + \bar{r}(\omega)}\right)\right)^{-1} \tag{20}$$

To illustrate the application of the presented approach to modeling of the impedance sensors, consider a sensor with free–free boundary conditions. Understanding this case is important in the sensor-characterization process before installation on a host structure. The generic admittance equation (19) is used with a notion that $\bar{r}(\omega) = 0$ for the unconstrained sensor. This formula is used for modeling piezoelectric sensors that measure vibrations along the dominant in-plane dimension. Results for sensor geometries ranging from a rectangular wafer with a 1 : 1 aspect ratio to a piezoelectric strip with the aspect ratio 4 : 1 are presented in Figure 4. Analysis of the high aspect ratio case is important for verifying the validity of the 1D model, while consideration of the low aspect ratio is useful from a practical point of view, as the popular geometry of the impedance sensor is a rectangular piezoelectric wafer. Difficulties in analytical modeling of the unconstrained rectangular piezoelectric wafers arise from the absence of the close-form solution for this essentially 2D case. Applying equation (19) for calculating admittance of the square plate sensor yields the admittance spectrum presented in Figure 4(a). The length, width, and thickness of the sensor are $l_a = 6.99\,\mathrm{mm}$, $b_a = 6.56\,\mathrm{mm}$, and $t_a = 0.215\,\mathrm{mm}$ respectively; the parameters of the piezoelectric ceramic are $\varepsilon_{33}^T = 15.470 \times 10^9\,\mathrm{F\,m^{-1}}$, $s_{11}^E = 15.3 \times 10^{-12}\,\mathrm{Pa^{-1}}$, $d_{31} = -175 \times 10^{-12}\,\mathrm{m\,V^{-1}}$, $\kappa_{31} = 0.36$. Theoretical resonance frequencies identifiable in Figure 4(a) include 208 kHz (1L), 222 kHz (1 W), 621 kHz (2L), 663 kHz (2 W), 1038 kHz (3L), 1108 kHz (3 W), and 1451 kHz (4L). The experimental admittance responses obtained with the impedance analyzer is also presented in the figure. Comparison of theoretical and experimental spectra reveals relatively high errors (19 and 37%) for the first length (1L) and width (1 W) modes. Discrepancy between experimental and calculated responses arises from the 2D stiffening effect typical of low-aspect ratio in-plane vibrations. This effect is not captured by the 1D theory. However, higher vibration modes, which are less affected by the 2D stiffening, show favorable agreement

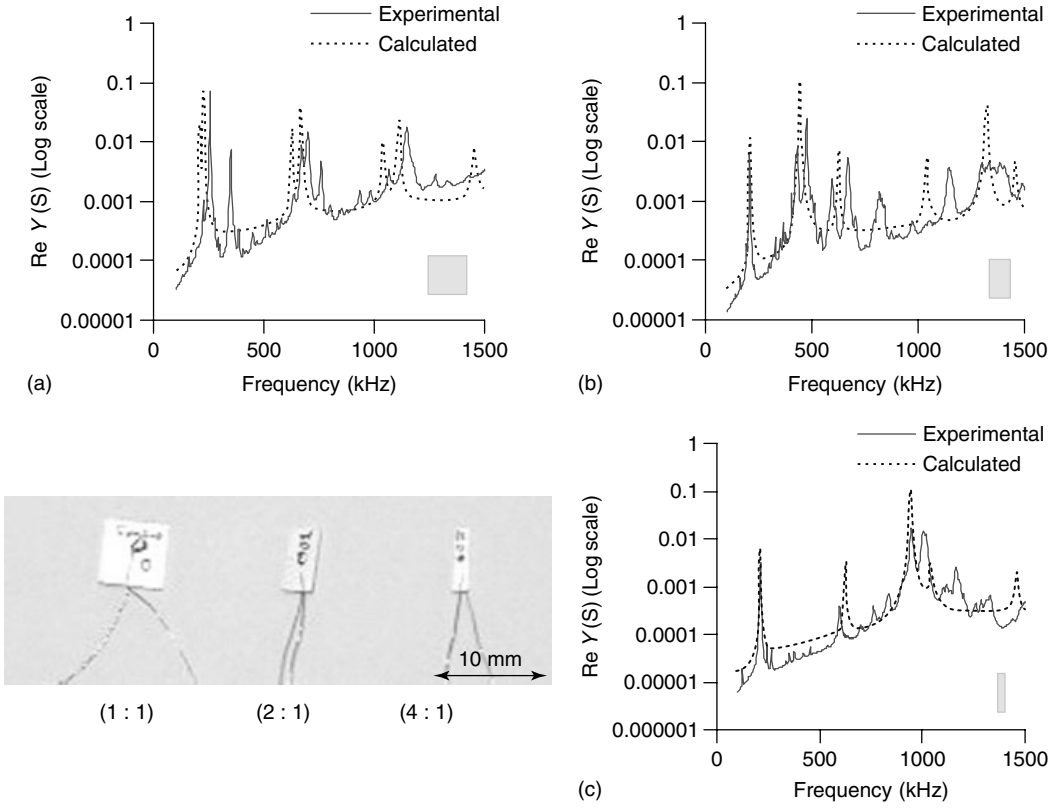

Figure 4. Experimental and calculated admittance spectra of PWAS with the following aspect ratios: (a) 1 : 1 — square wafer, (b) 2 : 1 — half-width wafer, and (c) 4 : 1 — quarter-width wafer.

between experimental and theoretical results. Hence, with the exception of the first modes, a reasonable approximation can be achieved by utilizing a 1D analytical formulation.

Agreement between theoretically calculated and practically measured resonances improves considerably for the piezoelectric wafers with increasing aspect ratio. Figure 4(b,c) provides a pictorial representation of this fact for piezoelectric sensors with aspect ratios of 2 : 1 and 4 : 1. For instance, predictions for the half-width sensor suggest less than 2% error for 1L and 1B resonances. A quarter-width sensor manifests outstanding agreement with the theory for vibration modes below 1 MHz. In addition to clearly identifiable vibration modes, several other peaks are present in the experimental curve. These modes are attributed to the edge roughness producing secondary vibration effects. Analysis of the admittance spectra in Figure 4 suggests a clear trend toward improving the prediction accuracy as the sensor geometry approaches the 1D case.

2.2 2D PWAS model

The one-dimensional modeling approach shows good agreement between the results of analytical calculation and experimental data for sensor geometries with well separated length, width, and thickness dimensions. However, the majority of structural identification and health monitoring applications of the impedance method feature sensors of rectangular or circular configurations. As was indicated in the previous section, no close-form solutions exist for the unconstrained rectangular (e.g., square) sensors and inferring the sensor response using numerical analysis is recommended. For two-dimensional (2D) modeling of the impedance sensors, consider

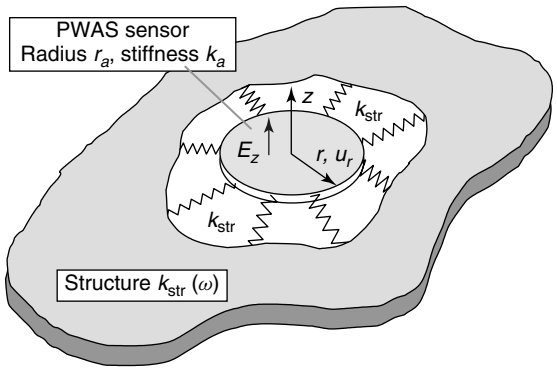

Figure 5. A circular impedance sensor constrained by the structural stiffness, $k_{str}(\omega)$.

circular plate piezoelectric wafers. This sensor geometry allows for the consideration of the axisymmetric problem and, hence, significantly simplifies the analysis procedure. The geometry of the circular PWAS bonded to the host structure is presented in Figure 5. The coordinate system with radial (r), circumferential (θ), and vertical (z) variables is adopted for describing the sensor response. The symmetry of the problem implies that derivatives with respect to the circumferential variable are zero. This results in the reduced set of equations in the system (1). Assuming the in-plane isotropy of the elastic and piezoelectric constants, one arrives at the following [6]:

$$\begin{aligned} S_{rr} &= s_{11}^E T_{rr} + s_{12}^E T_{\theta\theta} + d_{31} E_z \\ S_{\theta\theta} &= s_{12}^E T_{rr} + s_{11}^E T_{\theta\theta} + d_{31} E_z \\ D_z &= d_{31}(T_{rr} + T_{\theta\theta}) + \varepsilon_{33}^T E_z \end{aligned} \tag{21}$$

The analysis of the system (21) follows a procedure outlined for the previously discussed 1D case. It can be shown that the equation of motion for a thin circular plate is

$$\frac{\partial T_{rr}}{\partial r} + \frac{T_{rr} - T_{\theta\theta}}{r} = \rho_a \cdot \frac{\partial^2 u_r}{\partial t^2} \tag{22}$$

Using the definition of radial and circumferential strains,

$$S_{rr} = \frac{\partial u_r}{\partial r}, \quad S_{\theta\theta} = \frac{u_r}{r} \tag{23}$$

and stress relationships inferred from the first two of equations (21),

$$T_{rr} = \frac{1}{s_{11}^E(1-\nu^2)}\left(\frac{\partial u_r}{\partial r} + \nu\frac{u_r}{r}\right) - \frac{d_{31}E_z}{s_{11}^E(1-\nu)} \tag{24}$$

$$T_{\theta\theta} = \frac{1}{s_{11}^E(1-\nu^2)}\left(\nu\frac{\partial u_r}{\partial r} + \frac{u_r}{r}\right) - \frac{d_{31}E_z}{s_{11}^E(1-\nu)} \tag{25}$$

one obtains an equation of motion in terms of the sensor radial displacement, u_r,

$$\frac{\partial^2 u_r}{\partial r^2} + \frac{1}{r}\frac{\partial u_r}{\partial r} - \frac{u_r}{r^2} - \frac{1}{c^2}\frac{\partial^2 u_r}{\partial t^2} = 0 \tag{26}$$

where $c = 1/\sqrt{\rho_a s_{11}^E \cdot (1-\nu_a^2)}$ is the speed of axially symmetric extensional waves. Assuming a harmonic solution of equation (26) in the form

$$u_r(r,t) = \hat{u}_r(r) \cdot \mathrm{e}^{-i\omega t} \tag{27}$$

rearrangement and multiplication by r^2 yields

$$r^2\frac{\partial^2 \hat{u}_r}{\partial r^2} + r\frac{\partial \hat{u}_r}{\partial r} + \hat{u}_r\left(\frac{\omega^2 r^2}{c^2} - 1\right) = 0 \tag{28}$$

It can be shown that equation (28) is analogous to the Bessel differential equation [9] whose solution is readily obtained in terms of a linear combination of Bessel functions of the first and second kinds:

$$\hat{u}_r(r) = A \cdot J_1\left(\frac{\omega r}{c}\right) + B \cdot Y_1\left(\frac{\omega r}{c}\right) \tag{29}$$

Since the displacement of the plate is always finite, even as r approaches zero, one must choose $B = 0$. The final solution is

$$\hat{u}_r(r) = A \cdot J_1\left(\frac{\omega r}{c}\right) \tag{30}$$

The coefficient A is determined from the boundary conditions. For bonded or embedded piezoelectric wafers, these boundary conditions reflect the contribution of the structural stiffness. Figure 5 provides an illustration of the sensor constrained by the adjacent structure. Therefore, the force relationship at $r = r_a$ is

$$N_a(r_a) = -k_{str}(\omega) \cdot u_r(r_a) \tag{31}$$

Equation (31) is used to calculate radial and tangential stress components of the sensor:

$$T_{rr}(r_a) = \frac{N_a(r_a)}{t_a} = \frac{-k_{\text{str}}(\omega)u_{\text{PWAS}}(r_a)}{t_a}$$
$$T_{\theta\theta}(r_a) = \frac{1}{s_{11}^E}\left(\frac{u_r(r_a)}{r_a} - s_{12}^E T_{rr}(r_a) - d_{31}E_z\right) \quad (32)$$

Substituting the stress equations into the first expression in equation (21), one obtains as follows [5]:

$$\frac{\partial u_r(r_a)}{\partial r} = -s_{11}^E \frac{k_{\text{str}}(\omega)\cdot u_r(r_a)}{t_a} + \frac{s_{12}^E}{s_{11}^E} \times \left(\frac{u_r(r_a)}{r_a} - s_{12}^E \frac{k_{\text{str}}(\omega)\cdot u_r(r_a)}{t_a} - d_{31}E_z\right) + d_{31}E_z \quad (33)$$

A dynamic stiffness ratio is defined as

$$\chi(\omega) = \frac{k_{\text{str}}(\omega)}{k_{\text{PWAS}}^d} \quad (34)$$

where the static stiffness of the circular plate impedance sensor is $k_{\text{PWAS}}^d = t_a/[r_a s_{11}^E(1-\nu_a)]$.

Incorporating the dynamic stiffness ratio equation (34) into equation (33) leads to

$$\frac{\partial u_r(r_a)}{\partial r} = -\chi(\omega)\cdot(1+\nu)\frac{u_r(r_a)}{r_a} - \nu\frac{u_r(r_a)}{r_a} + (1+\nu)d_{31}E_z \quad (35)$$

where $\nu_a = -s_{12}^E/s_{11}^E$ is the Poisson ratio. The constant A in the general solution, equation (30), is obtained by the direct substitution of equation (30) into equation (35):

$$A = \frac{(1+\nu_a)\cdot d_{31}E_0}{\frac{\omega}{c}J_0\left(\frac{\omega r_a}{c}\right) - \frac{(1-\nu_a-\chi(\omega)\cdot(1+\nu_a))}{r_a}\cdot J_1\left(\frac{\omega r_a}{c}\right)} \quad (36)$$

The third of equations (21) yields the electrical displacement D_z:

$$D_z = \frac{d_{31}(1+\nu_a)}{s_{11}^E(1-\nu_a^2)}\frac{\omega}{c}AJ_0\left(\frac{\omega r}{c}\right) - \left(\frac{2d_{31}^2}{s_{11}^E(1-\nu_a)} + \varepsilon_{33}^T\right)E_0 \quad (37)$$

Equation (37), the electrical displacement, is integrated to obtain the charge

$$Q = \int_0^{2\pi} \mathrm{d}\theta \int_0^{r_a} D_z r\,\mathrm{d}r = \pi r_a^2 \varepsilon_{33}^T E_0 \mathrm{e}^{i\omega t}\cdot\left[1 - k_p^2 + k_p^2 \times \frac{(1+\nu_a)J_1(\varphi_a)}{\varphi_a J_0(\varphi_a) - (1-\nu_a-\chi(\omega)\cdot(1+\nu_a))\cdot J_1(\varphi_a)}\right] \quad (38)$$

where the planar coupling factor $k_p = \sqrt{2d_{31}^2/[s_{11}^E\cdot(1-\nu_a)\varepsilon_{33}^T]}$ is introduced to account for the EM coupling and $\varphi_a = \omega r_a/c$.

Differentiation of the charge in equation (38) with respect to time results in the electrical current $\hat{I} = i\omega\cdot\hat{Q}$ participating in the final expression for admittance

$$Y(\omega) = i\omega C(1-k_p^2)\left[1 + \frac{k_p^2}{1-k_p^2}\frac{(1+\nu_a)J_1(\varphi_a)}{\varphi_a J_0(\varphi_a) - (1-\nu_a)J_1(\varphi_a) + \chi(\omega)(1+\nu_a)J_1(\varphi_a)}\right] \quad (39)$$

It should be noted that the admittance in equation (39) accounts for the dynamics of the sensor element (through ϕ_a) and the dynamics of the host structure (through $\chi(\omega)$).

The impedance $Z(\omega)$ is defined as

$$Z(\omega) = \left\{i\omega C(1-k_p^2)\left[1 + \frac{k_p^2}{1-k_p^2}\frac{(1+\nu_a)J_1(\varphi_a)}{\varphi_a J_0(\varphi_a) - (1-\nu_a)J_1(\varphi_a) + \chi(\omega)(1+\nu_a)J_1(\varphi_a)}\right]\right\}^{-1} \quad (40)$$

It is worth noting that equation (40) represents a general formulation for vibration of an elastically constrained piezoelectric disk and provides a theoretical description of the impedance response seen by the impedance analyzer at the piezoelectric sensor terminals. Hence, expression (40) facilitates the comparison of the experimental and theoretical impedance signatures of 2D axisymmetric circular structures.

Equation (39), with $\chi(\omega) = 0$, was utilized to simulate an admittance response of an unconstrained piezoelectric circular wafer with diameter $d_a = 6.98\,\text{mm}$ and thickness $t_a = 0.216\,\text{mm}$. The following properties of piezoelectric material were considered: $\varepsilon_{33}^T = 15.470 \times 10^9\,\text{F m}^{-1}$, $s_{11}^E = 18 \times 10^{-12}\,\text{Pa}^{-1}$, $d_{31} = -175 \times 10^{-12}\,\text{m V}^{-1}$, $k_p = 0.63$. No damping was introduced in this simulation. Figure 6 shows experimentally obtained and theoretically calculated admittance. The figure presents the dynamic behavior of the sensor below 1.5 MHz. Within this frequency range, three in-plane radial modes are clearly identifiable: 300, 784, and 1247 kHz. The calculated response closely follows the experimental data. The maximum discrepancy between measured and predicted natural frequencies did not exceed 2.1%. Therefore, the suggested modeling approach can be employed to predict EMI and admittance responses of the 2D axisymmetric structures.

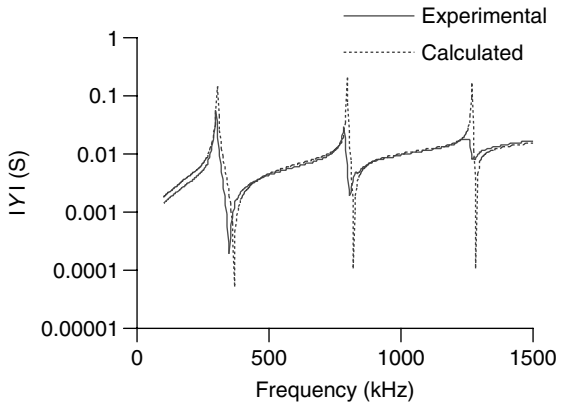

Figure 6. Experimental and calculated admittance responses of an unconstrained circular wafer impedance sensor.

3 ELECTROMECHANICAL IMPEDANCE MODEL FOR 1D STRUCTURES

3.1 Analytical model for 1D sensor/structure interaction

Previous sections discussed modeling of the impedance sensor elastically constrained by the adjacent structure. According to expressions (20) and (40), the sensor impedance contains contributions of both sensor dynamics and structural dynamics. The latter participates in the cumulative impedance response through the dynamic stiffness ratios. Therefore, to model the impedance measured across terminals of the sensor bonded to the structural surface or embedded into the host structure, an expression for the dynamic structural stiffness must first be determined. This can be achieved by considering mechanisms underlying structural excitation and sensing.

When an active sensor is bonded to the host structure as presented in Figure 7, the applied alternating voltage results in expansions and contractions of the sensor, which induce elastic waves traveling in the structure. Reflections of the elastic waves produce standing wave patterns associated with structural vibration modes. Finally, the dynamic deformation of the structural element during vibrations affects the sensor and, hence, is reflected in its impedance signature.

To illustrate the EMI modeling approach, consider a 1D elastic structure (a beam or a rod) with the bonded piezoelectric sensor. In the suggested representation depicted in Figure 7, the PWAS lies between points x_a and $x_a + l_a$ on the structural surface; l_a is the assumed length of the sensor. Expansion and contraction of the sensor produce a reaction

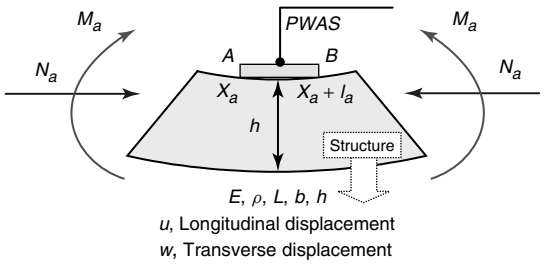

Figure 7. Forces and moments produced as a result of interaction between PWAS and a host structure.

force F_{PWAS} from the beam onto the sensor and an equal and opposite force from the sensor onto the beam. The sign of F_{PWAS} depends on the sign of the voltage applied to the piezoelectric. It is transparent from Figure 7 that the dynamic force $F_{\text{PWAS}} = \hat{F}_{\text{PWAS}} e^{i\omega t}$ induced by the sensor onto the beam results in the following axial force and bending moment [8]:

$$M_a = F_{\text{PWAS}} \frac{h}{2}, \quad N_a = F_{\text{PWAS}} \tag{41}$$

The spatial distribution of this axial force and bending moment is controlled by the sensor and can be expressed in terms of a Heaviside function, $H(x - x_a) = 1$ for $x_a < x$; 0 otherwise.

$$N_a(x,t) = \hat{N}_a[-H(x - x_a) + H(x - x_a - l_a)] \cdot e^{i\omega t} \tag{42}$$

$$M_a(x,t) = -\hat{M}_a[-H(x - x_a) + H(x - x_a - l_a)] \cdot e^{i\omega t} \tag{43}$$

It follows that the force induced by the impedance sensor produces both extensional (longitudinal) and transverse (flexural) vibrations. The initial work of Liang *et al.* [10] discussed flexural vibrations of an elastic beam. Park *et al.* [11] considered longitudinal modes but neglected flexural vibrations. In the following analysis, a unified treatment of longitudinal and flexural behavior is presented.

3.1.1 Extensional vibrations of 1D structure

It can be shown [8] that in the presence of an additional axial force acting on the infinitesimal element of the beam, in-plane displacement $u(x,t)$ is described by the following equation:

$$\rho A \cdot \ddot{u}(x,t) - EA \cdot u''(x,t) = N_a'(x,t) \tag{44}$$

Equation (44) includes parameters of the beam: cross-sectional area A, density ρ, and modulus of elasticity E. The solution is sought in terms of modal expansion [12]

$$u(x,t) = \sum_{p=0}^{\infty} B_p U_p(x) \cdot e^{i\omega t} \tag{45}$$

where $U_p(x)$ are orthonormal mode shapes satisfying $\int U_q(x) U_p(x)\, dx = \delta_{qp}$, with $\delta_{qp} = 1$ for $q = p$, and 0 otherwise. The modal participation factor B_p controls the amplitudes of vibration modes. Following the separation of variables solution procedure and utilizing the expression for natural frequencies, $c^2 \cdot U_p''(x) = -\omega_p^2 \cdot U_p(x)$, with $c = \sqrt{E/\rho}$, resulting from the consideration of the homogeneous equation $\rho A \cdot \ddot{u}(x,t) - EA \cdot u''(x,t) = 0$, upon multiplication by $U_q(x)$ and integration over the length of the beam, L, one obtains

$$B_p = \frac{\int_0^L U_q(x) N_a'(x)\, dx}{\rho A \cdot (\omega_p^2 - \omega^2)} = \frac{\hat{N}_a}{\rho A} \cdot \frac{[U_p(x_a + l_a) - U_p(x_a)]}{(\omega_p^2 - \omega^2)} \tag{46}$$

Expression (46) is derived for undamped vibrations. In practice, damping is always present in any dynamic system. To account for the energy dissipation, viscous damping with the factor ζ_p is introduced. The modal participation factor of the damped beam is

$$B_p = \frac{\hat{N}_a}{\rho A} \cdot \frac{[U_p(x_a + l_a) - U_p(x_a)]}{\omega_p^2 + 2i\zeta_p \omega \omega_p - \omega^2} \tag{47}$$

Substituting equation (47) into the modal expansion (45), the longitudinal displacement can be expressed as

$$u(x,t) = \frac{\hat{N}_a}{\rho A} \sum_{p=0}^{\infty} \frac{[U_p(x_a + l_a) - U_p(x_a)]}{\omega_p^2 + 2i\zeta_p \omega \omega_p - \omega^2} \times U_p(x) \cdot e^{i\omega t} \tag{48}$$

3.1.2 Transverse vibrations of 1D structure

The Euler–Bernoulli model of a beam is considered in this section. Flexural vibrations are excited by the bending moments because of expansion and contraction of the impedance sensor. The resulting equation of motion is

$$\rho A \cdot \ddot{w}(x,t) - EI \cdot w''''(x,t) = -M_a''(x,t) \tag{49}$$

The solution for transverse displacement is the modal expansion

$$w(x,t) = \sum_{s=0}^{\infty} C_s W_s(x) \cdot \mathrm{e}^{i\omega t} \tag{50}$$

where $W_s(x)$ are the orthonormal flexural mode shapes satisfying the homogeneous differential equation $EI \cdot W_s''''(x) = \omega_s^2 \cdot \rho A \cdot W_s(x)$. Substitution of $W_s''''(x)$ in terms of $W_s(x)$, multiplication by $W_v(x)$ and integration over the length of the beam gives the modal participation factor

$$\begin{aligned} C_s &= \frac{-\int_0^L W_s(x)\hat{M}_a''(x)\,\mathrm{d}x}{\rho A \cdot (\omega_s^2 + 2i\zeta_s\omega\omega_s - \omega^2)} \\ &= \frac{\hat{M}_a \cdot [W_s'(x_a) - W_s'(x_a + l_a)]}{\rho A \cdot (\omega_s^2 + 2i\zeta_s\omega\omega_s - \omega^2)} \end{aligned} \tag{51}$$

where a damping ratio ζ_s is introduced to account for energy dissipation.

Therefore, the expression for the flexural displacement is

$$\begin{aligned} w(x,t) = \frac{\hat{M}_a}{\rho A} \sum_{s=0}^{\infty} \frac{[W_s'(x_a) - W_s'(x_a + l_a)]}{\omega_s^2 + 2i\zeta_s\omega\omega_s - \omega^2} \\ \times W_s(x) \cdot \mathrm{e}^{i\omega t} \end{aligned} \tag{52}$$

3.1.3 Cumulative structural response

The dynamic structural stiffness, $k_{\mathrm{str}}(\omega)$, presented by the structure to PWAS can be represented as

$$k_{\mathrm{str}}(\omega) = \frac{\hat{F}_{\mathrm{PWAS}}(\omega)}{\hat{u}_{\mathrm{PWAS}}(\omega)} \tag{53}$$

where $\hat{u}_{\mathrm{PWAS}}(\omega)$ is the displacement amplitude at frequency ω and $\hat{F}_{\mathrm{PWAS}}(\omega)$ is the amplitude of the reaction force. Consider a generic point P on the surface of the beam; the horizontal displacement of this point is determined by contributions of longitudinal and flexural components:

$$u_P(x,t) = u(x,t) - \frac{h}{2}w'(x,t) \tag{54}$$

where $u(x,t)$ and $w(x,t)$ are displacements defined by equations (48) and (52), respectively. Letting P be A and B, as presented in Figure 7, and taking the difference, one determines the elongation

$$\begin{aligned} u_{\mathrm{PZT}}(x,t) &= u_B(x,t) - u_A(x,t) \\ &= u(x_a + l_a, t) - u(x_a, t) \\ &\quad - \frac{h}{2}\left[w'(x_a + l_a, t) - w'(x_a, t)\right] \end{aligned} \tag{55}$$

On substituting equations (48) and (52) into equation (55) and using formulation (41), $\hat{u}_{\mathrm{PWAS}}(\omega)$ becomes

$$\begin{aligned} \hat{u}_{\mathrm{PWAS}}(\omega) = \frac{\hat{F}_{\mathrm{PWAS}}}{\rho A}\Bigg\{ \sum_{p=0}^{\infty} \frac{[U_p(x_a + l_a) - U_p(x_a)]^2}{\omega_p^2 + 2i\zeta_p\omega\omega_p - \omega^2} \\ + \left(\frac{h}{2}\right)^2 \sum_{s=0}^{\infty} \frac{[W_s'(x_a + l_a) - W_s'(x_a)]^2}{\omega_s^2 + 2i\zeta_s\omega\omega_s - \omega^2} \Bigg\} \end{aligned} \tag{56}$$

The representation of the structural response in terms of the frequency response function (FRF) to the single input single output (SISO) excitation applied by PWAS can be achieved by dividing equation (56) by $\hat{F}_{\mathrm{PWAS}}$. Therefore, the cumulative FRF consists of longitudinal and flexural components $H(\omega) = H_u(\omega) + H_w(\omega)$:

$$\begin{aligned} H(\omega) = \frac{1}{\rho A} \cdot \Bigg[\sum_{p=0}^{\infty} \frac{[U_p(x_a + l_a) - U_p(x_a)]^2}{\omega_p^2 + 2i\zeta_p\omega\omega_p - \omega^2} \\ + \left(\frac{h}{2}\right)^2 \sum_{s=0}^{\infty} \frac{[W_s'(x_a + l_a) - W_s'(x_a)]^2}{\omega_s^2 + 2i\zeta_s\omega\omega_s - \omega^2} \Bigg] \end{aligned} \tag{57}$$

The structural response can be presented using the dynamic stiffness

$$k_{\mathrm{str}}(\omega) = [H(\omega)]^{-1} \tag{58}$$

3.1.4 Boundary conditions for the elastic beam

The mode shapes in the definition of FRF and dynamic structural stiffness depend on the boundary conditions of the host structure. Practical implementation of free–free boundary conditions is relatively straightforward and in further development it is attractive to consider an elastic beam with free ends.

The mode shapes of an extensionally vibrating free–free elastic beam are governed by the following

expression [12]:

$$U_p(x) = A_p \cos(\gamma_p x),\ \gamma_p = \frac{p\pi}{L},\ \omega_p = \gamma_p c,$$
$$c = \sqrt{\frac{E}{\rho}},\ p = 1, 2, \ldots \tag{59}$$

where the scale factor $A_p = \sqrt{2/L}$ is determined through a normalization process.

The mode shape functions for the transverse vibrations include harmonic and hyperbolic functions:

$$W_s(x) = A_s\big[\cosh\gamma_s x + \cos\gamma_s x - \sigma_s(\sinh\gamma_s x + \sin\gamma_s x)\big] \tag{60}$$

where wave speed $c_w = \sqrt{EI/\rho A}$, frequency $\omega_s = \gamma_s^2 c_w$, and scale factor $A_s = 1/\sqrt{\int_0^L W_s^2(x)\,\mathrm{d}x}$ participate in the definition. Numerical values of $L \cdot \gamma_s$ and σ_s for $s \leq 5$ can be calculated; for $s > 5$, $\gamma_s = 1/L(2s+1)\pi/2$ and $\sigma_s = 1$. The expressions above allow for modeling a 1D structure (elastic beam) with free–free boundary conditions. However, it needs to be mentioned that equations (57) and (58) are generic and permit incorporation of other sets of boundary conditions.

3.2 Experimental verification of the 1D impedance model

The model of the structural response introduced in the previous section plays an important role in determining the cumulative impedance of the sensor/structure system. In effect, the model suggests that the impedance signature measured by the impedance analyzer at the sensor terminals presents not only the sensor characteristic, but also structural dynamic features reflected in the dynamic stiffness (equation 58) and, hence, in the dynamic stiffness ratio $r(\omega)$. Therefore, expression (58) can be utilized in conjunction with equations (19) and (20) to predict impedance or admittance responses of the sensor/structure system and allow for direct comparison between theoretical and experimental data.

To determine the validity of the presented 1D impedance model, a set of experiments involving small steel beams has been conducted. Simulation parameters were selected to represent experimental specimens depicted in Figure 8. The specimens were

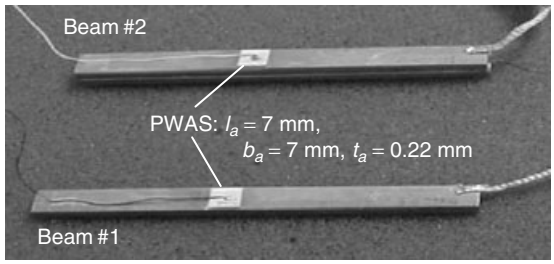

Figure 8. Experimental specimens representing one-dimensional structures.

fabricated from steel with nominal $E = 200\,\mathrm{GPa}$ and $\rho = 7750\,\mathrm{kg\,m^{-3}}$. The beams were of the same length and width, $L = 100\,\mathrm{mm}$ and $b = 8\,\mathrm{mm}$, but of different thicknesses: $h_1 = 2.6\,\mathrm{mm}$ and $h_2 = 5.2\,\mathrm{mm}$. The double-thickness beam was fabricated by gluing two single-thickness specimens back-to-back. This configuration was introduced to simulate the effect of corrosion in metallic structures and disbonding/delamination in composite structures. Noticeable in Figure 8, both specimens were instrumented with the impedance sensors placed at $x_a = 40\,\mathrm{mm}$ from the left end.

The numerical simulation was performed by coding equations (58) and (20) in the mathematical software. The viscous damping of $\zeta_p = \zeta_s = 1\%$ was introduced for steel beams. A frequency range that contains the first set of natural frequencies of the experimental specimens was considered and free–free boundary conditions were simulated using common foam. The real part of the structural system impedance was measured with the HP 4194A Impedance Analyzer. The results of the theoretical calculations and experimental testing are presented in Figure 9. For the single-thickness beam, discrepancy in the position of the experimental and calculated impedance peaks is within 4% for the first five frequencies. Consistent with the experimental observation, the model predicts five flexural peaks. The seventh peak in the impedance spectrum in Figure 9(a) is attributed to the longitudinal vibrations. It is observable at approximately 25 kHz in the single thickness specimen, causing peak splitting due to the close proximity of the flexural and longitudinal frequency contributions. As expected from the theoretical analysis, the longitudinal peak has the same 25 kHz location on the impedance spectrum of the double-thickness specimen presented

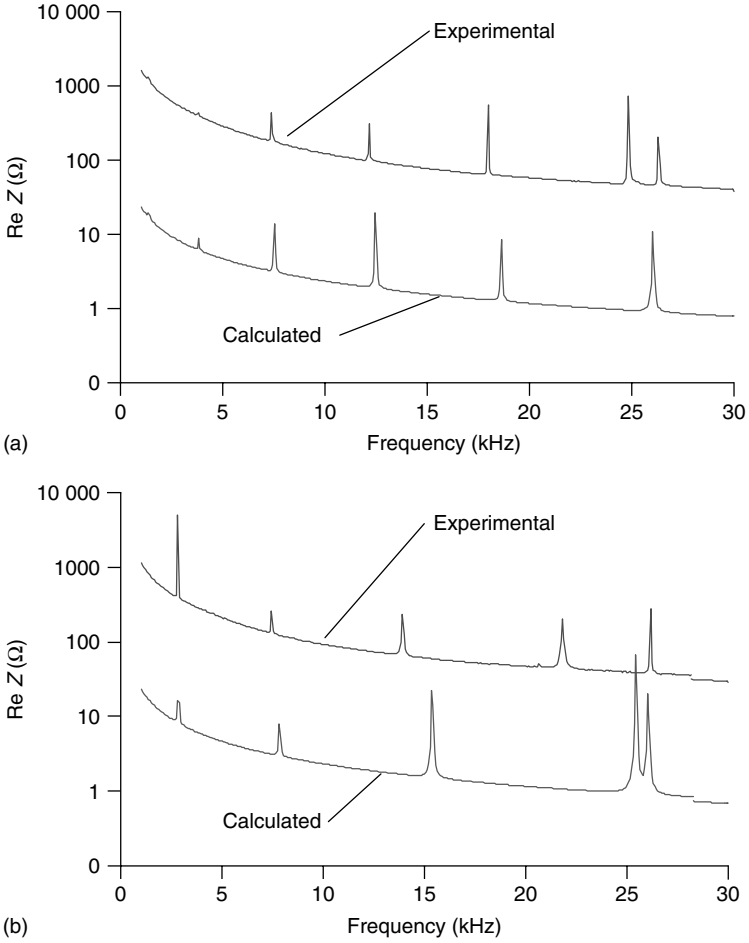

Figure 9. Experimental and calculated impedances of (a) single-thickness beam (beam #1) and (b) double-thickness beam (beam #2).

in Figure 9(b). The figure reveals a doubled period for the impedance peaks, which is in agreement with the theory for transverse vibrations. However, the discrepancy between the experimental and calculated data increases at higher frequencies and reaches almost 17% for the fifth impedance peak. It is likely that this discrepancy is caused by the adhesive layer between the two identical single-thickness beams. Even though the errors seem larger for the double-thickness beam, the confirmation of theoretical predictions by the experimental results is apparent. For the single-thickness beam, the errors between calculated and measured impedance peaks are small, and within the range normally accepted in experimental modal analysis.

4 ELECTROMECHANICAL IMPEDANCE MODEL FOR 2D STRUCTURES

4.1 Analytical model for 2D sensor/structure interaction

An axisymmetric two-dimensional geometry provides a straightforward modeling approach for the impedance sensor of a circular configuration. To take advantage of symmetry, the sensor is assumed to be bonded to the center of the circular plate. In this setting, the center of the circular plate coincides with the center of the sensor as presented in Figure 10.

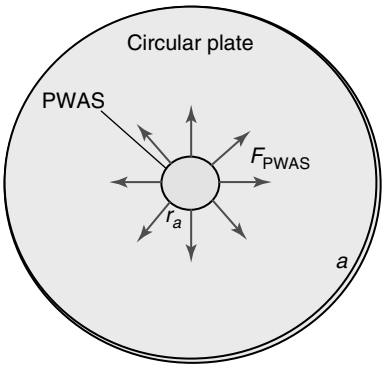

Figure 10. Excitation of a circular plate by PWAS.

Following considerations for the force and moment excitations discussed in the preceding section, the effect of the active sensor on the structure can be presented in terms of the following harmonic loads:

$$N_a(r,t) = \hat{N}_a \cdot [-H(r_a - r) + H(-r)] \cdot \mathrm{e}^{i\omega t} \quad (61)$$

$$M_a(r,t) = \hat{M}_a \cdot [H(r_a - r) - H(-r)] \cdot \mathrm{e}^{i\omega t} \quad (62)$$

Owing to the axially symmetric geometry, no circumferential component is entered into expressions (61) and (62).

4.1.1 Extensional vibrations of 2D structure

Extensional vibrations are generated by a harmonic axial force exerted by a piezoelectric sensor on a structural element. Adding this force to the balance of forces results in the equation of motion with an additional forcing component:

$$\frac{Eh}{1-\nu^2}(u''(r,t) + u'(r,t)/r - u(r,t)/r^2) - \rho h \cdot \ddot{u}(r,t) = -(N_a' + N_a/r) \quad (63)$$

where $(\dot{}) = \partial(\,)/\partial t$, $(\,)' = \partial(\,)/\partial r$ and $u(r,t)$ is the in-plane displacement of a circular plate, E is the modulus of elasticity, ν is the Poisson ratio, ρ is density, and h is the thickness of the plate.

Assuming the solution for the in-plane displacement that satisfies the homogeneous form of equation (63), one expresses $u(r,t)$ in terms of orthonormal mode shape functions $R_k(r)$.

$$u(r,t) = \sum_{k=0}^{\infty} P_k R_k(r) \cdot \mathrm{e}^{i\omega t} \quad (64)$$

where P_k is the modal participation factor for the extensional vibrations. Mode shapes $R_k(r)$ satisfy the orthonormalization condition

$$\rho h \cdot \int_0^{2\pi} \int_0^a R_k(r) R_l(r) r \, \mathrm{d}r \, \mathrm{d}\theta = \rho h \cdot \pi a^2 \cdot \delta_{kl} = \rho h \cdot \pi a^2 \cdot \begin{cases} 1 & k = l \\ 0 & k \neq l \end{cases} \quad (65)$$

Separation of the time- and space-dependent variables leads to the equation for natural frequencies

$$\frac{E}{\rho \cdot (1-\nu^2)} \left(R_k''(r) + \frac{1}{r} R_k'(r) - \frac{1}{r^2} R_k(r) \right) \cdot \frac{1}{R_k(r)} = -\omega_k^2 \quad (66)$$

Substituting solution equation (64) into equation (63), taking into consideration equation (66), multiplying by $R_l(r)$ and applying equation (65) gives a formulation for the modal participation factor P_k:

$$P_k = \frac{\int_0^{2\pi} \int_0^a R_k(r) \cdot (N_a' + N_a/r) r \, \mathrm{d}r \, \mathrm{d}\theta}{\pi a^2 \cdot \rho h \cdot (\omega_k^2 - \omega^2)} \quad (67)$$

The contribution of the force N_a is accounted for by substituting the excitation equation (61) into equation (67). Introducing viscous damping via ζ_k, one obtains

$$P_k = \frac{2\pi \hat{N}_a \cdot \left[r_a R_k(r_a) - \int_0^a R_k(r)(H(r_a - r) - H(-r)) \, \mathrm{d}r \right]}{\pi a^2 \cdot \rho h \cdot (\omega_k^2 + 2i\zeta_k \omega \omega_k - \omega^2)} \quad (68)$$

Considering the modal participation factor (68) and expansion (64), one arrives at the expression for the in-plane displacement of the circular plate,

$$u(r,t) = \frac{2\hat{N}_a}{a^2 \cdot \rho h} \cdot \sum_{k=0}^{\infty} \frac{\left[r_a R_k(r_a) - \int_0^a R_k(r)(H(r_a - r) - H(-r))\,\mathrm{d}r \right]}{(\omega_k^2 + 2i\zeta_k \omega\omega_k - \omega^2)} R_k(r) \cdot \mathrm{e}^{i\omega t} \tag{69}$$

4.1.2 Transverse vibrations of 2D structure

The problem of transverse vibrations of circular plates is very popular in engineering analysis owing to the large number of practical applications. In the particular geometry presented in Figure 10, the piezoelectric sensor expands (and contracts) axisymmetrically producing a symmetric bending moment $M_a(r,t)$. Hence, in the following derivation, the symmetric loading and boundary conditions are considered. It follows that for a plate continuous in the circumferential direction (i.e., $0 \le \theta \le 2\pi$), the load is θ-independent, and boundary conditions do not vary around the circumference. Adding moment $M_a(r,t)$ to the equilibrium of bending moments acting on the element of the plate, one arrives at the equation of motion describing transverse vibrations of a circular plate under the action of the piezoelectric impedance sensor

$$D\nabla^4 w(r,t) + \rho h \cdot \ddot{w}(r,t) = M_a'' + 2M_a'/r \tag{70}$$

where $D = Eh^3/12(1-\nu^2)$ is the flexural rigidity of a plate; for the particular axisymmetric case $\nabla^4 w(r,t) = w''''(r,t) + 2 \cdot w'''(r,t)/r - w''(r,t)/r^2 + w'(r,t)/r^3$.

The solution for transverse vibrations is presented in terms of superposition of modes

$$w(r,t) = \sum_{m=0}^{\infty} G_m Y_m(r) \cdot \mathrm{e}^{i\omega t} \tag{71}$$

Axisymmetric mode shape functions $Y_m(r)$ satisfy the orthonormalization condition

$$\rho h \cdot \int_0^{2\pi} \int_0^a Y_n(r) \cdot Y_m(r) r\,\mathrm{d}r\,\mathrm{d}\theta = \rho h \cdot \pi a^2 \cdot \delta_{mn} = \rho h \cdot \pi a^2 \cdot \begin{cases} 1 & m = n \\ 0 & m \ne n \end{cases} \tag{72}$$

and participate in the equation for natural frequencies

$$D \cdot \nabla^4 Y_m(r) = \omega_m^2 \cdot \rho h \cdot Y_m(r) \tag{73}$$

Substitution of the solution given by equation (71) into the equation of motion (70), enables one to apply the separation of variables solution procedure outlined in the preceding sections. Utilizing formulation (73) in conjunction with the effect of damping, multiplying the result by $Y_n(r)$ and applying equation (72), upon integration over the area of the plate, one obtains an expression for the modal participation factor

$$G_m = \frac{\int_0^{2\pi} \int_0^a Y_m(r) \cdot (M_a'' + 2M_a'/r) r\,\mathrm{d}r\,\mathrm{d}\theta}{\rho h \cdot \pi a^2 \cdot \left(\omega_m^2 + 2i\zeta_m \omega\omega_m - \omega^2\right)} \tag{74}$$

Substitution of the modal participation factor (74) into the solution equation (71) and consideration of the expression for moment load (equation 62) yields the final form of the transverse displacement

$$w(r,t) = \frac{-2\hat{M}_a}{\rho h \cdot a^2} \cdot \sum_{m=0}^{\infty} \frac{\left[r_a \cdot Y_m'(r_a) - Y_m(r_a) + Y_m(0) \right]}{\left(\omega_m^2 + 2i\zeta_m \omega\omega_m - \omega^2\right)} \times Y_m(r) \cdot \mathrm{e}^{i\omega t} \tag{75}$$

4.1.3 Structural response of the circular plate

The dynamic structural stiffness in terms of the force and displacement of the piezoelectric impedance sensor is given in expression (53). Since the displacement of the sensor at the center of the plate is zero,

the total displacement containing in-plane and out-of-plane (transverse) components is

$$u_{\mathrm{PWAS}}(r,t) = u(r_a,t) - \frac{h}{2}\cdot w'(r_a,t) \tag{76}$$

Therefore, a frequency-dependent amplitude $\hat{u}_{\mathrm{PZT}}(\omega)$ can be obtained by substituting extensional (equation 69) and transverse (equation 75) displacements of the circular plate into equation (76). Using $k_{\mathrm{str}}(\omega) = \hat{F}_{\mathrm{PWAS}}(\omega)/\hat{u}_{\mathrm{PWAS}}(\omega)$, it follows that the dynamic structural stiffness of a circular plate is

$$k_{\mathrm{str}}(\omega) = a^2\rho\cdot\left[\frac{2}{h}\sum_{k=0}^{\infty}\frac{\left[r_a R_k(r_a) - \int_0^a R_k(r)(H(r_a-r)-H(-r))\,\mathrm{d}r\right]R_k(r_a)}{(\omega_k^2 + 2i\zeta_k\omega\omega_k - \omega^2)} + \frac{h}{2}\sum_{m=0}^{\infty}\frac{[r_a\cdot Y_m'(r_a) - Y_m(r_a) + Y_m(0)]Y_m'(r_a)}{(\omega_m^2 + 2i\zeta_m\omega\omega_m - \omega^2)}\right]^{-1} \tag{77}$$

4.1.4 Boundary conditions for the circular plate

To facilitate comparison of experimental and theoretical results, it is attractive to consider a thin circular plate with free edges. Extensional vibration modes of a circular plate are governed by the following expression involving Bessel functions of the first kind:

$$R_k(r) = A_k\cdot J_1(\lambda_k r) \tag{78}$$

where λ_k is determined from the frequency equation

$$\frac{J_1(\lambda a)}{\lambda a}(1-\nu) = J_0(\lambda a) \tag{79}$$

With the first five roots

$$\lambda_k a = 2.05, 5.39, 8.57, 11.73, 14.88. \quad k = 1, 2, \ldots \tag{80}$$

Using equation (80), one determines natural frequencies corresponding to extensional vibrations of a circular plate with a free edge:

$$\omega_k = c\cdot\lambda_k \tag{81}$$

where $c = \sqrt{E\rho\cdot(1-\nu^2)}$. Implementation of the condition of equation (65) gives an expression for the amplitude constant A_k:

$$A_k = [J_1^2(\lambda_k a) - J_0(\lambda_k a)J_2(\lambda_k a)]^{-\frac{1}{2}} \tag{82}$$

Transverse vibration modes are described by Liessa [13]

$$Y_m(r) = A_m\cdot[J_0(\lambda_m r) + C_m\cdot I_0(\lambda_m r)] \tag{83}$$

Note that expression (83) is valid for the case when the nodal diameters are absent, which arises for axisymmetric vibrations under the applied symmetric load as suggested in Figure 10. In equation (83), m represents a mode shape number and is related to a number of nodal circles. The frequency equation for transverse vibrations of the circular plate with a free edge is relatively complex. Numerical procedures are employed to solve for λ_m, C_m, and A_m. Tabulation of these parameters for a particular case of free edge boundary conditions was presented by Itao and Crandall [14]. The availability of eigenvalues λ_m allows for the calculation of flexural natural frequencies according to the formulation

$$\omega_m = \frac{\lambda_m^2}{a^2}\cdot\sqrt{\frac{D}{\rho h}} \tag{84}$$

where a is a radius of the circular plate.

4.2 Experimental verification of the 2D impedance model

Experiments were conducted to investigate the dynamic behavior of thin circular plates subjected to free boundary conditions and the loading described in Figure 10. The experimental specimen was fabricated from aircraft-grade aluminum with $E = 70.3$ GPa,

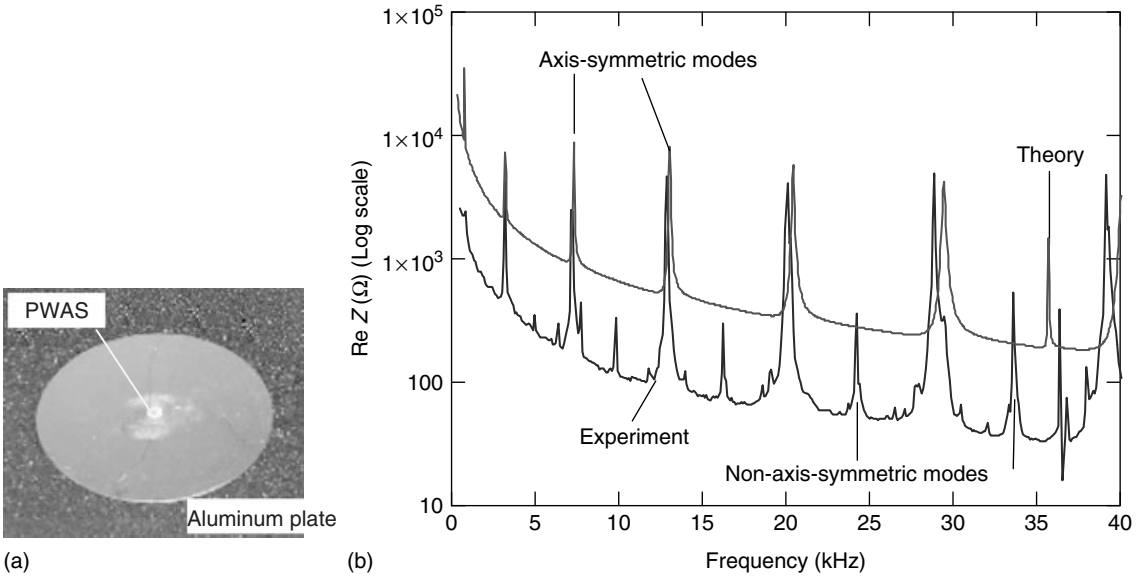

Figure 11. (a) An aluminum circular plate specimen featuring centrally located PWAS; (b) theoretical and experimental electromechanical impedances of a circular plate in (a).

$\rho = 2.8 \times 10^3\,\mathrm{kg\,m^{-3}}$, and $\nu = 0.345$. The thickness of the plate was 0.8 mm and the diameter was 100 mm. A circular PWAS (see Section 2.2 for details on sensor parameters) was installed at the center of the aluminum plate. An attempt was made to match the center of the plate with the center of the sensor as closely as possible to realize the axisymmetric geometry and load conditions considered in the theoretical development. Commercially available foam was utilized to imitate free edge boundary conditions. Figure 11(a) presents the configuration of the experimental specimen and the position of the impedance sensor.

The impedance of the 2D sensor/structure system was measured with an HP 4194A Impedance Analyzer. The experimental impedance is presented in Figure 11(b) along with the impedance calculated using expression (40). This expression describes an impedance of the sensor as measured at the electrical terminals and explicitly incorporates the structural dynamic stiffness from equation (77), reflecting the contribution of free edge boundary condition via equations (78–84). Noticeable from equations (40) and (77), the present model includes dynamics of a 2D impedance sensor and dynamics of the 2D structure with the generic boundary constraints. Theoretical consideration of a free edge boundary condition for the aforementioned plate and sensor geometries resulted in the impedance response featuring seven flexural peaks and one extensional peak. Damping was accounted for by assuming the extensional vibrations damping factor $\zeta_k = 0.07\%$ and the transverse vibrations damping factor $\zeta_m = 0.4\%$. Figure 11(b) indicates a good agreement between theoretically calculated and experimentally determined impedances. Comparison of the experimental and theoretical impedance data suggests validity of the presented modeling approach and advocates the importance of analytical procedures in improving our understanding of the EMI response of complex structures.

5 IMPEDANCE MODELING: CURRENT STATUS AND FUTURE PERSPECTIVES

Over the past decade, EMI modeling has evolved dramatically from the 1D approach pioneered by Liang *et al.* [10] to coupled numerical–analytical

techniques employed for 3D structures by Madhav and Soh [15]. Although it is probably impossible to provide a complete list of contributions, authors of this article would like to highlight some recent modeling efforts that may be of interest to researchers in this area.

The discussed EMI modeling approach incorporates both the dynamics of a piezoelectric impedance sensor and dynamics of the host structure. The latter includes longitudinal (extensional) and flexural vibrations. In this respect, the 1D development presented in this article further extends the work of Liang *et al.* [10]. Noticeably, this and most of the other models assume perfect bonding between the sensor and the host structure. Xu and Liu [16] introduced the impedance of a bonding layer and Bhalla and Soh [17] further advanced the model to include an effect of the shear lag.

Fundamental aspects of 2D impedance modeling were considered by Zhou *et al.* [18], who presented an analytical formulation for the rectangular geometry of the sensor and a thin plate; interaction of a sensor and the host structure via bending moments produced flexural vibrations of a plate. The impedance modeling for axisymmetric 2D structures was presented in this paper and in [5]. Dynamic behaviors of the sensor and a host structure were included, as well as extensional and transverse structural vibrations. Bhalla and Soh [19] introduced the concept of the effective impedance to address difficulties in model validation for complex structures. In a recent paper [15], the author's numerical–analytical procedure was extended into the 3D geometry. Cheng and Lin [20] developed a model that includes interaction of multiple impedance sensors and their respective masses. Addressing integration of the custom-built electronic circuitry into the impedance testing, several EMI models based on electrical circuit analysis [21, 22] have been suggested and validated against experimental data and established analytical formulations. There is no doubt that in future scientists and engineers will witness further improvements in the accuracy of impedance modeling, development of the EMI representations for structures of significant geometrical complexity, and increasing integration or cross-coupling of analytical formulations, numerical simulations, and experimental testing.

Chapter 4
Acoustic Emission

Michael R. Gorman
Digital Wave Corporation, Englewood, CO, USA

1 INTRODUCTION

Acoustic emission (AE) is a transient mechanical wave produced by some disturbance, such as a crack that suddenly grows when a material is stressed. The AE technique is one of the nondestructive evaluation (NDE) techniques recognized by American society for nondestructive testing (ASNT). The material needs to be stressed in order to use AE. The stress level should be low enough to be nondestructive; it should not compromise structural use. AE can be applied as part of routine quality assurance procedures. For example, most pressure vessels are routinely proofed as part of the manufacturing process. An advantage of AE is that it can be used to monitor structures in service and serve as an early warning of impending failure. AE signals in engineering structures can reveal the presence of growing flaws, detect impacts, locate leaks, locate frictional interferences, and, with the right setup, provide the precise load at the onset of fracture.

AE as an NDE technique has progressed to modal acoustic emission (MAE), which operates on a good physical basis. MAE is conceptually similar to seismology, SONAR and other branches of mechanics and acoustics. AE waveforms can be predicted by normal mode vibration solutions for finite plates. Wave modes allow identification of sources. This use of normal modes for interpreting AE waveforms significantly reduces the number of false calls that typically occur in amplitude/duration/counts (so-called AE parameters) techniques used in the past.

There were several problems with parameter AE, the major problem being that most of the information in the waves was filtered out by the resonant transducer, 100–300 kHz frequency filter, and "AE analyzer" circuits that reduced the signals to a handful of numbers thought to be representative of the AE wave. Dr Goranson, former Head of Structures at Boeing, in his paper titled

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

"Jet Transport Structures Performance Monitoring," Structural Health Monitoring, Current Status and Perspectives, *Proceedings of the International Workshop on Structural Health Monitoring*, Stanford University, CA, September 18–20, 1997, stated:

> 'Classical' AE data consists of various parameters intended to represent the AE waveform. The parameters characterizing a given waveform are not necessarily unique to that waveform and could be the same for other waves generated by other types of sources.

The MAE approach eliminates the nonuniqueness problem pointed out by Dr Goranson.

Another major problem practitioners soon discovered was that there were often significant errors in the source location as well. Source location is arguably the most critical part of AE. To date, source location is not part of any American society of mechanical engineers (ASME) codes. In contrast, SONAR and seismological methodologies focus on determining source location.

The language of MAE is much different than the old "parameter" or "counts" AE. The method uses familiar engineering terms and theoretically based Newtonian physics. This engineering language makes it easier to explain to personnel charged with deciding the fate of a given structure. The connections between sources and waves make physical sense, just as they do in seismology.

MAE has renewed interest in AE as an NDE technique. It has built confidence in its results. The main ideas of the waves are described in this article. Examples of waves in plates are given, which show the variation in the mode shapes and frequencies encountered as the plate thickness increases. This variation with plate thickness is probably the least understood part of MAE. Actual fracture waves in a steel pressure vessel are compared with theoretically predicted waves, and crack depth is obtained. Also, a new formula is presented for calculating front end frequency. Finally, a summary is provided with some further thoughts about using MAE in structural health monitoring (SHM).

1.1 MAE background

The physical material in which a wave propagates is called the *medium*. The discussion here is confined to guided waves in plates, which provides ample material since aircraft, pipelines, pressure vessels, storage tanks, spacecraft, and so on, are constructed with platelike sections. MAE waves in plates propagate for most practical purposes in just two modes. One mode is called the *extensional*, or E, wave, and the other mode is called the *flexural*, or F, wave. The term *mode* has a meaning similar to vibrational modes but that aspect is not important here.

It was shown in [1] that there is a simple and direct connection between a source and the waves excited in plate. An ordinary pencil lead, broken on the surface of a plate, creates a large F wave and very small E wave. A pencil lead break on the edge results in a much larger E wave. The F wave amplitude may still be quite large, depending on how near to the centroidal plane the lead is broken. A crack is generally an in-plane feature, so this source must produce an E wave. This general characteristic of cracks is the basic principle behind the practical use of MAE.

The theoretical study of elastic waves excited by fracture sources has great importance in the field of AE [2]. Without this understanding, it would not be known how to properly set up a test and the meaning of any waves captured would likely be unintelligible to the observer. Numerous solutions have been proposed to calculate the elastic waves excited in an infinite plate for various AE sources [3–7] using complicated transform and inverse transform integrals. Although those solutions found use in calibrating AE sensors [8], they are difficult to extend for studying AE waveforms in finite plates where arbitrary source and receiver positions and edge reflections must be considered.

If the normal mode solution to the classical plate bending equation could be used to compute the flexural wave excited by a step-function surface load on a finite thin plate, then reflections could be accounted for and, due to the simplicity of the equations, there would be a possibility of extending the solutions to composite materials. This calculation was done in [9]. The solutions obtained were simple explicit forms that showed good agreement with the low-frequency part of an experimentally measured pencil lead break signal, including the reflections. It is well known, however, that the solutions of the classical plate bending equation are invalid at higher frequencies, so the calculations did not give zero displacement

in the received waveform prior to the arrival of the Rayleigh surface wave. In addition, classical plate theory cannot be used to describe the dispersive behavior of the extensional mode. To overcome those limitations, a higher-order Mindlin plate theory [10, 11] was used to compute the elastic wave solutions using the same normal mode expansion approach for a finite plate [12, 13]. These solutions give very good agreement with experimentally measured E and F waves excited by various sources.

Phenomenologically speaking, the E and F waves are similar to the longitudinal (P or L) and shear (S) waves that are familiar in earthquake engineering (P, S) and in ultrasound (L, S), but there is a very important difference: L and S waves do not change shape as they propagate; E and F waves do. L and S are bulk waves; they propagate in media whose dimensions are large compared to the wavelength. Once the wavelength is on the order of one of the dimensions of the medium, like the thickness of a plate, the geometry of the part affects the wave motion considerably.

The E wave in a plate has its largest particle displacement in the plane of the plate, basically a stretching motion, while the F wave is a bending motion with its largest displacement out of plane or perpendicular to the plate's surface. The stretching motion of the E wave in the plane of the plate produces a motion of the surfaces of the plate, that is, the surfaces undergo a Poisson contraction toward each other. Visualizing the stretching of a rubber eraser in its long direction gives the correct image. It also demonstrates the inherent symmetric nature, with respect to the midplane. E and F waves have been observed in impacts on rods and plates (see [14] and [15] and the references therein).

The E wave has a "plate velocity" of around $5080\,\mathrm{ms}^{-1}$ in steel; the L wave has a velocity of $5920\,\mathrm{ms}^{-1}$. As noted above, the Fourier frequencies in an L wave pulse "stay together" as they propagate, that is, they all travel at the same speed and thus an L wave does not change its shape. This property makes the L wave useful for measuring the thickness of a material. A typical L wave frequency is 5 MHz. The wavelength is related to the frequency by

$$\lambda = \frac{c}{f} \tag{1}$$

Given a velocity of $5920\,\mathrm{ms}^{-1}$ in steel, the wavelength is 1.2 mm. This value is much smaller than the dimensions of the steel parts typically measured with an ultrasonic thickness gauge.

The E wave is dispersive, so the "plate velocity" only holds absolutely at zero frequency but is useful for estimating mode presence. At a frequency of 100 kHz, a typical MAE frequency, the wavelength is 5.1 mm. This is larger than the thickness of many structural sections. At 50 kHz, $\lambda = 10.2$ mm in steel.

For completeness of this present discussion, the E and F waves in plates are also known as the *lowest-order Lamb modes*, S_0 and A_0. S stands for symmetric and A stands for antisymmetric. Again, the plane of symmetry is the midplane of the plate. The inherent symmetry of a stretching motion was noted above. The inherent antisymmetry of a bending motion is also straightforward to visualize with the eraser. There are an infinite number of Lamb modes corresponding to the infinite number of sinusoidal standing waves (these are *the modes*) that are possible to imagine existing across the thickness of the plate.

Because the waves expected from crack growth can be predicted theoretically, the use of MAE is not dependent on a database of repeated tests on identical specimens. The need for such a database has often been a barrier to the use of the technique in the past. With the "counting" techniques for example, merely changing the gain changed the results and required a whole new database. Different manufacturers' equipment "counted" differently. This limitation was extremely frustrating, to say the least.

1.2 Practical testing

The main goal of MAE for SHM is to locate and identify indications for follow-up NDE techniques to characterize so that stress and fracture analysts can assess the importance of flaws.

To perform a test, broadband transducers are coupled to a part, the part is stressed appropriately, and the waves are recorded. An AE transducer is about the size and weight of a standard accelerometer and can be mounted on about any structure. An MAE recorder is essentially a multichannel digital oscilloscope with some specialized software. The frequency spectrum of AE waves ranges from the high sonic frequency, about 5 kHz, to the low

ultrasonic frequency, about 2 MHz. Frequencies in large structures rarely exceed a megahertz. Detection equipment is now inexpensive enough to be used for continuous monitoring for fail-safe applications.

Briefly put, the waves expected to propagate in a given test can be predicted in advance with reasonable accuracy. If the measured waves have the right shape and frequencies, the source can be attributed to crack growth (or delaminations, fiber breaks, etc., in composite materials). The tester should be very aware that waves created by noise will also propagate as E and F waves. Noise waves will, in general, look different from crack waves, i.e., their shapes and frequency spectra will be different. There are all sorts of sources of noise that can be introduced by direct contact or through the air.

Once the basic concepts and techniques are mastered for a given type of test, the technique is straightforward to apply and interpret. In fact, it is now regularly and routinely applied by technicians in the United States and Canada. In repetitive type tests, test technicians have been trained to recognize noise waves and crack waves. Handling new test situations requires more extensive training, and final interpretation of test results often requires significant expertise; a radiologist checks human X ray and MRI readings because the human brain is still the best at dealing with the complex mix of factors that go into the correct diagnosis.

2 MODELING MAE WAVES

2.1 Effect of plate thickness

It is well known that there are two parts to the solution to the wave equations governing plates. The homogeneous equation results when the forcing function is set to zero. The solution yields the dispersion equation. A dispersion plot shows how wave velocity varies with frequency for each mode of propagation. The inhomogeneous equation, or forced vibration problem, gives the displacements, i.e., the actual waveforms, for a given source. Just as in seismology and vibrations, closely matching the shape of AE waves to the predicted shape is critical for correct interpretation.

Many examples of MAE waves in very thin plates ($\lambda < h$, h = plate thickness) are now out in the literature. What is not well known, but has been critical in practical testing over the past 10 years, is how shapes of the E and F waves change dramatically when going from 5-mm-thick aircraft skins to 50-mm-thick pipelines and pressure vessels. Consequently, we show higher-order plate theory solutions for several plate thicknesses here. Both surface impulses and edge impulses are calculated. The impulse forcing function is an important case. Solutions for other functions can then be found by convolution. In practice, it has been found that the impulse source produces waveforms that match measured waveforms well enough to guide the data analyst to correct conclusions without knowing the exact source time and spatial functional dependence.

The calculations were performed using the tool WavePredictor™, which contains the higher-order plate theory governing equations described in [12] and [13]. The software tool allows selection of plate geometry, forcing function, source and receiver positions, transducer size, and digital recorder setup. WavePredictor™ is a Windows™-based software tool and a trademark of Digital Wave Corporation. Windows™ is a trademark of Microsoft Corporation.

The source motion and position directly influence the wave motion. Cracks open up in the plane of the plate and create an E wave. If the crack is symmetrically located about the centroidal axis, no bending moment is present and the wave motion is purely extensional, or an E, wave. When the crack tip is above or below the centroidal plane, crack growth generates both E and F waves. The F wave usually appears much larger on the recorder display because its motion is strongly out of plane and waves are usually measured with a normally sensitive transducer that is mounted on the plate surface.

The graph of phase velocity against frequency is a useful way of viewing the dispersion curve because it allows the tester, or the software, to determine the speed for a given frequency component in the FFT of a captured wave. If the arrival times are determined using the wave of that frequency, then the correct velocity can be used to calculate the source location. Source location determined in this manner will be accurate. For composite materials, the velocity varies as a function of the angle with respect to the main fiber axis. This is in addition to the variation of velocity with frequency. Effectively, a new dispersion curve is generated at each angle. A computer program can compute the source position accurately only if it

has the ability to properly account for all of these possibilities.

Dispersion curves are well known, but one is shown here for completeness. It has the typical shape for an E wave. Figure 1 shows a dispersion curve for an E wave in a 0.635 mm-thick aluminum plate. The velocity at zero frequency is called "the" plate velocity. Its value is very close to 5200 $m s^{-1}$. This is to be compared with the bulk longitudinal velocity of 6300 $m s^{-1}$ in aluminum.

There are several interesting points about this figure. First of all, there are two curves. The upper one is the phase velocity and the lower one is the group velocity. At the lower frequencies, both the phase and group velocities vary slowly with frequency and then drop rather quickly. Then they nearly level off once again at the higher frequencies. The intermediate range is said to be highly dispersive. The mildly dispersive range at the lower frequencies is very useful for estimating wavelength. This is the longest wavelength wave because it is the fastest; it will arrive before any other wave. The velocity used in source location is the group velocity because that is the velocity at which the energy of a narrow range, or group, of frequencies propagates. The double-valued nature of the velocities means that those frequency groups will mix. The bottom of the group velocity trough is an important point to keep in mind. These groups are moving more slowly than certain groups in the flexural mode and will, thus, arrive later. This can be confusing, if not understood, because it distorts the "standard look" of the E and F wave arrivals. The effect is particularly severe in thicker plate sections.

2.2 Sources normal to the plane of the plate

Figures 2–4 show waves in aluminum plates of standard US thicknesses of 0.25, 0.5, and 0.75 in. All other dimensions below are in meters. The waves were excited by an impulse source normal to the plate and on the upper surface where the receiver is also mounted. These cases are shown because the

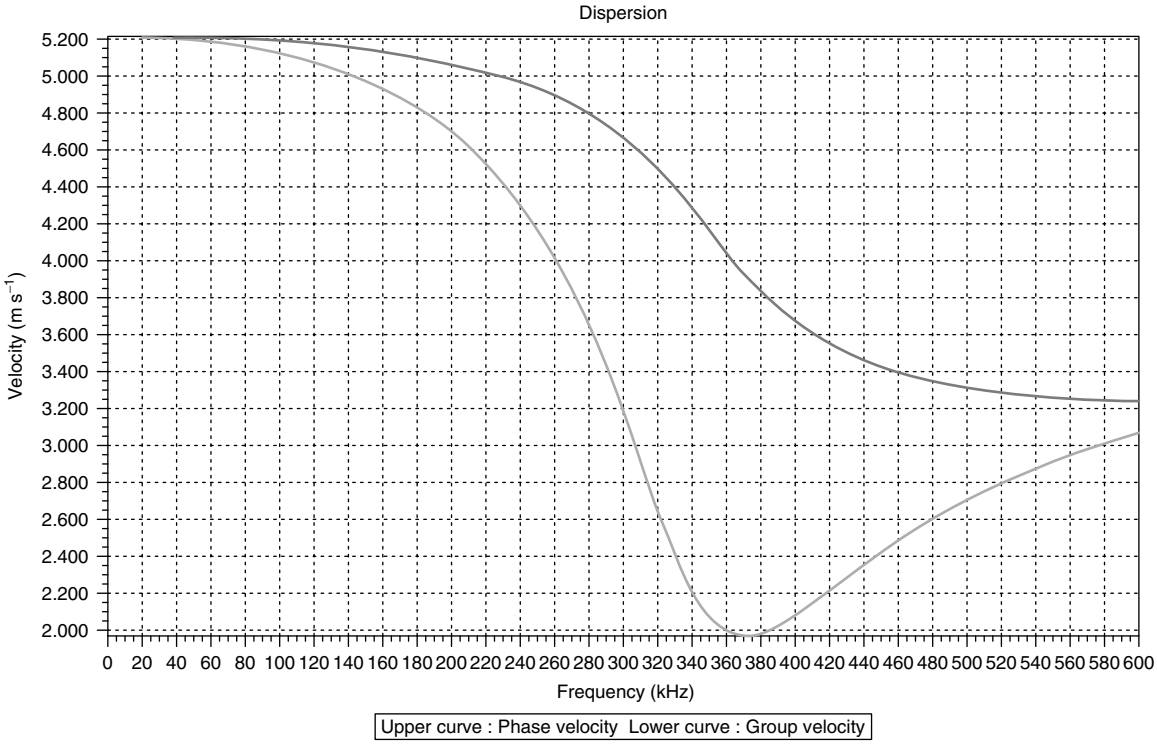

Figure 1. E wave dispersion curve for aluminum plate 0.0635 m (0.25 in.) thick.

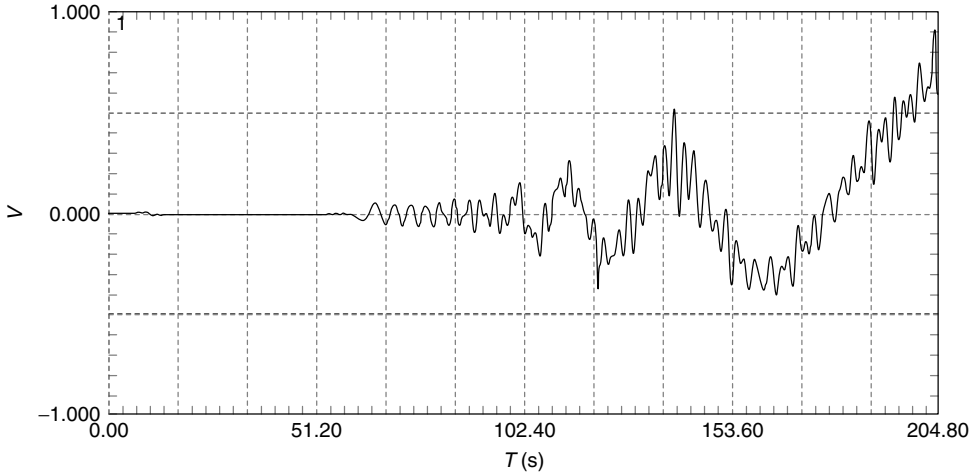

Figure 2. Wave in a 0.25-in.-thick Al plate excited by an impulsive source normal to the upper surface. The front-end frequency is about 180 kHz. Reflections are superposed on the low-frequency portion of the F wave. Small ripples at front are artifacts of calculation.

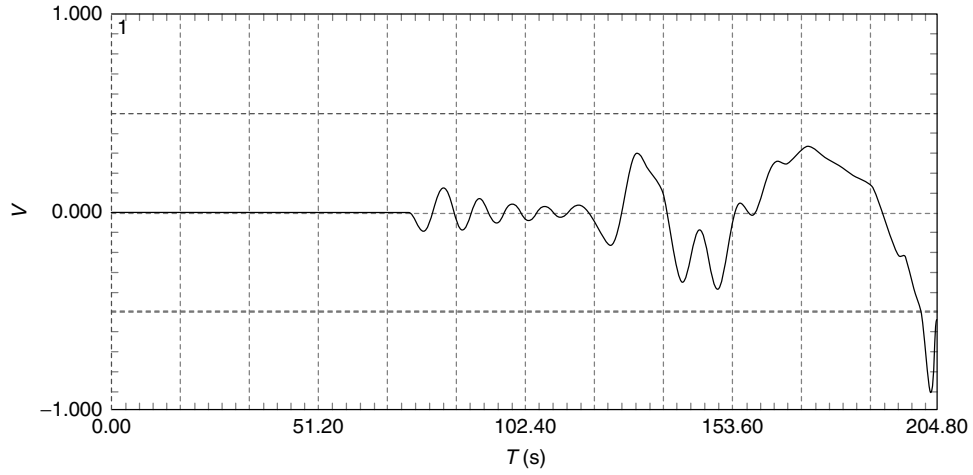

Figure 3. Wave in a 0.50-in.-thick Al plate excited by an impulsive source normal to the upper surface. The front-end frequency is about 100 kHz. Reflections are superposed on the low-frequency portion of the F wave.

pencil lead break source is the most used source and the break is almost always done on the surface of the plate. In contrast, the crack source, which is the source to be detected and located, is usually in-plane and not on the surface. The waves from this source are shown in the next section.

The lateral plate dimensions were chosen to be 0.8 m × 0.6 m in the x and y directions, respectively. The impulsive source was placed at (0.2, 0.2, $h/2$) m, where h is the plate thickness, and the receiver was fixed at (0.4, 0.4, $h/2$) m. The digitization rate was chosen to be 5 MHz. Low-pass filtering was applied so the essential features, particularly the front-end arrival and shape, were more prominent. A 20-kHz high-pass filter was applied. There were 1024 sample points, which gives 204.8 μs in the wave window. Owing to the digital nature of the calculation, small ripples can show up at early times. These ripples should be ignored. Voltage versus time is shown just as would be observed on a digital oscilloscope screen.

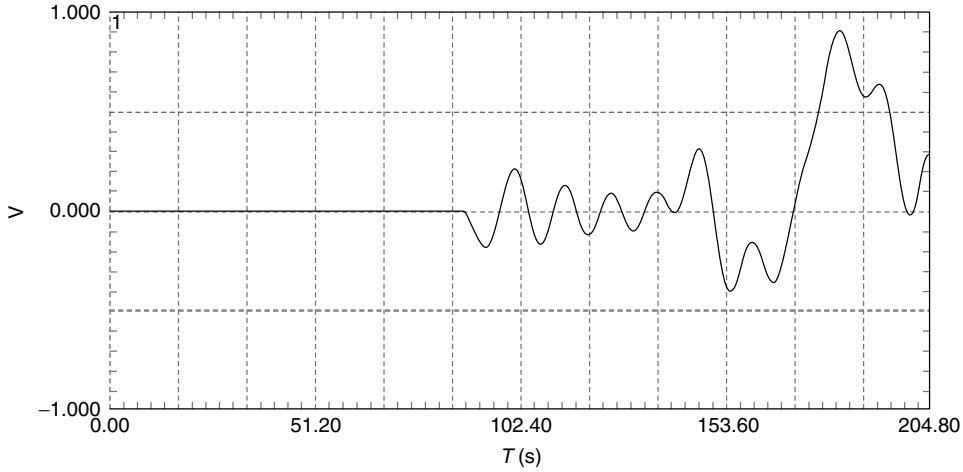

Figure 4. Wave in a 0.75-in.-thick Al plate excited by an impulsive source normal to the upper surface. Reflections are superposed on the low-frequency portion of the F wave. The front-end frequency is about 70 kHz.

The essential features to be observed in Figure 2 are the arrival of the E wave, with its low frequencies merging into higher frequencies, followed by the much larger F wave, with its high frequencies arriving before its lower frequencies. The front end of the E wave is very "clean", which is to say that there are no reflections superposed on it. It gradually merges into the F wave front end, unless the propagation distance is large enough for the two modes to separate, which is not the case here. The F wave invariably has reflections, or in the case of pressure vessels, "wrap" waves, superposed on it. Remember that the front end, or low frequency, part of the E wave travels about twice as fast as the fastest components in the F wave, so these E wave frequency components will speed around a vessel and will interfere with various parts of the direct wave depending on the source receiver distance.

Figures 3 and 4 show similar features for the thicker plates of the same lateral dimensions. The E wave reflection is interfering with the F wave. The reflection is more dispersed than the direct E wave.

For a 1-in.-thick plate, the front-end frequency is about 50 kHz. For a 2-in.-thick plate, the front-end frequency is about 25 kHz.

A formula that provides a straightforward means of calculating the front-end frequency of a pencil lead break on the surface of a material is

$$f = \frac{c}{4h} \tag{2}$$

where c is the plate wave speed for the material and h is the plate thickness [16]. This formula was determined by plotting the measured time between the first two peaks in a well-formed E wave against the thickness of plates of different thicknesses. It gives only an approximate value of the front-end frequency for a certain source to receiver distance at which the modes are well formed, which usually occurs at about $20-40h$ for a wide range of structural materials. This formula can be used to determine quickly, on the spot so to speak, if a tester is looking at plate waves.

2.3 Sources parallel to the plane of the plate

The impulse source on the edge is considered next. The "front-end frequency" is slightly lower for the in-plane source compared to the out-of-plane source. The effects of different source locations on the edge of a 0.25-in.-thick plate, relative to the midplane of the plate, are also studied. The effects are very noticeable and differences in the waveforms due to different source positions can give an idea of the length of the crack. For example, crack growth in a pressure vessel usually starts on the inner diameter (ID) surface and progresses, with pressure cycling, toward the outer diameter (OD). Initially the F wave is excited with very large energy compared to the E wave. As the crack tip progresses toward the midplane of

the plate, the relative energies in the modes changes dramatically. At the midplane the F wave energy vanishes entirely. As a crack progresses to through-wall, the modes change again. This knowledge has been used for some years to determine crack position and length in pressure vessels, and an example is given in Section 4.

For Figures 5–8 the plate dimensions are the same as above for the surface source. Now, however, the source is at (0, 0.2, z), where z is in the thickness direction. $z = 0$ is at the midplane. The receiver is mounted on the upper plate face, as in most AE tests. Again, voltage versus time is shown just as would be observed on an oscilloscope.

Figure 5 shows the waves excited for an impulsive source normal to the edge and at the midplane. The wave is purely extensional. Figures 6 and 7 show waves that result from the same type of impulsive

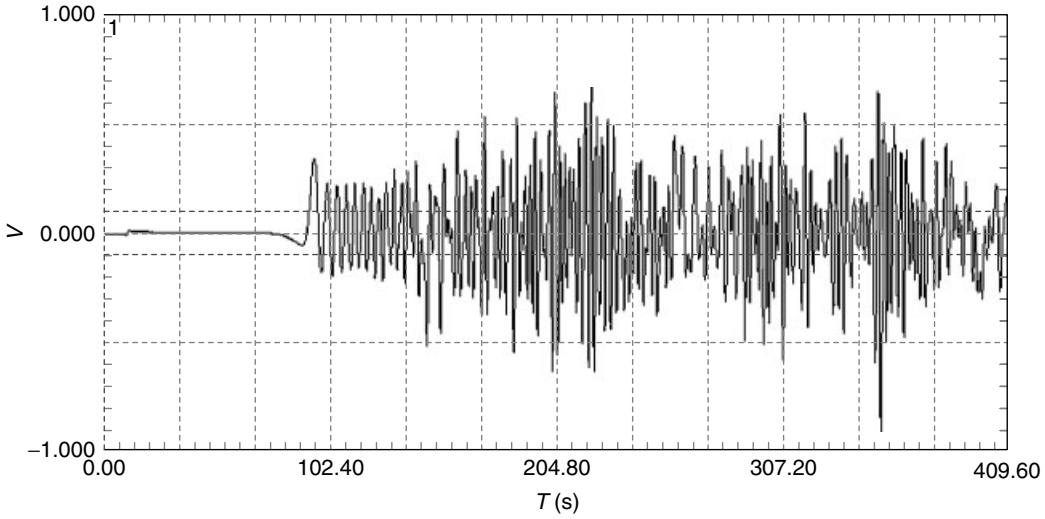

Figure 5. Waves due to impulsive source at midplane on the edge of a 0.25-in.-thick aluminum plate. Front-end frequency is about 100 kHz.

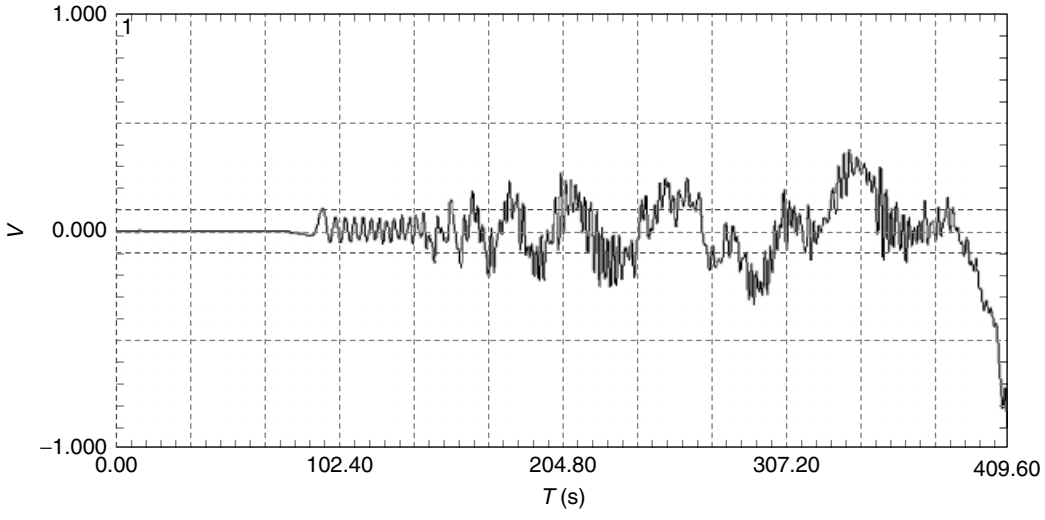

Figure 6. Same plate as Figure 5, only the source is at 0.00127 m up from center edge.

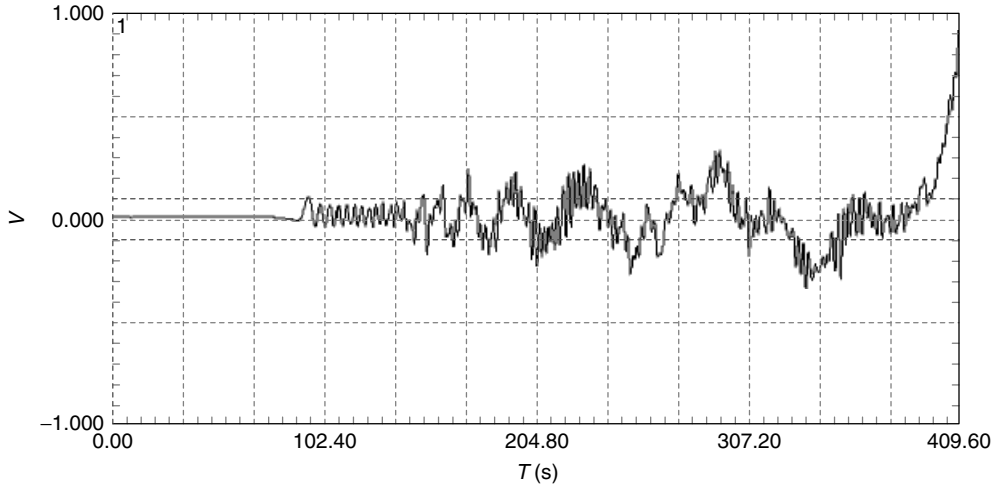

Figure 7. Same plate as Figure 5, but with source at −0.00127 m. Note the inversion of the F wave compared to the one seen in Figure 6.

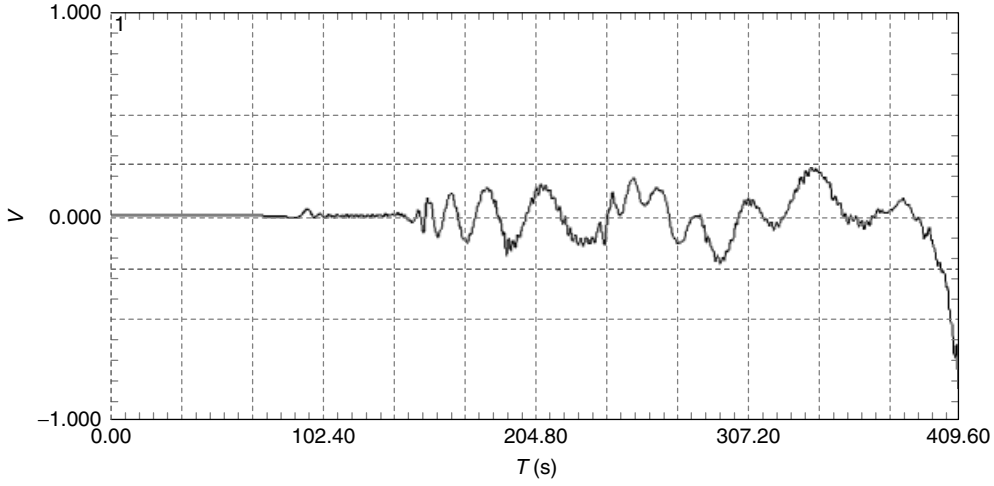

Figure 8. A 0.25-in.-thick aluminum plate. Source at 0.002875 m on edge. SR04. This is the 10% notch case. Note that E wave is far less prominent than when source is deeper but the front-end frequency is still critical and distinguishable.

source at identical positions above and below the midplane. The differences should be carefully noted. The E wave is identical in both figures but the F waves are 180° out of phase as expected. A growing crack would exhibit the same information and the inversion of the F wave would occur as the crack tip passed the midplane, thus revealing its progress from, say, ID to OD if it were in a pressure vessel.

Figure 8 shows the same type of source near the upper surface but still on the edge of the plate. In fact, this case represents the 10% notch situation. Now the E wave energy is a small fraction of the F wave energy. The bending moment is much greater than when the source was near the midplane and thus the F wave is excited to a greater degree. Although, the E wave energy is less, it is nevertheless observable and the front-end frequency, of which little has been said yet in this section, is still distinguishable. It is critical to verify the front-end frequency in order to confirm the crack growth. Noise sources are far

Table 1. Aluminum plate front-end frequencies for an in-plane source

Thickness	Front-end frequency (kHz)
0.006350 m (0.250 in.)	140
0.012700 m (0.500 in.)	80
0.019050 m (0.75 in.)	60
0.02540 m (1.0 in.)	47

less likely to have the same impulsive nature as a crack. The first arrival frequency has been used over and over in MAE testing to distinguish crack growth from noise. It is observed in a later section of this work that, in cyclic work, the presence of a crack can be observed by frictional emission emanating from interference of the crack faces, particularly as they close like teeth. This frictional-type emission is very repeatable and locates at precisely the same position in the specimen until the length of the crack macroscopically increases.

Table 1 gives the front-end E wave frequencies for an in-plane source (simulating a crack) for various thicknesses of 6061 aluminum plate.

These numbers are only approximate and correspond to a given source to receiver distance. They are displayed here to give an idea of what to expect in various thickness plates. The calculation (or measurement) for the actual source to receiver distance should be used for analysis of data. These numbers can be obtained for steel and various composites as well using the program WavePredictor™.

Note that, for greater than 0.25-in. wall, the frequency ranges above are not within the 100–300 kHz range commonly used in AE testing and called for in every american society for testing and materials (ASTM) and ASME standard. This is especially true for the thicker materials typically tested. Also, note that the "front-end frequency" is lower for an in-plane source than for an out-of-plane source. This is very useful for source identification.

3 BRIEF TREATMENTS OF OTHER IMPORTANT TOPICS

3.1 Noise

Noise must be mentioned to complete the sketch of MAE being given here. All sorts of unwanted acoustical events are generated and propagated in structures. These unwanted events are referred to as noise. Of great significance is the ability of MAE to identify noise events. Mechanical noise will propagate as plate modes. A resonant transducer and narrow bandwidth filter combination often make noise difficult to distinguish from fracture events (see the quote by Dr Goranson above).

Noise events can mislead a tester to conclude whether a part is defective or even failing. Wave modes are the key to separating fracture sounds from noise (unwanted sounds). This separation can be difficult; noise can be loud and is produced by a number of sources, particularly frictional rubbing on and in a material. The key to identifying noise is to check for the front-end frequencies and mode shapes calculated using wave mechanics.

3.2 Beneficial frictional emission

Sometimes mechanical rubbing can be useful. For example, the emissions produced by fretting of a crack's surface can be identified in many cases and used to accurately locate a crack in, say, a metallic wing skin. Frictional emission in composite materials can be used to accurately identify the location of delaminations. Relative amounts of frictional emission may be useful for characterizing damage in composites. The advantage of frictional emission is that it is a repeatable source.

3.3 Source location

Source location is extremely important [17–20]. It is also the most definite result that can be obtained from AE methods. Source identification may not always be possible due to distortion or propagation losses but source location can usually be achieved. The critical nature of a source depends on its location on a structure. Source location accuracy can also be limited by distortion, but only severe distortion makes the front end, or some definite phase point, difficult to determine with accuracy at the various arrival positions. The typical cause of severe distortion is an inhomogeneous propagation path. Placing a sensor on the outer bolted cap to a flange rather than on the vessel itself would result in a wave path with multiple

reflections that would result in severe distortion of the wave. However, the severity of these reflections needs to be determined on a case-by-case basis.

Usually the source can be located accurately only if the waves are used. Fixed thresholds often do not lead to accurate source location. With digital wave recorders, this disadvantage of fixed threshold recorders can be eliminated.

Figure 9 shows the same wave as captured at two different positions. It also shows two horizontal dotted red lines in each wave window. These are threshold crossing lines at an arbitrary 40 mV level. It can be readily seen that the waves cross the fixed threshold at very different phase points. The arrival time difference by threshold crossing is 46 μs. The correct time difference calculated from the front ends of the waves is 18 μs. On the basis of a velocity of 5.4 mm μs^{-1}, the error is 151 mm. The distance between the sensors was 152 mm. Adjusting the threshold for this particular case would mean it will be incorrect for another source position. Thus, source location based on fixed threshold crossings is to be avoided. Only source location based on methods of picking similar phase points on the waves themselves is to be considered acceptable.

Another point to mention is the use of pencil lead breaks to set up source location. The pencil lead break is usually done on the surface of a vessel, thus creating a large F wave. Usually, it is this wave that triggers the threshold crossing. However, the E wave is the one to look for when trying to detect crack growth. The only way to get around this discrepancy is to calibrate on the E wave created by a lead break or some source better suited to the vessel under test. The E wave created by a pencil lead break will be very small but still visible 40 ft away on the other end of a trailer tube. For thicker vessels, like metallic structures greater than 2-in. thick, and composite vessels greater than even 0.50-in. thick, the pencil lead break does not excite the appropriate lower frequencies with sufficient energy and another type of source is recommended such as a tap. Various devices that provide a predictable tap with the right frequency content can and should be improvised.

For composite materials, any noticeable anisotropy in the velocity curves must be taken into account.

4 EXAMPLE OF PRESSURE VESSEL TESTING

A DOT 3AA specification tube (steel, wall thicknesses of 0.590 in.) had an internal notch introduced by cutting one into the original seamless pipe and then forging the domes (Figure 10). The tube was then hydrostatically fatigued to grow a crack at the notch location.

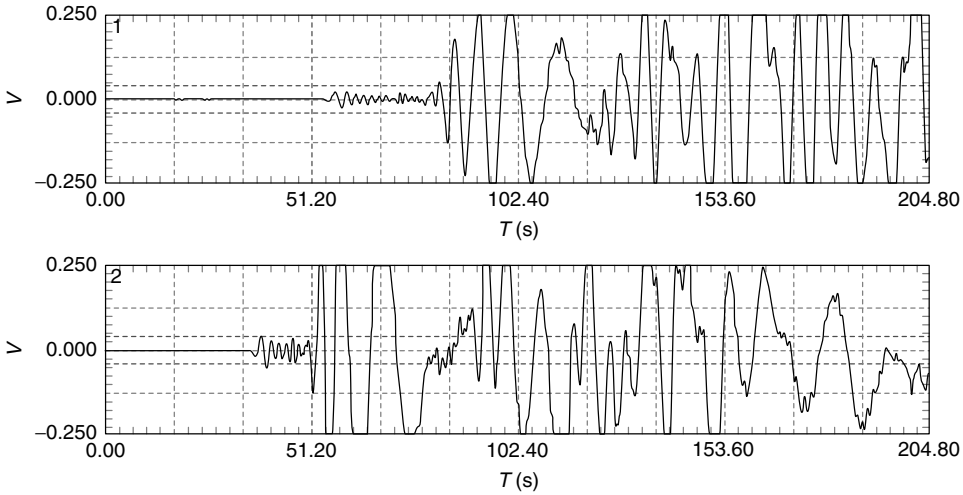

Figure 9. Waves from same source captured at two different positions. Inner most dotted horizontal lines represent positive and negative fixed voltage thresholds, both negative and positive.

Figure 10. DOT spec 3AA tube undergoing cyclic fatigue. Ellipse shows position of crack near the center. MAE transducers are at the ends of small white wires. A 3T tube, seen at the right, was also tested. Good crack growth data were obtained.

A fracture wave detector (Digital Wave Corporation, DWC) was used to record the wave signals from the sensors. The sensors used were DWC B225 sensors. These sensors have broad frequency response over the range of 50–350 kHz with a sensitivity of greater than 1 V μm^{-1}. PA2040 amplifiers and a filter/conditioning module (DWC) provided amplification and filtering. Two sensors were located near the notch, while two other sensors were located near the domes of the flask.

The 3AA cylinder was monitored with MAE equipment for 400 cycles from cycle 9001 to 9400. Figure 6 shows a typical waveform of a signal obtained for crack growth in the cylinder. It was deduced that this event came from the crack because it arrived at sensors 1 and 2 first (there were no other possible sources near these sensors), it occurred near the peak pressure of the cyclic pressure, and the correct wave mode (extensional) was formed. This event occurred near sensor number 2. As the wave propagated out from the crack growth, the plate modes began to form. The modes had not formed yet at sensors 1 and 2, because they were close to the source. It takes approximately 20–40 plate thicknesses for the modes to begin to clearly form [4].

The modes are clearly seen at sensor 3, while at sensor 4, the extensional mode is just beginning to separate from the flexural mode in the displayed A-scan. These points in time are noted in the figure. Figures 11–16 show the theoretically predicted waveforms from crack growth at various depths for a plate of the same thickness as the 3AA flask. It can be seen that the near-surface cracks (Figures 11 and 12) match the signal from the crack growth the closest. As the crack grew deeper (Figures 13–15) the extensional mode became larger, while the flexural mode decreased. Thus, by direct comparison of the crack growth signal to the theoretically predicted signals, the crack growth shown in Figure 11 is only 1–2-mm deep.

Figure 17 shows an event from corrosion on the outside diameter of a flask "popping off" the cylinder. Because there is no depth through the wall from the source, the waveform is purely flexural with no extensional components. Thus, by monitoring the wave modes, source can be identified, and follow-up inspections could be limited to those areas exhibiting flaw signals of interest.

5 EXAMPLE OF COMPOSITE ROCKET MOTOR CASE

Rocket motor cases are simply pressure vessels (Figure 18). They have two domes on the ends connected by a cylindrical section. Skirts cover up the domes, so the entire component looks like a long tube. The pressure vessel is designed to contain the pressure of the gas created when the fuel is ignited. Composite cases are usually filament wound on large mandrels. Some are very large. Others are quite small. The case shown here was made of graphite/epoxy.

The case was impacted by a blunt-nosed tup with a large mass attached just behind the nose. By varying the impact velocity, damaged areas of different sizes were created. Damage area was determined by an ultrasonic mapping that gave the extent of the damage.

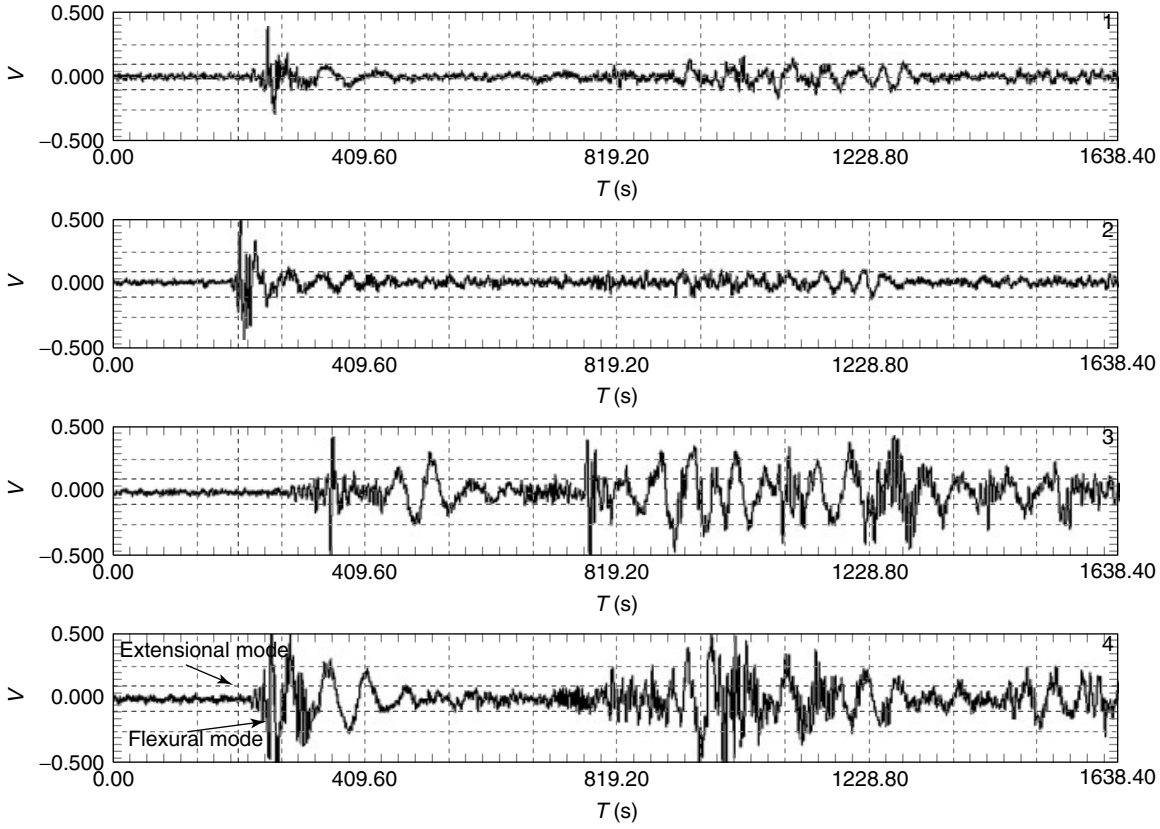

Figure 11. Waveform from actual crack growth in 3AA tube.

After a case is made, it is then moved into a hydrotest bay where it is filled with water and pressurized to ensure that it can withstand the pressure expected during actual firing of the motor, if it were loaded with propellant.

In this instance, the case was a test article. It was being studied to see the effect of impact of various energies, which is described here.

The case had wideband MAE sensors coupled to it and MAE waves were recorded as the case was pressurized. It is not the intent here to document all the details of the test. The intent here is to show some of the waves and describe their characteristics as they relate to the growth of delaminations in the case.

During pressurization, waves with both E and F waves were observed. The pressure was increased to a certain point, held for a specified period and then the case was depressurized. Every time events with large enough energy were observed, delamination growth was confirmed by ultrasonic methods. The delamination waves had very large flexural modes associated with them. The energy of the delamination wave was determined and a correlation with delamination growth area was observed. In fact, once this relationship was developed, the ultrasound confirmed it in every case. It became a dependable diagnostic tool.

The case was hydrotested to observe the effect of impact. A case of such large size could be impacted at several locations without interaction between impact sites. It was observed that increasing impactor energies created increasing damage in the composite. Delamination growth was detected by MAE and confirmed with ultrasound. An example from one of the impact sites is shown in Figure 19.

The delamination growth mapped by posttest ultrasound closely matched the source location map of MAE events. Following the ordinate upwards (increasing pressure), one can see the events begin

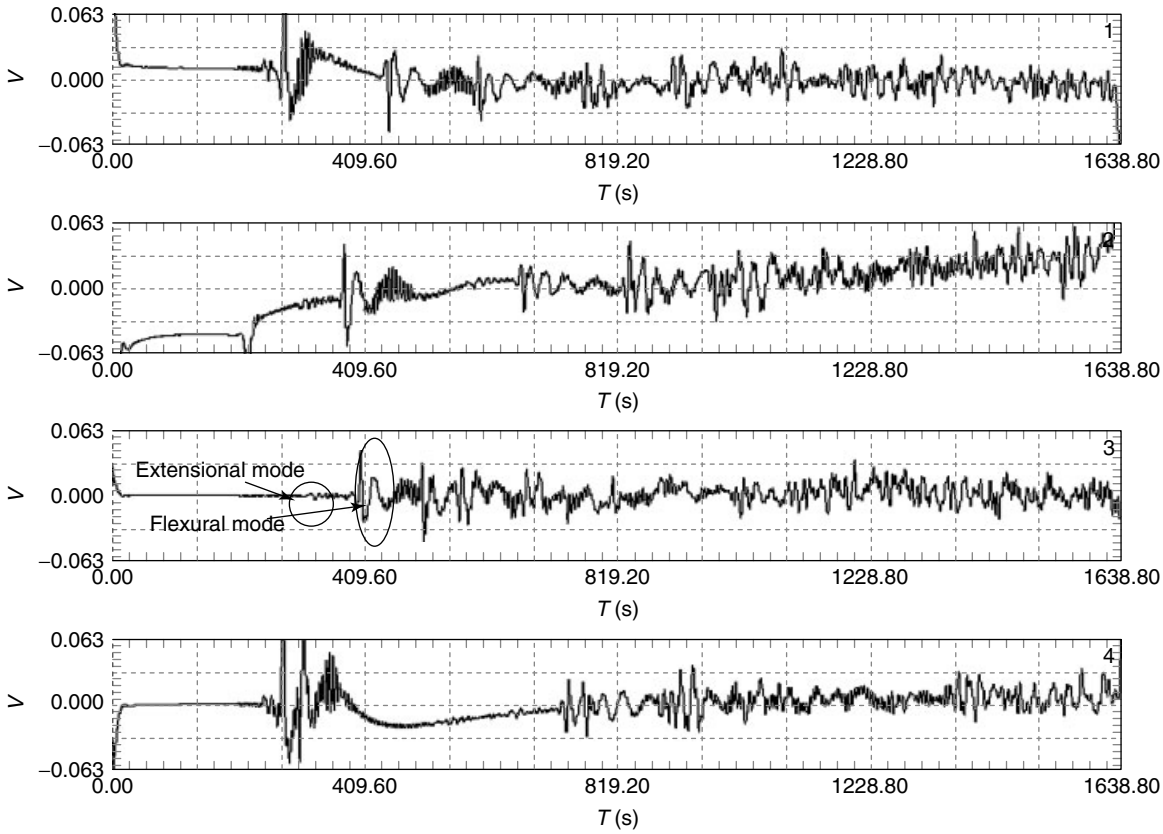

Figure 12. 0.04-in. (1-mm)-deep crack from OD. The modes have been identified on the waveform on channel 3. The waveforms show that the amplitude difference between the extensional mode and flexural mode is quite large. This is expected for near-surface cracks.

to spread outward on the composite laminate. Larger energies are also present.

Waveforms from the delamination growth are shown in Figures 20–24. Large flexural modes are observed with measurable delamination growth. This is to be expected because delamination growth is caused by interlaminar shear stresses between the delaminating layers. These double couples create bending waves, i.e., the flexural waves. These forces can be visualized as two typical pencil lead breaks displaced a small distance apart on opposite surfaces of the plate. Of course, the actual delamination source is somewhere in the plate's interior. This is why very large delaminations actually bulge out and are easily observed visually.

The waves shown in Figure 24 are those associated with damage growth at the impact site. The damage associated with the smaller energy events was too small to be observed ultrasonically. These are thought to be due to crack growth in the matrix that did not lead to observable growth in the delamination boundaries.

6 SUMMARY AND ADDITIONAL MATERIAL

AE as a nondestructive test technique has progressed to MAE, which operates on a good physical basis. It must be understood at the outset that even the language of MAE is much different than the old "parameter" or "counts" AE. This language is very important. The method is easier to explain both to technical and managerial personnel because it

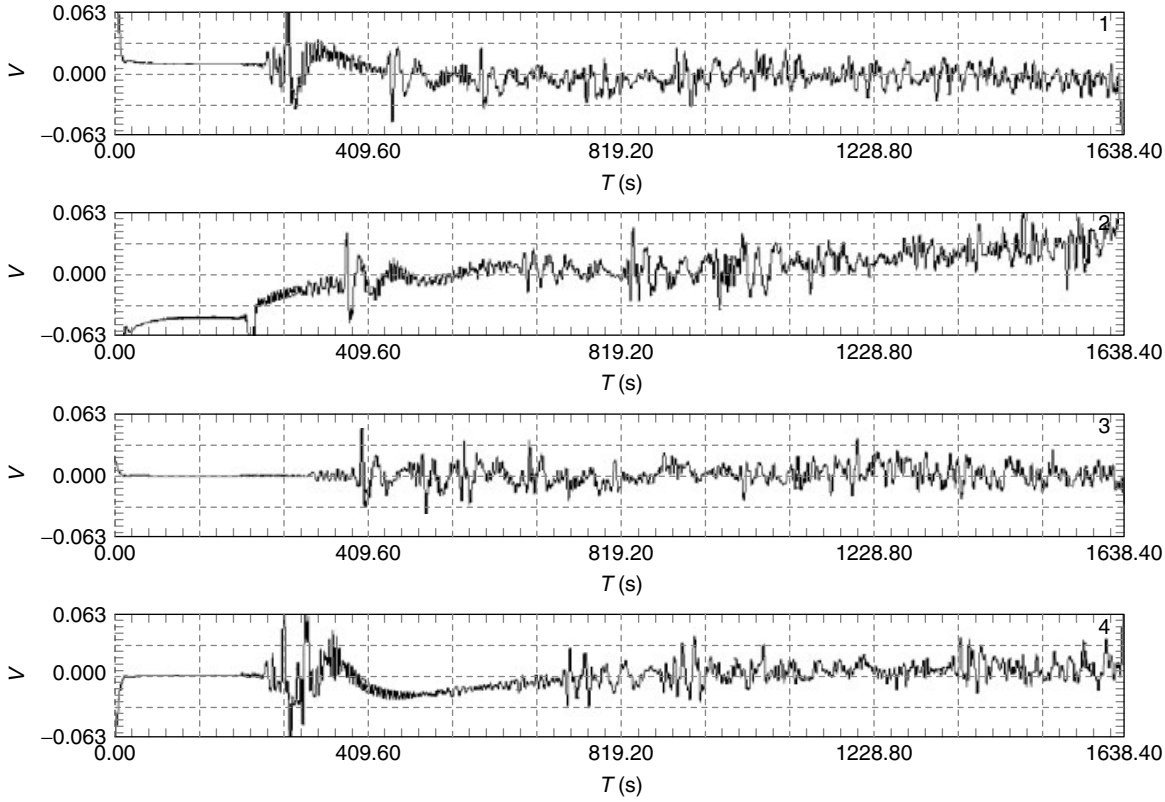

Figure 13. 0.079-in. (2-mm)-deep crack from OD. The extensional mode is now larger. This particular waveform seems to match the crack growth waveform the closest. The large offset in channels 1 and 2 is due to the numerical simulation.

contains familiar engineering terms that make a direct connection with related engineering fields.

Waves are either bulk or guided. Bulk waves are important for MAE tests of thick structures where the source to receiver distance is short and direct. Large engineering structures are built with platelike sections, so most of the practical MAE testing is concerned with plate wave propagation. The source motion and position directly influence the wave motion. An understanding of the material and its fracture behavior is very important.

As a crack propagates, from the ID to the OD of a pressure vessel, it generates both E and F waves. No E wave means the signal is not from a crack and is some form of noise.

MAE waves are broadband, that is, they contain a broad spectrum of frequencies (Fourier frequencies) depending on the source. A very sharp pulse consists of more and higher frequencies than a slower pulse. An understanding of the material and its fracture behavior is very important. Cracks usually generate sharp pulses. Some materials fail by ductile tearing. Stroking the plate's surface with a finger generates lower frequency waves.

The frequencies are created by the source. Those captured are influenced by the material. Higher frequency components present at the source may be rapidly attenuated by the material and not detected far away. This aspect is where experience plays a role in setting up a test. A few wave propagation checks with various sound sources are usually carried out prior to loading a structure. "Coverage" of an entire structure can usually be achieved with a reasonable number of sensors because plate waves are guided waves and travel great distances on the order of several meters depending on the material and geometry, and the presence of reflective surfaces or inhomogeneities that cause scattering.

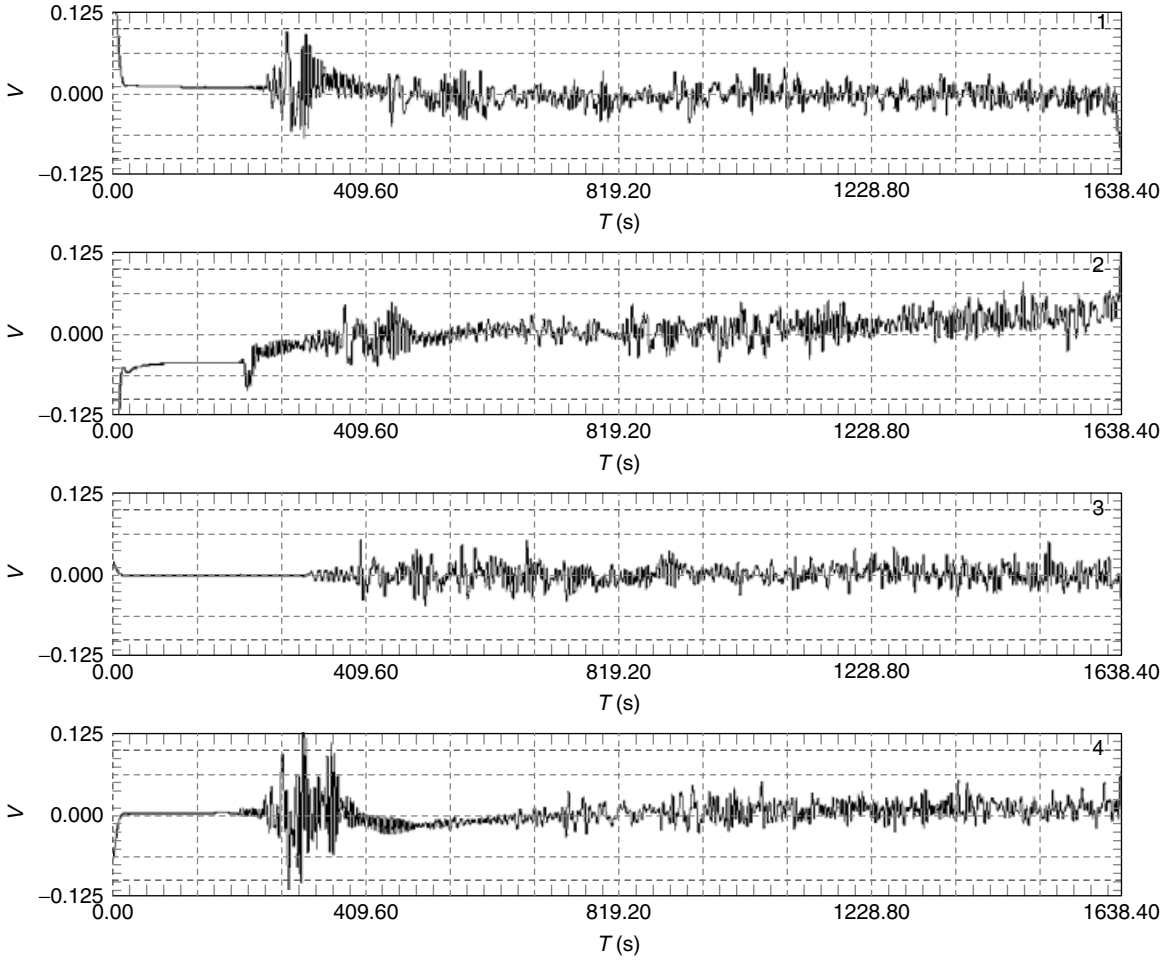

Figure 14. 0.12-in. (3-mm)-deep crack from OD. As the crack grows deeper, the extensional mode to flexural mode ratio gets larger.

Plate waves are dispersive meaning that they change shape as they propagate. This is because theory predicts that each Fourier component has a different velocity. A graph of phase velocity against frequency is called a *dispersion curve*. In practice, the two waves look almost like inversions of each other in that the low-frequency components of the E wave arrive before its high-frequency components, while the high-frequency components of the F wave arrive before its low-frequency components. It is important to use multiple channels in a test so that the dispersion behavior can be confirmed.

MAE is a predictive science that elucidates the direct connection between source and waves produced. Some think that the "digital" aspect is the whole difference between the old style AE and MAE. Nothing could be further from the truth. One method of AE is theoretically based, the other is not. Fewer specimens are needed with MAE and design changes can be handled theoretically, which means that a whole new series of tests can be eliminated.

Waveforms created by crack growth in a pressure vessel and delamination growth in composite rocket motor case were presented and briefly discussed. These examples demonstrate the power of the MAE technique to precisely identify and locate the source of emission. The defect growth was confirmed by ultrasound.

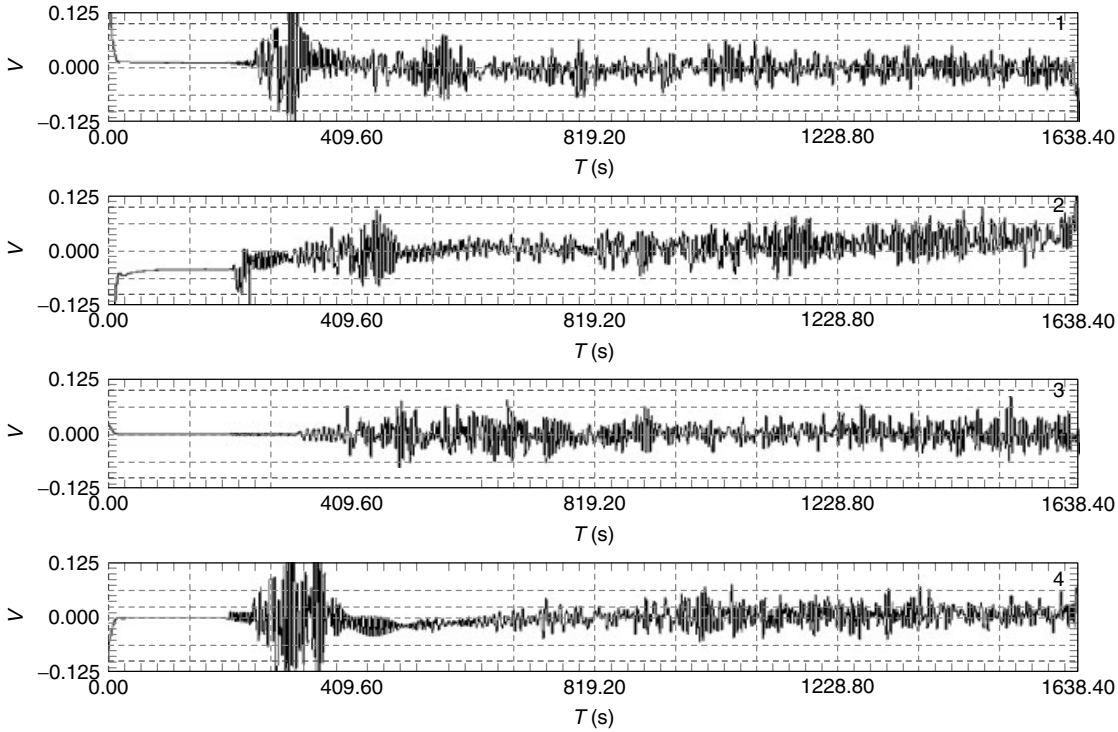

Figure 15. A 0.16-in. (4-mm)-deep crack from OD.

It is important to use multiple channels in a test so that the dispersion behavior can be confirmed.

Examples of noise were given. Noise is understood as sound waves that are undesirable in a given test. Frictional sounds produced by two parts rubbing together are very common. The waves created are usually narrowband and consist of low-frequency components. On the other hand, electromagnetic interference (EMI) is usually very high frequency but even this is not universal. Electromagnetic fields exhibit variations, too. Importantly, EMI does not exhibit modal propagation characteristics so EMI waves do not look like propagating plate waves. This is another reason why it is important to use more than one channel in any test.

It is important to capture the front end of the wave. This means allowing enough time in the pretrigger portion of the digital memory. Location analysis should be done with the front part of the E wave if possible. This is often the only undistorted part of the wave. The "front-end frequency" and its associated velocity give the most accurate location.

Like sonar, seismology, room acoustics, etc., further improvements in technology are still possible. The research areas are divided into three main areas: sources, sensors, and digital signal processing. The front-end frequency can be predicted only approximately for real sources. The exact time function of most real sources is not known especially in new testing situations. The impulse has worked well for fracture sources in steel and graphite/epoxy composites. The spatial part of the driving function depends on the stress state near the crack. This state is known inexactly. Theoretically, it is possible to determine crack length from AE waveforms as described in the text and given in the example on pressure vessel testing. Transducers have not had much fresh insight since the national institute for standards and technology (NIST) work in the early 1980s. Signal processing in MAE work is still in its infancy.

The opportunity is taken here to point out to the skeptics who have had negative experiences with AE in the past, and there are many, that the AE method developed a checkered past as attempts to use it for

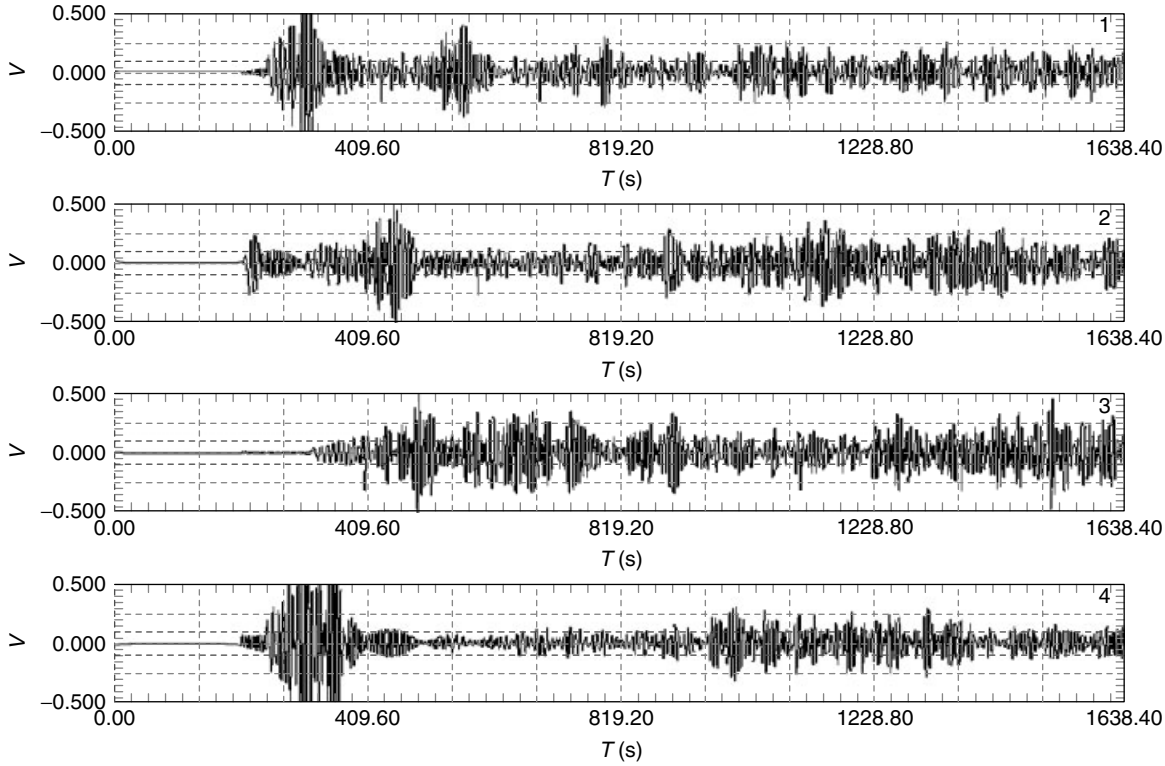

Figure 16. A 0.29-in. (7.5-mm)-deep crack from OD. This waveform is purely extensional, since it is at the midplane of the tube wall.

SHM without fundamental understanding resulted in disappointment, particularly in pressure vessels and aircraft. Practical testing is now on a firm theoretical footing. (Not all have learned from Goranson's experience—even as this paper was being written, a new standard was being balloted with the same old "one size fits all" approach—a resonant transducer and 100–300 kHz bandpass—which is found in nearly every Code and Standard extant regardless of the test article material and geometry. Professor Pao once pointed out with respect to an ASME standard balloted long ago "Were there not serious reservations expressed by concerned engineers, our honored society would have been burdened with a code that had no theoretical foundation" [2].)

To aid the buyer of SHM methods, no AE test should be performed unless the types of waves that will be measured are predicted and justified on fundamental theoretical grounds in advance. How would a good recording of music be made without knowing what type music was to be recorded and in what setting? The test equipment should be digital recorders set so the waves can be captured with clean front ends. Transducers should be of the appropriate size (diameter) and frequency range for the waves expected. (Are all sonar receivers the same?)

All analysis should be done, so the physics of source and wave is clear. The results should be as definitive and quantitative as possible. For source location, experimentally measuring wave velocity with an artificial source like a pencil lead break is acceptable in simple cases like isotropic linear source location on a tube trailer tube, but confirmation of the velocity with frequency on a theoretically predicted dispersion curve will lead to better results with a real crack source because the waves produced are different. This result means that the material properties used were correct and can be used in calculating the wave shapes, which, in turn, enables the tester to show the direct and physical meaning of the results

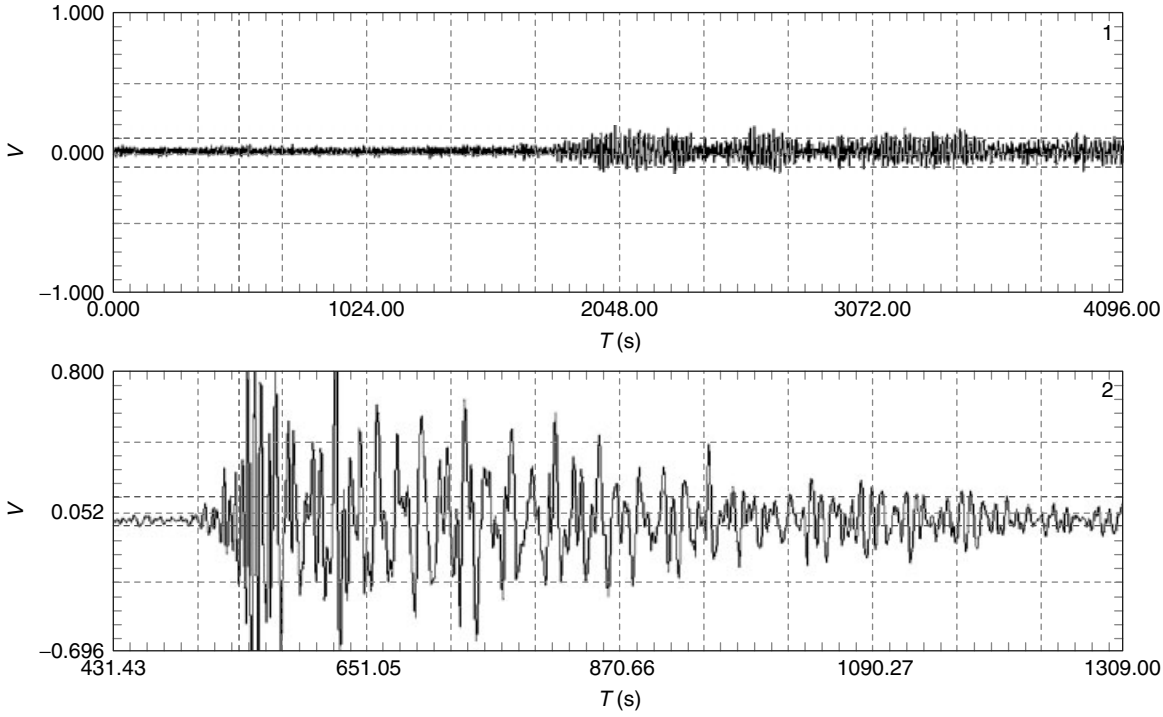

Figure 17. Waveform from corrosion on the outside of the tube. Channel 2 has been expanded to show the details in the waveform. Note the higher-to-lower frequency content as a function of increasing time. This is a characteristic of a flexural mode. Also, no extensional mode component is seen in channel 1. The extensional mode would have separated from the flexural mode component over the propagation distance, if it had been present, and been observed easily.

Chapter 6
Thermomechanical Models

Minh P. Luong
LMS CNRS UMR7649, Ecole Polytechnique, Palaiseau, France

1 INTRODUCTION

Thermomechanical coupling effects in engineering materials and structural components have traditionally been neglected in thermal stress analyses. The temperature field and the deformation induced by thermal dilation and mechanical loads were solved separately; however, this effect could become significant when mass inertia is not negligible, due to the flux of heat generated through the boundary of the body, or if the material is loaded beyond its stable reversible limit. The relevance of coupled thermomechanical analysis has been demonstrated for a variety of problems, such as fault analysis of nuclear reactors, damping of stress wave propagation, deformation localization after bifurcation, and strength softening of material due to the heat generated by repeated plastic deformations.

Internal energy dissipation was recognized by a number of well-known scientists [1–3]. By carrying out experiments on the cyclic twisting of cylindrical bars, Dillon [4] identified the work done to the system by plastic deformation as the major contribution to the heat effect, and proposed an internal dissipation rate **D** related to plastic strain rate. The thermal effect due to thermomechanical coupling at the tip of a moving crack has been investigated [5] within the framework of thermodynamics, taking into account stress and strain singularities. The heat generated owing to plastic deformation causes a large local temperature increase, which is expected to affect the selection of failure modes during dynamic fracture and thus influence the fracture toughness of the material. Well-developed empirical theories of plastic deformation in metals allowed engineers to successfully predict the behavior of a variety of structures and machine elements loaded beyond the elastic limit for purposes of design.

2 BACKGROUND OF THERMOMECHANICAL COUPLING IN SOLIDS

Infrared thermography is a convenient technique for producing heat images from the invisible radiant energy emitted from stationary or moving objects at a distance and without surface contact or in any way influencing the actual surface temperature of the objects viewed. The temperature rise ahead of a fatigue crack has been measured using a thermographic camera to demonstrate the local heating at the tip. Attempts have been made to measure and characterize the heat generated during the cyclic straining of composite materials. The scanning infrared camera has been used to visualize the surface-temperature field on steel [6], wood [7], engineering materials [8], and fiberglass–epoxy composite samples during fatigue tests. Recently, this infrared thermographic technique has been applied in sports engineering [9]. A consistent theoretical framework is necessary to correctly interpret the thermal images.

The development of the thermoelastic–viscoplasticity governing equations requires three types of basic assumptions [10–13].

1. The basic thermomechanical quantities completely describing the thermodynamic processes with time: the motion x, the second Piola–Kirchhoff stress tensor $\mathbf{S}$, the body force per unit mass b, the Helmholtz free energy ψ, the specific entropy s, the heat supply r, the mass density ρ in the reference configuration, the absolute temperature T, the heat flux vector per unit area q, the elastic strain tensor $\mathbf{E}^{\mathrm{e}}$, the inelastic strain tensor $\mathbf{E}^{\mathrm{I}}$, and a set of internal state variables $\mathrm{IV} = \alpha^{(\mathrm{I})}$ characterizing the material irreversible behavior. All these quantities are functions of the reference position vector $\mathbf{X}$ and the time t. It is noteworthy that the inelastic strain rate can be omitted from the aforementioned list, to be recovered as an internal state variable. However, the internal state variables (IVs) provide useful information on the microscopic state and on the microstructural defects, while the inelastic strain provides information only on the current geometry.
2. The fundamental equations of mechanics defining balance laws of linear momentum, angular momentum, mass, and energy, as well as the second law of thermodynamics expressed in the above variables.
3. The constitutive relations that describe the material response and assure the compatibility of the constitutive equations with the fundamental equations of mechanics.

When restricting the analysis to perfectly viscoelastic–plastic material and small perturbation assumption, this leads to the following coupled thermomechanical equation:

$$\rho C_v \theta_{,t} = \rho r + \mathrm{div}(k\ \mathrm{grad}\theta) - (\beta : D : \mathbf{E}^{\mathrm{e}}_{,t})\theta + \mathbf{S} : \mathbf{E}^{\mathrm{I}}_{,t} \tag{1}$$

where $\rho\,(\mathrm{kg}^{-1}\,\mathrm{m}^{-3})$ denotes the mass density, $C_v\,(\mathrm{J\,kg}^{-1}\,\mathrm{K}^{-1})$ the specific heat at constant deformation, $\theta_{,t}\,(\mathrm{K\,s}^{-1})$ the time derivative of the absolute temperature, r the heat sources, div the divergence operator, $k\,(\mathrm{W\,m}^{-1}\,\mathrm{K}^{-1})$ the thermal conductivity, grad the gradient operator, $\beta\,(\mathrm{K}^{-1})$ the coefficient of the thermal expansion matrix, : the scalar product operator, D the fourth-order elastic stiffness tensor, $\mathbf{E}^{\mathrm{e}}_{,t}$ the time derivative of the elastic strain tensor, $\mathbf{S}$ the second Piola–Kirchhoff stress tensor, and finally $\mathbf{E}^{\mathrm{I}}$ the inelastic strain tensor. The volumetric heat capacity $C = \rho C_v$ of the material is the energy required to raise the temperature of a unit volume by $1\ ^{\circ}\mathrm{C}$ (or 1 K).

Since the physical process underlying the problem is highly diversified, the modeling is thus approached from a purely phenomenological point of view. Such an approach can be useful in the interpretation of the energetics of the thermoelastic–plastic behavior. The classical theory of rate-independent isotropic or kinematic hardening plasticity is considered to be an adequate basis for such modeling as it offers the simplest constitutive model for elastic behavior of the material while still allowing consistent inclusion of two-way thermomechanical coupling effects.

When using internal state variables that describe structural changes in materials, the right-hand side member will be completed by other terms representing the cross-coupling effects [10]. These effects influence the evolution of temperature through the second-order terms when compared with the internal dissipation term. Their contribution to internal heating during the adiabatic process is small and so they are sometimes neglected.

This coupled thermomechanical equation suggests the potential applications of the infrared scanning technique in diverse engineering domains: detection of fluid leakage [14, 15], nondestructive testing using thermal conduction phenomena, elastic stress measurements [16], and localization of dissipative phenomena [17–19]. Thus the detected temperature change, resulting from four quite distinctive phenomena, must be correctly discriminated by particular test conditions and/or specific data reduction. This analysis is the principal difficulty when interpreting the thermal images obtained from experiments under the usual conditions.

3 THERMAL PHENOMENA

The first term on the right-hand side of equation (1) is related to the existence of sources or heat sinks in the scanning field [20]. The surface heat patterns displayed on the scanned specimen may result from either external heating, referred to in the literature as *passive heating* where local differences in thermal conductivity cause variations on isothermal patterns, or internally generated heat referred to as *active heating* [21].

3.1 Application to pharmacodynamics

This term has been recently exploited in a noninvasive technique to detect variations in skin temperature and thus to analyze the pharmacodynamic properties of topical corticosteroids using vasoconstriction as a marker [22]. Several subjective and objective methods are available to categorize the potency of topical corticosteroids on healthy skin. They are based on analysis of the vasoconstriction caused by corticosteroids. The parameters that have been studied involved changes in skin color. In this work, cutaneous thermal images were recorded in real time. A single application of short-duration test was performed without massage or occlusion. A predetermined 1.2-cm-radius template surface was used for all tests in order to standardize the results with those of the standard skin-blanching test that was performed after occlusion according to McKenzie's protocol (Figure 1).

Several skin disorders have been studied by infrared thermography, including allergies, skin infections, burns, tumors, and microangiopathy [23]. However, when used according to the standard method, this technique has been considered insufficiently sensitive to detect slight changes in superficial blood flow induced by topical corticosteroids relative to heat emitted from underlying vascularization [24]. This work proposed differential imaging that makes the

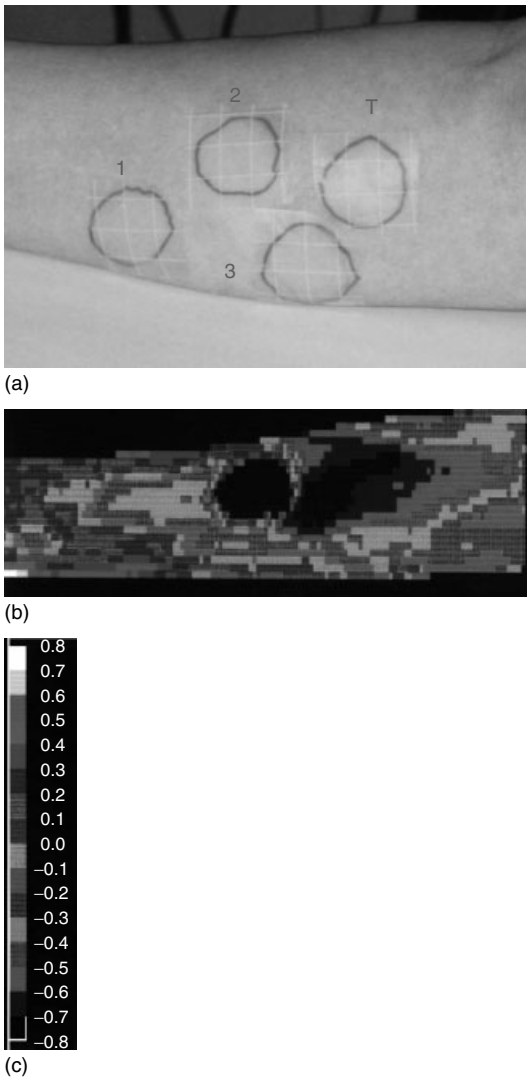

Figure 1. (a) Application of corticosteroids on a forearm to evaluate their bioavailability; (b) change in temperature of a forearm obtained by subtraction between two heat images before and 5 min after application of betamethasone dipropionate cream; and (c) temperature change scale ($\Delta\theta$ °C).

technique more sensitive. The possibility of analyzing thermograms recorded by subtraction of thermal images (differential thermography) allows for the distinction of changes in temperature by subtracting the areas, which do not change, similar to the radiological concept of quantitative or subtractive imaging. Moreover, when subtraction is performed as a function of time, the rate of variations in temperature (from $t = 0$ to t_x) over time, can be assessed, and the rate of change (acceleration between time points: t_x to t_{x+1} to t_{x+2}), can be calculated by subtracting the images from various time points. Differential infrared thermography, therefore, permits continuous quantitative evaluation of cooling in real time, without contact.

Four topical corticosteroids (reference: French classification: Class I (ultrapotent anti-inflammatory activity), Class II (potent anti-inflammatory activity), Class III (moderate anti-inflammatory activity), and Class IV (mild anti-inflammatory activity)) were tested simultaneously at different sites on the forearm to obtain as constant a background microcirculation as possible, as the background circulation depends on ambient skin temperature, resting state, and limb positioning [25]. The initial results reveal temperature changes in the first 3 h for each topical corticosteroid after a single application without occlusion (Figure 1b and c). In contrast, standard testing of vasoconstriction evaluates skin blanching after 6 h [26], as this is the minimum period accepted to date to obtain clear discrimination between topical corticosteroids. An interval of 16 h is often used because the patches can be applied in the evening for evaluation the following day.

The reference methods for evaluation of vasoconstrictive activity are based on the presence or absence of skin blanching, evaluated by attributing an arbitrary score from 0 to 3 or 4 by a trained reader, and it is, therefore, operator dependent [27]. The main value of differential infrared thermography compared to these methods is that of a *measurable objective parameter*.

In conclusion, differential infrared thermography has two notable advantages: (i) it provides a measurable objective parameter and (ii) it allows evaluation of the kinetics of topical corticosteroids shortly after application, well before the appearance of the skin-blanching effect.

3.2 Leakage detection on structural components

Infrared thermography is particularly useful when applied to the detection of thermal phenomena related to gas flow through holes in metallic walls. In these cases, calorific diffusion of the thermal gradient caused by the expansion or the compression of a gas during its passage through the hole is readily detected with an infrared camera. A short-duration test has been performed with success on large components of missile-jet tubes (Figure 2a–c). The results obtained confirmed that the infrared thermography is an excellent means of ready control, without contact, and can be easily set up for the detection of well-localized leakages.

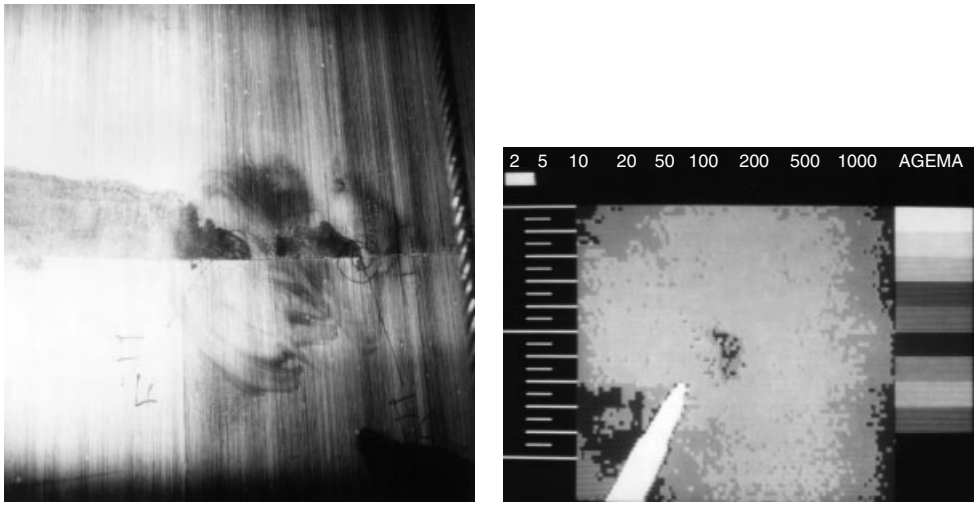
4 CONDUCTION PHENOMENA

The second term on the right-hand side of the thermomechanical equation governs the heat transfer by thermal conduction in which the heat passes through the material leading to a uniform specimen temperature. The second-order tensorial nature of the thermal conductivity, k, may sometimes be used for the detection of anisotropy in heavily loaded materials.

Variations in thermal conductivity may arise because of local inhomogeneities or flaws in the material [28]. Where an unsteady state exists, the thermal behavior is governed not only by its thermal conductivity but also by its heat capacity. The ratio of these two properties is termed the *thermal diffusivity*, $\alpha = k/C\ (\mathrm{m^2\,s^{-1}})$, which becomes the governing parameter in such a state. A high value of the thermal diffusivity implies a capability for rapid and considerable changes in temperature (Figure 3). It is important to bear in mind that two materials may have very dissimilar thermal conductivities but, at the same time, they may have very similar diffusivities. A pulsed heat flux has been used to characterize a delamination within a composite by the discontinuity caused in the temperature time history [29].

5 THERMOELASTIC COUPLING IN SOLIDS

The third term illustrates the thermoelastic coupling effect. The thermoelastic behavior of materials is



(a) (b)

(c)

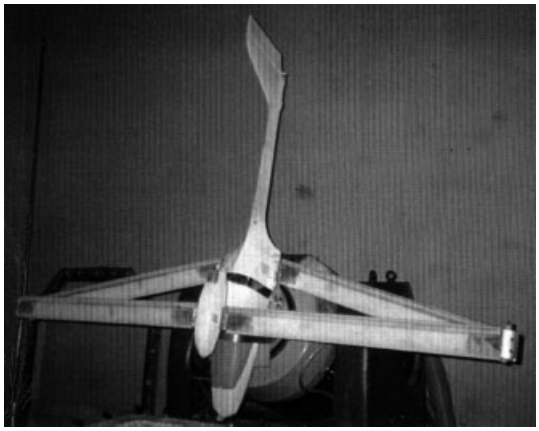
Figure 2. (a) Localization of gas leakage on a large component of missiles-jet tube; (b) leakage location #4 detected with a difference pressure of 2.5 kPa between the two faces (temperature full scale 2 °C); and (c) leakage location #5 detected with a difference pressure of 5 kPa between the two faces (temperature full scale 2 °C).

Figure 3. Thermal diffusivity characteristics of the front face of the royal palace in Fès Marocco.

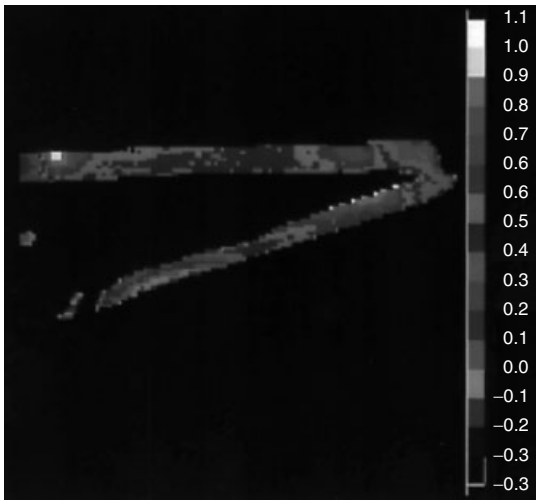
revealed by everyday experience in the form of linear or bulk expansions and contractions under the effect of temperature changes and in the applications of the elastic properties of metals and even polymers in the production of springs, pins, clips, and the like. From a phenomenological point of view, thermoelasticity is thereby linked to a notion of reversibility. The material responds to mechanical or thermal excitation in an instantaneous manner and, when the excitation is removed, returns to its initial state without showing any memory of the recent changes. Within the linear elastic range and when subjected to tensile or compressive stresses, a material experiences a reversible conversion between mechanical and thermal energy causing temperature change. Provided adiabatic conditions are maintained, the relationship between the change in the sum of principal stresses and the corresponding change in temperature is linear and independent of loading frequency [16]. This thermoelastic coupling term may be significant in cases of isentropic loading where no energy is added and no energy losses occur. A stress analysis technique is known as *stress pattern analysis by thermal emissions* (SPATE) that measures the temperature due to the thermoelastic heating and cooling of a body under cyclic loading [30].

Experience shows thermoelasticity to be a common type of behavior. It is characterized by *reversibility* of the response of the material to the excitation it undergoes. Thermoelastic behavior is modeled by assuming that current values of the temperature and strain tensor in the material element are sufficient to define its physical state. The free energy arises as the *thermodynamic potential*, a function of the current values of the temperature and strain tensor. The stress tensor is obtained by differentiating with respect to the strain tensor. In an isotropic material undergoing small perturbations, linear thermoelasticity is characterized by *two* elastic constants and *one* thermal expansion coefficient. Elastic and thermal strains can be uncoupled as follows: total strain = elastic strain + thermal strain. In practice, the thermoelastic equilibrium problem is solved by using the superposition principle. The problem consists of adding together the solutions (i) of the isothermal problem with excitations and (ii) of the purely thermal problem [31].

A vibratory test was performed on a reduced scale model of a double-winged aircraft (Figure 4a)



(a)



(b)

Figure 4. (a) Reduced scale model of a double-winged aircraft and (b) elastic stress concentration recorded on the test specimen (temperature scale is given in degrees Celsius).

in order to evaluate the weakness zones around connections between the two wings themselves and the two wings with the fuselage (Figure 4b). The double-wing design is assumed to lead to greater maneuverability. The big disadvantage of the biplane layout was that the two wings interfered with each other aerodynamically, each reducing the lift produced by the other. This interference meant that for a given wing area the biplane produced more drag and less lift than a monoplane. This mechanical statement is supported by the hot locations on the wings caused by stress concentrations.

6 OCCURRENCE AND DETECTION OF DAMAGE

The last term defines the energy dissipation generated by plasticity and/or viscosity [32]. Internal energy dissipation has been recognized by many scientists [33]. The work done to the system by plastic deformation is identified as the major contribution to the heat effect. In thermoelastic–plasticity, there exists a general acceptance that not all mechanical work produced by the plastic deformation can be converted to the thermal energy in the solid. A significant portion of the work is believed to have been spent in the change of material microscopic structure. The work done in plastic deformation per unit volume can be evaluated by integrating the material stress–strain curve. This internal dissipation term constitutes an important part of the nonlinear coupled thermomechanical analysis.

The quantification of this intrinsic dissipation for engineering materials is an extremely difficult task without infrared thermography [34].

The infrared thermographic technique is mainly concerned with temperature differences (or thermal gradients) that exist in the material rather than with the absolute values of temperature. It conveniently detects the dissipation regime of the material under loading.

Ignoring the significance of the coupled thermomechanical equation, an unsuccessful attempt [35] has been made to monitor thermoemissions during fatigue crack propagation tests. The technique used was unable to quantitatively detect the changes in thermoemission caused by small and slow crack-tip advances.

Experimental evidence shows that only part of the input plastic deformation power is expended to change the material's microstructure; the other part is dissipated in the form of heat (Table 1).

In materials testing in an industrial environment, thermal noise often generated by gripping systems may sometimes obscure the intrinsic dissipation of the tested specimen. This difficulty can be overcome when using thermal image subtraction or *differential thermography* as shown, for instance, in the case of an XC55 steel specimen subjected to rotating–bending fatigue testing. This procedure of thermal image processing provides the fatigue limit of steel materials within a few hours instead of the several months required when using the standard staircase method [40].

Table 1. Thermomechanical coupling models reported in literature

Postulates and internal variable IV	Internal energy dissipation rate
Dillon [4] IV = plastic strain rate	Plastic power

Raniecki and Sawczuk [38] IV = work hardening	A function of IV
Mroz and Raniecki [39] IV = work hardening	A function of IV
Lehmann [3] IV = a part of plastic power	A part of plastic power

6.1 Mechanical evaluation of wood construction materials

Damage and failure behavior of wood in tensile, compressive, or shear loading is an important consideration in connection with designs or regulations of wooden structures subjected to high allowable working stresses.

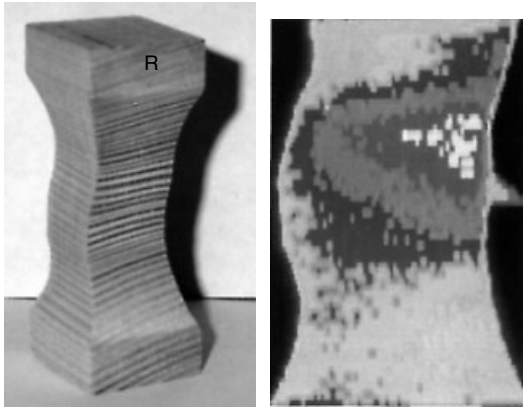

Figure 5. (a) Pine wood specimen sampled in the radial direction and (b) localization of intrinsic dissipation in wood specimen sampled in the radial direction (each color hue corresponds to 0.2 °C) evidencing the failure mechanism.

Several series of monotonic unconfined compression tests have been conducted on square specimens of pinewood, prepared along its anisotropy directions (longitudinal L, radial R, and transverse T). The wood specimens were especially designed (cross section $S_0 = 256\,\mathrm{mm}^2$, $h_0 = 20\,\mathrm{mm}$) with enlarged ends to prevent sliding, bending, or premature buckling, caused by heterogeneity, bad alignment of compression loading, or other significant end effects (Figure 5a). The thermography testing allowed observations of the physical process of failure (Figure 5b).

In several architectural applications, there is a need for development of high-ductility connections for braced frame systems and energy dissipating connections for antiseismic applications. Metal-plate-connected wood trusses are widely used in residential constructions (Figure 6a) and are increasingly used in agricultural and other commercial constructions. A reason for their widespread use and continued growth of applications for wood trusses concerns the efficiency and effectiveness of punched-metal-plate connectors. Extensive engineering design services support an almost unlimited variety of components that can be assembled with plates and dimension lumber (Figure 6b).

Failure modes including the teeth pulling out of the wood, failure of the wood member within the plated region, yielding of the plate loading, and buckling of the plate in gaps between wood members are depicted by thermal images (Figure 6c) before failure.

6.2 Application to plain concrete specimens

Concrete materials present a low thermomechanical conversion under monotonic loading. Plastic

deformation (whereby microcracking and slips occur creating permanent changes globally or locally) is one of the most efficient heat production mechanisms. Most of the energy required to cause such plastic deformations is dissipated as heat. Such heat generation is more easily observed when it is produced in a fixed location by reversed applied loads. These considerations define the use of vibrothermography as a nondestructive and noncontact technique for observing the damage process of concrete materials [41].

In the laboratory, the high-frequency servo-hydraulic test machine provides a means of vibration and dynamic testing of engineering materials. A vibratory loading at 100 Hz, applied to the specimen subjected to a given static compression, exhibits, in a nondestructive manner, the irreversible plastic strain concentrations around gaps or cracks. The contribution of the plasticity term is revealed by the rapid evolution of heat dissipation once the stable reversible stress domain is exceeded, demonstrating the occurrence of an unstable crack propagation or coalescence of flaws existing in the concrete specimen. Experimental results have already shown the following:

1. Under a vibratory excitation, between 25 and 50% of the nominal uniaxial compression $\sigma_N = F/S_0$, the heat dissipation, detected for 2000 load cycles, is small, even at the hottest location.
2. When $0.50 \leq \sigma/\sigma_N \leq 0.75$, stress concentrations around cracks or defects are readily detected at the 1000th load cycle.
3. For $0.63 \leq \sigma/\sigma_N \leq 0.88$, cracking occurs increasingly in the reduced section part of the specimen.

Infrared thermography readily depicts intrinsic dissipation localization, announcing quite different mechanisms of damage preceding concrete failure (Figure 7a). The different phases of heat dissipation, operating during an unstable failure, are readily described by heat patterns. When defects or weakness zones are present on the specimen, infrared observations evidence the progressive mechanism of defect coalescence (Figure 7b). The rate of heat generation at the hottest location is used to detect the threshold of the failure process if compared with the traditional stress–strain curve. These results have been readily extended to rock materials [42].

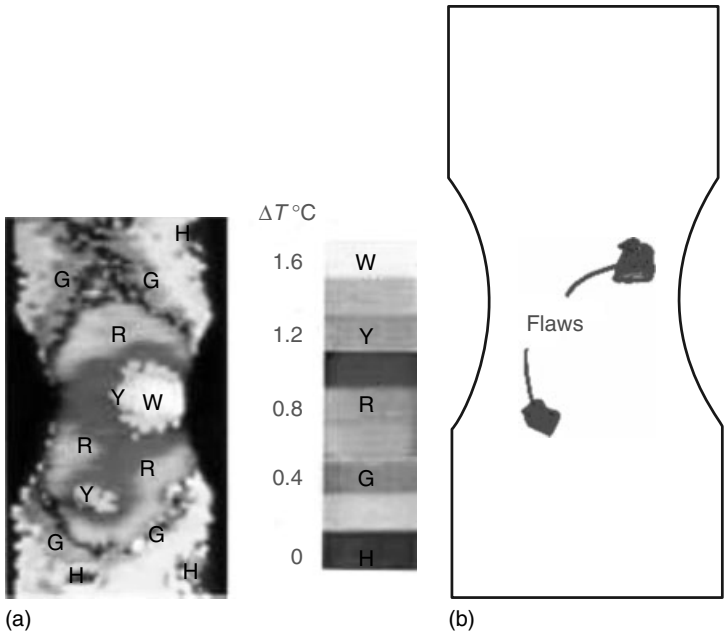

Figure 7. Plain concrete specimen subject to a nominal uniaxial vibratory compression σ_N between 63 and 88% of peak resistance. (a) Thermal image of the specimen and (b) examination of the specimen after test.

6.3 Rapid evaluation of the endurance limit of plain concrete

In accordance with the coupled thermomechanical equation, the analysis of thermal images consists of isolating the intrinsic dissipation from thermal noises by simply subtracting the thermal image at a reference time from the thermal image at 1000 load cycles. Computer-assisted thermography software allows for data reduction of the thermal images using the function subtraction of images. The resulting subtracted image shows the temperature change between two compared images, obtained under nearly identical test conditions. This image processing provides quantitative values of intrinsic dissipation.

This procedure is applied for each load step. The manifestation of the fatigue damage mechanism is revealed by a break in the intrinsic dissipation regime. The starting load level must be chosen below

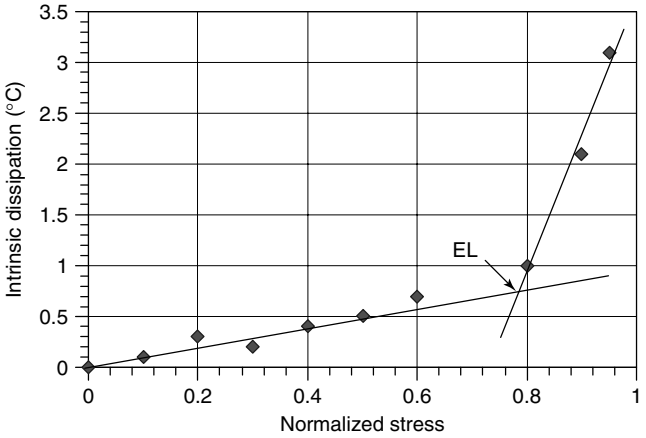

Figure 8. The endurance limit of the concrete specimen under compressive loading is graphically determined by an abrupt change of the dissipative regime.

Figure 10. (a) Thermal image of a column base of the reinforced concrete structure before seismic-type loading; (b) thermal image of a column base of the reinforced concrete structure after N load cycles; (c) intrinsic dissipation located at the column base obtained by thermal images subtraction; and (d) intrinsic dissipation due to $N = 270$ load cycles; (e) intrinsic dissipation due to $N = 360$ load cycles.

the fatigue limit. It depends significantly upon the concrete characteristics. For example, assume that a test is begun at a stress level of about 20% of failure nominal stress, then 30%, 40%, etc. This testing is continued until the temperature rise attains several degrees Celsius. For each load step, an averaging treatment (among 4, 8, 16, or 32 thermograms) provides more stable thermal images.

Experimental results are summarized in Figure 8, which illustrates how the endurance limit (EL) is determined using a graphical procedure. The threshold of critical thermal dissipation is roughly the same for different chosen number of load cycles. The threshold corresponds approximately to the value deduced from standard procedures. These experiments have shown that the infrared thermographic technique can provide the EL of concrete within a few hours instead of several months needed when using the traditional standard staircase method. These results are consistent with those obtained on concrete prisms subjected to compressive fatigue testing [43].

6.4 Infrared thermographic scanning of a full-scale earthquake resistant concrete structure

The damaged areas are located and highlighted by heat patterns. These results support and validate the assumptions to be taken into consideration in numerical procedures for stability and integrity assessment of concrete structures. The phenomenological behavior in consideration is therefore the standard of reference, allowing the use of the methods and results of continuum mechanics for analyzing and modeling their engineering performance. Information about the location and significance of structural defects as a basis for maintenance decisions, including the extreme case of removal from service, can be obtained through inspection and nondestructive evaluation.

The proposed infrared thermographic procedure involves careful examination of those areas where defects are most likely to occur. Analyzing the structure and the service histories of similar structures in similar environments can identify the critical areas. The application of infrared scanning to inspection of concrete structure relies on the fact that the energy is dissipated during the process of accumulative damage when internal cracks or flaws develop. The most likely severe earthquake can be withstood if the members are sufficiently ductile to absorb and dissipate seismic energy by inelastic deformations with little decrease in strength.

Under seismic-like loading, simulated by a rotating mass exciter placed on the top of the building, plastic hinges form progressively at the column bases where heat dissipation mainly occurs in the overstressed steel reinforcements. The heat, flowing out through the crushed concrete, can be observed using infrared thermography as a function of the number of load cycles (Figure 9).

Computer assisted thermography software allows the data reduction of thermal images using the function subtraction of images and shows the progressive evolution of heat dissipation at a column base before crack lines become visible. The resulting image is a subtracted image showing the temperature change between the reference time and after N

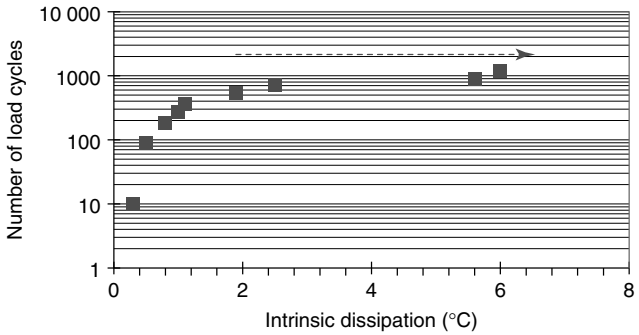

Figure 11. Endurance lifetime evaluation of a column base of the steel reinforced concrete structure subjected to seismic-type loading.

load cycles (Figure 10a–c). This image processing provides quantitative values of intrinsic dissipation corresponding to different numbers N of load cycles.

The results obtained after 270 load cycles (Figure 10d) and after 360 load cycles (Figure 10e) lead to a ($\log N$ – intrinsic dissipation) plot (Figure 11) that allows evaluation of fatigue lifetime of a column base of the experimental reinforced concrete structure subjected to seismic-type loading.

The above data processing (heat image subtraction) applied for the overall structure under solicitations readily provides useful information about localization of dissipation or damageable zones.

6.5 Infrared observations of energy dissipation on concrete structures subject to shaking table loading

Load-bearing walls in reinforced concrete structures are commonly used worldwide. The research described hereafter was done within the framework of the European Consortium of Earthquake Shaking Tables and the Innovative Seismic Design New and Existing Structures, Topic 5 Shear wall structures research project, which is supported by the European Commission. Two large-scale 360 MN specimens (SPECIMEN A and SPECIMEN B) representing one-third scale five-story buildings were tested under dynamic seismic-like loading on the large shaking table Azalée at the Commissariat à l'Energie Atomique Saclay (French Atomic Energy Agency, Saclay, France). The loading input signal is an artificial accelerogram (far-field earthquake) characterized by its peak ground acceleration (PGA) values.

The mock-up tests performed aimed at demonstrating the major influence of boundary conditions at the base of the model, and the feasibility of optimizing low ratio and adequate distribution of reinforcements to obtain multicracking zones (multifuse concept) in opposition with the traditional pseudo-plastic hinge localized at the base of a steel reinforced wall (monofuse concept).

6.5.1 SPECIMEN A highlighting the effects of reinforcement ratios

SPECIMEN A, composed of two lightly reinforced walls anchored to the shaking table, is designed as recommended in Eurocode 8 allowing a plastic hinge at the base. Special attention has been paid to the influence of different reinforcement ratios and boundary conditions. During the tests performed, SPECIMEN A mock-up suffered high damage levels. Its behavior was mostly conditioned by its flexural bending. Examination after tests evidenced failure of steel reinforcements (Figure 12).

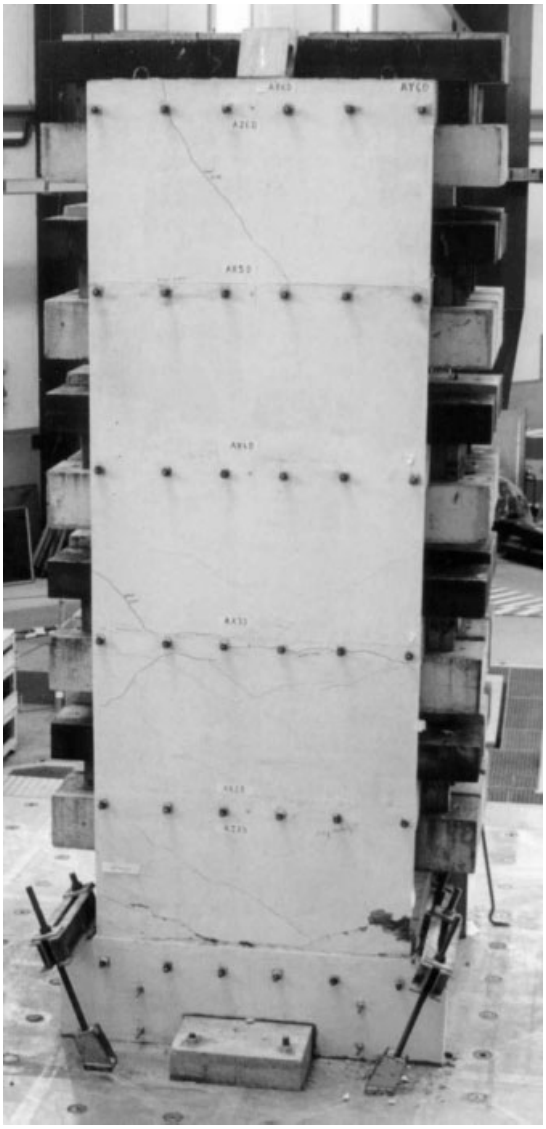

Figure 12. Experimental reduced scale structure in steel reinforced concrete SPECIMEN A tested on the shaking table of CEA Saclay.

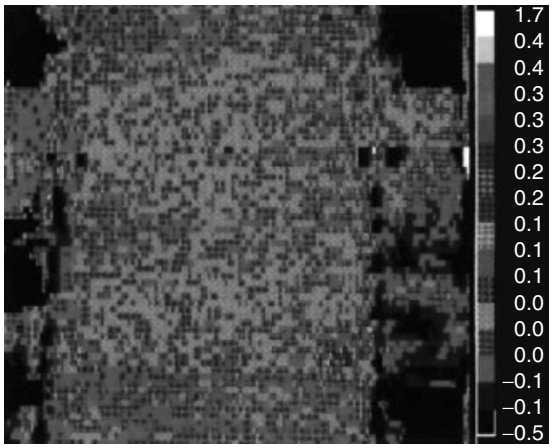
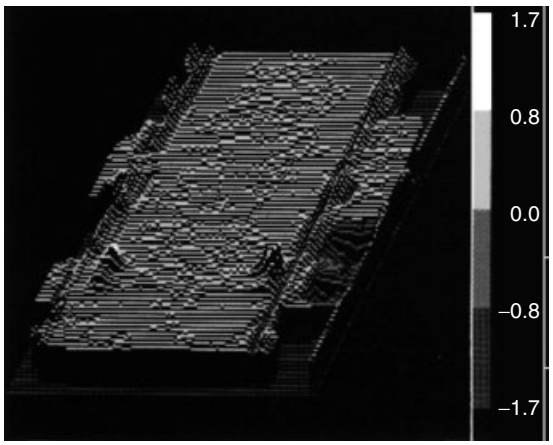


(a)



(b)

Figure 13. (a) Intrinsic dissipation caused by plasticity of the steel reinforcements after testing at peak ground acceleration $PGA = 8.0\,\mathrm{m\,s^{-2}}$ (temperature changes ΔT are given in degrees Celsius) and (b) visualization of dissipation mechanism due to plasticity of steel reinforcements.

In this case, the dissipation mechanism caused by plasticity of steel reinforcements can be considered as an internal parameter so that equation (1) has to be completed with two supplementary terms representing the cross-coupling effects, where the former is caused by the dependence of the stress tensor on temperature (reversible) while the latter is induced by the same dependence of the generalized force conjugated to the internal state vector (irreversible). This phenomenon appeared on the concrete surface with a delay depending on the depth of reinforcements. Thus, infrared thermography readily evidenced and localized, on the scanned wall surface, the plasticity of steel reinforcements with a delay due to heat conduction characteristics of concrete (Figure 13a and b).

6.5.2 SPECIMEN B highlighting the effects of boundary conditions

SPECIMEN B, composed of two lightly reinforced walls, was designed according to French seismic code PS92 recommendations and simply rested on a 40-cm-thick sand layer (Figure 14). This test aimed to reproduce the phenomena of uplift and the fact that such a nonlinear phenomenon was capable of isolating the structure from ground-borne excitation. In this case, it is expected that soft boundary conditions will determine the seismic behavior of structural walls.

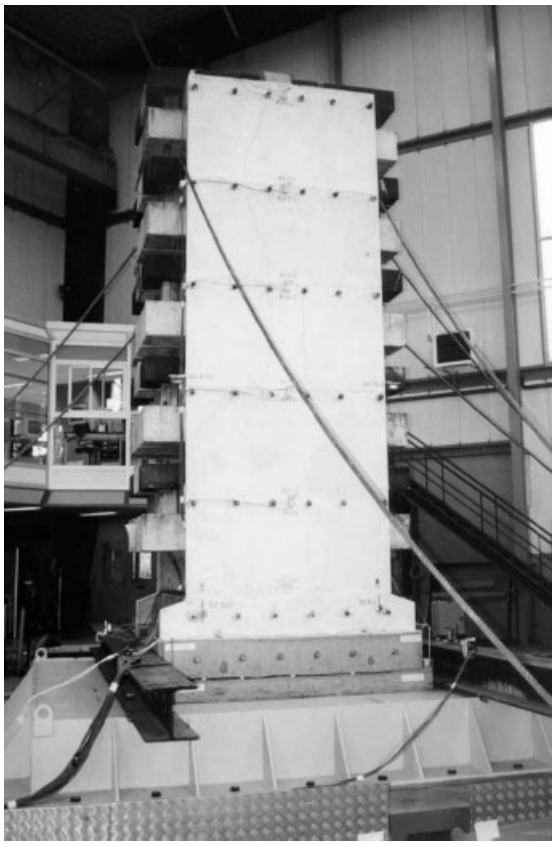


Figure 14. SPECIMEN B resting on a fine sand layer.

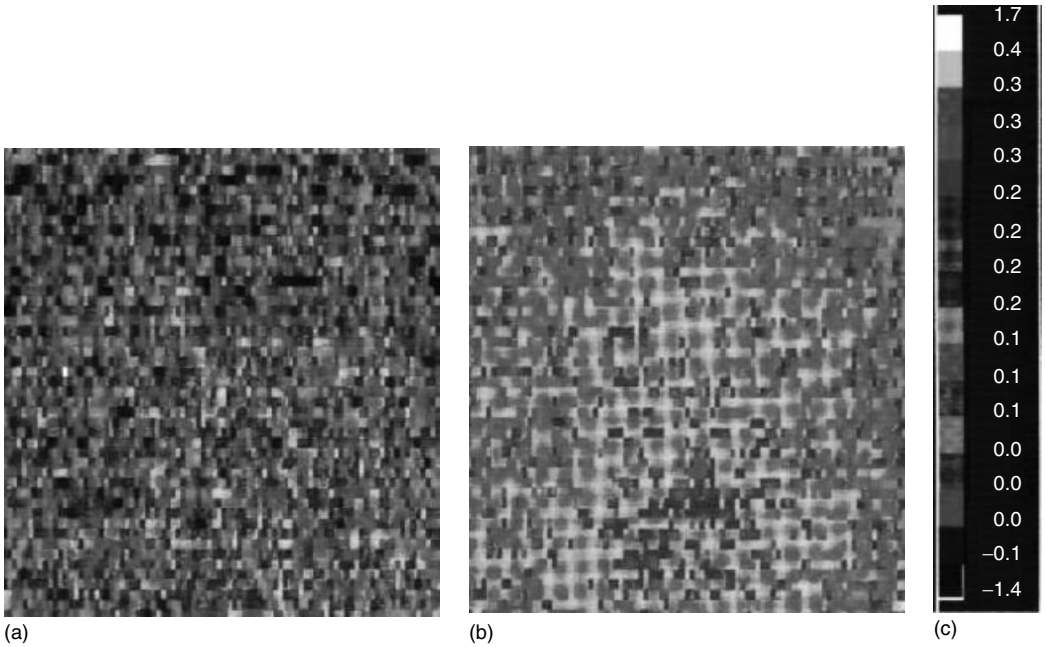

Figure 15. (a) Dissipation due to slippage of steel reinforcements recorded 6 min after seismic test at $PGA = 11\,\mathrm{m\,s^{-2}}$ during 30 s; (b) dissipation due to slippage of steel reinforcements recorded 10 min after seismic test at $PGA = 11\,\mathrm{m\,s^{-2}}$ during 30 s; and (c) heat changes are given in degree Celsius.

Table 2. Magnitude order of temperature change

Dissipative mechanisms	Range of temperature changes	Time delay
Plasticity of concrete under compression	Up to 10 °C	In real time
Plasticity of steel reinforcements	Some degrees Celsius	Several minutes of delay
Slippage between steel reinforcements and concrete matrix	Tenths of degrees Celsius	A delay of tens of minutes

As in the above case, infrared thermography evidenced friction between steel reinforcements and concrete matrix with a delay necessitated by heat conduction through the concrete layer (Figure 15a and b).

6.5.3 Dissipative mechanisms and their range of temperature changes

Experimental results showed that the discrimination of the involved dissipative mechanisms is very delicate. Fortunately, this work, originally intended to validate diverse different dissipative mechanisms, provided the interesting discriminative characteristics of temperature changes as in Table 2.

7 CONCLUDING REMARKS

This work has demonstrated that (i) the *evolution* of heat change facilitates the detection of thermobiological coupling and (ii) the *dissipativity* of engineering materials or structures under solicitations is a highly sensitive and accurate *manifestation of damage*.

Thanks to the thermomechanical coupling, infrared thermography provides a nondestructive, noncontact, and real-time test to observe the physical process of

concrete degradation and to detect the occurrence of its intrinsic dissipation. Thus, it readily provides a measure of the material damage and aids in defining a limit of acceptable damage and endurance limit of concrete under load beyond which the material is susceptible to failure. It should be pointed out that the inelastic strain due to compressive loading provides information only on the current geometry while the internal state variables provide information on the internal state and on the microstructural defects.

The method allows not only qualitative work such as finding flaws, defects, or weakness zones but also quantitative analysis of the effects of flaws and defects on strength and durability of concrete structural components. This useful and promising technique offers an accurate illustration of crack initiation, and readily detects the onset of its unstable propagation through the material and/or flaw coalescence when cyclic loading generates increasing irreversible microcracking. Mechanical test data generated under noncyclic conditions are insufficient to provide a comprehensive insight into the damage development in brittle concrete under cyclic loading. Design procedures ignoring fatigue phenomena may be seriously flawed if the concrete structures concerned are loaded cyclically.

The examples reported in this article and several published results (*see* **Thermal Imaging Methods**) demonstrate the versatility of infrared thermographic technique in various domains of application, provided that the physical phenomenon is correctly interpreted in a consistent theoretical framework.

The main interest of this energy approach is to unify microscopic and macroscopic test data. The parameter *intrinsic dissipation* under consideration is a scalar quantity, which is easy to evaluate accurately. Subsequently, it may suggest multiaxial design criteria, highly relevant for full-scale testing of engineering structures.

Chapter 7

Civil Infrastructure Load Models for Structural Health Monitoring

Udo Peil

Institute for Steel Structures, University of Technology Carolo-Wilhelmina at Braunschweig, Braunschweig, Germany

1 INTRODUCTION

The present and the future behavior of structures in the civil, mechanical, or aerospace engineering field can often be precisely assessed by means of certain monitoring measures. Structural health monitoring (SHM) is a general method that can be used for the assessment of local or global damage, the evolution of damage, and the prediction of the lifetime of a structure under certain loading conditions. Conventional lifetime assessment methods are not very reliable. Differences between theoretically calculated and observed lifetimes may differ by one order of magnitude [1]. Lifetime assessment by means of parallel SHM can considerably improve the accuracy of the prediction [2, 3]. SHM enables the determination of a wide range of monitoring measures including

- deflections and strains, e.g., of newly built structures due to special test loads to compare measured and theoretical results;
- system behavior for system identification;
- threshold crossings;
- input values for the assessment of the lifetime of structures;
- maintenance planning; and
- traffic analysis and control.

Any SHM measure is based on a precise knowledge of the system. The knowledge may be gained by conscientiously performed theoretical investigations, e.g., by means of the finite-element method (FEM), taking into account the actual system parameters and boundary conditions based on thorough inspections of the structure. The modeling must be done with high accuracy, since an oversimplified model of a structure may hide or fake weak points in the structure. Because it is difficult to determine certain system parameters precisely, e.g., boundary conditions (grade

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

of a fixed connection) and material parameters (stiffness, mass, or damping), the theoretical results must be verified.

Verification is accomplished by means of system identification. Defined loads are applied to the structure, and the response is monitored. The results can be used to update the physical model parameters. This type of identification is called *parametric identification*. Nonparametric identification is used if the system model is unknown. In this case, simple black-box models, e.g., fitted least-square functions, can be used to describe the system behavior. The system identification procedure is based on a comparison of the system response to a given action. The type of action needed depends on the response of interest. For example, a concrete structure only reacts to chemicals if there is a special reaction between the chemical substances and the surface of the structure. In any case, before establishing an SHM measure, the system must be identified by certain monitoring measures to begin a lifetime assessment with the best knowledge regarding the structure. For this purpose, precisely defined loads are needed. In Figure 1, the block titled Load model I reflects this knowledge.

To be able to predict the lifetime of the structure, a suitable load model, which may cause future damage, is required to describe the future actions on the structure because they may cause future damage. The models of codes are not usable, in general, because they describe ultimate load situations, which usually never occur in reality. Lifetime predictions must be formulated under typical actions, which are able to precisely describe reality in terms of time dependency and amplitudes and their statistics. These load models are included in the block titled Load model II in Figure 1.

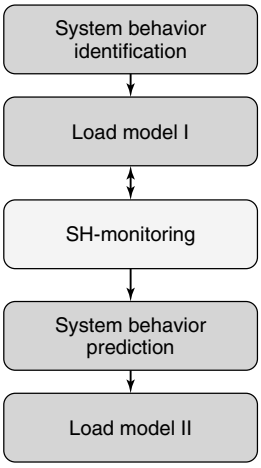

Figure 1. Use of load models.

The prediction of future system behavior and/or the lifetime of a structure only makes sense if the future actions are predictable, as with traffic on a bridge or wind or wave loads on a structure. Unpredictable events such as earthquakes, tsunamis, and blast loads are not suitable for monitoring and lifetime prediction. Wind effects due to vortex or self-excited vibrations on structures lead to the same lack of predictability. Since these types of loads are always dangerous events for a structure, which could cause very early fatigue damage, these loads must be prevented, e.g., by adding damping to the structure [4]. Therefore, these unpredictable events do not play a role in SHM and are not discussed here.

In this article, both types of loads mentioned in Figure 1 are briefly discussed:

- load model I: loads for system identification;
- load model II: realistic loads (traffic, turbulent wind) for the description of realistic future actions.

Load model I is usually needed for a single test when an SHM measure is being selected. It can be used again if, after a couple of years, changes in the structural parameter are being assessed, for instance, to check the predicted lifetime provided by Load model II. If any change in the system behavior is to be assessed, e.g., because of damage evolution, repeated or continuous measurements must be performed. With the aid of the updated measurement results, the system damage prediction models can be adapted to the modified situation (and, if necessary, verified using a procedure that applies load model I). These system damage prediction models are then called *adaptive or smart models* [2]. They can be identical to classical system or damage models, but the models are often much simpler because they only need to predict over a short period of time, e.g., up to the next measurement. Since the adaptive system or damage models can take into account any system change or change in expected actions, they are more reliable than theoretical prediction models, which predict the system behavior over a long time period starting at $t = 0\,\mathrm{s}$.

2 WEAK-POINT ASSESSMENT AND INHERENT DAMAGE

Irrespective of the type of structure to be monitored, the assessment of critical weak points is one of the most important steps in the procedure. Weak points or weak spots are areas of the structure that are prone to damages or where possible damages cause nontolerable consequences. Weak points of older structures, usually designed with very different safety levels, are normally well known and can be determined by existing structural calculations or by experience. They can simply be identified by means of theoretical modeling and parallel system identification measures.

New structures, however, show an equally distributed safety level over a large number of critical details. The critical details can then be detected by means of probabilistic methods, leading to a smaller number of measuring points. The procedure for reliability-oriented determination of weak points classifies critical weak points as points that contribute the largest part to the overall failure probability of the structure [2, 5, 6]. These points must be monitored. To determine the failure probability, the description of

- limit state functions and limit values;
- stochastic model;
- mechanical model; and
- analysis of sequences of events and fault trees

are prerequisites. For details see [6].

When the weak points are determined, the material state near the weak points must then be checked using nondestructive testing (NDT) techniques, such as ultrasonic, X-ray, magnetic tests, etc. NDT can find macrodamage in an order of magnitude of a 10th of a millimeter. Much smaller failures, e.g., microcracks due to fatigue loads on a steel structure, are difficult to measure, although this damage is inherent in any older, i.e., not virgin, structure. The assessment of inherent damage is a difficult part of the identification process. In general, two possibilities are available in general to determine the damage state: a theoretically, model-based and an experimentally based procedure (Figure 2). In this figure, three NDT-methods are shown, which seem to be able to give information about the inherent damage state. Modeling of former actions is based on load or action models of the past. This approach is also discussed in the next section.

3 LOAD MODELS FOR SYSTEM IDENTIFICATION

3.1 General remarks

If the overall system response to certain actions is to be determined, the system must be loaded so that a sufficient system response is generated. Therefore, the loads applied must have the same order of magnitude as the maximum expected loads. In civil engineering, these loads are prescribed by national load codes. The

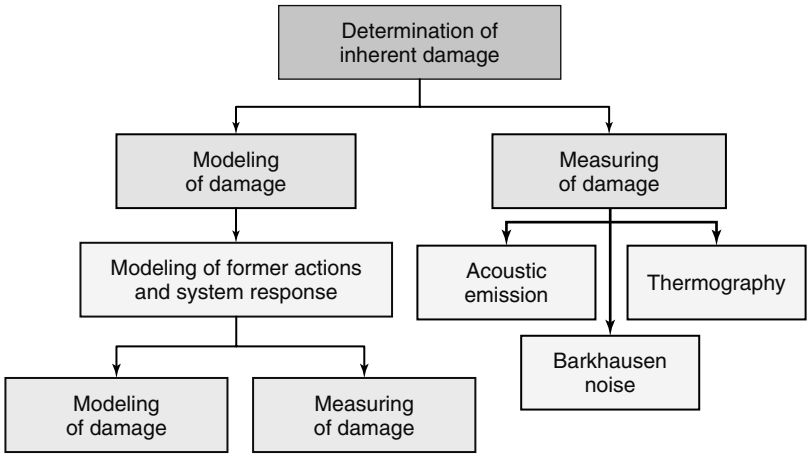

Figure 2. Determination of the inherent damage in a metallic structure.

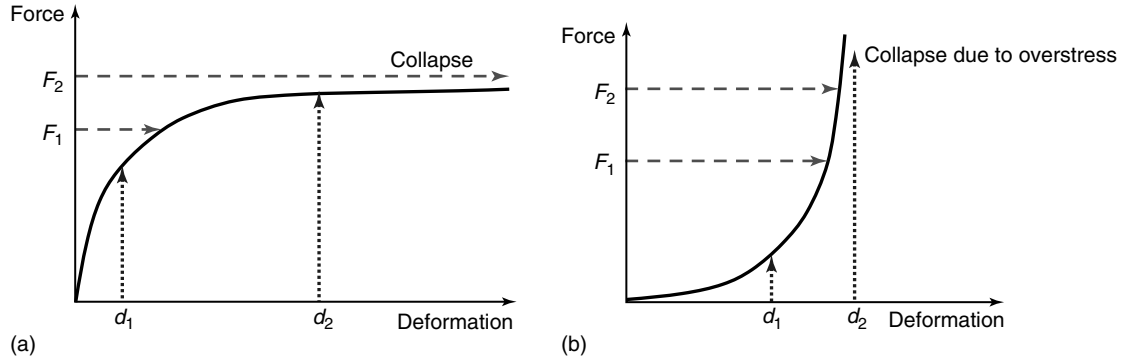

Figure 3. Effect of load and deformation control.

application of large loads may lead to a structural problem. If the structural behavior is completely unknown, e.g., an old bridge with unknown material behavior, the application of loads in the form of large weights (trucks or tanks if a bridge is tested) may pose a risk of global or local system collapse. Because of gravity, loads act continually, independent of any deformation due to dynamic loads. This type of loading of a structure is referred to as *force controlled*. If the gradient of the load deflection curve decreases (Figure 3a), which is usual in most cases, a complete collapse could easily occur if the load F_2 is larger than the ultimate load. For example, supposed a single-span girder is loaded by a rising water level in a tank. When the full plastic moment of the girder (or the lateral buckling load) is reached, the girder completely collapses because of the weight of the water still acting during the collapse process.

In such cases, so-called deformation-controlled loading is required. Deformations can be induced with hydraulic jacks or the like. The jack force causes a deflection of the structure. If the structure becomes weaker because of damage or nonlinearities, the force is automatically reduced and the given deflection is maintained (Figure 3a). This situation offers the possibility to measure the nonlinear behavior of a structure. If the deformations of the structure are increased by means of the hydraulic jacks, the required hydraulic force is automatically adjusted.

If the gradient of the load deflection curve increases (Figure 3b), which is typical for cable structures, which show a hardening effect during deflection, then a deformation-controlled procedure with a given deflection d_2 could possibly lead to damage due to material overstressing.

Despite the (rare) problems with hardening systems, a deformation-controlled test procedure is usually the best way to test a structure, but it is, in general, more expensive than a force-controlled procedure, especially if large loads must be applied. Large bridges, for instance, need expensive additional foundations for the tension bar elements and the hydraulic jacks. The use of trucks or tanks (force controlled) is much less expensive, in general.

3.2 Static loads

For investigation of the overall response of large structures such as the main girders of road bridges, many heavy trucks or tanks are often used. Railway bridges are loaded by engines (Figure 4). When statically undetermined structures are tested, the effect

Figure 4. Test loading of a railway bridge.

of the influence lines or areas could be used to increase the response of the structure by spanwise adapted loads. When substructures of the system, e.g., longitudinal or cross girders of bridges, are investigated, usually one or two trucks or engines may be sufficient.

Of course, the single loads must be known. Thus trucks and tanks must be weighted beforehand. The exact load due to engines is generally known.

In Germany, tests are carried out by building a special bridge loading truck, which is used for the large number of small bridges with a span <18 m, [7, 8]. This truck can strain the bridge with up to 100 t. Figure 5 explains the procedure. Figure 5(a) shows the special truck on the road. When arriving at the test site, the rear axles are braked and the traction engine is pulled out (Figure 5b). In this case, the bridge is loaded only by a small load. Figure 5(c) shows the final test position. The weight of the truck can be increased by 20 t of water to a total load of up to 100 t. If higher loads are needed, the truck must be anchored at both ends by tension bars to the supports.

One should keep in mind that such loading tests give good results for the purpose of system identification. An extrapolation of the system behavior under ultimate loads is difficult or impossible, owing to the effects of nonlinear system and, in particular, nonlinear material behavior.

Static tests of smaller structures are less expensive because the ultimate loads usually decrease. If single loads are used, the procedure is straightforward. The application of (approximately) continuous loads is more difficult. These loads can be realized, for instance, by a few hydraulic jacks, which are hydraulically coupled so that they do have the same

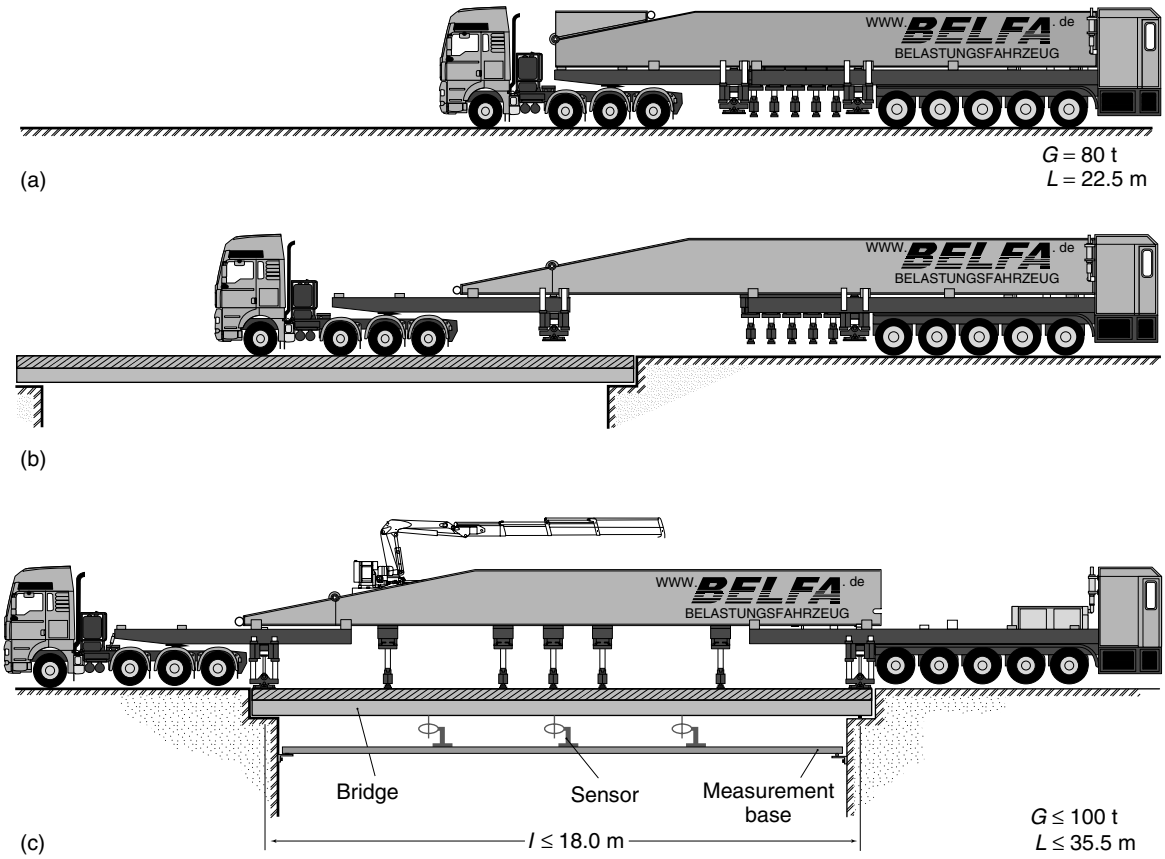

Figure 5. Special loading truck Belfa. [Reproduced with permission from Ref. 7. © Ernst und Sohn, 2001.]

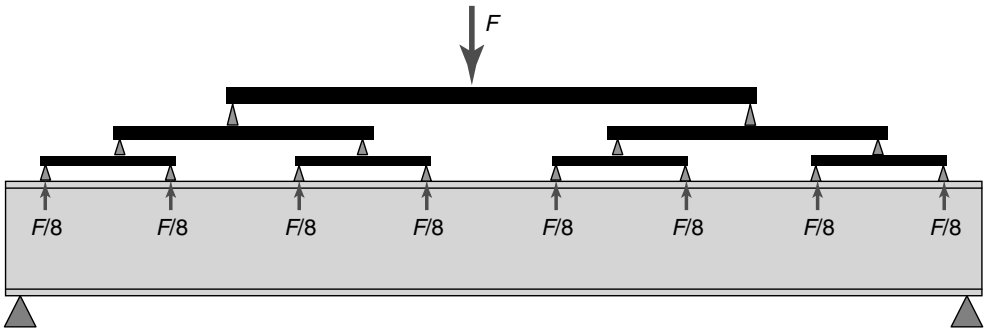

Figure 6. Loading with equal single loads.

oil pressure. However, if the jacks show different friction behavior, the activated loads are different. If a precise loading situation is needed, a load-distributing system can be used that leads to equal single loads as shown in Figure 6.

It is obvious that the loading system becomes more complicated and expensive as more single loads are needed, keeping in mind that a stabilization structure must be added to avoid lateral instability.

In such cases, it is much easier to use the hydrostatic (or the aerostatic) principle. If the load is applied by means of a pressure cushion, the loading system becomes very simple. Figure 7 shows a beam under uniform loading. The girder is turned upside down. It is loaded at its supports by means of a load-distributing girder and a hydraulic jack. The beam is pressed into a water-filled fire hose [9]. Thus, a perfect continuous constant load is produced. The aerostatic principle can be used in a similar way.

3.3 Dynamic loads

3.3.1 Large structures or global monitoring

Stationary excitation

The simplest way to produce a stationary excitation is the installation of an electrodynamic exciter. It is the simplest solution if tests could be performed in the laboratory, as is typical in the field of mechanical or aeronautical engineering, because those structures are small enough to be tested in the lab. The exciter system consists of a signal generator, a power amplifier and the exciter itself. In the lab, electromagnetic exciters with frequencies from 2 to 10 000 Hz, force amplitudes from 10 to 500 N, and dynamic deflections up to 2 cm are used. The exciters can be anchored at the ground or at large masses, which can carry the loads by inertia forces. This configuration must, of course, be conscientiously dynamically investigated before testing.

Figure 7. Constant continuous loading by means of the hydraulic principle.

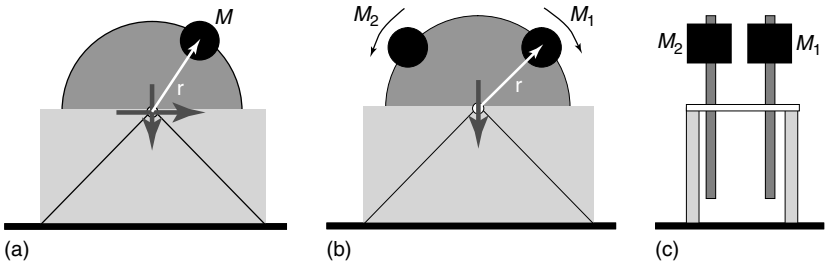

Figure 8. Excitation with unbalanced masses.

If the frequencies are much lower (<5 Hz), hydraulic jacks are used, which could produce much higher forces and deflections of the structure. This configuration is typically used for earthquake shaking tables.

The excitation could be stationary (harmonic excitation) or nonstationary (transient signals, swept sine, noise, etc.), depending on the target of the investigation.

Civil engineering structures can often not be tested in a lab. The use of a hydraulic exciter is often difficult because the exciter could not be anchored against the ground. In such cases, a dynamic exciter based on unbalanced masses is used to generate a stationary dynamic excitation. If just one mass is used, a rotating radial force occurs. The force has a horizontal and a vertical harmonic component, which shows a phase shift of $\pi/4$ (Figure 8a). It is often inconvenient to work with two force components. If two unbalanced forces, rotating in opposite directions are used, only one resulting force component occurs and the second one is internally balanced as shown in Figure 8(b).

The forces are proportional to the square of the circular frequency of rotation Ω (equation 1):

$$F = M \cdot r \cdot \Omega^2 \tag{1}$$

Stationary excitations have advantages because the energy is concentrated on one single frequency, thus the ratio between the signal and the noise is large. Since the transfer function can be measured directly, the nonlinear behavior of the system or frequency-dependent damping can be measured directly.

The effort can be substantial, in particular, if low frequencies must be excited. Since the circular frequency Ω is low, large masses are needed to generate sufficient force components. The rotational speed control must be precise enough to localize the very narrow resonance peaks that are exhibited by lightly damped systems. Sinusoidal excitation tests are time consuming as well. After changing the frequency, a new stationary state must be adapted before the measurements can be performed. Owing to feedback effects, it is often difficult to leave the resonance frequency because the rotational frequency persists at the resonance, if the power of the engine is not large enough.

One can reduce some of the above-mentioned disadvantages if a stationary excitation is used that is not purely sinusoidal but instead is swept sinusoidal with a frequency that changes slowly with time (Figure 9). This procedure also requires a precisely controlled unbalanced-mass engine and large masses if low frequencies are to be applied. The transfer function can then no longer be measured directly.

Transient excitation

Because of the above-mentioned disadvantages of the method of unbalanced masses, transient (from

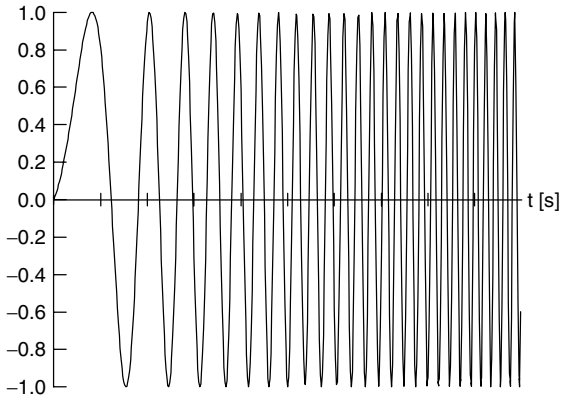

Figure 9. Swept sine.

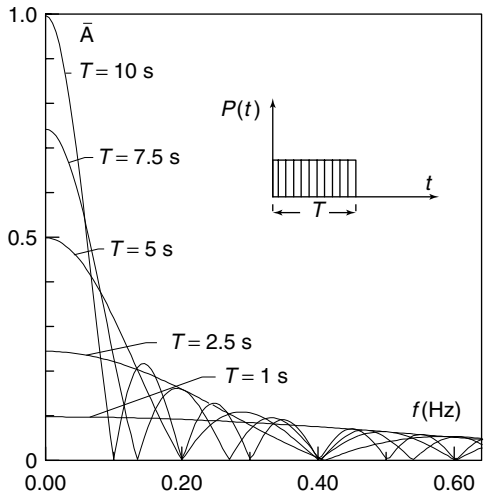

Figure 10. Normalized frequency spectra depending on the duration of a load pulse.

latin: *trans ire* — to pass) excitations are used in most cases. Depending on the size of the structure and of its eigenfrequencies, different methods may be used, bearing in mind, however, that short time signals cause a broadband frequency response and vice versa. A short load-time process, therefore, causes a broad frequency spectrum with higher frequencies, and a long lasting load-time process causes a narrow frequency spectrum with many low frequencies. Figure 10 shows different normalized frequency spectra depending on the duration of a rectangular load pulse.

Electromagnetic or hydraulic exciters can be used in the field as well. These approaches have already been discussed in the section on "Stationary excitation".

Smaller structures are usually excited by means of a hammer impact. Special impact hammers allow the load-time history to be measured. This information is not necessary, if only eigenfrequencies and the damping are to be measured. The eigenfrequencies can easily be determined from the peaks of the computed frequency spectrum and the damping is estimated from the time history by analyzing the decrease in amplitude. If more than one eigenfrequency is excited, the time history may need to be band-pass filtered to determine the frequency-dependent damping values [10, 11]. The information of the impact-force time history, measured by a special impact hammer, is, of course, important, if the system identification method requires the time history as an input.

As already mentioned, a short hammer impact generates a frequency spectrum with high frequencies and low frequencies possess low amounts of energy; thus, the low eigenfrequencies of the structure are only excited a little. Therefore, the hammer impact method is used if small structures with higher eigenfrequencies are investigated.

Large structures are often excited by means of sudden load relief, i.e., a load jump. This approach could be implemented, for instance, by cutting an auxiliary rope under a certain rope force. The frequency content of such a load relief jump shows large low-frequency content in the spectrum. This can also be derived from Figure 10. Therefore, it is ideal for exciting large structures with low frequencies.

If the method with auxiliary ropes is not practicable, other excitation mechanisms must be used. One possibility is to use special blasting cartridges, which generate a reaction like a rocket. If the cartridge is mounted on a special device, the time history of the force could be measured.

Ambient excitation

The use of ambient excitation, such as wind, waves, and traffic, is often a very quick and inexpensive method to assess the main dynamic properties of a structure. The main problem is that the excitation input is unknown. Keeping in mind that at a resonance peak only the accompanying eigenmode responds significantly, the problem can be partly solved.

Assuming that only one eigenmode responds at the resonance frequency and that the damping is small as usual, the excitation has no phase shift, thus the imaginary parts of the solution can be neglected. In this case, the response at two points (i.e., two degrees of freedom) can be expressed as follows (equations 2 and 3):

$$\boldsymbol{u}_{\mathbf{a}}(\omega_j) = \Phi_{aj} \cdot y_j(i\omega) \quad \text{and} \quad \boldsymbol{u}_{\mathbf{b}}(\omega_j) = \Phi_{bj} \cdot y_j(i\omega) \tag{2}$$

with

$$y_j = \frac{\boldsymbol{\Phi}_j^{\mathbf{T}} \times \boldsymbol{P}(i\omega)}{i \cdot 2 \cdot \xi_j \cdot k_j} \tag{3}$$

as the modal response in the jth eigenfrequency. Φ_{aj} is the value of the eigenvector $\boldsymbol{j}$ at point a, $\boldsymbol{P}$ is the unknown excitation vector, ξ_j is the damping value at the jth eigenfrequency, and k_j is the modal stiffness (equation 4):

$$k_j = m_j \cdot \omega_j^2 \tag{4}$$

If the ratio

$$\frac{\boldsymbol{u_a}}{\boldsymbol{u_b}} = \frac{\phi_{aj}}{\phi_{bj}} \tag{5}$$

is formed, one can see from equation (5) that the modal response, which contains the unknown excitation vector $\boldsymbol{P}$, is eliminated by reduction. Thus, the components of the eigenmode can be determined at $a = 1, 2, 3, \ldots$ degrees of freedom related to a reference degree of freedom at b [12].

This relation even holds true if, in the case of stochastic excitation, instead of the Fourier-transformed time histories, the power spectral densities (PSD) are used. For this purpose, the PSD are determined from the response time history. Information about this task can be found in [13]. The peaks of the PSD locate the eigenfrequencies. The modal masses cannot be determined, because the excitation forces are unknown.

The damping of the structure at ambient excitation can be determined from the autocorrelation function (Figure 11). If the structure is excited by a stochastic process in a frequency range that contains the main eigenfrequencies of the structure, the system response depends on its mechanical transfer function. If the excitation follows a white noise spectrum,

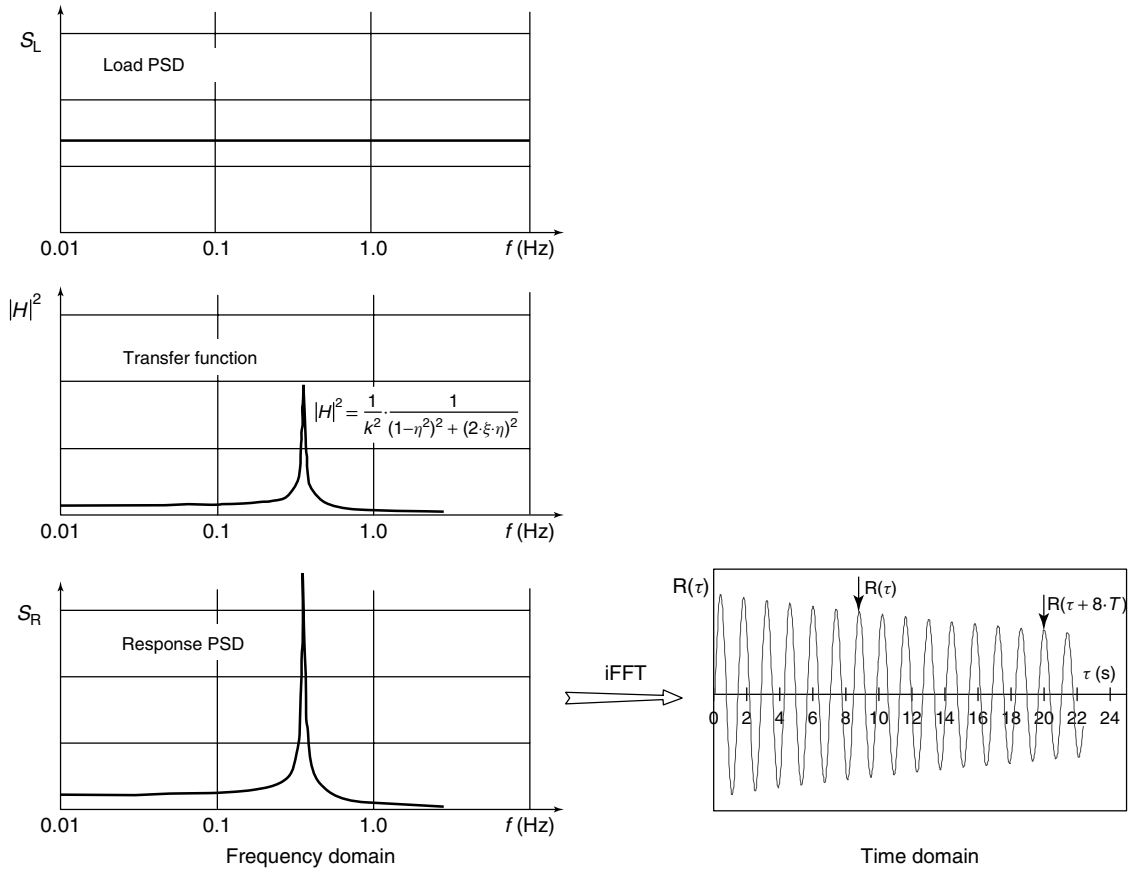

Figure 11. Damping assessment at ambient excitation.

the response function is proportional to the transfer function due to the multiplication of the load PSD and the system transfer function. In practice, it is sufficient that the load PSD is approximately constant around the eigenfrequencies. It is well known that the autocorrelation of the system response is the transformation of the PSD of the system response into the time domain (Wiener–Khintchine relation [13]). The autocorrelation of a system, which vibrates mainly at its main eigenfrequency, looks like a typical damped vibration function. Thus, the damping is determined in the usual manner (equation 6):

$$\delta = \frac{1}{k} \cdot \ln \frac{R(\tau)}{R(\tau + k \cdot T)} \tag{6}$$

where k is the number of cycles with the period T between the measured amplitudes of u ($k = 8$ in Figure 11).

In practice, this method is a very powerful one because the damping of large structures can be measured without expensive measurement devices. It is important to note that the method is a statistical one, which leads to reliable results only if the law of large numbers is observed. This law means that the measurement period must be long. Large structures with eigenfrequencies of about 0.4 Hz need measurement periods of 1 h or more. If the measurement periods are too short, accidental numbers will be the result.

3.3.2 Small structures or local monitoring

Impact loads

Small structures or local parts of larger structures can be dynamically excited by a hammer impact as mentioned above. This is a simple and inexpensive procedure. Owing to the higher eigenfrequencies of small structures, the higher frequency content of a hammer impact is perfect for the excitation of these eigenfrequencies. If the hammer allows the tip pressure time history to be measured, then the input for a parallel calculation of the forced vibration is available (Figure 12).

In some cases this method is not optimal, especially when repeated or continuous measurements are scheduled over the lifetime or repeated monitoring (and loading) is impossible owing to large heights or owing to dangerous environments (the inner parts of reactors). In these cases, it could be advantageous to use piezo elements.

Figure 12. Impact hammer.

Diverse piezoelectric materials of different dimensions, made as double-sided electroded discs, are available. The amount of the impact depends on the size of the piezo element, the direction of polarization, and on the electrical voltage applied to the piezo [14, 15]. For monitoring limited areas of flat structures, it is recommended to use simple circular discs with a diameter of 10–30 mm and a thickness of less than 0.5 mm (Figure 13). A two-component epoxy is used to bond the elements with a certain pressure to the structure. If the structure is metallic, it can be used as an electrical conductor. In this case, the epoxy must be made electrically conductive by adding copper powder with a particle size $<100\,\mu$m. Finite element (FE) simulations show that the thin epoxy layer can be regarded as a stiff bond [16].

Because of the free boundary conditions at its rear, the thickness mode of vibration of the piezo discs does not affect the structure in any significant way. In fact, in this case, the radial component caused by the lateral strain of the piezo is important. If the vertical component is used, additional masses at the rear must be added to permit a reaction supported by the inertia forces.

The elements can be used as actuators and/or as sensors. This is a great advantage because it reduces the costs.

A hybrid amplifier is used for excitation of the piezo elements [16]. This amplifier meets both requirements for improved control of the piezos compared to a regular voltage amplifier: with this equipment, the actuators with a relative small capacitance can be driven with signal frequencies of up to 200 kHz.

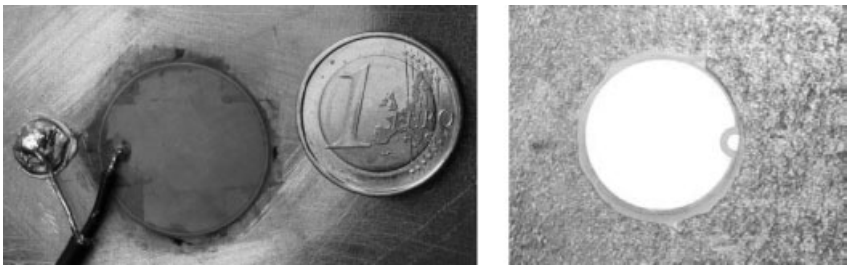

Figure 13. Piezo discs.

Ultrasonic loads

Ultrasonically excited infrared thermography (UT) is a relatively new NDT technique for detecting flaws and damages in different materials. The underlying idea of the technique is the thermal activation of defective locations, such as cracks, delaminations, and kissing bonds by high-intensity ultrasonic mechanical excitation in the frequency range $>20\,000$ Hz [14]. In the vicinity of defects, the elevated dissipation causes a local rise of the surface temperature, which is detected full field and noncontacting by highly sensitive infrared (IR) cameras [15]. A defect can clearly be distinguished from the undamaged structure if the presence of the defect causes a higher dissipation of mechanical energy than the surrounding material.

Numerous potential fields of application for this innovative NDT technique have been explored in the past. This includes flaw detection in laminates and composite materials, crack detection in lightweight metal and ceramic structures, as well as application in the automotive and aircraft industries. A major advantage of ultrasonically excited thermography is its fast applicability, the full-field resolution, and the selectivity in finding defects. Additionally, the equipment is reasonably lightweight for mobile testing. Despite its early successes, the technique is currently still under development. Numerous issues concerning the ultrasound excitation, measurement approach, and data processing of the IR images need to be addressed prior to a broader application of the technique. The application and further development of the technique for the detection of cracks and fatigue damages in metallic civil engineering structures is subject to current research activities. The primary concerns involve the optimization of mechanical excitations in the ultrasonic frequency range and the corresponding data processing techniques.

The excitation sources commonly applied are standard high-intensity ultrasonic converters used for metal and plastic welding [14]. The converters are designed to operate at a single frequency or within narrow frequency bands. Typical working frequencies are 20 000, 40 000, and 60 000 Hz. Some specialized ultrasonic generators allow the converters to be operated over a larger frequency range, i.e., 15 000–25 000 Hz. The extension of the frequency range is linked with some technical obstacles because the converters themselves are optimized to operate under resonance conditions at a single frequency. For good defect detection, variability of the excitation frequency f_U is of special importance. Mechanically, the system, composed of the component to be tested and the ultrasonic excitation, constitutes a two-degree-of-freedom system. Tests showed that similar to lower frequency vibrations, high energy input can be achieved if the vibration system is operated under resonance conditions. Resonance occurs if the excitation frequencies coincide with a natural frequency of the tested component, a practice that explains the selection of high frequencies for defect detection. If only a single frequency is used during excitation, a stationary vibration pattern develops. This causes poor defect detection capabilities of UT in the zero crossings of the vibration mode. The problem can be addressed by shifting or wobbling of the ultrasonic frequency during testing.

The aim of IR-image data processing is the detection and separation of defects from the thermal background radiation of the remainder of the structure. A promising approach is the so-called lock-in technique. For this purpose, the power output of the excitation source is modulated by a modulation frequency, f_m, which is much smaller than f_U. The amplitude modulation of the excitation leads to temporal periodic variations of the dissipated energy and the

corresponding temperature changes in the vicinity of defects. This variation of the surface temperature is captured by an IR-image sequence over a certain time interval and is analyzed on-line or off-line with respect to the periodic variations. A discrete Fourier transformation (DFT) of the temperature evolution of each pixel can be used to separate the temperature changes at the modulation frequency, whereas contributions at other frequencies are filtered out during data processing. The DFT can be used to calculate the amplitude of the temperature evolution and its phase shift with respect to the modulation cycle; these can be easily displayed as amplitude or phase images. The phase shift, especially, promises good results for defect recognition because it is not influenced by variations in the local surface emissivity.

4 LOAD MODELS FOR LIFETIME PREDICTION

4.1 General remarks

If the lifetime of structures is to be assessed, models of the structural behavior are needed. Usually three types of models are necessary:

- load or action model
- system model
- damage model.

In this article, the different types of load models are discussed. The load or action models can be deterministic or stochastic. Usually, nearly all loads are stochastic, but the variance may be very small, so they appear to be deterministic. Water loads acting on gates, for instance, of locks in a canal, do have very small variance as the water level changes between the lowest and the highest point. Such loads may be treated as deterministic.

Wind or wave loads and typical road traffic show a large variance. The scattering between very light vehicles and extremely heavy ones is large, for example. The same holds true for railway traffic. Although the sequence of trains is known by the time schedule, the single-axle load is not [17].

The scattering of the loads is increased by the dynamic system behavior. A load that passes a bridge causes vibration of the structure due to the deflection of the structure under the moving load and due to the additional pavement roughness.

In the following section, typical load or action processes and possible models are discussed.

4.2 Traffic model

4.2.1 Load generation

The generation of a load sequence of road traffic is difficult owing to the stochastic character of the loads, the widely scattered traffic behavior, the dependence on the local site, and the nonlinear effect caused by feedback of traffic to the drivers. Nonlinear effects are usually not taken into account. A sufficient micro-traffic model should, therefore, take into account the

- distribution of vehicle weights
- sequence of vehicle types
- time distance between vehicles.

These input values are stochastic variables. The statistical data of vehicle types may be estimated from vehicle registration data from the authorities. If no data are available, WIM (weigh-in-motion) data can be measured to get the input data, for instance, for a bridge. WIM, first proposed by Moses [18], has been applied worldwide for more than 20 years [19]. On the other hand, data can be achieved by means of strain measurements of, e.g., cross girders of bridges [20–22]. If measurements are not available, estimated load distribution functions must be used.

Typical vehicle sequences (e.g., clustering of trucks) and typical temporal distances between vehicles must be taken into account as well [2]. Experiments have shown that, for instance, the influence of a traffic time history with clustered trucks is large [2]. The fatigue of a specimen loaded with a force time history taking into account typical truck clustering is just 50% compared with a force time history, which shows exactly the same statistics, but includes stationary distributed trucks over time. The vehicle statistics (load distribution, clusters, and temporal vehicle distances) depend on the type of road (highway, country road, and city road) and on the local situation. The statistics of a certain road type can also be used for other similar cases, e.g., for other bridges of the same road. If the statistical input is known, artificial load–time histories can be generated by means of the Monte Carlo method.

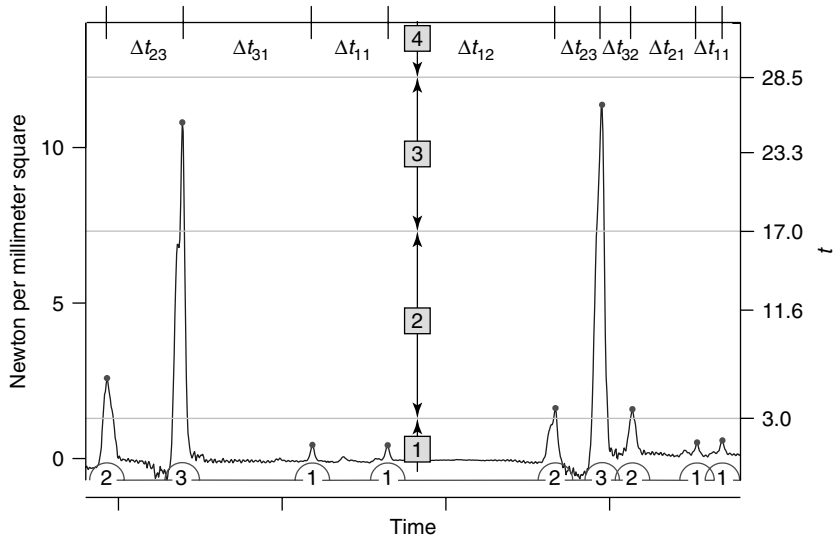

Figure 14. Time history of traffic and vehicle assignment.

In the first step, the measurement records must be analyzed. Figure 14 shows a small part of a long-term record. Heavy trucks and lighter cars are easy to identify. In the whole record, four different types of vehicles are identified: (i) cars, (ii) light or empty trucks, (iii) ordinary, and (iv) heavy trucks. The question is how to separate these different classes. To do this, the density function of the overall traffic is needed. As an example, Figure 15 shows the histogram of vehicle loads measured at a cross girder of a highway bridge. In the next step, four weighted normal distributions are used to fit the measured histogram. It is obvious that the overall traffic can be described well by the sum of four normally distributed vehicle types [2].

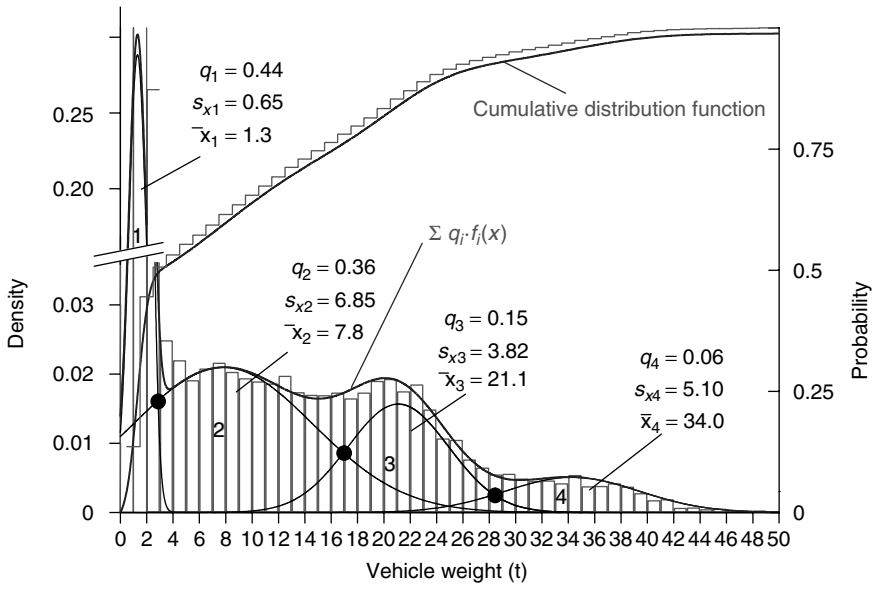

Figure 15. Load distribution and fitted combination of density functions.

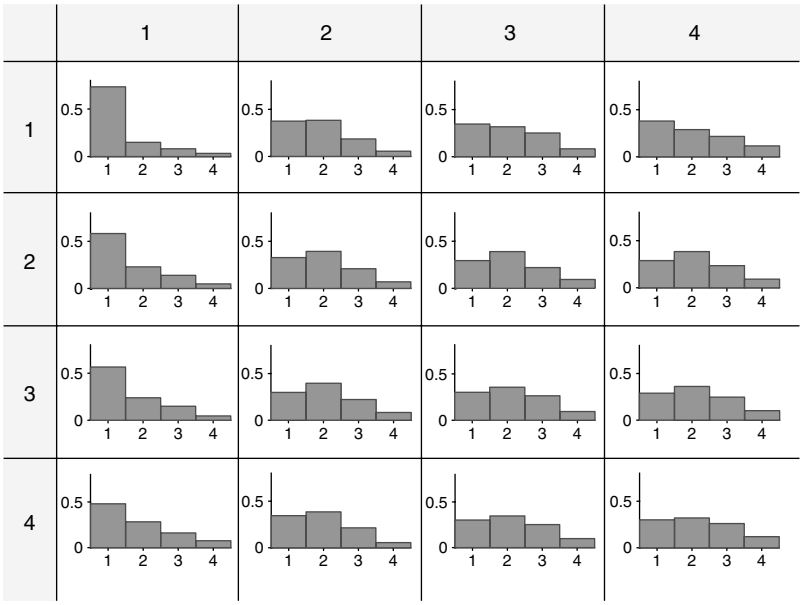

Figure 16. Matrix of sequence densities.

On the basis of the discriminate analysis method, e.g. [23], the intersections of the normal distributions represent the borders of the four accompanying classes. The intersection points in this example are 3, 17, and 28.5 t (Figure 15). With this class definition, the traffic stream plotted in Figure 14 can be classified into four classes. In the next step, the traffic stream is transposed into a stream of numerals, which define the adjacent classes, (lower part of Figure 14).

To classify the sequence and the temporal distances of the traffic (expressed by the numerals), an n-dimensional matrix can be used. First, the description of the vehicle subsequence is discussed (Figure 16). The rows belong to the class of the first vehicle, the columns to the subsequent one. The elements of the matrix then contain a histogram of the four vehicle classes. The histogram of element i, j shows the probability of occurrence of the next vehicle in that sequence. It is obvious that the probability of occurrence of succeeding trucks is high (see the high mode of the distributions in elements with a column number greater than 1). If n sequences of vehicles are to be taken into account, the matrix becomes $(n-1)$ dimensional.

A similar approach is used to describe the temporal distances of the vehicles. Figure 17 shows the density functions of the temporal distances in seconds between two successive vehicles sorted in a similar matrix. The row of a matrix element indicates the actual vehicle type and the column the next one. Elements (3,1) or (4,1) indicate, for example, cars (type 1) waiting impatiently for an opportunity to overtake trucks, as the modal value of the distributions in these elements is remarkably low. If n sequences of vehicles are to be taken into account, the matrix becomes n-dimensional.

With these data, an artificial traffic stream can be generated using the Monte Carlo method. A random generator generates vehicle types that always consider the most recent sequence generated on the basis of the densities shown in Figure 16. Temporal distances are chosen according to the densities in Figure 17. The actual load of a vehicle is then randomly determined on the basis of the corresponding density of the forecast vehicle type.

4.2.2 Strain-generating procedure

Although it is not a typical question of load generation, a few remarks are given about the generation of adjacent strains in a structure, e.g., a bridge [24]. The structure is usually modeled by the FEM

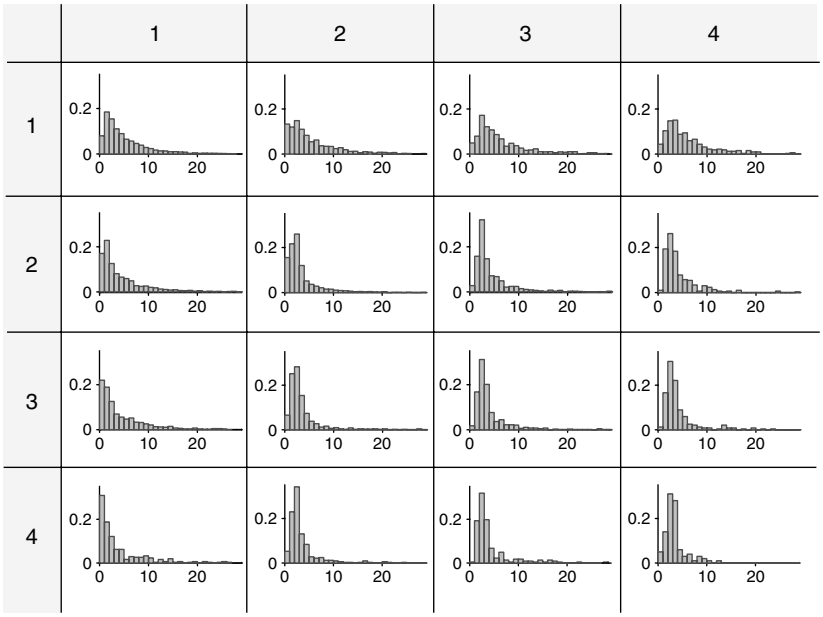

Figure 17. Matrix of temporal distance densities (time in [s]).

(Figure 18). In a preceding modal analysis, eigenvalues and eigenmodes are extracted as inputs to the iterative solution scheme. The different types of vehicles are idealized as damped 2-mass systems for each wheel. They consist of a wheel mass, a mass containing the corresponding part of vehicle body and payload, spring and damper between both, and another spring representing the tire tangent stiffness (Figure 19).

It should be noted that the use of the modal method implies that the passing vehicle masses are small compared with the structure mass because the vehicle masses are not included in the system modal parameters. If the loads are high (e.g., railway) and the bridge is short, i.e., light, then an expensive full time history calculation may be necessary.

A large number of measurements show that it is permissible to define the roughness of roadway surfaces to be a Gaussian, stationary, and ergodic process characterized by a power spectral density function. In [25] the exponential function

$$\phi(\Omega) = \phi(\Omega_0) \cdot \left(\frac{\Omega}{\Omega_0}\right)^{-w} \tag{7}$$

was proposed. Equation (7) describes the PSD by a reference frequency Ω_0 and the dimensionless

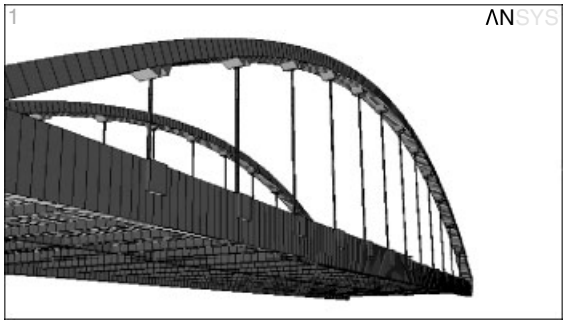

Figure 18. Finite-element model.

waviness w. Figure 20 shows some PSD functions of pavements of different conditions [24].

For use in numerical simulations, a discrete realization of a roughness function is needed. This realization can be generated from a finite Fourier series with random phase, where the amplitude $\hat{u}_i$ of each Fourier term is determined (equation 8) in accordance with the spectrum

$$\hat{u}_i = \sqrt{2 \cdot \Delta\Omega_i \cdot \phi(\Omega_i)} \tag{8}$$

Owing to the higher intensity of roughness at low circular frequencies (larger wavelengths), the smaller frequency interval $\Delta\Omega_0$ is chosen at this

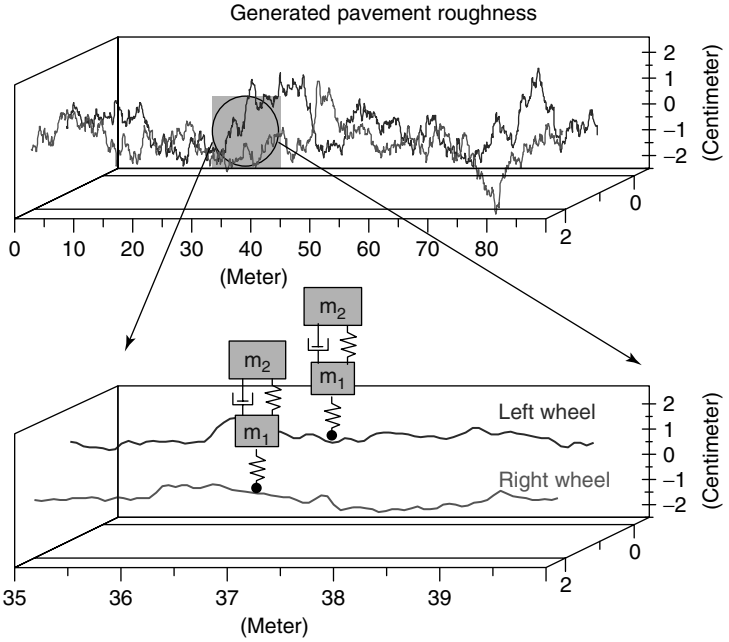

Figure 19. Wheels as 2-mass systems.

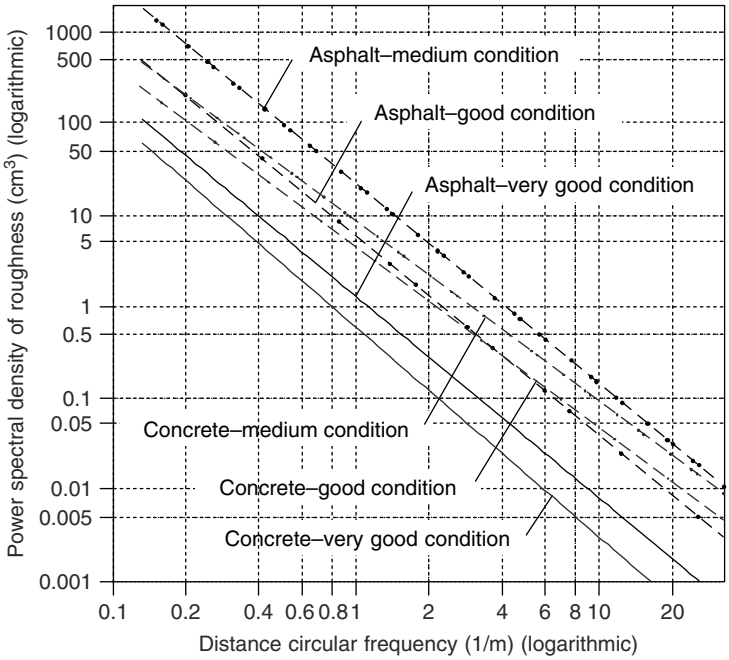

Figure 20. Power spectral densities.

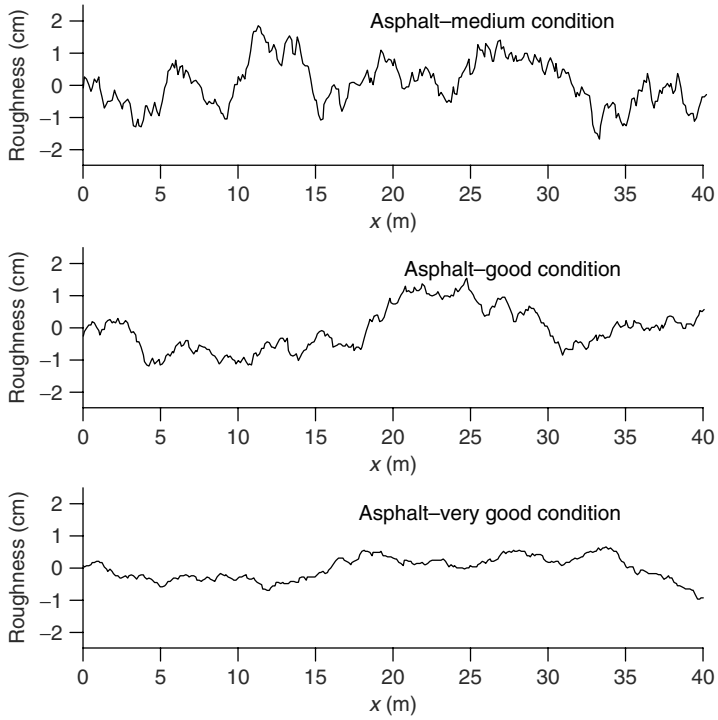

Figure 21. Pavement roughness profiles.

point. Figure 21 shows three generated roughness profiles as an example.

Because the system changes at each time step, the submodels of the bridge and vehicles must be treated separately. The coupling forces of both systems are calculated and an iteration must be performed until the Euclidean norm of the changes of the interactive forces fall below a given threshold. The solution of this iteration is saved for each time step in modal coordinates. Subsequently, displacements, velocities, accelerations, or stresses can be calculated from these data for nodes that are of particular interest.

4.3 Wind models

4.3.1 Introduction

The natural wind is the most important loading case for tall structures like skyscrapers, towers, masts, and chimneys. The wind process is highly dynamical, and the wind forces change in time and in space due to the roughness-induced gusts or turbulence [4]. In many codes, the wind load is statically modeled on the basis of an envelope of the maximum-gust wind speed. This assumption is on the safe side for freestanding structures, as it is the worst-case loading. Thus, it cannot be used for the assessment of the lifetime of a structure.

Because of the time-dependent wind forces, slender structures respond with vibrations. Furthermore, even a gust-free, laminar wind can excite vibrations. Examples are vortex-induced or self-excited vibrations like galloping or flutter. The latter occur if the structure is not rigid, but can respond to wind effects with deformations [4]. The structure itself may then control the wind force and the problem becomes aeroelastic. Since these events may cause long lasting vibrations with large amplitudes, they could cause structural collapse or early fatigue damage. Thus, they must be prevented, e.g., by adding damping to the structure. They do not play a significant role in SHM and thus will not be discussed here.

Vibrating structures, especially those made of steel, are prone to fatigue, even if the stresses are very

much lower than the yield stress. Thus, the adequate description and modeling of the stochastic turbulent wind process is a prerequisite for a lifetime assessment of a structure.

4.3.2 Models for gust-induced vibration

Description of the wind process

The natural wind changes in time and space. One can illustrate the process by imagining that a constant flow between high- and low-pressure zones is superimposed by wind balls (gusts) of any diameter and rotation direction near the rough earth surface. The rougher the surface, the more turbulent or gusty the wind is and vice versa. Figure 22 shows a measured wind profile. It is obvious that the wind speed increases with height.

The time record of a wind speed is normally split up into two parts: the mean wind speed and the superimposed fluctuating part due to turbulence (equation 9):

$$u(z,t) = \overline{u}(z) + u'(z,t) \tag{9}$$

Figure 23 describes the situation: the actual wind speed is the sum of the mean wind speed and the superimposed gusts.

The increasing profile of the mean wind with height can be described by a logarithmic or a power law [2, 26]. Both profiles are rather similar at lower heights (<100 m); over 100 m the power law is closer to reality [27]. The logarithmic law reads (equation 10)

$$\overline{u}(z) = \overline{u}(10) \cdot \frac{\ln \dfrac{z}{z_0}}{\ln \dfrac{10}{z_0}} \tag{10}$$

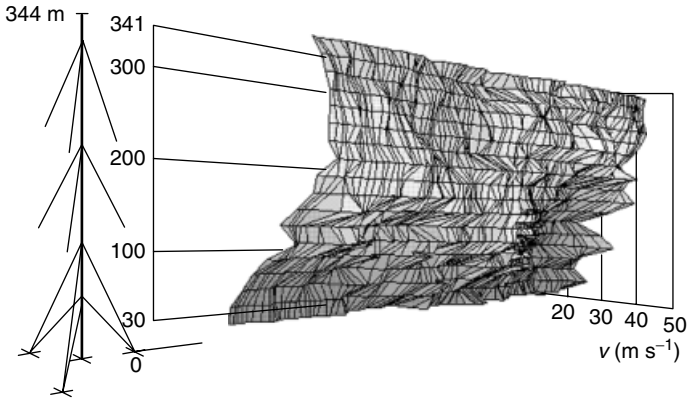

Figure 22. Wind field measured over 20 s.

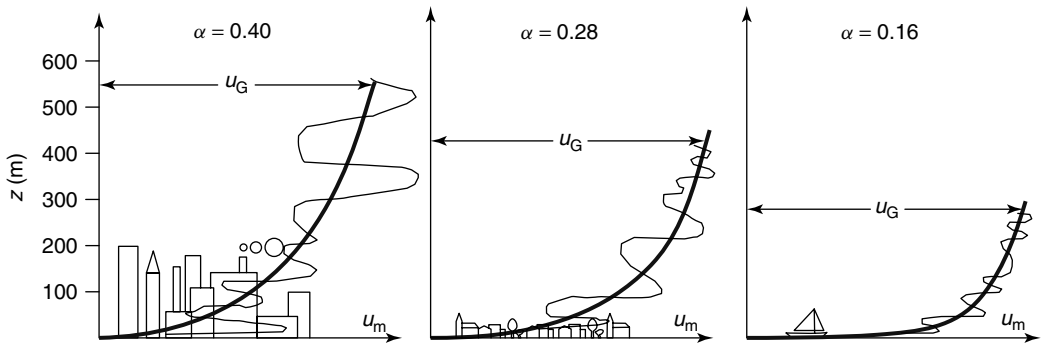

Figure 23. Wind speed depending on roughness and height.

z is the height at which the speed should be determined, and z_0 is a so-called roughness height depending on the roughness of the surface (Table 1). $u_m(10)$ is the mean reference speed at 10-m height, usually given by codes or meteorologists. For greater heights, the power law is closer to reality, and it reads as follows (equation 11):

$$\overline{u}(z) = \overline{u}(10) \cdot \left(\frac{z}{10}\right)^{\alpha} \tag{11}$$

where α is an empirical exponent depending on the roughness on site; its value can be taken from Table 1 [28].

If the influence of the changing roughness is to be investigated in more detail, the mixing of profiles must be taken into account [29, 30]. In the framework of this short article, no more details can be provided.

The turbulent wind is a stochastic process. For the lifetime assessment of a (vibrating) structure, the statistical input must be known. As already mentioned, the wind process is split up into a constant mean wind speed and a fluctuating speed. The structure response due to the mean wind speed is purely static. The remaining fluctuating part of the wind process results in stochastic random vibrations of the structure. It is not the aim of this article to deal with the problems of random vibrations; for a description of these, the reader is referred to, e.g. [31]. This article discusses just the stochastic load characteristics.

Table 1. Description of the terrain category

Terrain category	Description	z_0 (m)	α	ε	z_{min}
I	Open sea, lakes with minimum 5-km free area in wind direction, flat country without obstacles	0.01	0.13	0.13	2
II	Terrain with fences, single farm houses, trees, agricultural terrain	0.05	0.16	0.26	4
III	Suburbs, industrial or trade areas, forests	0.3	0.22	0.37	8
IV	Cities with a minimum 15% of built-up area with buildings with a mean height more than 15 m	1	0.3	0.46	16

Figure 24 shows three records of measured wind speeds. The passing gusts cause a correlation between the wind speed record at a certain height level and between the speeds of neighboring levels. The correlations can be described by auto- and cross-correlation functions. Figure 25 shows auto- and cross-correlation functions as an example. The symmeric function is the autocorrelation $R_{xx}(\tau)$ of the record at level a. The skew functions are the cross-correlations $R_{xy}(\tau)$. The broader the correlation function, the longer the signals are correlated, the larger the mean gusts. The maxima of the cross-correlation functions are shifted a little. The time shift indicates the time difference a gust needs to reach the other level. Figure 24 illustrates this correlation. The increase of wind speed indicates a gust. The height level 66 m is hit by a gust at about 50 s. The height level 30 m is reached by the same gust due to the ball shape about 4 s later, and both functions show the largest correlation if they are shifted by 4 s.

The auto- and the cross-correlations decrease with increasing time or distance. This trend is the consequence of the limited gust diameter. The value of the autocorrelation function at $\tau = 0$ is the variance

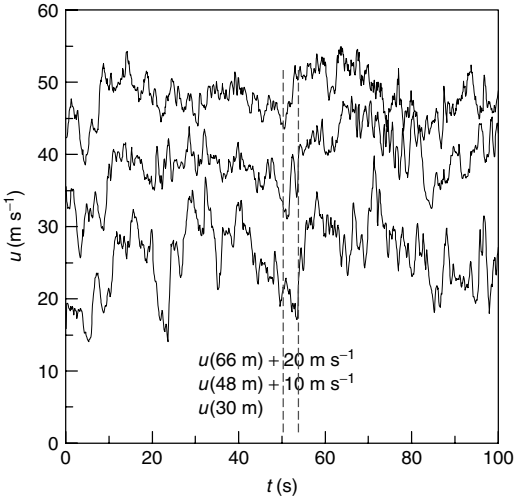

Figure 24. Wind speed records.

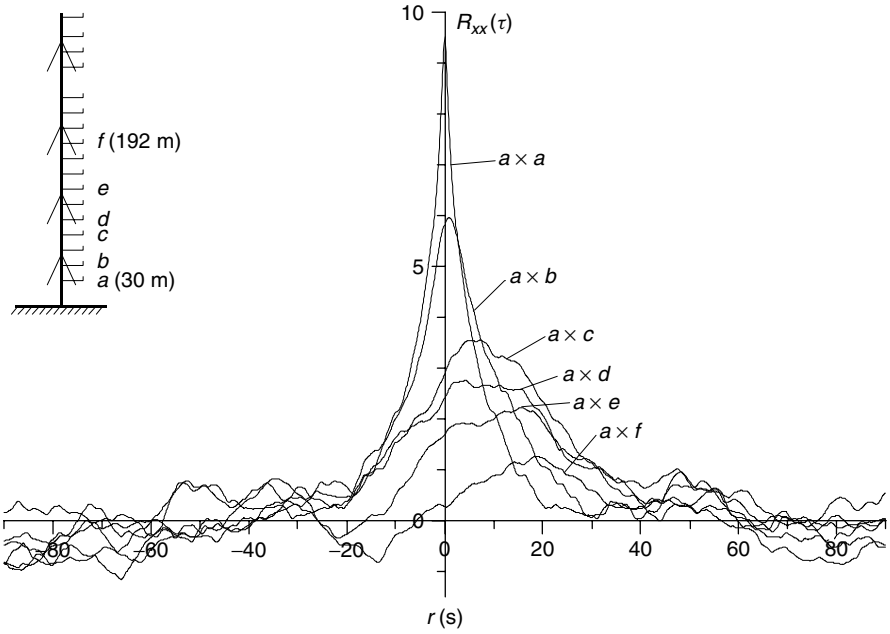

Figure 25. Measured auto- and cross-correlations.

of the stochastic wind process. For more information about the determination and interpretation of correlation functions, see e.g., [32].

If the correlation functions are Fourier-transformed into the frequency domain, the PSD function S_u is obtained (Wiener–Khintchine relation). An estimation of the PSD can be obtained by taking the Fourier transform of the measured records and then squaring the resulting PSD. A PSD describes the frequency-dependent variance of the stochastic process. The integral over the whole PSD gives the variance of the stochastic wind process.

In the past, many PSD functions S_u have been proposed [4, 26, 27]. Some of them are based on physical background, some are empirical functions, and others are limited to small heights (Figure 26). In this article, it is not possible to go into the details of the PSD functions.

The Eurocode [28] prescribes a PSD as follows (equations 12 and 13):

$$R_N = \frac{f_{1,x} \cdot S_u(n_{1,x})}{\sigma_u^2} = \frac{6,8 \cdot N_{1,x}}{(1 + 10,2 \cdot N_{1,x})^{5/3}} \tag{12}$$

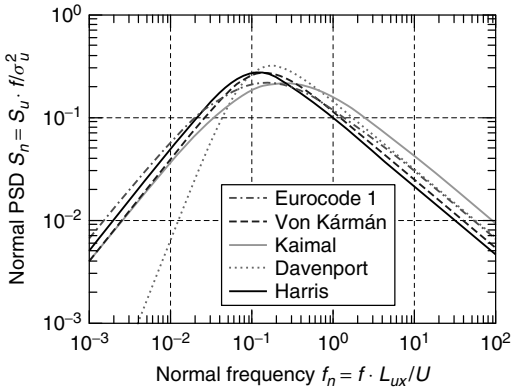

Figure 26. PSD of wind speed.

with

$$N_{1,x} = \frac{f_{1,x} \cdot L_{\mathrm{i}}(z_{\mathrm{eff}})}{\overline{u}(z_{\mathrm{eff}})} \tag{13}$$

where $f_{1,x}$ is the lowest eigenfrequency of the structure, ${\sigma_{\mathrm{v}}}^2$ is the variance of the wind process, $u_{\mathrm{m}}(z_{\mathrm{eff}})$ is the mean wind at the effective height z_{eff}, and L_{i} is the integral length scale. The integral length

scale is the mean gust diameter. It is assessed by integrating the autocorrelation function, i.e., determining the area under the function. This value is divided by the maximum at $\tau = 0$ (equation 14). The resulting rectangle has the same area as the autocorrelation function.

$$L_{\mathrm{i}}(z) = \frac{\int_{\tau=0}^{\infty} R_{xx}(\tau) \cdot \mathrm{d}\tau}{R_{xx}(0)} \tag{14}$$

The integral length scale L_{i} results from (equation 15)

$$\begin{aligned} L_{\mathrm{i}}(z) &= 300 \cdot (z/300)^{\varepsilon} \quad (L_{\mathrm{i}}, z \text{ in meter}) \\ &\qquad \text{for } z_{\min} \le z \le 300 \text{ m} \\ L_{\mathrm{i}}(z) &= 300 \cdot (z_{\min}/300)^{\varepsilon} \quad (L_{\mathrm{i}}, z_{\min} \text{ in meter}) \\ &\qquad \text{for } z \le z_{\min} \\ L_{\mathrm{i}}(z) &= 300 \text{ m} \quad \text{for} \quad z \ge 300 \text{ m} \end{aligned} \tag{15}$$

with

ε ... Exponent, (Table 1)

$z_{\min}$ (Table 1).

The variance ${\sigma_{\mathrm{v}}}^2$ of the wind process can be determined from the turbulence intensity I_u, which is defined to be the variation coefficient of the stochastic process (equation 16):

$$I_u(z) = \frac{\sigma_u(z)}{\overline{u}(z)} \tag{16}$$

This function can be expanded as follows (equation 17):

$$\begin{aligned} I_u(z) &= I_u(10) \left(\frac{z}{10}\right)^{-\alpha} \\ I_u(10) &= \frac{1}{\ln(10/z_0)} \end{aligned} \tag{17}$$

The turbulence intensity is provided in the codes [28, 30]. It should be noted that all codes present values for the maximum wind load situation. If—for lifetime assessment calculations—even lower wind speeds are taken into account, the values should be used with some reflection. In [27] values of nonextreme wind situations are given.

If the structure is hit by a turbulent wind at more than one point (which is usual), then the cross-correlations between the wind processes between these points become important. Coherence is introduced as a dimensionless characteristic number of the correlation of two spectra. It is given by (equation 18):

$$\gamma_{i,j} = \sqrt{\frac{|S_{i,j}(f)|^2}{S_i(f) \cdot S_j(f)}} \tag{18}$$

In practical cases, the auto-PSD is available from codes, but not the cross-PSD. Thus, the coherence must be determined on the basis of a proposal from Davenport [33] (equation 19):

$$\gamma_{ij}(f) = \mathrm{e}^{-\frac{f \cdot C \cdot \Delta z}{\overline{\mathrm{u}}_{10}}} \tag{19}$$

For the so-called decay constant, C, values between 5 and 12 are used. The coherence can be determined in any direction of space. In such cases, the coordinate Δz must be replaced by Δx or Δy. The decay constants depend on the direction [4, 26]. In equation (19), f is the frequency and $\overline{\mathrm{u}}_{10}$ the mean wind speed at 10-m height.

With the known coherence, the cross-PSD can now be determined (equation 20):

$$S_{ij} = \gamma_{ij}(f) \cdot \sqrt{S_i(f) \cdot S_j(f)} \tag{20}$$

For a structure with more than one point under wind loading, the auto- and cross-PSD are written in a spectral matrix. Equation (21) gives an example for three loaded points (Figure 27).

$$S_{ij}(f) = \begin{bmatrix} \tilde{\mathrm{S}}_{11} & \tilde{\mathrm{S}}_{12} & \tilde{\mathrm{S}}_{13} \\ \tilde{\mathrm{S}}_{21}^{*} & \tilde{\mathrm{S}}_{22} & \tilde{\mathrm{S}}_{23} \\ \tilde{\mathrm{S}}_{31}^{*} & \tilde{\mathrm{S}}_{32}^{*} & \tilde{\mathrm{S}}_{33} \end{bmatrix} \tag{21}$$

The tilde shows that the elements are complex values and the star indicates the conjugated complex values.

In the next step, the wind force must be calculated from the wind speed. Slender, linelike structures are usually investigated under the assumption of a

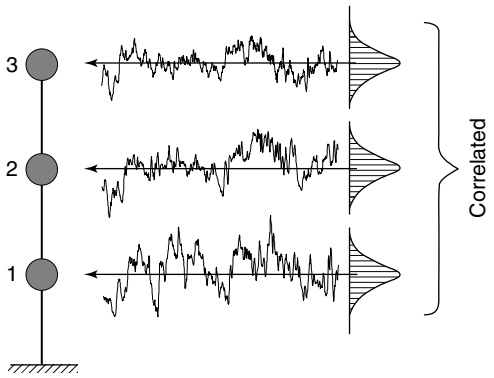

Figure 27. Structure with three correlated wind attacks.

quasi-steady theory (equation 22):

$$F_{\mathrm{w}}(t) = \frac{\rho}{2} \cdot C \cdot A \cdot u(t)^2 \approx \frac{\rho}{2} \cdot C \cdot A \cdot \overline{\mathrm{u}}^2 + \rho \cdot C \cdot A \cdot \overline{\mathrm{u}} \cdot u'(t) \quad (22)$$

Wind forces due to quadratic terms are neglected. This model simplifies in practice because it assumes that all wind gusts are equally transferred into wind forces. Owing to different gust diameters, which could be interpreted as different frequencies, the transfer function is frequency dependent. The smaller the gusts, the lower the resultant wind force, and the faster the gusts pass, the higher the frequency [4, 34]. Thus, the aerodynamic coefficient in the second part of equation (22) decreases with the frequency. To calculate the PSD of the wind forces, the PSD of the wind speed turbulence must be multiplied by the aerodynamic transfer function $\chi_{\mathrm{aero}}(f)$ (equation 23):

$$S_{\mathrm{iw}}(f) = (\rho \cdot C \cdot A \cdot \overline{\mathrm{u}})^2 \cdot \chi_{\mathrm{aero}}(f)^2 \cdot S_i(f) \quad (23)$$

Investigation in the frequency domain

To analyze the effects of wind loading in the frequency domain, the wind process is decomposed into a mean wind speed and the superimposed fluctuating part due to turbulence (equation 24):

$$w(z,t) = \overline{w}(z) + w'(z,t) \quad (24)$$

The determination of the system response under the static mean wind force $\overline{w}$ is performed by a static calculation and results in a static response $\overline{A}$.

The second step is the determination of the system response to the dynamic stochastic process. The dynamic behavior of the vibrating system can be described in the frequency domain by its mechanical transfer function [35]. Although this is not what this article focuses on, the methodology is briefly summarized. The transfer function is determined by calculating the steady dynamic response of a state variable of a structure under a variable harmonic load with constant frequency. If the calculation is performed for every single frequency in the range of interest, the dynamic transfer function for this state variable is obtained. The calculation is performed with standard dynamic analysis methods.

Multiplication of the PSD of the wind load $S_{\mathrm{W}}(f)$ and the dynamic transfer function results in the PSD of the response (equation 25):

$$S_A(f) = |H(f)|^2 \, S_{\mathrm{W}}(f) \quad (25)$$

If the mechanical transfer function is determined for a state variable deflection or for an internal force, the PSD of the response describes a deflection or an internal force. Because of the influence of the square of the mechanical transfer function, resonance peaks have a considerable effect on the response PSD. As the integral of the wind speed, PSD is equal to the variance of the wind speed process, the integral over the response PSD is equal to the variance of the response process (equation 26). The whole procedure is graphically described in Figure 28.

$$\sigma_A^2 = \int_0^\infty S_A(f) \, \mathrm{d}f \quad (26)$$

The overall response can then be determined by addition of the result of the static solution under mean wind and the dynamic response under turbulent wind (equation 27).

$$A = \overline{\mathrm{A}} + g \cdot \sigma_A \quad (27)$$

The so-called peak factor g depends on the level of probability of occurrence of the peak values; for extreme wind situations it is usually chosen to be about 3.5. If lower wind speeds are under investigation, the factor is different.

If structures with more than one degree of freedom are to be investigated, the influence of the cross-spectra must be taken into account. Equation (25) becomes a matrix formulation in these cases. The

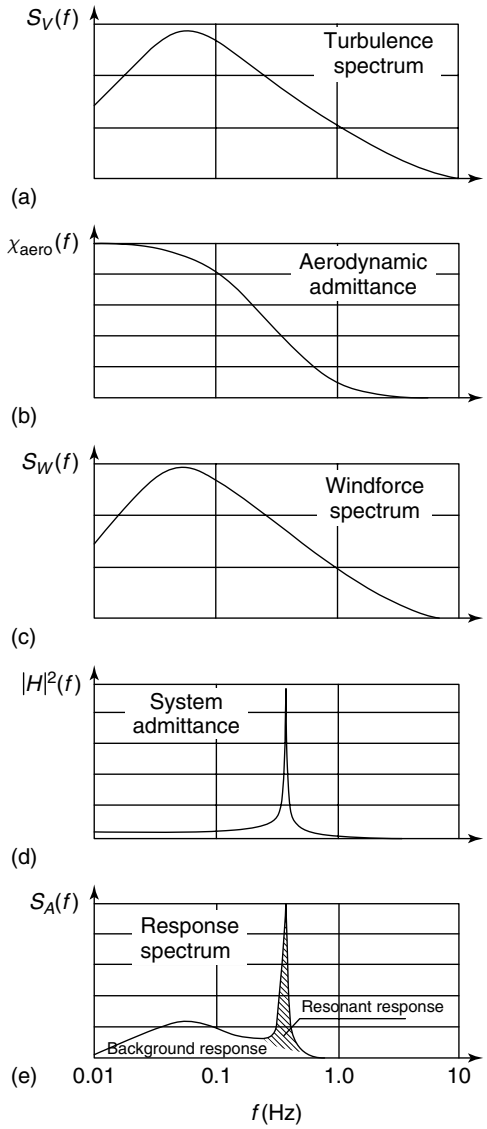

Figure 28. Procedure for the determination of turbulent wind effects.

general procedure is very similar, and is discussed in more detail in [35].

Owing to the assumption that the response contributions at all frequencies can be superimposed, the frequency-domain method is restricted to linear systems. If the nonlinearities are small, they often can be taken into account by means of linearization. For this purpose, the nonlinear response of the mean wind load situation is calculated taking into account the nonlinearities by means of a nonlinear static calculation. The system parameters of the state under mean wind are then used for a linear dynamic calculation, resulting in a tangential vibration around the operation point (Figure 29) with W as a wind force and f as a deflection. If the nonlinearities are small, the deviation from the real solution is small.

Investigation in the time domain

Investigations in the time domain are performed if structural nonlinearities (caused, for instance, by cable sag of guyed structures, certain material nonlinearities, etc.) play a significant role. Any time domain calculation requires that time-dependent forces be defined, i.e., wind forces. The wind forces are determined from the wind speeds, usually neglecting the influence of the frequency-dependent aerodynamic transfer function, because it is defined in the frequency domain and not in the time domain. If this influence is to be taken into account, fitted indicial functions calculated from the frequency-dependent aerodynamic transfer function can be used [36]. For the generation of an artificial wind speed record, the whole wind process is split up into a constant mean wind speed part and a fluctuating one. The following derivation is focused on the fluctuating part. The total wind speed record is then achieved by superimposing the mean wind speed to the fluctuating part.

The process of generating artificial wind speed records begins with a given statistical input that satisfies the total wind speed record. Input parameters include the variance of the process, the mean wind speed, the PSD, and the decay factors of the coherence functions.

For the generation of wind speed records, many numerical procedures are available:

- superposition of harmonic waves with different amplitudes and stochastic phases;
- filtering of a white noise with autoregressive filter (AR, ARMA models);
- data composition by means of wavelets.

Each method has its advantages and disadvantages. ARMA models required large storage space in the computer, but they are very fast. Wave superposition, on the other hand, requires more CPU time, but less storage space. The effectiveness of ARMA models strongly depends on the filter order and the chosen

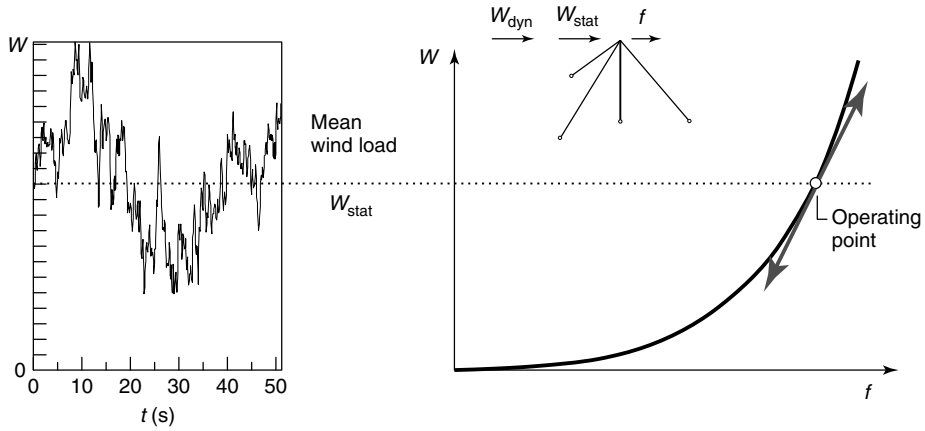

Figure 29. Linearization around the operating point.

time step. The wave superposition method seems to generate time records that correspond better to the statistical input values. Thus, the wave superposition method is explained in more detail; it is based on a fast algorithm [37, 38].

The wind speed time history at node j results from a type of cascade algorithm, starting from the wind process at node i, which depends only on its autospectrum. The wind speed process $u'_j(t)$ at every other node is generated by the addition of another independent process (equation 28).

$$u'_j(t) = \sum_{m=1}^{j} \sum_{n=1}^{N} |H_{jm}(f_n)| \cdot \sqrt{2 \cdot \Delta f} \cdot \cos(2\pi f_n t + \Theta_{jm}(f_n) + \Phi_{m,n}) \tag{28}$$

$|H_{jm}(f_n)|$ are the amplitudes of the harmonic components at node j, which could be determined from the spectral density matrix via a Cholesky decomposition. The elements $H_{jm}(f_n)$ must meet the condition (equation 29)

$$\mathbf{S}(f) = \mathbf{H}(f) \cdot \mathbf{H}^{*\mathrm{T}}(f) \tag{29}$$

In equation (28) Δf is the frequency distance between the discrete frequencies f_n and f_{n+1}. The phase angle Θ results from the complex cross-PSD and can be determined from the imaginary and real parts of $H_{jm}(f_n)$ by means of equation (30):

$$\Theta_{jm} = \arctan \frac{\Im\{H_{jm}(f)\}}{\Re\{H_{jm}(f)\}} \tag{30}$$

The spectral density matrix for this purpose is usually set to be real. Only a phase angle of $\Theta = 2 \cdot \pi \cdot f \cdot \Delta x / \bar{u}$ is taken into account (Taylor's hypothesis) in equation (28). The phase angle $\Phi_{m,n}$ of the mth process with frequency f_n in node j is a uniformly distributed random number between 0 and 2π.

The superposition of the harmonic components is performed with much less effort if it is done in the frequency domain. A summation over all components m results in a Fourier transformation of the time history in node j (equation 31):

$$c_j(f_n) = \sum_{m=1}^{j} |c_{jm}(f_n)| \cdot \mathrm{e}^{-i(\Theta_{jm}(f_n) + \Phi_m(f_n))} \tag{31}$$

The back transformation into the time domain yields (equation 32):

$$u_j(t) = \sum_{k=0}^{N-1} c_j(f_n) \cdot \mathrm{e}^{i2\pi nk/N} \tag{32}$$

If the number of Fourier coefficients is a power of 2, the calculation can be accelerated using the algorithm of Cooley and Tukey [39]. The amplitude of the harmonic wave with frequency f_n of the wind

component of the node m in node j can be determined by equation (33):

$$|c_{jm}(f_n)| = \frac{1}{2} \cdot |H_{jm}(f_n)| \cdot \sqrt{2 \cdot \Delta f} \qquad (33)$$

The factor 1/2 results from the spectral function defined over the whole two-sided frequency band up to the frequency of

$$f = \frac{N-1}{T} \qquad (34)$$

with N equal to the number of discrete values in the time domain and T equal to the length of the time record (equation 34).

The real and imaginary parts of the Fourier coefficients of the component m in node j are (equations 35 and 36):

$$\begin{aligned} \Re\{c_{jm}(f_n)\} &= 2 \cdot |c_{jm}(f_n)| \cdot \cos(\Theta_{jm}(f_n) \\ &\quad + \Phi_m(f_n)) \\ \Im\{c_{jm}(f_n)\} &= 2 \cdot |c_{jm}(f_n)| \cdot \sin(\Theta_{jm}(f_n) \\ &\quad + \Phi_m(f_n)) \end{aligned} \qquad (35)$$

with

$$c_{jm}(f_n) = \frac{1}{2} \cdot (\Re\{c_{jm}(f_n)\}) - \mathrm{i} \cdot \Im\{c_{jm}(f_n)\} \qquad (36)$$

Use of the Euler identity $\mathrm{e}^{-ix} = \cos(x) + i \cdot \sin(x)$ results in the complex Fourier coefficients (equation 37):

$$c_{jm}(f_n) = |c_{jm}(f_n)| \cdot \mathrm{e}^{-i(\Theta_{jm}(f_n)+\Phi_m(f_n))} \qquad (37)$$

2^M points in the time domain result in $2^{M-1} + 1$ points in the frequency domain. Compared with a pure time domain calculation as it is usually performed, a reduction of about 10 s in the CPU time is achieved using this method.

If the node distances are fairly large, a reduction of the wind loads at the nodes of interest due to the decreasing correlation can be taken into account [38].

The computation results in a couple of correlated wind speed records, which are used as inputs for a time domain calculation (Figure 27).

Finally, the mean wind speed at the different sites must be superimposed.

5 CONCLUSIONS

Any monitoring measure needs actions or loads to produce strains in the structure to be monitored. In this article, advice and references are given for the right choice of actions or loads and how to model these loads. Two types of loads are generally necessary for SHM measures. At the beginning of the SHM procedure, precise system identification is usually needed to adjust the theoretical model of the structure or parts of it. If a life time prediction of the structure should be performed, other types of load models must be used, which take into account the probability of occurrence of realistic load situations. Both types are discussed.

In this article, only traffic and wind load models are discussed in detail. Unexpected loads such as earthquakes, blasts, etc., cannot be predicted very accurately; thus, a lifetime assessment is not feasible. A similar situation exists with wind-induced vibrations, e.g., due to vortex shedding, galloping, flutter, etc. These vibrations are usually always dangerous for a structure and may cause heavy fatigue or other types of damage; therefore, wind-induced vibrations must be prevented rather than predicted.

Chapter 8
Static Damage Phenomena and Models

Shankar Sundararaman
Ray W. Herrick Laboratories, Purdue University, West Lafayette, IN, USA

1 INTRODUCTION

Models are used to describe the state of a structural material/component using a mathematical relationship based on observed measurement data and/or physics-based laws. Structural models can be classified as follows: (i) static and dynamic models, (ii) time and frequency-domain models, (iii) linear and nonlinear models, (iv) elastic, viscoelastic, plastic, and viscoplastic models (material-based), (v) micro, meso, and macromechanical models, and (vi) analytical models including three-dimensional elastic, plane strain, and plane stress models, empirical and numerical models such as finite element, finite difference, boundary element, and cellular models. A detailed description of different types of structural models is given in [1].

Damage phenomena can be analyzed using either static or dynamic models. Dynamic damage models trace the growth and retardation of damage. The use of static damage models enables the study of the structural response to damage while freezing variations due to damage growth and/or retardation. By solving the structural inverse problem, measurement data can be used to extract physical and modeling parameters that change due to damage.

Most structural models are based on an assumption of linear elasticity, which indicates that the stress is independent of the loading history [1]. Viscoelastic models are based on a cumulative loading history. Both elastic and viscoelastic models are limited to small deformations. Plasticity theory typically incorporates large deformations, usually past the yield criterion, through the use of a deviatoric stress tensor in addition to elastic volumetric stress, kinetic strain hardening, isotropic strain hardening, and other quantities. Additionally, plasticity theory describes physical mechanisms associated with irreversible behavior

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

observed in real structures, such as loading and unloading conditions leading to different structural states, due to changes in dislocation densities. From a design viewpoint, plasticity is concerned with identifying the maximum load that a structure can sustain without excessive yielding [2]. Material phenomena observed in other types of materials often reside outside the scope of plasticity theories that incorporate plastic anisotropy, martensitic states, time and temperature-dependent plastic strained materials (viscoplastic), elastic hysteresis, and directionality of strain hardening. Some details regarding these concepts are outlined in **Damage Evolution Phenomena and Models** [2, 3].

In the simplest description, the loss of structural integrity and reduction in performance can be identified on the basis of the sensory perception that a detrimental mechanical change has occurred. This perception can be visual/optical (for example, large cracks), sonic (for example, brake squeal), tactile (for example, surface roughness), or olfactive (for example, malodorous gas leaks). However, the concept of structural integrity as diagnosed by these conventional techniques is limited to identifying only when a component has failed or can no longer be reliably used. The need for developing objective indicators to improve safety and reliability of component operation, lower costs, facilitate maintenance scheduling, and monitor inaccessible structural locations resulted in the development of several nondestructive techniques. Physics-based structural models facilitate the continued and iterative development of these techniques by reconciling the input and response parameters from the experimentally observed phenomena. The parameters monitored and the structural model studied is ultimately dependent on the nondestructive technique used for structural diagnostics.

1.1 Static damage models

Broadly, the following macrostructural damage and defect phenomena are of interest:

1. Metals—corrosion, cracks (*see* **Free and Forced Vibration Models**, Figure 21), dents, manufacturing imperfections, residual stresses, inclusions, and fatigue damage (*see* **Free and Forced Vibration Models**, Figure 12);
2. Composites, laminated or otherwise—delaminations, debonds, fiber pullout, fiber breakage, and matrix cracking.

These damage types are typically identified in the literature by monitoring variations in geometrical dimensions, density, elastic modulus, damping, cyclic stress amplitude, wave speed, impedance, microhardness (a quantity based on durability and small-scale shear modulus), and/or electrical resistance changes [3]. Each of these monitored quantities produces different levels of effectiveness in identifying brittle, ductile, creep, and fatigue damage. Surveys of models presented in the literature that describe the cumulative effects of fatigue damage on metals and composites are provided in [4, 5].

It is important to emphasize that "static" damage can be monitored using static analysis methods such as geometrical measurement and microhardness measurements, as well as strain and dynamic analysis techniques such as standing wave/vibration methods and traveling wave methods. The term "static damage" is typically used to refer to electrostatic-induced damage or damage caused by static loads [6]. Here, the term is used in a more general sense to refer to all damage models that do not consider growth and retardation of damage. Static damage models can be classified as geometrical (associated with spatial changes, including, length, width, thickness), material (associated with modulus, density, damping), thermodynamic (humidity, temperature), and electromagnetic (resistivity, permittivity) models. The focus of most structural models is on geometrical and/or material parameters, while the thermodynamic quantities are usually classified as environmental factors. However, there has been increasing emphasis in the incorporation of thermodynamic and electromagnetic factors in structural health monitoring damage models to reduce model uncertainty.

Apart from damage types, damage models are also developed on the basis of the nondestructive testing measure administered to identify damage. Other factors that drive the use of static damage models include the form of the measured data including strain, pressure, and acceleration, and the instrumentation used including strain gauge, accelerometer, laser vibrometer, linear variable differential transformer, rotary variable differential transformer, force transducer, pressure transducer, thermocouple,

Table 1. Schematic of material and geometrical changes associated with different static damage types (adapted from [7])

Damage	Material	Geometrical model	Material model
Corrosion, oxidation	M	Thickness reduction	Density and/or stiffness change
Cracks, notch	All	Moment of inertia, cross-sectional area reduction	Local damping and impedance change
Buckling	All	Moment of inertia, cross-sectional area reduction	Global impedance reduction.
Creep	All	Geometrical distortion	Modulus change
Fastener preload loss; joint loosening	All	Cross-sectional area, length change	Impedance (stiffness)
Plastic deformation	M	Geometrical distortion	Stiffness and mass change
Microstructural degradation	All	Not applicable	Local modulus and damping change
Fiber pullout	LC	Fiber separation (gaps in fiber length)	Damping, stiffness, and density change
Fiber breakage	LC	Fiber distortion (changes in position of fibers)	Damping, stiffness, and density change
Matrix cracking	LC, Ce	Not applicable	Damping, stiffness, and density change
Debonding	Co, LC, Ce	Layer separation (thickness change)	Impedance reduction
Delamination	Co, LC	Local layer separation (thickness change)	Impedance change

M, Metals and alloys; LC, Laminated composite; Ce, Ceramic; Co, Generic orthotropic and composite materials (metallic/ceramic/LC); All = M, LC, Ce, Co.

hygrometer, electromagnetic sensors, X-ray radiographs, infrared cameras, and tomograms. Material models can be further divided into material property models that describe individual changes in physical parameters and impedance models. In all instances, there are changes in the stresses and strains that are manifested as changes in the material property matrices. Some of the methods used for modeling different damage types are described in Table 1. More details of geometrical and material models of some of these damage types are provided in [7]. Although these models provide an idea of the effect of a particular type of damage, the lack of information of modeling parameters because of uncertainties in the material stiffness properties, extent of material anisotropy, spatial spread of defects, and defect shape often results in insufficient modeling accuracy.

Defect types, mechanisms, and static damage models along with suitable references to the literature and some details of the historical background are provided in the remainder of this article.

2 DAMAGE DETECTION USING NONDESTRUCTIVE TECHNIQUES

The development of structural models can be traced to the need for information on the necessary geometrical and material parameters such as stiffness and mass density that ensure safety and structural integrity. A historical background of structural models from the time of Archimedes to the middle of the twentieth century is provided in a review book by

Timoshenko [8]. This book covers development of static and dynamic models associated with elasticity, material fatigue, brittle fracture, bending, elastic stability, impact, and vibrations. More recent overviews of dynamics-based structural diagnostic methods for wave propagation (*see* **Fundamentals of Guided Elastic Waves in Solids**) and vibration (*see* **Free and Forced Vibration Models**) methods are provided in **Damage Measures** and in the literature review articles by Doebling *et al.* [9] and Sohn *et al.* [10]. In general, both static and dynamic-based structural models make use of changes in mechanical properties associated with geometry, stiffness, mass density, and/or damping to model and diagnose damage.

Handbooks on nondestructive testing [11, 12] provide an overview with chronological developments of conventional nondestructive testing measures such as magnetic particle inspection, radiographic testing, ultrasonic inspection, eddy-current testing, thermal infrared, and acoustic emission (AE). In these methods, parametric changes associated with elastic properties (stiffness), tensile properties (yield strength, ultimate tensile strength, fatigue endurance, ductility), hardness, fracture toughness, impact resistance, stress intensity factor, S–N curves, creep range, thermal properties (specific heat, thermal expansion, thermal conductivity, thermal diffusivity), electrical properties (resistivity, permittivity, flux), and optical properties (spectral absorption, refractive index) are monitored [13]. Additionally, loading (*see* **Civil Infrastructure Load Models for Structural Health Monitoring**), environmental (temperature, pressure, humidity), and boundary conditions are also monitored to get a complete picture of structural integrity. A summary of some of the structural and damage models used in nondestructive tests is provided in Table 2. More details with a brief literature review are provided in the subsections that follows the description below.

It is evident that in most of these tools, damage is correlated to a visible change in a geometrical parameter. Most of the other parameters can be directly or indirectly related to the material properties of the structure such as mass, stiffness, or damping. For example, electrical equivalent circuits can be constructed wherein a transmission line model is used to describe electromagnetic wave propagation through layers having different capacitance (equivalently stiffness), inductance (mass), and resistance (damping) [14]. Electromechanical and thermomechanical (*see* **Thermomechanical Models**; **Thermal Imaging Methods**) models rely on the coupling between mechanical quantities with electromagnetic and thermodynamic parameters, respectively.

Table 2. Nondestructive tests, structural and damage models

Nondestructive test	Structural/damage model
Liquid penetrant testing	Chemical, geometry
Electromagnetic testing including eddy current, magnetic particle inspection, magnetic resonance imaging	Geometry, dielectric constant, magnetic susceptibility, charge density, current density, electric conductivity, electric polarization
Radiographic testing and tomography	Geometry, mass density, radioactive decay, wave speed
Modal impact testing	Mass, stiffness, damping, natural frequency, geometry
Ultrasonic testing	Mass, stiffness, damping, structural acoustic wave speed, impedance, coefficient of thermal expansion, geometry.
Infrared and thermal testing	Thermal emissivity, electrical conductivity, geometry, mass, stiffness, damping, impedance.
Leak testing	Geometry

2.1 Radiography

Radiography methods were some of the earliest techniques used for assessment of structural components on an industrial scale. Radiographic testing uses X rays, gamma rays, or neutron rays to inspect components for identifying surface and hidden nonplanar flaws in castings, welds [15], and forgings. Flaws in components are identified on the basis of

differential absorption of radiation and the resultant changes in exposure levels on a radiographic film. The energy absorbed by the component depends on the thickness and density of the material [11, 16]. Typical flaws in a weld [11] that can be evaluated include cracks that appear as dark, irregular, linear segments, lack of fusion that appears as sharp edges, incomplete penetration that appears straight, dark, and linear with sharp edges, inclusions wherein the shade of color is dependent on material properties of the inclusion, and porosity where the defect region is darker than the surrounding material.

2.2 Ultrasonic testing

Ultrasonic testing makes use of concentrated high-energy acoustic waves generated using a pulser–receiver and transducer in frequency ranges typically between 1 and 50 MHz to identify flaw existence and flaw dimensions, determine geometric dimensions, and characterize material properties [17–19]. The ultrasonic transducer can be operated in contact or noncontact mode and in either pulse–echo or through-transmission modes. In addition to the development of transducer and pulser–receiver technology, developments in systems, control, robotics, digitization, and signal processing have facilitated the development of this methodology to active use of ultrasonics in the inspection of multiple, large components. Ultrasonic testing has been used to detect defects in welds [20], inspect railroads [21], identify corrosion and disbonds [22], and estimate material properties [23].

2.3 Acoustic emission

AE testing uses changes in signal strength associated with the sudden release of energy emitted because of a changing stress field ([24]; **Acoustic Emission**). This changing stress field can be attributed to growth in structural damage. Prosser *et al.* [25] used AE to detect damage in cross-ply graphite/epoxy composite test specimens. Wevers [24] noted that AE provided good capabilities to identify fiber breakage, delaminations, matrix cracking, and debonds in a loaded composite as compared to other conventional nondestructive evaluation (NDE) techniques.

2.4 Vibration-based methods

Adams *et al.* [26] identified vibration as a tool for detecting damage in the form of resin-bound shear cracks. The technique was found to be more effective than ultrasonic attenuation or radiographic transmission methods. Cawley and Adams [27] located defects in composite structures using changes in natural frequencies through a detailed sensitivity analysis study. Yao [28] reviewed the techniques used at that time for studying structural damage and reliability assessment. These and other vibration-based techniques primarily relate changes in modal parameters such as natural frequency, mode shape, and damping to the mass, stiffness, and damping parameters associated with a structure.

2.5 Optical methods

Optical methods include approaches such as photoelasticity, holography, and Moirè methods [29]. These methods identify material changes based on variations in transmission intensities and phase changes, diffraction properties, and interference fringe patterns. Structural changes associated with delamination, crack, thermal and residual stress, creep, and fracture can be studied using this approach.

2.6 Thermography

Thermal methods such as thermography [30, 31] are used to detect and measure the infrared range of the electromagnetic spectrum emitted from objects. Structural components and defects have different specific heat constants, thermal diffusivity, and thermal conductivity. This difference is amplified when the components are hotter. Thermal wave propagation methods such as lock-in thermography [32] and pulsed thermography [33] have been used to detect delaminations, corrosion, surface cracks, and voids. Combined approaches such as vibrothermography where thermal wave propagation is used in conjunction with elastic wave propagation, has been used to effectively detect microcracks [34].

2.7 Electromagnetic testing

Electromagnetic induction was developed for railroad inspection in the late 1920s by Drake and Sperry. Electromagnetic techniques [35, 36] make use of induced electric current and/or magnetic field to test the response of a structural component. Eddy-current testing is one of the widely used electromagnetic methods of inspecting structures for surface and near-surface cracks [37], corrosion [38], delaminations [39], and other structural defects. The technique is used to identify defects in electrically conducting materials by correlating the measured impedance with calibrated defect dimensions. In certain cases, a pulsed eddy-current method has been used to speed up the process of structural testing using this technique. Apart from eddy-current methods, other electromagnetic methods [40] have been studied by researchers. Chen *et al.* [41] identified corrosion in pipelines using a magnetoresistance sensor for magnetic flux leakage testing. Lewis *et al.* [35] identified surface-level stress corrosion cracking using an alternating current field measurement technique. Collins *et al.* [42] and Michael *et al.* [43] identified surface cracks using an alternating current potential drop method.

2.8 Magnetic particle inspection

Magnetic particle inspection methods [44] are used to detect magnetic flux leaks from surface and near-surface flaws in ferromagnetic materials. These flux leaks can be traced to permeability variations within test specimens [45]. Magnetoelastic methods such as Barkhausen noise are used for detecting damage through inductive measurements of noise-like signals. Sablik *et al.* [46] modeled a welded specimen to assess creep damage using finite element analysis and identified that the heat-affected zone in welds have reduced permeability resulting in lower electromotive force (emf) than the parent material while creep damage produces additional emf reduction. While most of the magnetic particle methods have focused on ferromagnetic metals, researchers have also identified damage in ceramic and composite composites using nuclear magnetic resonance spectroscopy methods.

3 SCHEMATIC APPROACH TO MODELING DAMAGE

In the context of static damage models, a discussion of damage in the linear elastic regime will suffice because damage evolution (both time and stress state) is frozen and the material state can be considered as piecewise linear in the operating range of loads and induced strains. The dynamics of a structural system with damage, based on the description of Lemaitre [3] and Fritzen [47], among others, can be written as

$$\begin{aligned}\mathbf{M}(\mathbf{x}, t, \mathbf{q_d}, \mathbf{q_e})\ddot{\mathbf{x}} + \boldsymbol{\chi}(\mathbf{x}, \dot{\mathbf{x}}, t, \mathbf{q_d}, \mathbf{q_e})\dot{\mathbf{x}} \\ + \bar{\boldsymbol{\kappa}}(\mathbf{x}, \dot{\mathbf{x}}, t, \mathbf{q_d}, \mathbf{q_e})\mathbf{x} + \boldsymbol{\varepsilon}(\mathbf{x}, \dot{\mathbf{x}}, t, \mathbf{q_d}, \mathbf{q_e}) \\ = \mathbf{F}(\mathbf{x}, t, \mathbf{q_d}, \mathbf{q_e}) \qquad (1)\end{aligned}$$

where $\mathbf{q_d}$ is the material and geometrical damage parameter vector, $\mathbf{q_e}$ is the thermodynamic parameter vector, $\mathbf{F}$ is the external force applied to the system, $\mathbf{M}$ is the mass matrix, $\bar{\boldsymbol{\kappa}}\mathbf{x}$ is the equivalent elastic stiffness term, $\boldsymbol{\chi}\dot{\mathbf{x}}$ is the equivalent linear velocity-dependent damping term, and $\boldsymbol{\varepsilon}$ consists of the residual restoring forces dependent on the time-varying (t) displacement ($\mathbf{x}$) and velocity ($\dot{\mathbf{x}}$) states.

The damage parameter is obtained using a nonlinear differential equation of the form,

$$\dot{\mathbf{q}}_\mathbf{d} \doteq \mathbf{f}(\mathbf{x}, \dot{\mathbf{x}}, t, \mathbf{q_d}, \mathbf{q_e}, \mathbf{F}) \qquad (2)$$

where the damage evolution vector is dependent on the states of the system, material and geometrical damage parameters, and the cumulative loading history. Damage usually evolves at different, usually slower, rates than the static/dynamic mechanical processes associated with interrogation using external forces [47]. For this reason, the evolution rates of these parameters are set to zero (for example, $\dot{\mathbf{q}}_\mathbf{d} = 0$). Static damage models facilitate the interpretation of measurement data by providing an understanding of the geometrical and material property variations associated with damage. The variation in the response variables such as displacement $\mathbf{x}$, velocity $\dot{\mathbf{x}}$, and/or acceleration $\ddot{\mathbf{x}}$ for the damaged component with respect to a baseline response variable for the undamaged component is used for diagnosing damage. The response due to the presence of

damage is often identified by computing the difference response, Δy,

$$\Delta y = y_{\text{damage}} - y_{\text{baseline}} \tag{3}$$

where y refers to one or more of the response parameter variables ($\mathbf{x}$, $\dot{\mathbf{x}}$, and/or $\ddot{\mathbf{x}}$).

On the basis of the above description, equation (1) can be simplified to obtain the well-known linear dynamic model,

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{C}\dot{\mathbf{x}} + \mathbf{K}\mathbf{x} = \mathbf{F}(\mathbf{x}, t, \mathbf{q_d}) \tag{4}$$

where $\mathbf{M}$ is the mass matrix, $\mathbf{C}$ and $\mathbf{K}$ are the linear elastic damping and stiffness matrices respectively, and $\mathbf{F}$ is the external force. Damage is modeled as small changes in the mass ($\Delta\mathbf{M}$), stiffness ($\Delta\mathbf{K}$), and/or damping ($\Delta\mathbf{C}$) matrices.

3.1 Schema for modeling structural damage

The choice of the schema for different modeling approaches is based on the phenomena modeled. A typical schema for model development can be described as

1. identification of the damage mechanism such as cracking and/or corrosion that needs to be diagnosed and the nondestructive methodology such as vibration analysis that is adopted;
2. identification of mechanical (stiffness, density, geometry), electromagnetic and thermal parameters, loading conditions including tensile or compressive loads, and other constraint factors such as boundary conditions associated with the structure of interest (for example, a steel plate specimen of dimensions $1 \times 1 \times 0.02\,\text{m}^3$) in the context of the modeling method (for example, lumped mass and distributed stiffness vibration model);
3. modeling of structure and preliminary model validation through experimental comparisons such as modal testing using analytical or numerical approaches including lumped parameter, Rayleigh Ritz, and finite element approaches;
4. sensitivity study of the model through model variations, including variations in thickness, material properties, and boundary conditions;
5. modeling of the damage mechanism and model validation through experimental comparisons of healthy and damaged specimens;
6. sensitivity study of variations in damage parameters, including material properties such as stiffness and mass and geometrical parameters such as shape, size, and location of defect within the context of the model.

Variations to the above schema abound in the literature. For instance, thermomechanical models such as the techniques described in **Thermomechanical Models** could start out with a description of empirical structural models and progress toward damage identification based on correlation of phenomenological observations with known thermomechanical models; for example, variations in thermal conductivity and thermal dissipativity because of local inhomogeneities in the form of flaws. While it is not necessary to follow each step outlined above for the successful implementation of damage models, it is important to note that these models need to be validated adequately using experimental methods (in the lab and/or field) to improve reliability, iteratively modify model parameters and/or model techniques, identify potential roadblocks, and identify bounds for model applicability.

4 STRUCTURAL DAMAGE PHENOMENA

Models for damage can be determined by either solving the forward problem sequentially in a feedback cycle or by solving the inverse problem and predicting the material, thermal, electromagnetic, and geometrical parameters that affect measured data. Several techniques are available in the literature for estimating the material properties of a structure and that of the damage site. These include vibration-based methods such as embedded sensitivity functions [48], restoring force models [49], and ultrasonic-based [23, 50, 51] material property determination techniques.

4.1 Corrosion

Corrosion is an environment-induced deterioration of a structure that primarily occurs through electrochemical reactions [52, 53]. Corrosion is classified according to geometry as uneven and even

global corrosion (also called *uniform corrosion*) and local corrosion (wide, medium, and narrow pits; crevices in the interior of a structural component). It is also classified according to the forms of corrosion as galvanic corrosion (potential differences between components), high-temperature corrosion, stress corrosion cracking (accompanied by little material loss but with loss of strength), and fretting corrosion. Corrosion can also be classified on the basis of the environmental conditions, which can consist of atmospheric (reinforcing corrosion includes suspended salts and water vapour) conditions, underground (soil) conditions, suspensions in liquid, or high temperatures. The most common form of corrosion is rust, which is caused by the electrochemical oxidation of iron. Corrosion can be investigated using visual, X-ray (geometric details of subsurface flaws), ultrasonic (geometric discontinuities, material impedance variations, which include flaw detection, thickness determination, pulse–echo, transmission, and resonance), electromagnetic (based on electrical and magnetic properties of the fluid), liquid penetrant, and magnetic particle inspection.

Corrosion reactions consist of oxidation (loss of electrons with increase in positive charge) or reduction (gain of electrons with increase in negative charge) reactions involving an exchange of electrons that occur in an electrolyte medium. For instance, metals and alloys corrode when exposed to humidity and oxygen. Corrosion involves the loss of material associated with the metal reacting with hydroxyl ions (or, equivalently water and oxygen) and typically results in the formation of localized regions with loss of material in the form of a pit. Apart from oxygen and water, other favorable environmental conditions that tend to accelerate corrosion rates include the presence of metal cations, urea (and nitrogen oxide groups), sulfide (and sulfur oxide groups), bicarbonate, and halide groups [54, 55], increased temperature, increased pressure (indirect influence through increased solubility of gases in liquids), and the presence of microorganisms. In favorable environments, external factors such as high temperatures and severe tensile stresses tend to accelerate the rate of corrosion. The alkalinity or acidity of the medium surrounding the structural material of interest also influences corrosion. Localized corrosion spots can also lead to changes in stress concentrations resulting in the initiation of cracks.

Researchers have investigated the use of different static damage models for studying corrosion. The electrochemical nature of corrosion suggests that it can be monitored using electrochemical energy methods such as variations in electrical resistivity. Brown and Barnard [56] used a three-dimensional finite difference model based on the electrochemical relations to model localized corrosion in a zinc–aluminum galvanized steel alloy. Terrien *et al.* [57], among others, modeled corrosion as a small notch and studied the interaction of Lamb waves with different types of notch-like defects using a two-dimensional finite element analysis. In fact, corrosion is most often modeled as a mass loss or a geometrical change (for example, thickness reduction). Other aspects, including the energy sink behavior of corrosion spots, can be modeled as localized impedance increases around the corrosion spot (local impedance is calculated as the ratio of input force to the velocity $\mathbf{Z}(\omega) = \mathbf{C} + j(\omega\mathbf{M} - \mathbf{K}/\omega)$) due to increases in damping in the corroded region. Apart from density and geometrical changes, the wave speed across a corrosion spot also changes because of local changes in mass.

There are certain considerations that must be kept in mind when modeling corrosion damage. Some researchers model corrosion as a mass or a density change. It is important to note that a reduction in mass does not translate to an equivalent reduction in density and changes in the two parameters have differing trends [58]. In fact, corrosion models based on density changes need to incorporate changes in both geometry and density. The type of model needs to reflect the response variable being analyzed and the nature of the analysis techniques used. For instance, microhardness measurements require appropriate microstructural models, which consider localized variations in shear modulus, to adequately reconcile the experimental observations. The differences in micromechanic and macromechanic behavior will then need to be suitably incorporated into the model.

4.2 Cracks

Cracks (*see* **Free and Forced Vibration Models**, Figure 21) can be caused by multiple factors ranging from large cycles of loads during normal operation

to spikes in loading cycles due to sudden events in defective materials (for example, built-up residual stresses during manufacturing, the adoption of incorrect manufacturing methods, corroded spots, and/or dislocations). Cracks tend to initiate and propagate as microcracks or dislocation densities (initial flaws) from regions of high stress concentration. Significant focus of the work on crack modeling has been carried out in relation to fracture mechanics with a focus on crack initiation, crack growth, and acceleration of crack growth [59–61]. Most of these methods monitor crack growth associated with plastic deformation at the crack tip and the effects of fatigue loading applied to a cracked structure in the form of cycles of tensile and compressive loading. From the point of view of a static damage model (including propagating and standing wave models), a crack is associated with a localized geometrical discontinuity, mass change, stiffness loss, and/or damping change. Changes in the material and geometrical properties also affect the impedance (including attenuation and amplitude changes) and speed of the propagating waveform. On the basis of the observed changes in one or more of these parameters, the actual changes in physical parameters such as stiffness and damping can be obtained. Several crack models are available in the literature. The reader is referred to **Damage Evolution Phenomena and Models** for additional details.

4.3 Delamination and debonding

Delamination and/or debonding can be caused by the loss of adhesion of adjacent layers of curved sections such as laminated sections of tubular sections and shells, abrupt changes of section properties such as those associated with bonded and bolted joints, residual stress buildup due to differential thermal and hygroscopic (moisture) expansion/contraction rates, imperfect curing procedures during manufacturing, or the application of severe loads during operation [62–66]. The distinction between delamination and debonding is contextual. Delamination or debonding refers to the separation of layers of a layered composite material due to the inability of the specimen to resist the bending stiffness and loading conditions. Debonding can viewed as the surface separation of multilayered components, while delamination can refer to the separation of an internal layer of a multilayered component [53]. Studies of delamination mechanics have typically focused on damage growth models based on the descriptions provided by fracture mechanics models [67–69] such as J-integral [70] and virtual crack closure [71] techniques and damage mechanics models [72] such as cohesive zone models [73]. An example of delamination is illustrated in Figure 1. From the point of view of a static damage model, the delaminated (and debonded) site is modeled as a separation accompanied with an air gap between two material layers. This aspect suggests that there is a loss of mass, stiffness, and damping in the layer of interest and geometrical deformity in the overall structure. A delamination model should, in addition, include bending stiffnesses in a direction transverse to the plane of the layer to ensure that the model is different from that of a damage model for void space in material layers and to take into account the effect of stretched layers.

4.4 Fiber pullout, fiber breakage and matrix cracking

Matrix cracks are frequently observed flaws in composite specimens associated with pit-like indentations along the surface of the specimens [66]. In most

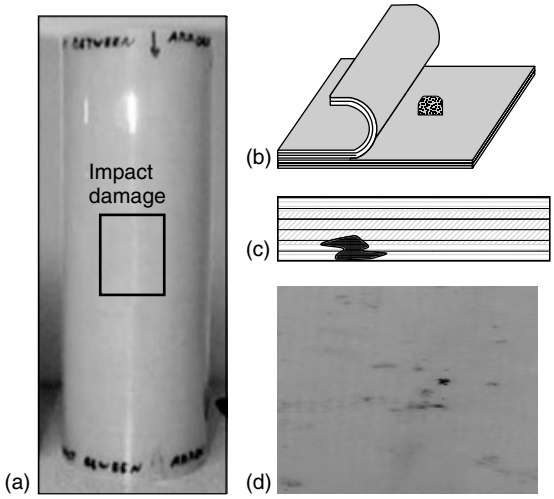

Figure 1. (a) Filament wound composite cylinder with impact damage, (b) laminated composite with delamination seed [Adapted from Purekar, 2006; reproduced by permission of A. Purekar], (c) fiber breakage, and (d) matrix cracking.

instances, matrix cracks are not defects that compromise the structural integrity of the specimen. In laminated composites, impact loading or manufacturing flaws can result in fiber pullout, fiber breakage, and matrix cracking. High tensile loads can lead to fiber separation and result in loss of structural integrity at the fiber pullout location. Fiber breakage (Figure 1c) can also result in similar phenomena except that there is no real separation, but there is, instead, a loss of stiffness along some of the in-plane dimensions (assuming fibers are primarily in one plane). The damage due to matrix cracking, fiber breakage and fiber pullout leads to a modification of the Voight–Reuss mixing criterion and result in a lower matrix or fiber volume and altered stiffness [53].

4.5 Fretting in crevices: slips, loose joints, and fasteners

In nonunitized structures, the more prevalent forms of damage include loosening and cracking of bolted joints and fasteners. The presence of fasteners tends to increase rubbing or fretting during component operation, leading to the formation of slips due to material degradation in the form of a loss of material in threaded joints, erosion, microcracking, loss of preload, etc. The built-up stresses during loading cycles create tension loads on the bolt and compression loads on the joints. Threaded connections can give rise to a number of defects in the joints including thread failures, corrosion, and loose joints because of insufficient torque at the time of threading in the components. Loose joints result in lowered stiffness (translational and torsional) and greater damping at the connection due to the loss in preload and increase in the nonlinear nature of the restoring forces. Damage in the bolt results in a stiffness reduction and can be associated with decreased cross-sectional areas, increased region of contact and an amplification of sliding tendencies of the bolt in the connection. Abrasion or cracking due to fretting/rubbing could also occur in the joints themselves. This aspect can potentially increase tendencies for bolt impacts within the connection joint leading to further bolt and connection damage. The gap between the fastener and the connection can also be modeled as a change in damping. Bolt loosening, loose joints, and damage at fasteners leads to nonlinear changes under loading associated with Coulomb friction [75]. More details about this damage type are discussed in **Free and Forced Vibration Models** [75].

4.6 Creep

Creep is a deformation mechanism associated with the long-term stress accumulation that results in permanent structural deformation. Creep is dependent on time, temperature, and the stress applied and is often associated with structural systems that are subjected to high-temperature loads. Because of the nature of creep and the timescales involved, the effects of creep deformation can best be modeled through dynamic damage models or through the incorporation of residual stresses in static damage models. Additional details are discussed in **Damage Evolution Phenomena and Models**.

4.7 Buckling

Buckling is an elastic instability mode associated with the failure of a material when it is subjected to compressive loads. Buckling is typically accelerated in the presence of material and/or load eccentricity [76]. The prominent forms of buckling include columnar buckling, thermoelastic buckling due to differential heating, and dynamic buckling (including nonlinear snap-through and snapback buckling (Figure 2, [77])). Modeling of buckling requires large displacement analysis and often piecewise linear models are employed to model buckling one load step at a time to avoid numerical instabilities associated with modeling large displacements. For example, finite element models are used to perform a load-controlled step-by-step analysis of models wherein the specimen curvature is changed at the end of each step. Buckling can also be modeled as a reduction in axial direction stiffness of cryogenic vessels that are subjected to permanent damage due to imposed off-axis shock loading [7]. Buckling is also modeled as a small change in curvature (with the change in curvature affecting the natural frequency [78]) and the wave speed [79]. The reader is referred to **Damage Evolution Phenomena and Models** for additional details.

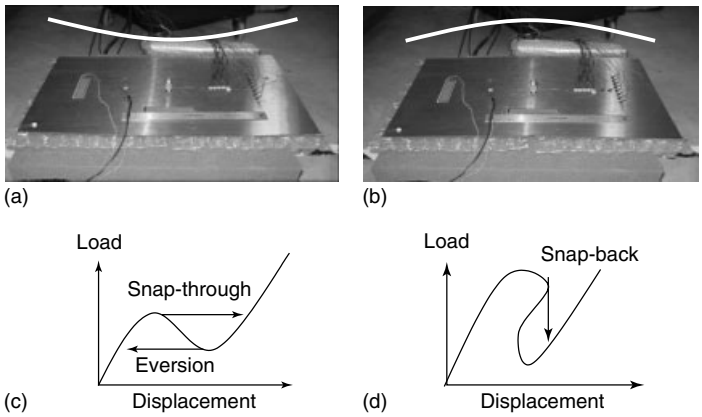

Figure 2. Snapshot of the gamma Ti–Al sheet with the reflected light at the center of the specimen showing the two different states of the specimen: (a) concave up and (b) convex up [77] (c,d) snap-through and snap-back buckling schematic. (adapted from [77]).

4.8 Penetration and plastic deformation

Plastic deformation, as the name suggests, is a large displacement that leads to irreversible material and geometric changes. In the context of a static model, plastically deformed specimens can be modeled as materials with different geometrical and material properties in the localized plastic zone region. Plastic deformation is induced by large acoustic, vibration, or thermal loads such as hail and extreme heat that lead to irreversible changes in the specimen structure. Figure 3 shows an example of this type of damage [80].

4.9 Welds, weld defects

Two metal pieces can be joined together by either riveting or welding. In general, it is preferable to join parts through welding because much of the damage at crevices can be minimized. Welding involves the permanent joining or fusing of two metallic specimens [81]. Welding results in thickness changes at the interface associated with the weld as well as a buildup of stresses at the weld interface and phase-transformations with changes in the grain structure in the welded region (thermomechanically affected and heat-affected zones are created). The changes in phase result in small changes in the overall impedance and more significant changes in the residual stresses associated with the weld formation. Welding also results in geometrical distortion of the welded specimen and increased/decreased volume of material in the weld zone. Additionally, improper weld formations in the form of metallic inclusions, voids, porosities, slag inclusions, spatter, and other defects such as cracks, rough weld formations, under-cut and excessive reinforcements can be introduced during welding because of exposure to the environment and the foreign materials used during welding. The influence of welds and weld defects can be modeled using changes in geometry, stiffness, density, and damping in suitable analytical and numerical analysis methods.

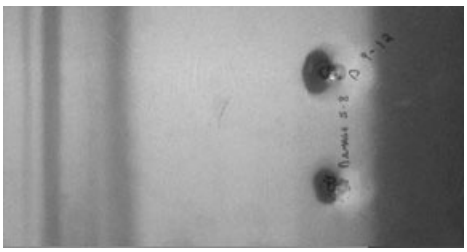

Figure 3. Plastic deformation and penetration resulting from impact damage [White, 2006; Reproduced by permission of J.R. White].

4.10 Residual stresses

The measurement and modeling of residual stresses is difficult. To select the proper residual stress model, measurement data are needed. Dilthey *et al.*

[82] provided a summary of work in the use of finite element simulations for the measurement of residual stresses. In the NDE context, residual stress measurements are evaluated either on the basis of the second-order mean stress effects or through thermal techniques such as thermal evaluation for residual stress analysis (TERSA). TERSA is carried out by heating with a laser, which provides a pseudodynamic signal [83]. The results from this analysis can then be used to incorporate residual stresses in models. Sundararaman and Adams [84] modeled a plate with a center weld and incorporated the changes associated with residual stresses as a small change in the material stiffness and density, on the basis of the assumption that the thickness of the welded region is identical to that of the parent material.

5 STATIC DAMAGE MODELS

The methods used for nondestructive testing can be associated with a change in geometric, material, electrical, and/or thermodynamic parameters. Damage models can make use of multiple studies of healthy and damage cases based on analytical, experimental or numerical (finite difference [85], finite element, boundary element, spectral element [86], and meshless methods [87]) approaches. Detailed literature surveys of nondestructive models that use finite element approaches are provided in [88–90]. Damage can also be studied using discrimination models that focus on differences between a baseline and expected behavior due to the presence of a defect. Examples of such discrimination methods include the expression in equation (3) to the more detailed descriptions presented in **Thermomechanical Models** and [91]. Typically, damage studies make use of a combination of discrimination models in conjunction with structural models of healthy and damage cases.

A diverse set of models discussed in the literature are included in the section below as an illustration of different types of damage models and their applicability to identify different damage phenomena.

5.1 Example 1: modeling cracks using stiffness models

Damage growth models such as linear elastic fracture mechanics and cohesive zone models consider the effects of damage at different points during the cycle of a component and correlate it with models. Cohesive zone models, used for simulating crack initiation and growth in fracture mechanics applications, describe the cohesive forces/tractions that occur when a material is stressed using an approach that deals with the nonlinear zone ahead of the structural discontinuity. For example, the formulation by Yang and Cox [92] is used to describe tractions directly instead of by the use of springs, thereby avoiding potential traction concentrations at mesh discontinuities. In addition to modeling crack growth, these models can also be used to model delaminations and other structural deformations such as microbuckling. While useful information can be gleaned from these growth models for identifying damage, a more realistic approach for modeling static damage is to directly incorporate local changes in stiffness and mass and to employ suitable structural models. Christides and Barr [93] modeled a cracked beam using a reduced stiffness *EI*. The stiffness reduction in the cracked region was expressed using

$$EI(x) = \frac{EI_0}{1 + (I_0 - I_C)I_0/I_C \exp(-2\alpha|x - x_C|/d)} \tag{5}$$

where I_0 and I_C are the second moments of areas associated with the undamaged beam and at the crack, respectively, d is the crack depth, α is an experimentally derived constant and set to 0.667 here, x is the position along the beam, and x_C is the crack position. Alternatively, the region associated with the crack can be modeled using a localized reduction in stiffness extending only to the cracked region or over a triangular region in the localized neighborhood of the crack [94]. Friswell and Penny [95] considered some of the above crack models and compared the model results with experimental vibration data and observed that despite the inherent simplicity of the models, these models adequately modeled the effects of a crack. A typical approach used to identify structural damage at a specific element, j, can be described by studying the kth frequency and can be obtained using [96],

$$\frac{\partial f_k}{\partial \alpha_j} = \frac{1}{8\pi^2 f_k} \cdot \frac{\{\phi\}_k^T [k_j] \{\phi\}_k}{\{\phi\}_k^T [\mathbf{M}] \{\phi\}_k} \tag{6}$$

where, f_k is the kth frequency, $\Delta\alpha_j$ describes the change in a suitable parameter, $[k_j]$ is the stiffness matrix, **M** is the mass matrix, and $\{\phi\}_k$ is the kth eigen vector of the structural system. Data for this approach can be obtained from structural models in standardized finite element packages. Apart from the expression in equation (6), other approaches can also be used to discriminate between baseline and damage states of the structure.

5.2 Example 2: influence of moisture uptake models to crack densities

Patel [97] provided a model to study the moisture uptake of a laminated composite with cracks in multiple directions by combining ideas from continuum damage mechanics and thermodynamics. The model represents an extension of the method presented in [98]. The governing equation for diffusion is described as

$$\frac{\partial m}{\partial t} = \frac{\partial}{\partial X_i}\left(D_i \frac{\partial \mu}{\partial X_i}\right) \tag{7}$$

where $\mu = \rho_s \dfrac{\partial \phi}{\partial m}$ is the chemical potential of the moisture in a polymer, ρ_s is the mass density of the polymeric solid, ϕ is the Gibbs potential, D_i is the diffusivity in a given direction i, m is the mass, t is time and f_i is the moisture flux. The author, in addition, considered the presence of only one nonzero normalized stress. The damage component is based on a damage model for cracks presented by Talreja [99] as

$$d_i = \frac{\kappa_i(m,T) h_c^2 \delta_{ii}}{h}, \quad i = 1, 2 \tag{8}$$

where $i = 1$ corresponds to transverse cracking and $i = 2$ corresponds to longitudinal cracking, $\kappa_i(m,T)$ is an experimental constraining parameter, h_c is the crack thickness, h is the laminate thickness, and δ_{ii} is the crack density in the direction i. The form of Gibbs potential is obtained from Roy [98] and incorporated into the model to obtain the governing equation for an unstressed orthotropic laminate with uniform temperature and damage distributions. The form of the equation is dependent on the parameters described in equations (7) and (8). Additional constants are then evaluated by estimating multiple moisture diffusivities at different states of laminate cracking. Static damage estimates can then be obtained at different points in the usage cycle.

5.3 Example 3: electrical resistivity as a damage discriminator

Irving and Thiagarajan [100] and Chung [101] used an electrical potential technique to characterize fatigue damage in carbon fiber composite materials. In the electromechanical analogies presented in the literature [14], resistance, capacitance, and inductance are the corresponding analogs to damping, compliance, and mass, respectively. Any structural changes associated with damage in the fiber or the matrix results in a loss of conduction and an increased resistance measure. Damage is indicated by an increase in resistivity. This method is used for identifying small damage of the dimensions of the fibers in a laminated composite. The resistivity can be described using

$$\rho = RA/L \tag{9}$$

where R is the sample resistance, A is the cross-sectional area, and L is the sample length. Irving and Thiagarajan [100], in addition, identified that the longitudinal resistivity was an order of magnitude higher than the transverse resistivity.

5.4 Example 4: thermoelastic models

Schmidt and Hattel [102] used a three-dimensional thermoelastic finite element model to study friction stir welds. The elastic portion of the model comprised of mass density, ρ, damping, c, and stiffness, k, components as described in the equation,

$$\rho\ddot{x} + c\dot{x} + kx = F \tag{10}$$

where F is the body force and x is the displacement. The thermal response is expressed using the thermomechanical diffusion equation,

$$\rho c_P \dot{T} = (kT_{,i})_{,i} + \eta s_{ij} \dot{\varepsilon}_{ij}^{pl} \tag{11}$$

where T is the temperature, c_P is the specific heat capacity, k is the thermal conductivity, η is the plastic

energy dissipation fraction, s_{ij} is the deviatoric stress tensor, and $\dot{\varepsilon}_{ij}^{pl}$ is the plastic strain rate tensor. The surface flux, $q_{\text{surf}} = \mu p \dot{\gamma}$, where μ is the friction coefficient, p is the pressure, and $\dot{\gamma}$ is the slip rate, is used to describe the contact boundary condition at the surface nodes. Suitable expressions are then used to appropriately discretize equations (10) and (11). This model can then be used to monitor the deformation field at different points in time during the welding process. For instance, Schmidt and Hattel [102] monitored the formation of defects such as voids for different parametric states. Note that this model is a damage evolution model and to glean static damage results, time-frozen snapshots need to be captured to evaluate the damage state of the structural component.

While the above examples provide a flavor for different damage models that are used to diagnose different sets of damage, they are by no means complete. A detailed description requires a full rendition of the sequential steps outlined in the schema for damage models described previously in this article. A case study in the form of a sensitivity analysis is presented in the next section involving the use of a numerical model based on a wave propagation model.

6 CASE STUDY: SENSITIVITY ANALYSIS OF DAMAGE PHENOMENA

6.1 Numerical modeling using a wave propagation model

The focus of the remainder of this article will be to study the sensitivity of model parameters to varying material (mass, spring, damping) and geometrical parameters. These parameters, either separately or in combination, are associated with each of the damage types listed in this article. In this article, component responses are simulated using static damage models based on changes in density, stiffness, damping and/or geometrical variations at macrostructural dimensions (>1 mm; >5% variations in density, stiffness, damping). Specifically, propagating elastic waves are simulated using a local interaction simulation approach (LISA)/sharp interface method (SIM) [84, 103–109]. The LISA/SIM has been developed for modeling propagating waves using a cellular model approach to obtain iterative difference relations and is used to illustrate the interaction of interrogating signal waveforms with different levels of changes in geometry, stiffness, and density in thin plate specimens. In these specimens, elastic bulk waves interact through multiple reflections between the top and bottom surfaces of plate specimens resulting in guided Lamb waves (*see* **Fundamentals of Guided Elastic Waves in Solids** for additional details).

6.2 Implementation

The implementation of numerical models requires an assessment of the model development (description of suitable material and geometrical models, environmental and operating conditions, damage model, and sources of input), study of model limitations (stability, accuracy, and convergence), and model validation (analytical and experimental validation). The three-dimensional linear elastodynamic equation for the propagation of bulk waves in orthotropic, inhomogeneous media is the basis for the simulation model used in this section. The equation of motion can be described as

$$\partial_l (S_{klmn} w_{m,n}) + F_k = \rho \ddot{w}_k + \chi_k \dot{w}_k \qquad k, l, m, n = 1, 2, 3 \tag{12}$$

where $S_{klmn}(x_1, x_2, x_3)$ is the stiffness tensor, $w_k(x_1, x_2, x_3, t)$ is the kth displacement, $F_k(x_1, x_2, x_3)$ is the body force applied at a local point, $\rho(x_1, x_2, x_3)$ is the material density, $\chi_k(x_1, x_2, x_3)$ is the material attenuation factor based on a proportional, viscoelastic damper, and the comma in $w_{m,n}$ indicates differentiation. In the absence of a stress field (for example, a stress field resulting from residual stresses), $S_{klmn}(x_1, x_2, x_3)$ represents the second-order elastic constants tensor. For an orthotropic solid, the stiffness tensor can be written as

$$S_{klmn} = \begin{pmatrix} \sigma_1 & \lambda_{12} & \lambda_{13} & 0 & 0 & 0 \\ \lambda_{12} & \sigma_2 & \lambda_{23} & 0 & 0 & 0 \\ \lambda_{13} & \lambda_{23} & \sigma_3 & 0 & 0 & 0 \\ 0 & 0 & 0 & \mu_{23} & 0 & 0 \\ 0 & 0 & 0 & 0 & \mu_{13} & 0 \\ 0 & 0 & 0 & 0 & 0 & \mu_{12} \end{pmatrix} \tag{13}$$

where λ_{pq} and μ_{rs} are the Lame constants, σ_p is the bulk stiffness, and the subscripts p, q, r, and s vary between 1 and 3 and are indicative of the stiffness dimension. Each pair of indices (k, l) and (m, n) in equations (5) and (6) can be replaced by a single index based on the Voight–Kelvin convention,

$$V(i, j) = i\delta_{ij} + (1 - \delta_{ij})(9 - i - j); \quad i \to k, m; \;\; j \to l, n \tag{14}$$

Propagating waves are modeled by using a discrete form of equation (3) and solving for the difference relationships using a LISA in conjunction with the SIM. The iterative difference relations are obtained using the method outlined in [105]. The final difference relation form is obtained for a rectangular cuboid grid. It was assumed that the displacements and the material properties of the cell are continuous although the adjacent cells at an interface can have significantly different material properties. Note that both displacement and stress continuity are maintained at these interfaces in the LISA/SIM technique. The three-dimensional relations at each point $P(i, j, k)$ are obtained for a rectangular cuboid grid. Each displacement degree of freedom is individually determined based on the stiffness, density, and geometrical properties of the neighboring grids using an iterative difference relation. A typical iterative difference relation is given by

$$u^{i,j,k,t+1} = -\bar{q}_1^2 u^{i,j,k,t-1} + 2\bar{q}_1 u^{i,j,k,t} + \frac{\bar{q}_1 \Delta t^2}{8\bar{\rho}} \times \sum_{a,b,c=\pm} \begin{bmatrix} -2u^{i,j,k,t}\left(\tilde{\eta}_1^2\tilde{\sigma}_1 + \tilde{\eta}_2^2\tilde{\mu}_{12} + \tilde{\eta}_3^2\tilde{\mu}_{13}\right) \\ + 2\tilde{\eta}_1^2\tilde{\sigma}_1 u\,(1^a) + 2\tilde{\eta}_2^2\tilde{\mu}_{12} u\,(2^b) \\ + 2\tilde{\eta}_3^2\tilde{\mu}_{13} u\,(3^c) \\ + ab\tilde{\eta}_1\tilde{\eta}_2\big[\left(\tilde{\lambda}_{12} + \tilde{\mu}_{12}\right)\left(v(6_b^a) - v\right) \\ + \left(\tilde{\lambda}_{12} - \tilde{\mu}_{12}\right)\left(v(2^b) - v\,(1^a)\right)\big] \\ + ac\tilde{\eta}_1\tilde{\eta}_3\big[\left(\tilde{\lambda}_{13} + \tilde{\mu}_{13}\right)\left(w(5_c^a) - w\right) \\ + \left(\tilde{\lambda}_{13} - \tilde{\mu}_{13}\right)\left(w(3^c) - w(1^a)\right)\big] \end{bmatrix} \tag{15}$$

where $a, b, c = \pm 1$, and $\bar{a}, \bar{b}, \bar{c} = -1$ when $a, b, c = -1$ and $\bar{a}, \bar{b}, \bar{c} = 0$ when $a, b, c = 1$, $\bar{q}_k = (1 + \Delta t/2 \sum_{a,b,c} \tilde{\chi}_k/\tilde{\rho})^{-1}$ is the transmission factor, $\bar{\rho} = \frac{1}{8}\sum_{a,b,c} \tilde{\rho}(a, b, c)$, (u, v, w) are the displacements in the three directions (x, y, z), $\tilde{\sigma}_k = \sigma_k(a, b, c)$, $\tilde{\eta}_1 = \eta_1(a, b, c) = 1/\Delta x$, $\tilde{\eta}_2 = \eta_2(a, b, c) = 1/\Delta y$ and $\tilde{\eta}_3 = \eta_3(a, b, c) = 1/\Delta z$. Similar expressions hold for other quantities with a tilde.

The discretization parameters for the numerical model are obtained by ensuring that the minimum criterion for stable solutions is met. This stability criterion, referred to as the Courant–Friedrich–Lewy (CFL) criterion, constrains the grid spacing for a given time step by

$$\text{CFL criterion}: c_{\max}\Delta t\sqrt{\frac{1}{\Delta x^2} + \frac{1}{\Delta y^2} + \frac{1}{\Delta z^2}} \leq 1 \tag{16}$$

where $c_{\max}$ is the maximum wave speed (usually the longitudinal wave speed), Δt is the time step, and Δx, Δy, and Δz are the spatial steps in the three Cartesian coordinates x, y, and z.

6.3 Model validation

A broadband rectangular pulse with a 2-MHz signal bandwidth was imparted at the center of a $609.6 \times 609.6 \times 2\,\text{mm}^3$ plate with grid dimensions of approximately $1 \times 1 \times 1\,\text{mm}^3$ using the three-dimensional LISA model for a homogeneous, isotropic aluminum plate. An aluminum plate structure with elastic modulus 70 GPa, density $2700\,\text{kg m}^{-3}$, and Poisson's ratio 0.334 was modeled. Data was collected at 608 nodal locations approximately 1 mm apart along the center of the plate structure. The numerical results obtained were then compared with the results obtained analytically from the Rayleigh–Lamb dispersion curves. The results in Figure 4(a) indicate a match between the modes obtained numerically and analytically. The lines that emanate backwards and forwards from the right edge in Figure 4(a) are spatially aliased segments of the different dispersion curves.

Next, a plate structure of dimensions $530 \times 306 \times 6.5\,\text{mm}^3$ was discretized into grids of dimension $1 \times 1 \times 1.625\,\text{mm}^3$. Dispersion curves were first obtained numerically to verify the material properties obtained through experimental analysis. A sinc pulse was used as the input in both the experimental and numerical

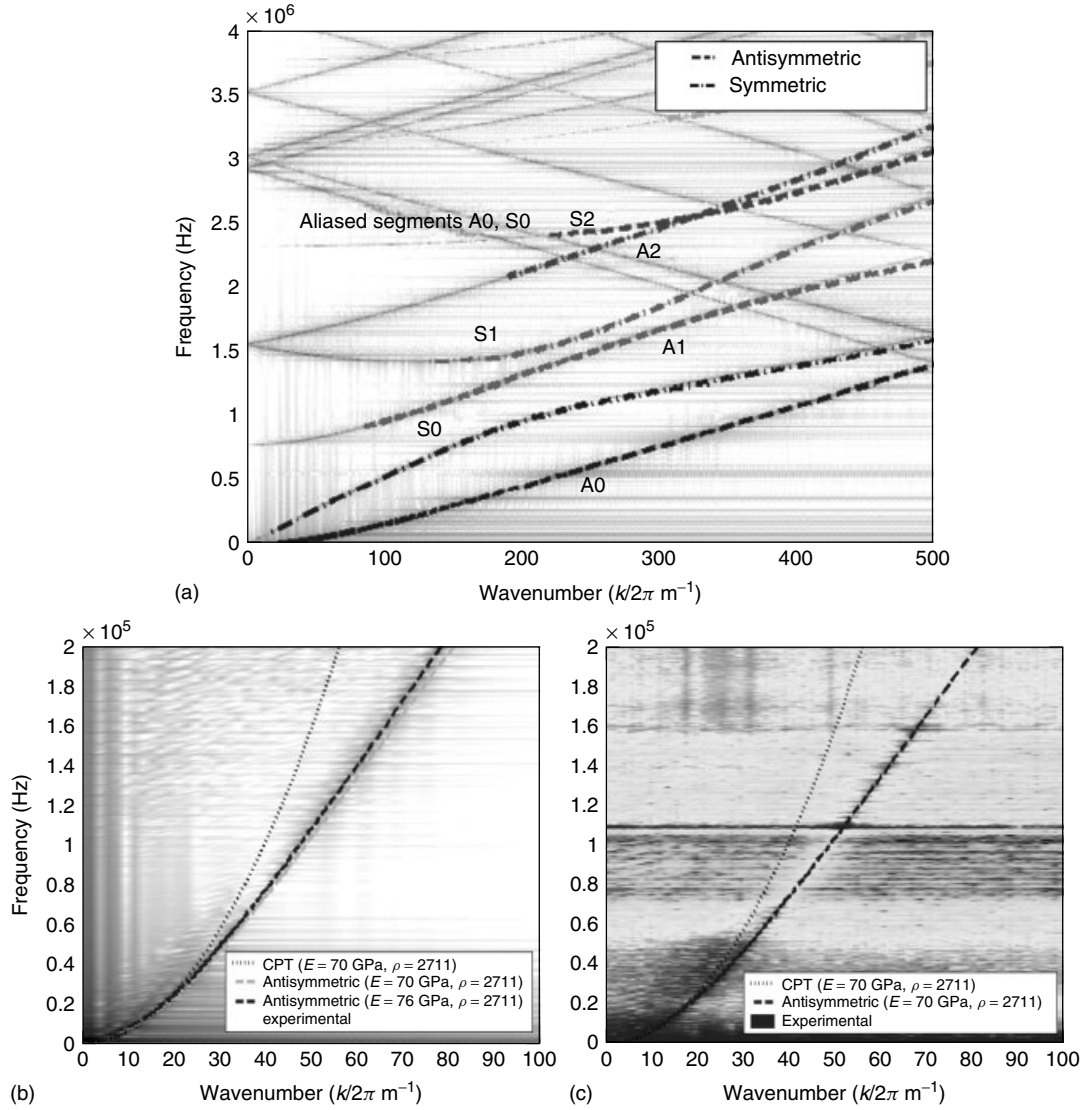

Figure 4. Comparisons of analytical Rayleigh–Lamb dispersion curves with (a) numerical dispersion curve results for a $609.6 \times 2\,\text{mm}^2$ aluminum section with approximate grid spacing of $1/8 \times 1/8\,\text{mm}^2$, (b) numerical dispersion curve results for 1-mm sensor spacing in a $530 \times 306 \times 6.5\,\text{mm}^3$ aluminum section with grid spacing of $1 \times 1 \times 1.625\,\text{mm}^3$ and (c) experimental results for 5-mm sensor spacing.

studies. The sampling frequency was set on the basis of the CFL criterion as 10 MHz and the signal was input at the left edge and center of the plate specimen (5, 153, 0) mm. The results obtained were then compared with the results obtained analytically from the Rayleigh–Lamb dispersion curves and the classical plate theory. The results indicate that a match is obtained between the antisymmetric (A_0) mode and the experimentally measured dispersion curves. However, it is seen in Figure 4(b) that the estimated stiffness is about 10% higher than the modeled stiffness. This result suggests that the coarse nature of the grid structure results in grids with higher stiffness. The experimental results for the edge of the aluminum

Table 3. List of specimens used

Plate	Al-1	Al-2	Or-1	LC-1
Material	Aluminum	Aluminum	Orthotropic	Laminated orthotropic
Dimensions (mm)	$300 \times 300 \times 2$	$400 \times 200 \times 4$	$450 \times 250 \times 3$	$400 \times 200 \times 4$
Grid (mm)	$1 \times 1 \times 0.5$	$1 \times 1 \times 1$	$1 \times 1 \times 1$	$1 \times 1 \times 1$
Density ($kg\,m^{-3}$)	2710	2710	1575	1600

Input signal	Directed in the in-plane directions.			

plate yielded similar results and, in this instance, matched the analytical results (Figure 4c). These comparisons indicate that the numerical methodology can be used to model real specimens.

6.4 Damage simulation studies conducted

The damage simulation studies were conducted on four different specimens. Elemental cells were defined on the basis of the material properties listed in Table 3. Additional grid points equivalent to one extra cell surrounding the entire medium were defined with the material properties of air (density $1.3\,kg\,m^{-3}$ and stiffnesses of 1/10 000th of that of the surrounding medium) to denote a traction-free boundary. The actuator was modeled such that a Gaussian pulse was sent into the plate structure over a diameter of 8 mm. The sensor was modeled to extract a response measurement as an output average of all points over a diameter of 8 mm. The sampling frequency was chosen based on the CFL criterion (equation 16). A listing of the classes of damage studied is provided in Table 4.

The damage sites in the studies described in this work were identified by using the difference data as calculated in equation (3) because the damage sites involve localized changes in stiffness, density, and damping with dimensions smaller than a wavelength of the interrogating waveform.

6.5 Discussion

An excitation was introduced at "Actuator-1" in a plate with dimensions $300 \times 300 \times 2\,mm^3$ (Al-1).

Table 4. Parametric sensitivity analysis study of damage in specimens

Figure	Description
	Al-1: $300 \times 300 \times 2\,mm^3$ aluminum plate with $1 \times 1 \times 0.5\,mm^3$ grids
6	Baseline studies.
7	[Cases 1–2]—multiple-site damage at two actuator locations D1 (150, 79, 0); D2 (80, 157, 0); D3 (248, 248, 0) mm. Changes in stiffness (D1: +10%, D2, D3: 0.01%) and change in density (D1: +5%, D2: 0.05%).
8	[Cases 3–8]—superposition of the above multiple-site damage at two actuator locations
9(a, b)	[Cases 9–12]—surface damage: damage size study (length: 3–9 mm in steps of 2 mm × width: 3 mm × thickness: 1 mm); location (60, 125, 0.5) mm; surface notch modeled with material properties of air.
9(c, d)	[Cases 13–16]—interior damage: change in stiffness and/or density; location (60, 125, 1) mm; 1.2 × stiffness, 0.8 × stiffness, 1.2 × stiffness 0.9 × density, 1.3 × density.
	Al-2: $400 \times 200 \times 4\,mm^3$ aluminum plate with $1 \times 1 \times 1\,mm^3$ grids
7	[Case 25]—multiple site damage at (170, 79, 0); (80, 157, 0); and (318, 108, 0) mm grids.
10	[Cases 17–19]—through the thickness damage: damping change at (240, 125, 2) mm (cases 1–3: 0.95, 0.95, 0.9 transmission factors as described in equation (15)); Case-2 damping study also includes 0.9 × stiffness and 0.9 × density.
	Or-1: $450 \times 250 \times 3\,mm^3$ orthotropic plate with $1 \times 1 \times 1\,mm^3$ grids.
11	[Cases 20–21]—multiple site surface damage at two actuator locations (140, 104, 0); (250, 25, 0) and (340, 175, 0) mm.
	LC-1: $400 \times 200 \times 4\,mm^3$ laminated composite plate with $1 \times 1 \times 1\,mm^3$ grids
12	[Cases 22–24]—impedance change at three frequencies (40, 150, and 300 kHz; single site subsurface damage with material properties of air) (240, 125, 1) mm.

The out-of-plane displacement responses at different sensor locations are shown in Figure 5(a). Additionally, the x-, y-, and z-displacement responses at one sensor location (200, 5, 2) mm are shown in Figure 5(b). The incident and reflected waveforms are clearly seen in the out-of-displacement response pattern, while it is not easy to discern the different waveforms from the in-plane displacement profiles.

A second aluminum plate with dimensions $400 \times 200 \times 4\,mm^3$ (Al-2) was also studied. The response at 120 μs captured for Al-1 (Figure 6a) is also shown for Al-2 (Figure 6d). The differences in the two profiles were observed here. The effects of multiple-site damage centered at three locations (Cases 1 (Al-1), 25 (Al-2); Table 4), interrogated using the actuator at (150, 5, 0) mm (Al-1) and (200, 5, 0) mm (Al-2) and after a difference response has been computed, are shown in Figure 6(b), (c), (e), and (f). Local changes in stiffness and density were expected to result in corresponding changes in the impedance and wave speed, resulting in waveform distortion. Figures 7(b), (c), (e), and (f) have directional conical spread signal patterns rather than the expected circularly symmetric patterns. This aspect can be traced to the dependence of a signal response at a particular point in the spatial domain on the original signal's response profile at that instant. In other words, at 120 μs, the original signal (Figure 6a, d) was directed toward the top boundary with some reflected profiles radiating in from the left- and right-hand boundaries. The difference response shares this pattern and was primarily illuminated along the excitation leading to directional difference profiles. Another reason for the lack of circular symmetry can be traced to the effects of discretization. Only five grid points were used along the thickness dimension in the simulation because of computational restrictions (runtime, memory, hard-disk space) even though the preferred number of grid points along the thickness dimension is between 8 and 20. Any reduction in accuracy is a

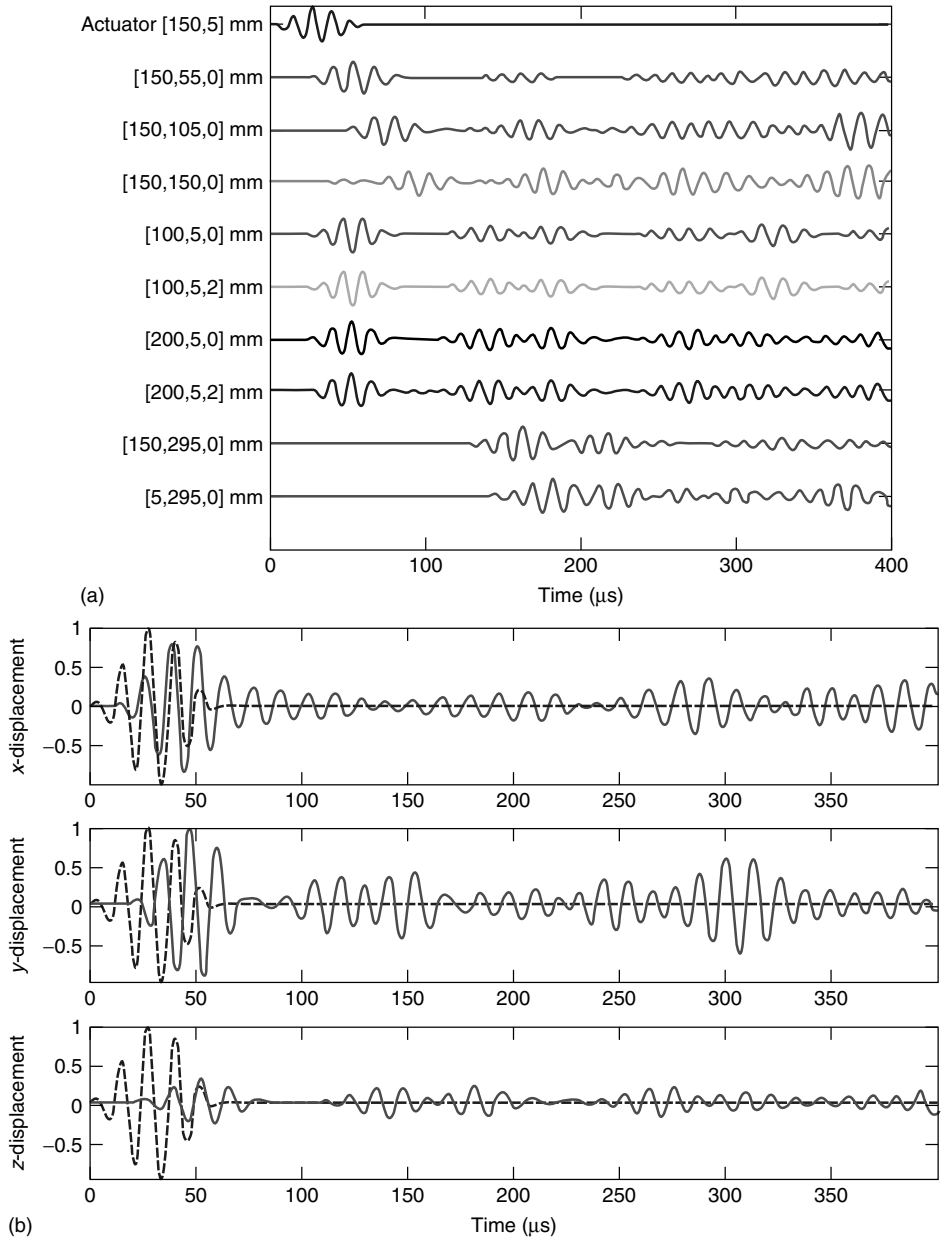

Figure 5. Displacement profiles at (a) different sensor locations and (b) at (200, 5, 2) mm in a $300 \times 300 \times 2\,\text{mm}^3$ aluminum plate subjected to a Hanning window excitation.

trade-off for modeling large specimens using three-dimensional analysis in serial computers.

The three damage sites considered in Figure 6 were then modeled separately and the difference patterns were recomputed for each case. The sensed response shows visible differences for the different types of damage in the plate. The patterns observed in Figure 7(a) indicate that the difference responses for each damage site were distinct and that the damage site closest to the actuator responds first followed

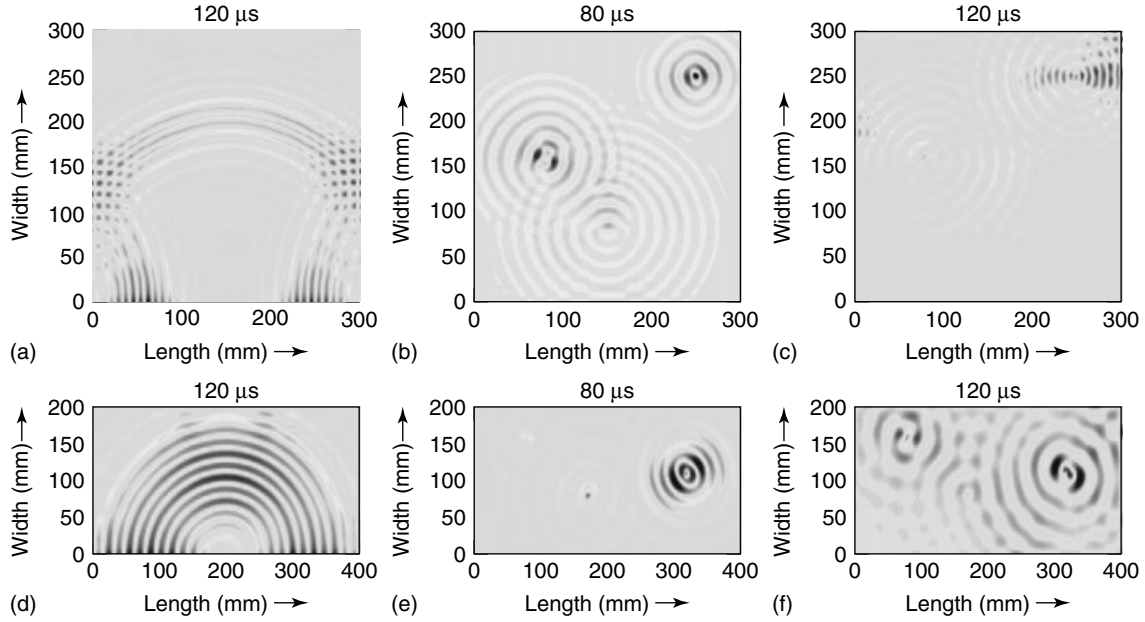

Figure 6. Damage identification through difference data. Time slices in $300 \times 300 \times 2\,\text{mm}^3$ (80 kHz) and $400 \times 200 \times 4\,\text{mm}^3$ (40 kHz) aluminum plates. (a, d) baseline data at 120 μs, (b–f) difference data at 80 and 120 μs.

by other locations in increasing distances from the actuator location. The relative amplitude levels of individual damage sites were dependent on the extent of damage and the closeness of the damage site to the actuator and sensor locations and the boundaries of the specimen. The differences from the three damage sites were summed and the results were compared with the multiple-site damage study in Figure 6. When the difference results were scaled by a factor of 10, it was found that the results in Figure 7(b) were significantly higher. This shows that the presence of any imperfections in a specimen makes it difficult to identify additional damage sites.

The peak difference response (both out of plane and in plane) at two sensor locations were then studied for all four cases (three damage sites individually and multiple-site damage instance) and the results are shown in Figure 7(c) and (d). The out-of-plane damage site showed the anticipated linear trends at both sensor locations. However, the characteristics of the in-plane difference responses showed slightly different trends. For instance, the x-displacement response showed a trend reversal for the multiple-site damage instance from the single site damage at D3 (Figure 7d). This aspect is seen because the difference response of the cumulative damage from the multiple damage instances is less than that of the single damage site. However, the constructive and destructive influence of signals from the damage sites (treating damage as a secondary source) were not considered, nor was the choice of the damage metric (here, peak amplitude), the location of the sensor, or the cumulative sum of the displacements in all three dimensions (both y- and z-difference responses are significantly higher). These aspects need to be kept in mind when using sensor responses to correlate with damage.

To study the influence of the size of damage, a rectangular damage region was introduced in plate Al-1 and the local stiffness and density were modified. The results were then computed for both in-plane and out-of-plane displacements. All three displacement components showed linear increases in damage with increasing size of damage (Figure 8a, b, Cases 9–12). The slope of this trend was higher for the x-displacement than either the y- or the z-displacements. This result was obtained because the damage site varied linearly along the x dimension. In

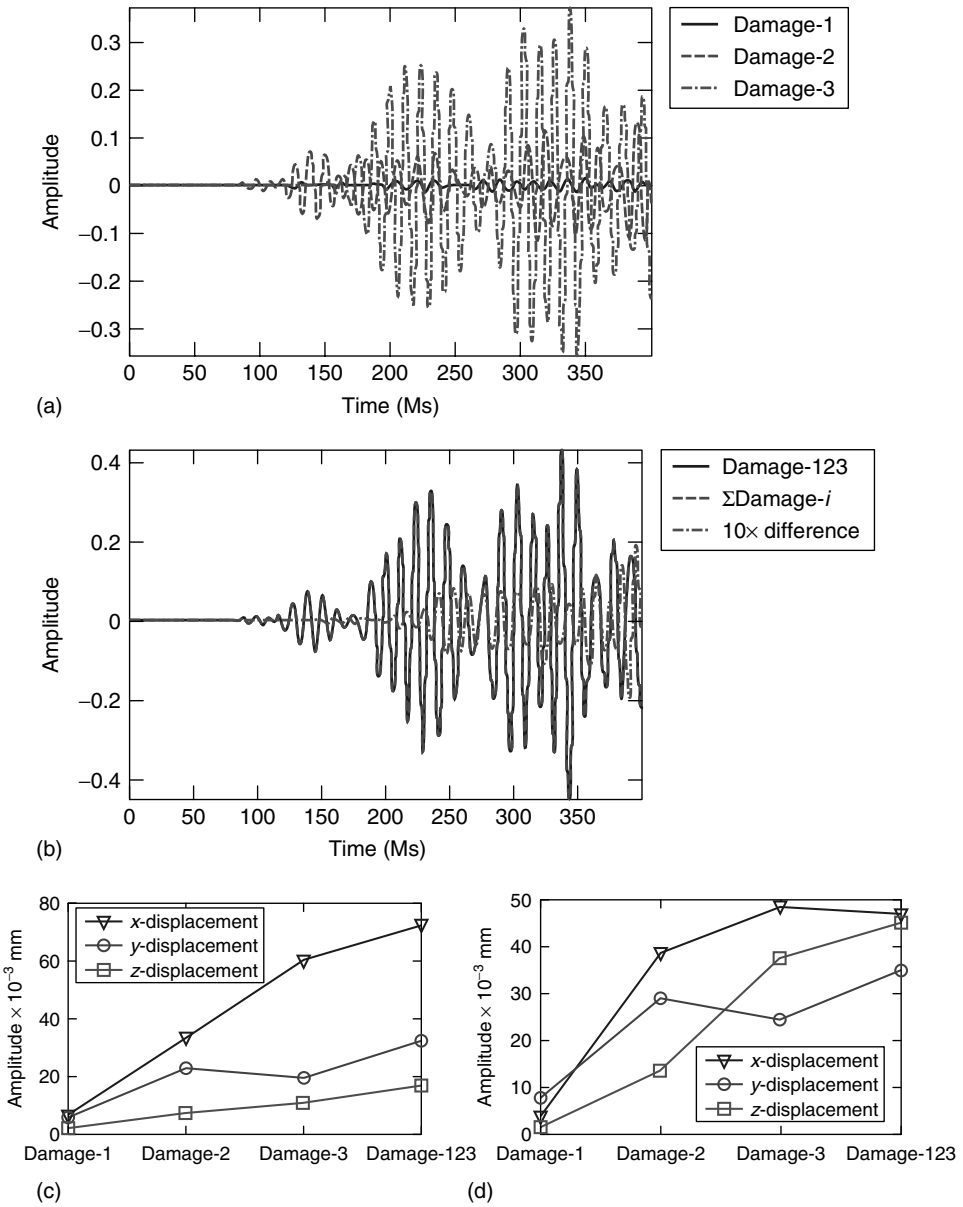

Figure 7. Single site damage for $300 \times 300 \times 2\,\text{mm}^3$ isotropic plate studying the superposition effects of damage identification using (a, b) an out-of-plane displacement comparison, (c, d) peak in-plane and out-of-plane displacements; (a, b, c) sensor at (295, 5, 0) mm and (d) sensor at (5, 245, 0) mm; actuator at (150, 5, 0) mm.

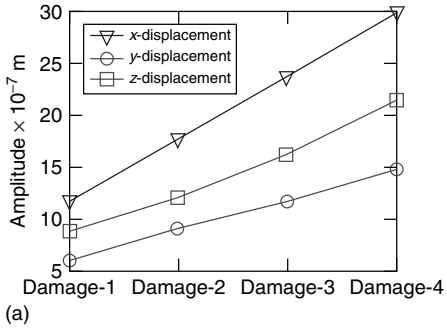
this instance, the study was carried out at a sensor location, which is positioned along different x and y dimensions than the actuator and damage locations. In the study by Sundararaman and Adams [107], the sensor was placed along the same y dimension as the actuator, resulting in negligible variation in the peak y-displacement response with increases in damage along the x dimension.

Next, the influence of changes in local material properties was studied for a given size of



(a)

Location (60,125,0.5) mm
Stiffness 0.01% medium
Density 0.1% medium

Damage	Dimensions (mm)

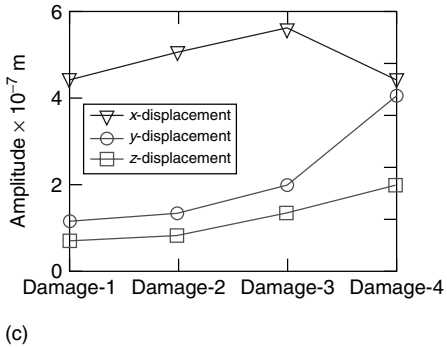
2	(5,3,1)
3	(7,3,1)
4	(9,3,1)

(b)



(c)

Location (60,125,0.25) mm
Dimensions: (9,3,0.5) mm

Damage	Stiffness	Density
1	120%	Same
2	80%	Same
3	120%	90%
4	Same	130%

Change in material properties in relation to the rest of plate.

(d)

Figure 8. Peak in-plane and out-of-plane displacement comparisons in a $300 \times 300 \times 2\,\text{mm}^3$ aluminum plate for (a) impedance study, (b) damage sizing study. (c,d) Tables of parameters used for generating the results displayed in Figure 9 (a,b) respectivrly. Sensor at (5, 245, 0) mm; actuator at (150, 5, 0) mm.

damage (Figure 8c,d, Cases 13–16). The peak in the difference in displacement response indicated increasing trends for the damage sequence described in Figure 8(d) for the y- and the z-displacements. On the other hand, the response in Figure 8(c) for the x-displacement indicated a decrease in the amplitude of the peak difference displacement for the last damage case. This result is similar to the result in [107] and highlights the influence of sensor location on the ability to discern actual trends associated with a given damage site. Overall, the net change in displacement patterns suggested that an increase in density leads to a greater change than a similar percent increase in stiffness. The results in Figure 8(a) and (c) also indicated that the in-plane displacements were dependent on changes in the wave speed although the out-of-plane displacement was strongly dependent on the mechanical impedance (product of the density and the wave speed).

Next, to study the effect of damping, the local transmission factors were modified in a $400 \times 200 \times 4\,\text{mm}^3$ aluminum plate. It was evident that a change in the transmission factor resulted in a significantly higher amplitude change than changes associated with stiffness and/or density. Two transmission factors were studied (Figure 9, Cases 17–19 in Table 4) with one of the transmission factors also accompanied by a decrease in both stiffness and density. It was observed that the net decrease in both stiffness and density accompanied by a decrease in the transmission factor resulted in an overall decrease in the peak difference amplitude for both sensor locations. In general, decreasing the transmission factor drastically altered the peak difference amplitude response.

The effects of damage identification in an orthotropic plate ("Or-1") of dimensions $450 \times 250 \times 3\,\text{mm}^3$ involving changes in unit cell properties as described in Tables 3 and 4 were also studied. The results from actuators located at (5, 125, 0) mm and (225, 245, 0) mm are shown in Figure 10(a)–(c) and Figure 10(d)–(f) respectively. The in-plane difference waveforms had highly directional responses with elliptical patterns, while the out-of-plane difference waveforms exhibited

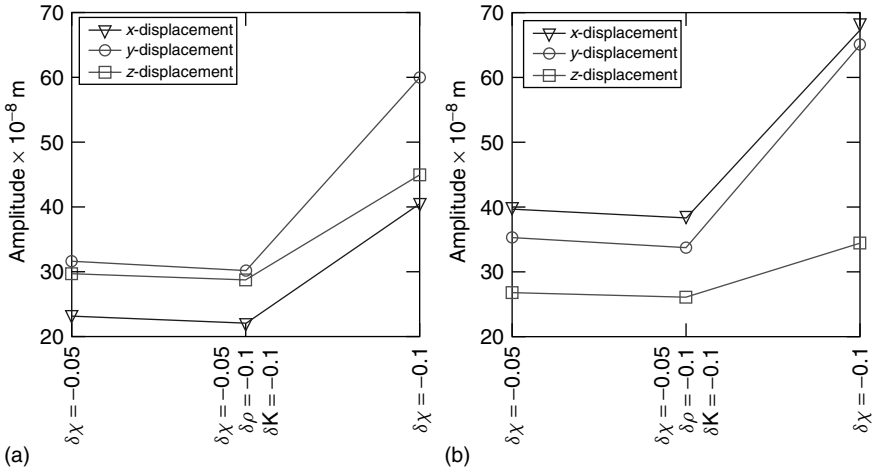


Figure 9. Peak in-plane and out-of-plane displacement comparisons in a $400 \times 200 \times 4\,\text{mm}^3$ aluminum plate for damping transmission factor variations with actuator located at (200, 5, 0) mm and sensors located at (a) (395, 5, 0) mm and (b) (200, 55, 4) mm.

circular patterns. The results described in Figure 10 were further exaggerated because of the grid profile chosen with no grid description at the center of the plate specimen. In general, it is not advisable to model guided waves without a center grid point; here, the results were used more for illustration of an exaggerated case of anisotropy. While the directionality observed was not surprising, the out-of-plane displacement response indicating circular profiles was somewhat counterintuitive. Within individual circular and elliptical profiles, the amplitude levels along different directions were different, depending on the location of the source signal at a certain point in time.

Finally, a laminated composite plate ("LC-1") of dimensions $400 \times 200 \times 4\,\text{mm}^3$ involving changes in unit cell properties as described in Tables 3 and 4 was studied. Excitations at three different signal frequencies (40, 150, and 300 kHz) were studied to investigate the influence of different modes. Single site damage was introduced into the plate specimen with no additional change introduced due to damping and involved subsurface damage in the form of an air gap between layers to mimic a separation mechanism such as delamination. It was observed that changes in signal frequency resulted in significant increases in the peak difference amplitude response (Figure 11a–c) along all three displacements. The rate of increase in the peak difference amplitude was higher for the out-of-plane displacements than the in-plane displacements. Additionally, out-of-plane time slices were also displayed as shown in Figure 11(d)–(f). The initial wavefront with slight directionality at 40 kHz gave way to circular wavefronts at 150 kHz and circular wavefronts with more complex patterns at 300 kHz. This aspect indicated that for subsurface defects, the higher frequencies (with more complex mode behavior) were more effective for damage identification.

7 SUMMARY

This article provides a brief introduction into nondestructive testing and variables of interest, damage mechanisms of interest, and examples that illustrate the use of different damage models. Additionally, it incorporates a detailed sensitivity analysis study that models damage as changes associated with localized material and geometrical properties.

The sensitivity analysis study is carried out using a time-domain numerical model based on the LISA/SIM that models propagating waves based on material property and geometrical changes. This exercise is undertaken without consideration of thermodynamic fluctuations (temperature, humidity) and large displacement considerations, models of which requires additional input parameters and the use of

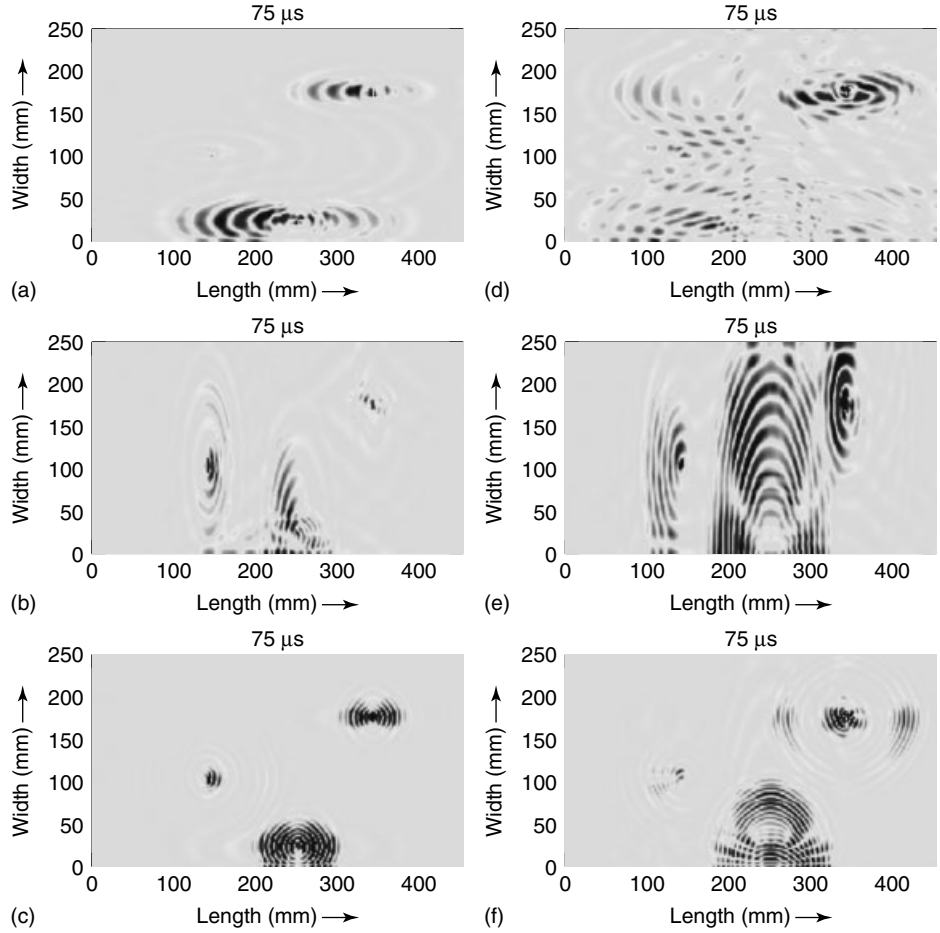

Figure 10. $450 \times 250 \times 3\,\text{mm}^3$ orthotropic plate specimen showing the displacement profiles of the difference between a damaged specimen and a pristine specimen subject to an excitation at 160 kHz corresponding to an actuator at (a, b, c) (5, 125, 0) mm and (d, e, f) (225, 245, 0) mm. Responses are obtained for all three displacements i.e., (a, d) are the x-displacements, (b, e) are the y-displacements and (c, f) are the z-displacements.

other modeling techniques. These changes in material and geometrical properties can be used to potentially improve the capabilities of a structural health monitoring methodology (for example, sensor and actuator location, displacement direction monitored). Localized changes are expressed in terms of changes in stiffness, density, and damping with geometrical dimensions not exceeding the wavelength of the waveform excited were considered in four different plate specimens. The four plate specimens consisted of plates of different sizes and material properties (isotropic, orthotropic, and heterogeneous orthotropic). It is shown that the models can be used to identify the extent of damage using time slices over the entire plate or through sensor locations at different points on the plate specimen. Different actuation, sensor and damage locations, and plate dimensions are considered. The effect of damage size is dependent on the sensor, actuator, and damage position in addition to the relative size of the damage to the wavelength of the excited waveform. Multiple-site damage is studied and the interaction of responses reflected and/or diffracted from the damage site is shown to be sometimes greater than small changes in stiffness and density. The benefits of using a three-dimensional model are shown by the differing trends

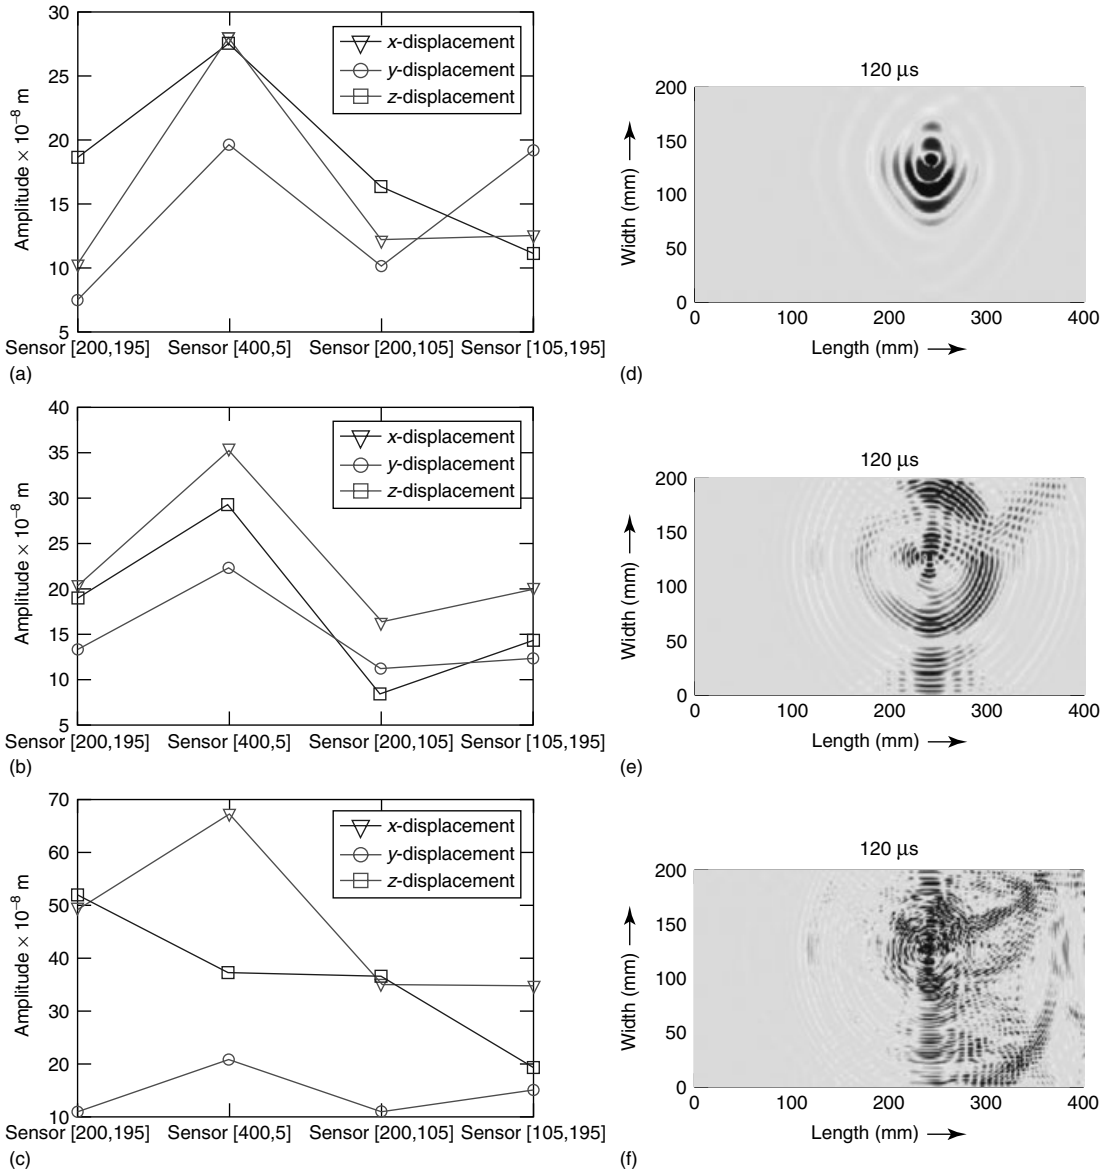

Figure 11. Laminated composite multimodal study for separation identification based on the difference out-of-plane displacements. (a, d) 40 kHz, (b, e) 150 kHz, (c, f) 300 kHz in all three directions, (a–c) peak difference in amplitude at four sensor locations, (d–f) time slice results.

due to changes in stiffness, density, and damping. Damage studies are also carried out in heterogeneous specimens. Structural heterogeneities are introduced into the plate specimen in the form of laminates along the out-of-plane dimensions. Here, the material property of the laminated heterogeneity is modeled to be the same as that of an orthotropic material (graphite epoxy).

The case study is organized along the lines of the general schema for modeling static damage. Specifically, this case study illustrates the need for validating models using experimental testing. One benefit of

studying static damage models is that it provides additional information in correlating observed changes in data with changes in the material property matrices. Static damage models are driven by the nondestructive tool used and the damage mechanism of interest.

ACKNOWLEDGMENTS

The work related to the numerical model was performed using computing facilities at the Ray W. Herrick Labs, Purdue University. The author would like to thank Purdue University Engineering Computing Network for providing access to the workstation from which the simulation results were obtained.

Chapter 9
Damage Evolution Phenomena and Models

Alten F. Grandt Jr.
School of Aeronautics and Astronautics, Purdue University, West Lafayette, IN, USA

1 INTRODUCTION

Although structural failures are rare, those that do occur are often related to preexistent manufacturing or service-induced damage and/or more severe service usage than anticipated. Such failures can be prevented though a combination of damage tolerant design, nondestructive inspections, and structural health monitoring (SHM). Damage tolerance is the ability of a structure to resist fracture from preexistent cracks for a given period of time and is the first line of defense for insuring that unanticipated damage does not lead to premature failure. Periodic inspections provide a second defense by determining the maximum size of life-limiting defects that could be present at a given time. Since structural damage can grow during service, inspection intervals are based on the time it would take for undetected damage to grow to failure under the anticipated service loads. Thus, failure prevention must consider not only the current damage state but also the expected rate of damage growth due to future loading conditions (including environmental influences). The latter task would include SHM of accumulated loads and environmental exposure experienced in service.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

2 OVERVIEW OF STRUCTURAL FAILURE MODES

Typical failure modes are briefly outlined below with the goal of setting the context for SHM requirements. It is important here to distinguish between pristine structures manufactured to "ideal" standards and components that have been subjected to service wear and tear or those that could contain initial manufacturing defects. Indeed, the initial structural and material condition has a tremendous influence on which failure modes limit structural performance. Since one must expect damage to develop and grow in service, an initially "perfect" structure will likely develop fatigue cracks, corrosion, or some other form of trauma that could ultimately lead to failure. The

fact that the limiting failure modes often change with use must be considered by SHM.

2.1 Deformation and creep

All structures are made from deformable materials that lead to changes in component dimensions caused by applied loads. Many materials behave in an elastic manner when forces are small and this results in deflections that are readily predicted by concepts governing the strength of materials [1–4]. These elastic deformations are controlled by the stiffness of the material and are recoverable when the component is unloaded (i.e., it returns to its original dimensions). Although elastic deformations are often not fatal by themselves, there are many instances when they can lead to structural "failure". Excessive deformations can, for example, eliminate tight clearances, resulting in interference between moving components that prevent a machine from performing properly. Another example is the aerodynamic "flutter" that can result in resonant vibrations that deteriorate to unstable conditions and/or lead to fatigue cracking.

If the applied forces exceed a given value for a particular material, the loaded member may continue to deform without fracturing and experience additional "inelastic" deformations that lead to permanent changes in shape. The maximum load that can be applied without causing inelastic deformation is related to the material yield strength. Although most structures are designed to prevent yielding, it should be noted that the component may continue to carry additional load and that inelastic deformations often provide a "safety factor" that is important for damage tolerant structures.

In many structural metals, yielding is specified by the maximum shear stress (Tresca) or von Mises yield criteria. The *maximum shear stress (Tresca) criterion* assumes that yield occurs in a ductile material when the maximum shear stress at the point of interest exceeds a critical material value. Stated mathematically, yield occurs when

$$\tau_{\max} \geq \text{material constant} = \frac{\sigma_{ys}}{2} \tag{1}$$

Here the material constant is half the tensile yield strength σ_{ys}, and $\tau_{\max}$ is the maximum shear stress determined at the point of interest. It is readily shown, for example, that $\tau_{\max} = \frac{1}{2}|\sigma_1 - \sigma_3|$, where σ_1 and σ_3 are the largest and smallest of the three principal stresses at the given point.

The *von Mises yield criterion* states that yield occurs when the following condition is met.

$$\begin{aligned}\sqrt{(\sigma_x - \sigma_y)^2 + (\sigma_y - \sigma_z)^2 + (\sigma_x - \sigma_z)^2 + 6(\tau_{xy}^2 + \tau_{xz}^2 + \tau_{yz}^2)} &\geq \sqrt{2}\sigma_{ys} \\ = \sqrt{(\sigma_1 - \sigma_2)^2 + (\sigma_1 - \sigma_3)^2 + (\sigma_2 - \sigma_3)^2} &\geq \sqrt{2}\sigma_{ys}\end{aligned} \tag{2}$$

Here again σ_{ys} is the tensile yield strength, (σ_x, σ_y, σ_z, τ_{xy}, τ_{xz}, τ_{yz}) are the six components of stress at the point of interest, and σ_1, σ_2, and σ_3, are the three principal stresses at that point.

Creep is a time-dependent distortion that occurs when a member continues to deform under extended application of a sustained static load. When the load is removed, some elongations may be recovered (elastic), whereas some deformations may remain at zero load (inelastic). These latter changes in dimension may be permanent or the member may gradually return to its original state after an additional period of time as these deformations continue to "relax". Creep is an important failure mode for metal components that operate for long periods at elevated temperatures and high loads (e.g., turbine engine blades). In addition, many polymers creep at room temperature.

2.2 Buckling

Buckling is a failure mode unique to slender members loaded in compression or shear. In this case, an instability develops that results in lateral deflections that, in turn, cause an additional bending moment that leads to further deflections and increased bending. Buckling can occur at very small elastic loads and is controlled by the material stiffness, the

unsupported length, the component cross-sectional moment of inertia, and the type of end support. Buckling is an important failure mode for thin, compression-dominated structures (e.g., upper wing skins in aircraft, building support columns). Although there are several forms of elastic and inelastic buckling, insight into this failure mode is given by examination of the elastic Euler buckling equation given by

$$P_{cr} = \frac{\pi^2 EI}{(kL)^2} \tag{3}$$

Here P_{cr} is the critical buckling force, E is the elastic modulus, I is the moment of inertia for the column cross section, L is the unsupported column length, and k is a dimensionless coefficient that depends on the constraint applied to the ends of the specimen. In general, k decreases as more constraint is provided at the column ends. Note that the column buckling load increases linearly with the elastic modulus E and the cross-sectional moment of inertia I but is inversely related to the square of kL (known as the *effective column length*). Thus, buckling resistance is greatly increased by shortening the column length and/or increasing the end constraint. Detecting loss of end constraint would be an important SHM task.

2.3 Corrosion

Corrosion is material degradation due to chemical attack and can occur in several forms: galvanic (dissimilar metal), pitting, exfoliation, intergranular attack, filiform, or, when combined with the presence of a tensile stress, stress corrosion cracking. This time-dependent failure mechanism is highly dependent on the particular combination of structural material and environment combination in question and is often accelerated by increasing temperature. Corrosion is a complex chemical phenomenon that can cause general thickness loss (and a corresponding increase in stress) as well as stress concentrations (i.e., pits and other localized areas of attack) that lead to fatigue cracking or fracture. Corrosion is difficult to predict, and its prevention requires careful materials selection, protective coatings, and periodic maintenance. Although corrosion can occur independent of applied loading, it frequently acts in conjunction with static or cyclic loading (e.g., stress corrosion or corrosion fatigue) to represent a particularly dangerous failure mode. Detecting the accumulation of corrosive fluids and/or break down of environmental protection systems would be key SHM tasks.

2.4 Fatigue

Cyclic fatigue is the failure mode associated with *repeated* loading and is one of the main life-limiting factors for mechanical devices. Consider, for example, a structural member that is subjected to repeated application and removal of remotely applied load cycles, as shown in Figure 1. Although the peak values of the maximum and minimum load per cycle may be tension or compression and may change during the component life (i.e., variable-amplitude loading), no single load application is large enough to fracture new components.

After repeated load cycles, however, small cracks will form, often at multiple locations in the structure. At the outset these cracks may be benign, but they do extend slowly after repeated cycling, and eventually some coalesce into a dominant crack(s) that continues to grow in a stable manner. Finally, the dominant crack reaches a size that causes fracture, and the member fails in a sudden, catastrophic manner. The

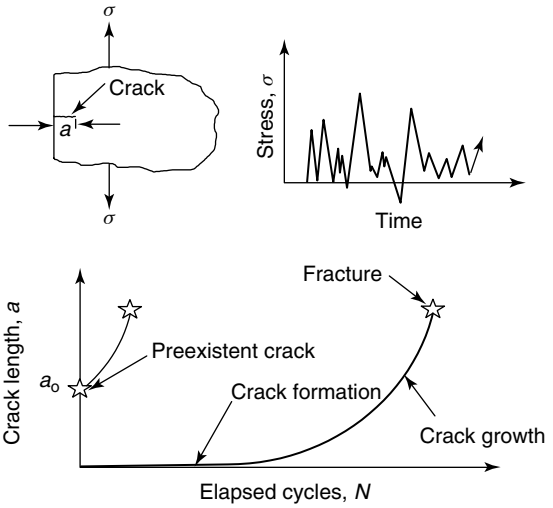

Figure 1. Schematic representation of fatigue failure mechanism, showing crack formation and propagation following a period of cyclic loading.

final fracture surface often exhibits a "brittle" appearance and may demonstrate characteristic markings that are remnants of the crack tip position at various stages in life. These "beach marks" are visible to the naked eye and are one of the distinguishing characteristics of a fatigue fracture. More detailed examination of the fracture surface under a microscope may reveal additional patterns of closely spaced lines, or "striations," that record the crack tip position after each cycle of loading. The striation spacing is the local fatigue crack growth rate, and if present, striations offer conclusive proof of a fatigue failure.

The fatigue failure mode is one of the main concerns for SHM, and is emphasized in this article. Note several points about this important failure mechanism. First, fatigue requires *cyclic* loading to occur. The number of cycles that can be applied before fracture takes place (i.e., the fatigue life) depends on the amplitude and mean value of the cyclic load, the sequence of applied loads (when variable-amplitude load histories are involved), and the component shape and material. The condition of the specimen surface is extremely important, as rough surfaces, notches, or material impurities can rapidly lead to cracks, eliminating the "crack formation" portion of the fatigue life. Thus, SHM should report evidence of structural or material trauma that could lead to fatigue cracking.

Residual stresses can also have a significant influence on the fatigue life. Intentional introduction of compressive residual stresses by shot peening or cold working can be quite beneficial, for example, and is a common technique for extending the fatigue life of a component. On the other hand, residual tensile stresses, such as those introduced by manufacturing processes, can be extremely detrimental to fatigue.

2.5 Fracture

Final catastrophic failure results when the member cleaves into two or more parts. Although fracture may occur in pristine structures subjected to overloads, it is frequently initiated at smaller loads by preexistent flaws or by service-induced damage (e.g., fatigue cracking and/or corrosion). Fracture can occur in a ductile manner that requires considerable expenditure of energy, but can also happen suddenly with little warning. This latter result may exhibit "brittle" behavior without evidence of plasticity and is a particularly dangerous failure mode. The fracture resistance of a material is characterized by its "toughness", a quantity that can be a function of temperature and loading rate, as well as geometric constraint to yielding (e.g., specimen thickness).

3 FATIGUE DAMAGE MODELS

This section briefly outlines life prediction models for the fatigue damage mechanism. The stress–life and strain–life methods are "crack nucleation" approaches that assume crack-free structures, and focus on the time that it would take for a fatigue crack to form. The damage tolerance or fatigue crack growth approach assumes that the component already contains a subcritical crack, and one is interested in determining the number of cycles that it takes for it to grow to final fracture. The initial crack size is a key for these analyses and is often based on the size that could be missed by a nondestructive inspection. As will be seen, fatigue life depends strongly on the applied stresses, and, in addition to component condition, determination of the actual load history is an important parameter to be obtained from SHM.

3.1 Crack nucleation

The *stress–life method* is the original approach to fatigue developed during the latter portion of the nineteenth century. The stress–life or S–N curve shown in Figure 2 is obtained from subjecting "smooth" specimens to a constant-amplitude stress. Here the applied stress amplitude is plotted against the measured fatigue life N_f, which could be the number of cycles to form a "detectable" crack, but is often simply the total number of cycles to fracture the small test coupon.

Some materials (steels in particular) demonstrate an endurance limit S_e, defined as the largest stress amplitude that can be applied without having a fatigue failure. It must be emphasized, however, that while endurance limits are an important measure of fatigue resistance, this property is measured in small, polished specimens subjected to constant-amplitude loading, and may not accurately reflect the fatigue behavior of large components that contain initial

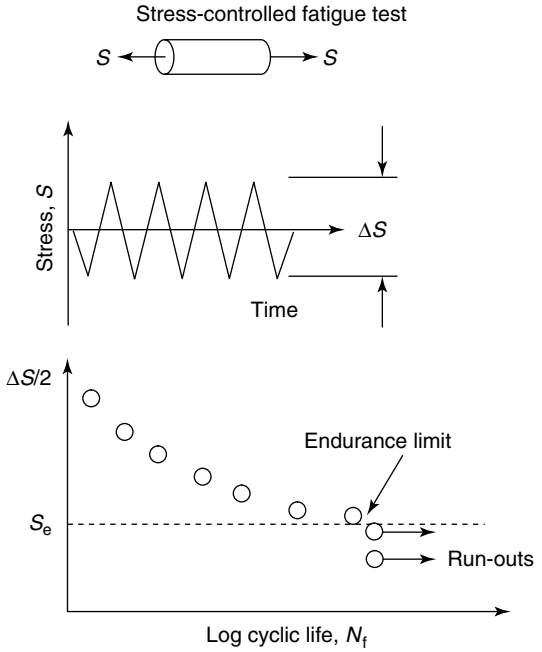

Figure 2. Schematic stress–life (S–N) curve showing relationship between applied stress amplitude $\Delta S/2$ and fatigue life N in small specimen subjected to constant-amplitude loading.

material and/or structural imperfections, residual stresses, variable-amplitude loads, and so on.

Test data above the endurance limit (i.e., the finite life regime) may be modeled by equation (4).

$$\frac{\Delta\sigma}{2} = \sigma'_f(2N_f)^b \tag{4}$$

Here $\frac{\Delta\sigma}{2}$ is the applied stress amplitude[a], $2N_f$ is the fatigue life measured in reversals (1 cycle = 2 reversals), and σ'_f (fatigue strength coefficient) and b (fatigue strength exponent) are empirically determined material constants. Since the basic S–N curve is obtained from small, polished specimens subjected to completely reversed constant-amplitude loading, this expression is quite limited in scope, and in practice one must account for specimen size, stress gradients, surface condition, mean stress, notches, and variable-amplitude loading for most practical applications [3–6].

The *strain–life approach* was developed in the 1950s and 1960s [7, 8] to handle shortcomings of the stress–life method associated with plastic deformation encountered during low cycle fatigue (LCF). This method involves testing smooth specimens under constant-amplitude "strain control", and measuring the number of *reversals* to failure $2N_f$. Although the applied strain amplitude $\Delta\varepsilon/2$ is kept constant, the corresponding stress amplitude $\Delta\sigma/2$ needed to maintain the strain limits may change as the material undergoes inelastic deformation. Materials may initially "cyclically soften" or "cyclically harden", although stable stress–strain behavior is usually observed by mid-fatigue life.

The *cyclic stress–strain* curve relates the steady-state stress amplitude $\Delta\sigma/2$ with the completely reversed applied strain amplitude $\Delta\varepsilon/2$ for a series of tests. It may be modeled for subsequent fatigue analyses by dividing the total applied strain amplitude $\Delta\varepsilon/2$ into elastic and plastic components.

$$\frac{\Delta\varepsilon}{2} = \frac{\Delta\varepsilon_{\text{elastic}}}{2} + \frac{\Delta\varepsilon_{\text{plastic}}}{2} \tag{5}$$

Equation (4) and Hooke's law give the *elastic* component of strain in equation (6), where E is the elastic modulus:

$$\frac{\Delta\varepsilon_{\text{elastic}}}{2} = \frac{\Delta\sigma}{2E} = \frac{\sigma'_f}{E}(2N_f)^b \tag{6}$$

Now, solving for the plastic strain amplitude and relating it to the stable stress amplitude $\Delta/\sigma 2$ with another power law defines the empirical constants K' (cyclic strength coefficient) and n' (cyclic strength exponent) in equation (7).

$$\frac{\Delta\sigma}{2} = K'\left(\frac{\Delta\varepsilon_{\text{plastic}}}{2}\right)^{n'} \tag{7}$$

Equations (5–7) are now combined to give the cyclic stress–strain curve:

$$\frac{\Delta\varepsilon}{2} = \frac{\Delta\sigma}{2E} + \left(\frac{\Delta\sigma}{2K'}\right)^{1/n'} \tag{8}$$

Fatigue life behavior is obtained by relating the total applied strain amplitude or the plastic strain amplitude to the lives of individual test specimens. The plastic strain amplitude $\Delta\varepsilon_{\text{plastic}}/2$ may be empirically related to fatigue life (given in reversals

$2N_f$) as follows:

$$\frac{\Delta\varepsilon_{plastic}}{2} = \varepsilon'_f(2N_f)^c \tag{9}$$

This expression defines the fatigue ductility coefficient ε'_f and the fatigue ductility exponent c. Now, as given by equation (10) and shown schematically in Figure 3, combining expressions gives the total strain amplitude in terms of fatigue life.

$$\frac{\Delta\varepsilon}{2} = \frac{\sigma'_f}{E}(2N_f)^b + \varepsilon'_f(2N_f)^c \tag{10}$$

This summation is the key to the powerful strain–life approach to fatigue, and effectively combines the original S–N curve with the plastic strain–life approach. In the LCF regime, elastic strains are small and fatigue life is dominated by the plastic strain. In the high cycle fatigue (HCF) regime, the applied loads are much smaller and the plastic strains are negligible, so that fatigue behavior is controlled by the elastic strain term.

So far, discussion has been limited to completely reversed cycling of smooth specimens without the presence of mean stresses. Mean stress does, however, influence both stress–life and strain–life behavior, with compressive mean stresses being beneficial and tensile means detrimental. Notches also significantly influence fatigue behavior, and are problematic for fatigue analysis. Further discussion of mean stress on fatigue behavior, along with complications of notches is, however, beyond the scope of this paper (see [3–6]).

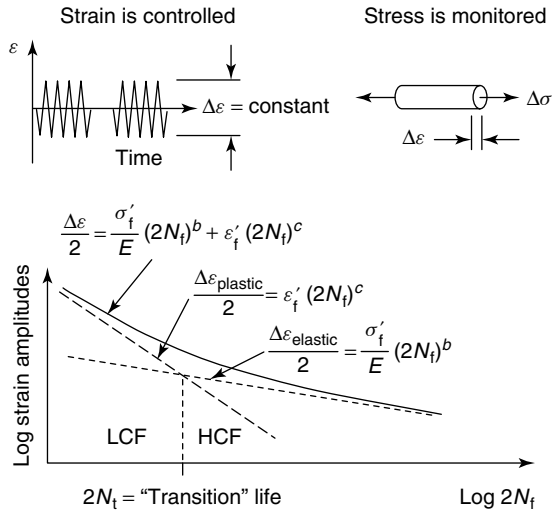

Figure 3. Schematic strain–life curve showing relationship between elastic, plastic, and total strain amplitude with fatigue life $2N_f$ in small specimen subjected to constant-amplitude loading.

3.2 Fatigue crack propagation

This section overviews linear elastic fracture mechanics (LEFM) concepts for crack growth analysis and describes the use of the stress intensity factor to characterize critical and subcritical crack growth. The stress intensity factor K is the LEFM parameter that relates remote load, crack size, and structural geometry, and may be expressed in the form

$$K = \sigma\sqrt{\pi a}\beta \tag{11}$$

Here σ is the applied stress, a is the crack length, and β is a dimensionless factor that depends on crack length and component geometry.

It should be emphasized that the LEFM stress intensity factor K used in the study of the strength of materials. (Note that the stress *intensity* factor has units of stress $\times$ length$^{1/2}$ while the stress *concentration* factor K_t is the dimensionless ratio of local stress at a notch divided by the remote stress.) The stress intensity factor has a rigorous mathematical definition in the context of elastic crack tip stress fields and is based on the fact that all cracks have a characteristic square root singularity at the crack tip [4, 9]. For practical engineering analysis purposes, stress intensity factor solutions have been obtained for many crack geometries, and several handbook compilations are available [10–12].

As a fracture criterion, LEFM employs the experimental observation that "brittle" materials fracture when the stress intensity factor reaches a "critical" value:

$$K = \sigma\sqrt{\pi a}\beta = K_c = \text{constant at fracture} \tag{12}$$

Here K_c is a thickness-dependent material property called the *fracture toughness* of the material and is the limiting value of the stress intensity factor that causes catastrophic fracture in all components made from the same material. Fracture toughness values

for many structural materials are reported in material handbooks [13]. Note that since K relates load, crack length, and structural geometry this simple fracture criterion allows one to correlate fracture measurements from laboratory specimens with fracture of actual structural components.

The fracture mechanics approach to fatigue is based on work by Paris [14], who demonstrated that the cyclic range in stress intensity factor ΔK controls the fatigue crack growth rate per cycle $\mathrm{d}a/\mathrm{d}N$. Here ΔK is the difference between the maximum and minimum stress intensity factors applied during a particular cycle of loading and is given by

$$\begin{aligned}\Delta K &= K_{\max} - K_{\min} \\ &= \left(\sigma_{\max} - \sigma_{\min}\right)\sqrt{\pi a}\beta \\ &= \Delta\sigma\sqrt{\pi a}\beta \end{aligned} \tag{13}$$

Now $\Delta\sigma$ is the cyclic stress range, a is the current crack length, and β is a dimensionless function of crack size and geometry as before.

Standard procedures [15] are available to establish the relationship between the applied ΔK and the measured fatigue crack growth rate per cycle $\mathrm{d}a/\mathrm{d}N$ in constant-amplitude fatigue tests with small laboratory specimens. This experimentally determined $\mathrm{d}a/\mathrm{d}N - \Delta K$ curve may be effectively treated as a material property and is also recorded in material handbooks [13]. Note that the ΔK parameter accounts for the stress range, crack size, and crack geometry (i.e., the β term) for the problem of interest.

When collected over a wide range of crack growth rates, $\mathrm{d}a/\mathrm{d}N - \Delta K$ curves for many materials have the characteristic sigmoidal shape shown schematically in Figure 4. A vertical asymptote is observed when $K_{\max} = K_{\mathrm{c}}$ since fracture occurs at that point. There may also be an asymptote at low ΔK levels, designated as the fatigue threshold stress intensity factor ΔK^{th}. Below ΔK^{th} cracks do not extend by cyclic loading ($\mathrm{d}a/\mathrm{d}N = 0$), and the specimen would have "infinite" life. The ΔK^{th} value is the fatigue crack growth analog to the endurance limit S_{e} measured in *uncracked* fatigue specimens.

A linear relation between log $\mathrm{d}a/\mathrm{d}N$ and log ΔK is often observed between the upper and lower asymptotes. Paris and Erdogan [14] expressed the crack growth behavior in that region by equation (14).

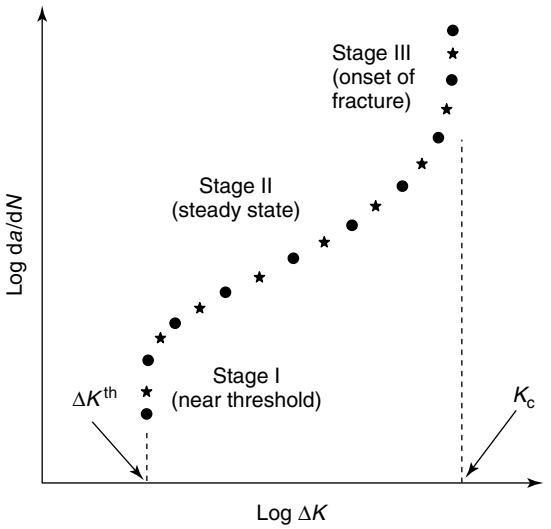

Figure 4. Schematic representation of sigmoidal relationship between fatigue crack growth rate and the cyclic stress intensity factor.

$$\frac{\mathrm{d}a}{\mathrm{d}N} = C\Delta K^{m} \tag{14}$$

Here C and m are empirical material constants obtained for a particular set of material data. Many other more general crack growth equations have been employed to relate $\mathrm{d}a/\mathrm{d}N$ with ΔK [4], yielding equations of the following form:

$$\frac{\mathrm{d}a}{\mathrm{d}N} = F(K) \tag{15}$$

Here $F(K)$ is a mathematical expression that fits $\mathrm{d}a/\mathrm{d}N$ over an appropriate range of ΔK values, including the upper and lower asymptotes. These crack growth models may also account for other loading variables, such as mean stress and temperature.

Returning now to the original objective of predicting the fatigue crack growth *life*, it is a simple task to integrate equation (15) for the total cycles N_{f} required to grow an initial crack of length a_0 to some final size a_{f}. Solving for the cyclic life gives

$$N_{\mathrm{f}} = \int_{a_{\mathrm{o}}}^{a_{\mathrm{f}}} \frac{\mathrm{d}a}{F(K)} \tag{16}$$

It is important to recognize limitations to the stress intensity factor approach described here. It is assumed that K is a valid crack parameter and that crack tip plasticity effects are negligible [4]. Large peak loads applied during the fatigue cycling can introduce large plastic zones, for example, which significantly influence subsequent fatigue crack growth (cause fatigue crack retardation as described in the following section). Sophisticated life analysis procedures have, however, been developed to analyze peak overloads, mean stress, temperature, and environmental influences (i.e., corrosion fatigue) that may occur in service. For variable-amplitude loading, for example, equation (16) cannot be integrated directly, but life is obtained by a cycle-by-cycle summation of crack growth rates for individual loading cycles. Additional details of those procedures are presented in [4].

The LEFM approach may also be applied to the stress corrosion problem where cracks can form and extend under the combined influence of a *sustained* tensile stress and an aggressive chemical environment. Again, laboratory tests are used to correlate the stress corrosion crack growth rate $\mathrm{d}a/\mathrm{d}t$ as a function of the applied stress intensity factor K. In this case, K results from a sustained tensile stress rather than a cyclic load as in fatigue, and crack growth is measured as a function of elapsed time (i.e., hours, days) rather than cycles. Again the curve of log $\mathrm{d}a/\mathrm{d}t$ versus log K assumes a sigmoidal shape between a lower (K_{ISCC}) and upper (K_{c}) asymptote. As before, these data can be represented by the empirical equation

$$\frac{\mathrm{d}a}{\mathrm{d}t} = f(K) \tag{17}$$

where $f(K)$ is some convenient mathematical function chosen to represent the test data. Now, the total time t_{f} required to grow a crack from length a_0 to a_{f} is given by

$$t_{\mathrm{f}} = \int_{a_0}^{a_{\mathrm{f}}} \frac{\mathrm{d}a}{f(K)} \tag{18}$$

Note that different crack geometries and component materials are treated in a manner analogous to computing fatigue crack growth lives.

It is important here to also note the significant effect environment has when combined with cyclic loading. In general, corrosion fatigue crack growth rates can be considerably faster than those observed for cyclic loading in an inert environment. The influence environment plays on fatigue life depends on the cyclic frequency, the shape of the curve of applied load versus time (i.e., the waveform), the temperature, the environment, the crack orientation (with respect to material axes), and, of course, the particular material of interest [4].

4 LOAD HISTORY EFFECTS

Local crack tip plasticity often limits application of the stress–life, strain–life, and LEFM methods, and leads to some peculiar crack growth behavior that can be important for SHM. Consider, for example, the "fatigue crack retardation" phenomenon shown schematically in Figure 5, where application of large tensile overloads can actually *increase* cyclic life. Note that this increase in life (or reduction in $\mathrm{d}a/\mathrm{d}N$) is *not* predicted by the fatigue crack growth rate models discussed in the previous section. Although

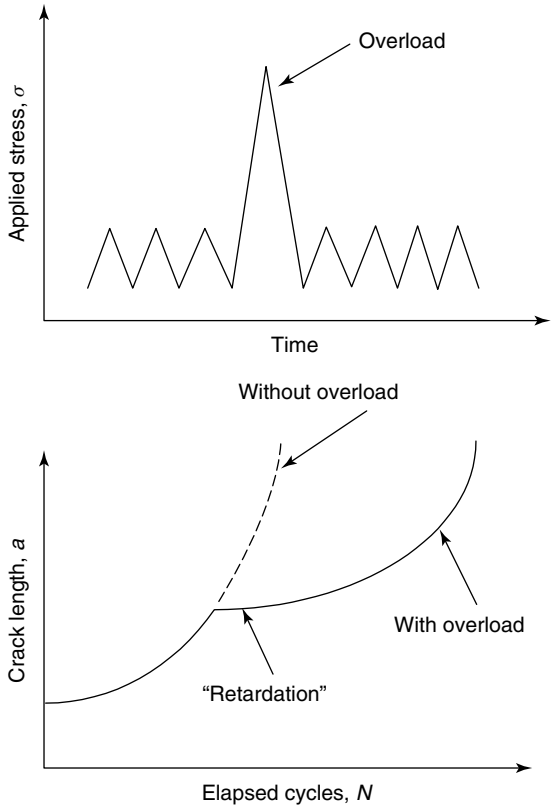

Figure 5. Schematic representation of fatigue crack retardation phenomenon.

the amount of crack delay depends on the particular test material in general, more ductility leads to larger crack tip plastic zones and more retardation. Increasing the magnitude or number of the overloads can also increase the fatigue life and, in some cases, it may be possible to permanently stop subsequent crack growth. (It is assumed here, of course, that $K_{max} < K_c$ during the overload cycle, so that it does not cause fracture.)

Test data showing the influence of overloads on fatigue crack growth lives in 7075-T6 aluminum specimens are given in Figure 6 [16]. Note that in the absence of peak overloads the fatigue life for a center-cracked specimen was less than 10 blocks of 4001 constant-amplitude cycles. Here the constant-amplitude loading during each block varied between 2.7 and 8.0 ksi (18.3 and 55.2 MPa) remote stress. When *one cycle* per block was changed to vary between 2.7 and 14.4 ksi (18.3 and 99.3 MPa), however, the life *increased* to approximately 480 blocks (a 50-fold increase in life).

The sign and sequence of the overload can have a tremendous influence on life, as shown in Figure 7 [17]. Here fatigue crack growth curves are given for

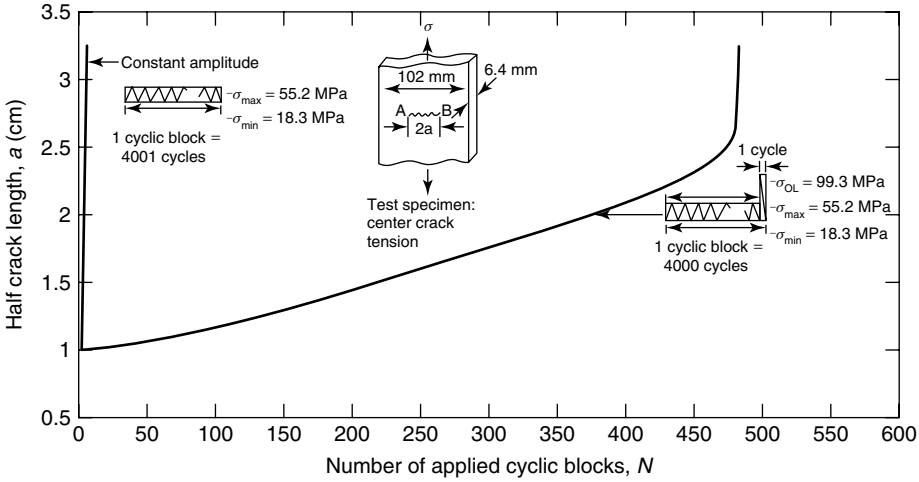

Figure 6. Fatigue crack retardation produced by a single peak overload in aluminum alloy 7075-T6 [16].

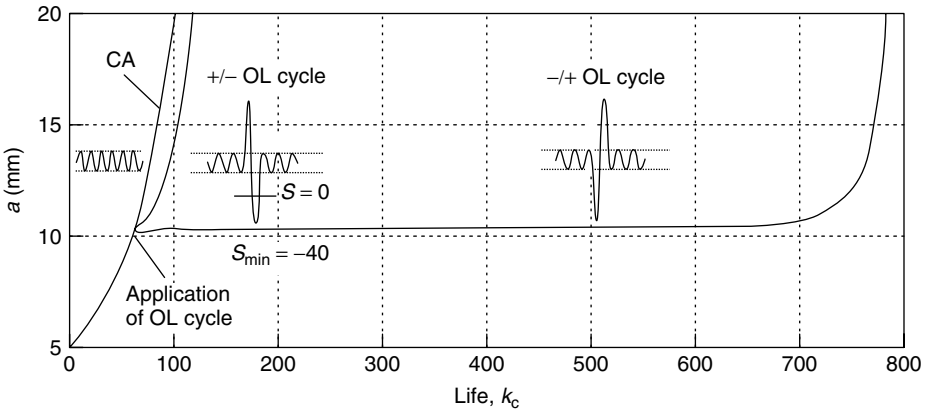

Figure 7. Test data showing the effect of two different overload cycles on fatigue crack growth in 2024-T3 aluminum. Mean stress is 80 MPa in all cases. Stress amplitude is 25 MPa for constant-amplitude cycles and 120 MPa for overload cycles [17].

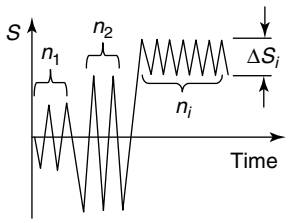
three center-cracked 2024-T3 aluminum specimens. Compare the crack growth behavior after a 0.4-in. (10-mm) crack length for these three cases. In the first instance, constant-amplitude cycling continued between 8.0 and 15.2 ksi (55 and 105 MPa) remote stress, and failure occurred within 50 000 additional cycles (curve CA in Figure 7). Another specimen, however, was subjected to a single peak under load of −5.9 ksi (−40 MPa) followed by a minimum peak overload of +29 ksi (200 MPa) at that time and then returned to the original constant-amplitude cycling. Note that this specimen lasted nearly 700 000 more cycles, an order-of-magnitude life increase compared to the original specimen without the overload cycle. When a third specimen was subjected to an overload cycle that was identical to that applied to the second specimen, *except that the order* of the −5.8 ksi and the +29 ksi (−40 MPa and +200 MPa) underload/overload peaks were *reversed*, the retardation effect was nearly eliminated, and the specimen had approximately the same life as for the original constant-amplitude loading. Thus, subtle changes in load sequencing can be very significant when the fatigue crack retardation phenomenon is present and pose a particular challenge for SHM (i.e., both magnitude *and* sequence of applied loads need to be considered).

Now consider the important issue of variable-amplitude fatigue life prediction by the stress–life or strain–life methods. Although this topic might best be approached by fatigue tests with the actual load history of interest, such experiments are cost prohibitive for all possible loadings, so there is great interest in predictive methods that employ the basic, completely reversed constant-amplitude data. Again, however, variable-amplitude fatigue analysis is a complex subject that can only be overviewed here, and the reader is referred to [3–6] for additional details.

Recall that the effects of constant-amplitude loading are described by equations (4) and (5) for the stress–life and strain–life approaches. Now consider the more general case where the applied load consists of various *blocks* with different stress amplitudes and mean stresses (or strains) or, in the limit, completely random loading. The simplest approach here is to assume that fatigue damage accumulates in a "linear" manner that is independent of load history. This assumption may be stated by equation (19) and is known as *linear cumulative damage* or *Miner's rule*.



Miner's rule: $\Sigma(n_i/N_{if}) = 1$

n_i = number of applied cycles of stress range ΔS_i

N_{if} = fatigue life for ΔS_i cycling only

Figure 8. Definition of Miner's rule for variable-amplitude loading.

$$\sum \frac{n_i}{N_{if}} = 1 \tag{19}$$

As shown in Figure 8, n_i is the number of *applied* cycles with the ith loading block that has a given stress range ΔS_i and mean stress, and N_{if} is the fatigue life that would result if only the ith block of loading were applied to the specimen. Basically, equation (16) states that n_i/N_{if} is the percentage of fatigue life exhausted for the ith loading block, and that when the damage summation for all blocks equals 1 (i.e., 100%), the total fatigue life is expended. Note that N_{if} for the ith block incorporates the effect of both mean stress and stress range but does not include potential load history effects (i.e., residual stresses) that could be developed by prior loading blocks. Miner's rule can also be employed with the strain–life approach by simply expressing the fatigue lives in terms of reversals (i.e., $2n_i$ and $2N_{if}$) and using the strain–life relationship (equation 10) to compute the percentage of damage accumulated during each loading block.

Although Miner's rule has seen wide use in industry, it has significant limitations that can lead to inaccurate results. The chief shortcoming is the failure to recognize that the *sequence* in which loads are applied can have a significant influence on life through development of residual stresses. Recalling the load history effects associated with fatigue crack growth, it is not surprising that similar issues also exist for the fatigue "nucleation" phenomena.

Crews [18], for example, reports the results of fatigue tests with 12 × 35-in. (30 × 87.5-cm)

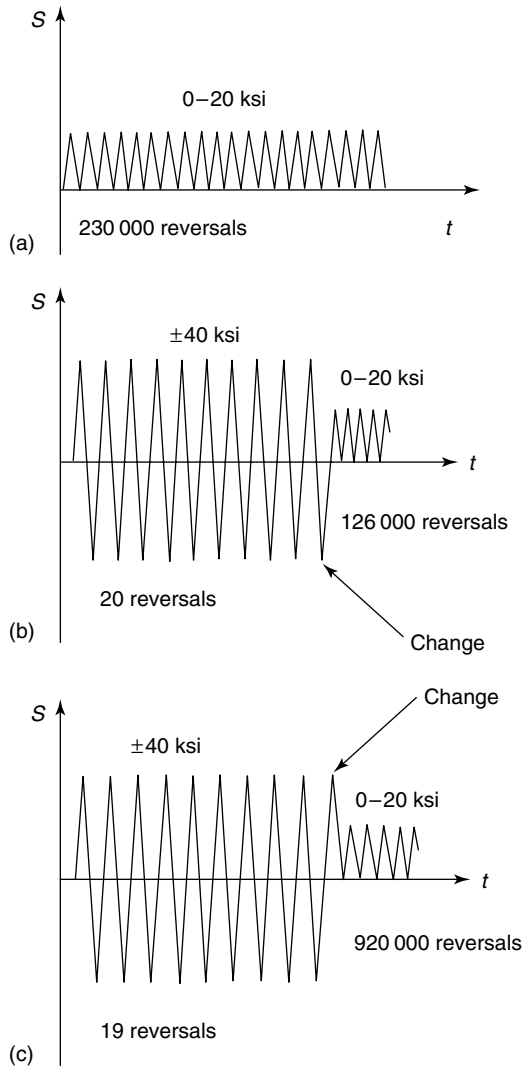


Figure 9. Stress–time histories showing effect of load sequence on fatigue life for notched aluminum specimens tested by Crews.

2024-T3 aluminum plates that contained 2-in. (5-cm) diameter open holes. As shown in Figure 9, one reference specimen subjected to a constant-amplitude remote stress that varied from 0 to 20 ksi (0–138 MPa) had a fatigue life of 230 000 reversals. Two identical specimens were subsequently tested to the same stress history, except for a few initial reversals of ±40 ksi (275 MPa) stress. Although similar, these two "high–low block" loads differed in one critical detail: the sign of the last large peak before the load amplitude was decreased. This subtle change in loading sequence had a large influence, however, on fatigue life. When 20 reversals of ±40 ksi (±138 MPa) were applied before reducing to the 0–20 ksi (0–138 MPa) load *after* the *last large compressive* (40 ksi = 276 MPa) peak, the specimen had a fatigue life of 126 000 reversals, less than the reference case without the large preloads. In a third specimen, the high–low load transition was made *after* the last 40-ksi (138-MPa) *tensile* peak and only involved 19 reversals of the larger preload. That specimen resisted 920 000 additional 0–20 ksi (0–138-MPa) reversals, over seven times as many as the prior sequence, and four times as long as the reference 0–20 ksi (0–138 MPa) loading. Thus, the large preloads actually *increased* the fatigue life as compared to the original case without the large loads. Clearly, load sequence effects play a significant influence on fatigue life that is not predicted by Miner's rule, which would give essentially the same total life for both high–low load sequences.

As shown schematically in Figure 10, the high–low load block sequencing phenomenon results from mean stresses created by overloads. Here two completely reversed strain blocks are applied to a smooth test specimen, and the resulting stress history required to maintain the strain peaks is shown. Note that the first large strain block develops a stable hysteresis loop, and continued cycling about this loop results in the large, *completely reversed* stress history shown.

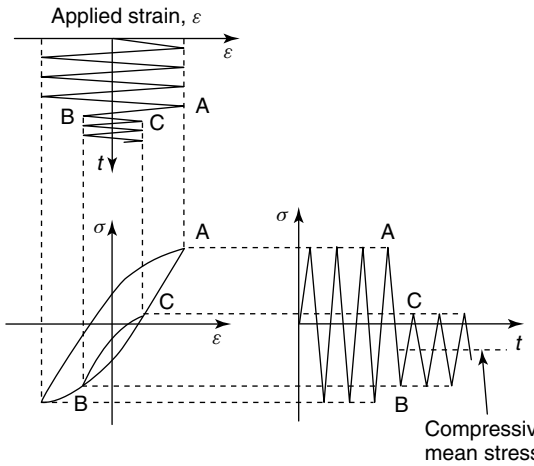

Figure 10. Strain–life sequence showing development of compressive mean stress under high–low strain loading sequence where the last large strain peak is tensile.

However, when the strain amplitude is reduced after a tension peak (i.e., the ABC sequence shown in Figure 10), subsequent strain-controlled cycling follows the smaller hysteresis loop BC contained in the original large loop. Note that this sequence develops a *compressive mean stress* for subsequent completely reversed cycling at the smaller strain amplitude. This compressive mean stress will increase the fatigue life for the small-amplitude strain block. If, instead, the sequence for changing from high to low strain amplitudes is reversed, so that the last large peak before changing amplitude is *compressive*, a deleterious tensile mean stress is created [4].

Thus, it is possible to develop tensile or compressive mean stresses during sequences of completely reversed strain cycling. These mean stresses may be estimated by the cyclic stress–strain curve (equation 8) for *simple* block loadings and incorporated into Miner's rule by modifying the N_{if} term in the denominator of equation (19) to account for the presence of a tensile or compressive mean stress. Details for these types of calculations are given in [3, 5]. Although not discussed here, cycle counting methods are another important aspect of this procedure for determining variable-amplitude fatigue lives (see [3, 19]).

5 PROPOSED WITNESS SAMPLE APPROACH FOR SHM

One goal of SHM programs is to ensure damage tolerance and durability by refining inspection and maintenance intervals based on actual usage. Although those intervals often employ design load assumptions, experience has shown that actual service differs significantly from that projected during design. The fact that individual members within a fleet may encounter large variations in load severity, combined with sequencing effects, indicates that individual structures will accumulate fatigue damage at significantly different rates. This issue is further complicated by the wide variation in the thermal–chemical environments encountered during service, so that the potential for corrosion and/or corrosion fatigue can also vary significantly. As discussed in the previous section, fatigue damage accumulation is particularly sensitive to the magnitude and *sequence* of applied loading, making fatigue monitoring problematic for SHM.

SHM uses data acquisition and reduction tools to measure loads applied to individual structures to predict potential damage in key structural components. Current tracking techniques employ mechanical and electronic strain gauges, acoustic emission monitors, counting accelerometers, flight load recorders, pilot logs and other devices to measure and record applied loads. This load information must then be analyzed by complicated computer algorithms to determine the extent of fatigue damage seen by the structure. These techniques require large capital, extensive effort, and many assumptions to reduce the data to fatigue life, and could introduce errors that lead to inspection intervals that are either too long or too short. Thus, a simplified SHM approach that is sensitive to parameters that control fatigue life is needed.

One method proposed by the author for SHM is the "witness sample" or "fatigue crack gauge" concept [20–25] for real time assessment of the potential for imminent failure due to service-induced damage accumulation. As shown schematically in Figure 11, the witness sample technique is a potentially simple and inexpensive prognosis sensor. The witness sample is simply a precracked coupon that is attached to a load bearing component. Since the "crack gauge" receives a predictable fraction of the component loads, it is also subjected to damage accumulation scaled to that seen by the parent structure. Moreover, since the gauge and structure are subjected to the same thermochemical environment, corrosive aspects of crack growth are automatically accounted for.

Now the crack gauge effectively acts as an analog computer that measures loads applied to the structure, determines their effect on fatigue crack growth, and responds with an output (gauge crack extension) that is directly related to damage formation in the component of interest. Thus, monitoring the gauge crack length gives a real time measure of the "potential" for crack growth in the structural member. It should be emphasized that although the gauge crack is physically present, the *structural* crack is a fictitious metric whose initial size and location are chosen to be consistent with the fracture mechanics worst-case initial crack assumption specified by the appropriate damage tolerant design criteria.

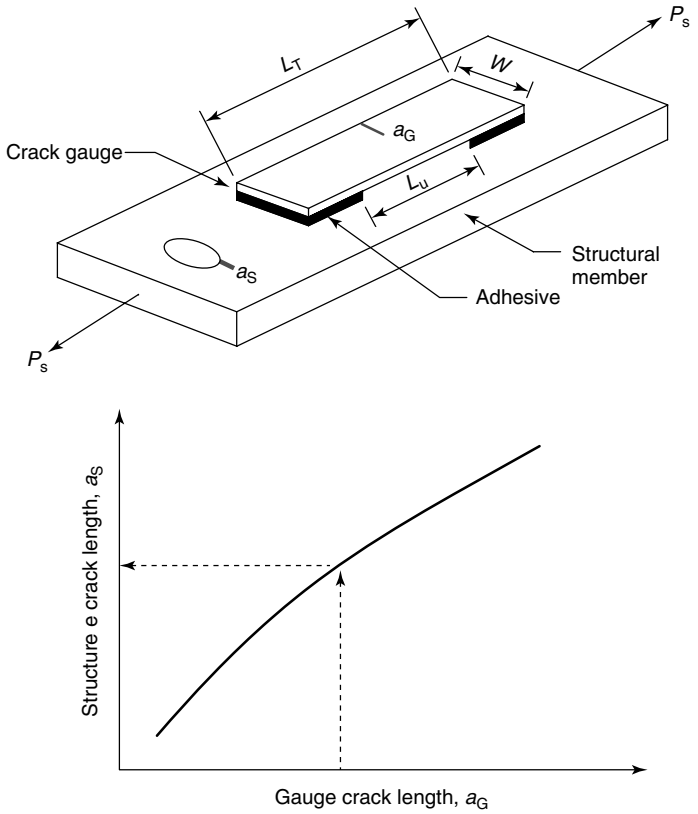

Figure 11. Schematic view of crack gauge mounted to structural component and transfer function relating measured gauge crack growth with extension of assumed structural flaw.

The theoretical basis for the fracture mechanics based "transfer functions" to relate gauge and structural cracks is discussed in [20–25] along with techniques for designing a crack gauge to give a desired response for the application of interest. Extensive laboratory testing has verified the transfer function calculations and has shown the crack gauge approach to have a firm foundation in fracture mechanics theory. Briefly, the theoretical model assumes the coupon is attached to the structure (by adhesive bonding, for example) in such a way that when a remote stress, σ_S, is applied to the structure, an effective stress, σ_G, is transferred to the gauge. This relationship can be represented by

$$\sigma_G = f\sigma_S \tag{20}$$

It has been shown that the load transfer function, f, depends on parameters such as gauge geometry and material properties, but not on the stress level. The load transfer function can be found by stress analysis, based on either theoretical or experimental techniques. Noting that at any point in time the gauge and structure have witnessed the same number of cycles, N, equation (16) can be solved for cyclic life, N:

$$N = \int_{a_{iS}}^{a_{fS}} \frac{da}{F_S(\Delta K)} = \int_{a_{iG}}^{a_{fG}} \frac{da}{F_G(\Delta K)} \tag{21}$$

Here a is crack length, the subscripts i and f refer to initial and final crack lengths, and the subscripts S and G refer to structure and gauge, respectively. In particular, a_{fG} would be the current crack length measured in the witness sample, and a_{fS} is the corresponding crack length in the structure (i.e., the SHM metric of interest).

Assuming the Paris law of equation (14) for the crack growth rate function $F(\Delta K)$, equations (20) and (21) give

$$N = \int_{a_{iS}}^{a_{fS}} \frac{da}{C_S(\Delta\sigma_S\sqrt{\pi a}\beta_S)^{m_S}} = \int_{a_{iG}}^{a_{fG}} \frac{da}{C_G(f\Delta\sigma_S\sqrt{\pi a}\beta_G)^{m_G}} \quad (22)$$

Note that crack length a is the variable of integration and neither f nor β depends on the cyclic load $\Delta\sigma_S$. Now if the gauge and structure have the same crack growth exponent, $m_S = m_G = m$ (a reasonable assumption if the gauge and structure are made of similar materials), $\Delta\sigma_S$ cancels and equation (22) reduces to

$$\int_{a_{iS}}^{a_{fS}} \frac{da}{C_S(\sqrt{\pi a}\beta_S)^m} = \int_{a_{iG}}^{a_{fG}} \frac{da}{C_G(f\sqrt{\pi a}\beta_G)^m} \quad (23)$$

While this expression no longer determines the cyclic life, N, it can be numerically integrated to provide information on the current structure crack length (a_{fS}) provided an initial structural crack length is assumed (i.e., the usual initial damage tolerant analysis assumption). Thus, equation (23) provides a "transfer function" that relates measured crack length in the coupon ($a_{fG} \equiv a_G$) with the current length ($a_{fS} \equiv a_S$) of an *assumed* structural crack as shown schematically in Figure 11. Note that all stress level terms effectively cancel, so that the relationship between the gauge and structure crack lengths is *independent* of loading. Indeed, a distinct advantage of this model over current fatigue tracking methods is that it requires no knowledge of the load history (i.e., the current gauge crack length a_{fG} is a measure of the actual applied load history). Experimental data verifying the accuracy of equation (23) as a transfer function are given in [20–25].

An alternate version of the witness sample transfer function model that employs two crack gauges is described in [24]. This "double gauge" procedure entails matching the output from two independent witness samples. In this case, however, one knows the current crack length in both coupons, and can solve equation (22) for an effective stress $\Delta\sigma_S$ that has been experienced by the structure. Once this effective stress has been determined, one would again use the output from one (or both) of the witness samples to determine the current length of the assumed structural crack. The advantage of this approach is that more general fatigue crack growth models may be employed for subsequent analysis than the limited Paris law.

6 CONCLUDING REMARKS

The objective of this article has been to introduce some of the challenges dealing with damage formation and growth that must be considered when designing an SHM system. Guaranteeing structural integrity requires anticipation of all possible failure mechanisms and then providing adequate resistance to these various threats. Whereas every effort is made to ensure high-quality construction, experience has shown that it is impossible to build complex mechanical devices that are free of initial manufacturing or material flaws. Moreover, accidental damage may occur during use, along with fatigue, corrosion, or other forms of material degradation. Although damage tolerant designs protect against such trauma by keeping stress levels small, employing damage resistant materials, and providing crack-arresting structural features, continued SHM during service is an important step for scheduling maintenance actions in the most cost-effective manner.

The foundations for structural integrity have been compared with the stability provided by a "three-legged stool". One leg is a rigorous inspection program that locates manufacturing or service-induced damage before it can lead to failure. Another leg is superior residual strength that ensures the catastrophic fracture load always exceeds the largest applied service load. The third leg of the damage tolerance stool is a long subcritical crack growth life that gives many opportunities to locate and repair any damage that does develop before it grows to a size that causes final fracture. These three legs work together to ensure structural integrity throughout the planned service life.

Since individual usage can fluctuate widely from the fleet average, however, different damage states can develop in particular structures at a given time, leading to a variation in required inspection intervals. Fatigue damage is especially sensitive to actual usage, and is difficult to predict without detailed knowledge of the unique service loads experienced by a given

component. SHM provides an extra dimension to the "three-legged stool" by providing the means to tailor inspection intervals and maintenance actions to individual members. Thus, SHM provides the means to maintain integrity in the most cost-effective manner.

END NOTES

[a.] Here the "engineering" stress S is replaced with the corresponding "true" stress σ (see [3–5]).

1 GENERAL REMARKS ON FAILURE PROCESS

Substantial research has been performed in the last few decades on understanding of nucleation and growth of cracks in materials, and as a result, failure modes on laboratory coupons are well understood for metallic alloys, ceramics, ceramic matrix composites (CMCs), organic matrix composites (OMCs), and carbon–carbon (C–C) composites. However, failures in the actual components in near-operational environments are still not well understood. The topic is too broad to cover in this article and, therefore, the discussion is restricted to laboratory coupon research in metals and OMCs.

Many of the structural components in use today are manufactured from metallic alloys. Aluminum alloys are most commonly used as airframe materials although the recent trend has been to use composites. Ti alloys are also used but in hotter sections of the airframe, and also as fan and compressor blades in turbine engines. Ni-based alloys (single crystals and equiaxed microstructures) are used in the high-temperature section of the turbine engine. In case of metals, it is important to have a good knowledge of chemical composition, primary processing and secondary processing methods used to produce the material and components, grain size and inclusion (impurity) content, and the morphology, shape, and size of strengthening precipitates. Grain size has a major role in determining the strength, ductility, fracture toughness, threshold for fatigue crack propagation rate, and creep. Strengthening precipitates determine strength, low-cycle fatigue life, fatigue crack growth resistance, and environmental fracture resistance. Inclusion content depends on the purity of an alloy. Large inclusion size is detrimental to fatigue crack initiation and result in low fracture toughness.

 ISBN: 978-0-470-05822-0.

The 7000-series and 2000-series aluminum alloys are commonly used as structural materials for airframe fuselage construction and wing structure. The 7000 series is high in strength and the 2000 series belongs to the damage tolerant class. Zn, Mg, and Cu are the strengthening elements for the 7000 series, whereas Mg and Cu are for the 2000 series; for both alloys Ti and Cr/Zr/Mn control grain size. Ti controls grain size during casting the ingot and Cr/Zr/Mn controls grain size during primary processing and solution heat treatment.

In aluminum alloys, primary processing varies depending on whether the product form is a forging, sheet, or a thick plate. Depending on this primary processing, fracture varies. For example, in the case of a thick plate, commonly employed for bulkheads and wing structure, grain size and chemical composition from the mid thickness of the plate to the top or bottom surface can result in a strength variation and crack propagation direction.

Secondary processing refers to the solution heat treatment temperature (400–550 °C depending on the alloy) and the aging treatment applied (120–170 °C depending on the alloy and desired temper) to attain desirable strength and damage tolerant characteristics in precipitation-hardened alloys. The solution treatment temperature, along with the amount of grain size refining elements listed above, can affect recrystallization and grain growth. Also, different aging temperatures and times can affect the precipitate distribution, size, and coherency of the precipitate. All these factors, i.e., grain size and precipitates, affect the strength, fracture toughness, and crack growth properties of the material.

The impurity content in alloys, primarily Si, and Fe in Al alloys, greatly affects ductility, fracture toughness, and nucleation of fatigue cracks. Obviously, higher impurity content results in inferior properties.

Besides the chemistry and heat treatments, defects arising from improper machining during component manufacturing can play havoc in failures. If sharp radii are present in the structure, stress concentration results causing fatigue crack nucleation if the structure is under fatigue loading or can become sites for promotion of brittle fracture during static loading in an otherwise ductile material.

In almost all metallic structures, large inclusions such as those formed from impurity content can give rise to premature crack nucleation under fatigue loading conditions. In very high pure alloys, slip bands can take over the nucleation of fatigue cracks. The load range then influences further crack growth. The later sections elaborate these points. The thickness of the structure can also play a role by influencing whether the structure would be under plane-strain or plane-stress conditions. Plane-strain conditions reduce the strain required for fracture. Industrial applications, therefore, minimize the use of thick structures to avoid plane-strain conditions unless required for load-carrying purposes. However, in some cases such as airframe bulkheads of fighter aircraft, it is not possible to avoid thick structures. Fatigue cracks initiate from the bolt-holes and the critical crack length to fracture (the crack length that corresponds to fracture toughness of the alloy) must be evaluated on thick sections of the alloy rather than thin sections. In the case of thin structures where plane-stress conditions exist, failure mode will shift from a catastrophic plane strain (with very little ductility) to a more slant fracture or a ductile fracture.

Gaseous species in the environment accentuate fracture. A very common static fracture that occurs is in the case of landing gear steels, where an improper electroplating process can lead to hydrogen embrittlement. (Hydrogen is adsorbed/absorbed into an alloy, such as steels, during electroplating and thus must be removed by a post-heat-treatment process.) Some alloys, high-strength aluminum alloys and high-strength steels, are susceptible to stress corrosion cracking (SCC) in the presence of aqueous environments such as high humidity and sodium chloride solution. A premature and unpredictable fracture may also occur when the structure is under fatigue load and environment-assisted crack growth (corrosion fatigue) can rapidly occur.

Airframe structures also employ Ti-6Al-4V and Ti-6Al-2Sn-4Zr-6Mo alloys but on a much smaller scale owing to prohibitive cost. Currently, a number of Ti alloy airframe applications require welding and the welding process of large structures for service conditions is difficult. During welding, tensile residual stresses are introduced. Their removal is critical as they promote unpredictable failures. Nickel alloys, used as engine materials, are much more complex than the aluminum class of alloys used in the airframe. Extensive database covering the failure modes for in-service environments are discussed

at length in handbooks such as the ASM Metals Handbook on fractography.

In the following section, physics of failures for metals is introduced and summarized.

2 PHYSICS OF FAILURE OF METALS

2.1 High-level classification

At a high level, failure modes in metals or alloys can be broadly classified under three categories: (i) deformation, (ii) fracture, and (iii) material loss (Table 1).

2.1.1 Deformation

A metallic alloy can fail to perform an assigned function owing to excessive deformation either arising from low-yield strength or through creep at high temperatures. Most of the plasticity associated with yield is athermal, whereas in the case of creep it is thermal. In both cases, plasticity plays a key role as a failure mode even though fracture has not occurred because the component is prevented from performing its function. Creep deformation resulting from applied stress and high temperature is a function of time. Many of the components that undergo creep deformation are designed not to exceed a certain amount of deformation under a given applied load over a specified time interval. The amount of creep deformation allowed in a design can lie in either the primary creep regime or secondary regime.

2.1.2 Fracture

Fracture is a very broad term; however, at a higher level it can be classified as static, dynamic, and creep rupture. Static fracture occurs when the load is applied monotonically, thus overloading or overstressing the material. Cyclic loads are absent in static fracture situations. Creep rupture (not deformation as discussed above) is the second major mode of failure that occurs in high-temperature components. Rotating engine parts such as turbine blades are influenced by centrifugal forces at high temperatures for prolonged periods. Excessive creep deformation may initially occur but continued exposure may lead to creep rupture, which may be owing to either a poor selection of materials or a poor definition of the operational environment. Creep rupture is a parameter commonly employed in the design of pipes carrying liquid through a boiler or a nuclear reactor. Creep in the pipe not only reduces the cross section of the pipe but also promotes the formation of small cavities over time at the operating temperature. The cavities form either intragranularly or at the grain boundaries, which eventually link up resulting in failure through creep rupture. The formation of cavities is a thermally activated process.

2.1.3 Dynamic fatigue

Major attention has been focused over the last few decades on the field of fatigue as the majority of failures occur under fatigue loading. When a component is subjected to cyclic stress, fatigue failure occurs with plasticity accumulation. Fatigue properties can be determined by using smooth bars that

Table 1. Classification of Failure Modes in Metallic Alloys

Deformation	Yield	Athermal plasticity	f (stress)
	Creep	Thermally activated plasticity	f (temperature, time, stress)
Fracture	Static	Athermal/acyclic fracture	f (stress)
	Creep rupture	Thermally activated cavitation leading to fracture	f (temperature, time, stress)
	Dynamic fatigue	Cyclic plasticity leading to nucleation/growth of cracks	f (cyclic stress, cycle#)
Material Loss	Corrosion	Athermal loss of material	f (time, environment)
	Oxidation	Thermally activated	f (time, temperature, O_2 pres)

can be subjected either to stress-controlled or strain-controlled cyclic loads. Smooth bars represent failure in the absence of cracks in the structure. In stress-controlled fatigue testing (high-cycle fatigue), applied stress is below the yield stress and very little plasticity is accumulated. In the case of strain-controlled fatigue (also known as *low-cycle fatigue*), applied stresses are beyond the yield stress of the material and the accumulated plasticity is considerably higher than that in high-cycle fatigue, resulting in fewer cycles to failure. Fracture mechanics tests are conducted for the evaluation of fatigue crack resistance in the presence of a sharp crack. Current fracture mechanics approaches use atomically sharp cracks or microstructural inhomogeneities as crack nucleation sites. In all fatigue situations, the applied stress range (maximum stress minus minimum stress) plays a key role. However, in the fracture mechanics approach, the stress intensity range is the parameter that extends the crack and crack growth rates, which dictate the remaining life. The number of cycles to failure are computed for a given crack size to reach a critical size. The presence of small cracks (equivalent to the size of a microstructure unit such as grain size) is detrimental to engine components; therefore, much attention has been focused in the literature on studying small crack behavior in engine component materials.

2.1.4 Material loss

The last failure mode listed in Table 1 is the loss of material that can occur owing to either corrosion or high-temperature oxidation. Loss of material in a corrosive environment is referred to as *general* or *uniform corrosion* and is strongly dependent on the environment and time of exposure. Many times, components undergoing such corrosion are either repaired by grinding out the corrosion or replaced after a certain amount of material loss has occurred beyond the amount allowed in the design of the component. Note that the time of exposure in corrosive environments is a key parameter. Many other corrosion mechanisms exist and these are discussed in the next level of failure processes. Material loss at high temperatures usually involves material oxidation. For a first-order approximation, material loss by such a mechanism depends on the partial pressure of O_2 and time and temperature of exposure. In this case, loss of material could be rapid as compared to the material loss experienced in the corrosion process.

2.2 Second-level classification

In this section, the factors associated with the first-level failure mechanisms, namely, yield, creep, static fracture, creep rupture, dynamic fatigue, corrosion, and oxidation, are discussed. Here, the goal is to provide a discussion of the microstructural parameters such as grain size, strengthening precipitates, and second-phase particle content that control these material failure modes.

2.2.1 Deformation

Depending on the service temperature, the two material properties that can lead to failure are the yield strength and creep resistance. If one needs to monitor failures due to large plastic deformation, then the athermal plasticity of the material in question must be considered. From the microstructure point of view, the logical question is "what material factors control the athermal plasticity?" For traditional structural engineering materials, the yield strength is inversely proportional to the square root of the grain size (a fundamental microstructure parameter) through the Hall–Petch relation:

$$\sigma_y = \sigma_0 + kd^{-n} \tag{1}$$

where σ_y is the yield strength, σ_0 is the yield strength of a single crystal, d is the grain size, k is the Hall–Petch coefficient, and n is the Hall–Petch slope, typically equal to 0.5.

In conventional airframe materials such as the aerospace aluminum alloys, grain size is controlled by special alloying elements [1], which have a low solid solubility limit at high temperatures and, hence, precipitate out during casting of the alloys. For example, titanium is normally added to castings to control the grain size. In addition, small amounts of manganese, chromium, scandium, and zirconium are added to control grain size and grain shape. Zirconium and scandium are the most effective elements because they form coherent dispersoids; for example, Al_3Zr dispersoid is a second phase that is dispersed in the matrix. They are also very effective in preventing

recrystallization. Apart from the grain size, a second factor that controls plastic deformation is the presence of second-phase particles. These second-phase particles are termed *strengthening phases* or *precipitates*. Additions of zinc and copper in combination with magnesium result in the formation of precipitates that provide the necessary strengthening in aluminum alloys. Many high-strength alloys (7xxx and 2xxx series) used in military and commercial aircrafts contain these elements.

Dislocations are line defects, which propagate resulting in plastic deformation. In an alloy with precipitates, the dislocations either cut through these obstacles or bypass them by leaving loops of dislocations around them. When dislocations shear these precipitates, the strength of a material increases with the increase in volume fraction and radius of the precipitate. When the precipitate size exceeds a "cutoff radius", it is too large to be cut by dislocations. This causes the dislocations to bypass the precipitates during deformation resulting in lower strength. The strength in the cutting regime (i.e., the regime where dislocation cuts through the precipitate) is determined by a variety of factors. The most prominent effect arises from the antiphase boundary (APB) energy in the case of ordered precipitates. The coherency strain (mismatch in lattice parameter between matrix and precipitate) plays a significant role in some systems. Other factors include the volume fraction, size of the precipitates, and friction stress in the matrix and precipitate. Equations describing these multiple effects can be quite complex. In the case of the bypass regime, the strength is dependent on fewer factors as given below:

$$\sigma_{\mathrm{y}} = \frac{\alpha G \mathbf{b}}{l} \tag{2}$$

$$l = \frac{2r}{f^{0.5}} \tag{3}$$

where l is the distance between precipitates, r is the radius of the precipitates, f is the volume fraction, a is a geometrical factor typically equal to 0.5, G is the shear modulus, and $\mathbf{b}$ is the Burgers vector of the dislocation, typically half the lattice parameter.

Thus, the second-phase/precipitate particles lose their ability to contribute to yield strength of the material when they exceed a certain size. In many aluminum alloys, for example, this loss in strength can occur at prolonged exposures to high temperature (approximately 150 $^{\circ}$C) owing to severe coarsening of the precipitates (severe over aging), with the level of coarsening dependent on the individual alloy and the precipitate-forming elements. Many of the designated tempers such as T3, T6, T8, and T7 refer to the extent to which the alloys have been aged at temperatures prior to use. Each temper thus corresponds to a prescribed strength, and each temper is suitable for different applications. However, at present, an on-line monitoring approach for structures that accounts for differences in these factors does not exist.

2.2.2 Creep deformation and rupture

Failures at high temperatures (<0.5 of melting point of material in kelvin) due to excessive deformation caused by creep are not uncommon. Components are not usually permitted to deform beyond a certain amount of strain or thermal plasticity over a specific period of time under load. However, in some instances the amount of creep is not critical, but failure due to creep rupture has to be avoided (such as in the case of a pipe carrying a hot fluid where a certain amount of deformation can be tolerated, but not rupture of the pipe). Creep rupture data, i.e., stress versus time to creep rupture, at desired temperatures are typically used. As shown in Table 1, to avoid such failures, stress, time, and temperature are key variables, and their effects need to be understood.

The dominance of a specific creep mechanism in any alloy is dependent on the applied stress and temperature [2]. Constitutive equations for each creep mechanism are readily available, and by solving these equations for a desired temperature and stress range, the strain rates can be plotted as isostrain rate contours in an Ashby map (Figure 1).

At high stress and high temperatures, creep rates are determined by a "power law", or "dislocation creep", regime where the creep rates vary with stress rapidly, as given by

$$\frac{\mathrm{d}\varepsilon}{\mathrm{d}t} = A \exp\left(-\frac{Q}{RT}\right)(\sigma - \sigma_{\mathrm{th}})^n \tag{4}$$

where ε is the creep strain, t is the time, A is a material constant, Q is the activation energy for

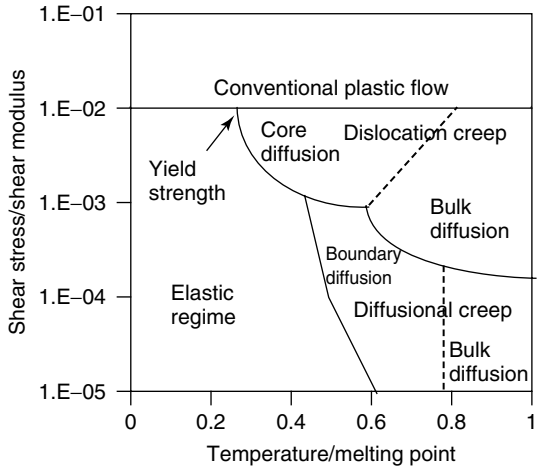

Figure 1. A notional creep deformation mechanism map showing isocreep strain rate contours, and creep mechanisms that can occur in metallic alloys under applied stress and temperature.

creep, R is the universal gas constant, σ is the applied stress, and σ_{th} is a threshold stress that depends on the microstructural state of the material.

At lower stresses, creep rates vary linearly with stress and are said to be undergoing "diffusion creep". Within this regime, at higher temperatures, the creep rate is determined by

$$\frac{\mathrm{d}\varepsilon}{\mathrm{d}t} = 10\frac{\sigma\Omega}{kT}D_{\mathrm{L,o}}\exp\left(-\frac{Q_{\mathrm{L}}}{RT}\right)\frac{1}{d^2} \qquad (5)$$

where Ω is the atomic volume, k is the Boltzmann's constant, $D_{\mathrm{L,o}}$ is the preexponent for bulk diffusion of atoms, Q_{L} is the activation energy for bulk diffusion, and d is the grain size. At lower temperatures, the creep is limited by "Coble" creep and the rate is given by

$$\frac{\mathrm{d}\varepsilon}{\mathrm{d}t} = 47\frac{\sigma\Omega}{kT}(\delta_{\mathrm{b}}D_{\mathrm{b,o}})\exp\left(-\frac{Q_{\mathrm{b}}}{RT}\right)\frac{1}{d^3} \qquad (6)$$

where $D_{\mathrm{b,o}}$ is the preexponent for grain-boundary diffusion, δ_{b} is the grain-boundary width, and Q_{b} is the activation energy for grain-boundary diffusion.

The isostrain rate contours in a plot of applied shear stress (normalized with respect to shear modulus) versus operating temperature (normalized with respect to melting temperature in kelvin) represent the boundaries that delineate different creep mechanisms. Figure 1 shows that at low stresses and high temperatures, Nabarro–Herring creep deformation dominates, where atomic diffusion takes place from boundaries normal to the stress axis to boundaries parallel to the stress axis. Vacancies diffuse in the opposite direction, i.e., from boundaries parallel to the stress axis to boundaries perpendicular to the stress axis. It is important to note here that the microstructural factor that governs the creep strain rate in this regime is proportional to $1/d^2$. Even at lower stresses, creep deformation occurs through vacancy migration but along grain boundaries, and the strain rate is very sensitive to the number of grain boundaries through a $1/d^3$ relationship. There is no dislocation motion in the high-temperature and low-stress regimes, and no grain elongation occurs. Grains, however, do rotate resulting in loss of the original texture and sliding of grain boundaries occur. At higher stress levels, creep is controlled by dislocation movement and is independent of grain size; this aspect is indicated as the dislocation creep regime in Figure 1. Grains here elongate and new textures form. Currently, in order to decipher the specific mechanism that is occurring in a component, specimens from the component are sectioned and prepared for scanning or transmission electron microscopy. Voids, grain size/orientation modification, and formation of new textures can then be studied and documented for any material component after the failure has occurred.

2.2.3 Static fracture

In aircrafts, there are very few metallic components that fail purely owing to a static overload mechanism. However, overload fracture can occur after a crack has first grown by a different fracture mechanism, for example, by stress corrosion. In such a case, a crack grows to a critical size by such a mechanism, and then the final fracture occurs by overload. Rather than using percent elongation or percent area reduction, fracture toughness ($K_{1\mathrm{c}}$) is used as an engineering indicator for a material's ability to withstand overloads under brittle conditions or plane-strain loading conditions.

In order to obtain $K_{1\mathrm{c}}$, a sharp crack is imbedded in a fracture mechanics specimen and fracture toughness

is evaluated using an approach outlined in the American Society for Testing of Materials (ASTM) Standard E399. J_{1c} (elastic–plastic fracture mechanics parameter) is used when the material exhibits considerable plasticity during loading and crack extension; therefore, linear elastic fracture mechanics is not applicable. The tearing modulus defined as dJ/da represents crack growth toughness and has been evaluated recently as an additional parameter to evaluate material fracture resistance. For thin sheet materials, such as the gauge used for aircraft fuselage, R-curves (crack resistance behavior) are generated on very large specimens according to the ASTM standards.

Figure 2 summarizes various microstructural parameters that govern the fracture toughness and tearing modulus for precipitation-hardened aluminum alloys routinely used for aircraft structures [3]. It may be observed that fracture initiation toughness (K_{1c}, J_{1c}) and crack growth toughness (also known as *tearing modulus*, T_r) decrease with an increase in yield strength. The figure also attempts to illustrate that for constant yield strength, as microstructural parameters such as grain size, strengthening precipitates, and impurity content are refined (reduced in size or extent), K_{1c}, J_{1c}, and T_r increase. Fine second-phase particles improve homogeneity of slip, thereby improving fracture toughness parameters. Homogeneity of slip also promotes ductile failure, void nucleation, and growth. Larger grain-boundary precipitates and impurity particles (also known as *inclusions*) decrease toughness through promotion of brittle fracture. Thus, grain size, strengthening phases, and second-phase particle distribution play a key role in fracture initiation, and crack growth toughness of many engineering alloys.

2.2.4 Fatigue

Fatigue is one of the dominant modes of failure, and has been investigated more thoroughly than any other fracture mechanism; numerous papers have been published in the technical literature. When a stress-controlled or high-cycle fatigue test is performed on a smooth or notched specimen, the number of fatigue cycles to failure represents the fatigue life. The cycles to failure normally depend on the R-ratio (the ratio of minimum to maximum applied stress in a cycle $= \sigma_{min}/\sigma_{max}$). In the case of high-cycle fatigue, the maximum applied stress is kept below the yield stress of the material. Cracks usually initiate on the surface either at the site of a large inclusion(s) or at a grinding or a tool mark due to improper machining of the component. In high-cycle fatigue applications, compressive residual stresses are usually induced on the surface either through shot peening or most recently by laser shock peening to increase the component life; however, the compressive residual stresses usually decay with fatigue cycling, so shot peening is not a permanent solution to the fatigue failure problem. Research has shown that the key

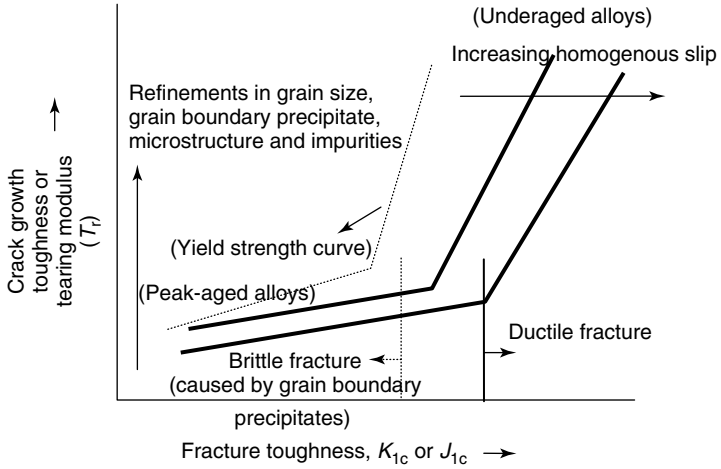

Figure 2. Relationship of crack initiation toughness and tearing modulus (or crack growth toughness) to various microstructural parameters in precipitation-hardened Al alloys.

microstructural parameter in high-cycle fatigue is the size of the largest inclusion or the range of size of inclusions that participate in the initiation of fatigue fracture.

In strain-controlled fatigue, a specimen is cycled within a prescribed strain range that could be below or above the yield of the material. Cyclic plasticity is accumulated as the specimen is cycled and the total accumulated plastic deformation dictates the (low-cycle) cycles to failure. Here, the plasticity is accumulated through slip or dislocation movement from the bulk of the material to the surface. Cracks initiate in slip bands and eventually link up causing failure. The Coffin–Manson law relates the applied plastic strain amplitude, $(\Delta\varepsilon_p/2)$, to the number of strain reversals to failure, $2N_f$, as given by the equation

$$\frac{\Delta\varepsilon_p}{2} = \varepsilon_f'(2N_f)^c \tag{7}$$

where ε_f' is the fatigue ductility coefficient (the value of the plastic strain amplitude when failure occurs in one strain reversal) and c is the fatigue ductility exponent (obtained by the slope of the line that relates the plastic strain amplitude to the cycles to failure).

However, a more important problem in structural fatigue is failure through fatigue crack propagation. Here, the assumption is that when a component is inserted into service after nondestructive evaluation (NDE) inspection, a crack population below the resolution limit of the NDE equipment or due to human error will go undetected. Cracks below the resolution limit of the NDE equipment are assumed to be present in the structure and then the fatigue crack growth law for that particular material in question is applied to estimate the number of cycles that will be needed to grow the crack or cracks to a critical crack size and cause failure. For airframe structures, it is common to assume that cracks below the size of 30 mil (0.762 mm) will go undetected. This number usually gets larger when the structure becomes complex from the point of view of number of material layers and the presence of sealants. As shown in Figure 3, many complex aerospace structures can be made up of multiple layers, sometimes up to five, separated by corrosion prevention compounds known as *sealants*. In addition, the multilayers can also be separated by shims with the structure held together by fasteners, which may or may not consist of the same material as the multilayers. All these factors make the detection, location, and sizing of the cracks extremely difficult, particularly when the NDE inspection is performed without disassembling the structure.

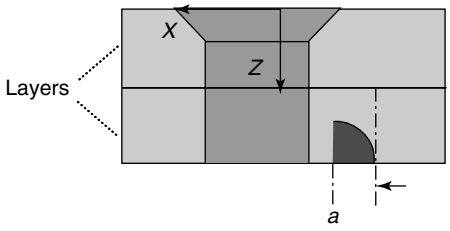

Figure 3. Aircraft lap joint, splice plates with a corner crack near the fastener.

Unlike airframe structures, a small flaw present in a rotating turbine engine component can create a major loss of the entire engine or even loss of the aircraft. Thus, the study of small cracks (cracks whose dimensions are of the same order as that of the grain size of the material or less) is of extreme importance in materials that are used for gas turbine engines. A number of investigations have been performed to understand the growth behavior of small cracks with respect to microstructure, residual stress, and grain size. The reader is referred to the article, [4], as a starting point on this subject. Fatigue crack growth rates (da/dN, where da is the increment in crack size and dN is the increment in number of applied load cycles) for larger cracks for a few common materials are shown in Figure 4 as a function of the stress intensity range ($\Delta K = \Delta\sigma\pi\sqrt{a}$), also termed the *crack driving force* [2]. When the crack growth rate decreases to very small values below 10^{-10} m/cycle, the corresponding stress intensity range is designated as ΔK_{th} and known as the *fatigue threshold stress intensity range*. In Figure 4, the curve designated as "striation model" refers to the *Paris law* and is determined by equation (7). Many aircraft structural components are designed for fatigue crack growth rates corresponding to those in Region II of the fatigue crack growth curve where Paris' law is obeyed and the fatigue crack extends by a striation mechanism given by equation (9) below,

$$\frac{da}{dN} = (\Delta K)^m \tag{8}$$

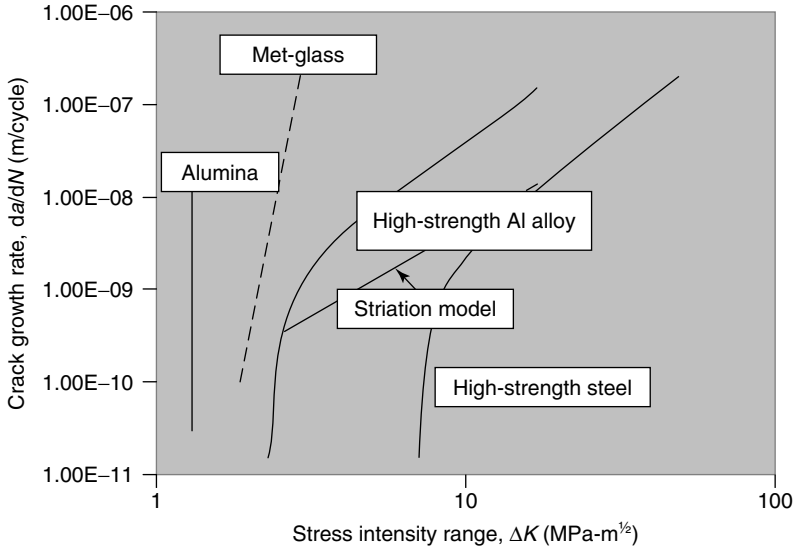

Figure 4. Fatigue crack growth rate versus stress intensity range of a number of materials. Striation models use the Paris law equation.

$$\delta = \beta \left(\frac{\Delta K^2}{E\sigma_{ys}} \right) \tag{9}$$

where δ is the crack-tip opening displacement related to crack growth rate per cycle in the material and β is a constant. In Figure 4, brittle materials such as amorphous glass and alumina exhibit very small crack opening displacement and, hence, need lower driving force or stress intensity range to extend the fatigue crack. In the case of materials such as high-strength steels and aluminum alloys, the stress intensity range for the cracks to grow is larger. Note that the crack opening displacement for a given stress intensity range is related to elastic modulus (E) and yield strength (σ_{ys}) of the material.

As discussed above, for the lower end of the stress intensity range, crack growth rates asymptotically decrease to very small values (10^{-11} m/cycle) and the stress intensity range reaches a fatigue threshold stress intensity ΔK_{th}. In this regime, fatigue crack growth rates are strongly influenced by microstructural parameters such as grain size and second-phase particles. In engineering materials, it is often difficult to isolate the effects of grain size from other microstructural parameters such as second-phase particles. Nevertheless, in precipitation-hardened aluminum alloys, it has been shown that for a uniform grain size, fatigue crack growth resistance is superior when strengthening phases are coherent (underaged alloys) and is inferior when they are incoherent (overaged Al alloys). These effects of strengthening phases are related to slip characteristics and nonlinearity of the crack path in the material. When particles are coherent, crack-tip plasticity is accumulated through planar slip and the fatigue cracks follow the slip planes resulting in a path that has many tilts. In the case of incoherent particles, nonplanar slip dominates, which results in a relatively straight crack path. The out-of-plane crack path (made up of tilted cracks) provides a higher fatigue crack growth resistance. Similarly, the fatigue threshold stress intensity range has also been shown to have a direct correlation with particle spacing and particle volume fraction. Particles with lower volume fractions and larger spacing decrease out-of-plane cracking resulting in larger fatigue thresholds [5–7].

Recently, a comparative study of grain size effects on crack propagation in nickel was performed [8]. The study showed that nickel containing nanosize grains had the least amount of nonlinearity in the crack path and exhibited the fastest crack propagation rates. Fatigue cracks in microcrystalline and conventional nickel with larger grains propagated with much more out-of-plane tilts providing slower fatigue crack

growth rates. In addition, fatigue threshold intensity factors for a number of important engineering alloys were compiled and analyzed and it was shown that the threshold stress intensity range increases with grain size [9]. Thus, the subject of fatigue is vast and the microstructural relationship to fatigue crack growth rate is clearly material dependent. Therefore, for prognosis, it is essential to know the material and its microstructural state so that the fatigue crack growth law corresponding to that particular material and material state in question can be applied.

2.2.5 Corrosion

Uniform corrosion is the term that is used in the corrosion literature and does not necessarily imply the loss of material through chemical reactions. The term is used even though the material loss is different at different locations. The corrosion does not impact structural integrity initially, but can do so if a large amount of material loss occurs. There are at least seven forms of corrosion [10] and of these the ones that affect the engineering structures include pitting, environmentally assisted cracking (EAC), and intergranular corrosion. SCC, corrosion fatigue, and hydrogen embrittlement fall under the category of EAC and, when they occur, can lead to very costly failures.

In the case of SCC, an existing crack in a material propagates under the combined influence of stress and a corrosive environment. The fracture toughness of the material is not altered owing to the environment but an existing crack can reach the critical crack size ($K_{1C} = \sigma\sqrt{\pi a_{cr}}$) through the combined influence of stress and environment. Fracture mechanics test methods exist to evaluate the threshold, K_{1scc} or K_{1EAC} (where EAC refers to environmentally assisted cracking, and the subscript "1" refers to crack opening mode 1, below which stress corrosion cracks will not propagate). The two regimes, "Region I" and "Region II", of SCC in fracture mechanics specimens or structures containing atomically sharp cracks are shown in Figure 5. Numerous reports exist in the literature for Al and Ti alloys where microstructure has been shown to play a dominant role in controlling the fracture mode. High-strength aerospace aluminum alloys

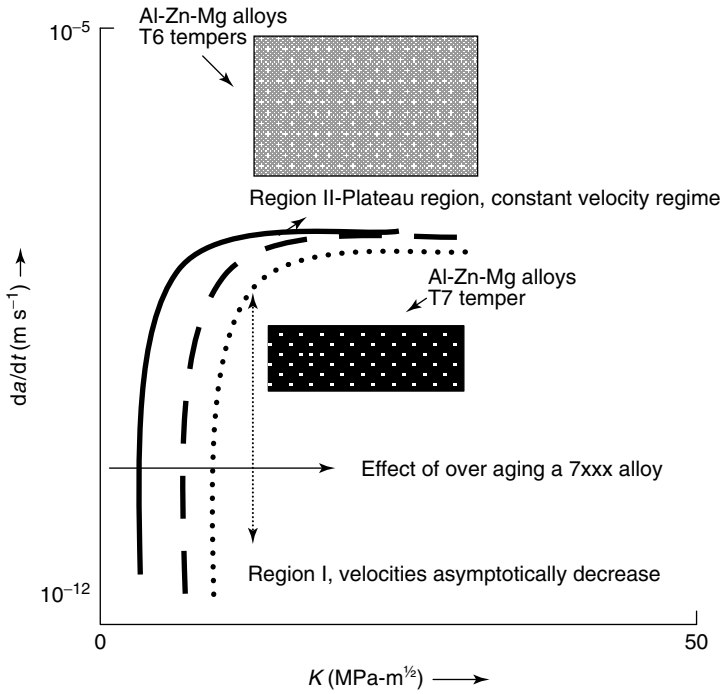

Figure 5. A schematic showing stress corrosion crack growth velocities as a function of stress intensity in high-strength Al alloys. Also stress corrosion crack growth rates are compared in T6 and T7 tempers for 7xxx alloys (notional).

have been investigated thoroughly for SCC in 3.5% NaCl (sodium chloride) solution. This electrolyte is of much interest since chloride ions contained in NaCl solution degrade these alloys significantly. A compilation of stress corrosion crack growth rates for 7079, 7039, 7049, 7075, and 7050 shows that the crack growth velocities (da/dt in $m\,s^{-1}$) are almost similar in the T7 temper, approximately $8 \times 10^{-10}\,m\,s^{-1}$. T7 is the overaged temper. However, many of the older aircraft (aging aircraft) used 7049, 7079, and 7075 in T6 temper that corresponds to a high-strength condition (peak aged) and were not optimized for SCC. In alloy 7079-T6, the SCC cracks grow at $10^{-5}\,m\,s^{-1}$ and at $10^{8}\,m\,s^{-1}$ in 7075-T7. Note that in this temper the stress corrosion crack velocity is much faster than $8 \times 10^{-10}\,m\,s^{-1}$.

However, the literature shows that the effect of aging (of aerospace aluminum alloys) on the SCC resistance is not that straightforward. It depends on the chemical composition of the alloy. For example, in some high-strength aerospace aluminum alloys, it has been shown that overaging (i.e., microstructure containing incoherent precipitates) can improve SCC thresholds, whereas in some alloys the thresholds were not affected; instead the plateau velocity in Region II (Figure 5) of the stress corrosion crack growth rate versus stress intensity was drastically improved [11]. For aluminum–lithium (Al–Li) alloys, the addition of trace elements (zinc or indium) has been shown to improve corrosion resistance or K_{1scc}. The overaged alloys also exhibit improved fatigue endurance limits under high-cycle fatigue (stress-controlled fatigue) conditions. Under corrosion-fatigue conditions in fracture mechanics samples, crack growth rates are found to be a function of cycling frequency. At low frequencies, environmental contributions increase and the crack growth rate increases. Recently, for Ti-8Al-1Mo-1V alloys in 3.5% NaCl solution, it has been shown through analysis of corrosion-fatigue data that the environmental contribution to fatigue increases as the frequency decreases [12]. A parameter that represents environmental contribution was plotted as a function of frequency and it was noticed that this parameter increased linearly as the frequency decreased from 15 to 3 Hz. At 3 Hz, the environmental contribution parameter leveled off. This value was found to be equivalent to the SCC threshold, K_{1scc}, of the alloy. Stress corrosion cracks can be identified as they branch out; however, careful analysis and experience are required to distinguish these cracks from others. Many of the fracture mechanisms and example fractographs can be found in [2, 10].

Hydrogen can also affect crack growth rates in many alloys including Ti-based alloys, which are of interest to the aerospace industry. In these alloys, hydrogen can accelerate crack growth rates by lowering the cleavage fracture stress and/or by forming titanium hydrides. The amount of hydrogen required to embrittle the Ti-based alloys depends on the volume fractions of various phases, stress state at the crack tip, temperature, and crack-tip strain rate. A large body of information on this subject has been published between 1973 and 1990 and the reader is referred to the textbooks referenced in this article.

2.2.6 Oxidation

In metallic alloys, material loss at low temperatures is dominated by the chemical action of the environment as discussed under corrosion. At higher temperatures, oxidation is the primary source of material loss. The rate at which a metal oxidizes varies from one metal to another depending upon the chemistry of elements that make up the alloy. In addition, the microstructural features also affect the oxidation rate. In a well-engineered alloy, the composition is tailored in order to form a very dense, tenacious, and adherent oxide film on the surface that prevents further oxidation by forming a physical barrier between the oxygen and the underlying material. For example, aluminum oxide has a very low permeability for oxygen. However, aluminum itself is a low-melting metal. Nickel has a high melting point and retains strength at higher temperatures, but nickel oxide is not a good barrier to oxygen owing to high permeability. Thus, an alloy of nickel and aluminum was conceived of in order to take advantage of the high-temperature capability of nickel and the oxidation barrier formation property of aluminum.

Real engineering alloys are much more complex than just containing two elements. Thus, the oxidation behavior is quite sensitive to actual composition as well as the microstructure of an alloy. During service, the alloy may change in composition, especially at the surface and in the microstructure throughout the material. For example, an engineering alloy of molybdenum and silicon with boron additions makes use of

the high-temperature capability of molybdenum and the low permeability of oxide of silica for the barrier [13, 14]. The silica barrier is formed using the silicon in the alloy, thus depleting the surface of the alloy in silicon. If the silica surface layer is damaged, the silicon content in the substrate may be insufficient to form a barrier once again to protect the base material. If a method by which the composition of the substrate underneath an oxide layer can be measured, then it is possible to predict the remaining life of the alloy. Properties that are sensitive to chemistry need to be identified and technologies that are suitable for measurement need to be invented for such applications.

In the current generation of nickel-based superalloys, the alloys are protected against oxidation by a layer of zirconia. This layer is, however, permeable to oxygen. The oxygen reacts and forms alumina beneath the thermal barrier. As this alumina layer grows in thickness, the thermal barrier becomes unstable and eventually spalls. Obviously, this spalling results in overheating of the Ni-based alloy underneath. It would be of great use if a method to measure the thickness of the alumina that forms under the thermal barrier layer becomes available. The dependence of the alumina layer thickness on the remaining life of the barrier layer is already known; thus, what remains is to come up with a method to measure *in situ* the alumina thickness beneath the thermal barrier layer.

3 FAILURE CHARACTERISTICS IN POLYMER MATRIX COMPOSITES

Polymer matrix composites (PMCs) are primarily made of two or more material phases of which the reinforcing phase in the form of fibers is held together by the binding material, commonly called as *matrix material*. Besides the fiber and matrix phases, other phases (such as nanoconstituents, interleave, fiber–matrix interface, etc.) are sometimes incorporated in composites for tailoring their specific properties or strength. The fiber and matrix materials possess distinctly different material characteristics, both in modulus and strength. Their distinctly different respective material properties cause stress concentration in the vicinity of the fiber and matrix interfaces resulting in complex failure modes, such as matrix failure, fiber breakage, fiber–matrix interface failure, etc. The relative degree of the difference in the fiber and matrix moduli and strength, along with their geometric configuration, dictates the initiation of these different failure modes. It is known that the interface response (either at the fiber–matrix or interply level of layered or three-dimensionally reinforced composites) critically influences the failure process. Engineered fiber–matrix interfaces are also implemented with controlled chemistry, and more recently with nanoengineering, to control the failure process more effectively. There have been extensive studies to analyze and to understand the physics of the failure process and failure modes of PMC since 1960s [15–18]. Although a great deal of understanding has been generated in the literature in developing PMC failure theories, the past development of PMC failure theories, due to the complex nature of the competing failure modes in composites, rely heavily on the extensive material testing, in which many a case becomes cost prohibitive for material insertion in structural components. Thus, recent research thrust on PMC failure understanding is toward developing phenomenological failure theories, minimizing material testing. A brief summary of the physics of the past and recent PMC failure theory development is discussed below.

Unlike metals, PMCs hardly exhibit any plasticity. The primary mechanism of energy absorption in PMC, beyond its usual elastic deformation, is through damage accumulation in the form matrix cracking, delamination between the lamina (plies) interfaces, and fiber breakage. A representative failure scenario in PMC of matrix cracks, delamination initiation, and fiber breakage, due to a tensile load, is illustrated in Figure 6. Typically in monotonous loading, the matrix crack, visible at the midsection at the bottom of the micrograph in Figure 6, grows with loading increase and hits the lamina interface and gets diverted at the lamina interface to initiate fracture surface at the lamina interface (known as *delamination*), as indicated in Figure 6. The presence of any large area of delaminated fracture surface at the lamina interface impairs composite performance (degrades structural rigidity and buckling resistance), especially under compressive and fatigue loadings. The accumulation of fiber breakage accelerates the failure process in PMCs and thus needs to be avoided

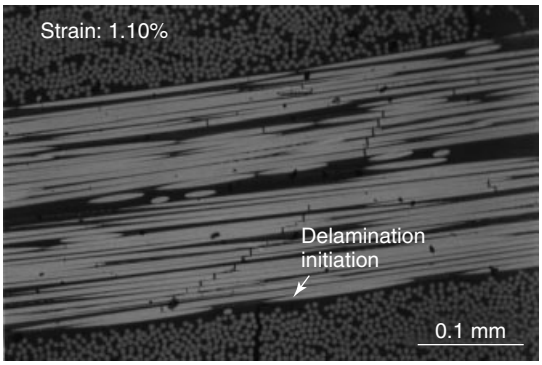

Figure 6. Damage in a $[90_2/0_2]_s$, laminate under a tensile load at a strain level of 1.1% indicating matrix cracks, initiation of delamination, and progression of fiber cracking prior to final failure.

while designing structural components with PMC. For designing composite parts, appropriate failure theories are required to quantify the damage accumulation process and assess these competing failure modes' effect on the final failure.

Owing to the presence of multiple phases in composites, the prediction of failure in PMC is rather much more involved than that of monolithic materials. The maximum stress and maximum strain criteria are very popular in predicting matrix cracking phenomena. The shear-lag theory is also commonly used in predicting the accumulation of the matrix cracking damage. Quantifying the delamination damage in PMC is rather a complex stress analysis problem. Fracture mechanics approach as well as composites failure under combined stress or strain components have been developed extensively to predict delamination in composites [15, 18].

It is observed that the failure in composites under combined loading, especially under combination of shear and normal stress components, the maximum stress or strain criteria are often not able to predict failure accurately. Tsai and Wu [19] in 1965 proposed interactive failure criteria, especially to predict failure under combined loading. The Tsai–Wu interactive failure criteria is expressed as

$$F_{ij}\sigma_i\sigma_j + F_i\sigma_i - 1 = 0 \qquad (10)$$

where, σ_i or $\sigma_j (i, j = 1, \ldots, 6)$ are the six stress components. The stress coefficients, F_{ij}, are dependent on the material properties and are to be determined by a few tests utilizing the directional material strength data as outlined in [19]. The Tsai–Wu failure criterion is considered to be a macroscopic failure criterion, mostly used for predicting laminate failure strength. Also, the criterion utilizes an interactive factor that is usually set empirically, requiring significant material testing.

The stress field in laminated composites (or PMC) in the vicinity of cutouts, open hole, or free edges, is not uniform. The material property disparity between the lamina near the lamina interface causes gradient stress field (in other words causes stress concentration) and at the free edge (the surface containing the thickness) of the laminate the stress components acting perpendicular to the lamina surface, $\sigma_z(\sigma_3)$, and $\tau_{xz}(\sigma_5)$, of the stress field become singular. An accurate prediction of such gradient and singular stress field is essential for reliable prediction of composite failure with open hole or bolted hole. Pagano and Pipes [20] provided the analytical solution to perform stress analysis to accurately capture the free-edge stress field. The nature of stress gradient such as the free-edge stress field for a $[30/-30/90]_s$ laminate, known to cause a highly gradient free-edge stress field, is shown in Figure 7. The true value of the free-edge stress is, however, influenced by the local material properties at the vicinity of the lamina interface, which is known to be somewhat different from that of the bulk lamina. Thus, even with sophisticated predictive tool developed by Pagano and Pipes [20], the use of pointwise failure criteria, such as Tsai–Wu, maximum stress, or maximum strain, becomes unreliable in open hole or bolted hole failure prediction, i.e., failure prediction in the presence of gradient stress field. To overcome this difficulty, Whitney and Nuismer [21] in 1974 introduced a criterion to average the gradient stress field over a characteristic length for predicting failure. This criterion is popularly known as *Whitney–Nuismer criterion*. The characteristic length in Whitney–Nuismer criterion is determined empirically through testing series of specimens of similar characteristic materials configuration. Thus, the utility of Whitney–Nuismer criterion is now in question owing to extensive materials and testing cost involved in developing strength allowable of materials.

Recently, Iarve *et al.* [22], to quantify the Whitney–Nuismer characteristic length more rigorously, introduced the critical failure volume (CFV)

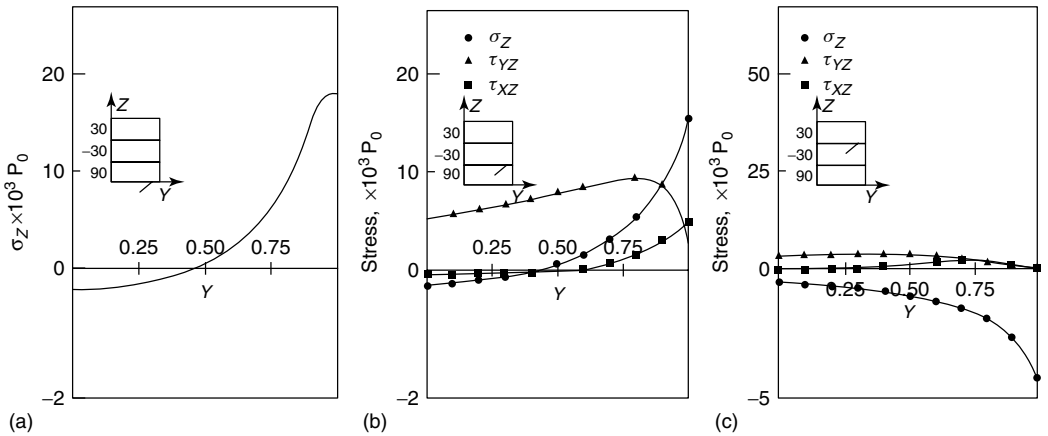

Figure 7. Interlaminar normal and shear stress distribution at ply interfaces of $[30/-30/90]_s$ laminates containing free edge under uniaxial tension loading. (a) [90/90], (b) [−30/90], and (c) [30/−30] interfaces. [Reproduced from Ref. 20. © Sage Publications, 1970.]

element concept. In order to minimize the empiricism in predicting failure in the presence of gradient stress field, they employed the Weibull statistics to tensile strength prediction in laminated composites with open holes. The statistical variability that is expected to exist in gradient stress field arising from the expected variability in the material properties is captured through the Weibull distribution concept. The CFV concept is based on the fact that a material sample under the applied load of a given volume has the following probability of failure under stress σ.

$$f(\sigma, V) = 1 - e^{-\frac{V}{V_0}B(\sigma)} \tag{11}$$

The CFV concept provides a systematic approach toward a methodology of predicting PMC failure in the presence of stress concentration and minimizing the volume of material testing in developing strength allowables.

Fiber–matrix interface failure is one of the prominent failure mechanisms influencing failures in PMCs. Even if the physics of the failure process is known through proper material characterization, unless an accurate value of the interface failure strength is known, optimizing the interface performance for tailored material design of PMC is not achievable. Traditional fiber–matrix interface testing is performed through fiber pullout, where interface failure happens under a combined shear and normal stress field and in the presence of stress concentration. Thus, determination of the interface strength from fiber pullout test is often inaccurate. Recently, Tandon *et al.* [23–25] developed a unique test using cruciform specimen geometry to determine the fiber–matrix interface strength. The cruciform specimen configuration eliminates the stress concentration at the failure surface and failure takes place under a single stress component (radial stress) when the winged arm of the cruciform specimen is perpendicular to the applied load [23]. The winged arm of the cruciform specimen can be oriented to any angle, other than 90°, to impose combined stress field on known ratio, as shown in Figure 8. The angle of the winged arm of the specimen is changed to apply combined normal and shear loading to determine the failure envelope, as shown in Figure 9. The experimental determination of such a failure envelope helps validation of failure criteria applicable to combined stress field, such as proposed by Gosse [26].

3.1 Failure in three-dimensional composites (3D PMC)

In spite of the superior strength-to-weight ratio advantage of PMC over metals, one of the weaknesses in laminated PMC is its poor interlaminar strength due to lack of fiber reinforcement through its thickness. The advent of textile composites utilizing the weaving and stitching (Z-pinning, etc.) technology overcomes this deficiency. PMC of three-dimensional

reinforcement (known as *3D PMC*) offers composite structures of complex shapes and contoured parts. Though the three-dimensional reinforcement offers improved through-the-thickness strength attributes, it imposes a complex failure scenario in the composite. During process curing of PMC, the matrix shrinks. In the case of laminated composites, such matrix shrinkage does not cause a major problem because the lamina is mostly able to accommodate the shrinkage, thus avoiding the lamina interface failure. However, in the case of 3D PMC, the interlocking effect imposed by the 3D reinforcement causes the lamina interface failure, as shown in Figure 10. Appropriate stress analysis is required to understand the interface cracking phenomena. Sihn and Roy [27, 28] and others have been developing three-dimensional stress analysis techniques to understand the matrix cracking process in 3D PMC. Accurate stress analysis tools are essential before one can apply failure criteria to understand the physics of the failure process in 3D PMC.

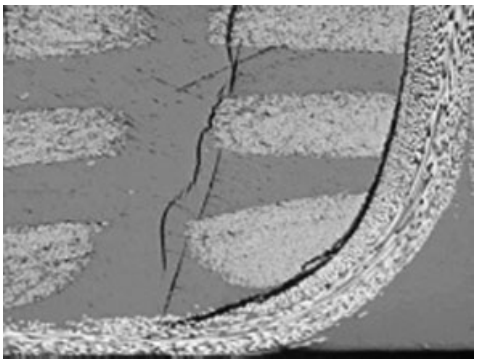

Figure 10. Lamina interface failure due to matrix shrinkage in three-dimensionally reinforced PMC.

3.2 Effect of gradient interface morphology in failure

The interface morphology tailoring between the constituent phases in composites (e.g., fiber–matrix, interlamina, interyarn, nanoconstituents-matrix, etc.) is essential in optimizing composite properties. As discussed earlier, in the case of composite strength, the mismatch of properties between the phases causes stress concentration at the interfaces, which, in turn, causes the initiation of damage and failure. A way of minimizing the mismatch of properties at the interface is demonstrated to reduce the interface stress concentration [29], and hence delay the damage initiation process together with improving composite strength. A gradient interface material morphology is thus desirable to enhance strength as well as other properties (e.g., thermal) of composites. Incorporation of nanoconstituents in composites, at present, potentially enable us to implement the gradient interface morphology at multiple scale level, from nanometer (nanoconstituent interface) to laminate ply interlayer (micrometer scale) [30, 31].

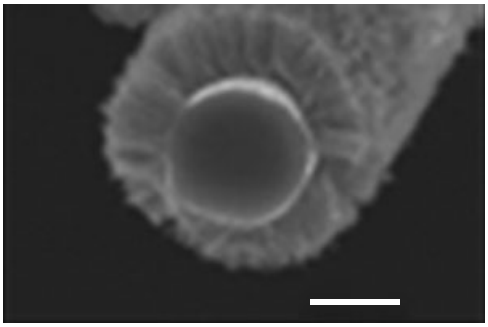

Figure 11. Carbon nanotubes grown on carbon fiber to introduce interface gradient morphology.

The current success of growing nanotubes on fiber is a possible mechanism of introducing gradient morphology at the fiber–matrix interface (Figure 11). The *in situ* polymerization of matrix (thermoset resin) with proper surface functionalization of fibers may provide gradient interface properties, as well. The *in situ* polymerization of functionalized nanofiber interface in epoxy matrix is shown to produce gradient epoxy modulus (qualitatively characterized by electron emission loss spectroscopy (EELS), Figure 13) resulting in suppressing failure at the fiber–matrix interface, as shown in Figure 12. One of the challenges is in quantifying the gradient material modulus at the fiber–matrix interface (of thickness in the order of 20–30 nm), without which the benefit of interface gradient morphology cannot be truly determined.

4 SUMMARY

Preventing failure of components is an important engineering function in several applications. It is well known that such failures are caused by progressive degradation of materials the components are made of (*see* **Static Damage Phenomena and Models**; **Damage Evolution Phenomena and Models**). For safety and cost considerations, early detection of material damage and monitoring its progression are of primary importance in vehicle or component health monitoring (*see* **Nonlinear Acoustic Methods**; **Time–frequency Analysis**; **Nonlinear Features for SHM Applications**; **Nondestructive**

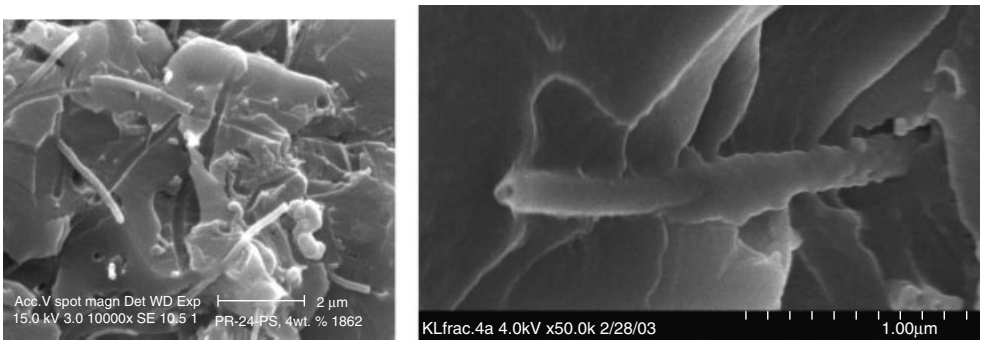

Figure 12. Micrographs of the failure surface of unfunctionalized and functionalized nanofibers in Epon 828. The strength for the case of functionalized fiber apparently increased by 140%. [Reproduced with permission from Ref. 31. © AIAA, 2007.]

Evaluation/Nondestructive Testing/Nondestructive Inspection (NDE/NDT/NDI) Sensors—Eddy Current, Ultrasonic, and Acoustic Emission Sensors). The detection methodologies have been the subject of extensive studies by a community of NDE experts that are different from those that study materials and their damage leading to failure (materials engineering). In this article, the authors assume that if the key principles of each discipline are understood by the others, a synergistic contribution to health monitoring is possible. This article presents the fundamental principles behind failure of engineering materials as introductory material for those who have expertise in NDE and wish to apply their expertise to the advancement of detecting material failures. Briefly, engineering materials can be classified into metals, ceramics, and polymers.

Advanced engineering metallic alloys are often limited by plastic deformation by yield at low temperature or by creep at high temperatures. In some applications, the metallic materials develop sufficient damage under stress and temperature through cavitation that results in premature failure. Thus, methods to detect plastic distortion and internal cavity damage would be of primary interest. In addition, environmental attack often results in the reduction of section resulting in enhanced local stresses leading to failure. Monitoring the extent of environmental attack could possibly be conducted through clever measurements of products of the environmental attack. Similarly, developing structural health monitoring methods to detect early fatigue (precursor fatigue) damage would be of great interest. All these functions should be performed at material, structure, and vehicle levels.

Advanced ceramics are made of a mixture of strong fibers and relatively weak matrices. The weaker matrix often fails early, but the fibers are protected from these matrix cracks providing damage tolerance. Ultimate failure is dominated by failure of the strong fibers. However, the component life is often limited by failure of the weaker matrix. Thermal gradients through material thickness results in shear stresses that result in delamination cracks where layers of fibrous material separate from each other through the failure of the weaker matrix that binds them. Detection of these subsurface failures is vital to predicting the remaining life of CMC components. Other failure mechanisms involve fiber–matrix interface degradation through environmental attack and fiber degradation through grain growth.

In an effort to provide an understanding of the improvement of failure strength of composites, a brief description of the physics of damage initiation and failure process in PMC was discussed. In a nutshell, the existence of material property (especially the modulus) mismatch of the different phases (i.e., fiber, matrix, or other constituents), under any loading conditions, causes stress rise (stress concentration) at the constituent interfaces. This interface stress concentration is the primary driver of the damage initiation and complex failure modes in PMC, in the form of matrix cracking, fiber–matrix failure, fiber breakage, etc. Development of failure theories to reliably predict the complex failure modes in composites has evolved over the last three decades. In a quest to understand the physics of the complex failure modes more accurately, probabilistic failure theories are recently being developed to capture the effect of statistical property distribution of the constituent in composite failure. It is quite obvious that the gradient morphology at the material interface, to minimize the interface stress concentration, provides an opportunity of enhancing composite failure strength. The inclusion of nanoscale constituents (such as, nanotubes, nanofibers, etc.) through nanotechnology is expected to offer such an opportunity.

Chapter 13

Applications of Acoustic Emission for SHM: A Review

Martine Wevers and Kasper Lambrighs

Department of Metallurgy and Materials Engineering, Katholieke Universiteit Leuven, Leuven, Belgium

1 INTRODUCTION

It is a well-known phenomenon that materials can produce audible sound at high loads. The cracking of timber in mineshafts, the crying of tin, the cracking of rocks, and the breaking of bones are some examples. The vibrations produced inside a material are a naturally occurring phenomenon and are called *acoustic emission* (AE). These vibrations are produced when strain energy is suddenly released owing to the occurrence of microstructural changes, resulting in transient elastic waves.

The sources of AE are, generally speaking, local instabilities where transient elastic waves are released because of changes in the local stress field. The AE continues until a local equilibrium is reached. The energy to produce the stress waves comes from the stored elastic energy that is redistributed. Only a small part of this released energy is transformed into AE.

When the elastic stress waves reach the surface of the specimen, small displacements are produced that can be detected by a sensitive piezoelectric transducer. The signals from one or more sensors are amplified and measured to produce data for display and interpretation. The process of generation and detection is illustrated in Figure 1.

By applying AE it should be possible to say when something is happening (detection), where it is happening (localization), and what is happening (discrimination). In general, detection and localization are possible at this moment. In some specific applications, discrimination methods are available.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

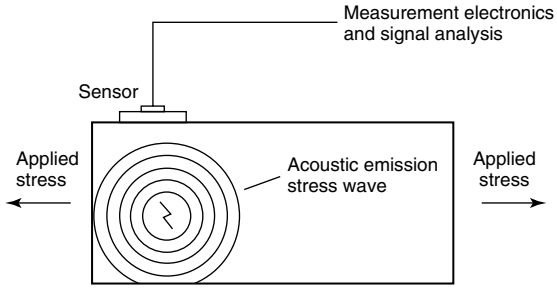

Figure 1. Working principle of the AE method.

The AE technique is somewhat different from other nondestructive test (NDT) methods. The most important differences are as follows [1]:

- The AE technique is a passive method; the technique only detects defects when they are activated by applying a stress that is adequately large. This means the defects have to produce the signals themselves and it is necessary to put an amount of energy into the material to activate the defects.
- The AE technique does not give direct information on the severity of the defects.
- Defects that are not activated by the applied stress will not be detected. Only the most critical defects for the applied loading condition will be activated.
- It is not necessary to place the sensor close to the defect; detection up to tens of meters is possible sometimes. This makes AE suitable for structural health monitoring (SHM) applications.

For SHM, AE is mostly combined with other NDT methods. The AE technique detects and localizes the critical defects, following which other techniques are used for the characterization of the defects.

To date, AE analysis is being used successfully in a wide range of applications including SHM; detection of leaks in storage tanks or piping systems; monitoring welding and other processes; monitoring chemical reactions including corrosion monitoring; and analysis of partial discharges from components subjected to a high voltage. As such, one of the main advantages of AE is its relative sensitivity to a range of phenomena leading to degradation.

2 HISTORICAL BACKGROUND

It is generally accepted that the research of the German scientist Kaiser [2] in the early 1950s represents the beginning of AE as it is known today. He was the first to carry out a systematic investigation of the noises that are generated when materials are deformed. He also discovered the phenomenon of nonrecovery of noises during repeated loading, known as the *Kaiser effect*. Further, he established the relations between the stresses during deformation and the intensity and amplitude of AE waves, which were found to be characteristic for each material. In Kaiser's work, it was already shown that not only stresses to which the material was subjected earlier but also residual stresses, changes in structure, phase transitions, stress relaxation, and decrease in elongation in creep play an important role.

In 1954, Schofield became aware of Kaiser's early work and initiated the first research program in the United States on material engineering applications of AE [3]. He detected, for example, the two different types of AE: continuous and burst emission.

Approximately at the same time, fundamental research on the AE phenomenon began in France as well. In 1958, a first work devoted to the origin of AE waves during the deformation of mild steel was published [4]. It was established that the generation of AE waves begins in the neighborhood of the yield zone and also prior to failure [5, 6].

In the former Union of Soviet Socialist Republics, the first applications of AE were connected with the prediction of coal and gas outbursts in collieries. Here, the seismoacoustic methods for investigating the state of a coal massif in the course of its underground mining were developed. Later, scientific works were published both in the Union of Soviet Socialist Republics and abroad [7–11].

On the basis of the results of the theoretical and experimental investigations mentioned above, the AE technique found its application in industry from the early 1960s on [12–14].

3 TYPES OF ACOUSTIC EMISSION

The AE produced by a source is phenomena and material dependent. The emitted transient elastic waves are basically pulselike. The width and height

of the primitive pulse depends on the dynamics of the source process. Source processes such as microscopic crack jumps and precipitate fractures are often completed in a few microseconds or fractions of a microsecond, so the primitive pulse has a correspondingly short duration. The amplitude and energy of the primitive pulse vary over an enormous range from submicroscopic dislocation movements to gross crack jumps. A distinction can be made between the two types of AE: continuous emission and burst emission (Figure 2).

In *continuous emission*, which is of low energy, the stress wave bursts are irresolvable. Moreover, the amplitude of the emission increases with increasing load. This type of emission can, for instance, be correlated with dislocation movements in metals. In some cases, it becomes necessary to monitor the continuous emission (leak testing).

Burst emission refers to a form of emission of much higher amplitude and energy in which the individual stress wave bursts are seen. It occurs when sources of higher energy are operating. Crack growth is an important example of such a source.

One can identify different factors that influence the detectability (amplitude) of the AE. These factors are summarized in Table 1 and can give an indication whether to use the AE technique for a particular material [1].

AE, in the proper sense, covers the audible frequencies up into the high ultrasonic range. Only a part of this range is used for measurements—normally the ultrasonic frequencies between 50 kHz and 2 MHz are the easiest to detect. At higher frequencies, the intensity of the AE signal is low because of attenuation and electronic field disturbance signals. At lower frequencies, the measurement is generally disturbed by background noise, e.g., vibrations from vehicles and noise from pumps or flowing media.

Table 1. Factors influencing the AE detectability [1]

Factors resulting in higher amplitude signals	Factors resulting in lower amplitude signals
High strength	Low strength
High strain rate	Low strain rate
Cleavage fracture	Shear fracture
Crack propagation	Plastic deformation
Anisotropy	Isotropy
Nonhomogeneity	Homogeneity
Thick section	Thin section
Twinning	—
Lower temperatures	High temperatures
Flawed material	Unflawed material
Martensitic phase transformations	Diffusion controlled transformations
Cast structures	Wrought structure
Coarse grains	Fine grains

4 WAVE PROPAGATION

The elastic stress waves generated by each AE source propagate through the material and any other path toward the AE sensor. This propagation greatly influences the resulting electrical signal from the sensor. Aspects of stress wave propagation that significantly influence the electrical signal are geometric spreading, losses due to material absorption, direct and indirect reflected paths from the AE source to the sensor, and different speeds of propagation along with the dispersion of the stress waves.

Geometric spreading is the loss in signal amplitude owing to the fact that, as the wave travels away from the AE point source in a two- or three-dimensional medium, the total area of material through which the wave front is passing increases. Conservation of energy can be used to calculate the resulting change in amplitude.

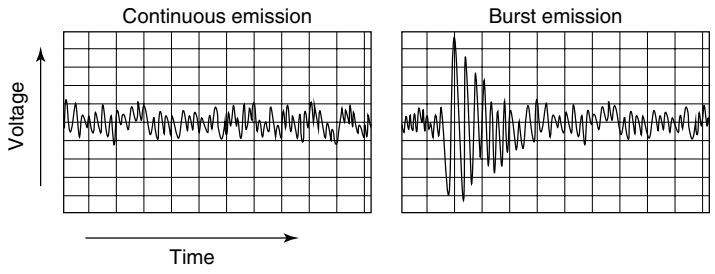

Figure 2. Continuous emission and burst emission.

Loss due to material absorption of the stress wave energy results in an attenuation of the amplitude of the wave as it propagates. This attenuation is more severe for the stress waves at higher frequencies and in viscoelastic materials.

The *different paths, direct and reflected*, of the stress wave in the material can lead to long signal durations measured by the sensor. This means the signal duration primarily results from the continued bouncing around of the stress wave in the material.

AE stress waves have *several components*: longitudinal, transverse, surface (Rayleigh waves), and plate waves (Lamb waves). These components propagate at different speeds and their existence depends on the geometry of the specimen (depending on the thickness of the specimen and the wavelength of the AE stress waves). Typically, two wave packets can be distinguished on the basis of wave speed: a generally lower amplitude first arrival and a higher amplitude second arrival.

For Lamb waves specifically, the plate wave theory states that mechanical waves propagate through plates in two modes: the symmetric or extensional mode and the antisymmetric or flexural mode. The main particle displacement is in the plane of the plate for the extensional mode and perpendicular to the plane of the plate for the flexural mode. The extensional mode generally travels at the highest velocity and is nondispersive in nature, meaning that all frequency components of this mode travel at the same velocity. The flexural mode travels at a lower velocity and is dispersive with the square root of frequency, meaning that the higher frequency components propagate faster than the lower frequency components. In practice, this will lead to a gradual decrease in the amplitude of the flexural mode as it propagates, owing to the spatial separation of the different frequency components [15].

The *dispersion of stress waves* refers to the propagation of different frequency components at different speeds. The net result of dispersion is a spreading in the time domain of the stress wave as a function of the traveled distance.

5 DETECTION

When a physical phenomenon suddenly releases a certain amount of elastic energy, elastic waves are formed; these can be picked up by a sensitive piezoelectric transducer (*see* **Piezoelectricity Principles and Materials**), which is placed on a surface. The key element in an AE resonant sensor is a piezoelectric crystal that converts movement into an electrical voltage. When temperature, strong electrical fields, high mechanical stresses, or radiation influence the piezoelectric properties of the sensor by depolarization, wave guides (rods or wires fabricated from steel, aluminum, or platinum) can be used.

The choice of a sensor depends on its resonance frequency band, the temperature, and its noise level. For sensitivity purposes, one often chooses a resonant sensor in a certain frequency domain coinciding with the frequency content of the AE signals. Broadband sensors with a flat frequency response over a wide frequency domain are often used for frequency analysis of the AE signals.

The AE sensor has to be calibrated to allow signal analysis techniques. The sensor calibration method most widely used is excitation with a standard broadband sensor and noting the resulting frequency response. A great deal of effort has gone into using mechanical sources such as fracture of lead pencils (Hsu–Nielsen source), calculating the transfer function from the source to the sensor locations, and comparing these to the transducer output. The Hsu–Nielsen source is widely accepted as a device to simulate an AE signal.

6 KAISER EFFECT AND FELICITY RATIO

When a sample is loaded and on producing AE, unloaded, and then reloaded in the same direction as the original load, AE often does not begin upon reloading until the previously achieved stress is reached. This phenomenon was first reported by Kaiser [2] and is known as the *Kaiser effect*. The physical basis for this effect is straightforward. AE is usually created by the formation or propagation of a defect under an applied stress, such as a crack, an avalanche of dislocations, decohesion of an interface, a twin, or a martensitic transformation. If the stress to form or propagate such a defect is not reached in the original loading, it will not be reached in the reloading until the applied stress exceeds the initial stress.

Dunegan and Tetelman [16] showed that for materials that obey the Kaiser effect, emission on reloading is still possible, which indicates that structural damage occurred between the first loading and the repeat. Recent test strategies pay much attention to emission that occurs at loads below the previous maximum and to emission that continues when the load is held at a constant level. The evidence is that structurally significant defects will produce AE at reloading before the previously achieved stress is reached. AE that is related to the stabilization of the structure, such as the relief of residual stresses, will tend not to recur upon reloading.

The Kaiser effect is observed in a general sense for many materials. The absence of the Kaiser effect is often expressed in the Felicity ratio. This is the ratio between the applied load at which the AE activity reappears during the subsequent application of loading and the previous maximum applied load. It is important to note that the Felicity ratio can decrease when the material approaches failure.

Careful attention must be paid to the loading schedule if AE testing is to be successful. Procedures for an AE test typically specify the loads that must be applied (relative to the working load or design load) and the upper and lower limits on the loading rate [17–20].

7 SIGNAL ANALYSIS

Once the AE signal has been detected, it is a general procedure to amplify, possibly filter, and then employ some type of signal processing to format and present the AE data for analysis (*see* **Signal Processing for Damage Detection**).

The oldest and easiest way to conduct data analysis is by using a comparator circuit, which generates a digital output pulse whenever the AE signal exceeds a fixed threshold voltage. The relationship between signal, threshold, and threshold-crossing pulses is shown in Figure 3. The threshold level is usually set by the operator; this is a key variable that determines test sensitivity. Depending on instrument design, sensitivity may also be controlled by adjusting the amplifier gain.

A more complex and extended way of data analyses involves the measurement of key parameters

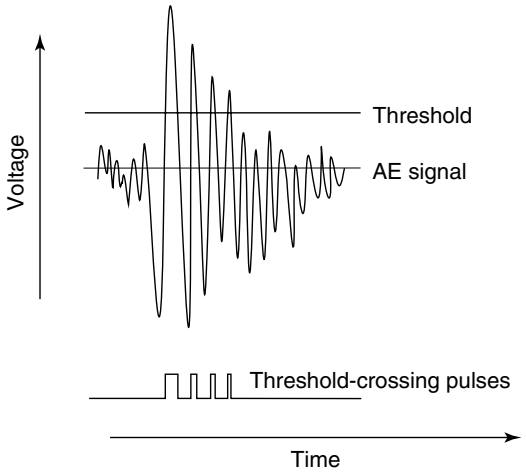

Figure 3. Principle of AE signal detection.

of each hit, that is, each AE signal that crosses the threshold. A digital description of each hit is generated by front-end hardware and is passed in sequence with other hit descriptions through a computer system.

The five most widely used signal measurement parameters are counts (Figure 3), amplitude, duration, rise time, and the measured area under the rectified signal envelope (MARSE) (Figure 4). Some tests are performed with fewer parameters, and some tests use others, such as true energy, counts to peak, average frequency, or spectral moment.

Along with these signal parameters, the hit description passed to the computer typically includes important external variables, such as the time of detection, the current value of the applied load, the cycle count (if it is a cyclic fatigue test), and the current level of continuous background noise.

The *amplitude* is the highest peak value attained by the AE waveform. This is a very important parameter because it directly determines the detectability of an AE signal. Acoustic emission amplitudes are directly related to the magnitude of the source, and they vary over an extremely wide range from microvolts to volts.

The *counts* are the threshold-crossing pulses discussed above (also called *ringdown counts*).

The *MARSE*, also called *energy counts*, is preferred over counts because it is sensitive to amplitude as well as duration, and it is less dependent on threshold setting and operating frequency.

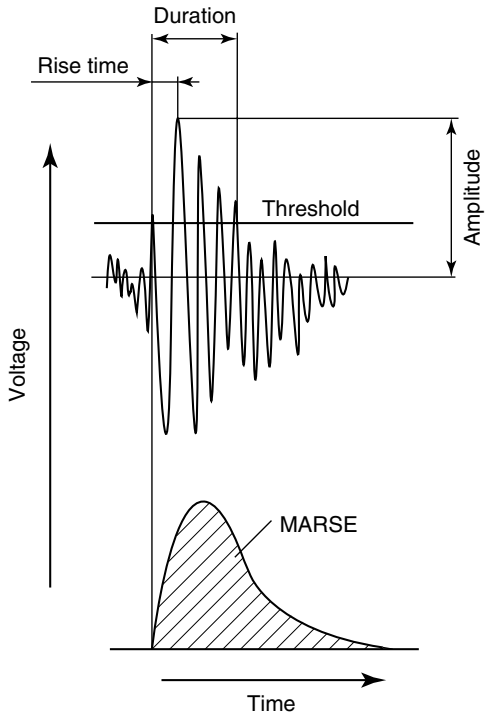

Figure 4. Key parameters of an AE burst signal.

The *duration* is the elapsed time from the first threshold crossing to the last and is directly measured in microseconds. This parameter depends on source magnitude, structural acoustics, and reverberation in approximately the same way as counts.

The *rise time* is the elapsed time from the first threshold crossing to the signal peak.

The counts are normally used for detection purposes, the time of detection for localization and the other parameters for discrimination purposes.

When the continuous emission is of interest (e.g., leak testing), it is sufficient to use AE instrumentation that measures the root mean square (RMS) voltage of the AE in a certain time window.

When a multichannel system is used, caution is needed for the interpretation of the received signals. An individual AE signal may hit just one channel or it may hit many channels, depending on the strength of the signal, the wave attenuation in the structure, and the sensor spacing. Therefore, an early task for the multichannel system is to determine whether a group of closely spaced hits on different channels is from the same source. The second, third, and later hits from one source can either be retained for the purposes of source location or discarded to keep the data clean and simple.

For the presentation and analysis of the AE data, many types of graphs are possible. Broadly, they can be defined as follows:

- history plots that show the course of the test from start to finish;
- distribution functions that show statistical properties of the emission;
- channel plots showing the distribution of detected emissions by channel;
- location displays that show the position of the AE source;
- point plots showing the correlation between different AE parameters;
- diagnostic plots showing the severity of AE indications from different parts of the structure.

More information on the presentation of AE data can be found in the ASM Handbooks online [21].

8 LOCALIZATION

If an AE source present in a material produces burst emission when loaded, localization of this source is possible. Source localization comes in handy when large structures are tested in which AE inspection is used to identify active regions and other NDTs are used to perform a more precise investigation. Large cost savings have been realized through this combination of global AE inspection and focused inspection by other methods.

There are two different types of source localization: zone location and point location.

Zone location only accepts the counts of a sensor that come in first. Hereby, all the activities of a zone around each sensor will be assigned to that sensor.

The reliability of this method is very good but an additional investigation with other NDTs is necessary to determine the exact location of the source.

Point location places the source precisely, by calculating from the relative arrival times of the AE wave at several sensors. Wave velocity is involved in these calculations. The attainable accuracy depends on the wave propagation processes by factors such as geometry, plate thickness, and contained fluids.

These factors alter the wave velocity, leading to errors in source location. In favorable cases, the attainable accuracy is better than 1% of the sensor spacing; in unfavorable cases, worse than 10% [21].

For the reader's convenience, the basic principles of a localization procedure are described using a similar example by Vink [1]. In this example, three sensors are attached to a structure in the form of a right-angled triangle as shown in Figure 5. It is important to note that for some applications other configurations can be more useful.

A calibration method has to be performed first to measure the wave velocity. An artificial AE wave is produced at a known location (the distances between the source and the different sensors are known). From the measured time difference between the excitation of the different sensors, the wave velocity, c, can be calculated using equation (1).

$$\left.\begin{aligned} s_2 - s_1 = \Delta s_{21} = c{\cdot}\Delta t_{21} \\ s_2 - s_3 = \Delta s_{23} = c{\cdot}\Delta t_{23} \end{aligned}\right\} \Rightarrow c \qquad (1)$$

When this sensor configuration is used for source localization, the difference in arrival time between sensors 1 and 2 (Δt_{21}) and between sensors 2 and 3 (Δt_{23}) have to be measured. This data can be used to construct lines with a constant Δt (hyperbola, not given in Figure 5). When the order in which the AE wave reaches the different sensors is registered, only one intersection of the hyperbola remains, indicating the location of the AE source. The AE source location can be calculated using equations (2) and (3).

$$\left.\begin{aligned} s_2 - s_1 = \Delta s_{21} = c{\cdot}\Delta t_{21} \\ s_2 - s_3 = \Delta s_{23} = c{\cdot}\Delta t_{23} \end{aligned}\right\} \Rightarrow \Delta s_{21},\ \Delta s_{23} \qquad (2)$$

$$\left.\begin{aligned} s_1 = \sqrt{(l_{12} - y)^2 + x^2} = s_2 - \Delta s_{21} \\ s_3 = \sqrt{(l_{23} - x)^2 + y^2} = s_2 - \Delta s_{23} \\ s_2 = \sqrt{x^2 + y^2} \end{aligned}\right\} \Rightarrow x, y \qquad (3)$$

For SHM applications, the amount of data that has to be analyzed can be reduced drastically by using a structural neural system (SNS), without loss of information (*see* **Artificial Neural Networks**). The SNS provides an architecture to connect n sensor nodes in series to form neurons, and the neurons in turn interact and pass signals similar to the way in which the biological neural system functions [22–24].

When the source location is not accurate enough, AE tomography [25, 26] can be used, leading to a better source location. AE tomography uses a wavespeed map of the structure rather than the average wavespeed. To apply this method, accurate sensor location, a large number of sensors, and the wavepath duration (time for a signal to travel from the source to the sensor) are required as an input for a specialized iterative AE localization algorithm.

When the requirements for AE tomography are unsuitable for a specific structure or environment, Delta T source location can be used [27]. The Delta T source location provides a novel approach for overcoming particular problems associated with source location in complex structures. This method uses an artificial source to record differences in arrival times from a number of locations to reduce the location error.

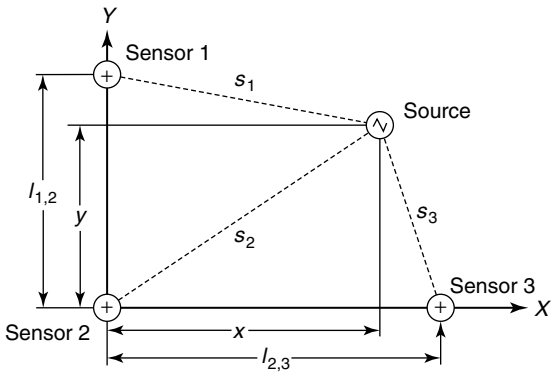

Figure 5. Basic principle of point localization.

9 DISCRIMINATION METHODS

By applying discrimination methods, it is possible to distinguish different kinds of AE sources. Discrimination methods can be divided into statistical and pattern-recognition techniques on one side and source characterization techniques, where the change of signal between the source and the sensor is calculated in, on the other side [28]. For pattern recognition, the AE waveforms can be used to get more information about the source and the transmission path [29].

A good example of source discrimination can be found in composite structures, where fiber fracture, delamination, matrix cracking, and debonding can be discriminated successfully [15, 30].

10 APPLICATIONS OF AE FOR STRUCTURAL HEALTH MONITORING

There are a number of successful applications of SHM via AE, such as the structural testing of aircraft, spacecraft, bridges (*see* **Long-term Monitoring of Dynamic Loads on the Brandenburg Gate**; **Development of a Monitoring System for a Long-span Cantilever Truss Bridge**; **Modular Architecture of SHM System for Cable-supported Bridges**; **Monitoring of Bridges in Korea**; **Bridge Monitoring in Japan**; **Continuous Vibration Monitoring and Progressive Damage Testing on the Z24 Bridge**; **Continuous Monitoring of the Øresund Bridge: Data Acquisition and Operational Modal Analysis**; **Condition Compensation in Frequency Analyses—a Basis for Damage Detection**; **Modal Testing of the Vasco da Gama Bridge, Portugal**), bucket trucks, buildings (*see* **Construction Process Monitoring at the New Berlin Main Station**; **SHM Actions on the Holy Shroud Chapel in Torino**; **SHM of a Tall Building**; **Dynamic Response of Buildings of the Cultural Heritage**; **Suspended Roof of Braga Sports Stadium, Portugal**), dams (*see* **Dams**), military vehicles, mines piping systems, pipelines, pressure vessels, railroad tank cars, rotating machinery (*see* **Wind Turbines**; **Large Rotating Machines**; **Gas Turbine Engines**), storage tanks, and other structures. The goal of structural AE testing is to find defects and to assess or ensure structural integrity.

SHM via AE is applied to highlight the regions that threaten the integrity of the structure. When a full-scale test with fixed sensors is performed, AE is normally complemented by other NDT methods, which are used to assist in determining the type and severity of structural significant defects.

A major advantage compared to other NDT methods is that it does not require access to the whole structure. Therefore, it is not necessary to completely remove insulation or internal process fluids, which is typically a major expense in other NDT methods.

When AE tests are performed, it is important to load the structure in such a way that all the structurally significant defects are activated. The continuous monitoring of a structure in service is possible as well, although it is difficult because a small amount of AE from defect growth must be separated from a large amount of noise over a long time period. On the other hand, this approach guarantees the proper loading of the structure.

The stimulation of the structure by a controlled load is more commonly used and can be performed in a short time, typically during maintenance operations. In most cases, this is satisfactorily accomplished by going somewhat above the normally apparent service loads. Attention is needed to the type, magnitude, and rate of the applied load because previously applied stresses will have a very strong influence on the observed AE. Further, it is important to note that this approach does not always work, e.g., when the defects are activated thermally instead of mechanically.

When AE is used for SHM, one should always follow standard test procedures [17, 20].

10.1 Corrosion monitoring

It is shown that AE monitoring of stainless steel is capable of detecting early stages of stress corrosion cracking prior to the growth of a single dominant crack. By measuring AE parameters such as event rate, amplitude, counts, and energy counts, the transition from crack initiation and short crack growth to rapid growth of dominant cracks can be seen clearly [31, 32].

Pitting corrosion can be detected by AE in an austenitic stainless steel. It is hard to detect the initiation process, but once the pits propagate, the AE activity increases [33]. Rise time and counts are seen as discriminating AE parameters for monitoring pitting corrosion of austenitic stainless steel. Time delay and event rate are found to be in very good agreement with the sensitivity of the material toward pitting and with the polarization procedure [34].

Storage tanks from the chemical and petrochemical industry are very often subjected to high stresses, fatigue, aging, and corrosion, reducing their lifespan. Corrosion phenomena related to the aggressiveness of the stored chemical products is often the origin of leaks in these storage tanks. Although successful

online corrosion monitoring of storage tanks is yet to be reported, there are some indications that it is feasible. It is already experimentally validated that the AE produced by the cracking and delamination of the formed corrosion products can be successfully distinguished from noise [35, 36].

Nowadays, the testing of storage tanks with AE is limited to maintenance purposes whereby the structure is overloaded and the AE produced gives an idea of the damage present [37, 38].

The deterioration of high-strength steel tendons of prestressed concrete bridges (*see* **Long-term Monitoring of Dynamic Loads on the Brandenburg Gate**; **Development of a Monitoring System for a Long-span Cantilever Truss Bridge**; **Modular Architecture of SHM System for Cable-supported Bridges**; **Monitoring of Bridges in Korea**; **Bridge Monitoring in Japan**; **Continuous Vibration Monitoring and Progressive Damage Testing on the Z24 Bridge**; **Continuous Monitoring of the Øresund Bridge: Data Acquisition and Operational Modal Analysis**; **Condition Compensation in Frequency Analyses—a Basis for Damage Detection**; **Modal Testing of the Vasco da Gama Bridge, Portugal**) progresses because of aging. The failures have been mostly attributed to corrosion because of a severe environment, such as salt attack. In theory, the corrosion process can be monitored by AE owing to the fact that elastic waves are produced due to the cracking and delamination of the corrosion products. In practice, however, these AE signals are hard to distinguish from the environmental noise (traffic). Therefore, the monitoring of high-strength steel tendons of prestressed concrete structures is possible only by detecting individual wire breaks, for which detection and localization is already successful [39, 40].

10.2 Rotating machinery

Rolling element bearing condition monitoring has received considerable attention for many years because the majority of problems in rotating machines are caused by faulty bearings. The classical failure mode of rolling element bearings is localized defects, in which a sizable piece of the contact surface is dislodged during operation, mostly by fatigue cracking in the bearing metal under cyclic contact stressing.

Counts and peak amplitude are conventionally known as good parameters for the detection of defects in rotating machinery [41–43]. It is also reported that the RMS voltage, used to monitor continuous emission, is a good parameter to monitor bearings [44].

10.3 Pressure vessels and pipes

The testing of pressure vessels and pipes is normally done by overloading the structure so that the defects present will be activated and produce AE. This allows defect detection and localization, after which the defects can be validated by other NDT methods and, depending on the criticality of the defect, be repaired.

The failures of metal pressure vessels and pipes are mostly attributed to corrosion [45, 46] or crack growth [47–49]. The measurement of corrosion by AE has already been described. For the measurement of crack growth in pressure vessel steels, it has been shown that the counts, the amplitude, the rise time, the average frequency, and the duration are important parameters for AE detection [49].

10.4 Concrete/buildings

The AE technique has been employed for many years to study damage and microcrack nucleation in concrete materials [50–59]. Here it is shown that AE analysis is, in principle, an effective method of damage assessment in concrete structures. Nevertheless, due to the complexity of most civil engineering structures, the applicability is limited to some isolated cases such as concrete bridges [39, 60, 61] (*see* **Long-term Monitoring of Dynamic Loads on the Brandenburg Gate**; **Modal Testing of the Vasco da Gama Bridge, Portugal**).

The most important AE parameters that correlate with the cracking process in concrete are counts, energy, and duration, together with the frequency characteristics [62]. For reinforced concrete, the most important AE parameters are peak amplitude and energy [56].

Recently, some reports were published on the use of AE methods for successful damage assessment of historical buildings (*see* **Construction Process**

Monitoring at the New Berlin Main Station; **SHM Actions on the Holy Shroud Chapel in Torino**; **SHM of a Tall Building**; **Dynamic Response of Buildings of the Cultural Heritage**; **Suspended Roof of Braga Sports Stadium, Portugal**). A new methodology is proposed, based on the counting of events, to determine the released energy and therefore the conditions of stability or the risk due to the spreading of discrete cracks [61–63].

10.5 Composites

A lot of studies have already been done on the use of AE for composite materials. Not only localization but also discrimination of the AE sources is found possible. It is reported that fiber fracture, delamination, matrix cracking, and debonding can be discriminated successfully [15, 30]. AE energy has shown good general correlation with parameters deduced from stress–strain curves, damage identified with ultrasonic C-scanning, and microscopic analysis of specimens subjected to static and fatigue testing [64].

The most important application of composite materials is in aviation. The condition monitoring and life prediction of the main structures of aircraft have received considerable attention because they are closely related to flight safety. The early detection of fatigue crack initiation and growth is, in general, beyond the capability of various conventional NDT means; AE, however, is more suitable to undertake the task. Although the AE technique is a generally accepted method for testing articles made of composite materials, a number of problems arise with its practical application. So far, there are no test methods that ensure the real-time localization of AE signals in large composite complex-shaped structures. A real-time AE instrument for health monitoring of aircraft structures, if not impossible, is difficult to realize to a great extent. With the help of the combination of AE waveform and parameter analysis, AE can still play an important role in new aviation material studies and in health monitoring of aircraft structures [65, 66].

11 FUTURE PROSPECTS OF AE

It has recently been shown by fundamental research that the formal expectations about the possibilities of AE for SHM were too high. It seems that the relations between the detected AE signal and the AE source are far more complicated than had been assumed before. It will be necessary to fully understand the effects that influence the AE signal, such as characteristics of the AE source, the wave propagation in the material, and the wave propagation at the interface of the sensor.

A part of the research on AE currently focuses on source discrimination methods with artificial intelligence techniques, where the system is "trained" to recognize certain parts of AE signals and connect them to an AE source. An example of such a system is a neural network (*see* **Artificial Neural Networks**), an area in which a lot of research is being carried out at present.

The development of new sensors for AE with a higher sensitivity and robustness could lead to more applications for real-time health monitoring of structures in their total life cycle. An example of such a sensor is the fiber-optic sensor (*see* **Fiber-optic Sensor Principles**; **Fiber-optic Sensors**) with the following advantages over conventional piezoelectric sensors: small diameter and light weight, flexibility, high strength, heat resistance, immunity to electromagnetic interference, durability, and resistance to corrosion. Further these sensors are believed to have a very high sensitivity in an extremely broad frequency range [67].

Chapter 12

Data Interrogation Approaches with Strain and Load Gauge Sensor Arrays

Michael D. Todd

Department of Structural Engineering, University of California, San Diego, CA, USA

1 INTRODUCTION

Any structural health monitoring (SHM) strategy for any application invariably must employ three fundamental components: (i) a sensor array that captures some form of local or global kinematic or kinetic response of the system at hand (such as a vibration response); (ii) a series of algorithms that process the raw sensor array data in such a way to extract "features" that convey meaningful information about the condition or performance of the system; and (iii) statistical modeling tools that appropriately classify these extracted features into assessment categories, ordered by increasing complexity: detection of damage, location of damage, level of damage, and type of damage. This is known as *the Rytter taxonomy* [1]. One may couple such a strategy for SHM to a *damage prognosis strategy* by employing operational and environmental monitoring, a probabilistic expected loading model, and an appropriate failure or degradation model for any such mechanism being targeted for assessment and prediction.

This overall approach clearly relies on both hardware (sensors and actuators, as appropriate) and software (data processing for feature extraction, statistical classification, model implementation/comparison, etc.) for execution. Both play critical roles: one certainly needs a means to observe system behavior (the role of sensors and measurement systems in hardware). However, there is no such thing as a "damage sensor" or a "condition assessment sensor"; all types of sensors do nothing but measure a system's field response, such as acceleration, pressure, strain, temperature, etc., to stimuli. To perform SHM with the goal of current state assessment—at any level of the Rytter taxonomy—one must mine information from the sensor's field measurements (the role of algorithms in software). Inevitably, this sensor data mining relies on pattern-recognition methods, where one must draw a comparison in some way between baseline data sets and test data sets. Such comparisons may be broadly classified into two classes: (i) direct waveform comparison or (ii) comparison between baseline and fitted model

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

parameters or between baseline and test residual error when using a fixed baseline model. The former class involves extracting direct features from raw waveform data obtained in both a baseline or reference condition and a test condition. Such features could be something as simple as a single peak or rms value over a given time window or a more complex signal-processing scheme such as a bispectral construction. The latter class involves fitting some sort of model to the data sets and comparing how a model fitted appropriately to a baseline data set compares to the same kind of model fitted to a test data set. Alternatively, one may fit a model to a reference or baseline data set only and then use it as a predictor for future data sets, using the resulting residual error as the primary feature set on which to make comparisons.

This section begins with a technology review of strain gauges and load cells primarily used in SHM today, and it follows with a presentation of data interrogation approaches used with these sensor modalities.

2 HARDWARE TECHNOLOGY OVERVIEW

2.1 Strain gauges

Strain measurements are likely the second-most commonly used data type (after acceleration, which is considered in another section) for SHM. Strain is a nondimensional measure of an object's deformation resulting from an applied stress. More formally, strain is defined as the displacement per unit length of the object; strain gauges have a finite gauge length that serves as a normalizing factor. As such, the strain gauge actually gives an average strain reading over the length of the gauge. Strain gauges, at least in their mature forms used most commonly, generally fall into two categories: (i) resistive foil gauges and their variants and (ii) fiber-optic gauges. The most common strain gauge technology is the resistive foil kind; in 1856, Lord Kelvin first noted that the resistive properties of some metallic conductors change as a function of applied strain; this effect was put into practical use by the 1930s. In practice, other properties such as capacitance or inductance also change with applied strain, and the hardware community has commercialized variations on the resistive theme as well, but their sensitivity to other measurands, mounting requirements, and complex circuitry have limited their application. Bulk optical methods, taking advantage of interference patterns produced by optical flats, are very accurate and highly sensitive, but these techniques are delicate and cannot withstand industrial applications in many cases. Finally, it is important to mention piezoelectric patches, which are increasingly being used as strain sensors. However, their initial uses were primarily in actuation or impedance measurement, and this architecture is not considered in this section.

2.1.1 Resistive strain gauges

The typical foil resistive-type gauge consists of a wire grid network (the resistor) embedded on an elastic layer, which in turn is bonded with an epoxy layer on to the object of interest. When the object deforms under load, the deformation is transferred to the wire network, causing resistive changes in the material. Typical materials include copper–nickel alloys, platinum alloys (usually tungsten), nickel–iron alloys, or nickel–chrome alloys, foils, or semiconductor materials. The most popular alloys used for strain gauges are copper–nickel alloys and nickel–chrome alloys. Two further improvements in strain gauge technology include the thin-film strain gauge and diffused semiconductor gauges, but despite these alternative piezoresistive designs, bonded metallic resistance strain gauges have the best reputation and are the most widely used. They are relatively inexpensive, can achieve overall accuracy of better than $\pm 0.10\%$, are available in a short gauge length, have high primary sensitivity, and have only moderate thermal sensitivity. One may operate these gauges in temperatures ranging from cryogenic to those found in jet engine turbines. One may also use them to measure both static and dynamic strain, as the inherent time constants in the material are negligibly small.

The changes in the resistive characteristics of metallic foil gauges to applied strain are very small, requiring signal processing to convert these changes into voltages that normal data acquisition systems may detect and process. The most popular detection networks are the Wheatstone bridge, Chevron bridge, and four-wire ohm circuit, all shown in Figure 1.

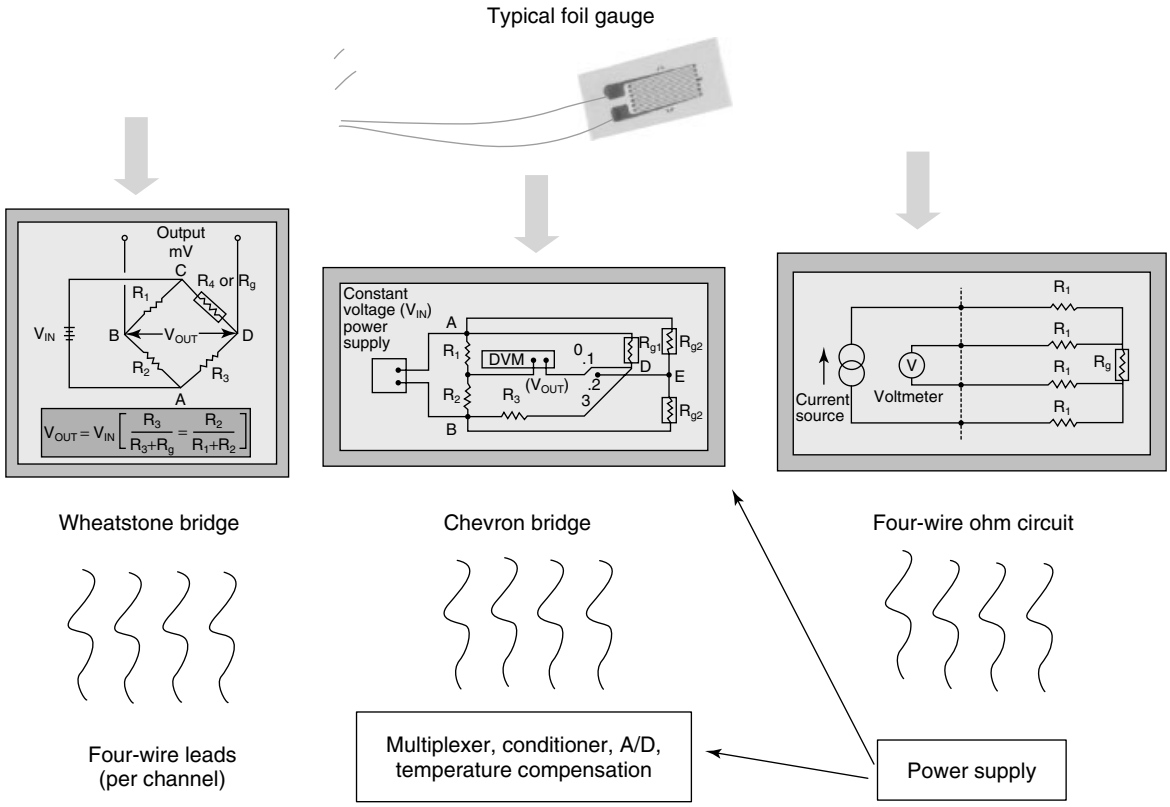

Figure 1. Common signal-processing networks for resistive strain gauges.

2.1.2 Fiber-optic strain gauges

Although foil resistive gauges dominate current market usage, an explosion of commercially available fiber-optic solutions for strain measurement has occurred over the last few years. The fiber-optic communications revolution of the late 1990s led to great improvement in component technologies at lower costs, and the sensor development community piggy-backed on these advances. The two dominant fiber-optic technologies are direct fiber interferometry and fiber Bragg gratings (FBGs) [2]. The former method is older, but its relative complexity (despite several orders of magnitude sensitivity improvement over foil gauges) and low multiplexing capability has limited its use to specialized military and industrial applications. Most commercial systems today take advantage of FBG technology.

FBGs are intrinsic structures that may be photo-written into the fiber. Silica glass, with germanium doping, is absorptive in the ultraviolet optical range, and such irradiation of the fiber core will cause an essentially permanent change in the refractive properties of the core. If the irradiation is performed in a spatially periodic fashion, then a series of gratings (a periodic change in refractive index) is introduced in the fiber core, and these act like a local bandstop optical filter. The physical periodicity is chosen so that when broadband light in the infrared range ($\sim$1300–1600 nm) is propagated down the fiber core, a narrowband component (width $\sim$0.2 nm) is rejected and reflected. The central wavelength of this narrowband component is directly proportional to the spacing in the FBG at that location; so, as that spacing physically changes (because of strain), the reflected wavelength shifts in proportion. In this way, tremendous multiplexing may be achieved: several FBGs may be individually photowritten into a single optical fiber with each one written to reflect at a unique wavelength (Figure 2).

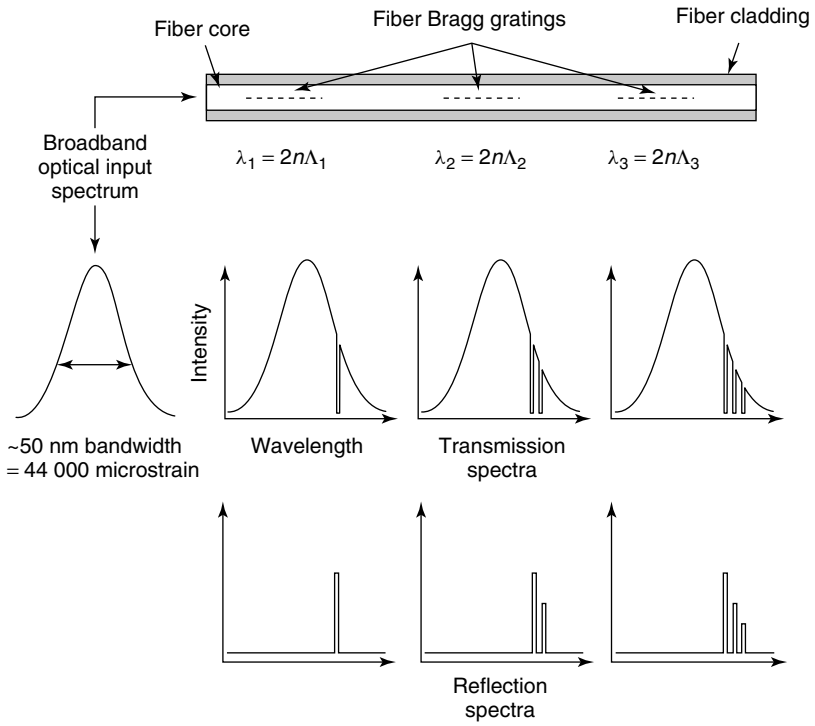

Figure 2. FBG wavelength-encoded multiplexing.

Thus, tracking the individual reflected wavelength shifts allows a direct measurement of strain at the various locations. There are several architectures possible for doing this interrogation, but a dominant approach is shown in Figure 3. Here, broadband light is inserted in an FBG array via a superluminescent diode, and the reflections from the array are coupled back through a Fabry–Perot filter. This device passes only a narrowband wavelength of light (designed to be commensurate with the FBG reflection width of $\sim$0.2 nm) dependent upon the spacing between mirrors in the device. This spacing, and thus the passband, is controlled by applying a rapidly stepped voltage to a piezoelectric driver controlling the mirrors. The passed light signal is sent to a photodetector and differentiated; the zero crossings of the differentiated signal correspond to the peak wavelengths of the reflected light, and correlation between the ramp voltage level and shifts in the zero-crossings results in obtaining the strain for each FBG sensor. The resolution of the voltage ramp and the spectral range of the filter primarily determine the optimal strain resolution, which has been demonstrated on the order of less than 1 microstrain; in some variations on this architecture, strain resolutions on the orders of tens of nanostrain have been reported [3]. This is several orders of magnitude more sensitive than the best foil resistive gauge, but the costs of FBG systems (and specifically, the FBGs themselves, which are $\sim$\$150–200 per sensor) have limited deep market penetration. However, since FBG systems are insensitive to electromagnetic interference, do not create a spark source, are extremely lightweight and nonintrusive, and are highly multiplexible, many application areas—particularly in aerospace structural monitoring—are emerging.

2.1.3 Strain sensing challenges

Despite significant commercialization and use, strain gauges of both types pose some challenges, particularly if being used to supply raw strain data to an SHM or damage prognosis algorithm suite. First, one must apply both strain gauge types to the host material with some form of epoxy. Such epoxies are typically not stiffness-matched with either the

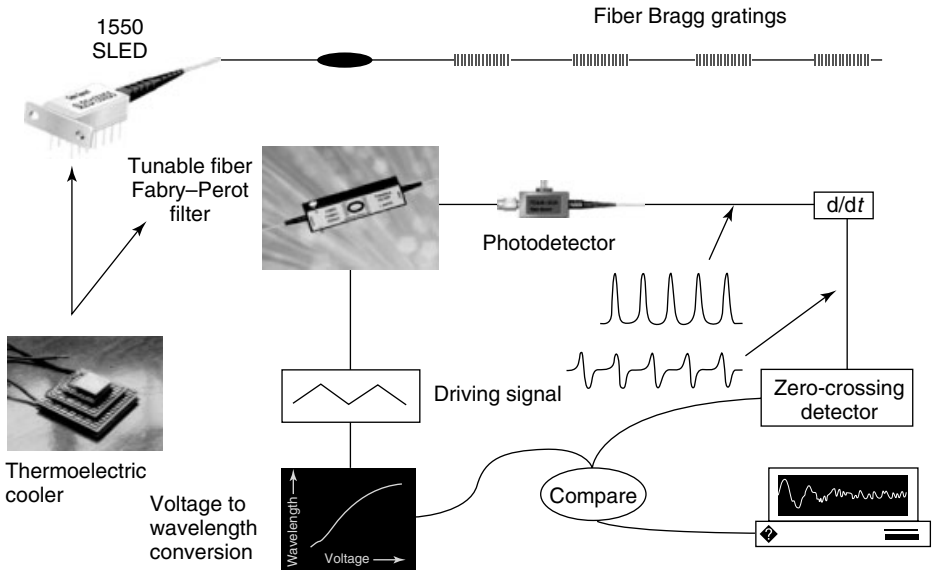

Figure 3. Tunable Fabry–Perot filter FBG interrogation.

gauge material or the host material, which means that strain does not completely transfer between host material and gauge. Typically, the epoxy bond layer will partially absorb some of the material-induced strain in a shear lag effect, leading to a reduced strain reading at the gauge. For simple gauge/host geometries, the community has developed shear lag correction models [4], but these models effectively have their use limited to simple load states and stationary environmental conditions. So, while one may find shear lag correction factors for a sensor array during a laboratory calibration step, it is very common for these factors to change with load level, load application rate, temperature, and humidity, rendering inaccurate strain readings that may introduce errors in subsequent data processing algorithms. Second, all strain gauges and their associated interrogation hardware are inherently sensitive themselves to extraneous measurands, such as temperature. Decoupling of mechanical and thermal strain is a critical issue, and one usually makes recourse to a "dummy" gauge approach whereby a number of gauges are left mechanically debonded from the host structure (thus free to measure temperature alone). Of course, such an approach effectively doubles the sensor requirement, so only a few dummy gauges are typically deployed. For structures such as space-deployable ones where large thermal gradients are observed over the length scales of the structure, this is a big problem, as the thermal correction map cannot accurately couple with the mechanical map, but in many small-scale applications or any application with negligible spatial temperature gradients, this is an acceptable solution. Finally, in the case of fiber-optic gauges, the issue of potential embeddability poses some unique challenges. Because of their small size and self-contained design, fiber gauges may be placed inside composite materials during their fabrication. However, such a benefit leads to problems of ingress/egress reliability, fiber microbending that leads to signal degradation, and the possibility of compromising the host structure's integrity. A number of studies are addressing these issues in fiber sensing [5–8].

2.2 Load/force gauges

The measurement of force or load is a very important component, particularly while doing damage prognosis since loading information is required for developing and updating predictive capability. Load sensors ("cells") fall into two broad classes, both of which enjoy significant market penetration: (i) strain gauge and (ii) piezoelectric. Vibrating wire load cells

Figure 4. Some typical strain gauge load cell transducer designs.

are a third design, but these are primarily used in geotechnical applications rather than SHM.

2.2.1 Strain gauge load cells

The first load cell class is exactly as one may surmise from its label: it consists of a strain gauge, operated as reviewed above, bonded to a specialized transducer that deforms predictably under load. The deformation in the transducer induces strain, which is calibrated through the transducer geometry to applied force. Popular transducer types include bending beam, multiple beam, shear beam, double shear beam, column, membrane, and ring. Some of these designs are shown in Figure 4. One may optimize designs for force detection below a few pound-force up to several thousand pound-force with resolutions dependent upon strain gauge resolution determined by signal processing. Measurement bandwidth ranges from static timescales (with drift compensation) up to whatever sampling limits the data acquisition hardware can sustain.

2.2.2 Piezoelectric load cells

Piezoelectric load cells operate using piezoelectric crystals. Piezoelectric crystals are made from ferroelectric materials (such as lead zirconate titanate, PZT) that induce electric charge (electric dipoles at the molecular level) when mechanically strained. The inertially induced strain on the crystal is contained within a damping block and an inertial seismic mass for frequency response tuning, and the resulting charge is picked up by wiring (Figure 5).

Signal processing is required to amplify and detect this charge, and there are two general architectures: high impedance and low impedance [9].

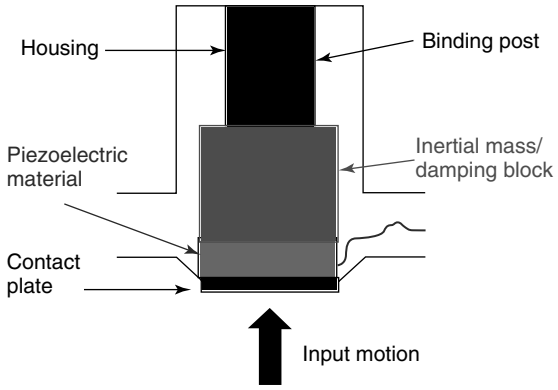

Figure 5. Generic piezoelectric sensor design.

High-impedance designs require a charge amplifier or external impedance converter for charge-to-voltage conversion. The charge amplifier consists of a high-gain inverting voltage amplifier with an Field-Effect Transistor (FET) at its input for high insulation resistance. Low-impedance designs use the same piezoelectric sensing element as high-impedance units, but they also incorporate a miniaturized built-in charge-to-voltage converter. They also require an external power supply coupler, which provides the constant current excitation required for linear operation over a wide voltage range and also decouples the bias voltage from the output. Both the power into and the signal out of the sensor are transmitted over this cable. These designs are shown in Figure 6.

Piezoelectric crystals produce an electrical output only when they experience a change in load; this means they cannot detect true static measurements. Essentially the sensor behaves as a single-degree-of-freedom underdamped oscillator. This means that the sensor is subject to resonance phenomena (frequency-dependent sensitivity in the resonance band, phase distortion, etc.) and operates well as a load cell in a

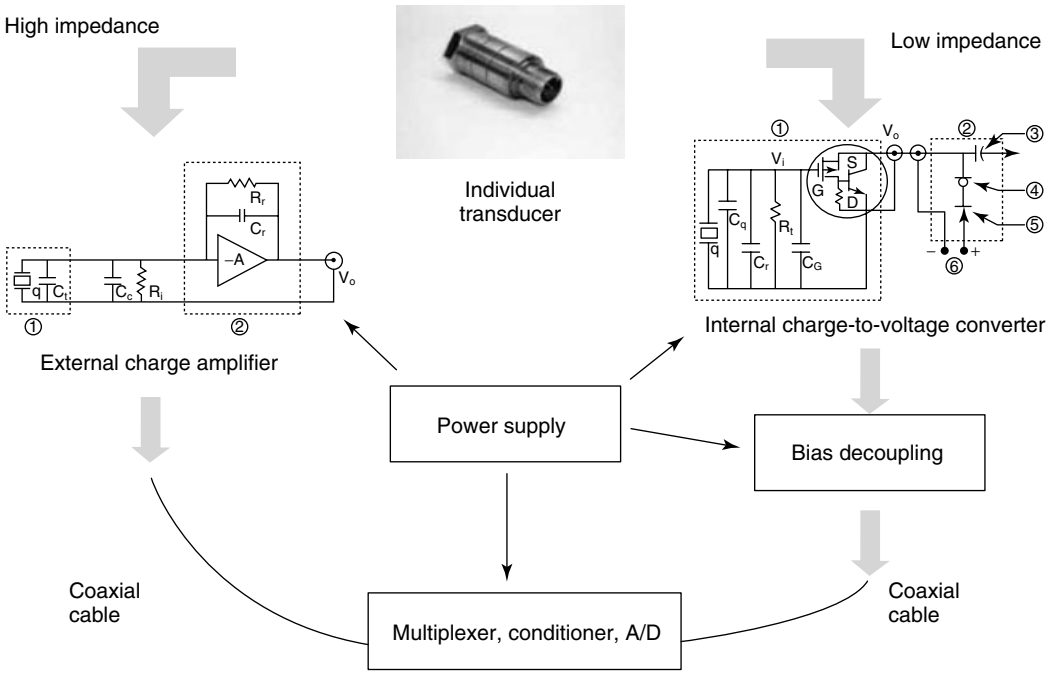

Figure 6. Signal processing for piezoelectric sensors.

finite frequency band below the resonant region, but not all the way to static time scales. Furthermore, these systems have characteristic time constants, which are defined to be the discharge time of the corresponding ac circuit. Time constants are usually partially selectable by resistors in the control circuit, although this depends on the design (low-impedance vs high-impedance). Systems may be designed to measure responses up to many kilohertz with micro-g sensitivity, so these sensors are used very frequently in SHM for measuring small dynamic forces. These load cells work on exactly the same principle as piezoelectric accelerometers, which are the most prolific sensor in current use for SHM applications.

2.2.3 Load sensing challenges

Load cells present their own challenges for effective use. Strain gauge load cells, of course, are subject to the same challenges as "pure" strain gauges described above. There is an added complexity due to the transducer, since the strain gauge itself is affixed to the transducer, but the transducer in turn must be affixed to the system of interest. This is often done with either wax (for temporary measuring), an epoxy (for semipermanent measuring), or through a mounting block (using fasteners). The latter is most desirable, assuming the mounting block's own dynamic response does not interfere with the desired measurement band. The primary issues with any mounting type are (i) maintaining good force transfer from host to sensor and (ii) ensuring that cross-axis sensitivity is minimized. In the latter issue, a sensor that is mounted slightly off of its primary sensing axis (or out of alignment with the desired measurement direction) will not measure what is actually being experienced and will also detect out-of-direction inputs, both of which can significantly corrupt the desired signal.

One other significant challenge with strain gauge load cells is fatigue, which is the accumulation of plastic (unrecoverable) deformation in the strain gauge as load cycles accumulate. All strain gauges suffer from this, but strain gauges used in the direct mode (as above) are not typically used in a highly dynamic, cyclical sensing mode, so fatigue is not as prevalent (other than possible low-cycle, high-amplitude fatigue). However, the dynamic usage

of load cells implies that such sensors have a finite useful life before readings become increasingly inaccurate, distorted, hysteretic, and/or nonlinear.

Piezoelectric load cells do not suffer from strain gauge-related issues, but one must still mount them to the host system in the same ways, so those issues remain. The biggest issue with piezoelectric load cells is their use outside of their calibrated measurement range. As mentioned, these sensors are ac coupled on the low-frequency end (there is significant low-frequency attenuation) and nonlinear beyond a critical high frequency (because of resonance). One has to ensure that force inputs are occurring on time scales commensurate with this frequency range.

3 DATA INTERROGATION STRATEGIES

As mentioned in the introductory remarks, SHM involves more than merely collecting sensor data such as that obtained from a strain gauge or load cell network. One must mine the sensor data for actual information ("features") that directly relates to the damage being assessed. This implies that SHM may be considered as a pattern-recognition problem whereby these features are compared by statistical testing between baseline data sets and test data sets. In the context of this section, strain and/or load gauges provide dynamic response baseline and test condition data, the same feature extraction algorithm(s) are applied to these data, and the features are compared via statistical modeling tools [10] (Figure 7). Feature extraction methods have received a tremendous amount of attention in the literature, and some good reviews may be found in two Los Alamos technical reports [11, 12] and in recent proceedings of the International and European Workshops on Structural Health Monitoring [13, 14]. Statistical modeling for feature discrimination and classification has received significantly less attention in the literature, but the references just cited contain a review of these approaches as well.

Also, as mentioned, feature extraction methods fall into either direct waveform comparisons of some kind or model usage of some kind. The following subsections will consider some examples of these two general types of feature extraction applied to strain/load data.

3.1 Direct waveform comparison

The majority of data interrogation methods with strain/load gauges fall into this group. This is primarily because of two reasons: (i) in general, direct waveform comparison techniques are less computationally burdensome and are more readily interpretable and adaptable and (ii) strain and load measurements are more directly related to damage realizations (strain or loath path changes, for example, when cracks develop and propagate) and existing prognosis models, which often use strain or load as input variables. The civil structural domain—and most notably bridges—has been a prominent application area in this regard [15, 16]. Many bridge

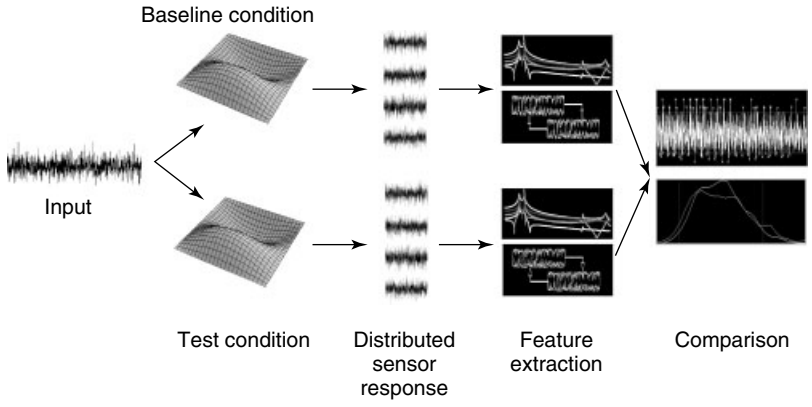

Figure 7. Statistical pattern-recognition approach for SHM.

applications have involved directly embedding strain gauges (typically fiber optic, because of their properties), usually inside specialized tubes [8] that are themselves subsequently placed inside concrete load-bearing members during fabrication. The raw static strain readings are then tracked over time to discover trends, such as seasonal thermal cycling that can lead to wear [17], localized plastic damage due to overload [18], or evidence of a fracture [19].

Researchers have also used direct strain array readings to detect cracks or bond strength verification in composite joints and repair patches (doublers) for aerospace structures [20, 21] and for localizing impacts on composite panels [22]. A number of aerospace applications may be found in [23].

3.2 Model usage for assessment and prognosis

This category involves mining raw strain/load information for damage-sensitive features (rather than directly comparing the waveforms themselves), which often employs using a model of some sort. Model parameters are then compared between baseline and test conditions, or, alternatively, a single model is fit to the baseline and used as a predictor for future test cases, with the resulting error being the feature of interest (i.e., increasing error indicates increasing change to the system). While such techniques typically require more complex computational analysis, they are often tailored for specific damage identification in an application, so they are often more sensitive. Such models may also be coupled to prognosis models, which are models used to predict future system states given the current state and a probabilistic future loading state.

Health assessment models take many forms, e.g., autoregressive models of directly measured time series, modal models of structural response, state space models, mechanics models, or neural networks. These models are broadly classified into physics-based and data-based classes. In the former class, physical first principles are applied to create deterministic relationships among variables that are fitted or tested with data from the sensor arrays. Conversely, data-based models create heuristic relationships among measured data that are tested against each other or a baseline model over time. Researchers have used both model classes with strain/load measurements in a variety of applications, such as detecting loosened bolts in jointed connections [24–26], detecting leaks in composite tanks [27], identifying degradation in bridge girders [28–30], and detecting impact-induced delamination in a composite Unmanned Aerial Vehicle (UAV) wing [31].

Prognosis models are physics-based or empirical (historically based data) models that relate measurable variables to failure criteria for a given failure mode [32], e.g., yielding, fatigue, creep, etc. Most yielding theories (Rankine, Tresca–Guest, St Venant, strain energy, Von Mises–Huber), for example, directly encode strain or stress measurements, so strain and load gauges are needed. High-cycle fatigue models also require stress/strain amplitude and cycle knowledge, so again strain/load gauges are most appropriate. Because of the nonstationary nature of fatigue-inducing stresses, however, several cumulative damage laws (Miner, Henry, Gatts) and subsequent fatigue crack propagation theories (e.g., Paris) have been postulated, all of which require stress as an input variable.

Using damage laws such as these and combining them with current structural health assessments to create damage prognosis technology is relatively new as of this writing. Some recent examples of such integrated technology include using linear cumulative damage laws for assessment of solid rocket motor casing [33], stress cycle curves for detection and prognosis of aircraft landing gear damage [34], and an energy method for fatigue crack detection and growth prediction [35].

1 INTRODUCTION

Structural health monitoring (SHM) arguably emerged as a subdiscipline of structural dynamics with an emphasis on determining the health or condition of a given structure on the basis of the sort of measurements that are commonly available from structural dynamic testing. The standard for a structural dynamic test is an application of *modal analysis*, where the measurements correspond to a modal model—an expansion of the system in terms of a sequence of fictitious single degree-of-freedom (SDOF) systems [1]. The *modal parameters* are the SDOF system-damping ratios and natural frequencies, together with the coefficients of the terms in the expansion that form the modeshapes. Vibration-based SHM does not solely use the modal quantities, it also uses the physical parameter matrices and quantities such as frequency response functions (FRFs) and transmissibilities considerably. The objective of this article is to describe the use of modal and general vibration-based quantities for SHM. It is not intended as a comprehensive review by any means. In fact, such a review already exists in the form of the extensive literature surveys carried out by researchers at Los Alamos National Laboratories in the United States [2, 3]. For a much more comprehensive overview, the reader is directed to these documents. This article is intended to illustrate the use of a small number of vibration-based methods by the consideration of case studies. The specific methods for illustration here are chosen simply by the particular tastes of the authors.

The rationale for vibration-based SHM is the long-held belief that any damage occurring within a structure will be reflected in a change in its dynamic properties. The problem of damage identification is then to translate the changes in the measured quantities into a diagnosis. This diagnosis may simply be a yes/no indication of the presence of damage

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

or may give more detailed information like location and severity. In any case, some degree of mathematical processing is required to translate the measurements into a diagnosis. At present, there are two main frameworks for carrying out this translation. The first is based on the linear-algebraic solution of the identification problem considered as an inverse problem. The second is based on concepts of machine learning and pattern recognition. This article concentrates on the former, as the pattern-recognition approach is adequately represented in other chapters of this Encyclopedia (*see* **Statistical Pattern Recognition**; **Machine Learning Techniques**; **Artificial Neural Networks**; and **Novelty Detection**). The omission of pattern-recognition approaches implies that this article does not consider methods based on passing vibration-based features into neural networks and other learning algorithms.

The breakdown of this article is as follows: Section 2 describes the basic use of modal features in detecting and locating damage. Only basic signal processing operations are considered at this stage. In addition to natural frequencies and modeshapes, derived features—curvatures and Yuen functions—are also dealt with. Section 3 expands on the use of curvatures by discussing the modal strain energy method in some detail, the application of the method is illustrated by use of a detailed experimental case study. Section 4 deals with more advanced algorithms for the processing of data based on the consideration of damage as an inverse problem: the predominant methodology is that of linear algebra or matrix analysis. Section 5 takes a more detailed look at the methodology of finite element (FE) updating and Section 6 contains a discussion of some of the issues that arise in developing a credible SHM methodology based on vibration measurements.

2 NATURAL FREQUENCIES AND MODESHAPES

A fundamental requirement for SHM is that measurements that are sensitive to the presence of damage must be available from a structural test. Such measurements are, in the terminology of pattern recognition, called *features*. A basic requirement of any feature for SHM is that it should distinguish between the normal condition of the structure and *any* damaged state. Such a feature allows *level one* damage identification under Rytter's generally accepted hierarchy [4]; this is simply *detection*. More advanced features allow one to advance further and potentially localize and quantify the damage.

The basic features that one can use for damage detection are the natural frequencies. These have the advantage that they can be acquired without recourse to a full modal test; a basic spectral analysis from a single random excitation test with one response sensor can suffice. A further advantage of the natural frequencies is that they can be estimated quite accurately, typically to within 1%. The use of natural frequencies dates back to the seminal paper of Cawley and Adams [5]. A change in the natural frequency can be taken as an indication of damage within the system. If one considers the changes in many natural frequencies, one can potentially deduce further characteristics of the damage.

Modeshapes can be considered rather than frequencies as they are well known to suffer local changes in the presence of localized damage. Thus, they may prove more effective in *locating* damage. The price one pays for the extra flexibility provided by the modeshapes is the expense of carrying out a full modal test with multiple response sensors and the associated instrumentation. A further problem with modeshapes is that it is not possible to measure them with the same accuracy as natural frequencies. Test errors in the range of 5–10% are typical.

The use of natural frequency and modeshape features is demonstrated here using case studies based on comparatively simple structures. The structures under investigation here are FE models of a beam and plate. To investigate the possibilities of further data processing, the curvatures of the modeshapes are also computed and used as features for network training, as are the diagnostic functions proposed by Yuen [6]. It is shown that the features computed by further processing of the basic modal quantities provide higher-level identification for the damaged structures.

2.1 A cantilever beam structure

FE simulation of the beam was carried out using the package LUSAS [7]. To allow experimental

validation of the model, the properties of a cantilever beam currently in use in the laboratory were adopted. This was of aluminum with dimensions $920 \times 50 \times 12.5\,\text{mm}^3$. Fifteen Timoshenko beam elements were used to model the system and the first five natural frequencies and modeshapes of the system were obtained. The value of each modeshape was specified at 16 nodes along the beam. Comparison of the predicted natural frequencies with those from the experimental beam showed almost perfect agreement. Damage to the structure at a given location was simulated by reducing the Young's modulus of the corresponding element and consequently reducing its stiffness. The results presented here are for 25, 50, and 75% reductions in Young's modulus (and hence stiffness) for the appropriate elements.

The first features to consider are the natural frequencies. These are tabulated below (Table 1 for a stiffness reduction in the fifth element from the cantilever root. (The precisions given is a reflection of the fact that the frequencies are derived from simulation.)

It is noted that increasing severity of damage causes a progressive reduction in all the natural frequencies. The extent of the reduction of a specific frequency depends on the position of the damage relative to the nodes of the corresponding modeshape. In this case, the largest relative decrease is for the first mode. The frequencies appear to provide an effective indication of damage. One problem with using natural frequencies as a damage indicator is the fact that the frequencies may also change for a structure under varying environmental or operational conditions [8]. This matter is discussed in **Statistical Pattern Recognition**. Generally speaking, as the natural frequencies are global properties of a structure, it is difficult to use them to progress beyond simple detection. Where this is possible, several frequencies are needed because the position of the damage affects each frequency differently, as described above. Also, if higher frequency, more local, modes are used, there is potential for damage location, if a higher frequency and more local modes are used, there is potential for damage location [5]. However, higher modes are not always available because of the high sensor density required and the associated instrumentation cost.

As a means of progressing beyond detection, one can consider the modeshapes of the structure. When the most severe level of damage (75% reduction in E) is induced in the model here at element 5, again, the resulting modeshapes are shown in Figure 1 (as solid lines) together with the modes for the undamaged structure (dashed). There is only a small distortion, even for this severely damaged condition. While it is true that distortion becomes more marked in the higher modes, these would not usually be available. It is assumed in the following that only the first few modeshapes are available. The low level of distortion suggests that it might be useful to consider further processing of the modeshapes to obtain features that are known to give at least a clear *visual* indication of the damage location. The derived quantities examined below are the Yuen functions [6] and the *mode curvatures*.

2.1.1 Yuen functions

These are functions defined over the length of the beam, and constructed from the eigenvectors and eigenvalues for the damaged and undamaged system. Suppose $\{\psi\}_i$ is the ith eigenvector of the undamaged system and λ_i is the corresponding eigenvalue.

Table 1. First five natural frequencies of the cantilever beam under various damage scenarios

Stiffness reduction (%)	Natural frequencies				
	1	2	3	4	5
0	12.15	76.05	212.7	415.9	686.0
25	11.96	75.71	208.9	413.1	683.6
50	11.62	75.08	202.6	408.7	679.1
75	11.30	74.53	197.6	405.2	675.0
Maximum % change	7.0%	2.0%	7.1%	2.6%	1.6%

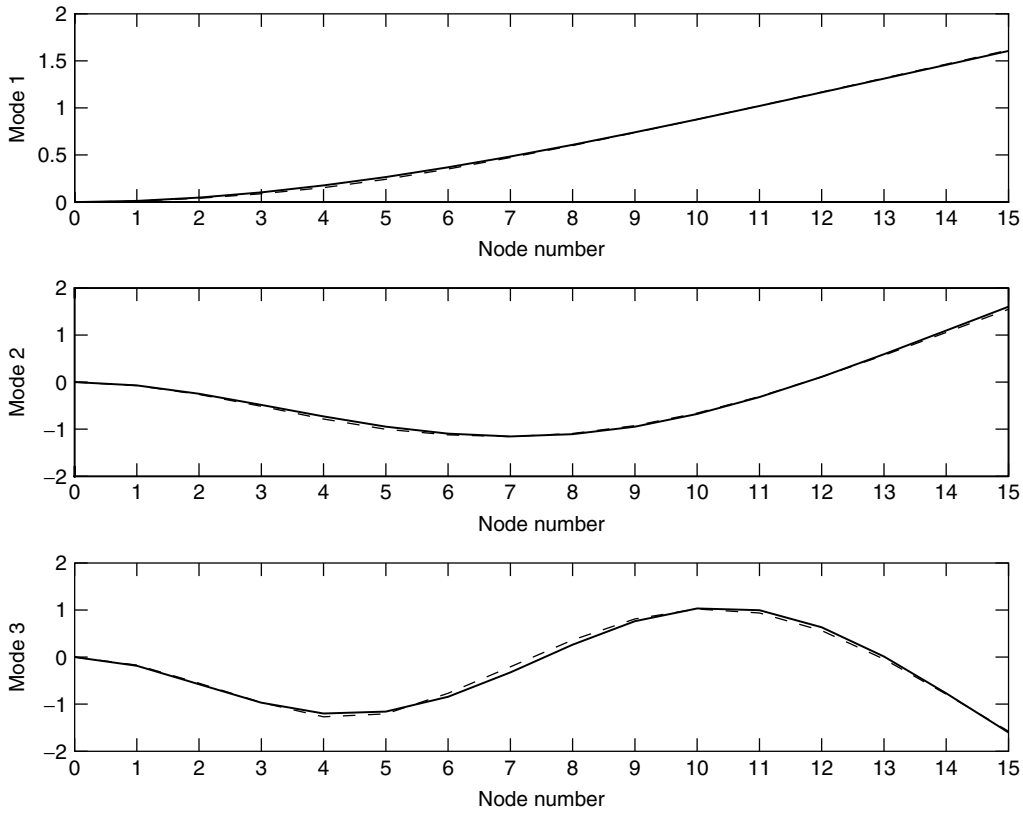

Figure 1. The first three modeshapes for the cantilever beam: undamaged (solid) and damaged (dashed).

Furthermore, suppose $\{\psi'\}_i$ and λ'_i are the corresponding quantities for the damaged system. Then the ith Yuen function is defined by

$$\{Y\}_i = \frac{\{\psi'\}_i}{\lambda'_i} - \frac{\{\psi\}_i}{\lambda_i} \tag{1}$$

The rationale behind these functions is given in [6], and their properties are most easily summarized in a diagrammatic form. Figure 2 shows the function $\{Y\}_1$ (i.e., from the first mode) for each of five damage locations (elements: 2, 4, 6, 8, and 10, with 75% reduction in stiffness). The location of the damage is signaled quite clearly as the node at which the function first becomes nonzero.

Note that the discontinuity in the function becomes less marked toward the free end of the beam; this is expected as very little strain energy is concentrated in this region for vibrations at the first natural frequency. As a consequence, it is difficult to distinguish between the damaged and undamaged modeshape if the fault is in this region.

2.1.2 Modeshape curvatures

Another possibility for a damage-sensitive feature is data obtained by taking derivatives of the modeshapes with respect to the position along the beam. This has the effect of amplifying any discontinuities in the modeshape caused by the localized damage. If the beam stiffness is small in a region, bending is large in that region, and, as a consequence, the beam curvature is high locally. The second derivative with respect to position is used here as an approximation to the curvature. One of the first papers to use curvatures for damage detection was [9]. In this study, the differentiation is carried out by using a centered difference in the main body of the beam with backward and forward differences for the ends.

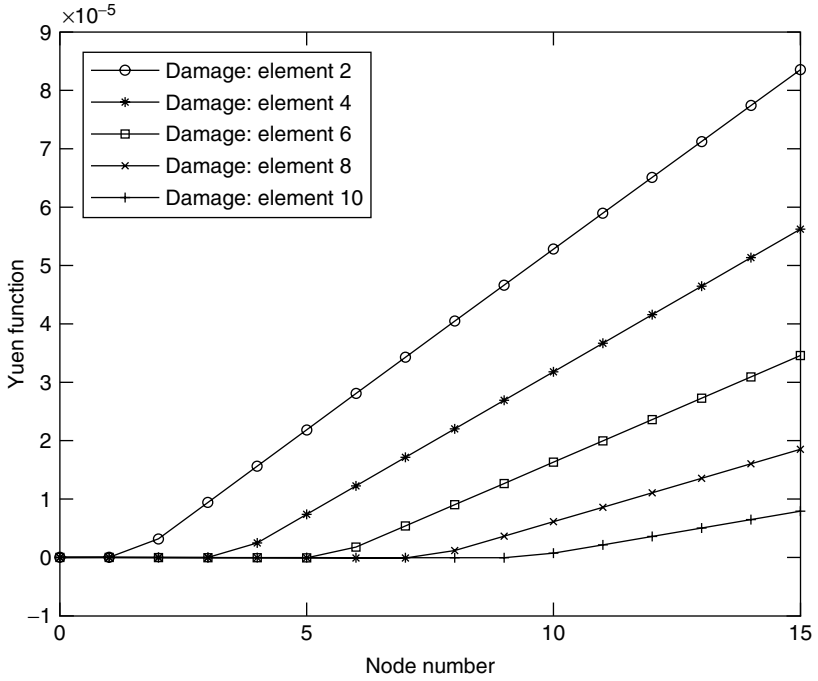

Figure 2. The first Yuen function for the cantilever beam for various different locations of damage.

Figure 3 shows the first mode curvatures when a 75% stiffness reduction is enforced at the five elements considered for the Yuen function. A clear maximum occurs near the location of the damage. This maximum is present for all fault locations. However, as with the Yuen functions, damage in the neighborhood of the free end is poorly indicated.

The effect of the damage can be amplified by subtracting the modeshape curvature of the undamaged structure as in Figure 4.

An interesting approach related to curvature modeshapes was developed by Ratcliffe in [10].

2.2 A cantilever plate structure

To illustrate the use of the modeshape–derived features in a slightly more realistic situation, a two-dimensional cantilever plate structure was considered. The plate was modeled using LUSAS in much the same way as the beam structure. The material constants of aluminum were used and the dimensions chosen were $300 \times 200 \times 2.5\,\text{mm}^3$; the built-in end was taken along one of the short sides. The aspect ratio of 1.5 was chosen to have a check on the results from the FE model; for this value, Leissa [11] provided estimates of the first six natural frequencies, namely, 23.7, 79.5, 147.3, 269.0, 367.0, and 422.3 Hz. The FE mesh was composed of 20×20 elements; however, as such dense sensor networks are not usually available, it was decided to also estimate the modeshapes on a regular 4×4 subgrid. The simulated faults were located within the areas defined by the coarse grid. Faults were simulated by lowering the stiffness of the elements as before; in this case, the Young's Modulus was reduced to 1% of its usual value. To give faults of different severities, different groups of elements were "deleted". Only the most severe case is considered here, where a 3×3 group of elements was deleted to give the fault.

For the FE model, eight-node semiloof elements were used, although this was a little time consuming, the results justified the expenditure. The estimated natural frequencies were 23.5, 79.4, 146.2, 364.6, and 419.2 Hz, agreeing with [11] to well within its stated confidence interval. Figure 5 shows the first modeshape for the undamaged system as a surface and in contour-map form.

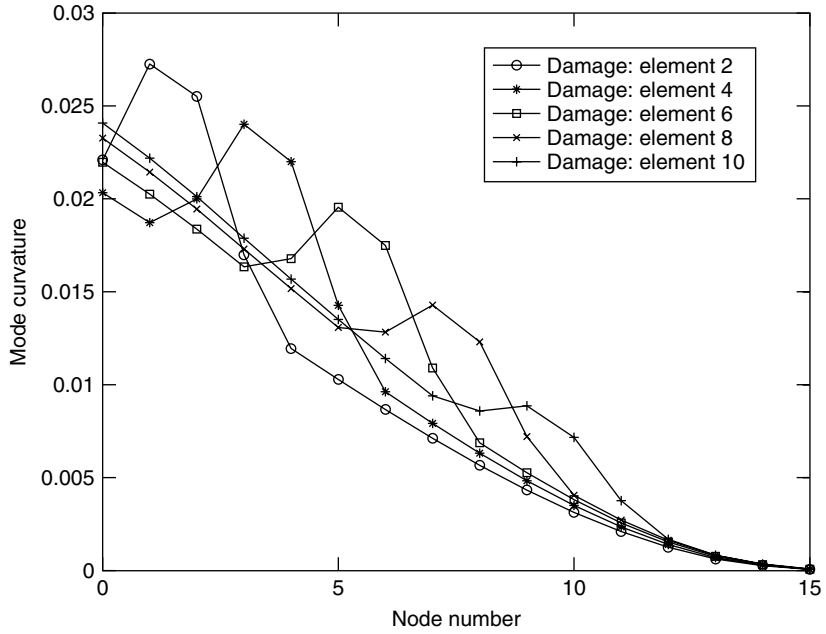

Figure 3. First modeshape curvature for cantilever beam for various different locations of damage.

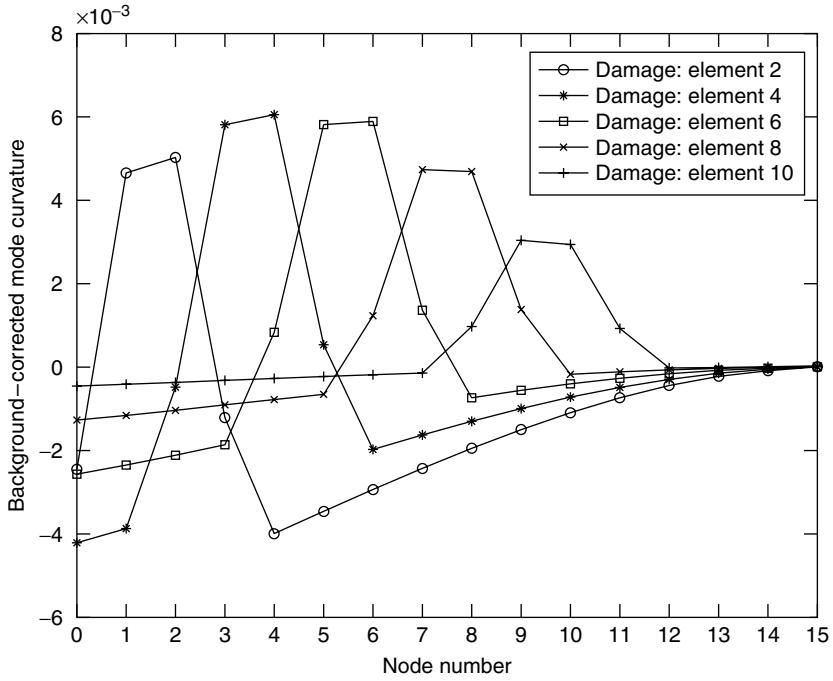

Figure 4. Background-corrected modeshape curvature for cantilever beam for various different locations of damage.

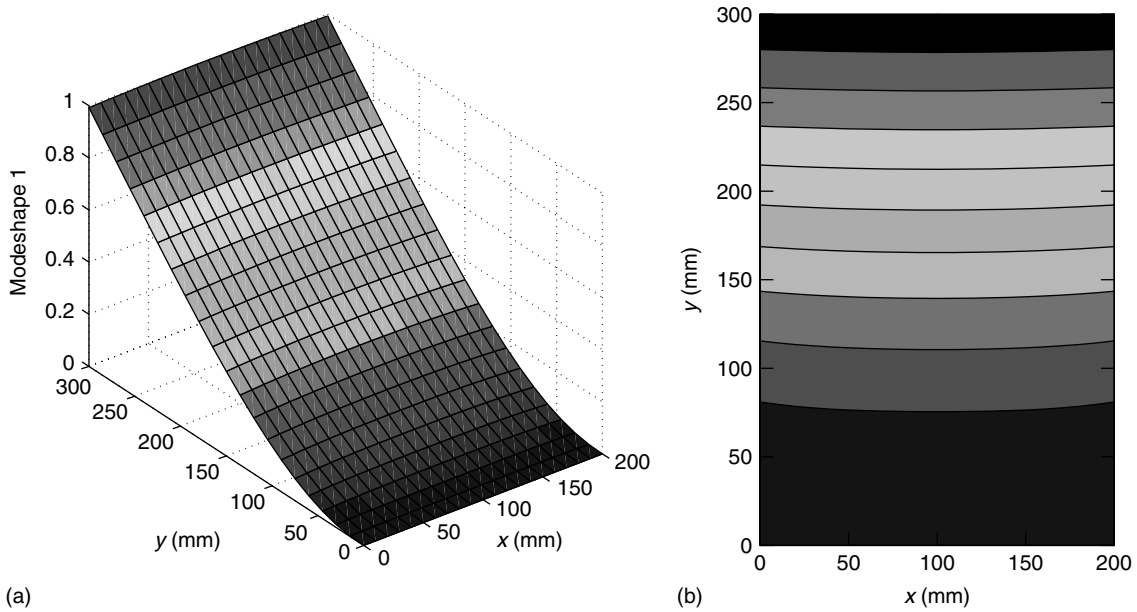

Figure 5. The first modeshape for the undamaged cantilever plate. (a) Surface and (b) contour.

First, the modeshape is considered as a feature for damage detection. When damage is induced in one of the edge cells nearest the clamped edge, there proves to be very little indication of damage in the modeshape. There is some improvement if the modeshape of the undamaged plate is subtracted. The result is shown in Figure 6.

As in the case of the cantilever beam, the modeshape itself gives very little indication of the damage; note that Figure 6 shows the modeshape over the fine mesh. Over the coarse mesh, which would represent a more realistic situation, there is very little discrimination. This is motivation for considering quantities derived from the modeshapes once more. As the modeshape curvatures proved useful in the one-dimensional case, they are considered here.

The curvatures proved a little more involved in this case; as the modal displacement $\{\psi\}$ was now a function of both x and y (convenient coordinates on the plate), the derivative was replaced by the gradient vector,

$$\underline{\nabla}\psi = \left(\frac{\partial \psi}{\partial x}, \frac{\partial \psi}{\partial y}\right) \tag{2}$$

As some scalar analog of the curvature was still required for visualization, the following quantity was chosen:

$$\kappa = \|\underline{\nabla}\|\underline{\nabla}\psi\|\| \tag{3}$$

where

$$\|\underline{\nabla}\psi\| = \sqrt{\left(\frac{\partial \psi}{\partial x}\right)^2 + \left(\frac{\partial \psi}{\partial y}\right)^2} \tag{4}$$

explains the use of the norm $\|\ \|$. A simple centered difference was used to estimate the partial derivatives. To amplify the disturbance due to the fault, the curvatures corresponding to the undamaged state are subtracted throughout. Figure 7 shows the first mode curvature for a fault at the same location as previously. The position of the fault is clearly visible, whereas it was not at all discernable in the modeshape.

A legitimate criticism at this point would be that the curvatures would usually be estimated from the data on the measurement grid and therefore would not be available with the accuracy shown here. In fact, the process of double differentiation to generate the modeshape curvatures is badly influenced by noise, and it was shown in [12] that numerical analysis gives unacceptable errors. However, it was shown

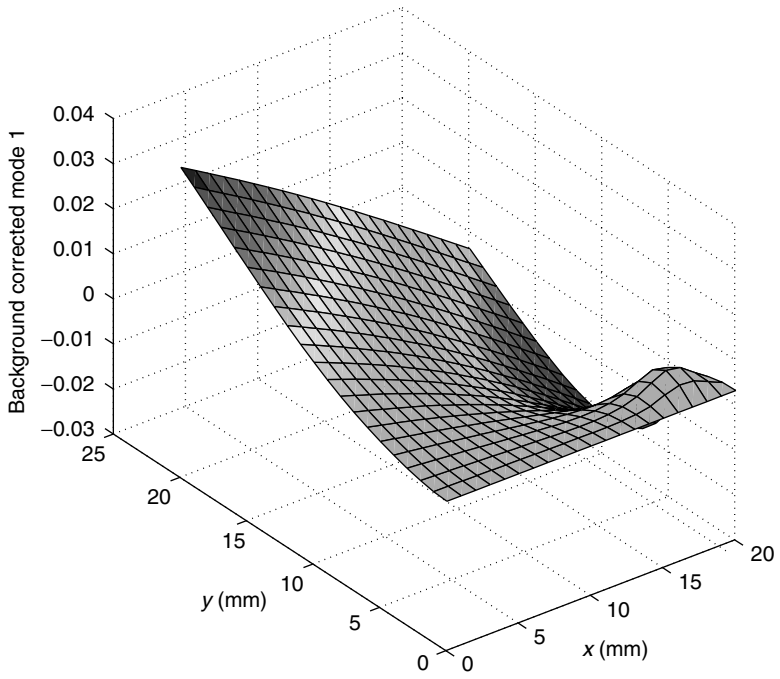

Figure 6. Background-corrected modeshape for the damaged cantilever plate.

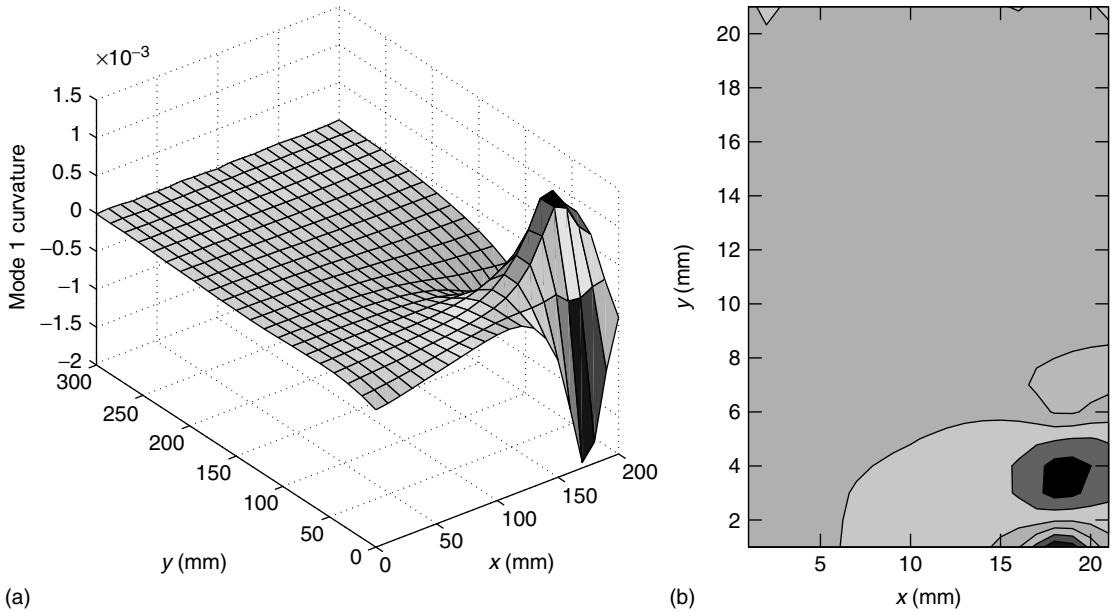

Figure 7. First modeshape curvature for damaged cantilever plate. (a) Surface and (b) contour.

in the same study that strain measurements make an acceptable proxy for the curvatures as long as the sensor density is reasonably high. The feasibility was demonstrated on an experimental cantilever beam with a machined element simulating a crack. Assuming that strain measurements are available, it will still not be possible to use the sort of sensor density implicit in Figure 7. If the coarse 4×4 mesh is used, which would require 16 sensors, the curvatures of Figure 8 are obtained.

The results are less impressive, but the vicinity of the damage is indicated. Before leaving the subject of modeshape features, it should be remarked that the modeshape curvatures play an important part in the *damage index* or *strain energy* method of Stubbs and Kim [13]. In Refs. 14 and 15, the authors compared a number of damage detection methods using the example of a road bridge with a concrete deck and steel supports. The strain energy method proved the most promising, and a detailed discussion is provided in the next section.

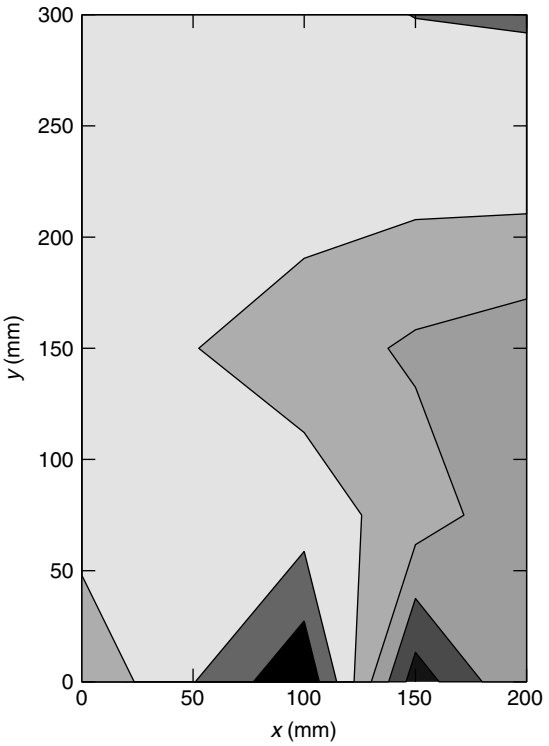

Figure 8. Background-corrected modeshape curvature for the damaged cantilever plate: coarse mesh.

3 THE STRAIN ENERGY METHOD

The approach considered here was developed by Stubbs and Kim [13, 16] and is based on *modal strain energy*. It has been applied in a number of experimental studies over the years, including an analysis of a full-scale bridge structure [17]. The method has mainly been applied to beamlike or one-dimensional structures. In fact, as the object of the exercise here is to identify and localize damage along an aircraft panel stringer, this is sufficient. The extension to two-dimensional structures was made in [18].

3.1 Theory

The analysis here closely follows that of [18]. Consider a beamlike structure discretized into a number of elements labeled by $j = 1, \ldots, N_e$, and suppose that measured modal data is available for N_m modes.

The strain energy of an Euler–Bernoulli beam of length L is given by

$$U = \frac{1}{2}\int_0^L \mathrm{d}x\,(\mathrm{EI})\left(\frac{\mathrm{d}^2 w}{\mathrm{d}x^2}\right)^2 \tag{5}$$

where $w(x)$ is the displacement profile of the beam and EI is the structural rigidity. The "fraction" of the energy associated with a given modeshape $\phi_i(x)$ is simply

$$U_i = \frac{1}{2}\int_0^L \mathrm{d}x\,(\mathrm{EI})\left(\frac{\mathrm{d}^2 \phi_i}{\mathrm{d}x^2}\right)^2 \tag{6}$$

If one further divides the energy among the N_e elements, one finds for element j,

$$U_{ij} = \frac{1}{2}\int_{a_{j-1}}^{a_j} \mathrm{d}x\,(\mathrm{EI})_j\left(\frac{\mathrm{d}^2 \phi_i}{\mathrm{d}x^2}\right)^2 \tag{7}$$

where a_{j-1} and a_j are the endpoints of element j. (The nodes at the ends of the beam are a_0 and a_{N_e}.)

The proportion of modal energy in the jth element is

$$F_{ij} = \frac{U_{ij}}{U_i} \tag{8}$$

and

$$\sum_{j=1}^{N_e} F_{ij} = 1 \tag{9}$$

If the system is damaged, there is a redistribution or scaling of the strain energy and the analogous quantities can be defined as

$$U_i^* = \frac{1}{2}\int_0^L \mathrm{d}x\,(\mathrm{EI})^* \left(\frac{\mathrm{d}^2\phi_i^*}{\mathrm{d}x^2}\right)^2 \tag{10}$$

$$U_{ij}^* = \frac{1}{2}\int_{a_{j-1}}^{a_j} \mathrm{d}x\,(\mathrm{EI})_j^* \left(\frac{\mathrm{d}^2\phi_i^*}{\mathrm{d}x^2}\right)^2 \tag{11}$$

$$F_{ij}^* = \frac{U_{ij}^*}{U_i^*} \tag{12}$$

where again

$$\sum_{j=1}^{N_e} F_{ij}^* = 1 \tag{13}$$

If the elements are small enough, the flexural rigidity is constant on the elements, and, if it is further assumed that (EI) and $(\mathrm{EI})^*$ are constant and equal for the purposes of evaluating U_i and U_i^*, then

$$F_{ij}^* = \frac{(\mathrm{EI})_j^*}{(\mathrm{EI})} \frac{\int_{a_{j-1}}^{a_j} \mathrm{d}x\ \left(\mathrm{d}^2\phi_i^*/\mathrm{d}x^2\right)^2}{\int_0^L \mathrm{d}x\ \left(\mathrm{d}^2\phi_i^*/\mathrm{d}x^2\right)^2} = \frac{(\mathrm{EI})_j^*}{(\mathrm{EI})} f_{ij}^* \tag{14}$$

with a similar definition for the undamaged quantity.

Now, suppose that the damage is only in element k and that all the undamaged elements store the same fraction of modal strain energy before and after damage i.e., $F_{ij}^* = F_{ij} \forall j \neq k$. It follows from (9) and (13) that $F_{ik}^* = F_{ik}$ or

$$\frac{(\mathrm{EI})_k^*}{(\mathrm{EI})} f_{ik}^* = \frac{(\mathrm{EI})_k}{(\mathrm{EI})} f_{ik} \tag{15}$$

so,

$$\frac{(\mathrm{EI})_k}{(\mathrm{EI})_k^*} = \frac{f_{ik}^*}{f_{ik}} = \beta_{ik} \tag{16}$$

The quantity β_{ik} is the *damage index* associated with mode i and element k. It is assumed that damage to an element manifests itself in a decrease in the flexural rigidity and a consequent increase in the index. To eliminate possible problems due to near-zero values of the denominator, a slightly modified version is used here.

$$\beta_{ik} = \frac{f_{ik}^* + 1}{f_{ik} + 1} \tag{17}$$

To obtain a more robust diagnostic, one can integrate the information across all the measured modes and form

$$\beta_k = \frac{\sum_{i=1}^{N_m} f_{ik}^* + 1}{\sum_{i=1}^{N_m} f_{ik} + 1} \tag{18}$$

As in most statistical detection methods, it is important to have a threshold, which asserts that there is a significant departure from unity for the damage index. In [19] and [18], it is assumed that the statistics can be obtained by taking the mean and standard deviation over all the elements. If the index is assumed to have a Gaussian distribution, then one can assert that indices more than two standard deviations above the mean can be associated with possible damage locations. Alternatively, if the normalized index Z_k is used, where

$$Z_k = \frac{\beta_k - \overline{\beta}}{\sigma_\beta} - 2 \tag{19}$$

then potential damage sites are associated with positive Z_k. Note that, if the statistics are estimated from index values on a damaged structure, this threshold is equivalent to using an inclusive discordancy measure to detect outliers of the index [20]. In practice, the statistics of Z_k are unlikely to be Gaussian and this means that the decision rule above will not usually give 97% confidence in the diagnosis as would be expected from the two standard deviations rule. Whether the decision rule is conservative or not will depend on the true statistics of Z_k. A more rigorous approach to determining the threshold could be by means of probability density estimation.

3.2 The experimental panel and data capture

The panel was constructed to the following specifications. The upper surface was $750 \times 500 \times 3\,\text{mm}^3$ aluminum sheet (Figure 9 shows a schematic figure). This was stiffened by the addition of two ribs composed of lengths of C-channel riveted to the short edges. Two stiffening stringers composed of angle section ran along the length of the sheet. The tests were all conducted with free–free boundary conditions for the panel, which was suspended from a substantial frame using springs and nylon line.

Damage was simulated by the introduction of a saw cut in the outside stringer, 125 mm from the edge of the panel (Figure 9). Nine levels of damage were investigated from 10% depth to 90%. As the stringer is 1 in. (25.4 mm) in depth, each level corresponds to 2.5 mm of damage.

The system was excited using a Gearing and Watson electrodynamic shaker driven by broadband white noise amplified by a Gearing and Watson power amplifier. The responses were measured using PCB resonant piezoelectric accelerometers and sampled using a DIFA/Scadas acquisition system running LMS software under the control of an HP computer. The DIFA system was also used to form the random excitation.

The object of the experiment was to carry out a complete top surface modal analysis using 19 measurement points (Figure 10) for each stage of damage (location 1 is the shaker attachment point, points 2–20 are the accelerometer positions). However, for the purposes of this illustration, only the data measured along the line of the stringer is relevant.

3.3 Results from the strain energy method

For the strain energy method, the analysis required the measurement of modeshapes from the structure. This was accomplished by using the LMS modal analysis package. The sensor layout was as shown in Figure 10. To use the 1D formulation of the strain energy method, only the modeshapes along the

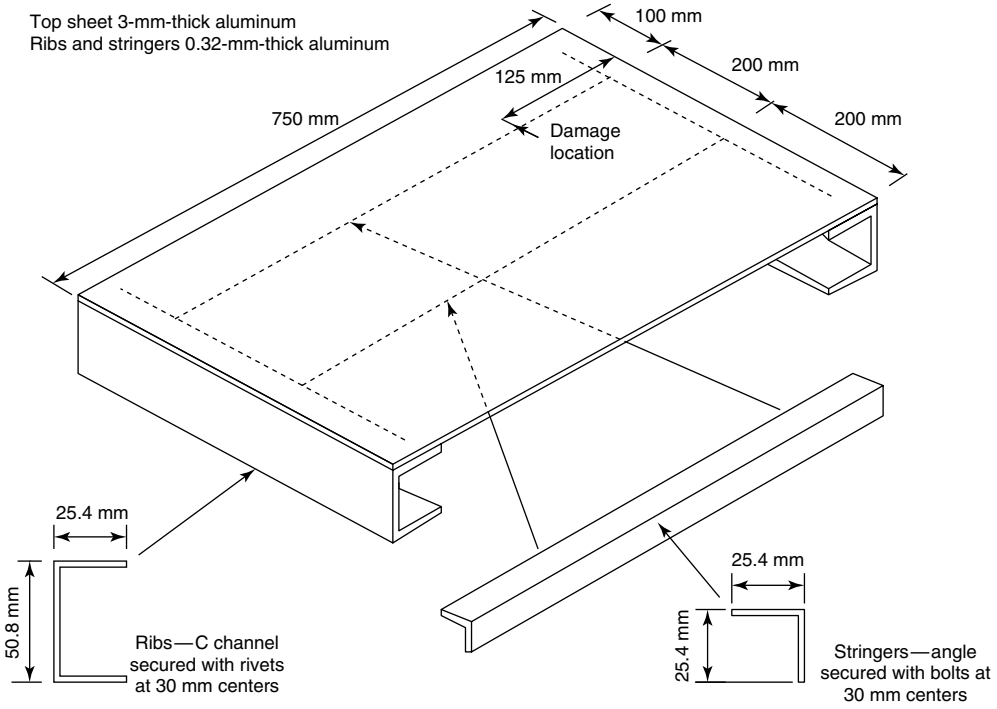

Figure 9. Schematic of the simulated skin panel.

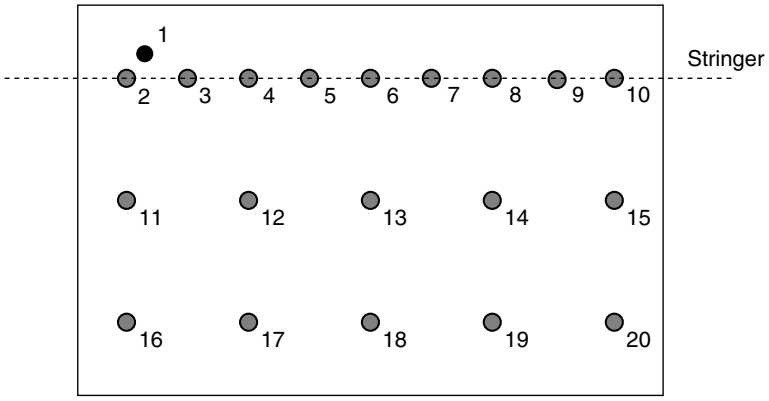

Figure 10. Modal analysis measurement points.

stringer are used in what follows i.e., those at sensors 2–10.

The frequency interval up to 150 Hz contained eight distinguishable modes. These were selected for the analysis. A time-domain curve-fitting technique was used to extract modal parameters from the measured FRFs; broadband excitation was used. A modal analysis was carried out for the normal condition and for all nine levels of damage. The natural frequencies of the eight modes of interest are given in Table 2 as a function of the damage level.

Only modes 6 and 8 show any significant systematic variation in their frequencies as the damage increases. Mode 4 was difficult to identify and in one case (damage level 50%) the curve fitting and subsequent stability analysis failed to identify it at all.

Figures 11 and 12 show some of the modeshapes along the stringer for each level of damage. The modeshapes are normalized so that $||\phi_i|| = 1$. The first mode appeared to be completely insensitive to damage, and the second mode was not much different. Mode 3 showed no variation until the damage level reached 90%, when there was a perturbation in the vicinity of sensor 9, which is closest to the damage site. Mode 4 showed a degree of variation, but, given that this mode was consistently difficult to identify, this may be a manifestation of a repeatability problem. Modes 5 and 6 both displayed some systematic variation with the level of damage. Modes 7 and 8 showed the most marked variation with damage (Figures 11 and 12, the highest levels are highlighted using dotted and dashed lines); in fact, the four highest levels for mode 7 can be distinguished by the eye.

It is rather surprising that there is not more correlation between the extent of the variation for natural frequency and that for modeshape. In particular, mode 7 shows by far the greatest change in modeshape while retaining a constant natural frequency over the different levels of damage.

Table 2. Natural frequencies from modal tests

Mode	Natural frequency (Hz)									
	0%	10%	20%	30%	40%	50%	60%	70%	80%	90%
1	24.2	24.2	24.2	24.2	24.2	24.2	24.2	24.2	24.2	24.2
2	30.9	30.8	31.0	31.0	31.0	30.2	30.9	31.0	30.8	30.7
3	65.1	65.0	64.9	65.0	65.1	65.0	65.0	65.0	65.1	65.1
4	79.7	80.9	79.8	79.8	79.8	—	79.6	79.8	79.6	79.4
5	86.7	86.7	86.7	86.7	86.7	86.7	86.7	86.7	86.6	86.8
6	108.5	108.6	108.5	108.5	108.5	108.3	108.0	107.7	106.4	103.5
7	110.3	110.3	110.3	110.3	110.2	110.3	110.3	110.3	110.3	110.3
8	118.4	118.4	118.3	118.0	117.5	116.6	115.1	114.0	111.9	110.8

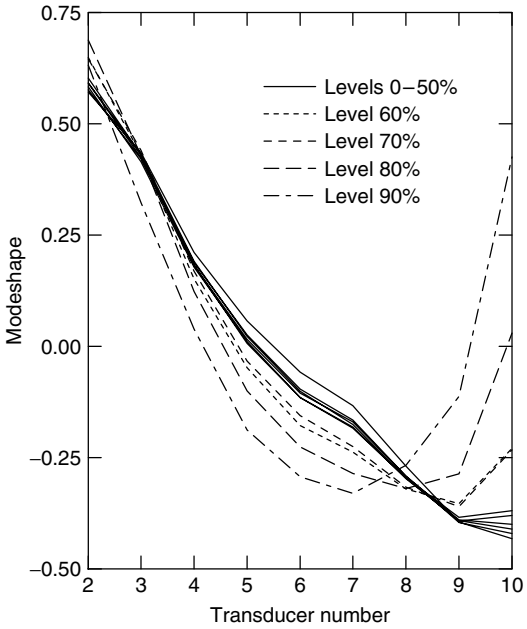

Figure 11. Measured modeshapes for mode 7 for all levels of damage.

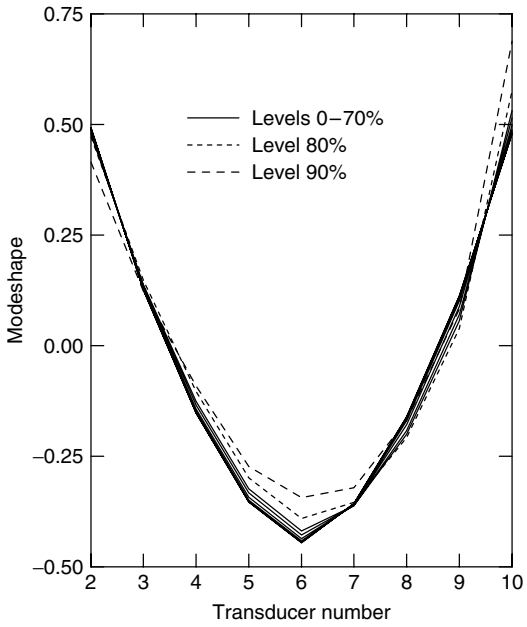

Figure 12. Measured modeshapes for mode 8 for all levels of damage.

The damage indices for all modes were computed using equation (17) and normalized as in equation (19). As the data stands, there are only nine measurement points per modeshape and it is therefore impossible to localize the damage at a nonsensor location. To increase the resolution, a cubic convolution polynomial interpolation was used to estimate the modeshape at 19 regularly spaced points between the sensors. This gave an array of 161 *pseudosensor* values for the modeshape. This, in turn, gave 160 elements. The differentiations that were needed to estimate the curvatures $\mathrm{d}^2\phi_i/\mathrm{d}x^2$ were carried out using a centered difference in the main body of the array and forward and backward differences at the ends. The computation was carried out in Matlab to take advantage of the built-in interpolation routines.

For the modal damage indices, modes 1–5 gave poor results; only the highest level of damage was flagged for modes 1, 3, and 5. (The statistics for normalizing the indices were computed for each mode individually, but averaging over all damage levels. Missing data from mode 4 at the 50% level was approximated by the corresponding 60% level data.) More worryingly, these indices showed many excursions above threshold at non-damaged locations e.g., see Figure 13 for mode 2. This behavior is consistent with the fact that the first five modes showed little or no systematic variation with the damage. The results for the three highest modes were far more encouraging. Each signaled damage: mode 6 from the 80% extent onward and modes 7 and 8 from the 60% level onward. Figure 14 shows the indices for mode 8. More importantly, there were no spurious excursions above the threshold. One of the main reasons for using the strain energy method was to locate the damage. The peaks in the index for mode 8, which is the clearest, are consistently over element 139. Note that this is the location of sensor 9. In reality, the damage is in element 134. As each element is 4.24 mm wide, this amounts to a location error of 21.25 mm. However, note that the index is not above the threshold at a single point; each excursion signals damage over an interval. The extent of the intervals for mode 8 are given in Table 3. A star in Table 3 indicates that the identified interval includes the damage location.

It can be seen from Table 3 that the correct damage element is included from the 80% extent onward. The starred values in the table indicate that the end effects from the interpolation routine have created a plateau,

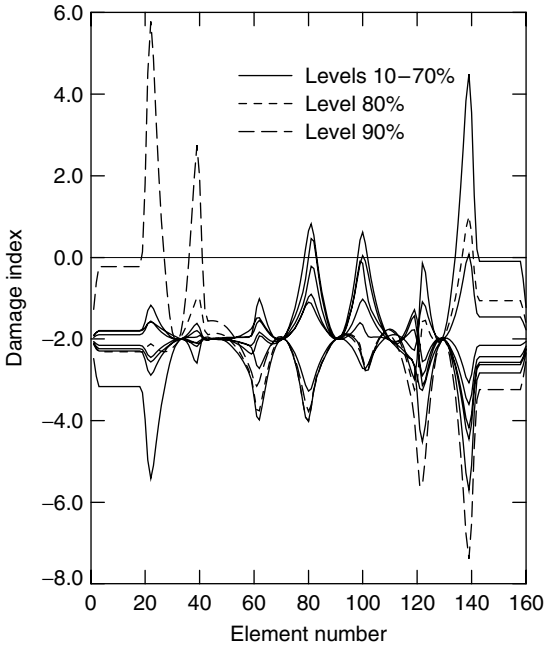

Figure 13. Damage indices for mode 2 for all levels of damage.

Table 3. Damage location intervals for mode 8 index

Level (%)	Interval
60	136–140
70	135–141
80	132–160*
90	132–160*

which causes the index to be above threshold over the whole region between the index maximum and the final element. This appears to be due to the cubic nature of the interpolation and might be avoided by passing to a higher-order interpolant. This plateau is also visible in the results of [21]. The plateaus can be eliminated by using a cubic spline; however, this option reduces the sensitivity to damage.

Multimode damage indices were also computed using equation (18). When all the modes were used, the two highest damage levels were detected and located in the correct vicinity (the plateau was present again). Unfortunately, there was a small indication of damage at a spurious location. Figure 15 shows the multimode index computed using modes 6–8; the

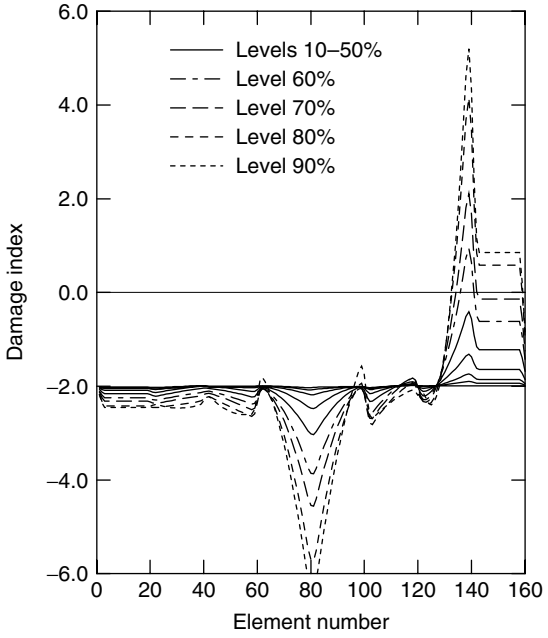

Figure 14. Damage indices for mode 8 for all levels of damage.

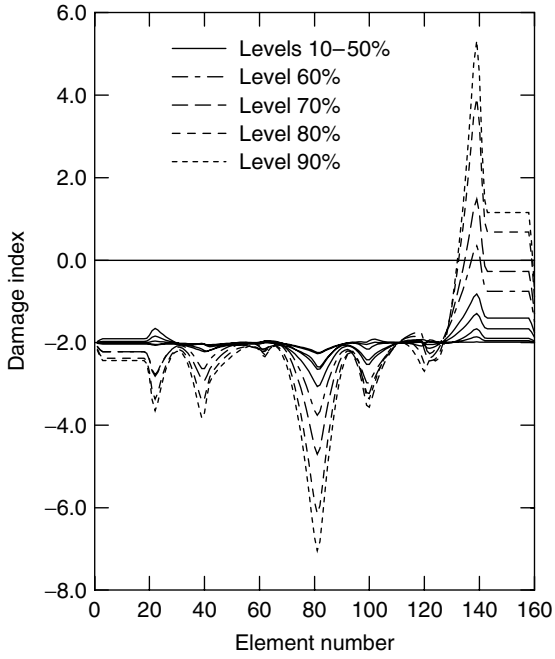

Figure 15. Damage indices for modes 6 to 8 for all levels of damage.

results are much better, damage is detected from the 60% level onward, the location accuracy is the same as before, and the most probable location appears to be at sensor 9.

4 LINEAR-ALGEBRAIC METHODS

The methods described so far are quite basic in the sense that they require only simple numerical operations (simple in nature, if not always in implementation) on single modeshapes. The object of this section is to look at methods based on more sophisticated numerical processing and involving more detailed specifications of the structure. If, for example, the modal and/or physical matrices for the structure are obtainable in the undamaged and (potentially) damaged states, it will be possible to make a comparison and this may allow one to identify the location and severity of the damage. All of the methods described in the section make critical use of the fact that "baseline" data is available for the undamaged structure. There is an extensive literature on the application of linear algebra in the context of SHM, and no attempt is made here to provide anything like a review. Only a small selection of the available techniques is presented here. The interested reader can consult the comprehensive reviews [2, 3] for a more complete coverage of the field. One linear-algebraic approach, the method of FE updating, has received a great deal of attention. Because this method is used extensively, it is described in detail in the following section.

4.1 A direct-update method

To apply this method, one must assume that one or more of the natural frequencies and corresponding modeshapes have been measured. Suppose $[M_u]$, $[C_u]$, and $[K_u]$ are the mass, damping, and stiffness matrices of the undamaged structure and that λ_{ui} and $\{\phi_{ui}\}$ denote the ith natural frequency and corresponding modeshape vector. The eigenvalue equation for the structure gives

$$(\lambda_{ui}^2[M_u] + \lambda_{ui}[C_u] + [K_u])\{\phi_{ui}\} = 0 \qquad (20)$$

For the corresponding quantities of the damaged structure (indicated by a subscript d), one has

$$(\lambda_{di}^2[M_d] + \lambda_{di}[C_d] + [K_d])\{\phi_{di}\} = 0 \qquad (21)$$

If one assumes, for simplicity, that damage only affects the stiffness matrix, then one can summarize the change between the undamaged and damaged systems by the simple expression

$$[K_d] = [K_u] + [\delta K] \qquad (22)$$

and the problem of damage identification is reduced to the problem of computing the "update" matrix $[\delta K]$. One makes use of equation (21), which now takes the form (noting that $[M_d] = [M_u]$ and $[C_d] = [C_u]$),

$$\begin{aligned}\{B_i\} &= [\lambda_{di}^2[M_u] + \lambda_{di}[C_u] + [K_u]]\{\phi_{di}\} \\ &= [\delta K]\{\phi_{di}\} \quad \forall i = 1, \ldots, r \end{aligned} \qquad (23)$$

where r is the number of measured modal properties. The vector $\{B_i\}$ can be tested to see whether it departs significantly from zero and this provides a detection method for damage. If the damage is local, one can further infer the location of the damage from the position of the nonzero entries within the vector $\{B_i\}$. Various methods of computing the physical matrices or their perturbations have been investigated and the reader is referred to [2] for a discussion under the title "Matrix update methods".

To illustrate the method, data were generated from a simple synthetic system. The system was a linear chain of 20 identical masses m, connected in series by identical springs of stiffness k. The two end masses were connected to the ground by two further springs of stiffness k. The damping of the system was assumed to be zero. Values of $m = 1\,\mathrm{kg}$ and $k = 10^4\,\mathrm{N\,m^{-1}}$ were used to generate the system matrices and solve the associated eigenvalue equation for the natural frequencies and modeshapes.

To simulate damage in the system, the stiffness of the spring joining masses 5 and 6 was reduced by 50%. When the residual vector $\{B_i\}$ was computed for the first three modes using equation (23), the results shown in Figure 16 were obtained.

The results are perfect and locate the damage to be between the fifth and sixth masses. However, one should be aware that the data used so far is also perfect as it has been generated from numerical simulation. To investigate the effects of noise, the

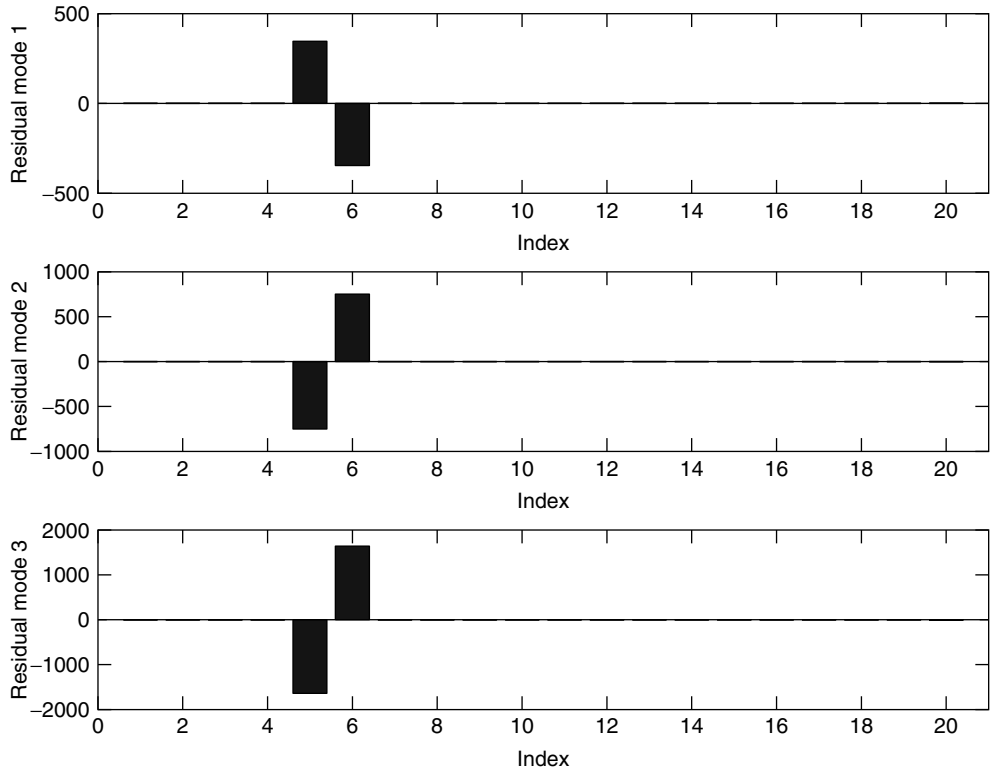

Figure 16. Residual vectors for the first three modes of the damaged system.

modeshapes from the damaged system were perturbed by Gaussian noise. The noise level was taken as 5% of the maximum modeshape value, which is a realistic level. The natural frequencies, which can be measured more accurately, were left clean. The residual vectors for the noisy modes are given in Figure 17. The average residual vector is also given, taken over the three modes.

Although the location is still indicated, the results are not as good. The problem is that the update with the noisy modeshape vectors has smeared the stiffness change over the whole stiffness matrix. One possible solution to this problem is given by the next method discussed.

4.2 A minimum-rank update method

Generally, one would wish to add a constraint to the computation of the residual vectors $\{B_i\}$ or perturbation matrix $[\delta K]$. This is the requirement that the perturbation, if it is to truly reflect a *local* change, must be mainly zero with only a small number of elements being nonzero. Unfortunately, the update method shown above has no such constraint and the result is that the effect of the damage is smeared across the residuals. Zimmerman and Kaouk [22, 23] proposed that one way to enforce locality within the perturbation matrix would be to demand that it had a low rank. The method proceeds by computing

$$[B] = [M_{\mathrm{u}}][\phi_{\mathrm{d}}][\Lambda_{\mathrm{d}}]^2 + [C_{\mathrm{u}}][\phi_{\mathrm{d}}][\Lambda_{\mathrm{d}}] + [K_{\mathrm{d}}][\phi_{\mathrm{d}}] = [\delta K][\phi_{\mathrm{d}}] \tag{24}$$

where $[\phi_{\mathrm{d}}] = [\{\phi_{\mathrm{d}1}\}\{\phi_{\mathrm{d}2}\}\ldots\{\phi_{\mathrm{d}r}\}]$ and $[\Lambda_{\mathrm{d}}] = \mathrm{diag}\,[\lambda_{\mathrm{d}1}, \lambda_{\mathrm{d}2}, \ldots, \lambda_{\mathrm{d}r}]$. Zimmerman and Kaouk showed that the minimum-rank solution to equation (24) is [22, 23],

$$[\delta K] = [B]([B]^{\mathrm{T}}[\phi_{\mathrm{d}}])^{-1}[B]^{\mathrm{T}} \tag{25}$$

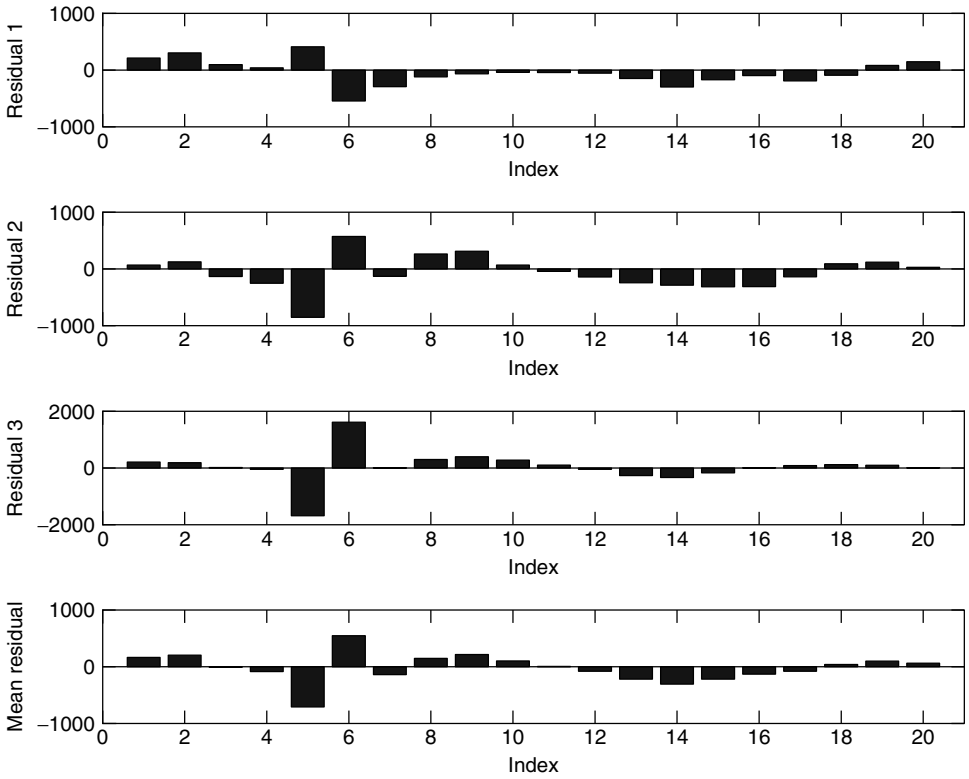

Figure 17. Residual vectors for the first three noisy modes of the damaged system.

To illustrate this approach, data from the same simulated 20-DOF system as before was used. The perturbation matrix for the damaged system in equation (25) was computed using all of the clean modeshapes. The resulting perturbation is shown in Figure 18.

The advantage of the minimum-rank update approach is shown clearly when the method is then applied to the noisy modeshapes. The results are as shown in Figure 19.

The position and size of the damage is shown just as clearly in Figure 19 as in Figure 18. Kaouk and Zimmerman further extended the approach so that it could simultaneously estimate perturbations to the mass, damping, and stiffness matrices [24].

4.3 Flexibilities

Rather than trying to estimate the change in the stiffness matrix, it is sometimes more straightforward to estimate the change in its inverse, namely, the flexibility matrix $[G] = [K]^{-1}$. In terms of modal quantities, the flexibility is given by

$$[G] = [\phi][\Lambda][\phi]^{\mathrm{T}} = \sum_{i=1}^{n} \frac{1}{\omega_i^2} \{\phi_i\}\{\phi_i\}^{\mathrm{T}} \qquad (26)$$

or, if only the first r modes are measured,

$$[G] \approx \sum_{i=1}^{r} \frac{1}{\omega_i^2} \{\phi_i\}\{\phi_i\}^{\mathrm{T}} \qquad (27)$$

It is clear from these expressions that the lowest modes have the most influence on the flexibility matrix. Pandey and Biswas [25] proposed a damage indicator based on the difference between the measured flexibilities of the damaged and undamaged systems,

$$[\delta G] = [G_{\mathrm{u}}] - [G_{\mathrm{d}}] \qquad (28)$$

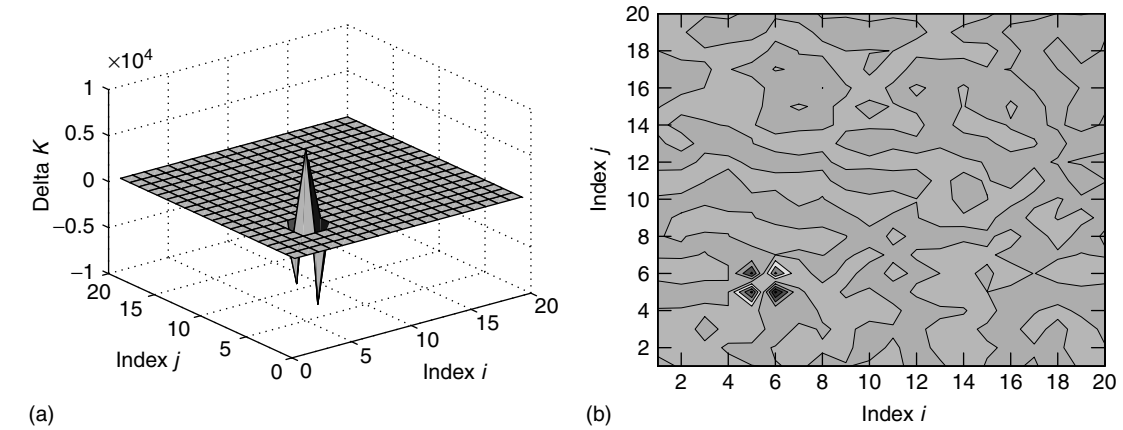

Figure 18. Perturbation matrix from the minimum-rank update for the damaged 20-DOF system: clean data. (a) Surface and (b) contour.

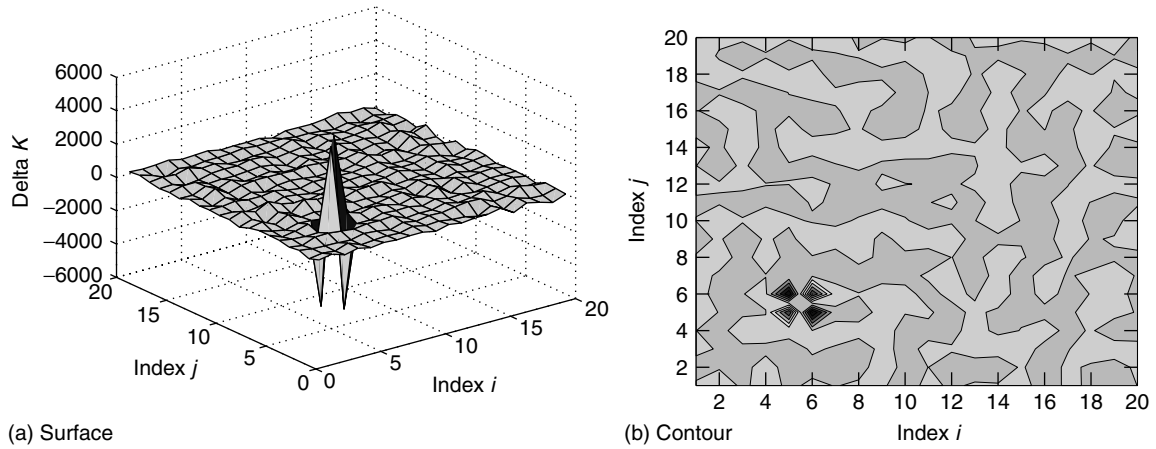

Figure 19. Perturbation matrix from the minimum-rank update for the damaged 20-DOF system: noisy data.

where, of course,

$$[G_{\mathrm{u}}] \approx \sum_{i=1}^{r} \frac{1}{\omega_{\mathrm{u}i}^2} \{\phi_{\mathrm{u}i}\}\{\phi_{\mathrm{u}i}\}^{\mathrm{T}} \tag{29}$$

and

$$[G_{\mathrm{d}}] \approx \sum_{i=1}^{r} \frac{1}{\omega_{\mathrm{d}i}^2} \{\phi_{\mathrm{d}i}\}\{\phi_{\mathrm{d}i}\}^{\mathrm{T}} \tag{30}$$

The use of this measure can be illustrated using the data from the simulated 20-DOF system introduced earlier. The change in flexibility for the damaged system was computed using (all of) the clean modeshapes and is displayed as a contour map in Figure 20.

The results of this method are often presented as a plot of selected columns of the flexibility difference, and the location of the damage is evident from the plot shown in Figure 21.

If the noisy modeshapes from the simulation are used to compute the flexibility change, there is not much degradation in diagnostic performance, as shown in Figures 22 and 23. Although there is some distortion in the plots, the features that indicate the location of damage are still present.

5 PARAMETRIC MODEL UPDATING

The alternative to the algebraic approach to model updating described in the previous section is sensitivity-type methods that rely on a parametric model of the structure and the minimization of some penalty function based on the error between the measured data and the predictions from the model. These methods offer a wide range of parameters to be updated that have physical meaning and allow a degree of control over the optimization process.

5.1 Objective functions

Friswell and Mottershead [26] have discussed sensitivity-based methods in detail. The approach minimizes the difference between modal quantities (usually natural frequencies and less often modeshapes) of the measured data and model predictions. This problem may be expressed as the minimization of J, where

$$J(\theta) = \left\| \{z_m\} - \{z(\{\theta\})\} \right\|^2 = \{\varepsilon\}^{\mathrm{T}}\{\varepsilon\} \qquad (31)$$

and

$$\{\varepsilon\} = \{z_m\} - \{z(\{\theta\})\} \qquad (32)$$

Here $\{z_m\}$ and $\{z(\{\theta\})\}$ are the measured and computed modal vectors, $\{\theta\}$ is a vector of all unknown parameters, and $\{\varepsilon\}$ is the modal residual vector. The modal vectors may consist of both natural frequencies and modeshapes, although often modeshapes are only used to pair individual modes. If modeshapes are included, then they must be carefully normalized, the sensor locations must be carefully matched to the FE degrees of freedom, and weighting should be applied to equation (31).

FRFs may also be used, although a model of damping is required, and the penalty function is often a very complicated function of the parameters with many local minima, making the optimization very difficult. dos Santos *et al.* [27] present an example of such a method for damage in a composite structure.

5.2 Sensitivity methods

Sensitivity-based methods allow a wide choice of physically meaningful parameters, and these advantages have led to their widespread use in model updating. The approach is very general and relies on minimizing a penalty function, which usually consists of the error between the measured quantities and the corresponding predictions from the model. Parameters are then chosen that are assumed uncertain, and these are usually estimated by approximating the penalty function using a truncated Taylor series and iterating to obtain a converged solution. If there are sufficient measurements and a restricted set of parameters, then the identification may be well conditioned. Often, some form of regularization must be applied. This is considered in detail later. Other optimization methods may be used such as quadratic programming and simulated annealing or genetic algorithms, but these are not considered further in this article. Problems also arise if an incorrect or incomplete set of parameters is chosen or, even worse, if the structure of the model is wrong.

The modal residual in equation (31) is a nonlinear function of the parameters and the minimization is solved using a truncated linear Taylor series and iteration. Thus, the Taylor series is

$$\{z_m\} = \{z_j\} + [S_j]\{\delta\theta_j\} + \text{higher-order terms} \qquad (33)$$

where

$$\{z_j\} = \{z(\{\theta_j\})\}, \quad [S_j] = [S(\{\theta_j\})],$$
$$\{\delta\theta_j\} = \{\theta_m\} - \{\theta_j\} \qquad (34)$$

The matrix $[S_j]$ consists of the first derivatives of the modal quantities with respect to the model parameters; index j denotes the jth iteration and $\{\theta_m\}$ is the parameter vector that gives the measured outputs. Standard methods exist to calculate the modal derivatives required [26, 28]. By neglecting higher-order terms in equation (33), an iterative scheme may be derived using the linear approximation

$$\{\delta z_j\} = [S_j]\{\delta\theta_j\} \qquad (35)$$

where $\{\delta z_j\} = \{z_m\} - \{z_j\}$ and $\{\delta\theta_j\} = \{\theta_{j+1}\} - \{\theta_j\}$. Often, for damage location studies, only the residual

and sensitivity matrix for the initial model are used. Avoiding iteration reduces the computation required, particularly where multiple parameter sets have to be estimated. However, particularly if the damage is severe, there is a risk that the wrong location is identified.

As indicated above, one of the problems with sensitivity methods is the need for a parametric model of the damage. Mottershead *et al.* [29] proposed an approach where the system was constrained so that unknown stiffnesses are replaced with rigid connections. The constraint is not imposed physically, but the behavior is inferred from the unconstrained measurements. The best fit between the measured and predicted data is obtained when the damage is located in the substructure that is made rigid.

5.3 Model parameters

One of the key aspects of a model-based identification method is the parameterization of the candidate damage. Since inverse approaches rely on a model of the damage, the success of the estimation is dependent on the quality of the model used. The type of model used depends on the type of structure and the damage mechanism, which leads to an increase either in local or the distributed flexibility. The damage model may be simple or complex. For example, a cracked beam may be modeled as a reduction in stiffness in a large FE or substructure, or alternatively using a very detailed model from fracture mechanics. Whether such a detailed model is justified often depends on the requirements of the estimation procedure and the quality of the measured data. Using a measured modal model consisting of the lower natural frequencies and associated modeshapes means that only a coarse model of the damage may be identified. The simple example used for illustration uses element stiffnesses as the parameters and is the simplest form of an equivalent model for the damage.

5.3.1 Crack models

The modeling of cracks in beam structures and rotating shafts has been a significant topic for research. The models fall into three main categories: local stiffness reduction, discrete spring models, and complex models in two or three dimensions. Dimarogonas [30] and Ostachowicz and Krawczuk [31] gave comprehensive surveys of crack modeling approaches. The simplest methods for FE models reduce the stiffness locally, for example, by reducing a complete element stiffness to simulate a small crack in that element [32]. This approach suffers from problems in matching damage severity to crack depth, and is affected by the mesh density. An improved method introduces local flexibility based on physically based stiffness reductions, where the crack position may be used as a parameter for identification purposes. The second class of methods divides a beam-type structure into two parts that are pinned at the crack location and the crack is simulated by the addition of a rotational spring. These approaches are a gross simplification of the crack dynamics and do not involve the crack size and location directly. The alternative, using beam theory, is to model the dynamics close to the crack more accurately, for example, by producing a closed-form solution giving the natural frequencies and modeshapes of cracked beam directly or using differential equations with compatible boundary conditions satisfying the crack conditions [33–35]. Friswell and Penny [36] compared several of the simple crack models that may be used for health monitoring for both the linear and nonlinear response. Alternatively, two- or three-dimensional FE meshes for beam-type structures with a crack may be used. Meshless approaches may also be used, but are more suited to crack propagation studies. No element connectivity is required and so the task of remeshing as the crack grows is avoided, and a growing crack is modeled by extending the free surfaces corresponding to the crack [37]. However, the computational cost of these meshless methods generally exceeds that of conventional finite element analysis (FEA). Rao and Rahman [38] avoided this difficulty by coupling a meshless region near the crack with an FEA model in the remainder of the structure. The two- and three-dimensional approaches produce detailed and accurate models but are a complicated and computational intensive approaches to model simple structures like beams, and are unlikely to lead to practical algorithms for damage identification.

Although the geometry of a crack can be very complicated, for low frequency vibration only an effective reduction in stiffness is required. Thus, for comparison, a simple model of an open crack, which

is essentially a saw cut, is used. This allows the comparison of models using beam elements with those using plate elements. Only a selection of beam models are used, which illustrates the fact that many beam models are able to model the effect of the crack at low frequencies. In the first approach, the stiffness of a single element is reduced, which requires a fine mesh, and also the derivation of the effect of a crack on the element stiffness. In the second approach, the beam is separated into two halves at the crack location. The beam sections are then pinned together and a rotational spring is used to model the increased flexibility due to the crack. Translational springs may also be used in place of the pinned constraint. The major difficulties with this approach are that an FE node must be placed at the crack location, requiring remeshing for health monitoring applications, and the relationship between the spring stiffness and crack depth needs to be derived. The third method is the model of Sinha *et al.* [34], which is based on the work of Christides and Barr [33]. The fourth model is based on fracture mechanics [35]. In the final model, the open crack is modeled using plate elements, and elements are removed where the crack is located.

Table 4. Natural frequencies (Hz) for the undamaged beam

Number DOF		Beam 40	Plate 13 233
Modes	1	20.709	20.707
	2	129.78	129.39
	3	363.40	360.62
	4	712.16	701.96
	5	1177.4	1150.6

The approaches to crack modeling are compared using a simple example of a steel cantilever beam 1 m long, with cross section $25 \times 50\,\text{mm}^2$. Bending in the more flexible plane is considered. The crack is assumed to be located at a distance of 200 mm from the fixed end, and has a constant depth of 10 mm across the beam width. The beam is modeled using 20 Euler–Bernoulli beam elements, and gives the natural frequencies shown in Table 4. For the plate elements, the length is split into 401 elements and the depth into 10 elements. Thus, the elements are approximately $2.5\,\text{mm}^2$. A large number of elements is required because an element with linear shape functions is used. Table 4 shows the estimated natural frequencies using the Quad4 element in the structural dynamics toolbox [39]. The damaged beam was modeled using the approaches discussed earlier, and the results are shown in Table 5. All the beam models contain 20 elements, and the nodes are arranged such that the crack occurs in the middle of an element. Of course, in the case of the discrete rotational spring, a node is placed at the crack location. The reduction in the element stiffness is adjusted so that the percentage change in the first natural frequency is the same as that for the plate model. The other beam models are adjusted in a similar way. In the plate model, the crack is simulated by removing four elements and thus represents a saw cut 10 mm deep. The row of elements below the crack is also made thinner, so that the crack has negligible width. The differences in the lower natural frequencies are very similar for all models, and these differences are smaller than the changes that would occur due to small modeling errors, or changes due to environmental effects. Of course, the accuracy at higher frequencies becomes less since the modes are influenced more by local stiffness variations.

Table 5. The percentage changes in the natural frequencies for the damaged beam

		Beam				Plate
		Element stiffness reduction	Discrete spring	Sinha *et al.* [34]	Lee and Chung [35]	
Modes	1	4.18	4.18	4.18	4.18	4.18
	2	0.07	0.04	0.08	0.04	0.04
	3	1.24	1.23	1.24	1.20	1.22
	4	2.99	3.08	2.98	2.99	3.07
	5	2.37	2.45	2.37	2.34	2.69

5.3.2 Composite structures

Composite structures have an excellent performance, although this deteriorates significantly with damage. Unfortunately, damage, due to impact events for example, is difficult to detect visually, and hence some method of nondestructive testing of these structures is required. Zou *et al.* [40] reviewed the vibration-based methods that are available to monitor composite structures. Since this article considers inverse methods for damage estimation, this section only considers the parameterization of the damage in composite structures, and, in particular, the modeling of delaminations. Although composite structures have other modes of failure, such as matrix cracking, fiber breakage, or fiber-matrix debonding [31], these damage mechanisms produce similar changes in the vibration response to that obtained for damage in metallic structures. However, delamination is a serious problem in composite structures, and has no parallel to damage mechanisms in other materials. Once the damage is parameterized, then inverse methods, such as sensitivity analysis, may be applied.

Zou *et al.* [40] reviewed methods to model delaminations. Here the focus is on simple models. For example, if a structure is modeled with beam or plate elements, then only beam or plate elements should be used to model the structure with delaminations. Delamination occurs when adjacent plies in a laminated composite debond. For beam structures, the simplest case of a through-width delamination, parallel to the beam surface, was modeled using four beam segments [41, 42]. Separate beam elements were used above and below the delamination, and the constraints to join these elements to those of the undamaged parts of the beam needed to be applied carefully. Zou *et al.* [40] detailed further development of these models. One difficulty with using these models for parameter-based identification is that changing the length and position of a delamination requires the model to be remeshed, and care must be exercised in calculating the associated sensitivity matrices. The techniques detailed by Sinha *et al.* [34] for the position of cracks might be extended to this case. Paolozzi and Peroni [43] highlighted that the most sensitive modes are those whose wavelength is approximately the same size as the delamination. Luo and Hanagud [44] used a sensitivity-based method to detect delaminations, and they also discovered that some modes split to give two closely spaced natural frequencies.

5.3.3 Joint models and generic elements

One major difficulty in parametric approaches is that a model is required that accurately reflects the effect of damage on the mass and stiffness matrices. To some extent, using low-frequency vibration measurements is of help because any local stiffness reduction will have a very similar effect on the dynamic response. Thus, it is possible to use equivalent parameters, such as element stiffnesses, to model the damage. Generic elements [45, 46] take this approach further by allowing changes to the eigenvalues and eigenvectors of the stiffness matrices of structural elements or substructures. These changes are usually constrained so that properties such as the rigid body modes and the geometric symmetry are retained.

Generic elements introduce flexibility into the joint in a controlled way. Other equivalent models, such as discrete rotational springs, offset parameters, or changing element properties may also be used, although generic parameters do have advantages [46]. In particular, all models prejudge how the damage will affect the full model of the structure, whereas the generic element approach automatically finds the likely low-frequency motion of the joint. Consider a two-dimensional T-joint constructed from three beam elements. Each node has three degrees of freedom and, since the substructure has four nodes, the substructure stiffness matrix has three rigid body eigenvectors and nine flexible eigenvectors [47]. The lower eigenvectors have much simpler deformation shapes that are more likely to represent the motion the substructure would undergo in many of the global modes of the structure. Thus, reducing the eigenvalues corresponding to these eigenvectors makes the joint substructure more flexible in the frequency range of the global dynamics, and may be used to model damage. Higher frequency eigenvectors of the substructure may also be included if the motion of the joint is more complex; however, the lower eigenvectors of the joint are likely to adequately characterize the low-frequency dynamics of the structure.

Generic elements have been developed for use in model updating and may be considered as equivalent models of elements or substructures [45]. Law *et al.* [48] applied generic elements to the FE model

updating of the Tsing Ma bridge in Hong Kong. Wang *et al.* [49] used generic elements in damage detection, dealing with the simulated problem of damage detection in a frame structure with flexible L-shaped and T-shaped structural joints. Titurus *et al.* [47, 50] used generic elements and subset selection for model updating and damage location of an experimental frame structure.

5.3.4 Distributed damage

Teughels *et al.* [51] presented a sensitivity-based FE updating method for damage assessment that minimized differences between the experimental and predicted modal data. The parameterization of the damage (both localization and quantification) was represented by a reduction factor of the element bending stiffness. The number of unknown variables was reduced to obtain a physically meaningful result by using a set of damage functions to determine the spatial bending stiffness distribution. The updating parameters were then the multiplication factors of the damage functions. The procedure was illustrated on a reinforced concrete beam and on a highway bridge [52].

5.4 Optimization procedures and ill-conditioning

When the parameters of a model are unknown, they must be estimated using measured data. Usually, the measured response is a nonlinear function of the parameters. In these cases, minimizing the error between the measured and the predicted response produces a nonlinear optimization problem, with the usual questions about convergence and local minima. The most common approach is to linearize the residuals, obtain a least squares solution, and iterate. If the identification problem is well posed, then this simple approach is adequate. The usual response to problems encountered in the optimization is to try more advanced algorithms, but often the issue is that the estimation problem has not been posed correctly, and including some physical insight into the problem provides a much better solution.

Probably the most important difficulty in parameter estimation is ill-conditioning. In the worst case, this can mean that there is no unique solution to the estimation problem, and many sets of parameters are able to fit the data. Many optimization procedures result in the solution of linear equations for the unknown parameters. The use of the singular value decomposition (SVD) [53] for these linear equations enables ill-conditioning to be identified and quantified. The options are then to increase the available data, which is often difficult and costly, or to provide extra conditions on the parameters. These can take the form of smoothness conditions (for example, the truncated SVD), minimum norm parameter values (Tikhonov regularization), or minimum changes from the initial estimates of the parameters [54, 55].

However, there are significant differences in the application of these methods in model updating and damage location, which necessitates different methods of regularization. In both cases, the number of potential parameters is very large and the estimation process is likely to be ill-conditioned unless the physical understanding can be used to introduce extra information. In model updating, the number of parameters may be reduced by only including those parameters that are likely to be in error. Thus, if a frame structure is updated, the beams are likely to be modeled accurately but the joints are more difficult to model. It would therefore be sensible to concentrate the uncertain parameters to those associated with the joints. Even so, a large number of potential parameters may be generated, the measurements may still be reproduced, and the parameters are unlikely to be identified uniquely. In this situation, all the parameters are changed, and regularization must be applied to generate a unique solution [46]. Regularization generally applies extra constraints to the parameter estimation problem to ensure a unique solution. Applying the standard Moore–Penrose pseudoinverse is a type of regularization where the parameter vector with the minimum norm is chosen. The parameter changes may be weighted separately to give a weighted least squares problem, where the penalty function is a weighted sum of squares of the measurement errors and the parameter changes. Such weighting may also be extended to include minimizing the difference between equivalent parameters that are nominally equal in different substructures such as joints. Although using parametric models can reduce the number of parameters considerably, for damage location there will still be a large number of parameters. Most regularization techniques rely on minimum-norm-type solutions that tend to spread the

identified damage over a large number of parameters. Using subset selection, where only the optimum subset of the parameters are used for the estimation [56], has been used for model updating and also for damage location.

Black box methods are often not considered as model-based approaches. However, any simulation of an input–output relationship must make some assumptions about the underlying process, and hence essentially has an underlying model. For example, a neural network is essentially a very sophisticated curve-fitting algorithm, and ill-conditioning is a major problem, evidenced by overfitting and a lack of generalization. The advantage of neural networks is that the class of input–output relationships that may be fitted is huge. However, better results are always obtained if physical insight is used to guide the modeling and estimation process. Indeed, there is often a need to reduce the number of input nodes to present to a neural network, and understanding is vital to obtain the correct feature extraction and data reduction. Another use of physical models is the generation of training or test data for these identification schemes. Typically, experimental data for a sufficient range of events is difficult or expensive to obtain. Since running a model many times is relatively easy and cheap, these simulations may be used to increase the quantity of the test data. However, it is vital that this simulated data correctly reproduces the important features of the real structure, and hence requires a validated and, if necessary, updated model.

Neural networks and genetic algorithms have been viewed as potential saviors for the solution of the difficult problems in damage location. Although these methods may be useful in some circumstances, they do not deal with the root cause of the problem. Genetic algorithms have some advantage in finding a global minimum in very difficult optimization problems, particularly where there are many local minima as is often the case in damage location. That said, the method still requires that the dynamics of the structure changes sufficiently and predictably enough for the optimization to be meaningful. The crucial decision and difficulty is often regarding what to optimize, not the optimization method used. Neural networks are able to treat damage mechanisms implicitly, so that it is not necessary to model the structure in so much detail. The method can also deal with nonlinear damage mechanisms easily. Models are still required to provide the training cases for the networks, and this is a major problem. There are always systematic errors between the model used for training and the actual structure. For success, neural networks require that the essential features in the damaged structure are represented in the training data.

5.4.1 Regularization with side constraints

Model updating often leads to an ill-conditioned parameter estimation problem, and an effective form of regularization is to place constraints on the parameters. This could be that the deviation between the parameters of the updated and the initial model are minimized, or differences between parameters could be minimized. For example, in a frame structure, a number of "T" joints may exist that are nominally identical. Owing to manufacturing tolerances, the parameters of these joints are slightly different, although these differences are small. Therefore, a side constraint is placed on the parameters, so that both the residual and the differences between nominally identical parameters are minimized. Thus, if equation (31) generates the residual, the parameter that minimizes the quadratic cost function is sought,

$$J(\{\theta\}) = \left\|\{z_m\} - \{z(\{\theta\})\}\right\|^2 + \lambda^2 \left\|[C]\{\theta\} - \{d\}\right\|^2 \tag{36}$$

for some matrix $[C]$, vector $\{d\}$, and regularization parameter λ. The regularization parameter is chosen to give a suitable balance between the residual and the side constraint. An example of the choice of $[C]$ is when there are only two parameters, which are nominally equal, then

$$[C] = [1 \ \ -1] \tag{37}$$

Equation (36) is usually linearized using the sensitivity matrix to give the regularized penalty function corresponding to equation (35). The resulting set of linear equations is often well conditioned. Indeed, the constraints should be chosen to satisfy Morozov's complementation condition,

$$\text{Rank}\begin{bmatrix}[S_j] \\ [C]\end{bmatrix} = p \tag{38}$$

where p is the number of unknown parameters, which ensures that the coefficient matrix is full rank.

5.4.2 Regularization using subset selection

One solution to the problem of ill-conditioning is to select only a subset of the parameters for updating [56]. The parameters that are chosen are those to which the response data is sensitive, but the parameters must also be able to correct the errors in the model. Parameter subset selection is a technique that selects the best subset of parameters from a candidate set, utilizing some application-dependent cost function that provides a measure of goodness of each subset. Often, these techniques only obtain a suboptimal estimate of the best subsets in some sense due to the excessive computational burden posed by the original problem. These techniques are firmly rooted in statistics and related fields [57], although recently applications in structural mechanics have appeared. Friswell *et al.* [56] gave an overview of subset selection and also proposed the use of this technique for damage detection. They suggested an approach based on forward parameter subset selection, which is especially suited to local damage, and applied the method to a simulated cantilever beam example with physical parameters corresponding to either element or node properties. Different selection and iteration strategies were evaluated, and the case where multiple measurement sets are available was handled by computing the principal angles between two vector subspaces. Fritzen *al.* [58] used a orthogonalization scheme for subset selection.

In damage location, statistical methods and performance measures have been used that work on a similar principle [5, 59, 60]. Only a limited number of sites are assumed to be damaged, and the model is updated based on the reduced number of parameters. This process is repeated for all possible combinations of damage sites, and possibly even damage mechanisms. The results from all the updated models are compared and the one that best matches the measured data is chosen.

The major problem with both subset selection and the statistical type approach is that many smaller model-updating exercises have to be performed. To optimally derive the best set of parameters, or the best damage location, requires the evaluation of many subsets of parameters. With a large number of parameters evaluating all subsets of even two or three parameters can become daunting. Thus, suboptimal methods must be used to derive good, but not necessarily the best, subsets of the parameters. In the forward approach, parameters are chosen one at a time, and the parameters selected previously are retained. However, there is no guarantee that the optimal subset will be found. The number of candidate damage locations may be controlled on the basis of the expected reduction in the residual [57]. The addition of a parameter to a previously selected subset inevitably reduces the residual terms, and thus there is a trade-off between the number of parameters selected and the magnitude of the residual. Often, only a single damage location is required, in which case the optimal parameter may be determined. Often, a reasonable number of parameter subsets (say between 3 and 20) are selected for a more detailed study [57]. Friswell *et al.* [56] reviewed the relationship between subset selection and matrix decomposition, and also expanded the methods to parameter groups using subspace angles.

The process of subset selection is now described. It should be highlighted that the standard approach to subset selection is not iterative, but only uses the sensitivity equation (35) evaluated at the initial parameter values. For ease of notation this equation is written as

$$[A]\{x\} = \{b\} \tag{39}$$

It would be possible to update each candidate parameter set until convergence, and then compare the performance of the different subsets, although, in practice, the computational cost is prohibitive. As the model parameters are usually local in nature and may also allow for different damage mechanisms, parameter subset selection selects parameters from $\{x\}$ that identify both the damage location and mechanism. This formulation requires the selection of the optimum parameter subset from $\{x\}$. The most straightforward approach is to use an exhaustive search where all $(2^p - 1)$ possible cases have to be searched. The number of cases renders this approach computationally intensive and thus impractical in many real situations. Consequently, suboptimal schemes have to be used. An additional problem is that the addition of a parameter to a previously

selected subset inevitably reduces the residual generated by equation (39). Thus, there is a trade-off between the number of parameters selected and the magnitude of the residual.

Equation (39) may be written as

$$[A]\{x\} = [\{a_1\}, \{a_2\}, \ldots, \{a_p\}]\{x\} = \{b\} \quad (40)$$

The case of a single damage location leads to a simplified version of the above philosophy. When only one parameter is selected, the optimum parameter is that which best fits the changes due to damage characterized by the vector $\{b\}$ in equation (40). Thus, the goal is to find the column $\{a_j\}$ of matrix $[A]$ that minimizes

$$J = \left\| \{b\} - \{a_j\}\hat{x}_j \right\|^2 \quad (41)$$

where $\hat{x}_j$ is the least squares estimate of the jth parameter in $\{x\}$. Friswell *et al.* [56] showed that minimizing equation (41) is equivalent to finding the column of $[A]$ that minimizes the angle with $\{b\}$. Hence, the best parameter is the jth and is found by

$$\min\left(\left\{\psi_1, \psi_2, \ldots, \psi_p\right\}\right) \Longrightarrow \hat{x}_j, \{a_j\} \quad (42)$$

where

$$\cos^2 \psi_i = \frac{\left(\{a_i\}^{\mathrm{T}}\{b\}\right)^2}{\left(\{a_i\}^{\mathrm{T}}\{a_i\}\right)\left(\{b\}^{\top}\{b\}\right)}, \quad i = 1, 2, \ldots, p \quad (43)$$

and ψ_i is the angle between vectors $\{a_i\}$ and $\{b\}$. This step is part of a general technique used in damage detection [56] and is called *forward parameter subset selection*. This is a suboptimal technique of subset selection, starting with the above step and continuing by additional parameter searches where the already selected parameters are retained. For subsequent steps, a new modified problem is created, respecting the previous parameter selections. Suppose the single parameter with index j_1 has been chosen, then the parameter estimate $\hat{x}_{j_1}$ and residual $\{\varepsilon\}$ are

$$\hat{x}_{j_1} = \frac{\{a_{j_1}\}^{\mathrm{T}}\{b\}}{\{a_{j_1}\}^{\mathrm{T}}\{a_{j_1}\}} \Longrightarrow \{\varepsilon\} = \{b\} - \hat{x}_{j_1}\{a_{j_1}\} \quad (44)$$

Note that $\{\varepsilon\}$ is orthogonal to $\{a_{j_1}\}$. A new parameter is then sought by considering the subspace defined by columns of $[A]$, but orthogonal to $\{a_{j_1}\}$. The modified problem is defined as [56]

$$\{a_j\} \rightarrow \{a_j\} - \alpha_j\{a_{j_1}\}, \qquad \{b\} \rightarrow \{b\} - \hat{x}_{j_1}\{a_{j_1}\} \quad (45)$$

where

$$\alpha_j = \frac{\left(\{a_{j_1}\}^{\mathrm{T}}\{a_j\}\right)}{\left(\{a_{j_1}\}^{\mathrm{T}}\{a_{j_1}\}\right)} \quad (46)$$

A second parameter may now be selected by means of the modified problem defined by equation (45), where $j \neq j_1$. Further parameters may be selected in the same way. An algorithm is thus created to search for the best parameter subset, denoted by $[\hat{x}_{j_1}, \hat{x}_{j_2}, \ldots, \hat{x}_{j_r}]$, that minimizes the cost function,

$$J_r = \left\| \{b\} - \sum_{i=1}^{r} \hat{x}_{j_i}\{a_{j_i}\} \right\|^2 \quad (47)$$

This cost function is also employed in Efroymson's algorithm for forward subset selection that focuses on adding or removing parameter selections from chosen subsets. Thus, the number of candidate damage locations may be controlled on the basis of the expected reduction in the residual [56, 57]. Since only single damage location cases are examined in detail here, this subject is not considered further.

5.5 A simple cantilever beam example

A simulated cantilever beam example is used to demonstrate some of the problems. Although the example is somewhat artificial, it highlights how easily methods fail even on very simple structures. Any practical method would have to be robust and should therefore succeed on simple structures, even though some systematic errors are included. This example also demonstrates the use of simulation in damage identification. Not all of the methods are tried and this example is not supposed to represent an extensive scientific evaluation of the methods. It is used here for the purpose of illustration.

The beam has a cross section of $25 \times 50\,\mathrm{mm}^2$, a length of 1m, and is assumed to be rigidly clamped at one end. Only motion in the plane of the thinner

beam dimension is considered. The beam has a Young's modulus of $210\,\mathrm{GN\,m^{-2}}$ and a mass density of $7800\,\mathrm{kg\,m^{-3}}$.

The first test of any method is its application to a simulated example with no noise or systematic errors. Any parameter changes in the model should be identified exactly. The simulated *measurements* are assumed to be the relative changes in the lower natural frequencies of the beam and are taken from a model with 20 elements. The undamaged natural frequencies are taken from the uniform beam, while the damaged frequencies are derived from a model where the stiffness of element 4 has been reduced by 30%. Table 6 gives the damaged and undamaged natural frequencies, showing that the 30% damage only results in a 2.4% change in natural frequency at most. These small frequency changes are typical in damage location and are one of the major difficulties in the identification of the location of damage. Measurement noise, environmental factors, and structure nonstationarity can easily lead to incorrect conclusions on damage location.

The standard sensitivity approach based on modal data is now used to identify the damage. The set of candidate parameters is chosen to be relatively large and consists of the stiffness of each of the 20 elements. If the relative changes to the first eight natural frequencies are used as the measurements, then the identification of the parameters is underdetermined. In this case, some form of regularization must be employed. Figure 24 shows the change in element stiffness required to reproduce the damaged natural frequencies, using a minimum norm constraint on the parameter changes. Although the largest stiffness change occurs at element 4, the identified damage is spread over the whole beam, and there are some significant increases in stiffness. Note that this is the ideal case with no measurement noise or modeling errors. Suppose, by some means, the damage is known to be somewhere in the eight elements closest to the fixed end. The number of parameters is now reduced to eight, the same as the number of natural frequencies. There is now a unique solution to the estimation problem, and this solution is given in Figure 25. Note that the stiffness of elements 9–20 cannot change, but are included in Figure 25 for easy comparison. The damage has clearly been correctly located to element 4. However, the magnitude of the damage is incorrect because the estimation is based on the sensitivity matrix, which is a linear approximation to the residual. The other seven parameters are nonzero for the same reason.

This simple cantilever beam is now used to demonstrate some of the properties of the subset selection

Table 6. Natural frequencies of the simulated undamaged and damaged beam

Mode number	Undamaged (Hz)	Damaged (Hz)	Difference (%)
1	20.96	20.45	2.39
2	131.3	131.1	0.15
3	367.7	366.6	0.31
4	720.6	711.3	1.29
5	1191	1172	1.61
6	1780	1762	1.02
7	2487	2479	0.32
8	3313	3303	0.30

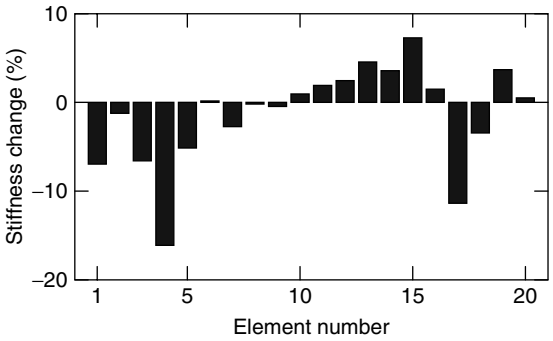

Figure 24. The change in element stiffness estimated for the cantilever beam example with no noise and a minimum norm constraint.

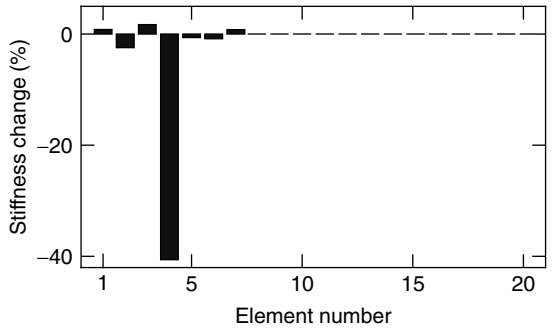

Figure 25. The change in element stiffness estimated for the cantilever beam example with no noise, but only eight nonzero parameters.

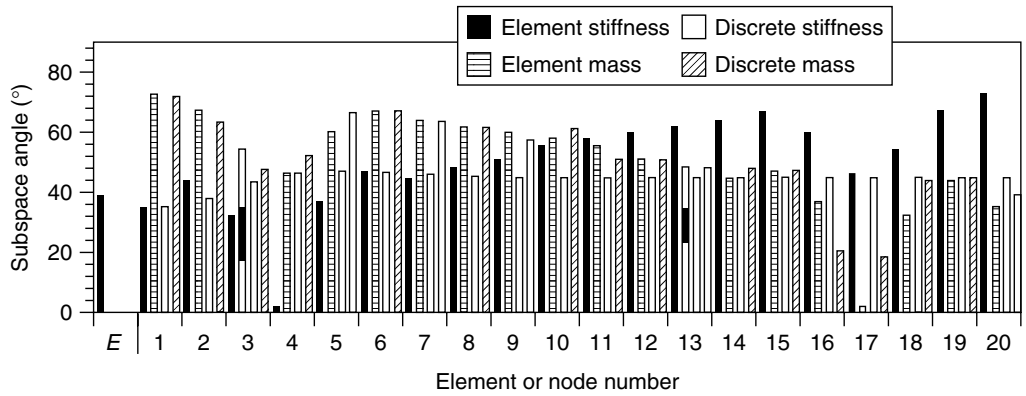

Figure 26. Subspace angles for a 30% change in the stiffness of element 4.

methods. Candidate parameters include element mass, and discrete mass and springs, as well as the element stiffness. Figure 26 shows the angles between the columns of the sensitivity matrix of the initial FE model and the vector of the relative changes in the first eight natural frequencies due to the damage. Clearly, the column relating to the stiffness of element 4 has a small angle, although it is not zero because the method is based on a first-order approximation and the extent of the damage (30%) is large. Changing the mass of element 17 also enables the modeling of the *measured* changes accurately. This is a problem that relates to the symmetry of the beam, and the fact than no spatial information is incorporated into the measurements. Modeshapes could also be incorporated into the measurement vector, although the accuracy with which they could be measured may be insufficient to show a change in modeshape due to damage. This is an example of the more general problem, where damage or changes in parameters at more than one location cause the same changes in the lower natural frequencies.

Subset selection is next demonstrated in an example where damage is introduced at two locations. A 0.1 kg mass is added to node 12, in addition to the 30% stiffness change to element 4. This example does not include any measurement noise or modeling errors. Table 7 shows the results when the best subsets of 1, 2, and 3 parameters are chosen. The parameters are specified by type and element or node number. Thus, $(\rho A)_{17}$ is the mass/unit length of element 17, $(\mathrm{EI})_4$ is the stiffness of element 4, k_1 is a discrete spring at node 1, and m_{12} is a discrete mass at node 12. At each stage, the two best parameters are chosen. The residuals under the first two parameters relate to the values when a subset of size 1 or 2 is selected. Also shown are the residuals after convergence based on optimizing the values of the chosen parameters. From the values of the residuals, it is clear that the two correct parameters should be selected. A number of

Table 7. The selection of three parameters for the beam example

Parameter 1			Parameter 2			Parameter 3		
	Residual	Converged		Residual	Converged		Residual	Converged
$(\rho A)_{17}$	154.6	160.4	m_{12}	1.49	0.782	m_8	1.21	0.701
						$(\rho A)_{12}$	1.48	0.286
			m_8	8.70	4.76	m_{12}	1.21	0.701
						$(\rho A)_{12}$	8.68	4.75
$(\mathrm{EI})_4$	154.7	160.5	m_{12}	1.49	0.000	m_8	1.20	0.000
						$(\rho A)_{12}$	1.48	0.000
			m_8	8.70	5.40	m_{12}	1.20	0.000
						$(\rho A)_{12}$	8.69	5.35

other parameter subsets have small residuals and the addition of random noise would make the selection of the best subset more difficult.

6 POTENTIAL PROBLEMS IN DAMAGE IDENTIFICATION USING VIBRATION DATA

The discussion thus far has indicated some of the problems with damage identification. There are always errors in the measured data and the numerical model that affect all of the algorithms. These errors, and the adequacy of the data, are now discussed. Damage identification algorithms should always be tested on realistic experimental examples, as many methods that work well on simulated data often fail due to the problems highlighted in this section. As a first step, methods may be tested using simulated data, but even then realistic systematic errors should be incorporated.

6.1 Modeling errors

One of the major problems in damage location is the reliance on the FE model. This model is also important because the incomplete set of measured data requires extra information from the model to enable identification of the damage location. There will undoubtedly be errors even in the model of the undamaged structure. Thus, if the measurements on the damaged structure are used to identify damage locations, the methods will have great difficulty in distinguishing between the actual damage sites and the location of errors in the original model. If suitable parameters are not included to allow for the undamaged model errors, then this will the result in a systematic error between the model and the data. Identification schemes generally have considerable difficulty with systematic errors. It is very likely that the original errors in the model will produce frequency changes that are far greater than those produced by the damage. There are two basic approaches to reducing this problem, although both rely on having measured data from an undamaged structure. The first is to update the FE model of the undamaged structure to produce a reliable model [26]. Obviously, the quality of the damage location assessment is critically dependent upon the updated model being physically meaningful [46, 61]. Generally, this requires model validation using a control set of data not used for the updating. The second alternative uses differences between the damaged and undamaged response data in the damage location algorithm [50, 62]. To first order, any error in the undamaged model of the structure that is also present in the damaged structure will be removed. This relies on the structure remaining unchanged, except for the damage, between the two sets of measurements.

Another potential source of error is the mismatch between the measurement locations and the model degrees of freedom. Such a mismatch makes the direct comparison of FRFs and modeshapes impossible, and the generation of residuals inaccurate. The magnitude of the errors involved depends on the mesh density in the sensor region and the complexity of the modeshapes. The best solution is to ensure that nodes in the model exist at the sensor locations. Alternatively, interpolation techniques may be used.

6.2 Environmental and other nonstationary effects

One very difficult aspect of damage assessment is the change in the measured data due to environmental effects. This is one undesirable nonstationary effect and makes damage location very difficult. Of course, progressive damage is also a nonstationary phenomenon, and damage can be difficult to identify if other nonstationary effects are also present. Typical environmental effects are demonstrated by highway bridges, especially those constructed using concrete, which have been the subject of many studies in damage location. For example, temperature changes can cause the stiffness properties of a bridge to change significantly, and the difficulty is to predict the effects of temperature from readily available measurements. Peeters and de Roeck [63] reported on measurements of the Z24 bridge over a whole year and suggested a *black box* model to predict the temperature variation. Sohn *et al.* [64] considered the effect of temperature on the Alamosa Canyon Bridge. Sohn *et al.* [65] used a combination of time series analysis, neural networks, and statistical inference to determine

the damage state for structures affected by environmental conditions. Mickens *et al.* [66] corrected FRF measurements by assuming that the temperature affected the global stiffness of the structure. On a highway bridge, the changing traffic conditions cause different mass loading effects that can change the natural frequencies by as much as 1% [67]. There are further difficulties with highway bridges because they are highly damped with low natural frequencies. They are in a noisy environment and are difficult to excite. The frequency resolution in the measurements is invariably quite low, leading to considerable difficulties in detecting small frequency changes due to damage.

Typical of environmental effects are those on highway bridges. These bridges have been the subject of many studies in damage location, but, in the United Kingdom, where most bridges are constructed using concrete, such identification has considerable problems with changes due to environmental factors [68]. For example, concrete absorbs considerable moisture during damp weather, which considerably increases the mass of the bridge. Temperature changes the stiffness properties of the road surface, known as the *black-top*, significantly. On a hot summer's day in the United Kingdom, the road surface provides little stiffness, but, on a cold winter's day, the stiffness contribution is considerable. The difficulty is trying to predict the effects of temperature and moisture absorption from readily available measurements.

6.3 The effect of frequency range

The range of frequencies employed in damage location has a great influence on the resolution of the results and also the physical range of application. The great advantage in using low-frequency vibration measurements is that the low-frequency modes are generally global and so the vibration sensors may be mounted remotely from the damage site; equally, fewer sensors may be used. The problem with low-frequency modes is that the spatial wavelengths of the modes are large, and are typically far larger than the extent of the damage. The spatial resolution of the damage identification scheme requires that there is a significant change in response between two adjacent potential damage sites. If low-frequency modes are used, then this resolution is closely related to the spatial wavelengths of the modes. Using high-frequency excitation uses very local modes, which are able to accurately locate damage, but only very close to the sensor and actuator position. Estimating accurate models at these high-frequency ranges is also very difficult, and often changes in the response are used for damage identification. For example, Park *et al.* [69, 70] used changes in measured impedance to identify damage in civil structures and pipeline systems. Schulz *et al.* [71] used high-frequency transmissibility to detect delaminations in composite structures.

Moving to even higher frequencies can also yield good results. Acoustic emission [72] is a transient elastic wave, typically in the region of 50–500 kHz, and is able, for example, to detect the energy released when cracks propagate. One approach to damage assessment is to use physical models to deduce quantitative relationships between measured acoustic emission signals and the damage mechanism that cause them. Significant research has been undertaken to obtain a physical understanding of various source mechanisms [73] and the radiation pattern of bulk shear and longitudinal acoustic waves that they produce [74]. The difficulty in using these models in inverse estimation procedures is the accuracy of these high-frequency models, and the huge computational requirements. In recent years, a pattern-recognition philosophy has dominated, that relies on using large databases of empirical data from which correlations between measured acoustic emission signals and damage mechanisms are inferred. Many advanced signal-processing algorithms have been employed to interpret experimental data. Damage location is often determined using time of flight methods, which require the events to be well separated in time, the wave speed to be approximately equal in all parts of the structure, and the effects of reflection and refraction to be insignificant.

6.4 Damage magnitude

A frequent problem that arises in model- and vibration-based damage detection, whether parametric or nonparametric, is the need for a very accurate mathematical model, so that it correctly captures the actual structural dynamic behavior in some predetermined frequency range. Often, in SHM, the changes

in the measured quantities caused by structural damage are smaller than those observed between the healthy (i.e., undamaged) structure and the mathematical model. Consequently, it becomes almost impossible to discern between inadequate modeling and actual changes due to damage. There are two alternative approaches to this problem. The first is to update the healthy model so that the correlation between the model and the measured data is improved. This approach requires that the errors that remain after updating are smaller in magnitude than the changes due to the damage. Furthermore, the changes to the model should be physically meaningful, so that the updating process corrects actual model errors, and does not merely reproduce the measured data. The second approach is based on the use of (relative) differences between data measured on healthy and potentially damaged structure. In this case, assuming that the only changes in the structure are due to damage, the problem may be reduced to finding those parameters that reproduce the measured changes.

6.5 Nonlinearity

Many forms of damage cause a change in the stiffness nonlinearity that qualitatively and quantitatively affects the dynamic response of a structure. For example, Nichols *et al.* [75, 76] used the features of the chaotic response of a structure to detect changes in a joint. Adams and Nataraju [77] gave a variety of features based on the nonlinear dynamic response. Kerschen *et al.* [78] considered model-based estimation methods and identified the form of nonlinearity that is most likely present in the measured data. Meyer and Link [79] identified a parametric nonlinear model using harmonic balance and a model-updating approach. A breathing crack, which opens and closes, can produce interesting and complicated nonlinear dynamics. Brandon [80] and Kisa and Brandon [81] gave an overview of some of the techniques that may be applied. Many techniques to analyze the resulting nonlinear dynamics are based on approximating the bilinear stiffness when the crack opens and closes. Linear approaches to damage estimation approximates a local reduction in the stiffness matrix of the beam. Since the nonlinearity introduced by a crack is often weak, many of the common testing techniques tend to linearize the response [36]. Sinusoidal forcing tends to emphasize the nonlinearity, thus damage detection methods based on detecting harmonics of the forcing frequency have been proposed [82]. In rotor dynamic applications, these approaches are useful because the forcing is inherently sinusoidal [30]. However, in SHM applications, this approach requires considerable hardware and software to implement, and also requires a lengthy experiment. Johnson *et al.* [83] used a transmissibility approach that was insensitive to boundary condition nonlinearities. Neild *et al.* [84] investigated the potential of a time–frequency analysis procedure to identify damage in concrete beams.

Although using the nonlinear response has a huge potential in health monitoring, model-based inverse approaches have a number of difficulties because of the high number of degrees of freedom required, and therefore the computational burden imposed. In practice, any realistic multiple degree of freedom nonlinear analysis would have to be based on a reduced order model of the structure. Furthermore, many of the difficulties outlined in this section for linear systems are also a problem for nonlinear systems.

6.6 Prognosis

Rytter [4] gave prognosis as the fourth level of damage estimation and Farrar *et al.* [85] gave a summary of the state of the art. The philosophy of damage detection using measured vibration data is based on the premise that the damage will change the stiffness of the structure. In some instances, there is a significant difference between strength and stiffness. Indeed, estimating the remaining useful life of a component based on conclusions from a dynamic analysis is very difficult. For example, a concrete highway bridge has steel reinforcement cables running in channels in the concrete. The cables are tensioned, either before or after the concrete has set, to ensure that the concrete remains in compression. One major failure mechanism is by the corrosion of these cables. Once the cables have failed, the concrete has no strength in tension and therefore the bridge is liable to collapse. Unfortunately, the stiffness of the bridge is mainly due to the concrete, and therefore the progressive corrosion of the cables is very difficult to identify from stiffness changes.

Essentially, the dynamics of the bridge changes very little until it collapses. Even for metallic structures, the estimation of remaining life requires an estimate of the damage present, an assessment of the probable future loads, and an accurate model of how the damage may develop and the structure might fail. Although this process is very difficult, the use of inverse methods to generate a physically meaningful model offers a route to prognosis.

6.7 The role of simulation and physical testing

Many of the algorithms suggested for damage location are tested on simulated data. It is necessary to fully test any method on both simulated and real data. The simulated tests are able to fully exercise the location methods, with the benefit that the answer is known. In simulation, far more damage cases may be used and the effect of errors may be fully investigated. The need for real testing arises because experimental work always produces errors and problems that are unexpected. For simulation to be useful, the errors that might be expected in real structures must be simulated. Thus, adding random noise to a model of the structure and then using the same model to identify the damage is not enough. Most identification schemes are able to cope very well with random noise, and although such simulations are important parts of the overall performance assessment of an algorithm, they are not sufficient. It is vital that systematic-type errors are included in the simulation. Thus, discretization errors may be included by generating the simulated measurements using a fine FE model; the damage mechanism introduced to generate the measurements may be different from those modeled for the identification; or boundary conditions on the structure could be changed between the measured data set and the identification.

7 CONCLUSIONS

Given the nature of the last section, this article does not require a detailed conclusions section. The objective has been to illustrate a number of modal vibration-based approaches to the SHM problem and to discuss the merits and demerits of such approaches. The overall judgment must surely be that vibration-based approaches have their place in the SHM canon, but that they have limitations. Arguably, the main limitation is the resolution or minimum level of detectable damage. If the damage is small compared to the spatial wavelength of the modal vibrations, then there is likely to be a problem. Another remark worth making here is that vibration-based damage identification arguably works best when the damage causes a change in the load path. Therefore, it would likely be good for the failure of a member in a truss, but not so good for a crack in a plate. (The authors would like to thank Dr Chuck Farrar of the Los Alamos National Laboratories in the United States for this observation.) In the situation in which one is effectively below the "diffraction limit" for detection by vibration-based methods, one would always have recourse to higher frequency wave-based approaches as used commonly by the NDT (nondestructive testing) community. For example, Lamb wave inspection has proved a powerful technique in platelike areas of structures. Such approaches are discussed in some detail elsewhere in this encyclopedia.

Chapter 15
Nonlinear Acoustic Methods

Dimitri M. Donskoy
Stevens Institute of Technology, Hoboken, NJ, USA

1 INTRODUCTION

Traditional active acoustic/ultrasonic methods utilize the linear effects of reflection, scattering, transmission, and attenuation of the elastic waves by structural inhomogeneities to identify damage (*see* **Ultrasonic Methods**). Despite the practical utility and success of these methods, there are inherent limitations. One of the major limitations includes difficulties in detecting a small-scale incipient damage of the size comparable to or smaller than the wavelength of the transmitted wave. Another difficulty is distinguishing between the actual damage and structural features of comparable or greater size, such as notches, holes, borders, and other structural features, which produce multiple reflections effectively masking the signals associated with the damage. One possible approach to circumvent these limitations is to explore the nonlinear nature of the material damage by utilizing nonlinear acoustic methods for damage detection.

Numerous experimental and theoretical studies [1–58] demonstrate that damaged or fatigued materials exhibit noticeable nonlinear properties (nonlinear stress–strain relationship) because of micro/meso and macro defects. Strong nonlinearities have been observed for defects having contact interfaces such as cracks, delaminations, and disbonds. This type of contact acoustic nonlinearity is explained by "clapping" and "rubbing" of the interfacial rough surfaces subjected to vibrations [2, 5–10]. The physical nature of the contact nonlinearity can be understood by considering a contact defect (crack) as a planar interface that separates two elastic materials with the surfaces in intimate contact but with no traction forces across the interface [2]. As a longitudinally polarized elastic wave (vibration) is applied to the interface, the surfaces are pressed together during the compression phase of the wave and then separate under the tensile phase (Figure 1a). The elastic deformation of the medium containing such a defect will be different for tension and compression leading to a bilinear (nonlinear) stress–strain relationship, as illustrated in Figure 1(b).

A more realistic model considers a defect's interface as two rough elastic surfaces with Hertzian contact at surface microasperities (Figure 2a). The

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

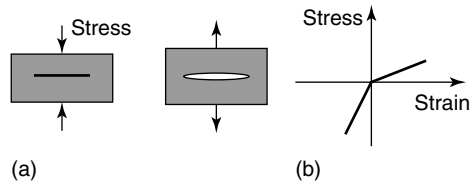

Figure 1. (a) Clapping defect and (b) its stress–strain bilinear dependence.

applied stress varies the asperity contact area leading to nonlinear elastic deformation of the defect (Figure 2b) [10, 11, 50]. Microasperity contacts may exhibit even more complicated nonlinear behavior such as hysteresis (Figure 2c) [12, 13], nonlinear thermal dissipation [14, 15], and nonlinear friction [33].

Another type of material degradation associated with increased nonlinearity is micro- and mesoscopic fatigue damage accumulation. Here the stronger nonlinearity is due to dislocations, hysteresis, formation of slip planes, and microcrack development and clustering [16–24].

It has to be understood, however, that not all types of material or structural flaws are characterized by strong nonlinearity. Large voids and porosity, dents, cuts and scratches, loss of material due to corrosion, breakage of structural components (cable wires, for example), and other flaws may not exhibit appreciable (or any) nonlinearity and, therefore, cannot be detected and characterized with nonlinear acoustic technique (NAT).

There are various acoustic manifestations of material and structural nonlinearities: generation of second- and higher-order harmonics [1–6, 24, 32], dependence of time-of-flight on applied external stress [25, 26], amplitude dependence of the resonance spectrum [27, 28], and the frequency mixing and modulation of high-frequency ultrasound by low-frequency vibration [7, 19–31]. Very intensive acoustic excitation may lead to the generation of subharmonics, intermodulation, and even chaotic behavior of highly nonlinear contact interfaces [33–35].

All of these phenomena have been explored for nondestructive testing and evaluation (NDT&E) of different materials and structures. The resulting nonlinear methods have advantages and disadvantages depending on the particular application. The principal advantage of all these methods is their highly *selective* sensitivity to flaws with nonlinear properties. Another important feature of the nonlinear techniques is their ability to detect flaws in highly nonhomogeneous and complicated geometries/structures, because structural inhomogeneities and features (holes, voids, channels, bonded laminations, boundaries, etc.) are linear and have no or little effect on the nonlinear readouts.

The NATs are not without limitations. One of the primary problems with their practical implementations for NDT&E is the need for a well-established reference. There are structural (nonflaw) sources of contact nonlinearity: structural supports and connections, inserts, etc.; all of these nonlinearities contribute to the nonlinear response. There could also be instrumentation and measurement nonlinearities, which may contribute to the "background" nonlinear readouts as well. Therefore, the background nonlinearity must be determined for a reference structure and particular measurement setup and then compared with the structure undergoing NDT&E. For many applications it is not easy to characterize this background nonlinearity. This drawback is, perhaps, one of the primary reasons that the nonlinear methods most reported till date are still experimental and are not yet established as practical and reliable defect detection and characterization tools.

In contrast to NDT&E, structural health monitoring (SHM) detects (monitors) changes in the materials/structure over time, so the initial measurements could be used as a reference for the very same structure. This approach makes SHM applications

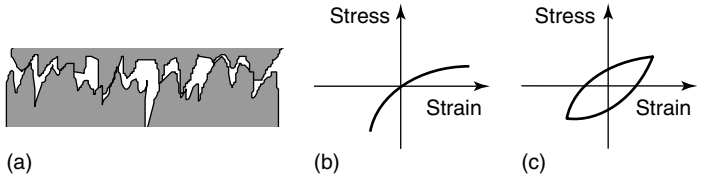

Figure 2. A defect with rough contact surfaces (a) and its stress–strain dependencies: Hertzian (b) and hysteretic (c).

extremely attractive for nonlinear techniques offering high sensitivity to the initiation and development of defects with a built-in nonlinear reference obtained from initial measurements on the healthy structure.

2 NONLINEAR ACOUSTIC METHODS FOR DAMAGE DETECTION

Among the number of different nonlinear methods mentioned above, there are two that are practically viable and most widely used: harmonic distortion and modulation methods. A simplified graphical illustration of these two methods is presented in Figure 3.

These methods rely on the experimental observations that the nonlinear response is proportional to the degree of damage regardless of the particular nonlinear mechanism involved: classical nonlinear elasticity, contact nonlinearity, hysteretic, thermal, frictional, slow dynamics, or any other yet-to-be-discovered nonlinearity.

2.1 Harmonic distortion methods

Historically, one of the first methods to characterize the acoustic nonlinearity is to measure the degree of the nonlinear (harmonic) distortion of a sinusoidal acoustic (vibration) signal. This approach has been widely used for the characterization of nonlinearity in fluids, biological media, electromechanical systems, and material nonlinearity of solids. The essence of the method is illustrated in Figure 3. An input signal is a sinusoidal waveform with frequency f_1 and

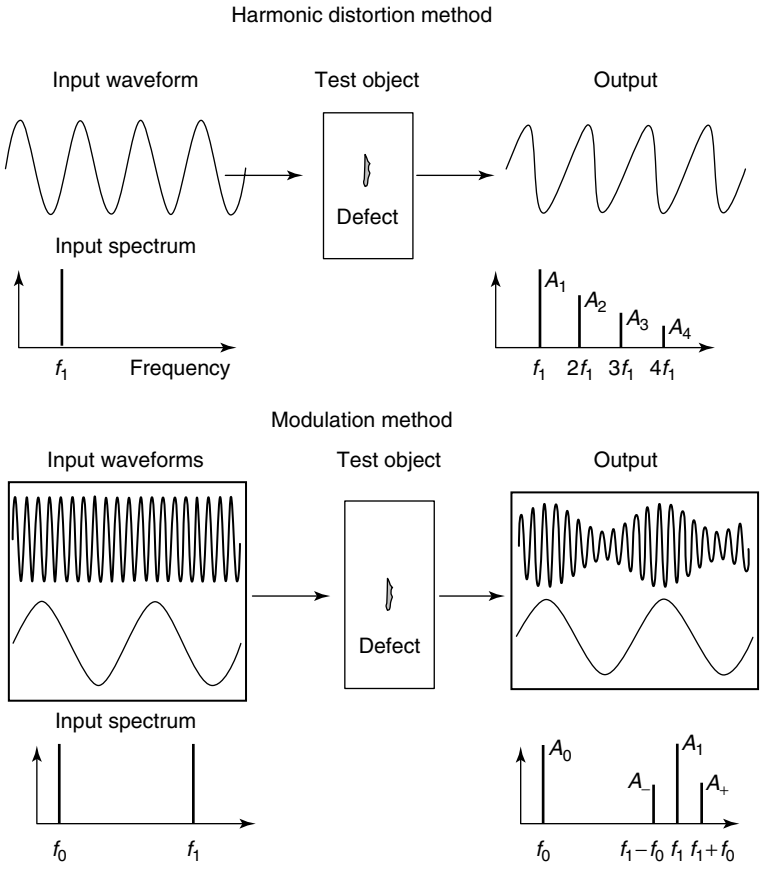

Figure 3. Illustrative diagrams of the harmonic distortion and modulation methods.

amplitude A_1. The nonlinearity distorts the waveform, so its spectrum contains additional harmonics. Typically, these are higher harmonics with frequencies $2f_1, 3f_1, \ldots$ and, respectively, diminishing amplitudes $A_1 > A_2 > A_3 > \cdots$. Because of this decrease in amplitude, most of the studies consider only the second harmonic for characterization of the defect's nonlinearity. The second-harmonic approach has been used for evaluation of fatigue cracks [1–3, 36], adhesive joints [5, 25, 26, 37–42], diffusion-bonded interfaces [43, 44], cracks in concrete [45], dislocations, and other fatigue damage [18, 24, 46–48, 56–58].

Very strong contact nonlinearity coupled with very large acoustic excitation may lead to much more pronounced nonlinear distortion with an appreciable level of higher-order harmonics and intermodulation and subharmonics [32–35]. Some of these high-order distortions could be localized in the vicinity of a defect, so the authors used a scanning laser vibrometer to visualize the location of the defect.

The range of frequencies and type of acoustic/vibration waves vary significantly depending on the specific applications: type of material, size of structure, and type and size of flaws. Thus, the reported frequencies used for the nonlinear detection span from hundreds of hertz to tens of megahertz. Flexural and torsional vibrations, longitudinal, shear, surface, and guided acoustic waves were utilized.

Two examples of investigations utilizing the second-harmonic method are presented here. Both investigations deal with the detection and characterization of disbonds in adhesive joints using very low-frequency vibrations, $f_1 = 190\,\text{Hz}$ [5], and high-frequency ultrasound $f_1 = 1.85\,\text{MHz}$ [37]. In both examples, the nonlinear measurements provided more sensitive evaluations when compared to the linear acoustic techniques.

The first exemplary study investigates the bonding quality of a thermoprotective coating (tiles) of a space shuttle [5]. The coating consists of the relatively rigid tiles attached to the ship's metal skin through an elastic bonding layer. The tiles (ceramic fiber) and the elastic bonding layer are so absorptive for the acoustic (ultrasonic) signals that only very low-frequency vibrations could be used. Then harmonic vibration was applied to the structure (and its level exceeds the static stress at the disbonded interface initiating its clapping), the tile's vibration was noticeably distorted as is evident in the vibration spectrum shown in Figure 4.

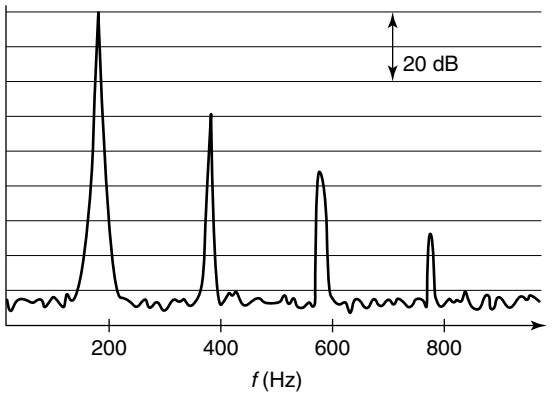

Figure 4. Harmonic distortion of sinusoidal vibration due to disbond.

The stiffness of the elastic layer with the clapping disbond is modeled as a bilinear spring (Figure 1b):

$$K(\varepsilon) = \begin{cases} \kappa S & \text{if } \varepsilon < 0 \\ \kappa\left(S - S_0\right) & \text{if } \varepsilon \geq 0 \end{cases} \tag{1}$$

where κ is the stiffness per unit area of the elastic layer without the defect, S is the full area of the layer, S_0 is the area of a disbond, and ε is the local strain at the elastic layer: negative ε corresponds to compression (full closure of the disbond) and positive ε is for tension (opening of the disbond).

Using a simple spring-mass oscillator model with the nonlinear stiffness (equation 1), the steady-state nonlinear solution (higher harmonics) of the oscillator's equation with nonlinear spring $K(\varepsilon)$ was found [5], using Bogolyubov–Mitropolsky's perturbation method. The results showed that the amplitude of the second harmonic A_2 is proportional to the area S_0 of the disbond:

$$A_2 \sim \frac{S_0}{S} A_1 \tag{2}$$

where A_1 is the amplitude of the fundamental (first) harmonic oscillation of the solid layer. This result is in good agreement with the experiment showing that the ratio of the amplitude of the second harmonic to the first may serve as a quantitative indicator of the defect.

It is interesting to note that the unique feature of the bilinear system is a linear dependence between

the second and the fundamental harmonic amplitudes (equation 2). For systems with a quadratic nonlinearity, the second harmonic is proportional to $A_1{}^2$.

The challenging problem of evaluating kissing bonds in aluminum–aluminum adhesive joints using a second-harmonic measurement is reported in [37]. Kissing bonds are disbonds between two compressively loaded disbonded surfaces creating contact, which is difficult to detect with conventional linear ultrasonic techniques. The result of this study demonstrated a high sensitivity of the nonlinear distortion technique to the disbond at a relatively low contact load. At higher compressive load, the disbond contact nonlinearity was reduced and "overwhelmed by the inherent system nonlinearity" [37] from the equipment and measurement setup.

The latter is a typical example highlighting the challenges in implementing the harmonic measurement approach: system nonlinearities from electronic and electromechanical equipment, such as signal generators, amplifiers, and transducers, generate a certain level of the harmonic distortion in the first place. This background level in the nonlinear signal limits the sensitivity of the method to defects with smaller nonlinearities.

2.2 Modulation methods

The modulation methods utilize the effect of the nonlinear interaction of acoustic/vibration waves in the presence of the nonlinear defects. There are two modifications of the method: vibromodulation (VM) and impact modulation (IM). The VM method utilizes two sinusoidal waves with the frequencies f_0 and f_1. The defect's nonlinearity leads to mixing of these two signals resulting in a new signal with the combination frequencies $f_1 \pm f_0$. Typically, the VM method employs lower frequency modulating and higher frequency probing signals: $f_0 \ll f_1$ [8–10, 28–31, 51]. Applied lower frequency vibration varies the contact area within a defect or damaged area (Figure 2a), effectively modulating the amplitude of the higher frequency probing wave passing through the varying contacts. In the frequency domain, the result of this modulation manifests itself as the sideband spectral components, $f_1 \pm f_0$, as shown in Figures 3 and 5. The defect or damage can be detected and characterized by the amplitude of the sideband components or, better, the modulation index (MI) (in decibel scale):

$$MI = 20\log_{10}\left(\frac{A_- + A_+}{2A_1}\right) = 20\log_{10}\left(\frac{A_- + A_+}{2}\right) - 20\log A_1 \quad (3)$$

In reality, the modulation phenomenon is more complicated because of the complexity of the nonlinear mechanisms at the interface as mentioned in the previous section of this article. Strong defect nonlinearities may lead to the occurrence of numerous sideband components with the frequencies $f_1 \pm mf_0$, where $m = 1, 2, \ldots$ as evident from Figure 5(b) and other experimental observations [8, 9, 15]. In practice, however, only the first sidebands ($m = 1$) are used as a reliable indicator of a damage.

The IM method uses impact-excited low-frequency vibration modes as the modulating signal for the

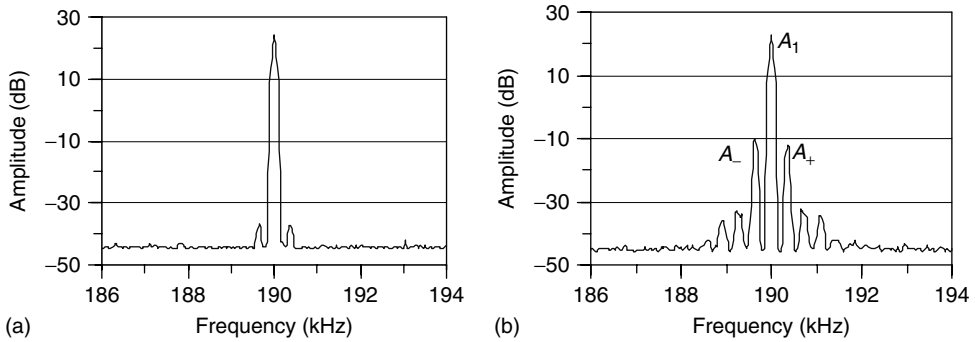

Figure 5. Spectra of a high-frequency ultrasonic signal modulated by a low-frequency vibration: (a) undamaged section of the steel pipe and (b) the same pipe section with stress-corrosion cracks.

high-frequency ultrasound [8–10, 49, 51]. The main advantage of IM over the VM approach is the ease of excitation of the low-frequency signal: a simple hammer can be used instead of an electronically controlled low-frequency vibration/acoustic source. IM works well, however, only for structures with low vibration damping. The impact-excited vibration modes should "ring" long enough, so that the resulting sideband component of the modulated ultrasonic signal can be resolved using Fourier spectrum analysis. At a minimum, the quality factor of the resonating vibration modes should be greater than 4 to resolve the sidebands. Calibration of the impact-excited vibration could also be a problem for comparative testing.

The modulation methods could be implemented using a continuous wave (CW) or a sequence of burst ultrasonic signals [51]. CW implementations of the VM (CW-VM) and IM (CW-IM) methods showed that the choice of the ultrasonic frequency, f_1, may have a significant impact on the MI, often leading to the erroneous interpretation of the test result. As seen from the recorded structural frequency responses of the probing ultrasonic signal and its sidebands (Figure 6), MI could vary as much as 40 dB depending on the choice of the primary frequency, f_1. This variation is due to resonances and antiresonances of the structure. Theoretical analysis [9] and numerous tests with various structures and materials [52] demonstrated that reliable damage detection and characterization could be achieved with frequency averaging as follows:

$$MI = 20\log_{10} \times \left(\frac{1}{N} \sum_{n=1}^{N} \frac{A_+ \left(f_n + f_0\right) + A_- \left(f_n - f_0\right)}{2A_1 \left(f_n\right)} \right) \tag{4}$$

where $f_n = F_{\text{start}} + n \cdot \Delta F$ is the fundamental ultrasonic frequency swept in steps n over the frequency range $F_{\text{start}} + N \cdot \Delta F$, with F_{start} being the starting frequency, ΔF the frequency step, and N the total number of steps. The choice of ΔF is determined by the density of the resonances of the particular structure's frequency response in the chosen frequency range. For proper averaging, ΔF should be less than the frequency separations between the resonances. The number of frequency steps should be at least 30, preferably 100.

In the burst implementation of the vibromodulation method (B-VM), a sufficiently long sequence of bursts with the central frequency f_1 for each burst and the repetition frequency $F_R > 2f_0$ is used instead of a CW ultrasonic signal. The bursts are effectively "sampling" the modulating envelope, as shown in Figure 7. The B-VM method does not require frequency averaging. Another significant

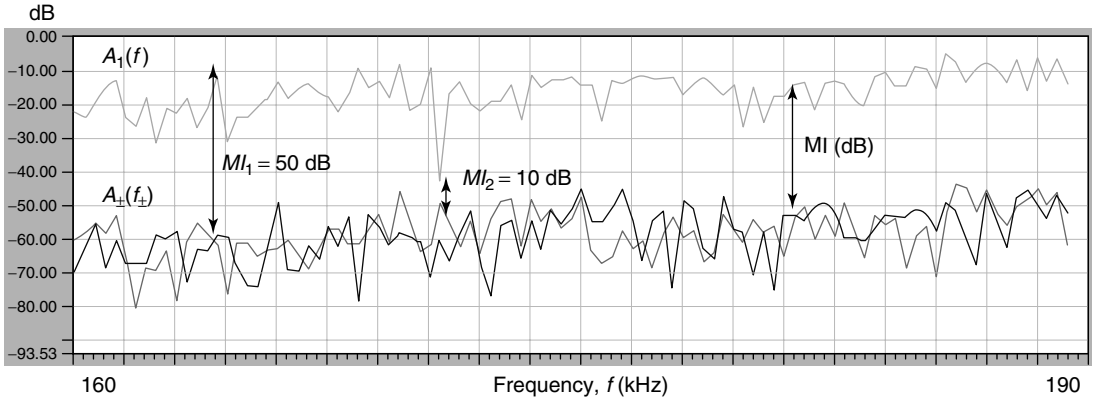

Figure 6. Frequency response ($A_1(f)$ upper curve, in decibels) of 0.5-m-long steel beam for the high-frequency ultrasonic signal f_1 swept the frequency range f: 160–190 kHz. Lower two curves are the corresponding frequency responses of the sidebands $A_\pm(f_\pm)$ (also in decibel scale) at the frequencies $f_\pm = f_1 \pm 250$ Hz recorded as f_1 is swept. MI is the modulation index (in decibels). It is graphically defined as a difference between the linearly averaged value of two lower curves and the upper curve. As can be seen, MI could vary as much 40 dB (MI_1–MI_2) simply due to resonances and antiresonances of the frequency response.

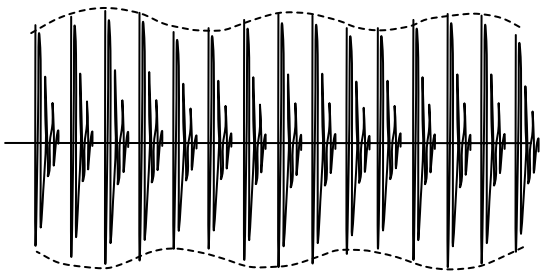

Figure 7. Burst VM method: sequence of ultrasonic bursts modulated by low-frequency vibration.

advantage of the B-VM method is an ability to localize a damage area and, because of localization, reduce the "background" nonlinearity contributed by structural connections and supports. However, the B-VM method may not work at all if there is no sufficient reflection from the damage (kissing bonds, for example) or there are significant reflections (reverberation) from the test object's structural elements, inhomogeneities and boundaries. The B-VM method is more complicated to implement, requiring more elaborate signal collection and processing.

There are numerous examples of damage detection and characterization using modulation methods. Examples of CW-VM and CW-IM methods (using longitudinal ultrasonic waves with frequencies up to 200 kHz) to detect fatigue cracks and characterize their size in steel pipes and beams can be found in [29] and [52]. The B-VM method utilizing 5 MHz surface acoustic waves has been used to characterize fatigue crack growth during a fatigue test of Al 2024-T3 alloy plate [31]. Some other examples of the VM tests include detection of fatigue cracks in automotive aluminum alloy casting parts [52], airframe [22], combustion engine parts [28], cracks in Plexiglas and other polymer materials [28, 34], stress-corrosion cracks in steel pipes, and cracks in concrete initiated by rebar corrosion [54].

Compared to the harmonic distortion method, the modulation methods are not influenced by nonlinearities in the signal-generating electronic equipment because the sources of the probe and modulating signals are independent. The use of low-frequency vibrations, especially flexural resonance vibrations, significantly amplifies nonlinearity of the defect, thus increasing the sensitivity of the measurements.

One of the problems implementing VM and, especially IM methods, for NDT&E screening for damage in multiple parts of the same kind is the calibration of the modulating vibration. In order to achieve repeatability and high sensitivity, the modulating stress applied to the damaged area should be constant or measured so that the MI can be normalized with respect to the modulating stress. It is not usually possible to measure this stress. Thus, if the modulating vibration utilizes resonating structural modes (this is always the case for IM methods and the most effective modulating signal for VM), the mode's frequencies and their quality factors could vary from part to part respectively varying the stress. If the position of the defect also varies from part to part and is unknown, there is no way to calibrate the modulating stress applied to the defect. This limitation, however, may not be so critical for SHM applications, which monitor changes in the same structure.

It should be mentioned that fatigue defects are developed in stress concentration areas most often caused by structural vibrations. Therefore, dynamic stresses provide the best modulation conditions for the probing ultrasonic signal because the stresses are concentrated exactly in the damaged area. In effect, this stress concentration enhances the nonlinear interaction between high- and low-frequency waves and improves damage detectability. This aspect, which is often overlooked, creates an interesting opportunity for SHM applications: VM techniques can utilize the structure's own vibration during its normal operation as a modulating signal. For example, aircraft in-flight VM SHM could use engine and fuselage vibrations; VM monitoring of a bridge could utilize vibration due to traffic and wind, etc.

3 FATIGUE DAMAGE ACCUMULATION MONITORING

The most challenging task for assessment and monitoring of structural health is the characterization of damage at the smallest possible scale often even before macrofracture is developed (*see* **Fatigue Life Assessment of Structures**). The sensitivity of linear ultrasonic testing (UT) significantly degrades as the damage size gets smaller. Being orders of magnitudes more sensitive to micro- and mesoscopic damages, [12, 17–19, 24] nonlinear acoustics offers a unique opportunity to monitor and characterize the damage accumulation at these scales.

There are growing numbers of studies devoted to characterization of precracking fatigue damage using nonlinear acoustics. Thus, a substantial increase of the nonlinear parameter during transition from micro- to macrodamage was reported in [55] using the VM technique. The harmonic distortion method was utilized to study the nonlinear acoustic response of metals (steel, aluminum, and titanium alloys) during fatigue tests [24, 47, 48, 56–58]. These investigations clearly demonstrated strong quantitative relationships between the nonlinear parameter measured with the second harmonic (and even third [58]) and fatigue damage.

Cantrell and Yost [24] investigated the effect of the dislocation dipoles on the nonlinear response of the aluminum 2024-T4 alloy. The authors measured the nonlinear parameter of the specimens subjected to an increasing number of fatigue cycles and suggested a relationship between the nonlinear acoustic parameter and the volume fraction of the persistent slip band consisting of dislocation dipoles. A model describing the contribution of the dislocation dipoles to the nonlinear acoustic parameter was proposed, and the theoretical predictions indicated reasonable agreement with the experimental data.

Jhang and Kim [56] measured the second harmonic of 5 MHz longitudinal ultrasonic wave to assess the damage accumulation in stainless steel samples subjected to static and dynamic tensile load. The test demonstrated proportionality between the measured nonlinear parameter and the fatigue load be it static or dynamic.

Frouin *et al.* [57] discussed the real-time finite amplitude measurements of the nonlinear acoustic parameter in titanium alloys subjected to low-cycle and the high-cycle fatigue. The authors used special grips and a transducer holder to enable acoustic measurements during the fatigue test. High-frequency transducers operating at 10 and 20 MHz were used to transmit a fundamental frequency signal and measure the material response at the second harmonic. Results obtained for both high-cycle and low-cycle regimes show stable growth of the nonlinear acoustic parameter at initial stages of the material deterioration.

Campos-Pozuelo *et al.* [58] developed a testing procedure for assessment of the fatigue behavior of titanium alloys and duraluminum using a very high intensity 22-kHz ultrasonic signal. Tuned to the test article's flexural or longitudinal resonances, the same excitation signal was used to fatigue the article as well as to measure the degree of nonlinear distortion. The setup enabled fatigue stresses up to 450 MPa. A strong nonlinear behavior was observed showing a 900 and 800% increase in the nonlinear parameter of the fatigued titanium alloy and duraluminum samples, respectively. These are compared to only a 0.8 and 1.4% change in linear response (resonance frequency shift) for the respective samples.

Donskoy *et al.* [19–23] conducted a series of CW-VM tests to characterize micro- and mesoscale damage accumulation during dynamic fatigue of Al 2024 T-4. The samples were fatigued at 10 Hz using the strain-control three-point bending test. The same dynamic load was used as a modulating stress. A specially developed correlation algorithm allowed for measuring and calculating an averaged MI (equation 4) every 18 s during the fatigue loading enabling essentially real-time continuous monitoring of the damage index (DI in decibels), defined as $DI = MI_{\text{damaged}} - MI_{\text{intact}}$. Over 100 samples were tested under different load condition demonstrating near linear dependency of the damage index versus number of fatigue cycles to failure. This observation suggests that the linear damage accumulation rule, a familiar concept in fracture mechanics, may be reformulated in terms of the nonlinear acoustic data to enable prediction of the specimen's remaining fatigue life. To confirm that the nonlinear acoustic damage index is responsive to the micro- and mesoscale structural changes, a microscopic analysis of the fatigue samples using a scanning acoustic microscope (SAM) and a scanning electron microscope (SEM) were conducted. The images depicting material in the damage accumulation area and the corresponding nonlinear damage index as a function of the number of fatigue cycles are shown in Figure 8. Under the cyclic fatigue load, the material transitions from a consistent microstructure to zones of extensive plastic deformation. During various stages of this transformation, SEM micrographs reveal nucleation of microdefects, formation of slip planes and striation marks, and development and clustering of microcracks. The coalescence of microfailures finally results in propagation of one or several macrocracks, which cause ultimate material fracture. The damage index presented in Figure 8 shows a gradual increase at all stages of the fracture

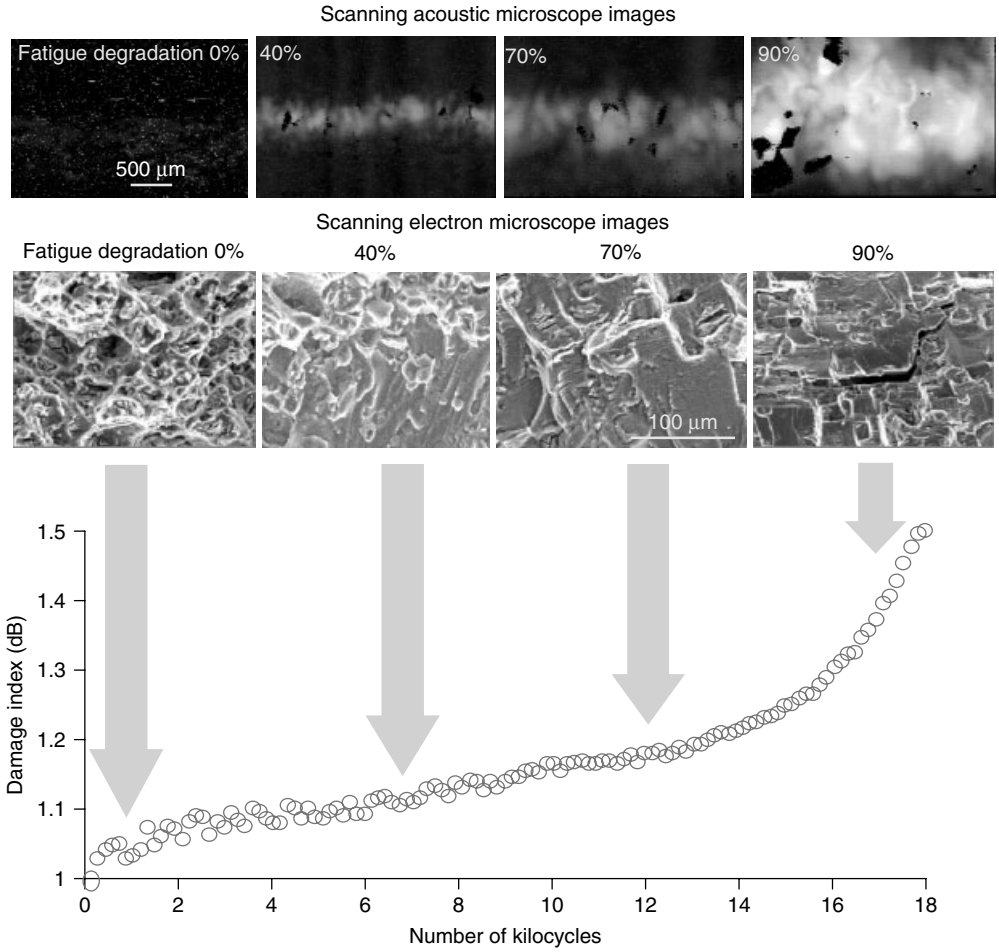

Figure 8. Nonlinear acoustic damage index versus number of fatigue cycles and corresponding sequential stages of the fracture process—SAM and SEM micrographs.

process and rapid growth just before the macroscale cracking.

4 CONCLUSION

Investigations of the nonlinear dynamics of materials with contact-type macrodefects (cracks, disbonds, delaminations) as well as fatigued materials with micro- and mesoscale damages reveal their unusually high acoustic nonlinearities, often orders of magnitude greater than found in undamaged materials. This phenomenon is utilized for detection and characterization of the nonlinear damages in a broad spectrum of materials: different metals, composites, wood, and concrete. There are two primary and most widely used NATs: harmonic distortion and modulation. The first correlates the amplitude of the second harmonic (sometimes higher-order harmonics and even intermodulation and subharmonics) with the presence and severity of the damage. The modulation methods employ the nonlinear interaction of two signals: typically lower frequency modulating vibration and higher frequency probing ultrasound. The strong low-frequency signal varies interface conditions at the damaged area. These variations effectively modulate the high-frequency signal passing through: the greater the damage, the greater the modulation effect.

Advantages of the NAT include much higher nonlinear response contrast between damaged/undamaged materials: studies report hundreds of percents change in the nonlinear response versus only a fraction of a percent in the linear response for the same damage. Being responsive to only nonlinear defects, the NAT can be used in structures with complicated geometries in which multiple reflections (reverberation) often preclude the use of the linear UT.

One of the difficulties in implementing NAT for many NDT&E applications is the requirement for a well-established "nonlinear background" reference for a particular structure. However, because SHM detects (monitors) changes in the materials/structure over time, the initial measurements could be used as a reference for the very same structure. This reference, coupled with the extremely high responsiveness to changes due to damage, makes the NAT highly attractive for SHM applications. Additionally, many implementations of the NAT are perfectly suited for monitoring of large portions of a structure using just a few sensors in fixed locations not requiring sensor spatial scanning. We believe these advantages are the primary reasons for selecting NAT over competing techniques in some SHM applications.

1 INTRODUCTION

Nondestructive testing (NDT) means to test materials and components in a way so that its later usage is not affected. NDT methods do not directly indicate flaws but only the variation of physical values. Therefore, it is the challenge to interpret flaws out of these variations. Reference standards (i.e., a test specimen with artificially inserted defects like flat bottom bore holes) are required for a calibration and a system check. Applications of NDT are quality control, determination of material properties, and defect detection.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

NDT started in 1900 when Roentgen discovered his X rays. Another old NDT method is the testing with sound; internal defects in forgings can be detected by changes in the sound when they are hammered. The beginning of ultrasonic testing (UT) started in 1929. Sokolow [1, 2] detected defects in components by applying UT-through-transmission techniques.

The UT is the most used NDT method without any negative impact on the environment. UT is a true NDT method because no loading and no chemical agents are necessary. There is no limit to the number of times that the UT testing can be carried out (recurring testing of components).

2 FUNDAMENTALS OF ULTRASONIC TESTING

2.1 Wave propagation and wave modes

2.1.1 Wave propagation

This article presents the basic principles of UT. Additional information can be found in the literature [3–6] and on websites [7, 8]. UT is based on elastic waves contrary to X-ray testing that uses electromagnetic waves. Contrary to electromagnetic waves, acoustic waves do not propagate in a vacuum.

A mechanical wave consists of mechanical vibrations of the particles in a material. This periodic movement is identified as an oscillation. The

recording of the movement versus time indicates a sinus curve:

$$x(t) = r \sin \alpha \tag{1a}$$

where

$$\alpha = \omega t \tag{1b}$$

$x(t)$ identifies the oscillation motion, t the time, r the amplitude, $\alpha = \omega t$ the phase, and ω the angular speed.

T is the oscillation period and indicates the time between two zero crossings. The number of oscillations per seconds is called *frequency f*

$$f = 1/T \tag{2}$$

The angular frequency ω is given by

$$\omega = 2\pi f = 2\pi/T \tag{3}$$

If all particles of a plan in a component (by excitation of an actuator) are vibrating sinuslike with the same clock, the outcome is an elastic wave. This excitation is propagating with the characteristic velocity v of the material. This velocity depends on the elastic properties of the material and can be determined out of measurements of the sound path s and its time of flight t:

$$v = s/t \tag{4}$$

An important factor of material testing is the wavelength λ. The wavelength is given by the regular spaces of the particles with the same vibration phases (Figure 1) and can be calculated by equation (5):

$$\lambda = v/f \tag{5}$$

The wavelength can be selected by the exciting (test) frequency f. For testing of homogeneous materials, frequencies in a range of 0.5–20 MHz

Mode	Vibration of particles	Velocity
Longitudinal wave		$v_L = \sqrt{\frac{E}{\rho} \cdot \frac{(1-\mu)}{(1+\mu)\cdot(1-2\mu)}}$
Shear wave		$v_T = \sqrt{\frac{E}{\rho} \cdot \frac{1}{2(1+\mu)}}$
Dilatational wave		$v_D = \sqrt{\frac{E}{\rho}}$
Bending wave		$v_B = \frac{2w}{\lambda} \sqrt{\frac{E}{\rho} \cdot \frac{I}{F}}$
Surface wave		$v_O = \frac{0.87 + 1.12\,\mu}{1-\mu} \cdot v_T$

Figure 1. Elastic wave modes in solid materials.

are mostly used. The wavelength is situated in the millimeter range.

2.1.2 Wave modes

The most used wave mode of the UT testing is the longitudinal wave (Figure 1).

It is characterized by the vibration of the particles in propagation direction. The longitudinal wave has the largest velocity of all elastic wave modes. The sound waves in air are longitudinal waves. Also, propagation in solids and in water is possible.

The equations in Figure 1 present the correlation between the velocities of the different wave modes and the elastic properties: the dynamic E modulus E_{dyn}, Poisson's ratio μ_{dyn}, as well as the density ρ.

In solids, a propagation of shear (transverse) waves is possible, too. The oscillation of the particles is perpendicular to the wave propagation. An excitation is possible by a periodic shearing force on the surface of the component so that the particles are periodically moved up and down. In solids, a shear force can be propagated to the next layer so that propagation in the material is possible.

In air and in liquids, no thrusts power can be carried so that propagation of shear waves is not possible. Using the same test frequency, the wavelength of shear wave is half of those ones of longitudinal waves because $v_{\mathrm{T}} \cong 0.5\, v_{\mathrm{L}}$.

Bending wave propagate in bars if the length is not larger than the wavelength, the diameter smaller than λ. In dependence of the excitation with longitudinal or shear waves, dilatational waves or bending waves are generated.

Surface or Rayleigh waves only propagate at the interfaces of components. These waves are very sensitive to surface defects.

There are different plate waves such as Lamb waves (*see* **Modeling of Lamb Waves in Composite Structures**) which are used for damage detection. Guided waves like Lamb waves can penetrate large areas and interact with defects and structural inhomogeneities. In contrary to UT, the sensors and actuators are permanently applied to the structure. This "long-range ultrasonics" enable a damage detection and SHM without time-consuming scanning. The most used guided waves are surface waves like Rayleigh waves and Lamb waves. These types of waves interact with defects and material discontinuities.

Lamb discovered these dispersive plate waves, which are propagating in solid plate with free boundaries [9]. For a plate with a thickness of 2 h, the symmetrical and the antisymmetrical modes can be expressed by [10]

$$(k^2 + s^2)^2 \cosh(qh) \sinh(sh) - 4k^2 qs \sinh(qh) \cosh(sh) = 0 \quad (6)$$

$$(k^2 + s^2)^2 \sinh(qh) \cosh(sh) - 4k^2 qs \cosh(qh) \sinh(sh) = 0 \quad (7)$$

with $q^2 = k^2 - k_{\mathrm{l}}{}^2$ and $s^2 = k^2 - k_{\mathrm{t}}{}^2$.

k indicates the wavenumber, k_{l} and k_{t} are wavenumbers for longitudinal and shear waves.

It is important to know that there exist multiple wave modes that satisfy equations (1a) and (1b).

A dispersion diagram (*see* **Modeling of Lamb Waves in Composite Structures**) presents a plot of the phase velocities versus the product of frequency and plate thickness. Using a broadband excitation, the different frequency components travel with different speeds through the material. As a result, the shape of the wave package changes during propagation and the receiver signals are difficult to evaluate.

In a defined frequency-thickness product only two fundamental modes exist; a symmetrical mode and an antisymmetrical one, which are widely separated by different phase velocities. Lamb wave testing should be carried out in this low-frequency range.

2.1.3 Properties of the sound field

An important factor of the sound field is the acoustic pressure (excess pressure) p. Bergmann [6] described the acoustic pressure and deflection of particles ξ in the case of plane waves and spherical waves in the following correlation:

$$p = \rho v \omega \xi \quad (8)$$

The product of density ρ and velocity v refers to the acoustical impedance z:

$$z = \rho v \quad (9)$$

Materials having high acoustic impedance are called *reverberant*.

Example For copper, the acoustic impedance z_c can be calculated as follows:

$\rho_c = 8.9 \times 10^3\,\mathrm{kg\,m^{-3}}$, $v_L = 4700\,\mathrm{m\,s^{-1}}$, $z_c = 8.9\,\mathrm{kg\,m^{-3}} \times 10^3 \times 4.7 \times 10^3\,\mathrm{m\,s^{-1}} = 41.8 \times 10^6\mathrm{kg\,m^{-2}\,s^{-1}} = 41.8 \times 10^6\,\mathrm{Ns\,m^{-3}} = 41.8\,\mathrm{MRayl}$

The intensity J is proportional to the square of the acoustic pressure.

$$J = 1/2p^2/z = 1/2z\omega^2\xi^2 \tag{10}$$

UT transducers deliver an output voltage proportional to the acoustic pressure.

For the determination of the intensity, the output voltage has to be squared.

2.2 Sound waves at plane boundaries

2.2.1 Normal incidence

For the testing of materials, the behavior of sound waves at boundaries and interfaces with different acoustic impedances is very important. Boundaries can be external surfaces of components and defects such as cavities in the component. A sleek boundary delivers a reflection, whereas a rough one delivers a scattering. The scale for sleek and rough is the wavelength.

If a plane wave with a sound pressure p_e perpendicularly reaches a sleek plane boundary, one part of the plane wave propagates the boundary (p_d), whereas the other one (p_r) is being reflected (Figure 2). The reflected part is contrarily propagating to the invading one.

$$R = p_r/p_e \tag{11}$$

and

$$D = p_d/p_e \tag{12}$$

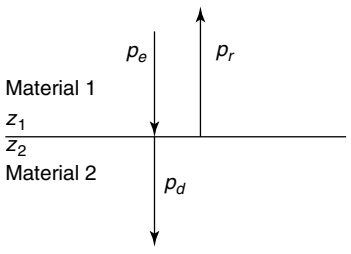

Figure 2. Perpendicular incidence on a flat interface.

R (reflection coefficient) and D (transmission coefficient) can be calculated out of the impedances z_1 and z_2:

$$R = (z_2 - z_1)/(z_2 + z_1) \tag{13}$$

$$D = 2z_2/(z_2 + z_1) \tag{14}$$

Reflection coefficient R and transmission coefficient D are referred to the sound pressure, which is measured by transducers. The following equations describe the relationships between the different sound pressures and R and D:

$$p_e + p_r = p_d \tag{15}$$

or

$$1 + R = \mathrm{D} \tag{16}$$

For the different intensities J, equation (15) calculated the balance

$$J_e = J_r + J_d \tag{17}$$

Equations (16) and (17) calculate the percentile parts of the reflected (r: reflection factor) and transmitted sound intensities (d: transmission factor) at a plane interface:

$$r = [(z_2 - z_1)/(z_2 + z_1)]^2 \tag{18}$$

$$d = 4z_2z_1/(z_2 + z_1)^2 \tag{19}$$

Because of the energy balance,

$$r + d = 1 \tag{20}$$

Note that in the literature there are different definitions for transmission factor d, transmission coefficient D, and reflection coefficient R, and reflection factor r. In order to prevent confusions, both possibilities are listed here.

The transducers deliver an electrical voltage, which is proportional to the sound pressure; therefore, it is more useful to use equations (11) and (12). The information about the phase (prefix of R) is loosening by calculating with intensities because $J \sim p^2$.

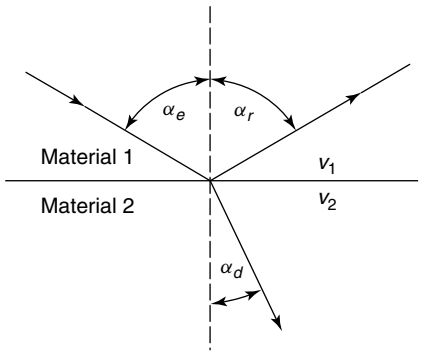

Figure 3. Reflection and refraction of a plane wave with angular incidence at a boundary between two materials.

2.2.2 Angular incidence

The incoming wave with the angle α_e to the perpendicular is reflected with the same angle. A part is penetrating material 2 with the angle α_d (Figure 3). The relationship between these angles and the velocities describes Snell's law:

$$\sin\alpha_e / \sin\alpha_d = v_1/v_2 \tag{21}$$

Using equation (21), it is possible to provide a conversion from one wave mode with a velocity v_1 to another one with v_2. Also, it is possible to select a defined mode.

2.3 Sound propagation

The amplitude of the spherical wave is inversely proportional to the distance from the transmitter. Besides this material-independent sound attenuation, there are also material-dependant influences like scattering and absorption. Both terms are summarized in attenuation. The sound pressure decreases exponentially as

$$p(x) = p_0 \mathrm{e}^{-\alpha x} \tag{22}$$

where p_0 identifies the sound pressure at the initial location, $p(x)$ the sound pressure in a distance x from the source, and α the sound attenuation.

It is also possible to refer α to the sound intensity. Because of $J \sim p^2$, equation (21) delivers

$$\alpha_J = 2\alpha \tag{23}$$

The sound attenuation can be divided into two parts:

$$\alpha = \alpha_\mathrm{a} + \alpha_\mathrm{s} \tag{24}$$

where α_a identifies the absorption and α_s the scattering coefficient.

The absorption increases nearly proportionally to the test frequency. The reason is the conversion of acoustical energy into heat. The absorption can be settled by a higher transmitter voltage and/or a higher gain of the receiver amplifier and also by a lower test frequency.

Contrary to the absorption, the scattering cannot be settled by a higher amplification. It is useful to compare scattering to the effect of fog on a car driver who is dazzled by his own headlamps. Scattering does not only provide attenuation but also several small additional echoes with different times of flight. Scattering is performed by inhomogeneities in the material, which are smaller than the wavelength. Inhomogeneities are interfaces at which the sound impedance is excursively changing.

Inhomogeneities that have a diameter below 1% of the wavelength do not produce scattering. With increasing diameter, the scattering increases with the third power of the diameter and the fourth power of the frequency [11]:

$$\alpha_\mathrm{s} \sim {d_k}^3 f^4 \tag{25}$$

In order to reach a high-resolution UT, the test frequency spectrum (which defines the band of wavelengths) has to be optimized carefully, especially for inhomogeneous materials. Using UT, it is not possible to distinguish between α_s and α_a because the resulting sound attenuation defines the sound pressure at the receiver.

3 ULTRASONIC TESTING

3.1 Transducers

3.1.1 Normal incidence

Transducers are used as a sender and a receiver for UT of materials. They are manufactured for a wide range of applications with different element diameters, center frequencies, bandwidths, and couple

techniques like immersion technique, water split, and squirter [6, 7]. Mostly, transducers provide normal incidence to the surface of the component. Such a contact transducer is shown schematically in Figure 4. These types of transducers are used for hand manipulating with hand-held ultrasonic flaw detectors. The active element consists, in most cases, of a piezoelectric crystal (*see* **Piezoceramic Materials—Phenomena and Modeling**; **Piezoelectricity Principles and Materials**). It is well protected in a rugged casing and with a wear plate, which is also used as a matching layer to the material.

In order to get a short pulse response, the active element is damped by a backing that reduces the ringing and increases the bandwidth. The bandwidth of the transducer (up to 100% of the center frequency) is inversely proportional to the pulse duration, which means that a high bandwidth provides a short pulse response of the transducer.

3.1.2 Sound field

The sound field of a transducer consists of a near field, which is characterized by interferences and a far field. The near-field length is given by (26) [3]

$$N = \frac{D^2 - \lambda^2}{4\lambda} \approx \frac{D^2 \cdot f}{4c} \tag{26}$$

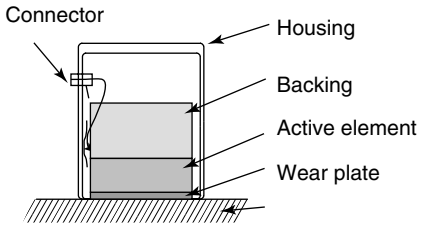

Figure 4. Construction of a normal incidence contact transducer.

where D is the element diameter, λ is the wavelength in the material, and c is the velocity in the material.

The sound pressure decreases inversely to the distance z, because the sound energy is distributed to even larger areas. Figure 5 shows the principle characteristic of the sound field of a flat cirque transducer, which is simultaneously used as a sender and receiver (echo technique). The smallest beam diameter can be found at the near-field distance N; for large distances the field is opened by the divergence angle γ.

3.1.3 Focused transducer

By bending the active element (polyvinylidene fluoride (PVDF) piezoelectric polymer film) or by applying a length the sound field can be focused. Focusing increases the lateral resolution and provides the detection of small flaws. A focusing always reduces the near-field length.

Figure 6 shows the focal distances of the same transducer in water without test specimen (left-hand side) and with test specimen (right-hand side). The velocity in the test specimen is higher than that in water; as a result, refraction reduces the focal distance.

The length of the water path calculates equation (27) [12, 13]

$$l_w = F - l_m \cdot \frac{c_m}{c_w} \tag{27}$$

where l_w is the water path, l_m is the focal distance from the surface, c_m is the material sound velocity, c_w is the water sound velocity, and F is the focus in water.

3.1.4 Phased array transducers

Contrary to single-element transducers, phased array transducers (Figure 7) consist of 8–256 small

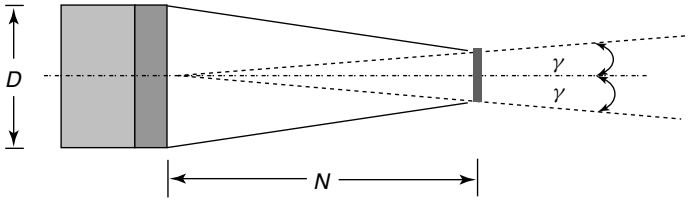

Figure 5. Sound field of a flat transducer.

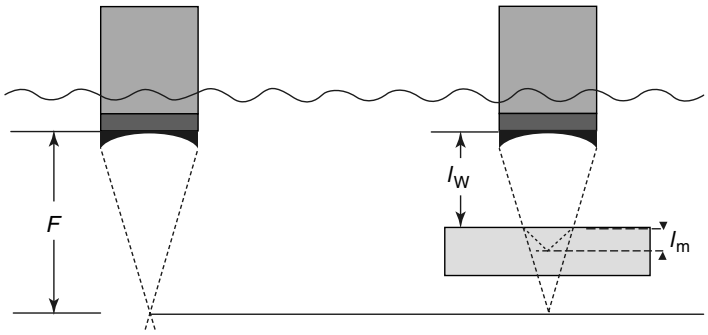

Figure 6. Focal distances in water and in material.

Figure 7. Phased array transducer (linear array with 64 elements, product of R/D-Tech/Olympus).

individual elements. Each element can be pulsed and received separately with sophisticated computer-based instruments.

The elements can be fired in groups where individual delays provide beam steering, sector scan, and linear scanning. The first application of these software-controlled transducers was in medical ultrasonic diagnostics. Because of the fast-developing electronic devices, computer systems, and the big drop of prices for hardware and software, the phased array technique is largely used for material testing [12–14]. More articles concerning phased array techniques can be found in the online journal NDT.net [8].

3.1.5 Coupling techniques

For a reproducible UT, it is important to have a constant coupling between the transducer and the component. Because of the high-impedance mismatch, air in the sound path would produce a reflection back to the transducer (see Section 6). For manual testing, a coupling paste or gel is used.

Immersion technique means that the component and the transducer are in a water tank (Figure 8). The transducer is moved by an XY scanning system, which provides automatic testing. An additional Z axis can be used for adjusting the water delay between the transducer and the component in order to set the focal point into the component. For curved components, additional axis is necessary for a normal incidence.

Squirter technique [15] is characterized by a plastic housing with a built-in transducer and a nozzle (Figure 9). The nozzle forms a guide for the water jet, which carries the ultrasound to the component.

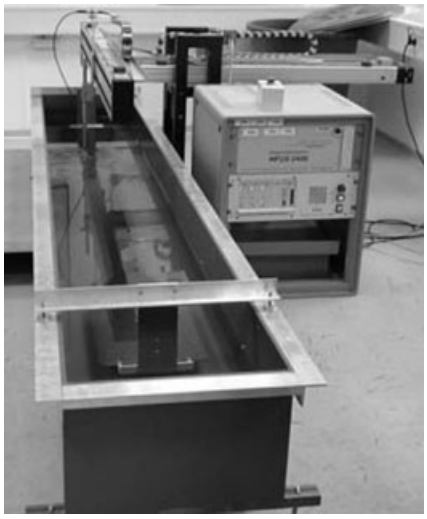

Figure 8. Immersion technique (DLR FA, Germany).

Figure 9. Inspection of a CFRP cylinder using squirter technique. (DLR FA, Germany).

Air bubbles and turbulences in the jet decrease the signal-to-noise ratio.

Water gap coupling also provides a reproducible coupling for automatic testing. The transducer is mounted on a carrier, which is guided by rollers on the surface of the component so that simply curved components can be tested with two-axis scanners. Figure 10 shows the testing of a curved carbon fibre reinforced plastic (CFRP) component with a water gap coupling device with rollers and a cardanic fixture.

3.2 Ultrasonic testing methods

3.2.1 Through-transmission technique

Through-transmission technique is useful for materials with high sound attenuation. This method is characterized by two transducers (one used as a transmitter, the other one used as a receiver) on opposite sides of the component. Contrary to the echo technique, the penetration of the material is only on time, but a double side's access of the component is necessary. An evaluation of the amplitude of the transmitted signal and a time-of-flight measurement are possible. The amplitude is dependant on the sound attenuation of the material.

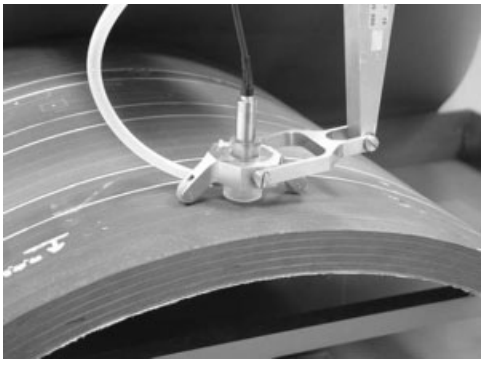

Figure 10. Water gap coupling for curved CFRP components, the transducer is mounted on a carrier with rollers and cardanic adapter to the scanning axis (DLR FA, Germany).

Defects principally produce an amplitude decrease and an increase in time of flight.

Measurements of the relative changes of amplitudes (A_1, A_2) caused by flaws or different attenuations can be calculated in dB (decibel):

$$\mathrm{dB} = 20 \log_{10}(A_1/A_2) \tag{28}$$

3.2.2 Pulse-echo technique

The most used testing method is pulse-echo technique, which provides a single-sided access. Only one transducer is necessary, which is simultaneously used as a transmitter and a receiver. This method is based on radar techniques and was a breakthrough for UT in the late 1940s.

Figure 11 demonstrates the echo technique. After a short excitation, the transducer converts the electrical signal to a longitudinal wave pulse, which propagates into the test object. The wave is reflected at the backwall of the transducer, which converts the acoustic wave back to an electrical signal, which is amplified and displayed. A defect in the test objects causes an additional reflection. Its time of flight (t_2) is smaller than that of the backwall (t_1). Time-of-flight measurements can be used for the determination of the material velocity (l: length of the test object):

$$v = 2l/t \tag{29}$$

and/or of the measurement of the distance d of the defect from the surface ("defect depth").

$$d = vt/2 \tag{30}$$

In dependence of the size and reflectivity of the defect, the amplitude of the backwall echo decreases.

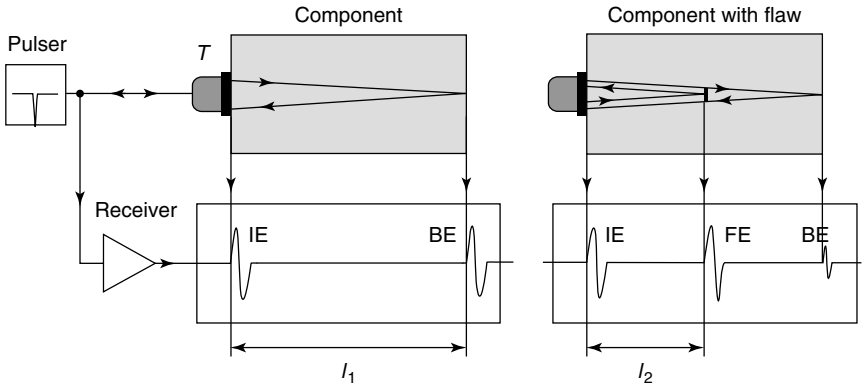

Figure 11. Principle of echo technique.

3.2.3 Immersion technique

Immersion technique is often combined with echo technique and a well-known method for automatic testing with ultrasonic imaging. The transducer and the test object are situated in the water tank (Figure 12).

The receiver signal displayed on the screen of the ultrasonic system consists of

1. interface echo
2. defect echo
3. backwall echo and
4. tank echo.

It should be noted that there are multiple reflections from the interface and, in some cases, form the defect(s), too. Therefore, the time of flight of the second reflection of the interface echo must be larger than the time of flight of the tank bottom echo.

For automatic testing and ultrasonic imaging, the echoes have to be evaluated automatically.

Therefore, different gates are used: gate A for the interface echo, B for the defect echo, C for the backwall echo, and D for the tank echo. The methods of imaging are described in Section 4.3.

It is also possible to use through-transmission technique in immersion technique. For this application, a u-shaped fixture for the two transducers is necessary.

4 AUTOMATIC ULTRASONIC SYSTEMS

4.1 Survey

Figure 13 shows the block diagram of an ultrasonic imaging system [16], with immersion technique

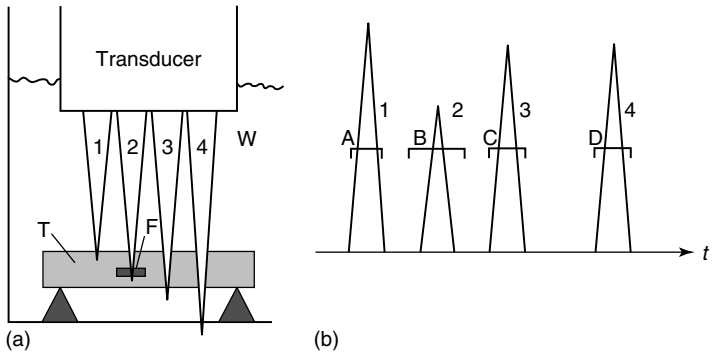

Figure 12. Principle of immersion technique: (a) test object (T) with transducer in water, F: defect and (b) echoes and gates versus time.

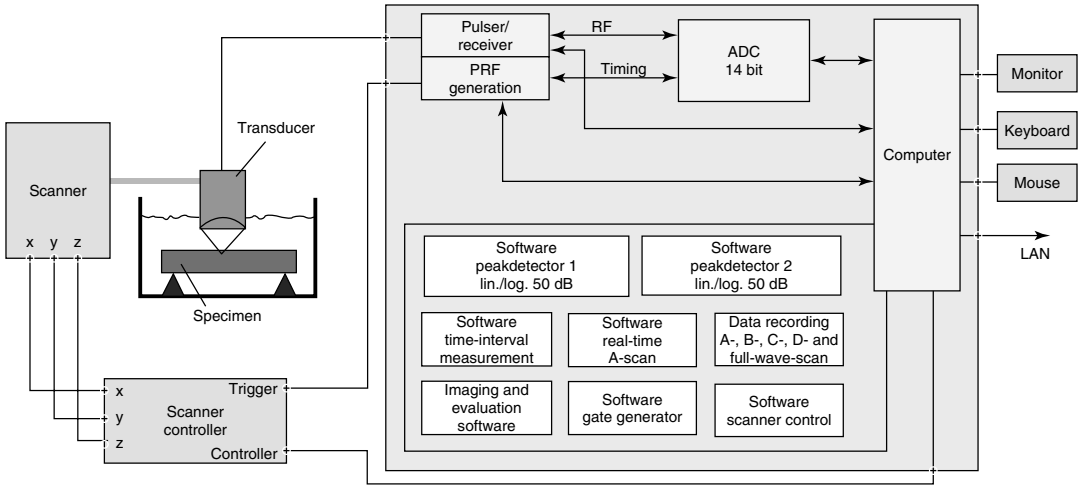

Figure 13. Block diagram of an ultrasonic imaging system.

consisting of a scanner with controller, immersion tank, a transducer with fixture, a pulser/receiver unit, an analog-to-digital converter (ADC), a timing unit for the trigger generation and a computer with ultrasonic software, which provides the control of the system, the data capture, procession, evaluation, and imaging.

4.2 Hardware

4.2.1 Pulser/receiver unit

The pulser/receiver unit consists of a pulser that generates the excitation for the transducer, an amplifier, a high- and a low-pass filter section, and a timing unit for the system trigger. This unit can be built on a Personal Computer PC-board [17]. Spike pulsers, which provide a broadband excitation and the shortest pulse responses, are the most used type of pulsers in ultrasonic systems. A capacity C is loaded and discharged by an electronic switch such as a field-effect transistor (FET) via a resistor R. With a short switching time of the FET, the frequency spectrum starts at 0 Hz and decreases (−3 dB) at

$$f = 1/2\Pi RC \tag{31}$$

Usually, the resistor is chosen near the impedance of the cable to the transducer (50−75 Ω), the capacity determines the maximum frequency. For high-frequency applications ($f > 20$ MHz), the FET should be replaced by an Avalanche transistor, which provides switching times lower than 1 ns. Also, for high-frequency application, the pulser/preamplifier unit should be built in a separate case and mounted nearby the transducer in order to get short cable to the transducer and to avoid electromagnetic noise (HFUS 2000 system [18]).

If a high-power excitation is required (for materials with a high sound attenuation, thick components, and others), a square pulser or a tone-burst pulser is the best solution. Such a device can also be a PC-board [18]. The energy of such a pulse is more concentrated on a smaller frequency range. Such kind of pulsers is useful for applications in a frequency range from 20 kHz up to 3 MHz.

The receiver consists of an amplifier, a gain setting and a high- and low-pass filter unit. Because of the large dynamic range of the input signals (>100 dB), the amplifier is separated in an input attenuator, a preamplifier, a fine-stepped attenuator and a main amplifier and a high- and low-pass filter unit. In order to get a constant sensitivity, for the inspection of thick components, a distance amplitude control unit (DAC) is intended.

The amplified signal is given to a high- and low-pass filter unit, which suppresses unwanted frequency parts and provides an antialiasing filter for the ADC board. The filter unit eliminates electromagnetic noise as well as the noise produced by ultrasonic scattering.

4.2.2 Analog-to-digital converter

An ADC converts the preprocessed analog receiver signal to a digital one (to a digital number). The digital signal cannot be influenced by noise and can easily be stored, digital processed, evaluated, and displayed by a computer system. There are two most important ADC features: the sampling frequency f_s (MHz) or sample rate (M samples per second) and the amplitude resolution (number of bits). The Shannon theorem says that for continuous signals, the sample frequency f_s must be larger than twice the input bandwidth B.

For ultrasonic applications, the sampling frequency is used up to 10 times larger than the maximum ultrasonic frequency in order to get a more precise amplitude and time-of-flight measurements. A low-cost ADC provides 8-bit amplitude resolution, 2^8 gives 256 levels of vertical resolution. Because of the bipolar ultrasonic (RF) signal, 128 steps are used for the positive amplitudes and 128 for the negative ones. An input range of 1 V_{pp} (peak to peak) provides a resolution of 3.906 mV.

Ultrasonic systems like USPC 3040 typically comprehend ADCs with 14 bits, which give 16 284 steps and 200-MHz sampling frequency. For example, if the maximum input voltage is 1 V_{ss}, the lowest step is 0.125 m $V_{ss} = 125\,\mu V_{ss}$, which means a dynamic range of about 78 dB. Therefore, it makes no sense to use high-gain preamplifiers, which only generate noise levels at their outputs much greater than the lowest amplitude step of the ADC. The higher the dynamic range, the better are the possibilities for digital signal processing after data capturing.

4.3 Software

The software not only controls the scanner and the ultrasonic hardware and displays the results but also replaces a lot of hardware. Examples are the gated peak detector (linear or logarithmic mode, 70-dB single-shot dynamic range) and the time-interval measurement system (resolution of 5 ns). These software solutions are more flexible than those of the hardware. The accuracy of these parts is given by the ADC. The user interface of the software is shown in Figure 14 [18]. The tap sheets on the left hand side provide the instrumentation settings; a large A-scan display is useful during the system setup. It can be separated into two parts in order to have an additional fast Fourier transform (FFT) display.

Figure 15 shows the possibilities for ultrasonic imaging. The A-scan presents the amplitude as a function of time (oscilloscope display of the echo signals), a B-scan gives a cross-sectional view of the component, whereas the amplitude is displayed along the vertical axis and the position of the transducer is displayed along the horizontal axis, a C-scan is a plan-type view or top view of the component with all flaws (two-dimensional amplitude presentation). For a C-scan, the amplitude of the flaw echo or the amplitude of the backwall echo has to be evaluated. Therefore, a precise gate setting is required in which the amplitude measurement is carried out. A D-scan also provides a plan-type view; however, contrary to a C-scan, the time of flight is displayed. A D-scan is able to display the depths of the flaws or the thickness of the component.

Figure 16 demonstrates the possibilities of ultrasonic imaging using an impacted CFRP panel. The C-scan of the defect echo is presented in Figure 16(a). For this presentation, the amplitude in gate B situated between the interface and the backwall echo is evaluated in a logarithmic scale (dB). The highest amplitude (100% in an A-scan) is calibrated to 0 dB and mapped to the color black in the C-scan. A defect is characterized by a higher amplitude than the "natural noise" caused by scattering at inhomogeneities. The black area indicates the delaminated area. A C-scan of the backwall echo is given in Figure 16(b). This one presents the "acoustic shadow" of the defect. Therefore, a defect causes smaller echo amplitudes than its surroundings. The delaminated area is indicated by the lighter region in the C-scan.

A D-scan of the defect echo shown in Figure 16(c) presents the different distances of the delaminations from the surface. The black area presents a distance of 0 mm (no defect) and white areas nearly 4 mm. It is shown that the damaged area consists of different delaminations in different depths, which means that they are situated between different layers. This information can also be received from a B-scan (Figure 16d), which presents a view into the material along a selected line out of a C-scan. Not only the different depths of the delaminations are indicated but also horizontal lines, which present layer echoes.

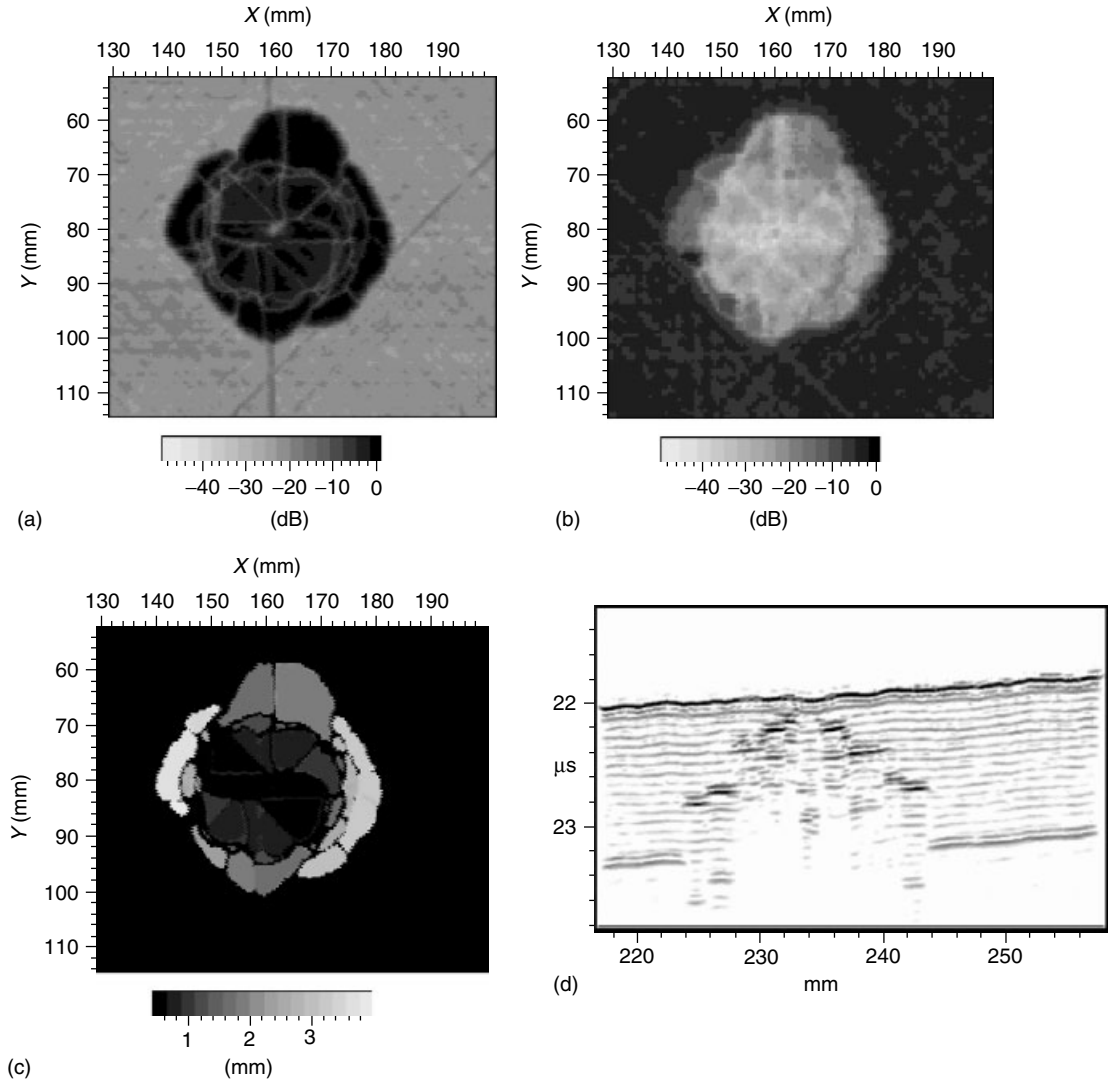

Figure 16. Ultrasonic imaging of an impacted CFRP panel. (a) C-scan defect echo, (b) C-scan backwall echo, (c) D-scan defect echo, and (d) B-scan.

These indications require a high-quality laminate and a well-optimized UT.

5 MOBILE ULTRASONIC INSPECTION SYSTEM "MUSE"

For in-service inspections of built-in aerospace components, a mobile equipment is necessary.

The manual scanning is time consuming and a reproducible coupling is difficult to achieve. Therefore, the mobile ultrasonic inspection system "mobile ultrasonic equipment (MUSE)" has been developed [19]. The manipulator is attached to the component with sucking devices. This system shown in Figure 17 consists of a motor-driven manipulation system, a water-circulation system for the coupling, and the PC-board-based ultrasonic system USPC built into a portable computer. The manipulator is attached to

MUSE manipulator with adapter for transducer | Water circulation system | Flaw detector with built-in motor controller

Figure 17. MUSE system for in-field inspections.

the component with sucking devices and provides an inspection area of 200–300 mm^2, a resolution of 0.020 mm and a maximum speed of 200 mm s^{-1}. The test frequency range for the MUSE is 0.05–35 MHz. Ultrasonic imaging is possible in A-, B-, C-, and D-scans.

The coupling technique developed for the MUSE ("local immersion technique") provides the application of focused transducers without problems with air bubbles so that the high resolution is also available for field inspections. The local immersion technique is also useful for laboratory investigations because no water tanks are required and the components stay dry.

6 AIR-COUPLED TECHNIQUES

Air-coupled ultrasonic testing (AC-UT) is a very attractive noncontact technique, which avoids the disadvantages of the coupling liquid (water, squirter, and immersion technique) or coupling paste [20–22]. However, the large impedance mismatch between solids and gas (air) produces an amplitude loss of more than 150 dB using through-transmission technique with separate standard transducers as a transmitter and a receiver on the opposite sides of a CFRP component [19].

Figure 18 shows the amplitude differences between water and air coupling using through-transmission technique with different transmitter and receiver transducers on the opposite sides of a thin CFRP specimen. We set the amplitude on the transmitter to 0 dB. Using water coupling, the sound pressure decreases to −21 dB in the water because of the differences in the acoustic impedance of piezoelectric material ($z_{\text{piezo}} = 35$ MRayl) and water ($z_{\text{water}} = 1.5$ MRayl). The amplitude on the CFRP surface ($z_{\text{CFRP}} = 4.5$ MRayl) increases to −18 dB and decreases again to −24 dB in the water. At least the amplitude on the receiver becomes −18 dB. This small amplitude difference between transducer and receiver can easily be compensated by amplification.

In the case of air coupling, the amplitude difference between transmitter and receiver reaches −156 dB. The extreme high differences between the impedance of air ($z_{\text{air}} = 0.0004$ MRayl) and of the lead zirconate titanate (PZT) material cause a decrease of −93 dB and also the interface between CFRP and air (−75 dB). In this very simple model, only the transmission factors are calculated and no losses of sound attenuation and sound divergences have been regarded.

Therefore, standard flaw detectors with standard transducers cannot be used for air coupling. Special transducers, transmitter and receiver electronics are required. Since 15 years, more papers have been describing the air-coupled technique [6]. Normally, the investigations are carried out in through-transmission technique.

In order to get better signal-to-noise ratio special transducers, an optimized excitation, ultralow noise preamplifier, and a signal processing are necessary. An example of a modular system is the USPC 4000 AirTech [15], which was used for the recording of the right hand side C-scan in Figure 6.

Figure 19 shows two C-scans of an impacted sandwich component consisting of two CFRP skins each 0.5 and 15-mm-thick honeycomb cores. The C-scan in Figure 19(a) was recorded in echo technique using a broadband transducer (2.2 MHz) with water gab coupling. In order to get a high signal-to-noise ratio, a square-pulse transmitter is used. The software receiver filter provides a center frequency of the back-wall echo (back skin) of 700 kHz. This frequency enables the detection of defects in the skins and core, demonstrated by the impact indication in the C-scan [8].

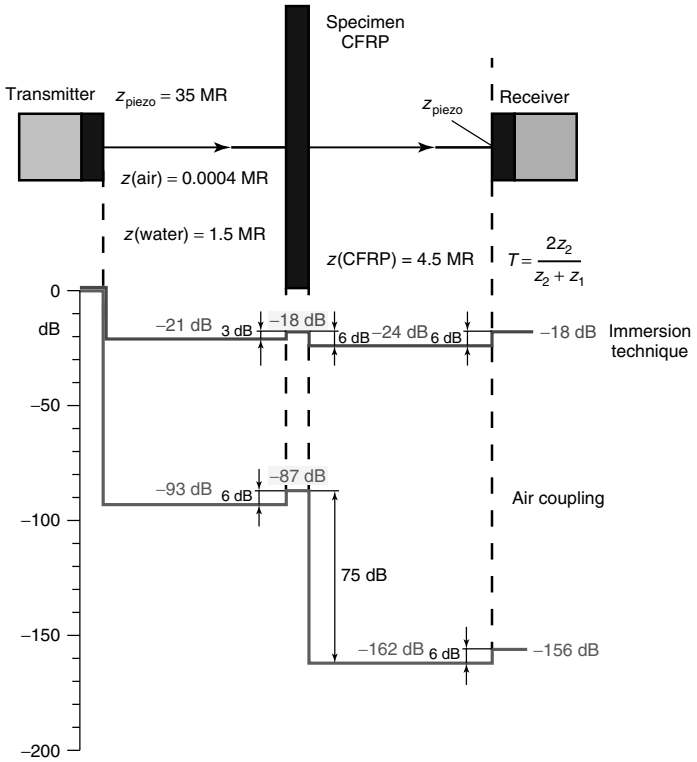

Figure 18. Sound pressure curves between transmitter and receiver probe using water and air coupling.

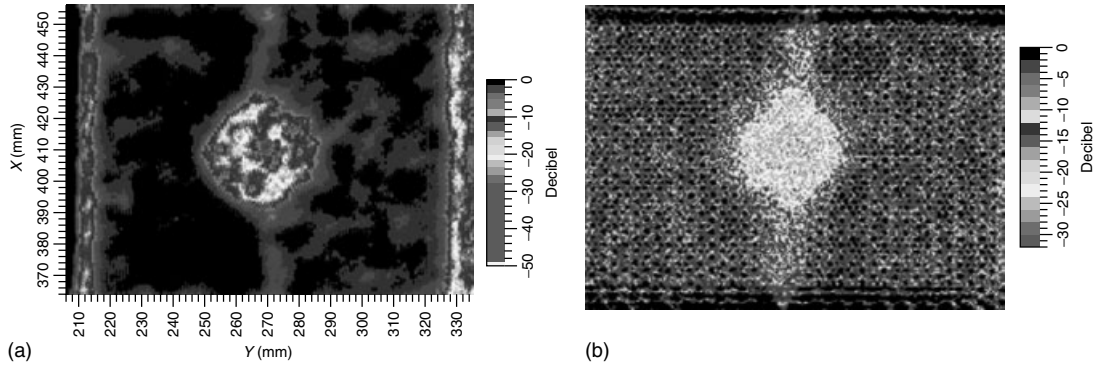

Figure 19. C-scans of an impacted CFRP sandwich component. (a) Echo technique with water gab coupling and (b) air-coupled ultrasonic testing.

The C-scan in Figure 19(b) of the same component is carried out by air coupling and gives a much clearer presentation. The reason for the better resolution using air coupling is the smaller velocity in air in comparison with water, which provides a smaller wavelength and—using focused transducers—a smaller beam size.

7 VISUALIZATION OF LAMB WAVE PROPAGATION

The knowledge of the propagation of different Lamb wave modes and their complex interactions with structure elements, discontinuities, and defects is a requirement for interpreting the complex receiver

signals and for optimizing all the parameters of Lamb wave system such as test frequency, design, number, and distribution of the transducers, required signal procession and evaluation. Only for simple geometries, the Lamb wave propagation can be calculated. Therefore, experimental methods are used in order to get this important information.

One actuator at a fixed position on the bottom of the specimen has been used as a transmitter (Figure 20) [23, 24]. The excitation is carried out by a burst generator. Because of the harmonics a filter on the receiver side is used, which provides a desired narrow band signal.

A second PZT patch is moved by an XY scanner in a meander track. Using a two-axis scanning system, the curve of the component can be compensated by a cardanic sensor holder. The scanning grid of 1.5 mm is used, which is smaller than a tenth of the Lamb wavelength. In order to get a reproducible acoustic coupling between the sensor and the component, a water split coupling is used.

During scanning at each point of the scanning grid, a full-wave Lamb wave A-scan is recorded. This 3-D recorded data file consists of a number of B-scans along the y axis (scanning axis). In x direction the index axis is situated, the time of flight in z direction. A scanning area of 400 mm $\times$ 500 mm with a scanning grid of 2 mm delivers the information of more than 50 000 virtual sensors.

Out of the 3-D- data files several presentations can be calculated and presented [23]:

- 2-D amplitude images, showing the maximal amplitude during a selected gate $[t_1, t_2]$ (C-scan);

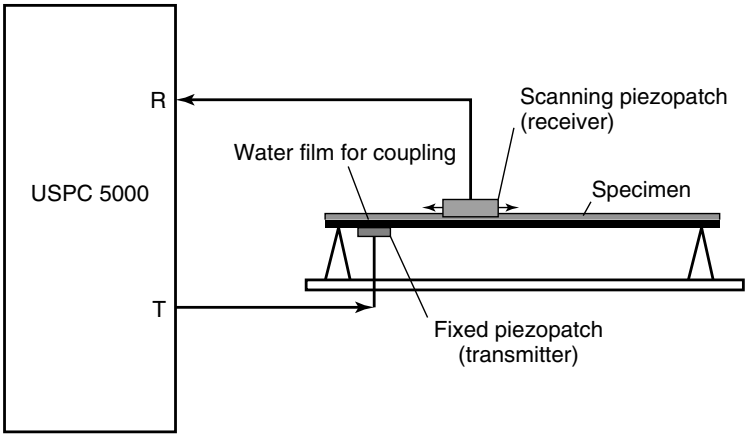

Figure 20. Experimental arrangement for the visualization of the Lamb wave propagation.

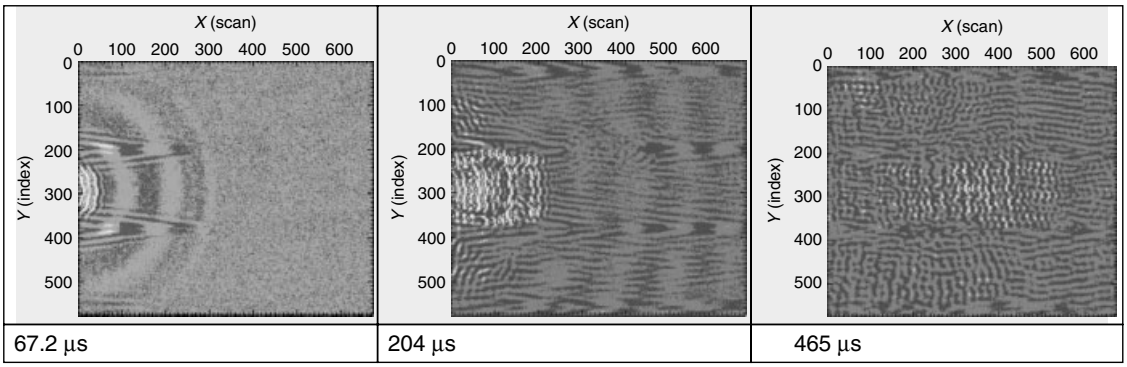

Figure 21. Video snap shots with excitation of PZT T4 situated on the skin between two stringers.

- 2-D time-of-flight images within a certain gate $[t_1, t_2]$ ("D-scan");
- Lamb wave A-scans at any recorded position together with spectral analysis;
- B-scans $[x, t]$, $[y, t]$; and
- Video animations showing the wave propagation.

Figure 21 presents three snap shots of a video animation with excitation of T4 situated on the skin. There are two wave modes generated on fast mode with a wavelength of 105 mm (s_0) propagating mainly on the stringers with a phase velocity of 5250 m s^{-1}. The wavelength of the slower mode (a_0) propagating between the stringers was measured to 15 mm with a phase velocity of 750 m s^{-1}.

The circular propagation in the skin is influenced by reflections from the stringers, so that after a time of flight of about 100 μs more interferences are indicated. After 465 μs, a chaotic wave field is visible.

Chapter 16
Guided-wave Array Methods

Paul D. Wilcox
Department of Mechanical Engineering, University of Bristol, Bristol, UK

1 INTRODUCTION

Ultrasonic array transducers for bulk waves were developed originally for medical imaging applications in the 1950s. In the last few decades, this technology has been taken up in the nondestructive evaluation (NDE) community as a superior alternative to conventional ultrasonic techniques using monolithic transducers. The enabling technology that has lead to the rapid growth in array-based systems for NDE has been in digital electronics and data processing in the supporting instrumentation, rather than the fabrication of the arrays themselves. In NDE, there are a number of different reasons for using arrays. First, they enable multiple conventional inspections (e.g., with ultrasonic probes at different angles) to be performed simultaneously, hence reducing inspection time and possibly inspection complexity. Second, they enable some form of scanning to take place without any physical movement of the device. This can be exploited to scan the interior of a complex component from a range of angles from one transducer position or to reduce the number of mechanical scanning dimensions in a raster scanning system. These two reasons for using arrays are essentially concerned with reducing the cost of NDE by performing an inspection more efficiently with an array. The third reason is somewhat different and is only just starting to be realized. This is the fact that arrays can potentially provide much richer information about a component than conventional NDE. A comprehensive review of the current state of the art in array-based NDE may be found in [1].

Digital electronics and computational power have also been key enabling technologies for long-range guided-wave NDE systems using arrays. The most commercially successful of these have been for the inspection of pipelines. Such systems allow the rapid inspection of long lengths of pipeline from a single access point and are now in widespread industrial use throughout the petrochemical industry and elsewhere. A review of applications may be found in [2]. Despite the success on pipeline inspection, there has been

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

very little commercial use of guided-wave NDE systems for large area inspection to date, although the technology has been demonstrated in research laboratories. Guided-wave NDE systems are based on the concept of a device that can be deployed on a structure when inspection is required. In principle, the same devices could be permanently attached to a structure to form the basis of a structural health monitoring (SHM) system, but this is not necessarily an economic solution because of the complexity of the arrays used. It is fair to say that guided-wave arrays specifically designed to be permanently attached for use in an SHM system are still a long way from widespread industrial usage.

This article begins with a brief overview of the salient features of guided waves and their application to damage detection. It then examines the various types of guided-wave arrays in use in NDE applications, beginning with those for one-dimensional (1D) waveguides such as pipes. The article compares and contrasts these with devices to perform inspection on two-dimensional (2D) platelike structures. The final section is on sparse distributed arrays specifically for SHM applications.

2 BACKGROUND

2.1 Guided-wave terminology

Guided waves are elastic waves that propagate along structures, their energy guided by the boundaries of the structure. In guided-wave terminology, the structure is referred to as the *waveguide*, and guided waves include waves on free surfaces (Rayleigh waves), waves in plates (Lamb waves and shear-horizontal or SH waves), waves in rods, and many others. Guided-wave phenomena exist over a wide frequency range from $<$1-Hz seismic waves generated by earthquakes to $>$100-MHz surface waves used in acoustic microscopes. There is sometimes debate about whether guided waves or bulk waves exist in a particular situation, but this is a misleading argument. The actual wavefield that exists is the solution that satisfies the governing partial differential equations and boundary conditions. The guided or bulk wave distinction is about the most appropriate way to formulate the solution. If the wavelength of bulk waves is small compared with the dimensions of the structure then the bulk wave formulation is most appropriate, but if the wavelength is comparable or greater than the dimensions of the waveguide a guided-wave solution is generally more useful. The ratio of waveguide dimension to bulk wavelength is therefore an important parameter, and for this reason, the various properties of guided waves in a particular shape of waveguide are often considered as functions of the product of a characteristic waveguide cross-section dimension and frequency (since this is inversely proportional to the bulk wavelength). Further details on the physics of guided waves may be found in **Fundamentals of Guided Elastic Waves in Solids** and **Modeling of Lamb Waves in Composite Structures**.

Key characteristics of guided waves are the presence of multiple modes of propagation, which generally have frequency-dependent (i.e., dispersive) velocities. Associated with each mode at each frequency is a characteristic pattern of particle displacements and stresses through the cross section of the waveguide that is referred to as the *mode shape*. By definition, the mode shape of a particular guided-wave mode at a particular frequency is invariant as the wave propagates along the waveguide, although the amplitude may diminish because of attenuation.

The interest in the use of guided waves for long-range NDE and SHM is their potential for detecting damage remote from the location of a sensor, an essential attribute if a limited number of sensors are required to detect damage at any location in a large structure. From a guided-wave perspective, structures can be divided into 2D waveguides where the structural elements are platelike (e.g., aircraft fuselages, ships' hulls, storage vessels, etc.) and 1D waveguides (e.g., pipes, rails, etc.). The two types are shown schematically in Figure 1.

In 2D platelike structures, the guided waves are Lamb and SH modes, and the salient dimension is the plate thickness. To give an idea of the numbers involved for typical engineering materials (steel, aluminum, many composites), a typical operating point for an SHM or NDE system is around 1 MHz mm (i.e., 1 MHz in a 1-mm-thick plate, 500 kHz in a 2-mm-thick plate, etc.). Up to around 2 MHz mm, only three fundamental modes (the A_0 and S_0 Lamb modes and the fundamental SH mode, SH_0) exist in platelike structures of such materials; above this value, higher order guided-wave

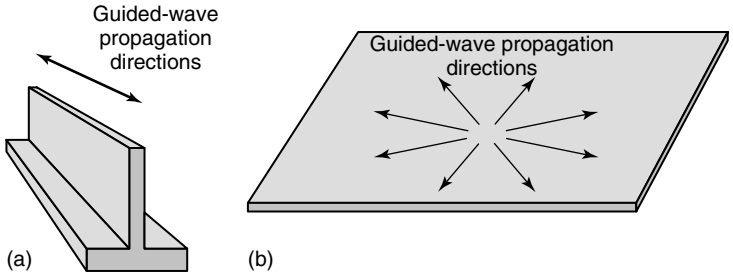

Figure 1. Schematic diagrams of typical (a) 1D and (b) 2D waveguides.

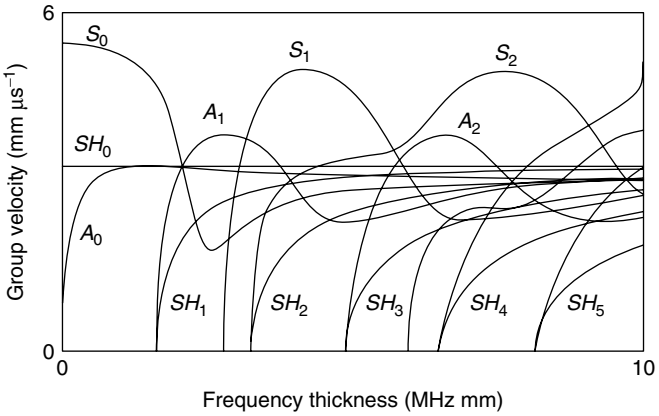

Figure 2. Group velocity dispersion curves for steel plate.

modes begin to appear and by 10 MHz mm there are some 15 possible modes. Example group velocity dispersion curves for steel are shown in Figure 2.

The usable propagation distances of guided waves for SHM or NDE in 2D waveguide structures are of the order of meters. The waves will actually propagate much further than this, but the complexity introduced by interactions with structural features make signal interpretation increasingly difficult. In 1D waveguide structures, such as pipes and rails, long lengths of uninterrupted structure may be present and interpretable guided-wave signals may be obtained even after propagation over distances of tens or even hundreds of meters.

2.2 Overview of guided-wave arrays

2.2.1 Monolithic devices versus arrays

The reason for using arrays for guided-wave testing is to allow waves from different modes and different directions to be separated, with the ultimate goal of localizing and characterizing damage by the guided waves scattered from that damage. Modal and directional selectivity can be achieved by various monolithic devices, including wedge transducers [3], electromagnetic acoustic transducers (EMATs) [4, 5], interdigital transducers (IDTs) [6], and comb transducers [7]. Examples of some of these devices are illustrated in Figure 3. The limitation of these devices is that they must be mechanically moved to obtain selectivity in different directions and need to be physically altered to obtain selectivity to different modes. The advantage of a correctly designed array is that this functionality can be obtained in postprocessing without any physical change to the array or its position.

2.2.2 Compact versus sparse distributed arrays

A distinction should be made between compact arrays where all the elements are in close proximity to

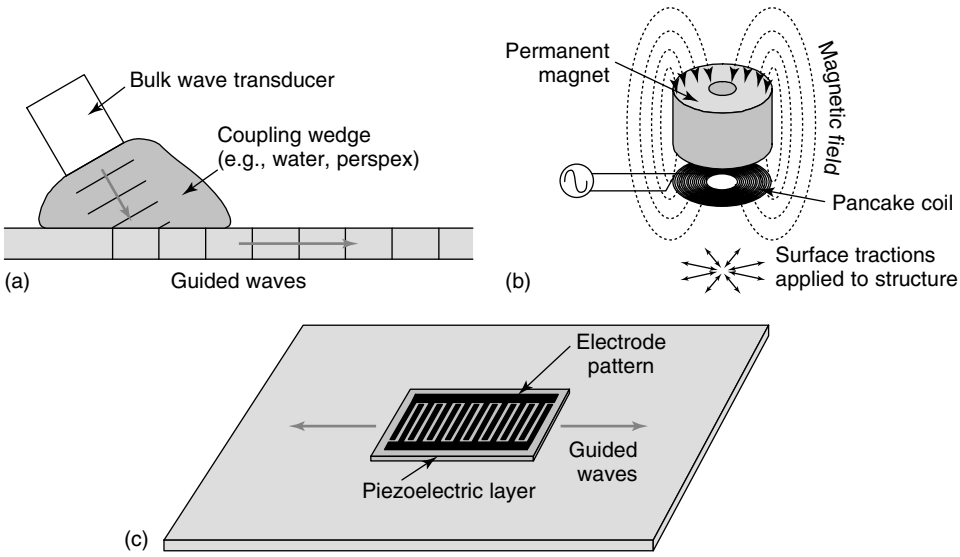

Figure 3. Monolithic transducers for guided waves: (a) wedge transducer, (b) EMAT [Reproduced from Ref. 5. © IEEE, 2005.] and (c) IDT. [Reproduced from Ref. 6. © Elsevier, 1997.]

one another, often in a single unit, and sparse distributed arrays. Deployable systems for NDE are generally compact arrays, while permanently attached systems may be either. The reason for using a compact array in a deployable system is to allow the reflected signals from multiple structural features to be resolved spatially. Without this attribute, it is generally impossible to reliably separate signals from damage, other than in structures with very low feature density or in laboratory experiments, where the location of damage can be controlled. In the case of a permanently attached system, the situation is potentially somewhat different, since subsequent data can be directly compared with the reference data. For this reason, the use of sparse distributed arrays is possible and may be a more economic solution than permanent attachment of compact arrays. Sparse distributed arrays are discussed separately in Section 5.

2.2.3 General requirements for compact arrays

To localize and characterize damage with a compact array, it is necessary to separate different guided-wave modes propagating in different directions. To achieve modal or directional selectivity, it is necessary to find a distinguishing guided-wave property that can be measured. Fundamentally, this must be one or more of the phase velocity, group velocity, or mode-shape properties. Differences in group velocity correspond to differences in arrival time and have limited use in deployable systems where there is often no *a priori* information about the location of scatterers. Measurements of differences in mode shape require access to different points in the cross section of the waveguide and are therefore generally not applicable to 2D waveguides, but are used extensively for mode separation in 1D waveguides. The measurement of differences in phase velocity (or wavenumber) is the fundamental basis of directional selectivity in guided-wave arrays. Phase velocity differences can also be used for modal selectivity if the phase velocities of the guided-wave modes are well separated.

The requirements and means of achieving modal and directional selectivity with compact arrays are somewhat different in the case of 1D and 2D waveguides as will be discussed in the following sections.

3 COMPACT ARRAYS FOR 1D WAVEGUIDE STRUCTURES

In a 1D waveguide, the number of possible propagation directions for guided waves is precisely two.

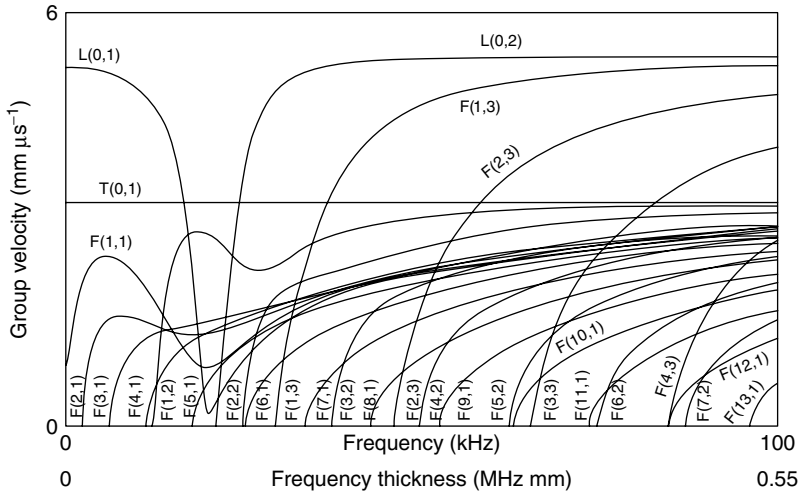

Figure 4. Group velocity dispersion curves for a 5.5-mm-thick steel pipe with internal diameter 76 mm, and also showing the equivalent frequency-thickness axis. [Reproduced from Ref. 9. © Elsevier, 1998.]

However, at useful operating frequencies for damage detection the number of possible guided-wave modes is high. For example, Figure 4 shows the dispersion curves for a 5.5-mm-thick steel pipe with an internal diameter of 76 mm. Although the frequency-thickness range in Figure 4 is much lower than that of the dispersion curves for steel plate shown in Figure 2, there are now many more modes. This is because of the additional constraint of periodicity around the circumference of the pipe, leading to the concept of angular order. A zero angular order mode has an axisymmetric and a first angular order mode has mode shape that is a sinusoidal distribution of displacements around the circumference with one period. In this article, the naming convention used for guided-wave modes in a pipe follows that described in [8]. The first numerical index refers to the order of the periodicity of the mode shape in the angular direction and the second refers to the through-thickness order of the mode. The prefix letters L and T are used to highlight axisymmetric (i.e., zero angular order) modes with through-thickness mode shapes similar to Lamb (L) or SH (T) type waves in a flat plate and the prefix letter F is used for all nonaxisymmetric modes.

The key to producing signals that can be readily interpreted is to achieve both modal and directional selectivity and this attribute is shared by all commercially successful guided-wave systems for NDE. In a 1D waveguide, directional selectivity is achieved by exploiting differences in phase velocity and modal selectivity by exploiting differences in phase velocity and/or mode shapes. In a 1D waveguide, differences in mode shape can be easily exploited as an array can contain multiple elements distributed around the perimeter of the waveguide cross section. In fact, the task of obtaining modal and directional selectivity can be generalized, but in the first instance the two are considered separately for the example case of a pipe.

3.1 Modal selectivity

The mode shapes of guided waves in pipes are characterized by various parameters, including the angular order. Of great importance in guided-wave NDE is the separation of modes with different angular orders, most commonly zero and one, as this provides valuable information about the nature of reflectors.

Consider a pipe instrumented with an array of four point transducers, identified by subscripts $j = 1-4$, evenly distributed around the outer perimeter as shown in Figure 5(a).

An angular datum is defined at the 12 o'clock position. As an example, it is assumed that under a particular set of operating conditions (i.e., frequency, transducer element type) only two modes of guided-wave propagation are possible, the first M_0, denoted

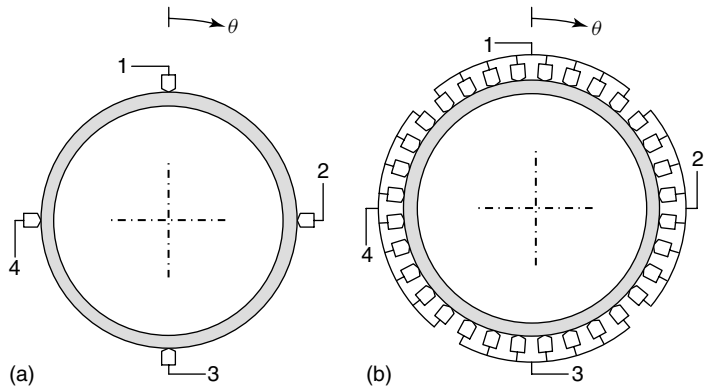

Figure 5. Schematic diagrams of pipe transducer arrays for modal selectivity based on angular order: (a) array of four transducers and (b) array of 32 transducers connected in quadrants.

by (0) superscripts, with angular order zero and the second, M_1, denoted by (1) superscripts, of angular order one. At a particular instant, the incident field on the array consists of quantities $A^{(0)}$ and $A^{(1)}$ of the two modes. The modal amplitudes are assumed to be defined in such a way that the particle displacement associated with each of the modes at a particular angular position, θ, around the circumference is expressed as

$$\begin{aligned} u^{(0)} &= A^{(0)} \\ u^{(1)} &= A^{(1)} \cos\left(\theta + \phi^{(1)}\right) \end{aligned} \tag{1}$$

where $\phi^{(1)}$ is the polarization angle of the mode M_1 (i.e., the angle at which its peak displacement occurs) with respect to the angular datum. Hence the associated particle displacement seen by the jth transducer in the array is

$$u_j = A^{(0)} + A^{(1)} \cos\left(\theta_j + \phi^{(1)}\right) \tag{2}$$

where $\theta_j = (j-1)\pi/2$ is the angle of the jth transducer. The objective of mode separation is to deduce the mode amplitudes $A^{(0)}$ and $A^{(1)}$ from the measured displacements u_j. In this case, the natural orthogonality of the different angular periodicity of M_0 and M_1 can be exploited. This means that the mode amplitudes can be extracted effectively from the first two terms of the discrete Fourier transform performed around the circumference with four sampling points at the transducer locations:

$$\begin{aligned} A^{(0)} &= \frac{1}{4}\sum_{j=1}^{4} u_j \\ A^{(1)} &= \frac{1}{2}\sqrt{\left(\sum_{j=1}^{4} u_j \cos\theta_j\right)^2 + \left(\sum_{j=1}^{4} u_j \sin\theta_j\right)^2} \end{aligned} \tag{3}$$

The two terms under the square root sign in the second expression relate to two perpendicular polarizations of the M_1 mode, the first term polarized in the vertical (0–180°) direction and the second polarized in the horizontal (90–270°) direction. For axisymmetric structures such as pipes, this type of Fourier approach can be extended to separating higher angular orders of modes in a straightforward manner. However, for waveguides with more complex cross sections, a more general approach is necessary. With this in mind, situation in the previous example can be described in matrix form:

$$\begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{bmatrix} = \begin{bmatrix} 1 & 1 & 0 \\ 1 & 0 & 1 \\ 1 & -1 & 0 \\ 1 & 0 & -1 \end{bmatrix} \begin{bmatrix} A^{(0)} \\ A^{(1v)} \\ A^{(1h)} \end{bmatrix} \tag{4}$$

where $A^{(1v)}$ and $A^{(1h)}$ refer to the components of the M_1 mode in the vertical and horizontal polarization directions and hence its overall amplitude is

$$A^{(1)} = \sqrt{\left[A^{(1h)}\right]^2 + \left[A^{(1v)}\right]^2} \tag{5}$$

The matrix equation (4) describes an overdetermined set of linear equations, and the matrix is referred to as the *mode-shape matrix*. Each column in the mode-shape matrix refers to the displacement of a mode at each of the transducer locations. The overdetermined system of equations can be solved in a manner that minimizes the least squares error by the application of the Moore–Penrose inversion technique [10]. This technique yields

$$\begin{bmatrix} A^{(0)} \\ A^{(1v)} \\ A^{(1h)} \end{bmatrix} = \frac{1}{4}\begin{bmatrix} 1 & 1 & 1 & 1 \\ 2 & 0 & -2 & 0 \\ 0 & 2 & 0 & -2 \end{bmatrix}\begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \end{bmatrix} \tag{6}$$

It is easy to see that this equation is equivalent to equation (3). However, this is a more general formulation that can be applied to 1D waveguides of arbitrary cross section. The requirement is that there must be more transducer positions than there are modes, and that the resulting mode-shape matrix is not ill-conditioned. Note that in the case of the pipe example, the mode-shape matrix is frequency independent and the mode separation technique could be applied in either the time or the frequency domain. However, this is not the case in general and if the mode-shape matrix is frequency dependent it should strictly be recalculated for each frequency present in the signals and applied in the frequency domain.

It should be noted that in 1D waveguides such as pipes the number of modes is potentially quite high because of the large number of angular orders possible. However, if higher order modes are not to be used for testing then they can be suppressed by the array design itself. For example, an array with 32 physical elements around the perimeter of a pipe could have groups of eight adjacent elements connected in parallel to form four quadrants as shown in Figure 5(b). Although this would only allow zero and first-order modes to be used for testing it would still suppress modes up to 16th order.

3.2 Directional selectivity

Point measurements at a single axial location along a 1D waveguide can be used to separate modes but not directions.[a] To separate directions of propagation, it is necessary to measure the relative phase of a wave at two different axial positions. As an example, consider the situation where harmonic waves of frequency ω of the same mode are propagating in both directions along a 1D waveguide. Let x be the distance along the waveguide, and $A^{(+)}$ and $A^{(-)}$ be the (complex) amplitudes of the wave propagating in the positive and negative x directions respectively. The measured displacement, U_j, at an axial position x_j along the waveguide is therefore

$$U_j = A^{(+)}\mathrm{e}^{\mathrm{i}(kx_j - \omega t)} + A^{(-)}\mathrm{e}^{\mathrm{i}(-kx_j - \omega t)} \tag{7}$$

where k is the wavenumber of the mode at the frequency ω. The problem is to deduce the values of $A^{(+)}$ and $A^{(-)}$ from the measured displacements, of which there must clearly be at least two. For the case of two transducers at locations x_1 and x_2 ($x_2 > x_1$), the previous expression can be written in matrix form as

$$\begin{bmatrix} U_1 \\ U_2 \end{bmatrix} = \begin{bmatrix} \mathrm{e}^{-\mathrm{i}k\delta} & \mathrm{e}^{\mathrm{i}k\delta} \\ \mathrm{e}^{\mathrm{i}k\delta} & \mathrm{e}^{-\mathrm{i}k\delta} \end{bmatrix}\begin{bmatrix} \mathrm{e}^{\mathrm{i}kx_0} & A^{(+)} \\ \mathrm{e}^{-\mathrm{i}kx_0} & A^{(-)} \end{bmatrix} \tag{8}$$

where $2x_0 = x_1 + x_2$ and $2\delta = x_2 - x_1$ and the time-harmonic term has been omitted for clarity. The complex exponential terms containing x_0 are grouped with the unknown amplitudes $A^{(+)}$ and $A^{(-)}$, since these are the unknown phase shifts due to propagation from the source of the waves (i.e., a reflector) and the center of the array. Once again, the solution is obtained by inversion of the matrix

$$\begin{bmatrix} \mathrm{e}^{\mathrm{i}kx_0} & A^{(+)} \\ \mathrm{e}^{-\mathrm{i}kx_0} & A^{(-)} \end{bmatrix} = \frac{-1}{2i\sin 2k\delta}\begin{bmatrix} \mathrm{e}^{-ik\delta} & -\mathrm{e}^{\mathrm{i}k\delta} \\ -\mathrm{e}^{ik\delta} & \mathrm{e}^{-\mathrm{i}k\delta} \end{bmatrix}\begin{bmatrix} U_1 \\ U_2 \end{bmatrix} \tag{9}$$

If $2k\delta = n\pi$ (n, an integer), then the matrix is singular, and the closer $2k\delta$ is to $n\pi + \pi/2$ the more stable the inversion. Practically, this means that the optimum spacing between transducers is 1/4λ, 3/4λ, etc. For nondispersive modes, the complex exponential terms in the matrix act as time shifts, but for accurate directional selectivity of dispersive modes, the procedure should again be applied in the frequency domain.

3.3 Generalized problem

From the preceding sections, it can be seen that the mathematical basis for separating received modes and

directions are very similar, and both can be combined in general form:

$$\mathbf{U}(\omega) = \mathbf{M}(\omega)\mathbf{A}(\omega) \tag{10}$$

where the vector **U** represents the measured displacements, **M** is the mode-shape matrix and **A** is the vector of unknown amplitudes. In this general formulation **U** now contains measurements both around the perimeter of the waveguide and along its axis. Similarly **M** contains both mode-shape information and phase according to the axial position of the associated transducer and the coefficients in **A** are for each possible mode in each direction. Again, the matrix **M** needs to be inverted using an appropriate technique.

The discussion thus far has considered reception only. The same arguments can be applied in transmission to determine what amplitude and phasing of transducers is required to transmit a particular mode in a particular direction. By virtue of reciprocity, the quantities turn out to be precisely the same as those required to receive the same mode in that direction. The most general form of the combined transmit and receive situation can be written in the same way as equation (10), except that the displacement vector **U** now has N^2 elements (N being the total number of elements in the array) and each element in **U** now corresponds to the signal transmitted and received between that pair of elements. This type of approach has been used to perform the processing in 1D waveguides such as rails [11] that support multiple modes.

3.4 Example—pipe inspection

Pipe inspection is the most successful example of any type of long-range guided-wave inspection. At least three companies, Guided Ultrasonics Ltd [12], Pipeline Integrity Ltd [13], and MKCNDT [14], supply commercial guided-wave systems for pipe inspection, primarily targeted at the petrochemical industry. The fundamental principles of these systems is similar, the main differences lie in the type of transducer elements used with guided ultrasonics and pipeline integrity favoring piezoelectric devices, while MKCNDT use magnetostrictive sensors. A typical result obtained using the guided ultrasonics system is shown in Figure 6 as an example, which illustrates the key aspects of long-range guided-wave NDE. The data is presented in the form of an A-scan, with the abscissa indicating range measured from the test location and the ordinate axis representing reflected signal amplitude. An array is used to transmit an axisymmetric torsional mode, T(0,1), into the pipe and then to separate received signals into those that return as the same mode, and those that have been mode converted to a mode with angular order one, F(1,2). The directly reflected T(0,1) signals are indicated by the black line and the mode converted T(0,1) to F(1,2) signals are indicated by the gray line. The dominant features in the black signal are a series of regularly spaced reflections from butt welds between pipe sections. The challenge is discriminating between signals from benign structural

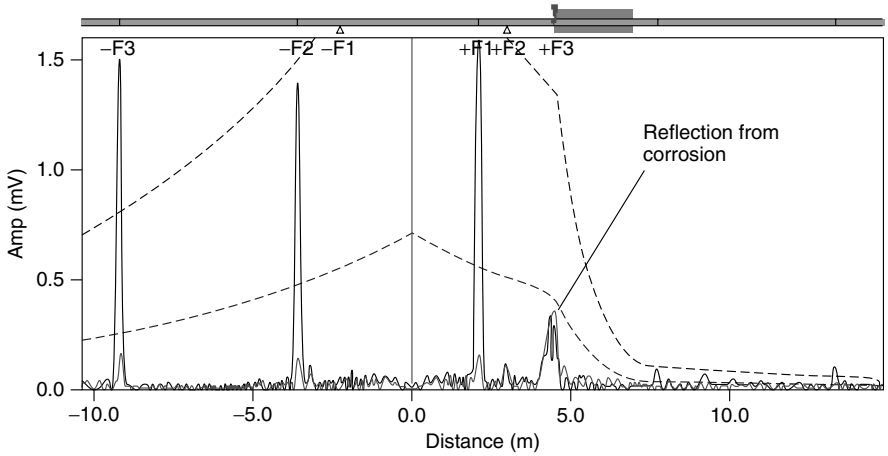

Figure 6. Example of results obtained from guided-wave pipe inspection system. [Reproduced with permission from Guided Ultrasonics Ltd.]

features such as these and defects. In pipe inspection, this is the reason for using multiple modes. The axisymmetric butt welds do not cause any mode conversion of the incident T(0,1) wave and hence there are no corresponding peaks in the gray mode converted signal. However a patch of localized corrosion at a distance of approximately 5 m produces a peak in both the reflected T(0,1) mode and the F(1,2) mode, indicating a nonaxisymmetric feature and possible defect.

4 COMPACT ARRAYS FOR 2D WAVEGUIDE STRUCTURES

In a 2D waveguide structure, access is generally restricted to one surface of the waveguide and differences in mode shape cannot be used to separate different modes.[b] Instead, modal and directional selectivity must be achieved by exploiting differences in the phase of waves at different points on the surface. This is much more similar to the case of a bulk wave ultrasonic array transducer, but with two important differences.

First, there are the usual complicating properties of guided waves, such as dispersion and multiple modes. However, the issue of modal selectivity is often overstated in the case of 2D waveguides, where there are only three possible modes (A_0, S_0, and SH_0) at typical operating frequencies below 2 MHz mm. These modes have significantly different properties and unwanted modes can generally be suppressed by the careful design of array elements themselves. For example, a piezoelectric disc operating in through-thickness mode is an order of magnitude more sensitive to A_0 than S_0 and completely insensitive to SH_0. Similarly, EMAT elements can be designed to be much more sensitive to S_0 than A_0 [5]. A general procedure for modeling the sensitivity of guided-wave transducers to different guided-wave modes in isotropic and anisotropic 2D waveguides using a Green's function formulation is described in [15]. The problem of dispersion is actually not a problem; as long as the dispersive properties of the waveguide are known, all processing can be performed in the frequency domain and dispersion compensation [16] applied.

The second and more important complication for guided-wave arrays over bulk wave arrays is the fact that a guided-wave array is in the middle of the wavefield rather than being at a boundary. This means that any consideration of directionality for guided-wave arrays must consider the wavefield in all 360° about the array, even if the array is only designed to detect damage over a limited range of angles. For example, the wavefield in front of a linear array comprising a single row of elements on the surface of a unimodal 2D waveguide will be very similar to the wavefield from an equivalent linear array for bulk waves. The crucial difference is that the guided-wave array will also emit an identical wavefield behind the array as well and it is impossible to subsequently distinguish which side of the array a reflector is on. This means that linear guided-wave arrays with a single row of elements have little practical use with 2D waveguides, although they have been used as a research tool in controlled laboratory experiments [17–19].

4.1 Omni-directional inspection

A generic application for 2D waveguide arrays is to interrogate the surrounding area of a structure in all directions. This suggests a layout of array elements that is approximately (i.e., as far as the discretization into elements will allow) axisymmetric. In such a design, the elements themselves should exhibit omnidirectional selectivity. For such arrays, it is useful to describe performance in terms of a polar coordinate system with its origin at the center of the array. Figure 7(a–c) shows some candidate designs for 2D arrays, including two that are axisymmetric and one gridlike design that is not.

The expression for the intensity, I, of a point in an image using data from a bulk wave array is given by the delay and sum equation:

$$I(\mathbf{r}) = \sum_{m=1}^{N} \sum_{n=1}^{N} A\left(\mathbf{r}, \mathbf{d}_{(\mathbf{m})}, \mathbf{d}_{\mathbf{n}}\right) h_{(m)n} \times \left(t = \tau\left(\mathbf{r}, \mathbf{d}_{(\mathbf{m})}, \mathbf{d}_{\mathbf{n}}\right)\right) \tag{11}$$

where $h_{(m)n}(t)$ is the time (t) domain recorded when the mth element acts as a transmitter and the nth element acts as a receiver, $\mathbf{r}$ is the point in the image, A is the amplitude factor, τ is the delay, $\mathbf{d}_{(\mathbf{m})}$ is the position of the transmitter element, and

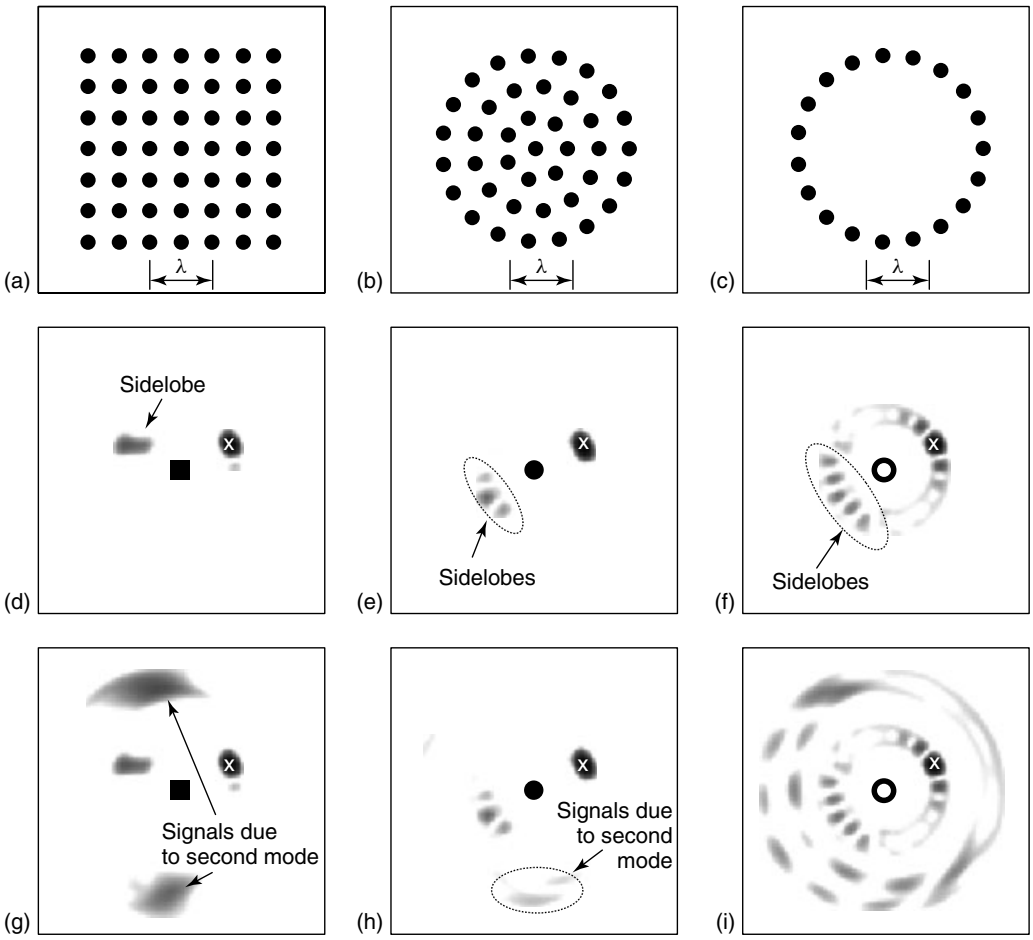

Figure 7. (a–c) Possible 2D array designs for omni-directional inspection of 2D waveguides showing the target wavelength; (d–f) associated PSFs for a reflector at the location marked x assuming a nondispersive unimodal system; (g–i) associated PSFs assuming a nondispersive bimodal system where the unwanted second mode has half the wavelength of the first mode. In (d–i) the signal used is a Gaussian windowed toneburst with an 80% bandwidth at −40 dB and the gray scale is from 0 dB (black) to −40 dB (white).

$\mathbf{d_n}$ is the position vector of the receiver element. The summations are performed over the N elements in the array, assuming in this case that each element acts both as transmitter and receiver, although this is not a necessity. This expression is applicable to all linear imaging algorithms, the difference being in the choice of coefficients, A, and delays, τ [1].

Equation (11) is also valid for a guided-wave array if the waves are nondispersive, but is more usefully written in the frequency domain, as this allows for frequency-dependent time delays to be applied (as phase shifts in the frequency domain) if necessary:

$$I(\mathbf{r}) = \int \sum_{m=1}^{N} \sum_{n=1}^{N} A\left(\mathbf{r}, \mathbf{d_{(m)}}, \mathbf{d_n}, \omega\right) H_{(m)n}(\omega)\, \mathrm{d}\omega \tag{12}$$

where $H_{(m)n}$ is the Fourier transform of the signal received when the mth element is transmitting and the nth element is receiving, and A is now a complex coefficient that includes phase and amplitude components. The challenge is the selection of coefficients, A, to give the best imaging performance. In terms of characterizing the imaging performance, both the

approaches of beam profile and point spread function (PSF) modeling may be employed [1].

The most conceptually simple choice of coefficients, A, is to select those which make the mode of interest arrive in phase when the array is focused at each point, $\mathbf{r}$, in the image. In this case,

$$A\left(\mathbf{r}, \mathbf{d}_{(\mathbf{m})}, \mathbf{d}_{\mathbf{n}}, \omega\right) = \mathrm{e}^{\mathrm{i}k(\omega)\left(|\mathbf{r}-\mathbf{d}_{(\mathbf{m})}|+|\mathbf{r}-\mathbf{d}_{\mathbf{n}}|\right)} \qquad (13)$$

where $k(\omega)$ is the wavenumber of the guided-wave mode. This is analogous to the total focusing algorithm for bulk wave arrays [20]. The larger the ratio of the overall dimension of the array to the wavelength of the guided-wave mode, the better the resolution. PSFs calculated using this approach for the arrays shown in Figure 7(a–c) are shown in Figure 7(d–f). In all cases, it is assumed that there is one nondispersive mode present with the wavelength indicated in the figure.

There are two reasons why this approach does not necessarily give good results in the case of a 2D guided-wave array. First, there is the potential problem of multiple modes. If the elements are sensitive to more than one mode, then application of equations (12) and (13) to one mode may cause an unwanted mode to be steered in a different direction. If this happens, phantom signals appear at incorrect positions in the PSF at different radial distances (because of the velocity differences between modes) and different angular positions. Whether this occurs depends on both the element configuration and the relative wavenumbers of the guided-wave modes involved. Example PSFs for the arrays shown in Figure 7(a–c) operating in a bimodal environment are shown in Figure 7(g–i). The second potential problem, that occurs even in a unimodal environment is the appearance of large sidelobes in the PSF over a wide range of angular positions, which can be seen to varying degrees in all of Figure 7(d–f). A fully populated circular array, Figure 7(b), comes close to providing optimum performance as shown in Figure 7(e). If the array only consists of the perimeter elements, Figure 7(c), then there is a severe degradation of the PSF as shown in Figure 7(f). The reason why the design shown in Figure 7(c) is of interest is because of the significantly reduced number of elements compared with a fully populated array of the same diameter.

To improve the situation with an array that is not fully populated such as that shown in Figure 7(c), it is necessary to choose different coefficients, A, than those suggested by equation (13). The problem with equation (13) is that the coefficients are chosen simply to maximize the signal due to the desired mode at each point in the image, $\mathbf{r}$, in turn; what occurs elsewhere in the image as a consequence of this is ignored. Conceptually this can be written as

$$\frac{|I(\mathbf{r})|^2}{\sum_{m,n} |A\left(\mathbf{r}, \mathbf{d}_{(\mathbf{m})}, \mathbf{d}_{\mathbf{n}}, \omega\right)|^2} \rightarrow \max^{\mathrm{c}} \qquad (14)$$

A more sophisticated choice of coefficients must in some way consider the overall image. One possibility that can be applied to axisymmetric element configurations is to use angular deconvolution [21]. This is because the PSF of such an array is angularly invariant, hence the angular content of an image obtained using equations (12) and (13) is the angular convolution of a number of delta functions with the angular PSF of the array. Conventional deconvolution techniques can therefore be applied and this is most easily performed in the Fourier domain. Here, the angular Fourier transform of an image obtained using equations (12) and (13) is divided by the angular Fourier transform of the PSF and the final image is the inverse angular Fourier transform of the result. The deconvolution technique does not allow perfect delta functions to be observed in the final image, as the angular Fourier transform of the PSF from a finite sized array only contains information up to a limited number of angular orders. Division of angular spectra beyond this point results in extreme sensitivity to noise in the original data and hence some form of angular order filter must be applied. However, as long as the angular spectrum of the PSF from the array does not contain any zeros up to this point, the final result is a PSF that resembles that which would be obtained by direct application of equations (12) and (13) to data from a fully populated array of the same size.

A more general approach that can be applied to any array configuration is the maximization of contrast technique [22]. This seeks to maximize the signal at the focal point relative to the total signal elsewhere in the image and can be written as

$$\frac{|I(\mathbf{r})|^2}{\int |I(\mathbf{r}')|^2 \, d\mathbf{r}'} \rightarrow \max \tag{15}$$

Unfortunately, direct application of this technique leads to an unstable solution, where a small amount of random noise in data leads to a major deterioration in image quality. This is because equation (15) implies that the array can be focused at a single point that cannot be physically achieved with an array of finite dimensions. This is analogous to performing the previously described angular deconvolution without a filter. An enhancement that improves stability is to perform the following optimization instead:

$$\frac{\int_{\mathbf{r}+\boldsymbol{\varepsilon}} |I(\mathbf{r}')|^2 \, d\mathbf{r}'}{\int |I(\mathbf{r}')|^2 \, d\mathbf{r}'} \rightarrow \max \tag{16}$$

where $\mathbf{r} + \boldsymbol{\varepsilon}$ is a region in the image in the vicinity of the focusing point. The choice of the size of $\boldsymbol{\varepsilon}$ is made with knowledge of the best resolution that the array can achieve. Again, the final result is a PSF close to that which would be obtained from a fully populated array with the same overall dimensions.

If the integrals in equations (15) and (16) are instead considered as summations over finite numbers of angular directions, it can also be shown that the maximization of contrast technique is the same as the Moore–Penrose solution to the generalized problem for 1D waveguide arrays, described in Section 3.3. Finally, it should be noted that the maximization of contrast techniques can, in principle, be readily extended to dealing with the suppression of unwanted modes. This is performed by extending the denominator of equation (16) to include the integrations over the images from unwanted mode combinations.

4.2 Examples

4.2.1 Deployable arrays

In 2000, Wilcox *et al.* [17] demonstrated a prototype design for a fully populated 2D array with 16 elements, as shown in Figure 8. The array used 5-mm-diameter piezoelectric elements operating in the through-thickness mode to excite and detect the A_0 Lamb wave mode. The array was able to achieve a signal to coherent noise ratio of more than 30 dB when deployed on a large 5-mm-thick aluminum plate and was able to detect the signal scattered from a bonded mass simulating the presence of a localized defect. It was recognized that in many practical situations the A_0 mode is not a suitable choice because of its high attenuation, if the plate is in contact with liquid on one or both sides.

To widen the application scope, the same authors subsequently developed a deployable omnidirection array using EMAT elements to perform 2D inspection using the S_0 Lamb wave mode [23]. The EMAT

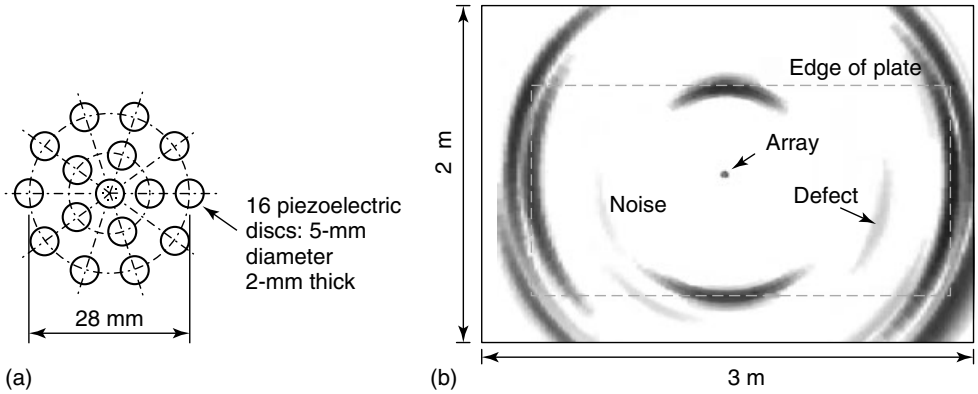

Figure 8. Example of use of deployable circular array from [17] showing (a) layout of array and (b) example results from a 2.5 m by 1.25 m by 5-mm-thick aluminum plate with a bonded mass simulating a defect. The gray scale in (b) is from 0 dB (black) to −30 dB (white). [Reproduced from Ref. 17. © American Institute of Physics, 2000.]

elements have the unique property of acting as omnidirectional sources and receivers of this mode. They also have the advantage of being noncontact and so do not require a couplant. It was shown [5] that the EMAT diameter required to optimize the S_0 sensitivity was considerably more than the maximum interelement spacing needed in an array to prevent spatial aliasing. As a result, it was necessary to overlap adjacent elements, an obstacle that was only surmountable because the EMAT coils could be printed onto a multilayer printed circuit board. The layout of elements is shown in Figure 9(a) and example results in Figure 9(b).

4.2.2 Permanently attached arrays

Subsequently, Fromme *et al.* [24] refined the A_0 array concept of [17] to make a compact self-contained device designed for permanent installation on offshore structures. The device is shown in Figure 10(a) and (b) and some example results from a 5-mm-thick steel plate are shown in Figure 10(c). The device achieved a superior angular resolution to that described in [17] by first, using 32 rather than 16 elements, and second, by arranging these in a ring and using the angular deconvolution algorithm to suppress sidelobes.

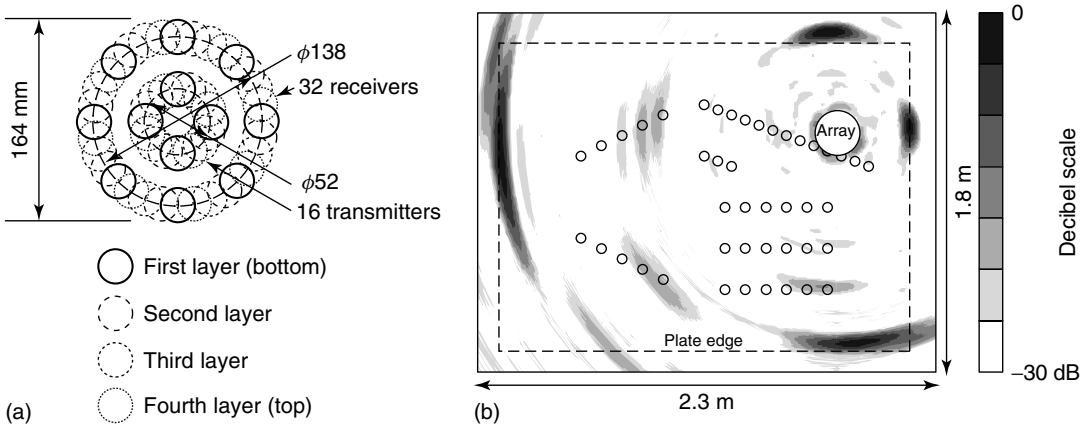

Figure 9. Example of deployable array from [23] with EMAT elements showing (a) array layout and (b) example results from a 6-mm-thick steel plate containing multiple artificial defects. [Reproduced from Ref. 23. © IEEE, 2005.]

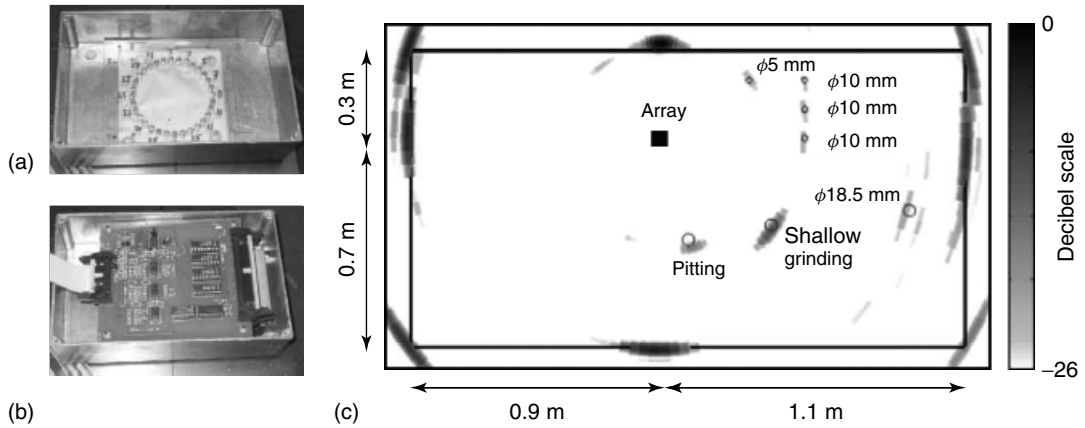

Figure 10. Prototype circular array from [24] showing (a) array, (b) multiplexing circuitry, and (c) example results from a 2 m × 1 m × 5 mm thick steel plate containing a number of artificially introduced defects. [Reproduced from Ref. 24. © IEEE, 2006.]

Giurgiutiu *et al.* [18] have also built permanently attached arrays, this time using so-called piezo wafer active sensors (PWASs) as the array elements (*see* **Piezoelectric Wafer Active Sensors**). The thin PWAS devices provide shear tractions on the surface of the waveguide and are hence particularly sensitive to S_0 Lamb waves, if bonded to the surface. Figure 11(a) shows the layout of a simple linear array of nine PWASs and Figure 11(b) shows example results where a crack was detected within the field of view of the array. Note that the linear array has no directionality about its centerline, hence the clarity of the image shown relies on the absence of any reflectors behind the array. Diamanti *et al.* [19] have also published results from a linear array, this time using the A_0 mode at low frequency (20 kHz) in a composite plate to detect impact damage in a composite plate. In this case, the array was mounted close to an edge of the plate, hence eliminating the problem of backward propagating waves.

The previous examples have all considered the plates as isotropic. In principle, many of the concepts can be applied to highly anisotropic composite plates, but these introduce some additional complexity. First, the choice of guided-wave mode in composites becomes more critical, as the attenuation of certain modes at certain frequencies can be prohibitively high. Secondly, the anisotropic material properties mean that guided-wave propagation is different in different directions. Rajagopalan *et al.* [25] have attempted to solve this problem through the adaptation of the basic imaging equation to account for directionally dependent wavenumbers.

Reference should also be made to the work of Sicard *et al.* [26] who have exploited array-based processing techniques with scanned guided-wave probes to perform defect characterization and Rose *et al.* [7] who have used comb type transducers for mode selection.

5 SPARSE DISTRIBUTED ARRAYS

For a permanently attached guided-wave system for damage detection, it is possible to exploit differences in the response of the structure over the course of time due to the appearance of damage. This approach is referred to as *reference signal comparison*. In the context of reference signal comparison, the compact arrays described previously are not necessarily the best solution, since the ability to detect damage by spatially resolving it from structural features is no longer required. Instead, the array needs only to be able to locate the signal from a single scatterer (the damage). The assumption of only one damage location occurring at any one time is a perfectly valid starting point in most practical situations where the occurrence of any damage is a fundamentally infrequent event.

5.1 Localization

If it is assumed *a priori* that there is only one scatterer present then localization is a trivial problem that can be achieved with as few as three sensing elements, by direct application of equations (12) and (13). The data

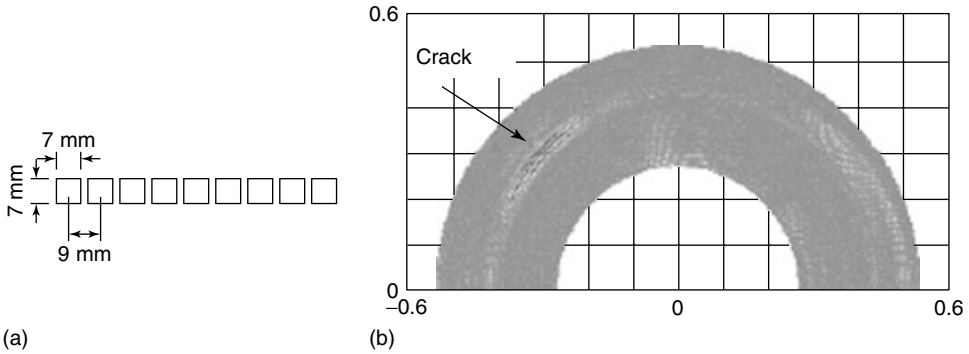

Figure 11. Permanently attached linear array using piezo wafer active sensors (PWASs) from [18] showing (a) array, (b) example results obtained on a 1-mm-thick aluminum plate containing a 19-mm-long machined crack. [Reproduced from Ref. 18. © Sage Publications, 2005.]

from a pair of sensors in the array produces an ellipse in the image with the sensors at the foci [27]. The intersection point of the ellipses from three or more pairs of sensors (i.e., at least three separate sensors acting in pitch–catch mode) defines the damage location. This is illustrated with simulated data in Figure 12(a). Note that the success of the approach is predicated on there being only one scatterer present, hence its use in conjunction with reference signal comparison. If there are multiple scatterers present, then the image rapidly becomes too complex to interpret, as shown in the example in Figure 12(b) where reflections from eight additional structural features as well as the direct transmission between transducer pairs have been added. The reflectors represent the edge and corner reflections from a rectangular plate.

5.2 Reference signal comparison

The far bigger challenge for any permanently installed system that relies on reference signal comparison is robustly performing the comparison itself, whether this is performed by simple subtraction or by more complicated methods. The problem is that the reference signal is likely to contain multiple large signals due to reflections from structural features, while the size of potential signals scattered from damage is much smaller. Whatever method of comparison is used, the signals from structural features must be suppressed by a significant amount, the remnants of these signals constituting the noise of the system [28]. If the noise is greater than the size of signals from damage, then the damage cannot be reliably detected. The following simple calculation gives an idea of the numbers involved and the degree of noise suppression necessary. A straight edge of a structure is the largest reflector likely to be encountered in practice, and has a 100% reflection coefficient for normally incident S_0 and A_0 guided waves. If a pointlike transducer emits a guided wave, then in the absence of material losses, the amplitude of the wave decreases in proportion to the square root of the propagation distance. The amplitude, A_{refl}, of

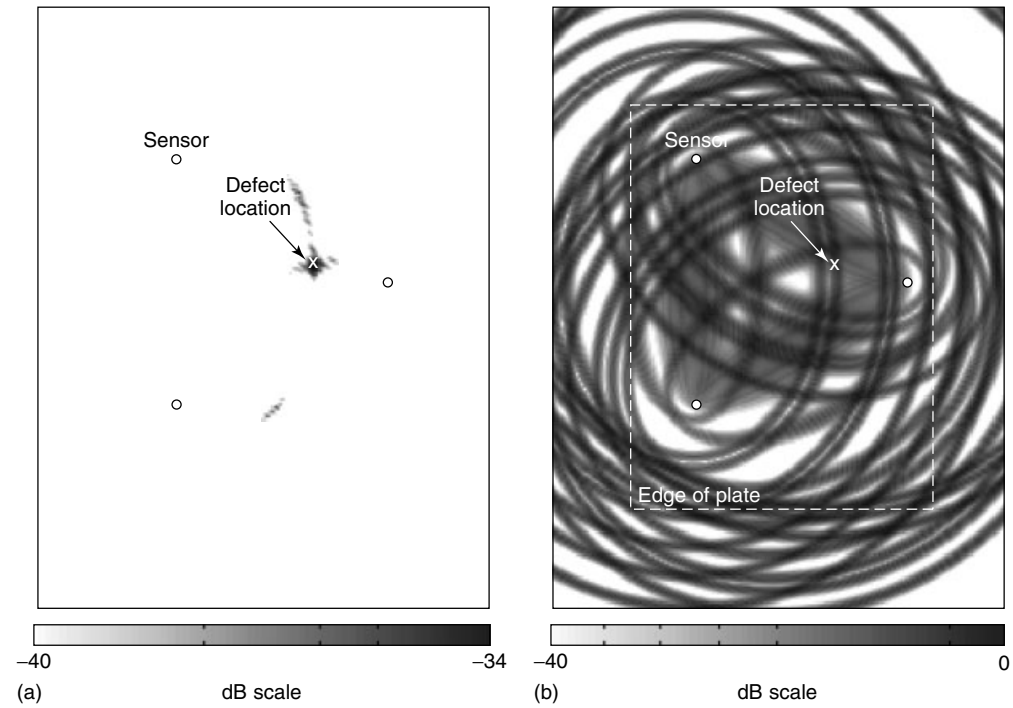

Figure 12. Localization using pitch–catch data from a sparse distributed array of three sensors in (a) the presence of a single scatterer and (b) multiple scatterers from the structural features indicated.

a received signal reflected back from an edge of the structure at a distance d from the transducer is therefore

$$A_{\text{refl}} = \frac{A}{\sqrt{2d}} \tag{17}$$

where A is the amplitude of the outgoing wave at unit distance. The fact that these signals decay with root distance dependence is very important. A signal reflected from damage will undergo secondary scattering and the received amplitude, A_{damage}, will be of the form:

$$A_{\text{damage}} = \frac{AR}{d} \tag{18}$$

where R is the backscattering reflection coefficient of the damage. Although at this stage R is not known, it is already clear from equations (17) and (18) that the anticipated signal amplitude as a function of distance from a particular type of damage decreases at a faster rate than that from large structural features. In other words, the ratio of signals from damage to signals from features is expected to decrease with $d^{-1/2}$. This in itself would not be a problem if the comparison process perfectly suppressed all signals due to structural features. Unfortunately, the signals from structural features do not remain precisely the same due to environmental changes such as temperature, which perturb the velocity of guided waves.

For signal comparison based on subtraction, it is straightforward to show that, if the temperature changes, the fraction of a signal from a structural feature remaining after subtraction increases in proportion to the propagation distance, d. This, combined with equations (17) and (18), means that the overall signal-to-noise ratio (SNR) decreases with $d^{-3/2}$. Without performing some sort of temperature compensation, it can be shown [28] that the inter-sensor spacing needed to reliably monitor a structure is very small indeed. As a consequence of the $d^{-3/2}$ signal to noise dependence, it can further be shown that each 15 dB improvement in the SNR corresponds to an order of magnitude reduction in the number of sensors required to monitor a given area of the structure. Hence, any improvement in the SNR is very valuable. Croxford *et al.* [29] demonstrated two candidate temperature compensation techniques that both gave SNR improvements of around 30 dB under varying temperature conditions, as shown in Figure 13. One technique was inspired by the work

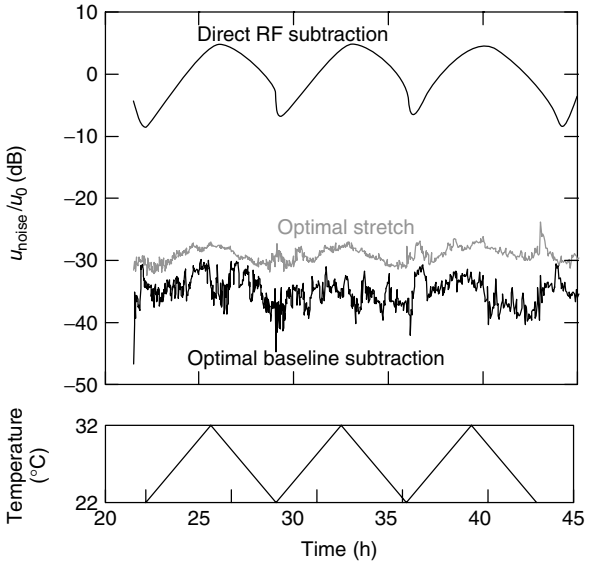

Figure 13. Measurement of remnant signal (u_{noise}) amplitude after performing reference signal comparison by subtraction under cyclic temperature variations of 10 °C. The reductions in noise level obtained by the application of two candidate compensation techniques (optimal stretch and optimal reference subtraction) are also shown. [Reproduced with permission from Ref. 29. © SPIE, 2007.]

of Lu and Michaels [30], where the best matched reference signal from an ensemble of signals recorded at different ambient temperatures was selected. The second is based on the optimization of a simple mathematical dilation operation applied to the reference signal that mimics the effect of the change in guided-wave velocity due to temperature variations.

5.3 Examples

Acellent Technologies Inc. [31] manufacture one of the few commercially available guided-wave SHM systems (*see* **Stanford Multiactuator–Receiver Transduction (SMART) Layer Technology and Its Applications**). Their product utilizes a distributed array of piezoelectric devices (the "SMART layer") in a grid pattern mounted on a flexible sheet that can be either embedded or mounted to the surface of a component. Guided-wave signals are transmitted between pairs of transducers. Proprietary software is used to detect changes between reference and subsequent signals and uses this information to produce a map of potential damage locations in a structure. As the sensor pitch is around 100 mm, the number of sensors required to instrument the whole of a large structure is very large and the system is presumably designed for damage detection in known "hot-spot" regions. A picture of the transducer layer is shown in Figure 14. The advantage of a small sensor pitch is, for the reasons described previously, a combination of increased sensitivity to damage (since the damage will necessarily be nearer to a sensor) and reduced sensitivity to temperature. Demonstration results have been obtained on a variety of components, including metals [32] and composites [33], but routine deployment in industrial situations has not yet occurred.

Konstantinidis *et al.* [27] and Lu and Michaels [30] both attempt to use widely spaced arrays of sensors for damage detection, although the subsequent

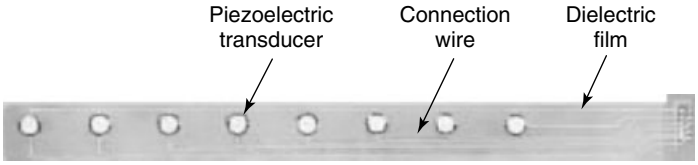

Figure 14. Picture of the Acellent SMART layer device. [Reproduced from Ref. 27. © Institute of Physics Publishing, 2006.]

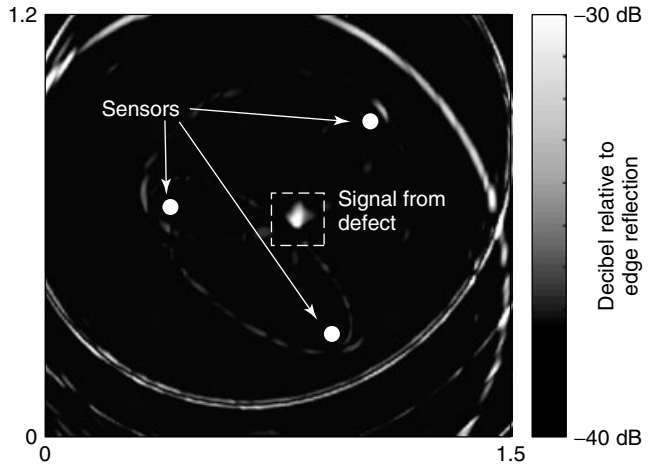

Figure 15. Results obtained by Konstantinidis *et al.* [27] on a 1.5 m × 1.25 m × 3 mm thick aluminum plate using an array of three piezoelectric transducers and optimal reference subtraction. [Reproduced from Ref. 32. © Institute of Physics Publishing, 2006.]

processing methodology is different. The former simply use the earlier part of the time–domain signal recorded from different sensor pairs and effectively isolate the signal directly scattered from a defect. Lu and Michaels use information in the diffuse field that occurs over a much longer time period. Both groups of workers use reference signal comparison to identify changes in the structural response, with Konstantinidis *et al.* opting for a direct subtraction and Lu and Michaels using an integrated root mean square approach. The reference signal comparison methods are both sensitive to temperature fluctuations and similar temperature compensation schemes based on ensembles of reference signals are used. Example results obtained by Konstantinidis *et al.* are shown in Figure 15.

It is appropriate to mention the use fiber Bragg gratings (FBGs) as detectors of guided-wave signals. The advantage is the relative ease with which a distributed network of such sensors can be embedded in a composite structure. The principle is that multiple FBGs can be etched onto the same fiber and interrogated separately either using temporal or (optical) wavenumber multiplexing. Betz *et al.* [34, 35] have studied the sensitivity of such sensors to Lamb waves, and the sensors appear to be ideal for use as a distributed array of guided-wave receivers. It should be stressed that FBGs do not overcome any of the other difficulties associated with distributed guided-wave arrays, and still require a different device, such as a piezoelectric one to act as a transmitter. The latter point is a rather major limitation, since if the transmitters in an array still need to be piezoelectric elements, the advantage of using FBG receivers is somewhat reduced.

6 CONCLUSIONS

The physical principles of array operation and processing have been reviewed with specific reference to the use of guided-wave arrays for NDE and SHM applications. The reason for using arrays in these applications is to improve the detection, localization, and characterization of defects. In all cases, the factor that ultimately limits detectability is coherent noise because of interaction between guided waves and benign features in the structure. In the case of deployable arrays for NDE, the primary purpose of using an array is to enable signals from defects to be resolved from signals due to benign features. This resolution is generally achieved spatially, but can also be achieved by separating different types of interaction with guided waves, using the information in multiple modes. However, even with state-of-the-art spatial resolution, long-range guided-wave NDE is fundamentally limited to structures with low feature density such as pipes. For this reason, widespread use of guided-wave NDE devices for complex structures, such as aircraft fuselages, is unlikely to ever occur, as interpretation of signals is too difficult.

Demonstrator SHM systems operating on the same principles as the NDE devices have been built, but there has been little or no commercial take up to date. The reason for this is that such systems remain limited to geometrically simple structures with low feature density, and the cost and complexity of such systems is prohibitively high for most suitable applications. However, within the SHM paradigm of a permanently installed system, the obstacle of structural complexity may be surmountable in the future. This is because comparison with reference signals can be performed, that, in principle, enables signals due to structural features to be eliminated. If this can be achieved, the requirements for array processing become trivial, since the *a priori* assumption that there is only one scatterer present (the defect) can be made.

Unfortunately, the suppression of signals from structural features using a reference signal is a very difficult problem, because of environmental fluctuations. Even temperature changes of a few degrees have been shown to cause changes in signals that are much larger than those due to defects. Robustly discriminating between environmental changes and signals from defects is one of the grand challenges for guided-wave SHM that must be surmounted before such systems can be used commercially. Recently, quantitative experiments and modeling are providing a better understanding of environmental effects and initial concepts for temperature compensation schemes appear promising.

END NOTES

[a.] Directional selectivity by mode shape is theoretically possible from a single point if the relative phase of displacements in different directions can

be measured. For example, the in-plane and out-of-plane surface displacements of a Rayleigh wave are in quadrature, with the particles moving in clockwise elliptical trajectories for waves traveling right to left and counterclockwise for waves traveling left to right.

[b.] Differences in mode shape between the top and bottom surfaces of a plate can be used to a limited extent in a laboratory where both surfaces can be accessed to separate symmetric and antisymmetric modes. Separation by mode shape is also used in finite element (FE) [15] where displacements can be monitored at any point through the thickness of the waveguide.

[c.] The normalization by the amplitude of the coefficients is necessary because otherwise the absolute amplitude of the PSF is unlimited and its maximization is meaningless.

Chapter 18

Piezoelectric Impedance Methods for Damage Detection and Sensor Validation

Gyuhae Park and Charles R. Farrar

Engineering Institute, Los Alamos National Laboratory, Los Alamos, NM, USA

1 INTRODUCTION

Piezoelectric (PZT) materials produce an electric charge when mechanically stressed and a strain when an electric field is applied across them. This electromechanical coupling property is extremely useful because it can be used to develop a transducer that serves both as a sensor and an actuator. An important characteristic of PZT materials is that they provide an unobtrusive, integrated, and distributed way to add actuation and sensing to a structure. This characteristic makes PZT devices ideal for use in structural health monitoring (SHM) for systems that do not contain natural excitation forces or for diagnostic algorithms that require a known, well-controlled excitation. An SHM technique, which utilizes the benefits of PZT materials and shows great promise for SHM systems, is the impedance-based health monitoring method.

The basic principle of the impedance method is to use high-frequency vibrations to monitor a local area of a structure for changes in mechanical impedance that would indicate damage or imminent damage. This concept is implemented using PZT sensors/actuators whose electrical impedance is directly related to the mechanical impedance of the structure. The impedance measurements are correlated with changes in mechanical parameters, such as resonant frequencies or damping, which enables damage to be detected and located. The impedance method also has applications in the field of sensor self-diagnostics in determining the operational status of PZT active sensors used in SHM.

This chapter provides a brief overview on research work on the impedance method. The first part of this section deals with theoretical background and experimental investigations of impedance-based SHM. A sensor diagnostics and validation process based on impedance measurements that performs *in situ* monitoring of the operational status of PZT active sensors

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

in SHM applications is then presented. This section also includes an investigation into the effects of the sensor/structure bonding defects on high-frequency SHM techniques, including Lamb wave propagation and impedance methods. It has been found that the effects are remarkable, modifying the phase and amplitude of propagated waves and changing the measured impedance spectrum, which could lead to false indications of structural conditions.

2 PRINCIPLE OF IMPEDANCE METHOD

The application of impedance measurements to SHM has its theoretical development first proposed by Liang *et al.* [1] and substantially developed by Chaudhry *et al.* [2, 3], Sun *et al.* [4], Park *et al.* [5–9], Peairs *et al.* [10], Giurgiutiu *et al.* [11–13], Giurgiutiu and Zagrai [14, 15], Soh *et al.* [16], Bhalla and Soh [17–20], Park *et al.* [21–23] and their coworkers. The reader is referred to (*see* **Electromechanical Impedance Modeling**) of the Encyclopedia for more details on the underlying theory. This chapter provides an overview of the experimental implementation of impedance-based damage detection.

When measurements from a damaged structure are compared with baseline measurements from the undamaged structure, the damaged structure will exhibit changes in its stiffness and damping characteristics that affect the mechanical impedance. Because direct measurements of the mechanical impedance of a structure are difficult to obtain, the electromechanical coupling effect of PZT materials is utilized to estimate this impedance in the impedance method. Any damage to a host structure will result in changes to its mechanical impedance, and these changes will be observed through changes in the electrical impedance of the PZT materials. In order to ensure high sensitivity of the electrical impedance to small defects in a structure, the impedance measurements are usually made at higher frequency ranges, typically greater than 30 kHz. At such high-frequency ranges, the dynamic response of the host structure is generally concentrated in a local area near the PZT device. PZT patches require very low level voltages, typically less than 1 V, to exert high-frequency excitations on the host structure.

An electromechanical model, which quantitatively describes the impedance measurement process, is presented in Figure 1. Assuming that an axial PZT actuator is attached to one end of a single degree-of-freedom mass-spring system, whereas the other end is fixed, Liang *et al.* [1] showed that the electrical admittance $Y(\omega)$, which is the inverse of the electrical impedance, of the PZT actuator is a combined function of the mechanical impedance of the PZT actuator $Z_a(\omega)$ and that of the host structure $Z(\omega)$:

$$Y(\omega) = \mathrm{i}\omega \frac{wl}{t_c}\left(\varepsilon_{33}{}^{T} - d_{31}{}^{2}Y_p^E + \frac{Z_a(\omega)}{Z_a(\omega)+Z_s(\omega)} \times d_{31}{}^{2}\hat{Y}_p^E\left(\frac{\tan kl}{kl}\right)\right) \quad (1)$$

where V is the input voltage, and I is the output current from the PZT transducer. $a, d_{3x}, Y_{xx}{}^{E}$, and $\bar{\varepsilon}_{33}^{T}$ are the geometry constant, PZT coupling constant, Young's modulus, and complex dielectric constant of the PZT transducer, respectively. The wavenumber of the PZT patch, k, is defined as

$$k = \omega\sqrt{\frac{\rho}{\hat{Y}_p^E}} \quad (2)$$

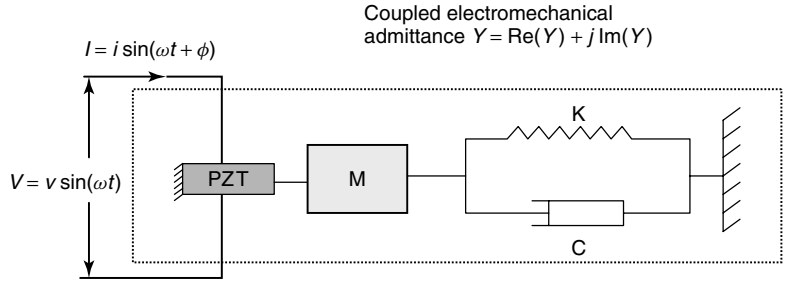

Figure 1. Single degree-of-freedom model used to represent a PZT-driven dynamic structural system.

where ρ is the mass density of the PZT material. The term $\frac{\tan kl}{kl}$ is close to 1 when the frequency range of excitation is much smaller than the first resonant frequency of the PZT patch.

Because all parameters except Z_s, the mechanical impedance of the host structure, are properties of the PZT material, only the mechanical impedance of a structure uniquely defines the electrical impedance of the PZT transducer. As a result, the electrical impedance signature of the PZT transducer is affected by changes in the mechanical impedance of the host structure. Therefore, by monitoring the electrical impedance and comparing this impedance to a baseline impedance measurement, one can determine when structural damage has either occurred or is imminent. The variation in the PZT electrical impedance over a range of frequencies is analogous to that of the frequency response functions of a structure, which contains vital information regarding the health of the structure. Bhalla and Soh [18] extended the 1D impedance model, which is expressed in equation (1), to the 2D governing equation for the PZT electrical impedance.

The impedance method tracks changes in the mechanical properties of structures as in global vibration-based methods. However, impedance measurements are made at much higher frequencies than those used in global vibration-based methods, which are described in (*see* **Free and Forced Vibration Models** and **Modal–Vibration-based Damage Identification**) leading to greater sensitivity to localized damage. Ultrasonic methods, acoustic emission, eddy current, or any other high-frequency testing method can provide detailed information regarding anomalies in some structures, but these methods usually require complex instrumentation and expertise to interpret the measured data. Most of these methods must also be applied when structures are out of service, or can be applied only at certain time intervals, which may not be suitable for autonomous on-line SHM. The sensitivity of the impedance method to minor defects is comparable to that of ultrasonic methods, but the method does not require experienced technicians to discern the details. With the development of low-cost impedance measuring circuits, the cost required for impedance hardware and sensors/actuators is also less than the cost for equipment needed to implement other non-destructive evaluation (NDE) techniques. The sensing regions of impedance sensors are much larger than those of local ultrasonic or eddy current sensors, which are usually moved to scan over certain areas to detect damage in a structure. Detailed comparisons between the impedance method and other NDE approaches can be found in the literature [6, 9, 13].

3 SIGNAL PROCESSING OF IMPEDANCE METHOD

Although the impedance response plots provide a qualitative approach for damage identification, the quantitative assessment of damage is traditionally made using a scalar damage metric. In [4], a simple statistical algorithm is used that is based on frequency-by-frequency comparisons, referred to as the *root mean square deviation* (RMSD),

$$M = \sum_{i=1}^{n} \sqrt{\frac{\left[\mathrm{Re}\left(Z_{i,1}\right) - \mathrm{Re}\left(Z_{i,2}\right)\right]^2}{\left[\mathrm{Re}\left(Z_{i,1}\right)\right]^2}} \qquad (3)$$

where M represents the damage metric, $Z_{i,1}$ is the impedance of the PZT measured in a healthy structural condition, and $Z_{i,2}$ is the impedance in a new structural condition for comparison with the baseline measurement in frequency interval i. In a RMSD damage metric chart, larger numerical values of the metric correspond to larger differences between the baseline reading and the comparison reading indicating the presence of damage in a structure. Another scalar damage metric, referred to as the *cross-correlation* metric, can be used to interpret and quantify the information from different data sets. The correlation coefficient between two data sets determines the relationship between two impedance signatures, and provides an aesthetic metric chart. In most cases, the results with the correlating metric are consistent with those of RMSD, in which the metric values increase when there is an increase in the severity of damage.

Temperature changes, among all other ambient conditions, significantly affect the electric impedance signatures. Some PZT material parameters, such as the dielectric and strain constants are strongly dependent on temperature. Generally speaking, an increase in temperature causes a decrease in the magnitude of electric impedance, and leftward shifting of the

real part of the electric impedances. The RMSD and cross-correlation based damage metrics do not account for these variations. Park *et al.* [5] used a modified RMSD metric, which compensates for horizontal and vertical shifts of the impedance in order to minimize the impedance signature drifts caused by the temperature or other normal variations.

Lopes *et al.* [24] incorporated neural network features with the impedance method for somewhat quantitative damage analysis. The authors proposed a two-step damage identification scheme. In the first step, the impedance-based method detects and locates structural damage and provides an indication of damage in a green/red light form with the use of the modified RMSD. When damage is identified, the neural networks, which are trained for specific damage levels, are then used to estimate the severity of damage. Zagrai and Giurgiutiu [25] investigated several statistics-based damage metrics, including RMSD, mean absolute percentage deviation (MAPD), covariance change, and correlation coefficient deviation. It was found that the third power of the correlation coefficient deviation, $(1 - R^2)^3$, was the most successful damage indicator, which tends to linearly decrease as the location of a crack in a thin plate moves further away from the sensor. Tseng and Naidu [26] also investigated the performance of RMSD, MAPD, covariance and correlation coefficients as indicators of damage. The RMSD and the MAPD were found to be suitable for characterizing the growth and the location of damage, whereas the covariance and the correlation coefficient were efficient in quantifying the increase in damage size at a fixed location.

A debonding detection method for composite patches was proposed based on the coupled use of the impedance method and hybrid genetic algorithms [27]. The impedance methods were also used with an outlier detection framework [28], principle component analysis [29], and frequency-domain autoregressive model for nonlinear feature identification in a structure [30] for improved damage identification performance.

4 EXPERIMENTAL STUDIES

Impedance-based SHM has been successfully implemented on several complex structures; a four bay space truss [4], an aircraft structure [2], complex precision parts [31], temperature varying applications [5], spot-welded structural joints [11], civil structural components [6], concrete structures [17], a reinforced concrete bridge [16], composite reinforced polymers [32], civil pipelines [8], prestress monitoring [33], and corrosion detection [34, 35]. A complete review summarizing experimental results using the impedance method can be found in [9]. Only a few case studies are described here in order to illustrate how the impedance method can be used to monitor the conditions of structures.

A built-in pipeline structure has been investigated by Park *et al.* [8], as shown in Figure 2. The objective of this investigation was to utilize the impedance method for identifying structural damage in areas where rapid condition monitoring is urgently needed, such as in a postearthquake analysis. One PZT sensor/actuator ($15\,\text{mm} \times 15\,\text{mm} \times 0.2\,\text{mm}$) is bonded on each joint to monitor the conditions of this structure. The impedance measurements of a PZT transducer at the joint with three levels of local damage are shown in Figure 2. It can be seen that, with increasing the level of damage, the impedance signature shows a relatively large change in shape and is clearly indicative of imminent damage. For the first level of damage (loosening two bolts), only a small variation along the original signal (curve for undamaged condition) was observed. When four bolts have been loosened, the impedance showed more pronounced variations as compared to previous readings, and finally, when eight bolts have been loosened, it showed a distinct change in the signature pattern, i.e., new peaks and valleys appear in the entire frequency range. This change occurs because the damage modifies the apparent stiffness and damping of the joint, which results in changes in electric impedance of the PZT transducer.

Giurgiutiu *et al.* [11] presented health monitoring results of spot-welded structural joints. The impedance signature was recorded up to 1100 kHz. The initiation and propagation of damage were successfully correlated with the impedance measurements. In addition, through the use of multisite impedance measurements, the sensitivity to minor cracks, localization of damage, and rejection properties to far-field changes have been observed.

Monitoring of a massive built-in bridge structure using impedance sensors are shown in Figure 3. The

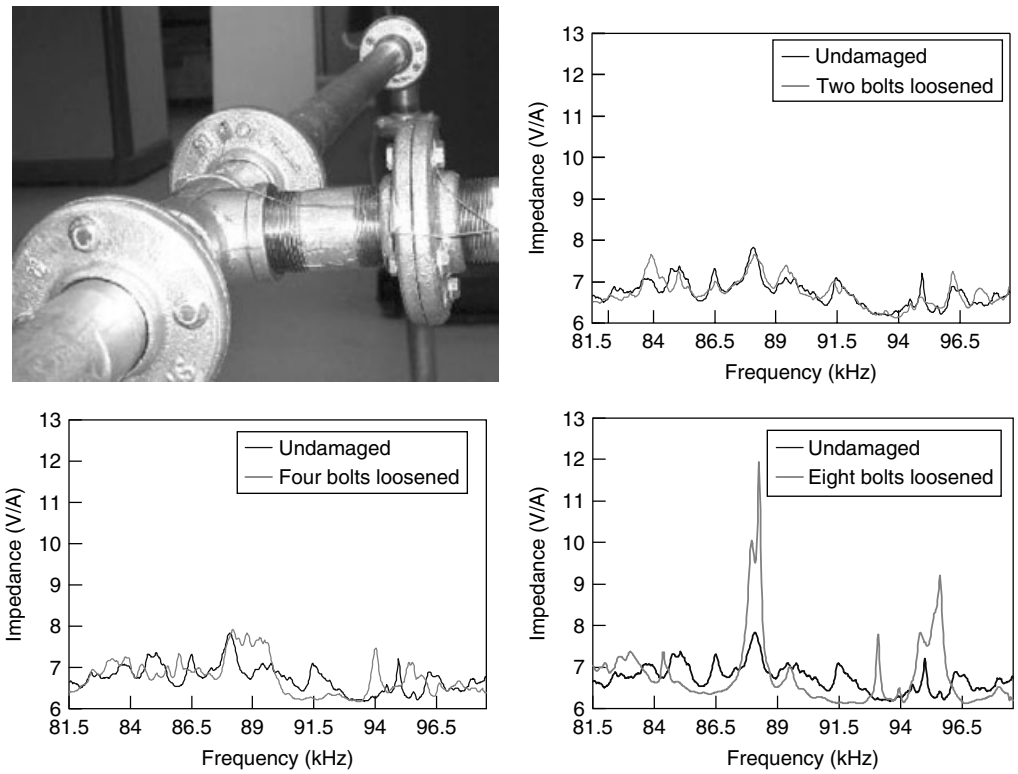

Figure 2. Pipeline experimental results. The impedance variation became more pronounced as the extent of damage increased.

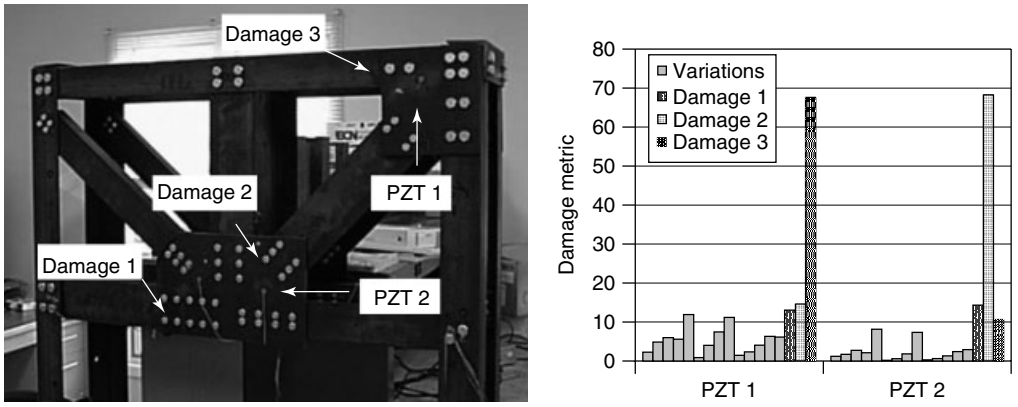

Figure 3. A 1/4 scale steel bridge section. The damage metric shows the localized effect of the impedance method.

bridge model consists of steel angles, channels, plates, and joints connected by over 200 bolts. The structure was 1.8-m tall and it weighed over 250 kg. Some environmental condition changes were imposed on this structure including changes in temperature, addition of a mass, and application of low-frequency vibrations. As can be seen in the damage metric values of Figure 3, these conditions resulted in relatively small variations and would be considered as minor changes. The first 14 variations are those from

the change in environmental conditions. Damage was simulated by loosening connection bolts at the selected locations, as shown in the figure. Damage 1 is believed to be well out of sensing range of both PZT 1 and PZT 2. Hence, only a small increase in damage metric is shown for both PZT transducers. Damage 2 is located close to the PZT 2 and Damage 3 is within sensing region of the PZT 1. Hence the increase in damage metric values are the highest for both PZTs. Note that the effect of loosening a single bolt on the entire structure is minor, and thus damage can be detected in its early stage [6].

Yang *et al.* [36] investigated the use of PZT impedance sensors with fiber-optic sensors for damage assessment and load history monitoring of underground structures, including rock samples. A fuzzy probabilistic damage model was proposed to quantify damage in rock based on the signal captured by piezo-impedance transducers. Soh and Balla [37] also investigated the possibility of monitoring concrete strength gain during its curing process. The stiffness of the concrete was well correlated with variations in impedance peaks, where the peaks shifted rightward and became sharper progressively with time, suggesting that the stiffness was increasing.

The integration of impedance methods with wave propagation-based SHM techniques was also investigated by many researchers [12, 13, 38–40]. Most of the wave propagation approaches utilize the sensing and actuation capability of the PZT patches, which can be nicely integrated with the impedance method. In addition, the waves usually travel long distances and cover a relatively large area, which complement the strengths of impedance-based health monitoring. Some studies include damage detection in the near-field with impedance methods and in the far-field using wave propagation [12, 13], while others utilize different sensitivities to different types of damage [39]. For instance, in pipeline monitoring, the impedance methods are used to detect structural damage occurring at pipeline connection joints, while the Lamb wave propagation measurements identify cracks and corrosion along the surface and through the wall thickness of the pipeline structure [40].

As described in this chapter, the impedance-based health monitoring technique has been successfully applied to various structures ranging from aerospace to civil structures. Because of the high frequencies employed, the method is very sensitive to minor defects in a structure and not affected by any far-field changes. Recognizing that damage is a local phenomenon and that one often knows where to expect damage (either from previous testing or from geometry, such as joints), the impedance method is ideal for tracking and on-line monitoring of critical sections in various structures.

5 SENSOR SELF-DIAGNOSTICS AND VALIDATION USING IMPEDANCE MEASUREMENTS

One critical aspect of PZT active-sensing technologies is that large numbers of distributed sensors and actuators are usually needed to monitor the condition of a structure. In addition, the structures in question are usually subjected to various external loading and environmental condition changes that may adversely affect the functionality of SHM sensors and actuators. The PZT active sensor diagnostic and validation process, where the sensors/actuators are confirmed to be operational, is therefore a critical component to successfully implement SHM. Because piezoceramic materials are brittle, sensor fracture and subsequent degradation of mechanical/electrical properties are the most common types of sensor/actuator failures. In addition, the integrity of bonds between a PZT patch and the host structure must be maintained and monitored throughout their service lives because degradation in bonds modifies the strain and stress transfer mechanism.

For PZT sensors, Saint-Pierre *et al.* [41], Pacou *et al.* [42], and Giurgiutiu *et al.* [15] proposed a debonding identification algorithm by monitoring the resonance of a PZT sensor based on the electrical impedances. As the debonding area between the PZT wafer and the host increased, the shape of the resonance of the PZT wafer became sharper and more distinctive, and the magnitudes of the host resonances decreased. This method requires a high-frequency data-acquisition system because even the first resonance of PZT wafers in SHM applications usually lies in the range of hundreds of kilohertz. In addition, this method is not able to account for sensor fracture, which may simultaneously occur with debonding, as the sensor breakage would apparently generate changes in the resonances of a PZT sensor. Bhalla and Soh [18] investigated the effect of shear-lag loss

on electromechanical impedance measurements. They found that the bond layer can significantly modify the measured admittance signatures, and suggested the use of adhesives with high-shear modulus, the smallest practicable bond thickness, and small-sized PZT transducers in order to minimize the influence of the bond layer. They also suggested that the imaginary part of the electrical admittance of PZT transducers may play a meaningful role in detecting deterioration of the bond layer. However, by concentrating on the effects of bond layers on the electromechanical impedance spectrums only, the metrics that can be used for bond quality assessment was not clearly identified, and the ability to discriminate bond failures from structural damage was not thoroughly investigated.

In general, a completely broken PZT active sensor can be easily identified if a sensor does not produce any meaningful output or an actuator does not reasonably respond to applied signals. However, if only a small fracture or debonding occurs, the sensors/actuators are still able to perform adequately (with distorted signals after the sensor fracture), potentially leading to false indications of the structural condition. In order to fully implement current active-sensing systems into SHM practice beyond the proof-of-concept demonstration, an efficient sensor self-diagnostic procedure should be adopted in the SHM process.

5.1 Sensor diagnostics and validation process

The premise of the sensor self-diagnostic process is to track changes in the capacitive value of PZT materials, which is manifested in the imaginary part of the measured electrical admittances of the PZT material. It has been found that the degradation of the mechanical/electrical properties of the PZT sensor and its attachment to the external structure produces measurable and distinct changes in the capacitance of PZT materials [43–45]. This section briefly describes the sensor diagnostic procedure.

The electrical admittance of a PZT transducer, which is defined as the ratio of the energizing voltage to the resulting current, under a free–free boundary condition is given in the following relation,

$$Y_{\text{free}}(\omega) = \frac{I}{V} = \mathrm{i}\omega\frac{wl}{t_c}\left(\varepsilon_{33}{}^{T}\,(1-\mathrm{i}\delta)\right) \qquad (4)$$

where w, l, t_c is the width, length, and thickness of a PZT transducer, respectively, and δ is the dielectric loss tangent of the PZT wafer. When a PZT patch is surface bonded to a structure, it was shown in equation (1) that the electrical admittance of the PZT transducer is a combined function of the mechanical impedance of the host structure and that of the PZT wafer.

The sensor diagnostic process is based on equations (1) and (4). The electrical admittance is clearly a function of its geometry constants (w, l, t_c), mechanical properties (Y_p^E), and electrical properties $(\varepsilon_{33}{}^{T}, d_{31}, \delta)$ of the PZT transducer. It is also obvious from the equations that the changes in these properties are manifested more distinctly in the imaginary part of the electrical admittance. Therefore, the breakage of the sensor and the degradation of the sensor's quality can be identified by monitoring the imaginary part of the electrical admittance. The breakage/degradation of the sensor quality would cause a downward shift in the slope of the admittance (i.e., decrease in the capacitive value) because the effective size of the sensor would decrease with breakage and the values of dielectric constants and PZT coupling constants would decrease with increasing degradation.

Another significant observation that can be made from equations (1) and (4) is that one can identify the effect of the bonding layer on the measured electrical admittance. The effect of the bonding layer obtained by assuming the mechanical impedance of a structure is much larger than that of the PZT transducer in equation (1), which makes the last term in equation (1) close to zero. The result is as follows:

$$\begin{aligned} Y_b(\omega) &= \mathrm{i}\omega\frac{wl}{t_c}\left(\varepsilon_{33}{}^{T}(1-\mathrm{i}\delta) - d_{31}{}^{2}Y_p^E\right) \\ &= Y_{\text{free}}(\omega) - \mathrm{i}\omega\frac{wl}{t_c}\left(d_{31}{}^{2}Y_p^E\right) \end{aligned} \qquad (5)$$

It is clear from equations (4) and (5) that the electrical admittance of the same PZT patch is different if it is under a free–free or surface-bonded (or commonly referred to as *blocked*) condition. The blocked condition would cause a downward shift in

the slope of the electrical admittance (decrease in the capacitive value) of a free PZT with the factor of $\frac{wl}{t_c} d_{31}{}^2 Y_p^E$. The assumptions that led this result are usually valid, especially at lower frequencies (<20 kHz), because the mechanical impedance of the structure is usually several orders of magnitude greater than that of a PZT transducer. Even though this derivation does not explicitly consider the parameters of bonding materials (such as thickness or shear modulus), it is obvious from equation (5) that the use of a PZT transducer with lower Y_p^E and smaller dimensions, such as a small PVDF patch, will reduce the effect of the bonding layer on the measured admittance, which is consistent with the shear-lag analysis available in the literature [18, 46]. The importance of equation (5) is that the bonding layer also contributes to the overall admittance (capacitance) of PZT patches bonded to a structure.

Figure 4 illustrates the measured admittance of free and surface-bonded PZT patches. The 5A PZT materials with dimensions of 20 mm × 20 mm × 0.25 mm are used. The admittances of three free PZT patches were measured in the frequency range of 40–20 000 Hz using an Agilent 4294A impedance analyzer. These PZT patches were then surface-mounted to a thick aluminum beam and plate using superglue. The admittance measurements were then repeated.

As can be seen in Figure 4, the downward shifting effect of the bonding layer is remarkable. The slope of the imaginary part, which is the capacitive

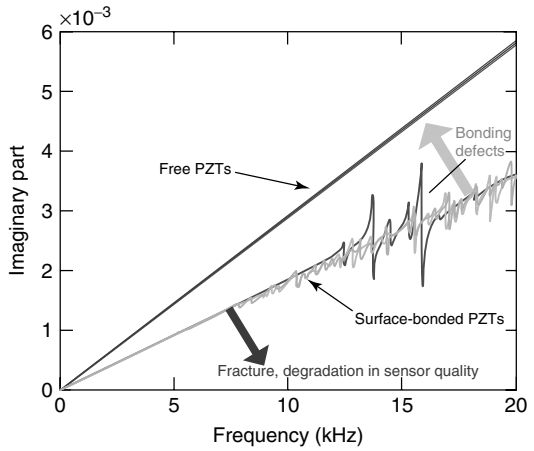

Figure 4. Electrical admittance measurement from PZT patches under free and surface-bonded conditions.

value of the PZT material, was changed from 29.1 to 18 nF resulting in a 38% reduction. Therefore, the sensor functionality including sensor breakage and the degradation of the bonding condition can be assessed by monitoring the imaginary part of the admittances (capacitance) of the PZT materials. Figure 4 also graphically describes the effects of sensor failures, both the sensor fracture and the bonding defects, on the measured electrical admittance.

5.2 Operational status validation of sensing network and the effects of bonding defects on Lamb wave propagations

A series of experimental results are presented to demonstrate the performance of the sensor diagnostics and validation process. This sensor diagnostic process is applied to confirm the operational status of a PZT sensing network right after the installation on an aluminum plate and a bolted washer. The effects of faulty sensors, in particular the bonding defects, on Lamb wave propagations and electromechanical impedance measurements are also presented.

For SHM approaches based on the use of Lamb wave propagation, a single sensor failure creates major problems including failure of signal processing algorithms, or at a minimum, the lack of inspection in a large area of a structure. Sensors can fail owing to extreme operational condition, such as an impact by foreign objects. However, the sensor failure can also occur due to improper installation of the sensors, including imperfect bonding or accidental sensor breakage during handling. The sensor diagnostic process described in the previous section can be efficiently used to determine the operational status of the sensing network immediately after the installation, as shown in the following example.

The test structure shown in Figure 5 is an aluminum plate (1200 mm × 1200 mm × 2 mm). Nine circular PZT patches are mounted using superglue on one surface with a 3 × 3 array with equal distances in all directions. The locations and the numbering schemes of these actuators/sensors are also shown in Figure 5. The circular PZT patch is 5.5 mm in diameter with 0.2-mm thickness. Admittance

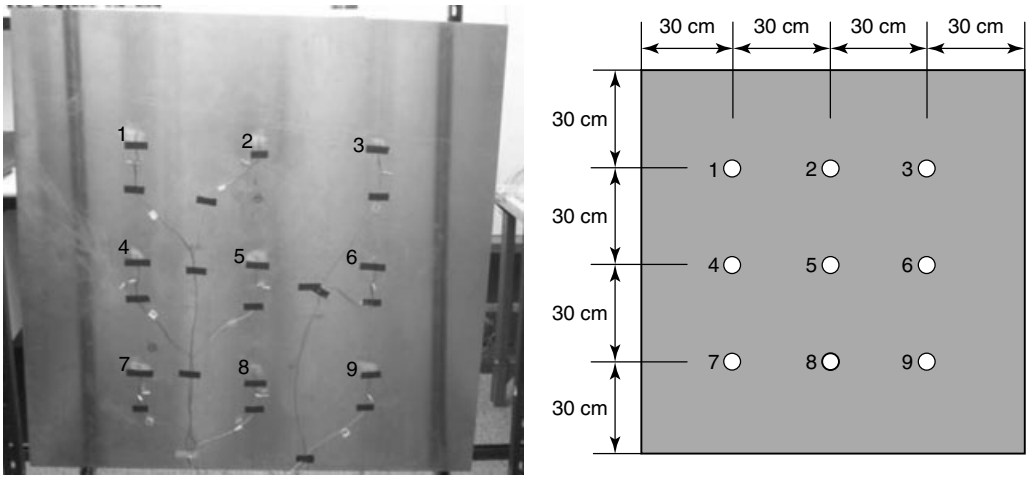

Figure 5. An aluminum plate with PZT transducers attached.

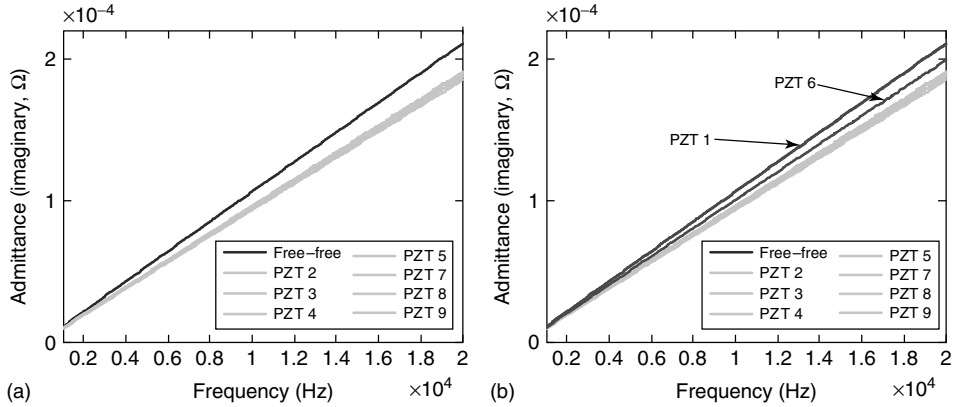

Figure 6. Admittance measurements (imaginary part) from PZT transducers. (a) PZT patches under free–free and healthy conditions and (b) PZT patches under healthy and faulty conditions.

measurements in the frequency range of 1–20 kHz were made at each PZT patch before and after the installation using an Agilent 4294A impedance analyzer.

The admittance measurements of PZT transducers before and after the installation are shown in Figure 6(a). For most PZT patches, the downward shifting effect caused by bonding is evident. The slope of the imaginary part, analogous to the capacitive value of the PZT wafer, results in a 4.5% reduction. However, for PZT 1, virtually no change in the slope of the imaginary part of admittance was observed as shown in Figure 6(b). Further, for PZT 6, only a 2% change in the slope was observed. As described, the small or almost no change in the slope could be an indication of imperfect bonding condition. Therefore, these two sensors are classified as faulty by the sensor diagnostic method. This poor bonding will be problematic because the condition can be easily degraded during the operation.

The effect of bonding defects on the Lamb wave propagation was also investigated. First, the wave propagation (at 100 kHz) in the paths consisting of sensors with the good bonding condition were measured (between PZT 2 and 3, PZT 3 and 5, PZT 4 and 8, and PZT 5 and 9) and are plotted in Figure 7. Because the paths are of equal distance and traverse the same materials, the propagated waves show the

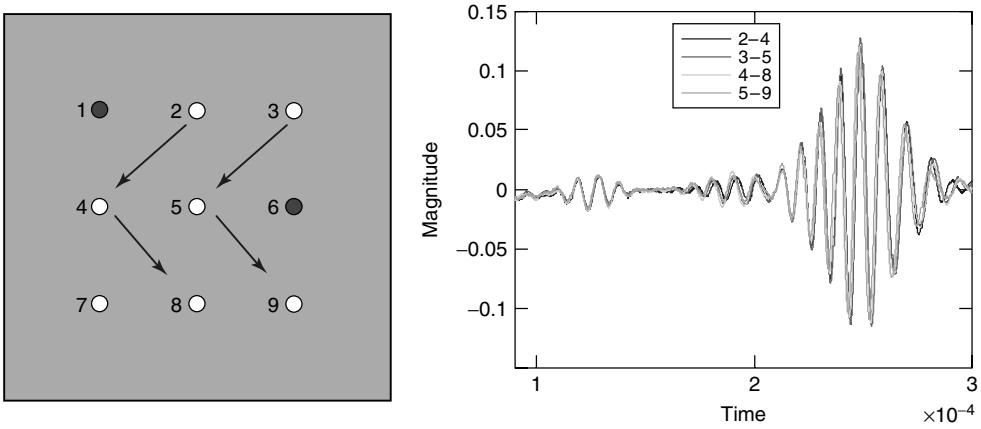

Figure 7. Lamb wave propagations between healthy sensors.

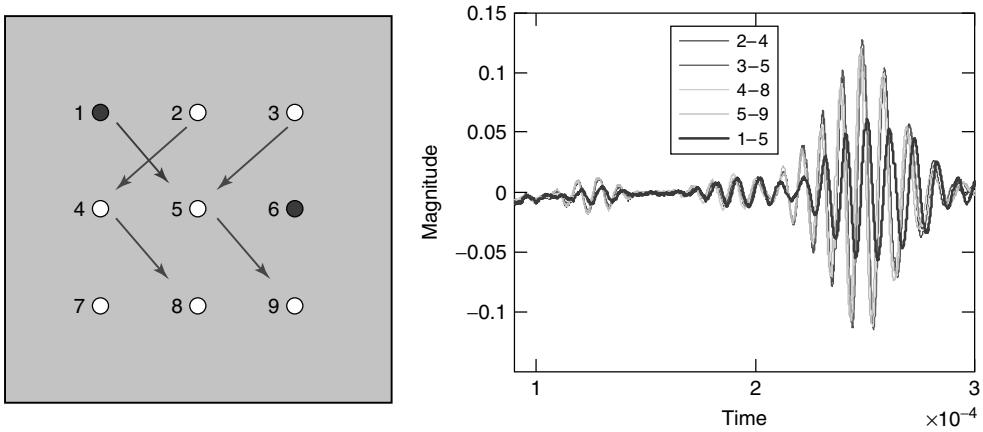

Figure 8. Lamb wave propagations between healthy sensors and faulty sensors.

same characteristics. The arrival times of the first S_o and A_o mode are evident and they also exhibit similar magnitudes. Figure 8 shows the overlap of propagating waves in the path between PZT 1 and 5. PZT 1 was identified as a faulty sensor by the sensor diagnostic process. There is a remarkable change in the measured response. There is a clear change in the magnitude, and further, the arrival time changes significantly. It should be noted that the effects of bonding defects are very similar to those caused by structural damage. If signal processing methods based on the wave attenuation or time of flight are used and the bonding defect occurs during operation, these changes can be mistakenly considered as structural damage, which points to the importance of sensor diagnostics in real-world operation. As shown in this example, the sensor diagnostic method can be used to monitor the operational status of the PZT transducers immediately after their installation. Furthermore, the degradation of bonding conditions over the service life of the PZT sensors could also be identified by tracking changes in the admittance measurements.

5.3 Bonding condition assessment and effects of bonding defects on electromechanical impedance measurements

In lower vibration frequency ranges, several studies [47, 48] have shown that the bonding layer plays a critical role in determining the measured dynamics,

resulting in changes to the measured modal frequencies and damping ratios. Because the frequency range of the impedance method is much higher, the effects of the bonding layer could be much more significant and should be well understood for this method to be successfully applied in practical applications.

A set of experimental tests were performed using different bonding conditions of the PZT patches. In order to assess the effects of different sensor bonding conditions on measured impedance, an aluminum hexagonal washer (with geometry 25.4-mm high, and 31.75 mm across the flats with a 12.7-mm diameter hole) was instrumented with two circular PZT patches (12.7-mm diameter, 0.2-mm thickness), each on a different face, as shown in Figure 9. The patches were attached to the plates using two different bonding techniques to simulate both good and poor bonding conditions. One bonding condition was achieved by using 3M thermo bond film for a temporary (and poor) bond, whereas the other was achieved using superglue to produce a more permanent bonding condition.

Figure 10 shows the imaginary part of the admittance of each of the sensors bonded to the aluminum hexagonal washer in the frequency range up to 20 kHz. This plot also includes an admittance measurement for an unbonded 11-mm-diameter PZT patch. The quality of the bond can be determined based on the changes in the slope steepness of the admittance measurement. From Figure 10, one can see that the superglued sensor demonstrates the lower slope, and therefore, can be considered to have a better bonding condition.

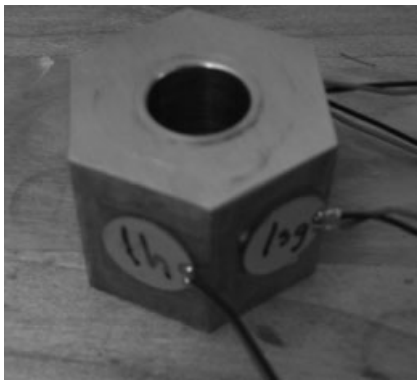

Figure 9. An aluminum washer with two PZT patches installed with different bonding conditions.

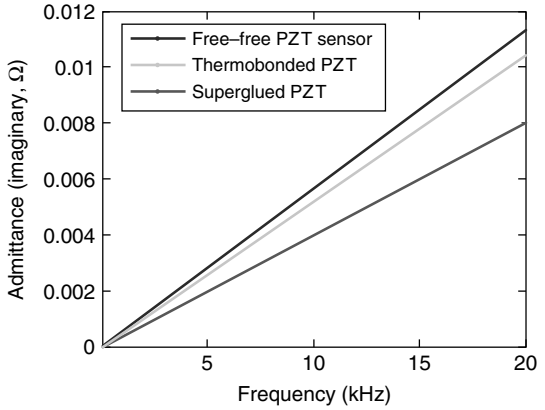

Figure 10. Admittance measurements from different bonding conditions from an aluminum washer.

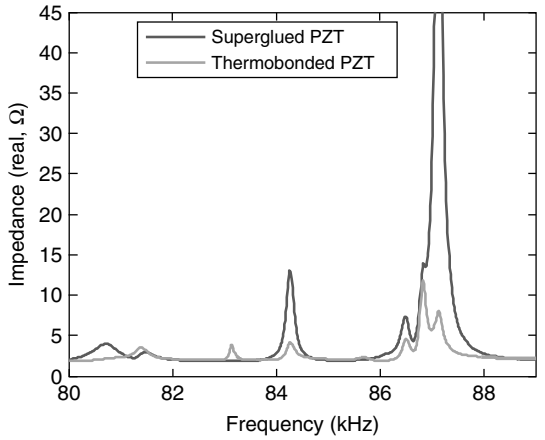

Figure 11. Impedance measurement (real part) under different bonding condition.

The impedance measurements (the real part) under the different conditions are shown in Figure 11. It is clear from the figure that the PZT bonded with the superglue shows resonances near 84 and 87 kHz to be at least an order of magnitude greater than the sensor bonded with the thermo film. From the measurements, it once again confirms that the magnitude of the resonance is affected by the bonding conditions. The poor bonding condition may result in erroneous or misleading results as the stress/strain transfer mechanism is modified by the changed electromechanical interaction between the structure and PZT patches. Furthermore, near the frequency range

at 83 kHz, the PZT active sensor with the thermo-bonded condition exhibits a new resonance of the structure. Therefore, it can be concluded that, as the bonding condition changes, the identified resonances and associated magnitudes are significantly affected. It is very clear from this figure that the bonding condition significantly influences structural identification and health assessment if degradation in bonds is not carefully accounted for. Further, it is obvious that, in order to minimize false indications of the structural condition, the sensor diagnostic process needs to be implemented to discriminate changes due to sensor degradation from structural damage in SHM field applications.

6 SUMMARY

With continual advances in sensor/actuator technology, signal processing techniques, and damage prognosis algorithms, impedance-based SHM methods will continue to attract the attention of researchers and field engineers for monitoring of various structural components. The impedance method provides several advantages over traditional approaches. First, because of the high-frequency range employed, the method is very sensitive to incipient damage in a structure and unaffected by changes in boundary conditions, loading, or operational vibrations. The method is very suitable for an autonomous monitoring system because the data-acquisition procedure can be automated and requires minimal user interference. An analytical model of the structure is also not required, making the method attractive for use on complex structures. Furthermore, the method can be efficiently used for sensor self-diagnostics and validation processes.

Although several successful examples of the use of impedance methods have been presented, it is important to note that extensive research efforts are being devoted to studying the practical implementation issues in real-world field applications. These issues include: (i) developing miniaturized and portable impedance measurement equipment with wireless communication capabilities [49–51]; (ii) packaging of the sensors to facilitate installation; and (iii) integrating these methods with other techniques, such as wave propagation methods and acoustic emission.

Chapter 19
Thermal Imaging Methods

Daniel L. Balageas
Structure and Damage Mechanics Department, ONERA (The French Aerospace Lab), Châtillon, France

1 INTRODUCTION

The analysis of the space distribution and time evolution of the surface temperature of a structure can permit the establishment of a diagnostic of the structural health of the structure. This analysis is based on the fact that all mechanical phenomena are accompanied by correlated thermal effects (thermomechanical coupling). These effects can be reversible or irreversible. The reversible thermal phenomena are linked to the strain (and stress) state of the structure. Mapping the thermal state of the structure is a means to detect abnormalities in its mechanical behavior. Generally, irreversible phenomena are the signature of the occurrence of a damage. Until recently, the thermomechanical approach was scarcely applied in experimental mechanics, partly due to the lack of sensitivity of the temperature detection hardware. In recent years, infrared (IR) detectors and data processing techniques have achieved considerable improvements, opening new possibilities in this field. The other approach for structural health monitoring (SHM) comes from classical nondestructive evaluation (NDE). Damages are detected, localized, and characterized by the disturbance they introduce in the local physical properties of the structure. These properties are not mechanical, but their evolution can be correlated to a loss of mechanical performance. The variety of physical phenomena used in NDE to detect these damages is very wide. Among them, the thermal properties (heat conduction, heat diffusion, heat capacity, effusivity, interface thermal resistance) are currently used.

Thermal NDE techniques are essentially applied with the help of IR radiometry, although there are several other means of measuring temperature: thermoelectric effect (thermocouples), thermoresistive effect [1], thermochromic liquid crystals [2, 3], thermocolor or heat-sensitive paints [4], fluorescence [5], etc. The present article focuses on IR radiometry, more particularly on IR thermography, the most practical way to easily map surface temperature fields of structures, without any contact, with very high bandpass and sensitivity, allowing a detailed analysis of space and time distributions.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

In the present article, the physical principle of IR radiometry and state of the art of IR thermography are recalled. The analysis of the thermographic process shows how to perform a quantitative measurement, a requisite for the identification of structural health and characterization of damages. Different ways to perform SHM with IR thermography are finally detailed: diagnostic elaboration based on a thermomechanical analysis (strain mapping and fatigue detection), and damage detection and characterization by stimulated thermography.

2 RECALL ON TEMPERATURE MEASUREMENT BY RADIOMETRY

All materials emit and absorb energy by radiation. The amount of energy and the spectral domain of the emitted radiations strongly depend on temperature. This thermal emission may also vary with the direction of emission. Thermal emission has been modeled by introducing the concept of the "blackbody" or perfect radiator. The radiations emitted by the blackbody are a function of its absolute temperature, T, and their magnitudes are a function of the wavelength, λ, but are independent of the direction (isotropically diffuse or Lambertian surface). For a given temperature and wavelength, no other surface can emit more energy. This ideal concept is approached by real blackbodies: isothermal cavities and corrugated blackened isothermal surfaces.

Planck's law describes blackbody emission. It expresses the power irradiated per unit surface, unit solid angle, and unit wavelength domain ($\mathrm{W\,m^{-2}\,\mu m^{-1}\,sr^{-1}}$). This power is called the *spectral radiance*, L_λ, and is given by the following formula:

$$L_\lambda(\lambda, T) = 2hc_0^2\lambda^{-5}\left[\exp\left(\frac{hc_0}{\lambda KT}\right) - 1\right]^{-1} \qquad (1)$$

where c_0 is the speed of light in vacuum ($2.9979 \times 10^8\,\mathrm{m\,s^{-1}}$), h the Planck constant (6.626076×10^{-34} Js), and K the Boltzmann constant ($1.380658 \times 10^{-23}\,\mathrm{J\,K^{-1}}$).

Wien's law expresses the wavelength of the maximum emission as a function of the temperature: $\lambda_{\max} = 2897.7/T$. For near-ambient temperatures, the spectral domain for which the thermal emission is maximum is the IR between 5 and 15 μm.

For real materials, the thermal emission can be different from the blackbody radiation. The ratio of this thermal emission to the blackbody emission is the *spectral emissivity*. A first approximation consists in supposing that the emissivity is independent of the wavelength and direction of emission. A body that satisfies this condition is called a *gray body*. In practice, when measuring the thermal emission by radiometry, very often this assumption is assumed to have been verified.

If the real body differs strongly from a gray body, to be quantitative, radiometry requires knowledge of the value of the spectral emissivity in the spectral domain of measurement. With regard to the influence of the direction of emission, in general, radiometric measurements are performed following lines of sight corresponding to angles $\theta < 50^\circ$, making the directional effect negligible and validating the Lambertian assumption.

Radiometry consists of detecting and measuring radiant electromagnetic energy. These tasks are achieved by conjugating an element in the region of thermal activity with a radiation detector and with the help of lenses. The energy received can be related to the temperature of the emitter, at least in the simpler case (see Section 3). If a calibration is made, the radiometer signal can measure the emitter temperature. Generally, the measurement is performed in the IR domain (see above). For more details on the subject, please refer to DeWitt and Nutter [6].

3 INFRARED THERMOGRAPHY

If a scanning system is included between the lenses and the detector, or if there is an array of detectors instead of a unique detector, it is possible to measure the temperature in a certain field of view and to build a thermal image. Such an instrument is a thermographic imager, also called *infrared camera*. Figure 1 presents two types of cameras. The first type is the single detector camera with an optomechanical scanning system allowing to successively image all the points of the region and to build an image with the help of video-type scanning. This type of camera is less in use and is now being replaced by the focal plane array (FPA) cameras. In the FPA camera,

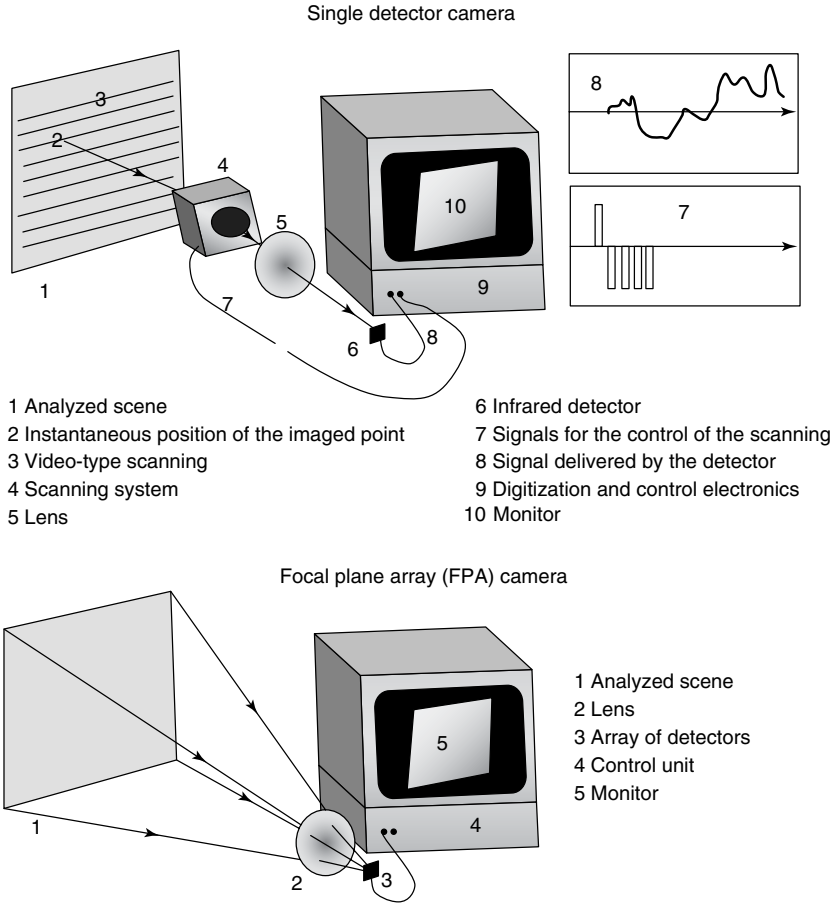

Figure 1. The two types of infrared cameras: single detector cameras and focal plane array (FPA) cameras.

there is no scanning device. Using lenses, the region is imaged onto an array of detectors. This type of camera is much simpler, and the electronics does not need a high bandpass as in the single detector cameras; this leads to a higher signal-to-noise ratio and consequently a higher sensitivity. More details can be found in the books by Gaussorge [7] and by Maldague [8].

3.1 Complexity of a quantitative absolute thermographic measurement

Measuring the distribution of temperature in space and its evolution with time is then possible with a thermographic instrument. Nevertheless, the quantitative measurement of the absolute value of the temperature remains difficult. This result is shown in Figure 2.

The radiant energy received by the camera is a complex function of the temperatures of the object, T_o, surroundings, T_{amb}, and atmosphere, T_{atm}, of the emissivity of the object, ε_o, and of the transmissivity of the atmosphere, τ_{atm}. The simplest case—radiometric signal only depending on the temperature of the object—is obtained when ε_o and τ_{atm} are both equal to 1. The second assumption is generally satisfied when the camera–object distance is of the order of a few meters. To satisfy the first assumption, black coatings are often applied on the object. Another realistic condition can lead to simple interpretation: the object is assimilable to a gray body with a temperature notably higher than the ambient temperature. Then the radiometric

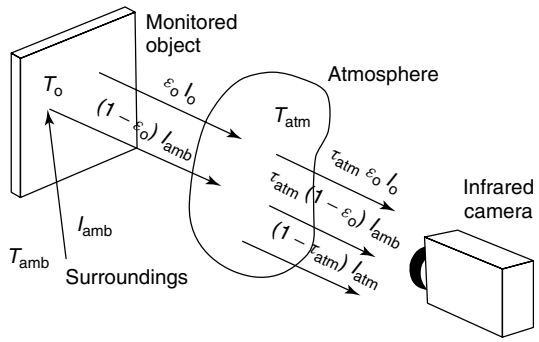

Figure 2. The complexity of the energy balance in a thermographic measurement.

signal depends only on the temperature and the emissivity of the object. These considerations explain why measurements of absolute temperatures by thermography are not very accurate. Generally, the absolute temperature accuracy is near 2 K or 2% of the range [9]. Hopefully, in most of the applications the measurement is relative: the interesting information is the difference of temperature, ΔT, between the monitored point and a reference one, which can be another point of the structure that is supposedly sound, or the same point at a different time, for instance, before stimulation in active thermography.

3.2 Thermographic hardware

Today, two main types of FPA cameras exist: cameras with cooled quantum detectors and bolometric cameras. The first type has the best noise equivalent temperature difference (NETD), the most important characteristic for ΔT measurements. Typically, the NETD is near 20 mK. The second type has a NETD of roughly 100 mK, but does not require a cooling system and its cost is lower. The size of the array is a second discriminating parameter because it influences the space resolution of the thermal images. There are now large size arrays, such as 320×256 or 640×512, and it is possible to make windowing with a correlative frame rate increase (several thousands of frames per second).

It is possible to enhance the NETD by simple data processing [10]: mean value of adjacent pixels ($3 \times 3, 5 \times 5, \ldots$) or mean image of successive images. The NETD is improved in both cases, but with the drawback of respectively decreasing the space or the time resolution. A third possibility that recently appeared is applicable when the monitored thermal phenomena are periodic. In these cases, a lock-in thermographic system permits imaging the modulated part of the thermal field, in amplitude and phase, with an NETD, which can be better than 1 mK, depending on the number of raw images considered by the data processing [11]. Lock-in thermography is particularly useful for experimental mechanics and NDE applications.

3.3 Analysis of the thermographic measurement

The procedure for performing a thermography is presented in Figure 3. There are three "actors" in this process: the thermographer, the thermographic system used, and the monitored structure. The thermographer can be passive, just monitoring the steady state or the time evolution of the structure. This structure state, permanent or evolving, is governed by the interactions with the surroundings. These interactions are the heat transfer, which takes place by conduction, convection, and radiation. A second possibility for the thermographer consists in stimulating the structure with the aim of monitoring its reaction to the stimulation. The result of the stimulation must be thermal (heat sources) to be detected by thermography, but the nature of the stimulation can be extremely varied because heat is the degraded form of all energies: mechanical, electromagnetic, thermal, etc. The information recovered by the thermographic system is the space distribution and/or the time evolution of the structure's surface (assuming the structure is composed of opaque materials). The surface temperature depends

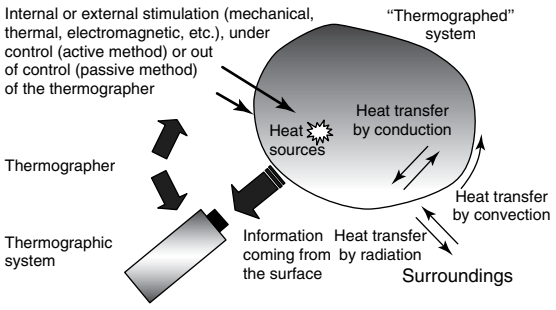

Figure 3. The process of performing thermography.

on (i) the internal structure, (ii) its thermal properties, (iii) its other properties governing the relations existing between the stimulating phenomena and the heat production, and (iv) the possible abnormalities or damages existing inside the structure.

From this analysis we can conclude that (i) to achieve an appropriate and quantitative diagnostic result, the thermographer must have a basic knowledge of heat transfer science; (ii) an active attitude, when possible, is more efficient for establishing a diagnosis; (iii) using mechanical stimulation (pressure, static or dynamic loads, vibrations, waves, etc.) may allow the identification of possible abnormalities of mechanical parameters of the structure, which is useful information to judge the structural health; and (iv) using varied types of stimulations, it is possible to detect thermal abnormalities induced by the presence of defects such as voids, delaminations, debonds, cracks, etc. The last two points are developed next.

4 STRUCTURAL HEALTH MONITORING USING INFRARED THERMOGRAPHY

4.1 Diagnostic based on thermomechanical analysis

The basics of thermomechanical coupling are derived from thermodynamics. We use the generalized standard materials formalism to derive the local heat equation [12]. The equilibrium state of each volume material element is characterized by a set of n state variables: T, the absolute temperature, ε, a strain tensor, and $(\alpha_1, \ldots, \alpha_{n-2})$, the $n-2$ scalar components of the vector $\boldsymbol{\alpha}$ of "internal" variables that characterize the microstructural state of the material. Combining both the first and second principles of thermodynamics, the local heat equation is obtained as follows:

$$\rho C\dot{T} - \mathrm{div}(k\cdot\mathrm{gradT}) = \rho T\frac{\partial^2\psi}{\partial T\,\partial\varepsilon} : \dot{\varepsilon} + \rho T\frac{\partial^2\psi}{\partial T\,\partial\alpha}\cdot\dot{\alpha} + \left(\alpha - \rho\frac{\partial\psi}{\partial\varepsilon}\right) : \dot{\varepsilon} - \rho\frac{\partial\psi}{\partial\alpha}\cdot\dot{\alpha} + r_{\mathrm{e}} \qquad (2)$$

where ψ, the thermodynamic potential, is the Helmholtz free energy, and ρ, C, and k, respectively, the density, heat capacity, and thermal conductivity. On the left side of this equation, two terms describe the changes of temperature versus time and space that can be measured by an IR camera. This left side is in fact the heat diffusion equation without sources. On the right side, the energy production terms (sources) are found. The first two terms represent the thermomechanical coupling sources. Sometimes, these terms are called the reversible coupling between heat sources and mechanical sources. The first term is linked to the time derivative of the strain and represents the heat produced by the change of local strain. The second term, introducing the parameter α, is linked to the internal properties of the material. It may exist and it represents possible interactions between temperature and microstructure. Let us call the sum of these two terms w_{ctm}, the thermomechanical coupling source term. The third and fourth terms are linked to dissipative sources (mainly the plastic energy). The third term, linked to the rate of change of strain, is the product of stress by strain. The fourth term is linked to internal variable α describing internal phenomena. The sum of these two terms, d_1, is the dissipative source term. The last term, r_{e}, represents all external sources.

To solve the heat diffusion equation easily, the following hypotheses are required: the material is thermally linear (thermal properties not depending on temperature) and isotropic (thermal and mechanical properties independent of the direction). Instead of using the absolute temperatures, T, the changes in temperature, θ, can be considered. In this case, the left side of the heat equation can be simplified using the Laplacian of the temperature change:

$$\rho C\dot{\theta} - k\nabla\theta = d_1 + w_{\mathrm{ctm}} + r \qquad (3)$$

In equation (3), temperature and energy are not simply linked, but are related to time and space. To solve this equation, the question of how to link more simply the local value of temperature and the density of energy must be answered. An extra hypothesis is required: the condition of adiabaticity, which assumes that the rate of stress change is such that the conduction inside the material can be considered negligible compared to the rate of heat production. In these conditions, the heat conduction

equation becomes very simple:

$$\rho C\dot{\theta} = d_1 + w_{\text{ctm}} + r \tag{4}$$

The change of temperature is directly linked to the production of energy by the different sources. This result also supposes that the heat losses in the environment are negligible. Under these conditions, variations in temperature are, in fact, equivalent to energy variations. The key question is how can we practically extract energy production from temperature data? There are two ways to solve the problem: (i) standard thermography, which requires recording the full field of the surface temperature, precisely knowing the limit conditions, working on thermally thin specimens, and controlling all heat transfer not connected to the mechanical loading; and (ii) periodic loading and lock-in thermography, which enables one to directly measure energy variations, eliminating all external sources.

Standard thermography gives temperature variations with time for every pixel. With lock-in thermography, the reference parameter is not time but the applied load. Lock-in thermography gives temperature as a function of load. The second solution is more interesting. In periodic regimes (angular frequency ω), adiabaticity is verified if the thermal diffusion length in the specimen, $L_{\text{D}} = (2\kappa/\omega)^{1/2}$, κ being the diffusivity, is smaller than the spatial resolution δ of the thermographic system in the test conditions. This result leads to a condition on the modulation frequency, which depends on instrumentation, test conditions, and the specimen thermal properties: $f \gg \kappa/(\pi\delta^2)$. Critical frequencies calculated using this formula are given in Table 1. Increasing the space resolution requires changing the lens and increasing the modulation frequency of the applied loads at the same time. It is possible with modern cameras to respect these minimum frequencies, in particular, using windowing options for the highest frequencies.

4.1.1 Thermoelasticity and strain measurement

Let us consider the simple case of thermoelasticity. The heat equation is

$$\rho C\dot{\theta} = w_{\text{ctm}} \tag{5}$$

The thermoelastic coupling term of the local heat equation, considering an isotropic standard material, in adiabatic conditions, with harmonic loads and Young modulus independent of temperature, reduces to a simple expression in which α is the thermal expansion coefficient:

$$w_{\text{ctm}} = -T\cdot\alpha\cdot\frac{\mathrm{d}(tr(\sigma))}{\mathrm{d}t} \tag{6}$$

Solving the heat equation leads to the simple following expression for the amplitude, $\Delta\theta$, of the modulated part of the temperature induced by the harmonic loading:

$$\Delta\theta = -K_{\text{M}}\cdot T\cdot\Delta tr(\sigma) \tag{7}$$

which shows that the variation of the temperature is linked to the variation of the applied load or more exactly to the variation of the sum of the principal stresses. This relationship introduces the thermoelastic coefficient of the material, $K_{\text{M}} = \alpha/(\rho C)$. Table 2 presents values of the thermoelastic coefficient for some usual metallic materials.

For composite materials, which are often orthotropic, the relationship is

$$\Delta\theta = -K_M T\left(\Delta\sigma_{11} + \Delta\sigma_{12}\cdot\frac{\alpha_{12}}{\alpha_{11}}\right) \tag{8}$$

Table 1. Critical frequencies to obtain adiabaticity in periodic thermomechanical regime

Critical frequency for adiabaticity (Hz)		Material		
		Carbon/epoxy $\kappa = 1.2\times10^{-6}\text{m}^2\,\text{s}^{-1}$	Stainless steel $\kappa = 7.4\times10^{-6}\text{m}^2\,\text{s}^{-1}$	Aluminum $\kappa = 9.8\times10^{-5}\text{m}^2\,\text{s}^{-1}$
Spatial resolution (mm)	0.50	1.5	9.0	125
	0.15	17	105	1400

Table 2. Thermoelastic coefficient of some usual metallic materials

Material	Cast iron	Iron	Steel	Aluminum
$K_M\ (MPa^{-1})$	2.6×10^{-5}	3.5×10^{-6}	3.1×10^{-6}	2.0×10^{-6}

with $K_M = \alpha_{11}/(\rho C)$, showing that the temperature change is a linear combination of the principal stresses along the material orthotropic axes on the surface.

It is then possible to obtain maps of stresses and, consequently, by comparing the experimental values to references values (theory or experiment on sound structures), to establish a diagnosis of the structural health, and to detect and localize defective areas. In practice, strain maps can be obtained with varied types of mechanical loading: static, periodical, random, etc. Figure 4 presents a stress distribution measured by a thermoelastic stress analyzer CEDIP Infrared System. The system comprises of (i) a JADE IR camera, with a frame rate between 170 Hz and 23 kHz (windowing) and a thermal resolution of 20 mK; (ii) a real-time lock-in module with a frequency range of 0–19 kHz giving a stress resolution of 2 MPa for steel and an adiabatic spatial resolution down to 10 μm; and (iii) a dedicated software, Altair-Li. Stresses are measured during a fatigue test of the structure (a steering knuckle). The load frequency is 5 Hz. Four types of images are produced: (i) a thermal image presenting the mean value of the absolute temperature, in a gray scale; (ii) the peak-to-peak value of the modulated part of temperature, in false colors; (iii) the phase in a color spectrum between blue (areas in tension) and red (areas in compression), black areas corresponding to pixels where amplitudes are null and phases have no sense and are not calculated; and (iv) the local stress distribution. This last image is based on the knowledge of the thermoelastic coefficients and the absolute temperature distribution. It is clear that thanks to the good signal-to-noise ratio of this image the presence of a damage, a crack, for instance, would produce a very local stress contrast, which would be easily detected in the fourth image.

An illustration of the technique at higher frequencies is given in Figure 5. The camera integration time is lower than 100 μs permitting frequency exploration up to 10 kHz. The same system produces stress distributions for the first four modes of vibration of a turbine blade. All images are obtained with an equal processing time of 7 s. A localized damage mechanism would be easily detected and it could be possible to compare the images corresponding to the different modes to deduce information on the size of the defective area.

4.1.2 Dissipative phenomena and fatigue

Structures in service are often subject to fluctuating stresses. Repeated loads, which may or may not be periodic, change and degrade the material properties and may lead, in the long term, to failure (fatigue damage). This phenomenon occurs at levels of stress significantly lower than the resistance limit measured in static conditions, and even lower than the yield strength. Fatigue phenomena produce a continuous degradation of the microstructure. Intracrystalline microcracks first appear, gradually evolving because the stress in their vicinity can be much higher than the mean stress level. Then, they cross the grains when the number of cycles increases (nucleation phase) and eventually coalesce to form a macrocrack oriented in the maximum shear stress direction. Later in the growth phase, the macrocrack propagates perpendicularly to the maximum tensile stress direction, until it reaches a critical size at which the cracked part becomes unstable. The crack then propagates rapidly, leading to catastrophic failure.

Generally, damage occurs without any previous visible modification of shape or aspect. That is why fatigue failure is so threatening. Therefore, there is an interest, in the frame of the SHM approach, for the early detection of damage and also for evaluation of the residual life. This need in SHM is why thermomechanical coupling analysis by means of thermography is a promising technique [13].

These irreversible processes correspond to heat sources described by the term d_l of equation (2). During the mechanical loading of a structure, thermal effects related to these dissipative phenomena can be measured. Let us consider the application of a periodic load. The total temperature change, ΔT, results

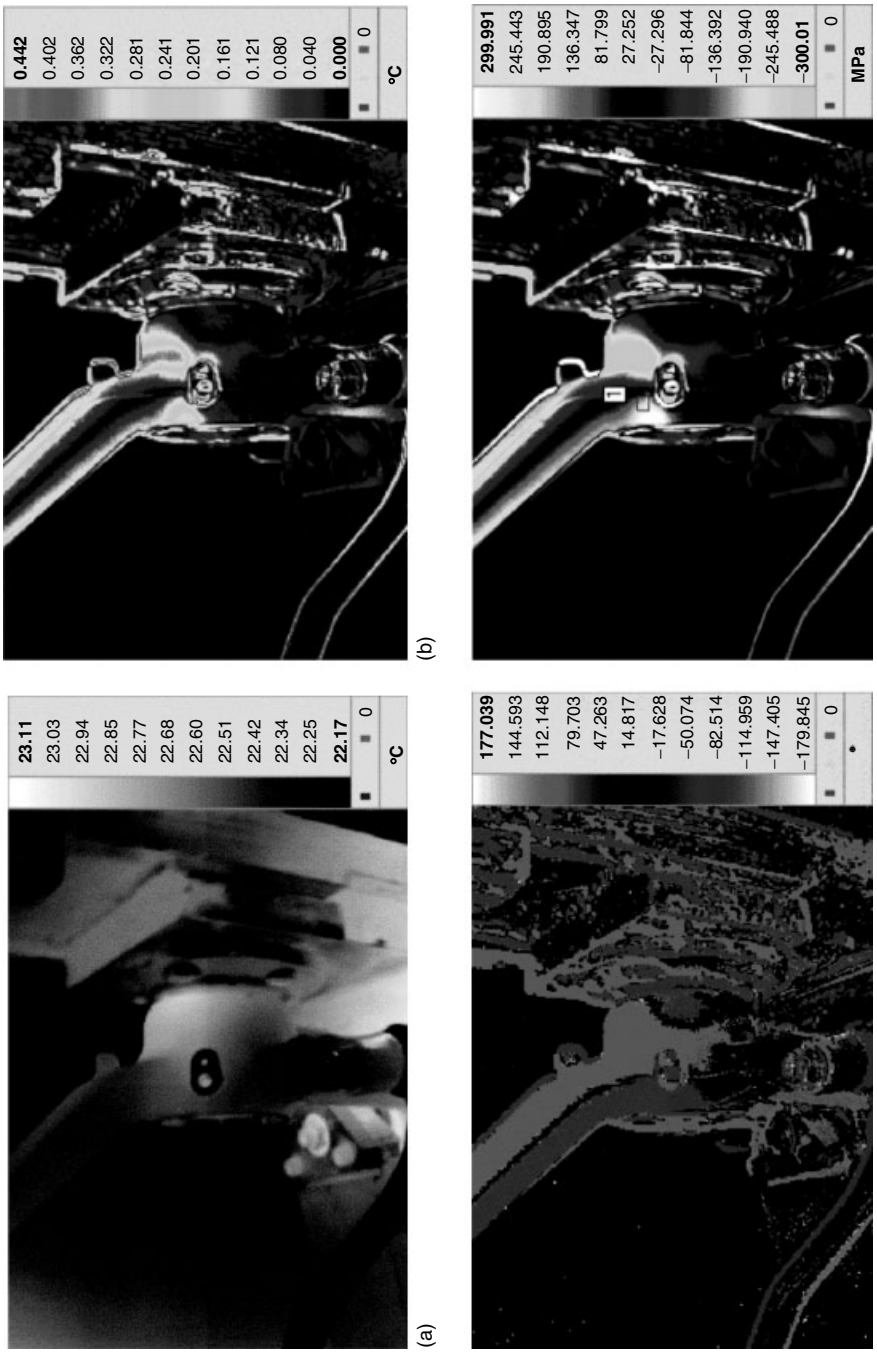

Figure 4. Images of a steering knuckle obtained with a thermographic stress analyzer. (a) Raw thermal image, (b) modulated temperature amplitude, (c) phase image, and (d) stress map. [Reproduced by permission of CEDIP Infrared System.]

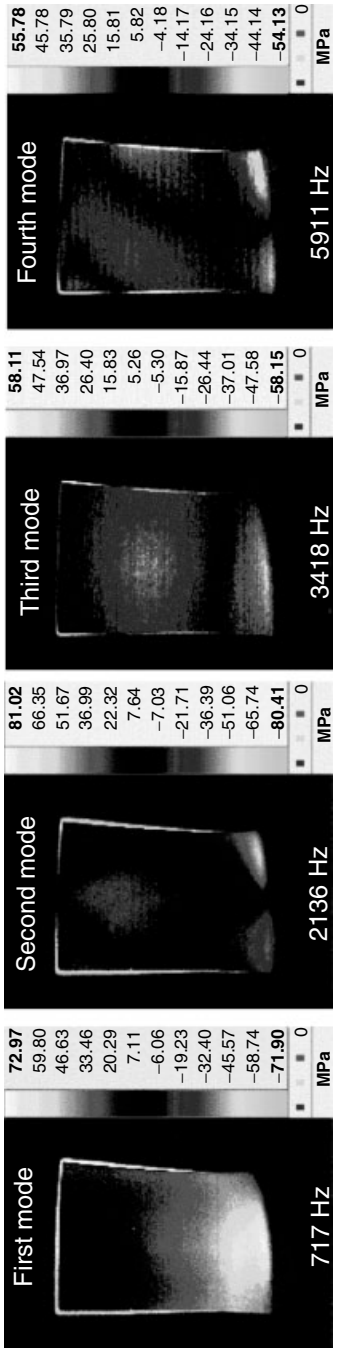

Figure 5. Visualization of the thermoelastic coupling linked to the first modes of a turbine blade. [Reproduced by permission of CEDIP Infrared System.]

from the superposition of temperature variations due to the thermoelastic effect, ΔT_{el}, the dissipated heat, ΔT_{diss}, and the heat energy losses to the environment. Figure 6 schematically presents the variation of the material temperature, ΔT, during a sinusoidal mechanical loading process. Just after the start of the mechanical loading (short-term loading), the time-dependent temperature increase is adiabatic (no influence of the heat losses) and the dissipative contribution, ΔT_{diss}, is linear with time. The mean slope of the curve only depends on dissipation, defining a thermal parameter characteristic of these irreversible phenomena: $\Delta\tau_{diss}$, the temperature change due to heat dissipation per single mechanical loading cycle ($\Delta\tau_{diss} = \Delta T_{diss}/N$, where N is the number of initial cycles). The slope progressively decreases and finally becomes zero when an equilibrium is reached between the internal generation of heat and the heat losses. Measuring this initial slope with standard thermography is a possible technique to monitor the damage process. Rösner *et al.* [14] applied a 30-Hz-cyclic loading ($\sigma_{alt} = 400\,\text{MPa}$, $\sigma_{mean} = 468\,\text{MPa}$) to Ti–6Al–4V specimens and monitored the temperature evolution with an IR camera. The chosen stress amplitude led to failure after about 8×10^4 cycles. Temperature increased continuously until failure occurred. After stopping the cyclic loading and then reloading, the new $\Delta\tau_{diss}$ was shown to be an increasing function of the number of already applied stress cycles.

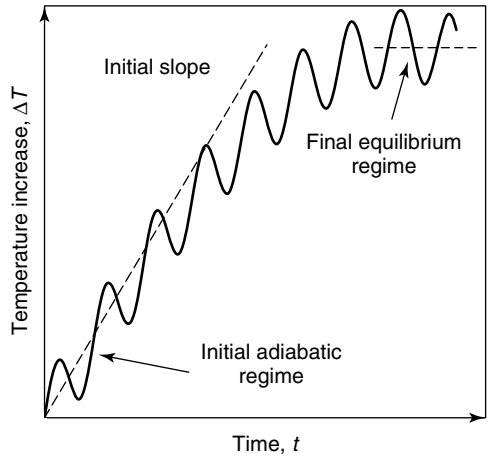

Figure 6. Temperature–time variation during short-term mechanical loading and evaluation of the initial slope.

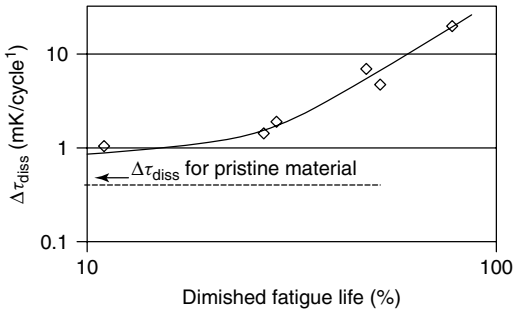

Figure 7. Comparison of the thermal parameter measured on several specimens with varied percentage of diminished fatigue life.

Thus, heat dissipation measurement yields information about the residual life of the structure Figure 7). The same authors later demonstrated that for heat dissipation measurements, short-term loading with a reduced stress could be applied too. For this purpose, they applied both a tensile stressing at 30 Hz and an ultrasonic excitation at 20 kHz [15].

4.2 Damage detection by stimulated thermography

In the previous section of this article, thermographic techniques used in experimental mechanics were presented as candidate techniques for SHM. They have the potential of assessing the distribution of stresses and dissipative heat sources.

Another approach in the use of thermography for SHM consists of detecting the damage itself acting as a heterogeneity of thermal properties or a discontinuity in the internal structure arrangement. This approach comes from classical NDE. The technique involved in this approach is called *stimulated thermography*. The stimulation is generally a flux of photons (*photothermal thermography*). This type of technique is described in the following section.

A new and promising way to monitor defects consists of propagating ultrasound in the structure and detecting the heat sources generated by their interaction with the defects. This approach is very briefly mentioned here.

4.2.1 Photothermal thermography

There are mainly two types of photothermal thermography: the pulsed technique, which can be applied with standard thermographic systems, and the modulated technique, one requiring lock-in thermographic systems.

Pulsed or transient photothermal thermography
Using thermal models [16–18] developed for photothermal radiometry at the end of the 1980s and inversion methods [19–23], the first quantitative thermographic works appeared at the beginning of the 1990s. During this period, this approach was the subject of numerous works and led to robust procedures allowing the production of *depthgrams* (equivalent to an ultrasonic D-scan) and evaluation of the equivalent thermal resistance for defects parallel to the structure surface [24–27].

With such inversion procedures, pulsed photothermal thermography has become a well-established technique in NDE, very attractive for the rapid obtainment of extended images. The comparison of such a technique [25] with a very different NDE technique (Compton backscatter) is presented in Figure 8 to show the ability of thermography to recover the exact shape of delaminations inside a complex composite structure.

Modulated or lock-in photothermal thermography
Lock-in thermography has a similar history, with its basis coming from photothermal radiometry in the 1980s [28]. Very soon, it appeared that the problem of the lack of rapidity of the measurements due to point-by-point scanning could be solved by a lock-in thermography technique [29–31]. In the 1990s several groups actively developed this technique and correlated inversion procedures for NDE purposes [32–35].

An example of application of the technique to an aircraft, the Dornier Do328, is given in Figure 9. The modulation frequency is 0.015 Hz. The area of the aircraft monitored is the tail core. The stiffeners are very visible on the phase image obtained. The image confirms the integrity of the structure. Of course, the analysis of this IR image requires a thorough knowledge of the internal structure.

Both techniques, pulsed and modulated, have their advantages and drawbacks. The lock-in technique, thanks to the production of phase images, does not have the problem of normalization caused by the unavoidable nonuniformity of practical heat depositions, but requires several experiments when the depth

of the damage is unknown. Furthermore, the inverse problem is not simple. On the contrary, the pulsed technique permits finding with a unique test a damage site lying at an unknown depth; the inverse problem is more simple, allowing the use of analytical algorithms to deduce the depth and equivalent thermal resistance of the damage [19]. In compensation, normalization is required. The most accurate solution consists of using the early detection of the thermal contrast [26] and not the maximum contrast as commonly used by most of the experimenters.

More recently, a hybrid approach was proposed [37]: the pulsed thermogram is analyzed by a Fourier transform, which permits the establishment of phase

images not requiring normalization. This technique, called *pulsed phase thermography*, is frequently used nowadays, but until now no really objective and quantitative comparative studies between this technique and the other two have been done.

4.2.2 Ultrasonic vibrothermography

Ultrasonic vibrothermography is an NDE technique based on the application of modulated mechanical stresses produced by the propagation of ultrasounds in the structure, while an IR camera maps the surface temperature [38]. Thermomechanical coupling is responsible for heat production, particularly in damaged regions, which convert energy into heat through enhanced viscoelastic dissipation, collisions, and/or rubbing of internal free surfaces present in delaminations and cracks. Surface and internal defects appear hotter in surface temperature images. This recent technique is presented in detail elsewhere in the Encyclopedia (*see* **Nondestructive Evaluation of Cooperative Structures (NDECS)**, Section 6).

5 CONCLUSIONS

After a recall on radiometry and thermal imagery, a very general analysis of the thermographic measurement has been made, emphasizing the particular interest of active thermography, which can be used to monitor the structural health state of a structure through the detection of abnormalities in the strain distribution, dissipative heat sources or disturbances of the temperature field after a stimulation of the structure. Then, two types of active thermography applicable to SHM have been detailed: thermography with thermomechanical stimulations and photothermal thermography. Ultrasonic vibrothermography, a third type of active thermography, has been only briefly mentioned since this technique is presented elsewhere in detail (*see* **Nondestructive Evaluation of Cooperative Structures (NDECS)**).

These powerful techniques are more NDE techniques than SHM techniques because the detection is achieved with a camera, without contact, from outside the structure. Nevertheless, an attempt to couple this detection system with embedded stimulations could lead to a hybrid or semi-integrated approach (*see* **Nondestructive Evaluation of Cooperative Structures (NDECS)**).

Chapter 20
Eddy-current Methods

Neil Goldfine, Andrew Washabaugh, Yanko Sheiretov and Mark Windoloski
JENTEK Sensors, Inc., Waltham, MA, USA

1 INTRODUCTION

Eddy-current testing (ET) is a nondestructive testing (NDT) technique that uses time-varying magnetic fields to induce eddy currents in a conducting material. ET is used to assess the material under test conditions or to detect flaws. A time-varying current in a drive coil, at a prescribed frequency or with a prescribed shape in time (i.e., a pulse), creates a time-varying magnetic field that induces an eddy current in the material with a pattern that follows the drive coil geometry. The electrical conductivity, magnetic permeability, and thicknesses of material layers (or process-affected zones), as well as the sensor proximity to the surface (i.e., the liftoff), affect the sensed response at the terminals of the drive coil or at the terminals of one or more sensing elements. Sensing elements can be inductive coils that respond to time-varying fields or alternative field sensors, e.g., magnetoresistive sensors. The sensitivity of different sensing element types is not as important as the actual signal to noise achievable for a given application. The signal to noise is a measure of the sensor response to a change in specific material condition or to a specific flaw type and size of interest compared to all relevant sources of noise/errors. This comparison must be made under actual (or at least representative) inspection conditions. The presence of a flaw (e.g., crack, inclusion, and porosity) or a variation in a material condition (e.g., residual stress effects on magnetic permeability) is sensed by the ET sensor (one sensing element) or ET array (multiple sensing elements) in the region immediately under the sensor. Thus, ET is a local measurement, but ET can provide rapid wide area coverage using manual or automated scanners.

In the context of structural health monitoring (SHM), ET is one of several techniques that the

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

maintainers of high-value assets can select as part of an asset life management program. In this article, conventional ET and advanced ET methods are described. The focus is on scanning and point-by-point ET using handheld or automated systems.

In a companion article on eddy-current *in situ* sensors (*see* **Eddy-current *in situ* Sensors for SHM**), the focus is on surface-mounted and embedded sensors for SHM, using onboard instrumentation or portable data-acquisition units. Using a portable data-acquisition system with onboard ET sensors is a direct replacement for conventional ET (NDT), but with the advantage that difficult-to-access locations can be inspected without disassembly to gain access. However, as described in this and the companion article, the achievable signal-to-noise ratio will vary for three types of ET: (i) single inspections with point-by-point measurements or scanning arrays, (ii) embedded or surface-mounted sensors with portable instruments for scheduled or unscheduled inspections of difficult-to-access locations, and (iii) continuous monitoring of onboard sensors with onboard instrumentation.

This article, in combination with the *in situ* sensor article *see* **Eddy-current *in situ* Sensors for SHM**, is designed to help operators and maintainers make intelligent decisions based on the realistic capabilities of today's NDT and SHM solutions, as well as the anticipated new NDT and SHM developments expected within the near future. It is particularly important to remember that NDT capabilities are not stagnant and continue to evolve. Thus, future SHM developments should be compared to anticipated advances in NDT and not only current methods.

This article is organized as follows: (i) Section 2 provides the authors' perspective on the roles of NDT and SHM in life management of legacy and new assets; (ii) Section 3 lists different electromagnetic methods, such as magnetic flux leakage (MFL) and remote field eddy-current methods, and explains how these methods relate to ET; (iii) Section 4 describes the important issues that must be addressed when selecting and applying ET methods; (iv) Section 5 provides a brief introduction to ET as a foundation for understanding the new capabilities offered by advanced methods; (v) Section 6 describes the MWM®-Array ET method, as an advanced ET method that addresses many of the limitations of conventional ET; and (vi) Section 7 describes the importance of real-crack standards when using NDT methods and provides an overview of ET methods for the SHM encyclopedia, because surface-mounted ET sensors offer a new method for generating real-crack standards.

2 BACKGROUND

This encyclopedia of SHM is designed to provide a foundation for maintainers and operators of high-value assets to select the appropriate solution for asset life management. Historically, SHM has been limited to measurement of usage states such as strain, temperature, and vibrations. However, direct monitoring capabilities for fatigue and corrosion damage are now becoming available. In this transition period, for the next decade or so, a balance between conventional NDT, advanced NDT, and SHM solutions will most often be appropriate. Even in the long term, SHM is not expected to replace NDT completely for legacy or even next-generation aircraft, ships, pipelines, bridges, and other high-value assets. Thus, a comprehensive adaptive life management (ALM) approach would incorporate both SHM and NDT data for decision support.

Furthermore, diagnostic methods that temporarily place and/or monitor sensors on structures, e.g., for stress or temperature sensing, offer valuable solutions for some applications, such as bridge assessments and machinery testing, without providing an integrated SHM capability. New magnetic stress gauges and guided-wave ultrasonic methods offer new promise for such diagnostic needs, without requiring significant surface preparation and with limited interference with asset availability.

NDT has clear advantages over SHM for some applications. For example, advanced NDT methods such as locally applied phased array ultrasonics or meandering winding magnetometer (MWM) and MWM-Array ET are highly sensitive and reliable for scanning of large areas and for detecting relatively small cracks. Currently available wide area SHM methods cannot match the sensitivity and reliability of these advanced NDT methods, but new methods such as guided-wave ultrasonic testing (GWUT) may offer solutions for some wide area inspection needs. Other local SHM methods, such as surface-mounted ET, may offer high sensitivity, but still will not offer all of the advantages and reliability of scanning methods for all applications.

This is an important practical distinction. Highly sensitive results have been demonstrated in recent years by SHM tests performed in a laboratory environment, but this sensitivity does not always translate into achievable measurement capabilities for installed systems on aircraft. Controlled laboratory testing over relatively short periods does not capture the realistic conditions encountered when monitoring components over years or decades in service (e.g., cable and sensor degradation and instrumentation drift). For example, one advantage of continuous fatigue monitoring in a laboratory is that permanently mounted sensors (e.g., ET or ultrasonic testing (UT)) can monitor response changes over relatively short periods (such as hours or days) avoiding substantial instrumentation variations, while continuously monitoring the crack growth without interruption.

In practice, continuous monitoring with SHM requires highly reliable, *in situ* (i.e., on aircraft) instrumentation. This is necessary to avoid gaps in health monitoring, during which damage can grow substantially (or an event, e.g., overload or impact, can occur) reducing the reliability of such onboard methods for monitoring a specific defect initiation and growth. The problem with SHM is that onboard sensors can lose their reference frame if cracks or other damage can grow when data is not being acquired. For NDT, neighboring areas with no damage can usually be scanned for comparisons (it is not always sufficient to add channels in areas that do not experience damage, since, for example, channel drift may vary). In the near term (over the next five years) before onboard instrumentation is widely available, SHM using direct damage monitoring sensors, such as ET and UT or even GWUT, will rely on portable data-acquisition units for most implementations; thus, performance will be similar or possibly substantially worse than that achievable with conventional or advanced NDT scanning methods.

Consequently, the main advantage of direct damage monitoring SHM in the near term will be access to difficult-to-access locations without requiring substantial disassembly. This is a big advantage in many applications in which a few (up to 50) critical locations must be inspected to enable life extension/sustainment of legacy fleets. There are, however, many applications that cannot be addressed by NDT. For example, NDT methods cannot protect against rapid damage evolution, e.g., from foreign object damage (FOD) in flight. Thus, onboard vibration sensing or other sensing modes for rapid (and large) damage evolution offer immediate benefits for avoiding catastrophic failures from such unpredictable events.

Thus, before selecting an onboard sensor solution for SHM, it is important to consider the advancements of ET and other NDT methods. Many of these advances have been aimed at increasing the reliability of the measurement. Unfortunately, the range of performance offered by different sensor designs and data analysis methods has broadened, making it increasingly difficult to define ET capabilities in general terms. Although probability of detection (POD) studies on real-crack specimens are recommended, in practice, the costs and convenience of such studies are not always practical. Many studies use electrical discharge machined (EDM) notches or other simulated flaws (flat bottom holes) that are far from representative of actual damage. Care should be taken to assess the actual achievable signal-to-noise ratio for in-service generated flaws, before setting safety margins based on POD performance on simulated flaws. This is often difficult.

This article does not attempt to provide a comprehensive history or catalog of methods; instead, the goal is to provide a perspective on the advances of the last decade and the promise of improved capabilities in the next decade. Conventional ET methods are being increasingly used in the aerospace, automotive, energy, infrastructure, and manufacturing sectors. In many cases, these methods have demonstrated high reliability compared to visual inspection and other NDT methods, resulting in wide acceptance for in-service inspection and manufacturing quality assurance. However, anecdotal stories about conventional NDT performance failures are common and performance in-service is often well below the expectations set by POD studies. It is not unusual to hear comments from world renowned NDT/POD experts such as "sometimes ... we are performing inspection ceremonies", or from high-level military officials, saying "it's as if it was never inspected" after large cracks were found on multiple aircraft in a fleet, even after repeated inspections.

The growing divide between the performance that can be achieved with a modern automated method and that which can be achieved with a conventional operator-driven ET or UT method further

confuses this issue. For many applications, conventional methods are more than adequate. However, for some applications, such as critical engine component and landing gear inspection of shot peened surfaces, conventional methods simply do not work reliably (for detection of relatively small cracks—as now required in many cases, to ensure safety), and more advanced methods are needed.

Furthermore, conventional ET methods require different training than automated ET methods, not only for operation but also for assessment. Understanding how to use a conventional ET method, even for "Level II" and "Level III" practitioners, is not necessarily adequate background for assessing advanced methods. At times, this makes it difficult for senior management to obtain correct assessments from their NDT departments regarding the capabilities of advanced NDT methods, especially when compared to the conventional methods that these practitioners are most comfortable with. Unbiased management oversight is absolutely needed to ensure that the best solutions are used for each application. Entrenched practices that give comfort to management (and continuity with historical practice) and do not evolve with changing mission requirements are common and can result in significant lapses in safety, and sometimes huge increases in life cycle costs (i.e., when large component populations are unnecessarily retired, or when undetected damage progresses to levels requiring far more expensive repairs than necessary).

It is a common perception that there is value in maintaining the consistency of future inspections with historical ET and UT databases even though the performance of such methods may be far inferior to that achievable with newer advanced methods. This can be avoided. Historical ET and UT data can be replaced with modern methods without losing continuity by providing an overlap period during which both methods are employed. This is already happening in isolated cases. Fortunately, we expect this to be the rule moving forward—not the exception.

Still, advanced methods must be proven before they are introduced widely. One often misstated disadvantage of advanced NDT methods is that they are "proprietary" and therefore will result in higher costs. This is simply untrue and the evidence strongly indicates that many implementations of advanced methods offer substantial savings in reduced labor costs, increased reliability, and reduced false indication rates. Furthermore, even conventional implementations of NDT by original equipment manufacturers (OEM)s are often considered proprietary; thus, the apparent advantages of conventional (open access) methods are more perceived than real.

Another common misconception is that very sensitive methods will detect defects so small that too many "good" parts will be retired. Modern methods such as the MWM-Array ET method, described later, offer new size thresholding capabilities that can suppress detection of defects below a prescribed threshold, while more reliably detecting flaws with sizes above the threshold. This discrimination capability will actually result in retirement of far fewer "good" parts, and dramatically reduce the most important safety risk, i.e., missing large defects.

The goal of this article is to provide the reader with an understanding of the capabilities of both conventional and advanced/automated ET methods. This is not intended to replace training in specific methods. Any NDT method must be qualified for each application by an experienced professional. Even fully automated NDT methods require training to enable proper interpretation of results for life management decision support.

3 ELECTROMAGNETIC TESTING METHODS

Electromagnetic fields are commonly used in NDT to detect defects and characterize material conditions, including manufacturing quality and serviceability. Electromagnetic NDT methods can be divided into three groups: those that operate in the dynamic regime (typically above 100 MHz), those that operate in the quasistatic regime (typically between 10 Hz and 50 MHz), and those that use constant fields (generated by permanent magnets or direct current (dc) sources) [1, 2]:

- Electromagnetic methods in the dynamic regime include
  - ground penetrating radar (GPR, frequency range: 30–3000 MHz);
  - visual inspection (frequencies of order 10^{15} Hz);

  - microwave (frequency range: 300 MHz to 300 GHz).
- Electromagnetic methods that operate in the quasistatic regime include
  - low-frequency and high-frequency ET (10 Hz to 40 MHz); and
  - capacitive sensing (i.e., dielectric spectroscopy; 0.0001 Hz to 10 MHz).
- The quasistatic regime also includes electromagnetic methods that use constant fields such as
  - MFL, which uses a permanent magnetic source; and
  - magnetic particle inspection (MPI), which magnetizes ferromagnetic components.

Some methods can operate in both the quasistatic or constant field modes. For example, some methods use inductive coils to excite either time-varying (alternating current, ac source) or constant fields (dc source) and use sensors that measure field intensity (i.e., using Hall sensors or magnetoresistive sensors) instead of coils that sense the rate of change of the field (as accomplished in a conventional ET method).

This article describes methods that operate in the quasistatic mode, called *magneto-quasistatics* [1]. This mode includes both quasistatic, time-varying magnetic fields and constant magnetic fields. Magneto-quasistatics is defined as the regime within which the wavelength of traveling waves is significantly longer than the characteristic dimensions of the sensor, coatings/process-affected zone, liftoff, or other system dimensions.[a] This includes ET, MFL, MPI, and other methods that take advantage of time-varying or constant field sources in the quasistatic regime.

The choices of winding constructs are broad and it is no longer practical to divide these methods into narrowly defined categories such as remote field ET or MFL or "reflectance" probes or even remote field ET. There are clear strengths and limitations to coil designs, however. For example, the use of conventional differential coils was driven, over a decade ago, by the need to reduce noise and increase sensitivity for crack detection. Today, much of this motivation for such differential designs no longer exists. Improvements in cable designs and instrumentation have reduced many electrical noise sources so that material noise from grains, inclusions, and inconsequential defects can produce eddy-current sensor signals that are larger than noise levels of existing instruments. Thus, using differential coils to reduce the impact of instrumentation noise no longer impacts performance for most advanced applications of modern eddy-current systems. Instead, the focus is now on reducing material noise and other noise sources (e.g., from edges, roughness, and other interferences).

Also, continuous wave versus pulsed ET modes are often discussed. Continuous wave methods use one or more frequencies for the input current to the ET drive winding. In general, these single and multiple frequency methods offer substantial advantages over pulsed ET methods that excite time domain signals. Historically, it was less expensive to use pulsed ET methods. One inherent *disadvantage* of pulsed ET methods is the wide bandwidth of frequency content excited in a pulsed ET mode. Because pulsed ET signals include high-frequency and low-frequency content, these methods excite noise sources in a material or construct (e.g., near-surface anomalies or inconsequential structure behind layers) that can otherwise be suppressed in a multiple frequency continuous wave method. Also, efforts to "deconvolve" pulsed ET data have been ongoing for decades. Researchers often state that it is an *advantage* to "take all the multiple frequency data at the same time." This is actually a substantial disadvantage because numerically, when one combines information and then tries to "deconvolve" it, noise will increase. Thus, when possible, continuous wave methods are generally recommended. However, in some limited applications, pulsed ET can actually reduce noise levels (pulsed ET methods are not discussed in detail here). In any case, selection of methods and performance comparisons should always be based on achievable signal to noise (and other reliability metrics) for specific applications, not on anecdotal perceptions.

4 POD STUDIES, NOISE ISSUES, CALIBRATION, AND PERFORMANCE VERIFICATION

Performance assessment for both NDT and SHM solutions should be divided into two key areas including:

- logistics (data format convenience, throughput, portability, required support equipment, size/weight, scanning/coverage, ease of use, training requirements, operator capability/experience requirements, cost, etc.) and
- reliability (reproducibility, signal to noise/sensitivity, selectivity/robustness/classification of defects, etc.).

The use of POD studies can play an integral role in providing a performance assessment of NDT systems. Unfortunately, the common practice of using POD studies, performed under unrealistic conditions and on unrealistic test specimens, has confused the practical assessment of actual NDT capabilities. It is essential that actual performance on service-generated damage (e.g., cracks) is verified whenever practical. Inspection of actual components is practical, at least to evaluate noise levels, for *all* applications. For example, the first 10 or more components inspected should provide a basis for an initial assessment of inherent noise levels under actual inspection conditions. No system should be considered qualified for a specific application before scanning on actual hardware to assess noise levels. It is not relevant to test on a large set of cracks or EDM notch specimens that do not have representative noise levels and the likely variety of noise sources. For example, flat and smooth specimens are often used to assess ET capability, when varied curvatures and surface roughness variations are two of the major sources of ET sensor noise and consequently, performance limitations.

Also, calibration is extremely important. It must be possible to verify that the ET calibration and signal to noise achieved in an actual inspection is practically the same as that in the POD study. Otherwise, the POD study results should not be referenced when making NDT/SHM decisions. For example, all ET methods are sensitive to liftoff (proximity to the surface) variations. Thus, if performance on the test samples is limited to a fixed liftoff range (i.e., the test specimens are smooth and flat), and the actual service-exposed components have higher levels of roughness or curvature, then the resulting higher liftoffs can substantially reduce detection performance.

This introduces a paradox, since most conventional ET methods cannot accurately record liftoff at each inspection location. Fortunately, new advanced systems can provide this capability. This is particularly important for curved component surfaces and rough (e.g., shot peened) or fretted regions. Thus, recording the actual liftoff at each location within an inspection area is one way of ensuring proper performance.

Consistent evaluation criteria are critical to selection of NDT/SHM solutions. Performance for the specific problem being addressed may be very different from performance in a generic POD study sample set. Generic "round robin" POD studies often avoid the most important challenges of specific field and depot inspection applications. Eliminating these challenges makes it impossible to assess the advantages of advanced methods, often making methods look essentially equivalent in performance. Also, advanced methods may require more customization, so low-cost comparisons are generally not possible. This is another reason that, sometimes, inferior conventional methods continue to receive more use than far-superior advanced methods. Fortunately, this is also changing.

Many mistakes are common in anecdotal comparisons of ET methods; these include (i) focusing on signal and not on signal to noise, i.e., using ferrite cores and lots of turns in drive and sensing elements, at the expense of model-based predictability of ET response—*this is one example where performance would be improved on flat smooth specimens but not be realized on actual components*, (ii) assuming that the response to an EDM notch is related in any relevant way to the response on an actual crack—*note for relatively large cracks or buried cracks this may be a good assumption, but for relatively small and tight surface-breaking flaws this is not a good assumption*, and (iii) assuming that noise sources from the field or depot can be represented sufficiently in laboratory studies—*and not including evaluations on actual components early in comparisons of advanced and conventional methods*. These and other mistakes can result in poor selection of NDT/SHM solutions.

One area of critical importance is the inspection of shot peened components in landing gear and engines. It is a mistake to assume that NDT performance for EDM notches or even for real cracks grown in specimens that are not shot peened (even for cracks grown from EDM notches in shot peened

specimens) will be useful for performance evaluations. Shot peening and other cold working methods, such as burnishing, and laser shock processing introduce compressive stresses at the surface; this extends fatigue life. Thus, if a fatigue crack grows in the service of a shot peened part, when the part is at rest, then the crack will be "tight", because it will be under compression. Thus, ET or UT or other NDT methods must be tested with real cracks under the same conditions.

The generation of real-crack standards is addressed near the end of this article. Today, methods are available to generate real-crack specimens in shot peened components without using starter notches, at a comparable cost to EDM notches. Thus, it is no longer necessary to make compromises in performance testing that are so unrealistic.

The focus in future developments of advanced ET should be on reducing the impact of material noise. Two ways to address material noise (the primary limitation for some advanced ET methods) are (i) to use spatial filters, multiple frequencies and two- and three-dimensional defect models, and to enable discrimination between signals from different noise sources and defects of interest and (ii) to use time-based filtering, if possible, to image the material before damage occurs, and then subtract or otherwise filter out the impact of material noise that is not associated with the evolution of the damage/defect of interest. Of course, the latter only works for in-service defect generation, as opposed to manufacturing-induced defects for which precrack imaging may not be possible.

5 CONVENTIONAL ET METHODS

This section briefly reviews some of the capabilities of conventional ET methods, but the focus is on the limitations of these conventional methods to lay the foundation for understanding the advantages of advanced ET methods and ET-based SHM. There are other more comprehensive references on conventional ET methods [3].

NDT methods use sensors to inspect a material for defects or condition/quality. ET uses time-varying magnetic fields to induce eddy currents in a material under test. For crack detection, the induced eddy-current pattern is interrupted by the presence of a crack in the material. For condition/quality assessment (also referred to as *material characterization*), the properties of the material or a coating/process-affected layer are measured and related to a property of interest such as heat-affected zone thickness or cold-work (shot peen[b]) quality. Conventional ET can be used to examine both nonferrous and ferrous metals. However, protective coatings, such as cadmium plating, and surface processing, such as shot peening, traditionally lead to difficulties and poor performance for ferrous alloy inspection.

Historically, ET developed from numerous scientific investigations involving electricity and magnetism that started in the nineteenth century. For example, Han Christian Oersted discovered the presence of a magnetic field in the vicinity of a current-carrying wire. This was followed shortly thereafter by Michael Faraday demonstrating electromagnetic induction, in which current could be induced in a coil by the motion of magnet relative to the coil or by passing a time-varying current through an adjacent coil. Mathematical formulations for electromagnetic induction were developed by Heinrich Friedrich Lenz and Hermann L. von Helmholtz, with James Clerk Maxwell ultimately developing the basic expressions governing electromagnetic phenomenon.

Three simple applications of conventional ET are briefly described: (i) conventional ET-based crack detection, (ii) conventional ET-based conductivity measurement, and (iii) conventional ET-based coating thickness measurement.

5.1 Conventional ET crack detection

For crack detection, conventional ET methods use impedance plane analysis to compensate for liftoff. As shown in Figure 1, the liftoff response is rotated to the horizontal axis and the crack signal is measured in the vertical direction. An operator views the impedance plane, and cracks above a given threshold are determined to be crack indications. To calibrate, first the liftoff direction is determined and then the scale is typically set using an EDM notch (e.g., 0.03 in. long by 0.015 in. deep, and a few thousandths wide). For example, the EDM notch response may be set to 80% of the scale and any ET response above 50% may be recorded as a crack indication.

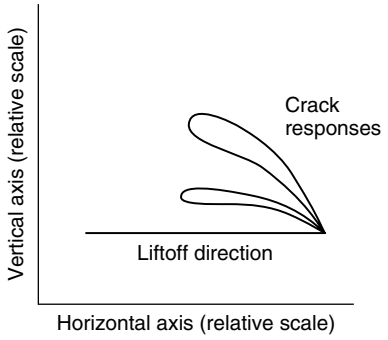

Figure 1. Typical impedance representation of a crack response.

There are many concerns with conventional ET methods for crack detection; some are listed below:

1. Calibration verification
Detection sensitivity of the probe is assumed to be the same as that of a different probe used, perhaps in a POD study. If the sensor is significantly different (as indicated by Auld and Moulder [4], where the fields from conventional ET probes were shown to vary by as much as 35% even when the terminal response was essentially identical), then the signal-to-noise level may be much lower than expected, producing significant false indications even though the "signal" level for a given EDM notch has been set to the same value as for the POD study. Also, if the conditions change from calibration on the test block to measurement on the part (e.g., temperature shifts, roughness differences, curvature variations, probe cable damage, or just cable motion), there is no method to verify that the correct calibration is sustained throughout the actual inspection. For example, a conventional ET probe calibrated in a ship bay at room temperature will respond substantially differently when the same probe is used in more extreme temperatures shipboard.

2. Curvature, roughness, and paint thickness
Variations in the material under test curvature, surface roughness, paint thickness, and other effects such as probe tilt will each reduce sensitivity significantly compared to performance on a flat, smooth, and unpainted calibration or test specimen. Although this is also the case for advanced methods, some advanced methods enable the operator to verify that these variations are maintained to within acceptable levels to insure acceptable performance, and some methods use conformable sensors and other means to substantially limit these response variations.

3. Human error
These can manifest themselves in a variety of forms. Conventional methods do little to avoid such errors. These errors include (i) selecting the wrong probe, (ii) not verifying the noise level on the standard, both away from flaws and by multiple repeated measurements both before and after an inspection, (iii) improper setting of displays and scales, (iv) scanning at speeds above that used in the POD study, (iv) tilting the probe, (v) not scanning the entire surface of interest (for manual scanning) or scanning with less sensor overlap on successive incremental scans, (vi) calibrating on the wrong crack/EDM notch standard, and (vi) not accounting well for temperature variations in the standards and in the component under test. There are also many less obvious human error sources.

4. Tight cracks in shot peened surfaces
This is a severe limitation of conventional methods. Conventional ET probes cannot reliably detect tight cracks in shot peened specimens. As described in Section 6, a linear drive design has advantages over conventional (more circular) coil designs, and use of higher frequencies is often necessary to achieve sufficient sensitivity.

5. Limited frequency range
Most ET probes have a limited frequency range of operation (e.g., 1–5 kHz, 50–500 kHz, or 1–2.5 MHz). This narrow frequency range is a limitation for crack-depth sizing using two frequency methods. Furthermore, conventional ET instruments and probes are typically limited to operation below 5 MHz. Some advanced probes have extended this range, but only a few provide reliable operation at these elevated frequencies. For example, high frequencies above 10 MHz and high reliability are needed to detect small cracks in shot peened superalloy components (e.g., 0.016 in. length by 0.008 in. depth).

6. Throughput
Conventional ET probes are limited in their ability to provide rapid imaging capability compared to array-based solutions that can scan wide areas with 10–50 times the throughput. Fully parallel instrument

channels are needed to provide reliable throughput increases with complete and uniform coverage control. Some instruments that use excessive multiplexing during scanning have most channels turned off at any one time. This introduces concerns about the uniformity of coverage of the inspected area, compared to that in the POD study. It is essential that these are the same or better on a component if the POD performance is to be assumed. Furthermore, even arrays of conventional ET probes are limited in that the crack signal varies dramatically across the sensor and between sensing elements. Some advanced eddy-current arrays have solved these issues, but most are plagued by poor reliability in actual implementations.

7. Poor sensitivity to tight cracks
For both shot peened surfaces and for detection of smaller (shallow) cracks, circular drive winding configurations are typically less sensitive than some more advanced linear drive designs.

8. Sensitivity to mechanical damage
This is a major weakness that dramatically increases false indications. Scratches, nicks, and dings can produce false indications for conventional ET, forcing detection thresholds to be raised to avoid costly false indications. This is particularly difficult in regions with fretting damage, e.g., for engine disk slots and bolt holes.

9. Severe scanner and alignment requirements
The high sensitivity of conventional ET probes to tilt and liftoff variations and the need to scan large areas with a single coil have introduced severe scanner requirements. Huge steel gantry structures are common for costly ET scanners. The high cost and large footprints of these scanners can be avoided by using modern conformable ET array technologies and using self-diagnostics to ensure proper performance. This is true both for depot/production ET scanners and for portable field scanners.

10. No self-diagnostics capability
Conventional ET, using either differential or absolute coils and calibrating on crack standards, is inherently a relative method (i.e., measurement amplitudes are relative to the reference standard properties). Thus, there is no mechanism for verifying that either the liftoff value or the effective conductivity measurements on the material under test are within a range that would indicate proper performance. This issue has been addressed by some advanced ET methods.

11. Other limitations
Many ET sensor arrays consist of a collection of conventional ET coils (with individual drive and sensing elements). These arrays have several major limitations:

(a) Cross talk between sensing elements
Neighboring drives produce signals that are not only captured by the associated sensing element but also by neighboring sensing elements. One common practice is to multiplex the sensors in an array to avoid measuring on neighboring sensing elements, reducing cross-talk effects. This approach introduces concerns regarding coverage and must be performed with care to ensure POD performance is maintained. Other advanced arrays such as the MWM-Array use linear drive wires that eliminate this cross-talk issue entirely.

(b) Variable sensing element responses
Arrays of conventional ET sensors and variability in lead configurations for each sensing element cause variability in the individual sensing element responses to cracks. This makes it difficult to assess POD performance using a conventional ET array. Advanced flexible arrays use microfabrication methods to produce nearly identical sensing elements but many of these designs still suffer from sensing element response variations due to variability in instrumentation and leads. MWM-Array methods address this need by using a patented calibration methodology that corrects for these element-to-element variations, while using microfabrication and a linear drive to limit the severity of these variations. It is anticipated that arrays such as the MWM-Array that address these concerns will become more and more widely used in the near future.

5.2 Conventional ET conductivity measurement

Conventional ET conductivity measurements use one or more conductivity reference standards to calibrate

the instrumentation. The standards have an electrical conductivity comparable to the expected conductivity of the material to be examined and preferably bracket the measured conductivity. Depending upon the probe and instrument configuration, the standards can be used to determine the liftoff direction as with ET crack detection. Many of the limitations described above are also relevant for single sensing element methods or array-based methods for conductivity measurement. The use of conductivity standards to calibrate conventional ET sensors introduces opportunities for human error and eliminates the capability to provide self-diagnostics by verifying performance on a conductivity standard instead of calibrating on such a standard. Also, such methods are typically limited by the available range of conductivity standards.

In most applications, conventional ET examinations use a circular coil. This creates a rotationally symmetric magnetic field so that the probe response is independent of orientation on the material surface. As a consequence, anisotropic (directional) conductivity variations cannot be measured. While this can be an advantage because it removes sensitivity to such variations, in some situations this anisotropy is in itself the material variation of interest for quality or degradation assessments. For example, for the roller burnishing quality inspection of the C-130 and P-3 propellers, the conductivity is measured in two directions (using an MWM® sensor) and the ratio is used to assess the roller burnishing quality.

Advanced methods, which do not require the use of standards for calibration and are calibrated using model-based methods, offer wider range of conductivity measurement reliability and robustness. Furthermore, the use of air as a calibration material, as described in ASTM E2338 [5], offers a self-diagnostic capability that can allow the sensor performance to be verified on a reference standard for each individual sensing element in an ET array. This ASTM standard describes the air calibration method in detail.

5.3 Conventional ET coating thickness measurement

For coating thickness measurements, conventional ET requires a set of coating thickness reference standards [6]. As with the conductivity measurement, this yields a limited performance range and eliminates much of the potential for self-diagnostics. More important, however, is that conventional ET coating property measurements require that the conductivity of the coating standards and the conductivity of the actual coating being tested are essentially the same (i.e., close enough to ensure that the thickness measurement is sufficiently accurate). Advanced methods, performed in accordance with ASTM E2338 [5], offer substantial improvements by enabling calibration without coating standards and by independently measuring the coating conductivity and thickness. This is an enabling feature not only for coating thickness measurement but also for detection of cracks in components with coatings, for identification of coating thermal aging, and for detection of manufacturing quality lapses, e.g., excessive porosity.

6 ADVANCED ET METHOD EXAMPLE: THE MWM®-ARRAY

The MWM-Array is a conformable ET array that was specifically designed for model-based inverse methods. Multivariate inverse methods convert the sensor response into absolute property estimates. Multiple sensor responses, for each individual sensing element at each location in an image, are converted into estimates of several material properties at each location along the inspected surface of the material under test. These methods can also be used to estimate geometric parameters (e.g., liftoff or coating thicknesses) and other dependent properties, such as stress (typically related to either magnetic permeability or electrical conductivity) and temperature (typically related to electrical conductivity).

The MWM-Array addresses most of the limitations listed above for crack detection, conductivity imaging, and coating characterization. For example, the MWM-Array is currently used by the US military for detection of fretting fatigue cracks in engine disk slots. Direct comparison of performance between this advanced method and conventional ET and liquid penetrant inspection (LPI) for actual implementations illustrates the dramatic advances that are possible. Also, this method and the JENTEK Sensors, Inc., Federal Aviation Administration (FAA), Navy, and Air Force team members were selected for the FAA 2007 “Better Way” Award, specifically for engine

component automated disk and blade dovetail inspection solutions.

In one direct comparison, on a US Navy engine population, over 3000 engine disk slots were inspected during an 18-month period at a Navy Depot using a 36-channel MWM-Array with a fully parallel architecture JENTEK impedance instrument. The automated MWM-Array system performed these inspections and (i) there were zero false indications, (ii) the speed achieved was less than 1 min per slot, (iii) over 9 disks in over 130 were detected with cracks, (iv) all detected cracks were verified by destructive testing, i.e., fractography, or other means, and (v) most of these cracks were missed by conventional ET and LPI.

Of course, this unusual level of performance reliability (POD and false indication rate) cannot be expected in all applications of the MWM-Array. However, such advanced automated ET systems are now available at a fraction of the cost of previous automated solutions and with substantial improvements in ease of use, inspection throughput (e.g., 1 min per slot vs 20 min per slot); they offer substantially smaller system footprint, and in some cases are semiportable.

This is an important example because it highlights the difficulty of managing NDT decisions and selecting solutions. Conventional NDT (ET and LPI) are expected to perform reliably; however, instances continue to occur where the original performance expectations (based on POD studies that may not have represented realistic conditions) are not being sustained in service. This highlights the need to improve performance evaluation methods.

Figure 2 illustrates measurement data using an advanced ET method that enables rapid conversion of sensor data into conductivity and liftoff data. The bottom right shows a model-based predicted sensor response as the conductivity and liftoff of a test material are varied. The sensor response, expressed in complex notation in terms of the real (in-phase) and imaginary (out-of-phase) components, depends upon the conductivity and liftoff in a nonlinear fashion. The measurement data for a single channel of a sensor array shows liftoff variation as the sensor array is scanned over the part, as well as the presence of a crack. Using advanced instrumentation, the acquisition rate for the data can be fast compared to the scan speed, which allows multiple data points (in this case 22) to be acquired over the crack. Other references describe how this same method can be used for more unknowns (e.g., for the thickness and conductivity of a coating, as well as the substrate conductivity and liftoff).

As shown in the upper left of Figure 2, a conductivity image is created using a precomputed database of sensor responses called a *measurement grid*. This database enables the rapid conversion of ET data into both conductivity and liftoff values, at each location along the surface being inspected. Multiple frequencies can be used to obtain effective conductivity measurements at each applied frequency. As shown on the bottom left of Figure 2, a typical ET impedance plane response, similar to those obtained for conventional ET methods, is produced. However, here the software automatically interprets the raw sensor data and builds images in near real time.

The key to making this method practical is the design of sensors, such as the MWM-Array, that eliminate most unmodeled dynamics and enable calibration in air without the use of crack, conductivity, or coating standards. The next three subsections describe three brief case studies that illustrate this capability for engine disk slot inspection, blade dovetail inspection, and bolt-hole inspections.

6.1 Case study I: engine disk slot inspection

Figure 3 shows a photograph of the MWM-Array systems at a NAVAIR Depot (Cherry Point) used for engine disk slot inspection, along with conductivity and liftoff image results. The engine disks are placed onto the conical supports and the sensor arrays are scanned through complex-shaped slots in the disks. The performance of these two systems is summarized below:

- *in use at* NAVAIR Depot, Cherry Point, since April 2005;
- *nine disks* with cracks detected, several of these *large and small cracks not detected by conventional ET and LPI;*
- *all crack detections verified by destructive testing or other means;*
- *no false indications* on 131 disks (over 3000 slots inspected with zero false calls resulting in a false call rate per slot of $<0.03\%$);

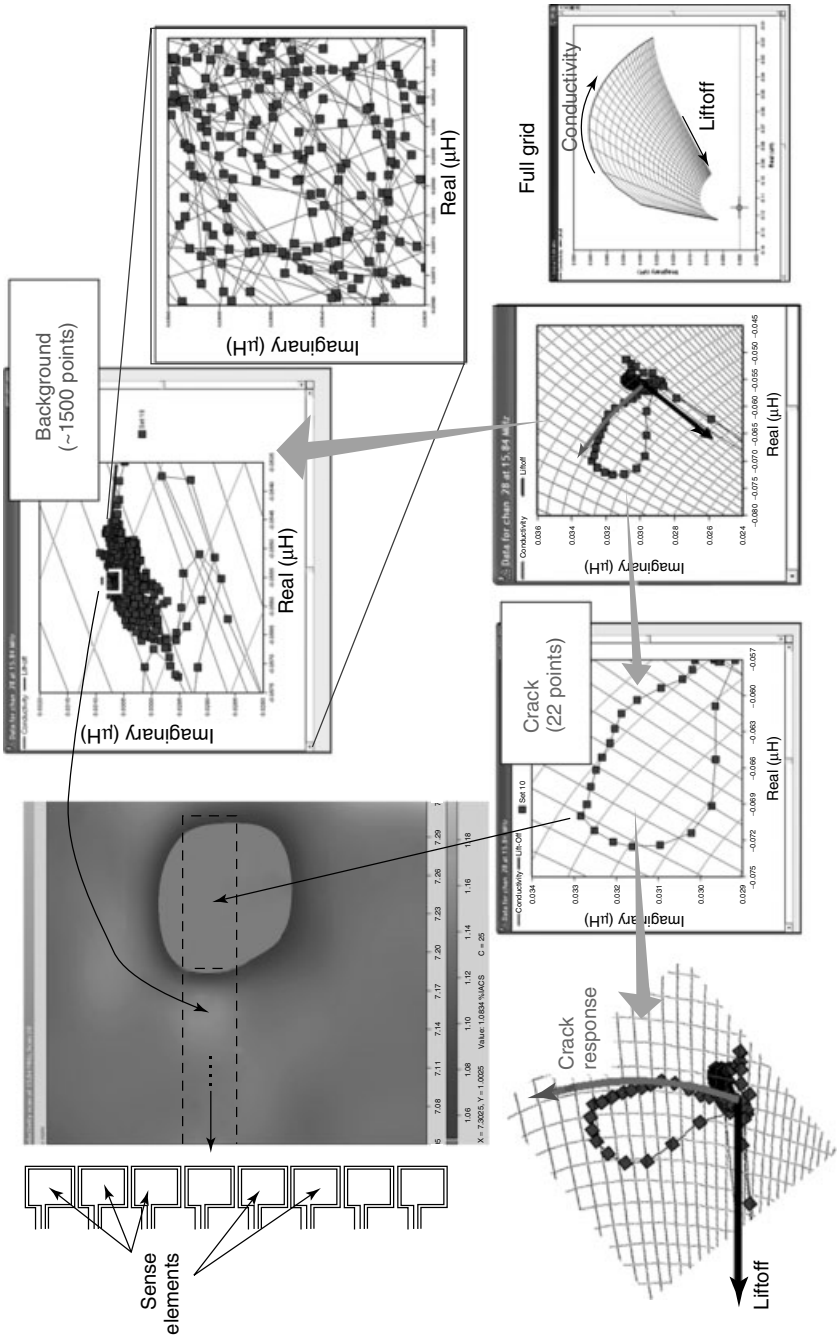

Figure 2. Example of rapid data processing using grid methods (precomputed databases), to convert impedance data for each MWM-Array channel (sense element) into conductivity and liftoff at each point in the image (patents issued and pending).

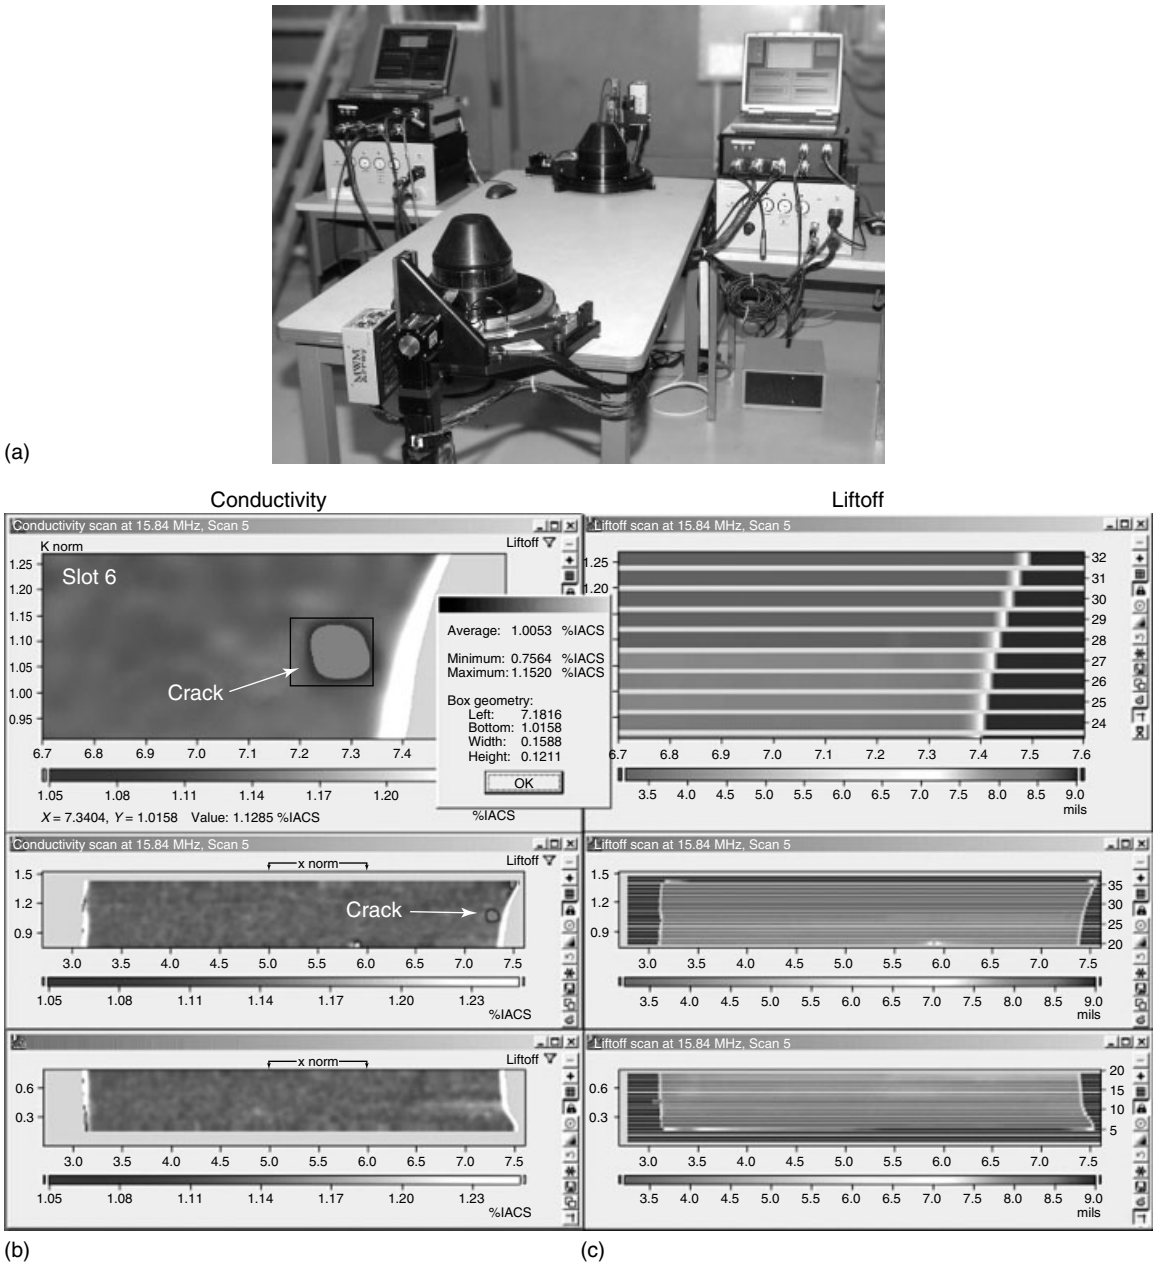

Figure 3. (a) Two automated GridStation Systems at NAVAIR Depot, Cherry Point, for engine disk slot inspection, (b) 37-channel, MWM-Array eddy-current sensor inspecting an engine disk slot, and (c) conductivity and liftoff images of MWM-Array results.

- *all disks now subjected to mandatory inspection* using the MWM-Array system during engine processing at this depot.

This data continues to be accumulated on this particular engine disk slot population. This data is a valuable asset for developing next generation

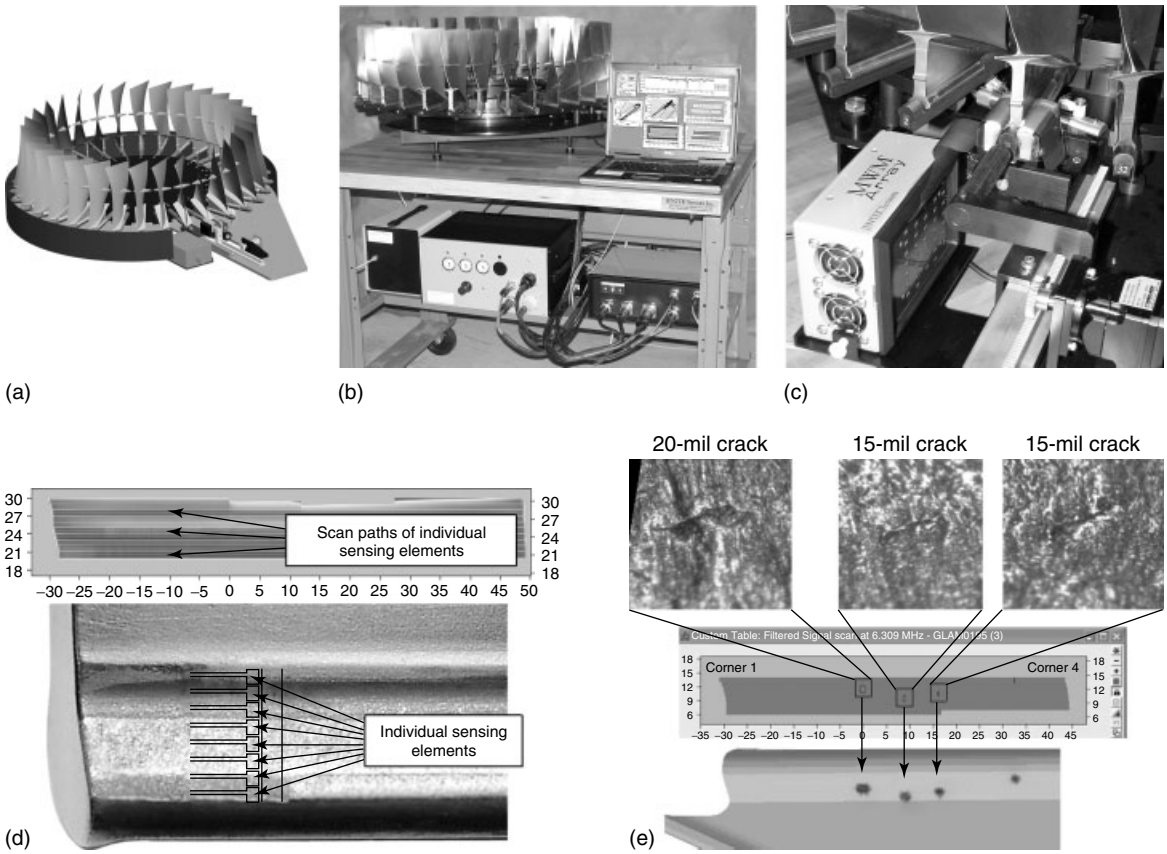

Figure 4. (a) Early design for automated blade dovetail inspection system; (b, c) photograph and detail of system delivered to the US Navy in 2007; (d) close-up of blade dovetail and liftoff image showing scan paths of individual sensing elements and acceptable liftoff values (indicted by green on a green-to-yellow-to-red color scale for liftoff); and (e) MWM-Array results with cracks indicated in the conductivity image (blue), verified by optical microscopy, and mapped onto a 3D image of the blade dovetail.

ALM approaches, i.e., as disks are reinspected after years in service, damage evolution history can be investigated.

The images in Figure 3(b) and (c) are for conductivity and liftoff respectively. These liftoff images enable real-time self-diagnostics by verifying that the liftoff is within an acceptable range. And the blue conductivity images further confirm that the absolute conductivity is within an acceptable range. The combination of these two absolute measurements at each of thousands of locations within an engine disk slot offers a built-in verification of sensor performance for each slot. Furthermore, this inspection is performed using an air/shunt calibration as described in ASTM Standard E2338.

6.2 Case study II: blade dovetail inspection

The inspection of blade dovetails has been funded by NAVAIR under a similar effort. Pilot line testing is ongoing at NAS, Jacksonville. Figure 4(a–c) shows the JENTEK Blade Dovetail Carousel and GridStation® System for automated inspection of an entire blade set in about 1 h. In this system, the sensor array is scanned over the complex-shaped dovetail of the blades. A pneumatic actuator clamps the sensor array to the dovetail so that the surfaces on both sides are examined at the same time. Figure 4(d) and (e) shows where the dovetail is inspected with the conformable MWM-Array sensor (which is shown in

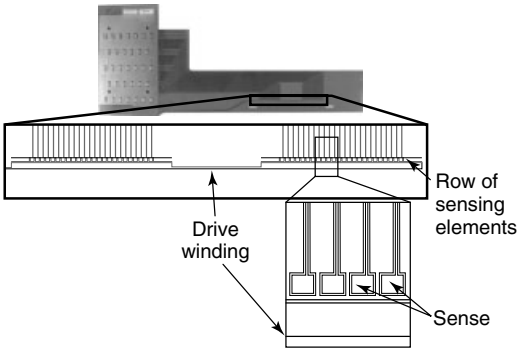

Plate 5. MWM-Array used for disk slot and blade dovetail inspections of regions experiencing fretting damage, for case studies I and II (patents issued and pending). MWM is a registered trademark of JENTEK Sensors, Inc.

Figure 5 and is the same sensor used for the disk slot inspection shown in Figure 3) and resulting MWM-Array images with associated crack indications.

6.3 Case study III: bolt holes

Bolt-hole inspection is also possible with MWM-Arrays. This demonstration illustrates the capability to inspect bolt holes and track crack-growth behavior. Figure 6(a) and (b), respectively, shows the bolt-hole scanning apparatus and MWM-Array sensor used for this demonstration. Figure 6(c) provides an example of conductivity (blue, with red crack indication) and liftoff (green-to-yellow-to-red color scale, where green indicates acceptable liftoff). Note that the conductivity images are cut off when the liftoff is above a specified level, automatically indicating the edge location.

Figure 7 provides the filtered response and the corresponding images of a crack (in a bolt hole) at three different stages of growth during a coupon test. This data might be stored for multiple coupon tests in a database (empirically generated) and then searched and calibrated using results from service components to enable not only estimation of crack sizes but also as a means for estimating damage evolution behavior (e.g., the probability of a failure occurring before the next inspection).

Figure 8 shows the response of a surface-mounted MWM-Array used during the coupon test. These arrays provide real-time, continuous fatigue test monitoring and are used to schedule the C-Scan imaging with the bolt-hole MWM-Arrays. This allows for very efficient generation of time-sequenced NDT (scanning) images at various damage levels, and significantly reduces the costs and labor needed to generate empirical NDT databases.

As illustrated in Figure 8, the surface-mounted MWM-Arrays detected the fatigue crack long before it reached a crack length of 0.0175 in. Also, the high signal to noise for the scanning MWM-Array data in Figure 7 makes it likely that much smaller cracks can be detected and the damage progression tracked.

7 REAL-CRACK STANDARDS

There are several practical methods available for generating real-crack specimens. Figures 7 and 8 illustrate one such method that uses advanced ET arrays either mounted permanently on the specimen or scanned periodically across the specimen during fatigue coupon testing. The configuration in Figures 7 and 8 is for bolt holes. Figure 9 shows a similar capability for generating real cracks in curved and shot peened or coated components. In this example, mechanical damage in the form of a ding is included to illustrate the generation of real-crack specimens with crack initiation at a mechanical damage site.

Thus, generation of real-crack specimens for NDT POD studies are no longer significantly more expensive than that of specimens with EDM notches. Crack specimens with real cracks can be generated without starter notches in bolt holes and curved surfaces. This can be accomplished for shot peened surfaces and even with coatings. Thus, it is no longer necessary to use EDM notches to perform POD studies for ET methods on surface-breaking flaws.

8 SUMMARY AND CONCLUSIONS

The fundamental developments of advanced ET methods that can address the limitations of conventional ET are the following:

1. *Low-cost processing power*—this enables the generation of precomputed databases of sensor responses and/or real-time processing of large volumes of sensor digital sensor data.
2. *Digital signal-processing chips*—these enable the development of highly accurate, absolute,

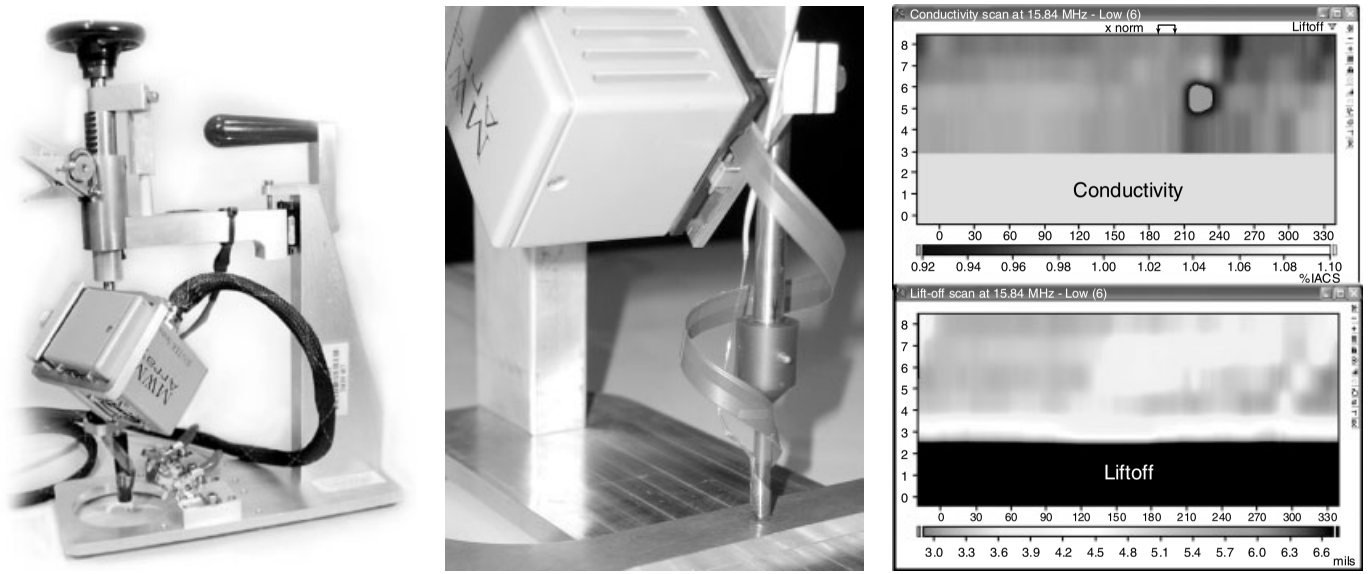

Figure 6. (a) Bolt-hole scanning apparatus, (b) close-up view of MWM-Array sensor scanning a fatigue coupon with a hole (*see* **Eddy-current *in situ* Sensors for SHM**, Figure 3(c) for schematic of 7-channel sensor), and (c) MWM-Array conductivity (blue) and liftoff (green) images.

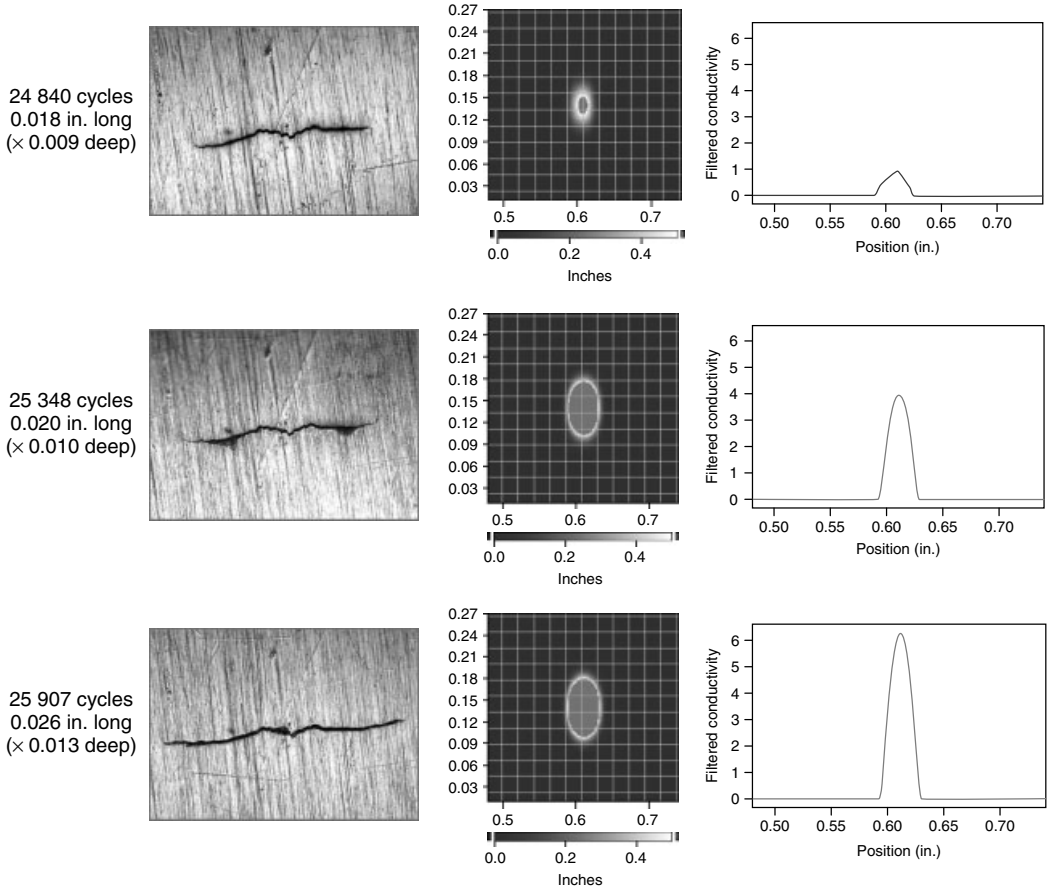

Figure 7. Spatially filtered MWM-Array scan images of a crack produced inside a hole in a Ti-6Al-4V fatigue coupon with two holes. Data are from scans of the hole with the MWM-Array FA43 sensor (*see* **Eddy-current *in situ* Sensors for SHM**, Figure 3(c) for photo) at various stages of the fatigue test. Crack photomicrographs on the left are from acetate replicas taken after each MWM-Array scan.

high-throughput parallel architecture impedance instrumentation that is suitable for use with model-based inverse methods (that require such highly accurate, absolute impedance measurements).

3. Low-cost instrumentation fabrication—this enables the fabrication of relatively low-cost, portable, and powerful high-throughput parallel architecture and high-fidelity impedance instrumentation.
4. Rapid modeling methods—these combined with processing power enable the generation of precomputed databases of sensor responses and/or real-time processing of large volumes of sensor digital sensor data using model-based inverse methods.
5. Rapid multivariate inverse methods—these enable the rapid processing of sensor data without running the model successively. This alone has a huge impact on throughput and reliability.
6. ET sensor designs that can be accurately represented by rapid models >—these combined with the rapid inverse methods enable many of the features needed by advanced methods to overcome the limitations of conventional methods.
7. Flexible ET arrays with no sensing element cross talk—this is required to enable rapid

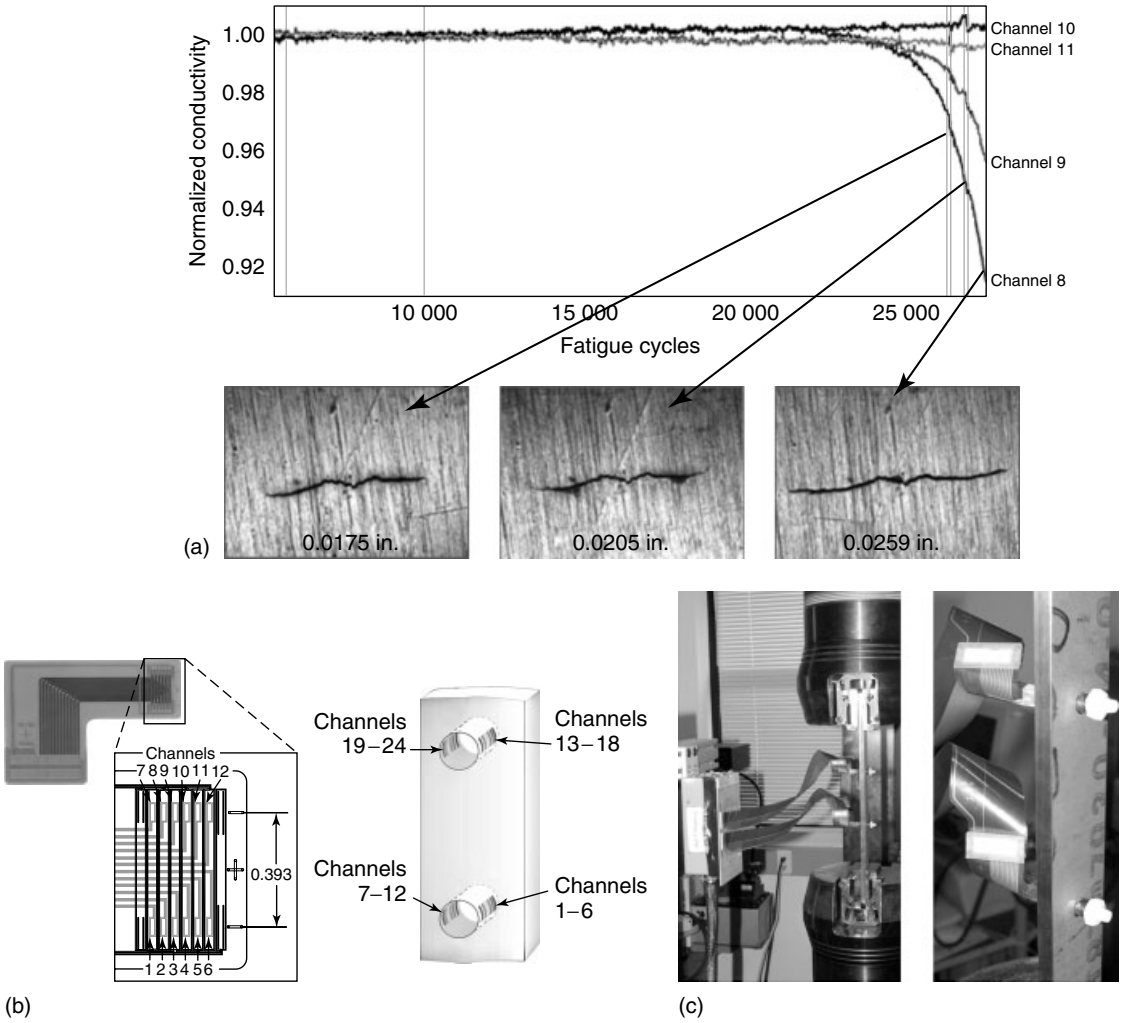

Figure 8. (a) MWM-Array data for the same Ti-6Al-4V coupon as shown in Figure 7, (b) photograph and schematic of the FA75 MWM-Array demonstrating how it was mounted in the two holes, and (c) setup for fatigue coupon testing.

wide area scanning of complex curved surfaces. Many "advanced" ET arrays use more conventional designs for which each sensing element responds differently and do not provide consistent responses for each element in the array, making detection reliability unpredictable.

8. Air calibration methods—as described in ASTM Standard E2338-04 that enable reliable calibration of ET arrays and single sensing element ET sensors and also provide the foundation for inherent self-diagnostics.
9. Self-diagnostics—by reliably measuring conductivity and liftoff at all noncrack locations within and ET image to ensure that performance of at each inspection location remains within the assumed range and that the sensor and instrumentation continue to perform properly.
10. Linear drive configurations—these provide a high-density eddy-current flow in the direction perpendicular to the crack (for improved crack detection sensitivity, particularly for shot peened components) and to provide a reduced

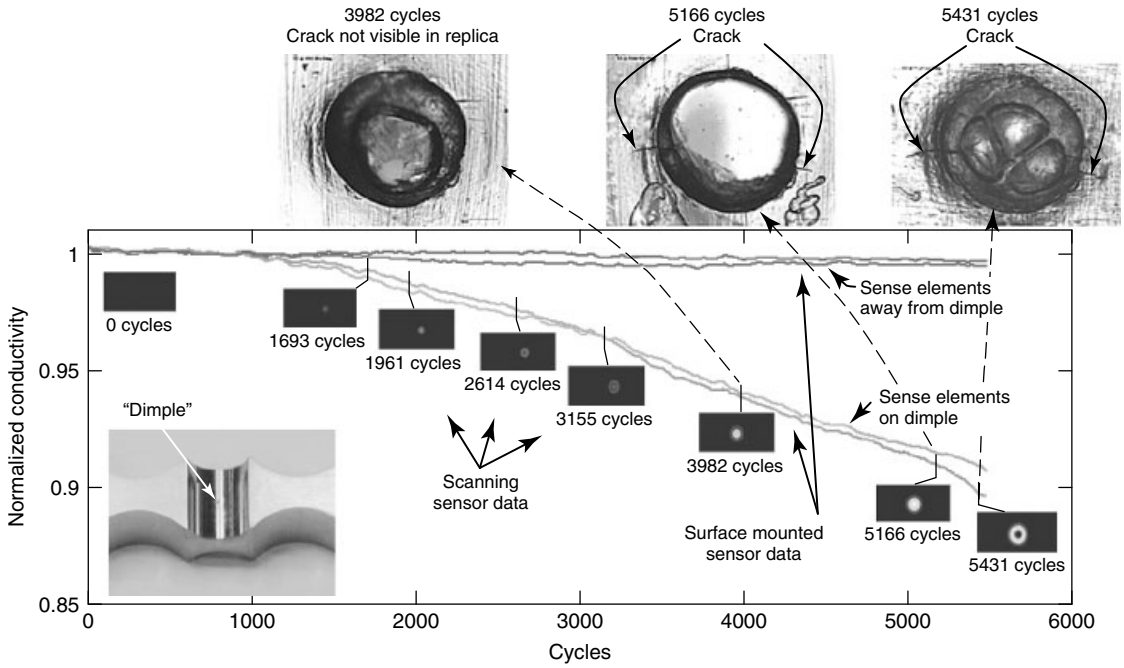

Figure 9. Progression of fatigue damage in Ti–6Al–4V captured by three different methods—(top) optical microscopy of acetate replicas, (solid lines) output of surface-mounted MWM-Arrays, and (purple images) eight C-scan images from periodic inspection with a scanning MWM-Array. At 5166 cycles, the crack length outside the dimple was 0.006 in. (left side) and 0.005 in. (right side). At 5431 both cracks were approximately 0.008 in. in length along the surface. The distance from tip to tip at 5431 cycles was 0.054 in.

sensitivity to crack position within the footprint, as well as a substantial reduction of edge effects associated with drive position relative to the edge.

11. High frequencies and wide dynamic range—this is required to enable improved coating characterization, high sensitivity to tight cracks, and measurement of crack depths (although accurate crack-depth measurement remains a difficult problem when crack morphologies vary significantly or cracks occur in clusters).

Furthermore, repeated imaging to *map and track* early damage growth is a new practice in NDT that is expected to be used more and more as NDT methods are upgraded. This will be complementary to the evolution of SHM and is expected to result in an integrated suite of advanced NDT/SHM solutions over time.

One advantage of using embedded SHM sensors compared to conventional NDT solutions is the capability to monitor damage at a single location before and after damage initiation. This enables removal of component-to-component variations and use of the undamaged material response as a reference for damage detection.

Conventional NDT solutions have, historically, not offered either the reproducibility or the digital archiving necessary to enable such comparisons of component conditions before and after damage initiation. In the next decade, this will change dramatically, since both advanced (scanning) NDT methods (with newly achieved levels of repeatability) and onboard sensors can monitor the damage sites both before and after damage occurs. The relative performance of each method will thus depend on the reproducibility and overall reliability of this repeated measurement data over long periods of time (weeks and months in some cases, to many years in other cases).

There are many factors that will introduce noise (structured and random) in both advanced NDT and

SHM sensor data. Thus, in every application, the relative performance of each should be evaluated. In some cases, reduction of uncertainty to required levels will require a combined solution to accommodate anticipated random and deterministic error/noise sources.

END NOTES

[a.] Wavelength—In dynamics, the wavelength is determined by the velocity of an electromagnetic traveling wave in a medium divided by the oscillation frequency. For example, the wavelength of a traveling wave at 13 MHz in air is 23 m. In quasistatics, this wavelength is long compared to the relevant system dimensions.

[b.] Shot peening is a cold working method that induces residual stresses at the surface of a component to extend fatigue life. Cold working processes include shot peening, burnishing, and laser shock processing.

1 INTRODUCTION

1.1 Area of application

The area of application is known as *three-dimensional digital image correlation* (3D-DIC), a noncontacting measurement method capable of accurately quantifying small or large three-dimensional surface displacements and surface strains on specimens ranging from a 10^{-3} to 10 m or larger.

1.2 Motivation

With the increase in computer processing speed, the ability to computationally predict a wide range of complex phenomena has increased dramatically (*see* **Free and Forced Vibration Models**; **Fundamentals of Guided Elastic Waves in Solids**; **Acoustic Emission**; **Electromechanical Impedance Modeling**; **Thermomechanical Models**; **Civil Infrastructure Load Models for Structural Health Monitoring**; **Static Damage Phenomena and Models**; **Damage Evolution Phenomena and**

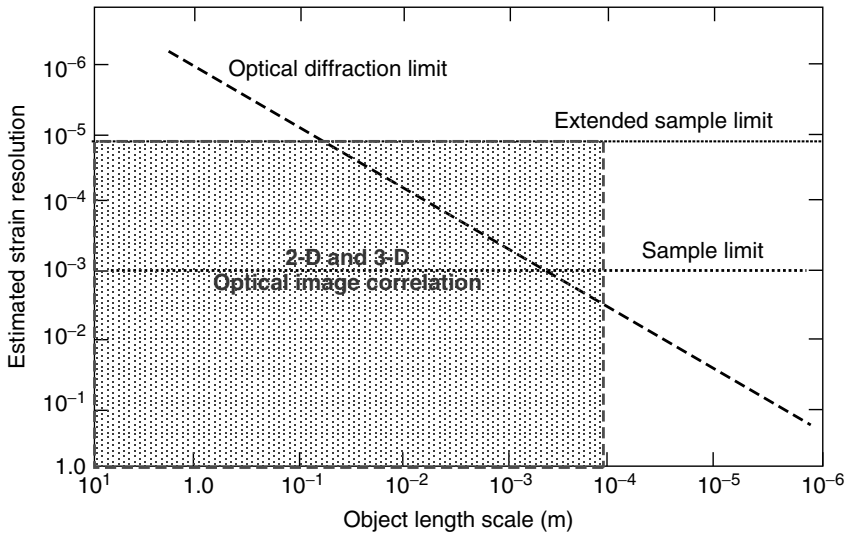

Figure 1. Schematic relating strain resolution to object dimensions. The graph focuses primarily on small-scale 2-D measurements. IC denotes *image correlation*, which appears to be a viable method for measurements over several orders of magnitude in out length scale. Optical IC includes both 2-D and 3-D methods. (The graph shown is a modified version of one developed by Prof. K.S. Kim, Brown University.)

Phenomena such as stable crack growth, dynamic crack growth, mechanical response of complex structures, impact and blast loading, as well as a wide range of other phenomenon can be simulated with modern computational algorithms and associated software.

Until recent years, the ability to obtain accurate, full-field measurements under general conditions including (i) three-dimensional motions, (ii) large deformations, and (iii) high rate loading has been limited by the methods available. To validate the simulations, one approach is to compare specific predictions to experimental measurements. For example, if a fracture criterion is assumed as part of a simulation (*see* **Static Damage Phenomena and Models**; **Damage Evolution Phenomena and Models**; **Failure Modes of Aerospace Materials**), then measurements such as the following can be directly compared with theoretical predictions to provide quantitative measures of the quality of the predictions:

- load-crack extension
- crack-tip strain field during crack extension
- crack opening displacement.

Figure 1 presents one view[a] of the relationship between strain sensitivity and specimen length scale for digital image correlation (IC) methods. As shown in this figure, for structural measurements on components on the order of 100 μm or larger, optical IC methods offer investigators the ability to quantify strains on the order of 10^{-4} or larger. Though originally developed for 2-D measurement methods (e.g., 2-D IC), stereovision concepts have been used to formulate a general, noncontacting method designated *three-dimensional digital image correlation* (3D-DIC) that has an accuracy similar to that of two-dimensional digital image correlation (2D-DIC), while extending the capability to 3-D motion measurements on 3-D objects. Applications in the past two decades have shown conclusively that 3D-DIC is capable of making full-field deformation

measurements on curved or planar specimens in a wide range of applications, with strain accuracy on the order of 10^{-4}.

1.3 Historical background

A cursory review of the literature indicates that the earliest developments in image-based shape measurements resulted in the formation of the field of photogrammetry. Originally focused on extracting height/shape information through comparative photography, it appears that some of the first work in the area of "image correlation" was performed by Gilbert Hobrough in the 1950s. Hobrough compared analog representations for photographs to register features from various views [1], and later designed and built an instrument to "correlate high-resolution reconnaissance photography with high precision survey photography in order to enable more precise measurement of changeable ground conditions" [2], thereby being one of the first investigators to attempt a form of digital IC to extract height information from the IC/matching process.

As digitized images became available in the 1960s and 1970s, researchers in artificial intelligence and robotics began to develop vision-based algorithms and stereovision methodologies in parallel with photogrammetry applications in aerial photography (see Rosenfeld [3] for an extensive bibliography). As noted by Rosenfeld, engineering applications for shape and deformation measurements using digital images were either nonexistent or rare up to 1980.

While digital image analysis methods were undergoing explosive growth in many areas, much of the field of experimental solid mechanics was focused on applying recently developed laser technology. Holography [4–6], laser speckle [7], laser speckle photography [8, 9], laser speckle interferometry [10], speckle shearing interferometry [11], moire' methods [12, 13], holographic interferometry [14] and fiber optic sensors (*see* **Free and Forced Vibration Models**; **Fundamentals of Guided Elastic Waves in Solids**; **Acoustic Emission**; **Electromechanical Impedance Modeling**; **Thermomechanical Models**; **Civil Infrastructure Load Models for Structural Health Monitoring**; **Static Damage Phenomena and Models**; **Damage Evolution Phenomena and Models**; **Failure Modes of Aerospace Materials**; **Modeling Aspects in Finite Elements**; **Finite Elements: Modeling of Piezoceramic and Magnetostrictive Sensors and Actuators**; **A Simplified Damage Model for SHM Metallic and Composite Structures**; **Modeling for Detection of Degraded Zones in Metallic and Composite Structures**; **Fatigue Life Assessment of Structures**) are typical examples of the type of measurement techniques developed for use with coherent light sources. In all cases except fiber optic sensing, the measurement data (surface slopes and displacements) was most often embedded in the photographic medium, typically in the form of a fringe pattern. Since the photographic recording process is generally nonlinear, resulting in difficulties in extracting partial fringe positions with high accuracy, the most common process employed by experimental mechanicians was a laborious determination of estimates for fringe center locations at a few points.

Given the difficulties encountered by experimental mechanicians during the postprocessing of photographically recorded measurement data, it was natural for researchers to employ recent progress in digital imaging technology and develop (i) methods for digitally recording images containing measurement data, (ii) algorithms to analyze the digital images and extract the measurement data, and (iii) approaches for automating the entire process.

One of the earliest papers that proposed the use of computer-based image acquisition and deformation measurements in material systems was written by Peters and Ranson in 1982 [15]. Originally envisioned as a method for use with ultrasonic waves, the authors suggested comparing small regions (known as *subsets*) from each of the digitally recorded ultrasonic images before and after deformation. Using fundamental continuum mechanics concepts governing the deformation of small areas, subset matching throughout each image was proposed to obtain a dense set of full-field, two-dimensional displacement measurements. Over the next decade, the basic concepts were extended and applied to optical images of an undeformed and deformed object. The proposed methodology was modified and refined, resulting in a set of numerical algorithms that were validated through a combination of

experimental and computational studies [16–23]. The 2D-DIC method has been used to measure crack-tip strain fields [24–27], creep deformations at elevated temperature [28], and tensile deformations of thin paper sheets [29, 30]; a high contrast random pattern was applied to the paper sheets using Xerox toner power. For these measurements, a random pattern and incoherent illumination were used to obtain high-contrast, white-light speckle images. By selecting subsets from the pattern and comparing deformed and undeformed patterns, the matching process is used to obtain full-field displacements.

More recently, investigators have begun to probe the fundamentals of the image-matching process and quantify the potential accuracy of the method. For example, Schreier *et al.* [31] showed that intensity interpolation must be performed to improve the accuracy of the displacement measurements. In follow-on on studies, Schreier and Sutton [32] have shown that quadratic shape functions provide some advantages when performing the matching process, especially for nonuniform strain fields. Relative to the importance of distortions in pattern matching, Schreier *et al.* [33] developed and applied nonparametric distortion measurement and removal methodologies.

Since 2D-DIC requires predominantly in-plane displacements and strains, relatively small out-of-plane motion of the object will change the magnification and introduces errors in the measured in-plane displacement. To overcome this limitation, stereovision principles developed for robotics, photogrammetry, and other shape and motion measurement applications were modified and used by Chao *et al.* to successfully develop and apply a two-camera stereovision system for the measurement of three-dimensional crack-tip deformations [34–36]. To overcome some of the key limitations of the method (square subsets remained square in both cameras, mismatch in the triangulation of corresponding points, and a calibration process that was laborious and time consuming), the stereovision method was modified to include (i) the effects of perspective on subset shape and (ii) constraints on the analysis to include the presence of epipolar lines [37]. The method has been used successfully in several small- and large-scale applications [38–40].

2 KEY TECHNOLOGIES USED IN THREE-DIMENSIONAL COMPUTER VISION (3D-DIC) FOR STRUCTURAL MEASUREMENTS

Figure 2 shows several actual stereovision systems that have been used successfully to measure 3-D shape and 3-D displacement fields. Key technologies used to construct 3D-DIC measurement systems include the following:

- High-resolution, scientific-grade, charge coupled device (CCD) or complementary metal oxide semiconductor (CMOS) cameras
  - Typical cameras record in monochrome with 8 bits.
  - Spatial resolution is on the order of 1024 × 1024 pixels.
  - Pixels are square in physical dimension.
- Quality optical lenses for imaging during experiments
  - Nikon, Canon, Sigma, and Schneider lenses are typical brands used.
  - Lenses with focal lengths in the range from f19 to f200 are commonly used.
- Stable, durable camera support structures
  - Heavy-duty tripods, or equally strong structures, to support the cameras.
  - Rigid cross members to maintain the relative positions of cameras during an experiment.
- Translation stages to adjust camera position(s)
  - Digitally controlled stages for automation of adjustment process have been used successfully.
  - Rigid cross members with cameras attached can be moved as a unit without affecting the calibration.
- Temporal synchronization unit for simultaneous multicamera image acquisition during calibration and experiment

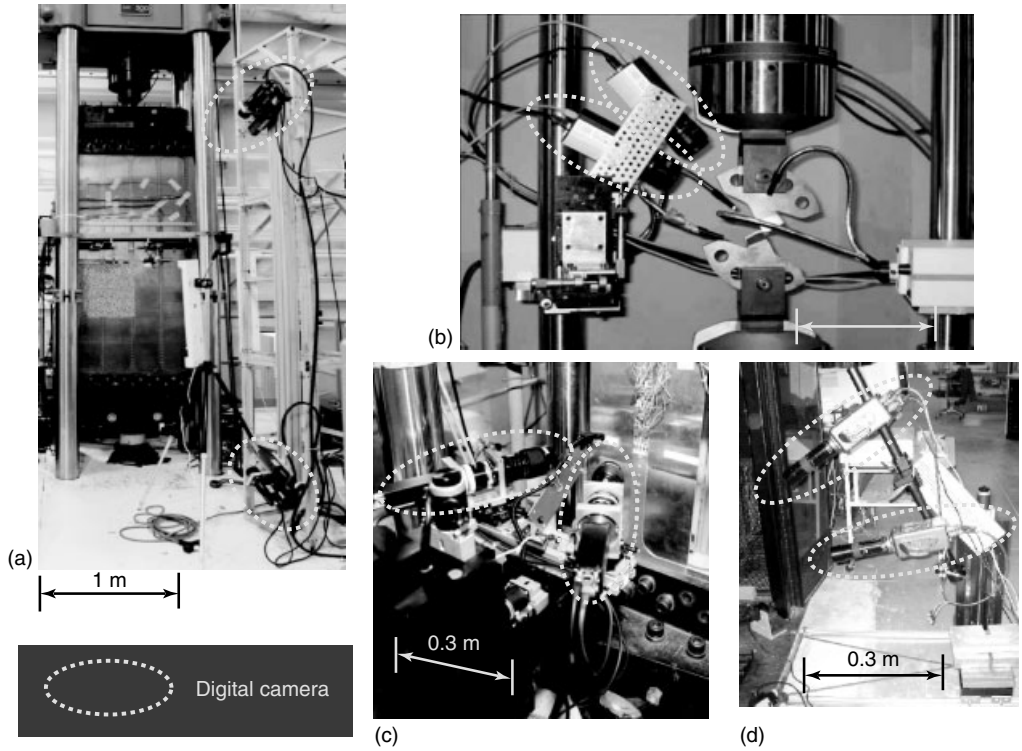

Figure 2. Typical stereovision systems used for laboratory measurements; (a) Pulnix cameras attached to 3-m gantry structure to view 1-m-wide specimen in 300-kips (1334 kN) loading frame; (b) Q-imaging cameras mounted to loading frames via translation stages to view specimen—the small angle between the cameras is due to space constraints for this application; (c) Pulnix cameras viewing rivet holes in 0.3-m-wide specimen undergoing tensile loading; and (d) high-speed Phantom V7.1 cameras viewing specimen mounted inside drop tower.

- Computer
  - Image acquisition and storage.
  - Postprocessing of images.
- Software[b]
  - Image acquisition.
  - Postprocessing of images.
  - Profile, displacement, and strain measurements.
  - Graphical presentation of measurements.
- Lighting to maintain adequate pattern contrast during calibration and experimentation.

Figure 3 presents a flow chart for a typical experiment using a two-camera stereovision system to acquire images of an object subjected to known mechanical loading and environmental conditions. In practice, the computer control system may also serve as (a) the image storage device and (b) the platform for postprocessing and data analysis.

3 BASIC CONCEPTS IN THREE-DIMENSIONAL COMPUTER VISION (3D-DIC) FOR STRUCTURAL MEASUREMENTS OF DEFORMATION AND SHAPE

A stereovision system consists of at least two views of the object from different orientations and positions. Figure 4 presents a schematic containing the key parameters related to the imaging process.

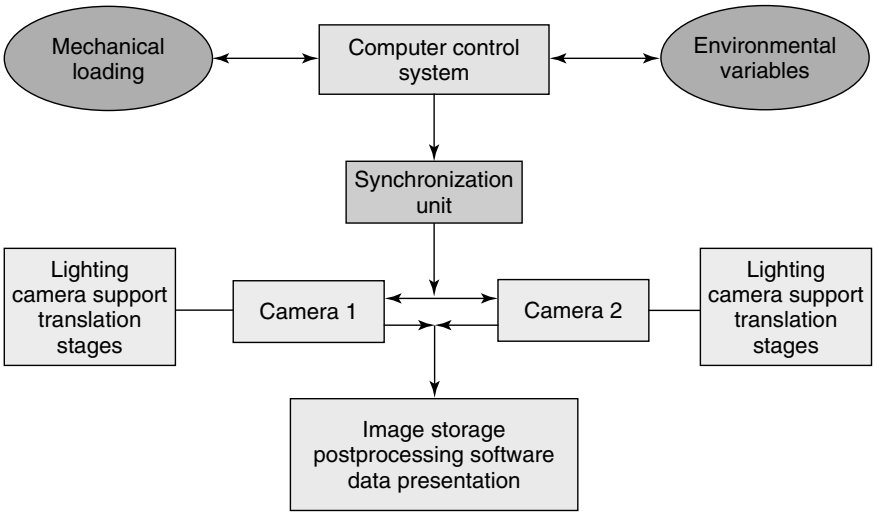

Figure 3. Flow chart for acquisition of synchronized images using a typical stereovision system.

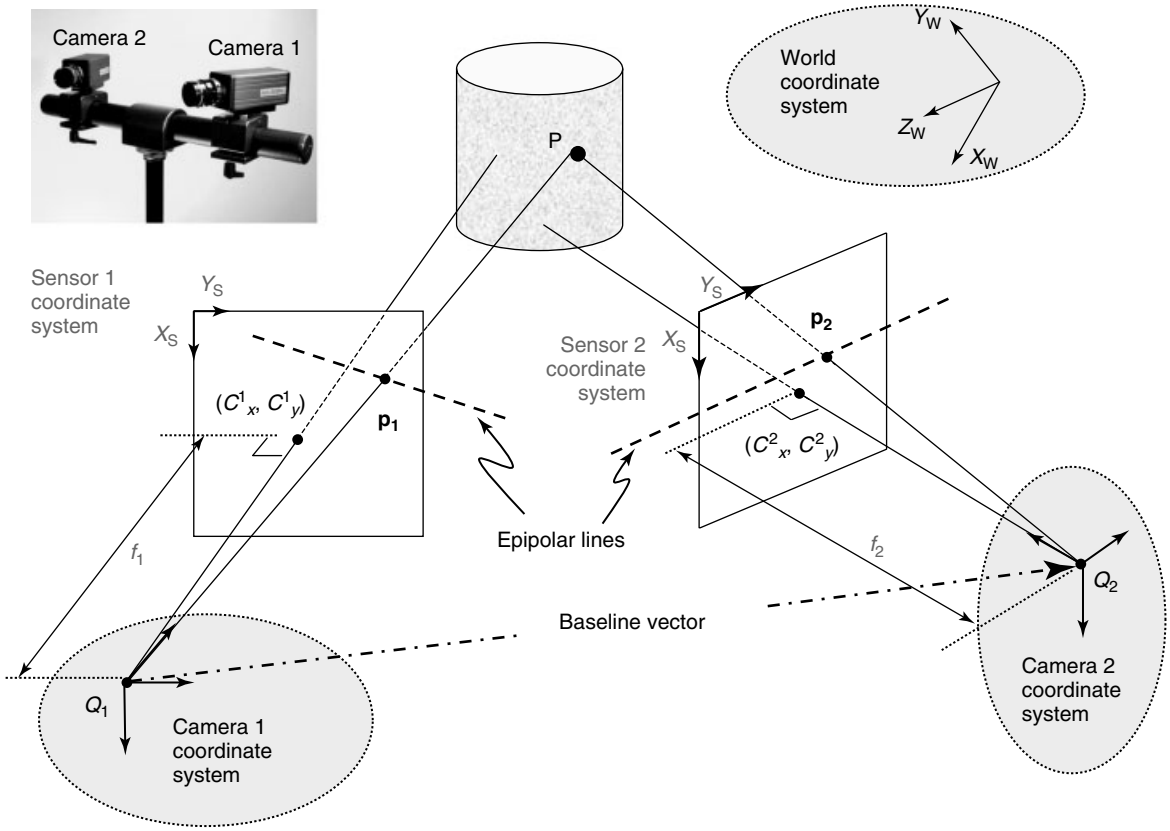

Figure 4. Actual stereovision system and schematic showing pinhole camera models for each camera.; the parameters in the model must be determined to convert the image positions ($\mathbf{p}_1$ and $\mathbf{p}_2$) into an accurate 3-D location of the point **P**.

In this study, each image system is modeled as a pinhole camera. Intrinsic parameters for each camera include (i) the focal length, f, (ii) the image plane center, (C_x, C_y), (iii) lens distortion coefficient, κ, and (iv) scale factors, λ_x and λ_y relating metric distance on the object to pixel position in the image plane. Extrinsic parameters for each camera include (i) three independent components of the rotation matrix [**R**] and (ii) three components of the translation vector to orient the world coordinate system (WCS), with axes (X_W, Y_W, Z_W), relative to a camera coordinate system (CCS) located at a camera pinhole, either Q_1 and/or Q_2.

In practice, the WCS axes oftentimes are defined to be at a specific object position during the calibration process. For example, if a two-dimensional planar grid is used for calibration then (i) the plane of the grid lines can be assumed to be the plane $(X_W, Y_W, 0)$, (ii) the grid intersection at the lower left corner can be defined to be the origin (0, 0, 0), and (iii) the Z_W axis is perpendicular to the planar grid.

In a similar manner, each CCS is generally located at the pinhole, Q. In many cases, the Z_C axis is aligned with the optical axis through the points Q–C, while X_C and Y_C are oriented to align with the camera sensor axes.

The final coordinate system defines the sensor coordinate system (SCS) with (X_S, Y_S) aligned with the row and column directions of the sensor plane, and Z_S perpendicular to the sensor plane. Located in the retinal or image plane of the pinhole camera, the SCS has units of pixels for (X_S, Y_S) to define sensor locations.

Assuming the rows and columns in the sensor plane are orthogonal, transformations among the WCS, CCS, and SCS are performed to develop the relationship between sensor plane coordinates (X_S, Y_S) of point **p** and a 3-D position of a point **P** at (X_W, Y_W, Z_W). The resulting scalar form can be written as

$$\left\{ \begin{array}{l} X_S = C_x + f\lambda_x \dfrac{R_{11}\ X_W + R_{12}\ Y_W + R_{13}\ Z_W + t_x}{R_{31}\ X_W + R_{32}\ Y_W + R_{33}\ Z_W + t_z} \\ Y_S = C_y + f\lambda_y \dfrac{R_{21}\ X_W + R_{22}\ Y_W + R_{23}\ Z_W + t_y}{R_{31}\ X_W + R_{32}\ Y_W + R_{33}\ Z_W + t_z} \end{array} \right\} \tag{1}$$

In equation (1), [**R**] is the rotation matrix and has three independent angles to define all components in [**R**].

Since equation (1) assumes an ideal, undistorted imaging system, improved accuracy in the measured positions can be obtained by including the effect of radial lens distortion at any point in the sensor plane. Such distortions are typically defined as the difference between undistorted and distorted sensor plane position using a cubic function of the radial distance from the image center. Defining the distortion vector, $\boldsymbol{d}$, and the distorted image position by (X^d_S, Y^d_S), then the corrected position, (X_S, Y_S), can be written as follows:

$$\begin{aligned} (X_S, Y_S) &= (X^d_S - d_x, Y^d_S - d_y) \\ d_x &= \kappa[(X^d_S - C_x)^2 + (Y^d_S - C_y)^2]^{3/2} \bullet \cos(\zeta) \\ d_y &= \kappa[(X^d_S - C_x)^2 + (Y^d_S - C_y)^2]^{3/2} \bullet \sin(\zeta) \\ \boldsymbol{r}(\mathbf{p}) &= [|\boldsymbol{r}| \bullet \cos(\zeta)]\boldsymbol{e}_x + [|\boldsymbol{r}| \bullet \sin(\zeta)]\boldsymbol{e}_y \\ &= \text{vector location of point } \mathbf{p} \text{ relative} \\ &\quad \text{to image center } (C_x, C_y) \\ \zeta &= \text{counterclockwise polar angle from} \\ &\quad X_S \text{ axis, with origin at } (C_x, C_y) \\ &\quad \text{with } (-\pi < \zeta \leq \pi) \\ \kappa &= \text{ratial distortion coefficient} \\ (\boldsymbol{e}_x, \boldsymbol{e}_y) &= \text{unit vectors in } X_S \text{ and } Y_S \\ &\quad \text{directions, respectively} \end{aligned} \tag{2}$$

It is worth noting that all digitized intensity patterns are recorded at integer pixel locations. Since the distortion-corrected positions typically form a nonuniform grid at noninteger pixel positions, interpolation of the pixel values is required to make measurements with optimal, subpixel accuracy.

3.1 Camera calibration

As shown in equations (1 and 2), there are 11 independent parameters for each camera to be determined during the calibration process; six extrinsic parameters ($t_x, t_y, t_z, \theta_x, \theta_y$, and θ_z) and five intrinsic parameters ($C_x, C_y, f\lambda_x, f\lambda_y$, and k). A typical camera-calibration process uses a calibration target with known grid spacing. During the calibration process, the target is translated and/or rotated in three

dimensions, with images acquired by both cameras at each position during the motion sequence. By locating at least three noncollinear points in each deformed image, the extrinsic parameters for each view (orientation and translation) are estimated and used to give initial locations for corresponding grid points throughout the view.

Defining an image-based objective function in the form

$$E = \sum_{i=1}^{M} \sum_{j=1}^{N} \{(X_{\mathrm{S\ measured}}^{ij} - X_{\mathrm{S\ model}}^{ij})^2 + (Y_{\mathrm{S\ measured}}^{ij} - Y_{\mathrm{S\ model}}^{ij})^2\} \quad (3)$$

where $X_{\mathrm{S\ model}}$ and $Y_{\mathrm{S\ model}}$ are given by equations (1) and (2), and the measured locations of features in the calibration standard ($X^{\mathrm{d}}{}_{\mathrm{S}}{}^{ij}$, $Y^{\mathrm{d}}{}_{\mathrm{S}}{}^{ij}$) are extracted from $j = 1, 2, \ldots, N$ pixel locations by analyzing all $i = 1, 2, \ldots, M$ images of the calibration standard. Though several approaches have been used to perform the nonlinear optimization of equation (3) for each camera, approaches such as steepest descent, Newton–Raphson, or a combined method such as Levenberg–Marquardt, have been used effectively.

3.2 Three-dimensional measurements

If one considers a specific point, **P**, with position (X_{W}, Y_{W}, Z_{W}), then equation (1) relates this position to the corresponding image location (X_{S}, Y_{S}) in the sensor plane for each camera; the image points are denoted by $\mathbf{p_1}$ and $\mathbf{p_2}$ for cameras 1 and 2, respectively, in Figure 4. When equation (1) is applied to both calibrated cameras, there are four equations with three unknowns, specifically the 3-D position of the point **P**. An optimal solution can be obtained through a least-square process to locate the best estimate for the position (X_{W}, Y_{W}, Z_{W}). By repeating this process for each position of interest, a full field of 3-D points can be determined at each load level. The difference between the initial position, $\mathbf{P_0}$, and the deformed position at time t, $\mathbf{P_0(t)}$, is the displacement vector with components $\{(U(\mathbf{P};t), V(\mathbf{P};t), W(\mathbf{P};t))\}$.

3.3 Image-based correlation for subset matching

To determine the corresponding image location (X_{S}, Y_{S}) in the sensor plane of each camera with utmost accuracy (this is essential for accurate 3-D measurement), the procedure used in this study is to perform optimal matching of image plane subsets; this is shown schematically in Figure 5. Defining an image of the object in one of the cameras (e.g., camera 1 in Figure 1) as the "reference" image, the matching process is typically completed by selecting a dense set of subregions (subsets) in the reference image and performing digital IC to identify the corresponding intensity pattern for each subset in (i) the other view of the undeformed object and (ii) both views of the deformed object (*see* **Statistical Pattern Recognition** for pattern recognition concepts).

Though a variety of matching metrics can be used to optimally locate the point, a normalized cross-correlation is oftentimes used. Since a nonlinear search process is required to locate the best match, most applications use an initial estimate for the parameters to initiate the search process. Typically, initial estimates for the rotation and translations of a subset are determined visually by locating the pixel positions for at least three, noncollinear, matching points and using these approximate matches to initiate the search process. As with the camera-calibration problem, a wide range of optimization methods have been used successfully.

3.4 Overall procedure for 3D vision-based measurements

The following procedure is typical for most practical situations:

1. Set up the stereovision system in preparation for the actual experiment. Cameras and lenses are selected to obtain high spatial resolution over the required visual field of view. For a stereovision system, the cameras and lenses typically are matched to simplify the setup and calibration procedures.
2. Arrange the cameras to meet the physical constraints in the application. In many cases, the

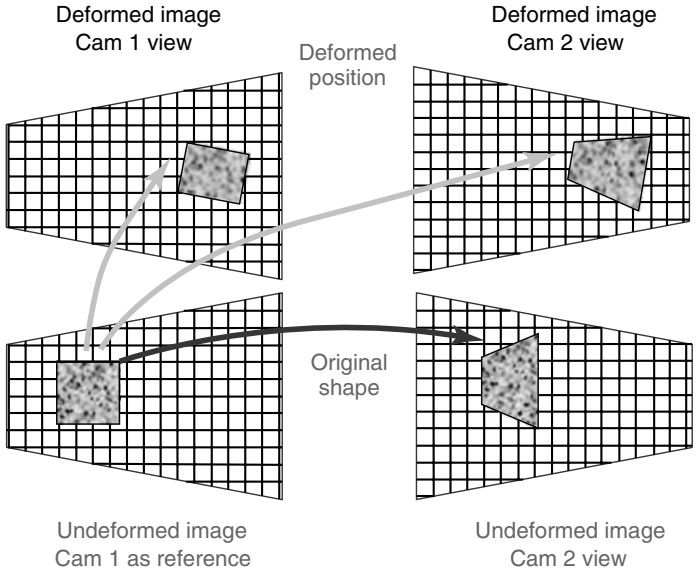

Figure 5. Schematic of image-matching process required to obtain the 3-D position of the object given corresponding images in different views. Camera 1 and camera 2 undeformed views are used to obtain initial 3-D shape of the object. Camera 1 and camera 2 deformed views are combined with camera 1 reference view to obtain the deformed 3-D position of the object.

position of the cameras is dictated by the layout (e.g., laboratory configuration).

3. Carry out a complete calibration of the stereo-vision system, using several motions of a calibration target. During this process, it is recommended that image acquisition be synchronized between both cameras.
4. Remove the calibration grid, install the specimen in the loading system, and verify that the loading is synchronized with the image acquisition process so that both cameras acquire images simultaneously during the experiment.
5. Postprocess all images to determine shape and deformations. After acquiring N pairs of images during the loading process, the analysis process requires that the images from one camera be designated as the *reference* images (e.g., camera 1).
6. To determine the initial shape (see Figure 5), subsets are selected in camera 1 and IC is performed to locate the matching position in the initial image for camera 2. Using the dense set of center-point locations obtained by the correlation process, the procedure described in Section 3.2 is used to obtain a dense set of 3-D points to define the initial object shape. For each loading state, cross-camera image matching and 3-D point generation also obtains the object shape in any configuration.
7. To determine the true 3-D position of a deformed body (see Figure 5, all four images are used as shown), subsets are selected in camera 1 and IC is performed (i) to locate the matching position in the initial image for camera 2, (ii) to locate the matching position in the deformed state as viewed by camera 1, and (iii) to locate the matching position in the same deformed image as viewed by camera 2. Using the dense set of center-point locations obtained by the correlation process, the procedure described in Section 3.2 is used to obtain a dense set of 3-D points for points in both the initial and deformed configurations. These are used to define the 3-D displacement vector for each point $\mathbf{P}$ after undergoing deformation. For each loading state, the process is repeated to obtain the displacement field for each deformed state, generating $\{(U(\mathbf{P};t), V(\mathbf{P};t), W(\mathbf{P};t))\}$.

4 APPLICATION OF THE TECHNIQUE FOR LARGE COMPONENT MEASUREMENTS

Figure 6 shows (i) a 305-mm-wide, 2.3-mm-thick, center-notched Al2024-T3 sheet with notch length/specimen width, $a/w = 1/3$, in the L–T orientation, as well as the tensile grip components, (ii) speckle pattern on the bottom half of the specimen as viewed by the left camera, and (iii) the stereocamera arrangement for acquiring 3-D shape and deformation data on the specimen as it is subjected to far-field tensile loading in a 446-kN tensile loading frame. References [38–40] provide details for similar experiments on a 0.61-m-wide panel; the configuration of cameras and specimen in these previous experiments is shown in Figure 2(a).

Canon lenses with a focal length of 28 mm were attached to Pulnix 9701 cameras with 8-bit intensity resolution and 768 × 484 spatial resolution, and used to image the specimen. As shown in Figure 6, the cameras were separated horizontally with a viewing angle difference of ≈53°. To obtain similar spatial resolution in the horizontal and vertical directions, the camera bodies were rotated 90° so that 768 pixels in the CCD sensor are aligned with the longer vertical direction of the sheet. Magnification is ≈1.5 pixels/mm. Owing to specimen size, the global speckle patterns were applied using a self-adhesive vinyl sheet with a random pattern of appropriate size for the magnification printed on the visible surface.

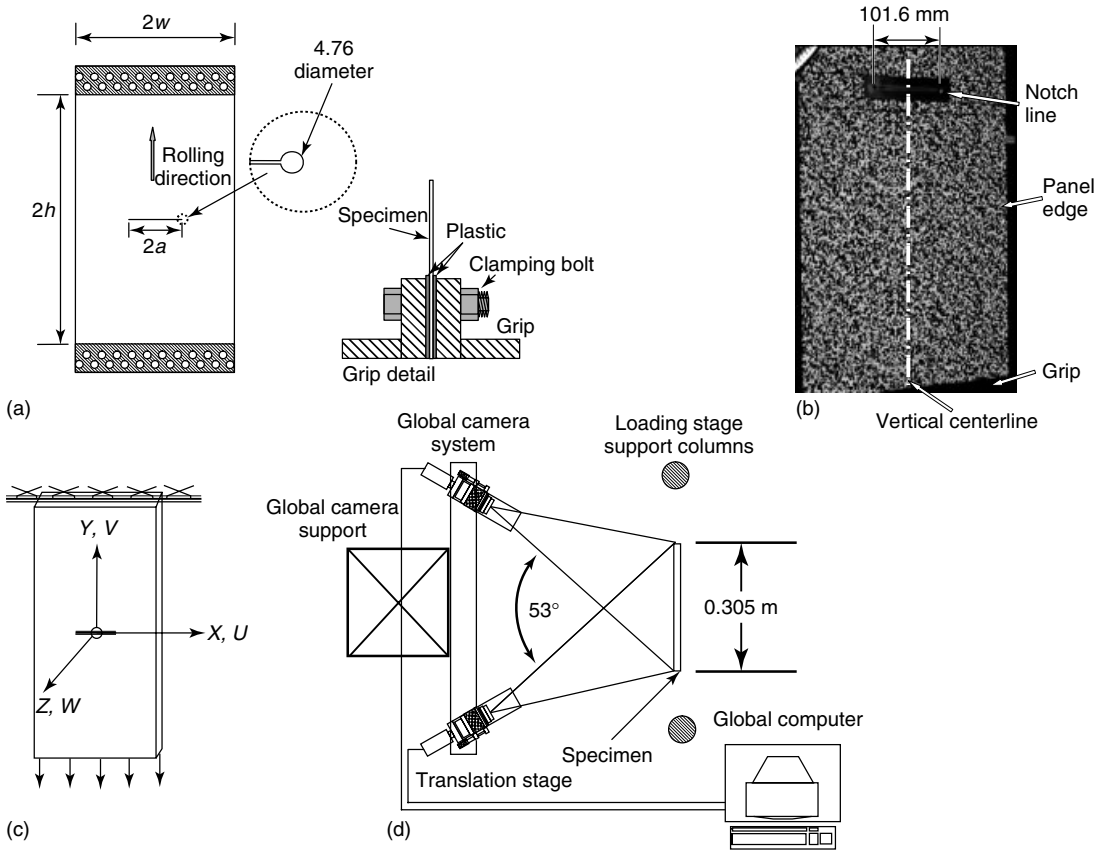

Figure 6. (a) Uniaxial tensile specimen with grips; in this work, $w = 0.1525$ m, $h = 0.330$ m, and $a/w = 1/3$; (b) speckle pattern on the bottom half of the specimen as viewed by the left camera; (c) specimen-based coordinate system to display output results; and (d) schematic of camera arrangement for the experiment. The cameras are mounted horizontal to the gantry system, at a distance of ≈1.2 m from specimen.

Camera calibration is performed using images of a calibration grid with known grid spacing. Owing to the physical size of the specimen field of view, a specially designed glass grid with grid spacing of 101.6 mm is used. To simplify the calibration process, the large glass grid is held stationary and the camera is moved approximately perpendicular to its sensor plane to acquire additional image(s). Using (i) the known spacing of the grid, (ii) the known movement(s) of the camera, and (iii) the location of the grid intersections, as extracted from the calibration images, nonlinear optimization is used to find the camera parameters that best describe the position and operating characteristics of the camera. The process is then repeated, without moving the grid, for the second camera. With this reduced motion process, measurement error had a standard deviation of ± 0.01 mm (± 0.015 pixels) with peak-to-peak values of ± 0.05 mm (± 0.075 pixels)[c]. After completing the calibration process, both CCS were transferred to the specimen shown in Figure 6(d).

The experiment was conducted using grip displacement control with a ramp rate of $2.83\,\mu\text{m}\,\text{s}^{-1}$. The experiment was paused each time the axial load increased by an increment of 2.22 kN, to acquire image data. This process was continued until the panel failed, at a load just beyond 116 kN. Load and ram displacement data were recorded every 5 s throughout the experiment.

4.1 Results

Figure 7 presents the applied load–vertical displacement data for the specimen, where the axial displacement is obtained by averaging the vision-based vertical displacement along the horizontal grip line located near the bottom of speckled image in Figure 6.

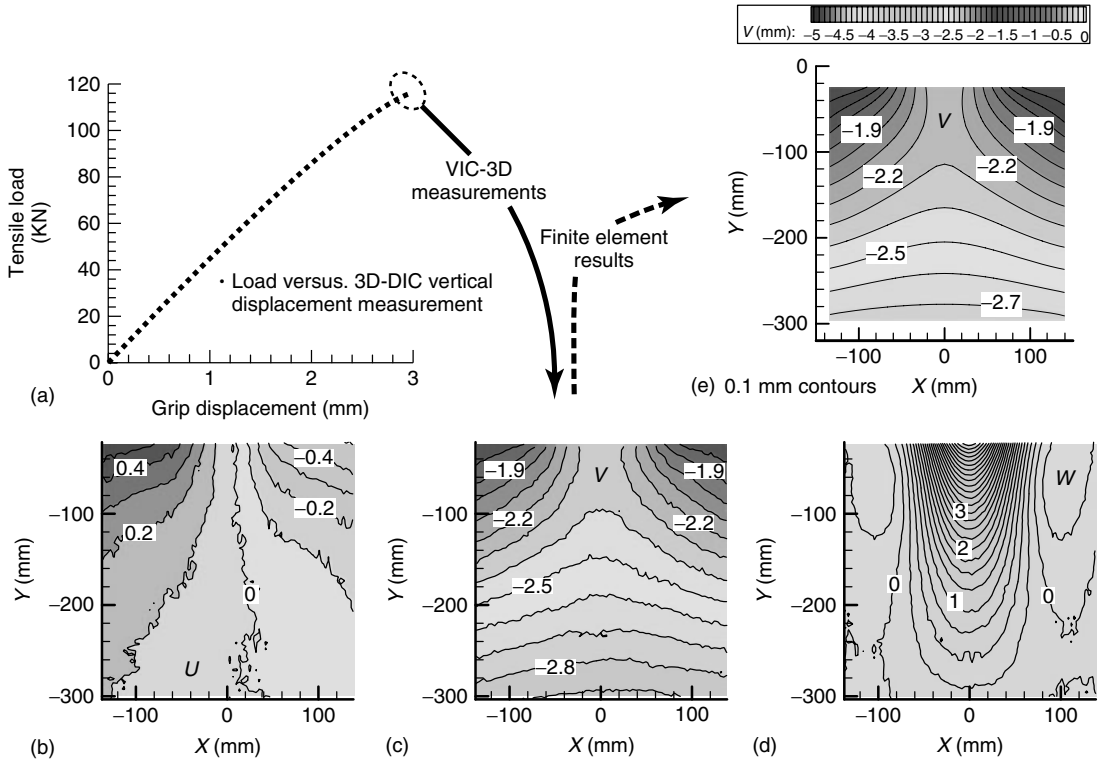

Figure 7. (a) Measured load–displacement data for specimen; (b–d) measured full-field horizontal (U), vertical (V), and out-of-plane (W) displacement fields at maximum tensile load (116 kN); (e) finite element prediction for vertical displacement field ($V(x, y)$) at maximum tensile load, assuming uniform displacement along lower boundary. All displacements are in millimeters. Measurement region is the lower half of specimen shown in Figure 6.

Inspection shows that the load–displacement data is slightly nonlinear for $P > 50$ kN, coinciding with the onset of increased out-of-plane displacements along the notch line.

Also shown in Figure 7 are the full-field plots of the displacement components in the lower half of the sheet, with (i) U, parallel to the notch line; (ii) V, perpendicular to the notch line; and (iii) W, perpendicular to the specimen surface.

As expected, the U-displacement field is antisymmetric relative to the Y axis, with both sides of the sheet moving approximately 0.40 mm toward the centerline. The V-displacement field is symmetric relative to the Y axis and nominally negative, since the bottom edge of the specimen undergoes applied downward displacement (see Figure 6(c)). As expected, the bottom edge of the specimen undergoes nearly constant displacement, confirming that the "rigid" grip was performing as expected. The W-displacement field is also symmetric relative to the Y axis, with maximum out-of-plane motion of 6 mm occurring along the centerline.

To show that the measured displacement fields are consistent with model predictions, Figure 7(e) shows a direct comparison between the V-displacement fields obtained by finite element analysis and stereovision measurements; similar comparisons are obtained for all displacement components.

5 CONCLUSIONS AND REMARKS

At the time of this article, both software and hardware are available commercially; Hardware costs include (i) scientific grade, 8–12 bit digital camera with 1000×1000 pixel array ($4000–6000); (ii) heavy-duty support structures for camera ($1000); (iii) commercial-grade, two-dimensional computer vision software and computer with data-acquisition, data-analysis, and data-presentation capability ($10 000–20 000); and (iv) commercial-grade, three-dimensional computer vision software and computer with data-acquisition, data-analysis, and data-presentation capability ($40 000–65 000).

The combination of modern digital image processing with stereovision imaging offers a unique opportunity to obtain quantitative deformation data on specimens that are undergoing a combination of in-plane and out-of-plane deformations. As long as the specimen remains within the depth of field for both cameras, the method is capable of measuring full-field 3-D shape, 3-D displacements, and surface strains on planar or curved specimen surfaces. The method has been used to make measurements in a wide range of applications including the following:

1. surface strains in excess of 100% on a highly ductile elastic–plastic metallic materials;
2. thermal strains on metallic specimens heated to 700 °C (*see* **Thermal Imaging Methods** for thermal imaging methods, **Gas Turbine Engines**);
3. thermal and mechanical strains on specimens being imaged in a scanning electron microscope;
4. deformations on curved fuselage structure during both internal pressurization and external dynamic impact (*see* **Civil Infrastructure Load Models for Structural Health Monitoring**; **Static Damage Phenomena and Models**; **Damage Evolution Phenomena and Models**; **Failure Modes of Aerospace Materials**; **A Simplified Damage Model for SHM Metallic and Composite Structures**; **Fatigue Life Assessment of Structures**; **Nondestructive Evaluation/Nondestructive Testing/Nondestructive Inspection (NDE/NDT/NDI) Sensors—Eddy Current, Ultrasonic, and Acoustic Emission Sensors**; **Damage Presence/Growth Monitoring Sensors**; **Principles of Structural Degradation Monitoring**; **Design Principles for Aerospace Structures**; **Design Principles for Civil Structures**; **Risk Monitoring of Aircraft Fatigue Damage Evolution at Critical Locations**; **Risk Monitoring of Civil Structures**; **Environmental Monitoring of Aircraft**; **Maintenance Principles for Civil Structures**; **Use of Leave-in-place Sensors and SHM Methods to Improve Assessments of Aging Structures**; **Usage Management of Military Aircraft Structures**; **Usage Management of Civil Structures**; **Value Assessment Approaches for Structural Life Management**; **Commercial Fixed-wing Aircraft**; **History of SHM for Commercial Transport Aircraft**; **Fatigue Monitoring in Military Fixed-wing Aircraft**; **Agile Military Aircraft**; **Unmanned Aerial Vehicles**; **Health and Usage Monitoring Systems (HUM Systems) for Helicopters: Architecture and Performance**; **Validation of SHM Sensors in Airbus A380 Full-scale**

5. concrete, asphalt, polymers, and fiber-reinforced composites during mechanical loading (*see* **Lamb Wave-based SHM for Laminated Composite Structures**; **Modeling Aspects in Finite Elements**; **Design, Analysis, and SHM of Bonded Composite Repair and Substructure**; **Fatigue Monitoring in Nuclear Power Plants**).
6. civil engineering structures including bridges and joints (*see* **Applications of Acoustic Emission for SHM: A Review**; **Design Principles for Civil Structures**; **Risk Monitoring of Civil Structures**; **Maintenance Principles for Civil Structures**; **Long-term Monitoring of Dynamic Loads on the Brandenburg Gate**; **Development of a Monitoring System for a Long-span Cantilever Truss Bridge**; **Modular Architecture of SHM System for Cable-supported Bridges**; **Monitoring of Bridges in Korea**; **Bridge Monitoring in Japan**; **Continuous Vibration Monitoring and Progressive Damage Testing on the Z24 Bridge**; **Continuous Monitoring of the Øresund Bridge: Data Acquisition and Operational Modal Analysis**; **Condition Compensation in Frequency Analyses—a Basis for Damage Detection**; **Modal Testing of the Vasco da Gama Bridge, Portugal**; **Multiple-model Structural Identification**; **Construction Process Monitoring at the New Berlin Main Station**; **SHM Actions on the Holy Shroud Chapel in Torino**; **SHM of a Tall Building**; **Dynamic Response of Buildings of the Cultural Heritage**; **Suspended Roof of Braga Sports Stadium, Portugal**; **Dams**; **Condamine Floating Dock, Monaco**; **Soil–Structure Interaction and Seismic Effects**; **System Identification for Soil–structure Interaction**).

ACKNOWLEDGMENTS

The author wishes to thank Dr Jeffrey D. Helm for his tireless efforts in completing the bulk of the wide panel experimental work at NASA Langley Research Center. In addition, the technical and editorial support of Dr Hubert Schreier, Dr Stephen R. McNeill, and Dr Junhui Yan in completing this manuscript is deeply appreciated. The financial support of (i) Dr Charles E. Harris, Dr Robert S. Piascik, and Dr James C. Newman, Jr. at NASA Langley Research Center, (ii) Dr Oscar Dillon, Dr Clifford Astill, and Dr Albert S. Kobayashi, former NSF Solid Mechanics and Materials Program Directors, (iii) Dr Bruce LaMattina at the Army Research Office through several grants including ARO 50408-EG-DPS, (iv) Dr Kenneth Chong through NSF CMS-0201345, and (v) the University of South Carolina, Office of Research, are gratefully acknowledged. Finally, the support provided by Correlated Solutions, Inc., through the granting of access to their commercial software for our internal use is deeply appreciated. Through the unwavering technical and financial assistance of all these individuals and organizations, the true potential of image correlation methods is now being realized.

END NOTES

[a.] The original version was developed by Prof. K.S. Kim, Brown University, with emphasis on methods available for measurements on reduced-length scale specimens.

[b.] All image analysis in this work was performed using VIC-2D and VIC-3D software developed by Correlated Solutions Inc.; 120 Kaminer Way, Columbia, SC 29205, www.correlatedsolutions.com.

[c.] Modifications to this procedure have been developed and converted into commercial code. In the version developed by Correlated Solutions, Inc., the grid can be moved and rotated freely, acquiring images simultaneously by all stereo cameras and using equation (3) to efficiently convert grid images into calibration parameter sets for both cameras.

Chapter 63

Electric and Electromagnetic Properties Sensing

Michel B. Lemistre

Laboratoire SATIE/CNRS, Ecole Normale Supérieure de Cachan, Cachan, France

1 INTRODUCTION

In the domain of aeronautics, particularly in the area concerning composite structures, electromagnetic techniques are little used for structural health monitoring (SHM). This could be explained by the fact that the main researchers working in the field of SHM have mechanical engineering training. One possible exception concerns eddy currents techniques, but these are mainly used for metallic structures [1]. In fact, in the case of composite structures, eddy currents techniques are impossible or very difficult to use and generally give poor results, these kinds of structures being either purely dielectric or poor conductors (e.g., carbon epoxy). However, another method also based on eddy currents, but using a low frequency holographic technique [2–4], gives good results on carbon–epoxy structures; nevertheless, this method is not easily transposable into the SHM domain, the external equipment required being too complicated. However, there is a possible application for SHM by measurement of electrical resistance or electrical potential [5, 6]. One other possibility is a dynamic capacitive method [7, 8] uniquely used in the domain of civil engineering.

A new family of electromagnetic techniques, which makes it possible to obtain good information on the health of structures made of composite (i.e., carbon fiber reinforced plastic (CFRP) and glass fiber reinforced plastic (GFRP)) has been developed. These techniques consist of determining the state of the health of a structure by measurement of its two electrical parameters, the electric conductivity σ and/or the dielectric permittivity ε, since damages induces locally significant variations of these parameters. The goal of this article is to explain these techniques and to give their field of application.

First, we shall provide a recall of the electromagnetic theory necessary for gaining a full understanding of the electromagnetic techniques developed.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

Next, the various techniques will be explained with examples of application. The transposition of these techniques in the domain of SHM are fully explained in **The HELP-Layer® System**.

2 THEORETICAL CONSIDERATIONS

2.1 Surface impedance

Let us consider a plane structure made of a material having the following electrical properties:

- magnetic permeability $\mu = \mu_0$;
- dielectric permittivity $\varepsilon = \varepsilon_0 \varepsilon_\mathrm{r}$;
- electric conductivity σ;
- thickness d.

The structure is illuminated by a plane wave with an inclined incidence (see Figure 1).

Electric and magnetic components of the incident wave $\vec{p}_\mathrm{i}$ are $\vec{E}_\mathrm{i}$ and $\vec{H}_\mathrm{i}$ respectively, $\vec{E}_\mathrm{r}$ and $\vec{H}_\mathrm{r}$ being the components of the refracted wave $\vec{p}_\mathrm{r}$; θ_1 and θ_2 are the angles of incidence and refraction, respectively; N_1 is the refractive index of the external medium and N_2 is the refractive index of the structure. θ_1 and θ_2 are linked by the following relation:

$$N_1 \sin\theta_1 = N_2 \sin\theta_2 \tag{1}$$

If one considers that the external medium is in free space, $N_1 = 1$. Taking into account the complex relative permittivity of the material $\varepsilon_\mathrm{r}^* = \varepsilon'_\mathrm{r} - j\varepsilon''_r$, N_2 the index of the material is given by

$$N_2 = \sqrt{\varepsilon_\mathrm{r}^*} = \sqrt{\varepsilon'_\mathrm{r} - j\frac{\sigma}{\omega\varepsilon_0}} \tag{2}$$

If one considers the material as a good conductive material (i.e., $\sigma \gg j\omega\varepsilon$), N_2 can be reduced to the following:

$$N_2 = \sqrt{-j\frac{\sigma}{\omega\varepsilon_0}} \tag{3}$$

then the relation (1) becomes

$$\sin\theta_2 = \frac{1}{N_2}\sin\theta_1 \tag{4}$$

or

$$\cos\theta_2 = \left(1 - \left(\frac{1}{N_2}\right)^2 \sin^2\theta_1\right)^{\frac{1}{2}} = \left(1 + j\frac{\omega\varepsilon_0}{\sigma}\sin^2\theta_1\right)^{\frac{1}{2}} \tag{5}$$

For good conductive materials, neglecting the second term of the parenthesis, the relation (5) yields

$$\cos\theta_2 \cong 1 \tag{6}$$

Therefore, the wave penetrates through the material perpendicular to the surface of the structure ($\theta_2 = 0$). Figure 2 shows the field's configuration inside the structure.

The two fields $\vec{E}(z)$ and $\vec{H}(z)$ can be written as follows:

$$\vec{E}(z) = \vec{E}_a \exp(-\gamma z) + \vec{E}_b \exp(+\gamma z) \tag{7a}$$

$$\vec{H}(z) = \left(\vec{n} \times \vec{E}_a\right)\frac{\exp(-\gamma z)}{Z} + \left(\vec{n} \times \vec{E}_b\right)\frac{\exp(+\gamma z)}{Z} \tag{7b}$$

with Z being the wave impedance inside the material defined by the relation

$$Z = \sqrt{\frac{\mu_0}{\varepsilon^*}} = (j+1)\sqrt{\frac{\mu f \pi}{\sigma}} = \frac{j+1}{\sigma\delta} \tag{8}$$

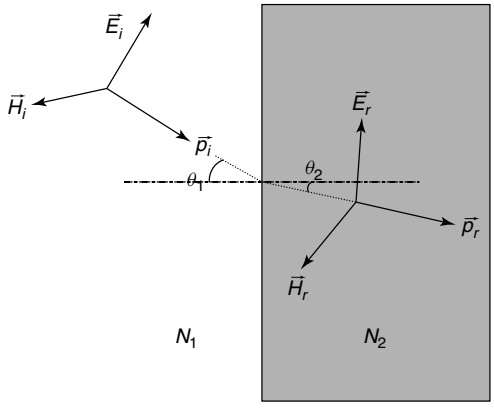

Figure 1. Illumination of a conductive material.

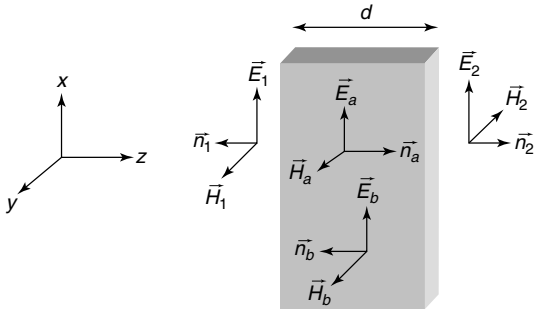

Figure 2. Field configuration inside a structure of thickness d.

and γ the propagation constant given by

$$\gamma = j\omega\sqrt{\varepsilon^*\mu_0} = (j+1)\sqrt{\mu f \pi \sigma} = \frac{j+1}{\delta} \quad (9)$$

where $\vec{n}$ is the unit vector in the z direction (i.e., the thickness of the material), f the frequency of the incident wave, and δ the skin depth defined by the following relation:

$$\delta = \frac{1}{\sqrt{\mu f \pi \sigma}} \quad (10)$$

Electric and magnetic fields tangential to the structure, on each one of its faces, $\vec{E}_1$, $\vec{H}_1$ and $\vec{E}_2$, $\vec{H}_2$ (Figure 2), are given by the following equations:

$$\vec{E}_1 = \frac{Z}{th(\gamma d)}\vec{n}_1 \times \vec{H}_1 + \frac{Z}{sh(\gamma d)}\vec{n}_2 \times \vec{H}_2 \quad (11a)$$

$$\vec{E}_2 = \frac{Z}{sh(\gamma d)}\vec{n}_1 \times \vec{H}_1 + \frac{Z}{th(\gamma d)}\vec{n}_2 \times \vec{H}_2 \quad (11b)$$

One can define a surface current density $\vec{J}_s$, which is the integral of the volume current density $\vec{J}$ in the thickness of the structure. One can write the boundary equations:

$$\vec{J}_s = \vec{n}_1 \times \left(\vec{H}_1 - \vec{H}_2\right) = \vec{n}_2 \times \left(\vec{H}_2 - \vec{H}_1\right) \quad (12)$$

For low frequencies such as $d \ll \delta$, that is, $|\gamma d| \ll 1$, one can write the following approximations:

$$sh(\gamma d) \cong \gamma d \quad (13a)$$

and

$$th(\gamma d) \cong \gamma d \quad (13b)$$

Relations (11a) and (11b) yield

$$\vec{E}_1 = \vec{E}_2 = \vec{E}_{tg} = \frac{1}{\sigma d}\vec{J}_s \quad (14)$$

E_{tg} being the electric field tangential to the surface of the structure, it is now possible to define the surface impedance Z_s as

$$\vec{E}_{tg} = Z_s \vec{J}_s \quad (15)$$

with

$$Z_s = \frac{1}{\sigma d} \quad (16)$$

One can see that at low frequencies, the current density is distributed uniformly in the material. One can then neglect the skin effect and resonances inside the material. The condition $|\gamma d| \ll 1$ (or $\delta > d$) defines the domain of application of the concept of surface impedance; the material is then called *electrically thin*. In the case of $\delta < d$, the material is called *electrically thick*; losses by attenuation inside the material and by reflection are then the main phenomena.

The surface impedance is given in "square ohm" (symbol Ω_c); it is the impedance of an electrically thin square sample, having a conductivity σ. One can represent the equivalent electric diagram to the surface impedance by Figure 3.

2.2 Diffraction by a circular aperture

For an incident plane wave, Bethe [9] has given an approximate analytical representation of diffracted

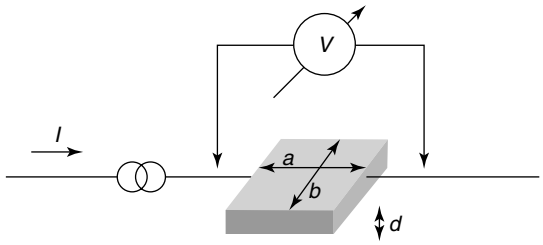

Figure 3. Equivalent electric diagram of the surface impedance.

fields by a small circular aperture in a structure that is considered as infinitely conductive (a good conductive metal such as aluminum can be considered as infinitely conductive), having an infinite surface (i.e., large compared with the diameter of the aperture), with the following assumptions:

- The size of the aperture is small compared with the wavelength of the incident field.
- The fields are calculated at a large distance compared with the size of the aperture.

Bethe has given the concept of "short-circuit fields" $\vec{E}_{cc}$ and $\vec{H}_{cc}$, which represent the fields on the aperture loaded by a perfectly conductive material. These fields are defined in the following manner:

$$\vec{E}_{cc} = 2\vec{E}_0 \tag{17a}$$

and

$$\vec{H}_{cc} = 2\vec{H}_0 \tag{17b}$$

where $\vec{E}_0$ and $\vec{H}_0$ are the orthogonal electric component and the tangential magnetic component of the incident field, respectively. The diffracted fields by the aperture are the sum of the radiated fields by an electric dipole having a moment $\vec{P}_e$ and a magnetic dipole having a moment $\vec{P}_m$. These two dipoles model the orthogonal and tangential fields, respectively as shown in Figure 4.

Let us introduce the concept of "polarizability"; the dipolar moments are related to short-circuit fields by the following relations:

$$\vec{P}_e = \varepsilon\alpha_e\vec{E}_{cc} \tag{18a}$$

and

$$\vec{P}_m = -\overline{\overline{\alpha}}_m\vec{H}_{cc} \tag{18b}$$

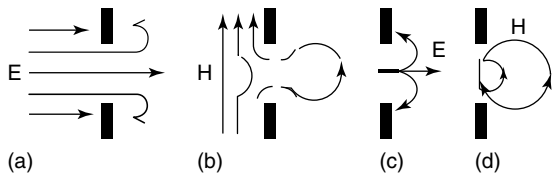

Figure 4. Incident fields and equivalent dipoles: (a) orthogonal electric field, (b) tangential magnetic field, (c) equivalent electric dipole, and (d) equivalent magnetic dipole.

where α_e and $\overline{\overline{\alpha}}_m$ are the electric polarizability and the magnetic polarizability, respectively, given by an aperture of radius a.

The polarizability depends on the geometry of the structure and the aperture. For a plane aperture of any geometry, the electric polarizability is a scalar number and the magnetic polarizability is a tensor of rank 1. For a plane circular aperture of radius a, the magnetic polarizability is a diagonal tensor with the two diagonal terms being equal.

$$\alpha_e = \frac{2}{3}a^3 \tag{19a}$$

$$\alpha_{mxy} = \alpha_{myx} = 0 \tag{19b}$$

$$\alpha_{mxx} = \alpha_{myy} = \alpha_m = \frac{4}{3}a^3 \tag{19c}$$

With Bethe's assumptions, Casey [10] has calculated the moment of the magnetic dipole for a plane circular aperture having a radius a, loaded by a nonperfect conductive material such as carbon epoxy. Casey defines a resistance of "electrical gasket" R_g as the contact resistance between the conductive structure and the material loading the aperture. R_g is given by the product ohm × meter (length of contact between the material and the structure). Casey's method involves the solution of an integral equation. Two solutions are proposed—the first one being exact leads to a semianalytical expression of the magnetic dipole, including a coefficient that must be calculated numerically; the second one, obtained by an approximate method, leads to the dipolar moment $\vec{P}_m$ under the form of the transfer function of a first order low pass filter.

$$\frac{\vec{P}_m}{\vec{P}_{m0}} = \frac{1}{1 + j\dfrac{f}{f_c}} \tag{20}$$

In this expression, $\vec{P}_{m0}$ is the magnetic dipolar moment given by a free aperture, f represents the frequency of the incident wave, and f_c is the cutoff frequency given by the following relation:

$$f_c = \frac{3}{8\mu_0}\frac{Z_s}{a}\left(1 + \frac{R_g}{aZ_s}\right) \tag{21}$$

It should be noted here that the cut-off frequency is a function of the surface impedance Z_s and thus

the conductivity σ of the material (relation 16). This cutoff frequency is called *Casey's frequency*.

2.3 Polarization of dielectrics

All materials that have a conductivity $\sigma \leq 10^{-20}$ $S{\cdot}m^{-1}$ at room temperature ($\approx$300 K) are called *dielectrics*. On a large scale, dielectrics seem to be electrically neutral. However, on a microscopic scale, dielectrics show an "assembly" of elementary electric dipoles having a random space orientation. For a large number of dipoles, one can consider dielectrics as statistically neutral. If a dielectric material is subjected to an electric field, elementary dipoles tend to orient in the direction of the incident electric field; one can define a polarization vector per unit volume $\vec{P}$ as

$$\vec{P} = Nq\vec{\delta} \tag{22}$$

with q elementary charges (per atom or molecule), separated by a distance $\vec{\delta}$ and N the number of atoms (or molecules) per unit volume. The product $q\vec{\delta}$ represents the elementary dipolar moment $\vec{p}$ for each atom (or molecule); this dipolar moment is related to the local electric field $\vec{E}_0$ by $\vec{p} = \alpha\vec{E}_0$. In this relation, the proportionality factor α is called *polarizability*, and it is a function of the electrical characteristics of the medium (i.e., the dielectric) and more precisely of its dielectric relative permittivity ε_r, defined by the Clausius–Mossoti's relation [11]:

$$\alpha = \frac{3}{4\pi N}\left(\frac{\varepsilon_r - 1}{\varepsilon_r + 2}\right) \tag{23}$$

The polarization phenomenon in dielectric medium results from three different sources: electronic polarization, ionic polarization, and orientation polarization. These three sources admit polarizability coefficients α_e, α_i, and α_o, respectively; the real part of the coefficient α is the sum of the three real parts of elementary polarizability.

Electronic polarization arises because the center of local electronic charge cloud around the nucleus is displaced under the action of the electric field $\vec{P}_e = N\alpha_e\vec{E}_0$.

Ionic polarization occurs in ionic materials because the electric field displaces positives and negatives ions in opposite directions $\vec{P}_i = N\alpha_i\vec{E}_0$.

Orientation polarization can occur in materials composed of molecules that have permanent electric dipoles. The alignment of these dipoles depends on temperature and leads to an "orientational polarizability" per molecule $\alpha_o = \frac{p^2}{3KT}$, where p is the permanent dipolar moment per molecule, K is the Boltzmann constant, and T is the temperature.

Because of the different nature of these three polarization processes, the response of a dielectric solid to an applied electric field will strongly depend on the frequency of the field. The resonance of the electronic excitation takes place in the ultraviolet part of the electromagnetic spectrum; the characteristic frequency of the ions' vibration is located in the infrared, while the orientation of dipoles requires fields of much lower frequencies (below 10^9 Hz). This response to electric field of different frequencies is shown in Figure 5.

For a low-frequency excitation (i.e., 1 kHz to 10 MHz), one can consider the response of the dielectric medium to be quasi-static. So, it is possible to describe the electric field inside the dielectric by the following equation:

$$\nabla{\cdot}\vec{E} = \frac{\rho_l + \rho_p}{\varepsilon_0} \tag{24}$$

where ρ_l is the free charge density and ρ_p an apparent density of charges due to the polarization phenomenon. The field $\vec{E}$ can be considered as the resultant of two components: the field resulting from the free charges $\vec{E}_f$ and the field resulting from the polarization phenomenon $\vec{E}_p$, that is, $\vec{E} = \vec{E}_f + \vec{E}_p$.

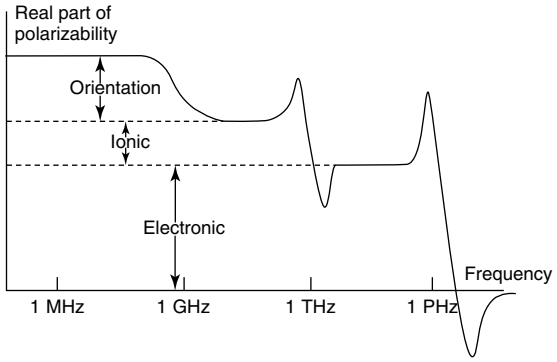

Figure 5. Frequency dependence of the different contribution to polarizability. From Handbook of Chemistry and Physics.

Then

$$\nabla\cdot\vec{E} = \nabla\cdot\vec{E}_{\mathrm{f}} + \frac{\rho_{\mathrm{p}}}{\varepsilon_0} \tag{25}$$

One can define a polarization vector $\vec{P}$ by $\rho_{\mathrm{p}} = -\nabla\cdot\vec{P}$ (see [12]). Equation (25) can be rewritten as

$$\vec{E} = \vec{E}_{\mathrm{f}} + \frac{\vec{P}}{\varepsilon_0} \tag{26}$$

The vector $\vec{P}$ is linked with the incident field $\vec{E}_{\mathrm{i}}$ by the following relation:

$$\vec{P} = \chi_{\mathrm{e}}\varepsilon_0\vec{E}_{\mathrm{i}} \tag{27}$$

where χ_{e} is the electric susceptibility and is linked with the relative electric permittivity ε_{r} by the expression

$$\varepsilon_{\mathrm{r}} = 1 + \chi_{\mathrm{e}} \tag{28}$$

Taking into account relations (26–28), one has

$$\vec{E} = \vec{E}_{\mathrm{f}} + \left(\varepsilon_{\mathrm{r}} - 1\right)\vec{E}_{\mathrm{i}} \tag{29}$$

However, in most of dielectrics, the term due to the free charges can be neglected and the value of the electric field $\vec{E}$ is reduced to the polarization term $(\varepsilon_{\mathrm{r}} - 1)\vec{E}_{\mathrm{i}}$.

3 ELECTRICAL CAPACITANCE SENSORS

Let us consider a dielectric material having an electric relative permittivity ε_{r}, in the presence of an electric field $\vec{E}_{\mathrm{i}}$, the material being considered in a macroscopic manner (i.e., quasi-isotropic). The electric field $\vec{E}_{\mathrm{i}}$ induces a phenomenon of polarization inside the material (see Section 2.3), characterized by the vector $\vec{P}$. The total electric field $\vec{E}_{\mathrm{T}}$ measured at point A (Figure 6) can be written as

$$\vec{E}_{\mathrm{T}} = \vec{E}_{\mathrm{i}} + \frac{\vec{P}}{\varepsilon_0} = \vec{E}_{\mathrm{i}} + \left(\varepsilon_{\mathrm{r}} - 1\right)\vec{E}_{\mathrm{i}} \tag{30}$$

After subtraction of the incident electric field $\vec{E}_{\mathrm{i}}$, one can obtain directly the value of ε_{r}. Note that, the frequency of excitation must be lower than the cutoff frequency of the orientation polarization phenomenon (i.e., 10 MHz).

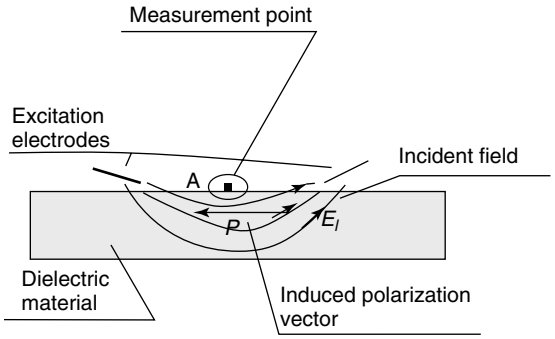

Figure 6. Configuration of measurement applied to dielectric materials.

This method can be applied to all dielectric composite materials such as GFRP, sandwich, etc. An electric sensor has been designed [13] allowing to detect some defects in dielectric composites. This sensor performs a differential measurement between two adjacent zones (Figure 7).

Figure 8 shows an example of detection performed on a sample of glass epoxy sandwich with a lack of foam in the middle of the lower part. Figure 8(b) shows the electric image obtained by scanning the material.

This sensor allows designing a system of SHM dedicated to glass epoxy or sandwich structures and more generally all dielectric composite structures (*see* **The HELP-Layer® System**).

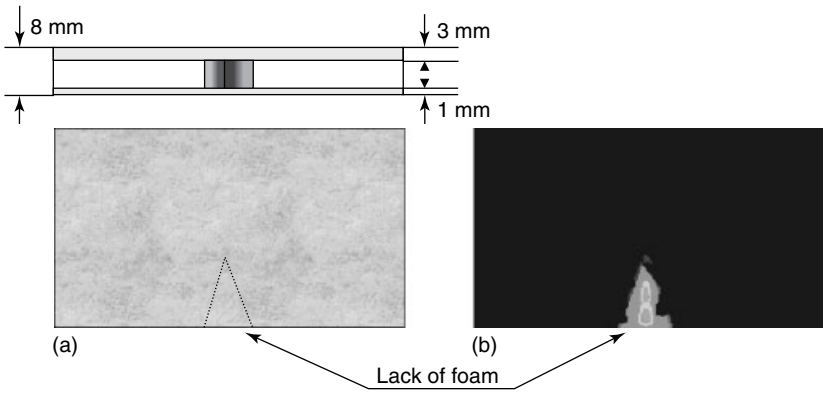

Figure 8. Example of damage detection in a sandwich structure.

4 ELECTROMAGNETIC SENSORS FOR COMPOSITE MATERIALS

4.1 Magnetic sensor

The conductive materials such as metallic structures having a conductivity σ between 10^7 and $10^8\ \mathrm{S{\cdot}m^{-1}}$ will not be considered here. For such materials, the effectiveness of classical methods using eddy currents is well established and is not necessary to demonstrate here. Here we consider composite materials having a mean conductivity σ about $10^4\ \mathrm{S{\cdot}m^{-1}}$ such as CFRP, so-called nonperfectly conductive materials.

One has seen, in Section 2.2 that the magnetic dipolar moment $\vec{P}_{\mathrm{m}}$ of an aperture loaded by a nonperfectly conductive material, can be represented in the form of a transfer function of a first-order low pass filter. The dipolar moment being directly proportional to the magnetic field, the terms $\vec{P}_{\mathrm{m}}$ and $\vec{P}_{\mathrm{m0}}$ can be replaced by $\vec{H}$ and $\vec{H}_0$, respectively in relation (20):

$$\frac{\vec{H}}{\vec{H}_0} = \frac{1}{1 + j\dfrac{f}{f_{\mathrm{c}}}} \tag{31}$$

where $\vec{H}_0$ is the magnetic field measured through a free aperture and $\vec{H}$ is the magnetic field measured through a loaded aperture by a conductive material. The cut-off frequency f_{c} being a function of the surface impedance Z_{s}, one has direct access to the value of the conductivity σ of the considered material by using the relation (21).

Let us now consider a local excitation by a near magnetic field (e.g., with a Hertz loop), and a local measurement of the resulting magnetic field, as shown in Figure 9; one can omit the infinite conductive plane and the contact resistance R_{g}.

An analytical calculus gives a new transfer function between $\vec{H}$ and $\vec{H}_0$:

$$\frac{\vec{H}(f,r)}{\vec{H}_0(f,r)} = \left(1 + \left(\frac{r}{a}\right)^2\right)^{\frac{3}{2}} \int_0^{\infty} \frac{u^2}{u + j\dfrac{f}{f_{\mathrm{c}}}} \times J_1(u)\, \mathrm{e}^{-u\frac{r}{a}}\, \mathrm{d}u \tag{32}$$

with r being the distance between the two loops, a the radius of the emission loop, and J_1 the Bessel function of first order, and the cutoff frequency f_{c}

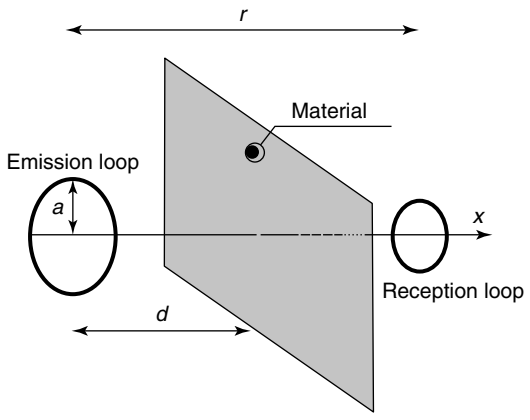

Figure 9. Excitation with near magnetic field.

having the following expression:

$$f_c = \frac{1.4}{\pi \mu_0 \sigma a e} \tag{33}$$

where a represents the radius of the emission loop and e the thickness of the material. The distance between the emission loop and the material d has no influence on the transfer function; it is possible to put the material immediately "after" the reception loop as shown in Figure 10—that is, allowing to test the material only on a single face.

However, in this case, the transfer function $\vec{H}/\vec{H}_0$ is given by the sum of the two following terms T_1 and T_2:

$$T_1 = 1 - \frac{\left(1 + \left(\frac{r}{a}\right)^2\right)^{\frac{3}{2}}}{\left(1 + \left(\frac{2d - r}{a}\right)^2\right)^{\frac{3}{2}}} \tag{34a}$$

$$T_2 = \left(1 + \left(\frac{r}{a}\right)^2\right)^{\frac{3}{2}} \int_0^{\infty} \frac{u^2}{u + j\frac{f}{f_c}} \times J_1(u) \mathrm{e}^{-u\frac{2d-r}{a}} \mathrm{d}u \tag{34b}$$

One can state that when f tends toward infinity, the function $T_1 + T_2$ tends toward the constant T_1. So, if the distance d increases, the value of the constant T_1 becomes close to the value of the transfer function before attenuation (i.e., $f < f_c$); this is the problem of the "lift-off" well known in the eddy current techniques.

The goal of this kind of analysis is not necessarily to measure the exact value of the conductivity of a material under test, but to detect damages inducing a local variation of this conductivity. A differential sensor [13, 14] measuring the "contrast" of the conductivity between two adjacent zones has been designed (Figure 11). This sensor compares the magnitude of the magnetic field between the two zones, 1 and 2 (Figure 11); when the two magnetic fields are different, the voltage V_{out} is nonzero.

The excitation frequency f is set between two characteristic frequencies: the skin frequency f_s and the Casey's frequency f_c (relation 33). The excitation frequency must be smaller than the skin frequency f_s but greater than the Casey's frequency f_c to have a significant variation of the measured magnetic field due to the variation of the local conductivity σ (relation 34). Figure 12 shows the evolution of these two frequencies as a function of the thickness of a quasi-isotropic carbon–epoxy multilayer structure.

By scanning a structure, one can build an image in which damaged areas appear clearly; an example is given in Figure 13. This figure shows the magnetic

image (i.e., σ contrast) performed on a quasi-isotropic carbon–epoxy multilayer sample of 60 mm × 60 mm ×2 mm dimension, including a delamination and fiber break. The delamination has been performed by a calibrated impact with energy 3 J.

4.2 Hybrid electromagnetic sensor

One can consider that a carbon–epoxy structure is made up of two different media: a conductive medium, the carbon fibers (conductivity $\sigma \approx 10^4\,\mathrm{S{\cdot}m^{-1}}$), and a dielectric medium, the resin (relative dielectric permittivity $\varepsilon_r \approx 4$).

The local electric field $\vec{E}_l$ induced inside a conductive structure by a magnetic induction $\vec{B}$, can be represented by the following Maxwell's equation:

$$\nabla \times \vec{E}_l = -\frac{\partial \vec{B}}{\partial t} \tag{35}$$

This electric field itself induces a current density $\vec{J} = \sigma \vec{E}_l$. However, in a carbon–epoxy media, the current density $\vec{J}$ is the sum of two terms: $\vec{J} = \vec{J}_c + \vec{J}_d$. The first term $\vec{J}_c$ (conductive current density) is due to the conductivity of the carbon fibers; the second one $\vec{J}_d$ (displacement current density) is a transient term due to the polarization phenomenon in the resin epoxy. Let us consider the quasi-static hypothesis, frequency below 10^7 Hz (i.e., below the cutoff frequency of the orientational polarization phenomenon); taking into account equation (26), the measured local electric field $\vec{E}_m$ can be written as follows:

$$\vec{E}_m = \frac{\vec{J}_c}{\sigma} + \frac{\vec{P}}{\varepsilon_0} \tag{36}$$

where $\vec{P}$ is the polarization vector due to the resin epoxy. With the relation (29) one can write

$$\vec{E}_m = \frac{\vec{J}_c}{\sigma} + \vec{E}_l\left(\varepsilon_r - 1\right) \tag{37}$$

So the measured electric field $\vec{E}_m$ is a function of the conductivity σ of the medium and also of its relative dielectric permittivity ε_r. This technique based on the magnetic induction (i.e., eddy currents) and on the analysis of the resulting electric field is called *hybrid electromagnetic method*.

The possibility to have simultaneous access to the main electric properties of the medium presents a great potential for carbon–epoxy structures used in the aeronautical domain, for detecting main damages that are found in these structures. These damages can be classified into three categories:

- The damages having a mechanical origin—they are provoked by impacts, inducing delaminations and generally, fiber breakage. These critical damages are common for carbon (fibers); so in term of electrical properties, they induce uniquely a local variation of the conductivity.
- The thermal damages arise either from proximity to a hot body or from an electrical impact (i.e., spark, lightning). In the first case, one can detect the damage uniquely by conductivity variation. In the second case, if the burn is light, there is not much σ variation, but only significant ε_r variation due to the pyrolysis phenomenon of the resin. Nevertheless, this kind of damage generally affects the two electrical parameters.
- The damages resulting from liquid ingress (water, oil, fuel) can be critical because of the fact that the liquid can start a chemical reaction and weaken the structure. This kind of damage induces uniquely a variation in ε_r due to the

presence of a new medium having a different dielectric permittivity (i.e., the liquid).

From this hybrid concept, a new sensor has been designed [15]. This sensor can be considered as a combination of the electric capacitance sensor and the magnetic sensor, including some improvements. Figure 14(a) presents a photograph of a probe based on this technique, designed with a dielectric parallelepiped (3 cm × 3 cm × 1 cm) including on one face an inductive coil and a differential dipole for the measurement of the electric field on the opposite face. Figure 14(b) shows a schematic view of this probe.

The inductive coil appears as a Moebius loop made with a hard coaxial cable (Figure 14c).

This geometry allows the formation of a double induction loop with preservation of real impedance equal to the characteristic impedance of the coaxial (i.e., 50 Ω), for the entire frequency domain, from 100 kHz to 10 MHz. The measurement unit appears as double crossed dipole (Figure 14d) that allows to perform differential measurements with a sensitivity to the two orthogonal components of the tangential electric field $\vec{E}_x$ and $\vec{E}_y$.

The operating frequency f is not submitted to the same imperative as magnetic measurement. It is only necessary to operate with a frequency below the orientational polarization phenomenon cutoff (i.e., $f < 10^7$ Hz). However, the magnitude of the electric field induced inside the material is directly proportional to the frequency of the inductive magnetic field (equation 35), and it is preferable to use a frequency as high as possible. Nevertheless, too high a frequency does not allow penetration through the total thickness of the material such as carbon–epoxy multilayer, due to the skin effect. For this kind

of material, the good frequency domain is between 100 kHz and 10 MHz.

Figure 15(a) shows the electromagnetic image of a quasi-isotropic sample of carbon epoxy (200 mm × 150 mm × 4 mm) with various burns. These results are compared with a C-scan ultrasonic image shown in Figure 15(b). Only the electromagnetic hybrid investigation is able to detect light burns.

5 CONCLUSION

The examples presented are results of various methods of signal processing used to extract relevant information, particularly the methods using wavelet transform. It is a fact that the resulting signal is very weak and the signal/noise ratio is close to 1. So, the main process for data reduction consists of performing a noise reduction by discrete wavelet transform (DWT) by using Donoho's method [16]. With regard to electromagnetic techniques, one can say that it is possible to detect practically all kinds of damage and their severity. However, the sensitivity of these methods is lower than the classical ultrasonic C-scan method as regards damages having a mechanical origin, such as light delaminations without fiber breaking, because of the fact that there is no variation of electric conductivity and the very weak variation of dielectric permittivity induced by the air layer of the delamination is not significant. Conversely, these techniques show greatest sensitivity as regards to other kinds of damages (i.e., thermal damages, liquid ingress, etc.). One of the interests of these methods lies in the fact that it is very easy to transpose them in the domain of SHM and it is possible to design a fully integrated SHM system for composite structures.

1 INTRODUCTION

Optical fiber sensors present numerous advantages for the measurement of strain, temperature, humidity, pressure, and other parameters. For a review of their application to structural health monitoring, *see* Measures [1] and **Fiber-optic Sensors**. Optical fiber sensors are immune to electromagnetic interference, do not present an ignition hazard, are lightweight, relatively unobtrusive, and are durable and resistant to corrosion (with appropriate coatings). Additionally, a large number of sensors can be multiplexed into a single optical fiber, drastically reducing the amount of cabling required to access the sensors. This can be an important weight and fire hazard reduction. This article presents the fundamental principles common to all optical fiber sensors, as well as general issues concerning their application to structural health monitoring systems. More detailed descriptions of specific optical fiber sensors can be found in **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors** and **Fiber Bragg Grating Sensors**.

2 LIGHTWAVE PROPAGATION IN OPTICAL FIBERS

Optical fibers generally consist of a fused silica (SiO_2) core and cladding. During drawing of the optical fiber, dopants are added to the silica to provide an index of refraction distribution throughout the cross section of the optical fiber [2]. Typical core diameters are $5-10\,\mu m$ for single-mode optical fibers and greater than $50-200\,\mu m$ for multimode optical fibers. The cladding diameter for almost all optical fibers is standardized at $125\,\mu m$ to permit standardized couplers. Small diameter fibers ($80\,\mu m$) have also been developed for sensing applications [3]. The

small diameter makes the fiber sensor less invasive when the fiber is embedded in a host material system and increases the sensitivity of the sensor to applied loads.

Standard optical fibers are coated with a UV-cured acrylate to prevent moisture from entering the fiber and make the fiber more durable for handling. Humidity can induce microcracking in the fiber and cause premature failure of the fiber. A standard diameter for acrylate coatings is 250 μm. For optical fiber sensors, different coatings may be applied such as polyimide, which is stiffer, to provide better protection and strain transfer and is able to withstand higher working temperatures. Removal of the polyimide coating for connectors is considerably more difficult, however, than removal of acrylate coatings. Sensing applications also often require bare optical fibers or coatings that are specially fabricated to increase sensitivity of the optical fiber to outside parameters such as humidity (*see* **Fiber Bragg Grating Sensors**) [4–7].

2.1 Step-index fibers

The cross section of a step-index optical fiber is shown in Figure 1. The index of refraction distribution is only a function of the radius with

$$n(r,\theta) = n_1 \quad r \le a$$
$$n(r,\theta) = n_2 \quad r > a \tag{1}$$

In order for propagation of guided lightwaves to occur $n_1 > n_2$.

The index of refraction difference between the core and cladding is typically less than 1%, therefore we can use the weakly guiding assumption to describe lightwave propagation through the fiber [8]. This assumption states that lightwave can be divided into transverse electric (TE) and transverse magnetic (TM) fields that are orthogonal to one another as they propagate. The two fields also have the same propagation constant, i.e., phase shift per unit distance. Therefore, we can study either the TE or TM mode individually and apply the same results to the other component. Applying the weakly guiding assumption, each component of the lightwave propagating along the fiber in the z direction satisfies the scalar wave equation,

$$\psi(r,\theta,z,t) = \bar{\psi}(r,\theta)\, e^{i(\omega t - \beta z)} \tag{2}$$

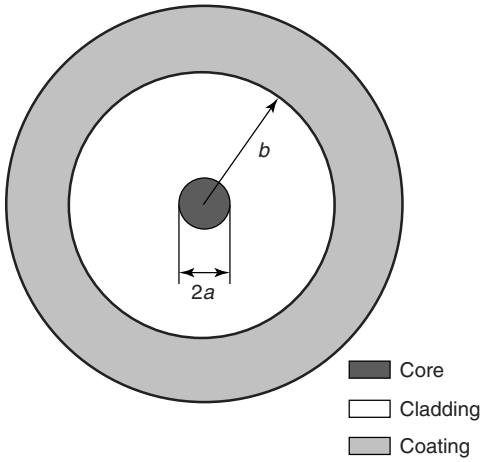

Figure 1. Cross section of step-index optical fiber. Figure not to scale.

where $\bar{\psi}$ is the energy distribution in the plane perpendicular to the propagation direction, ω is the angular frequency ($\omega = 2\pi c/\lambda$ where c is the speed of light in a vacuum and λ is the free space wavelength of the lightwave), and β is the propagation constant of the mode (phase shift per unit length). We assume an infinite diameter cladding and solve over equation (2) in each of the index of refraction regions defined by equation (1). Next, we apply continuity conditions at $r = a$ and find a number of distinct guided modes,[a] which are commonly referred to as the *linearly polarized* (LP) modes.

The energy distribution of the $LP_{\ell m}$ mode in the cross section of the fiber can be written as

$$\bar{\psi}(r,\theta) = \begin{cases} A_0[J_\ell(pr)/J_\ell(pa)]\cos(\ell\theta) & r < a \\ A_0[K_\ell(\gamma r)/K_\ell(\gamma a)]\cos(\ell\theta) & r > a \end{cases} \tag{3}$$

where $J_\ell(r)$ is the Bessel function of the first kind of order ℓ, $K_\ell(r)$ is the modified Bessel function of the first kind of order ℓ, $p = \sqrt{4\pi^2 n_1^2/\lambda^2 - \beta^2}$ and $\gamma = \sqrt{\beta^2 - 4\pi^2 n_2^2/\lambda^2}$ [8]. For each choice of ℓ, there exists zero, one, or multiple solutions to β within the guided range $n_2 < (\beta\lambda)/(2\pi) < n_1$. We order these solutions beginning with the highest value, and thus the $LP_{\ell m}$ corresponds to the mth solution. The energy distribution of equation (3) is different for each mode, due to the different values of β and therefore p and γ. The intensity distribution, $I(r,\theta) = |\bar{\psi}(r,\theta)|^2$, for several of the lowest propagating

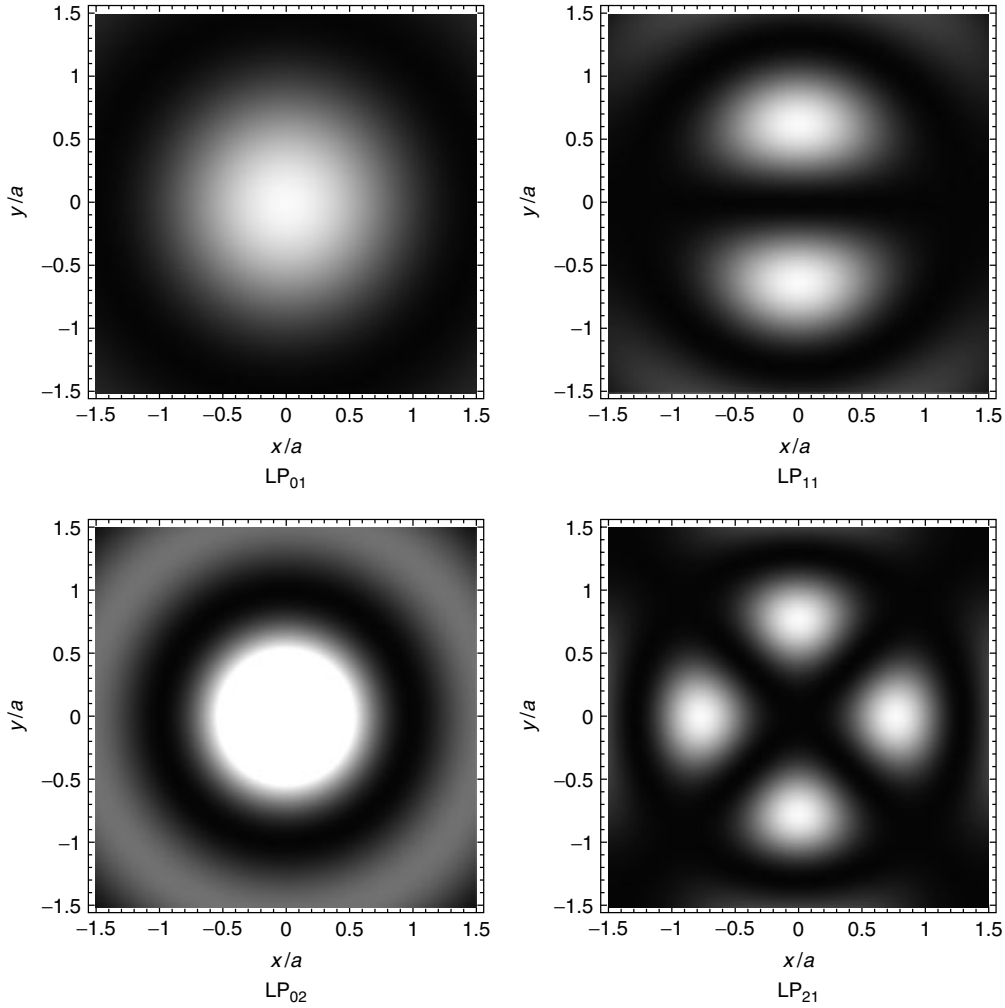

Figure 2. Intensity distribution plots for first four modes (LP_{01}, LP_{11}, LP_{02}, and LP_{21}) for step-index fiber. Radius of core is a. White area represents maximum intensity. [Reproduced from Ref. 2. © Cambridge University Press, 1998.]

modes are plotted in Figure 2. For each propagating mode, we can also define an effective index of refraction, $n_{\text{eff}} = \beta\lambda/(2\pi)$, where n_{eff} corresponds to the index of refraction of an equivalent homogeneous material for which the planar wave would propagate with the same propagation constant β as through the step-index fiber above. For guided modes, $n_2 < n_{\text{eff}} < n_1$. The effective index of refraction, or mode propagation constant β, will play a critical role in the response of many optical fiber sensors (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**; **Fiber Bragg Grating Sensors**).

The number of modes that can propagate at a particular wavelength depends upon the normalized frequency at that wavelength, V,

$$V = \frac{2\pi a}{\lambda}\sqrt{n_1^2 - n_2^2} \tag{4}$$

Figure 3 plots a normalized propagation constant b,

$$b = \frac{n_{\text{eff}}^2 - n_2^2}{n_1^2 - n_2^2} \tag{5}$$

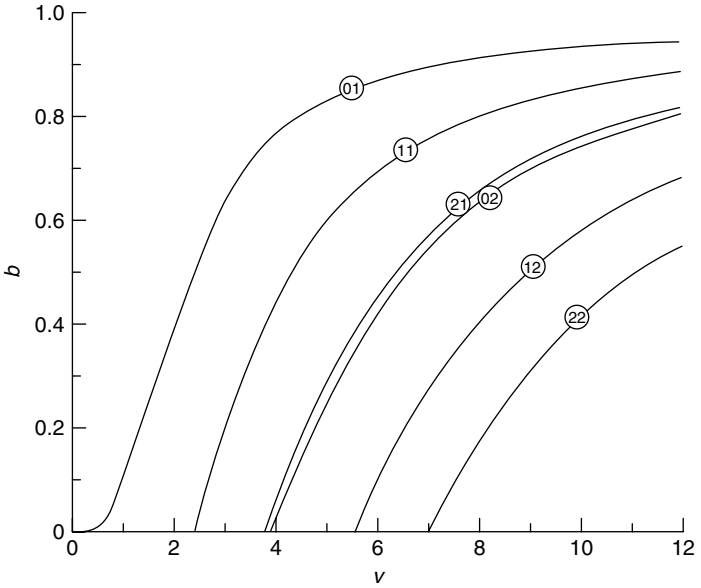

Figure 3. Propagation constant versus normalized frequency for modes LP_{01}, LP_{11}, LP_{21}, LP_{02}, LP_{12}, and LP_{22} of a step-index fiber [2].

for the first six modes of a step-index fiber as a function of the normalized frequency. The normalization allows one to apply Figure 3 to any step-index fiber parameters. As can be seen in Figure 3, each mode has a cutoff value of V such that it will not propagate at any value of V lower than the cutoff value. The cutoff value for the LP_{11} mode is at $V = 2.4048$. Below this value only one mode, the LP_{01} mode, can propagate through the fiber. Under these conditions, the fiber is referred to as a *single-mode fiber*. The LP_{01} is referred to as the *fundamental mode* as it has the highest power density in the core of the optical fiber. For many sensing applications, it is important to utilize fibers that are single mode at the wavelength to be interrogated so that the mode of propagation and coupling is well defined. Additionally, the fundamental mode is the least affected by bending losses, as the energy is concentrated in the center of the fiber. The input light is then coupled to individual modes.

For optical fibers operating at $V > 2.4048$, input lightwaves are coupled into multiple modes. The specific power distribution between the multiple modes is a function of the coupling. Multimode sensors do exist and are generally easier to practically couple to instrumentation as the fiber core is larger and the modes are more spread out throughout the fiber cross section (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**) [9–14]. As the normalized natural frequency V increases, the number of modes rapidly increases, with a good approximation of $N \simeq V^2/2$ for $V \gg 1$. Therefore, when a large number of modes are present, one can assume a uniform distribution of energy throughout the cross section [8].

Finally, as the cladding diameter is not actually infinite, additional mode solutions are possible due to the interface condition between the outer diameter of the fiber and the surrounding medium. The form of these modes depends upon the index of refraction of the surrounding medium, n_3. First, consider the case of $n_3 < n_2$ such as when the fiber has been stripped of any coating and is exposed to air. Solving equation (2), taking into account the cladding diameter yields additional discrete guided modes, called *cladding modes*, with β values below those of the guided modes. The power distributions of the cladding modes are spread over a much larger area of the cross section of the optical fiber, therefore they are far more sensitive to imperfections and microbends in the drawn silica. The cladding modes can be excited locally in long period grating sensors

and exploited for the measurement of cure monitoring, chemical or environmental sensing (*see* **Fiber Bragg Grating Sensors**) [15].

2.2 Other fiber types

Although the step-index fiber is the easiest for which to analyze mode propagation, most commercially available optical fibers have different index distributions as shown in Figure 4 [2]. Such index distributions provide better dispersion properties, important for long-haul telecommunication networks. While most optical fiber manufacturers do not provide detailed information on the index distributions, they do provide data such as the core radius, design operating wavelength, and n_{eff} at common wavelengths (see, for example, [16]). From this information, the user can calculate the response of the optical fiber sensor using the same principles as for the step-index fiber (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**).

A second important class of optical fibers applied for sensing is high-birefringence fibers, also referred to as *polarization maintaining* (PM) fibers (see examples in Figure 5) [17]. PM fibers propagate two separate, LP fundamental modes (LP_{01}) at two separate propagation constants, β_1 and β_2. The modes are polarized about orthogonal axes, referred to as the *fast and slow axes*. As the polarization axes are orthogonal, the two modes do not interfere with one another as they propagate along the optical fiber. These orthogonal modes can be used to independently measure multiple parameters (*see* **Fiber Bragg Grating Sensors**). The fiber types shown in Figure 5 can be divided into two categories. The first group shown in Figure 5(a) and (b), the elliptical core fiber and D-fiber, are PM fibers owing to the fact that the fibers are not geometrically axisymmetric. These fibers are considered mechanically homogeneous. The second group of fibers shown in Figure 5(c–e) achieve birefringence due to the lack of geometric symmetry as well as residual stresses induced by the stress-applying portion (SAP) surrounding the core. This SAP has different mechanical and thermal expansion properties than the fused silica, inducing large residual stresses on the fiber core during cooling of the fiber after it is drawn. The residual stresses induce birefringence at the core through the photoelastic effect. The magnitude of birefringence due to the residual stresses is much higher than the geometric effect, and therefore the fiber types of Figure 5(c–e) are more suitable for sensor applications as the measurands will be easier to distinguish. Owing to the presence of the SAP, these fibers are considered to be mechanically inhomogeneous.

3 LIGHTWAVE SOURCES

Lightwave sources for optical fiber sensors generally fall into three categories: light emitting diodes (LEDs), laser diodes, and superluminescent diodes

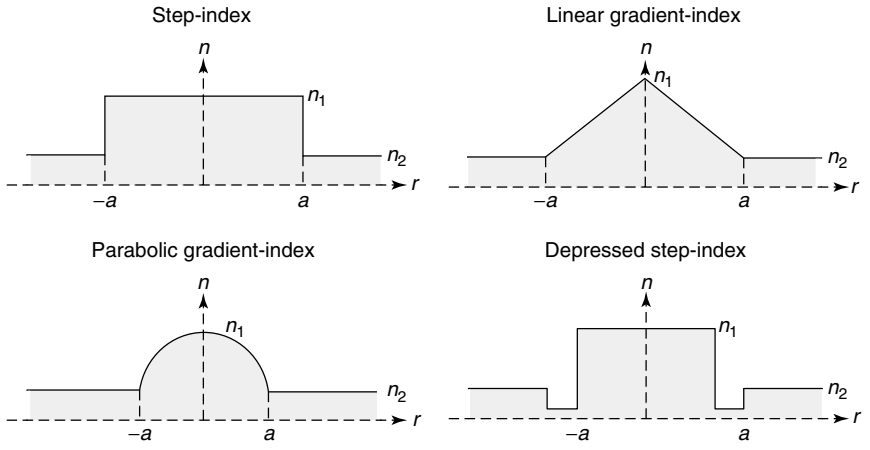

Figure 4. Common fiber index of refraction profiles.

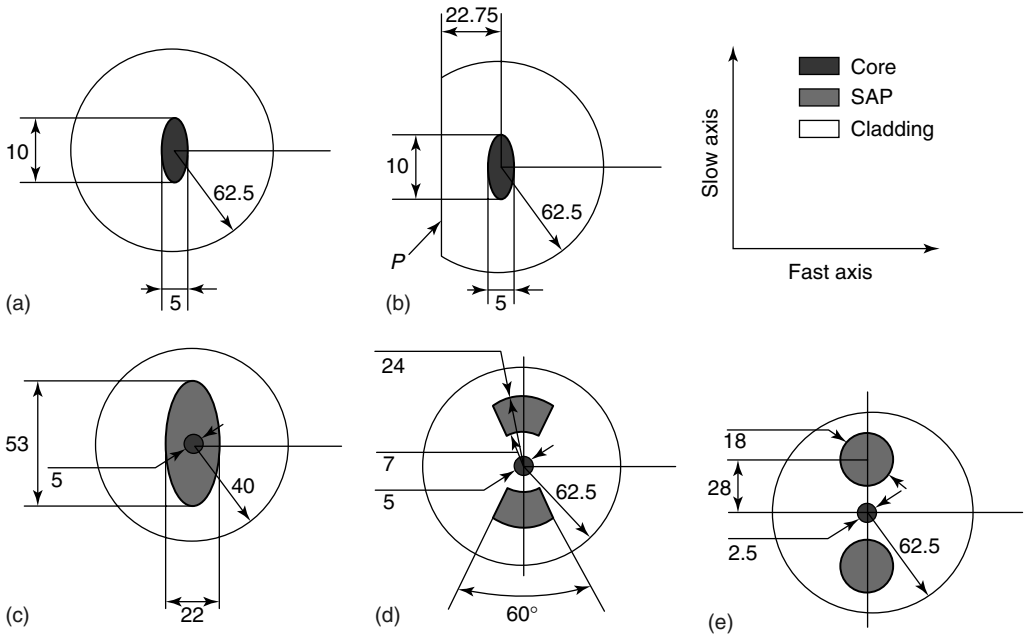

Figure 5. Geometry of common PM fiber types: (a) elliptical core fiber; (b) D-fiber; (c) elliptical core SAP fiber; (d) bow-tie fiber; and (e) panda fiber. The slow and fast axes are also indicated. All dimensions are shown in micrometers.

(SLDs). A summary of each of these is provided in this section; for further information, see [1, 2, 18]. Each of these light sources has advantages and disadvantages based on the output bandwidth, power, coherence length, and cost. The coherence length is defined as the distance over which the amplitude modulation falls off to a certain percentage of the original lightwave amplitude and can be estimated by

$$L_c = \frac{c}{dv} \tag{6}$$

where dv is the spectral frequency width of the light source. The coherence length determines the optical path length difference that can be allowed when interfering with multiple lightwaves from the same original source (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**). Additional light sources exist such as gas lasers; however, it is not practical to couple them into optical fibers for field applications.

LEDs provide a broad spectral output at a relatively low cost and low sensitivity to back reflections. LEDs are most suitable for intensity-based sensors. However, their low-coherence length makes them not suitable for interferometric applications other than low-coherence interferometry. LEDs exist in two forms: surface emitting diodes and edge emitting diodes. The surface emitting diodes provide an output spectrum that is difficult to focus in a single direction. Therefore, they are more suitable for coupling to large core size multimode optical fibers than to single-mode fibers. Edge emitting diodes provide a more easily focused output for coupling into optical fibers; however, the total amount of optical power input to the optical fiber tends to be low.

SLDs operate on the principle of amplified spontaneous emission and also provide a broadband spectrum, however, at much higher output power than LEDs. The angular narrowing of the output of the SLD also allows improved coupling into single-mode optical fibers, with output powers on the order of 8 mW.

Laser diodes emit a very narrow bandwidth spectrum with a large coherence length at high output powers. Laser diodes sources are highly susceptible to back reflections; however, these can be reduced or eliminated by applying antireflection coatings to or angling the end of the coupled optical fiber or

through optical isolators. Laser diodes also require accurate temperature control to control the spectral output. One of the advantages of laser diodes is that they can be coupled with single-mode optical fibers through microlenses to produce fiber laser diodes that operate with high output powers, on the order of 10 mW. By combining the fiber laser diode with a Fabry–Perot cavity, one can produce an extremely strong, narrow bandwidth output. Additionally, the cavity length can be scanned to provide a laser with a narrow bandwidth, wavelength tunable output.

4 SENSING MECHANISMS

External sensing parameters are generally encoded into information within lightwaves propagating through an optical fiber in one of four manners, summarized in Figure 6.

4.1 Intensity modulation

The intensity of the lightwave propagating through an optical fiber can be modified through microbending of the optical fiber, a change in coupling from the fundamental mode to other nonguided modes, fracture of the optical fiber or a change in power coupled into the fiber (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**). In general, the input power entering the optical fiber is held constant, while the intensity of the light transmitted through the fiber or reflected back to the input of the fiber is measured with a photodetector. Measuring the intensity of the propagating lightwave is relatively simple; however, light sources themselves often fluctuate in intensity. Feedback control loops can be applied to reduce these fluctuations, or the illuminating lightwave divided to create a reference intensity, as shown in Figure 7(a). Intensity-based sensors provide absolute measurements, meaning that they are insensitive to power interruptions between data collections. One drawback to intensity-based sensors, however, is that they cannot be multiplexed for sensor networks.

4.2 Phase modulation

The application of strain or temperature to an optical fiber changes the optical path length traversed by the lightwave propagating through the fiber, $n_{\text{eff}}L$

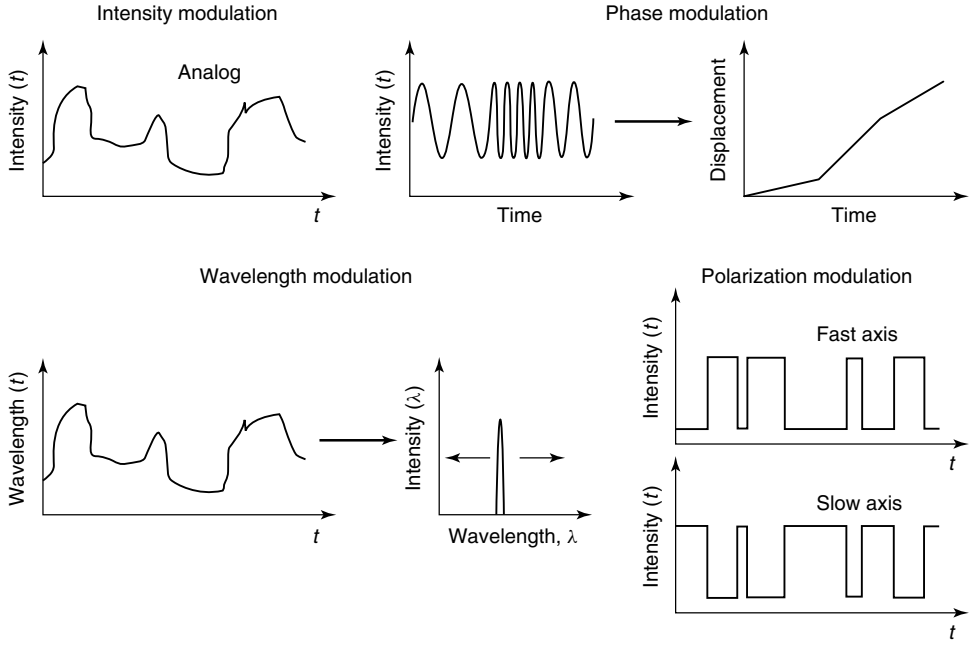

Figure 6. Output signals of optical fiber sensors using four primary sensing mechanisms.

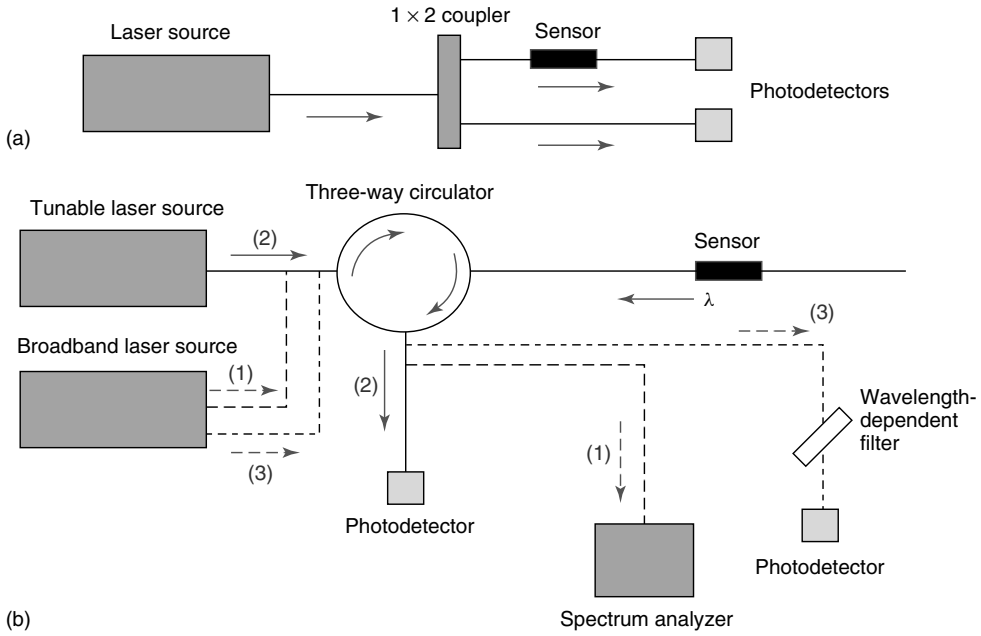

Figure 7. Sensor interrogation schemes for (a) intensity-based sensors and (b) wavelength (frequency) based sensors. For (b), three different possible schemes are shown. See text for details.

(*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**). As the phase of the lightwave cannot be measured directly, the lightwave is generally recombined with a reference lightwave from the same laser source (so that the two are coherent). When the reference lightwave is not exposed to the external parameters, their relative phase shift between the signals can be related to the applied strain or temperature. The phase modulation is extremely sensitive to strain and therefore can provide very accurate measurements [1]; however, the measurement of phase shift is not absolute owing to the signal periodicity and is therefore affected by power interruptions between data collections. Additionally, fluctuations in the laser source intensity can be misinterpreted as phase shifts. Several systems are now commercially available to alleviate these problems, each with relative advantages and disadvantages (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**). Interferometric measurements also cannot generally be multiplexed. The reference signal can be completely sheltered from external parameters or used for compensation of unwanted measurands such as temperature.

4.3 Spectral modulation

External sensing parameters can also be converted into spectral information of the lightwave, for example, using fiber Bragg gratings (*see* **Fiber Bragg Grating Sensors**) or Fabry–Perot interferometers (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**). Such sensors typically act as filters, transmitting certain wavelengths and radiating or reflecting others. Changes in external parameters are therefore converted into a wavelength shift of the transmitted or reflected spectrum of the sensor. A typical signal is shown in the example of Figure 6, for which the reflected wavelength is changing with time. The wavelength encoded signal must then be interpreted, which is commonly performed in using one of three methods: (i) by launching a broadband of light into the fiber and applying a spectrum analyzer to select the reflected wavelength; (ii) by applying a tunable laser for which the output wavelength can be scanned while the reflected intensity is measured by a photodetector; or (iii) by launching a broadband of light and using a wavelength-dependent filter to identify the reflected wavelength (Figure 7b). Other,

more complex methods based on three-way couplers or fast Fourier transforms are also available for data acquisition at higher scan rates or multiplexing sensors (*see* **Fiber Bragg Grating Sensors**).

4.4 Polarization modulation

A final method to encode sensing information for transmission through an optical fiber is through the polarization state of the propagating lightwave [1, 19, 20]. For the example shown in Figure 6, the power of a lightwave propagating through a PM fiber is transferred between the mode polarized about the fast axis and the mode polarized about the slow axis. The power in each mode can be determined by applying a polarizing filter to the output signal. As mentioned above, the two modes propagating through a PM fiber do not normally transfer power as they propagate since they are orthogonally polarized. However, external stimuli such as pressure or twisting of the optical fiber will induce transfer between the two modes.

5 MECHANICAL PROPERTIES OF OPTICAL FIBERS

It is important to know the strength and attenuation characteristics of optical fibers to apply them for sensing applications where severe loading conditions may occur. This is particularly true for many structural health monitoring applications. Additionally, attenuation properties often determine the maximum number of sensors that can be applied in a single network or the physical distance over which the network may span.

5.1 Stiffness and strength

Standard fused silica fibers are linear elastic until failure with the following material properties: the elastic modulus, $E = 72\,\text{GPa}$, Poisson's ratio, $\nu = 0.20$, and thermal expansion coefficient, $\alpha = 5.5 \times 10^{-7}/^{\circ}\text{C}$ [21]. Fused silica optical fibers are extremely brittle and their tensile strength follows a Weibull distribution. The cumulative survival probability, P, of a fiber of length L at an applied axial stress level S is therefore

$$P(S, L) = \exp\left[-\left(\frac{S}{S_0}\right)^m \left(\frac{L}{L_0}\right)\right] \tag{7}$$

where m is the material Weibull parameter and S_0 is the inert strength of the fiber (under pristine conditions), measured for a length of fiber L_0 and a survival probability of 36.8% [22]. The medial strength, σ_{med} corresponds to a failure probability $P = 0.5$. Another important material property is the corrosion susceptibility, n, which determines the growth rate of a microcrack in the fiber,

$$\frac{\mathrm{d}w}{\mathrm{d}t} = AK_I^n \tag{8}$$

where w is the crack length and A is a constant. Typical measured values for standard silica optical fibers are $m = 112, n = 14, \sigma_{\text{med}} = 5.13\,\text{GPa}$ [23]. Kapron and Yuce [22] tested a large set of standard optical fibers in static and dynamic fatigue. The bending strength of optical fibers can be described similarly by a Weibull distribution; however, a general rule is that standard silica sensor fibers can be safely bent to a radius of 5 mm [24].

A second common material class used for optical fibers is polymers. Polymer optical fibers (POFs) have considerably lower stiffness than silica fibers, with $E = 2.4\text{–}3.0\,\text{GPa}$, $\nu = 0.34$ [25]. Their stress–strain response is also extremely sensitive to strain rate, temperature, humidity, and hysteresis effects. POFs are more flexible in bending those silica fibers; therefore, they can be handled and embedded without a protective coating.

5.2 Attenuation and dispersion

The two major factors that determine the maximum length of signal transmission in an optical fiber are the attenuation and dispersion properties of the fiber. For a fixed length of optical fiber, the attenuation, $\bar{\alpha}$, is defined as the ratio of power input, P_{i}, to the power output, P_{o}, of a given length of optical fiber and is measured in decibels [2],

$$\bar{\alpha} = 10 \log_{10} \frac{P_{\text{i}}}{P_{\text{o}}} \tag{9}$$

On the other hand, dispersion (or broadening of propagating pulses) is generally due to the wavelength-dependent properties of silica and, therefore, the wavelength-dependent propagation constants. For telecommunication applications these factors limit the length of an optical fiber that can be used; however, for sensing applications these limits are rarely an issue, except for large structural applications.

For fused silica optical fibers, three main phenomena contribute to attenuation [2, 8]:

- Rayleigh scattering occurs owing to inhomogeneities in the amorphous glasslike silica. The resulting attenuation is proportional to λ^{-4}.
- The infrared absorption properties of silica essentially prevent transmission at wavelengths above 1600 nm.
- OH impurities in the fused silica create "water" absorption peaks at wavelengths of 950, 1240, and 1390 nm.

The resulting attenuation spectrum of a silica optical fiber can be seen in Figure 8. Three primary transmission windows are therefore used in telecommunication applications: (i) around 850 nm with an approximate attenuation of $2\,\mathrm{dB\,km^{-1}}$; (ii) around 1300 nm with an approximate attenuation of $0.4\,\mathrm{dB\,km^{-1}}$ (here the material dispersion is practically zero); and (iii) around 1550 nm with an approximate attenuation of $0.25\,\mathrm{dB\,km^{-1}}$. The transmission windows at 1550 and 1300 nm are most commonly used since the attenuation is the lowest of the three windows at 1550 nm, and at 1300 nm the material dispersion is practically zero. The same three transmissions windows are typically used for optical fiber sensors owing to the relative low cost, wide selection and high quality of components including optical fibers, couplers, and laser sources available for telecommunications applications.

POFs considerably demonstrate different attenuation characteristics than fused silica. Most noticeably, the magnitude of attenuation is orders of magnitude larger than that of silica [25]. Therefore, POFs are most often used for short connector applications that require a flexible fiber. Secondly, whereas the attenuation of silica decreases with wavelength in the infrared region, the attenuation of the polymer materials rapidly increases with wavelength. Therefore,

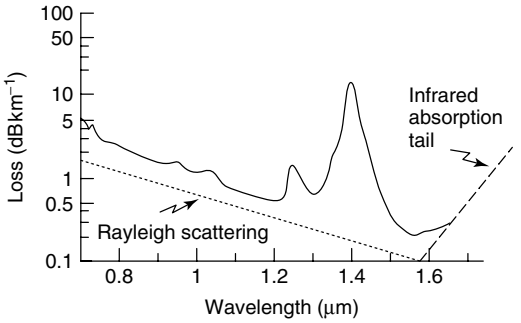

Figure 8. Material attenuation losses as a function of wavelength for fused silica (SiO_2) [2]. [Reproduced with permission from Ref. 2. © Cambridge University Press, 1998.]

POF sensors typically operate in the visible wavelength ranges rather than in the infrared ranges. Most commercially available POFs are multimode fibers in the visible wavelengths; however, recent advances in fabrication techniques have produced single-mode POFs for visible wavelength transmission [26–29] (*see* **Novel Fiber-optic Sensors**).

Other important factors contributing to signal losses in optical fiber sensors are splice losses, component losses, and bending losses. Splice losses depend upon the type of splice applied; fusion splices yield much lower losses than mechanical splices for example. Component losses appear in network components such as couplers or circulators. Finally, one important difference between optical fiber sensor networks and electrical sensor networks is that the optical fiber cannot be bent to an arbitrary radius of curvature. The bend loss in a step-index fiber per unit

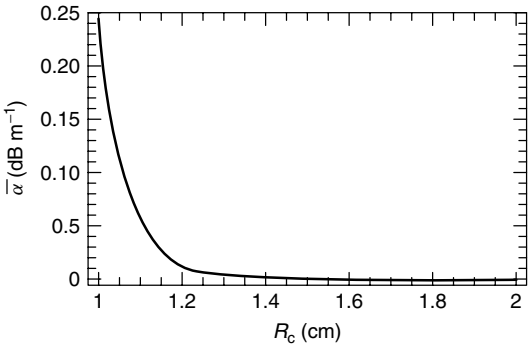

Figure 9. Bending loss as a function of bend radius of curvature ($a = 4\,\mu\mathrm{m}$, $\lambda = 1550\,\mathrm{nm}$, $n_1 = 1.460$, and $n_2 = 1.453$).

fiber length can be approximated by

$$\alpha = 4.343\left(\frac{\pi}{4aR_c}\right)^{1/2}\left[\frac{pa}{K_1(\gamma a)}\right]^2\frac{1}{(\gamma a)^{3/2}} \times \exp\left[-\frac{2(\gamma a)^3}{3k_0^2a^3n_1^2}R_c\right] \quad (10)$$

where R_c is the radius of curvature of the bent fiber and p and γ were defined for equation (3) [2]. Equation (10) is plotted for typical single-mode fiber properties in Figure 9, from which one can see that the bending loss increases exponentially for small radii of curvature.

6 INTEGRATION OF OPTICAL FIBER SENSORS IN STRUCTURAL COMPONENTS

In this section, we summarize the general issues to consider when integrating sensors into structural components, particularly embedded sensors. These include coating options, material compatibilities, strain transfer, and structural integrity. Specific issues related to composite laminates and concrete structures are included.

Various coating materials have been applied for embedded applications including the standard acrylate, which is relatively pliable and allows the fiber to slide within the coating, to reduce crimping of the fiber. However, the acrylate coating does not provide good strain transfer between the sensor and the host material owing to the low stiffness of the coating and the fact that the fiber debonds from the coating well before failure occurs in the host material [30]. As an alternative, polyimide coatings are stiffer and well bonded to the optical fiber. Polyimide coatings provide excellent strain transfer and excellent durability of the sensor during high temperature (up to 600 °C) and high-pressure fabrication conditions [21]. The main disadvantage to polyimide coatings is that removal of the coating for coupling, splicing, etc. must be done chemically. Bare optical fibers have also been embedded for good stress–strain transfer when durability concerns are not as important. Several researchers have calculated optimal coating properties to minimize the obtrusivity of embedded sensors [31, 32] or maximize the measurement capabilities of embedded sensors considering induced strains and their criticality for damage initiation [33]. For composites with other than polymer matrices, surface bonding of the optical sensor is often possible. For example, Figure 10 shows a gold coated silica optical fiber bonded to a titanium matrix composite using a Ni-based plasma spray.

One of the challenges to apply embedded optical fibers for structural health monitoring applications is to calculate the stress–strain state in the host material as a function of the stress–strain state in the optical fiber sensor. A variety of models have been developed for the stress–strain transfer to optical fiber sensors with and without coatings embedded in isotropic materials [35–38]. These models are based on shear-lag analysis, originally derived for stress transfer between reinforcing fibers in fiber reinforced composites. Li *et al.* [39] and LeBlanc [40, 41] extended the shear-lag analysis to include plastic yielding of the coating and debonding at the coating–fiber interface. For the application of optical fiber sensors embedded in orthotropic materials, Van Steenkiste and Springer [42] treated the optical fiber as an inclusion in the composite cross section and applied elasticity to calculate the relationship between the strain in the host material and strain in the optical fiber. Each of these approaches assumes that the strain field is slowly varying; therefore, the average strain at the location of the sensor is sufficient to predict

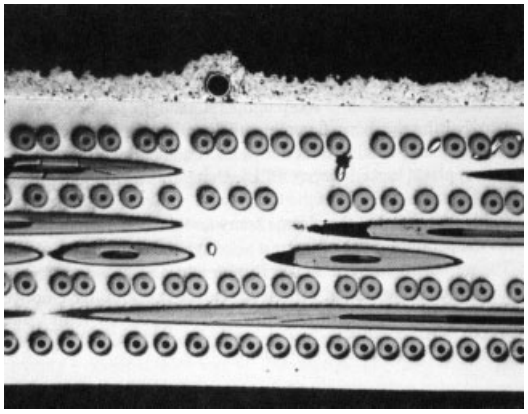

Figure 10. Gold coated silica optical fiber surface bonded to titanium matrix composite with silicon carbide reinforcing fibers using Ni-based plasma spray (image scale 32×) [34]. [Reproduced with permission from Ref. 34. © Cambridge University Press, 1998.]

its response. For more rapidly varying strain fields such as near the location of damage, Prabhugoud and Peters [43] incorporated the shear-lag theory to predict the response of a sensor located near matrix cracking in a unidirectional composite ply.

Finally, one of the major advantages of optical fiber sensors for structural health monitoring of composite structures is that large networks of sensors can be relatively unobtrusively embedded into the laminate for measurement throughout the lifetime of the structure. Owing to their high multiplexing capability (*see* **Fiber Bragg Grating Sensors**), a single optical fiber strand can contain a large number of sensors, requiring only a single ingress and egress location. It is necessary to protect the optical fiber well and eliminate strong stress concentrations that would otherwise appear at the ingress or egress points since the optical fibers are extremely fragile in bending. Commonly, this can be accomplished using polymer cabling; however, for some structural applications more advanced strategies are required [44].

6.1 Laminated composites

Optical fiber sensors are well suited for strain monitoring in polymer matrix–fiber reinforced composites because the failure strain of the optical fiber is significantly larger than that of typical reinforcing fibers such as carbon [45]. A typical carbon–fiber reinforced epoxy composite has carbon reinforcing fibers of 5–10 μm diameter and ply thicknesses

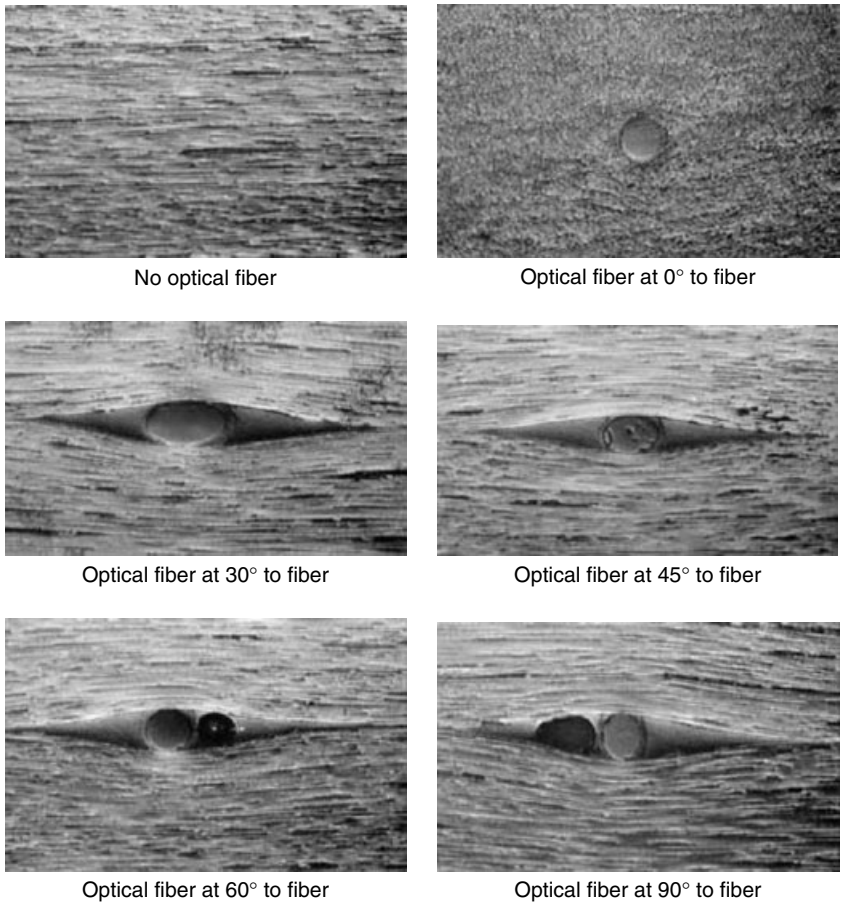

Figure 11. Micrograph of embedded optical fibers at different orientation to reinforcing fibers. Air voids next to optical fibers can be seen for orientations at 60° and 90° [47]. [Reproduced from Ref. 47. © Sage Publications, 2006.]

of 120–140 μm. Therefore, the optical fiber size (without coating) is on the order of one-ply thickness. When embedded between partially cured (prepreg) plies during the lamination fabrication, the presence of the optical fiber therefore introduces a perturbation to the local material system, typically resulting in a resin-rich zone referred to as a *resin eye* which forms around the fiber as seen in Figure 11. This resin eye enhances the local stresses surrounding the optical fiber and potentially induces local matrix cracking in adjacent plies or delamination [31]. For optical fiber sensors embedded within a single ply, the interphase region between the host epoxy and the embedded sensor can also play a significant role in the durability of the composite. Sirkis and Lu [46] used electron backscatter and acoustic emission to measure interphase thicknesses. They also determined that the residual stresses present in the optical fiber sensor after laminate fabrication can be significant.

Sirkis and Lu [46] and Jensen *et al.* [48, 49] demonstrated that optical fibers embedded parallel to the reinforcing fibers do not degrade the axial tensile strength of the laminate; however, the laminate transverse tensile strength and axial compressive strength are reduced by 20–70%. Embedding optical fibers at orientations other than parallel to the reinforcing plies does decrease the axial tensile strength of the composite [50, 51]. Kim *et al.* [51] demonstrated that there was not a significant decrease in axial tensile strength until the relative angle reached 45°, after which point the strength decreases rapidly with relative angle. They attributed this decrease in strength to the aspect ratio of the resin eye, which increased with relative angle. This was later confirmed by Shivakumar [47] (Figure 11) who also observed the presence of air voids next to the optical fiber at high relative angles. Similar observations on the laminate strengths have been made for fatigue loading conditions. The presence of the optical fiber does not noticeably reduce the fatigue life for laminates in tension–tension fatigue [52, 53], however, does create a significant decrease in fatigue life for tension–compression fatigue [53].

Optical fiber sensors embedded between multiple plies of two-dimensional woven composites demonstrate additional challenges. In addition to the resin eye formation, the presence of the optical fiber also introduces additional stresses owing to the undulations in the woven plies surrounding the optical fiber as can be seen in Figure 12. Lebid *et al.* [54] measured varying residual stresses along the optical fiber due to the undulations and observed that this must be accounted for when interpreting the sensor response. Optical fiber sensors do survive when embedded in woven composites when high temperature and pressure are applied during the laminate fabrication, although the transmission losses due to the undulations are more significant than those for nonwoven laminates [55].

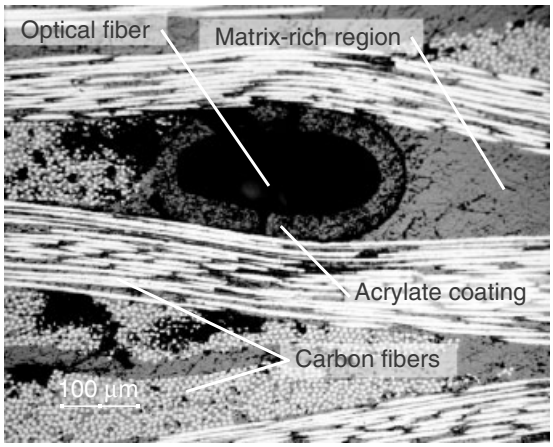

Figure 12. Optical micrograph of embedded optical fiber with acrylate coating in two-dimensional woven graphite–epoxy composite after impact loading. Optical fiber has fractured during polishing, therefore all of surface is not visible.

Finally, researchers have also demonstrated the advantages of embedding optical fiber sensors in composite laminates for impact detection and identification of the resulting internal damage. Similar to the previous loading conditions, optical fibers embedded parallel to the reinforcing fibers showed little or marginal effects on the extent and form of damage induced in the laminates [55–57]. Fibers embedded perpendicular to the reinforcing fibers increased the extent of damage, once again due to the presence of large matrix-rich regions [57].

6.2 Concrete infrastructures

Another promising application for optical fiber sensors is for long-term monitoring of civil infrastructures, specifically concrete structures. Researchers have demonstrated that optical fiber sensors can

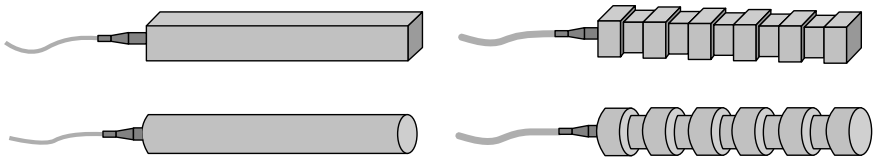

Figure 13. Regular and corrugated preembedded concrete bar sensors [67]. [Reproduced from Ref. 67. © Elsevier, 2000.]

be embedded during casting of concrete structures and provide accurate strain measurements under a variety of conditions [58, 59]. In addition to strain measurements, optical fiber sensors have been used for the measurement of crack opening displacements [60] and chloride penetration [61]. The properties of concrete are significantly different than those of polymer matrix composites; therefore several different issues become important.

For example, the gauge length of the optical fiber sensor must be chosen to be larger than the aggregate size so as to provide useful measurements [62]. Bending of the optical fiber around the individual aggregates can also induce significant signal loss over long sections of the optical fiber [63]. Another challenge to embedding optical fiber sensors in concrete can be the placement and protection of the sensor during the casting process, particularly for large-scale structures. Researchers have bonded optical fibers to rebars prior to casting to prevent movement of the optical fiber during cure of the concrete [64–66]. An alternative idea is to precast the sensor into smaller concrete blocks and then place these precast blocks into the larger structure [67]. Such blocks can be cast with a variety of surface features to improve bonding between the precast block and the concrete structure as shown in Figure 13.

Another significant challenge to embedding optical fiber sensors in concrete structures is the high alkali and moisture content of the concrete, which can degrade the coating and fiber-coating bonding over time [63, 68]. Further, once the coating has been removed, the hydroxide ions diffuse into the optical fiber surface and induce microcracking, leading to eventual failure of the optical fiber. Habel *et al.* [69] and Leung *et al.* [68] studied the long-term performance of potential optical fiber coatings including acrylate, which was rapidly degraded, and polyimide and Tefzel–silicone, which provided excellent long-term protection for the sensor. Alternatively, Kuang *et al.* [70] embedded POFs, which do not degrade as rapidly with moisture and demonstrated that they are compatible with concrete.

7 CONCLUSIONS

Fiber-optic sensors are versatile sensors for structural health monitoring applications owing to the fact that they are durable, immune to electromagnetic interference and corrosion, can be multiplexed into large sensor networks, and can be embedded in a variety of materials including composite laminates and concrete. External parameters for sensing are generally encoded in the lightwave signal through intensity, polarization states, wavelength or phase information. A variety of optical fiber types and coatings have been applied for structural health monitoring applications. The prediction of the response of optical sensors to external parameters requires an understanding of the basic principles of lightwave propagation and its sensitivity to physical changes applied to the optical fiber, which have been introduced in this chapter. Chapter 61
Fiber Bragg Grating Sensors

Kara Peters
Department of Mechanical and Aerospace Engineering, North Carolina State University, Raleigh, NC, USA

1 INTRODUCTION

Fiber Bragg grating (FBG) sensors have many advantages for strain sensing in structural health monitoring applications including their small size, the potential to multiplex hundreds of sensors with a single ingress/egress fiber, their immunity to electromagnetic interference, and their corrosion resistance [1]. FBG sensors have been applied for a variety of structural health monitoring applications including spacecraft [1, 2], bonded aircraft repairs [3–5], cryogenic composite tanks [6, 7], highway and railway bridges [8, 9], fiber reinforced polymer (FRP) composite bridges [10], FRP strengthened concrete [11], offshore platforms [12], and nuclear reactors [13]. Researchers have also applied FBG sensors for modal-based damage identification [14, 15], the identification of multiple failure modes in composite laminates [16–18], and monitoring of welded and composite joints [19, 20].

The FBG sensor, shown in Figure 1, is a permanent periodical perturbation in the index of refraction of the optical fiber core. This index modulation can be written mathematically as

$$n_{\text{eff}}(z) = n_{\text{eff}} + \overline{\delta n_{\text{eff}}} \left\{ 1 + \nu \cos \left[\frac{2\pi}{\Lambda} + \phi(z) \right] \right\} \quad (1)$$

where ν is the fringe visibility, Λ the grating period, $\phi(z)$ the grating chirp function (which describes any variation in the grating period), n_{eff} the effective index of refraction of the fiber for the fundamental mode, and $\overline{\delta n_{\text{eff}}}$ the "dc" average index change [21]. Hill *et al.* [22] first fabricated permanent Bragg gratings in an optical fiber as a filter for telecommunication applications.

The FBG sensor acts as a "wavelength-dependent filter" as shown in Figure 1. When a broad spectrum of wavelengths is passed through the FBG, a narrow bandwidth of wavelengths is reflected, while all

others are transmitted. The wavelength at maximum reflectivity is referred to as the Bragg wavelength, λ_B, and is determined by the condition

$$\lambda_B = 2n_{\text{eff}}\Lambda \tag{2}$$

As axial strain, ε, is applied to the FBG, the Bragg wavelength shifts to lower wavelengths (compression) or higher wavelengths (tension). The applied strain is thus encoded in the FBG Bragg wavelength shift. If the applied axial strain is not constant along the length of the grating, the spectrum will distort as well as shift. Section 6 describes how this distortion can be interpreted to measure the applied strain distribution along the FBG.

2 FIBER BRAGG GRATING PARAMETERS

The phenomenon of wavelength selective reflection is due to coupling between various modes propagating through the FBG. For short period FBGs ($\Lambda < 1\,\mu$m), coupling occurs between a forward propagating fundamental (LP_{01}) mode and a backward propagating LP_{01} mode (*see* **Fiber-optic Sensor Principles**). The coupling condition can be described through the coupled mode equations

$$\frac{dR}{dz} = i\hat{\sigma}R(z) + i\kappa S(z)$$

$$\frac{dS}{dz} = -i\hat{\sigma}S(z) - i\kappa R(z) \tag{3}$$

where $R(z)$ and $S(z)$ are the amplitudes of the forward and backward propagating lightwaves, respectively, and z is the coordinate along the axis of the fiber [21]. The coefficients $\hat{\sigma}$ and κ are defined as

$$\hat{\sigma} = \frac{2\pi}{\lambda}\left(n_{\text{eff}} + \overline{\delta n_{\text{eff}}}\right) - \frac{\pi}{\Lambda} - \frac{1}{2}\frac{d\phi}{dz}$$
$$\kappa = \frac{\pi}{\lambda}\nu\overline{\delta n_{\text{eff}}} \tag{4}$$

where λ is the wavelength of the propagating lightwaves.

For a grating with a constant period (i.e., nonchirped grating), we have a constant grating chirp function, $\phi(z) = \phi_0$. Therefore, the parameters $\hat{\sigma}$ and κ are constants and equation (3) can be solved analytically. We find the solution to equation (3) for the reflectivity coefficient,

$$r = \left|\frac{S(-L/2)}{R(-L/2)}\right|^2 = \frac{\sinh^2\left(L\sqrt{\kappa^2 - \hat{\sigma}^2}\right)}{\cosh^2\left(L\sqrt{\kappa^2 - \hat{\sigma}^2}\right) - \dfrac{\hat{\sigma}^2}{\kappa^2}} \tag{5}$$

This solution is plotted for different values of κL in Figure 2. One can see in Figure 2 that for the case of strong coupling ($\kappa L = 6$) the grating is supersaturated. For sensing applications, FBGs with a

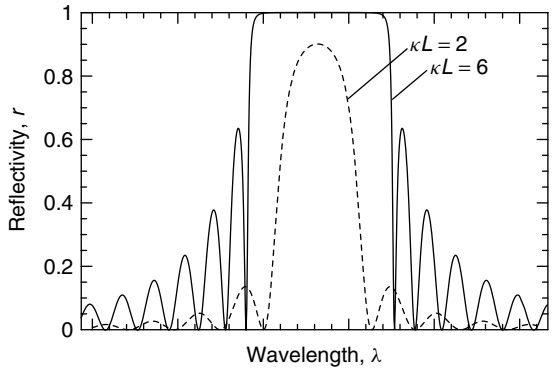

Figure 2. Reflectivity as a function of wavelength for FBG with coupling coefficients $\kappa L = 2$ and $\kappa L = 6$ ($n_{\text{eff}} = 1.46$, $\overline{\delta n_{\text{eff}}} = 3 \times 10^{-6}$, $\nu = 1$, $\lambda_{\text{B}} = 1550\,\text{nm}$).

narrow bandwidth and high reflectivity (i.e., $\kappa L = 2$ in Figure 2) produce the largest signal-to-noise ratio. The maximum reflectivity of the grating, $r_{\max}$, and bandwidth between the first zero crossings, $\Delta\lambda_0$, are found from equation (5),

$$r_{\max} = \tanh^2(\kappa L) \tag{6}$$

$$\frac{\Delta\lambda_0}{\lambda_{\text{B}}} = \sqrt{\left(\frac{\nu\overline{\delta n_{\text{eff}}}}{n_{\text{eff}}}\right)^2 + \left(\frac{2\Lambda}{L}\right)^2} \tag{7}$$

Procedures such apodization are often applied to the FBG sensor during fabrication to reduce the secondary peaks and narrow the bandwidth [23].

As strain is applied to the FBG sensor, the Bragg wavelength shifts according to

$$\Delta\lambda_{\text{B}} = 2\left(\Delta n_{\text{eff}}\Lambda_0 + n_{\text{eff}}\Delta\Lambda_0\right) \tag{8}$$

where Δn_{eff} is due to the strain–optic effect and $\Delta\Lambda_0$ is due to the change in period of the grating. For the specific case of pure axial loading we find (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**),

$$\Delta\lambda_{\text{B}} = \lambda_{\text{B}}\left[1 - \frac{n_{\text{eff}}^2}{2}(p_{12} - \nu p_{12} - \nu p_{11})\right]\varepsilon \tag{9}$$

in terms of the Pockel's constants of silica, p_{11} and p_{12}. Defining the effective photoelastic constant for axial strain, $p_{\text{e}} = n_{\text{eff}}^2(p_{12} - \nu p_{11} - \nu p_{12})/2$ we can write,

$$\frac{\Delta\lambda_{\text{B}}}{\lambda_{\text{B}}} = (1 - p_{\text{e}})\varepsilon \tag{10}$$

Thus, the shift in Bragg wavelength is linearly related to the applied axial strain. Typical values for silica optical fibers are $p_{11} = 0.12$, $p_{12} = 0.27$, and $p_{\text{e}} = 0.22$ [24].

Similar to electrical resistance strain gauges, FBG sensors are also sensitive to temperature through

$$\frac{\Delta\lambda_{\text{B}}}{\lambda_{\text{B}}} = 2\left(\frac{\partial n_{\text{eff}}}{\partial T}\Lambda_0 + \frac{\partial\Lambda}{\partial T}n_{\text{eff}}\right)\Delta T = (\alpha + \zeta)\Delta T \tag{11}$$

where α is the thermal expansion coefficient and ζ is the thermo-optic coefficient of the optical fiber material. A typical value for fused silica is $(\alpha + \zeta) = 6.67 \times 10^{-6}/^{\circ}\text{C}$ [24]. It is important to note that the thermal sensitivity of an FBG sensor is considerably higher than that of its electrical strain gauge counterpart, increasing the need for thermal compensation for strain measurement applications.

One method of temperature compensation is to write two FBGs at different Bragg wavelengths, λ_{B1} and λ_{B2}, and to measure the Bragg wavelength shifts in each grating due to the applied strain and temperature. The strain and temperature can thus be independently determined from the equation

$$\begin{pmatrix}\Delta\lambda_1\\ \Delta\lambda_2\end{pmatrix} = \begin{pmatrix}K_{\varepsilon 1} & K_{T1}\\ K_{\varepsilon 2} & K_{T2}\end{pmatrix}\begin{pmatrix}\varepsilon\\ \Delta T\end{pmatrix} \tag{12}$$

where the K terms are the sensitivities of each grating to strain and temperature. Xu *et al.* [25] fabricated a two FBG sensor with $\lambda_{\text{B1}} = 850\,\text{nm}$ and $\lambda_{\text{B2}} = 1300\,\text{nm}$. Experimental measurements demonstrated a 6.5% difference in $K\varepsilon$, and a 9.8% difference in K_T for the two FBGs. One difficulty with this approach is that λ_{B1} and λ_{B2} must be sufficiently far apart to obtain a significant difference in the FBG sensitivities and therefore an accurate calculation of the strain and temperature when inverting equation (12). This often requires two separate laser sources for the sensor interrogation.

3 FABRICATION AND STRENGTH OF FIBER BRAGG GRATING SENSORS

Several methods are commonly used for the fabrication of FBGs, each based on the exposure of the optical fiber core to ultraviolet (UV) laser light [26]. The UV exposure increases the index of refraction of the silica locally through the process of photosensitivity. Prior to exposure, the optical fiber is typically doped to increase the photosensitivity of the silica, e.g., through high-pressure hydrogen loading of the fiber. Molecular hydrogen diffuses in the central core region due to its small size. This increase in photosensitivity is not a permanent effect since the hydrogen diffuses out over time. However, if the fiber is exposed to UV radiation during this period, the hydrogen molecules react in the silica Si–O–Ge sites forming OH species and UV bleachable germanium oxygen deficiency centers, which are responsible for the enhanced photosensitivity [23].

Several fabrication techniques are commonly applied for FBG sensors. For excellent reviews see [23] and [27]. The interferometric technique is based on a bulk interferometer that splits the incoming UV light into two beams and then recombines them to form an interference pattern that is focused onto the optical fiber core (Figure 3). The interference pattern exposure induces a refractive index modulation in the fiber core. The periodicity of the refractive index modulation is related to the UV source wavelength, λ_{UV}, by

$$\Lambda = \frac{\lambda_{UV}}{2\sin(\theta/2)} \tag{13}$$

By changing the intersecting angle θ between the two writing beams, it is possible to write Bragg gratings for almost any wavelength. However, the stability of the interference pattern is extremely difficult to maintain due to mechanical vibrations that may be present in the bulk interferometer.

Because of its simplicity, the phase mask technique is the most widely used method of FBG fabrication (see Figure 4). The phase masks themselves may be formed holographically or by electron-beam lithography from fused silica. A near-field fringe pattern is produced by the interference of the plus and minus first-order diffracted beams. The period of the fringes produced is one-half of the phase mask period, Λ_{pm}.

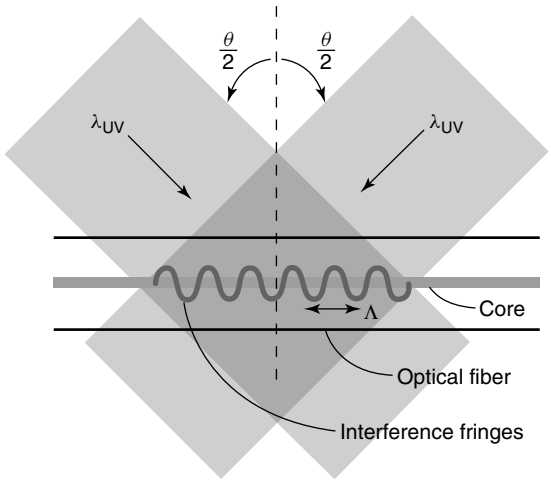

Figure 3. Bulk interferometer arrangement for the fabrication of fiber Bragg gratings.

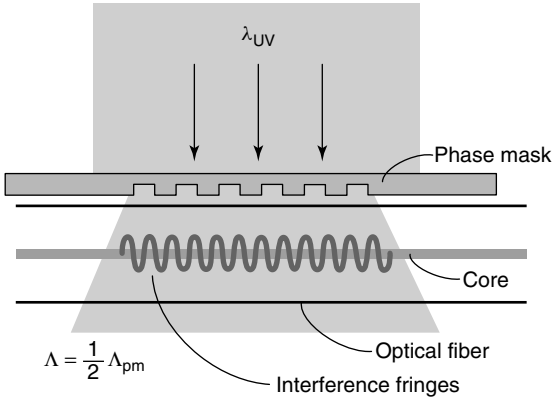

Figure 4. Phase mask arrangement for the fabrication of fiber Bragg gratings.

The simplicity of the phase mask writing technique provides a robust and inherently stable method for producing FBGs. Since the fiber is usually placed close to the mask, the sensitivity to mechanical vibrations is minimized. The main disadvantage of the phase mask technique, however, is the need to produce a phase mask for each desired wavelength. This limitation can be partially overcome by applying tension to the phase mask to vary the period and provide a range of possible Bragg wavelengths (typically $\pm 5\%$ of the original Bragg wavelength).

Stripping the coating from an optical fiber prior to writing the FBG is necessary as the coating will reduce the amount of UV light arriving at the optical

Table 1. Summary of FBG fabrication methods and resulting strengths

Reference	Fiber Bragg grating fabrication method	σ_{med} (Gpa)	m
Wei *et al*. [28]	Pristine fiber	4.95	66.6
	Fiber after chemical stripping	3.38	3.1
	Pulsed laser exposure + chemical stripping	2.52	3.2
Varelas *et al*. [29]	Pristine fiber + chemical stripping	5.13	112
	Continuous wave UV exposure + chemical stripping	> 5	57
Askins *et al*. [30]	Pristine reference fiber (Corning SMF-28)	5.6 – 6.0	90
	Single pulse exposure, writing during draw tower process prior to coating	5.4	45
Gu *et al*. [31]	One-step process of writing through polysiloxane buffer, no stripping required	3.76	13.2
Han *et al*. [32]	LPG fabrication via residual stress relaxation with CO_2 laser (no UV irradiation required)	4.9	10.5

fiber core. However, mechanical stripping of the coating introduces microcracks at the surface of the optical fiber and can significantly reduce the strength of the fiber at the location of the FBG. Researchers have developed several techniques to increase the strength of FBGs, including chemically stripping the coating from the optical fiber and writing the grating in the optical fiber during the drawing of the fiber prior to coating. A summary of the resulting FBG strength properties taken from the literature is listed in Table 1. For definitions of the Weibull modulus and median strength, *see* **Fiber-optic Sensor Principles**. Additionally, description of common coating types for FBG sensors for durability in structural health monitoring applications are provided in **Fiber-optic Sensor Principles**.

4 MULTIPLEXING AND INTERROGATION OF FBG SENSOR NETWORKS

One of the strongest advantages of FBG sensors over other available strain or temperature sensors for structural health monitoring applications (*see* **Nondestructive Evaluation/Nondestructive Testing/Nondestructive Inspection (NDE/NDT/NDI) Sensors—Eddy Current, Ultrasonic, and Acoustic Emission Sensors**; **Piezoelectric Paint Sensors for Ultrasonics-based Damage Detection**; **Directed Energy Sensors/Actuators**) is the fact that they can be multiplexed into a large sensor network. For structural health monitoring applications, having only a single or limited ingress/egress points and lead cables is a notable advantage because it can significantly reduce the weight of the lead cables and disruptions to the structure itself [1].

Several approaches to multiplexing large FBG sensor networks have been applied in which the sensors are interrogated using wavelength division multiplexing (WDM), time division multiplexing (TDM), and combinations thereof (*see* **Fiber-optic Sensor Principles**). For single FBG sensors, the most common method to measure the peak shifts is to pass the reflected signal from the FBG through a wavelength-dependent filter that outputs a different intensity based on the input wavelength. Examples of wavelength-dependent filters include Fabry–Perot cavities [33], acousto-optic filters [34], chirped Bragg gratings [35, 36], long period gratings (LPGs) [37], and WDM couplers [38, 39]. These techniques have been expanded to WDM FBG sensor networks by scanning the filters to cover the peak wavelengths of multiple sensors. For example, Davis *et al.* [40] demonstrated interrogation of 60 FBGs in 2.5 s with 50 averages per sensor.

The interrogation of a large number of FBGs along a single optical fiber is limited by the power reflected from each grating, since each FBG reflects a portion of the wavelengths in the vicinity of the Bragg wavelength. For WDM applications, reducing the spacing between each FBG reduces the time required to scan the network; however, it also increases the cross talk losses between FBGs. For TDM applications, low reflectivity gratings ($r_{max} \cong 1\%$) should be used to allow for a large number of multiplexed sensors. By combining WDM with TDM, as shown in Figure 5, one can reduce the power loss per FBG,

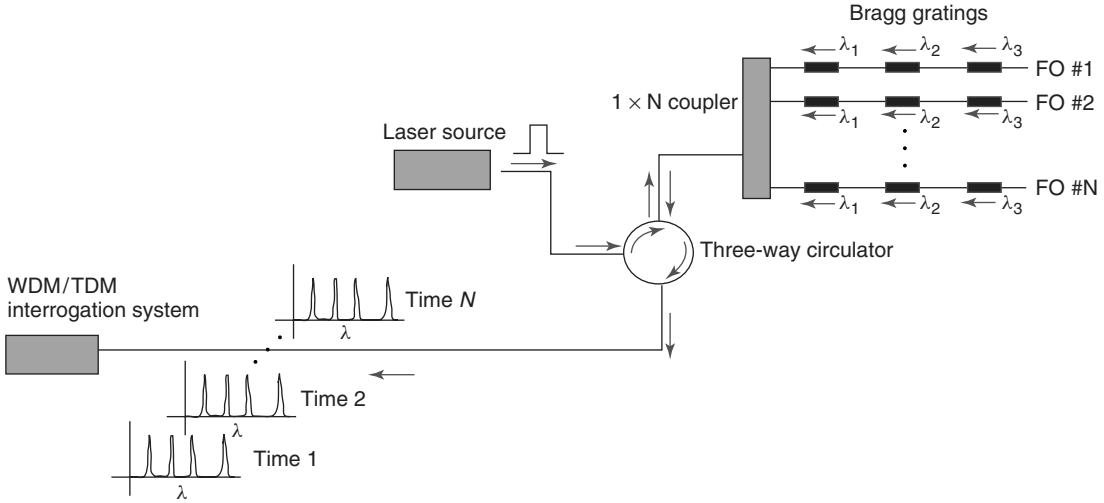

Figure 5. Combined wavelength division multiplexing and time domain multiplexing for FBG sensor network.

as well reduce the total wavelength range that must be scanned to interrogate the entire network [24]. In this case, each parallel network of FBGs has the same wavelength range, while the laser output is pulsed and the particular network being interrogated determined by the time of arrival of the signal.

Alternative approaches to interrogating FBG sensor networks include expanding the output-reflected spectrum via a plane grating or prism to a linear charge-coupled device (CCD) array that would then operate as a CCD spectrometer. In this manner, Askins *et al.* [41] achieved interrogation of 20 sensors at 3.5 kHz. A network of FBG sensors that have the same initial Bragg wavelength can also be interrogated quasi-statically through interpretation of the inverse Fourier transformation of the reflected spectrum [42]. Finally, interferometric methods have also been applied for high-speed interrogation of FBG sensor networks [43–45].

5 MULTIPLE AXIS SENSING

One unique characteristic of the FBG as a strain sensor is its ability to measure and distinguish between multiple strain components. Researchers have fabricated FBG rosettes, following the same strategy as for electrical resistance strain gauges [46, 47]. However, the FBG itself can also be used to monitor axial and transverse strain components through the birefringence that occurs in the optical fiber due to applied transverse loads. Figure 6 shows an example of three independent loads applied to the optical fiber, along with the resulting three principal strain components at the center of the fiber core. The effect of the axial load (P_1) is to shift the reflected peak to higher or lower wavelengths; however, the effect of the transverse loads (P_2 and P_3) is to create peak splitting due to the fast and slow axes that develop in the optical fiber (for a discussion of birefringence, *see* **Fiber-optic Sensor Principles**). A typical example of peak-splitting behavior is also shown in Figure 6.

In general, FBGs written in polarization maintaining (PM) optical fibers exhibit enhanced discrimination between multiple loading components due to geometrical and stress-induced birefringence in the fibers (*see* **Fiber-optic Sensor Principles**). The stress-induced portion of the birefringence can be due to residual stresses and/or the applied transverse loading components. This birefringence effect has been exploited for the independent measurement of multiple strain components and/or temperature changes using single or multiple Bragg gratings [48]. This capability makes the FBG sensor ideal for the monitoring of residual stresses during curing of FRP laminated composites as well as further monitoring of internal stresses during loading of the laminates [17, 49–52]. Additionally, by writing two FBGs with different Bragg wavelengths, λ_{B1} and λ_{B2}, at the same

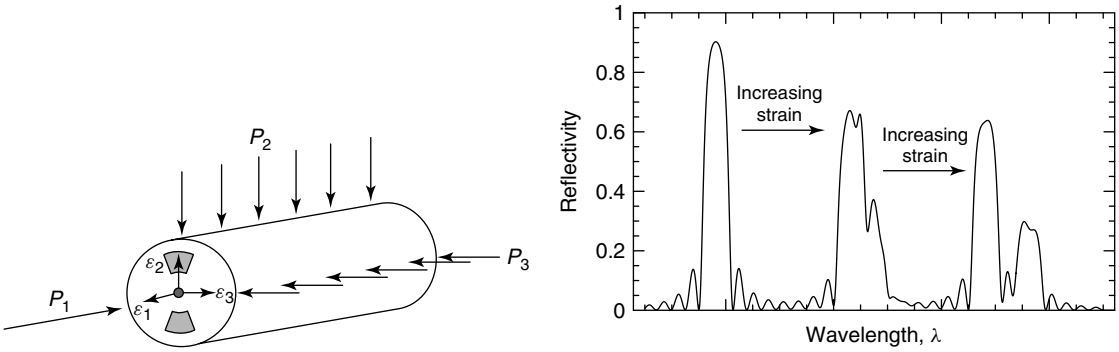

Figure 6. Multiaxis loading applied to FBG sensor written into bow-tie PM fiber. The graph plots the effects of the multiaxis loading on a single FBG (the peak on the left-hand side is the initial peak before load is applied).

location and monitoring the peak wavelength shifts for the fast and slow axes of each grating, one can independently calculate the three principle strains as well as a uniform temperature change applied to the sensor [48],

$$\begin{pmatrix} \Delta\lambda_{1f} \\ \Delta\lambda_{1s} \\ \Delta\lambda_{2f} \\ \Delta\lambda_{2s} \end{pmatrix} = \begin{pmatrix} K_{11f} & K_{12f} & K_{13f} & K_{1Tf} \\ K_{11s} & K_{12s} & K_{13s} & K_{1Ts} \\ K_{21f} & K_{22f} & K_{23f} & K_{2Tf} \\ K_{21s} & K_{22f} & K_{23f} & K_{2Ts} \end{pmatrix} \begin{pmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \Delta T \end{pmatrix} \tag{14}$$

Generally, the relative sensitivities of the FBG written in a PM fiber are calibrated because of the complexity of predicting these sensitivities and the lack of detailed material information for the particular PM fibers used. Urbanczyk *et al.* [53], Chehura *et al.* [54], Lawrence *et al.* [48], and Bosia *et al.* [55] performed experimental measurements of the wavelength shifts in FBGs due to multiaxis loading in various PM fiber types. Chehura *et al.* [54] also performed a comparative experimental study of various PM fiber types to determine which fiber type was optimal for multiaxis strain sensing and temperature monitoring. The authors determined that amongst the specific, commercially available PM fibers studied, the elliptical core stress-applying portion (SAP) fiber provided the maximum sensitivity to transverse loading, while the Panda fiber provided the maximum sensitivity to temperature loading. However, the particular elliptical core SAP fiber used had a significantly smaller cladding diameter than the other fibers, which the authors note was the cause of the increased transverse load sensitivity. The transverse load and temperature sensitivities of the FBG can also be increased through the simultaneous measurement of the response of both the fundamental LP_{01} and LP_{11} modes; however, propagating the LP_{11} mode in the FBG presents substantial challenges [56].

To predict the response of an FBG written in a PM fiber to transverse loading, Kim *et al.* [57] considered the PM fiber to be optically and mechanically homogeneous with orthotropic material properties. As in later models, the assumption is made that most of the energy of the fundamental mode propagating in the fiber is contained in the core; therefore, the principal strains at the center of the fiber are sufficient to estimate the wavelength shift. Sirkis [58] later related the change in Bragg wavelengths, $\Delta\lambda_{B1}$ and $\Delta\lambda_{B2}$, to the principal strains at the center of the core: ε_1, ε_2, and ε_3 (see Figure 6),

$$\begin{aligned} \frac{\Delta\lambda_{B1}}{\lambda_{B1}} &= \varepsilon_1 - \frac{1}{2}n_{\text{eff}}^2\left(p_{11}\varepsilon_2 + p_{12}\varepsilon_3 + p_{12}\varepsilon_1\right) \\ \frac{\Delta\lambda_{B2}}{\lambda_{B2}} &= \varepsilon_1 - \frac{1}{2}n_{\text{eff}}^2\left(p_{12}\varepsilon_2 + p_{11}\varepsilon_3 + p_{12}\varepsilon_1\right) \end{aligned} \tag{15}$$

Lawrence *et al.* [48] and later Bosia *et al.* [55] modeled the mechanical inhomogeneities in the optical fiber due to the SAP and applied the finite element method to calculate the strains at the center of the fiber due to transverse loading. Both the experimental and numerical studies of Lawrence *et al.* [48] and Bosia *et al.* [55] demonstrate that for a PM fiber, the shift in Bragg wavelength is nonlinear with transverse load for certain loading angles. Prabhugoud and Peters [59, 60] performed finite element

analyses of FBGs written in PM fibers analysis incorporating the photoelastic-induced index distribution throughout the cross section of the optical fiber and calculating its contribution to the wavelength shift of the FBG. Comparison of this method with the previous assumption of principal strains at the center of the core in equation (15) for a variety of PM fiber types and loading cases reveals that the approximation of equation (15) is sufficient for most loading cases; however, its accuracy varies between the different fiber types.

6 NONUNIFORM SENSING

Distortion of the grating spectrum due to strain gradients has been observed in several applications of embedded FBG sensors [61–74]. An example of experimentally measured spectral distortion due to the highly nonuniform strain field near a notch tip is shown in Figure 7 [61]. This sensitivity of the sensor response to the form of the strain profile is unique to the optical FBG since other strain gauges (e.g., the classical electrical strain gauge) average the applied strain over the gauge length. This section presents both the forward prediction of the FBG spectral response due to the applied nonuniform strain field and the reverse calculation of the applied strain field from the spectral response.

6.1 Prediction of FBG response

The T-matrix approximation, first introduced by Yamada and Sakuda [75], is widely used to model Bragg gratings with nonconstant properties as explained in Figure 8. The primary advantage of the T-matrix method is that it is computationally efficient as compared to direct numerical integration of equation (3) [21]. This approach divides the grating into M smaller sections each with uniform coupling properties. Defining R_i and S_i to be the amplitudes $R(z)$ and $S(z)$ after each lightwave traverses the ith section, the propagation through this uniform section can be described in the form of a transfer matrix

$$\begin{bmatrix} R_i \\ S_i \end{bmatrix} = F_i \begin{bmatrix} R_{i-1} \\ S_{i-1} \end{bmatrix} \tag{16}$$

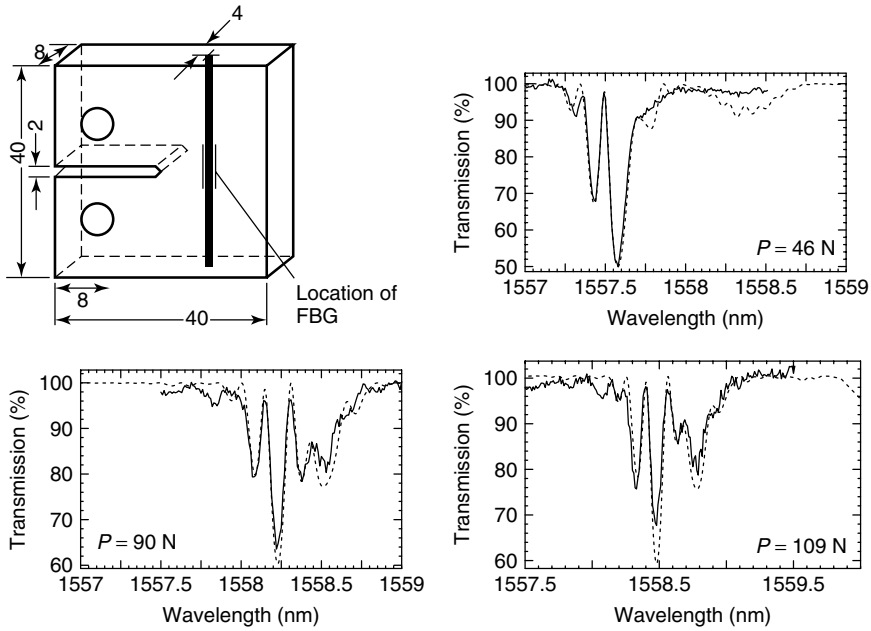

Figure 7. Response of FBG embedded in a compact tension specimen. Location of 10-mm grating is shown in the sketch of the specimen. Experimental grating spectral data in transmission (solid lines) are shown for three load levels (P). The simulated spectra calculated using the transfer matrix method are also plotted (dashed lines). [Reproduced with permission. © Springer, 2001.]

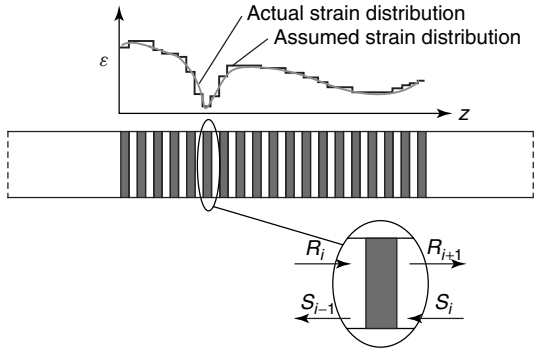

Figure 8. Schematic of transfer matrix approximation for FBG subjected to nonuniform strain field. [Reproduced with permission. © Springer, 2001.].

The optical transfer matrix can be derived as

$$F_i = \begin{bmatrix} \cosh(\gamma_B \Delta z) - i\dfrac{\hat{\sigma}}{\gamma_B}\sinh(\gamma_B \Delta z) & -i\dfrac{\kappa}{\gamma_B}\sinh\left(\gamma_B \Delta z\right) \\ i\dfrac{\kappa}{\gamma_B}\sinh(\gamma_B \Delta z) & \cosh(\gamma_B \Delta z) + i\dfrac{\hat{\sigma}}{\gamma_B}\sinh\left(\gamma_B \Delta z\right) \end{bmatrix} \quad (17)$$

where $\gamma_B = \sqrt{\kappa^2 - \hat{\sigma}^2}$ and Δz is the length of the section. For the entire grating, the combined optical transfer matrix can then be written as

$$\begin{bmatrix} R(-L/2) \\ S(-L/2) \end{bmatrix} = F \begin{bmatrix} R(L/2) \\ S(L/2) \end{bmatrix} \quad (18)$$

where $F = F_M \cdot F_{M-1} \ldots \cdot F_1$. The reflectivity as a function of wavelength can be calculated from equation (18). A limitation of the T-matrix approximation, however, is that the number of sections M cannot be arbitrarily large since several grating periods are required for complete coupling. However, $M \cong 100$ is typically more than sufficient to accurately model chirped gratings.

For axial strain-sensing applications, the T-matrix method was first applied to a Bragg grating subjected to a nonuniform strain distribution by Huang *et al.* [76]. Huang *et al.* [76] approximated the applied strain as a piecewise continuous function, calculating the average period in each grating segment due to the applied strain and substituting this local period into the coupling coefficient for the T-matrix method. The validity of this approximation was later demonstrated by Peters *et al.* [77] for various nonuniform strain fields. Prabhugoud and Peters [78] demonstrated that this prediction works well for small magnitudes of strain gradients. For an arbitrary nonuniform strain field one can enter the strain field into the coupled mode equations or transfer matrix through an "equivalent" period that accounts for both geometrical and photoelastic effects,

$$\Lambda(z) = \Lambda_0\left[1 + (1 - p_e)\varepsilon(z) + (1 - p_e)z\varepsilon'(z)\right] \quad (19)$$

where $(\,)'$ refers the derivative with respect to z [78]. A similar expression for the equivalent period for cases where the grating is originally chirped can be found in Prabhugoud and Peters [78].

6.2 Inversion of measured spectrum

When the axial strain applied to the sensor is nonconstant along its gauge length, one can no longer simply measure the shift in wavelength at maximum reflectivity to obtain useful strain data. Rather, the calculation of the applied strain profile from the spectral response becomes an inverse problem. The most commonly used inversion techniques for optical FBG strain sensor spectra are reviewed by Huang *et al.* [76]. The simplest technique is the intensity-spectrum-based approach, which requires only the amplitude information from the complex reflected spectrum. Although suitable for some applications, this technique is only valid for monotonically varying strain fields and averages out rapidly changing strain fields. A second approach based on the Fourier transform is more suitable to invert nonmonotonic strain profiles. However, this technique requires both intensity and phase information from the reflected spectrum, which significantly increases the cost and complexity of sensor data collection. Several other techniques to invert the spectral information based on heuristic approaches have been developed, including iterative solutions to the coupled mode equations (3) [79], inverse scattering algorithms (*see* **Time–frequency Analysis**) [80–82], time–frequency transform methods [83], neural networks (*see* **Artificial Neural Networks**) [84], and genetic algorithms [85, 86]. Such techniques do not

identify the direction of the strain profile; however, Kitcher *et al.* [87] have demonstrated the presence of directional dependent losses in FBGs, which could be used to identify the orientation of the strain field.

7 LONG PERIOD GRATINGS

While short period FBGs reflect or transmit lightwaves at certain wavelengths based on coupling between counterpropagating core modes, LPG sensors are based on coupling between the forward propagating core mode and forward propagating cladding modes (*see* **Fiber-optic Sensor Principles** for a description of cladding modes). While both of these and other coupling phenomena occur for both types of grating sensors, the large period of the LPG ($100\,\mu\text{m} < \Lambda < 1\,\text{mm}$) results in cladding mode coupling at wavelengths in the near-IR range. Because of the fact that cladding modes attenuate rapidly in optical fibers, the LPG coupling is not measurable from the reflected spectrum, but rather appears as multiple loss peaks in the transmission spectrum (see Figure 9). The phase matching condition for each of these loss peaks is given by

$$\lambda_i = \left[n_{\text{eff}} - n_{\text{clad}}^{(i)}\right]\Lambda \tag{20}$$

where $n_{\text{clad}}^{(i)}$ is the effective index of refraction of the ith cladding mode [88]. The maximum transmission loss for the ith cladding mode is given by

$$T_i = 1 - \sin^2(\kappa_i L) \tag{21}$$

where κ_i is the coupling coefficient for the mode (similar to κ for the short period FBG).

Because of the larger scale of the LPG features as compared to that of short period FBGs, a variety of fabrication procedures have been demonstrated to write LPGs in silica fibers including photosensitivity [89], electric arc discharge [90], etching of the fiber using hydrofluoric acid [91], and CO_2 lasers [92]. Additionally, nonpermanent LPGs have been fabricated in optical fibers by applying mechanical pressure to the fiber with an undulating surface to create a photoelastic effect–induced change in index within the fiber core [93, 94].

While LPG sensors themselves have primarily been applied to the measurement of environmental or chemical parameters because of their strong sensitivity to the index of refraction of the surrounding material system, researchers have also combined them with other optical fiber sensors for multiple parameter sensing. LPGs react to applied strain and temperature fields in much the same manner as short period FBGs, including peak splitting due to transverse loading. A significant difference between the two sensors is that the temperature sensitivity of LPGs typically ranges from 3 nm/100 °C to 10 nm/100 °C, an order of magnitude greater than that of FBGs [88]. Additionally, the strain and temperature sensitivity can be tuned by writing LPGs with different properties. Bhatia *et al.* [95] designed a "strain insensitive" LPG for which the photoelastic effects, Poisson contraction, and period extension as a function of strain canceled each other out, leading to an independent temperature sensor. Patrick *et al.* [96] fabricated a hybrid FBG/LPG sensor for independent strain and temperature measurements. Kim *et al.* [97] fabricated a hybrid LPG/Fabry–Perot interferometer (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**) for the simultaneous measurement of refractive index and temperature.

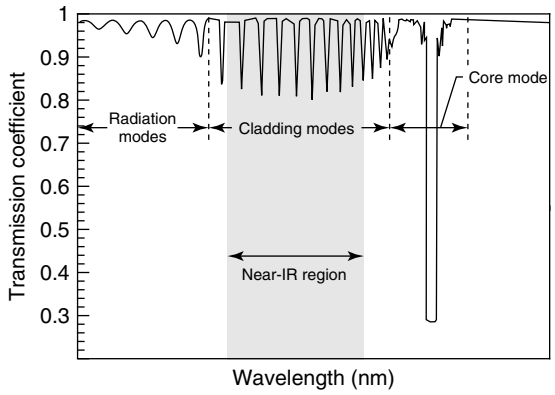

Figure 9. Theoretical transmission spectrum for long period FBG. Portion of spectrum in near-IR region is indicated.

8 CONCLUSIONS

FBGs are versatile and lightweight sensors that can be multiplexed into sensor networks and embedded into various material systems for the measurement of strain and temperature. For structural

health monitoring applications, FBG sensors offer the advantages of immunity to electromagnetic interference and the ability to measure multiaxis strain fields and local strain distributions. As compared to electrical resistance or piezoelectric strain gauges, these advantages come at the cost of expense and data acquisition rate limits for large networks. At the same time, advances in telecommunication networking and devices have led to recent advances in these areas (for example, high-speed tunable microelectromechanical systems (MEMS) filters). Recent developments including the topics of FBG sensors for high-temperature applications and FBGs in polymer and photonic crystal optical fibers can be found in **Novel Fiber-optic Sensors**.

Chapter 62
Novel Fiber-optic Sensors

Kara Peters

Department of Mechanical and Aerospace Engineering, North Carolina State University, Raleigh, NC, USA

1 INTRODUCTION

Fiber-optic sensors have been applied for a variety of structural health monitoring applications because of their immunity to electromagnetic interference, low weight, small size, and multiplexing capabilities (*see* **Fiber-optic Sensors**). Some of the articles in this encyclopedia review optical fiber concepts useful for understanding fiber-optic sensors (*see* **Fiber-optic Sensor Principles**), as well as the basic operating principles for intensity-based, interferometric, and fiber Bragg grating (FBG) sensors (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**; **Fiber Bragg Grating Sensors**). The goal of this article is to present recent, novel concepts for fiber-optic sensors. Most of these sensors are based on recent advances in optical fiber technology, including single-crystal sapphire, single-mode polymer, and microstructured and multicore optical fibers. Such advances allow the use of optical fiber sensors for high-temperature and large-strain applications.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

2 EXTREME TEMPERATURE SENSORS

A variety of factors limit the usable temperature range for fiber-optic sensors including the material limits of the optical fibers themselves and temperature limits for any adhesives used in packaging. Another important limit for FBG sensors (*see* **Fiber Bragg Grating Sensors**) is that the index modulation in the FBG written through photosensitivity can be erased at approximately 200 °C. This limitation could be important for many composite applications, as processing temperatures of polymer matrix–based composites may exceed this limit. Other matrix materials have even higher processing temperatures. Coating the optical fiber with polyimide does increase the temperature survival range for the FBG to 500 °C [1]; however, this may not be suitable for many high-temperature applications. The temperature limit for

FBG erasing is well below the material limit for fused silica, typically 1000–1100 °C. As one solution, Luo *et al.* [1] developed a "Bragg stack" by depositing quarter-wavelength-thickness layers on the end of a polyimide-coated silica optical fiber. The alternating layers of silicon nitrite and silicon-rich silicon nitrite acted as a Bragg diffraction grating, which could be interrogated in reflection through the optical fiber. The Bragg stack was applied as a temperature sensor and was demonstrated to survive to at least 800 °C with a 2 °C temperature resolution.

An alternative fabrication method was applied by Lowder *et al.* [2], who fabricated FBGs through first etching a significant portion of the cladding on the flat surface of a D-fiber. Then a surface relief FBG close to the core of the optical fiber was etched. Similar methods have been applied to write long period gratings (*see* **Fiber Bragg Grating Sensors**). As the FBG is created mechanically, rather than chemically as in the case of photosensitive FBGs, the FBG can withstand significantly higher temperatures. Lowder *et al.* [2] demonstrated the linearity of the sensor up to 1100 °C.

To overcome the temperature limit of the silica itself, researchers have also developed optical fiber sensors based on single-crystal sapphire fibers, which have a melting point of 2050 °C [3–5]. Tong *et al.* [4] demonstrated a single-crystal sapphire fiber temperature sensor based on blackbody radiation for high-temperature applications; however, they discovered that surface contamination can significantly degrade the measurements at high temperatures. Wang *et al.* [3] and Xiao *et al.* [5] designed extrinsic Fabry–Perot white-light interferometer sensors, coupling the light-wave from a single mode to a multimode sapphire fiber and achieving a strain resolution of 0.2 microstrain up to 1004 °C. Zhu and Wang [6] later extended the sapphire fiber sensor by bonding the single-crystal sapphire fiber to the surface of a sapphire wafer whose optical path length through the thickness changes with temperature. By further splicing the sapphire fiber to the standard silica fiber lead, removing the need for optical adhesives, the authors demonstrated a temperature resolution of 0.4 °C up to 1170 °C.

At the other end of the usable temperature range for fiber-optic sensors, Zeisberger *et al.* [7] demonstrated that FBGs can be applied for accurate strain measurements at extremely low temperatures, specifically in the temperature range of 30–300 K. The measured wavelength shift of an FBG due to only the thermo-optic effect reported by the authors is plotted in Figure 1. For these measurements, the FBG was constrained so as to not permit thermal expansion.

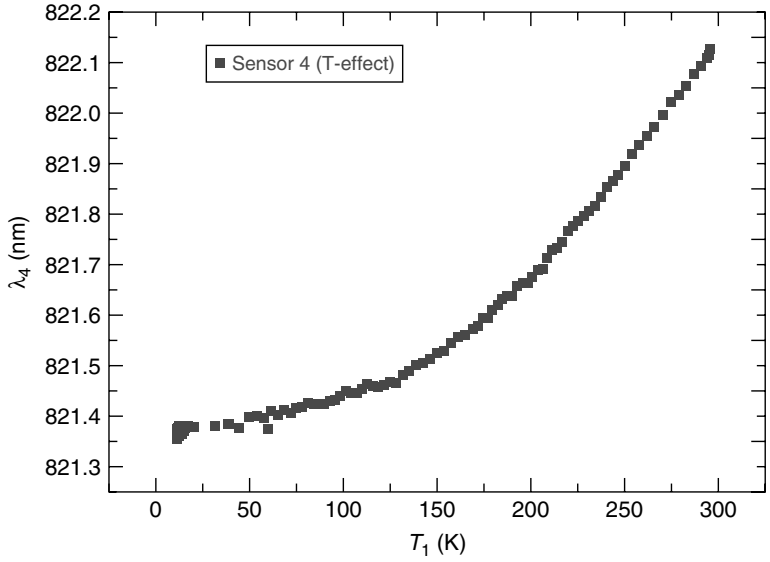

Figure 1. Measured Bragg wavelength of FBG as a function of temperature (change due to thermo-optic effect only). [Reproduced with permission from Ref. 7. © 2005, IEEE.]

The response of the FBG to temperature is linear to approximately 250 K, and then strongly nonlinear at lower temperatures.

3 POLYMER LARGE-DEFORMATION SENSORS

As demonstrated by the large number of optical fiber sensors and their applications (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**; **Fiber Bragg Grating Sensors**; **Fiber-optic Sensors**), optical fiber sensors are extremely versatile. However, the brittle nature of silica limits their maximum strain range to approximately 1–2%, particularly for FBGs [8]. This measurement range is comparable with electrical resistance strain gauges. Polymer optical fibers (POFs) on the other hand offer a much larger potential strain measurement range. In general, the fabrication of POFs is not as well controlled as for silica fibers; therefore, their performance has not been comparable. At the same time, intrinsic material losses in polymers are orders of magnitude higher than for silica. Therefore, POFs have primarily been used for short, flexible optical connections and as sensors operating through bending or environmental intensity losses. However, recent advances in the fabrication of single-mode POFs with minimal attenuation levels have changed the potential for POF sensors [9–13].

Figure 2 plots the inherent material losses for several optical polymers and silica. The material losses in polymethylmethacrylate (PMMA) generally increases with wavelength, and therefore POFs are often designed to operate at wavelengths below the near-IR wavelengths used with silica fibers. Fabricating single-mode fibers at these lower wavelengths requires smaller core diameters in order to keep the normalized frequency, V, in the single-mode range (*see* **Fiber-optic Sensor Principles**). Kuzyk *et al.* [9] first fabricated PMMA optical fibers with a dye-doped core that were single mode at an operating wavelength, $\lambda = 1300$ nm. These fibers

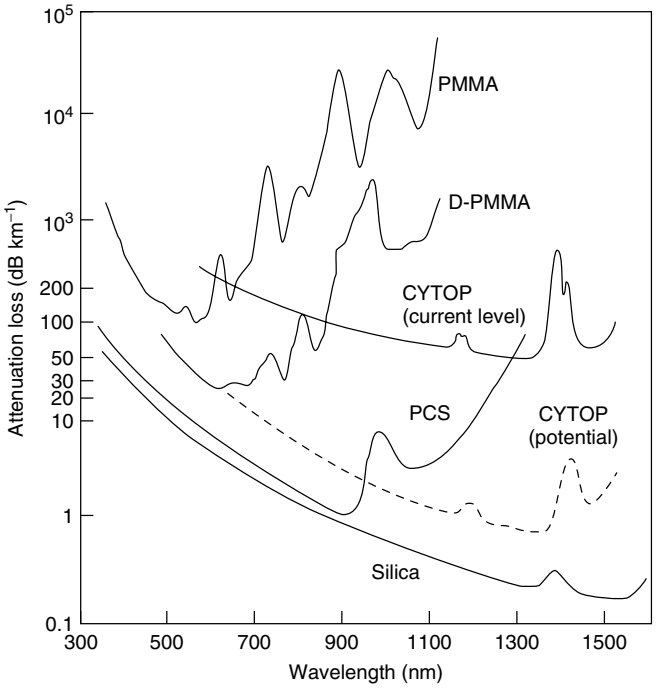

Figure 2. Transmission loss spectra for various polymer optical fiber materials: PMMA, D-PMMA (deuterated), CYTOP, and PCS. Loss spectra for silica is also plotted for comparison. [Reproduced with permission from Ref. 14. © 2001, Elsevier.]

demonstrated attenuation levels of approximately $0.3\,\mathrm{dB\,cm^{-1}}$, close to the intrinsic material attenuation for PMMA at that wavelength. Bosc and Toinen [10] later fabricated single-mode PMMA optical fibers with attenuation levels of $0.25\,\mathrm{dB\,cm^{-1}}$ at $\lambda = 1550\,\mathrm{nm}$ and $0.05\,\mathrm{dB\,cm^{-1}}$ at $\lambda = 850\,\mathrm{nm}$. Finally, Garvey *et al.* [11] improved the process to create single-mode POFs at $\lambda = 1060\,\mathrm{nm}$ with an attenuation level of $0.18\,\mathrm{dB\,cm^{-1}}$.

3.1 Sensing properties of POFs

Silva-López *et al.* [15] first measured the sensitivity of dye-doped single-mode POFs to strain and temperature. The POFs were designed to be single mode at 850 nm with an acrylic cladding ($n = 1.4905$) and doped PMMA core ($n = 1.4923$). The authors operated the fibers with a visible light source at $\lambda = 632\,\mathrm{nm}$, outside of the single-mode region; however, they only observed the fundamental, LP_{01}, mode propagating through the fiber. Using a Mach–Zender interferometer arrangement and loading the optical fiber on a translation stage, they measured a phase sensitivity to displacement of $131 \times 105\,\mathrm{rad\,m^{-1}}$ and temperature sensitivity of $-212\,\mathrm{rad\,m^{-1}\,K^{-1}}$. The phase sensitivity to displacement measured is in good agreement with the properties of bulk PMMA. When compared with silica optical fibers, the sensitivity to displacement of the PMMA fiber is 14% higher than that of the silica, which is an advantage for strain sensing. The difference is primarily due to the large difference in Poisson's ratio and the photoelastic constants (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**). On the other hand, the temperature sensitivity of the PMMA fiber is negative, whereas the temperature sensitivity of silica optical fibers is positive. The temperature sensitivity was also about 25% more than predicted. The maximum operating temperature for the fiber was predicted to be in the 80–120 °C range.

The measurements of Silva-López *et al.* [15] provide useful information on the behavior of POF sensors and can be used to predict the response of a variety of sensors based on them. However, the measurements were made in the strain range of 0–0.04% strain, which is a limited portion of the strain range over which they have potential to be applied. For this reason, Kiesel *et al.* [16] derived a formulation to predict the phase sensitivity to strain of the dye-doped PMMA POF for the full usable range of the sensor (≅0–6%) and measured the mechanical properties of the fiber in this range. The formulation includes both the finite deformation of the optical fiber and nonlinear photoelastic effects, both potentially significantly important over the usable strain range. The measured true stress–strain response curve of the PMMA POF is plotted in Figure 3 for multiple strain rates in the range of $0.01–3.05\,\mathrm{min^{-1}}$. One can see from Figure 3 that the response of the sensor is very sensitive to strain rate and that the yield strain increases with strain, typical of polymer fibers [13]. The failure strain of the POF was around 30%, while transmission of the coherent lightwave for sensing was demonstrated to be 15.8%, well beyond the yield strain of the POF [17]. Using the mechanical properties measured from the single-mode POF samples, Kiesel *et al.* [16] predicted the phase sensitivity of the POF over a strain range of 0–6%. This sensitivity is plotted in Figure 4 with the response of a silica fiber for comparison. The important differences between POF sensor and silica sensor from Figure 4 are as follows: (i) the PMMA has a high strain sensitivity throughout the strain range, (ii) the nonlinearity in the PMMA phase response is of the opposite sign and an order of magnitude greater than for silica, and (iii) the importance of including the nonlinearity in the phase response is evident at a much lower strain value (≅1%) for PMMA than for silica (≅3%). Additional effects are expected to be important when applying

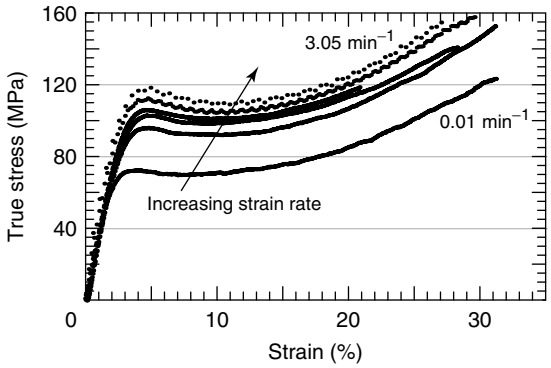

Figure 3. Measured true stress–strain curves for PMMA POF at various strain rates. Strain rates plotted are 0.01, 0.30, 0.60, 0.90, 1.22, and $3.05\,\mathrm{min^{-1}}$. [Reproduced with permission from Ref. 16. © IOP Publishing, Ltd., 2007.]

POFs as large-strain sensors, including material hysteresis, creep effects (especially at elevated temperatures), and the anisotropy of the polymer.

3.2 Fiber Bragg gratings in POFs

Peng and Chu [12] first demonstrated the writing of FBGs in POFs through the same photosensitivity process used for writing FBGs in silica optical fibers. The FBGs were fabricated by UV exposure of PMMA single-mode optical fibers (fabricated by the authors) with dye-doped cores to increase the photosensitivity of the polymer. Peng and Chu [12] wrote FBGs operating in near-IR wavelengths ($\lambda_B \cong 1570\,\mathrm{nm}$) with reflectivities >80% and a bandwidth of 1 nm. By applying strain to the FBG, the authors shifted the Bragg wavelength by a total of 73 nm (Figure 5), which is an order of magnitude larger than that previously achieved with FBGs in silica optical fibers. The large wavelength shift was partially due to the increased sensitivity of the POF described in the previous section and partially due to the large yield strain of the POF (Peng and Chu report 6.1% yield strain for the fiber used [12]). Applying thermal loading, the authors tuned the FBG over 20 nm; however, erasing of the FBG occurred when the grating was exposed to thermal loads for extended periods of time [18].

Liu *et al.* [19] later wrote FBGs in CYTOP optical fibers, which have a lower intrinsic material loss than PMMA (Figure 2). The sensitivity of the FBGs in CYTOP fibers was not as high as for those in PMMA fibers, for example, the gratings could only be tuned thermally over 10 nm. However, thermal erasing of the gratings did not occur when they were exposed to thermal loads for long durations.

Liu *et al.* [18] combined FBG sensors in silica and PMMA optical fibers in series to independently measure strain and temperature, through the equation

$$\begin{pmatrix} \Delta\lambda_p \\ \Delta\lambda_s \end{pmatrix} = \begin{pmatrix} K_{\varepsilon p} K_{Tp} \\ K_{\varepsilon s} K_{Ts} \end{pmatrix} \begin{pmatrix} \varepsilon \\ \Delta T \end{pmatrix} \qquad (1)$$

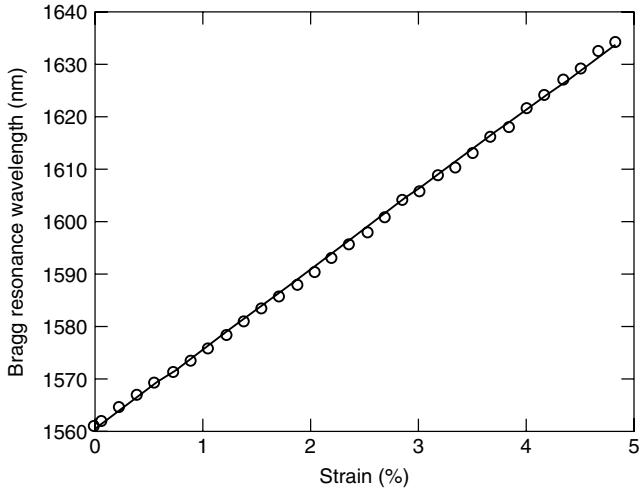

Figure 5. Measured Bragg wavelength shift due to axial strain for FBG written in polymer optical fiber. [Reproduced with permission from Ref. 12. © Taylor & Francis, Ltd., 2000.]

where the K matrix is constructed of the sensitivities of the Bragg wavelength of the FBGs in the polymer ($\Delta\lambda_p$) and silica ($\Delta\lambda_s$) fibers to strain and temperature (*see* **Fiber Bragg Grating Sensors**). These measurements are significantly better than those previously obtained using two FBGs in silica fibers at different wavelengths (*see* **Fiber Bragg Grating Sensors**) due to the fact that the sensitivity to strain and temperature is very different for the polymer and silica. The measured strain sensitivities were $K_{\varepsilon 1} = 1.48\,\text{pm}\ \mu\varepsilon^{-1}$ for the PMMA FBG and $K_{\varepsilon 2} = 1.15\,\text{pm}\,\mu\varepsilon^{-1}$ for the silica FBG. Additionally, the temperature sensitivity of the silica FBG is positive, while the temperature sensitivity of the PMMA FBG is negative.

Challenges to applying polymer FBGs for large-strain sensing include high attenuation in the fibers, difficulties in preparing the fibers for coupling, and thermal erasing of the gratings. This last challenge could be important for many structural health monitoring applications, but is still not fully understood. Similar to the writing process for FBGs in silica fibers, the grating depth increases with exposure time until a threshold is reached, at which point damage to the polymer fiber occurs and transmission losses are introduced in the fiber [20]. On the other hand, Liu *et al.* [21] observed that, when FBGs were written with lower power UV exposures, the FBG peak depth increased, reached a maximum, remained constant, then began to erase during the exposure time. Once the FBG was completely erased, the UV exposure was stopped and the FBG reappeared over a period of 8 h, then was permanent and stable. The authors speculate that the heating of the fiber during the UV exposure temporarily changed the index of refraction, counteracting the change due to photosensitivity.

4 MICROSTRUCTURED FIBER SENSORS

Microstructured optical fibers, also referred to as *photonic crystal fibers*, have been fabricated in a variety of forms including solid core, "holey" fibers, as shown in Figure 6. For a first approximation, the holey fiber acts as an index-guiding waveguide in the same manner as conventional solid optical fibers (*see* **Fiber-optic Sensor Principles**). The air holes

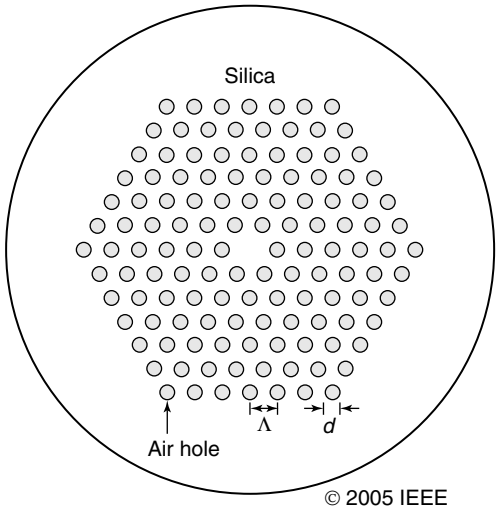

Figure 6. Schematic representation of a typical microstructured holey optical fiber. Λ and d are the hole pitch and diameter respectively. [Reproduced with permission from Ref. 24. © IOP Publishing Ltd., 2005.]

in the cladding region reduce the effective index of the cladding and therefore provide much stronger confinement of the lightwave as it propagates through the fiber [22]. Such microstructured optical fibers are typically fabricated by drawing a preform consisting of capillary tubes with a solid silica rod replacing the center tube to form the solid core. The complex geometry of these holey fibers provides both new sensing possibilities and enhanced response characteristics for conventional fiber-optic sensors applied to these fibers. For example, Ju *et al.* [23] fabricated an interferometric sensor based on a holey fiber and observed a nonmonotonic temperature dependence on wavelength.

Nasilowski *et al.* [25] and Bock *et al.* [26] applied microstructured holey fibers for the measurement of temperature and pressure. Through measurement of the group refractive index change, Bock *et al.* [26] estimated the temperature, axial strain, and pressure sensitivity of such fibers. The primary differences observed as compared to conventional fibers were that the reduced Poisson contraction of the cross section (i) reduced the strain sensitivity slightly and (ii) changed the pressure sensitivity to be negative rather than positive as for solid fibers. Nasilowski *et al.* [25] applied a high-birefringence holey fiber, created by introducing several defects to form a

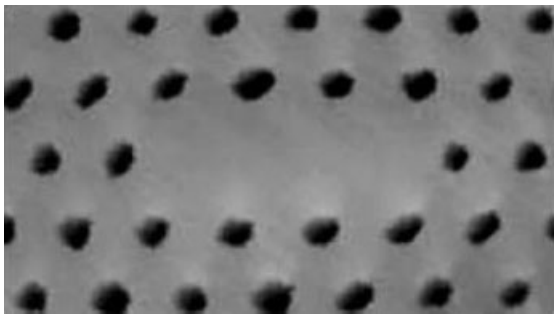

Figure 7. Scanning-electron-microscope image of the core of high-birefringence holey fiber showing the triple defect core. [Reproduced with permission from Ref.23. © Springer Verlag, 2005.]

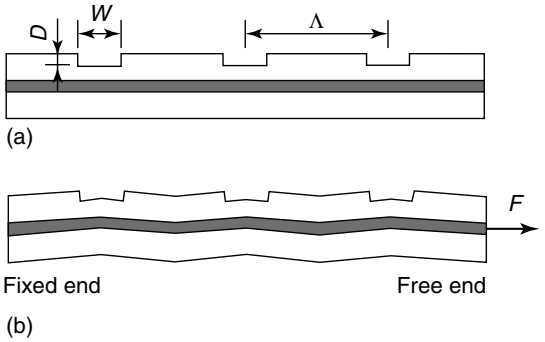

Figure 8. Schematic of CO_2 laser carved LPG (a) before and (b) after axial force is applied to the fiber. Λ, D, and, W are the grating pitch, depth, and, width of the grooves, respectively. [Reproduced with permission from Ref. 27. © OSA Publishing, 2006.]

noncircular core, as a pressure sensor. An image of the fiber core and surrounding region is shown in Figure 7. An important feature of high-birefringence holey fibers is that strong birefringence can be obtained without inducing thermal residual stresses through a different material region in the fiber (*see* **Fiber-optic Sensor Principles**). From a sensing perspective, this birefringence is therefore stable with temperature and does not introduce temperature errors into high-birefringence sensors [25].

Several researchers have written long period fiber Bragg gratings (LPGs) in microstructured fibers through CO_2 laser or electric arc etching [27–29]. These LPGs demonstrate an excellent strain sensitivity, with little or no temperature sensitivity, meaning that temperature compensation is not required [27, 29]. When bending the optical fiber, He *et al.* [28] observed mode splitting and bending directional dependence in the output of the LPG, phenomena not observed with LPGs written in conventional solid silica optical fibers. The directional dependence is due to the fact that the in-plane stiffness of the cross section has been significantly weakened due to the presence of the holes. The response of the LPG does appear to strongly depend on the fabrication method, as Petrovic *et al.* [29] did not observe such phenomena in similar tests. Wang *et al.* [27] also found that, during axial stretching of the optical fiber, the periodic grooves in the LPGs created local microbending around the grooves (Figure 8). This microbending increased the sensitivity of the LPG to axial strain. Demonstrating the fabrication of grating structures through photosensitivity, Dobb *et al.* [30] successfully wrote FBGs in PMMA holey fibers operating at $\lambda_B = 1569\,\text{nm}$ with a 0.5 nm bandwidth. The FBGs were fabricated in both few-mode and single-mode holey fibers.

Zou *et al.* [31] demonstrated independent strain and temperature measurements through stimulated Brillouin scattering in microstructured optical fibers (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**). In contrast to scattering in conventional solid fibers, several peaks were observed in the scattered frequency spectrum due to independent interactions between the lightwave and stimulated acoustic waves occurring in the graded-Ge-doped core region, the intermediate silica region, and the microstructured cladding region. The response of the peak in the core region was the same as for a doped solid optical fiber; however, the other peaks had differing sensitivities to temperature and strain.

One final example of a microstructured fiber sensor is the tapered holey fiber sensor demonstrated by Villatoro *et al.* [32]. The authors tapered the middle section of a holey fiber to a diameter of 28 μm (the original diameter was 125 μm), which caused the holes to collapse in the cross section. The output lightwave intensity from the optical fiber was then an interference pattern between the multiple modes of the tapered waist [33]. These interference peaks shifted linearly with strain and were insensitive to temperature up to 180 °C.

5 MULTICORE OPTICAL FIBER SENSORS

Multicore optical fibers have great potential for the measurement of strains and curvatures over large, flexible structures such as aircraft wings or towed hydrophone arrays. When multiplexed, these local strain and curvature measurements can be used to determine the shape of the flexible structure. The concept for curvature measurements based on differential strain measurements between core pairs is shown in Figure 9 for a four-core optical fiber. The presence of multiple cores within a single fiber can provide more stable curvature measurements than those from separate single-mode fibers because more accurate spacing is maintained between the cores [34]. The choice of spacing between the cores can be an important design consideration for multicore sensors. Close spacing of the cores makes the sensor more compact as well as less sensitive to temperature gradients across the fiber cross section. However, reducing the core spacing also increases the coupling between modes propagating through the cores and reduces the accuracy of curvature measurements [35]. Methods to couple the multicore fiber to multiple single-mode fibers for data acquisition include graded index (GRIN) lenses and fan-outs [35]. Multicore optical fibers have also been applied for Doppler differential velocimetry [36] and pitch and roll sensing [35].

Blanchard *et al.* [34] first demonstrated strain and curvature measurements using a multicore optical fiber. They fabricated a three-core holey fiber by drawing silica capillary tubes with silica rods introduced for the cores, shown in Figure 10. The cores were placed sufficiently far apart such that each core acted as a separate single-mode waveguide with no coupling between propagating lightwaves (assuming that no twisting is applied). Light was launched into the optical fiber, creating a far-field interface pattern at the end of the 23-cm sensor length, which was then projected onto a Charge-Coupled Device (CCD) camera. The optical phase difference of each core was extracted from the Fourier transform of the interference pattern. On the basis of the differential phase differences, the sensor demonstrated a strain resolution of 7.4 nε and bend angle resolution of 100 μrad. MacPherson *et al.* [38] later demonstrated that the phase sensitivity to displacement ($\Delta\phi/\Delta L$) of the multicore holey fiber is approximately the same as a solid fiber. Using only a two-core holey fiber, they obtained a bend angle resolution of 170 μrad.

MacPherson *et al.* [37] wrote FBGs into each of the cores of the four-core solid optical fiber of Figure 9

for shape monitoring of a tunnel structure. Multiplexing a large number of FBGs along the length of the optical fiber allows for a distributed measurement of the curvature, which can be integrated to obtain the shape of the structure [39]. MacPherson *et al.* obtained a shape resolution of ± 0.1 mm between two sets of FBGs spaced over a length of 5 mm along the fiber. Flockhart *et al.* [40] and Cranch *et al.* [41] used the same fiber configuration, but wrote sets of FBG pairs in each core to act as a low-finesse Fabry–Perot interferometer to enhance the static and dynamic resolution of the shape measurement. Applying differential interferometric demodulation between the grating pairs, the authors obtained a strain resolution of $0.6\,\mathrm{n\varepsilon\,Hz^{-1/2}}$ and curvature resolution of $0.012\,\mathrm{km^{-1}\,Hz^{-1/2}}$ for measurement frequencies above 1 Hz, a 30 times improvement over the previous curvature measurements.

6 MEMS OPTICAL FIBER SENSORS

The ability to multiplex a large number of sensors into a single optical fiber is one of the key advantages to optical fiber sensors for structural health monitoring. Additionally, their relatively small size makes them reasonable to embed or surface mount to a variety of structures (*see* **Fiber-optic Sensor Principles**). However, more and more sensors are being developed for applications where size is critical, thus, necessitating microelectromechanical systems (MEMSs) fabrication techniques. To date, MEMS technology has primarily been applied to optical fiber sensors for Fabry–Perot temperature and pressure sensors (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**). Watson *et al.* [42] reviews the state of the art for low-profile external Fabry–Perot diaphragm sensors. However, due to their extrinsic nature, the outside diameters of these sensors are generally larger than the outside diameter of the optical fiber itself. To reduce the outside sensor diameter of end-face Fabry–Perot pressure sensors, Watson *et al.* [42] fabricated a MEMS Fabry–Perot sensor. The authors ablated the end of an optical fiber with an excimer laser, and then bonded an aluminized polycarbonate foil diaphragm to the end of the fiber, which can be seen in Figure 11. The laser ablation

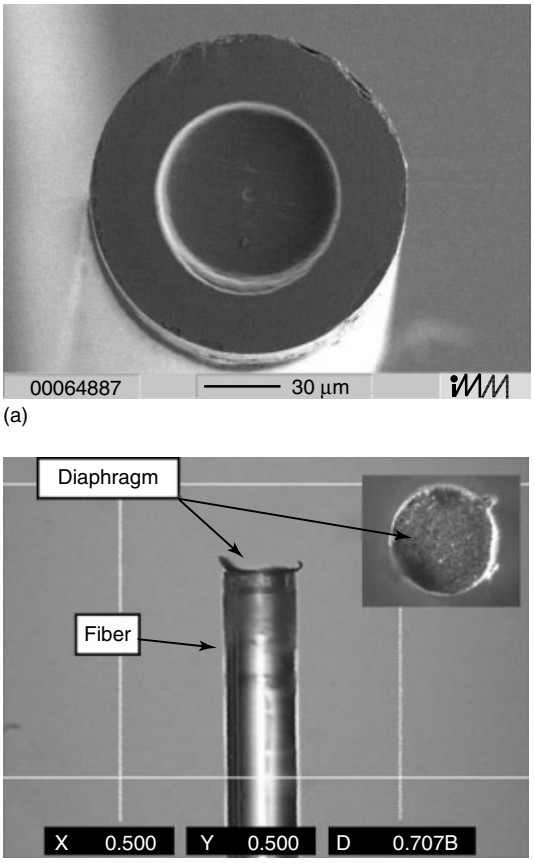

Figure 11. (a) A 70-µm-diameter cavity ablated into the end of a single-core fiber and (b) photograph of the side view of a single-core fiber sensor (the inset shows the top view). [Reproduced with permission from Ref. 42. © OSA Publishing, 2006.]

produced a good quality cavity; however, the authors encountered some difficulties due to tearing of the diaphragm during bonding and poor adhesion of the diaphragm.

The requirement to adhere the diaphragm with an adhesive glue also limits the temperature range over which such MEMS sensors can be applied [43]. Abeysinghe *et al.* [43], therefore, developed a Fabry–Perot temperature and pressure sensor without adhesives, also applying a MEMS fabrication technology. They micromachined the end of the optical fiber through wet etching to create a cavity similar to the last example, but then bonded a crystalline silicone membrane to the end face of the optical

fiber through anodic bonding. The authors experimentally demonstrated the excellent performance of the MEMS sensor in a 25–300 °F thermal environment.

At a smaller scale, Iannuzzi *et al.* [44] and Deladi *et al.* [45] machined a thin rectangular beam out of the cleaved edge of an optical fiber, as shown in Figure 12. The vertical displacement of the cantilever was determined by measuring the amplitude of interference of laser light reflected by the fiber–air interface and reflected by the cantilever. The authors prepared the cantilevered sensor by coating a standard single-mode optical fiber with a thin metallic layer (5-nm Cr, 20-nm Pd) and then machining the cantilever using focused ion beam machining. A 100-nm layer of silver was then deposited on the sensor to increase the reflectivities. For a further description of focused ion beam machining applied to optical fiber sensors, see Nellen and Brönnimann [46]. The authors demonstrated that the subnanometer displacement resolution of the cantilever beam sensor was comparable with results from atomic force microscopy.

7 CONCLUSIONS

This article reviews recent advances in fiber-optic sensor technology based on surface relief gratings and sapphire optical fibers for high-temperature applications; single-mode POFs for large-deformation sensors; and microstructured and multicore optical fibers. Applications of MEMs fabrication technique to fiber-optic sensors are also presented. These advances have extended the range for optical fiber sensors such that they can now be uniquely applied for structural health monitoring applications in extreme environments.

Chapter 60

Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors

Kara Peters

Department of Mechanical and Aerospace Engineering, North Carolina State University, Raleigh, NC, USA

1 INTRODUCTION

Optical-fiber sensors present numerous advantages for the measurement of strain, temperature, humidity, pressure, and other parameters. This article focuses on sensors that use the intrinsic properties of optical fibers themselves as a transducer. By evaluating the behavior of a lightwave propagating through an optical fiber, strain and temperature fields can thus be inferred from microbending, microfracture, or scattering losses that occur along the fiber. Alternatively, the phase shift of the propagating lightwave can be used to determine the strain or temperature profile along the fiber through the photoelastic effect. In comparison, fiber Bragg gratings and other optical-fiber sensors are reviewed in **Fiber Bragg Grating Sensors** and **Novel Fiber-optic Sensors**.

A summary of the fundamental principles for optical fibers, useful to understand the sensing phenomena described in this article, can be found in **Fiber-optic Sensor Principles**. General issues concerning the application of all the sensors described in this article to structural health-monitoring systems are also presented in **Fiber-optic Sensor Principles** and **Fiber-optic Sensors**.

2 INTENSITY-BASED OPTICAL-FIBER SENSORS

Intensity-based optical-fiber sensors are potentially the simplest in-fiber sensors to apply. Typically, these are based on the measurement of the loss of intensity transmitted through an optical fiber. Such sensors can be interrogated with low-cost lightwave sources and detection systems such as light emitting diodes (LEDs) and photodetectors. Measures *et al.* [1, 2] presented the first example of an intensity-based optical-fiber sensor for the

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

measurement of structural damage. As shown in Figure 1, the authors sensitized discrete regions of the optical fiber by etching the cladding to reduce the diameter of the optical fiber. The optical fibers were then embedded to form a two-dimensional grid network in an aircraft wing. The optical fiber in these regions was thus sensitive to damage at approximately the same level as the surrounding aramid fiber reinforced composite. During impact testing of the wing, microfractures in the optical fiber produced the bleeding of light from the fibers. By measuring the total intensity of the lightwave transmitted through each fiber, the researchers could therefore determine the extent of damage within the composite.

Intensity-based sensors that load the optical fiber through microbending have been developed for the measurement of strain, temperature, pressure, or other parameters [4–7]. Significant microbending along the optical fiber creates transmission losses that increase rapidly with the bend radius of curvature (*see* **Fiber-optic Sensor Principles**). Figure 2 presents a schematic of a typical microbend sensor design. As tensile strain is applied (for the example of Figure 2), the microbending applied to the optical fiber is reduced and therefore the transmitted intensity increases. Conversely, if compressive strain is applied, the transmitted intensity is reduced. To prevent errors due to fluctuations in the intensity of the light source, a reference optical fiber and a dual photodetector are also included. While relatively inexpensive, the accuracy of intensity-based sensors can be limited.

3 INTERFEROMETRIC OPTICAL FIBER SENSORS

Butter and Hocker [8] designed and demonstrated the first in-fiber strain sensor. This "fiber-optics strain gauge" was based on the measurement of the change in phase shift of a lightwave propagating through an optical fiber due to axial strain applied to the

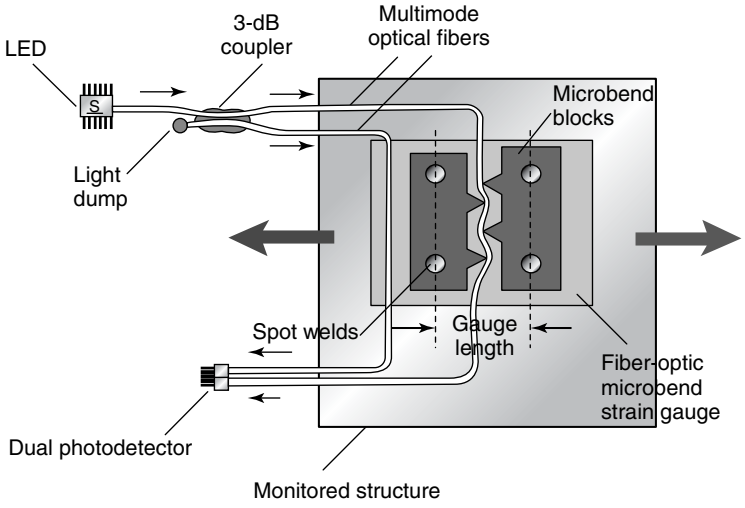

Figure 2. Schematic of a typical intensity-based microbend. [Reproduced with permission from Ref. 3. © Elsevier, 2001.]

optical fiber. This section derives the change in phase shift of the lightwave due to mechanical and thermal loads and presents common interferometer configurations for the measurement of this change in phase shift. Finally, more recent distributed interferometer sensor devices based on low-coherence interferometery and stimulated Brillouin scattering are also described.

3.1 Strain and temperature sensitivity

We assume that the optical-fiber material is an optically isotropic single crystal with an index of refraction in the unstressed state of n_0 (this would be the effective index of refraction of the fundamental mode, *see* **Fiber-optic Sensor Principles**). Since the fiber cross section is a two-dimensional surface, we define the orthogonal coordinate system with the axes p and q shown in Figure 3. These axes are the principal optical axes, which correspond to the propagation axes for the fiber. We write the field vector for an electromagnetic plane wave of wavelength λ, propagating in the axial, 1, direction (Figure 3) as

$$\mathbf{E} = A^p \mathbf{S}^p \sin\left[\omega t - \frac{2\pi n^p}{\lambda} x_1\right] + A^q \mathbf{S}^q \sin\left[\omega t - \frac{2\pi n^q}{\lambda} x_1\right] \qquad (1)$$

where $\mathbf{S}^p$ and $\mathbf{S}^q$ are orthogonal unit vectors in the 2–3 plane in the direction of the principle optical axes, ω is the angular frequency of the lightwave, and A^p and A^q are the amplitudes of the orthogonal components [9]. The propagating lightwave is thus split into two orthogonal lightwaves, both with the same wavelength and frequency as the original wave, but each experiencing a separate index of refraction, n^p and n^q.

The vector field, $\mathbf{E}$, must satisfy the planar wave equation

$$\mathbf{R} \times (\mathbf{R} \times \mathbf{B}\mathbf{E}) + \frac{1}{n^2}\mathbf{E} = 0 \qquad (2)$$

where n is the index of refraction experienced by the field and $\mathbf{R}$ is the unit vector in the direction of propagation; in this case, $\mathbf{R} = (1, 0, 0)$. The tensor $\mathbf{B}$ is the material dielectric impermeability tensor,

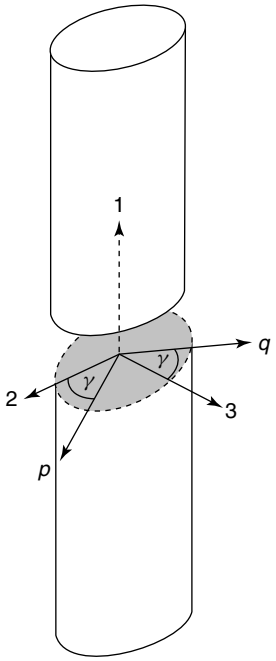

Figure 3. Sketch of optical fiber with coordinate systems highlighted on an arbitrary cross section ($p - q$ are the principal optical axes; 1–2–3 are the applied strain directions).

which is directly related to the index of refraction of the material.

$$\mathbf{B} = \begin{bmatrix} B_1 & B_6 & B_5 \\ B_6 & B_2 & B_4 \\ B_5 & B_4 & B_3 \end{bmatrix} \qquad (3)$$

For an isotropic material, $B_1 = B_2 = B_3 = n_0$, $B_4 = B_5 = B_6 = 0$ [10]. Since the vector field is propagating in the 1 direction, $\mathbf{E}$ has spatial components in the 2 and 3 directions, $\mathbf{E} = (0, E_2, E_3)$. Substituting $\mathbf{E}$ and $\mathbf{R}$ into equation (2) and expanding yields the two equations

$$\begin{bmatrix} B_2 - 1/n^2 & B_4 \\ B_4 & B_3 - 1/n^2 \end{bmatrix} \begin{pmatrix} E_2 \\ E_3 \end{pmatrix} = 0 \qquad (4)$$

Nontrivial solutions for E_2 and E_3 occur only when the determinate of the matrix on the left-hand side is zero. Applying this condition and solving for n yields

$$\frac{1}{n^2} = \frac{(B_2 + B_3) \pm \sqrt{(B_2 - B_3)^2 + 4B_4^2}}{2} \qquad (5)$$

In general, there are therefore two solutions to n, which we previously labeled as n^p and n^q. For the isotropic fiber, we simply have $n^p = n^q = n_0$; therefore, there is only one propagation solution.

The next step is to calculate the change in phase shift of the lightwave propagating through a length L of the optical fiber. As the lightwave, **E**, propagates through the optical fiber, it experiences a total phase shift, φ,

$$\varphi = \beta L = \frac{2\pi}{\lambda} nL \tag{6}$$

β is thus the propagation constant or phase shift per unit length, $\beta = 2\pi n/\lambda$. Once strain or thermal loading is applied to the optical fiber, both the length of the fiber and the effective index of refraction change, altering the phase shift of the propagating lightwave [8],

$$\Delta\varphi = \frac{2\pi}{\lambda}(\Delta nL + n\Delta L) \tag{7}$$

The change in length of the optical fiber is directly related to the axial strain, ε_1, and the coefficient of thermal expansion, α, as $\Delta L = \varepsilon_1 L + \alpha \Delta T$.

We now calculate the term Δn of equation (7). The photoelastic effect describes the change in optical properties of the material due to strain and temperature. Since the components of the tensor **B** are dependent on the material indices of refraction, we can write $B_i = B_i^0 + \Delta B_i$ and apply this to equation (5). Simplifying this expression and using the isotropic values for B_i^0, we find

$$\frac{1}{n^2} = \frac{1}{n_0^2} + \frac{(\Delta B_2 + \Delta B_3) \pm \sqrt{(\Delta B_2 - \Delta B_3)^2 + 4\Delta B_4^2}}{2} \tag{8}$$

Assuming the applied strains are small, we can apply the linear thermoelastic strain-optic effect, which can be written as

$$\Delta B_i = p_{ij}(\varepsilon_j - \alpha_j \Delta T) + W_i \Delta T \tag{9}$$

where the summation convention is applied and the strain components are written in compact notation [9]. Here we consider that all six components of strain can be applied to the optical fiber; more specific loading cases will be considered later. The terms W_i are the changes in B_i due to temperature measured at a constant stress state, $W_i = \partial B_i / \partial \Delta T|_{\sigma=\text{const.}}$. The components of the **p** matrix are commonly referred to as the *Pockel's constants* for the material. For an isotropic material, **p** has the form [10]

$$\mathbf{p} = \begin{bmatrix} p_{11} & p_{12} & p_{12} & 0 & 0 & 0 \\ p_{12} & p_{11} & p_{12} & 0 & 0 & 0 \\ p_{12} & p_{12} & p_{11} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{(p_{11}-p_{12})}{2} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{(p_{11}-p_{12})}{2} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{(p_{11}-p_{12})}{2} \end{bmatrix} \tag{10}$$

Similarly, for an isotropic material,

$$\mathbf{W} = \begin{bmatrix} -\frac{2}{n_0^3}\frac{\mathrm{d}n_0}{\mathrm{d}T} \\ -\frac{2}{n_0^3}\frac{\mathrm{d}n_0}{\mathrm{d}T} \\ -\frac{2}{n_0^3}\frac{\mathrm{d}n_0}{\mathrm{d}T} \\ 0 \\ 0 \\ 0 \end{bmatrix} \tag{11}$$

Typical values for fused silica fibers are $p_{11} = 0.17$, $p_{12} = 0.36$, $\mathrm{d}n_0/\mathrm{d}T = 1.2 \times 10^{-5}/^{\circ}\mathrm{C}$ [9]. Combining equations (8–11), we find the general expression for the index change due to strain and temperature loading

$$\frac{1}{n^2} = \frac{1}{n_0^2} + p_{12}\varepsilon_1 + \frac{(p_{11}+p_{12})}{2}(\varepsilon_1 + \varepsilon_2) \pm \frac{(p_{11}-p_{12})}{2}\sqrt{(\varepsilon_2 - \varepsilon_3)^2 + 4\varepsilon_4^2} - \frac{2}{n_0^3}\frac{\mathrm{d}n_0}{\mathrm{d}T}\Delta T - \alpha\Delta T(p_{11} + 2p_{12}) \tag{12}$$

where the strain components are the total strain due to both the thermal and mechanical loading.

Considering the specific case of pure axial tension without thermal loading, for which $\varepsilon_1 = \varepsilon$, $\varepsilon_2 = \varepsilon_3 = -\nu\varepsilon$, we find

$$\frac{1}{n^2} = \frac{1}{n_0^2} + \left[p_{12} - \nu(p_{11} + p_{12})\right]\varepsilon \tag{13}$$

Calculating $n - n_0$ and linearizing with respect to strain, we find

$$\Delta n = -\frac{1}{2} n_0^3 \left[p_{12} - \nu(p_{11} + p_{12}) \right] \varepsilon \qquad (14)$$

and substituting into equation (7),

$$\begin{aligned} \Delta\varphi &= \frac{2\pi}{\lambda} n_0 L \varepsilon \left\{ 1 - \frac{1}{2} n_0^2 \left[p_{12} - \nu(p_{11} + p_{12}) \right] \right\} \\ &= \frac{2\pi}{\lambda} n_0 L \varepsilon (1 - p_e) \end{aligned} \qquad (15)$$

where p_e is referred to as the *effective photoelastic constant* for applied axial strain [8]. The phase shift is therefore linearly proportional to the change in length of the optical fiber, or the applied strain.

Adding the effect of a temperature change ΔT to equation (15), where the axial elongation ε is now the total axial elongation, we find

$$\begin{aligned} \Delta\varphi = \frac{2\pi}{\lambda} n_0 L \Bigg\{ &\varepsilon - \frac{1}{2} \varepsilon n_0^2 \left[p_{12} - \nu(p_{11} + p_{12}) \right] \\ &+ \frac{1}{n_0} \frac{\mathrm{d}n_0}{\mathrm{d}T} \Delta T + \frac{n_0^2}{2} (p_{11} + 2p_{12}) \alpha \Delta T \Bigg\} \end{aligned} \qquad (16)$$

[9]. Typical material property values for fused silica are $\nu = 0.16$ and $\alpha = 0.5 \times 10^{-6}/\,^{\circ}\mathrm{C}$.

The above equations consider a constant strain field applied along the gauge length of the optical fiber. In general, the fiber can be mounted in any orientation on a surface; therefore, these strain components can also vary along the length of the gauge. Sirkis and Haslach [11] first calculated the total phase shift, φ, in the optical fiber due to a known strain field. We define the variable s to be the variable along the path length of the fiber. We find the total phase shift by integrating the local phase shift along the optical fiber

$$\begin{aligned} \varphi &= \int_0^L \left(\frac{\mathrm{d}\varphi}{\mathrm{d}s} \right) \mathrm{d}s \\ &= \left(\frac{2\pi}{\lambda} \right) \int_0^L n_0 (1 - p_e)(1 + \varepsilon_n)\, \mathrm{d}s \end{aligned} \qquad (17)$$

where ε_n is the strain component tangent to the fiber path at each location. Sirkis and Haslach also showed that transfer of shear stress and transverse stresses was negligible for surface-mounted sensors; however, these components could be significant for sensors embedded in materials. Details on the inclusion of these strain components for embedded sensors can be found in [9, 12].

3.2 Conventional interferometers

Interferometric sensors present an extremely high sensitivity to external parameters. Additionally, as the optical fiber itself is used as the measurement device, such sensors are beneficial for simplicity and cost as compared to other optical fiber–based sensors. When using an optical fiber as strain sensor, it is not possible to measure the phase shift directly, and therefore we typically measure the interference between the sensor fiber and a second, reference fiber, which is not exposed to the environmental changes and therefore has a constant phase shift. Additionally, this second fiber can be exposed to only some of the loading, for example, temperature, so as to provide compensation during the measurements. The interferometric measurement of phase shifts for in-fiber sensors parallels that for classical free-space interferometers. The two most commonly applied interferometric arrangements are the Mach–Zehnder and Michelson interferometers [13]. Figures 4 and 5 show each of these classical interferometers and their equivalent for in-fiber sensors.

Assuming that the light source has a high coherence length and polarization effects are compensated between the two fibers, the average intensity of the interference pattern varies sinusoidally, as shown in Figure 6. The cyclic form of the intensity measurement presents two challenges when the intensity is near one of the quadrature points, i.e., where $\mathrm{d}I/\mathrm{d}\varphi = 0$. The first challenge is that the direction of fringe movement cannot be determined at the quadrature point (directional ambiguity) and the second is that the measurement sensitivity goes to zero at the same point (signal fading). A variety of signal-processing techniques have been applied to remove these difficulties, generally categorized into passive and active demodulation. Each of these categories can be further divided on the basis of whether the output signal is divided into multiple branches at the same frequency (homodyne) or different frequencies (heterodyne) [14]. One example of a passive homodyne demodulation is shown in Figure 6. For

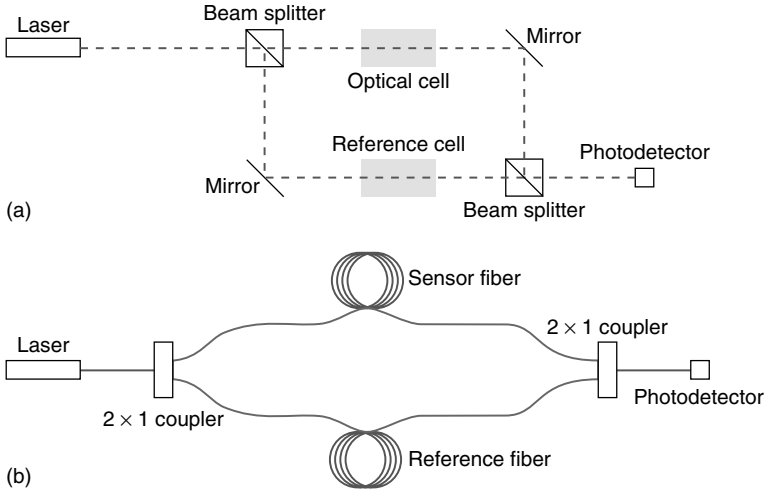

Figure 4. Schematic of Mach–Zehnder interferometer: (a) free-space optics version measures the difference in optical path length through the optical cell and reference cell and (b) in-fiber version measures the difference in optical path length through sensor fiber and reference fiber.

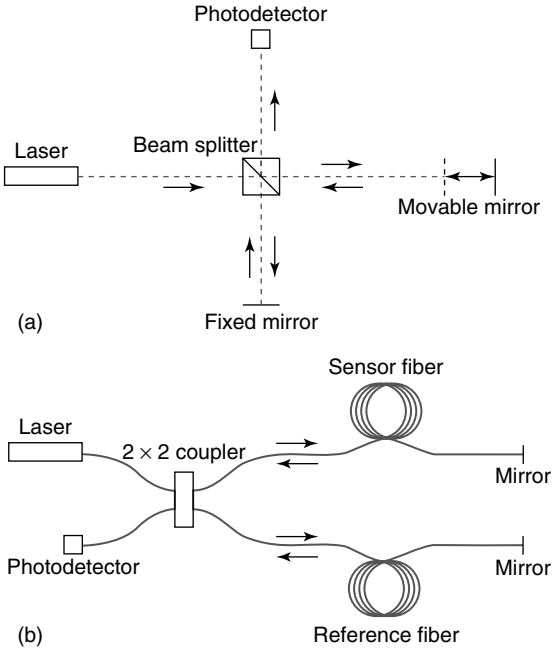

Figure 5. Schematic of Michelson interferometer: (a) free-space optics version and (b) in-fiber version.

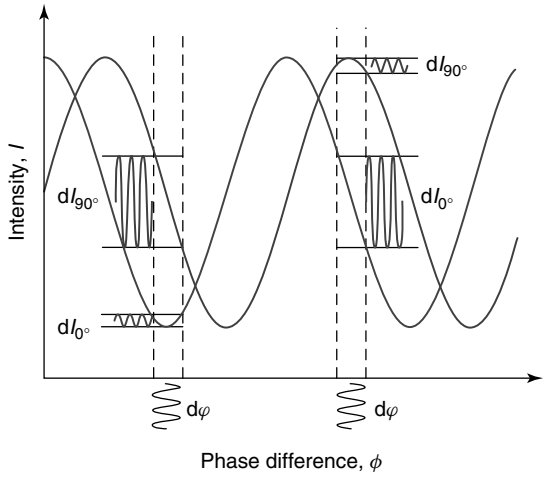

Figure 6. Intensity signals as a function of interferometer phase difference for two sensor signals, phase shifted by 0° and 90°. When one signal is as a quadrature point ($dI/d\varphi = 0$), the other is at the location of maximum sensitivity. [Reproduced from Ref. 14. © John Wiley & Sons Inc., 2006.]

this example, the sensor lightwave is divided into two channels, with one phase shifted by 90°, and interfered with the reference lightwave. As seen in Figure 6, when one signal is near a quadrature point, the other is at the point of maximum sensitivity, removing both the signal fading and directional ambiguity issues. A second popular example of passive demodulation is the use of a 3×3 coupler, exploiting the phase shifts between the various outputs [15]. Active homodyne demodulation involves actively

loading the reference fiber to keep the interferometer signal 90° from the quadrature point (or at the quadrature point for some examples), for example, by wrapping the reference fiber around a piezoelectric cylinder [16]. Kersey [17] reviews multiplexing strategies for interferometric optical-fiber sensors, including time-division multiplexing and frequency-division multiplexing examples.

The measurement of phase shift is not an absolute measurement. Specifically, in order to know the current strain level, the system must be continually operated throughout the lifetime of the structure. This presents significant challenges for monitoring of structures since power interruptions could invalidate all later measurements. One solution to this problem is through low-coherence interferometry, which is described in the following section.

3.3 Low-coherence interferometers

One technique to provide an absolute measurement is through the use of low-coherence interferometry, also referred to as *white-light interferometry*. This measurement technique is particularly useful for large structural applications as the spatial resolution is significantly less than the previous interferometers. However, the system would not be affected by power interruptions that may occur over the lifetime of the structure. Until recently, low-coherence interferometry had also been limited to quasi-static applications; however, it has been demonstrated successfully in many field applications. Bock *et al.* [18] applied low coherence in high-birefringence fibers (*see* **Fiber-optic Sensor Principles**) for the measurement of pressure. Inaudi *et al.* [19] embedded low-coherence interferometric sensors in a concrete structure to measure shrinkage of the concrete during cure and later strain during loading of the structure. Yuan and Ansari [20] applied a similar embedded low-coherence interferometric sensor to measure crack-tip openings in a concrete structure.

The fundamental measurement concept applied to low-coherence interferometric sensors is to interrogate a primary interferometer consisting of a sensor and reference arm (referred to as the *sensing interferometer*) with a second similar interferometer for which the optical path difference between the two arms can be scanned (referred to as the *scanning interferometer*). A typical low-coherence interferometer configuration for optical-fiber sensors is shown in Figure 7. Interference fringes are observed only when the optical path difference in the scanning interferometer is within the coherence length of the laser or when the optical path difference between the two interferometers is within the same coherence length. By selecting a laser source with an extremely low-coherence length such as a superluminescent diode or multimode laser diode, the displacement of the sensing interferometer can be determined within a reasonable precision [21].

The interference between two beams from a low-coherence source can be described by

$$I = I_0\left[1 + V(nx)\cos\left(\frac{2\pi}{\lambda}nx\right)\right] \qquad (18)$$

where nx is the optical path difference in the interferometer, I_0 is the mean intensity, and V is the variation in fringe visibility as a function of optical path difference for the laser source (typically a Gaussian profile) [22]. This equation yields a wave packet whose width is approximately equal to the coherence length and centered around the condition $nx = 0$, as seen in Figure 8. For the interferometer of Figure 7, the optical path difference in the sensing interferometer to be measured is ΔL_1. The movable mirror in the scanning interferometer is displaced while the interference pattern between the two interferometers is measured. When $\Delta L_2 \cong 0$, the strongest interference occurs (as seen in Figure 8), and this condition is used as a reference point. For $\Delta L_2 \cong +\Delta L_1$, the phase imbalance in the sensing interferometer is offset by the phase imbalance of the scanning interferometer for a portion of the lightwave. Thus, interference also occurs at a lower maximum intensity. From these two measurements, ΔL_1 can be determined, which is the optical path difference in the original sensing interferometer. As in the previous section, this optical path difference can then be converted into the physical change in length of the sensing fiber, ΔL, through [19]

$$\Delta L = \frac{\Delta L_1}{n_0(1 - p_e)} \qquad (19)$$

Inaudi *et al.* [19] demonstrated a low-coherence optical-fiber sensor using a LED with a coherence length of 30 μm. By calculating the center of

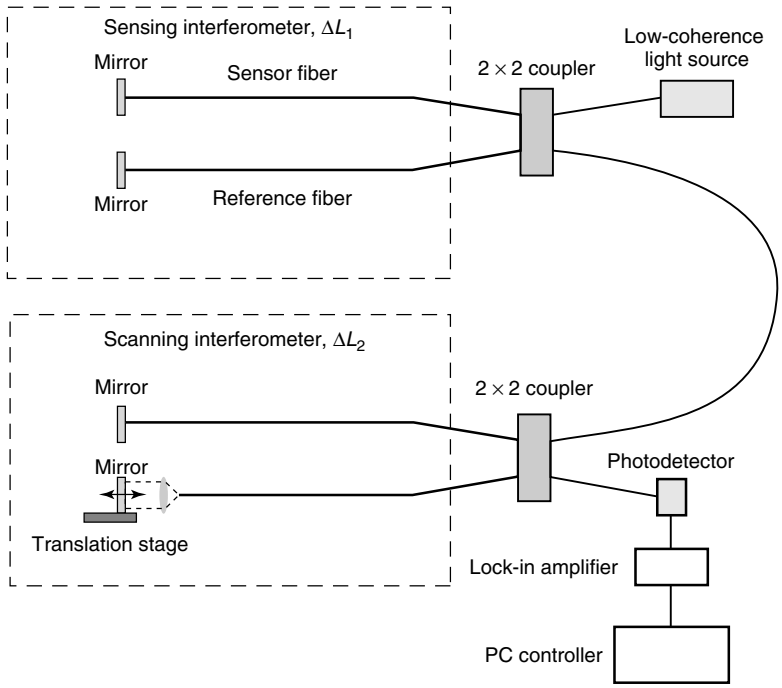

Figure 7. Typical low-coherence in-fiber interferometer configuration. [Reproduced with permission from Ref. 19. © Elsevier, 1994.]

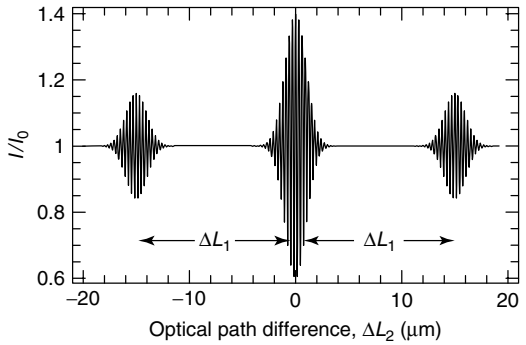

Figure 8. Interference signal from double Michelson interferometer with low-coherence source shown in Figure 7. [Reproduced with permission from Ref. 19. © Elsevier, 1994.]

gravity of the interference pattern, they were able to increase the displacement resolution to 10 μm. Rao and Jackson [23] provide an excellent review of signal processing for low-coherence interferometric sensors, as well as methods to increase the accuracy of the maximum point on the interference envelope. Meggitt *et al.* [22] replaced the translational stage for the scanning mirror by wrapping an optical fiber around a piezoelectric cylinder. Therefore, the optical path difference could be scanned by applying an electrical current to the cylinder, without the need for externally moving components.

To increase the spatial resolution of the basic low-coherence interferometer for structural measurements, Inaudi [24] implemented partial reflectors along the sensing arm to provide multiple interference lengths. By placing the reflectors sufficiently apart and scanning all possible interference distances, it is possible to use the same interrogation system for multiple sensors. A typical output from this system, demonstrating the interference lengths for each sensor, is shown in Figure 9. Later, Yuan and Ansari [25] multiplexed several sensing lengths using partial reflectors and a low-coherence source; however, they applied N balance arms for N sensors and switched between the balance arms to measure each sensor. Most recently, Lloret *et al.* [26] applied amplitude modulation of the low-coherence light source at high frequencies to obtain dynamic strain measurements up to 100 Hz.

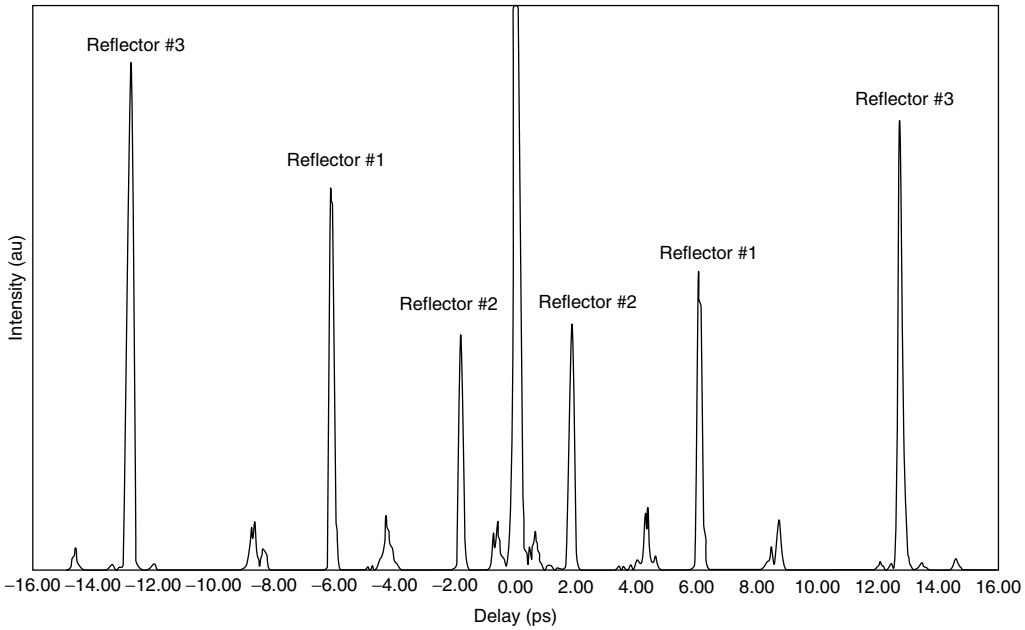

Figure 9. Interference signal from multiplexed low-coherence interferometric sensors (only envelope of demodulation signal is plotted). [Reproduced with permission from Ref. 24. © SPIE, 1995.]

3.4 Fabry–Perot interferometers

A second absolute interferometer configuration is the Fabry–Perot interferometer (FPI), first demonstrated by Murphy *et al.* [27]. FPI sensors provide local strain and temperature measurements. FPI sensors have been surface mounted on composites for the measurement of acoustic emission signals [28] and impact detection [29]. They have also been embedded in composite structures for the detection and measurement of fatigue crack propagation in bonded composite patch repairs [30], delamination and buckling [31], process-induced residual stresses [32], and the development of impact damage [33]. They have also been combined with fiber Bragg grating sensors for the independent measurement of strain and temperature [34] (*see* **Fiber Bragg Grating Sensors**). The miniaturization of FPI sensors is also discussed in **Novel Fiber-optic Sensors**.

A schematic of a Fabry–Perot in an optical fiber is shown in Figure 10(a). The sensor cavity of length L is formed between two partial reflectors with reflectivities r_1 and r_2. These partial reflectors are typically partial mirrors, but fiber Bragg gratings have also been used [35]. For high reflectivity values, the FPI acts as a "multipass" interferometer whose transmission characteristics are wavelength dependent. We can assume that no losses are incurred at the reflectors so that the transmissivities $t_1 = 1 - r_1$ and $t_2 = 1 - r_2$. The cavity itself can be a section of the optical fiber (as shown in Figure 10a) for which the sensor is termed *intrinsic*. Extrinsic FPIs can be formed using external air gaps or other mediums to be analyzed. An example of an extrinsic Fabry–Perot interferometer (EFPI) is shown in Figure 10(b). Extrinsic FPI sensors are larger than intrinsic sensors and therefore more intrusive; however, they are easier to fabricate and have less inherent noise. They also demonstrate low transverse strain sensitivities and low apparent thermal strains [36].

To calculate the response of the FPI, we define the index of refraction of the cavity medium as n. Considering a plane wave (arriving from the left in Figure 10a) that has passed through the first reflector, we can write its time-averaged (or steady-state) amplitude as $E = E_0 \exp(\mathrm{i}\beta z)$ (*see* **Fiber-optic Sensor Principles**). When this wave reaches the second partial reflector $E = E_0 \exp(\mathrm{i}\beta L)$, the transmitted and reflected portions of the waves are

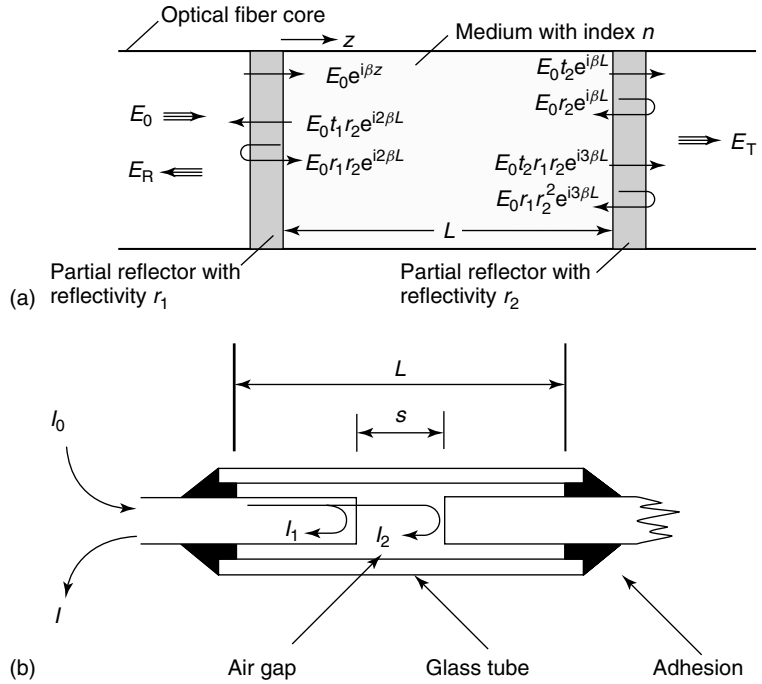

Figure 10. (a) Representation of multipass interference in a Fabry–Perot interferometer and (b) extrinsic Fabry–Perot interferometer. [Reproduced from Ref. 31. © Sage Publications, 2000.]

$E_t = t_2 E_0 \exp(i\beta L)$ and $E_r = r_2 E_0 \exp(i\beta L)$ respectively. The reflected portion then reaches the first partial reflector, at which point $E = r_2 E_0 \exp(i2\beta L)$. The reflected portion of this wave reaches the second reflector, at which point $E_t = t_2 r_1 r_2 E_0 \exp(i2\beta L)$ and $E_r = r_1 r_2^2 E_0 \exp(i2\beta L)$.

Continuing these calculations for an infinite number of passes, we find the total lightwave exiting the FPI to the right,

$$\begin{aligned} E_T &= t_2 E_0 \exp(i\beta L)\left[1 + r_1 r_2 \exp(2i\beta L)\right. \\ &\quad \left. + r_1^2 r_2^2 \exp(4i\beta L) + \cdots\right] \\ &= \frac{E_0 t_2 \exp(i\beta L)}{1 - r_1 r_2 \exp(2i\beta L)} \end{aligned} \tag{20}$$

We could also calculate the total lightwave reflected from the cavity, $E_R = E_0 - E_T$. The intensity of the transmitted lightwave is then

$$I_T = \frac{1}{2}\varepsilon_0 c |E_T|^2 = \frac{I_0 t_2^2}{(1-R)^2[1 + \mathcal{F}\sin^2(\beta L)]} \tag{21}$$

where ε_0 is the permittivity of the vacuum ($\varepsilon_0 = 8.854 \times 10^{-12}\,\mathrm{F\,m^{-1}}$), c is the speed of light in a vacuum, $R^2 = r_1 r_2$, and $I_0 = \varepsilon_0 c E_0^2/2$ is the intensity of the input lightwave. The coefficient $\mathcal{F}$ is referred to as the *coefficient of finesse* of the FPI and determines the response characteristics of the FPI. $\mathcal{F}$ is given by the expression

$$\mathcal{F} = \frac{4R}{(1-R)^2} \tag{22}$$

Figure 11 plots the normalized transmitted intensity of the FPI as a function of wavelength. The peaks in the transmission spectrum correspond to the condition $L = m\lambda/2n$, where m is an integer. By measuring the wavelength location of one of these peaks, one can determine the length of the cavity and therefore the applied strain, displacement, pressure, or temperature. For this measurement strategy, it is best to have high finesse values to narrow the peaks as much as possible [37]. Spectral measurements provide absolute strain or temperature measurements without the problems of directional ambiguity and signal fading previously described.

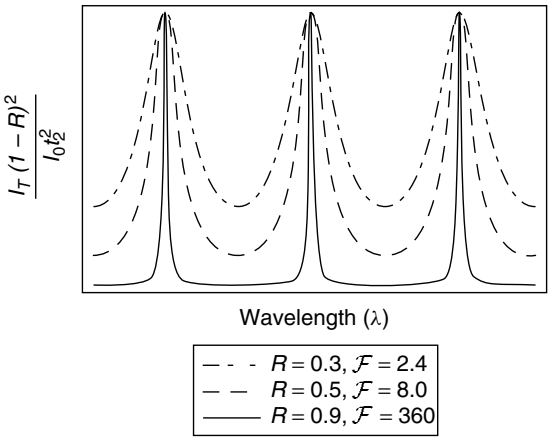

Figure 11. Typical normalized transmitted intensity spectrum for a Fabry–Perot interferometer. Three different finesse values are plotted.

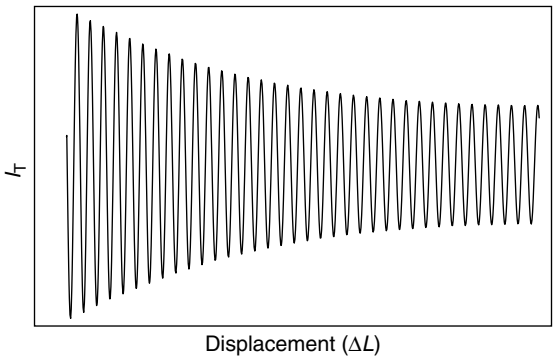

Figure 12. Transmitted intensity for a low-finesse Fabry–Perot interferometer as a function of displacement of one of the reflectors ($R = 0.1, \mathcal{F} = 0.49$).

High-speed interrogation of spectral sensors is discussed in **Fiber Bragg Grating Sensors**. Rao [38] presents a review of multiplexing and signal interrogation of FPI sensors.

Alternatively, low-finesse FPI sensors can also be applied for high-resolution, dynamic strain sensing [27]. For very low values of reflectivity (and finesse), the FPI acts as essentially a two-beam interferometer. A plot of the response of a low-finesse FPI as a function of the displacement of one of the mirrors is shown in Figure 12. For small displacements, this sensor can be interrogated similar to the Mach–Zehnder or Michelson configurations previously described. Various signal interrogation methods have been applied to remove the direction ambiguity including quadrature phase shifted signals [27], path-matched differential interferometry [39], and low-coherence interferometry [40, 41].

4 SCATTERING-BASED OPTICAL-FIBER SENSORS

A final property of optical fibers that has been exploited for the measurement of strain and temperature is the intrinsic scattering property of the fused silica material. As a lightwave propagates through the optical fiber, an extremely small portion is backscattered owing to local inhomogeneities in the material and therefore the index of refraction. Several forms of scattered waves can be detected, including Rayleigh, Brillouin, and Raman components. Figure 13 shows a typical scattering spectrum for an optical fiber. As can be seen, the Rayleigh component is the largest component of the scattering spectrum. Brillouin scattering occurs due to interactions with acoustic waves known as *phonons* and is therefore frequency shifted (through the Doppler effect) as compared to the Rayleigh scattering component. This frequency shift is dependent upon the local density of the fused silica and is therefore linearly related to applied strain or temperature [42]. The Brillouin backscattered light is an extremely weak signal and difficult to measure outside of the laboratory; however, this scattering can be amplified by stimulating acoustic waves through the use of a second pulsed laser connected to the opposite end of the optical fiber. By scanning the frequency of the pulsed laser, the relative frequency shifts at which the stimulated

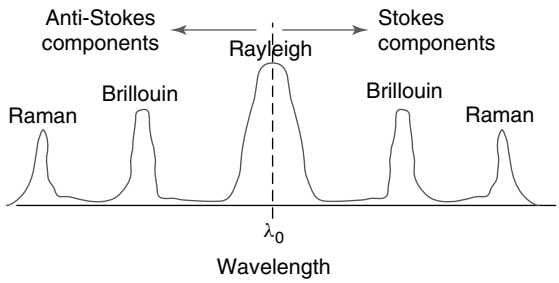

Figure 13. Spectrum of intrinsic material scattering for fused silica. Stokes and anti-Stokes components are indicated.

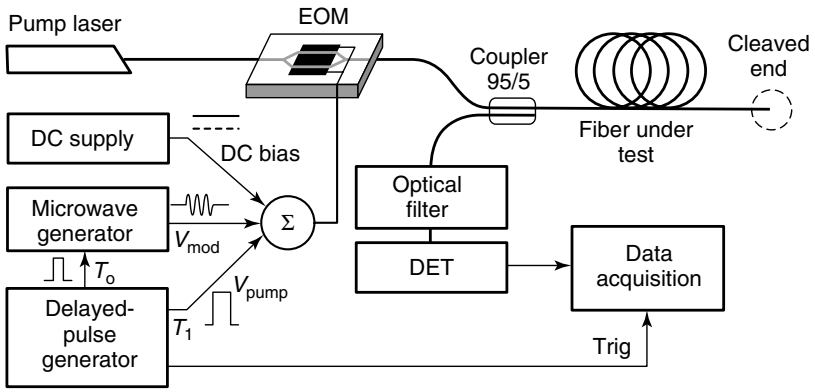

Figure 14. Experimental setup for distributed Brillouin gain spectrum analysis. [Reproduced with permission from Ref. 43. © 1996, OSA Publishing.]

Brillouin scattering occurs can be identified and converted into the applied strain or temperature. To determine the location of each Brillouin scattering event, the time of arrival of the scattered light is interrogated. In this manner, the strain or temperature distribution along an optical fiber can be measured. A schematic of a typical stimulated Brillouin scattering data-acquisition system is shown in Figure 14. Bao *et al.* [42] first demonstrated the use of stimulated Brillouin scattering as a temperature and strain sensor, achieving a strain and temperature resolution of $20\,\mu\varepsilon$ and $2\,^{\circ}\mathrm{C}$ with a spatial resolution of 5 m, over a sensing length of 22 km. Later, Niklès *et al.* [43] improved the strain and temperature resolution to $5\,\mu\varepsilon$ and $0.25\,^{\circ}\mathrm{C}$ using a single laser source, however, with a spatial resolution of 35 m.

Brillouin scattering–based optical-fiber sensors provide a unique distributed sensing capability using only the intrinsic properties of the optical fiber itself. Generally, such sensors have been applied for the monitoring of large-scale structures due to the limits on the spatial resolution. Example applications include composite cure sensing [44], monitoring of steel beam and composite fuselage structures [45, 46], and damage identification in sandwich composites [47]. At the same time, researchers have recently applied signal-processing techniques and hardware configurations to reduce the spatial resolution substantially. For example, Song *et al.* [48] recently demonstrated a spatial resolution of 1.6 mm, applying Brillouin optical correlation domain analysis.

5 CONCLUSIONS

As reviewed in this chapter, optical fibers can be applied as strain and temperature sensors through their intrinsic properties. Intensity-based optical-fiber sensors offer low-cost, simple solutions to complete optical measurements. For more precise measurements, a variety of interferometer configurations and interrogation methods are also available, including variations for high-speed and absolute measurements. Finally, low-coherence interferometry and stimulated Brillouin scattering–based sensors permit distributed measurements for large structural applications. As compared to their electrical counterparts, optical-fiber sensors can require more complicated and expensive instrumentation. On the other hand, they can be readily multiplexed into large sensor networks with a single data-acquisition system and can therefore be less obtrusive to the structure. Additionally, the distributed examples discussed in this article emphasize that simple optical fibers can be used to instrument large structures without the need to monitor a large number of sensors.

Chapter 55
Piezoelectric Wafer Active Sensors

Lingyu Yu and Victor Giurgiutiu
University of South Carolina, Columbia, SC, USA

1 INTRODUCTION

In recent years, piezoelectric wafer active sensors (PWAS) permanently attached to the host structures have been used for guided-wave generation and detection during the structural health monitoring (SHM) process. PWAS are inexpensive transducers that operate on the piezoelectric principle. PWAS are used for SHM employing the following three methods: (i) modal analysis and transfer function; (ii) electromechanical (E/M) impedance; and (iii) wave propagation. The use of PWAS for high-frequency local modal sensing with the E/M impedance method as well as for damage detection with Lamb wave propagation has been pursued by many researchers [1]. PWAS are no more expensive than conventional high-quality resistance strain gauges. However, PWAS performance by far exceeds that of conventional resistance strain gauges because they can be used as active interrogators. PWAS can be used in high-frequency applications at hundreds of kilohertz and beyond. In summary, PWAS can be used in several ways:

1. Piezoelectric resonator
A PWAS has the property of performing mechanical resonances under direct electrical excitation; thus, very precise frequency standards can be created with a simple setup consisting of the PWAS and a signal generator. The resonant frequencies depend only on the wave speed in the PWAS material and the geometric dimensions. Precise frequency values can be obtained through machining the PWAS geometry.

2. High bandwidth strain exciter and detector
As an exciter, a PWAS directly converts electrical energy into mechanical energy; thus, it can easily induce vibrations and waves in the substrate material. PWAS acts very well as an embedded generator of waves and vibration. High-frequency waves and vibrations are easily excited with input signals as low as 10 V. As a sensor, PWAS directly converts

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

mechanical energy to electrical energy. The conversion effectiveness increases with the signal frequency. In the kilohertz range, signals of the order of hundreds of millivolt are easily obtained. No conditioning amplifiers are needed; the PWAS can be directly connected to a high-impedance measurement instrument, such as a digitizing oscilloscope. These dual-sensing and excitation characteristics of PWAS justify their name of "active sensors". A particularly fruitful application is the PWAS phased-array approach, which uses steered guided waves to effectively scan large areas of thin-wall structures from a single location.

3. High-frequency modal sensor

The PWAS can directly measure the high-frequency modal spectrum of the support structure. This is achieved with the E/M impedance method, which reflects the mechanical impedance of the support structure into the real part of the electrical impedance measured at PWAS terminals. The high-frequency characteristic of this method, which has been proven to operate at hundreds of kilohertz and beyond, cannot be achieved with conventional modal instrumentation techniques. Thus, PWAS are the sensors of choice for high-frequency modal measurement and analysis.

2 PWAS PRINCIPLES

This section addresses the behavior of a bonded (constrained) PWAS when excited by an alternating electric voltage. As shown in Figure 1(a), PWAS are small and unobtrusive and utilize the coupling between in-plane strain and transverse electric field. A 5 mm × 5 mm × 0.2 mm square PWAS weighs about 50 mg and costs about $10.

2.1 1D PWAS analysis

Consider a PWAS of length l_a, width b_a, and thickness t_a that is undergoing longitudinal expansion (u_1) induced by the thickness polarization electric field (E_3), as shown in Figure 1(b). The electric field is produced by the application of a harmonic voltage, $V(t) = \hat{V}e^{j\omega t}$, between the top and bottom surfaces (electrodes). The resulting electric field, $E_3 = V/t$, is assumed to be uniform over the PWAS. Assume that h, b, l have widely separated values ($h \ll b \ll l$) such that the length, width, and thickness motions are practically uncoupled. The motion predominantly in the longitudinal direction (x_1) will be considered (1D assumption). PWAS operate on the piezoelectric principle that couples the electrical and mechanical variables in the material in the form

$$S_1 = s_{11}^E T_1 + d_{31} E_3 \tag{1}$$

$$D_3 = d_{31} T_1 + \varepsilon_{33}^T E_3 \tag{2}$$

where S_1 is the strain, T_1 is the stress, D_3 is the electrical displacement (charge per unit area), s_{11}^E is the mechanical compliance at zero field, ε_{33}^T is the dielectric constant at zero stress, and d_{31} is the induced strain coefficient (mechanical strain per unit electric field). When PWAS is bonded to the structure, the structure constrains the PWAS motion with a structural stiffness (k_{str}); that is to say, PWAS are elastically constrained as shown in Figure 1(b). In this model, the overall structural stiffness applied to the PWAS is split into two equal components, $2k_{\text{str}}$ each, applied to the ends of the PWAS, such that

$$k_{\text{total}} = \left[\left(2k_{\text{str}}\right)^{-1} + \left(2k_{\text{str}}\right)^{-1}\right]^{-1} = k_{\text{str}} \tag{3}$$

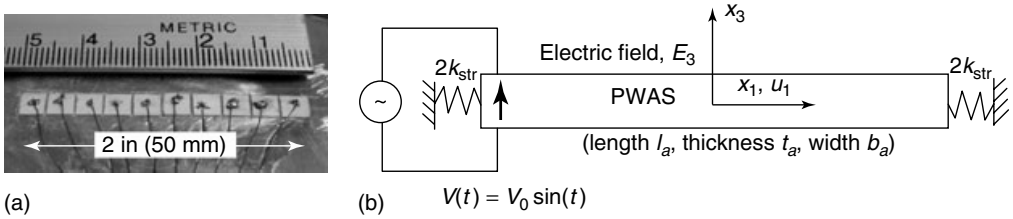

Figure 1. Embedded piezoelectric wafer active sensors: (a) a phased array composed of 10 PWAS, each 5-mm square, permanently attached to the host structure and (b) a one-dimensional bonded PWAS under electric excitation, constrained by structural stiffness k_{str}.

Note that the effective structural stiffness, k_{str}, is a frequency-dependent complex quantity reflecting the structural dynamics. The boundary conditions applied at the ends of the PWAS balance the resulting stress ($T_1 b_a t_a$) with the spring reaction force ($2k_{\text{str}}u_1$)

$$T_1\left(\frac{l_a}{2}\right)b_a t_a = -2k_{\text{str}}u_1\left(\frac{l_a}{2}\right),$$
$$T_1\left(-\frac{l_a}{2}\right)b_a t_a = 2k_{\text{str}}u_1\left(-\frac{l_a}{2}\right) \tag{4}$$

Using the Newton's law of motion ($T_1' = \rho\ddot{u}_1$) and the strain-displacement relation ($S_1 = u_1'$), the axial wave equation can be obtained:

$$\ddot{u}_1 = c_a^2 u_1'' \tag{5}$$

2.1.1 PWAS responses

Introduce the notations: induced strain $S_{\text{ISA}} = d_{31}\hat{E}_3$, displacement $u_{\text{ISA}} = S_{\text{ISA}}l = (d_{31}\hat{E}_3)l$; wave number γ, $\gamma = \omega/c$; wavelength λ, $\lambda = cT = c/f$, $f = \omega/2\pi$, quasi-static PWAS stiffness $k_{\text{PWAS}} = A_a/s_{11}^E l_a$, piezoelectric material wave speed $c_a^2 = 1/\rho s_{11}^E$, and $\frac{\partial}{\partial x_1}(\,) = (\,)'$, $\frac{\partial}{\partial t}(\,) = \dot{(\,)}$, the general solution $u_1(x,t) = \hat{u}(x)e^{j\omega t}$ of equation (5) can be obtained as

$$\hat{u}(x) = \frac{1}{2}u_{\text{ISA}}\frac{\sin\gamma x}{\gamma l\cos(\gamma l/2)/2 + \gamma\sin(\gamma l/2)} \tag{6}$$

if the system determinant is nonzero ($\Delta \neq 0$)

$$\Delta = \begin{vmatrix} \phi\cos\phi + r\sin\phi & -(\phi\sin\phi - r\cos\phi) \\ \phi\cos\phi + r\sin\phi & (\phi\sin\phi - r\cos\phi) \end{vmatrix}$$
$$= 2(\phi\cos\phi + r\sin\phi)(\phi\sin\phi - r\cos\phi) \tag{7}$$

The electrical responses of PWAS under harmonic electric excitation can be represented as the admittance (Y), which is defined as the ratio between the current and the voltage and the admittance (Z), which is the inverse of admittance.

$$Y = \frac{\hat{I}}{\hat{V}} = j\omega C\left[1 - k_{31}^2\left(1 - \frac{1}{r + \phi\cot\phi}\right)\right] \tag{8}$$

$$Z = \frac{\hat{V}}{\hat{I}} = \frac{1}{j\omega C}\left[1 - k_{31}^2\left(1 - \frac{1}{r + \phi\cot\phi}\right)\right]^{-1} \tag{9}$$

with $\phi = \gamma l/2$, $k_{31}^2 = d_{31}^2/(s_{11}^E\varepsilon_{33}^T)$ (E/M coupling coefficient), $C = \varepsilon_{33}^T b_a l_a/t_a$ (stress-free PWAS capacitance), and r as the structural stiffness ratio. For free PWAS, $r = 0$ ($k_{\text{str}} = 0$) and full constrained PWAS, $r \to \infty$($k_{\text{str}} \to \infty$). When the oscillation frequency is so low that the dynamic effects inside the PWAS are negligible, quasi-static conditions are encountered with $\phi = 0$, i.e., $\gamma l = 0$.

2.1.2 PWAS resonances

The determinant in equation (7) is zero when the first or second parenthesis is zero, corresponding to two types of PWAS resonances, mechanical resonances ($\phi\sin\phi - r\cos\phi = 0$) or E/M resonances ($\phi\cos\phi + r\sin\phi = 0$). The E/M resonances are specific to piezoelectric materials. They reflect the coupling between the mechanical and electrical variables. During E/M resonances, there are two possibilities that arise:

- *Resonance*, when $Y \to \infty$; that is, $Z = 0$. This resonance is associated with the situation in which a device draws very large current when excited harmonically with a constant voltage at a given frequency.
- *Antiresonance*, when $Y = 0$; that is, $Z \to \infty$. This antiresonance is associated with the situation in which a device under constant voltage excitation draws almost no current.

2.2 2D circular PWAS

The 2D constrained PWAS behavior can be analyzed using constitutive equations in cylindrical coordinates (r, θ, z),

$$S_{rr} = s_{11}^E T_{rr} + s_{12}^E T_{\theta\theta} + d_{31}E_z \tag{10}$$
$$S_{\theta\theta} = s_{12}^E T_{rr} + s_{11}^E T_{\theta\theta} + d_{31}E_z \tag{11}$$
$$D_z = d_{31}\left(T_{rr} + T_{\theta\theta}\right) + \varepsilon_{33}^T E_z \tag{12}$$

The wave equation in polar coordinates is

$$\frac{\partial^2 u_r}{\partial r^2} + \frac{1}{r}\frac{\partial u_r}{\partial r} - \frac{u_r}{r^2} = \frac{1}{c_p}\frac{\partial^2 u_r}{\partial t^2} \tag{13}$$

where $c_p = \sqrt{1/[\rho s_{11}^E(1-\nu_a^2)]}$, $\nu_a^2 = s_{12}^E/s_{11}^E$. Equation (13) provides a general solution in terms of Bessel functions of the first kind (J_1) in the form

$$u_r(r,t) = AJ_1\left(\frac{wr}{c}\right)e^{j\omega t} \tag{14}$$

where the coefficient A is determined from the boundary conditions. When PWAS is bonded to a structure, at the boundary $r = r_a$, the boundary condition is

$$T_{rr}\left(r_a\right)t_a = k_{\text{str}}(\omega)\,u_r\left(r_a\right) \tag{15}$$

The electric impedance is calculated as the ratio between voltage and current amplitudes

$$Z(\omega) = \left\{ j\omega C\left(1-k_p^2\right)\left[1 + \frac{k_p^2}{1-k_p^2}\frac{(1+\nu_a)J_1(\phi_a)}{\phi_a J_0(\phi_a) - (1-\nu_a)J_1(\phi_a) - \chi(\omega)(1+\nu_a)J_1(\phi_a)}\right]\right\}^{-1} \tag{16}$$

with $\phi_a = \omega r_a/c$, $\chi(\omega) = k_{\text{str}}(\omega)/k_{\text{PWAS}}$ (dynamic stiffness factor), and $k_p^2 = 2d_{31}^2/[s_{11}^E(1-\nu_a)\varepsilon_{33}^T]$ (planar coupling factor). Equation (16) predicts that the E/M impedance spectrum can be measured by the impedance analyzer at the embedded PWAS terminals during an SHM process and it allows for direct comparison between calculated predictions and experimental results. The structural dynamics is reflected in equation (16) through the dynamic stiffness factor $\chi(\omega)$, which is a measure of the dynamic stiffness of the structure.

3 PWAS ULTRASONIC TRANSDUCERS

For embedded nondestructive evaluation (NDE) applications, PWAS can be used as embedded ultrasonic transducers. PWAS act as both Lamb wave exciters and detectors (Figure 2). PWAS couple their in-plane motion with the particle motion of Lamb waves on the material surface. The in-plane PWAS motion is excited by the applied oscillatory voltage thought the d_{31} piezoelectric coupling.

The PWAS ultrasonic transducer operation is fundamentally different from that of conventional ultrasonic probes

1. PWAS achieve Lamb wave excitation and sensing through surface "pinching" (in-plane strains), while conventional ultrasonic probes excite through surface "tapping" (normal stress).
2. PWAS are strongly coupled with the structure and follow the structural dynamics, while conventional ultrasonic probes are relatively free from the structure and follow their own dynamics.
3. PWAS are nonresonant wideband devices, while conventional ultrasonic probes are narrowband resonators.

Optimum Lamb wave excitation and detection happen when the PWAS length is an odd multiple of the half wavelength of particle wave modes. Geometric tuning can be obtained through matching between

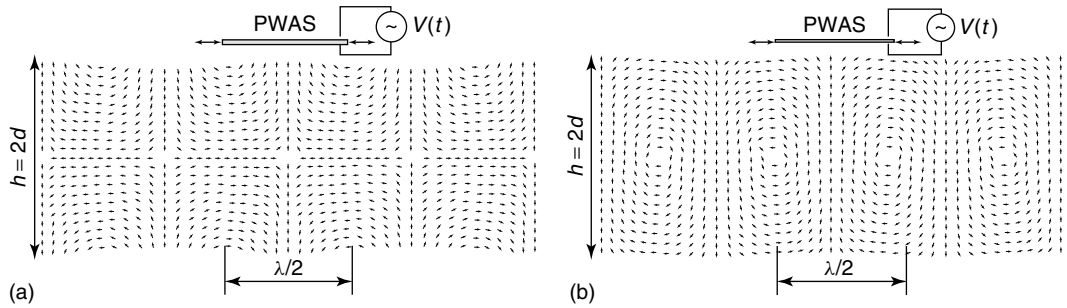

Figure 2. PWAS interaction with Lamb waves in a plate: (a) S_0 mode and (b) A_0 mode.

their characteristic direction and the half wavelength of the excited Lamb wave mode. Circular PWAS excite omnidirectional Lamb waves that propagate in circular wave fronts. Omnidirectional Lamb waves are also generated by square PWAS, though their pattern is somewhat irregular in proximity to the PWAS. At far enough distance ($r \gg a$), the wave front generated by square PWAS is practically identical with that generated by circular PWAS.

3.1 Shear-layer interaction between PWAS and the host structure

The transmission of actuation and sensing between the PWAS and the structure is achieved through the adhesive layer. The adhesive layer acts as a shear layer, in which the mechanical effects are transmitted through shear effects. As shown in Figure 3(a), a thin-wall structure of thickness t and elastic modulus E is attached with a PWAS of thickness t_a and elastic modulus E_a to the upper surface through a bonding layer of thickness t_b and shear modulus G_b. The PWAS length is l_a while the half length is $a = l_a/2$. In addition, $t = 2d$. Upon application of an electric voltage, the PWAS experiences an induced strain of $\varepsilon_{ISA} = d_{31}V/t$. The induced strain is transmitted to the structure through the bonding layer interfacial shear stress (τ). Upon analysis, we obtain the PWAS displacement,

$$u_a(x) = \frac{\alpha}{\alpha+\psi}\varepsilon_{\mathrm{ISA}} a\left(\frac{x}{a} + \frac{\psi}{\alpha}\frac{\sinh\Gamma x}{(\Gamma a)\cosh\Gamma a}\right) \tag{17}$$

the interfacial shear stress in bonding layer,

$$\tau(x) = \frac{t_a}{a}\frac{\psi}{\alpha+\psi}E_a\varepsilon_{\mathrm{ISA}}\left(\Gamma a\frac{\sinh\Gamma x}{\cosh\Gamma a}\right) \tag{18}$$

and the structural displacement at the surface,

$$u(x) = \frac{\alpha}{\alpha+\psi}\varepsilon_{\mathrm{ISA}} a\left(\frac{x}{a} - \frac{\sinh\Gamma x}{(\Gamma a)\cosh\Gamma a}\right) \tag{19}$$

where $\psi = (Et)/(E_a t_a)$, and α is a parameter that depends on the stress and strain distribution across the thickness. Under static and low-frequency dynamic conditions (i.e., uniform stress and strain for the symmetric deformation and linear stress and strain for antisymmetric deformation), elementary analysis yields $\alpha = 4$. For Lamb wave modes, which have complex stress and strain distributions across the thickness, the parameter α varies from mode to mode. These equations apply for $|x| < \alpha$. The shear-lag parameter [$\Gamma^2 = (G_b/E_a)(1/t_a t_b)((\alpha+\psi)/\psi)$] controls the x distribution. The effect of the PWAS is transmitted to the structure through the interfacial shear stress of the bonding layer. A small shear-stress value in the bonding layer produces a gradual transfer of strain from the PWAS to the structure,

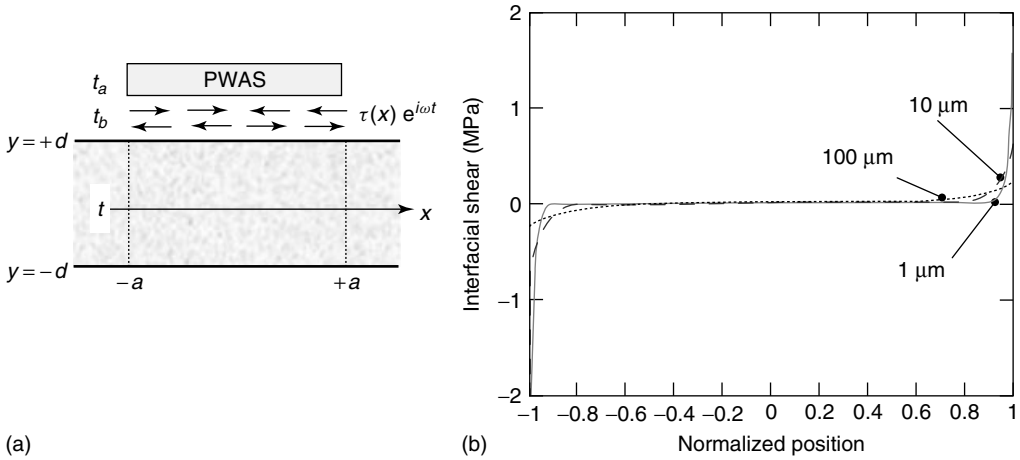

Figure 3. Shear-lag interaction between PWAS and structure: (a) interaction between the PWAS and the structure and (b) variation of shear-lag transfer mechanism with bond thickness.

whereas a large shear stress produces a rapid transfer. Because the PWAS ends are stress free, the build up of strain takes place at the ends, and it is more rapid when the shear stress is more intense. For large value of Γa, the shear transfer process becomes concentrated toward the PWAS ends. Figure 3(b) presents the results of the simulations on an APC-850 PWAS ($E_a = 63\,\text{GPa}$, $t_a = 0.2\,\text{mm}$, $l_a = 7\,\text{mm}$, and $d_{31} = -175\,\text{mm}\,\text{kV}^{-1}$) bonded to a thin-wall aluminum structure ($E = 70\,\text{GPa}$ and $t = 1\,\text{mm}$) using cynoacrylate adhesive ($G_b = 2\,\text{GPa}$) of various thicknesses, $t_b = 1,\ 10,\ 100\,\mu\text{m}$. It reveals that a relatively thick bonding layer produces a low Γa value—a slow transfer over the entire span of the PWAS (the 100-μm curves)—whereas, a very thin bonding layer produces a very rapid transfer (the 1-μm curves) that is confined to the ends, i.e.,

$$\tau(x) = a\tau_0[\delta(x-a) - \delta(x+a)] \tag{20}$$

The shear-lag analysis indicates that in the limit, as $\Gamma a \to \infty$, all the load transfer can be assumed to take place at the PWAS actuator ends. This leads to the concept of ideal bonding, also known as the *pin-force model*, in which all the load transfer takes place over an infinitesimal region at the PWAS ends, and the induced-strain action is assumed to consist of a pair of concentrated forces applied at the ends. The ideal bonding stress is then given by

$$\tau(x) = a\tau_a[\delta(x-a) - \delta(x+a)] \tag{21}$$

Using the shear-lag model, the energy transferred from PWAS to the structure can be found by analyzing either the elastic energy in the structure or work done by the shear stresses at the structural surface.

3.2 PWAS Lamb waves excitation and reception

Lamb waves, also known as *guided plate waves*, are a type of ultrasonic waves and are guided between two parallel free surfaces, such as the upper and lower surfaces of a plate (*see* **Fundamentals of Guided Elastic Waves in Solids**). Lamb waves can exist in two basic types: symmetric (designated as $S_0, S_1, \ldots$.) and antisymmetric (designated as $A_0, A_1, \ldots$.). For each propagation type, a number of modes exist, corresponding to the solutions of the Rayleigh–Lamb equation. The symmetric Lamb waves resemble the axial waves while the antisymmetric Lamb waves resemble the flexural waves. Lamb waves are highly dispersive and their speed depends on the product of frequency and the plate thickness. Details of Lamb wave theory can be found in [1, 2]. Traditional generation of Lamb waves has been through a wedge probe, and modification of the wedge angle and excitation frequency allows the selective tuning of various Lamb wave modes. Another traditional way is to cause excitation through a comb probe, in which the comb pitch is matched with the half wavelength of the targeted Lamb mode. However, both the wedge and comb probes are relatively large and expensive and not appropriate for installation in large numbers in an aerospace structure as part of an SHM system. Being smaller, lighter, more affordable, PWAS could be deployed into the structure being permanently wired and could interrogate at will.

3.2.1 Lamb wave excitation by PWAS

The excitation of Lamb waves with PWAS is studied by considering the excitation applied by the PWAS through a surface stress $\tau = \tau_0(x)e^{j\omega t}$ applied to the upper surface of a plate in the form of shear-lag adhesion stresses over the interval $(-a, +a)$. Applying a space domain Fourier transform analysis of the basic Lamb wave equations to yield the strain wave and displacement wave solutions [3], we have

$$\varepsilon_x(x,t)|_{y=d} = -i\frac{a\tau_0}{\mu}\left[\sum_{\xi^S}\sin\left(\xi^S a\right)\frac{N_S\left(\xi^S\right)}{D_S'\left(\xi^S\right)} \times e^{i\left(\xi^S x-\omega t\right)} + \sum_{\xi^A}\sin\left(\xi^A a\right) \times \frac{N_A\left(\xi^A\right)}{D_A'\left(\xi^A\right)}e^{i\left(\xi^A x-\omega t\right)}\right]$$

$$N_S = \xi\beta\left(\xi^2+\beta^2\right)\cos(\alpha d)\cos(\beta d),$$

$$D_S = \left(\xi^2-\beta^2\right)^2\cos(\alpha d)\sin(\beta d) + 4\xi^2\alpha\beta\sin(\alpha d)\cos(\beta d)$$

$$N_A = \xi\beta\left(\xi^2+\beta^2\right)\sin(\alpha d)\sin(\beta d),$$

$$D_A = \left(\xi^2 - \beta^2\right)^2 \sin(\alpha d)\cos(\beta d) + 4\xi^2\alpha\beta\cos(\alpha d)\sin(\beta d) \qquad (22)$$

where ξ^S and ξ^A are the zeros of D_S and D_A, respectively. We can note that these are the solutions of the Rayleigh–Lamb equation. Raghavan and Cesnik [4] extended these results to the case of a circular transducer coupled with circular-crested Lamb waves and proposed corresponding tuning prediction formulae based on Bessel functions:

$$\varepsilon_r(r,t)|_{z=d} = \pi\frac{\tau_0 a}{\mu}e^{i\omega t}\left[\sum_{\xi^S} J_1\left(\xi^S a\right)\xi^S\frac{N_S\left(\xi^S\right)}{D'_S\left(\xi^S\right)} \times H_1^{(2)}\left(\xi^S r\right) + \sum_{\xi_A} J_1\left(\xi^A a\right)\xi^A \times\frac{N_A\left(\xi^A\right)}{D'_A\left(\xi^A\right)}H_1^{(2)}\left(\xi^A r\right)\right] \qquad (23)$$

3.2.2 PWAS Lamb wave tuning

An important characteristic of PWAS, which distinguishes them from conventional ultrasonic transducers, is their capability of tuning into various guided-wave modes. A comprehensive study of these prediction formulae in comparison with experimental results has recently been performed by Bottai and Giurgiutiu [5]. Simulation plot of the equation (22) is presented in Figure 4(a) using a 7-mm square PWAS installed on 1.07-mm-thick 2024-T3 aluminum alloy plate. Note that the efficient PWAS length for a 7-mm PWAS has been verified as 6.4 mm [5]. Equation (22) contains the $\sin(\xi a)$ behavior that displays maxima when the PWAS length $l_a = 2a$ equals an odd multiple of the half wavelength, and minima when it equals an even multiple of the half wavelength. A complex pattern of such maxima and minima emerges, since several Lamb modes, each with its own different wavelength, coexist at the same time. The plot in Figure 4(a) shows that at 210 kHz, the amplitude of the A_0 mode goes through zero, while that of the S_0 is close to its peak. This represents an excitation "sweet spot" for S_0 Lamb waves. Experimental results confirming this prediction are presented in Figure 4(b).

3.3 PWAS Lamb wave structural health monitoring

As active sensors, PWAS interact directly with the structure and find its state of health and reliability through the use of ultrasonic Lamb waves [6]. Similar to the conventional ultrasonic transducers, PWAS can operate in pitch–catch, pulse–echo, or be wired into phased array to implement structural scanning.

3.3.1 Pitch–catch method

The pitch–catch method detects damage from the changes in the Lamb waves traveling through a

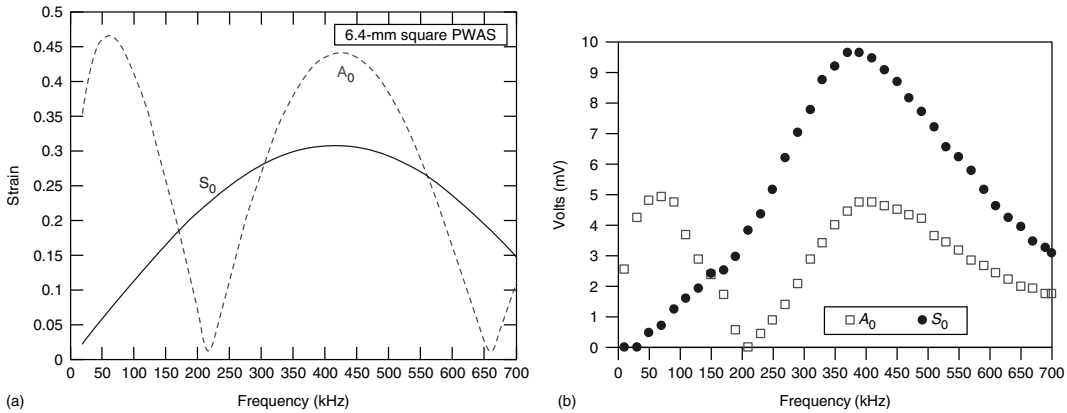

Figure 4. PWAS Lamb wave tuning using a 7-mm square PWAS placed on 1.07-mm 2024-T3 aluminum alloy plate: (a) prediction with equation (22) for 6.4-mm effective sensor length and (b) experimental results.

damaged region. The method uses the transducers in pairs: one as transmitter, and the other as receiver. The pitch–catch SHM method has been used extensively [7–10]. Changes occurring owing to damage in the properties of the transmitted medium induce changes in the signal transmitted through the medium. Of particular interest is the time reversal of the pitch–catch SHM method. In the PWAS time reversal procedure [11], an input signal is reconstructed at an exciter point if an output signal recorded at a receiver point is reversed in time domain and emitted back to the original source point. The reversion is conducted in the frequency domain and depends on the structure transfer function $G(\omega)$. When the reversed signal is reconstructed, it is compared with the original transmission signal to detect the damage occurrence along the transmission–reception line. Figure 5(a) shows the block diagram of PWAS Lamb wave time reversal procedure. With the time reversal method, the original status of the structure is no longer needed for damage detection, so it is known as a *baseline-free* methodology. In PWAS time reversal procedure, it is important to use a single Lamb mode such that the transfer function $G(\omega)$ can remain constant [12]. A simulation with 16-count Hanning window smoothed transmission signal has been conducted in a 1-mm aluminum plate using 7-mm round PWAS. The result of S_0 mode excitation at 290 kHz is shown in Figure 5(b) with noticeable residual waves, while the result of A_0 mode at 30 kHz in Figure 5(c) demonstrating no residual wave packets beside the reconstructed wave.

3.3.2 *Pulse–echo crack detection*

The embedded PWAS pulse–echo method follows the general principles of conventional Lamb wave NDE. A PWAS transducer attached to the structure acts as both transmitter and detector of guided Lamb waves traveling in the structure. The wave sent by the PWAS is partially reflected at the crack. The echo is captured at the same PWAS, which acts as receiver. To ensure the crack detection, an appropriate Lamb wave mode must be selected. It has been verified that the S_0 Lamb waves can give much better reflections from the through-the-thickness cracks than the A_0 Lamb waves [3]. The selection of such a wave is achieved through the Lamb wave tuning. A wave propagation experiment was conducted on an aircraft panel to illustrate crack detection through the pulse–echo method (Figure 6). A baseline signal was first collected, and then after the simulated crack was added, another reading was recorded. By comparing

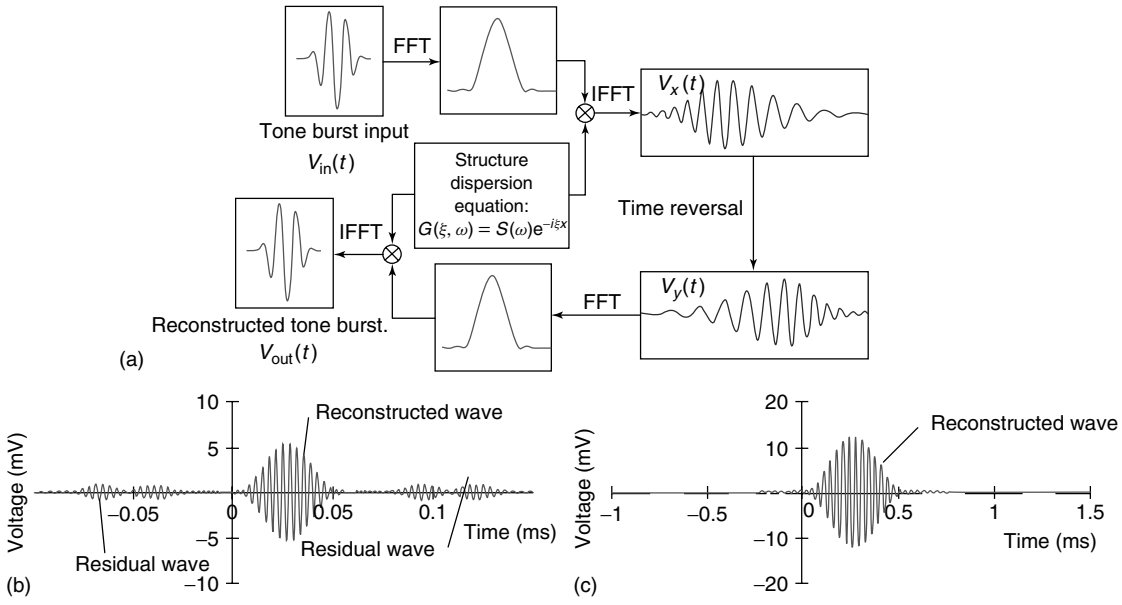

Figure 5. PWAS Lamb wave time reversal procedure. (a) Flowchart block diagram; (b) S_0 mode time reversal at 290 kHz showing residuals; and (c) A_0 mode time reversal at 30 kHz with no residual wave packets present.

the difference between the reading and baseline, the reflection caused by the crack could be extracted and detected.

3.3.3 Phased arrays for large area imaging

PWAS can also be wired as phased arrays to detect damage in thin-wall structures (*see* **Guided-wave Array Methods**). Using guided-wave PWAS phased-array methods, wide coverage could be achieved from a single location. PWAS phased arrays have been developed for thin-wall structures (e.g., aircraft shells, storage tanks, large pipes, etc.) that use Lamb waves to cover a large surface area through beam steering from a central location [13]. Its principle of operation is derived from two general concepts:

1. the generation of tuned guided Lamb wave with PWAS;
2. the principles of conventional phased-array radar.

The embedded ultrasonic structural radar (EUSR) algorithm [13] using PWAS is different from the conventional phased-array approach in two aspects:

1. it uses structurally embedded PWAS transducers;
2. it works in virtual time, not in real time.

The latter observation is very important for SHM, because it allows the phased-array benefits without the drawback of real-time multichannel phased excitation equipment. Whereas real-time phased-array transducers require heavy and complex multichannel phasing equipment, the virtual-time approach adopted by the EUSR method can be carried out with only one channel and very simple equipment. Figure 7(a) shows the typical setup of using a nine 7-mm square PWAS array to detect a broadside crack in a 1-mm-thick aluminum plate. On the investigated structure, the EUSR method captures and stores signals of an M-PWAS array in a round-robin fashion, i.e., one PWAS being activated as transmitter, while all the other PWAS act as receivers. Thus a matrix of $M \times M$ elemental signals is generated. In the post-processing phase, the elemental signals are assembled into the synthetic beamforming response using the synthetic beamforming algorithm and the scanning result is given as a 2D planar image (Figure 7b).

4 PWAS HIGH-FREQUENCY MODAL SENSORS

Modal analysis and dynamic structural identification are an intrinsic part of current engineering practice. Structural frequencies, damping, and modes shapes identified through this process are subsequently used to predict dynamic response, avoid resonance, and even monitor structural change that are indicative of

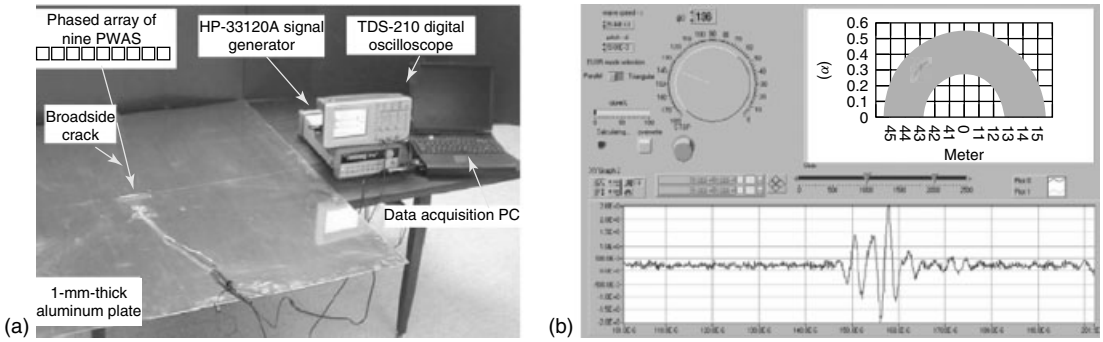

Figure 7. EUSR PWAS phased-array damage detection: (a) equipment setup and (b) EUSR scanning image.

incipient failure. The advantage of using PWAS for damage detection resides in their very high frequency capability, which exceeds by orders of magnitudes the frequency capability of conventional modal analysis sensors. They can be permanently attached to the structural surface and could form sensor and actuator arrays that permit effective modal identification in a wide frequency band. Thus PWAS are able to detect subtle changes in the high-frequency structural dynamics at local scales. Such local changes in the high-frequency structural dynamics are associated with the presence of incipient damage, which would not be detected by conventional modal analysis sensors that operate at low frequencies.

4.1 Analytical model

Consider a 1D structure with a PWAS attached to its surface (Figure 8a). Upon activation, the PWAS expands by $\varepsilon_{\text{PWAS}}$, generating a reaction force F_{PWAS} from the beam onto the PWAS and an equal and opposite force from PWAS onto the beam (Figure 8b).

The force excites the beam. As the PWAS is electrically excited with a high-frequency harmonic signal, it induces elastic waves into the beam structure. The elastic waves travel sideways into the beam structure and set it into oscillation. In a steady-state regime, the structure oscillates at the PWAS excitation frequency. The dynamic stiffness presented by the structure to the PWAS depends on the internal state of the structure, excitation frequency, and the boundary conditions as

$$k_{\text{str}}(\omega) = \frac{\hat{F}_{\text{PWAS}}(\omega)}{\hat{u}_{\text{PWAS}}(\omega)} \tag{24}$$

where $\hat{F}_{\text{PWAS}}(\omega)$ is the reaction force and $\hat{u}_{\text{PWAS}}(\omega)$ is the displacement amplitude at frequency ω. The symbol $\hat{}$ signifies the complex amplitude of a time-varying function. Because the size of the PWAS is very small with respect to the size of the structure, equation (24) represents a pointwise structure

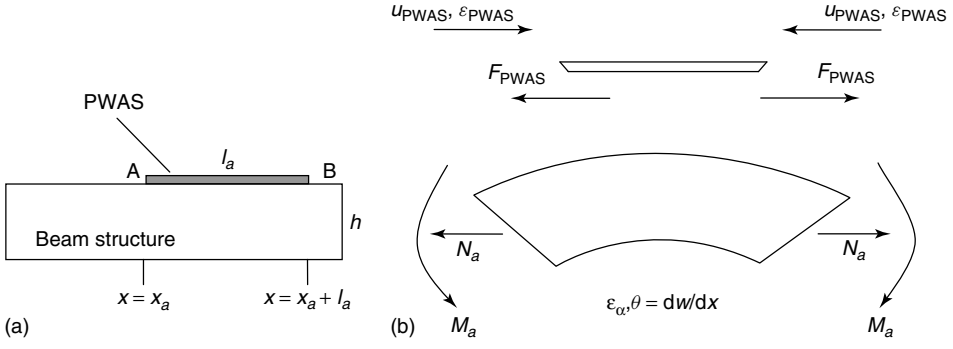

Figure 8. Interaction between a PWAS and a beamlike structural substrate: (a) geometry and (b) forces and moments.

stiffness. The response of the structural substrate to the PWAS excitation can be deduced from the general theory of beam vibrations. However, note that the PWAS excitation departs from the typical textbook formulation since it activates a pair of self-equilibrating axial forces and bending moments that are separated by a small finite distance l_{PWAS}. Kinematic analysis finally gives the dynamic structural stiffness as

$$k_{\text{str}}(\omega) = \rho A \left\{ \sum_{n_u} \frac{\left[U_{n_u}(x_a + l_a) - U_{n_u}(x_a)\right]^2}{\omega_{n_u}^2 + 2j\varsigma_{n_u}\omega_{n_u}\omega - \omega^2} + \left(\frac{h}{2}\right)^2 \sum_{n_w} \frac{\left[W'_{n_w}(x_a + l_a) - W'_{n_w}(x_a)\right]^2}{\omega_{n_w}^2 + 2j\varsigma_{n_w}\omega_{n_w}\omega - \omega^2} \right\}^{-1} \tag{25}$$

where $n_u, \omega_{n_u}, U_{n_u}(x)$ and $n_w, \omega_{n_w}, U_{n_w}(x)$ represent the axial and flexural vibrations frequencies and mode shapes, respectively.

4.2 Simulation and experimental results

The analytical model was used to perform numerical simulations that directly predict the E/M impedance and admittance signature at PWAS terminals during structural identification. Numerical simulations were performed with steel beams assuming damping coefficient at 1% over a modal subspace that incorporated all modal frequencies in the frequency bandwidth of interest. Finite element method (FEM) was also conducted to predict the structural natural frequencies using (i) the purely mechanical response via conventional structural elements and (ii) directly the E/M response via coupled-field elements [14]. The stiffness k_{str} in equation (25) is used to get the structural stiffness and calculate the E/M impedance. Subsequent experiments were performed to verify these predictions using a small steel beam ($100 \times 8 \times 2.6$, in millimeter) ($E = 200\,\text{GPa}$, $\rho = 7750\,\text{kg m}^{-3}$) instrumented with 7-mm square PWAS ($t_a = 0.22\,\text{mm}$) placed at $x_a = 40\,\text{mm}$ from one end (Figure 9(a) and (b)). During the experiments, recording of the E/M impedance real part spectra was performed with the HP4194A impedance analyzer in the $1 \sim 30\,\text{kHz}$ range. Numerical and FEM simulations and experimental results are given in Figure 9(c) and (d). Note that the experimental results are consistent with the predictions regarding the natural frequencies. Comparing the two FEM methods, it is noted that the impedance data obtained from the coupled-field analysis was more close to the experimental data, validating the possibility of using

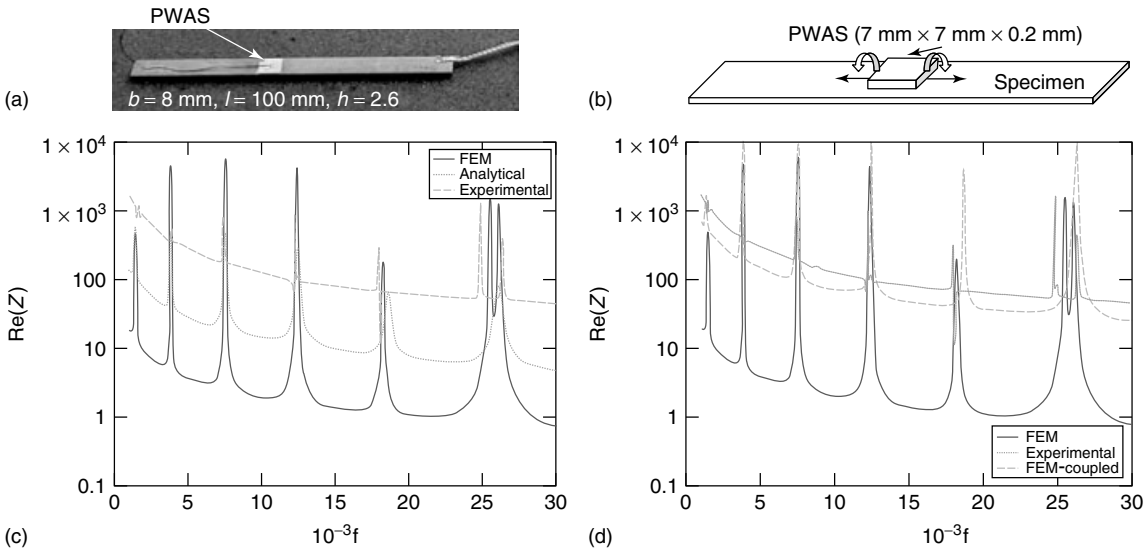

Figure 9. 1D structure simulation and experiments: (a) narrow-beam specimen; (b) beam structure layout for simulation analysis; (c) real part impedance spectra using structure FEM method; and (d) real part impedance spectra using coupled-field FEM method.

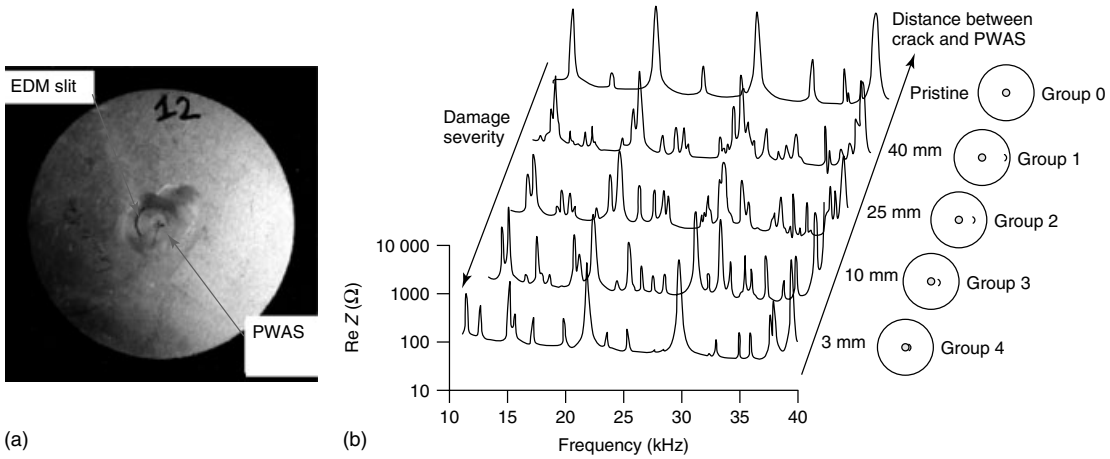

Figure 10. Experiments on dependence of the E/M impedance spectra on the location of damage on metallic plate specimen, E/M impedance in $0.5 \sim 40$ kHz frequency range: (a) the aluminum plate specimen with PWAS installed in the center and (b) E/M impedance spectra at various crack situations.

this method to analyze and simulate the structure with PWAS [14].

4.3 Damage detection with PWAS modal sensors

PWAS and the associated structural dynamics identification methodology based on the E/M impedance response are ideally suited for small machinery parts that have natural frequencies in the kilohertz range [15–17]. PWAS are able to detect subtle changes in the high-frequency structural dynamics at local scales. Such local changes in the high-frequency structural dynamics are associated with the presence of incipient damage, which would not be detected by conventional modal analysis sensors that operate at low frequencies. The E/M impedance of a 7-mm round PWAS has been measured with an HP4194A impedance analyzer at various crack situations on an aluminum metallic plate to assess the crack-detection capabilities, as shown in Figure 10.

5 NOVEL PWAS UNDER DEVELOPMENT

PWAS transducers have been proven to be valuable enablers of SHM systems. As a small embedded sensing device, PWAS have also shown great potential for many other applications such as biomedical applications (bio-PWAS) for *in vivo* monitoring of the bodily reaction to implants [18]. However, the bonded interface between the PWAS and the structure is often the durability weak link for SHM applications. The bonding layer is susceptible to environmental ingression that may lead to loss of contact with the structural substrate. The bonding layer may also induce acoustic impedance mismatch with detrimental effects on damage detection. Additionally, prefabricated piezoelectric sensors such as PWAS do not fit well on surfaces with complex geometry. Better durability may be obtained from a built-in sensor that is incorporated into the structure.

5.1 *In situ* fabricated PWAS

Polymer-based piezoelectric paints have been investigated as a potential substitute for PWAS in certain sensing applications. A new type of smart material, piezoelectric paint that cures at ambient temperature, has been developed by Zhang and Li [19] as sensing material for ultrasonic-based NDE (*see* **Piezoelectric Paint Sensors for Ultrasonics-based Damage Detection**). Piezoelectric paint is a composite piezoelectric material that is composed of tiny piezoelectric particles randomly dispersed within a polymer matrix phase with adjustable material

properties that are not easily attainable in a single-phase material. Through judicious selection of the polymer matrix, the composite properties of the piezoelectric paint can be tailored to meet the specific requirements of an application condition. Because of its ease of application, piezoelectric paint can be easily deposited onto the complex surface of host structures; the paint uniformly cures at ambient temperature. On the basis of the preliminary results from the experimental study and finite element simulation, piezoelectric paint sensor appears to have a great potential for use as distributed sensors for fatigue crack monitoring in metallic structures.

5.2 Thin-film nano-PWAS

An alternative way to incorporate PWAS into the structure is the ferroelectric thin-film PWAS that uses nanofabrication technology to produce the sensors directly on the structural substrate [20]. Ferroelectric thin films have been shown to have piezoelectric properties that are those of single-crystal ferroelectrics, which are an order of magnitude better than common piezoceramics. In addition, the thin films require much smaller poling voltage/power. Thin film can get the same strain as that obtained by the PWAS with a much lower voltage, and through layering, the power of the device can be amplified many times. Figure 11 illustrates the thin-film multilayer PWAS development process [20]. C-axial preferred oriented ferroelectric $BaTiO_3$ thin films have been successfully fabricated on Ni metal tapes with a thin NiO buffered layer by pulsed laser ablation. Ferroelectric polarization measurements have shown the hysteresis loop at room temperature in the film with a large remnant polarization, indicating that the ferroelectric domains have been created in the as-deposited BTO films. These excellent properties in this piezoelectric thin film indicate that the as-fabricated BTO films show promise in the development of SHM systems. Hudak *et al.* [21] successfully pursued the alternative path of magnetostrictive thin-film PWAS and achieved enhanced thin-film performance by optimizing architecture through multilayered films, which demonstrated a 4 times stronger receiving signal in pulse–echo experiments. The guided waves have been used in pulse–echo mode to clearly detect

6 SUMMARY AND CONCLUSIONS

This article has presented the use of PWAS as resonators, ultrasonic transducers, and high-frequency modal sensors for ultrasonic SHM. The PWAS transducer can be permanently attached to structures for *in situ* health monitoring to determine the structural state of health and predict the remaining life. After reviewing the PWAS operational principles, the PWAS piezoelectric properties (actuation and sensing) were presented in connection with Lamb wave excitation and detection. It was shown analytically and verified experimentally that Lamb wave mode tuning can be achieved by the judicious combination of PWAS dimensions, frequency values, and Lamb wave mode characteristics. For example, the A_0 and S_0 Lamb modes could be separately tuned by using the same PWAS installation but different frequency bands. Next, the use of embedded PWAS transducers as modal sensors was introduced for dynamic structural identification. The PWAS are able to detect subtle changes in the high-frequency structural dynamics at local scales, which are associated with the presence of the incipient damage, which would not be detected by conventional modal analysis sensors that operate at low frequencies. Finally, with all the success of using PWAS transducer for *in situ* SHM, several on-going novel PWAS developments were introduced, including the *in situ* fabricated PWAS and thin-film nano-PWAS.

Although remarkable progress has been made in using PWAS for NDE, considerable work remains to be done. To increase the acceptance of this emerging technology, the refining of the theoretical analysis and calibration against well-planned experiments is needed. However, to deploy the PWAS transducers to *in situ* SHM applications, several hurdles have still to be overcome. In particular, the operational and environmental variations of the monitored structure need to be addressed. In addition, a better understanding of the micromechanical coupling between PWAS and structure for various Lamb wave modes must be achieved. The behavior of the bonding layer between the PWAS and the structure must be clarified as well, such that the predictable and repeatable results are achieved. The durability of this bond under extended environmental exposure must be determined. Last, but not least, the signal analysis methods must be developed to achieve probability of detection values at least comparable with that of conventional NDE methods.

1 INTRODUCTION

An online structural health monitoring system provides information about the integrity of the structures in use in a real-time basis. This is very important to the end user, as it allows an optimal use and reduces the probability of catastrophic failure, and also to the manufacturer as it helps in decision making regarding the improvement of the product. Even in normal operating conditions, both automobile and aircraft tires experience large strain, pressure, and impact force. It makes a tire prone to catastrophic failure in different complex modes. Underinflation causes excessive sidewall flexing, heat generation and consequent tread separation, and sudden blowout. Overinflation and overloading result in excessive pressure and strain and make the tire more vulnerable to damage due to uneven surface. Manufacturing defects result in poor adhesion between tread and belt and may result in tread separation and blowout. These necessitate the development of a real-time structural health monitoring system for tire. Detailed understanding of tire–vehicle system dynamic behavior, development of a multifunctional sensor system, development of a wireless communication, among others are major challenges in the development of a tire structural health monitoring system [1].

The development of tire pressure monitoring systems (TPMSs) has allowed for indirect monitoring of tire health by analyzing both pressure and temperature data. The accuracy of indirect tire health monitoring based on tire pressures and temperatures is low due to the complexity of the tire structure and various operating conditions that a tire commonly encounters. To provide a more accurate means of

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

accessing overall tire health, a variety of new sensing technologies have been developed and employed to measure various characteristics of the tire such as the longitudinal/lateral forces, friction between the tire and the roadway, deformation and displacement of the tire during operation, strain in the tire, acoustic signatures, accelerations, etc. By measuring these quantities, we can get a much more accurate description of the mechanical response of the tire, and therefore a more accurate view of the tire's overall health. The various tire health monitoring sensors can be separated into two groups: noncontacting and embedded. The embedded sensors are either bonded to the inner liner of the tire or are embedded into the tire during manufacture. Noncontacting tire health monitoring sensors commonly utilize optical, electromagnetic, or acoustic phenomena to measure tire deformations, wheel speed, temperature, and friction. Noncontacting systems are generally desirable since they are not mechanically coupled to the tire, which improves reliability and other operational factors, but these systems can be large and may not be appropriate for some service environments. Another issue for some noncontacting measurements is the need for complex signal processing in order to evaluate sensor data, which increases cost and complexity of the system. Embedded sensors allow for direct measurement of the mechanical response such as temperature, strain, displacement, accelerations, etc. of the tire, but must operate in a harsh environment, and transmit data from the tire into the vehicle. There is also some concern about the presence of embedded sensors reducing the structural integrity of the tire due to localized stress phenomena. The following section discusses various sensor technologies that are currently being investigated for use in a tire health monitoring system. There is currently no widely accepted sensor technology that has proven to be the best for tire health monitoring applications, but significant advances in measurement accuracy, reliability, size, power consumption, and cost are continually being made, which will allow adoption of these sensor technologies in the near future.

1.1 Noncontacting sensors

A sidewall torsion sensor developed by Continental Inc. [2] utilizes a specially manufactured tire, which has two magnetized strips incorporated in the tire rubber on the inner sidewall and two sensors mounted on the chassis of the vehicle to measure the magnetic field strength from these strips on the tire. On the basis of phase changes in the upper and lower sensor signals and variations in magnetic field intensity between the two sensors, the deformation of the tire in the longitudinal and lateral directions can be determined and the forces acting on the tire can be estimated. This system was initially designed to be used for antilock brake and electronic stability control systems, but work is continuing to allow for detection of tire defects based on changes in the magnetic sensor signals.

The Apollo project for "Intelligent Tyre for Accident-free Traffic" [3] developed an optical positioning sensor, which used infrared (IR) diodes as a light emitter bonded to various locations on the inner liner of the tire and a position-sensing diode mounted on the wheel. A schematic of the optical positioning sensor is shown in Figure 1.

The displacement of the contact patch relative to the rim can be measured using this sensor. A light beam emitted from the IR diode is focused onto the Position Sensitive Diode (PSD) chip through a lens. On the basis of changes in the current at the corners of the PSD generated from the light from the IR diodes, the movement of the light beams can be determined. This information can then be processed to determine the distance from the rim to the inner liner.

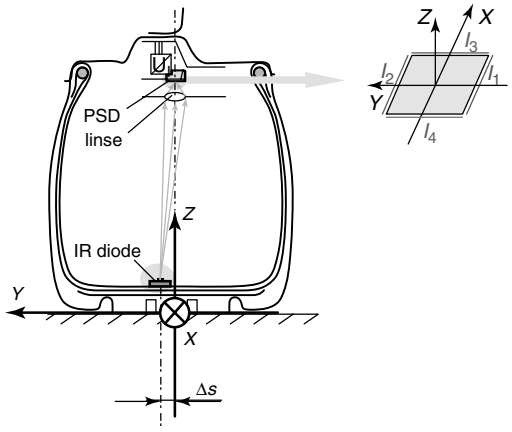

Figure 1. Schematic of optical positioning sensor and location of IR diode and PSD in the tire (image from Apollo final report). [Reproduced with permission from Ref. 3. ©, APOLLO, 2005.]

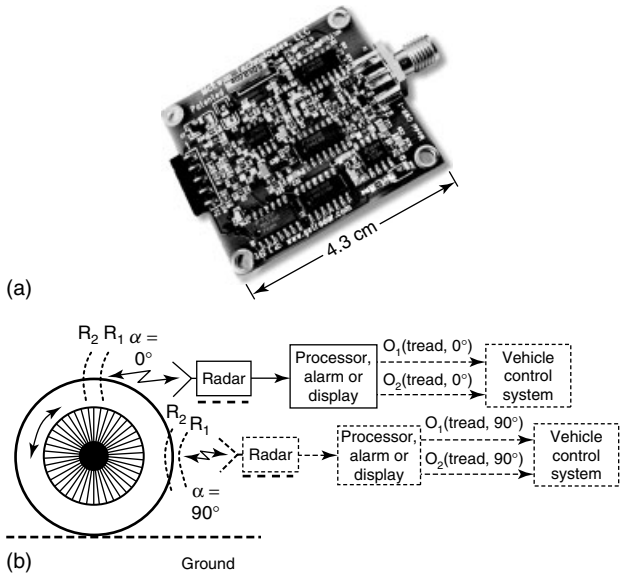

Figure 2. (a) Image of Model R-1 UWB Impulse Radar from McEwan Technologies (picture from: http://www.getradar.com/DemoUnits/Demo8.htm) and (b) MIR-based tire health monitoring system from patent application [5].

Preliminary results showed that this sensor performed well for measuring the displacement of the contact patch, but the diodes consumed a significant amount of power, which could limit its applicability because the sensor is mounted between the tire and the rim.

A German company, Optimess, has developed a laser-sensing system, which is mounted on the chassis of the vehicle to perform noncontact scanning of the tire tread surface during vehicle operation. This system performs scans over the entire tread surface after fixed driving intervals, and can detect tread wear as well as tire expansion during high-speed operation. Another application of the laser sensor could be placed on the rim to measure the contact patch displacement of the tire or measure the road surface conditions during vehicle operation.

Micropower impulse radar (MIR) developed in the early 1990s as a form of ultra wideband (UWB) radar is capable of high-resolution tire deformation measurements by utilizing small, low-power radar transmitter/receivers mounted externally, in close proximity to the tire. A recent patent by Michelin [4] discusses an MIR-based tire health monitoring system, which utilizes a 24-GHz pulse Doppler radar from McEwan Technologies [5] to detect tire abnormalities such as tread delamination, uneven tread wear, foreign object detection, and sidewall bulging. An image of the MIR and schematic of the tire health monitoring system are shown in Figure 2. The system makes use of a signal processor to analyze the signal generated by the MIR to detect the onset of various tire anomalies. This signal processor compares the reflected radio frequency (RF) signal energies over various frequency bands to detect the existence of a tire anomaly. Testing showed that this system was sensitive to tire wear and tread separation, but careful selection of the appropriate frequency bands was required to ensure accurate detection.

UWB radar-based tire health monitoring has not been fully investigated to determine its reliability and accuracy, but initial results show that this is a promising technology. Some complications that may arise during the implementation of this type of system are limitations on the power of the UWB radar by the Federal Communications Commission (FCC) in the United States in order to minimize potential interference. Currently, UWB radar use is not approved for use outside of the United States, which may also hinder potential widespread use of this technology.

Tekgenuity Limited has developed chromasonic sensors [6], which utilize acoustic emissions from the tire/road interface to identify tire anomalies. Various acoustic sensors such as microphones, strain gauges,

and optical microphones can by utilized in an array on the chassis of the vehicle around the tire to measure the acoustic emissions. Signal processing using Gabor transforms is then performed to extract important information from the sensor signals. The chromasonic sensors have shown the ability to detect pressure loss in tires, change in tracking angle, damage to tread area, objects embedded in tire, and changes in tire tread wear.

1.2 Embedded sensors

Embedded sensors for tire health monitoring are required to meet a number of performance requirements. They should have a wide frequency response and dynamic range, high resolution, and acceptable nonlinear characteristics. These sensors also must be compact, light, robust, and consume as little power as possible. Given all these requirements, very few current sensor technologies are acceptable for tire health monitoring, but rapid advances are being made and sensor performance is constantly increasing. The following sections discuss current embedded sensor technologies for tire health monitoring applications.

1.2.1 Acceleration sensing

The use of microelectromechanical systems (MEMSs) technology has drastically reduced the size of numerous sensor packages. MEMS accelerometers, which are both small and inexpensive, have become commercially available in common integrated circuit platforms. Owing to these benefits, MEMS accelerometers have been investigated for use as an embedded tire health monitoring sensor. The Apollo project investigated the use of custom-designed accelerometer circuits [3] to be embedded in the tire tread as well as bonded to the tire inner liner (Figure 3).

Results from testing of these sensors showed that they perform reliably and consume relatively low power, but these sensors were only capable of providing useful data in the radial direction of the tire. This type of sensor information could be used to estimate the wheel loads and possibly the contact patch length, but this information would be difficult to utilize for tire health monitoring applications.

Figure 3. MEMS accelerometer bonded to the inner liner of the tire using silicone rubber (image from Apollo final report [3]).

A significant issue with the use of accelerometers for tire health monitoring is that they detect all accelerations including rotational, gravitational, and vibrations from the mounting point, which requires significant signal processing to extract desired acceleration data. Another complication is the temperature dependence of the accelerometers, which can become a significant issue for sensors embedded in the tread due to frictional heating.

1.2.2 Force/friction sensing

A sensor system developed by Darmstadt University of Technology uses magnets placed in the tread block of the tire and a Hall sensor to monitor movements of the magnet [7]. The position sensor utilizes four monolithically integrated Hall crosses and an additional temperature sensor. This sensor allows movements of the tread block due to friction and forces of the tire/road contact to be measured. Test stand experiments have shown the potential to measure tire pressure, wheel load, and longitudinal/lateral forces. Miniaturization of the sensor makes it possible to integrate the chip and magnet into a single tread lug, so that sensor measurements can be made without interference from steel belts in radial tire applications. Another tire friction sensor is also being developed by Siemens in collaboration with Continental and Darmstadt University of Technology, which utilizes surface acoustic wave-sensing technology [7, 8].

1.2.3 Strain sensing

The direct measurement of strain in the tire would be very useful because tire degradation and tread separation can be directly related to high strains in

various locations on the tire. Owing to the importance of strain measurements in tires, there have been numerous approaches, but few are applicable for tire health monitoring applications. The Apollo project [3] evaluated the use of piezoelectric strain sensors made of Polyvinylidene fluoride (PVDF), which were bonded to the inner liner of the tire. These strain sensors were capable of monitoring the longitudinal and lateral strains in the tire during operation. These strain measurements could be used to estimate the contact patch length, possibly road conditions by analyzing the variations in strain signals. The interpretation of the strain signals was also generally simpler to interpret than the accelerometer data since only local deformations around the strain sensor were sensed. The PVDF material was highly sensitive to temperature variations in the tire, and this required temperature compensation to ensure reasonable accuracy of the measured responses. There were also questions regarding the reliability of this strain sensor for use in commercial scale production.

An alternative strain-sensing method was developed by Luna Innovations [9], which utilized fiber-optic strain sensors embedded in the tire or bonded to the inner liner of the tire after manufacture. This sensing technology allows for numerous strain sensors on a single optical fiber using extrinsic Fabry–Perot interferometry. Owing to the small size of the optical fiber, the effects of embedding the sensor on the structural integrity of the tire were small and strain sensor is less sensitive to temperature variations than other technologies such as PVDF strain sensors. Significant issues exist for using this technology on a commercial basis, such as the cost and size of signal conditioning and processing hardware and efficient methods for condensing and transmitting sensed data. The durability of the optical fibers in the harsh environments in which tires frequently operate also need further study.

Another feasible strain-sensing technology, which has not been fully tested for tire health monitoring applications, is the vibrating string sensor. This technology, developed by Vibstring [7], uses a thin wire set in a plastic tube and a standard microwave radio transceiver. Vibrations of the wire were found to modulate the RF. When strain is applied to the wire, the natural frequency of the wire changes. These changes in natural frequency, and therefore strain, can be determined by demodulating the modulated radio signals. The modulation due to the wire overrides all other vibration effects since the wire acts as an antenna, with its length selected in accordance to the high-frequency radio signal. No research currently exists, which discusses the performance of this sensor for tire health monitoring applications. It does not seem likely that this sensor could be embedded in the tire rubber without compromising the tire, and there are questions regarding the durability over long time periods.

Other more exotic strain sensors have also been proposed such as MetalRubber™ by NanoSonic, Inc. (NanoSonic), a novel and innovative new product that is a freestanding, conductive, elastomeric material based on electrostatic self-assembly comprising multiple alternating layers of electrostatically deposited monolayer metal and latex layers. The material can be cyclically stretched in uniaxial strain to more than 200% with good elastic recovery, exhibiting electrical resistivity as low as 10^{-5} Ω·cm, and remains viable over the temperature range bracketing the tire vulcanization process. MetalRubber™ may be capable of measuring very large strains (greater than 200%), but this material is very new, developmental, and it remains as a part of this research to prove the reliability and survivability of this material in the hostile environment of a radial tire. Another potential challenge is the creation of a strain sensor that minimizes the mismatch in material moduli between the rubber and the sensor material. Because the rubber is significantly less stiff than most sensor materials, there may be difficulty in determining the strain state in rubber with conventional sensors. These technical challenges could be significantly mitigated if the material from which the structure has been fabricated could be used as a matrix to incorporate conductive particles, such as high-aspect ratio single-wall carbon nanotubes (SWCNTs) and/or multiwall carbon nanotubes (MWCNTs) to facilitate the fabrication of a matched-compliance, conductive, elastomeric strain sensor that could be cured *in situ* as part of the tire tread, in the vicinity of the steel belt edges of a tire, where tread separation initiates.

1.2.4 Capacitance sensing

Recently, another form of embedded sensing for tire health monitoring has been developed, which is based

on capacitance changes to measure global strain in the tire. Virtually all these techniques employ the wires in the steel belts used in radial tire construction as electrodes in a circuit to monitor belt separation through changes in electrical circuit capacitance. An important feature and benefit of these systems is that the tire construction serves as the sensor. Therefore, no additional sensing elements are necessary that could induce a mechanical flaw and compromise tire structural integrity. Some examples of applied circuitry vary as follows:

1. Connecting the steel wires as a condenser within a Hartley-type oscillating circuit whereby the changes in the frequency of the circuit correspond to changes in the wire-to-wire capacitance [10]. This technique has been demonstrated successfully in both wired and wireless signal transmission modes but requires an external power source such as a battery to generate the oscillating circuit.
2. Connecting the steel wires as a condenser in an inductance–capacitance *LC* resonator circuit, whereby the changes in the frequency of the passive filter circuit correspond to changes in the wire-to-wire capacitance [11]. The change in the capacitance causes a change in the filtering frequency of a radio wave passed through the filter circuit, which provides a wireless measure of strain in the tire tread.
3. Connecting the steel wires as a condenser in a temperature-compensated capacitance–resistance *CR* resonator circuit, whereby the changes in the frequency of the circuit correspond to changes in the wire-to-wire capacitance [12]. Wireless strain measurements are possible for cyclic loading rates between 1 and 10 Hz. Static compression and dynamic rotation tests confirm the methodology to be applicable to deployment in commercial radial tires.

2 DISCUSSION OF DIRECT TIRE HEALTH MONITORING SENSORS

Numerous sensing technologies exist for tire health monitoring applications. In general, it would be desirable to isolate the sensors from the tire itself for three major reasons: avoiding the harsh operational environment inside and on the tire, avoid reducing the structural integrity or changing performance of the tire by introducing a sensor, and limited means for powering sensors inside the tire. Noncontact sensors offer the ability to measure the deformation of the tire during operation using various electromagnetic, optical, and acoustic methods. These methods currently appear to be the most commercially viable since they avoid the aforementioned issues, but do suffer some drawbacks themselves. These noncontact sensors can be susceptible to poor performance in driving conditions such as rain, dirt, and mud. Noncontact sensor systems also rely heavily on signal-processing systems to extract meaningful data from the raw sensor signals that may be expensive or bulky. Noncontact sensors also do not have the capability to measure the same quantities such as strain, tire forces, and friction, which may reduce their ability to perform tire damage identification and provides less information for tire life prediction methods.

1 INTRODUCTION

In the 1980s and early 1990s, a number of losses of tankers and bulk carriers resulted in the environmental pollution owing to oil spills and the loss of lives. For example, from 1990 to mid-May 1997, a total of 99 bulk carriers were lost with the death of 654 people. Even the large tanker accidents, including *Erika* and *Prestige*, occurred relatively in recent years. Figure 1 shows the accident of the tanker *Prestige* (Single hull oil tanker, 81 000 ton) in the coast of Spain.

In this regard, International Maritime Organization (IMO), International Association of Classification Societies (IACS), and individual Classification Societies (Lloyd's Register of Shipping, LR; Det Norske Veritas, DNV; and American Bureau of Shipping, ABS) have recommended the use of hull stress monitoring systems for bulk carriers of 20 000 dwt and above to reduce the risks of structural failure since 1994. More recently, there is an increasing demand for documentation of safety and hull conditions for ships carrying oil and gas owing to the oil and gas sector's movement toward harsher environment. For example, as the offshore oil production moves from the North Sea toward the Barents/Kara Sea in Russian Arctic, LNG (liquefied natural gas) ships, FPSO (floating production storage and offload vessels), and shuttle tankers have to withstand longer, harsher winters and fatigue loads.

Hull monitoring system enables the operator of the vessel to monitor all relevant responses (motions, accelerations, loads, bending moments, stresses,

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

Figure 1. The accident of tanker "Prestige" (November 2002).

etc.) and provides rational guidance as preventive measures in heavy weather conditions. The hull stress monitoring system (HSMS) is a system that provides real-time information such as motions and global stress experienced by the ship to crew of the ship while navigating as well as during loading and unloading operations.

Hull monitoring system consists of an affordable number of strain, temperature, or acceleration sensors placed in carefully selected positions on the structure. The sensors are connected to a central processing unit that converts the sensor signals into digital data, which are analyzed by the computer on the ship's navigation deck, allowing an operator to monitor hull stresses even under altering sea states. The system alarms when there is a risk of damage to the hull structures or cargo caused by improper loading or high stress in heavy weather. The lifetime history of the ship recorded by the monitoring system assists the operator in determining hull condition evaluation and fatigue life assessment, thus providing the possibility to prevent cracking and severe casualties. In addition, recorded data is useful when planning hull inspections and maintenance.

Recently, new ideas have been proposed, and advanced techniques have been developed for various measurements and applications. Some hull monitoring systems (HMS) have been already commercialized and user interface computation modules run over a distributed network system.

This article presents examples of current integrated HMS, as well as examples of innovative sensor systems.

2 HULL MONITORING SYSTEM RECOMMENDED BY CLASSIFICATION SOCIETIES

The basic rule requirements of HSMS are in accordance with IMO recommendations for "fitting of HSMS (MSC/Circ.646 6th June 1994, Maritime Safety Committee)". The major classification societies such as LR, DNV, and ABS not only provide similar monitoring guidance for minimum parameters to be monitored but also recognize the fitting of enhanced and more comprehensive monitoring systems through notations. The notations and requirements of classification societies concerning the provision of the typical monitoring for bulk carrier and tankers are summarized in Table 1.

Bulk carrier and tanker hulls could be instrumented with four sensors on the main deck to monitor the dominating sagging and hogging motion. The system monitors the longitudinal bending moments within the structure and compares permissible values that are predetermined by the class rules in conjunction with ship designer. Additional sensors are available to meet higher specifications required by some classification societies' notations, such as DNV HMON-2 and ABS HM3 [1]. The number of sensors that are required depends on the complexity of the structure and the level of ambition of the owner. More number of sensors enables more advanced analyses and the monitoring of more bending modes. The level of analysis can vary from simply monitoring the stress levels and issuing alarms if they approach dangerous levels. Additionally, the level of analysis can be

Table 1. Notations and requirement of the classification societies

Class	Notation	Gauges
LR	SEA (HSS-4)	4 LBSG, 1 bow vertical accelerometer
DNV	HMON-1	4 LBSG, 1 bow vertical accelerometer, 1 midship accelerometer
ABS	HM2 + R	4 LBSG, 1 bow vertical accelerometer

LBSG, long-based strain gauge.

extended to determining overall loads on the structure by converting strains and stresses to global moments, as well as to closely monitoring the fatigue cycles on selected structural details and thereby gather information about the fatigue status.

3 TYPICAL HULL MONITORING SYSTEM

In practice, a typical installation for a large bulk carrier or tanker consists of four long-based strain gauges (LBSGs) and an accelerometer linked to a display monitor, which is illustrated in Figure 2.

Hull monitoring system gives global hull stress response and provides alarm warnings to ship staffs if stress measurement values approach a prespecified level at which corrective action is advisable. The system supports the graphical confirmation that the corrective action has produced the desired reduction in stress levels. Stress signals from the sensors are analyzed in several minutes. Each channel passes through the routine for statistical data analysis, which calculates mean stress, maximum peak stress, standard deviation, peak-to-peak, and mean zero upcrossing periods. Fatigue strength is represented by the number of cumulative stress cycles up to measuring time. The counting is carried out using the rainflow method, and stress range are divided into a number of blocks with a constant stress range. Fatigue monitors indicate the amount of usage of the initial fatigue strength over time relative to the approved scantlings by use of Miner's rule in conjunction with rainflow counting. It is recommended that the measured data can also be used later for crack growth calculations using a method submitted for review. The data is also required to be recorded for later analysis and for new shipbuilding.

3.1 Long-based strain gauge (LBSG)

The LBSG measures the hull girder response of the vertical still water bending moment (SWBM) and wave-induced bending moment (WIBM) at selected points along the vessel. Figure 3 shows an exaggeration of how a ship bends owing to these loads. The permissible bending moment for both sea and harbor condition is provided by classification rules.

By means of continuous measurements and displays in real time using LBSG, the longitudinal stresses at strategic locations on the hull girder are simultaneously monitored in real time. A minimum of four LBSGs are fitted: two at midship and two at approximately 25% from the bow and stern. The precise location may vary per different ships. The LBSG consists of about 2-m stainless steel rod, fixed at one end and free to move against a displacement transducer at the other end. The electrical transducer is a liner variable differential transformer (LVDT).

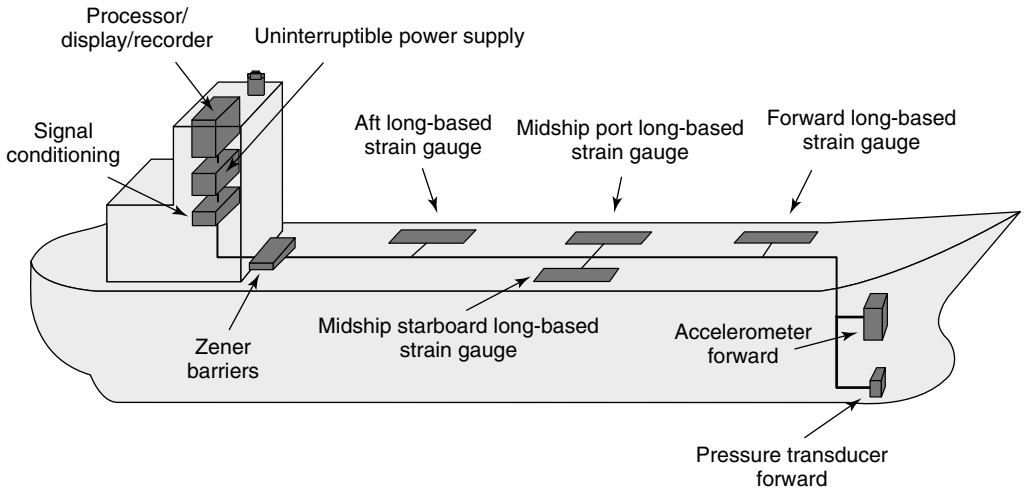

Figure 2. Typical hull monitoring system for a bulk carrier.

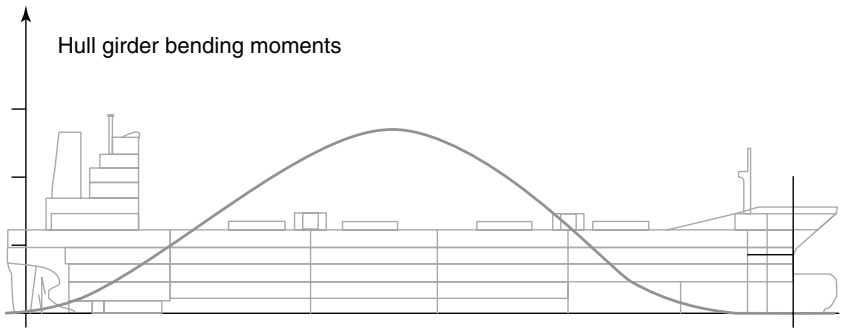

Figure 3. The bending moment display for a bulk carrier.

The end mountings are bolted to plates welded to the deck with centers about 2 m apart and located along a longitudinal deck. The unit is waterproof and fitted with a protective cover. Figure 4 shows the mounting plate with a strain gauge rod and a protect cover.

3.2 Accelerometer

The accelerometer with the range of $\pm 2\,g$ is used to measure the vertical acceleration at the bow. It is used to give an indication of the probability of slamming in heavy weather. It operates via a line amplifier that provides output signal to the display logger unit. The accelerometer unit shown in Figure 5 should be attached to the bracket that is welded to a secure structural member of the ship. In addition, the system should calculate and store the impact energy of a slamming by calculating area under the acceleration versus displacement curve.

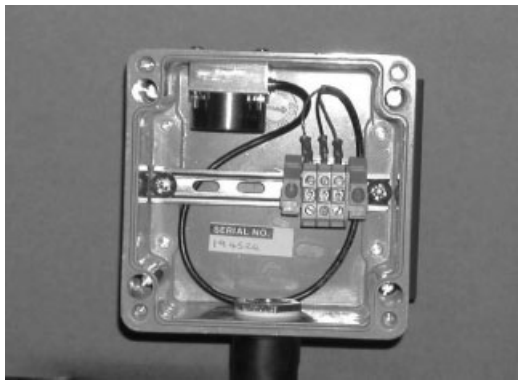

Figure 5. The accelerometer unit.

3.3 Additional sensors

In addition to the typical specification of four LBSG and one bow accelerometer, additional sensors could be added to extend the functionality to meet client-specific requirements, or the higher rules of the certifying authorities. The following lists some examples of sensors that may be installed:

- strain gauge: measures localized stress, e.g., for ice loadings on the bow and stern structures. Strain gauges are typically required to have accuracy better than ± 5 microstrain and be capable of measuring in the 0–5-Hz frequency range;

- six degree of motion sensor: roll, sway, heave, pitch, yaw, and surge accelerations;
- pressure transducer: measures pressures on the bow or stern and the depth of water at the bow and gives indication of draft as well as the detection of the bow leaving the water at the onset of slamming.

4 EMERGING TECHNOLOGIES FOR SHIP HULL MONITORING

In recent years, HMS has attracted much attention in new technology. Fiber-optic sensor (FOS), acoustic emission (AE) sensor, and crack monitoring sensor are promising sensing alternatives in HMS. New HMS was developed to describe and predict how damage evolves in structures before their reliability can be accurately forecasted in real time. This intelligent system offers services in onshore data management to help the maintenance planners and other onshore personnel manage the assets in an optimal way. Reports, which summarize the hull condition, are available based on the data from the HMS. Data can be transferred for onshore analysis by automatic e-mails or by backup media. In addition, the transferred data is useful when planning hull inspections and maintenance.

Monitoring contributes to increased safety and may facilitate an increase in fatigue lifetime for the structure. In the case of offshore structures, the problem is also compounded by harsh marine environment. Offshore structures must withstand cyclic wave loading, severe storms, sea quakes, and the corrosive effects of sea water, particularly for long period of time. Furthermore, the process of visually inspecting marine structures, especially those in deep water, is much more difficult than that for land-based structures.

4.1 Fiber-optic sensor (FOS)

One of the new methods for measuring the hull stress and the health of ship hulls is to apply FOS. Optical fibers, which usually consist of three layers: fiber core, cladding, and jacket, are dielectric devices used to confine and guide light. The majority of optical fibers used in sensing applications have silica glass cores and claddings, and the refractive index of the cladding is lower than that of the core to satisfy the condition of Snell's law for total internal reflection and thus confine the propagation of the light along the fiber core only. The outer layer of a FOS, called jacket, is usually made of plastic to provide the fiber with appropriate mechanical strength and protect it from damage or moisture absorption. In some sensing applications, a specialized jacket is required to enhance the fiber's measurement sensitivity and to accommodate the host structure.

There are a number of different concepts for turning optical fiber into a sensor. The new structure monitoring systems use fiber-optic sensors based on Bragg gratings (FBG), which is shown in Figure 6.

FBG is such a sensor technology, creating an optical strain gauge within the core of an optical fiber through the use of a wavelength-specific filter. As the FBG experiences induced strain along its major axis, its light signal indicates the amount of strain with great accuracy and sensitivity. In FBG applications, where loading may occur in all directions, complex changes take place in the FBG signal.

The generalized strain–optic relationship between the optical path length (Δ_l) and the axial strain, ε_{xx}, induced over the gauge length of a single segment of the optical fiber is given below:

$$\Delta_l = n_{\text{eff}} L \varepsilon_{xx} \tag{1}$$

and

$$n_{\text{eff}} = n - \frac{1}{2}\left[P_{12} - \nu_f (P_{11} + P_{12})\right] \tag{2}$$

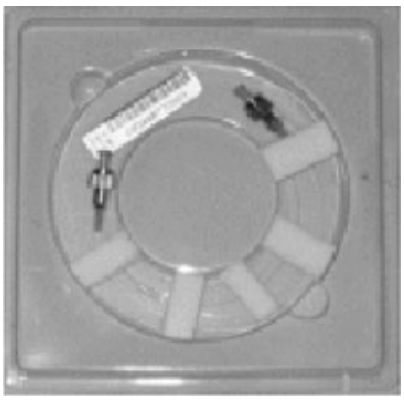

Figure 6. Typical fiber-optic sensors based on Bragg gratings (FBG).

where P_{11} and P_{12} are Pockels constant, ν_f is the Poisson's ratio, n is the refractive index of the fiber, and L is the length (gauge length) of the optical fiber to which the strain is applied.

The FOS have a number of advantages over the electrical alternatives, especially in harsh environments: small size, light weight, immunity to electromagnetic interference (EMI), passive composition, high-temperature performance, large bandwidth, higher sensitivity as compared to existing monitoring techniques, and multiplexing capabilities. Multiplexing of Bragg grating sensor would allow for a number of strain measurements along one fiber, which is shown in Figure 7. This arrangement maximizes the multiplexing potential of Bragg gratings and keeps system cost to a minimum.

Application of fiber Bragg grating sensors for the purpose of ship hull monitoring is reported by Norwegian Defense Research Establishment. FOS are embedded in composite hull, and real-time strains as well as global loads are measured in actual sea-keeping tests [2].

4.2 Acoustic emission (AE) sensor

Crack growth due to fatigue and stress corrosion is normally a slow degradation process up to a point, beyond which failure may be sudden and catastrophic. Detection as early as possible during this initial period of crack growth is essential if the consequences of an unexpected failure are to be avoided.

AE monitoring can overcome many of the difficulties with crack detection in service and is potentially a most powerful method of inspection. It is sensitive to the propagating cracks, that is, the structurally significant defects, and provides information on growth rate under service loading conditions, guiding inspection and repair work for maximum cost-effective maintenance.

Examination of the microstructure of fatigue and stress corrosion cracks, see Figure 8(a), reveals that fracture on a microscale involves crack steps of magnitude comparable to the grain size of the material. In the case of stable crack growth due to fatigue, the crack will extend only if the stress

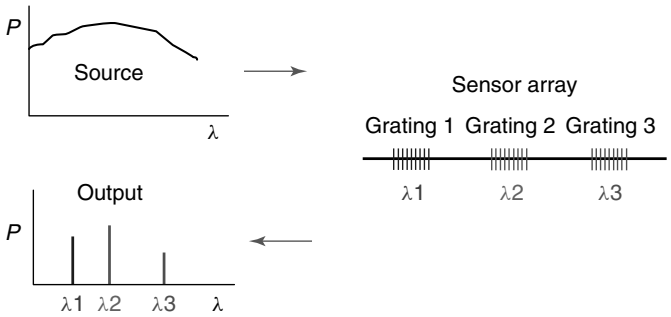

Figure 7. Schematic for multiplexing of Bragg grating fiber-optic sensor.

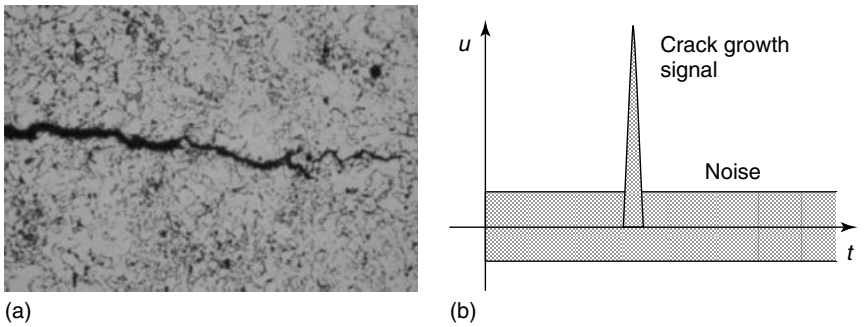

Figure 8. Schematic representation of extremes of fracture behavior. (a) Microstructure of a fatigue crack and (b) fast brittle crack advance in poor toughness material.

concentration is sufficient for the material to yield over a short distance ahead of the crack tip. This distance is referred to as the threshold plastic zone size.

This monitoring technology can provide improved assurance of overall integrity, justifying the additional work and cost involved. By continuously monitoring a vessel or offshore structure for a period of time, usually several weeks or months, depending on the minimum acceptable defect size, enhanced assurance of structural integrity can be obtained. The underwater sensor shown in Figure 9 is attached to a marine structure (ballast tank in vessel or jack-up platform), which is the most effective sensor for monitoring.

The period of monitoring must be predetermined as adequate for a measurable amount of crack growth to occur. It is typically specified by the minimum size of structurally significant size defects (e.g. propagating fatigue cracks) that can be identified. By relating crack growth to the loading and environmental forces driving the crack and the stress concentration due to geometry, it is possible to model the crack growth accurately. In addition, the effectiveness of different methods of inhibiting or arresting crack growth can be evaluated by continuing the monitoring for a period of time.

Sources of AE are defect-related processes such as crack extension and plasticization of material in the highly stressed zone adjacent to the crack tip. In general, the form of the primitive wave changes during propagation through the medium, and the amplified signal from a resonant piezoelectric sensor bears little resemblance to the original pulse. The transducer produces an electrical pulse that can be analyzed to provide information about the original AE source and, hence, facts about the structure.

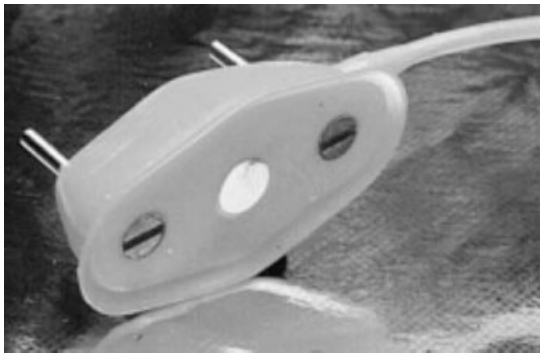

Figure 9. A new AE sensor for use on underwater marine structure.

4.3 Fatigue crack monitoring sensor

Fatigue crack monitoring sensors are developed for detecting fatigue cracks occurring in welded structures. These sensors are cheap, small in size, and made of thin metal pieces as shown in Figure 10. This type of fatigue crack sensors can be placed in front of stress-concentrated area for detecting fatigue cracks, particularly in welded joints.

When fatigue crack propagates through the surface of the sensor due to repeated fatigue loadings, the sensor can be used for measuring the fatigue crack length. The crack length information then can be used for calculating the remaining fatigue life of the welded joint using the following equation:

$$Ds = \frac{\Delta a}{a_0} \tag{3}$$

Here, a_0 and Δa denote the initial crack length and the crack propagation, respectively. $Ds = 0$ indicates intact state, while $Ds = 1$ indicates fatigue fracture. This type of fatigue crack sensors can be placed in many fatigue-prone locations and can be used for monitoring fatigue cracks in ships and offshore structures.

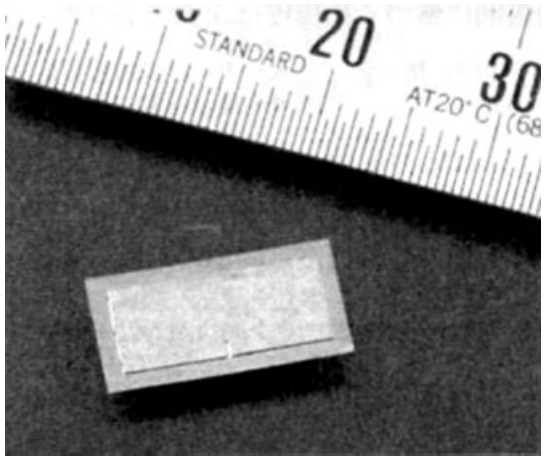

Figure 10. Fatigue crack monitoring sensor.

5 FUTURE TRENDS

The consumption of LNG is increasing and the market for oil transport for cold climate (ice/arctic) is expanding at an unprecedented pace. As there is increase in the size of vessels and cargo containment systems, navigating in new region and the demands on the classification societies are also very challenging. At the same time there is increasing demand for documentation of safety and, in particular, of hull conditions for ships carrying oil and gas.

Sloshing-induced impact load can cause a critical damage on tank structure. Sloshing is especially troublesome in LNG cargo tank. A sloshing monitoring system should measure impact pressure and strain in large LNG carriers. A new line of FOS has been recently developed for monitoring the sloshing pressure in low-temperature insulation tanks. Traditional pressure sensor cannot be used for measuring pressure inside the containment system owing to the cryogenic environment. The newly developed sensors are applicable to LNG cargo containment systems at $-163\,^{\circ}C$ and offer the possibility to measure sloshing pressures in nonintrusive manner without penetrating the primary membrane. The pressure sensors may be fitted with integrated temperature sensors and may be combined with fiber-optic stress sensors on the tank walls.

As the oil and gas sector moves to cold climate environments, the infrastructure must take an increasing load. Ice load as a phenomenon is largely statistical in nature. The arctic provides a harsh environment to survive in. Cold temperatures, ice, snow, and freezing fog pose additional factors for ship design, construction, and operation. Hull monitoring system is an integral part to ensure the vessels' capability to survive and to give a measure of safety when navigating in ice water.

The ice load monitoring system is always tailor-made according to the particular needs of each project. The system is based on large amount of previous field-testing. The system shows ice load, trend, severity measure, and prediction for the crew. The measured data is stored in the system, and it can be downloaded from the storage for further analysis.

For offshore structures, there are many locations that are difficult to access, and therefore it is not an easy task, if not impossible, to inspect all the damage-prone locations. Besides, they operate at very harsh environment. Also, it is complicated to distinguish the structural response between those due to wave loading and damages. Therefore, health monitoring technique would be an ideal candidate for this type of application since the frequency range of interest is much higher than the environmental excitation.

With the increasing market demand for vessels operating in cryogenic environment, such as LNG and arctic ships, new and more effective health monitoring techniques should be developed.

6 SUMMARY AND CONCLUSIONS

In this article, various techniques for monitoring structural integrity of ship and offshore structures are discussed. Typical HMS with common sensor locations are introduced as well as measurement parameters to be monitored are discussed. LBSG is typically installed at the deck of midship and at quarter length of vessels for monitoring hull girder strength. Ship motion and slamming pressures are measured by accelerometers and pressure sensors located at the bow of vessels. Different requirements for hull monitoring system are summarized for each classification societies. This is followed by a review on the introduction of emerging new technologies that are applicable for ship and offshore structures. The basic principles and the application of FOS, AE sensors, and crack detection sensors (CD) are reviewed. Finally, new requirements and future trends in terms of structural health monitoring in marine industries are introduced. In particular, the importance of structural health monitoring technology that is applicable in cryogenic environment is presented. In conclusion, structural health monitoring technique is an integral system for ensuring the safety of ships and offshore structures as well as for protecting environment.

1 INTRODUCTION

The interaction of electromagnetic energy with matter represents one of the most common and useful methods for inspecting and assessing a material or structure. Visual inspections, in fact, continue to be one of the most widely used and effective methods for characterizing the surface properties of a material or system [1]. By studying the reflective properties of a surface, for example, structural damage in the form of surface-breaking cracks, corrosion, and disbonds can be distinguished from undamaged areas based on surface roughness or topographic variations, which tend to reflect visible light differently, providing a simple means for detecting damage easily with the naked eye.

 ISBN: 978-0-470-05822-0.

Of course, the characterization of surface properties alone represents a somewhat limited capability for understanding the structural health state of a material system. With the fundamental scientific discovery in the mid-seventeenth century that the electromagnetic spectrum is actually a continuum of frequencies/wavelengths, and the subsequent discovery of X rays [2], microwaves [3], and radar [4], the material penetration capabilities of electromagnetic radiation were revealed with profound implications. In particular, the ability to "see" into or through a visibly opaque material became possible using radiography at high frequencies ($\sim 10^{18}$ Hz) and microwave imaging at low frequencies ($\sim 10^{11}$ Hz).

The present article is concerned with the use of *directed energy* as an inspection tool for use in structural health monitoring applications. Directed energy sensing can be loosely defined as "the controlled insertion of electromagnetic energy into a material or system, where the observation of electromagnetic–material interactions is used to characterize the structural health of the system". At the core of this definition is the electromagnetic–material interaction, which uses the changes induced in an electromagnetic wave/field by a material system as its measurand. These changes can involve phase, amplitude, frequency, directionality, polarization, time of flight, and many other phenomena that are usually associated with wave phenomenon. It is in this basic theme that the article is organized, where fundamental principles related to electromagnetic

fields/waves, directed energy beam characteristics, radiation–material interactions, and damage sensing are covered. An initial historical overview is first given followed by a brief description of the state-of-the-art directed energy sensing methods. A general overview of each of the major directed energy inspection methods is then provided, where physical principles of each method are covered along with specific measurement examples.

1.1 Historical background

Electromagnetic radiation has been at the forefront of scientific discovery for several millenniums. What began as a need for understanding the stars and heavens has grown to a scientific and technological discipline, which touches every part of human life and existence. Much of what we know about visible light and its interaction with materials was first studied in the Renaissance period (fourteenth to seventeenth centuries) by Descartes [5], Newton [6], Fermat [7], Snell [8], Huygens [9], Fresnel [10], and others [11–13]. The principles of light reflection, refraction, scattering, and diffraction were identified and systematically studied in much of this early work. The concept of "light waves" versus "light particles" was also debated during this period, which is currently known as the *wave-particle duality* of electromagnetic waves and photons of energy [14]. Both of these concepts play an important role in directed energy sensing methods.

For the next 200 years, theoretical and experimental work defined the inner workings of electromagnetism, culminating in the work of Maxwell [15] who demonstrated mathematically that electric and magnetic fields travel through space, in the form of waves, and at the constant speed of light. In 1861, Maxwell wrote his four-part publication in the *Philosophical Magazine* called "On Physical Lines of Force", where he first proposed that light was a form of energy composed of both electric and magnetic phenomena [15]. This fundamental discovery made the basic connection between electromagnetic waves and electronic material states possible, where electromagnetic fields exert a force (the Lorentz force) on the charged particles in a material system. The set of four equations known as *Maxwell's equations* describes this interrelationship between electric fields, magnetic fields, electric charges, and electric currents, forming the foundation of classical electromagnetism and electrodynamics. The material property concepts of permittivity, permeability, and complex dielectric were also defined, providing a means for characterizing electromagnetic–material interactions, where Maxwell's equations can be used in conjunction with the dielectric properties of a material to understand how light interacts with a material in a classical sense.

Around this same time (1860), the term *blackbody* was introduced by Kirchhoff [16], which relates the electromagnetic radiation emission properties of an object at increasing temperatures. In effect, the amount of electromagnetic radiation (and its corresponding wavelength) emitted by a black body source is directly related to its temperature. Black bodies above ~700 K (430 °C) produce radiation at visible wavelengths starting at red, going through orange, yellow, and white before ending up at blue as the temperature increases. This discovery represented a key connection between electromagnetic and thermodynamic physics (*see* **Thermal Imaging Methods**).

The early work of Hertz [17] and Roentgen [2] in the 1880s–1890s extended the useful range of the electromagnetic spectrum to radio frequencies and to X-ray frequencies, respectively. Earlier in 1886, Hertz developed the dipole antenna receiver, which helped to establish the photoelectric effect, and represented the first practical instrument for producing and receiving electromagnetic wave energy (at ultra high frequency (UHF) radio frequencies). At the other end of the electromagnetic spectrum, Roentgen discovered X rays on November 8, 1895 when he observed a fluorescent glow from crystals near a cathode-ray tube. His systematic characterization of the penetrating nature of the radiation emitted by cathode-ray tubes ushered in the scientific field of radiography. The first practical use of electromagnetic energy as an inspection tool soon followed when X-ray fluoroscopes were used in 1896 to inspect postal packages, porcelain materials, precious stones, and simple metal welds [2] (*see* **Nondestructive Evaluation/Nondestructive Testing/Nondestructive Inspection (NDE/NDT/NDI) Sensors—Eddy Current, Ultrasonic, and Acoustic Emission Sensors**).

In 1900, Planck presented a paper at the German Physical Society in which he proposed the revolutionary scientific thought of quantum

mechanics, which describes submicron particles as being composed of discrete states of energy [18]. In that work, Planck used the blackbody radiation concepts of Kirchhoff [16] and Wien [19] to mathematically describe the distribution of electromagnetic energy emitted by the different modes of charged oscillators in matter—what is known today as *Planck's law* for blackbody radiation. Building on these original ideas, in 1905 Einstein proposed that light can act as individual, discrete energy states—what we now know to be *quantum* of radiant energy or photons [20]. Einstein further described a new relationship between the energy and frequency of a photon as $E = h\nu$, where h is known as *Planck's constant* [20]. The foundation of electromagnetic–material interactions at a quantum mechanical level was based on these early ideas, which were verified by the end of the 1920s by Bohr, Born, Heisenberg, Schrödinger, De Broglie, Pauli, Dirac, and others. The work of Bohr, in particular, set forth in 1913 the fundamental quantum mechanical relationship between atomic states and electromagnetic energy emission and absorption, where he predicted the wavelengths of emission for a hydrogen atom [21]. The light emitted (and absorbed) by an atom, molecule, or material is now understood to arise from the transition of electrons between discrete energy states in a material system, where electromagnetic energy is either given to or taken from the system. The fundamental nature of electromagnetic–material interactions was, therefore, found to be both discrete in nature—quantum mechanics and photon energies—and continuous in nature—electromagnetic wave interactions with dielectric material properties (*see* **Electric and Electromagnetic Properties Sensing**).

1.2 State of the art

The use of directed energy methods for material inspections and structural health monitoring has seen significant progress and advancement in the past decade. The state of the art now permits detailed characterization of numerous materials with unprecedented spatial resolutions and damage sensitivity levels [22]. Perhaps, the most impressive are the three-dimensional imaging approaches (X-ray computed tomography [23], optical coherence tomography [24], microwave holography [25], and terahertz time-domain spectroscopy [26]), which have recently shown capabilities for probing materials with thicknesses of more than 25.4 cm (10 in.) (e.g., ceramic foams) and at spatial resolutions approaching 1 μm [27] (*see* **Nondestructive Evaluation/Nondestructive Testing/Nondestructive Inspection (NDE/NDT/NDI) Sensors—Eddy Current, Ultrasonic, and Acoustic Emission Sensors**).

The detailed characterization of surface and near-surface damage (e.g., surface-breaking cracks) using laser ultrasound [28], thermosonics [29], and optical coherence tomography [24] methods have also produced damage sensitivity levels, which now permit damage initiation, damage growth, and damage precursor indications to be measured. The whole-field imaging of structural microcracks using thermosonics, in particular, has been shown to be a powerful tool for imaging cracks, disbonds, and delaminations in complex geometry aerospace structures with damage features approaching 10 μm in size [29] (*see* **Full-field Sensing: Three-dimensional Computer Vision and Digital Image Correlation for Noncontacting Shape and Deformation Measurements**).

The detection of hidden damage has also been reported recently using penetrating, nonionizing radiation in the terahertz [26], microwave [30], and millimeter-wave frequency bands, where damage hidden beneath aerospace coatings, insulation, composite, and ceramic materials has been reported [26, 30]. Significant advances in active and passive thermography have also been made in a large part due to improvements in focal plane array camera technologies, which have dramatically improved spatial resolution, thermal sensitivity, and noise rejection levels [31–33] (*see* **Thermal Imaging Methods**).

2 PHYSICAL PRINCIPLES

Directed energy sensing fundamentally involves the interaction of electromagnetic energy with a material system. The sensing process can involve a number of different physical processes depending on the type of electromagnetic radiation used and the specific characteristics of the materials involved (*see* **Electric and Electromagnetic Properties Sensing**). A decrease in X-ray beam intensity, for example, can be attributed to an increase in material density or sample thickness based on material absorption

principles, while a phase shift in a reflected laser beam at visible wavelengths may be due to surface motions of a vibrating material surface. In this section, a description of the physical principles involved in directed energy sensing is given, where similarities and differences between the electromagnetic frequencies are highlighted.

2.1 Electromagnetic radiation

Electromagnetic radiation propagates through space as an oscillating electric and magnetic field. The two field components are in phase, and oscillate at right angles to each other and to the direction of propagation. In 1861, Maxwell derived what is referred to as the electromagnetic *wave equation*, which governs the propagation of electromagnetic energy in free space and within a given material [34]. In general, electromagnetic radiation can be classified according to the frequency of the wave: radio waves, millimeter waves, microwaves, terahertz radiation, infrared radiation, visible light, ultraviolet radiation, and X rays. Figure 1 shows a diagram of the electromagnetic spectrum, where key frequency ranges are highlighted along with technologies associated with each frequency range.

An electromagnetic wave, like other wave phenomena, can be characterized by its wavelength (the distance from a point on one cycle to the corresponding point on the next cycle) or its frequency (the number of oscillations per second). In a vacuum, all electromagnetic waves travel at the same speed, the speed of light, $c = 299\,792\,458\,\mathrm{m\,s^{-1}}$. The wavelength, λ, and frequency, ν, of an electromagnetic wave are related by the equation

$$\nu = \frac{c}{\lambda} \tag{1}$$

which holds true for all forms of electromagnetic radiation. The energy of an electromagnetic wave is related to its frequency and wavelength by the relationship

$$E = h\nu = h\left(\frac{c}{\lambda}\right) \tag{2}$$

where h is a constant known as *Planck's constant*.

2.2 Radiation and matter

Depending on the frequency used, electromagnetic energy can interact with matter in very different ways. In a classical sense, electromagnetic energy interacts with materials as a localized field or wave phenomenon through material properties like the complex dielectric, the index of refraction, and the absorption coefficient. In a quantum mechanical sense, photons of electromagnetic energy interact with specific energy states in a material through

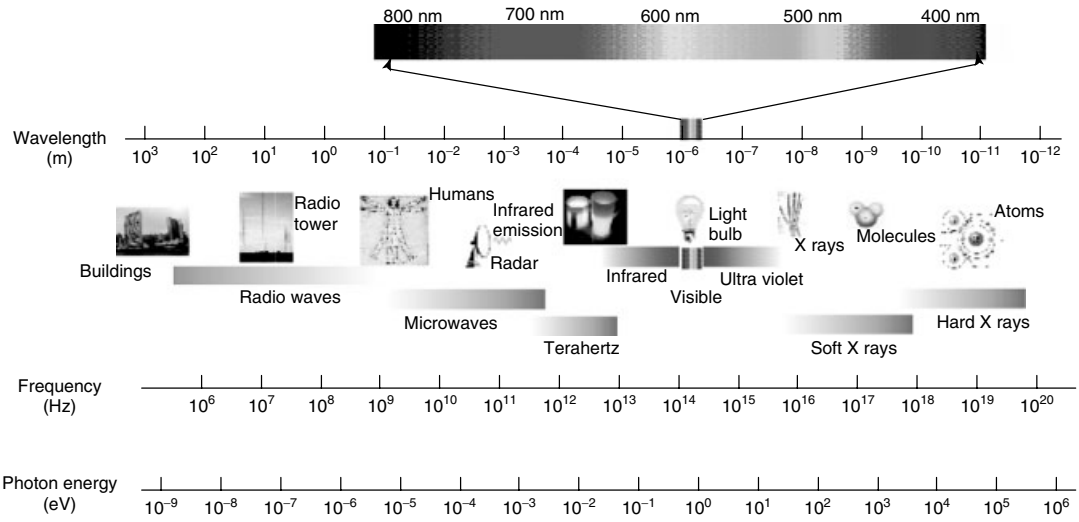

Figure 1. Electromagnetic spectrum with associated length scales and technologies.

probability functions and allowable transitions. Both of these concepts play a role in directed energy sensing (*see* **Electric and Electromagnetic Properties Sensing**).

In the classical approach, matter consists of a positive charge centers surrounded by clouds of negative charge [35]. In the presence of an electromagnetic field, the charge cloud distorts, which constitutes a simple dipole through the dipole moment. Mathematically, this process can be described using the dielectric properties of the material through a complex quantity denoted by

$$\varepsilon = \varepsilon' - \mathrm{j}\varepsilon'', \varepsilon_\mathrm{r} = \varepsilon_\mathrm{r}' - \mathrm{j}\varepsilon_\mathrm{r}'', \varepsilon = \frac{\varepsilon}{\varepsilon_0} \qquad (3)$$

where ε is called the absolute complex dielectric constant of the medium, ε_r is the relative complex dielectric constant, ε' is the permittivity (the ability of the material to store electromagnetic energy), ε'' is the dielectric loss factor (the ability of the material to absorb electromagnetic energy), and $\varepsilon_0 = 8.85419 \times 10^{-12}\,(\mathrm{F\,m^{-1}})$ is the permittivity of free space [30].

For a plane electromagnetic wave propagating in the z direction and polarized along the x axis inside a medium with a dielectric constant of $\varepsilon_\mathrm{r} = \varepsilon_\mathrm{r}' - \mathrm{j}\varepsilon_\mathrm{r}''$, the electric field intensity at any point can be described by the relationship [30]

$$\vec{E}(z) = E_0 \mathrm{e}^{-(\alpha+\mathrm{j}\beta)z}\,\hat{a}_x = E_0 \mathrm{e}^{-\gamma z}\hat{a}_x,$$
$$\alpha = k_0 |Im\{\sqrt{\varepsilon_\mathrm{r}}\}| \quad \beta = k_0 Re\{\sqrt{\varepsilon_\mathrm{r}}\} \qquad (4)$$

where E_0 is the electric field intensity at $z = 0$, α is the absorption constant, β is the phase constant, $\gamma = \alpha + j\beta$ is the propagation constant, and $k_0 = 2\pi/\lambda_0$ is the wave number in free space, and λ_0 is the wavelength in free space. For a plane electromagnetic wave traveling through a thickness, d, of material, the product $\gamma \cdot d$ determines the amount of attenuation and phase shift that the wave will experience [30].

When an electromagnetic wave traverses a boundary between two media, the concept of index of refraction becomes useful. Similar to the complex dielectric concept, the complex refractive index of a material determines how much the wave speed is reduced inside a medium and how much absorption loss occurs through the expression

$$\tilde{n} = n - \mathrm{i}k \qquad (5)$$

where n is the index of refraction, k is the extinction coefficient, and n is related to the material's relative permittivity, ε_r, and relative permeability, μ_r, through the expression $n = \sqrt{\varepsilon_\mathrm{r}}\sqrt{\mu_\mathrm{r}}$. The mathematical expressions describing the electromagnetic wave reflection and transmission at a boundary are referred to as the *law of reflection* and *Snell's law*, which are depicted schematically in Figure 2, and are given by the expressions: $\theta_\mathrm{i} = \theta_\mathrm{r}$ and $n_\mathrm{i} \sin\theta_\mathrm{i} = n_\mathrm{t} \sin\theta_\mathrm{t}$, respectively, and where $\theta_{\mathrm{i,r,t}}$ are the angles of incidence, reflectance, and transmission.

In addition to the reflection, refraction, and transmission of light, the absorption and scattering of electromagnetic energy by a material represents a key aspect of most directed energy measurement approaches (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**). In particular, the scattering of wave energy becomes important when the wavelength of an electromagnetic wave approaches (Mie scattering), or becomes larger than (Rayleigh scattering), the size of a scattering object.

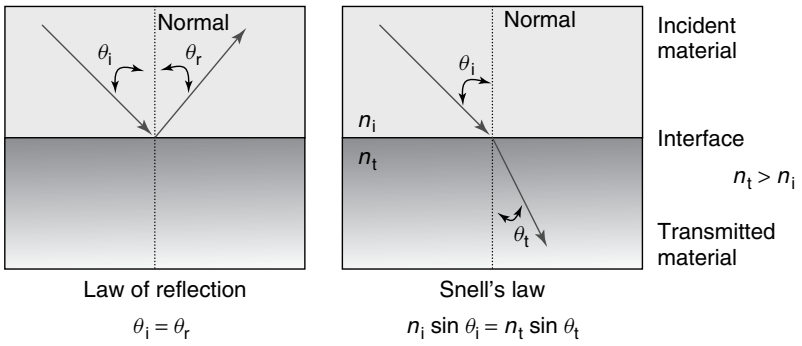

Figure 2. Reflection and refraction of electromagnetic radiation at a material interface.

For an electromagnetic wave incident on a single small scattering object, the intensity, I, of the scattered light can be written as follows:

$$I \cong I_0 \frac{1+\cos^2\theta}{2R^2}\left(\frac{2\pi}{\lambda}\right)^4\left(\frac{n^2-1}{n^2+2}\right)^2\left(\frac{d}{2}\right)^6 \quad (6)$$

where R is the distance from the particle, θ is the scattering angle, n is the refractive index of the scattering object, and d is the nominal size of the object. An important feature of equation (6) is the intensity of the scattered energy scaling inversely with the fourth power of the wavelength.

The absorption of electromagnetic energy by a material is traditionally described by Beer's law, which states that a logarithmic dependence exists between the transmission of light through a substance, the concentration/density of the substance, and the length of material that the light travels through. If the linear absorption (or attenuation) coefficient is defined as μ, then Beer's law can be written as follows:

$$I_z = I_0 \exp -[\mu z] \quad (7)$$

where I_z is the intensity of the beam at a distance z and I_0 is the intensity at the specimen surface. The primary factor that determines how radiation will be absorbed by a material is based on the atoms and molecules that make up the material. At a very fundamental level, the energy of an atomic and molecular system is quantized (i.e., made up of discrete levels). If a particular electromagnetic radiation energy matches one of these quantized energy states, then a strong interaction will result (e.g., absorption, reflection, refraction, and scattering), and if there are no available energy levels that match the energy of the incident radiation, then the material will typically be transparent to that radiation. In the following subsections, this basic concept is built upon, where the major features of each frequency range are covered.

2.2.1 X-ray interactions

The quantum energy of X-ray photons is ~124 eV and greater, which is much too high to be absorbed in electron transitions between states for most atoms and molecules [36–39]. Because of this fact, most X rays penetrate through materials, with only the occasional X ray knocking an electron completely out of an atom/molecular system. During this process, the X ray can give up all of its energy to the electron (photoionization), or it can give up part of its energy (Compton scattering). A third possibility also exists if the X ray has sufficient energy, resulting in the creation of an electron–positron pair. A few electron volts of photon energy are typically required to eject an electron and ionize an atom, which places the threshold for ionization somewhere in the ultraviolet region of the electromagnetic spectrum. The X-ray wavelength range is ~10 nm and shorter, while the frequency range is $\sim 3 \times 10^{16}$ Hz or greater. X-ray energies below 10 keV are typically referred to as *soft* X rays, which are used for porous or thin material measurements, while more energetic X rays above 10 keV are referred to as *hard* X rays for dense, thick material measurements.

2.2.2 Visible and ultraviolet light interactions

The quantum energy of visible and ultraviolet photons is in the range ~1.65–124 eV, which is the dominant range of energies for elevating bound electrons to higher energy levels within an atomic or molecular system [36–39]. There are typically many available states in most material systems, so visible and ultraviolet light are strongly absorbed by most materials. The shorter ultraviolet wavelengths can reach the ionization energy for some molecules, which permits them to act in a similar fashion to "soft" X rays, while the net result of an absorption event by nonionizing visible radiation is generally just to heat the material sample. The wavelength range for visible–ultraviolet radiation is from ~750 to 10 nm, while the frequency range is from $\sim 4 \times 10^{14}$ to 3×10^{16} Hz.

2.2.3 Infrared interactions

The quantum energy of infrared photons is in the range 0.001–1.7 eV, which corresponds to the range of energies required for separating the quantum states of molecular vibrations [36–39]. Infrared radiation is typically absorbed more strongly than terahertz and microwave frequencies, but less strongly than visible light. The result of an infrared absorption event is the heating of the material due to increased molecular vibrational activity. Infrared radiation can

penetrate further into most materials relative to visible light due in part to its longer wavelength and in part to the reduced number of available quantum states for infrared energy coupling with the material. The wavelength range for infrared radiation is from $\sim$30 μm to 750 nm, while the frequency range is $\sim 0.003-4 \times 10^{14}$ Hz.

In addition to the absorption of electromagnetic energy, infrared energy can flow or move within a material (thermal diffusion), and it can be radiated or emitted by a material according to Planck's law for blackbody radiation. The thermal transport or diffusion of heat energy within a material is important for infrared directed energy measurements, where active heating is used (e.g., pulsed thermography). For passive measurements, the emission of thermal radiation from a material is important. This "emissivity" depends on factors such as temperature, emission angle, and wavelength [31–33] (*see* **Thermal Imaging Methods**).

2.2.4 Terahertz, microwave, and millimeter-wave interactions

The quantum energy of terahertz, microwave, and millimeter-wave photons is in the range $\sim 0.00001-0.001$ eV, which is in the range of quantum state energies for molecular rotation and torsion [26, 30, 36–39]. Terahertz energy is absorbed more strongly than microwaves, but less strongly than infrared light. The interaction of terahertz/microwave radiation with matter results in the rotation of molecules and the production of heat as a result of that molecular motion. Conductors strongly absorb microwaves (and lower frequencies) because they cause electric currents to form, which quickly heats the material. Most dielectric materials are largely transparent to both terahertz and microwaves energies/frequencies. Because the quantum energies of terahertz and microwave radiation are approximately million times lower than those of X rays, they do not produce ionization and are, therefore, a safer method for characterizing materials when depth penetration is needed. Most microwave applications fall in the range 3000–30 000 MHz (3–30 GHz). Current microwave ovens operate at a nominal frequency of 2450 MHz, a band assigned by the Federal Communications Commission (FCC). There are also some amateur and radio navigation uses of the 3–30 GHz range. The wavelength range for terahertz radiation is from $\sim$30 μm to 1 mm, while the frequency range is from $\sim 3 \times 10^{11}$ to 1×10^{12} Hz. The wavelength range for microwave (and millimeter-waves) radiation is $\sim$1 mm and greater, while the frequency range is $\sim 3 \times 10^{11}$ Hz and smaller.

2.3 Directed energy measurements

As stated earlier, directed energy sensing methods use electromagnetic energy to probe and characterize a material or structure. In most cases, active illumination is used to irradiate the material at some standoff distance, and a light-sensitive detector is used to collect the transmitted, reflected, or scattered electromagnetic energy from the material system (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**). Material characterization or damage identification is then accomplished by analyzing the collected signals and applying the appropriate physics to extract material information of interest.

Figure 3 depicts the three primary approaches used in directed energy sensing measurements. If the electromagnetic radiation is not transmissive (or partially transmissive), then single-sided measurements are typically used (Figure 3a and b), where electromagnetic energy reflected from the material surface or scattered from within the near-surface region of the material is collected and analyzed. Most ultraviolet, visible, and infrared wavelength methods fall into this category. Some terahertz time-domain spectroscopy and near-field microwave methods also use the single-sided detection method depicted in Figure 3(a). If the electromagnetic radiation is transmissive, then volumetric measurements are possible using the through-transmission measurement approach depicted in Figure 3(c).

A wide variety of sources are available from broadband radiating sources (e.g., thermal radiation blackbody sources as previously described), to X-ray tubes, to microwave horns, to laser sources. An equally broad range of detectors are also available from semiconductor diodes, photomultiplier tubes, to photosensitive films and electronic imaging arrays. In most cases, the goal of a directed energy measurement is to collect the electromagnetic radiation energy and convert it to an electrical

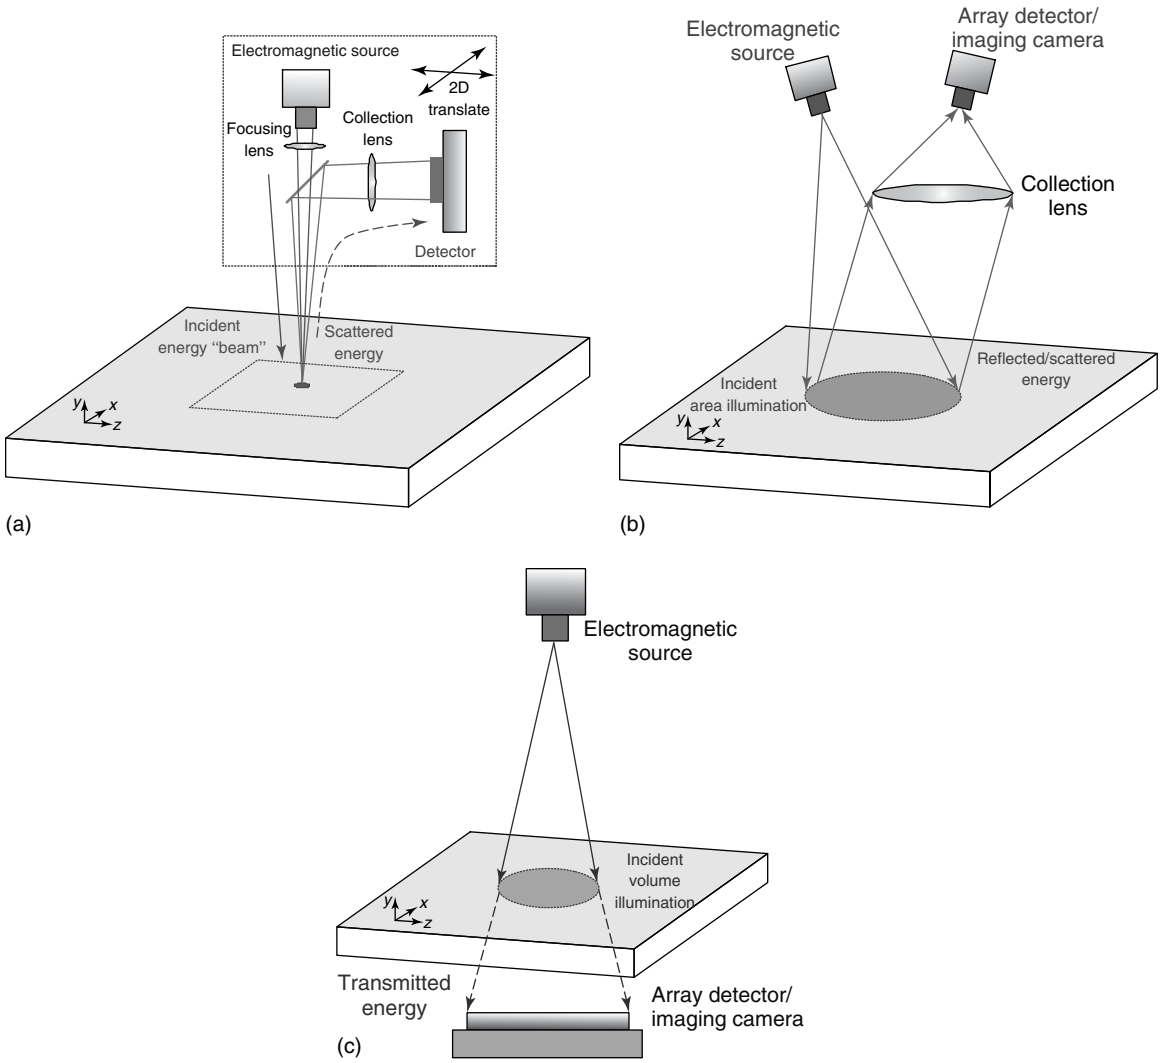

Figure 3. Directed energy measurement approaches: (a) single-sided, single-point measurement; (b) single-sided, imaging measurement; and (c) through-transmission, volumetric measurement.

signal, which can then be further analyzed. Simple measurements involve detecting raw intensity, while more sophisticated measurements keep track of phase, amplitude, and frequency. Two-dimensional imaging systems and three-dimensional computed tomographic systems also keep track of spatial position. Raster scanning of the single-point measurement system depicted in Figure 3(a) permits two-dimensional information to be obtained, while lenses and other beam manipulation systems permit whole-field images to be captured.

3 DIRECTED ENERGY SENSING METHODS

In this section, a variety of directed energy measurement examples are provided for electromagnetic energy in the X-ray, visible, infrared, terahertz, and microwave frequency bands. The examples show only a very small sampling of the available directed energy methods, which currently number in the hundreds to thousands. The interested reader is encouraged to

refer to the numerous cited articles, and also to the books by Cartz [40], Demtroder [41], Scruby and Drain [28], Mittleman [26], and Zoughi [42] for additional methods and more detailed information.

3.1 Radiographic methods

Radiography is one of the five traditional nondestructive evaluation methods [40] (*see* **Nondestructive Evaluation/Nondestructive Testing/Nondestructive Inspection (NDE/NDT/NDI) Sensors—Eddy Current, Ultrasonic, and Acoustic Emission Sensors**). In recent years, technological advances in sources, detectors, and analysis methods have resulted in significant improvements in spatial resolution and sensitivity levels [43]. In addition, computed tomographic approaches have provided unmatched three-dimensional measurement capabilities for complex geometry structures and dense material samples [44]. Although different types and levels of radiographic energy can be used, X rays are most often used for most materials, while film radiography is quickly being replaced by electronic detector systems.

In most X-ray measurements, the basic setup depicted in Figure 3(c) is used, where the output signal is related to the material density according to an expression similar to equation (7). Subtle variations in material composition can also be characterized when dual-energy approaches are used [45]. Figure 4 depicts a series of measurements taken with a Phillips MGC-03 film radiography system, which represents a medium-resolution X-ray capability with a nominal 0.4-mm focal spot size [46]. The current, exposure time, and distance for the measurements depicted in Figure 4 correspond to 5 mA, 1.5 min, and 1.016 m (40 in.), respectively. The material sample (a laser-machined reference standard) was placed on the film and exposed to the X rays at a certain kilovolt energy level. The X-ray film was subsequently digitized. The image on the far left was taken at 55 kV energy level, and shows a series of laser-machined triangle features with increasing sizes and depths. The five images on the right correspond to a magnified view of the smallest (1 mm) and deepest (260 μm) triangle taken at increasing kilovolt energy levels (55–80 kV). As the kilovolt energy level increased, the signal-to-noise ratio decreased from 27.11 at 55 kV to 2.7 at 80 kV, while the image contrast remained almost constant at a ratio of $\sim 1.2 : 1.0$.

The ability to create fully three-dimensional characterizations of solid structures represents one of the most important capabilities for radiography, where X-ray computed tomography can be used. An example of an X-ray computed tomography measurement is provided in Figure 5(a), where a cross-sectional cut is depicted for the reference standard depicted in Figure 4. In this case, an ARACOR Tomoscope system was used, which uses a 225-kV, 50-μm microfocus X-ray source, and a fiber-optic scintillator/charge-coupled device (CCD)

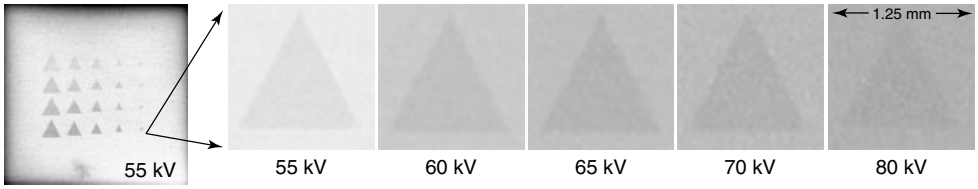

Figure 4. Radiographic through-transmission images of laser-machined triangle reference sample.

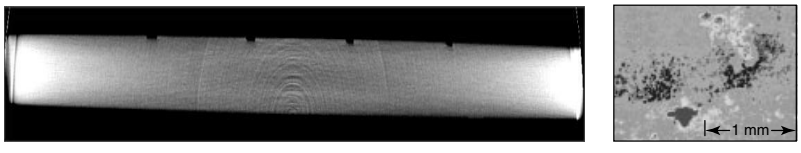

Figure 5. (a) Radiographic computer tomography measurement result showing a cross-section image through the laser-machined triangle sample and (b) X-ray measurement of corrosion.

image sensor system for detection. Thickness changes as small as 2% of the equivalent thickness were measured with an accuracy of ±1%. Figure 5(b) shows a similar measurement capability, where 1–5% corrosion material loss has been characterized [46].

3.2 Visible radiation and laser methods

Visible radiation represents one of the most prolific directed energy methods in use today. Spectroscopic measurements, in particular, provide a particularly useful characterization tool for identifying atomic and molecular states for a wide range of applications. As a material and system health monitoring capability, visible wavelength radiation has found use in a number of methods. Optical interferometry and holography, for example, provide a means for measuring surface topography and dynamic vibrations in a noncontact manner (*see* **Intensity-, Interferometric-, and Scattering-based Optical-fiber Sensors**). Figure 6 provides an example of an interferometric measurement system capable of measuring vibration features on a material surface with micron spatial resolution levels in the 25 kHz to 20 MHz frequency bandwidth range.

When combined with an ultrasonic wave or vibration source, the system depicted in Figure 6 can be used to characterize surface damage with microscopic precision. An example of such a measurement is provided in Figure 7, where the motion field of a surface-acoustic wave (SAW) has been imaged with the laser vibrometry system to detect and characterize a microscopic surface-breaking crack feature. The crack feature is measured as a "brightness" increase in the lower right image field due to increased vibration levels near the crack [47].

The crack image in Figure 7 was made by raster scanning the laser probe position in a two-dimensional manner, similar to the depiction in Figure 3(a). At each scan position, the out-of-plane motions were captured by the laser interferometry system, which was collected and analyzed to provide a displacement versus time signal level at each position on the material surface. Similar measurements have been made with a moderate intensity pulsed laser to excite elastic waves in the material. This type of directed energy measurement system is termed *laser ultrasound*, which has found use recently as an effective means for assessing the structural health status of composite materials. Similar to other directed energy methods, the laser ultrasound approach provides a noncontact measurement capability that can be done at a standoff distance.

3.3 Infrared methods

Thermographic imaging is a relatively new nondestructive evaluation (NDE) technology, which uses thermal differences between a material defect and its local surroundings as a noncontact and full-field NDE measurement tool (*see* **Thermal Imaging Methods**). Infrared cameras with higher sensitivities and resolutions are currently helping to transition the technology from a novelty to a comprehensive and quantitative NDE measurement tool. Materials are characterized based on variations in thermal absorption, transport, diffusion, and emission. In a passive thermography measurement, the material surface naturally radiates,

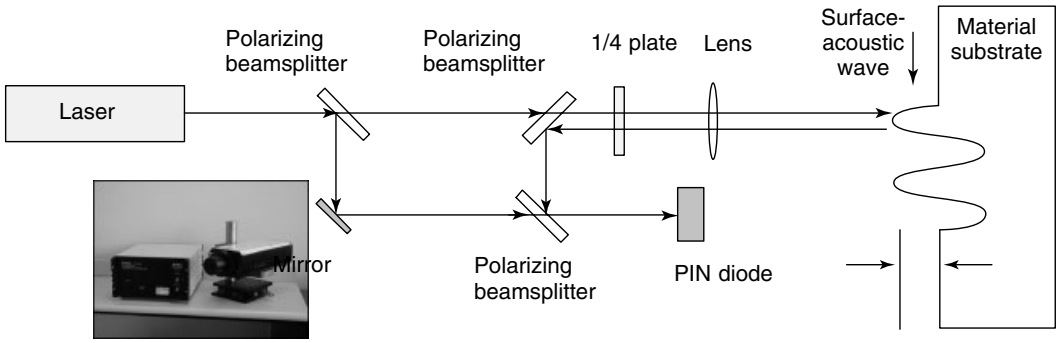

Figure 6. Laser interferometry system for measuring surface vibrations and displacements.

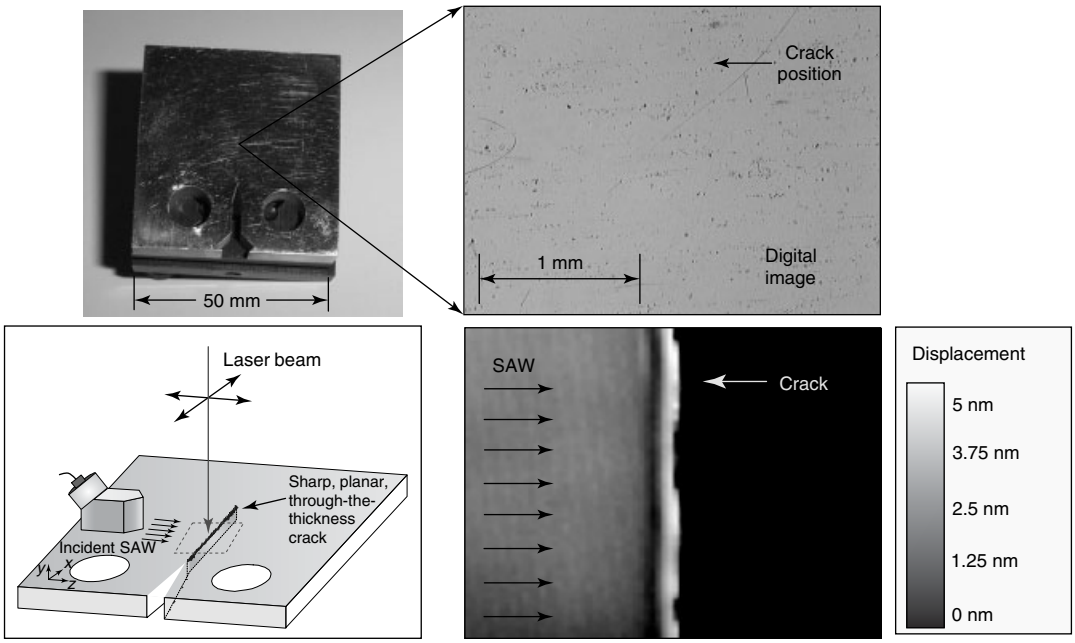

Figure 7. Laser interferometry measurement of surface-acoustic wave interaction with crack.

scatters, and reflects infrared energy that can be imaged by the thermal camera. Differences in thermal emissivity are imaged as differences in brightness by the camera, allowing corrosion, voids, and other damage to be detected and characterized.

In certain instances, thermographic measurements can be made in a spectral band-pass window that allows the infrared energy to propagate efficiently through a coating layer to probe the material substrate underneath [48]. This in fact is the case for many aerospace coating materials. Figure 8 depicts a spectral transmission window for a 3-mil-thick paint layer (∼75 microns) between the 2 and 12 μm wavelength range, which occurred between 3.5 and 5.8 μm, peaking at 5.2 μm. By using a midwave infrared camera sensitive to 3–5 μm thermal energies, and/or using band-pass filters in that wavelength range, damage (e.g., hidden corrosion) can be imaged directly through the paint with a simple mid-IR camera system (Figure 8a).

The combination of ultrasonics and thermal imaging has also recently shown promise as a new directed energy sensing method for detecting microscopic cracks, composite disbonds, and delaminations [29]. The method termed *thermosonics* or *sonic-IR* uses an infrared camera to monitor the local heating that can occur in a material when vibrational energy causes frictional rubbing of surfaces at crack boundaries or disbonded/delamination locations. Figure 9(a) depicts a typical thermosonics system, which was used to detect a microscopic fatigue crack (Figure 9c) in a turbine engine blade (Figure 9b).

3.4 Terahertz methods and microwave methods

Terahertz and microwave measurement systems, like thermal imaging systems, are relatively new technologies. For directed energy measurements, terahertz and microwave methods provide a unique ability for penetrating through most dielectric materials. When this is the case, both methods can provide a volumetric measurement capability similar to X-ray measurements without the safety hazard problems. In addition, simple and effective imaging capabilities may be possible soon, where direct imaging through various dielectric material layers may be possible with the appropriate choice of directed energy frequency/wavelength.

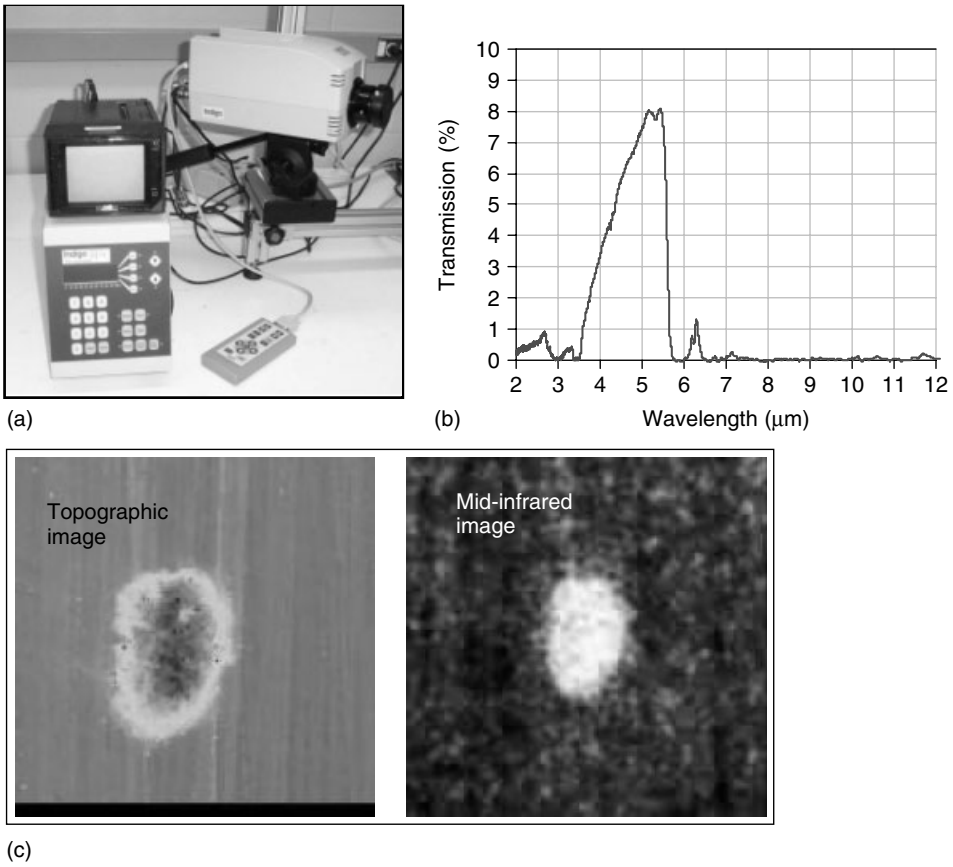

Figure 8. (a) Midinfrared camera system, (b) midinfrared transmission window through aerospace coating, and (c) passive infrared image of corrosion feature hidden under the coating.

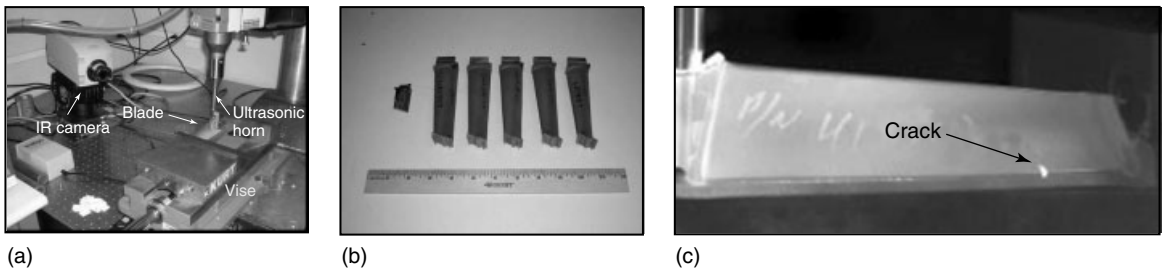

Figure 9. (a) Thermosonics system, (b) turbine engine blades, and (c) crack measurements.

An example of an evanescent microwave probe measurement taken through an aerospace coating is provided in Figure 10. An evanescent microwave probe is a coaxial resonator system that operates nominally at 1–4-GHz frequencies. The probe depicted in Figure 10(a) was resonant at ~2.485 GHz, and had a sharp coupling tip that permitted near-surface, evanescent field measurements, which enhanced spatial resolution levels and measurement sensitivity [48]. By raster scanning the probe over the sample surface, an image can be produced, which represents changes in dielectric properties of

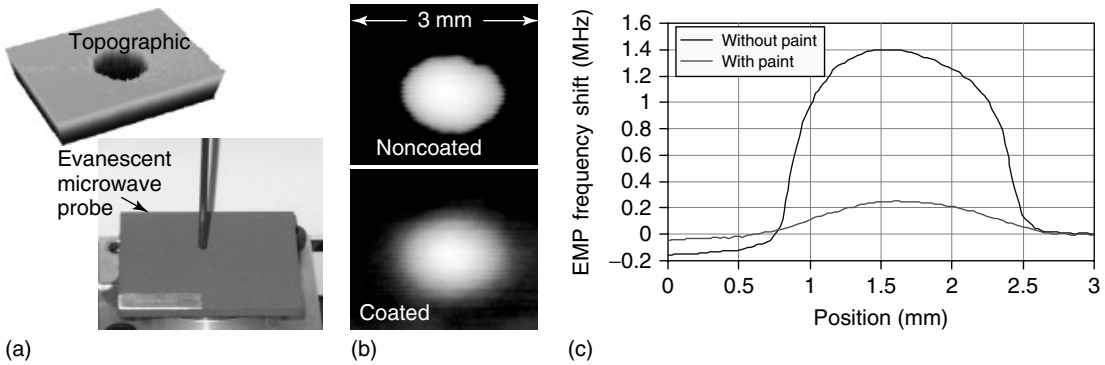

Figure 10. (a) Evanescent microwave probe system, (b) microwave measurements taken with and without coating layer present, and (c) comparison of response signals across corrosion pit.

the material according to equations (3) and (4). The presence of a hidden corrosion pit feature through an aerospace coating is depicted in Figure 10(b) and (c).

Terahertz measurement systems have also become available recently, with the promise of microwave-type penetration capabilities in reduced sizes and with improved spatial resolutions. Terahertz time-domain spectroscopy systems, in particular, have recently shown promise for measuring damage and material state through coatings, foam materials, ceramics, and composites [48]. Figure 11 depicts a typical time-domain spectroscopy system along with two measurement examples showing terahertz transmission properties through aerospace coating materials

(Figure 11b), and thermal protection system foam insulation materials (Figure 11c).

4 CONCLUSIONS

Directed energy sensing methods are becoming more capable and are finding more uses for nondestructive evaluation and structural health monitoring applications. Recent technological breakthroughs in numerous electromagnetic radiation sources and detectors are providing sensing capabilities across the entire electromagnetic spectrum from X rays to millimeter waves and beyond. In this brief review article, the key underlying principles of directed energy sensing are presented with a special emphasis on material inspections, nondestructive evaluation, and structural health monitoring applications. Specific examples are provided for directed energy sensing with X rays, laser ultrasonics, passive thermal imaging, thermosonics, evanescent microwaves, and terahertz time-domain spectroscopy. It is anticipated that directed energy sensing will continue to expand in capabilities and uses in the future, providing improved noncontact inspection capabilities for many years to come.

1 INTRODUCTION

Safety statistics data from the US Federal Railroad Administration (FRA) [1] indicate that train accidents caused by track failures including rail, joint bars, and anchoring resulted in 2700 derailments and $441 million in direct costs during the decade 1992–2002. The primary cause of these accidents is the "transverse-type defects" that was found responsible for 541 derailments and $91 million in cost during the same time period. Transverse defects are cracks developing in a direction perpendicular to the rail running direction, and include transverse fissures (TFs, initiating in a location internal to the rail head) and detail fractures (DFs, initiating at the head surface as rolling contact fatigue defects) (Figure 1).

The most common methods of rail inspection are magnetic induction and contact ultrasonic testing [2, 3]. The first method is affected by environmental magnetic noise and it requires a small liftoff distance for the sensors to produce adequate sensitivity. Ultrasonic testing is conventionally performed from the top of the rail head in a pulse-echo configuration. Such an approach suffers from a limited inspection speed and from other drawbacks associated with the requirement for contact between the rail and the inspection wheel. More importantly, horizontal surface cracks such as shelling and head checks can prevent the ultrasonic beams from reaching the internal defects (IDs), resulting in false negative readings. These problems were highlighted in the derailments of Superior, WI, USA, in 1991 and Hatfield, UK, in 2000.

Guided ultrasonic waves are being considered in recent years for rail inspections as an improvement over wheel-type ultrasonic methods [4–11]. Guided

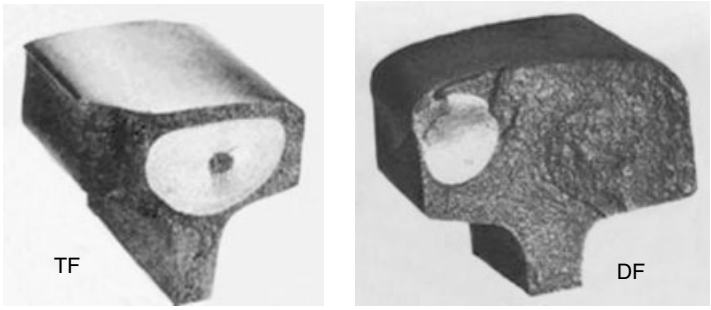

Figure 1. Transverse defects in rail: a transverse fissure (TF) and a detail fracture (DF).

waves propagate along, rather than across the rail, and are thus ideal for detecting the critical transverse defects. Guided waves are also potentially not sensitive to surface shelling since they can run underneath this discontinuity.

Techniques that do not require contact with the rail are being investigated to generate and detect guided waves. Noncontact rail testing has been demonstrated by the use of pulsed lasers and air-coupled transducers [7, 11], electromechanical acoustic transducers [7, 12, 13], and laser vibrometers [6]. However, the drawback of any noncontact ultrasonic testing is a reduced signal-to-noise ratio of the defect detection procedure when compared with conventional contact testing. The use of signal processing based on the discrete wavelet transform (DWT) helps overcoming this problem, as recently demonstrated [11, 14–16].

This article describes a rail inspection system based on guided ultrasonic waves generated and detected in a noncontact manner. The system uses a pulsed laser and an array of air-coupled sensors. Defects in the rail head are detected by monitoring changes in the energy strength of the transmitted waves. The raw ultrasonic signals are processed by the DWT in pseudo-real-time for increasing the defect detection reliability. Laboratory and field results of this system will be presented.

2 WAVE PROPAGATION MODELING

Proper modeling of guided waves propagating in the rail is important to identify modes, enhance sensitivity to certain defects, and select low-loss mode–frequency combinations. In the context of noise suppression, theoretical solutions of waves propagating in rails have been obtained below 6 kHz using beam theories [17]. For ultrasonic testing, these solutions have been extended to 50 kHz by using semianalytical finite element (SAFE) methods [18], and up to 350 kHz by using finite element analyses with cyclic symmetry [6]. The arbitrary shape of the cross section of a rail lends itself to SAFE modeling, where only a 2D mesh is required.

In the SAFE method, at each frequency ω, a discrete number of guided modes is obtained. For the given frequency, each mode is characterized by a wavenumber ξ, and by a displacement distribution over the cross section (mode shape). The SAFE algorithm used here is based on the three-dimensional theory of linear viscoelasticity. For a Cartesian reference system, the waveguide cross section is set in the y–z plane while the x axis is parallel to the waveguide length. Subdividing the cross section via finite elements, the approximated displacement at a point $\mathbf{u} = \mathbf{u}(x, y, z, t)$ is given by

$$\mathbf{u} = \mathbf{N}\mathbf{U}^{(e)} \mathrm{e}^{\mathrm{i}(\xi x - \omega t)} \tag{1}$$

where $\mathbf{N} = \mathbf{N}(y, z)$ is the matrix of the shape functions, $\mathbf{U}^{(e)}$ is the nodal displacement vector for the eth element, t is the time variable, and i the imaginary unit. It can be noted that the displacement is described by the product of an approximated finite element field over the waveguide cross section and the exact time harmonic function, $\exp[\mathrm{i}(\xi x - \omega t)]$, in the propagation direction x. The compatibility and constitutive equations can be written in synthetic matrix forms as follows:

$$\boldsymbol{\varepsilon} = \mathbf{D}\mathbf{u}, \ \boldsymbol{\sigma} = \mathbf{C}^{*}\boldsymbol{\varepsilon} \tag{2}$$

where $\boldsymbol{\varepsilon}$ and $\boldsymbol{\sigma}$ are the strain and stress vector, respectively, $\mathbf{D}$ is the compatibility operator, and $\mathbf{C}^*$ is the complex constitutive linear viscoelastic tensor. More details on the compatibility operator can be found in [19]. The principle of virtual works with the compatibility and constitutive laws (equation 2) leads to the following energy balance equation:

$$\int_{\Gamma} \delta \mathbf{u}^{\mathrm{T}} \mathbf{t} \, \mathrm{d}\Gamma = \int_{V} \delta \mathbf{u}^{\mathrm{T}} (\rho \ddot{\mathbf{u}}) \, \mathrm{d}V + \int_{V} \delta (\mathbf{uD})^{\mathrm{T}} \mathbf{C}^* \mathbf{Du} \, \mathrm{d}V \tag{3}$$

where Γ is the waveguide cross-section area, V is the waveguide volume, $\mathbf{t}$ is the external traction vector, and the overdot means time derivative. The finite element procedure reduces equation (3) to a set of algebraic equations:

$$[\mathbf{A} - \xi \mathbf{B}]_{2M} \mathbf{Q} = \mathbf{p} \tag{4}$$

where the subscript $2M$ indicates the dimension of the problem, with M the number of total degrees of freedom of the cross-sectional mesh. Details on the complex matrices $\mathbf{A}$,$\mathbf{B}$, and vector $\mathbf{p}$ can be found in [18]. By setting $\mathbf{p} = \mathbf{0}$ in equation (4), the associated eigenvalue problem can be solved as $\xi(\omega)$. For each frequency ω, $2M$ complex eigenvalues, ξ_m, and $2M$ complex eigenvectors, $\mathbf{Q}_m$, are obtained. The solution is symmetric, i.e., for each pair $(\xi_m - \mathbf{Q}_m)$, representing a forward guided mode, a pair exists representing the corresponding backward mode. The first M components of $\mathbf{Q}_m$ describe the cross-sectional mode shapes of the mth mode. Once ξ_m is known, the dispersion curves can be easily computed. The phase velocity can be evaluated by the expression $c_{\mathrm{ph}} = \omega/\xi_{\mathrm{real}}$, where ξ_{real} is the real part of the wavenumber. The imaginary part of the wavenumber is the attenuation, $att = \xi_{\mathrm{imag}}$, in nepers per meter. As reported in [20], for damped waveguides, the group velocity

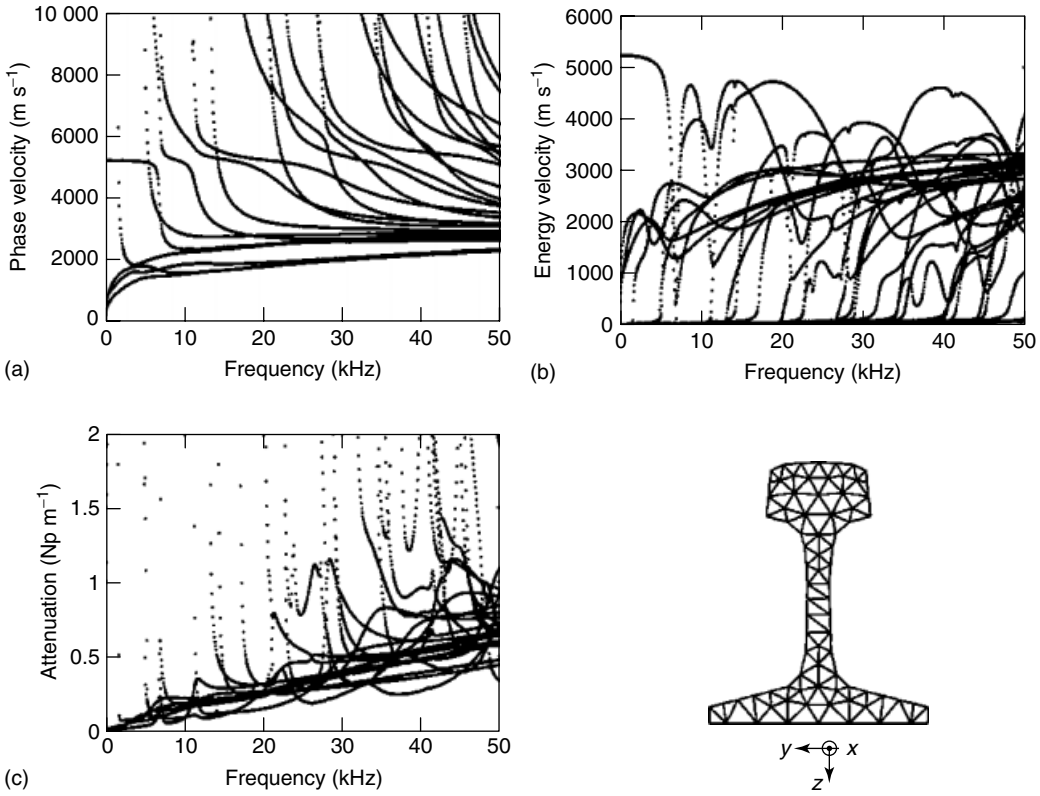

Figure 2. Dispersion results for a 115-lb AREMA viscoelastic rail for waves propagating along the rail running direction: (a) phase velocity, (b) energy velocity, and (c) attenuation.

does not coincide with the speed of propagation. In this case, the energy velocity, V_e, is the physically meaningful parameter. Energy velocity can be also readily calculated from the SAFE eigenvalues [18].

3 WAVE PROPAGATION RESULTS

The rail considered in this study is a typical 115-lb American Railway Engineering and Maintenance-of-way Association (AREMA) section, modeled as an isotropic material with hysteretic damping, and having the following properties: density $\rho = 7932\,\mathrm{kg\,m^{-3}}$, bulk longitudinal velocity $c_L = 5960\,\mathrm{m\,s^{-1}}$, bulk shear velocity $c_T = 3260\,\mathrm{m\,s^{-1}}$, longitudinal attenuation $\kappa_L = 0.003$ Np/wavelength, and shear attenuation $\kappa_T = 0.043$ Np/wavelength. The mesh of the rail cross section, shown in Figure 2 and generated by MATLAB's "pdetool", used 81 nodes for 106 triangular elements with linear interpolation displacement functions.

The dispersion results are shown in this figure up to a frequency of 50 kHz. The complexity of the modes is evident. However, these results are

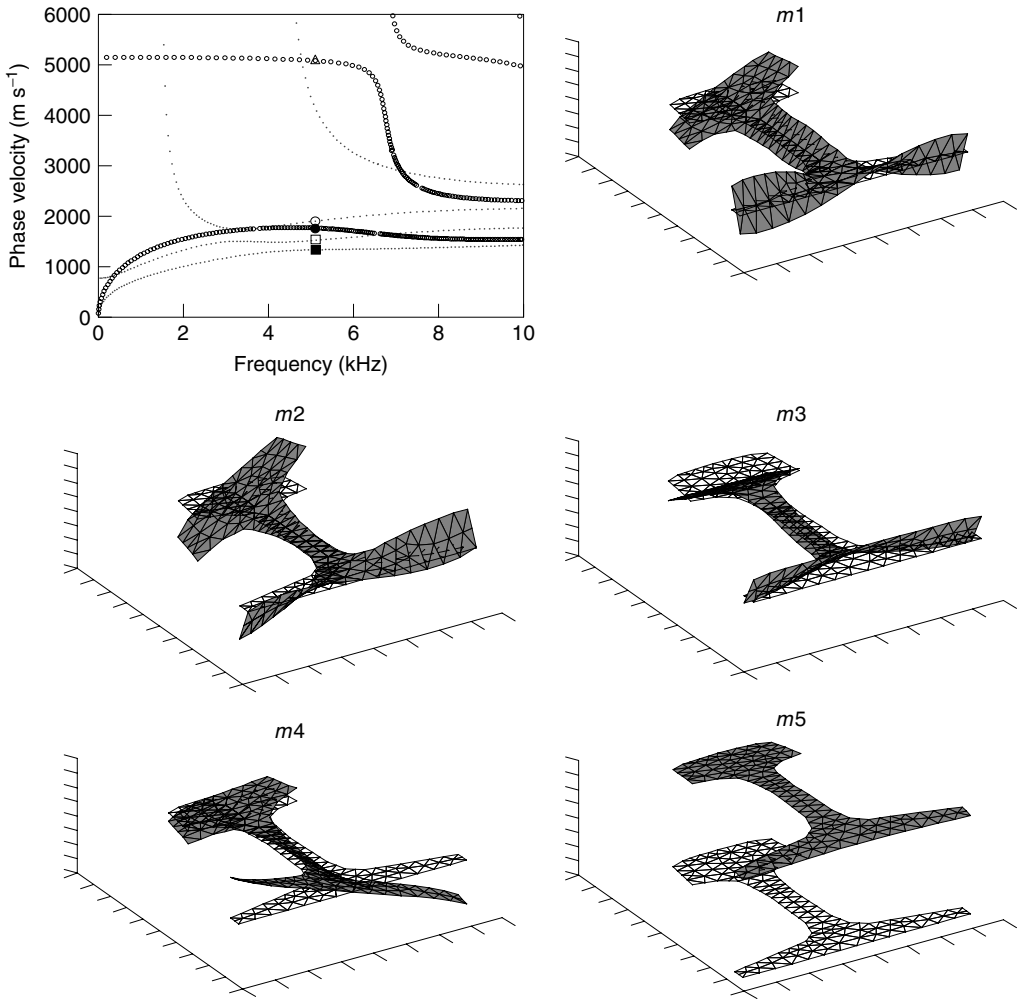

Figure 3. Dispersion results for a 115-lb AREMA viscoelastic rail: phase velocity for frequencies below 10 kHz, and first five cross-sectional mode shapes at 5 kHz, where ■, mode $m1$; □, mode $m2$; •, mode $m3$; ◯, mode $m4$; Δ, mode $m5$; ooooo, symmetric mode; · · · · · · ·, antisymmetric modes.

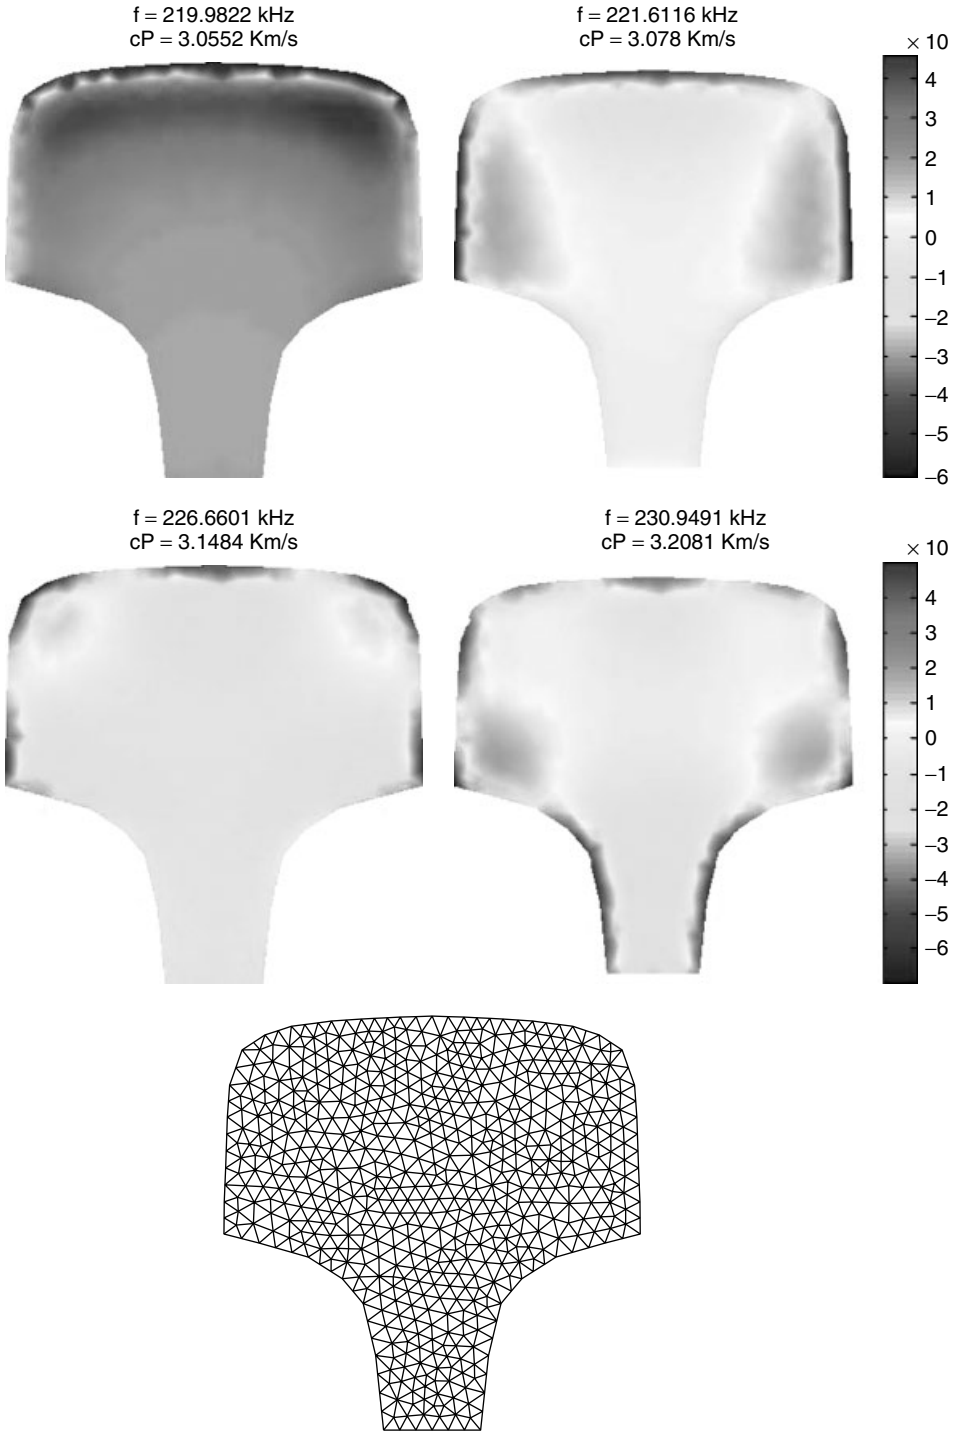

Figure 4. Axial displacement mode shapes for various symmetrical modes at frequencies around 200 kHz. The mesh used for the SAFE analysis is also shown.

useful to design an efficient NDE system, which uses mode–frequency combinations sensitive to given defects. A zoom into the low-frequency phase velocity curves is shown in Figure 3, along with the first five cross-sectional mode shapes at 5 kHz. It can be seen that modes $m1, m2$, and $m4$ are antisymmetric with respect to the x–z plane, while modes $m3$ and $m5$ are symmetric. It can also be seen that some of the modes excite preferably a certain portion of the rail, either the head or the base. Hence defects located at various locations in the rail section can be targeted selectively.

Figure 4 shows the displacement mode shapes (x component) for the first four symmetric modes at high frequency values, around 200 kHz. The character of these high-frequency modes is that of Rayleigh-surface waves, where the penetration depth is roughly equal to the wavelength. These "surface" modes in rails were examined in depth in [6]. The plots in Figure 4 were obtained using 1118 triangular elements with a total number of degrees of freedom of 1815 (see mesh in the figure).

The laser/air-coupled system presented in the following sections uses high-frequency, surface-type waves in the frequency range of 50 kHz to 1 MHz of the type shown in Figure 4 to detect transverse defects in the rail head.

4 NONCONTACT ULTRASONIC RAIL INSPECTION

4.1 Inspection prototype

The University of California at San Diego (UCSD) rail inspection prototype is based on laser excitation and air-coupled detection. The laser generator is a Nd:YAG, Q-switched type, lasing at 1064 nm with a ~10-ns pulse duration. When illuminating the rail head, it generates broadband symmetric waves of the type shown in Figure 4. An array of air-coupled sensors is used to receive the waves. The sensors are inclined at an angle of $\sim 6^{\circ}$ to maximize the sensitivity to the Rayleigh-type phase velocity owing to Snell's law. The air-coupled sensors are located at distances larger than 50.8 mm (2 in.) from the top of the rail head, thus satisfying the clearance envelope recommended by the railroad industry for inspection systems claiming noncontact operation. A portable, National Instruments unit running under LabVIEW has been assembled and programmed to perform laser control, data acquisition, processing, and reporting.

A laptop is used in conjunction with the PXI unit to form a client–server Ethernet-linked platform. The server (PXI unit) controls the laser operation and the acquisition, processing, and display of the measurements by the air-coupled sensors. Data from a positioning system are constantly acquired by the server. From the serial port (RS-232), the server triggers the laser to start the data acquisition. The ultrasonic signals detected by the air-coupled sensors are digitized through the analog input boards, processed, and logged into the server. On the client end (laptop), the user is able to start and stop the acquisition, adjust the laser power, change the lasing frequency, modify the ultrasonic and signal-processing settings, monitor the results in real time, and open a report window.

The defect detection strategy is based on "transmission" rather than on "reflection" measurements. In the "transmission mode", a defect is detected by monitoring the attenuation of the wave as it travels past the flaw. In its simplest implementation, two air-coupled sensors can be used as shown in Figure 5. In the prototype, a damage index (DI) is calculated in real time as the ratio between certain features of the signal detected by the sensor closer to the laser source $F_{\text{sens}\,1}$, over the same features from the sensor further from the laser source $F_{\text{sens}\,2}$:

$$DI = \frac{F_{\text{sens}\,1}}{F_{\text{sens}\,2}} \tag{5}$$

If a defect is located in the section of rail between the two sensors, $F_{\text{sens}\,2}$ will be smaller than $F_{\text{sens}\,1}$ and

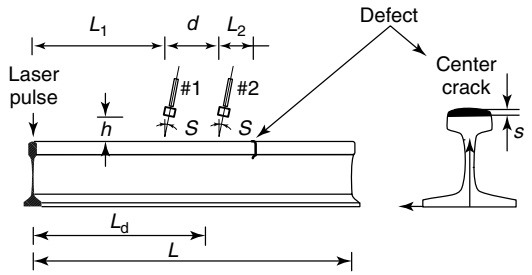

Figure 5. Laser/air-coupled system for detecting transverse defects in the rail head (sensor arrangement in the "transmission mode").

the DI will increase compared with its normal, defect-free value (nominally one). The DI in equation (5) is also expected to increase with increasing defect size.

4.2 Laboratory tests

A number of laboratory tests were conducted on 52-kg (115-lb) AREMA rail sections donated by San Diego Trolley with simulated surface defects of increasing depths. The results from the laboratory tests have been discussed extensively in recent publications [11, 15, 16]. A summary of these is presented here.

The cracks were simulated by narrow notches that were machined at depths (s in Figure 5) ranging from a minimum of 0.5 mm to a maximum of 8.5 mm, all corresponding to a cross-sectional area reduction of the rail head (% Head Area (HA) reduction) below 20%.

The ultrasonic signals were acquired at a 5-MHz sampling rate from 10 laser pulse generations at each damage condition. DWT processing (Daubechies 10 mother wavelet) was applied in real time to the raw measurements. The wavelet coefficients at detail levels 3, 4, and 5 were considered to retain the frequency band of interest. A transmission DI vector was used as a defect indicator. Thresholds equal to 70, 50, and 80% of the maximum coefficient amplitude of detail levels 3, 4, and 5, respectively, were applied in this case. The features of variance, root mean square (RMS), peak amplitude, and peak-to-peak amplitude of the thresholded wavelet coefficient vectors were computed. The reconstructions of the signal received from both sensor #1 and sensor #2 were then processed through the fast-Fourier transform (FFT) and the Hilbert transform (HT). The following additional features were finally extracted: the peak amplitude and the area below the FFT frequency spectrum, in addition to the peak and position of the amplitude of the HT.

Nine different damage conditions, ranging from pristine structure to $s = 8.5$ mm were monitored. Figure 6 shows a component of the DI vector calculated from equation (5) using the variance of the thresholded wavelet coefficients, along with a picture of the defect. Notice that for these results the inverse of the relation in equation (5) was used, thus DI decreases with increasing defect size. The mean value of 10 measurements is plotted as a function of the crack depth and the extension of the vertical line is equal to 2 SD. The monotonic decrease in the DI with increasing defect size shows the potential for crack sizing.

The defect sizes were subdivided into three classes (classes 1, 2, and 3), corresponding to % HA reduction in the ranges 0–1.1% (pristine condition), 1.5–9.9%, and 10–20%. Each class was coded with a two-digit binary number. A feed-forward, back-propagation artificial neural network with three layers was employed. Five of 10 acquisitions for each damage condition were used as training data, while the remaining data were used as testing data. The learning rate and additional momentum were equal to 0.2 and 0.5, respectively. Figure 7(a) and (b) illustrate, respectively, representative classification

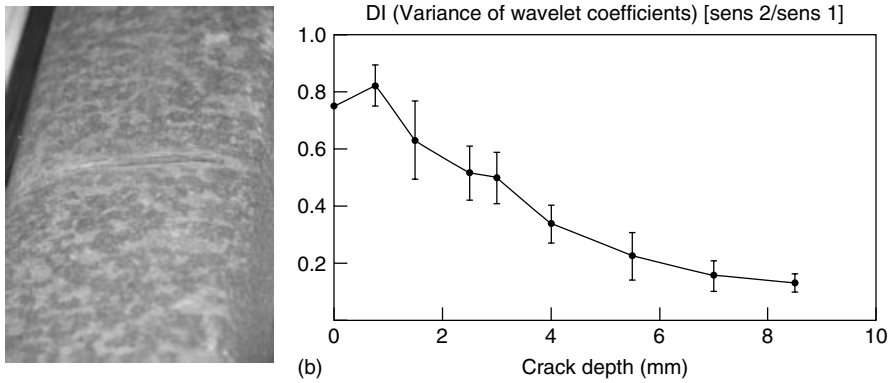

Figure 6. (a) A surface-breaking transverse head crack and (b) measured damage index (variance of wavelet coefficients) as a function of crack depth.

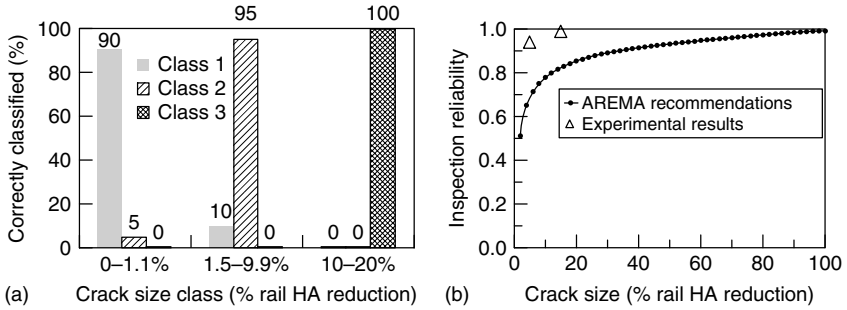

Figure 7. (a) Defect classification performance as a function of size classes; (b) inspection reliability of proposed defect detection method compared with AREMA standards.

results and a comparison with the AREMA recommendations for rail inspection reliability.

A parametric analysis identified the following four features providing the best classification performance: the variance, the RMS, the peak amplitude of the wavelet coefficient vectors, and the area below the FFT spectrum of the reconstructions. Classes 1, 2, and 3 were properly classified in 90, 95, and 100% of the cases, respectively. Thus all defects larger than 10% HA reduction were properly classified. The algorithm gave a total of 10% false positives and only a total of 5% false negatives.

5 FIELD TESTS

The first field test of the prototype was conducted in March 2006 with the technical support of ENSCO, Inc. ENSCO's support consisted of the design and construction of a cart hosting the prototype elements and managing the use of the FRA's hy-railer to tow the cart over the test track.

A picture of the laser and air-coupled sensors installed on the cart is shown in Figure 8. The black metallic box was devised to protect the laser head and the optics from accidental impacts and dust; in addition, the box avoided accidental reflections of the laser beam.

The sensor layout used in the field tests is schematized in Figure 9. The minimum distance between the first sensor (#1) and the laser was chosen so as to avoid the superposition between the air shock and the ultrasound traveling in the rail. Sensors #1 and #3 formed the first pair, hereafter indicated as sensor pair 1 (sp1); sensors #2 and #4 formed the sensor pair 2 (sp2). The sensor liftoff distance h was maintained

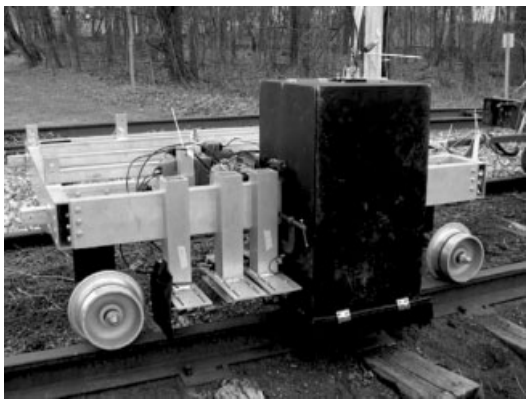

Figure 8. Laser head (inside black box) and air-coupled sensors on cart at the Gettysburg test site.

equal to 63 mm (2.5 in.). The sp1 was placed right above the center of the rail head, whereas the sp2 was placed closer to the rail gauge-side corner. The lateral offset between the two pairs was around 19 mm (0.75 in.).

5.1 Test site layout

The test site (Figure 10) was located near Gettysburg, PA, and consisted of a dismissed portion of railroad. In total, a length of 61 m (200 ft) was tested.

A total of six joints were present along the test section; some of them created a gap as large as 0.50 in. between two rail sections. Three, 1.8-m (6-ft) long, 139-lb AREMA sections with known IDs in the head were inserted in the inspected portion of the rail and fixed by joint bars. From ultrasonic hand mapping prior to the tests, the three IDs were determined to

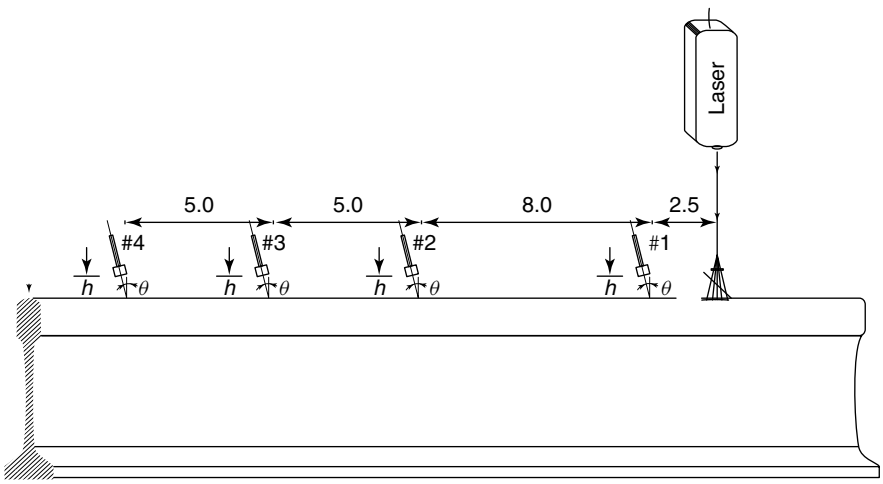

Figure 9. Laser/air-coupled sensor layout for the field tests (dimension in inches; drawing not to scale).

Figure 10. Test site near Gettysburg, PA.

extend, respectively, for 80, 10, and 40% HA. All IDs were believed to be primarily transverse to the rail running direction. Two surface cuts (SCs) were also machined perpendicular to the rail running direction causing 5 and 2% HA reductions, respectively. Two oblique SCs (45° inclination from the running direction) were also added, at a size corresponding to about 3.5% HA.

5.2 Test results

A total of 32 tests were conducted in two days. Some of the tests were performed under dry conditions, i.e., ultrasound was generated by the laser pulse irradiating the dry surface of the rail head. In the other tests, the rail was wetted by using a water pressure sprayer during the tests. Wetting was performed to examine the effect of increasing the ultrasound generation power of the laser under ablative regime.

As representative data, Figures 11 and 12 present the recordings from tests 1 and 2, respectively. The results are shown for the portion of the rail between 76 and 120 ft where the IDs and the SCs were located. Notice that no oblique cuts (OCs) were present in these runs as these were machined later in the tests. Each figure displays the DI recorded as a function of position (ft) by the two sensor pairs and for two different filtering bandwidths, namely, (a) high-frequency DI for sensor pair 1 (HF-DI sp1), (b) low-frequency DI for sensor pair 1 (LF-DI sp1), (c) high-frequency DI for sensor pair 2 (HF-DI sp2), and (d) low-frequency DI for sensor pair 2 (LF-DI sp2). The plot (e) is included to ease in the visualization of the position of each of the discontinuities. In this plot (e) the joints are placed at ordinate 5, the transverse SCs at ordinate 4, the IDs at ordinate 3, and the flaking at ordinate 1. In the four DI plots, successfully detected joints (J), SCs, or IDs are highlighted with circles. Since the two sensor pairs and filtering bandwidths cover complementary regions of the rail head, a defect should be considered successfully detected if any of the four DI plots shows an

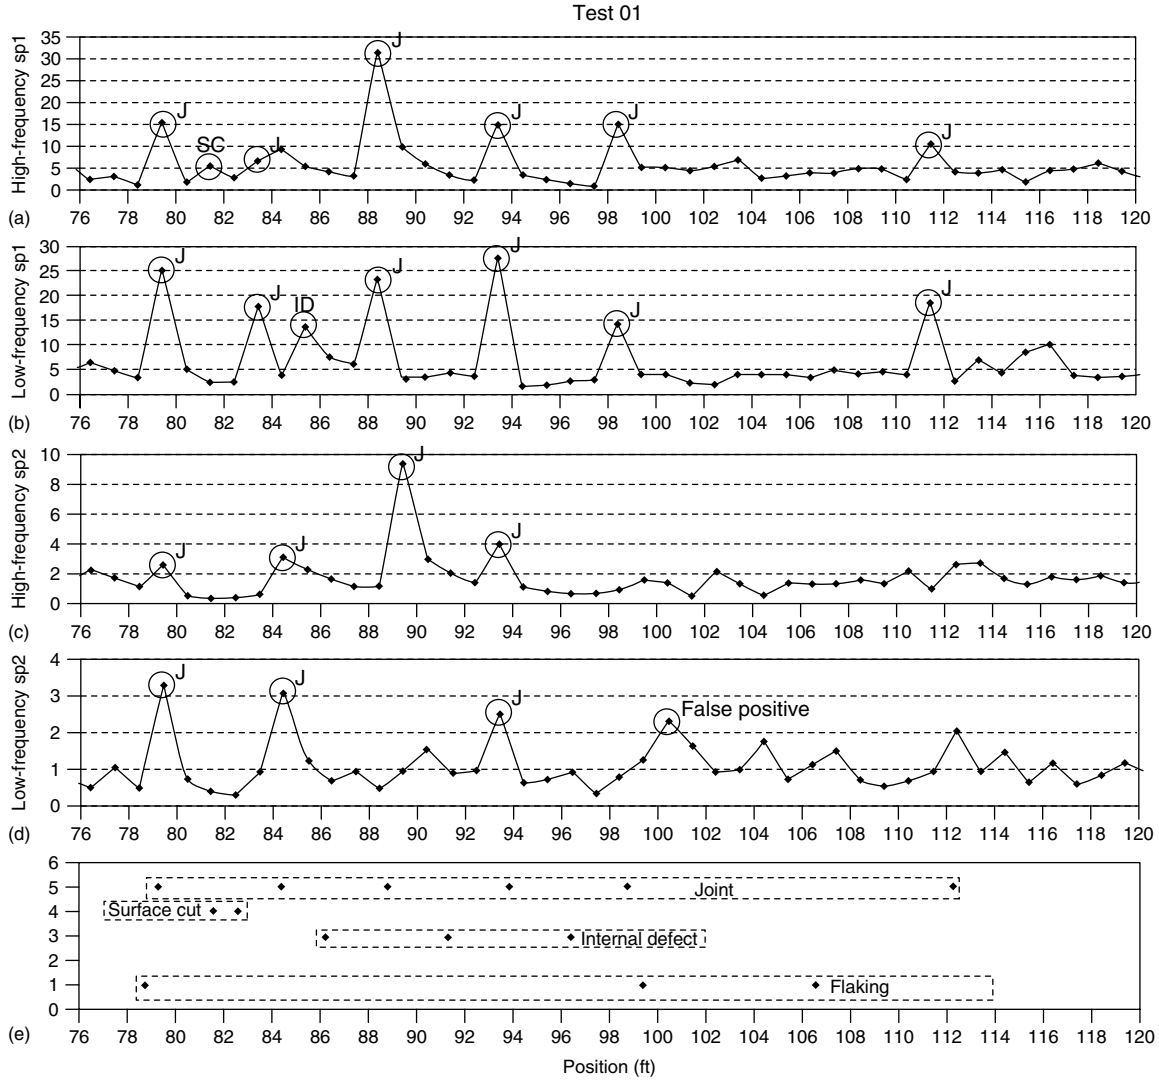

Figure 11. Results of field test no. 1 (J, joint; SC, surface cut; ID, internal defect).

index clearly above the baseline (defect-free) value. For example, Figure 12 shows that all major defects, with the exception of the third ID, were detected by at least one of the four DI plots.

The fact that the baseline DI values in Figures 11 and 12 are not necessarily those as theoretically expected from equation (5) is simply due to the practical impossibility of obtaining exactly the same sensitivities from the two sensors in each pair. This, however, does not constitute a problem since only relative changes in DI from the baseline value are monitored to detect a potential defect.

A probability of detection (POD) was estimated from a total of 30 tests. As discussed earlier, a defect was considered successfully detected if at least one of the four DI (HF-DI sp1, LF-DI sp1, HF-DI sp2, or LF-DI sp2) was activated. The results are shown in the histogram in Figure 13. In summary, it was found that the system performed very well in detecting the two SCs, two of the three IDs

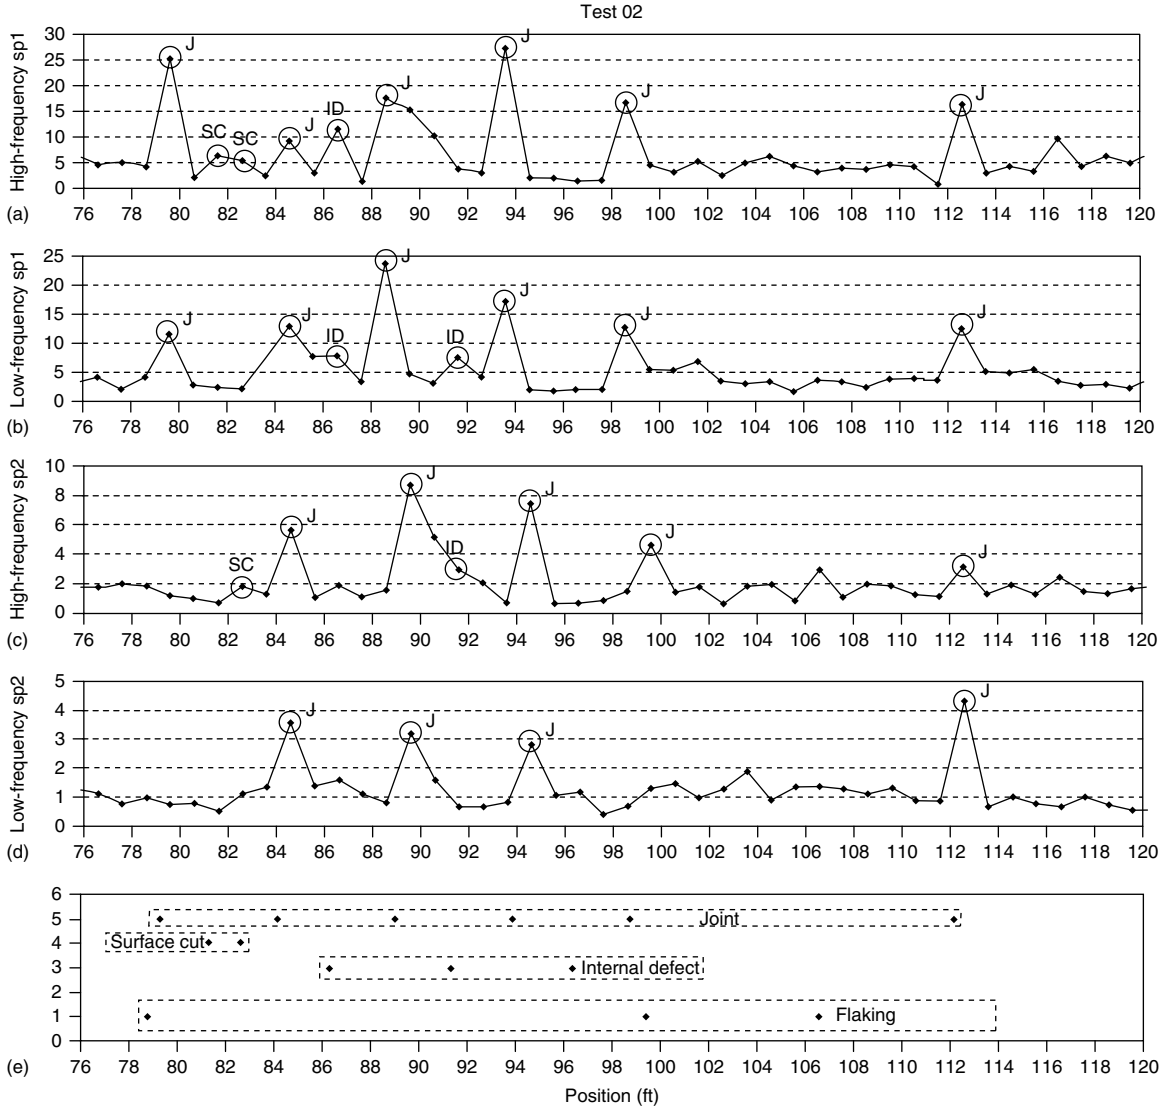

Figure 12. Results of field test no. 2 (J, joint; SC, surface cut; ID, internal defect).

(80 and 10% HA), and the second oblique SC. The detection performance was poor for the third ID (40% HA) and the first oblique SC. The fact that the SCs 1 and 2 (5 and 2% HA, respectively) were successfully detected demonstrated the ability of the system to target defects well below the 10% HA limit commonly used by railroad owners to consider removing the rail from service. The fact that the IDs 1 and 2 (80 and 10% HA) were successfully detected demonstrated that the 10% HA detectability limit also applies to internal flaws. It is unclear why ID 3 (40% HA) was seldom detected. Hand remapping of this flaw is being scheduled to verify its dimensions prior to the second field test.

In terms of dry versus wet surface, it was found that wetting the rail surface increased the POD for all defects (with the exception of oblique SC 2). The improvement from the water, although significant,

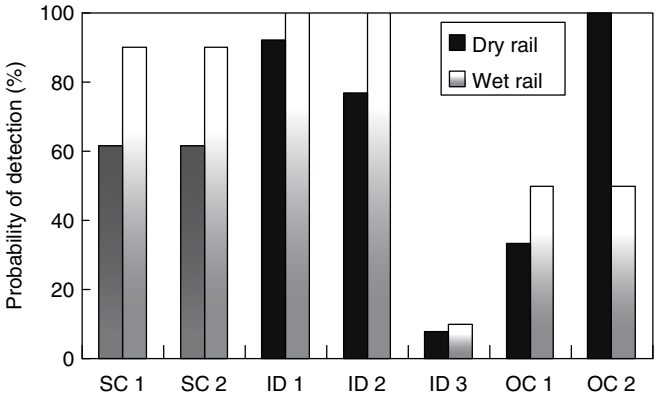

Figure 13. Probability of detection results obtained during field test under either dry or wet conditions of the rail surface (SC, surface cut; ID, internal defect; OC, oblique cut).

was not dramatic. In the end, a compromise must be struck between the burden of carrying a water supply and an acceptable level of POD.

The defect discrimination based on detection frequency band was generally successful. The SCs were predominantly detected by the HF-DIs mostly sensitive to surface features. Similarly, ID 1 was predominantly detected by the LF-DIs mostly sensitive to features deeper inside the rail head. Interestingly, ID 2 was primarily detected by the HF-DIs, suggesting that the flaw was very close to breaking the surface. This hypothesis was confirmed by an independent hand mapping performed on this defect prior to the tests.

6 CONCLUSIONS

This article discusses the topic of guided-wave defect detection in rails, and it presents in particular a prototype under development for noncontact testing. Guided waves are excellent candidates for interacting with the dangerous transverse defects in rails. However, their multimode and dispersive behavior complicates signal interpretation and inspection design. A SAFE method is an ideal tool for modeling these waves because of the lack of high-frequency (above 6 kHz) theoretical solutions for waveguides of arbitrary cross section such as rails. This modeling was used to generate dispersion curves, attenuation curves, and mode shapes of 115-lb AREMA rails. It was confirmed that high-frequency waves (~200 kHz) are predominant Rayleigh-wave type, whose penetration depth is related to their wavelength. Hence, defect sizing is possible by monitoring different frequency bands of the propagating waves.

Waves from 50 kHz to 1 MHz range are used in the prototype, which also employs a pulsed laser and air-coupled sensors for noncontact probing of the rail head. Software has been developed to denoise the measurements by DWT processing, and then compute a DI based on transmission measurements. The DI is related to the size and the position of transverse defects within the rail head (whether at the surface or internal) through its magnitude and associated frequency band. Laboratory tests showed that the prototype yields defect detection reliability for surface-breaking cracks comparable to or better than industry (AREMA) standards. Field tests also showed large probabilities of detection for both surface and IDs, with some exceptions. A second field test of an improved version of the prototype will be carried out to validate the defect detection performance, particularly at normal testing speeds.

ACKNOWLEDGMENTS

This work was performed under research grant DTFR53-02-G-00011 awarded by the Federal Railroad Administration (FRA) of the US Department of Transportation. The authors are grateful to Mahmood Fateh, the FRA's Technical Representative, for his technical guidance and valuable comments during all phases of this research, and to Gary Carr, Senior

Mechanical Engineer of ENSCO during the field tests, and now FRA's Chief of Track Research Division, for providing technical and logistic support during the prototype assembling and field testing.

Chapter 21
Signal Processing for Damage Detection

Wieslaw J. Staszewski and Keith Worden
Department of Mechanical Engineering, University of Sheffield, Sheffield, UK

1 INTRODUCTION

Structural health monitoring (SHM) has become an important element of all maintenance activities in operation of aerospace, mechanical, and civil infrastructures. *Damage, health*, and *monitoring* of structures can be described using various definitions. In general, *health* is the ability to function/perform and maintain the structural integrity throughout the entire lifetime of the structure; *monitoring* is the process of diagnosis and prognosis, and *damage* is a material, structural, or functional failure. Also, in this context, structural integrity is the boundary condition between safety and failure of engineering components and structures.

SHM, damage detection/monitoring, and nondestructive testing (NDT) are often used interchangeably to describe the process of nondestructively evaluating the structural condition. However, only SHM defines the entire process of implementing a strategy, which includes the five most important identification elements (or levels). These are [1]; detection, classification, localization, assessment, and prognosis, as illustrated in Figure 1. In this context, *detection* gives a qualitative indication that damage might be present, *classification* gives information about the damage type, *localization* gives information about the probable position of damage, *assessment* estimates the severity of damage, and finally *prognosis* estimates the residual structural life. All these elements require various levels of data, signal, and/or information processing. What distinguishes SHM from NDT is the global and on-line implementation of various damage-detection technologies, which require periodically spaced measurements (or observations), as accurately pointed out in [2]. This process of on-line implementation needs more advanced signal processing for reliable damage detection than classical NDT techniques.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

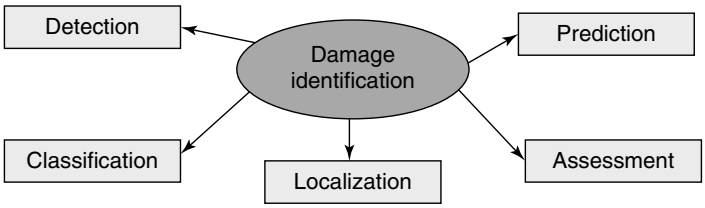

Figure 1. Damage identification levels in SHM.

Most SHM methods can be classified into model-based and signal-based (data-based) approaches. Vibration-based methods often utilize physical and/or modal parameters, obtained from physical models, for damage detection. Models are also essential when loads are monitored to obtain information about structural usage. Signal-based methods rely on various types of direct measurements such as noise, vibration, ultrasound, and temperature. Both model-based and signal-based approaches require signal-processing techniques, the former to develop appropriate models and to analyze changes in these models that are relevant to damage, and the latter to extract features and establish a relationship between these features and possible damage.

In summary, it appears that signal processing is essential for implementation of any SHM system. There exist various signal-processing techniques that are currently used and are considered for application in damage detection [3, 4]. Figure 2 shows examples of advanced methods and techniques developed over many years of research investigations. Some of these methods are well established and widely used, whereas others are more advanced and recently developed. There are six major areas where signal processing has an important role to play in SHM. These are as follows:

- measurements and data acquisition;
- data preprocessing;
- feature extraction, selection, and compression;
- pattern recognition and machine learning;
- reliability and statistical analysis;
- uncertainties and information gaps.

All these elements are briefly discussed below and relevant references are given to subsequent articles in the Encyclopedia for more reading.

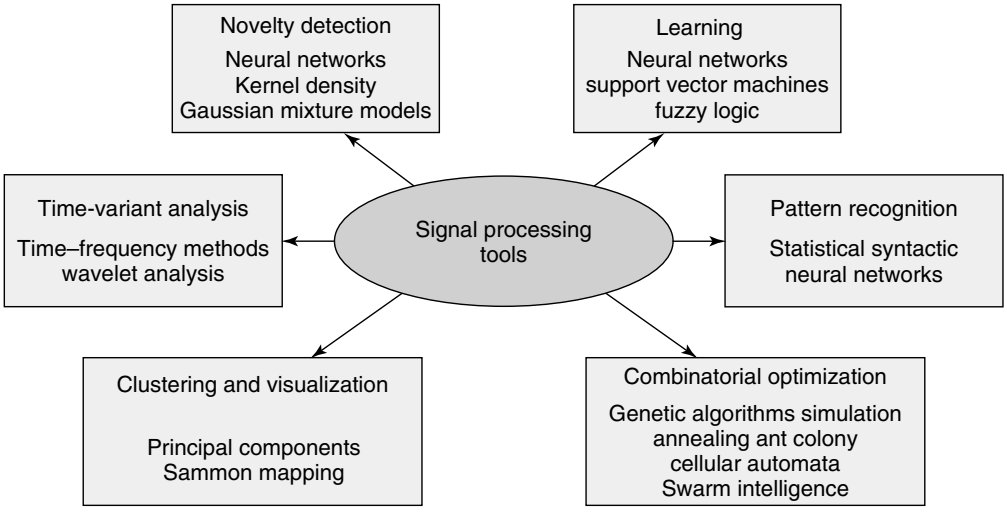

Figure 2. Selection of advanced signal-processing tools used for damage detection.

2 MEASUREMENTS AND DATA ACQUISITION

Various types of signals can be used for health monitoring, as illustrated throughout different sections of this encyclopedia. Measurements are performed using contact and noncontact approaches, which require selecting the number and locations of measuring points. Signal processing can be used to enhance this selection process. Numerous optimization techniques have been developed for optimal sensor location. This includes classical optimization techniques and various combinatorial approaches, as illustrated in **Optimization Techniques for Damage Detection**. The information content of features can be also used for assessing different types of sensors, their performance regarding required features, and their location regarding desired information, as discussed in **Sensor Placement Optimization**.

A number of measures have been developed to assess informativeness. For example, mutual information, based on Shannon entropy, can reduce the dimensionality of the space by eliminating sensors (or locations of sensors) with low information content or with high redundancy with respect to other sensors.

3 DATA PREPROCESSING

Once data from various sensors are acquired (and optionally stored), preprocessing is the first important element of the entire signal-processing analysis. It involves two major operations, namely, normalization and cleansing. The former is required to simplify and present the data collected under varying conditions to separate effects related to possible damage from operational and environmental conditions. The latter involves (i) various procedures to remove undesired features from data such as trends or noise; (ii) filtering and resampling; and (iii) selection procedures that either accept or reject data before further analysis is performed.

Trends show unwanted temporal relationships in the data. Trend analysis and removal requires some kind of model of the data. Noise is unwanted, a meaningless spectral part of the data, which does not carry any desired information. It is usually associated with higher frequencies. The level of noise in the data can be reduced by local and/or global averaging, smoothing, and denoising procedures. Filtering removes certain parts of the data within specific frequency ranges. The operations can be performed in the time, frequency, or spatial domains. Some filters can be used for smoothing and denoising. Resampling is used to reduce the frequency range of the acquired data. Finally, bad-quality data can be rejected before or even after preprocessing on the basis of individual experience and judgments and may be due to, for example, loose sensor mounting, poor connections, failure of acquisition hardware, or human error. Signals that are far from expected observations are often called *outliers*. Outliers can often be eliminated using standard statistical analysis.

A variety of different signal preprocessing methods are illustrated in Figure 3. More details related to different procedures can be found in **Data Preprocessing for Damage Detection**.

4 FEATURE EXTRACTION, SELECTION, AND COMPRESSION

Time histories acquired from sensors are very rarely used for damage detection. Most health monitoring techniques are indirect methods; in other words, measurements used in the form of different types of signals need to be transformed into features that can indicate possible damage. Various approaches can then be used. Trending analysis employing different parameters—often called *damage indices*—can be applied. The value of *damage index* is then plotted against lifetime to reveal gradual degradation. The maximum amplitude of Lamb wave response plotted against fatigue cycles is an example. Alternatively, time histories are mapped directly into patterns describing various damage conditions. For example, strain, widely used in many engineering applications, needs to be mapped into loads in order to obtain information about usage. Often sets of features in both approaches are compared with baseline measurements representing the *no-damage* condition.

Various features can be used to indicate damage. Features are any parameters extracted from the measurements through signal processing. There exist different types of features used for damage detection. Dimensionality of the features and complexity

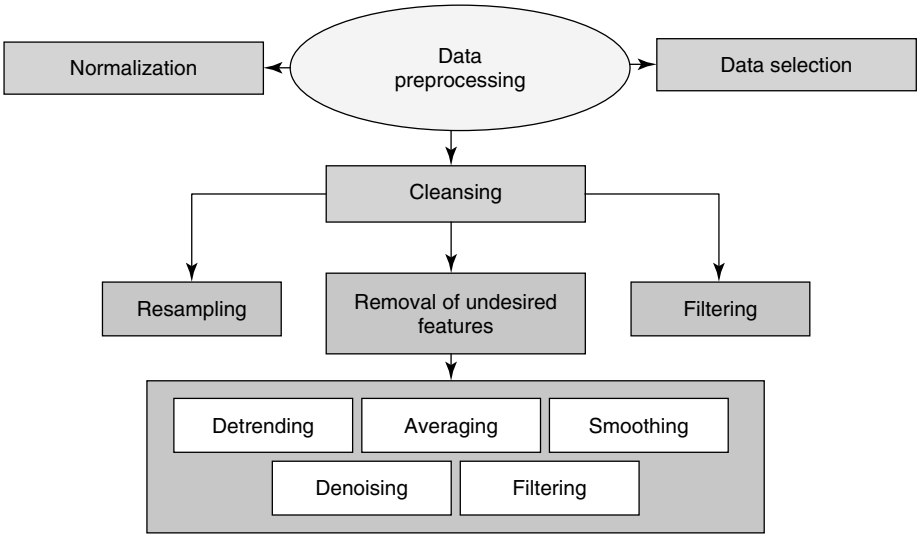

Figure 3. Data preprocessing procedures used for damage detection.

of signal processing decide the possible applications. Simple features, such as statistical parameters (e.g., maximum value, average value, root-mean-square level, and kurtosis), can be used to detect severe damage. However, information for early detection of incipient or small damage severity requires advanced signal-processing procedures. Such procedures often result in simple one-dimensional characteristics (e.g., set of principal components) or lead to more complex, multidimensional representations (e.g., timescale wavelet plots). In general, the choice of features is a trade-off between computational feasibility associated with low-level features and extensive signal processing required for high-level features.

Feature extraction, selection, and compression has received considerable attention in signal-processing research related to damage detection and has led to many different techniques and approaches. Sensor measurements can be analyzed in the time, frequency, combined time–frequency, and spatial domains. Various statistical parameters (e.g., mean and maximum value) and probability distributions can be used to analyze signal amplitudes. Time histories can be also analyzed using discrete-time models. Time-domain measurements are often transformed to another domain; various linear and nonlinear transformations are used in practice. Spectral analysis can be applied to obtain frequency content of analyzed signals, as shown in **Statistical Time Series Methods for SHM**. A variant on the spectrum—the cepstrum (*see* **Cepstral Methods of Operational Modal Analysis**)—has been applied successfully in the context of condition monitoring and may prove to be of value for SHM. This is discussed in **Cepstral Methods of Operational Modal Analysis**. Higher order spectral analysis can reveal various nonlinear interactions in data that prove to be of value in indicating damage (*see* **Higher Order Statistical Signal Processing**). Instantaneous phase and amplitude characteristics are often useful and can be obtained using the Hilbert transform, as discussed in **Hilbert Transform, Envelope, Instantaneous Phase, and Frequency**. The combination of the Hilbert transform with so-called empirical mode decomposition has led to the Hilbert–Huang transform, which has applications in nonstationary signals (*see* **Damage Detection Using the Hilbert–Huang Transform**). The analysis of nonstationary signals, in general, requires specific techniques that go beyond the classical Fourier approach. There have been major developments in the area of time–variant analysis over the past 20 years. Currently, there exist many different methods, which can be classified into two major groups, i.e., those based on time–frequency analysis (*see* **Time–frequency Analysis**) and those based on timescale analysis, as discussed in **Wavelet Analysis**. The latter approach leads to wavelet

analysis, which has received major attention in recent mathematical and signal-processing developments. Various procedures have been developed for the analysis of nonlinear systems (*see* **Nonlinear Features for SHM Applications**). Altogether, transformation of data can not only reveal specific characteristics/features related to damage but can also lead to data reduction and preferable statistical properties/parameters.

Transformed signals are often inappropriate for analysis owing to redundancy or high degree of correlation. Additionally, such analysis does not necessarily lead to reduced dimensionality. There exist different procedures that are used to deal with this problem. Altogether these procedures condense information, i.e., combine existing features into new features, select subsets of features, and map signals (features) into smaller sets of features or compress signals (features).

A number of measures have been developed to assess the informativeness of features. Mutual information, based on entropy, is an example. The method based on Fisher's linear discriminant performs an optimal linear dimensionality reduction based on the magnitude of the discriminant vector. It leads to maximum class separation in the output space. The classification binary tree uses a binary decision tree based on Kolmogorov–Smirnov minimization criterion of the Bayesian probability. The "goodness" of features for damage identification can also be estimated on the basis of the Fisher information matrix. This matrix is the inverse of the covariance matrix associated with the analyzed features. Maximizing the trace or determinant and minimizing the condition number of the Fisher information matrix corresponds to the process of feature selection. Applications of this principle can be found in the section on sensor optimization (*see* **Sensor Placement Optimization**).

Mapping techniques are capable of reducing the point dimensionality of data. Principal component analysis (PCA) is one of the most commonly used linear techniques for dimensionality reduction. PCA is a classical multivariate statistics technique that maps the original data to a space of reduced dimension using a linear transformation. The procedure seeks to retain the variance in the analyzed data as much as possible. Sammon mapping is a nonlinear equivalent of the PCA technique. The method projects the N-dimensional data into a two-dimensional (2-D) space preserving all interpoint distances, i.e., two samples that are close to each other in the original space remain close in the new space. The objective is to reveal the underlying structure of the data preserving the original topology. The general problem of dimensionality reduction is discussed in the context of SHM in **Dimensionality Reduction Using Linear and Nonlinear Transformation**.

Dimensionality reduction can be also achieved using data compression. Recent developments in this area include applications of wavelets. The wavelet transform can give a compression basis, which is independent of the data set, and can reveal local temporal correlations in the data.

5 PATTERN RECOGNITION AND MACHINE LEARNING

Time histories obtained through various measurements and features, which result from signal processing, form data sets that can be seen as patterns. This leads to damage detection based on pattern recognition. Patterns are continuous, discrete or binary, or combined variables, which are formed in vector or matrix notation. In a damage detection approach, the assumption is that patterns represent different damage conditions. Various pattern-recognition techniques can be used to indicate whether a structure is undamaged or damaged and then to assess the severity of possible deterioration. Classical approaches to pattern recognition can be categorized as statistical and syntactic methods. Syntactic pattern recognition classifies data according to its structural description, whereas statistical pattern recognition (SPR) assigns features to different classes using statistical density functions. Applications of structural pattern recognition to SHM vary and SPR is the general approach as discussed in **Statistical Pattern Recognition**. Recent advancements in pattern recognition include applications of artificial neural networks (ANN), which have proved fruitful in the context of SHM as described in **Artificial Neural Networks**.

Pattern recognition itself forms a subdiscipline of the broader field of machine learning, which is currently receiving considerable attention for SHM, and **Machine Learning Techniques** gives a brief overview of the field. The discipline of machine

learning is characterized by the fact that computational rules are inferred or *learned* on the basis of observational evidence. This contrasts with the "classical" view of computation where the algorithmic rules are imposed in the form of a sequence of serially enacted instructions. It is sometimes stated that learning theory is designed to address three main problems [5]:

- Classification, i.e., the association of a class or set label with a set or vector of measured quantities. The set of observations may be sparse and/or noisy. This is very often applied in the context of damage location, where the structure of interest is divided into a number of substructures and a class label is assigned to each.
- Regression, i.e., the construction of a map between a group of continuous input variables and a continuous output variable on the basis of a set of (again, potentially noisy) samples. This can also be used in damage localization by attempting to predict the real-valued coordinates of the damage; it can also be used for the problem of severity assessment.
- Density estimation, i.e., the estimation of probability density functions from samples of measured data. This is one of the approaches to damage detection via novelty detection as discussed below.

A further division of learning algorithms may be made between *unsupervised* and *supervised* learning. The former is concerned with characterizing a set on the basis of measurements and perhaps determining underlying structure. The latter requires examples of input and output data for a postulated relationship so that associations might be learnt and errors corrected. This approach presents serious problems in the SHM context as it is very rarely possible to acquire sufficient data covering the various possible damage states. Although it is not universally so, regression and classification problems usually require supervised learning, while density estimation can be conducted in an unsupervised framework. In general, novelty detection can be carried out in an unsupervised context. This is the basic process of distinguishing data from data measured in the normal condition of the structure of interest and thus serves as a method of detection. A number of approaches to novelty detection are discussed in **Novelty Detection**.

A powerful approach to the handling of disparate sources of information is given by the class of *data fusion* algorithms. Data fusion can operate at a number of levels within the SHM context. At a basic level, one can use the methodology to combine features into finer features for diagnostics. At a higher level, fusion can be used to combine the results of disparate classifiers in order to refine the decision process. The basic methodology of data fusion is described in **Data Fusion of Multiple Signals from the Sensor Network**.

6 RELIABILITY AND STATISTICAL ANALYSIS

One of the basic problems in SHM is the fact that many of the quantities of interest for diagnosing damage as well as the damage states themselves are often random variables. This means that the appropriate analysis is usually within a probabilistic context. At the lowest level, even the models constructed for model-based diagnosis will have to incorporate random variables in the form of unmeasured effects like noise and environmental variations. Statistical analysis has developed a number of very powerful techniques for building models under uncertain circumstances and some of the foremost approaches are discussed in **Model-based Statistical Signal Processing for Change and Damage Detection**.

A major problem is that the features extracted from measured data to accomplish diagnosis are also random variables. This means that classifier design is best carried out within a principled statistical framework like SPR as discussed above (*see* **Statistical Pattern Recognition**). SPR is able to accommodate the fact that classes will sometimes overlap, i.e., there will be situations where a given set of features may or may not indicate damage. SPR allows one to assign a probability to the diagnosis and this is critical when one needs to make a decision on the basis of the diagnosis. In the case of regression analysis, a principled statistical approach allows one to assign a confidence interval or error band to a prediction and, again, this can prove invaluable in the decision process.

7 UNCERTAINTIES AND INFORMATION GAPS

There are essentially two types of uncertainty in general. The first is *aleatory* or *irreducible* uncertainty. This is the type of uncertainty associated with, for example, the microscopic variation of material properties within a structure. The uncertainty may be characterized by a probability distribution and is irreducible to the extent that there exists no possible program of experimentation that can reduce the uncertainty, e.g., to allow better prediction of the pointwise value of a material property. Another source of aleatory uncertainty is in the predicted future loading of a given structure or component. Both these examples of uncertainty present problems in terms of damage prognosis or level five of the damage identification hierarchy. At the lower levels of damage identification like localization, the uncertainty is partly addressed by adopting a principled framework like SPR. The second type of uncertainty is *epistemic* or *reducible* uncertainty. In this case, the uncertainty is caused by a lack of knowledge, which could potentially be acquired by, say, more careful modeling or by experimental campaign. The precision limits of instrumentation are a potential cause of epistemic uncertainty as it may be possible to acquire more precise instrumentation. It is clear that SHM damage identification will potentially suffer from the presence of both flavors of uncertainty and this must somehow be accommodated within the data-to-decision process, which leads from measurements to a decision.

The problem of uncertainty is sometimes only optimally addressed in the probabilistic context on the assumption that certain *a priori* information is available. Where such information is not available, an information gap or ignorance occurs and it may be that probability theory is suboptimal. A number of other uncertainty frameworks are available, which offer the possibility of accommodating ignorance in a potentially more conservative manner than probability theory. It is useful to have such techniques available for SHM analysis as there are many sources of uncertainty in the data-to-decision process. A number of the alternative uncertainty theories are described in the context of SHM in **Uncertainty Analysis**, which also presents case study material.

8 SUMMARY

Whatever the specialism of the SHM researcher or practitioner, few would argue that signal processing is a crucial ingredient in the SHM process and will be a vital ingredient in moving SHM from the research laboratory to everyday maintenance practice. The object of the article here is to present the basic facts regarding signal processing as applied in the context of SHM. While much of the material is textbook in terms of its basic development, it is included here so that the reader can see it exposed in the damage identification context. Other materials will certainly be unfamiliar as it is only very recently beginning to penetrate the SHM literature. Overall, this article is intended to be exhaustive only in the sense of *introducing* relevant technologies; however, the references within each section are intended to provide comprehensive guidance for further reading at greater depth.

1 INTRODUCTION—THE SIGNAL PATH AND THE SOURCE OF MEASUREMENT ERRORS

Measurement errors and erroneous noise are introduced along the signal path between the measurement transducer and the structural health monitoring (SHM) processor. A typical signal path for SHM measurement data is illustrated in Figure 1.

A *transducer* or *sensor* takes a physically measurable quantity such as strain or temperature and converts it to an electrical signal that can be processed. The electrical signal is usually expressed as voltage, current, charge, or resistance. Examples include strain—converted to electrical resistance, or temperature—converted to electrical voltage (also see Section 14 in the encyclopedia).

The *signal conditioning* unit takes the low-level electrical signal and "conditions" it ready for analysis. Typical conditioning steps include amplifying, filtering, and any necessary conversion of current, charge, resistance, or pulse frequency to an analog voltage.

The *analog-to-digital converter* (*ADC*) takes the amplified analog signal from the signal conditioning unit and converts it to a digital form suitable for computer-based analysis. This is a two-stage process. The ADC first samples the stream of continuous analog data selecting discrete values from the stream at periodic intervals. This stage is called *sampling* and the frequency at which samples are taken is called the *sample rate*. In the second stage, the discrete analog values are converted to a digital representation. This is referred to as *digitization* or *quantization*.

In smaller SHM systems, the ADC converter is often integrated in the SHM processor unit and sensors are connected directly to the unit. However, in larger systems, this arrangement is impractical due to the number of analog cables required to connect all the transducers, and also the effect of electrical interference on low-level analog signals. A *digital communication network* requires only one cable and is far more tolerant of electrical interference. Several digital communication standards are commonly used

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

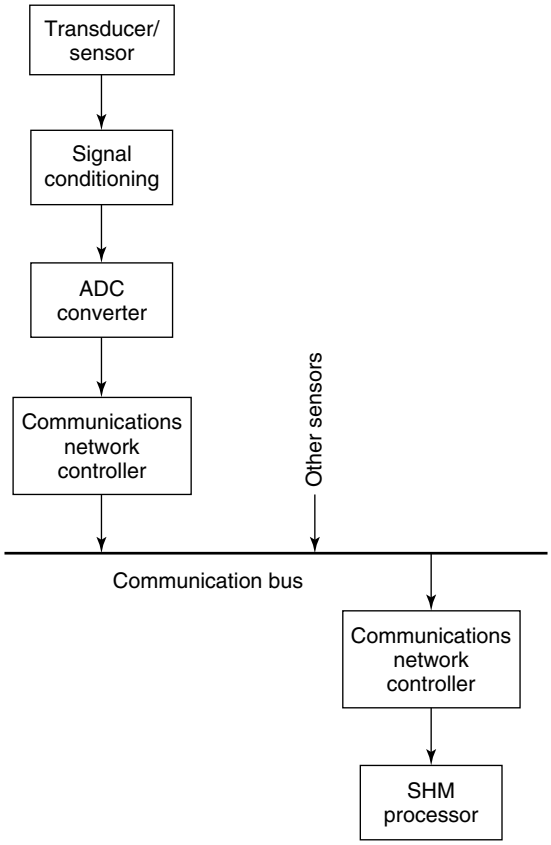

Figure 1. The signal path.

for SHM and are discussed in [1]. The controller area network (CAN) and Ethernet systems are most commonly used for wired networking although others can be found. The CAN is preferred over short distances in very noisy conditions such as engines and electromechanical machinery. Ethernet is more common for larger networks in less noisy conditions. Both standards divide the data into small "packets", which are transmitted along the cable. The packets are received by other nodes on the network and reassembled to represent the original signal. They are known as *asynchronous* communication because each sensor samples, digitizes, and transmits its signal independently, so data points in one channel are not sampled simultaneously with data points in another. Wireless networking standards are also common and include "Bluetooth" and "WiFi". Bluetooth is most commonly used for short range ($<10\,\mathrm{m}$) communication between remote sensors, whereas WiFi is more suitable for longer distances and can replace the wired network. Proprietary remote wireless telemetry systems are also common.

A good account of sensor technology and digital communication systems used in automotive engineering is presented by Hillier *et al.* [2] and also Bosch [3].

The *SHM processor* unit collates data from each sensor and performs the damage-detection analysis. This is usually done by a digital computer or, in some smaller SHM systems, a digital signal processor (DSP) or field-programmable gate array (FPGA). A good review of the various technologies is given in [4]. Data is often stored by the SHM processor for off-line analysis; this is known as *data logging*. Before performing the damage calculation, the SHM processor must validate all the measured data to ensure that errors and noise are adequately suppressed. Most cases of false damage detection are attributable to errors and noise in the measurement data. In this article, we are particularly interested in the types of noise and error present in the data, and we investigate methods of detection and cleansing. The article is concerned with the following errors:

- System errors—calibration and system faults
  - frequency sampling errors—amplitude attenuation, aliasing, phase lag, and downsampling
  - quantization error, overflow error, and underflow error
  - calibration errors—polarity, gain, offset, and linearity
  - signal clipping, saturation, and dropout errors
  - transmission lag and asynchronous channel phase lag
- Signal noise
  - Gaussian noise, tonal noise, and ac power-line interference
  - transducer resonance and mounting resonance
  - inductive coupling, capacitive coupling, and ground loops
  - low-frequency signal drift
  - signal spikes
- Noise in rotating machinery
  - pulse-transducer errors—runt pulse and pulse spike

– Gaussian noise in rotating machinery
– order analysis of rotating machinery.

2 SHM SYSTEM ERRORS—CALIBRATION AND SYSTEM FAULTS

In this section, we look at errors associated with system configuration and describe how these can be detected and avoided. It is important to eliminate these errors because they will affect the SHM analysis. We cover the following errors:

1. frequency sampling errors—amplitude attenuation, aliasing, phase lag, and downsampling;
2. quantization error, overflow error, and underflow error;
3. calibration errors—polarity, gain, offset, and linearity;
4. signal clipping, saturation, and dropout errors;
5. transmission lag and asynchronous channel phase lag.

2.1 Frequency sampling errors—amplitude attenuation, aliasing, phase lag, and downsampling

Frequency sampling occurs at the ADC stage. The ADC converter periodically samples a continuous stream of analog data and then digitizes each sampled value. The rate at which the analog signal is sampled is called the *sample rate* and is expressed in hertz (i.e., samples per second). Selecting a very high sample rate ensures a good approximation to the analog signal; however, the quantity of data collected can quickly swamp the communication network or the SHM processor and quickly fill the available memory if data logging is required. Conversely, setting a low value can introduce several serious and irrecoverable errors in the signal. It is therefore important to establish an appropriate sample rate and provide means to avoiding errors.

To establish an ideal sample rate, we should first look at the process being measured and the analysis required. For example, if we are concerned with damage accumulation on the chassis of a ground vehicle, then most of the vibration energy is in the very low frequency range (typically 0–35 Hz). Therefore, in this case, we are not interested in the higher frequency ranges. According to the Nyquist–Shannon sampling theory [5, 6], we need to set a sample rate of at least twice the desired frequency range. In our example, we therefore require a sample rate of at least 70 Hz. Although the Nyquist–Shannon theory does provide sufficient data for assessing the frequency content of the data, it is not adequate for representing the true amplitude.

Amplitude attenuation errors occur when there are insufficient samples to adequately define the peaks and troughs in the signal. Consider the simple time signal illustrated in Figure 2(a). This signal is made by summing two sinusoidal waves of similar amplitude: the first has a frequency of 5 Hz and the second 35 Hz. If the signal were sampled at only 75 Hz as in Figure 2(b), we see that the amplitude peaks are not captured by the digitized signal. Amplitude attenuation errors are reduced significantly by increasing the sample rate to 5–10 times the highest frequency component in the measured signal (i.e., 350 Hz). This ensures an adequate representation of the peaks and troughs as illustrated in Figure 2(a).

Aliasing errors are illustrated in Figure 2(c) and (d). According to the Nyquist–Shannon sampling theory, the maximum frequency range contained in a sampled signal is equal to half its sample rate. This is commonly referred to as the *Nyquist frequency*. The Nyquist frequency is the highest frequency we can see in a sampled signal. A question therefore arises, when we sample a continuous stream of data at a given sample rate, what happens to frequencies, which exceed the Nyquist frequency? This effect is called *aliasing* and the higher frequencies are effectively reflected back into the lower frequency data causing undesirable and erroneous noise. Figure 2(c) and (d) illustrate the effect of aliasing. In Figure 2(c), the signal is sampled at 70 Hz, so the Nyquist frequency coincides with the high-frequency sine wave (35 Hz) and, consequently, the digitized points miss the 35-Hz wave completely. In Figure 2(d), the high-frequency sine wave (35 Hz) is sampled at only 60 Hz. This gives a Nyquist frequency of only 30 Hz, so the 35 Hz wave is reflected back in the low-frequency region causing a false wave at 25 Hz. This is also illustrated in the frequency domain by showing a plot of the amplitude versus frequency. In this plot, we see, more

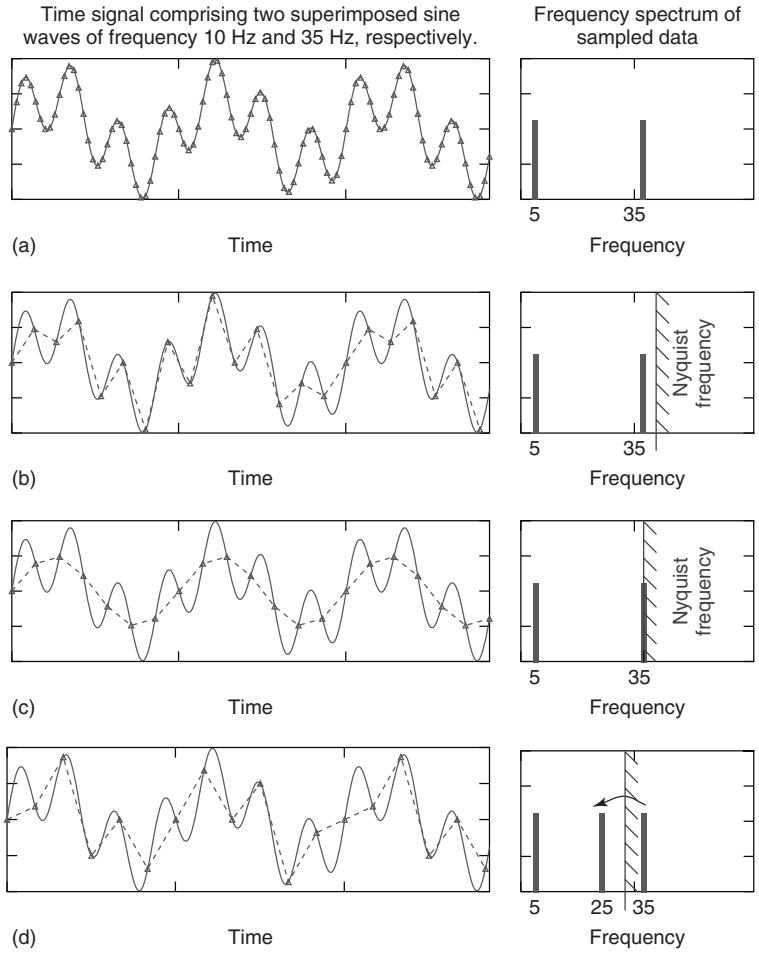

Figure 2. Illustration of amplitude attenuation and aliasing. (a) Data is sampled at 350 Hz (i.e., 10 times maximum frequency) and shows good amplitude and frequency resolution. (b) Data is sampled at 75 Hz; therefore, the Nyquist frequency is $75/2 = 37.5$ Hz. The sampled data therefore shows adequate frequency, but very poor amplitude definition around the peaks. (c) Data is sampled at 70 Hz with a Nyquist frequency equal to the 35 Hz sine wave. The sampled data only shows the 10-Hz component and misses the 35 Hz wave. (d) Data is sampled at 60 Hz therefore the Nyquist frequency is 30 Hz. The 35-Hz wave is now reflected causing an erroneous sine component of 25 Hz.

clearly, how the high-frequency data is reflected back to corrupt the low-frequency signal.

Aliasing errors cannot be corrected after the ADC stage and are very difficult to detect from the digitized data. It is, therefore, very important to filter out all frequencies greater than the Nyquist frequency in the analog signal before the ADC sampling stage. This is accomplished using a hardware "antialiasing" filter. This filter uses an analog electronic circuit that allows low frequencies to pass while higher frequencies are attenuated. It is known as a *low-pass filter*. There are several commonly used hardware filters available including Butterworth, Chebyshev, and Bessel filters. More information on data acquisition and hardware filtering is given in [7].

- **Phase lag**

Antialiasing filters often introduce a phase lag between the input signal and the filtered output. The extent of differential phase lag between channels is an important concern when developing SHM damage algorithms. For example, if we wanted to calculate

the torque in an electric motor by dividing the power by the speed, differential phase lag between the two channels could introduce errors in the calculated values. It is, therefore, important to maintain relative phase between channels by using the same antialiasing filter configuration. This implies using the same sampling rate for all measured channels. In many SHM systems, this is not practical and so phase errors are likely to occur (Section 2.5).

- **Downsampling errors**

Very often it is necessary that we further "downsample" the digitized data on the SHM unit to improve data storage or calculation efficiency. All of the errors discussed above are equally applicable when downsampling digitized data. We must, first of all, filter the data using a low-pass filter and then resample the filtered signal. In the case of software filtering, it is common to use Fourier transform–based filters, or Butterworth, or Chebyshev time-domain filters. In the latter case, we often eliminate phase-lag errors by applying a two-pass approach. The first filter introduces a phase lag as we discussed earlier, so during the second stage we pass the filtered data back through the filter in reverse order. This gives an equal and opposite phase lag, which negates the effect. This two-stage filtering process is only possible in software and is not appropriate for in-line hardware filtering of analog data; it is therefore unsuitable for the antialiasing filter.

2.2 Quantization error, overflow error, and underflow error

Quantization errors (or rounding errors) occur at the ADC stage when the analog signal is converted to a digital representation of ones and zeros. Quantization is the process of approximating a continuous range of analog values to a small set of discrete values. The quantization error is the difference between the true analog value and the approximated (or rounded) digital value. The effect is illustrated in Figure 3.

The straight line in Figure 3 represents the true relationship between voltage measured at the transducer and, in this example, the calibrated acceleration response. However, the ADC converts this into a digital representation. The quality of this representation is governed by the number of bits used. If an 8 bit representation is used over an acceleration range $\pm 50g$, then the maximum quantization resolution is given by equation (1).

$$\text{Quantisation resolution} = \frac{100g}{2^8} = 0.391g \quad (1)$$

In this case, the SHM configuration is unable to detect any change in acceleration less than $0.391g$. The resolution can be improved by increasing the number of bits (12 bit ADC gives $0.024g$ resolution) or decreasing the full-scale accelerometer range ($\pm 5g$ with an 8-bit ADC gives $0.0391g$ resolution). A

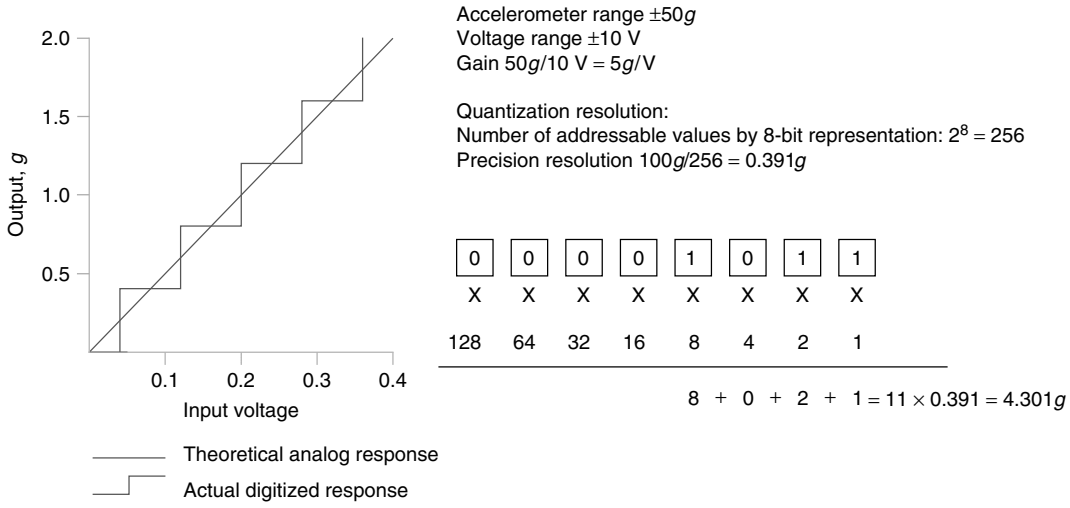

Figure 3. The effect of quantization resolution.

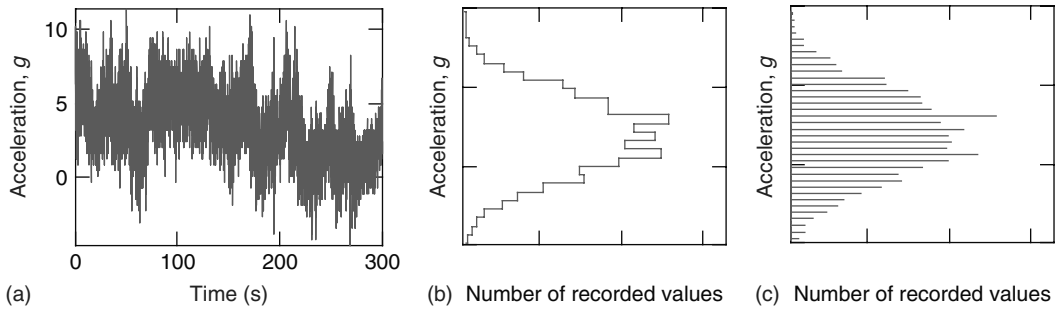

Figure 4. Checking for an adequate quantization resolution. (a) Time signal quantized with 8-bit resolution over a full-scale range $\pm 50g$. (b) Histogram of point values with 8-bit resolution. All histogram bins contain data. (c) Histogram of point values with 12-bit resolution. Many histogram bins contain no data.

process called *dithering* can also be used prior to the ADC stage to improve the apparent resolution. In this case, random noise is added to the analog signal and the signal is sampled at a much higher rate than is actually required (oversampling). The high-frequency signal is then filtered through a low-pass filter and downsampled through averaging. This randomizes the quantization errors and significantly increases the apparent resolution. A detailed review of dithering is offered in [8].

The quantization resolution should be established during the design of the SHM system. This error cannot be properly corrected by digital signal processing during service operation. Digital filtering and signal smoothing appear to improve the resolution, but they merely interpolate between the values and cannot adequately resolve peak values in the signal.

If we are worried about quantization errors, a simple histogram of point values can be used. Calculate the histogram of point values using the desired resolution; if all the histogram bins are filled, then the quantization resolution is satisfactory; if there are significant bins containing no points, then the quantization resolution is less than that required. This is illustrated in Figure 4.

Overflow and *underflow* errors are also associated with quantization. These usually occur at the digital communication or the SHM stage when the bit resolution is inadvertently reduced. For example, a 12-bit value is recoded to 8 bit. If the most significant bits are missed, then this is referred to as an *overflow* error and results in the time signal being reflected back to zero as shown in Figure 5(a). It is often difficult to identify this error from the time signal; however,

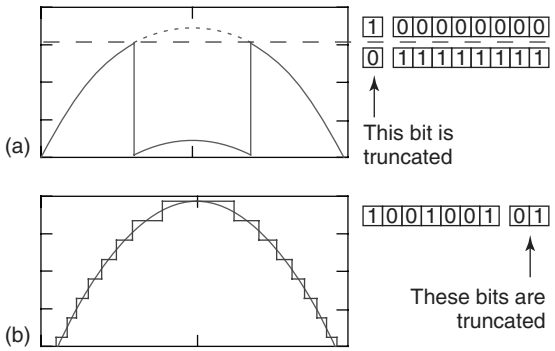

Figure 5. Illustration of overflow and underflow errors. (a) Overflow error: bit representation truncated and misses most significant bits. (b) Underflow error: bit representation truncated and misses least significant bits.

it becomes quite clear from the irregular profile of the amplitude probability distribution function (PDF) and the kurtosis statistic. If the least significant bits are missed then this is referred to as an *underflow* error and the quantization resolution is significantly reduced as illustrated in Figure 5(b). Although it is possible to correct overflow errors, it is very undesirable and so care should be taken when specifying the SHM system to avoid these. It is not possible to correct underflow errors as these lead to quantization error as discussed previously.

2.3 Calibration errors—polarity, gain, offset, and linearity

In a well-calibrated system, the digital signal reaching the SHM processor is proportional to the physical

measurement at the sensor. Most individual components along the signal path are calibrated individually, but very often we prefer to adjust this calibration at the SHM processor to account for the overall system calibration.

Polarity is the most simple calibration parameter. With the correct polarity, an increasing physical measurement should correspond with an increasing digital signal. Although this sounds trivial, it is unfortunately very common to reverse the polarity during installation. One common problem is associated with poor communication of the axis convention between the system designer and those installing the equipment. The error is usually identified during full-system calibration testing. Rather than rewiring or changing the transducer, the effect is more easily remedied at the SHM processor by negating the input signal (or multiplying the signal by -1.0).

Gain and *offset* are two factors used to establish the linear transfer function between input signal and output in the physical units (e.g., acceleration in g or temperature in K). The simple linear transfer function is expressed in equation (2). The gain and offset values are usually established from the full-scale range of the transducer.

$$\text{Output measurement} = (\text{input signal} \times \text{gain}) + \text{offset} \tag{2}$$

Nonlinearity errors occur when the transducer output is not linearly related to the desired measurement parameter. In most cases, this is handled by software at the ADC stage or analog circuitry in the signal conditioning unit. However, it can also be performed by the SHM processor through simple arithmetic manipulation. The most common nonlinear calibration is via a look-up table or a calibration curve that is usually expressed as a polynomial transfer function as illustrated in equation (3). The effect of gain, offset, and linearity is illustrated graphically in Figure 6.

$$\text{Output measurement} = a_0 + a_1 x + a_2 x^2 + a_3 x^3 + \cdots + a_n x^n \tag{3}$$

where x is the input voltage and a_n are the nonlinear coefficients.

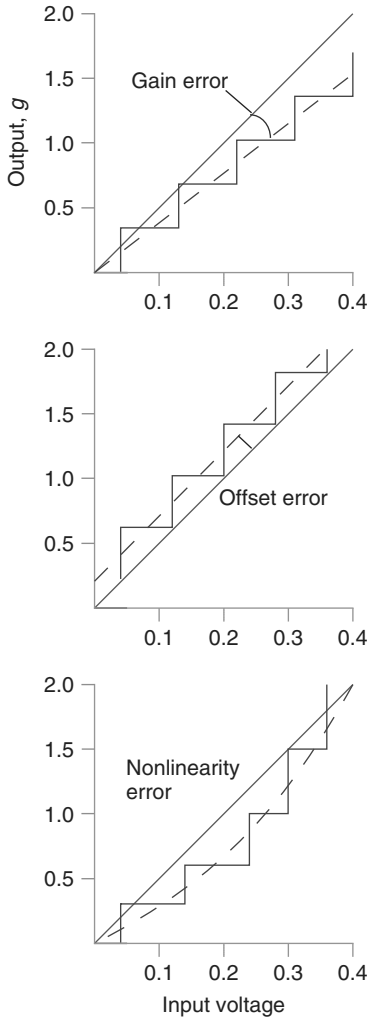

Figure 6. Calibration gain, offset, and nonlinearity.

2.4 Signal clipping, saturation, and dropout

Signal clipping occurs when a measured value exceeds the full-scale range of the SHM sensor. At this point, we are unable to predict the real physical measurement, so damage diagnosis and prognosis are impossible. It is not possible to correct these errors and a change in the hardware configuration is required. Clipping can also indicate a damaged component, so it is always important to address clipping errors unless they are attributable to an erroneous data spike (Section 3.5). Clipping can

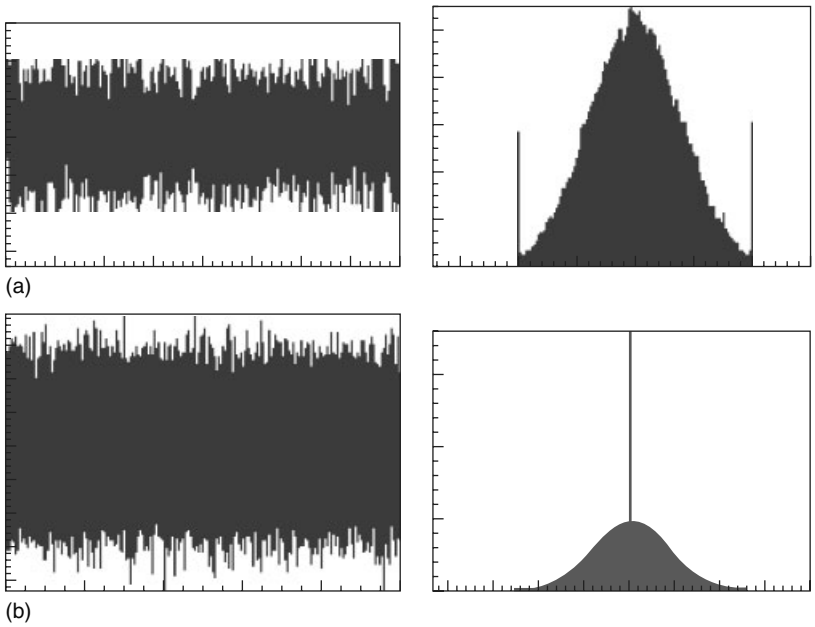

Figure 7. Illustration of clipped data and signal dropout. (a) Example of clipped data. Although it is difficult to detect by simply visualizing the whole time signal, it is clearly visible from the amplitude probability density function (PDF) as peaks at the extreme range. (b) Example of data drop out when the values periodically fall to zero. This can be difficult to detect from the time signal unless you can zoom in on the problematic area of data; however, it is clearly visible from the amplitude probability density function (PDF) as an irregular zero amplitude peak.

be detected by monitoring data values exceeding a particular threshold amplitude. They are also easily identified using the amplitude PDF as illustrated in Figure 7(a). The clipped values create a discontinuity in the PDF at the extremities.

Signal dropout can occur through circuit failure or communication failure. In this case, the measured channel can read full scale or zero depending on the type of sensor and the configuration. Intermittent dropout is usually quite easy to detect as the signal suddenly changes values (to zero or full scale) and then just as suddenly reacquires the value. In these cases, it is easy to locate the erroneous segments but it is impossible to ascertain what the correct values should have been. Damage detection and prognostic algorithms are usually designed to be tolerant of these types of error. They usually interpolate between the correct data and increase the damage parameters proportionally. A fault should be logged when dropout or saturation becomes too frequent as data analysis is unreliable. It can be difficult to determine dropout in data, which spends long periods at zero. The most revealing detection is offered by the amplitude PDF as illustrated in Figure 7(b). Dropout is indicated by an irregular zero amplitude peak.

Signal dropout can also occur due to digital communication errors such as priority override where the channel priority is low on a busy communication bus. In these cases, the SHM usually logs the time of the arriving data packet and can, therefore, asses the last valid data point. Subsequent points usually retain the last valid point.

2.5 Transmission lag errors and asynchronous channel phase lag

Transmission lag affects data transmitted by asynchronous packet-based digital communication. Each sensor periodically tries to broadcast its data along the communication bus. When the data is ready, it checks to make sure the bus is free. If it is busy, then it usually waits for the current transmission to finish before trying again. When the bus is free, the sensor starts to transmit a data packet. The data

packet usually starts with the sender's address. As the address is transmitted, the sender listens to the bus to see if another channel happened to start transmission at exactly the same instance in time. With an Ethernet-based system, both senders would stop and wait a random period before trying to retransmit. In a CAN-based system, the sender with a lower priority stops and waits for the higher priority signal to finish before trying to transmit again. The lower priority sensor notices a higher priority channel because it detects a bit being transmitted in the higher priority address when it, having a lower priority, contains a null bit. This approach to communication is known as *collision-based* and means that there is often a short delay between the data being read and the packets being received by the SHM processor. Also, the delay is not consistent and data received by each channel is not synchronized, i.e., not simultaneously sampled.

To mitigate these transmission errors, the SHM processor usually resamples the channels using a "pseudosimultaneous sample and hold" function as illustrated in Figure 8.

The sample-and-hold buffer monitors the communication bus for transmission of the required sensor channel. This is then held in the buffer awaiting a request from the trigger to present the value. If the buffer is not refreshed between triggers, then the previous value held in the buffer is returned again. If the buffer is refreshed several times between triggers, then either the final buffer value is returned or the value returned is the weighted mean of the values based on recent values having a greater relevance than the earlier ones. This offers an antialiasing capability.

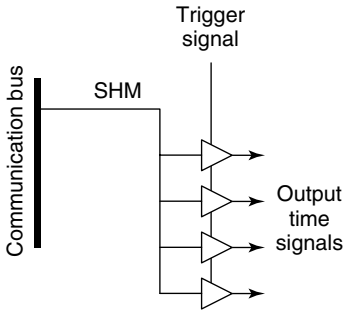

Figure 8. Illustration of pseudosimultaneous sample and hold for nonsynchronous digital communication. Buffers monitor and store communication signals as they arrive on the bus in an asynchronous fashion. The buffers are then read simultaneously based on a periodic trigger signal.

If damage-detection algorithms require simultaneous values from several channels, then this asynchronous form of communication can lead to spikes and dropout in the derived data. It is, therefore, important that these errors are also detected and cleansed before the derived data is used in diagnostic algorithms (Sections 3.5 and 2.4).

3 SIGNAL NOISE

In this section, we look at the effect of interference noise in the signal. We categorize these effects and present signal-processing techniques appropriate for denoising the signal. The types of noise considered include

1. Gaussian noise, tonal noise, and ac power-line interference
2. transducer resonance and mounting resonance
3. inductive coupling, capacitive coupling, and ground loops
4. low-frequency signal drift
5. signal spikes.

3.1 Gaussian noise, tonal noise, and ac power-line interference

The term *noise* is generically used to describe an undesirable component within the signal. Noise is very subjective and depends on what we want to find from the measured signal. For example, we might want to measure the torque on a vehicle drive shaft from the gearbox. In this case, we are interested in a fairly low frequency signal and we might consider the higher frequencies as inconvenient noise that should be removed. However, if we were looking for the progressive fretting of gear teeth, then it is the high-frequency signal that is important and the low-frequency components are now the noise. It is fairly easy to separate frequency-delimited noise using a simple low-pass or high-pass filter. In this example, the low-pass filter isolates the torque component, while the high-pass filter isolates the fretting. However, it is much more complicated when the frequencies start to overlap. Figure 9 illustrates the effect of Gaussian noise on a signal.

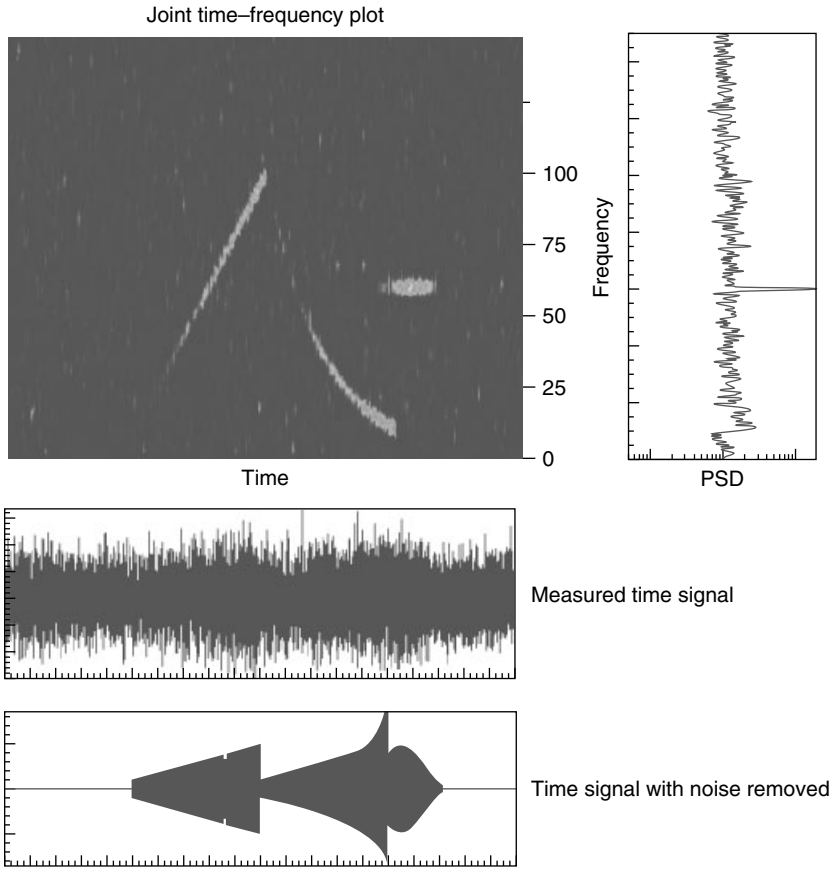

Figure 9. Illustration of Gaussian noise superimposed on an underlying signal.

Gaussian noise is a broadband random noise that is superimposed on the desired signal. It is representative of general background noise when no single source is dominant. It is usually assumed to cover the entire frequency spectrum with constant amplitude and is quantified by the signal-to-noise ratio (SNR). This is the ratio of the signal power to the noise power and is usually expressed in decibels as equation (4):

$$SNR = 10 \times \log_{10}\left(\frac{\text{signal power}}{\text{noise power}}\right) \qquad (4)$$

Tonal noise is narrow band and usually deterministic in nature. It is representative of a single source of harmonic interference. The most common form of tonal noise is due to ac power-line interference.

3.1.1 Frequency-delimited noise—high-pass, low-pass, band-pass, and band-reject filters

When the important signal and the noise occur over separate frequency ranges, we can separate one from the other using simple block filters. In the above example, we can isolate the torque signal from the high-frequency noise by using a low-pass filter, which allows only the lower frequencies to pass through while the higher frequencies are attenuated. The four common block filters are illustrated in Figure 10. In practice, it is undesirable to create very steep filters like these and the attenuation rate is rather lower than the plots suggest. It is, therefore, necessary to ensure an adequate frequency separation between the signal and noise. An excellent introduction to digital filters is offered by Hamming [9].

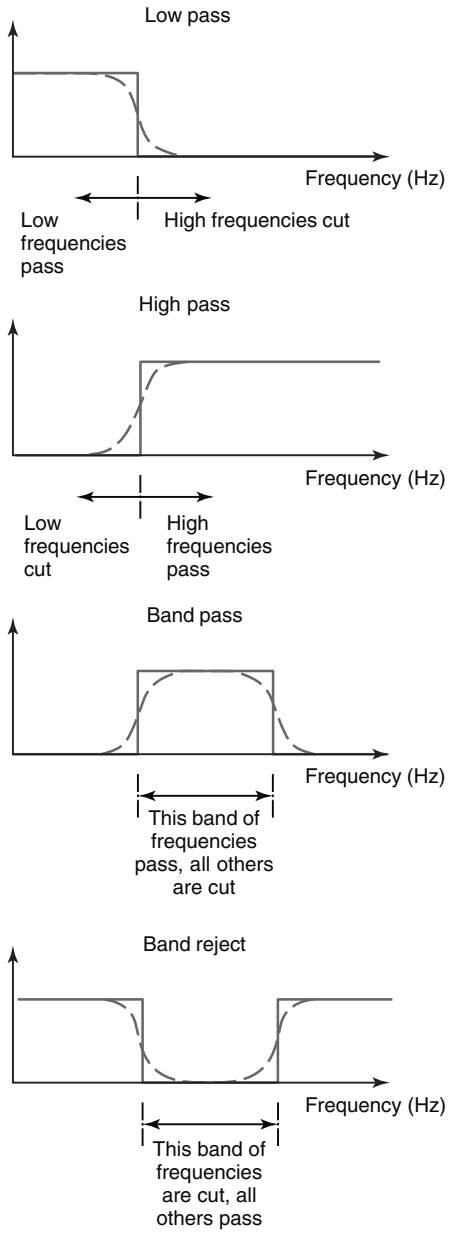

Figure 10. Standard block filters.

Frequency filtering offers a fine control on which frequencies are extracted from the data. A more generic approach to removing high-frequency noise and attenuating spikes is also offered by median smoothing, moving average, or the Loess smoothing approach.

Median smoothing involves taking a buffer of n data points and replacing the midpoint with the median value of the buffer. The buffer is then advanced by one point and the process is repeated. It is a simple and robust filter and is unlikely to be affected by spurious data points making it ideal for spike removal (Section 3.5). However, it does tend to excessively smooth over some sharp features in the data and can also give an irregular and "stepped" profile to the data. This can cause problems in subsequent analysis and is illustrated in Figure 11(a).

Moving average is similar to median smoothing except that the midpoint is now replaced with the mean or the weighted mean of n data points in a buffer. The weighted mean is often preferred as this

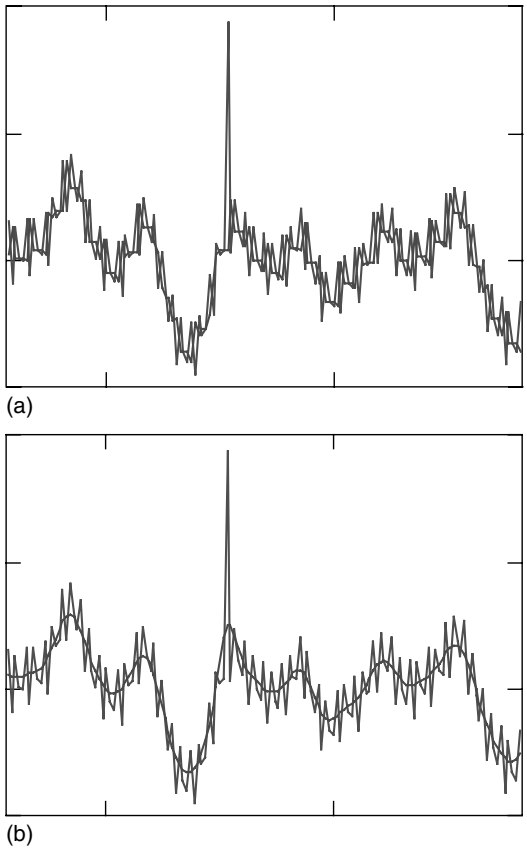

Figure 11. The effect of median smoothing and Gaussian-weighted moving averages. (a) Median smoothing on a sample of data containing high-frequency noise and spike. (b) Gaussian weighted moving average on a sample of data containing high-frequency noise and spike.

lends bias to the values in the immediate vicinity of the point. The most commonly used bias function, (also known as *kernel*), is the Gaussian distribution centered on the point of interest. This approach leads to a smooth data curve that effectively removes high-frequency noise as illustrated in Figure 11(b). It is very similar in application to a time-domain low-pass filter and, in most cases, the low-pass filter is preferred as it allows the engineer to select the noise-frequency delimitation.

Loess smoothing is based on fitting a polynomial regression curve through each local region of the data. By choosing a long period, we can successfully isolate low-frequency contributions such as mean drift. By selecting shorter intervals, we can offer an equivalent low-pass filter as illustrated in Figure 12.

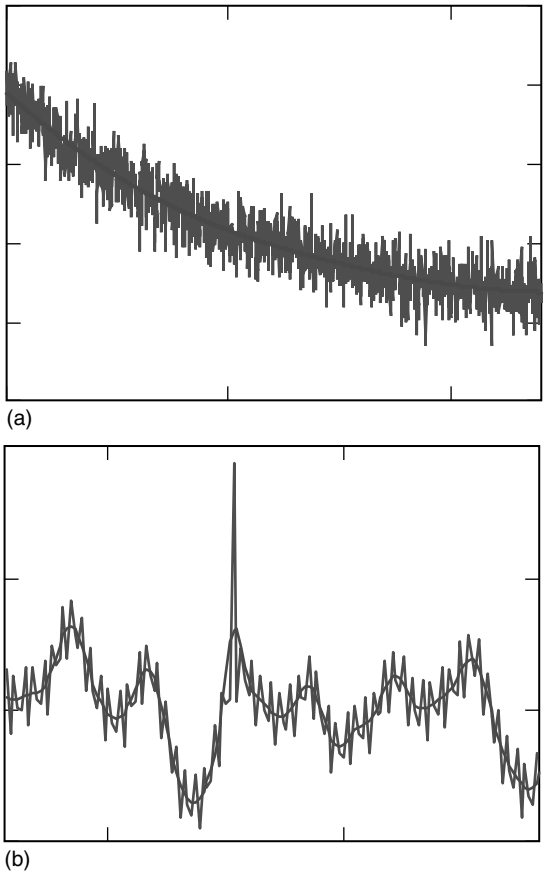

Figure 12. The effect of Loess smoothing for drift correction and high-frequency noise attenuation. (a) Loess smoothing over a long time period can be used to identify the mean drift component in a signal. (b) Loess smoothing over a short period can be used for removing high-frequency noise and attenuating spikes.

3.1.2 Frequency overlapping noise

If the frequency of the noise coincides with the underlying signal, then we cannot use the simple block filters discussed earlier. In this case, a wavelet-based approach is preferred. Using an orthogonal wavelet transform, like the Daubechies D10 wavelet, we can represent the measured time signal in the wavelet domain. We then perform the filtering operations and inverse transform back to the time domain.

There are two types of wavelet filtering known as *scale thresholding* and *magnitude thresholding*. Each wavelet scale pertains to a particular range of frequencies and scale thresholding involves setting all values in a particular scale to zero. This is directly analogous to frequency filtering. Magnitude thresholding involves looking through all the wavelet coefficients and setting those values below a given threshold to zero. This allows us to remove low-energy noise from the signal even though it coincides with the same frequency as the underlying good data. There are two approaches to magnitude thresholding called *hard* and *soft thresholding*. Hard thresholding simply sets the values below the threshold to zero and leaves the higher values untouched. Soft thresholding again sets the values below threshold to zero but also reduces the larger values by the threshold amount.

With both methods, it is important to establish a suitable threshold that extracts noise while leaving the good signal intact. Determining this threshold is usually done through trial and error by visually comparing the filtered signal. Another approach is to compare the mean square error between the filtered signal and the original. As the threshold increases, the mean square error also rises. As we approach the optimal threshold, we notice a pronounced increase in the mean square error. A more general approach is the use of the universal threshold. This offers a simple and convenient way of estimating a suitable threshold for most practical applications. The universal threshold is determined using equation (5). An excellent introduction to wavelet thresholding can be found in Addison [10], while Mallat [11] offers a thorough development of the subject (*see*

Wavelet Analysis).

$$\lambda_U = \sigma(2\ln(N))^{1/2} \tag{5}$$

where σ is the standard deviation of the noise.

3.2 Transducer resonance and mounting resonance error

Transducer resonance occurs when the frequency range of loading starts to excite the natural resonant frequencies of the transducer or the transducer mounting assembly. Resonance errors are minimized by ensuring that the resonant frequencies of the transducer or mounting assembly are at least three times greater than the maximum loading frequency.

It is seldom possible to correct a signal containing transducer resonance unless the resonant frequency and the damping ratio are known. In some cases, this can be determined with reference to the measured frequency response function (FRF). Where these are known, it is possible to construct a Fourier transform–based filter to reduce the amplitude of the resonance from the signal.

3.3 Analog conductor noise—inductive coupling, capacitive coupling, earth looping (ground looping), and cross talk

There are three types of noise associated with analog wiring: inductive coupling, capacitive coupling, and ground looping. An excellent account of these is presented by Bolton [12] and Putten [13].

Inductive coupling is caused by a changing current in a nearby circuit causing a magnetic field, which induces an electromotive force (emf) on the conductors in the analog wiring. This type of noise can be significantly reduced by using twisted pair cabling. The magnetic field induces an opposite emf in each loop, which negates the interference effect. Radio interference is also fairly common and can be significantly attenuated by using an Radio Frequency suppressor. Differential amplifiers can also be used to considerably reduce noise. This is where the required data is obtained by amplifying the difference between the two signals. If both signals contain the same interference, then the amplifier will not amplify any of the interference noise.

Earth looping (ground loop) is where multiple earth points occur and can be the cause of seemingly random drift as both earth points may be at a different potential. This source of error can be eliminated by ensuring only a single earth.

Capacitive coupling is caused by capacitance between the conductor and nearby power cables or earth. This type of noise can be reduced by adequate screening of signals using earthed enclosures and coaxial cabling. Although the screen should be earthed, this can give rise to earth loops, so care is required to ensure that cables are earthed at only one end.

Channel cross talk is where a signal transmitted in one channel has an undesirable effect on another. This can occur through poor screening. Cross-talk interference is a mixture of inductive and capacitive interference. In most cases, the cross-talk component will be low compared with the required signal and the wavelet-based denoising approach is sufficient to remove the noise component.

3.4 Low-frequency signal drift errors—mean drift and dc drift

Drift is the term used to describe a signal whose mean level is slowly changing over time as illustrated in Figure 13. Signal drift can occur for many reasons, such as the differential thermal expansion of a strain gauge with respect to the component it is measuring, or ground looping.

Drift is easily detectable by eye and also from trends in the ensemble mean. It is also often possible to detect drift using the skewness statistic and the shape of the amplitude probability distribution. Mean drift can be easily corrected through frequency filtering, regression analysis, or by using a wavelet-based approach.

Where the drift frequency is low compared with the frequency content of the measured signal, we can use a high-pass filter to remove the low-frequency drift component. Butterworth, Chebyshev, and Bessel filters are all suitable for software implementation. However, they become progressively less suitable as the drift frequency becomes very low (typically less than 1% of sample rate), or where there is a significant

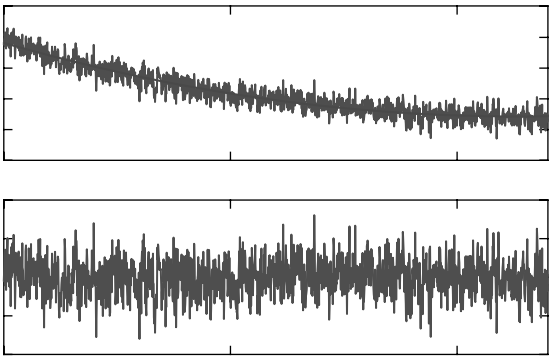

Figure 13. Illustration of mean drift. Measured strain data containing very low frequency drift due to differential thermal expansion of the strain gauge. Calculate polynomial regression line though data and subtract to two signals to recreate the corrected response.

low-frequency component in the real signal that makes it difficult to isolate the drift frequency from that of real data. Fourier-based filtering techniques should be avoided because the buffer must be larger than the drift period, which often makes them impractical.

For very low frequency drift, it is more appropriate to fit a statistical regression curve through the data and then extract the values from the original data as illustrated in Figure 13. The *Loess* smoothing technique is often most suitable in identifying the appropriate regression curve. Loess smoothing is based on fitting a polynomial regression curve through each local region of the data. By choosing a long period, we can successfully isolate low-frequency drift and then subtract this from the original measured signal.

Wavelet-scale thresholding can also be used to remove the low-frequency drift. Each wavelet scale pertains to a particular range of frequencies and scale thresholding involves setting all values in a particular scale to zero. This is directly analogous to frequency filtering. Wavelet filtering is based on the Fourier transform and will require a buffer that is longer than the period of the drift; this often renders the approach impractical.

3.5 Signal spikes

A spike is usually defined as a freak data point whose amplitude is significantly different from that of the immediate surrounding data. Spikes can originate from communication errors and capacitive and inductive noise in the analog signal path. Figure 14 illustrates three cases of spike.

- ***Extreme amplitude spikes***

In many cases, a spike will have an extreme amplitude, which approaches full scale. In this case, it is quite easy to detect and remove the spike. An amplitude threshold is established within which all data is determined as clean. Points exceeding this threshold are classified as spikes and are replaced with interpolated values based on the adjacent data points. The threshold values are easily determined using an amplitude PDF as shown in Figure 14(a). This clearly differentiates between the range of good data and the apparent spikes. The presence of high-amplitude spikes also affects the kurtosis and crest factor statistics of the data. It is, therefore, possible to monitor changes in the ensemble statistics to quickly locate areas of spikes and then process them using the spike cleansing routine described here. Extreme amplitude spikes are very similar to clipping but spikes are usually recognized as erroneous data, whereas clipping is real data.

- ***Extreme gradient spikes***

Some spikes do not have an extreme amplitude, which is distinguishable from the amplitude PDF used above. In these cases, the spike amplitude is still clearly different from that of the surrounding data; however, it is not outside the amplitude PDF of the real data. These are typical of erroneous communication packets where the erroneous data is often replaced with a zero value. This is the same phenomenon as dropout. In these cases, we can usually look at the instantaneous gradient of the data (derivative of the data). Spikes are usually classified by abnormal gradients and can be seen quite clearly from the gradient PDF as illustrated in Figure 14(b). A simple running calculation can be performed to calculate the gradient of each point and identify those exceeding the threshold. The spikes are then replaced with data based on interpolation of the clean data that surrounds them as before.

- ***Running standard deviation***

This method calculates the standard deviation over a short window of data and identifies a spike as the point that exceeds a specified multiple of the

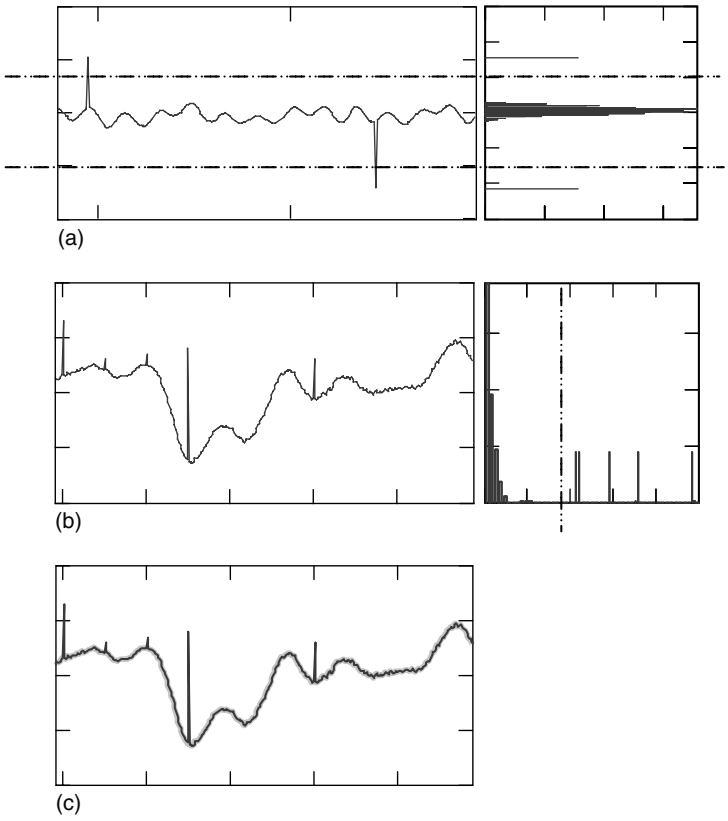

Figure 14. Illustration of spike-detection algorithms. (a) Extreme amplitude spikes: Amplitude of spikes significantly exceed amplitude of real data. Determine threshold amplitude using amplitude probability distribution. (b) Extreme gradient spikes: Gradient of spikes significantly exceed gradient of real data. Determine threshold gradient using probability distribution of gradient. (c) Running standard deviation: Calculated the running standard deviation. A spike is detected when a value passes through a specified multiple of this value.

standard deviation. The buffer is then advanced by one point and the standard deviation is recalculated. In this way, spikes can be identified on the basis of a combination of amplitude and gradient. The window varies in length and is often defined by a decaying function where neighboring points are most influential and more distant points are less influential. A Gaussian kernel function is often used in this application. A problem with this approach occurs when the signal remains at a constant value for some time: the standard deviation then tends to zero, so any departure from the constant would be falsely identified as a spike. A "gate" value is then applied, which represents the minimum amplitude change for the spike-detection algorithm. An analogous approach based on the *running crest factor* might also be used.

- ***Important note***

Data spikes are easily detectable provided that the data has not been filtered using a low-pass filter or a smoothing technique beforehand. Low-pass filtering not only attenuates the amplitude of the spike but also rescales the adjacent points and consequentially smooths the signal. The smoothed spike is undetectable using these algorithms and so it is important to remove spikes prior to using any low-pass filter. Although low-pass filtering and smoothing attenuate the spike amplitude, the amplitude can still incur significant errors in prognostic and diagnostic SHM algorithms, especially where damage is exponentially related to cycle amplitude. It is, therefore, preferable to remove the spike rather than simply smoothing it.

4 NOISE IN ROTATING MACHINERY

In this section, we look at specific techniques for removing noise and errors in signals recorded from rotating machinery. In particular, we consider

1. pulse-transducer errors—runt pulse and pulse spike
2. Gaussian noise in rotating machinery
3. order analysis of rotating machinery.

4.1 Pulse-transducer errors—runt pulse and pulse spike

Many pulse-train transducers such as Hall-effect and variable-reluctance transducers are used for rotational speed and position sensing. These transmit a digital pulse as a toothed gear approaches and then retreats from the transducer. The rotational speed can be determined by either measuring the number of pulses seen over a fixed period of time, or alternatively by measuring the time elapsed between two successive pulses. Where rotational position is also required, there are several methods of locating the reference point and these are discussed by Gyorki [7] and Hillier *et al.* [2]. A cost-effective and commonly used approach uses a missing tooth as the reference point. A typical system is illustrated in Figure 15. When rotational direction is also important, a second transducer can be placed out of phase with the first one. The phase difference between the two pulse trains then indicates direction of revolution. This is known as *quadrature position measurement.*

When rotation speed is measured by frequency, i.e., by counting the number of pulses that arrive in a specified period of time; errors in resolution are caused at low speed when only a few pulses arrive. For instance, a slowly rotating shaft gives an average pulse count of 4.5 pulses per period. This results in 4 pulses in the first period followed by 5 in the second, etc. This leads to low resolution at lower rotational speeds. The resolution problem is less problematic as the rotational speeds increase. We can improve resolution by increasing the size of the window; however, that means a longer time period and therefore a reduced time resolution. This is directly analogous to quantization error (Section 2.2).

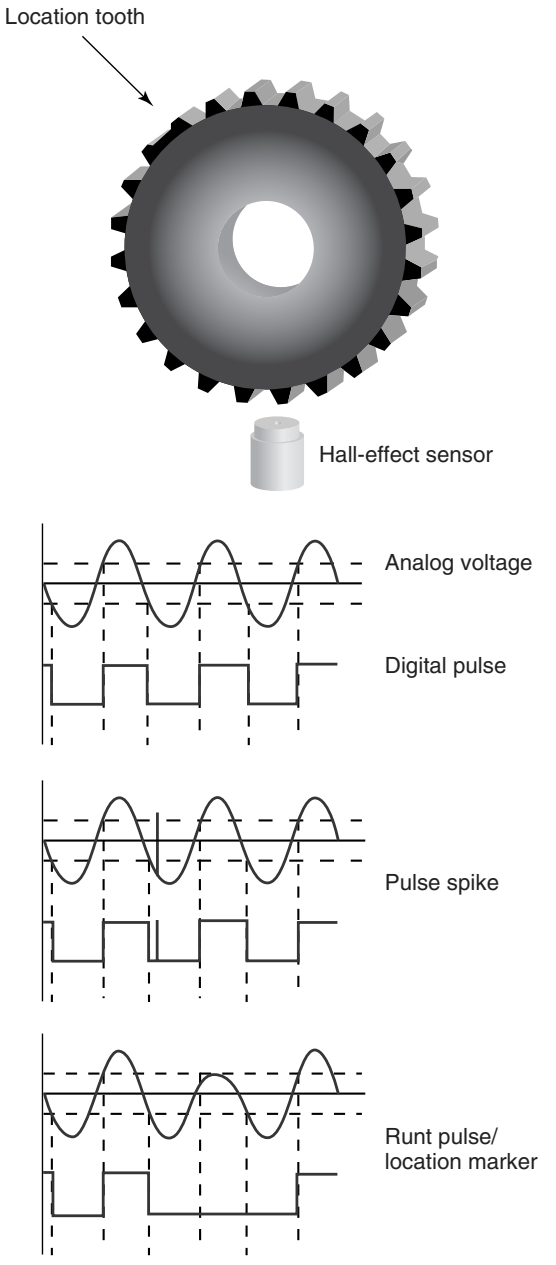

Figure 15. Illustration of pulse spike and runt pulse errors.

When rotation speed is measured by taking the time between successive pulses, a very accurate low-speed resolution is achievable; however, this is reduced as the rotation speed increases and the time between pulses is shorter. When the pulse rate approaches half

the clock rate, errors will start to increase. When the pulse rate exceeds half the clock rate, aliasing will occur Section 2.1.

A *runt pulse* is defined as a pulse that is too small to be detected by the transducer. This is fairly common in exposed sensors where debris can build up between the teeth and reduce the pulse definition. A *pulse spike* is the opposite problem where a false pulse is detected owing to electrical interference in the system or "contact bounce" in the signal.

Where speed is measured by counting the number of pulses passing over a specified period, runt pulses and spikes result in a slowly building inaccuracy that depends on the ratio of erroneous pulses to the average number of pulses counted. When speed is measured by counting the time elapsed between successive pulses, the errors result in large and immediate spikes in the observed speed. In this case, it is easy to identify and locate the erroneous pulse using the spike-detection methods described earlier (Section 3.5). This approach is hampered when rotational position is also coded using a missing tooth because this has the same effect as the runt pulse. It is, therefore, necessary to differentiate between the correct position reference and the runt pulse. If this error occurs, then the system will generally require maintenance.

4.2 Gaussian noise from rotating machinery—time synchronous averaging

Many signals measured from rotating machinery show strong correlation in the angle domain. For example, suppose we want to measure the cylinder pressure in a petrol engine; if we sample the cylinder pressure at a constant sample rate, we observe the pressure variations with respect to time along with a superimposed Gaussian noise. However, if we consider how the pressure varies over time at only one particular crank angle, say 10°, we see a much steadier variation of pressure. The Gaussian noise effectively introduces a symmetric random scatter to the steady underlying signal. We can, therefore, remove this noise by simply averaging the constant angle values. So, for any particular rotation angle, we can compute the running average of the measured values to remove the Gaussian noise component. This process is called *time synchronous averaging* (*TSA*).

TSA requires that we simultaneously measure the rotation angle of the machine as well as the actual signal required. We can then filter the measured signal as follows:

1. choose a set of desired rotation angles (e.g., 0, 1, 2,. . ., 359°);
2. interpolate the rotation angle signal to find the times at which the required angle is encountered;
3. interpolate the measured signal at the times derived above and extract the values;
4. perform a running average (or median smoothing) on the extracted values to establish the clean signal; and
5. increment the angle in step 1 and recalculate steps 2–4.

In many cases, the results in the angle domain from step 5 will be suitable for SHM analysis directly; however, if we need to reconstruct a constant sample rate time signal, then we would need to interpolate the filtered values between successive rotation angles over the constant sample rate. This stage is often computationally intensive and care is required to avoid aliasing errors introduced by resampling the data over a limited set of angles. Assuming that we want to obtain a new time signal with the same sample rate as the original time series, the minimum number of angle increments is determined from equation (6). We can then downsample the time signal by low-pass filtering and resampling if required.

$$\text{Number angle increments} > \frac{\text{Sample Rate}}{\text{Minimum rotational speed (rps)}} \tag{6}$$

4.3 Order analysis from rotating machinery—Vold–Kalman order tracking

When we review the measured data recorded off complex rotating machinery, we often observe dominant harmonics of the rotor frequency. For example, a four-cylinder, four-stroke engine "fires" twice with each rotation of the crank giving a dominant vibration at twice the engine speed. Similarly, the cam turns

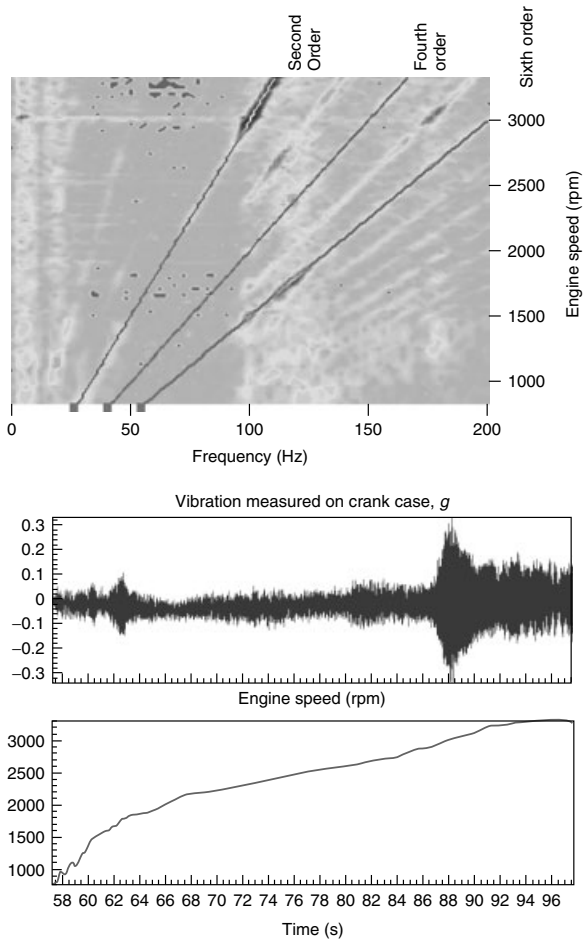

Figure 16. Rotational order analysis of a four-cylinder, four-stroke engine.

once for every two rotations of the crank and various pumps may rotate several times. It is often desirable for SHM analysis to look at trends in the harmonic response and this is called *order analysis*. The first order is the engine frequency, while the nth order is defined as $n\times$ engine speed, where the engine speed is usually expressed in hertz (or revolutions per second (rps)). The vibration response measured on a typical four-cylinder engine is illustrated in Figure 16.

In many cases, we are only interested in the signal pertaining to a particular order and ideally we should filter out the other frequencies to make any trend in the desired order more pronounced. In this case, we could use a band-pass filter but the filter frequency must continually change with respect to the engine speed. The Vold–Kalman order tracking filter is often used for this purpose. It is an adaptive band-pass filter in which the pass-band varies with respect to the engine speed and the order required.

5 CONCLUSION

This article has described how measurement errors and noise are introduced to SHM signals between the transducer and the SHM processor. The errors are classified in terms of system errors—including calibration and system configuration errors and signal noise interference along the signal path. It has described the physical cause of the errors and

identified how the symptoms can be identified within the signal, using basic signal-processing analysis. Wherever possible, algorithms are described, which can remove the erroneous artifacts and effectively denoise the signal. Many methods are discussed ranging from real-time cleansing of data spikes and frequency extraction to more complicated wavelet-based techniques.

Chapter 23
Statistical Time Series Methods for SHM

Spilios D. Fassois and John S. Sakellariou
Department of Mechanical and Aeronautical Engineering, University of Patras, Patras, Greece

Important Conventions

Bold-face upper/lower case symbols designate matrix/column—vector quantities, respectively.

Matrix transposition is indicated by the superscript T.

A functional argument in parentheses designates function of a real variable; for instance, $x(t)$ is a function of analog time $t \in \Re$.

A functional argument in brackets designates function of an integer variable; for instance, $x[t]$ is a function of normalized discrete time ($t = 1, 2, \ldots$). The conversion from discrete normalized time to analog time is based upon $(t-1)T_s$, with T_s designating the sampling period.

A functional argument including the imaginary unit j designates complex function; for instance, $X(j\omega)$ is a complex function of ω.

A hat designates estimator/estimate of the indicated quantity; for instance, $\widehat{\boldsymbol{\theta}}$ is an estimator/estimate of $\boldsymbol{\theta}$.

1 INTRODUCTION

Statistical time series methods for structural health monitoring utilize (i) random excitation and/or vibration response signals (time series), (ii) statistical model building, and (iii) statistical decision making for inferring the health state of a structure. This includes fault detection, identification (localization), and magnitude estimation, which may be collectively referred to as *fault diagnosis*. As with all vibration-based methods, the *fundamental principle*

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

upon which they are founded is that small changes (faults) in a structure cause discrepancies in its vibration response, which may be detected and associated with a specific cause (fault type and magnitude). See references [1–11] for overviews of general vibration-based methods; also see [12, 13]. Statistical time series methods are discussed in references such as [14–19]—see [20] for a recent overview.

Statistical time series methods for structural health monitoring use random excitation and/or response (displacement or velocity or acceleration) signals from the structure in its healthy state, as well as from a number of potential faulty states, identifying suitable (parametric or nonparametric) statistical time series models describing the structure in each state, and extracting a statistical quantity (*characteristic quantity*) characterizing the structural state in each case (*baseline phase*). When the structure is to be inspected for faults, the procedure is repeated under the current conditions, and the current characteristic quantity is obtained. Fault detection, identification, and estimation are then accomplished via statistical decision making consisting of "comparing", in a statistical sense, the current characteristic quantity with that of each potential state as determined in the baseline phase (*inspection phase*).

Statistical time series methods are fundamentally of the inverse type, as the models used are *data based* rather than physics based, and inherently account for uncertainty. In addition to the main features of general vibration-based methods (no need for visual inspection, "global" coverage of the structure, time and cost effectiveness, and automation capability), statistical time series methods offer further unique advantages such as (i) no need for physics-based or finite element models; (ii) no need for complete structural models—in fact, partial models and a limited number of excitation-response signals are often used; (iii) inherent accounting of (environmental, measurement, and so on) uncertainty; (iv) statistical decision making with specified performance characteristics; and (v) effective use of natural random vibration data records (no need to interrupt normal operation).

On the other hand, as complete structural models are not employed, time series methods may identify (locate) a fault only to the extent allowed by the type of model employed. Other limitations include the need for extensive "training" in the baseline phase (necessary for fault identification and estimation), adequate expertise on part of the user, potentially limited physical insight, and sensitivity expectedly lower than that of "local" nondestructive testing-type methods.

In this article, an overview of the main classes of statistical time series methods for structural health monitoring is presented. *Parametric* and *nonparametric* methods in either time or frequency domains are outlined for the *excitation–response* and *response-only* cases. The focus is on *periodic inspection*, although extensions to *continuous monitoring* are possible—a simple generalization may be based on the continuous repetition of the inspection phase with data corresponding to a moving time window. The focus is also on *time-invariant* (stationary) *linear* structures in *Gaussian* environments, although certain versions of the methods are available for alternative cases and pertinent references are provided in the bibliographical remarks. For simplicity of presentation, the *scalar* vibration response signal case is treated.

2 THE WORKFRAME

Let $\mathcal{S}_o$ designate the structure under consideration in its *nominal* (healthy) state, $\mathcal{S}_A$, $\mathcal{S}_B$, ... the structure under fault of *type (mode)* A, B, ..., and so on, and $\mathcal{S}_u$ the structure in an unknown (to be determined) state. Each fault type includes a continuum of faults, which are characterized by common nature or location but distinct magnitudes (for instance, damage of various magnitudes in a specific structural element). The structure under a fault of type, say V, and magnitude k is designated as $\mathcal{S}_V^k$, while the fault itself is designated as F_V^k.

Statistical time series methods are based on discretized excitation $x[t]$ and/or response $y[t]$ (for $t = 1, 2, \ldots, N$) random vibration data records. Note that t refers to discrete time, with the corresponding actual time instant being $(t-1)T_s$, where T_s stands for the sampling period. Let the complete excitation and response signals be represented as X and Y, respectively, or collectively as Z, that is, $Z = (X, Y)$. Like before, a subscript (o, A, B, ..., u) is used for designating the corresponding state of the structure that provided the signals.

Note that all collected signals need to be suitably preprocessed [3, 21, 22]. This may include low- or band-pass filtering within the frequency range

Table 1. Workframe setup: structural state, vibration signals used, and the estimated characteristic quantity (baseline and inspection phases)

Structural state	Vibration signals	Estimated characteristic quantity
	Baseline phase	
S_o (healthy structure)	$z_o[t] = (x_o[t], y_o[t])\ t = 1, 2, \ldots, N \quad Z_o = (X_o, Y_o)$	$\widehat{Q}_o$
S_A (fault A)[(a)]	$z_A[t] = (x_A[t], y_A[t])\ t = 1, 2, \ldots, N \quad Z_A = (X_A, Y_A)$	$\widehat{Q}_A$
S_B (fault B)[(a)]	$z_B[t] = (x_B[t], y_B[t])\ t = 1, 2, \ldots, N \quad Z_B = (X_B, Y_B)$	$\widehat{Q}_B$
$\vdots$	$\vdots$	$\vdots$
	Inspection phase	
S_u (current structure) (unknown state)	$z_u[t] = (x_u[t], y_u[t])\ t = 1, 2, \ldots, N \quad Z_u = (X_u, Y_u)$	$\widehat{Q}_u$

[(a)] Normally various fault magnitudes are considered.

of interest, signal subsampling (in case the originally used sampling frequency is too high), estimated mean subtraction, as well as proper scaling. The latter is not only used for numerical reasons but also for counteracting—to the extent possible—different operating (including excitation levels) and/or environmental conditions. In the case of linear time-invariant structures, the estimated mean for each signal is typically subtracted, and the signal is scaled (being divided) by its estimated standard deviation. In case of multiple excitations, care should be exercised in order to ensure minimal cross-correlation among them.

The obtained data are subsequently analyzed by parametric or nonparametric time series methods and appropriate models are identified and validated [23–26]. Such models are identified on the basis of data Z_o, Z_A, Z_B, ... in the *baseline* or *training phase* (normally data sets corresponding to various fault magnitudes per fault type are used), and based on data Z_u in the *inspection phase*. From each estimated model, the corresponding estimate of a characteristic quantity Q is extracted ($\widehat{Q}_o$, $\widehat{Q}_A$, $\widehat{Q}_B$, ... in the baseline phase; $\widehat{Q}_u$ in the inspection phase—see Table 1).

Fault detection is then based on proper comparison of the true (but not precisely known) Q_u to the true (but also not precisely known) Q_o via a binary composite statistical hypothesis test that uses the corresponding estimates—see Table 2 in which $\sim$ indicates a proper relationship (such as equality, inequality, and so on). *Fault identification* is similarly based on the proper comparison of Q_u to each of Q_A, Q_B, ... via a multiple statistical hypothesis test that also uses the corresponding estimates, and *fault estimation* is based on interval estimation techniques (Table 2). The workframe of a general statistical time series method is illustrated in Figure 1.

Note that the design of a binary statistical hypothesis test is generally based on the probabilities of *type I* and *type II* error, or else the *false alarm* (α) and *missed fault* (β) probabilities. The designs presented herein are based on the false alarm probability. In selecting α it should be born in mind that as α decreases (increases) β increases (decreases). The

reader is referred to references such as [27, subsection 4.2]; [28, subsection 3.3] for details on statistical hypothesis testing.

Statistical time series methods may be classified as *parametric* or *nonparametric*, depending upon whether the characteristic quantity Q is based on a parametric or nonparametric statistical model; see Section 3. Section 4 discusses model identification. Nonparametric methods tend to be simpler and computationally more efficient—they are treated in Section 5. Parametric methods may offer superior performance—they are treated in Section 6. Statistical time series methods may be also classified as *excitation–response*, where both excitation and response signals are used, or *response-only*, where only response signals are used. Both types are treated in the present article. The application of the methods for fault detection, identification, and magnitude estimation on a laboratory structure is illustrated in Section 7.

3 STATISTICAL TIME SERIES MODELS

Time series models for linear time–invariant (stationary) structures operating in a Gaussian environment are briefly reviewed in this section. Reference to models applicable to alternative cases are provided within the bibliographical remarks made within the presentation of the methods (Sections 5 and 6).

Let $h[t]$ designate the time-discretized impulse response function describing the causality relationship between an excitation and a response location on a linear time-invariant structure (Figure 2). Also let $n[t]$ designate a stationary Gaussian noise corrupting the response signal. The noise is generally assumed to be zero mean but of unknown autocovariance (or auto power spectral density) and mutually uncorrelated with the excitation $x[t]$. The convolution summation plus noise expression relating these signals is

$$y[t] = h[t] \star x[t] + n[t] = \sum_{\tau=0}^{\infty} h[\tau] \cdot x[t-\tau] + n[t] \tag{1}$$

with $\star$ designating discrete convolution. Alternatively, using the backshift operator $\mathcal{B}$ ($\mathcal{B}^i \cdot y[t] =$

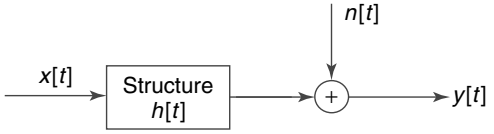

Figure 2. Time-domain representation of a linear time-invariant structure with additive response noise.

$y[t-i]$):

$$y[t] = H(\mathcal{B}) \cdot x[t] + n[t] \tag{2}$$

$$H(\mathcal{B}) = \sum_{\tau=0}^{\infty} h[\tau] \cdot \mathcal{B}^{\tau} \tag{3}$$

with $H(\mathcal{B})$ designating the discrete-time structural transfer function.

3.1 Nonparametric models

Assuming $x[t]$ to be a random stationary excitation, $y[t]$ will also be stationary in the steady state. In addition, $y[t]$ will be Gaussian if $x[t]$ and $n[t]$ are jointly Gaussian. Then each signal is fully characterized by its first two moments, *mean* and *autocovariance function (acf)*—or its normalized version, or its Fourier transform referred to as the *auto power spectral density (psd)* [24, p. 3], [25, pp. 39–40], as shown in Table 3. Note that $E\{\cdot\}$ designates statistical expectation, j the imaginary unit, τ time lag, $\omega \in [0, 2\pi/T_s]$ frequency in rad/s, and T_s the sampling period.

In the excitation–response case, a complete joint description of the excitation and response signals is given in terms of the means and the acfs/cross covariance function (ccf)—or their normalized versions, or the auto psds and the cross spectral density (csd), as indicated in Table 4.

Note that the characteristics of the response are related to those of the excitation and the noise through the expressions [25, pp. 455–456]:

$$\mu_y = H(j\omega)|_{\omega=0} \cdot \mu_x \tag{4}$$

$$\gamma_{yx}[\tau] = \gamma_{xx}[\tau] \star h[\tau]$$

$$\gamma_{yy}[\tau] = \gamma_{yx}[\tau] \star h[-\tau] + \gamma_{nn}[\tau] \tag{5}$$

$$\left.\begin{aligned} S_{yx}(j\omega) &= H(j\omega) \cdot S_{xx}(\omega) \\ S_{yy}(\omega) &= H^{\star}(j\omega) \cdot S_{yx}(j\omega) + S_{nn}(\omega) \end{aligned}\right\} \Longrightarrow$$

$$S_{yy}(\omega) = |H(j\omega)|^2 \cdot S_{xx}(\omega) + S_{nn}(\omega) \tag{6}$$

$$\text{Coherence: } \gamma^2(\omega) = \frac{|S_{yx}(j\omega)|^2}{S_{xx}(\omega) \cdot S_{yy}(\omega)} = \frac{1}{1 + \dfrac{S_{nn}(\omega)}{|H(j\omega)|^2 \cdot S_{xx}(\omega)}} \quad \in [0, 1] \tag{7}$$

where $\star$ designates discrete convolution, the superscript * complex conjugation, $|\cdot|$ complex magnitude, $H(j\omega) = H(B)|_{B=e^{-j\omega T_s}}$ is the corresponding structural frequency response function (frf), $S_{nn}(\omega)$ the noise auto psd, and the last expression defines the (squared) coherence function [29, p. 196].

3.2 Parametric models

Parametric models may be obtained via proper parametrizations of equation (1). In the response-only case it is assumed, without loss of generality,

Table 3. Nonparametric response-only models

Mean	$\mu_y = E\{y[t]\}$	Autocovariance function (acf): $\gamma_{yy}[\tau] = E\{\tilde{y}[t] \cdot \tilde{y}[t-\tau]\}$ or normalized acf: $\rho_{yy}[\tau] = \gamma_{yy}[\tau]/\gamma_{yy}[0] \in [-1, 1]$ or auto psd: $S_{yy}(\omega) = \sum_{\tau=-\infty}^{\infty} \gamma_{yy}[\tau] \cdot e^{-j\omega\tau T_s}$

$\tilde{y}[t] = y[t] - \mu_y$.

Table 4. Nonparametric excitation–response models

Means	μ_x	μ_y

	$\rho_{xx}[\tau]$	$\rho_{yy}[\tau]$	$\rho_{yx}[\tau] = \gamma_{yx}[\tau]/\sqrt{\gamma_{xx}[0] \cdot \gamma_{yy}[0]} \in [-1, 1]$
auto psd and csd	$S_{xx}(\omega)$	$S_{yy}(\omega)$	$S_{yx}(j\omega) = \sum_{\tau=-\infty}^{\infty} \gamma_{yx}[\tau] \cdot e^{-j\omega\tau T_s}$

$\tilde{x}[t] = x[t] - \mu_x$, $\tilde{y}[t] = y[t] - \mu_y$.

Table 5. Parametric response-only models

ARMA model	$y[t] + \sum_{i=1}^{na} a_i \cdot y[t-i] = w[t] + \sum_{i=1}^{nc} c_i \cdot w[t-i]$	$A(\mathcal{B}) = 1 + \sum_{i=1}^{na} a_i \mathcal{B}^i$
	$\Longleftrightarrow A(\mathcal{B}) \cdot y[t] = C(\mathcal{B}) \cdot w[t]$	$C(\mathcal{B}) = 1 + \sum_{i=1}^{nc} c_i \mathcal{B}^i$
	$w[t] \sim$ i.i.d. $\mathcal{N}(0, \sigma_w^2)$	na, nc : AR, MA orders
State space (SS) model	$\boldsymbol{\psi}[t+1] = \boldsymbol{A} \cdot \boldsymbol{\psi}[t] + \boldsymbol{v}[t]$	$\boldsymbol{\psi}[t]$: state vector
	$y[t] = \boldsymbol{C} \cdot \boldsymbol{\psi}[t]$	$\boldsymbol{v}[t] \sim$ i.i.d. $\mathcal{N}(\boldsymbol{0}, \boldsymbol{\Sigma}_v)$ $\boldsymbol{A}$: system matrix $\boldsymbol{C}$: output matrix

that the excitation is white (uncorrelated, that is, $\gamma_{xx}[\tau] = 0$ for $\tau \neq 0$, in which case the signal is often designated as $w[t]$) and $n[t] \equiv 0$. The signals are assumed zero mean; to comply with this requirement, the signal $\tilde{y}[t] = y[t] - \mu_y$ is typically used (also see the related comment on signal preprocessing in Section 2). This leads to the autoregressive moving average (ARMA) model [25, pp. 52–53], which may be alternatively set into state-space form [25, pp. 163–164]; [30, p. 157] consisting of a set of first-order state equations plus an output equation (Table 5). Note that in the ARMA expression, a_i and c_i are the autoregressive (AR) and moving average (MA) parameters, respectively, while $w[t]$ coincides with the model-based *one-step-ahead prediction error*, and is also referred to as the *model residual* or *innovations* [25, p. 134], [26, p. 70]. i.i.d. stands for identically independently distributed, and $\mathcal{N}(\cdot, \cdot)$ designates normal distribution with the indicated mean and variance/covariance.

In the excitation–response case, various parametrizations of equation (1) lead to a number of models, including the autoregressive with exogenous excitation (ARX) and autoregressive moving average with exogenous excitation (ARMAX) models [22], [26, pp. 81–83]; [30, p. 149–151], the Box–Jenkins model [22], [26, p. 87]; [30, p. 152], the output error (OE) model [26, pp. 85–86]; [22] which represents the structural dynamics by a rational transfer function but leaves the noise unmodeled, and the state-space model consisting of a set of first-order state equations plus an output equation (see [26, pp. 97–101] for additional versions). These are shown in Table 6. Like before, the signals are assumed zero mean; to comply with this, the signals $\tilde{x}[t] = x[t] - \mu_x$ and $\tilde{y}[t] = y[t] - \mu_y$ are typically used (also see the related comment on signal preprocessing in Section 2). $w[t]$ coincides with the model-based *one-step-ahead prediction error* and is, in this case as well, referred to as *residual* or *innovations*.

4 IDENTIFICATION OF TIME SERIES MODELS

The term identification refers to the estimation of statistical time series models based on (properly preprocessed) excitation $x[t]$ and/or response $y[t]$ (for $t = 1, 2, \ldots, N$) random vibration data records, collectively designated as $Z = (X, Y)$. This is done via *estimators*, which operate on the data records to provide *estimates* of the quantities of interest. Let $\widehat{Q}$ designate the estimator of a quantity Q. The estimator is a function of the data Z, $\widehat{Q} = g(Z)$. Considering each data point as the observed value of an underlying random variable, the estimator is a function of the data random variables, and therefore a random variable by itself.

As such, the estimator $\widehat{Q}$ is characterized by a probability density function $f_{\widehat{Q}}$, and by (at least) its first- and second-order moments $\mu_{\widehat{Q}} = E[\widehat{Q}]$, $\text{var}[\widehat{Q}] = E[(\widehat{Q} - \mu_{\widehat{Q}})^2]$. If the distribution is Gaussian, one writes $\widehat{Q} \sim \mathcal{N}(\mu_{\widehat{Q}}, \text{var}[\widehat{Q}])$. An estimator is called *unbiased* if its mean coincides with the true value of the quantity under estimation, that is, $\mu_{\widehat{Q}} = E[\widehat{Q}] = Q$. Oftentimes, the determination of the probability density function for an estimator is done asymptotically, as the data record length (in samples) tends to infinity ($N \to \infty$).

Table 6. Parametric excitation–response models

ARX model	$A(\mathcal{B}) \cdot y[t] = B(\mathcal{B}) \cdot x[t] + w[t]$	na, nb: AR, X orders $A(\mathcal{B}) = 1 + \sum_{i=1}^{na} a_i \mathcal{B}^i$ $B(\mathcal{B}) = b_0 + \sum_{i=1}^{nb} b_i \mathcal{B}^i$
ARMAX model	$A(\mathcal{B}) \cdot y[t] = B(\mathcal{B}) \cdot x[t] + C(\mathcal{B}) \cdot w[t]$	na, nb, nc: AR, X, MA orders $C(\mathcal{B}) = 1 + \sum_{i=1}^{nc} c_i \mathcal{B}^i$
Box–Jenkins model	$y[t] = \frac{B(\mathcal{B})}{A(\mathcal{B})} \cdot x[t] + \frac{C(\mathcal{B})}{D(\mathcal{B})} \cdot w[t]$	$D(\mathcal{B}) = 1 + \sum_{i=1}^{nd} d_i \mathcal{B}^i$
Output error (OE) model	$y[t] = \frac{B(\mathcal{B})}{A(\mathcal{B})} \cdot x[t] + n[t]$	$n[t]$: autocorrelated zero mean
State space (SS) model	$\boldsymbol{\psi}[t+1] = \boldsymbol{A} \cdot \boldsymbol{\psi}[t] + \boldsymbol{B} \cdot x[t] + \boldsymbol{v}[t]$ $y[t] = \boldsymbol{C} \cdot \boldsymbol{\psi}[t] + \boldsymbol{D} \cdot x[t]$	$\boldsymbol{\psi}[t]$: state vector $\boldsymbol{v}[t] \sim$ i.i.d. $\mathcal{N}(\mathbf{0}, \boldsymbol{\Sigma}_v)$ $\boldsymbol{A}$: system matrix, $\boldsymbol{B}$: input matrix $\boldsymbol{C}$: output matrix, $\boldsymbol{D}$: dir. transm. matrix

$w[t] \sim$ i.i.d. $\mathcal{N}(0, \sigma_w^2)$.

Some of the estimators for nonparametric time series models, along with certain of their properties, are summarized in Table 7.

The estimation of parametric time series models involves parameter and structure estimation. The parameter vector $\boldsymbol{\theta}$ of a selected model (for example, $\boldsymbol{\theta} = [\text{coef}A, \text{coef}B, \text{coef}C]$ for an ARMAX model—coef designating the coefficients of the indicated polynomial) is estimated on the basis of an appropriate estimation method. Typical methods include prediction error (PE) and least square (LS), maximum likelihood (ML), correlation, and subspace methods [22], [26, Chapter 7]; [30, Chapters 7–8].

Model structure estimation (referring, for instance, to the determination of the AR, X, and MA orders for an ARMAX model) is more complicated, and is typically achieved by fitting increasingly higher order models to the data until no further improvement—in a proper sense—is observed. Improvement may be judged via order-selection criteria, such as the Akaike information criterion (AIC) or the Bayesian information criterion (BIC), but additional practical criteria, such as modal frequency stabilization diagrams, are useful [22], [26, pp. 505–507], [30, pp. 442–443].

5 NONPARAMETRIC TIME SERIES METHODS

Nonparametric time series methods are those in which the characteristic quantity Q is constructed on the basis of nonparametric time series models. Three such methods that operate in the frequency domain are presented. For alternative methods that employ a novelty measure, see [32–34].

5.1 Power spectral density (psd)-based method

This method's characteristic quantity is the auto psd of the vibration response signal, $Q = S_{yy}(\omega) = S(\omega)$; hence it is appropriate for the response-only case. The main idea is on the comparison of the current structure's response psd $S_{\text{u}}(\omega)$ to that of the healthy structure's, $S_{\text{o}}(\omega)$—or, in fact, to that corresponding to any other structural condition. It should be noted that response signal scaling is important in order to properly account for potentially different excitation levels.

Table 7. Estimation of nonparametric time series characteristics

Quantity	Estimator	Properties	Comments/references
Mean	$\widehat{\mu}_y = \frac{1}{N}\sum_t y[t]$	$\widehat{\mu}_y \sim \mathcal{N}\left(\mu_y, \frac{\sigma_y^2}{N^2}\sum_{\tau=1}^{N}\sum_{s=1}^{N}\rho_{yy}[s-\tau]\right)$	[23, p. 319]; [31, p. 213]
Normalized acf	$\widehat{\rho}_{yy}[\tau] = \widehat{\gamma}_{yy}[\tau]/\widehat{\gamma}_{yy}[0]$	$\widehat{\rho}_{yy}[\tau] \sim \mathcal{N}\big(\rho_{yy}[\tau],\ \mathrm{var}\big[\widehat{\rho}_{yy}[\tau]\big]\big)$	For $N \to \infty$
	$\widehat{y}[t] = y[t] - \widehat{\mu}_y$	$\mathrm{var}\big[\widehat{\rho}_{yy}[\tau]\big] \approx \frac{1}{N}\left[1 + 2\sum_{i=1}^{q}\rho_{yy}^2[i]\right]$	$\rho_{yy}[\tau] = 0$ for $\tau > q$
	$\widehat{\gamma}_{yy}[\tau] = \frac{1}{N}\sum_t \widehat{y}[t]\widehat{y}[t-\tau]$		[25, pp. 30–34]; [31, pp. 214–215]
Normalized ccf	$\widehat{\rho}_{yx}[\tau] = \widehat{\gamma}_{yx}[\tau]/\sqrt{\widehat{\gamma}_{xx}[0]\widehat{\gamma}_{yy}[0]}$	$E\{\widehat{\rho}_{yx}[\tau]\} = \rho_{yx}[\tau]$	For $N \to \infty$ [31, p. 398]
	$\widehat{\gamma}_{yx}[\tau] = \frac{1}{N}\sum_t \widehat{y}[t]\widehat{x}[t-\tau]$	$\mathrm{var}\big[\widehat{\rho}_{yx}[\tau]\big]$: see [25, pp. 411–415]	[25, pp. 411–415]; [23, p. 693]
Power spectral density (psd)	$\widehat{S}_{yy}(\omega) = \frac{1}{K}\sum_{i=1}^{K}\widehat{Y}_L^i(j\omega)\widehat{Y}_L^i(-j\omega)$	$\frac{2K\widehat{S}_{yy}(\omega)}{S_{yy}(\omega)} \sim \chi^2(2K)$	Welch method (no overlap) [24, p. 76]
	$\widehat{Y}_L^i(j\omega) = \frac{1}{\sqrt{L}}\sum_{t=1}^{L} a[t]\widehat{y}^i[t]\ \mathrm{e}^{-j\omega t T_s}$		K: number of data segments
	$\widehat{y}^i[t] = y^i[t] - \widehat{\mu}_y$		$a[t]$: time window
	(ith segment of length L)		[31, pp. 352–353]; [29, p. 309]
Cross spectral density (csd)	$\widehat{S}_{yx}(j\omega) = \frac{1}{K}\sum_{i=1}^{K}\widehat{Y}_L^i(j\omega)\widehat{X}_L^i(-j\omega)$	$E\{\lvert\widehat{S}_{yx}(j\omega)\rvert\} \approx \lvert S_{yx}(j\omega)\rvert$	Welch method (no overlap)
		$\mathrm{var}[\lvert\widehat{S}_{yx}(j\omega)\rvert] \approx \frac{\lvert S_{yx}(j\omega)\rvert^2}{\gamma^2(\omega)K}$	For $N \to \infty$, $a[t]=1$
	$\widehat{x}^i[t] = x^i[t] - \widehat{\mu}_x$	$E\{\arg\widehat{S}_{yx}(j\omega)\} \approx \arg S_{yx}(j\omega)$	$\gamma^2(\omega) \to 1$ or $K \to \infty$
	(ith segment of length L)	$\mathrm{var}[\arg\widehat{S}_{yx}(j\omega)] \approx \frac{1-\gamma^2(\omega)}{\gamma^2(\omega)2K}$	[29, pp. 318, 320, 325–326]
Frequency response function (frf)	$\widehat{H}(j\omega) = \widehat{S}_{yx}(j\omega)/\widehat{S}_{xx}(\omega)$	$E\{\lvert\widehat{H}(j\omega)\rvert\} \approx \lvert H(j\omega)\rvert$	Welch method (no overlap)
		$\mathrm{var}[\lvert\widehat{H}(j\omega)\rvert] \approx \frac{1-\gamma^2(\omega)}{\gamma^2(\omega)2K}\lvert H(j\omega)\rvert^2$	For $N \to \infty$, $a[t]=1$
			$\gamma^2(\omega) \to 1$ or $K \to \infty$ [29, pp. 329, 338]
(Squared) Coherence	$\widehat{\gamma}^2(\omega) = \lvert\widehat{S}_{yx}(j\omega)\rvert^2/\widehat{S}_{xx}(\omega)\widehat{S}_{yy}(\omega)$	$E\{\widehat{\gamma}^2(\omega)\} \approx \gamma^2(\omega) + \frac{1}{K}[1-\gamma^2(\omega)]^2$	Welch method (no overlap)
		$\mathrm{var}[\widehat{\gamma}^2(\omega)] \approx \frac{2\gamma^2(\omega)}{K}[1-\gamma^2(\omega)]^2$	For $N \to \infty$, $a[t] = 1$, $K \to \infty$ [29, pp. 333–335]

[(a)] $\widehat{x}[t]$, $\widehat{y}[t]$: sample versions of $\tilde{x}[t]$, $\tilde{y}[t]$.
[(b)] arg designates argument (angle) of the indicated complex quantity.
[(c)] $\omega \in [0, 2\pi/T_s]$ stands for frequency in radian per second. j stands for the imaginary unit. K stands for the number of segments used in Welch spectral estimation.
[(d)] The frequency-domain estimator distributions may be approximated as Gaussian for small relative errors (that is, $\gamma^2(\omega) \to 1$ or $K \to \infty$) [29, pp. 274–275].

The following hypothesis testing problem is then formulated for fault detection:

$$H_0: S_u(\omega) = S_o(\omega)$$
(null hypothesis—healthy structure)
$$H_1: S_u(\omega) \neq S_o(\omega)$$
(alternative hypothesis—faulty structure) (8)

As the true psd's, $S_u(\omega)$, $S_o(\omega)$, are unknown, their estimates $\widehat{S}_u(\omega)$, $\widehat{S}_o(\omega)$ obtained via the Welch method (with K nonoverlapping segments; refer to Table 7) are used. Then the quantity F, given in the subsequent text, follows F distribution with $(2K, 2K)$ degrees of freedom (as each of the numerator and denominator follow normalized χ^2 distribution with $2K$ degrees of freedom; refer to Table 7 and the Appendix):

$$F = \frac{\widehat{S}_o(\omega)/S_o(\omega)}{\widehat{S}_u(\omega)/S_u(\omega)} \sim F(2K, 2K) \tag{9}$$

Under the null (H_0) hypothesis the true psd's coincide, $S_u(\omega) = S_o(\omega)$, and therefore F equals $\widehat{S}_o(\omega)/\widehat{S}_u(\omega)$. This should be then in the range $[f_{\alpha/2}, f_{1-\alpha/2}]$ with probability $1-\alpha$, and decision making is as follows at the α risk level (type I error probability of α):

$$f_{\frac{\alpha}{2}}(2K, 2K) \leq F \leq f_{1-\frac{\alpha}{2}}(2K, 2K) \quad (\forall\omega)$$
$$\Longrightarrow H_0 \text{ is accepted (healthy structure)}$$
$$\text{Else} \Longrightarrow H_1 \text{ is accepted (faulty structure)} \tag{10}$$

with $f_{(\alpha/2)}$, $f_{1-(\alpha/2)}$ designating the F distribution's $\alpha/2$ and $1-(\alpha/2)$ critical points (f_α is defined such that $\text{Prob}(F \leq f_\alpha) = \alpha$; Figure 3).

Note that fault identification may be similarly achieved, while fault estimation may be achieved by possibly associating specific quantitative changes in the psd with specific fault magnitudes.

Bibliographical remarks. See [35] for the application of the method to fault detection in a railway vehicle suspension. In the nonstationary or nonlinear cases, time–frequency, polyspectra, or wavelet-based models may be used [36–42].

5.2 Frequency response function (frf)—based method

This method is similar to the psd method, the difference being in that the excitation–response frf magnitude is used as the characteristic quantity, $Q = |H(j\omega)|$. It is thus appropriate for the excitation–response case, although it may also be used in case the excitation is unavailable but more than one responses are available [43]. The main idea is on the comparison of the frf magnitude $|H_u(j\omega)|$ of the current structure to that of the healthy structure $|H_o(j\omega)|$—or, in fact, to that corresponding to any other structural condition.

The following hypothesis testing problem is then formulated for fault detection:

$$H_0: \delta|H(j\omega)| = |H_o(j\omega)| - |H_u(j\omega)| = 0$$
(null hypothesis–healthy structure)
$$H_1: \delta|H(j\omega)| = |H_o(j\omega)| - |H_u(j\omega)| \neq 0$$
(alternative hypothesis–faulty structure) (11)

As the true frf's, $H_u(j\omega)$ and $H_o(j\omega)$, are unknown, their respective estimates $\widehat{H}_u(j\omega)$ and $\widehat{H}_o(j\omega)$ obtained as indicated in Table 7 are used.

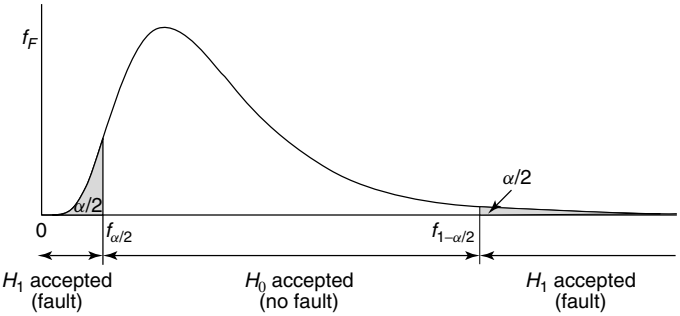

Figure 3. Statistical hypothesis testing based on an F distributed statistic (two-tailed test).

The frf magnitude estimator may, asymptotically ($N \to \infty$), be considered as approximately following Gaussian distribution (refer to Table 7). Owing to the mutual independence of the Z_u and Z_o data records, the two frf magnitude estimators are mutually independent, and thus their difference is Gaussian with mean equal to the true magnitude difference, $|H_o(j\omega)| - |H_u(j\omega)|$, and variance equal to the sum of the two variances.

Under the null (H_0) hypothesis, the true frf magnitudes coincide ($|H_u(j\omega)| = |H_o(j\omega)|$), hence

$$\text{Under } H_0\text{: } \delta|\widehat{H}(j\omega)| = |\widehat{H}_o(j\omega)| - |\widehat{H}_u(j\omega)| \sim \mathcal{N}(0, 2\sigma_o^2(\omega)) \qquad (12)$$

The variance $\sigma_o^2(\omega) = \text{var}[|\widehat{H}_o(j\omega)|]$ is generally unknown, but may be estimated in the baseline phase via the expressions of Table 7. Treating this estimator as a fixed quantity, that is a quantity characterized by negligible variability (which is reasonable for estimation based on long data records), the equality of the two frf magnitudes may be examined at the α (type I) risk level through the statistical test (Figure 4):

$$Z = |\delta|\widehat{H}(j\omega)||/\sqrt{2\widehat{\sigma}_o^2(\omega)} \le Z_{1-\frac{\alpha}{2}} \quad (\forall\omega)$$
$$\Longrightarrow H_0 \text{ is accepted (healthy structure)}$$
$$\text{Else} \Longrightarrow H_1 \text{ is accepted (faulty structure)} \qquad (13)$$

with $Z_{1-(\alpha/2)}$ designating the standard normal distribution's $1 - (\alpha/2)$ critical point. Alternatively, treating $\widehat{\sigma}_o^2(\omega)$ as a random variable leads to a *t*-distribution-based test—this approaches the above normal test for long data records (see Appendix).

Note that fault identification may be similarly achieved, while fault estimation may be achieved by possibly associating specific quantitative changes in the frf magnitude with specific fault magnitudes.

5.3 Coherence measure–based method

This method is based on the heuristic premise that, under constant experimental and environmental conditions, the integral of the coherence over frequency decreases with fault occurrence. This can be justified by the nonlinear effects introduced, or strengthened, with fault occurrence. Like the previous method, this method pertains to the excitation–response case.

The *coherence measure* defined over the discrete frequencies ω_i ($i = 1, 2, \ldots, n$; frequency resolution $\delta\omega$):

$$\Gamma = \delta\omega \cdot \sum_{i=1}^{n} \gamma^2[\omega_i] \qquad (14)$$

is used in approximating the coherence integral, and constitutes the method's characteristic quantity Q.

Fault detection is then based on the confirmation of a statistically significant reduction in the coherence measure Γ_u of the current structure (compared to Γ_o of its healthy counterpart) through the statistical hypothesis testing problem:

$$H_0\text{: } \delta\Gamma = \Gamma_o - \Gamma_u = 0$$
(null hypothesis–healthy structure)
$$H_1\text{: } \delta\Gamma = \Gamma_o - \Gamma_u > 0$$
(alternative hypothesis–faulty structure) (15)

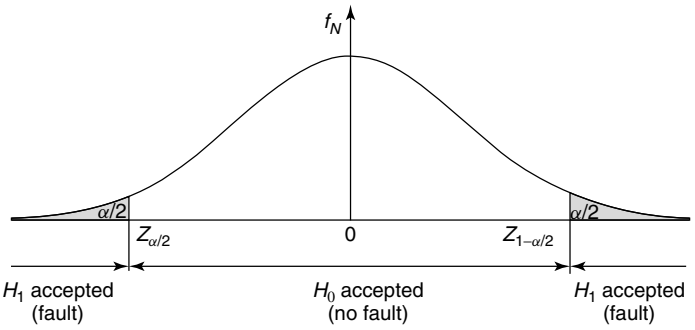

Figure 4. Statistical hypothesis testing based on a Gaussian distributed statistic (two-tailed test).

As the true Γ_u and Γ_o are unknown, their respective estimates are employed.

Owing to the properties of the Welch-based coherence estimator of Table 7 and the central limit theorem [44, p. 273] (also see Appendix), the corresponding coherence measure estimator approximately follows, for a large number of discrete frequencies ($n \to \infty$), Gaussian distribution, that is,

$$\widehat{\Gamma} \sim \mathcal{N}(\Gamma, \sigma_\Gamma^2)$$

with

$$\sigma_\Gamma^2 = (\delta\omega)^2 \sum_{i=1}^{n} \mathrm{var}[\widehat{\gamma}^2[\omega_i]] \tag{16}$$

with Γ designating the coherence measure's true value. Notice that in obtaining this expression, the bias terms present in the coherence estimator (refer to Table 7) are neglected, which is justified for either large number of segments K or for true coherence close to unity. Furthermore, the variance of $\widehat{\Gamma}$ is equal to the sum of the individual coherence estimator variances due to the fact that the coherence estimators at different frequencies are mutually independent random variables [45, p. 204].

Furthermore, as $\widehat{\Gamma}_u$ and $\widehat{\Gamma}_o$ are mutually independent and Gaussian, $\delta\widehat{\Gamma}$ will be Gaussian as follows:

$$\delta\widehat{\Gamma} = \widehat{\Gamma}_o - \widehat{\Gamma}_u \sim \mathcal{N}(\delta\Gamma, \delta\sigma_\Gamma^2)$$

with

$$\delta\Gamma = \Gamma_o - \Gamma_u, \quad \delta\sigma_\Gamma^2 = (\sigma_\Gamma^2)_o + (\sigma_\Gamma^2)_u \tag{17}$$

Under the null (H_0) hypothesis $\delta\Gamma = \Gamma_o - \Gamma_u \leq 0$ and $\delta\sigma_\Gamma^2 = 2(\sigma_\Gamma^2)_o$, thus

$$\text{Under } H_0 : \delta\widehat{\Gamma} = \widehat{\Gamma}_o - \widehat{\Gamma}_u \sim \mathcal{N}(\delta\Gamma, 2(\sigma_\Gamma^2)_o) \quad (\delta\Gamma \leq 0) \tag{18}$$

The variance $(\sigma_\Gamma^2)_o$ is unknown, but may be estimated in the baseline phase. Treating this estimator as a fixed quantity, the equality (null) hypothesis for the two coherence measures may be examined at the α (type I) risk level through the statistical test (Figure 5):

$$\begin{aligned} Z = \delta\widehat{\Gamma} / \sqrt{2(\widehat{\sigma}_\Gamma^2)_o} \leq Z_{1-\alpha} \\ \Longrightarrow H_0 \text{ is accepted (healthy structure)} \\ \text{Else} \Longrightarrow H_1 \text{ is accepted (faulty structure)} \end{aligned} \tag{19}$$

with $Z_{1-\alpha}$ designating the standard normal distribution's $1-\alpha$ critical point.

Note that the method is not appropriate for fault identification, as different types of faults may cause similar or identical reduction in the coherence measure. Assuming that only one type of fault is possible, fault estimation may be possible by associating specific quantitative reductions in the coherence measure with specific fault magnitudes.

Bibliographical remark. The method was introduced and applied for skin damage detection and restoration quality assessment in aircraft panels [46].

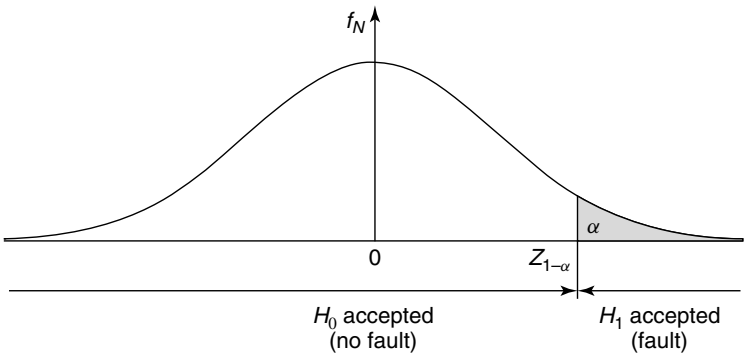

Figure 5. Statistical hypothesis testing based on a Gaussian distributed statistic (one-tailed test).

6 PARAMETRIC TIME SERIES METHODS

Parametric time series methods are those in which the characteristic quantity Q is constructed on the basis of parametric time series models. They are applicable to both the response-only and excitation–response cases, as each situation may be dealt with through the use of proper models [14], [27, subsection 6.2], [47, subsection 4.2]. Parametric methods may operate on either time or frequency domains, with the former being more frequently used and being in the focus of the present article. Parametric methods may be further classified into a number of categories, including model parameter–based methods, residual-based methods, and functional model (FM)–based methods.

6.1 Model parameter–based methods

These perform fault detection and identification by using a characteristic quantity $Q = f(\boldsymbol{\theta})$, which is a function of the parameter vector $\boldsymbol{\theta}$ of a parametric time series model ($Q = \boldsymbol{\theta}$ in the typical case).

Let $\widehat{\boldsymbol{\theta}}$ designate a proper estimator of the parameter vector $\boldsymbol{\theta}$ [22], [26, pp. 212–213]; [30, pp. 198–199]. For sufficiently long signals (N large), the estimator is (under mild assumptions) Gaussian distributed with mean equal to its true value $\boldsymbol{\theta}$ and a certain covariance $\boldsymbol{P}_{\boldsymbol{\theta}}$ [30, pp. 205–207]:

$$\widehat{\boldsymbol{\theta}} \sim \mathcal{N}(\boldsymbol{\theta}, \boldsymbol{P}_{\boldsymbol{\theta}}) \tag{20}$$

Fault detection is based on testing for statistically significant changes in the parameter vector $\boldsymbol{\theta}$ between the nominal and current structures through the hypothesis testing problem:

$$\begin{aligned} &H_0 : \delta\boldsymbol{\theta} = \boldsymbol{\theta}_{\mathrm{o}} - \boldsymbol{\theta}_{\mathrm{u}} = \mathbf{0} \\ &\quad \text{(null hypothesis—healthy structure)} \\ &H_1 : \delta\boldsymbol{\theta} = \boldsymbol{\theta}_{\mathrm{o}} - \boldsymbol{\theta}_{\mathrm{u}} \neq \mathbf{0} \\ &\quad \text{(alternative hypothesis—faulty structure)} \end{aligned} \tag{21}$$

Toward this end observe that, owing to the mutual independence of the Z_{u} and Z_{o} data records, the difference between the two parameter vector estimators also follows Gaussian distribution:

$$\delta\widehat{\boldsymbol{\theta}} = \widehat{\boldsymbol{\theta}}_{\mathrm{o}} - \widehat{\boldsymbol{\theta}}_{\mathrm{u}} \sim \mathcal{N}(\delta\boldsymbol{\theta}, \delta\boldsymbol{P})$$

with

$$\delta\boldsymbol{\theta} = \boldsymbol{\theta}_{\mathrm{o}} - \boldsymbol{\theta}_{\mathrm{u}}, \quad \delta\boldsymbol{P} = \boldsymbol{P}_{\mathrm{o}} + \boldsymbol{P}_{\mathrm{u}} \tag{22}$$

where $\boldsymbol{P}_{\mathrm{o}}$, $\boldsymbol{P}_{\mathrm{u}}$ designate the corresponding covariance matrices. Under the null (H_0) hypothesis $\delta\widehat{\boldsymbol{\theta}} = \widehat{\boldsymbol{\theta}}_{\mathrm{o}} - \widehat{\boldsymbol{\theta}}_{\mathrm{u}} \sim \mathcal{N}(\mathbf{0}, 2\boldsymbol{P}_{\mathrm{o}})$ and the quantity $\chi^2_{\boldsymbol{\theta}}$, below, follows χ^2 distribution with d (parameter vector dimensionality) degrees of freedom (as it may be shown to be the sum of squares of independent standardized Gaussian variables [26, p. 558]–also see Appendix):

$$\text{Under } H_0 : \mathcal{X}^2_{\boldsymbol{\theta}} = \delta\widehat{\boldsymbol{\theta}}^{\mathrm{T}} \cdot \delta\boldsymbol{P}^{-1} \cdot \delta\widehat{\boldsymbol{\theta}} \sim \chi^2(d)$$

with

$$\delta\boldsymbol{P} = 2\boldsymbol{P}_{\mathrm{o}} \tag{23}$$

As the covariance matrix $\boldsymbol{P}_{\mathrm{o}}$ corresponding to the healthy structure is unavailable, its estimated version $\widehat{\boldsymbol{P}}_{\mathrm{o}}$ is used. Treating it as a quantity characterized by negligible variability (which is reasonable for large N) leads to the following test constructed at the α (type I) risk level (Figure 6; see [26, p. 559] for an alternative approach based on the F distribution):

$$\begin{aligned} &\mathcal{X}^2_{\boldsymbol{\theta}} \leq \chi^2_{1-\alpha}(d) \\ &\quad \Longrightarrow H_0 \text{ is accepted (healthy structure)} \\ &\text{Else} \Longrightarrow H_1 \text{ is accepted (faulty structure)} \end{aligned} \tag{24}$$

with $\chi^2_{1-\alpha}(d)$ designating the χ^2 distribution's $1-\alpha$ critical point.

Fault identification may be based on the multiple hypotheses testing problem of Table 2, comparing the current parameter vector $\widehat{\boldsymbol{\theta}}_{\mathrm{u}}$ to those corresponding to different fault types, $\widehat{\boldsymbol{\theta}}_{\mathrm{A}}, \widehat{\boldsymbol{\theta}}_{\mathrm{B}}, \ldots$. Nevertheless, this is expected to work only for faults of specific magnitudes and cannot generally account for the continuum of fault magnitudes possible within each fault type. A geometric method that aims at circumventing this difficulty and also used for fault estimation is presented in [43, 48, 49].

Bibliographical remarks. The principles of this method have been used in a number of studies. Sohn

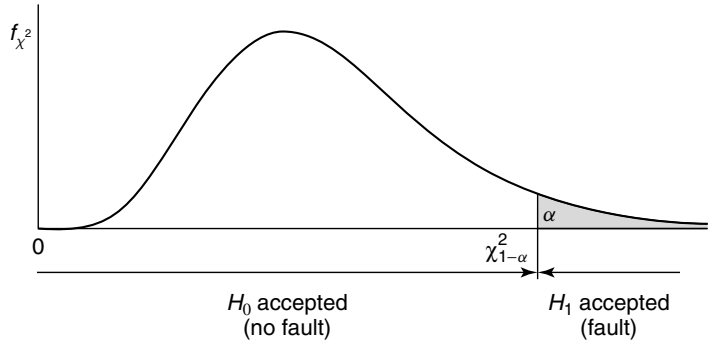

Figure 6. Statistical hypothesis testing based on a χ^2 distributed statistic (one-tailed test).

and Farrar [16] use the parameters of an AR model and statistical process control charts for fault detection in a concrete bridge column, as the column is progressively damaged. Sakellariou and Fassois [43] use the parameter vector of an OE model for fault detection in a six-story building model under earthquake excitation. Adams and Farrar [50] use ARX models in the frequency domain for fault detection and estimation in a simulated structural system and in a three-story building model. Wei *et al.* [51] use nonlinear autoregressive moving average with exogenous excitation (NARMAX) models for fault detection and identification in carbon fiber-reinforced epoxy plates based on a deterministic index, which mirrors changes incurred in the model parameters. Nair *et al.* [52] employ ARMA models, a damage-sensitive feature that depends on certain AR parameters, and statistical hypothesis testing to detect and localize (identify) faults in an ASCE benchmark structure consisting of a four-story steel-braced frame. In a follow-up study, Nair and Kiremidjian [53] employ Gaussian mixture modeling of the feature vector. Carden and Brownjohn [19] use ARMA model parameters for fault detection and localization (identification) in the IASC-ASCE benchmark four-story frame structure, in the Z24 bridge, and in the Malaysia–Singapore Second Link bridge. It should be noted that model parameter–based methods may be also used with alternative models, such as *modal models*. In this case, fault detection and identification are based on the detection of changes incurred in the structure's modal parameters [1, 2, 6, 39, 46, 54, 55]—also see Subsection 6.2.4. This topic has attracted considerable interest, although not necessarily in a statistical framework.

6.2 Model residual–based methods

These methods base fault detection, identification, and estimation on characteristic quantities that are functions of residual sequences obtained by driving the current signal(s) Z_u through predetermined—in the baseline phase—models $\mathcal{M}_o, \mathcal{M}_A, \mathcal{M}_B, \ldots$, each one corresponding to a particular state of the structure. The general idea is that the residual sequence obtained by a model that truly reflects the actual (current) state of the structure will possess some distinct properties, and will be thus possible to distinguish. An advantage of the methods is that no model identification is performed in the inspection phase. The methods have a relatively long history—mainly within the general context of engineering systems; for instance, see [14, 27, 47, 56–60].

Let $\mathcal{M}_V$ designate the model representing the structure in its V state ($V = o$ or $V = A, B, \ldots$ under specific fault magnitudes). Also, let the residual series obtained by driving the current signals Z_u through each one of the above-mentioned models be designated as $e_{ou}[t]$, $e_{Au}[t]$, $e_{Bu}[t]$, ... and be characterized by respective variances $\sigma^2_{ou}, \sigma^2_{Au}, \sigma^2_{Bu}, \ldots$—notice that the first subscript designates the model employed and the second the structural state corresponding to the current excitation and/or response signal(s) used.

Fault detection, identification, and estimation may be then based on the fact that under the H_V hypothesis (that is, the structure being in its V state, for $V = o$ or $V = A, B, \ldots$ under specific fault magnitudes), the residual series generated by driving the current signal(s) Z_u through the model $\mathcal{M}_V$ possesses the

property:

$$\text{Under } H_{\mathrm{V}}: e_{\mathrm{Vu}}[t] \sim \text{i.i.d. } \mathcal{N}(0, \sigma^2_{\mathrm{Vu}})$$

with

$$\sigma^2_{\mathrm{Vu}} < \sigma^2_{\mathrm{Wu}} \text{ for any state W} \neq \mathrm{V} \tag{25}$$

It is tacitly assumed that under H_{V} $\sigma^2_{\mathrm{Vu}} = \sigma^2_{\mathrm{VV}}$, implying that the excitation and environmental conditions are the same in the baseline and inspection phases. Descriptions of four model residual–based methods follow.

6.2.1 Residual variance-based method

In this method, the characteristic quantity is the residual variance. Fault detection is based on the fact that the residual series $e_{\mathrm{ou}}[t]$, obtained by driving the current signal(s) Z_{u} through the model $\mathcal{M}_{\mathrm{o}}$ corresponding to the nominal (healthy) structure, should be characterized by variance σ^2_{ou}, which becomes minimal (specifically equal to σ^2_{oo}) if and only if the current structure is healthy ($\mathcal{S}_{\mathrm{u}} = \mathcal{S}_{\mathrm{o}}$).

The following hypothesis testing problem is then set up:

$$\begin{aligned} &H_0: \sigma^2_{\mathrm{oo}} = \sigma^2_{\mathrm{ou}} \text{ (null hypothesis—healthy structure)} \\ &H_1: \sigma^2_{\mathrm{oo}} < \sigma^2_{\mathrm{ou}} \text{ (alternative hypothesis—faulty structure)} \end{aligned} \tag{26}$$

Under the null (H_0) hypothesis, the residuals $e_{\mathrm{ou}}[t]$ are (just like the residuals $e_{\mathrm{oo}}[t]$) i.i.d. zero mean Gaussian with variance σ^2_{oo}. Hence the quantities $N_{\mathrm{u}}\widehat{\sigma}^2_{\mathrm{ou}}/\sigma^2_{\mathrm{oo}}$ and $(N_{\mathrm{o}} - d)\widehat{\sigma}^2_{\mathrm{oo}}/\sigma^2_{\mathrm{oo}}$ follow (central) χ^2 distributions with N_{u} and $N_{\mathrm{o}} - d$ degrees of freedom, respectively (sum of squares of independent standardized Gaussian random variables—see Appendix). Note that N_{o} and N_{u} designate the number of samples used in estimating the residual variance in the healthy and current cases, respectively (typically $N_{\mathrm{o}} = N_{\mathrm{u}} = N$), and d designates the dimensionality of the model parameter vector. Also note that N_{u} and N_{o} should be adjusted to $N_{\mathrm{u}} - 1$ and $N_{\mathrm{o}} - 1$, respectively, in case each estimated mean is subtracted from each residual series. Consequently, the following statistic follows F distribution with $(N_{\mathrm{u}}, N_{\mathrm{o}} - d)$ degrees of freedom (ratio of two independent and normalized χ^2 random variables—see Appendix):

$$\text{Under } H_0: F = \frac{\dfrac{N_{\mathrm{u}}\widehat{\sigma}^2_{\mathrm{ou}}}{\sigma^2_{\mathrm{oo}} N_{\mathrm{u}}}}{\dfrac{(N_{\mathrm{o}} - d)\widehat{\sigma}^2_{\mathrm{oo}}}{\sigma^2_{\mathrm{oo}}(N_{\mathrm{o}} - d)}} = \frac{\widehat{\sigma}^2_{\mathrm{ou}}}{\widehat{\sigma}^2_{\mathrm{oo}}} \sim F(N_{\mathrm{u}}, N_{\mathrm{o}} - d) \tag{27}$$

The following test is then constructed at the α (type I) risk level (Figure 7):

$$\begin{aligned} &F \leq f_{1-\alpha}(N_{\mathrm{u}}, N_{\mathrm{o}} - d) \\ &\Longrightarrow H_0 \text{ is accepted (healthy structure)} \\ &\text{Else} \Longrightarrow H_1 \text{ is accepted (faulty structure)} \end{aligned} \tag{28}$$

with $f_{1-\alpha}(N_{\mathrm{u}}, N_{\mathrm{o}} - d)$ designating the corresponding F distribution's $1 - \alpha$ critical point.

Fault identification may be similarly achieved via pairwise tests. An alternative possibility may be based

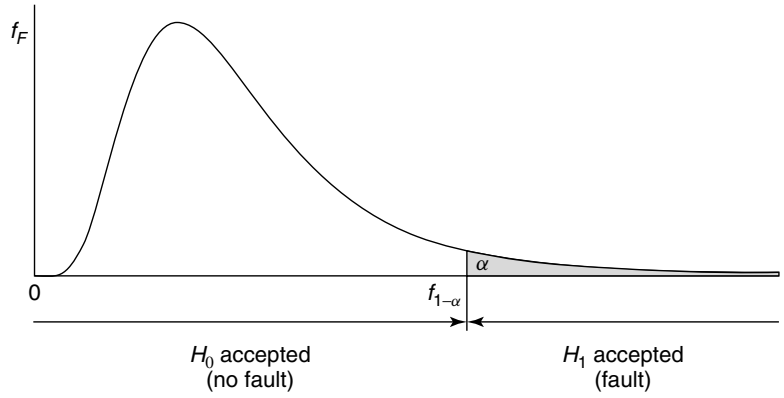

Figure 7. Statistical hypothesis testing based on an F distributed statistic (one-tailed test).

on obtaining the residual series $e_{\mathrm{Au}}[t]$, $e_{\mathrm{Bu}}[t]$,..., estimating their variances, and declaring as current fault that corresponding to minimal residual variance. Notice that by including $e_{\mathrm{ou}}[t]$, fault detection may be also treated. Fault estimation may possibly be achieved in the limited case of a single type of faults, by associating specific values of the residual variance with specific fault magnitudes.

Bibliographical remarks. Similar methods, that combine AR and ARX models, are used by Sohn and Farrar [61] and Sohn *et al.* [62] for fault detection in an eight degree-of-freedom mass-spring system and in a fast patrol boat. In a similar framework, Sohn *et al.* [63] explore the use of extreme value statistics. Fugate *et al.* [17] use an X-bar control chart for detecting changes in the mean and variance of AR model residual series for the continuous monitoring of a concrete bridge column, as the column is progressively damaged. Yan *et al.* [18] use an X-bar control chart on state-space model residuals for fault detection and identification in an aircraft skeleton and the Z24 bridge benchmark. Lu and Gao [64] use an ARX model and the standard deviation of its residuals for fault detection and localization in a two and an eight degree-of-freedom simulated mass-spring system. Zhang [65] explores data normalization procedures and a probability-based measure expressing changes in ARX residual variance for fault detection and identification in a three-span continuous girder bridge simulation model. A time-varying autoregressive with exogenous excitation (TARX) model along with statistical hypothesis testing on its residual variance is used by Poulimenos and Fassois [66] for the detection of faults in a time-varying, bridgelike, laboratory structure. Additional statistical modes (such as the mean, skewness, and kurtosis) of the residuals associated with a vector AR model are explored by Mattson and Pandit [67]. Methods employing neural network type nonlinear models and deterministic decision making based on the response error (residual) are presented in [55, 68, 69].

6.2.2 Likelihood function-based method

In this method, fault detection is based on the likelihood function under the null (H_0) hypothesis of a healthy structure [47, pp. 119–120]. The hypothesis testing problem considered is

$$\begin{aligned} &H_0 : \boldsymbol{\theta}_{\mathrm{o}} = \boldsymbol{\theta}_{\mathrm{u}} \text{ (null hypothesis—healthy structure)} \\ &H_1 : \boldsymbol{\theta}_{\mathrm{o}} \neq \boldsymbol{\theta}_{\mathrm{u}} \text{ (alternative hypothesis—faulty structure)} \end{aligned} \tag{29}$$

with $\boldsymbol{\theta}_{\mathrm{o}}$, $\boldsymbol{\theta}_{\mathrm{u}}$ designating the parameter vectors corresponding to the healthy and current structure, respectively. Assuming independence of the residual sequence, the Gaussian likelihood function for the data Y given X is [25, p. 226]:

$$\begin{aligned} L_{\mathrm{y}}(Y, \boldsymbol{\theta} / X) &= \prod_{t=1}^{N} \frac{1}{\sqrt{2\pi\sigma^2}} \cdot \exp\left\{ -\frac{e^2[t, \boldsymbol{\theta}]}{2\sigma^2} \right\} \\ &= \frac{1}{(\sqrt{2\pi\sigma^2})^N} \cdot \exp\left\{ -\frac{1}{2\sigma^2} \sum_{t=1}^{N} e^2[t, \boldsymbol{\theta}] \right\} \end{aligned} \tag{30}$$

with $e[t, \boldsymbol{\theta}]$ designating the model residual (one-step-ahead prediction error) characterized by zero mean and variance σ^2.

Under the null (H_0) hypothesis, the residual series $e_{\mathrm{ou}}[t]$ generated by driving the current signal(s) through the nominal model $\mathcal{M}_{\mathrm{o}}$ is (just like $e_{\mathrm{oo}}[t]$) i.i.d. Gaussian with zero mean and variance σ^2_{oo}. Decision making may be then based on the likelihood function under H_0 evaluated for the current data, by requiring it to be larger or equal to a threshold l (which is to be selected) in order for the null (H_0) hypothesis to be accepted:

$$\begin{aligned} &L_{\mathrm{y}}(Y, \boldsymbol{\theta}_{\mathrm{o}} / X) \geq l \\ &\Longrightarrow H_0 \text{ is accepted (healthy structure)} \\ &\text{Else} \Longrightarrow H_1 \text{ is accepted (faulty structure)} \end{aligned} \tag{31}$$

The evaluation of the likelihood $L_{\mathrm{y}}(Y, \boldsymbol{\theta}_{\mathrm{o}} / X)$ requires knowledge of the true innovations variance σ^2_{oo}. If this quantity is known, or may be estimated with good accuracy in the baseline phase (which is reasonable for estimation using a large number of samples N), it may be treated as a fixed quantity (negligible variability). The above decision making rule may be then reexpressed as

$$\begin{aligned} &\chi^2_N = \sum_{t=1}^{N} \frac{e^2_{\mathrm{ou}}[t]}{\widehat{\sigma}^2_{\mathrm{oo}}} = \frac{N\widehat{\sigma}^2_{\mathrm{ou}}}{\widehat{\sigma}^2_{\mathrm{oo}}} \leq l^* \\ &\Longrightarrow H_0 \text{ is accepted (healthy structure)} \\ &\text{Else} \Longrightarrow H_1 \text{ is accepted (faulty structure)} \end{aligned} \tag{32}$$

where l^* designates the corresponding (to be selected) threshold.

Under the null (H_0) hypothesis, the statistic $\mathcal{X}_N^2$ follows χ^2 distribution with N degrees of freedom (sum of squares of mutually independent standardized Gaussian variables—see Appendix), and this leads to the following test at the α risk level (Figure 6):

$$\mathcal{X}_N^2 = \frac{N\widehat{\sigma}_{\text{ou}}^2}{\widehat{\sigma}_{\text{oo}}^2} \leq \chi_{1-\alpha}^2(N)$$
$$\Longrightarrow H_0 \text{ is accepted (healthy structure)}$$
$$\text{Else} \Longrightarrow H_1 \text{ is accepted (faulty structure)} \quad (33)$$

with $\chi_{1-\alpha}^2(N)$ designating the χ^2 distribution's $1-\alpha$ critical point.

Note that N should be adjusted to $N-1$ in case the estimated mean is subtracted from the residual series $e_{\text{ou}}[t]$. Also note that the above decision making is similar to that of the previous (residual variance based) method. The essential difference is that the variability of the estimator $\widehat{\sigma}_{\text{oo}}^2$ is accounted for in the residual variance–based method, thus leading to an F distribution of the pertinent statistic. Of course, the two tests coincide for $N_{\text{o}} \to \infty$ in equation (27), as the F distribution then approaches the χ^2 distribution [44, p. 523] (also see Appendix).

Fault identification may be achieved by computing the likelihood function for the current signal(s) for the various values of $\boldsymbol{\theta}$ ($\boldsymbol{\theta}_{\text{A}}, \boldsymbol{\theta}_{\text{B}}, \ldots$) and accepting the hypothesis that corresponds to the maximum value of the likelihood—by including $\boldsymbol{\theta}_{\text{o}}$ fault detection may be also treated. Fault estimation may be possibly achieved in the limited case of a single type of faults, by associating specific values of the likelihood with specific fault magnitudes.

6.2.3 Residual-uncorrelatedness-based method

This method is based on the fact that the residual sequence $e_{\text{ou}}[t]$ ($e_{\text{Vu}}[t]$) obtained by driving the current signal(s) Z_{u} through the model $\mathcal{M}_{\text{o}}$ ($\mathcal{M}_{\text{V}}$) will be *uncorrelated* (white) if and only if the current structure is in its nominal (healthy) S_{o} (S_{V}) state (see equation (25)).

Fault detection may be then based on the hypothesis testing problem:

$$H_0\colon \rho[\tau] = 0 \quad \tau = 1, 2, \ldots, r$$
(null hypothesis—healthy structure)
$$H_1\colon \rho[\tau] \neq 0 \quad \text{for some } \tau$$
(alternative hypothesis—faulty structure) (34)

with $\rho[\tau]$ designating the normalized autocovariance (or else correlation coefficient–refer to Table 7) of the $e_{\text{ou}}[t]$ residual sequence. The method's characteristic quantity thus is $Q = [\rho[1]\,\rho[2]\,\ldots\,\rho[r]]^{\text{T}}$, with r being a design variable.

Under the null (H_0) hypothesis, $e_{\text{ou}}[t]$ is i.i.d. (white) Gaussian with zero mean, and the statistic $\mathcal{X}_\rho^2$ below follows χ^2 distribution with r degrees of freedom ($r-1$ in case the estimated mean is subtracted from the residual series) [25, p. 314]:

$$\text{Under } H_0\colon \mathcal{X}_\rho^2 = N(N+2)\cdot\sum_{\tau=1}^{r}(N-\tau)^{-1}\cdot\widehat{\rho}^2[\tau]$$
$$\sim \chi^2(r) \quad (35)$$

with $\widehat{\rho}[\tau]$ designating the estimator of $\rho[\tau]$. Decision making is then based on the following test at the α (type I) risk level (Figure 6):

$$\mathcal{X}_\rho^2 \leq \chi_{1-\alpha}^2(r)$$
$$\Longrightarrow H_0 \text{ is accepted (healthy structure)}$$
$$\text{Else} \Longrightarrow H_1 \text{ is accepted (faulty structure)} \quad (36)$$

with $\chi_{1-\alpha}^2(r)$ designating the χ^2 distribution's $1-\alpha$ critical point.

Fault identification may be achieved by similarly examining which one of the $e_{\text{Vu}}[t]$ (for V = A, B, ...) residual series is uncorrelated. As with the previous methods, only faults of specific magnitudes (but not the continuum of fault magnitudes) may be considered. On the other hand, the method, as such, is not suitable for fault estimation.

6.2.4 Method based on residuals associated with subspace identification

This method is motivated by stochastic subspace identification (the response-only case is presently

treated; see [15] for details). It performs fault detection in the *modal space* by considering the parameter vector

$$\boldsymbol{\theta} = \begin{bmatrix} \boldsymbol{\lambda} \\ \text{vec } \boldsymbol{\Phi} \end{bmatrix} \tag{37}$$

where $\boldsymbol{\lambda}$ designates the vector containing the eigenvalues of a discrete-time structural model (the eigenvalues of the system matrix $\boldsymbol{A}$ in the state-space representation), $\boldsymbol{\Phi}$ the matrix with columns being the vectors $\boldsymbol{\phi}_\lambda$ where $\boldsymbol{\phi}_\lambda = \boldsymbol{C}\boldsymbol{\varphi}_\lambda$, with $\boldsymbol{\varphi}_\lambda$ being the corresponding eigenvectors, and $\boldsymbol{C}$ the output matrix in the state-space model (Table 5). The vec of a matrix designates the vector formed by stacking the columns of the indicated matrix one underneath the other.

Fault detection is based on the fact that for a given state-space model (characterized by a given $\boldsymbol{\theta}$), the system's $(p+1)$th order (p selected sufficiently large) observability matrix:

$$\boldsymbol{\mathcal{O}}_{p+1}(\boldsymbol{\theta}) = \begin{pmatrix} \boldsymbol{\Phi} \\ \boldsymbol{\Phi}\boldsymbol{\Lambda} \\ \vdots \\ \boldsymbol{\Phi}\boldsymbol{\Lambda}^p \end{pmatrix} \tag{38}$$

with $\boldsymbol{\Lambda} = \text{diag}(\boldsymbol{\lambda})$ (diagonal matrix with the system eigenvalues), and the structure's block Hankel matrix:

$$\begin{aligned} \boldsymbol{\mathcal{H}}_{p+1,q} &= \begin{pmatrix} \gamma_{yy}[0] & \gamma_{yy}[1] & \dots & \gamma_{yy}[q-1] \\ \gamma_{yy}[1] & \gamma_{yy}[2] & \dots & \gamma_{yy}[q] \\ \vdots & \vdots & \ddots & \vdots \\ \gamma_{yy}[p] & \gamma_{yy}[p+1] & \dots & \gamma_{yy}[p+q-1] \end{pmatrix} \\ &= \text{Hank}(\gamma_{yy}) \end{aligned} \tag{39}$$

with q selected such that $q \geq p+1$, and $\gamma_{yy}[\tau]$ designating the response's theoretical autocovariance, have the same left kernel space.

Let $\boldsymbol{\theta}_\text{o}$ designate the parameter vector corresponding to the healthy structure. Pick an orthonormal basis of the left kernel space of the matrix $\boldsymbol{W}_1\boldsymbol{\mathcal{O}}_{p+1}(\boldsymbol{\theta}_\text{o})$ ($\boldsymbol{W}_1$ is a selectable invertible weighting matrix), in terms of the columns of a matrix $\boldsymbol{S}$ of co-rank n (the system order) such that

$$\boldsymbol{S}^\text{T} \cdot \boldsymbol{S} = \boldsymbol{I} \tag{40}$$

and

$$\boldsymbol{S}^\text{T} \cdot \boldsymbol{W}_1 \cdot \boldsymbol{\mathcal{O}}_{p+1}(\boldsymbol{\theta}_\text{o}) = \boldsymbol{0} \tag{41}$$

with $s = (p+1)r - n$ (r designating the vibration response vector dimensionality). Notice that the matrix $\boldsymbol{S}$ is not unique. It may be, for instance, obtained through the singular value decomposition (SVD) of $\boldsymbol{W}_1\boldsymbol{\mathcal{O}}_{p+1}(\boldsymbol{\theta}_\text{o})$, and implicitly depends upon the parameter vector $\boldsymbol{\theta}_\text{o}$; hence it may be designated as $\boldsymbol{S}(\boldsymbol{\theta}_\text{o})$. The block Hankel matrix corresponding to the same system should then satisfy the following property:

$$\boldsymbol{S}^\text{T}(\boldsymbol{\theta}_\text{o}) \cdot \boldsymbol{W}_1 \cdot \boldsymbol{\mathcal{H}}_{p+1,q} \cdot \boldsymbol{W}_2^T = \boldsymbol{0} \tag{42}$$

with $\boldsymbol{W}_2$ being an additional selectable invertible weighting matrix.

Given data Y_u from the current system (with parameter vector designated as $\boldsymbol{\theta}_\text{u}$), the residual signal (compare with equation (42)):

$$\boldsymbol{\zeta}_N(\boldsymbol{\theta}_\text{o}) \triangleq \sqrt{N}\text{vec}\left(\boldsymbol{S}^\text{T}(\boldsymbol{\theta}_\text{o}) \cdot \boldsymbol{W}_1 \cdot \widehat{\boldsymbol{\mathcal{H}}}_{p+1,q} \cdot \boldsymbol{W}_2^\text{T}\right) \tag{43}$$

where $\widehat{\boldsymbol{\mathcal{H}}}_{p+1,q}$ is the estimated (sample) block Hankel matrix obtained from the current data Y_u, will have zero mean under H_0 ($\boldsymbol{\theta}_\text{u} = \boldsymbol{\theta}_\text{o}$) and nonzero mean under H_1 ($\boldsymbol{\theta}_\text{u} \neq \boldsymbol{\theta}_\text{o}$) (in fact, it should be zero under H_0 if the theoretical block Hankel matrix is used—see equation (42)).

Testing whether the current structure (with parameter vector $\boldsymbol{\theta}_\text{u}$ and associated with the estimated block Hankel matrix) coincides with the healthy (with parameter vector $\boldsymbol{\theta}_\text{o}$) is based on a "statistical local approach", according to which the following "close" hypotheses are considered:

$$\begin{aligned} &H_0 : \boldsymbol{\theta}_\text{u} = \boldsymbol{\theta}_\text{o} \\ &\quad \text{(null hypothesis—healthy structure)} \\ &H_1 : \boldsymbol{\theta}_\text{u} = \boldsymbol{\theta}_\text{o} + \frac{1}{\sqrt{N}}\delta\boldsymbol{\theta} \\ &\quad \text{(alternative hypothesis—faulty structure)} \end{aligned} \tag{44}$$

with $\delta\boldsymbol{\theta}$ designating an unknown but fixed error vector.

Let $\boldsymbol{M}(\boldsymbol{\theta}_o)$ be the Jacobian matrix designating the mean sensitivity of $\boldsymbol{\zeta}_N$, and $\boldsymbol{\Sigma}(\boldsymbol{\theta}_o) = \lim_{N\to\infty} E_{\boldsymbol{\theta}_o}\{\boldsymbol{\zeta}_N \boldsymbol{\zeta}_N^T\}$, with $E_{\boldsymbol{\theta}_o}\{\cdot\}$ designating the expectation operator when the actual system parameter is $\boldsymbol{\theta}_o$ (these matrices do not depend upon the sample size N and may be estimated from the healthy structure during the baseline phase). Provided that $\boldsymbol{\Sigma}(\boldsymbol{\theta}_o)$ is positive definite, the residual $\boldsymbol{\zeta}_N(\boldsymbol{\theta}_o)$ of equation (43) asymptotically follows Gaussian distribution:

$$\boldsymbol{\zeta}_N(\boldsymbol{\theta}_o) \xrightarrow{N\to\infty} \begin{cases} \mathcal{N}\big(\mathbf{0}, \boldsymbol{\Sigma}(\boldsymbol{\theta}_o)\big) & \text{under } H_0 \\ \mathcal{N}\big(\boldsymbol{M}(\boldsymbol{\theta}_o)\delta\boldsymbol{\theta}, \boldsymbol{\Sigma}(\boldsymbol{\theta}_o)\big) & \text{under } H_1 \end{cases} \tag{45}$$

Now let $\widehat{\boldsymbol{M}}$ and $\widehat{\boldsymbol{\Sigma}}$ be consistent estimates of $\boldsymbol{M}(\boldsymbol{\theta}_o)$ (assumed to be full column rank) and $\boldsymbol{\Sigma}(\boldsymbol{\theta}_o)$, respectively, obtained in the baseline phase (details in [15]). Under the null (H_0) hypothesis, the statistic $\mathcal{X}_\zeta^2$, below, follows χ^2 distribution with rank $\boldsymbol{M}$ degrees of freedom, that is,

$$\begin{aligned} \text{Under } H_0\colon \mathcal{X}_\zeta^2 = \boldsymbol{\zeta}_N^T(\boldsymbol{\theta}_o)\widehat{\boldsymbol{\Sigma}}^{-1}\widehat{\boldsymbol{M}}(\widehat{\boldsymbol{M}}^T\widehat{\boldsymbol{\Sigma}}^{-1}\widehat{\boldsymbol{M}})^{-1} \\ \widehat{\boldsymbol{M}}^T\widehat{\boldsymbol{\Sigma}}^{-1}\boldsymbol{\zeta}_N(\boldsymbol{\theta}_o) \sim \chi^2(\text{rank } \boldsymbol{M}) \end{aligned} \tag{46}$$

and decision making may be accomplished by examining—at a certain risk level—whether the residual sequence has mean that is significantly different from zero (similar to the previous method).

Fault identification could be similarly based on consecutive tests of the above-mentioned form, each one corresponding to each one of the parameter vectors $\boldsymbol{\theta}_A, \boldsymbol{\theta}_B, \ldots$. Nevertheless, as with most methods, this may only work with faults of specific magnitudes but not for the continuum of fault magnitudes possible within each fault type. Finally, note that the method is not immediately suitable for fault magnitude estimation.

Bibliographical remark. The method has been effectively used in various structures, including the Z24 bridge benchmark [70] and a steel-quake benchmark [71].

6.3 Functional model–based methods

Functional model (FM)-based methods provide a framework for the combined treatment of the fault detection, identification, and magnitude estimation subproblems in the common and practically important case of a double continuum of fault types (locations) and magnitudes [72–74]. An important aim is overcoming the limitation of identifying faults of a limited number of prespecified types and magnitudes, while allowing for the correct identification and magnitude estimation for faults of any magnitude.

The cornerstone of the methods is their unique ability to accurately represent a structure for its double continuum of fault types (locations) and magnitudes via a *single* FM. FMs, or more precisely referred to as *functionally pooled* (FP) models, as they are based on pooling together multiple data records, assume various forms, and in the general case, are explicitly parametrized in terms of both fault type (location) and magnitude [74]. An infinite number of fault types and magnitudes can thus be accommodated by a single model. In the simpler case where only a small, finite number of fault types is considered, the parametrization may be in terms of fault magnitude alone [72]—a single model is then limited to a single fault type.

Consider, for the sake of clarity, the simpler case of fault magnitude parametrization. Letting the fault magnitude (within a particular fault mode V) be represented by $k \in \Re$ (typically $k = 0$ is selected to, without loss of generality, correspond to the healthy structure), a suitable linear model for the structure under fault mode V is the functionally pooled autoregressive with exogenous excitation (FP-ARX) model:

$$\begin{aligned} &\mathcal{M}_V(a_{ij}, b_{ij}, \sigma_w^2(k))\colon y_k[t] + \sum_{i=1}^{na} a_i(k)\cdot y_k[t-i] \\ &\quad = \sum_{i=0}^{nb} b_i(k)\cdot x_k[t-i] + w_k[t] \\ &w_k[t] \sim \text{i.i.d.}\,\mathcal{N}(0, \sigma_w^2(k)), \\ &a_i(k) = \sum_{j=1}^{p} a_{ij}\cdot G_j(k), \\ &b_i(k) = \sum_{j=1}^{p} b_{ij}\cdot G_j(k), \quad k \in \Re \end{aligned} \tag{47, 48}$$

In this model, $x_k[t]$, $y_k[t]$, and $w_k[t]$ are the excitation, response, and innovations (prediction error) signals, respectively, corresponding to a particular fault magnitude k. Note that the FP-ARX model resembles a conventional ARX model (refer to Table 6), but explicitly accounts for the continuum of fault magnitudes (within the particular fault mode) by allowing its parameters and innovations variance to be functions of the fault magnitude k. In fact, the model parameters belong to a p-dimensional functional subspace spanned by the mutually independent functions $G_1(k), \ldots, G_p(k)$ (*functional basis*), while the constants a_{ij} and b_{ij} designate the model's AR and X, respectively, coefficients of projection. A suitable FM, corresponding to each particular fault mode, is estimated in the baseline phase using data obtained from the structure under various fault magnitudes (details in [72, 74]).

In the inspection phase, given the current signals $Z_u = (X_u, Y_u)$, fault detection is based on the FP-ARX model of any (e.g. V) fault mode. This model is reparametrized in terms of the currently unknown fault magnitude k and the innovations variance $\sigma^2_{e_u}$ (the coefficients of projection being replaced by estimates available from the baseline phase; $e_u[t]$ represents the reparametrized model's innovations):

$$\mathcal{M}_V(k, \sigma^2_{e_u}) : y_u[t] + \sum_{i=1}^{na} a_i(k) \cdot y_u[t-i] = \sum_{i=0}^{nb} b_i(k) \cdot x_u[t-i] + e_u[t] \tag{49}$$

The following hypothesis testing problem is then formulated:

$$H_0 : k = 0 \text{ (null hypothesis—healthy structure)}$$
$$H_1 : k \neq 0 \text{ (alternative hypothesis—faulty structure)} \tag{50}$$

Estimates of k, $\sigma^2_{e_u}$ are obtained on the basis of the current data Z_u and the nonlinear least squares (NLLS) estimator (refer to [26, pp. 327–329] for details on NLLS estimation):

$$\widehat{k} = \arg\min_k \sum_{t=1}^{N} e_u^2[t] \tag{51}$$

$$\widehat{\sigma}^2_{e_u} = \frac{1}{N} \sum_{t=1}^{N} \widehat{e}_u^2[t] \tag{52}$$

Assuming that the structure is indeed under a fault belonging to the V fault mode (or healthy), the estimator may be shown to be asymptotically ($N \to \infty$) Gaussian distributed, with mean equal to its true value and variance equal to that provided by the Cramer–Rao lower bound [72]:

$$\widehat{k} \sim \mathcal{N}(k, \sigma_k^2) \tag{53}$$

Then t, below, follows t distribution with $N-1$ degrees of freedom (which should be adjusted to $N-2$ in case the estimated mean is subtracted from the residual series in the computation of $\widehat{\sigma}_k^2$). This is due to the fact that it is the ratio of a standardized normal random variable over the square root of an independent and normalized χ^2 random variable with $N-1$ degrees of freedom (see Appendix):

$$t = \widehat{k}/\widehat{\sigma}_k \sim t(N-1) \tag{54}$$

which leads to the following test at the α (type I) risk level (Figure 8):

$$\begin{aligned} & t_{\frac{\alpha}{2}}(N-1) \leq t \leq t_{1-\frac{\alpha}{2}}(N-1) \\ & \Longrightarrow H_0 \text{ is accepted (healthy structure)} \\ \text{Else } & \Longrightarrow H_1 \text{ is accepted (faulty structure)} \end{aligned} \tag{55}$$

with t_α and $t_{1-(\alpha/2)}$ designating the t distribution's corresponding critical points.

Once a fault is detected, its identification is achieved through successive estimation (using the current data Z_u) and validation of the reparametrized models $\mathcal{M}_V(k, \sigma^2_{e_u})$ (equation 49) for $V = A, B, \ldots$ corresponding to the various fault types. The procedure stops as soon as a particular model is successfully validated, with the corresponding fault mode being identified as current. Model validation may be based on statistical tests examining the hypothesis of excitation and residual sequence uncrosscorrelatedness and/or residual uncorrelatedness (see Subsection 6.2.3).

An interval estimate (at the α risk level) of the fault magnitude k is finally constructed on the basis

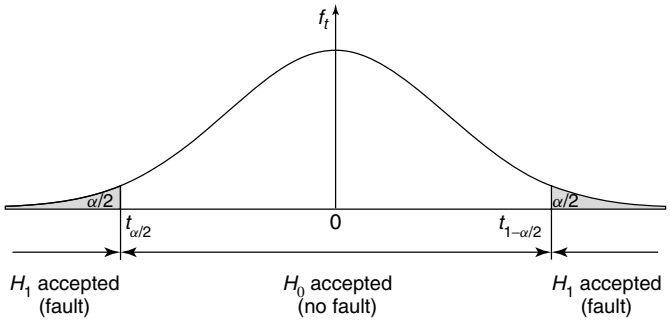

Figure 8. Statistical hypothesis testing based on a t distributed statistic (two-tailed test).

of the point estimate $\widehat{k}$ and $\widehat{\sigma}_k^2$:

k interval estimate:

$$\left[\widehat{k}+t_{\frac{\alpha}{2}}(N-1)\cdot\widehat{\sigma}_k,\ \widehat{k}+t_{1-\frac{\alpha}{2}}(N-1)\cdot\widehat{\sigma}_k\right] \quad (56)$$

7 APPLICATION OF THE METHODS TO FAULT DIAGNOSIS ON A LABORATORY STRUCTURE

Consider the scale aircraft skeleton structure of Figure 9, which has been constructed according to the Garteur SM-AG19 specifications. The structure consists of six solid beams representing the aircraft fuselage, the wings, the horizontal and vertical stabilizers, and the right and left wing tips. All elements are constructed from standard aluminum and are joined together via steel plates and screws (total skeleton mass ∼50 kg—also see [72]).

The faults considered correspond to the placement of a potentially variable number of small masses (simulating local elasticity reductions) at point B (right wing tip) or point E (horizontal stabilizer; Figure 9). Each fault is designated as F_{B}^k or F_{E}^k, with k representing the fault magnitude in gram of added mass and B or E the fault type (location). Four test cases are considered (Table 8). The structure is

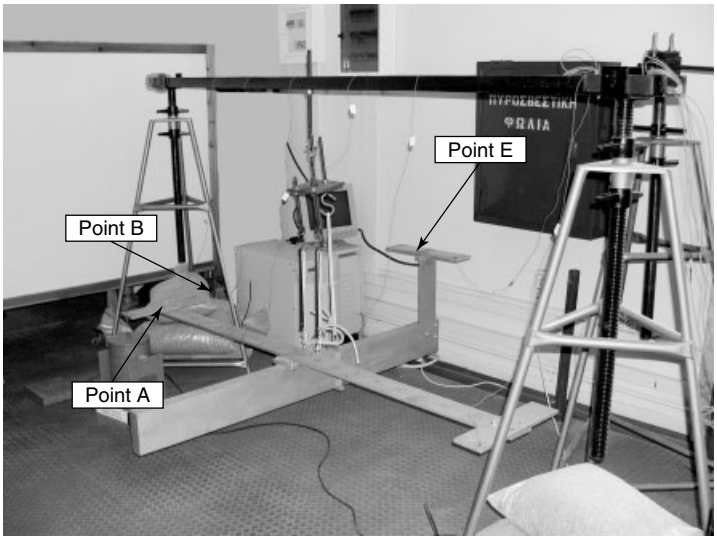

Figure 9. Aircraft scale skeleton structure and the experimental setup. The force/vibration measurement location (point A) and the fault locations (points B and E) are marked.

Table 8. The considered test cases

Test case	Structural state	Description
I	$k = 0$	Healthy structure (no mass attached)
II	$F_{\mathrm{B}}^{8.1}$	Mass (8.1 g) at point B
III	$F_{\mathrm{B}}^{24.4}$	Mass (24.4 g) at point B
IV	$F_{\mathrm{E}}^{16.3}$	Mass (16.3 g) at point E

healthy in test case I, under type B faults in test cases II and III, and under a type E fault in test case IV.

Fault detection, identification, and estimation (fault diagnosis) are based on vibration data records obtained under free–free boundary conditions. A white (uncorrelated) random Gaussian force excitation is applied vertically at the right wing tip (point A) through an electromechanical shaker equipped with a stinger. The exerted force and the resulting vertical vibration acceleration are measured via an impedance head and a lightweight accelerometer at point A (sampling frequency $f_s = 256\,\mathrm{Hz}$, signal bandwidth $3-100\,\mathrm{Hz}$, signal length $N = 5000$ samples). The estimated mean is also subtracted from each signal, plus scaling by the signal's estimated standard deviation is implemented. Note that while the type B faults occur "close" to the measurement location, the type E fault is "remote," and thus potentially harder to detect.

Results obtained by most of the presented methods are shown in the sequel—note that the coherence measure–based method is not applicable as the nature of the considered faults does not lead to nonlinear dynamics behavior.

7.1 Fault diagnosis

1. *Nonparametric methods.* The psd- and frf-based methods use Welch spectral estimates (signal length $N = 5000$ samples, segment length $L = 500$ samples, number of segments $K = 10$, zero overlap—refer to Table 7). Fault detection results are presented in Figure 10. Evidently, correct detection is obtained in each case and by both methods, as the test statistic is shown not to exceed (exceed) the critical point in the healthy (faulty) cases. This is true for the "remote" fault (test case IV) as well. Rather expectedly, the frf-based method (risk level $\alpha = 0.001$) provides clearer detection than the psd-based method (risk level $\alpha = 0.05$).
2. *Parametric methods.* The model parameter-, residual variance-, likelihood function-, and residual uncorrelatedness–based methods use excitation–response ARX modeling and a Prediction Error (PE) estimator based on $N = 5000$ sample–long signal records. The identification procedure leads to an ARX(62,62) model, which is selected as adequate. Fault detection results are presented in Figure 11, with the combined AR/X parameter vector used as the characteristic quantity in the model parameter–based method. Evidently, correct detection is obtained in each case and by all four methods, as the test statistic is shown not to exceed (exceed) the critical point (at the $\alpha = 0.01$ risk level) in the healthy (faulty) cases. As expected, the residual variance and likelihood function–based results are similar. The "remote" fault (test case IV) is clearly detected by all parametric methods, in particular, by the model parameter and residual uncorrelatedness–based ones.
3. *The functional model–based method.* This method uses $N = 4000$ sample-long excitation–response signals in both the baseline and inspection phases. The modeling of fault mode F_{B} (type B faults) is based on signals obtained from 11 experiments (for $k \in [0, 81.32]$ g; increment $\delta k \approx 8.132\,\mathrm{g}$). FP–ARX$(n, n)$ modeling leads to an FP-ARX(62,62) representation with unity excitation–response delay and functional basis consisting of the first $p = 11$ Chebyshev II polynomials [75, p. 782]. Fault detection results are presented in Figure 12(a)–(d): A fault is detected if the point $k = 0$ lies outside the shaded zone (which is equivalent to the t statistic exceeding the critical values) at the $\alpha = 0.05$ risk level. Evidently, the detection results are very accurate; no fault is detected in test case I, while a fault is detected in every other case, including very clear detection for the "remote" fault of test case IV.

Once a fault is detected, its identification (localization) is based on the residual uncorrelatedness test of Figure 12(e): the pertinent statistic must be below

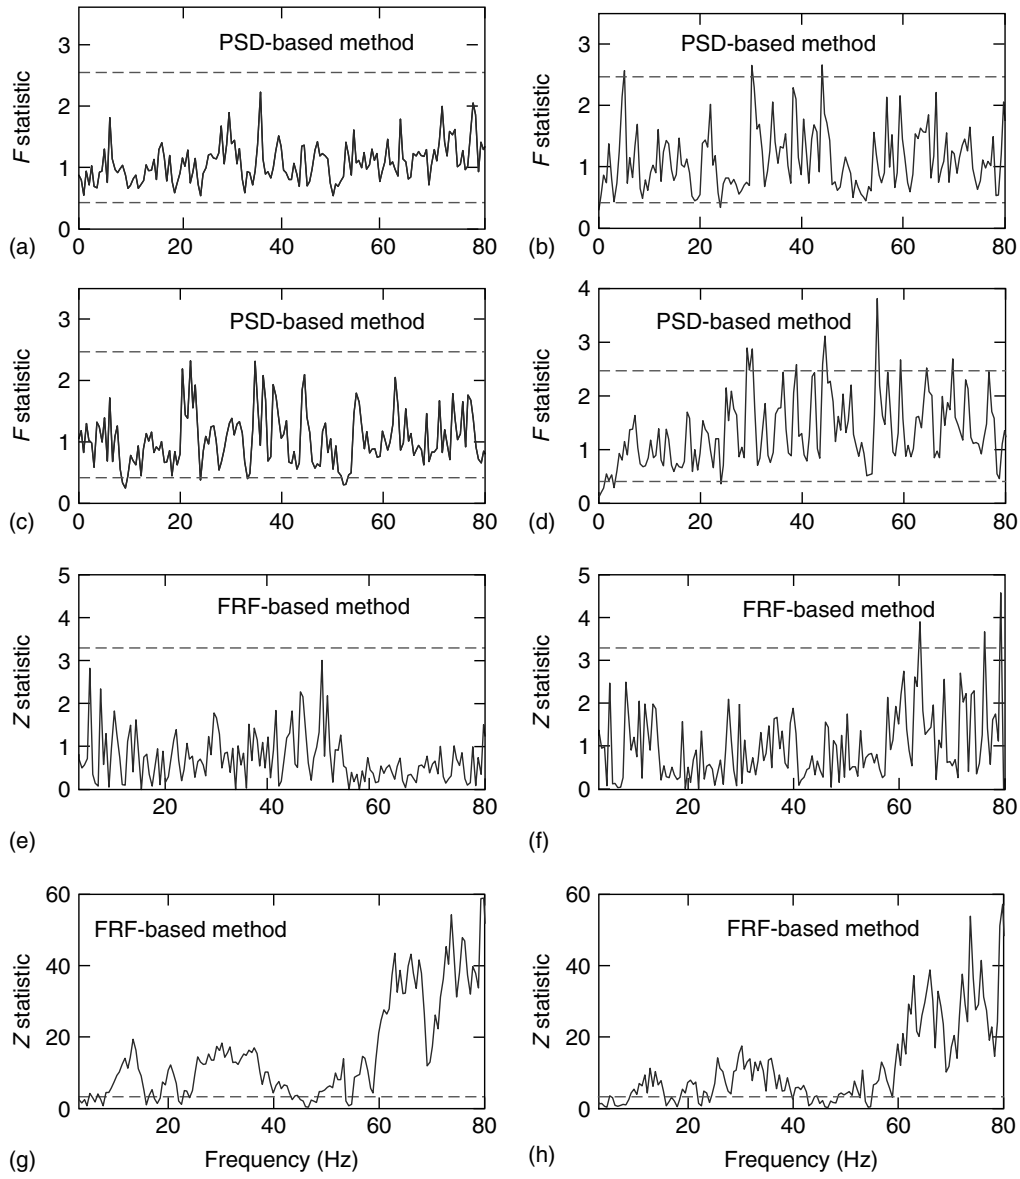

Figure 10. Fault detection results via nonparametric methods. (a–d) PSD-based method (risk level $\alpha = 0.05$); (e–h) frf-based method (risk level $\alpha = 0.001$). A fault is detected if the test statistic exceeds the critical points (dashed horizontal lines).

the critical value (dashed horizontal line; risk level $\alpha = 0.05$) for a fault to belong to fault mode (location) B. Evidently, all faults are correctly identified: the faults in test cases I–III are properly identified as belonging to fault mode B, while the fault in test case IV is very clearly and properly identified as not belonging to it (note that the healthy structure by definition belongs to any fault mode). For the faults confirmed as belonging to the modeled fault mode B (test cases I–III, but not test case IV), the shaded zones in Figure 12(a–c) then correspond to fault magnitude interval estimates (at the $\alpha = 0.05$ risk

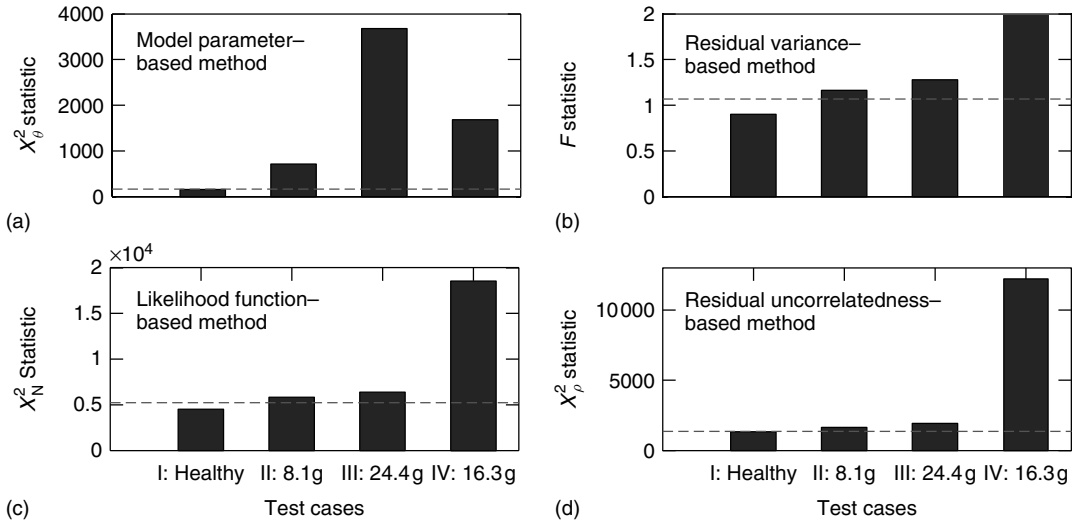

Figure 11. Fault detection results via parametric methods. (a) Model parameter; (b) residual variance; (c) likelihood function; and (d) residual uncorrelatedness-based methods. A fault is detected if the test statistic (bar) exceeds the critical point (dashed line; risk level $\alpha = 0.01$).

level), with the point estimates $(\widehat{k})$ indicated by the middle solid vertical line. The accuracy achieved in fault magnitude estimation is very good—it is worthwhile observing that the true fault magnitudes (dashed vertical lines) lie within the interval estimates.

8 CONCLUDING REMARKS

- Statistical time series methods for structural health monitoring achieve fault detection, identification (localization), and estimation based on (i) random excitation and/or vibration response signals, (ii) statistical model building, and (iii) statistical decision making under uncertainty.
- The methods are data based, inverse type, and thus of quite general applicability.
- In addition to sharing the benefits of general vibration-based methods—no visual inspection, "global" coverage, time and cost effectiveness, automation capability—statistical time series methods offer a number of unique advantages: (i) No need for physics–based or finite element models; (ii) no need for complete structural models (partial models and a limited number of responses suffice); (iii) inherent accounting of uncertainty; (iv) statistical decision making with specified performance characteristics; and (v) effective use of natural random vibration data records for in-operation structural health monitoring.
- On the other hand, statistical time series methods may identify a fault only to the extent allowed by the type of model used, require adequate expertise on part of the user, may offer limited physical insight, and sensitivity lower than that of "local" nondestructive testing-type methods.
- Statistical time series methods may be either of the nonparametric or parametric types. The latter are generally more elaborate, but offer improved capabilities particularly for the fault identification and estimation subproblems.
- Further research is necessary, in particular, for exploring the limits and limitations of the methods, as well as for tackling the less-studied fault identification (localization) and estimation subproblems.
- Research should be also devoted to attaining robustness under substantial uncertainty and varying environmental or operating conditions, achieving high levels of automation, the capability to work with large arrays of sensors, adaptation to real-time operation, as well as effective operation under nonGaussian environments and with nonlinear and time-varying structures.

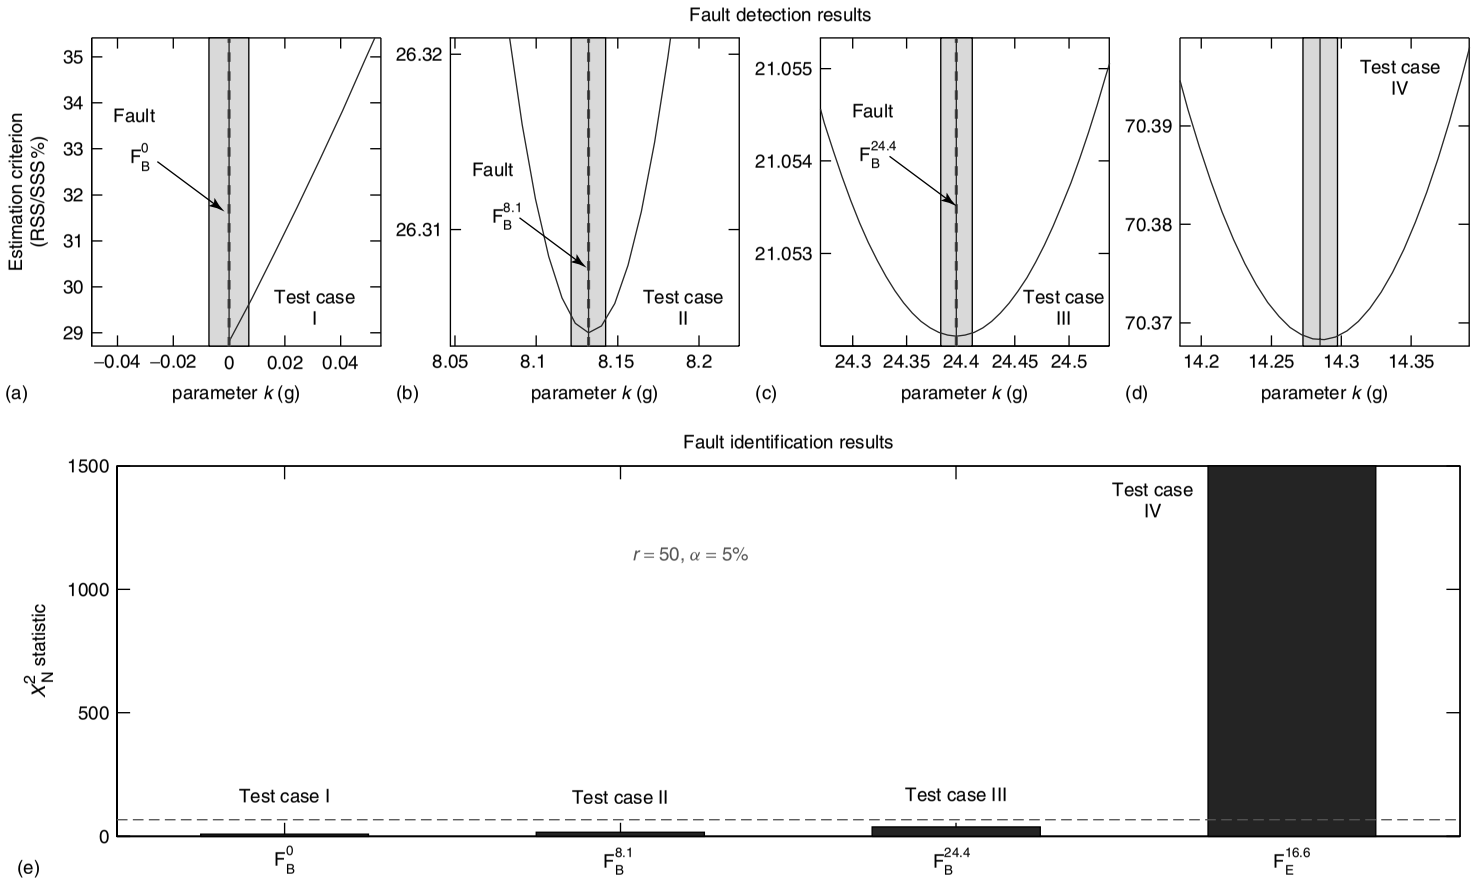

Figure 12. Fault detection, identification, and estimation results via the functional model–based method. (a–d) Fault detection results: a fault is detected if $k = 0$ lies outside the shaded zone ($\alpha = 0.05$). The curve shown is the estimation criterion as a function of the fault magnitude k. (e) Fault identification results: each fault is accepted as type B if the test statistic (bar) lies below the critical point (dashed horizontal line; $\alpha = 0.05$). For such faults, each shaded zone above then corresponds to the fault magnitude interval estimate at the $\alpha = 0.05$ risk level—the point estimate being indicated by the middle solid line and the true magnitude by the dashed line.

APPENDIX: CENTRAL LIMIT THEOREM AND STATISTICAL DISTRIBUTIONS ASSOCIATED WITH THE NORMAL

The central limit theorem (CLT)

([28, p. 46]; [44, p. 273], [76, Vol. I p. 420]). Let $Z_1, Z_2, \ldots Z_n$ designate mutually independent random variables each with mean μ_k and (finite) variance σ_k^2. Then, for $n \to \infty$ the distribution of the random variable $X = \sum_{k=1}^{n} Z_k$ approaches the Gaussian distribution with mean $E\{X\} = \sum_{k=1}^{n} \mu_k$ and variance $\text{var}(X) = \sum_{k=1}^{n} \sigma_k^2$.

The χ^2 distribution

Let $Z_1, Z_2, \ldots Z_n$ designate mutually independent, normally distributed, random variables, each with mean μ_k and standard deviation σ_k. Then the sum:

$$X = \sum_{k=1}^{n} \left(\frac{Z_k - \mu_k}{\sigma_k} \right)^2 \tag{A.1}$$

is said to follow a (central) χ^2 distribution with n degrees of freedom ($X \sim \chi^2(n)$). Its mean and variance are $E\{X\} = n$ and $\text{var}(X) = 2n$, respectively. Notice that imposing p equality constraints among the random variables $Z_1, Z_2, \ldots, Z_n$ reduces the set's effective dimensionality, and thus the number of degrees of freedom, by p [44, pp. 506–507].

For $n \to \infty$ the $\chi^2(n)$ distribution tends to normality [44, p. 523].

The sum $X = \sum_{k=1}^{n} Z_k^2/\sigma_k^2$ is said to follow noncentral χ^2 distribution with n degrees of freedom and noncentrality parameter $\lambda = \mu_k^2/\sigma_k^2$. This distribution is designated as $\chi^2(n;\lambda)$ [76, Vol. II p. 33].

Let $\boldsymbol{x} \in \Re^n$ follow n-variate normal distribution with zero mean and covariance $\boldsymbol{\Sigma}$ ($\boldsymbol{x} \sim \mathcal{N}(\boldsymbol{0}, \boldsymbol{\Sigma})$). Then the quantity $\boldsymbol{x}^{\mathrm{T}}\boldsymbol{\Sigma}^{-1}\boldsymbol{x}$ follows (central) χ^2 distribution with n degrees of freedom [30, p. 557]; [44, pp. 486–487], [47, p. 120].

The Student's t distribution

Let Z be the standard (zero mean and unit variance) normal variable. Let X follow a (central) χ^2 distribution with n degrees of freedom and be independent of Z. Then the ratio

$$T = \frac{Z}{\sqrt{X/n}} \tag{A.2}$$

is said to follow a Student's or t (central) distribution with n degrees of freedom (central because it is based on a central χ^2 distribution; [76, Vol. II p. 34]). Its mean and variance are $E\{T\} = 0$ ($n > 1$)

and $\mathrm{var}(T) = n/(n-2)$ $(n > 2)$, respectively [44, p. 513].

The (central) t distribution approaches the standard normal distribution $\mathcal{N}(0, 1)$ as $n \to \infty$ [44, p. 523].

The Fisher's F distribution

Let X_1, X_2 be mutually independent random variables following (central) χ^2 distributions with n_1, n_2 degrees of freedom, respectively. Then the ratio

$$F = \frac{X_1/n_1}{X_2/n_2} \tag{A.3}$$

is said to follow a (central) F distribution with n_1, n_2 degrees of freedom ($F \sim F(n_1, n_2)$) (central because it is based on central χ^2 distributions; [76, Vol. II p. 34]). Its mean and variance are $E\{F\} = n_2/(n_2 - 2)$ $(n_2 > 2)$ and $\mathrm{var}(F) = 2n_2^2(n_1 + n_2 - 2)/(n_1(n_2 - 2)^2(n_2 - 4))$ $(n_2 > 4)$, respectively [44, p. 518].

Note that for the distribution's $1 - \alpha$ critical point $f_{1-\alpha}(n_1, n_2) = 1/f_\alpha(n_2, n_1)$.

The (central) F distribution approaches normality as $n_1, n_2 \to \infty$. For $n_2 \to \infty$ $n_1 F$ approaches a (central) χ^2 distribution with n_1 degrees of freedom [44, p. 523].

Chapter 24

Cepstral Methods of Operational Modal Analysis

Robert B. Randall

School of Mechanical and Manufacturing Engineering, University of New South Wales, Sydney, NSW, Australia

1 INTRODUCTION

The cepstrum was originally proposed by Bogert *et al.* [1] as a better alternative to the autocorrelation function for detecting echo delay times, specifically for seismic signals. At that time, it was defined as the power spectrum of the logarithm of the power spectrum. The "power cepstrum" was later redefined [2] as the inverse Fourier transform of the log power spectrum, partly because it is more logical to use the inverse transform between a function of frequency and a function of time, and partly because it is then reversible to the power spectrum (e.g., after editing). At about the same time, the "complex cepstrum" was defined as the inverse Fourier transform of the complex logarithm of the complex spectrum [2], this being reversible to a time function, and, for example, permitting removal of echoes from a time signal. This article uses the complex cepstrum, and other versions that have the same property of retaining phase information from the spectrum. It is shown below that the complex cepstrum of minimum-phase functions can be obtained from the power cepstrum, since the phase is determined by the log amplitude. Thus, for a time signal $f(t)$, its complex cepstrum is defined as

$$C(\tau) = \Im^{-1}\{\log(F(f))\} = \Im^{-1}\{\ln(A(f)) + j\phi(f)\} \quad (1)$$

where

$$F(f) = \Im\{f(t)\} = A(f)\ \mathrm{e}^{j\phi(f)} \quad (2)$$

in terms of the amplitude and phase of the spectrum of $f(t)$. The phase function $\phi(f)$ must be unwrapped to a continuous function of frequency. The independent variable τ of the cepstrum has the dimensions of time but is known as *quefrency*. It is analogous to the time variable of the autocorrelation function, and represents lag time or periodic time rather than absolute time. It is worth noting that the "complex cepstrum" is real, because the log amplitude of the spectrum is even, and the phase spectrum is odd.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

For SIMO (single input, multiple output) systems, any output signal is the convolution of the input signal with the impulse response function of the transmission path, and this convolutive relationship is converted to an addition by the cepstrum operation as follows:

If

$$y(t) = f(t) * h(t) \tag{3}$$

then

$$Y(f) = F(f) \cdot H(f) \tag{4}$$

$$\log(Y(f)) = \log(F(f)) + \log(H(f)) \tag{5}$$

and

$$\Im^{-1}\{\log(Y(f))\} = \Im^{-1}\{\log(F(f))\} + \Im^{-1}\{\log(H(f))\} \tag{6}$$

The cepstrum is said to have "homomorphic" properties since it converts a convolution into an addition, meaning that deconvolution can be achieved by linear filtering (subtraction) [3].

It is this property that makes the cepstrum interesting for determining the dynamic properties of structures (modal analysis), since in the cepstrum of the response these are added to the cepstrum of the forcing function, under certain conditions in disparate regions, thus allowing separation without full knowledge of the force.

1.1 Terminology

In their original paper [1], Bogert *et al.* coined the word "cepstrum" by reversing the first syllable of "spectrum", the justification being that it was a "spectrum of a spectrum". Similarly, the word "quefrency" was obtained from "frequency", and the authors also suggested a number of others, including

rahmonic	from	harmonic
lifter	from	filter
short-pass lifter	from	low-pass filter
long-pass lifter	from	high-pass filter
gamnitude	from	magnitude
saphe	from	phase

Of these terms, the first four are useful in clarifying that the operations or features refer to the cepstrum, rather than the spectrum or time signal, and are still regularly used in the literature as well as in this article. Note that the autocorrelation function is also a "spectrum of a spectrum", so the distinctive feature of the cepstrum is the log conversion of the spectrum.

2 THE CEPSTRUM OF STRUCTURAL TRANSFER FUNCTIONS

To determine the cepstrum of structural transfer functions, it is convenient to assume that all signals are digitized, so that the Fourier transform can be replaced by the Z transform. For a general impulse response function,

$$h(n) = \sum_{i=1}^{2N} A_i \, \mathrm{e}^{s_i n \Delta t} = \sum_{i=1}^{2N} A_i z_i^n \tag{7}$$

where the A_i are residues, s_i and z_i poles in the S plane and Z plane, respectively, and Δt the time sample spacing, the transfer function in the Z plane is given by

$$H(z) = \frac{Bz^r \prod_{i=1}^{M_i} (1 - a_i z^{-1}) \prod_{i=1}^{M_0} (1 - b_i z)}{\prod_{i=1}^{N_i} (1 - c_i z^{-1}) \prod_{i=1}^{N_0} (1 - d_i z)} \tag{8}$$

where the c_i and a_i are poles and zeros inside the unit circle in the Z plane, respectively, and the d_i and b_i are the (reciprocals of the) poles and zeros outside the unit circle, respectively (so that $|a_i|, |b_i|, |c_i|, |d_i| < 1$). Oppenheim and Schafer [3] showed that for this transfer function $H(z)$ the cepstrum can be represented as

$$\begin{aligned} C_h(n) &= \ln(B), && n = 0 \\ C_h(n) &= -\sum_i \frac{a_i^n}{n} + \sum_i \frac{c_i^n}{n}, && n > 0 \\ C_h(n) &= \sum_i \frac{b_i^{-n}}{n} - \sum_i \frac{d_i^{-n}}{n}, && n < 0 \end{aligned} \tag{9}$$

Here, the discretized time variable n represents quefrency, and the time delay represented by z^r in equation (8) should first be removed.

The development is illustrated by taking the log of the c_i terms (poles inside the unit circle) as follows:

$$-\sum_{i=1}^{N_i}\log(1-c_i z^{-1}) = \sum_{i=1}^{N_i}\sum_{n=1}^{\infty}\frac{c_i^n}{n}z^{-n}$$
$$= \sum_{n=1}^{\infty}\left(\sum_{i=1}^{N_i}\frac{c_i^n}{n}\right)z^{-n} = \mathrm{Z}\left\{\sum_{i=1}^{N_i}\frac{c_i^n}{n}\right\} \qquad (10)$$

so that the cepstrum for those terms is given by the inverse Z transform as $\sum_{i=1}^{N_i}(c_i^n/n)$, as in equation (9), and the other terms are completely analogous.

From equation (9) it can be seen that for minimum-phase functions, with no zeros or poles outside the unit circle, the cepstrum is zero for negative quefrency, and is thus causal. For this reason, the real and imaginary parts of the Fourier transform of the cepstrum of minimum-phase functions (i.e., the log amplitude and phase of the spectrum) are related by a Hilbert transform, so the complex cepstrum can be obtained from the log amplitude spectrum alone, avoiding the necessity to measure or unwrap the phase [3]. The real, even cepstrum obtained by inverse transforming the log amplitude spectrum is converted into the complex cepstrum of the minimum-phase function by doubling the value of positive quefrency components, and setting negative quefrency components to zero (i.e., by multiplying it by $2H(\tau)$ where H is the Heaviside function).

There is another related function with homomorphic properties known as the "differential cepstrum" [4], which is defined as the inverse transform of the derivative of the log spectrum; thus,

$$C_d(\tau) = \mathrm{Z}^{-1}\left\{\frac{\mathrm{d}}{\mathrm{d}z}[\log H(z)]\right\} = \mathrm{Z}^{-1}\left\{\frac{H'(z)}{H(z)}\right\} \qquad (11)$$

Since taking the derivative in one domain corresponds to multiplication by the independent variable in the other domain, the differential cepstrum can be written in terms of the poles and zeros in the Z plane (*cf* equation 9) as

$$C_{hd}(n) = -\sum_i a_i^n + \sum_i c_i^n, \quad n > 0$$

$$C_{hd}(n) = \sum_i b_i^{-n} - \sum_i d_i^{-n}, \quad n < 0 \qquad (12)$$

Note that in [4] these equations are given for quefrency displaced by one sample ($0 \rightarrow 1$), but the zero origin has been maintained here to emphasize the similarity with the complex cepstrum.

It will be recognized that the form of the differential cepstrum (sums of complex exponentials) is the same as that of the impulse response function, and this can be used for parameter extraction as shown below.

Another advantage of the differential cepstrum is that it can be directly calculated from a time signal as

$$C_{hd}(n) = \Im^{-1}\left[\frac{\Im\{n\ x(n)\}}{\Im\{x(n)\}}\right] \qquad (13)$$

which avoids the necessity to unwrap the phase of the spectrum.

Another version proposed by Antoni *et al.* [5] is the "mean differential cepstrum" (MDC), which is formally defined in terms of the partial derivative of the logarithm of the spectral correlation function, but can be calculated by a formula similar to equation (11), to which it reverts for a single realization:

$$C_{hmd}(\tau) = \Im^{-1}\left\{\frac{E[H'(f)\ H^*(f)]}{E[H(f)\ H^*(f)]}\right\} \qquad (14)$$

This permits averaging over a number of realizations, for example, of the response of a system excited by a burst random sequence and Antoni demonstrates in [5] that this gives a more repeatable result.

3 MODAL ANALYSIS USING THE CEPSTRUM OF RESPONSE SIGNALS

Where the log spectrum of the excitation is relatively smooth and flat (e.g., excitation by an impulse), its cepstrum is very short and the higher quefrency part of the cepstrum of the response is completely dominated by the structural function. It is possible to curve fit this part of the cepstrum for the poles and zeros of the transfer function as illustrated in Figure 1 (from [6]).

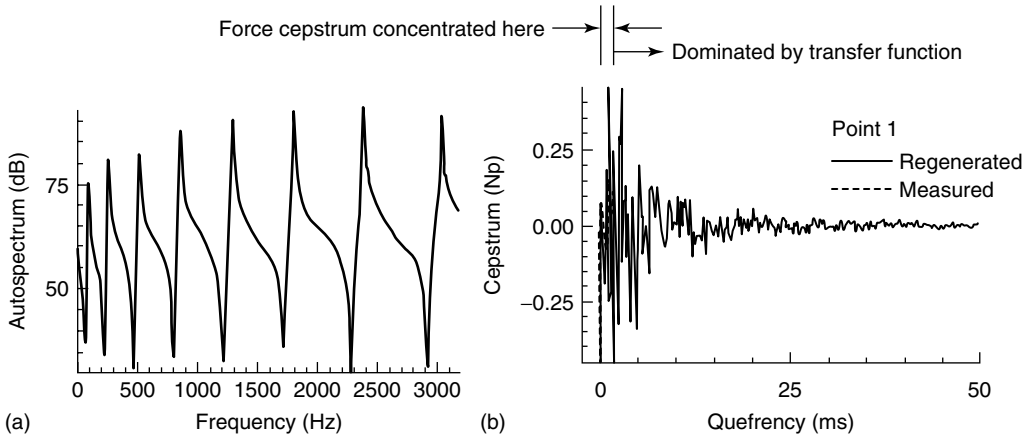

Figure 1. Extraction of the complex cepstrum of a transfer function from the response autospectrum of a beam excited by a hammer blow (a) driving point response autospectrum (b) measured and regenerated cepstra. [Reproduced from Ref. 6. © Elsevier, 1996.]

Figure 1(a) shows the response autospectrum at the driving point (one end) of a free–free beam excited by a hammer blow. Noise in the response is negligible. Figure 1(b) shows the cepstrum derived from this and the cepstrum of the transfer function obtained from it assuming minimum-phase properties. Equations of the form of (7) were curve fitted for the poles and zeros inside the unit circle using a least squares optimization (Levenberg–Marquardt) method [6]. The cepstrum of the transfer function was then regenerated using equation (7). It is seen that the regenerated and measured cepstra correspond almost perfectly at the higher quefrencies dominated by the transfer function. Equally good results were obtained in [6] by curve fitting the differential cepstrum, using both the Levenberg–Marquardt method and the ITD (Ibrahim time domain) method originally developed for extracting impulse responses from free decay vibration signals.

When an attempt was made to regenerate the frequency response functions (FRFs) from the curve-fitted poles and zeros, it was realized that there are two pieces of information that are lacking to fully restore them:

1. an overall scaling factor that is part of the zero quefrency value of the cepstrum, which is not curve fitted and
2. an equalization curve due to the lack of residual information from out-of-band modes that are excluded from the measured cepstrum.

In [7], it is described how this information can be obtained by other means from earlier or similar FRFs, for example, a finite element (FE) model of the structure. Neither of the two above factors is sensitive to small changes in the exact pole and zero positions, and so it is possible to track slow changes in the dynamic properties (such as from a developing crack) or update the FE model to have the correct (measured) in-band poles and zeros.

Figure 2 illustrates the results of both types of model updating on the free–free beam excited by hammer blows [7]. Since these FRFs have minimum-phase properties, the autospectra were used for generating the cepstra. The particular result shown is for excitation at one end and response measured near the middle, giving a number of zeros approximately half the number of poles. In [7], it is shown that the amount of correction required by the equalization function depends on the imbalance of zeros and poles in the (truncated) out-of-band region. For a driving point measurement, with the same number of poles and zeros, the correction required is minimal, since the poles and zeros can be arranged in pairs that almost balance each other in terms of amplitude and phase correction.

The advantage of the cepstral method of regenerating FRFs, compared with other methods from response measurements only, is that the zeros contain much of the information in the residues of the FRF, and when combined with the scaling and equalization

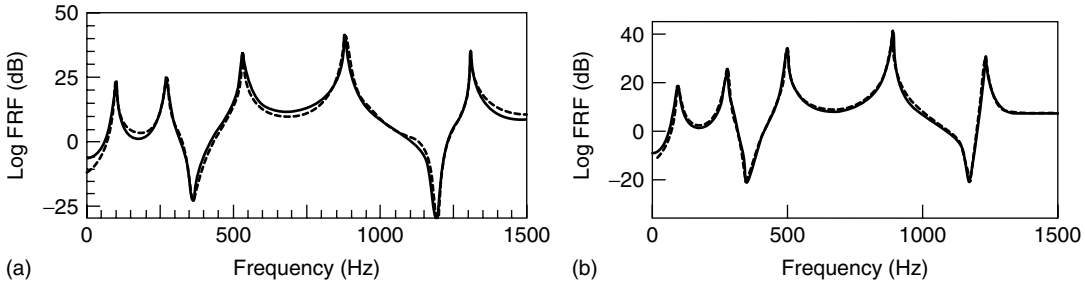

Figure 2. Use of the cepstrum to update FRFs from response measurements of a free–free beam excited by hammer blows (dashed line—measured and solid line—regenerated). [Reproduced from Ref. 7. © Elsevier, 1996.] (a) Updated FE model from cepstrum of response autospectrum and (b) model further updated to track the effects of a slot in the middle of the beam affecting the symmetric modes. Note the reduction in frequency of the odd-numbered modes.

information give the possibility of obtaining fully scaled modes that can be used for predicting forced response. Figure 2(a) was obtained by combining the in-band poles and zeros extracted from the measured autospectra with equalization and scaling information obtained from an approximate FE model of the beam as discussed below. Figure 2(b) also illustrates that these methods can be used to track changes due to increasing damage (in this case a deepening slot), and the same scaling and equalization information could be used for this further development, illustrating its insensitivity to the detailed positions of the poles and zeros. As discussed in the next section, it is possible to extract scaled mode shapes with accurate natural frequencies, and changes in either or both could be used to track the development of the "crack". This indicates a potential application to structural health monitoring.

Figure 3 (from [7]) illustrates the changes in natural frequencies due to the increasing slot, which were tracked by the cepstral method.

3.1 Obtaining scaled modes from response measurements

In [7], the equalization was done using "phantom zeros" [8], extra in-band zeros added to a transfer function to compensate for missing out-of-band poles and zeros, as commonly done in modal analysis curve-fitting software [9] to obtain a match between measured data and theoretical models. The overall scaling was done on the basis of low-frequency values, which can be inferred from static inertial properties for free–free systems or static stiffness properties for restrained systems. Later, it was realized that both corrections could be obtained by the simple expedient of comparing the amplitudes of the regenerated FRFs (on log scales) using only the in-band poles and zeros, with close estimates of the true FRF based on a similar measurement or an approximate FE model. The dB difference curve, smoothed by "short-pass liftering" to remove high-quefrency errors gives a good estimate of the scaled equalization curve. Figure 4 gives an example from [10] showing an equalization curve generated in this way, together with the two curves from which it was derived and the corrected estimate. It will be noted that the equalization curve in that example has some ripple, which represents the major source of error in the final estimate, but it should be possible to reduce this by using an improved smoothing, as well as adding an estimated "mass line" (from static properties) to the FRF calculated from the in-band poles and zeros.

Note that the compensation given by the equalization curve is purely for out-of-band modes and is virtually independent of the color of the excitation as long as the spectrum of the latter is reasonably smooth and flat. This obviates the requirement of many operational modal analysis techniques where the excitation is assumed white.

The procedure proposed in [10] for obtaining scaled mode shapes is illustrated in Figure 5.

The FE model to be used for equalization and scaling should first be updated using resonance (pole) information from any operational modal analysis (OMA) technique, including the cepstral techniques

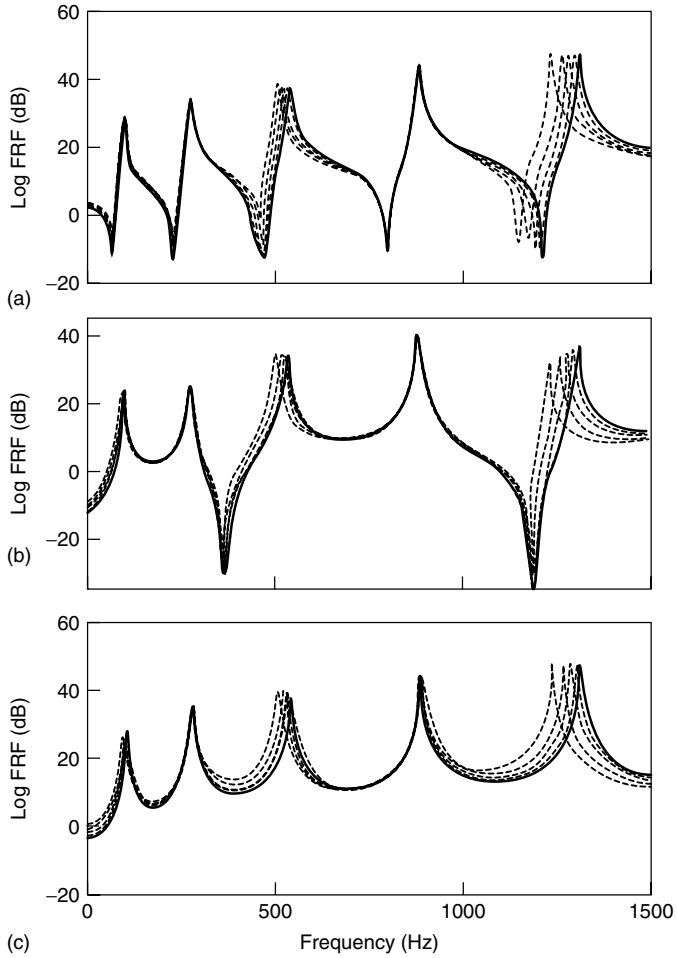

Figure 3. Changes in the FRFs between one end of a free–free beam and (a) the same point, (b) near the middle, and (c) the other end due to a slot cut progressively in the middle of the beam to a final depth of half the thickness.

proposed here. Note that most FE model updating techniques (e.g., [11]) use only resonance information. The resulting FRFs should be more accurate than the original estimates at low frequencies, which is important for the scaling. For free–free objects, the "mass" matrix should be reasonably well estimated even before updating, but for constrained objects the original stiffness matrix will usually suffer from poor estimates of joint stiffness, etc., and a good fit to the lowest modes will go a long way toward improving the stiffness matrix and the estimates of static stiffness that are important for scaling.

Otherwise, the updated model does not have to be perfect to obtain good results. Figure 6 shows the example from [10] where after updating there are still discrepancies at high frequencies, and in the estimated damping.

The equalization curves from the updated FE model are used to obtain scaled FRFs using the (in-band) pole and zero information from the cepstral curve-fitting method. Figure 7 gives two examples of the corrected FRFs from [10] using this approach. There are two main errors evident in these results:

1. Local amplitude deviations coming from the ripple referred to above, the reduction of which should be possible.

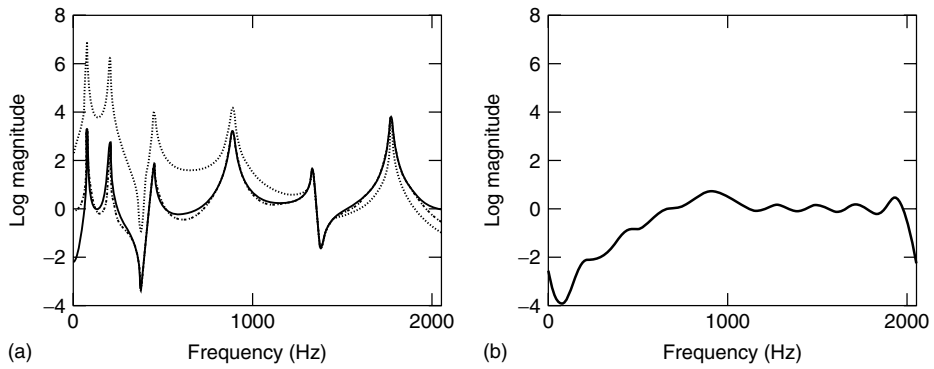

Figure 4. Typical FRFs (a) reference (solid line), regenerated (· · · ·) and scaled (– · – · –), and the corresponding equalization curve (b). [Reproduced from Ref. 10. © Elsevier, 2007.]

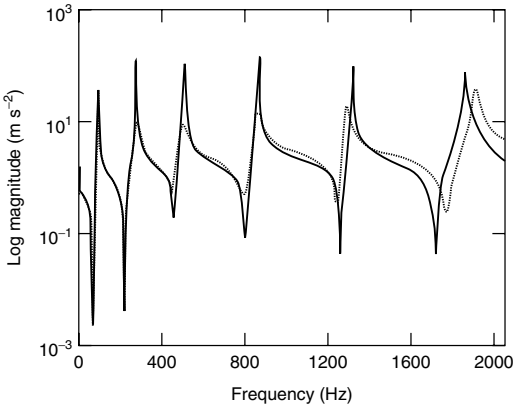

Figure 6. Comparison of the driving point FRF from measurement (solid line) and from the updated finite element model (dashed line). [Reproduced from Ref. 10. © Elsevier, 2007.]

2. Differences in frequency of the modes, most evident at the higher frequencies. These are purely the result of the fact that the measurement object in this case was a steel beam excited by two small shakers, so that the identified resonances were those of the beam plus shaker moving elements, somewhat lower than those of the beam alone. This is a problem common to any OMA technique, but exacerbated in many laboratory experiments as opposed to real practical situations where the actual excitation does not give added mass.

Despite these minor errors, the resulting mode shapes compared very well with the true measured ones, including with respect to scaling.

3.2 The mean differential cepstrum

Antoni *et al.* in [5] have shown that mixed-phase FRFs can be obtained using the MDC even in the presence of noise in the signals. A typical result is shown in Figure 8.

4 MIMO SITUATION

In the above cases, there was only one effective excitation force applied in one degree of freedom (DOF). In most cases, in practice, there are several sources acting simultaneously, which gives a MIMO (multiple

input, multiple output) situation. In that case, the response at any point is a sum of convolutions, so that equation (6) no longer applies. It is necessary to separate out the response(s) to a single source applied in a single DOF. Several ways of achieving this have been attempted.

4.1 Periodic impulsive excitation

Since the excitation must have a flat spectrum, it must either be impulsive or broadband random. If a periodic impulse can be applied in one DOF, the response to it can be extracted by synchronous averaging. Experiments were made on a free–free beam with two excitations, one periodic impulsive and the other broadband random, applied by small shakers [12]. The intended application was to the determination of the modal properties of a rail vehicle, by mounting one wheel with a flat.

Figure 9(a) shows a typical response spectrum, where the apparently shaded area is actually separate harmonic lines of the periodic part, with a separation of 1 Hz. The continuous part of the spectrum at the base is dominated by the random part. Figure 9(b) shows the spectrum of the periodic part (one period only, so that the spectrum appears continuous), which was extracted by synchronous averaging. Figure 9(c) shows the averaged power spectrum of the residual random signal. Each individual spectrum in the average has four times better resolution than that of the periodic part, as does the averaged spectrum.

Since the spectrum of the periodic part has limited resolution, determined by the fundamental frequency, it was proposed that it could be used to determine the residues (and/or zeros) of the SIMO FRF representing the response to the periodic excitation only, and possibly the frequencies of the poles, but, in particular, the accuracy of the damping would be limited by the resolution.

On the other hand, since the frequencies and damping of the poles are global values, they can be determined with more accuracy from the broadband part of the spectrum, even if they correspond to MIMO or distributed excitation. In [13], a number of methods are compared for determining the frequency and damping of the poles from the broadband residual spectrum, after the poles and zeros (and thus implicitly the residues) are obtained using the cepstrum on the periodic part.

4.2 Cyclostationary input

An *n*th-order cyclostationary signal is defined as one whose *n*th-order statistics are periodic. Thus, a first-order cyclostationary signal has a periodic mean

value (e.g., a periodic signal plus noise), while a second-order cyclostationary signal has a periodic variance (e.g., a white noise modulated by a sinusoid). Many practical signals have cyclostationary properties, and if only one of the excitations in an MIMO situation has second-order cyclostationary properties at a particular cyclic frequency, it is possible to separate out the response to it at each measurement point, thus reducing the problem to SIMO, and allowing the use of cepstral techniques to separate the forcing and transfer functions.

The so-called spectral correlation function allows signals to be separated into periodic, stationary random, and cyclostationary components. It can be obtained from the generalized autocorrelation function defined as

$$R_{yy}(t, \tau) = E[y(t - \tau/2)y(t + \tau/2)] \quad (15)$$

by a two-dimensional Fourier transform with respect to lag τ (into normal frequency f) and time t (into cyclic frequency α). Thus, the Fourier transform in the τ direction gives continuous spectra from the transformation of a transient, while the Fourier transform in the t direction (actually a Fourier series) gives discrete components at the harmonics of the cyclic frequency because of the periodicity in this direction. Note that periodic (or first-order cyclostationary) signals have a spectral correlation function, which is discrete in both directions (a "bed of nails"), but if the mean value is first subtracted only second-order components are left. These can be separated from stationary random components, which only appear at zero cyclic frequency because they do not vary with time, by definition.

The spectral correlation can also be directly calculated in the frequency domain using the formula

$$S_y^\alpha(f) = \lim_{W\to\infty} \frac{1}{W} \mathrm{E}\left\{ Y_W\left(f + \frac{\alpha}{2}\right) Y_W^*\left(f - \frac{\alpha}{2}\right)\right\} \quad (16)$$

where second-order cyclostationarity is assumed at cyclic frequency α. Note that at $\alpha = 0$ the normal autospectrum is obtained.

It can be shown as in [14] that the structural dynamic properties are contained in the spectral correlation of a response signal $y(t)$ at cyclic frequency α. For minimum-phase systems, it is convenient to use the asymmetrical version of equation (16)

$$S_y^\alpha(f) = \lim_{W\to\infty} \frac{1}{W} \mathrm{E}\{Y_W(f) Y_W^*(f - \alpha)\} \quad (17)$$

Substituting the relationship $Y(f) = H(f)X(f)$ into equation (17) gives

$$S_y^\alpha(f) = H(f)H^*(f - \alpha)S_x^\alpha(f) \quad (18)$$

Taking the log and inverse Fourier transform to obtain the cepstrum

$$C_y^\alpha(\tau) = C_h(\tau) + C_h(-\tau)\ \mathrm{e}^{j2\pi\alpha\tau} + C_x^\alpha(\tau) \quad (19)$$

meaning that the response cepstrum at cyclic frequency α contains the cepstrum of the transfer function and only the input at cyclic frequency α.

Moreover, for minimum-phase systems the cepstrum is zero for negative quefrency and for broadband excitation functions has a short cepstrum equal to zero for $|\tau| > \tau_0$. Thus

$$C_y^\alpha(\tau) = C_h(\tau), \quad \tau > \tau_0 \quad (20)$$

In [14], it is shown that a somewhat more complex procedure can be used for nonminimum phase systems, where both the positive and negative quefrency parts of the cyclic cepstrum are used. The symmetric definition of the spectral correlation (equation 16) can then be used, where the cyclic cepstrum will be phase shifted for both positive and negative quefrencies.

The minimum-phase approach was applied in [14] to vehicles driven by internal combustion engines, such as diesel railcars, a result from which is presented in Figure 10, although the excitation in that case was a burst random signal applied by a shaker. Figure 10 shows the spectral correlation (cyclic spectrum) for a typical response measurement.

The spectral correlation at cyclic frequency $\alpha = 1/T$ was analyzed using the cyclic cepstrum as one of a number of SIMO responses, and gave scaled mode shapes very similar to those measured directly (see Figure 11 for an example).

Many naturally occurring signals are cyclostationary rather than periodic, so it is possible that this

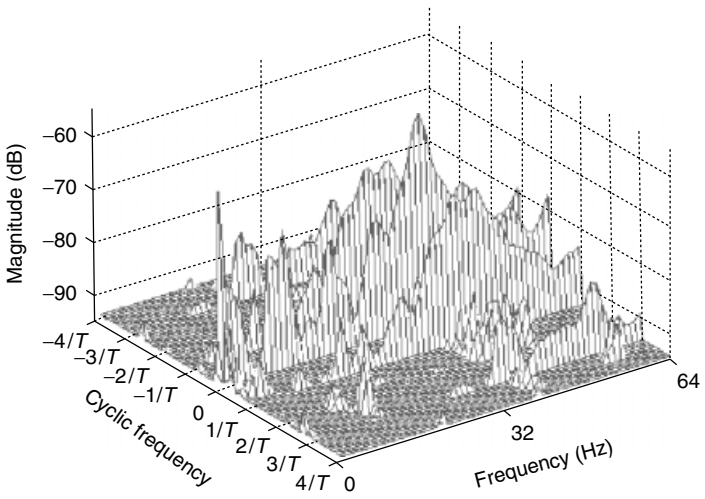

Figure 10. Cyclic spectrum of a response measurement from a passenger rail vehicle. [Reproduced from Ref. 14. © Elsevier, 2007.].

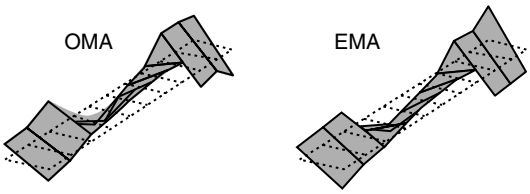

Figure 11. Comparison of mode shapes from cyclic cepstrum analysis (OMA) and direct experimental modal analysis (EMA).

technique might be applicable to OMA of structures excited by such signals.

4.3 Blind source separation

In recent years, there has been a steady development in the topic of blind source separation (BSS), initially with applications in telecommunications, but later increasingly with applications in mechanical problems [15, 16]. The idea is to separate out the responses to a number of sources at a number of measurement points, with no direct knowledge of the sources or transmission paths, but based solely on the assumption that the different sources are statistically independent.

In most mechanical problems, there is a variable transmission path from each source to each measurement point, and the mixing is convolutive, as represented by the equation:

$$\mathbf{Y}(t_n) = \mathbf{h} * \mathbf{X}(t_n) \quad \text{where} \quad \mathbf{h} = [h_{ij}]_{N\times M} \tag{21}$$

the matrix of impulse response elements h_{ij} as a mixing system convolved with the source signals.

The (Fourier transformed) FRF matrix $\mathbf{h}$ can be decomposed by SVD (singular value decomposition) as

$$\mathbf{h} = \mathbf{UDV} \tag{22}$$

where $\mathbf{U}$ and $\mathbf{V}$ are unitary (rotational) matrices, and $\mathbf{D}$ is a diagonal (scaling) matrix. $\mathbf{U}$ and $\mathbf{V}$ have the property that $\mathbf{UU}^{\mathrm{H}} = \mathbf{VV}^{\mathrm{H}} = \mathbf{I}$, the identity matrix (superscript H means Hermitian transpose).

From the response vector $\mathbf{Y}$, it is possible to form the cross spectral matrix:

$$\mathbf{S} = \mathrm{E}[\mathbf{Y}\ \mathbf{Y}^{\mathrm{H}}] \tag{23}$$

and substituting equation (22) in the frequency domain (multiplicative) gives

$$\begin{aligned}\mathbf{S} &= \mathrm{E}[\mathbf{UDVX}\ \mathbf{X}^{\mathrm{H}}\mathbf{V}^{\mathrm{H}}\mathbf{D}^{\mathrm{H}}\mathbf{U}^{\mathrm{H}}] \\ &= \mathbf{UDV}\ \mathrm{E}[\mathbf{XX}^{\mathrm{H}}]\mathbf{V}^{\mathrm{H}}\mathbf{D}^{\mathrm{H}}\mathbf{U}^{\mathrm{H}} \\ &= \mathbf{UD}^2\mathbf{U}^{\mathrm{H}}\end{aligned} \tag{24}$$

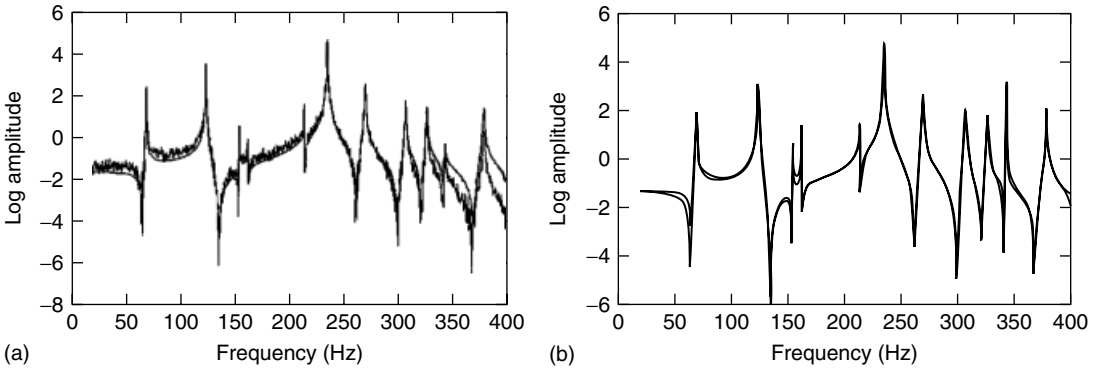

Figure 12. Reconstruction of an FRF using SVD and cepstral curve fitting. [Reproduced with permission from Ref. 17. © KUL, 1998.] (a) Comparison of first principal autospectrum with the corresponding FRF and (b) comparison of measured and regenerated FRFs.

since the source vector **X** has independent components and without loss of generality can be taken to be spatially white (any differences in gain can be assigned to the transfer functions). Thus, **U** and **D** can be found by SVD, but not the further rotational matrix **V** required to determine **h** completely.

4.3.1 Separation by SVD alone

In [17], it was found purely empirically that if one of the sources was dominant, i.e., with rms value greater than the others by a factor of at least 4, then SVD alone gave a reasonable separation, at least in terms of the zeros of the autospectrum of the first principal component obtained by SVD. Figure 12(a) compares the extracted principal autospectrum with the FRF between the dominant forcing function and the measurement point corresponding to the autospectrum. In this case, the measurement object was a steel frame excited by two broadband sources in different points, one four times stronger than the other. It is seen that the poles and zeros coincide, even though the forcing spectrum was not completely white, but rolling off by about 15 dB toward the higher frequencies. Figure 12(b) shows that the FRF reconstructed by the same method as Figure 2 corresponds very well with that measured directly, using the forces that were measured at the same time as the responses.

Note that the cepstral curve fitting was able to determine accurate pole and zero values (by least squares optimization) even in the presence of noise in the autospectrum caused by the limited number of averages. Moreover, because the reconstructed FRFs were scaled, it was possible to perform a modal analysis with scaled modes.

4.3.2 Separation by other means

Currently, a number of studies are under way to effect true blind separation using other means. It is necessary to use further information to determine the unknown rotational matrix **V**. One possibility discussed in [15] is to use higher order statistical (HOS) properties (such as different kurtosis) to effect the separation, but this limits the sources (except possibly one) to be non-Gaussian since the HOS properties of Gaussian signals are zero (*see* **Higher Order Statistical Signal Processing**). A problem with many of the methods that have been developed to date (for example, for applications in telecommunications) is that the number of sources must be known in advance, and each must be independent and applied in a single DOF. Many mechanical excitations are distributed and/or correlated at different excitation points, so the best potential appears to be the methods that separate out the response to a single source (among an unknown number), which is independent of the others and applied in a single DOF. Note that the convolutive mixing of equation (21) becomes multiplicative in the frequency domain, giving the possibility to use methods developed for the case of simple multiplicative mixtures, e.g., independent components analysis (ICA). However, these suffer from three problems:

1. An unknown gain factor between the components. This corresponds to an unknown filter in the convolutive mixture, but is not a big problem where only the responses to each source are to be separated and not the sources themselves. After separation to a SIMO situation, the cepstral methods can determine the filter functions.
2. An unknown permutation of the separated components at each frequency, which must be resolved before all frequency components can be combined to form time signals. A method is proposed in [18].
3. The fact that frequency analysis into narrow bands tends to make any signal more Gaussian and thus more difficult to be separated by HOS techniques. This is influenced by the resolution of the practical fast Fourier transform (FFT) analysis, and the spectral kurtosis can be used as a guide to the choice of resolution [18].

4.4 MIMO version of the mean differential cepstrum

In [5], Antoni proposed a MIMO version of the MDC, without developing it further. By analogy with equation (14) a matrix version of it is proposed, which does not use the logarithm explicitly. The basic derivation is as follows:

$$\begin{aligned}\mathbf{D}_{yy} &= \mathrm{E}\left(\mathbf{Y}'\mathbf{Y}^{\mathrm{H}}\right) \quad \mathrm{E}\left(\mathbf{Y}\mathbf{Y}^{\mathrm{H}}\right)^{-1} \\ &= \mathrm{E}\left(\left[\mathbf{h}'\mathbf{X} + \mathbf{h}\,\mathbf{X}'\right]\left[\mathbf{X}^{\mathrm{H}}\mathbf{h}^{\mathrm{H}}\right]\right) \\ &\quad \times \mathrm{E}\left([\mathbf{h}\ \mathbf{X}]\left[\mathbf{X}^{\mathrm{H}}\mathbf{h}^{\mathrm{H}}\right]\right)^{-1} \\ &= \Big[\mathbf{h}'\underbrace{\mathrm{E}\left(\mathbf{X}\mathbf{X}^{\mathrm{H}}\right)}_{\mathbf{I}}\mathbf{h}^{\mathrm{H}} + \mathbf{h}\underbrace{\mathrm{E}\left(\mathbf{X}'\mathbf{X}^{\mathrm{H}}\right)}_{\left[\ddots jC\right]}\mathbf{h}^{\mathrm{H}}\Big] \\ &\quad \times \Big[\mathbf{h}\underbrace{\mathrm{E}\left(\mathbf{X}\mathbf{X}^{\mathrm{H}}\right)}_{\mathbf{I}}\mathbf{h}^{\mathrm{H}}\Big]^{-1}\end{aligned}$$

$$\mathbf{D}_{yy} = \left[\mathbf{h}'\mathbf{h}^{\mathrm{H}} + \mathbf{h}\left[\ddots jC\right]\mathbf{h}^{\mathrm{H}}\right] \quad \left[\mathbf{h}\mathbf{h}^{\mathrm{H}}\right]^{-1}$$

$$\mathbf{D}_{yy}\left[\mathbf{h}\mathbf{h}^{\mathrm{H}}\right] = \mathbf{h}'\mathbf{h}^{\mathrm{H}} + \mathbf{h}\left[\ddots jC\right]\mathbf{h}^{\mathrm{H}}$$

$$\mathbf{D}_{yy}\mathbf{h} = \mathbf{h}' + \mathbf{h}\left[\ddots jC\right]$$

$$\mathbf{h}' - \mathbf{D}_{yy}\mathbf{h} = 0 \tag{25}$$

The same assumptions are made as for equation (24) and, in addition, the purely imaginary time shift constants $\left[\ddots jC\right]$ can be arbitrarily set to zero because response signals have no zero time reference.

This is seen to result in a matrix differential equation (DE) in $\mathbf{h}$ for which there is no closed-form solution, but can be solved numerically by finite difference methods. A recent PhD thesis [19] has examined this possibility in some depth, but problems still remain. In [19], the matrix DE is developed further to give a similar matrix DE in terms of the unknown unitary matrix $\mathbf{V}$, which is somewhat more well behaved than $\mathbf{h}$, and thus easier to solve for by numerical means. Since the solution of the DE is propagative from one frequency to the next (starting from known static values near zero frequency) the permutation problem is resolved. One result from [19] is that if the matrix method is collapsed to a scalar problem, the propagative method gives an alternative way of producing the MDC, which may be found to have advantages in some situations.

Despite suffering from noise problems at this stage, these matrix methods are presented because they may be further developed in the future.

5 CONCLUSION

The cepstrum has valuable properties for determining modal properties from response measurements, since in the SIMO case the contributions of the forcing and transfer functions are additive. In addition, if the force spectrum is smooth and flat (impulsive or broadband random), its cepstrum is short, and the remainder of the response cepstrum can be curve fitted for the poles and zeros of the transfer function. With some a priori information, this gives the possibility of obtaining scaled modal properties, which is very difficult with other methods. Since operational measurements normally represent an MIMO situation, various methods are discussed to effect BSS, so as to convert the MIMO situation to a sum of SIMOs (or at least extract one SIMO system of interest) and thus permit the cepstral methods to be used more generally.

While not yet specifically applied to structural health monitoring, the successful tracking of the development of a slot in a beam (simulating a crack)

indicates the potential of these methods for this purpose.

Chapter 25

Hilbert Transform, Envelope, Instantaneous Phase, and Frequency

Michael Feldman

Technion–Israel Institute of Technology, Haifa, Israel

1 INTRODUCTION

The Hilbert transform (HT), as a kind of integral transformation, plays a significant role in signal processing, vibration analysis, dynamic system monitoring, diagnostics, and identification. The HT was first introduced to signal theory by Denis Gabor in 1946. He defined a generalization of the well-known Euler formula $e^{iz} = \cos(z) + i\sin(z)$ in the form of the complex function $Y(t) = u(t) + iv(t)$, where $v(t)$ is the HT of $u(t)$ [1]. In signal processing, when the independent variable is time, this associated complex function is known as the *analytic signal* and the HT $v(t)$ is called *quadrature* (or *conjugate*) *function* of $u(t)$. The application of the HT to the initial signal provides some additional information about amplitude, instantaneous phase, and frequency of vibrations. This information can be useful when applied to analysis of vibration motions, including a decomposition of the signal into its simplest components and an inverse problem of vibration system identification.

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

2 NOTATION

The HT of the function $x(t)$ is defined by an integral transform [1]:

$$H[x(t)] = \tilde{x}(t) = \pi^{-1} \int_{-\infty}^{\infty} \frac{x(\tau)}{t - \tau} \, d\tau \qquad (1)$$

Because of the possible singularity at $t = \tau$, the integral is to be considered as a Cauchy principal value. The HT is equivalent to a special kind of filter, in which all the amplitudes of the spectral components are left unchanged, but their phases are shifted by $-\pi/2$ (Figure 1).

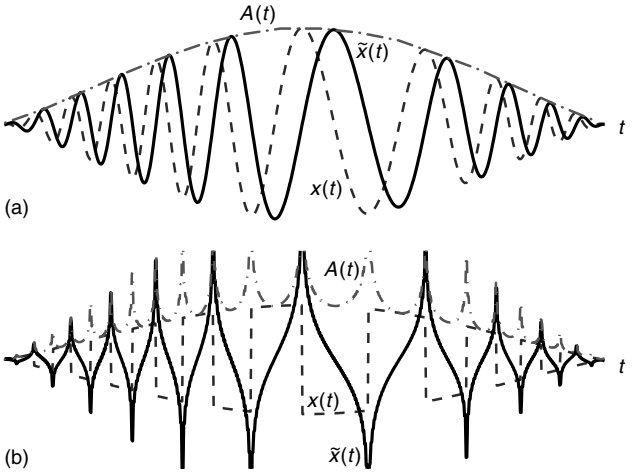

Figure 1. The initial signal $x(t)$, the Hilbert transform $\tilde{x}(t)$, and the envelope $A(t)$: quasi-harmonics (a); nonstationary square wave (b).

3 PROPERTIES OF THE HT

The HT of a real-valued function $x(t)$ extending from $-\infty$ to $+\infty$ is a real-valued function defined by equation (1). Thus, $\tilde{x}(t)$ is the convolution integral of $x(t)$ with $(\pi t)^{-1}$, written as $\tilde{x}(t) = x(t) * (\pi t)^{-1}$. The HT of a constant is zero. The double HT (the HT of a HT) yields the original function having the opposite sign, and hence it carries out a shifting of the initial signal by $-\pi$. The HT used four times on the same real function gives us the original function back. The power (or energy) of a signal and its HT are equal. A function and its HT are orthogonal over the infinite interval $\int_{-\infty}^{\infty} x(t)\tilde{x}(t)\,\mathrm{d}t = 0$. The HT of the derivative of a function is equivalent to the derivative of the HT of the function.

For $n(t)$ low-pass and $x(t)$ high-pass signals with nonoverlapping spectra, $H[n(t)x(t)] = n(t)\tilde{x}(t)$. More generally, the HT of the product of two arbitrary functions with overlapping spectra can be written in the form of a sum of two parts [1]: $H\{n(t)x(t)\} = H\{[\overline{n}(t) + n_1(t)]x(t)\} = \overline{n}(t)\tilde{x}(t) + \tilde{n}_1(t)x(t)$, where $\overline{n}(t)$ is the slow (low-pass) signal component, $n_1(t)$ is the fast (high-pass) signal component, and $\tilde{n}_1(t)$ is the HT of the fast component $n_1(t)$. The proof of the decomposition of a signal into a sum of low- and high-pass terms is based on Bedrosian's theorem for the HT of a product. For example, the HT of the cube of the harmonics $x^3 = (A\cos\varphi)^3$ is equal to $H[x^3(t)] = H[x^2(t)x(t)] = A^3(3\sin\varphi + \sin 3\varphi)/4$.

4 DIGITAL HILBERT TRANSFORMERS

We can form the HT by designing a filter with the frequency response corresponding to the impulse response $(\pi t)^{-1}$. This response is $H(\omega) = -i\,\mathrm{sgn}(\omega)$. This frequency response describes an ideal wideband 90° phase shifter, the positive frequencies of which are shifted by -90° $(-\pi/2)$ and negative frequencies by $+90^\circ$ $(\pi/2)$. There are mainly two methods for obtaining a real approximate Hilbert transformer: frequency domain and time domain.

4.1 Frequency domain

This technique is based on computing the Fourier transform of a signal. If $x(t)$ is the real input data record of length N, then the analytic signal $X(t) = x(t) + i\tilde{x}(t)$ can be obtained by: $X(t) = \mathrm{IFFT}\{B(n) \cdot \mathrm{FFT}[x(t)]\}$, where $B(n) = 2$ for $n = \{0, (N/(2-1))\}$ and $B(n) = 0$ for $n = \{N/2, (N-1)\}$. FFT is the fast Fourier transform and IFFT is the inverse fast Fourier transform. The imaginary portion of $X(t)$ contains the HT projection $\tilde{x}(t)$ and the real portion contains the real input signal $x(t)$.

Windowing and/or zero padding may have to be used to avoid ringing.

4.2 Time domain

The phase shift can be implemented by a convolution filter, obtainable by the convolution theorem relating convolution to multiplication in the frequency domain. The finite impulse response (FIR) digital Hilbert transformers (Figure 2) have the advantage of providing exactly linear phase, but at the expense of requiring a higher filter order as compared to the infinite impulse response (IIR) designs, to achieve a given negative frequency attenuation level.

5 HT AND DYNAMIC SYSTEMS

5.1 Kramers–Kronig relations

For a causal function, the HT presents interesting mathematical properties named the *Kramers–Kronig relations* [2]. The properties connect the real and imaginary parts of any complex analytic function in the upper half plane. We can associate the imaginary part of a complex frequency response function as the HT of the real part of the function. In other words, the real and imaginary parts of the transfer function form a Hilbert pair. The imaginary part of a response function describes how a system dissipates energy, since it is out of phase with the driving force. These relations imply that observing the dissipative response of a system is sufficient to determine its in-phase (reactive) response, and vice versa. Any departure from an initial linear frequency response function, i.e., distortion, can be attributed to nonlinear effects.

5.2 Hysteretic damping

Most real materials show an energy loss per cycle with a less pronounced dependency on frequency. In fact, many materials indicate force–deformation relations that are independent of the deformation rate amplitude—so-called hysteretic relations. A

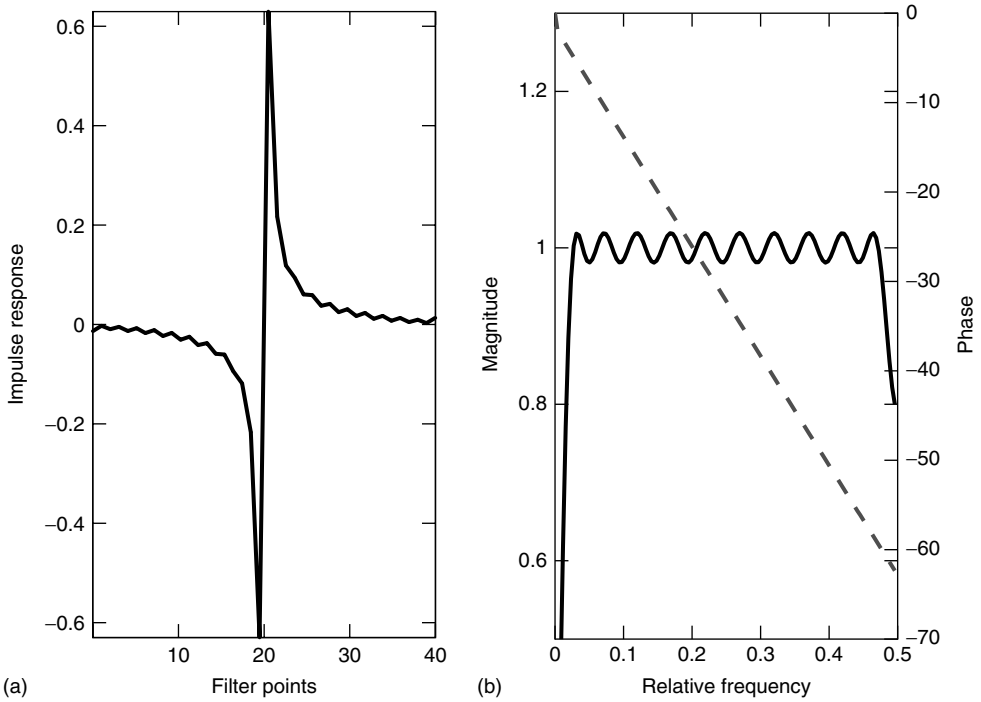

Figure 2. Length 39 Hilbert transformer (digital filter). Impulse response (a) and frequency response function (b)—magnitude (———) and phase (- - - -).

known mechanical element model shows frequency-independent storage and loss moduli. This implies that the Fourier transforms of both the element force $F(\omega)$ and the element deformation $\Delta(\omega)$ satisfy $F(i\omega) = k[1 + i\eta\text{sgn}(\omega)]\Delta(i\omega)$, where k is the stiffness and η is the loss factor (ratio of the loss and storage moduli of element). In this model, the dissipated energy in a harmonic deformation cycle of constant amplitude is independent of the frequency of deformation. Only the HT gives a correct time domain expression for the concept of linear hysteretic damping [3]. This transform can be used to replace complex-valued coefficients in differential equations modeling mechanical elements.

6 ANALYTIC SIGNAL

The complex signal whose imaginary part is the HT (equation 2) of the real part is called the *analytic* or *quadrature signal* [1]. Such a signal is a two-dimensional signal whose value at some instant in time is specified by two parts, the real and the imaginary part: $X(t) = x(t) + i\tilde{x}(t)$, where $\tilde{x}(t)$ is related to $x(t)$ by the HT. To return from a complex form of the analytic signal $X(t)$ back to the real function $x(t)$, one has to use the substitution $x(t) = 0.5[X(t) + X^*(t)]$, where $X^*(t)$ is the complex conjugate signal of $X(t)$. The analytic signal has a one-sided spectrum of positive frequencies. The conjugate analytic signal has a one-sided spectrum of negative frequencies.

6.1 Polar notation

According to analytic signal theory, a real vibration process $x(t)$, measured by, say, a transducer, is only one of possible projections (the real part) of some analytic signal $X(t)$. Then the second or quadrature projection of the same signal (the imaginary part) $\tilde{x}(t)$ will be conjugated according to the HT. The analytic signal has a geometrical representation in the form of a phasor rotating in the complex plane, as shown in Figure 3. Using the traditional representation of the analytic signal in its trigonometric or exponential form

$$\begin{aligned} X(t) &= |X(t)|[\cos\psi(t) + j\sin\psi(t)] \\ &= A(t)\ \mathrm{e}^{j\psi(t)} \end{aligned} \tag{2}$$

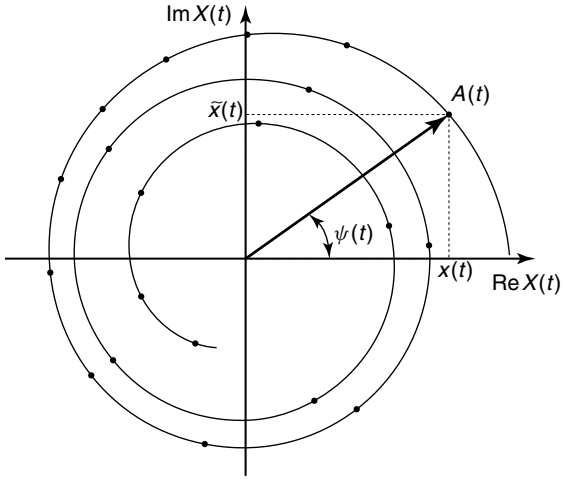

Figure 3. Analytic signal representation.

one can determine its instantaneous amplitude (envelope, magnitude, modulus)

$$A(t) = |X(t)| = \sqrt{x^2(t) + \tilde{x}^2(t)} = \mathrm{e}^{\mathrm{Re}[\ln X(t)]} \tag{3}$$

and its instantaneous phase

$$\psi(t) = \arctan\frac{\tilde{x}(t)}{x(t)} = \mathrm{Im}[\ln X(t)] \tag{4}$$

The change of coordinates from rectangular $(x, \tilde{x})$ to polar (A, ψ) gives $x(t) = A(t)\cos\psi(t)$ and $\tilde{x}(t) = A(t)\sin\psi(t)$.

7 HT AND VIBRATION SIGNALS

The analytic signal method is equally applicable to deterministic and random processes, although, generally speaking, it does not divide them into two separate groups. It enables us to investigate any oscillating time function from a general point of view. The method is also good for solving problems concerning linear and nonlinear vibration systems, stationary and nonstationary vibrations, as well as narrow- and/or wideband signals. It also allows precise analysis of the dissipation of vibration energy and vibration effects on machine durability.

7.1 Signal differentiation and integration

The analytic signal notion (equation 2) allows us to describe a relationship between an initial complex signal and its first derivative as $\dot{X} = X\left((\dot{A}/A) + i\omega\right)$. The second derivative of the signal takes the form $\ddot{X} = X\left((\ddot{A}/A) - \dot{\psi}^2 + 2i\dot{A}\psi + i\ddot{\psi}\right)$. Integration of analytic signals may also be of importance for signal processing. A complex function of a real variable t is an integral of the analytic signal if the real and the imaginary parts of the function are corresponding integrals forming a pair of the HT.

7.2 Signal demodulation

Traditional Fourier analysis simply assumes that the signal is the sum of a number of sine waves. The HT allows a complex demodulation analysis, adapted to signals of the form of a single, but modulated (perturbed), sine wave. As a vibration signal is exactly of the model that the method assumes, it is no wonder that in some cases the HT performs better than the Fourier analysis. Demodulation removes the modulation from a signal to get the original baseband signal back. For example, an envelope detector based on the HT takes a high-frequency signal as input, and provides an output that is the envelope of the original signal.

7.3 Fatigue estimation

The HT approach can be used to count fatigue cycles in an arbitrary loading waveform. It processes a time history representing the random wideband loading condition to generate the number of cycle counts with their corresponding amplitudes. The approach is general, is accurate within any desirable degree of accuracy, and is amenable to modern signal processing.

8 SIGNAL ENVELOPE

The amplitude of the oscillation can vary with time, and the shape of such time variation is called the *envelope* $A(t)$ (equation 3). The initial signal and its envelope have common tangents at points of contact (extrema points), but the signal never crosses the envelope. The plus sign of the root square corresponds to the upper positive envelope and the minus sign corresponds to the lower negative envelope, so they are always in antiphase relation. The envelope function contains important information about the energy of the signal. By using the HT, the rapid oscillations can be removed from the amplitude-modulated (AM) signal to produce a direct representation of the slow envelope alone. For example, the impulse response of a linear single-degree-of-freedom (SDOF) system is an exponentially damped sinusoid. The envelope of the signal is determined by the monotonic exponent decay rate.

AM signals can be described with the constant carrier frequency ω_0. Then the initial complex signal (equation 2) will be given by $X(t) = A_0 e^{j\psi(t)} = A_0 e^{j\psi_0(t)} e^{j\omega_0 t}$, where $A_0 e^{j\psi_0(t)}$ introduces a new complex expression as the complex envelope. The spectrum of the complex envelope can be obtained by shifting an initial signal spectrum to the left toward the origin of axes.

8.1 Average values and amplitude distribution function

The mean value of the envelope takes the form $\overline{A} = \int_{-\infty}^{\infty} A(t)\,dt$. The mean value of the square of the time-derivative of the envelope is $\overline{[\dot{A}(t)]^2} = \int_{-\infty}^{\infty} \dot{A}^2(t)\,dt$. This quantity determines the level of the envelope variation ($\overline{A} = 1$).

The envelope probability density $p(A)$ is related to the signal probability density function $p(x)$: $p(x) = \pi^{-1} \int_{|x|}^{\infty} p(A)\,dA/(A^2 - x^2)^{1/2}$. As an example of this relation, a typical classical Gaussian (normal) form of the probability density of the random vibration that conforms to the Rayleigh probability density of the vibration envelope is shown in Figure 4.

9 INSTANTANEOUS PHASE

The instantaneous phase notation (equation 4) indicates the multibranch character of the function, as shown in Figure 5, line 2, when the phase angle jumps between π and $-\pi$. These phase jumps can be unwrapped into a monotone function by an artificial changing of the phase values (Figure 5, line 1). The instantaneous relative phase shift in the case of two

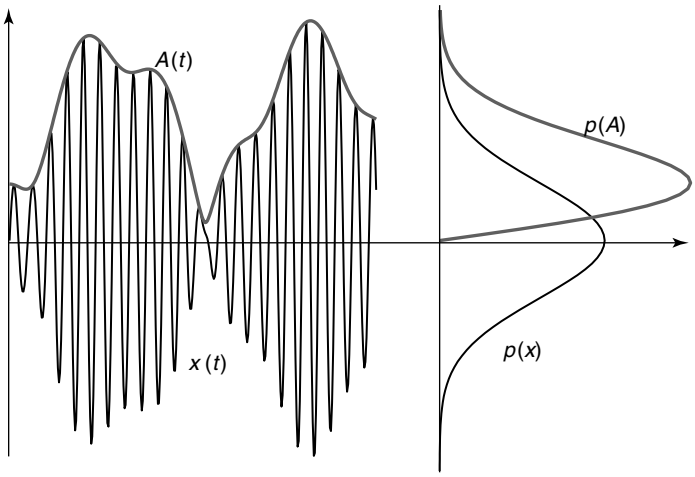

Figure 4. Random signal with envelope and their distributions.

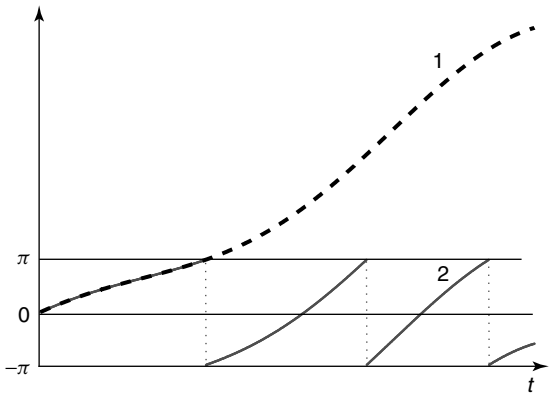

Figure 5. Instantaneous phase: unwrapped (1) and wrapped (2).

different real signals $x_1(t)$ and $x_2(t)$ can be estimated as the instantaneous relative phase between them, according to the formula $\psi_2(t) - \psi_1(t) = \arctan(x_1(t)\tilde{x}_2(t) - \tilde{x}(t)x_2(t))/(x_1(t)x_2(t) + \tilde{x}_1(t)\tilde{x}_2(t))$.

10 INSTANTANEOUS FREQUENCY

The first derivative of the instantaneous phase (equation 4) as a function of time $\omega(t) = \dot{\psi}(t)$, called the *instantaneous angular frequency*, plays an important role. The angular frequency $\omega(t) = 2\pi f(t)$ has the dimension radian per second and the cycle frequency $f(t)$ has the dimension hertz. There is a simple way to avoid the whole phase-unwrapping problem. It can be done when finding the instantaneous frequency (IF) by differentiation of the signal itself:

$$\omega(t) = \frac{x(t)\dot{\tilde{x}}(t) - \dot{x}(t)\tilde{x}(t)}{A^2(t)} = \mathrm{Im}\left[\frac{\dot{X}(t)}{X(t)}\right] \quad (5)$$

The IF $\omega(t)$ measures the rate of phasor rotation in the complex plane. Naturally, for a simple monoharmonic signal, the envelope and the IF are constant, and the phase angle increases linearly with time. In the general case, the IF of the signal is a varying function of time. Moreover, the IF in some cases may change sign in some time intervals. This corresponds to the change of rotation of the phasor from the counterclockwise to the clockwise direction. The IF always has physical meaning and is nothing more than just the varying speed (rate) of the phasor rotation in polar axes. In the time domain, the negative IF corresponds to the appearance of a complex riding cycle (complicated cycle of an alternating signal).

10.1 Average values, central frequency, and distribution function

The instantaneous amplitude and frequency of complicated vibration signals are nonconstant; they vary in time. While the IF is a positive function, the signal itself has the same numbers of zero crossings and extrema. When the IF has a negative value, the signal has one or multiple extrema between successive

zero crossings. The mean value of the IF $\omega_0 = \overline{\omega} = \int_{-\infty}^{\infty} \omega(t) A^2(t)\,\mathrm{d}t = (m_1/m_0)$, equal to the first normalized moment of the signal spectrum, is called the *central frequency* (here m_i is the ith moment of the spectrum) [4]. The mean value of the modulus of the IF given by $\overline{|\omega|} = \int_{-\infty}^{\infty} |\omega(t)| A^2(t)\,\mathrm{d}t = (m_2/m_0)^{1/2}$ is equal to the number of the signal zero crossing.

The mean value of the IF squared $\overline{\omega^2} = \int_{-\infty}^{\infty} \omega^2(t) A^2(t)\,\mathrm{d}t = (m_2/m_0) - \overline{\dot{A}^2(t)}$ determines the level of the IF variation. Some typical examples of the central frequency estimation based on the IF are shown in Table 1.

It is notable that, in the case of the SDOF vibration system, its free vibration natural frequency value equal to $(\omega_0^2 - h^2)^{1/2} \approx \omega_0 - (h^2/2\omega_0)$, where h is the viscous damping, lies between these central moments of the IF (Table 1).

As the IF may be considered to be the average of the signal frequency at a given time instant, it seems reasonable to inquire about the probability density function or spread at that time. For the random normal narrowband signal, the probability density function of the IF was derived by Bunimovich [4] $p(\omega) = (\Delta\omega^2)/(2(\omega^2 + \Delta\omega^2)^{3/2})$. From the last formula, a probabilistic prerequisite to the formation of the negative value of the IF is as follows:

$$p[\omega(t) < 0] = 0.5\left(1 - \frac{\overline{\omega}}{\overline{|\omega|}}\right) \tag{6}$$

For example, the probability of a negative value of the IF of a random signal after an ideal rectangular narrowband filter is directly proportional to the relative filter width $p[\omega(t) < 0] = \Delta\omega^2/144\omega_0^2$, where ω_0 is the central filter frequency and $\Delta\omega$ is the filter width. This indicates that after any narrowband filtering, the random signal will still have the negative value of the IF. However, for very small widths like $(\Delta\omega/\omega_0) \leq 0.01$, the probability will be less than one in a million, and the IF can be practically considered as always positive. From equation (6) it follows, for example, that the probability of a negative value of the IF of random vibration of the SDOF system (Table 1) is proportional to the system viscous damping coefficient.

Table 1. The spectral central frequencies

Vibration signal	Central frequency	
	Mean value $\overline{\omega}$	Mean modulus $\overline{\lvert\omega\rvert}$
Harmonics $\cos\omega_0 t$	ω_0	ω_0
Random vibration of the system $\ddot{y} + 2h\dot{y} + \omega_0^2 y = F(t)$	$\omega_0 - \dfrac{2h}{\pi}$	ω_0
Narrowband random noise $\omega_0 - \dfrac{1}{2}\Delta\omega < \omega < \omega_0 + \dfrac{1}{2}\Delta\omega$	ω_0	$\omega_0\left(1 + \dfrac{\Delta\omega^2}{24\omega_0^2}\right)$

10.2 Signal bandwidth

There are several techniques for estimation of the spectrum bandwidth. Probably the most familiar and simplest is the half peak level width. Also, the spectrum bandwidth could be estimated as a width of a hypothetical square with the same energy and the peak value $\Delta\omega_1 = \int_0^{\infty} S(\omega)\,\mathrm{d}\omega / S_{\max}$. In the case of the IF analysis, it is useful to introduce one more width parameter that is equal to the mean absolute value of the IF deviation from its central value plus the envelope variations. By summing up the IF variation around the mean value and the envelope variations, we obtain the average spectrum bandwidth of the signal $\Delta\omega_2$ [5]:

$$\begin{aligned}\Delta\omega_2^2 &= \int_0^{\infty} (\omega - \omega_0)^2 S(\omega)\,\mathrm{d}\omega = \overline{\omega^2} + \overline{\dot{A}^2(t)} - \overline{\omega}^2 \\ &= \frac{m_2}{m_0} - \left(\frac{m_1}{m_0}\right)^2 \end{aligned} \tag{7}$$

where, again, m_i is the ith moment of the spectrum $S(\omega)$. Equation (7) is derived from Parseval's energy identity relation for time and frequency domains. It indicates that the signal spectrum bandwidth is equal to the sum of the IF and the envelope variations. For AM signals, the spectral bandwidth is equal to the mean square value of the velocity of the amplitude change. For signals which are only frequency modulated, the spectral bandwidth is equal to the mean square value of the IF.

Some typical examples of the spectral bandwidth estimation are shown in Table 2.

Taking into account these representations of analytic signals enables one to consider a vibration

Table 2. The spectral bandwidth

Vibration signal	Spectral bandwidth	
	Energy equivalent $\Delta\omega_1$	IF deviation $\Delta\omega_2$
Random vibration of the system $\ddot{y} + 2hy + \omega_0^2 y = F(t)$	πh	$2\left(\frac{h\omega_0}{\pi}\right)^{1/2}$
Narrowband random noise $\omega_0 - \frac{1}{2}\Delta\omega < \omega < \omega_0 + \frac{1}{2}\Delta\omega$	$\Delta\omega$	$\frac{\Delta\omega\sqrt{3}}{6}$

process, at any moment of time, as a quasiharmonic oscillation, amplitude and frequency modulated by time-varying functions $A(t)$ and $\omega(t)$: $x(t) = A(t)\cos\int_0^t \omega(t)\,\mathrm{d}t$. The instantaneous parameters are functions of time and can be estimated at any point of the vibration signal. The total number of these points, which map the vibration, is much greater than that of the peak points of the signal. This opens the way for averaging and for other statistical processing procedures, making vibration analysis more precise.

11 NARROW- AND WIDEBAND SIGNALS

Classically, the relations between the spectral bandwidth and the central frequency divide vibration signals into two groups: narrowband ($\Delta\omega \ll \overline{\omega}$) and wideband ($\Delta\omega \gg \overline{\omega}$) signals. Also a vibration-detrended (centered) signal can be considered a narrowband signal if its IF and envelope are always positive ($\omega(t) > 0$, $A(t) > 0$), and the vibration signal with zero or negative IF is considered a wideband signal ($\omega(t) \leq 0$). A slow frequency-modulated signal is a typical example of the narrowband signal. With this definition, the narrowband signal in each cycle, defined by the central frequency, involves only one mode of oscillation; no complex riding waves are allowed [6]. In effect, in this case the IF will not have the fast fluctuations induced by asymmetric waveforms.

Such a detrended vibration signal will always alternate around zero. In the narrowband case, its envelope coincides with the local maxima function. Moreover, the envelope and the opposite sign envelope for narrowband signals are always in antiphase. In the wideband case, the negative IF and the corresponding complicated riding cycle indicate the existence of the local negative maximum or the local positive minimum of the signal.

11.1 Example of two harmonics

If a signal composition is a sum of two harmonics: $x(t) = A_1(t)\cos\omega_1 t + A_2(t)\cos\omega_2 t$, the envelope $A(t)$ (equation 3) of the double-component signal composition could be written as $A(t) = [A_1^2 + A_2^2 + 2A_1A_2\cos(\omega_2 - \omega_1)t]^{1/2}$. The signal envelope $A(t)$ consists of two different parts, that is, a slow varying part, including the sum of the component amplitudes squared, and a rapidly varying part, oscillating with a new frequency equal to the difference between the component frequencies.

The IF $\omega(t)$ (equation 5) of the double-component composition is as follows:

$$\omega(t) = \omega_1 + \frac{(\omega_2 - \omega_1)[A_2^2 + 2A_1A_2\cos(\omega_2 - \omega_1)t]}{A^2(t)} \tag{8}$$

The IF of the two tones considered in equation (8) is generally time-varying and exhibits asymmetrical deviations about the frequency ω_1 of the largest harmonics. In addition, these deviations always force the IF beyond the frequency range of the signal components. The IF, in principle, consists of two different parts, that is, a frequency of the first largest component ω_1 and a rapidly varying asymmetrical oscillating part. For large amplitude of the second harmonics when $(A_2/A_1) > 1 - \sqrt{1 - (\omega_1/\omega_2)}$, the IF of the composition becomes negative.

12 MONO- AND MULTICOMPONENT SIGNALS

In the simple case, a nonstationary signal has constant or slow varying amplitude and a slow varying positive IF. This kind of signal is often referred to as a *single-* (*mono-*) *component* or *monochromatic signal*.

The term *monocomponent signal* corresponds to the "intrinsic mode function (IMF)" and is suggested in [6]. Monocomponent signals belong to the group of narrowband signals whose IF is always greater than zero. However, not every narrowband signal is a simple monocomponent signal. For example, a slow AM signal is a narrowband signal, but it is not a monocomponent, because it can be separated into three simpler components. Often, measured signals can be represented by a composition (sum) of a small number of the monocomponent signals [7]:

$$x(t) = \sum_l A_l(t) \cos\left(\int \omega_l(t)\,\mathrm{d}t\right) \tag{9}$$

where $A_l(t)$ is the instantaneous amplitude and $\omega_l(t)$ is the angular radian IF of the l component. In other words, the signal consists of l monocomponents, where each has a constant or a slowly varying amplitude $A_l(t)$ and the IF $\omega_l(t)$.

The multicomponent signal can be defined as follows: an asymptotic signal is referred to as a *multicomponent composition* if there exists even a single narrowband component such that its extraction from the composition decreases the average spectrum bandwidth of the remainder signal. This definition means that, after breaking up a signal into its simplest components and taking out any component, the envelope and the IF of a residue part will have smaller deviations in time. The signal example considered in Section 11.1 can be decomposed into pure harmonic components, each one without a deviation and with a zero spectrum bandwidth.

12.1 Upper and lower amplitude bounds (envelope of the envelope)

In the case of the multicomponent signal, its envelope sometimes exceeds the signal local maxima. To estimate the acting upper and lower bounds of the signal, consider a general l-component real signal $x(t)$ with the amplitudes and the instantaneous frequencies according to equation (9). Naturally, this multicomponent phasor as a composition $X(t) = \sum_{l=1}^{N} A_l(t)\mathrm{e}^{j\phi_l(t)}\mathrm{e}^{j\omega_l(t)t}$ will have a more complicated and faster varying envelope function. Here $X(t)$ is the signal in the analytic form and $A_l(t)\mathrm{e}^{j\phi_l(t)}$ is the complex amplitude (envelope) of every component.

For a signal formed from the summation of many components, we can invoke the generalized triangle inequality property for complex functions. The triangle inequality states that the sum of the moduli of complex numbers is greater than the modulus of the sum of these complex numbers: $|\sum_{l=1}^{N} C_l| \le \sum_{l=1}^{N} |C_l|$. In our case, the modulus on the left-hand side is the signal envelope $A(t)$ of the composition $X(t)$, and the sum of the moduli on the right-hand side is the sum of the component envelopes, thus yielding

$$A_{\mathrm{env}}(t) \le \sum_{l=1}^{N} A_l \mathrm{e}^{j\phi_l} \tag{10}$$

A new term, *envelope of the envelope* (EoE) $A_{\mathrm{env}}(t)$, is defined as the tangent curve to the local extrema, which touches only maximum points during every longest period of the composition. The EoE represents the acting maximum height (intensity) of the signal and forms the shape of the time variation of the acting extreme points. The EoE varies much more slowly with time than the signal envelope itself. To estimate the EoE, we first need to produce a decomposition of the signal and then to construct the algebraic summation of the envelopes of all the decomposed components. Such successive signal decomposition (disassembling) and the subsequent summation (reassembling) of the component envelopes generate the desirable EoE as a slow function of time. The EoE function plays an important role in the precise identification of nonlinear vibration systems by taking into consideration their high-frequency nonlinear components [8].

12.2 Average frequency and the largest energy component

For combination of two harmonics (see Example in Section 11.1) the IF consists of two different parts, that is, a slow varying frequency of the first component ω_1 and a rapidly varying asymmetrical oscillating part. However, the rapidly varying asymmetrical oscillating part of the IF has an important feature. If we now integrate the oscillating part with the integration limits corresponding to the full period

of the difference frequency $\left[0\ T = 2\pi/(\omega_2 - \omega_1)\right]$,

$$\int_0^T \frac{(\omega_2 - \omega_1)\left[a_2^2 + 2a_1a_2\cos\left(\int(\omega_2 - \omega_1)\,\mathrm{d}t\right)\right]}{a^2(t)} \times \mathrm{d}t = 0 \qquad (11)$$

we get the definite integral equal to zero. This means that the average value of the first moment of the IF (equation 8) is just equal to the frequency of the largest harmonics $\langle\omega(t)\rangle = \omega_1(t) + \int_0^T \omega(t) = \omega_1(t) + 0$. This interesting property of the IF offers the simplest and most direct way of estimating the frequency of an *a priori* unknown largest signal component [9]. In the more general case of three and more quasi-harmonics in the composition, the IF will take a more complicated form, but again, the averaging or the low-pass filtering will extract only the IF of the largest energy component.

13 HT SIGNAL DECOMPOSITION

HT decomposition methods allow any complicated data set to be decomposed into a finite and often small number of IMFs. Recently, Huang *et al.* [6, 7] proposed the empirical mode decomposition (EMD) method to extract monocomponent and symmetric components, known as *IMF*, from nonlinear and nonstationary signals (*see also* **Damage Detection Using the Hilbert–Huang Transform**). The term *empirical* chosen by the authors emphasizes the empirical essence of the proposed identification of the IMF by their characteristic timescales in the initial complicated data. Some years later, a different technique, called the *Hilbert vibration decomposition* (HVD) *method*, dedicated to the same problem of decomposition of nonstationary wideband vibration, was developed in [9]. The global HVD method is based on the HT presentation of the IF and does not involve spline fitting.

13.1 Local EMD method

The EMD method [6] automatically generates a collection of IMFs that satisfy two conditions: (i) in the complete data set, the number of extrema and the number of zero crossings must either be equal or differ at most by one; and (ii) at any point, the mean value of the envelope defined by the local maxima and the envelope defined by the local minima is zero. The EMD algorithm requires the following procedures at every iteration step: (i) estimation of all extrema; (ii) spline fitting of all minima and maxima, ending up with two extrema functions; (iii) computation of the average function between maxima and minima; (iv) extraction of the average from the initial signal; and (v) iteration on the residual (the sifting procedure). When applied to a nonstationary signal mixture, the EMD algorithm yields efficient estimates for the instantaneous amplitude and frequency signals of each component.

For illustration purposes, let the signal be a composition of two nonstationary harmonics, each one with a varying amplitude (Figure 6a). The EMD method successfully decomposes both the amplitude and frequency of each intrinsic function (Figure 6b, c) from the initial wideband signals, but it cannot decompose the narrowband bi-harmonics signal [10, 11].

13.2 Global HVD method

The important property of the IF (equation 11) offers the simplest and most direct way of estimating the frequency of an *a priori* unknown largest signal component. If we replace the integration of the IF by convolution with a low-pass filter instead of averaging, we will cut down the asymmetrical oscillations and leave only the slow varying frequency of the main component. Thus, the IF becomes a useful function

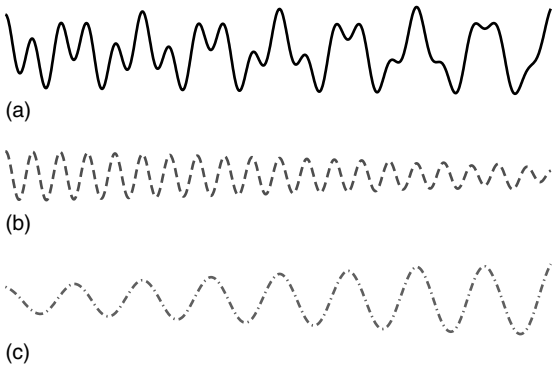

Figure 6. EMD signal decomposition: initial signal (a) and nonstationary components (b and c).

enabling detection of the largest energy component. A low-pass filter will eliminate all high-frequency components outside of the cutoff frequency, leaving the low-frequency components of the IF without modification. Such low-pass filtering of the IF corresponds to the narrowband filtering of the signal around its central frequency, and the cutoff frequency of the IF is equal to the relative bandwidth frequency of the signal.

The HVD method [9] at every iteration step requires the following procedures: (i) estimation of the IF of the largest component by low-pass filtering of the signal IF; (ii) detection of the corresponding envelope of the largest component; and (iii) subtraction of the largest component from the composition. At each iteration step, the corresponding slow varying vibration component is extracted using the low-pass filtering of the IF. Correspondingly, on each iteration step the residual contains the lower-energy components. As a result, we automatically separate the initial composition into several slowly varying oscillating components. At each iteration step after subtracting the largest component, the IF of the residual will be filtered again, and the components will be separated if the difference between their frequencies is greater than the cutoff frequency value. For illustration purposes, let the carrier signal be a harmonic $\cos t$, and let the modulation also be a single but nonstationary tone with decreasing modulation index and with increasing modulated frequency. The signal waveform is shown in Figure 7(a) and the decomposed components according to the proposed HVD method are shown together in Figure 7(b).

13.3 Comparison of the HT decomposition methods

13.3.1 Local versus global

A varying signal can be described by different signal attributes that change over time. To estimate attributes such as amplitude or frequency, any procedure will need some measurements during a definite time. Generally two approaches exist for such estimation: a local approach that measures attributes at each instant without knowing the entire function of the process and a global approach that depends on the whole

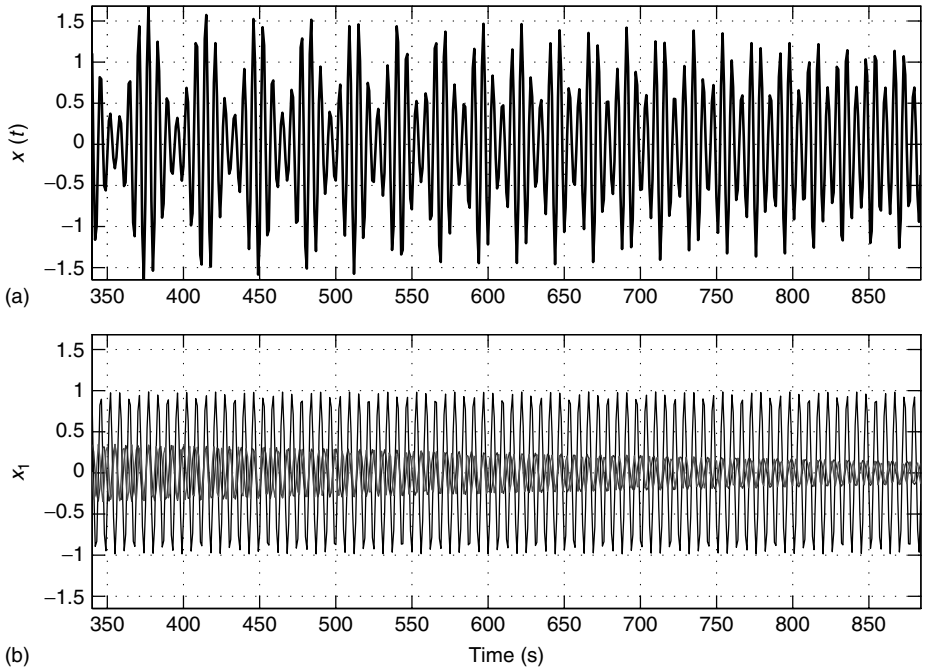

Figure 7. HVD signal decomposition: initial signal (a) and nonstationary components (b).

signal waveform during a long (theoretically infinite) measuring time. An example of the local (or differential, microscopic) approach is the estimation of a frequency by measuring the interval (spacing) between two successive zero crossings. Examples of the global (or integral, macroscopic) approach are estimating the average frequency by taking the first moment of the spectral density, estimating the envelope or the IF. In other words, local estimations consider the signal locally, i.e., in a very small interval around the instant of analysis. Quite to the contrary, global estimations have to use the whole real signal. The global versus local estimations provide different precisions and resolutions depending on many conditions, primarily noise distortions and random flicker phase modulation in a signal [4, 5].

14 HT NONLINEAR SYSTEM IDENTIFICATION

By observation (experiment), we acquire knowledge of the position and/or velocity of the object as well as the excitation at several known instants of time. The nonparametric identification will determine the initial nonlinear restoring and damping forces. In the case of free vibration, we have only the output signal—the vibration of the oscillators—whereas in the case of forced vibration we also deal with the input excitation. In modern signal processing, the HT method is more and more widely applied for analysis and identification of nonlinear dynamic structures.

14.1 Elastic nonlinearities in vibration systems

The important type of nonlinearity arises when the restoring force of a spring is not proportional to its deformation. There are several known types of static force characteristics (load–displacement curve) representing different types of nonlinearity in elastic springs: backlash, preloaded (precompressed), impact, and polynomial ones. In most nonlinear vibration systems, the natural frequency will depend decisively on amplitude of the vibrations (Figure 8). Every typical nonlinearity in a spring has its unique form of skeleton (backbone) curve [8, 12]. The unique topography of the skeleton curve is essential for the properties evaluation of the tested vibrating system, e.g., in reconstructing characteristics of the nonlinear elastic forces.

14.1.1 Small-amplitude nonlinear behavior: preloading and backlash

There are cases where vibration systems show their specific nonlinear behavior only in a small-amplitude range of vibrations. Such a system is a spring backlash (clearance). For small vibration amplitudes, the system will display its nonlinear properties

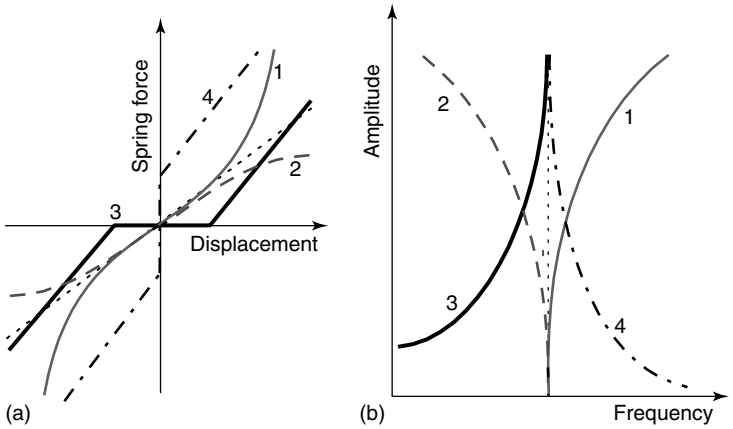

Figure 8. Characteristics of typical nonlinear vibration systems (hardening (1), softening (2), backlash (3), preloaded (4)): backbones (a) and static elastic force (b).

where natural frequency decreases with decreasing of amplitude.

Another typical example of nonlinearity in the small-amplitude range is a vibration mechanical system with preloaded (pretensioned) restoring force. Only for small amplitudes of vibration motion commensurable to a preloaded deformation the natural frequency will increase extremely with decreasing of amplitude.

14.1.2 Large-amplitude nonlinear behavior: polynomial model

Most of the known cases of nonlinear manifestation occur in the large-amplitude range of oscillation, like a nonlinear spring element with hardening or softening restoring force, or nonlinear friction quadratic or cubic force. These typical nonlinear spring elements of a mechanical vibration system could be expressed as a power series $k(x) = (\alpha_1 + \alpha_3 x^2 + \alpha_5 x^4 + \cdots)x$. In general, a second-order conservative system with a nonlinear restoring force $k(x)$ and a solution $x(t) = A\cos\omega t$ takes a simple form $\ddot{x} + k(x) = 0$. Applying the multiplication property of the HT for overlapping functions [12] to the last equation, we obtain a new form of time-varying equation of motion $\ddot{x} + j\delta(t)x + \omega_0^2(t)x = 0$, where $\omega_0(t)$ is the fast-varying natural frequency function and $\delta(t)$ is the fast-varying fictitious damping function. If we consider only the mean value of the varying natural frequency function square, we get an important result [12] $\langle\omega_0^2\rangle = T^{-1}\int_0^T \omega_0^2(t)\,\mathrm{d}t = \alpha_1 + (3/4)\alpha_3 A^2 + (5/8)\alpha_5 A^4 + \cdots$, which proves that the averaged natural frequency has, correct to the polynomial constant coefficients, the same expression as the initial nonlinear restoring force $k(x)$. This general result means that the estimated average natural frequency, and hence the system skeleton curve (backbone) $A(\langle\omega_0\rangle)$, includes the main information about the initial characteristics of nonlinear elastics and can be used for nonlinear system identification.

14.2 Damping nonlinearities in vibration systems

Vibration systems also can show their damping nonlinearities only in a small- or a large-amplitude range, depending on the type of nonlinear damping force characteristics. As an example of a small-amplitude nonlinear behavior, we mention a system with Coulomb (dry) friction, whose plot of logarithmic decrement versus vibration amplitude is a monotonic hyperbola [12]. In some other cases, like nonlinear turbulent friction, the nonlinear damping behavior appears in the large-amplitude range. But in practice, the real small damping forces practically have no effect on the mechanical system backbones.

14.3 Theoretical bases of nonlinear system identification

The time-domain techniques, based on the HT, allow direct extraction of linear and nonlinear systems parameters from a measured time signal of input and output of the vibration system [12]. The HT methods, namely, free vibration (FREEVIB) and forced vibration (FORCEVIB), of free and forced vibration analysis determine instantaneous modal parameters, even if an input signal is a high-sweep frequency signal. Such direct determination of a relationship between amplitude and natural frequency, which characterizes elastic properties, and a relationship between amplitude and damping characteristics, enables an efficient nonlinear system testing without long forced response analysis.

A second-order conservative system with a nonlinear restoring force $k(x)$, a nonlinear damping force $h(\dot{x})\dot{x}$, and a solution $x(t) = A(t)\cos[\omega(t)t]$ can be represented in a general form $\ddot{x} + h(\dot{x})\dot{x} + k(x) = 0$. In the first stage of the identification technique, the envelope $A(t)$ and the instantaneous frequency $\omega(t)$ are extracted from the vibration and excitation signals on the base of the HT signal processing. In the next stage, by applying the multiplication property of the HT for overlapping functions to the equation of motion, the instantaneous undamped natural frequency and the instantaneous damping coefficient are calculated according to formulas [12]

$$\omega_0^2(t) = \omega^2 - \frac{\ddot{A}}{A} + \frac{2\dot{A}^2}{A^2} + \frac{\dot{A}\dot{\omega}}{A\omega};$$
$$h_0(t) = -\frac{\dot{A}}{A} - \frac{\dot{\omega}}{2\omega} \tag{12}$$

where $A(t)$ and $\omega(t)$ are the envelope of the IF of the vibration.

In the last stage of low-pass filtering, the set of duplet modal parameters (the instantaneous natural frequency $\langle\omega_0^2(t)\rangle$ and instantaneous damping $\langle h(t)\rangle$) of each natural mode of vibration are defined. As a result of the HT method, the corresponded set of the duplet modal parameters as functions of the envelope (the skeleton and the damping curves) of each natural mode of vibration describe the dynamic behavior of the structure.

It is notable that for linear systems with a constant natural frequency f_0 the damping coefficient $h_0(t)$ (equation 12) depends only on the varying envelope. By estimation of the average damping coefficient as an integral in the interval of time, we will get the well-known approximate formula for the logarithmic decrement from the decay envelope:

$$\frac{\overline{h}}{f_0} = \frac{1}{(t_1 - t_2) f_0} \int_{t_1}^{t_2} \frac{\dot{A}(t)}{A(t)} \, \mathrm{d}t = n^{-1} \ln \frac{A_{i+n}}{A_i}$$

14.4 Considering high harmonics for identification

The modern vibration decomposition approaches [6, 9] divide the real multicomponent motion into a number of separated principal and high-frequency superharmonics. These approaches, considering the high superharmonics, yield more precise identification of nonlinear systems, including the nonlinear elastic and the damping static force characteristics. Theoretically, summarizing an infinitive number of partial static force characteristics will provide the exact initial static force characteristics of the nonlinear system. To precisely reconstruct the initial nonlinear force characteristics, we deduce the form of each oscillating function by using the EoE (equation 10).

In the first stage of the identification technique considering high harmonics, the signal envelope, together with the instantaneous undamped natural frequency and the instantaneous damping coefficient,

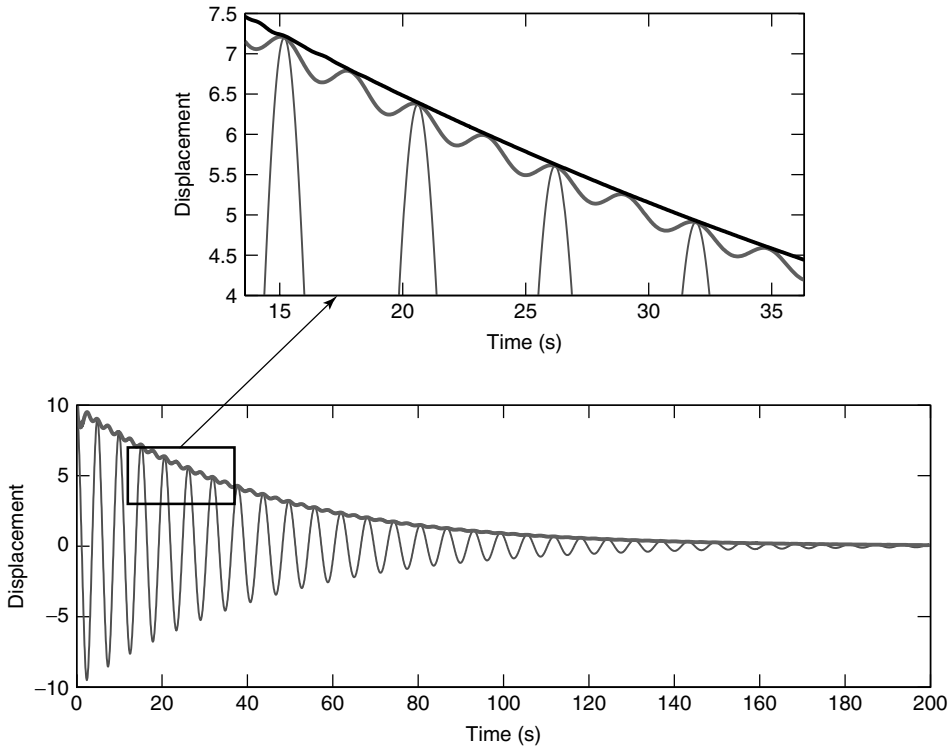

Figure 9. Nonlinear spring free vibration: the displacement (———), the envelope (▬▬), the envelope of the displacement envelope (smoothed bold line ▬▬).

is extracted from the vibration and excitation signals based on HT signal processing [8]. In the next stage, the EoE is generated by considering nonlinear high harmonics for every obtained instantaneous function, according to equation (10). In the final stage, the precise nonlinear static elastic and the damping force characteristics are constructed as a multiplication of two corresponding EoEs (for example, displacement and stiffness) according to the technique described in [8]. It is convenient to represent the final result of HT identification in a standard form that includes the skeleton curves with the initial static force characteristics of the nonlinear vibration system.

14.5 Example of nonlinear spring identification

As an example of a nonlinear elastic force, we refer to the classic Duffing equation with a hardening spring and a linear damping characteristic $\ddot{x} + 0.05\dot{x} + x + 0.01x^3 = 0$; $x_0 = 10$, $\dot{x}_0 = 0$. A simulation of the free vibration signal was carried out by using an initial displacement as shown in Figure 9. A part of the displacement envelope is shown separately with zoom to emphasize its oscillating behavior.

The obtained results of the HT identification are shown in Figure 10. The fast-varying instantaneous natural frequency (before the decomposition) is plotted against the envelope as a fast-changing spiral (Figure 10a, thin line). The same figure includes also the low-pass filtered skeleton curve (dashed line) that only approximately restores nonlinear forces correct to the first term of motion. The final precise "envelope" skeleton curve, which considers, in addition, two high superharmonics, is shown in Figure 10(a) with a bold line. The resultant identified spring data and damping force characteristics completely coincide with the initial cubic spring static force characteristics $k(x) = 1 + 0.01x^3$ (Figure 10b, dashed line)

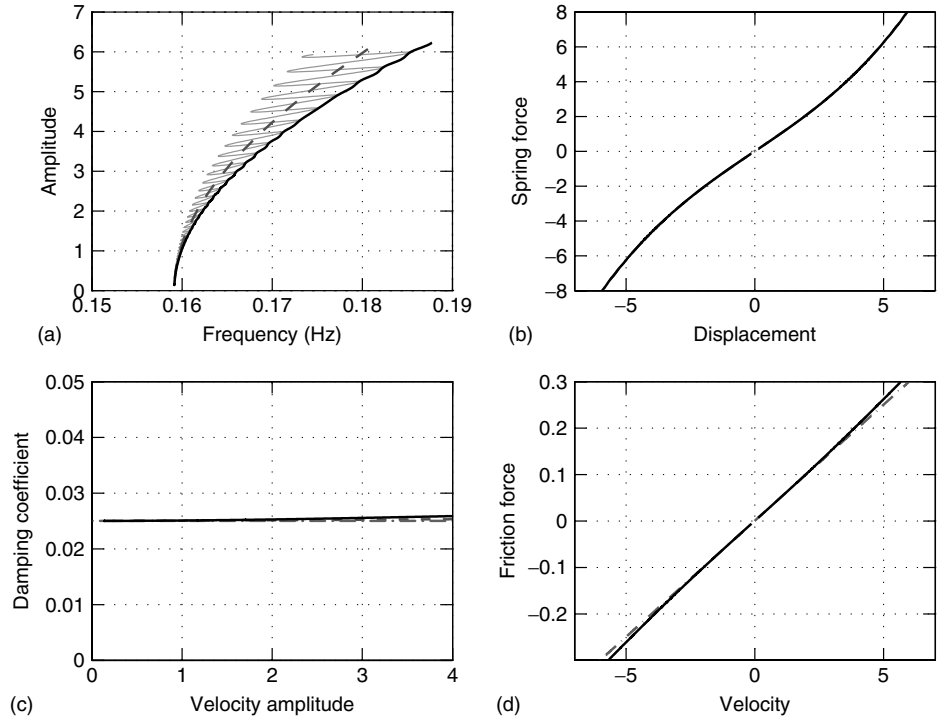

Figure 10. Identified nonlinear spring. The backbone (a): instantaneous (———), averaged (- - - -), with high harmonics (▬▬); The static spring force characteristics (b): initial (-•-), with high harmonics (▬▬); The damping curve (c): initial (-•-), averaged (- - - -), with high harmonics (▬▬); The static friction force characteristics (d): initial (-•-), with high harmonics (▬▬).

and the initial trivial straight friction force characteristics (Figure 10c and d, dashed line).

15 CONCLUSION

The HT is accepted as a standard procedure in the field of signal processing and has been used for more than 60 years. The application of the HT to the initial signal provides some additional information about instantaneous amplitude, phase, and frequency. This important information was valid when applied to monitoring and analysis of varying signals.

Two known HT signal decomposition methods (the EMD and the HVD) allow automatic and adaptive extraction of *a priori* unknown narrowband components from the nonstationary composition. The HT decomposition methods are dedicated primarily to decomposition of quasi and almost periodic oscillating-like signals. Such oscillating types could be, for example, multicomponent nonstationary modulated vibrations similar to rotor start-up or shutdown vibration, or motion of nonlinear dynamic system.

The instantaneous amplitude, phase, and frequency have valuable properties for determining changes from signal measurements. Not only this but also the instantaneous parameters are able to solve an inverse problem—the problem of identification of dynamic nonlinear systems. The HT-based technique facilitates direct estimation of system instantaneous dynamic parameters (i.e., natural frequencies and damping characteristics) as well as their dependence on vibration amplitude and frequency.

Chapter 26
Time–frequency Analysis

Rosario Ceravolo

Dipartimento di Ingegneria Strutturale e Geotecnica, Politecnico di Torino, Torino, Italy

1 INTRODUCTION

Interest in time–frequency representation is motivated by the limitations of classical spectral estimation techniques in analyzing strongly nonstationary behaviors [1]. Owing to the importance of nonstationary components in vibration signals, several studies have proposed the adoption of time–frequency analysis in structural diagnostics [2, 3] and machine fault detection [4].

Encyclopedia of Structural Health Monitoring. Edited by Christian Boller, Fu-Kuo Chang and Yozo Fujino © 2009 John Wiley & Sons, Ltd. ISBN: 978-0-470-05822-0.

Though a huge variety of plausible theories and perspectives has been proposed for time–frequency analysis, one method cannot be claimed to be superior to the others under all conditions. The benefits of each time–frequency approach should be highlighted and demonstrated by referring to specific applications. In the particular field of "structural health monitoring" (SHM), many authors have applied linear tools, such as the short-time Fourier transform and the wavelet transform, or in some cases their squared magnitudes, known as *spectrogram* (SPEC) and *scalogram* (SCAL), respectively. Others have appealed to quadratic structures, since energy is a quadratic signal representation.

The adoption of a quadratic representation makes it possible to overcome limitations due to the time–frequency resolution, since energetic and correlative transforms are not based on signal segmentation. Specifically, among the quadratic transforms, those belonging to the Cohen class [1] are characterized by their invariance to time and frequency shifts. Shift invariance is of great importance when processing signals measured on mechanical systems and justifies the interest that many researchers have shown for this approach.

The present article is intended as a comprehensive overview of some recent advances in the field of time–frequency analysis for structural identification. We focus on the shift-invariant class, including the SPEC. Other time–frequency analysis techniques include, but are not limited to, wavelet analysis (*see* **Wavelet Analysis**) and empirical mode

decomposition combined with Hilbert transform (*see* **Damage Detection Using the Hilbert–Huang Transform**).

In more detail, the exposition starts with a brief review of the main time–frequency transforms, laying a special emphasis on properties that are desirable in SHM applications. Time–frequency analysis is then discussed from the stochastic perspective, which entails the definition of time-dependent spectra that reflect the time evolution of the second-order properties of the processes. Much of the practical interest in stochastic formulation lies in defining proper time–frequency estimators for output-only system identification. Structural dynamics models are then introduced in formulations, so as to support data analysis of time series and, specifically, linear and nonlinear identification techniques.

The article concludes with a numerical example showing the identification of a simple nonlinear system, and with an experimental application to the dynamic characterization of a real reinforced concrete building.

2 JOINT TIME–FREQUENCY REPRESENTATION

The main advantage of time–frequency domain analysis is its ability to handle nonstationary waveform signals, which are very common when structural defects and machinery faults occur.

As an example, let us consider a signal that features a time localization of spectral components. The Fourier transform is not suited for the analysis of such components, since it projects the signal on infinite harmonics, which are not localized in time. If at any time instant only a single frequency is present, an instantaneous frequency may be variously defined; this quantity is commonly identified with the rate of phase change in the analytic signal (*see* **Hilbert Transform, Envelope, Instantaneous Phase, and Frequency**; **Damage Detection Using the Hilbert–Huang Transform**). Such a definition is capable of describing the time localization of a specific class of signals, but proves to be unsuitable for multicomponent ones.

In all cases where monodimensional representations are inadequate, one can turn to bidimensional (joint) functions $T_x(t, f)$ of the variables time and frequency. $T_x(t, f)$ is referred to as *time–frequency representation* (TFR) of the signal $x(t)$.

2.1 Linear time–frequency transforms

2.1.1 Short-time Fourier transform (STFT)

In order to introduce the time localization of frequency components, a simple solution is obtained by prewindowing the signal around a particular time t, as shown in Figure 1, calculating its Fourier transform, and doing that for each time instant t. Accordingly, the "short-time Fourier transform" (STFT) of a signal $x(t')$ is defined as [5, 6]

$$STFT_X^{(\gamma)}(t, f) = \int_{-\infty}^{+\infty} x(t')\gamma^*(t - t')\,\mathrm{e}^{-jft'}\,\mathrm{d}t' \quad (1)$$

where $\gamma(t)$ is a short-time analysis window centered around t. The superscript * denotes complex conjugation.

Since multiplication by the relatively short window $\gamma(t' - t)$ effectively suppresses the signal outside a neighborhood around the analysis time point $t' = t$, the STFT is a "local" spectrum of the signal $x(t')$ around t.

The STFT is evidently linear and is complex-valued, in general. Provided that the short-time window is of finite energy, the STFT is invertible through

$$x(t) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} STFT_X^{(\gamma)}(t', f')g(t - t') \times \mathrm{e}^{jf't}\cdot \mathrm{d}t'\cdot \mathrm{d}f' \quad (2)$$

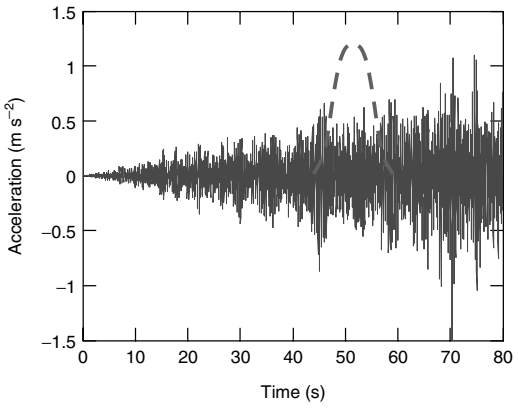

Figure 1. Prewindowing of a nonstationary signal.

with $\int g(t)\gamma^*(t)\,\mathrm{d}t = 1$. Equation (2) implies that the total signal can be decomposed as a weighted sum of elementary waveforms

$$g_{t,f}(t') = g(t'-t)\cdot \mathrm{e}^{\,jft'} \tag{3}$$

which can be interpreted as "atoms". Each atom is obtained from the window $g(t)$ by a shift in time and frequency (modulation).

The STFT may also be expressed in terms of signal and window spectra:

$$STFT_x^{(\gamma)}(t,f) = \int_{-\infty}^{+\infty} X(f')\Gamma^*(f'-f) \times \mathrm{e}^{j(f'-f)t}\,\mathrm{d}f' \tag{4}$$

where X and Γ are the Fourier transform of x and γ, respectively. Accordingly, the STFT can be interpreted as the result of passing the signal through a filter with frequency response $\Gamma(f'-f)$ and is, therefore, deduced from a mother filter $\Gamma(f)$ by a translation of f. The STFT is thus similar to a bank of band-pass filters with constant bandwidth.

The STFT preserves time–frequency shift (property P2 in Table 1). Such transform, as well as its squared magnitude, the SPEC, is frequently used in many application fields, including modal decoupling, system identification (e.g., [7, 8]), group velocity, speech recognition, etc.

2.1.2 Time–frequency resolution

The time resolution of the STFT can be obtained by considering for x a Dirac impulse:

$$x(t) = \delta(t-t_0) \Rightarrow STFT_x^{(\gamma)}(t,f) = \mathrm{e}^{-jft_0}\gamma(t-t_0) \tag{5}$$

Thus, the time resolution of the STFT is proportional to the effective duration of the analysis window γ. Similarly, to obtain the frequency resolution, we have to consider a complex sinusoid (an impulse in the frequency domain)

$$x(t) = \mathrm{e}^{j2\pi f_0 t} \Rightarrow STFT_x^{(\gamma)}(t,f) = \mathrm{e}^{-j2\pi f_0 t}\Gamma(t-t_0) \tag{6}$$

Hence, the frequency resolution of the STFT is proportional to the effective bandwidth of the analysis window γ. As a consequence, for the STFT, we have a "trade-off" between time and frequency resolutions: while a good time resolution requires a short window γ, a good frequency resolution requires a narrow-band filter i.e., a long window. This limitation is a consequence of the Heisenberg–Gabor inequality [1, 9]:

$$T\cdot B \geq 1 \tag{7}$$

where T is the signal's temporal length and B is the bandwidth. The lower bound of the product is reached for Gaussian functions.

2.1.3 Discrete STFT

Equation (1) can be sampled on a rectangular grid:

$$STFT_x^{(\gamma)}(n,m) = STFT_x^{(\gamma)}\left(nt_0, mf_0\right) = \int_{-\infty}^{+\infty} x(t')\gamma^*\left(t'-nt_0\right)\mathrm{e}^{-j2\pi m f_0 t'}\mathrm{d}t' \tag{8}$$

where n and m are integers.

The problem is then to choose the sampling period t_0 and frequency f_0 so as to minimize the STFT inherent redundancy without losing any information [6, 10]. For a sampled signal $x[n]$ whose sampling period is noted Δt, t_0 has to be chosen as a multiple of Δt such that $t_0\cdot f_0 \leq 1$. We then have the following analysis and synthesis formulae [6]:

$$STFT_x^{(w)}[n,m] = \sum_k x[k]\cdot\gamma^*[k-n]\cdot \mathrm{e}^{-j\cdot 2\pi\cdot mk} \quad \text{for } -\frac{1}{2} \leq m \leq \frac{1}{2} \tag{9}$$

$$x[k] = \sum_n \sum_m STFT_x^{(w)}[n,m]\cdot g[k-n]\cdot \mathrm{e}^{j\cdot 2\pi\cdot mk} \tag{10}$$

Equations (9) and (10) can be implemented efficiently by means of overlap "fast Fourier transform" (FFT) techniques.

Alternatively, a filter-bank implementation is possible, based on sampling equation (4).

Table 1. Properties satisfied by time–frequency transforms and corresponding kernel conditions

	Property	Condition on the kernel
P0	Nonnegativity: $T_x(t, f) \geq 0 \ \forall t \ \forall f$	$g(\nu, \tau)$ is the AF[(a)] of some $f(t)$
P1	Realness: $T_x(t, f) = T_x^*(t, f)$	$g(\nu, \tau) = g^*(\nu, \tau)$
P2	Time–frequency shift: $y(t) = x(t - t_0) \Rightarrow T_y(t, f) = T_x(t - t_0, f)$ $y(t) = x(t)\ \mathrm{e}^{2\pi f_0 t} \Rightarrow T_y(t, f) = T_x(t, f - f_0)$	$g(\nu, \tau)$ independent of t and f
P3	Time marginal: $\int_{-\infty}^{+\infty} T_x(t, f)\,\mathrm{d}f = \lvert x(t)\rvert^2$	$g(\nu, 0) = 1 \ \forall \nu$
P4	Frequency marginal: $\int_{-\infty}^{+\infty} T_x(t, f)\,\mathrm{d}t = \lvert X(f)\rvert^2$	$g(0, \tau) = 1 \ \forall \tau$
P5	Instantaneous frequency: $\dfrac{\int_{-\infty}^{+\infty} f T_x(t, f)\,\mathrm{d}f}{\int_{-\infty}^{+\infty} T_x(t, f)\,\mathrm{d}f} = -\dfrac{\mathrm{d}}{\mathrm{d}t}\{\arg(x(t))\}$	$\left.\dfrac{\partial(g(\nu, \tau))}{\partial \tau}\right\rvert_{\tau=0} = 0 \ \forall \nu$
P6	Group delay: $\dfrac{\int_{-\infty}^{+\infty} t T_x(t, f)\,\mathrm{d}t}{\int_{-\infty}^{+\infty} T_x(t, f)\,\mathrm{d}t} = -\dfrac{\mathrm{d}}{\mathrm{d}t}\{\arg(X(f))\}$	$\left.\dfrac{\partial(g(\nu, \tau))}{\partial \nu}\right\rvert_{\nu=0} = 0 \ \forall \tau$
P7	Finite time support: $x(t) = 0 \quad \text{if } \lvert t\rvert \geq T$ $\Rightarrow T_x(t, f) = 0 \text{ per } \lvert t\rvert \geq T$	$\varphi(t, \tau) = 0 \ \lvert\tau\rvert < 2\lvert t\rvert$
P8	Finite frequency support: $X(f) = 0 \quad \text{if } \lvert f\rvert \geq B$ $\Rightarrow T_x(t, f) = 0 \quad \text{if } \lvert f\rvert \geq B$	$\int_{-\infty}^{+\infty} g(\nu, \tau)\ \mathrm{e}^{-j2\pi f \tau}\,\mathrm{d}\tau \ \lvert\nu\rvert < 2\lvert f\rvert$
P9	Reduced interference	$g(\nu, \tau)$ is a low-pass filter type in (ν, τ) plane

2.1.4 Wavelet transform

Another important TFR is the time–frequency version of the Wavelet transform (WT) defined as [5, 6, 11]

$$WT_x^{(\psi)}(t, f) = \int_{t'} x(t') \cdot \sqrt{\left|\frac{f}{f_c}\right|} \cdot \psi^*\left(\frac{f}{f_c}(t' - t)\right) \cdot \mathrm{d}t' \tag{11}$$

where $\psi(t)$ is a real or a complex band-pass function centered around $t = 0$ in the time domain. The parameter f_c in equation (11) corresponds to the center frequency of $\psi(t)$. The WT was originally introduced as a timescale representation and, in fact, retains the important property of preserving time shifts and timescaling. It does not, however, preserve frequency shifts.

The WT's time and frequency resolutions are related via the Heisenberg–Gabor inequality, like in the STFT case. However, while the STFT's resolution is the same for each analysis frequency, the WT's frequency resolution (respectively time resolution) becomes poorer (respectively better) as the analysis frequency grows.

Scale shift invariance makes the WT, or its squared magnitude, the SCAL, a frequent choice in pattern recognition and many other application fields, including ridge and phase estimation (e.g., [12, 13]) and SHM (e.g., see the list of references in [2–4]). Details on the WT and its application to SHM are found in **Wavelet Analysis**.

2.2 Quadratic time–frequency transforms

Although linearity is a desirable property, quadratic TFRs [5, 14] allow for interpreting the distributions from an energy point of view. This interpretation is expressed by the so-called marginal properties:

$$\int_{-\infty}^{+\infty} T_x(t, f)\,\mathrm{d}f = |x(t)|^2;$$
$$\int_{-\infty}^{+\infty} T_x(t, f)\,\mathrm{d}t = |X(f)|^2 \qquad (12)$$

having defined the "instantaneous power" $|x(t)|^2$ and the "spectral energy density" $|X(f)|^2$. Consequently, the signal energy is

$$E_x = \int_{-\infty}^{+\infty} |x(t)|^2\,\mathrm{d}t = \int_{-\infty}^{+\infty} |X(f)|^2\,\mathrm{d}f$$
$$= \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} T_x(t, f)\,\mathrm{d}t\,\mathrm{d}f \qquad (13)$$

The marginal properties are not sufficient to identify an energy density at every point in the time–frequency plane, since the uncertainty principle does not allow such a notion. Vice versa, many quadratic TFRs may loosely support an energetic interpretation even if they do not satisfy the marginal properties, among them the SPEC and the SCAL.

$$SPEC_x^{(\gamma)}(t, f) = |STFT_x^{(\gamma)}(t, f)|^2 \qquad (14)$$
$$SCAL_x^{(\psi)}(t, f) = |WT_x^{(\psi)}(t, f)|^2 \qquad (15)$$

In equation (14) the linearity structure of the STFT is violated, and, in fact, any quadratic TFR satisfies the "quadratic superposition principle":

$$x(t) = c_1 x_1(t) + c_2 x_2(t) \Rightarrow$$
$$T_x(t, f) = |c_1|^2 T_{x_1}(t, f) + |c_2|^2 T_{x_2}(t, f)$$
$$+ c_1 c_2 T_{x_1 x_2}(t, f) + c_2 c_1 T_{x_2 x_1}(t, f) \qquad (16)$$

The last two terms in equation (16) are the cross terms or interference terms. The interference terms are oscillatory structures, which are restricted to those regions of the time–frequency plane where the autoterms (or authentic terms) overlap. In the specific cases of the SPEC and the SCAL, if two components are sufficiently far apart in the time–frequency plane, then their interference terms are virtually nil.

Quadratic representations have recently served as an effective tool in structural diagnostics and machine fault detection [2–4].

2.2.1 *The autocorrelation form and the Wigner–Ville transform*

A general approach to deriving time-dependent spectra is by generalizing the Wiener–Khintchine theorem: the correlation function and the power spectrum form Fourier transform pair (*see* **Higher Order Statistical Signal Processing**). By assuming the symmetric form for the instantaneous temporal and spectral autocorrelation, which are also functions of the time lag τ and the frequency lag ν, respectively,

$$r_x(\tau, t) = x\left(t - \frac{\tau}{2}\right) x\left(t + \frac{\tau}{2}\right) \qquad (17)$$
$$r_x(\tau, t) = X\left(f - \frac{\nu}{2}\right) X\left(f + \frac{\nu}{2}\right) \qquad (18)$$

and by transforming equations (17) and (18) one obtains [1]

$$W_x(t, f) = \int_{-\infty}^{+\infty} x\left(t + \frac{\tau}{2}\right) x^*\left(t - \frac{\tau}{2}\right) \mathrm{e}^{-j2\pi f\tau}\,\mathrm{d}\tau$$
$$= \int_{-\infty}^{+\infty} X\left(f + \frac{\nu}{2}\right) X^*\left(f - \frac{\nu}{2}\right) \mathrm{e}^{j2\pi t\nu}\,\mathrm{d}\nu \qquad (19)$$

Equation (19) gives the "Wigner distribution" (WD), a transformation well known in quantum mechanics, whose signal-processing version is often referred to as *Wigner–Ville distribution*.

By taking the instantaneous cross correlation between two signals, $x_1(t)$ and $x_2(t)$, the WD assumes the following more general form:

$$W_{x_1 x_2}(t, f) = \int_{-\infty}^{+\infty} x_1\left(t + \frac{\tau}{2}\right)$$
$$\times\, x_2^*\left(t - \frac{\tau}{2}\right) \mathrm{e}^{-j2\pi f\tau}\,\mathrm{d}\tau$$

$$= \int_{-\infty}^{+\infty} X_1\left(f + \frac{\nu}{2}\right) \times X_2^*\left(f - \frac{\nu}{2}\right) \mathrm{e}^{j2\pi t\nu}\,\mathrm{d}\nu \quad (20)$$

The WD satisfies a large number of desirable properties (Tables 1 and 2), in particular, marginals, shift invariance, and real-valuedness. The instantaneous frequency (*see* **Hilbert Transform, Envelope, Instantaneous Phase, and Frequency**; **Damage Detection Using the Hilbert–Huang Transform**) and the group delay can be evaluated using the local first-order moments of the WD [1].

Among the dual class of correlative TFRs, which combine temporal and spectral correlations, an important role is played by the "ambiguity function" (AF) [5]

$$A_{x_1,x_2}(\tau,\nu) = \int_{-\infty}^{+\infty} x_1\left(t + \frac{\tau}{2}\right) x_2^*\left(t - \frac{\tau}{2}\right) \mathrm{e}^{-j2\pi\nu t}\,\mathrm{d}t = \int_{-\infty}^{+\infty} X_1\left(f + \frac{\nu}{2}\right) \times X_2^*\left(f - \frac{\nu}{2}\right) \mathrm{e}^{j2\pi\tau f}\,\mathrm{d}f \quad (21)$$

The AF may be viewed as a joint time–frequency correlation function. Along $\nu = 0$ and $\tau = 0$ axes, AF reduces to the time correlation function and the frequency correlation function, respectively (correlative marginal properties).

2.2.2 Cohen class of transforms

Among quadratic transforms, those belonging to the Cohen (or shift-invariant) class are characterized by the invariance of its members to time and frequency shifts (P2 in Table 1), a property that is desirable for correlating the signal characteristics to phenomena that take place in the mechanical system, which generates the signal. Cohen demonstrated that every member of the shift-invariant class is a filtered version of the WD, and that it is possible to use a general formula for describing all of them [1]. Indeed, equivalent formulas can be written in four different domains: temporal correlation domain (t, τ), time–frequency domain (t, f), AF domain (τ, ν), and spectral correlation domain (ν, f) [15, 16]. For instance, the following relation holds in the temporal correlation domain:

$$T_x(t,f) = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty} r_x(t',\tau)\varphi(t-t',\tau) \times \mathrm{e}^{-j2\pi f\tau}\,\mathrm{d}t'\,\mathrm{d}\tau$$
$$\varphi(t,\tau) = \int_{-\infty}^{+\infty} g(\nu,\tau)\ \mathrm{e}^{-j2\pi\nu t}\,\mathrm{d}\nu \quad (22)$$

where $g(\nu, \tau)$ is the kernel that uniquely identifies the specific TFR ($g(\nu, \tau) = 1$ for the WD).

2.2.3 Desirable properties of the t–f distributions

A standard set of desirable properties is usually referred [1, 5, 16] to compare the performance of different transforms. Herein, we consider a subset that contains the main characteristics that are of interest in the application context under discussion. In Table 1, properties are related to the corresponding requirements on the kernel. Table 2 reports the properties of eight important shift-invariant transforms, including the SPEC. The SPEC is, in fact, a member

Table 2. List of desirable properties satisfied by different quadratic transforms

Transforms	P0	P1	P2	P3	P4	P5	P6	P7	P8	P9
Spectrogram (SPEC)	√	√	√							√
Wigner distribution (WD)		√	√	√	√	√	√	√	√	
"Alias-free" Wigner		√	√	√	√	√	√	√	√	
Pseudo-Wigner		√	√	√		√				
Smoothed pseudo-Wigner		√	√							√
Cone–kernel		√	√					√		√
Reduced interference		√	√	√	√	√	√	√	√	√
Choi–Williams distribution (CWD)		√	√	√	√	√	√	√[(a)]	√[(a)]	√

[(a)] Not in a strict sense, but only approximately.

of Cohen's class, but, since it does not offer independence of temporal and spectral resolutions, it is generally classed as linear [1]. It is worthy to note that only the SPEC satisfies P0, while sacrificing nonnegativity is mandatory in order to gain time–frequency resolution.

The WD does not satisfy P9 (reduced interference), which is a desirable property, as it preserves only the authentic (e.g., modal) components. Figure 2(a–f) [17] shows the results obtained by applying different transforms to three sinusoidal components and two delta functions. Figure 3 [17] reports the contour plots obtained by applying the WD and the "Choi–Williams transform" (CWT) to an accelerometric signal recorded on a simply supported alloy beam in free vibration. It clearly outlines the interference term filtering operated by the CWT.

Detailed theoretical discussions on different TFRs may be found in the specialized literature [15, 16, 18].

3 TIME–FREQUENCY REPRESENTATION OF STOCHASTIC PROCESSES

3.1 Stationary processes

The notion of spectral density, which is well consolidated in the field of stationary processes, may constitute a valuable starting point for approaching nonstationary problems.

One of the reasons of the popularity of the Wigner transform is its desirable property to preserve the instantaneous spectral information in stationary processes. In fact, introducing the autocovariance function of a process F, $C_F(t, \tau) = \mathrm{E}\{r_F(t, \tau)\}$, and taking the expectation in both sides of equation (19), we obtain the Wigner spectrum [11, 19]:

$$\mathrm{E}\{WD_F(t, f)\} = \int_{-\infty}^{+\infty} C_F\left(t + \frac{\tau}{2}, t - \frac{\tau}{2}\right) \times \exp(-j2\pi f\tau)\,\mathrm{d}\tau \qquad (23)$$

In the stationary case, the quantity expressed in equation (23) is independent of t and reduces to the usual spectral density $\mathrm{E}\{WD_F(t, f)\} = S_F(f)$ [11, 19]. In this situation, in fact, the covariance operator is a convolution operator, which is known to be diagonalized by the complex exponential functions.

Unfortunately, in practical applications, a limited number of signals is available. If the process is ergodic, a WD estimate of the spectral density may be obtained from a single realization $x(t)$ by averaging over time instantaneous spectra [20]:

$$V_B(f) = \frac{1}{B}\int_{-\frac{B}{2}}^{\frac{B}{2}} |WD_x(t, f)|\,\mathrm{d}t \qquad (24)$$

On the basis of equation (24), it also proves possible to quantify the degree of nonstationarity of a stochastic process on the given time interval via a distance measure [20]

$$d_B^2(f) = \frac{1}{B}\int_{-\frac{B}{2}}^{\frac{B}{2}} |WD_x(t, f)|^2\,\mathrm{d}t - S_x^2(t, f) \qquad (25)$$

If the process is stationary d_B reduces to zero.

In multicomponent signals, however, the Wigner representation of a single realization of the process is affected by interference terms, which can be filtered out in the AF domain but at the cost of losing resolution. There is, in fact, a tradeoff between cross-term filtering and time–frequency resolution, and hence the representation is kernel dependent. Another problem is that the Wigner transform misses the desirable property of nonnegativity over the $t-f$ plane [21]. These two aspects may have some negative implications in the definition of instantaneous estimators to be used in the analysis of deterministic signals.

Going back to linear TFRs, the square modulus of the STFT, or SPEC, of a stationary process may be

written in the form [11]

$$\mathrm{E}\left\{SPEC_F^{(\gamma)}(t, f)\right\} = \int_{-\infty}^{\infty} \left|\Gamma\left(f' - f\right)\right|^2 S_F(f)\,\mathrm{d}f' \tag{26}$$

where $\Gamma(f)$ is the spectrum of a window function $\gamma(t)$, such that $\|\Gamma(f)\| = 1$ and $S_F(f)$ is the spectral density associated with the process. Equation (26) shows that the value of the spectrum at f is a weighted average of the spectral density, when $f \sim f'$. As long as the Fourier transform of the window is still localized near the origin, the spectrogram provides, for each fixed f, information on the part of the original signal, which comes from the frequency contributions localized near f.

If one were to work with a sample realization $x(t)$, by assuming the ergodicity of the signal, an estimator of the spectral density may be defined as follows [11]:

$$V_B(f) = \frac{1}{B}\int_{-\frac{B}{2}}^{\frac{B}{2}} SPEC_x^{(\gamma)}(t, f)\,\mathrm{d}t \tag{27}$$

Owing to the weighting average operation, the spectral function expressed by equation (27) is a biased estimator. A spectral function that supports a weighted average interpretation may be also defined for the SCAL [11].

3.2 Locally stationary processes
