The capacity to detect and respond to changes in environmental illumination is a fundamental survival skill present, to different degrees, in all living beings. Opsin-like molecules first appeared in prokaryotes (bacteria and archaea) and could function as proton-pumps to transfer energy within a unicellular organism. Activation of opsin-like molecules in response to circadian rhythms and dark–light cycles might sustain a primitive form of flagella and pili phototaxis. The capacity to perceive light stimuli further evolved in protozoa, where opsins allow for rudimental vision to sense the environment and guide adaptive movements. However, only metazoans (animals) display anatomical structures dedicated to detection and processing of light stimuli, with graded complexity from the pit eyes of worms and mollusks to the camera-type eyes of vertebrates, all of which contain light-responsive photoreceptors.

Evolution has resulted in two primary types of photoreceptor cells: rhabdomeric and ciliated. In both, the cell membrane has evolved to accommodate the maximum number of opsin molecules to increase the probability that one is activated by a single photon of light. Photoreceptors in most invertebrates are rhabdomeric with thousands of opsin-containing microvilli, whereas most vertebrates have a ciliated structure containing multiple invaginations of opsin-rich stack of membranous disks, known as the outer segment. Furthermore, as described elsewhere in this encyclopedia, other marine mollusks – such as the Pectin – contain rhabdomeric and ciliary photoreceptors in separate layers in the same retina. While phototransduction leads to membrane depolarization in rhabdomeric photoreceptors, it results in hyperpolarization in ciliated photoreceptors. Developmental

processes also differ between invertebrates and vertebrates, even in those species displaying a camera-type structure. In the former (e.g., the octopus), the eye is of epidermal origin and mature photoreceptors face the vitreous cavity. In the latter, the eye develops from the neural plate (neuroectodermal origin) and mature photoreceptors are oriented away from the vitreous.

This article follows the developmental pathway that results in the generation of rods and cones from pools of retinal progenitor cells (RPCs) in the mammalian retina. We describe the factors involved in photoreceptor cell-fate specification, determination, and maturation. We have focused on human photoreceptors for their relevance in retinal degenerative diseases and on the mouse because of abundant available literature in this model pertaining to photoreceptor development.

Photoreceptor Development

Rod and Cone Pattern in Human and Mouse Retina

Photoreceptors are characterized by distinct morphology and synaptic connections that reflect their unique functions in light detection and visual process. Rod photoreceptors function in dim light, whereas cones are responsible for chromatic vision and visual acuity in bright light. These differences in light sensitivity are made possible by distinct visual pigments (opsins) and other proteins that mediate the phototransduction cascade.

All rod photoreceptors express rhodopsin from the *OPN2/RP4/RHO* gene and display peak sensitivity at a wavelength of approximately 500 nm. Cone photoreceptors can be further distinguished in different subtypes, based on the wavelength sensitivity conferred by their characteristic opsin photopigment. Humans and old world primates have three subtypes of cone photoreceptors. Cones sensitive to blue light express short-wavelength-sensitive (S)-opsin from the *OPN1SW* gene (S cones); cones sensitive to green light express medium-wavelength-sensitive (M)-opsin from the *OPN1MW2* gene (M cones); whereas those sensitive to red light express long wavelength-sensitive (L)-opsin from the *OPN1LW* gene (L cones). On the other hand, only S-opsin and M-opsin from *Opn1sw* and *Opn1mw* genes, respectively, are expressed in mouse cone photoreceptors.

In humans and mice, rods represent over 95% of the photoreceptors. The remaining 5% (human) and 3% (mouse) are cone photoreceptor subtypes. Rods and cones are arranged in a spatial mosaic in the human retina, where cones are concentrated in a region at the center of the macula – the fovea. The innermost 100-μm-wide central fovea – known as the pure cone area – contains a dense population of L and M cones and it is completely devoid of S cones, which are distributed in the peripheral fovea. Rods appear only approximately 300 μm from the center of the fovea and their density peaks outside the fovea at the eccentricity of the optic disc. A smaller proportion of cones are found interspersed within the more numerous rods in the peripheral retina. The ratio of L-to-M cones in the pure cone area and between central and peripheral retina varies considerably among individuals, and no characteristic cone-subtype distribution pattern is evident.

In the mouse retina, rods are relatively homogeneously distributed, and there is no structure resembling the human fovea. However, S- and M-opsins are expressed in cones in a reciprocal dorsal-to-ventral gradient with S-opsin-expressing cones localized predominantly in the ventral portion of the retina and M-opsin cones predominantly in the dorsal region. Differences in photoreceptor subtypes and distribution are reflected in the developmental events that generate photoreceptors in the human and mouse retina.

Development of Cone and Rod Photoreceptors

The retinal neuroepithelium is populated by proliferating, undifferentiated, multipotent RPCs (neuroblasts), from which all neural retinal cell types – including rod and cone photoreceptors – are generated during retinogenesis. Cell birth refers to the time when a cell exits the final mitotic cycle and commits to a specific differentiated fate. Birth-dating studies in the murine retina have shown that RPCs destined to become cone photoreceptors exit the cell cycle between embryonic day (E) 11 and E18 starting from the central retina and proceeding toward the periphery (**Figure 1(a)**). In an overlapping wave, rod progenitors exit the cell cycle between E12 and postnatal day (P) 10. Initiation of opsin protein expression occurs later, with S-opsin protein first detected around E19, followed by rhodopsin around P2 and M-opsin around P7.

Immunohistochemical analysis of the developing human retina, together with data from Macaque monkeys, suggests that cone photoreceptors are generated in the human retina starting from the prospective fovea in a period of time from fetal week (Fw) 8 to Fw34 (**Figure 1(b)**). In humans, rod genesis begins after cone birth around Fw10 but overlaps with cone genesis and continues into the first 8 months of postnatal life. Unlike the mouse, S-opsin expression in humans initiates around Fw12, preceding rhodopsin and L-/M-ospin expression, which are evident by Fw15. In humans, synaptic and neurotransmitter proteins are expressed in association with the initiation of synaptogenesis during the lag period between cone genesis and production of cone opsin. However, synaptogenesis in rods occurs only after the onset of rhodopsin synthesis.

In the mouse, the above-mentioned events occur first in the center of the retina and proceed toward the periphery; this is similar to humans where, generally, new developmental events start in the pure cone area. In the early postnatal human retina, the fovea is still immature with a

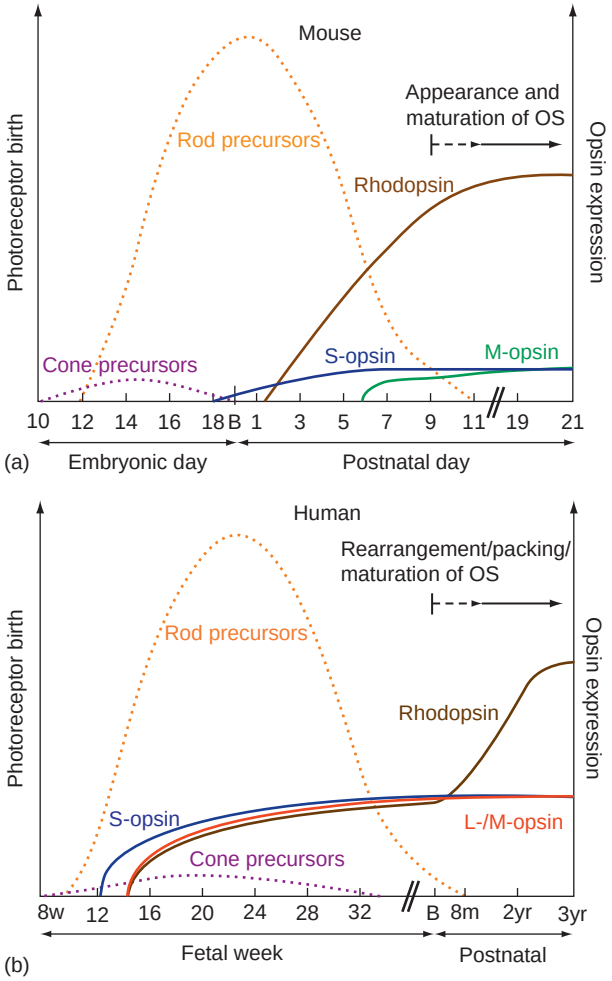

Figure 1 Photoreceptor development in mouse (a) and human (b) retina. In the first stage of photoreceptor development, prospective cone and rod precursors exit the cell cycle in sequential (cone first and rod after), yet overlapping waves (dotted lines). Postmitotic cells lose their apical process while retaining their connection to the outer limiting membrane and have elongated cuboidal morphology (cones) or a round shape (rods). The amplitude of the dotted curves in (a) and (b) represents the proportion of cells becoming postmitotic and fated to differentiate into cones (purple) and rods (orange), and the period of time in which all cells exit the cell cycle. Synthesis of specific opsins initiates the differentiation stage. Solid lines in (a) and (b) illustrate the temporal protein expression pattern of rhodopsin (brown), S-opsin (blue), M-opsin (green), and L-/M-opsin (red). In the mouse (a), S-opsin (blue) is expressed first, followed by rhodopsin (brown) and then M-opsin (green). The relative amount of rhodopsin expressed is considerably higher than S- and M-opsin, consistent with the higher proportion of rods (>95%) in the photoreceptor cell population. Photoreceptor maturation is completed between the second and the third postnatal week (arrow). In the human (b), S-opsin is synthesized first, followed shortly after by overlapping rhodopsin and L-/M-opsins. Rhodopsin production increases dramatically after birth, coincidental with outer segment formation and maturation. Cone and rod photoreceptors are rearranged after birth, with packing of cones in the fovea (dashed arrow). Outer segments continue to expand until they reach their mature size by the third year of age (solid arrow). B, birth; OS, outer segment.

greater proportion of rods than cones at the edge of the pure cone area. The mature fovea becomes evident by 1 year of age with the characteristic packaging of cones in the center. Rod outer segments continue to grow in length well into the first postnatal years until the human retina reaches full maturation by approximately 3–5 years of age.

Factors Affecting Photoreceptor Genesis

In the stereotypical progression of cell differentiation in the retina, cone genesis is initiated from common proliferating RPCs, in a sequential manner after RGCs and before horizontal and amacrine neurons. Rod birth is initiated later compared to cone genesis, but it precedes bipolar and Müller glia cells. However, the time intervals during which full complements of cone and rod photoreceptors are generated largely overlap (see **Figure 1**). Lineage and birth-dating analyses of mouse retina indicate that photoreceptor cell-fate decisions are made at the time of terminal mitosis; however, additional investigations are necessary. Two key elements control the commitment and differentiation of photoreceptors: gene-regulatory networks that confer competence to the RPC and dictate differentiation events (**Figures 2** and **3**), and extrinsic factors that modulate transcriptional cascades in differentiating RPCs and later modulate cell–cell communication (**Figure 2**). In addition, epigenetic mechanisms (such as chromatin modifications) appear to play a significant role in directing photoreceptor specification and differentiation.

Early Stages in Photoreceptor Development

From RPC to Photoreceptor Precursor

At the time of their last mitosis and prior to exiting the cell cycle, RPCs fated to become photoreceptors upregulate the expression of paired-class homeodomain transcription factor orthodenticle protein homolog 2 (OTX2) (**Figure 2**). In the mouse, OTX2 is first detected at E11.5–12.5 in the retinal neuroblastic layer (**Figure 3**). OTX2 expression increases thereafter, concomitantly with early cone and rod development, and persists in the postnatal mouse retina in bipolar and photoreceptor cells. *Otx2* plays an important role as an early factor that specifies photoreceptor cell fate, and probably as a late factor that may promote terminal differentiation by participating in upregulation of photoreceptor-specific genes. When *Otx2* is conditionally knocked out in the developing mouse eye, photoreceptors do not develop and are replaced by amacrine-like cells. Furthermore, when *Otx2* is ubiquitously expressed in RPCs, all cells follow the photoreceptor fate. In humans, *OTX2*

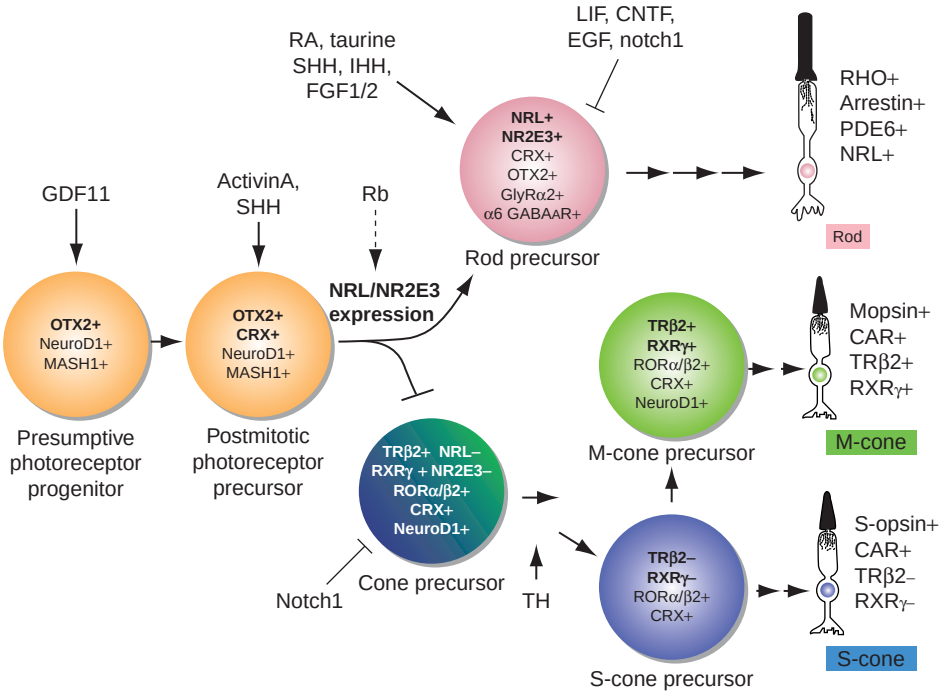

Figure 2 A model of photoreceptor development in the murine retina. Rods, S and M cones are generated from a common pool of retinal progenitor cells (RPCs), which exit the cell cycle at specific times during retinogenesis. A synergistic interaction between intrinsic and extrinsic factors progressively restricts cell fate, biasing individual cells toward differentiation into a unique mature cell type. Some of the known molecules involved are illustrated here. Proteins that appear to be major contributors to specification/determination of cell fate are shown in bold. Expression of OTX2 and CRX defines the postmitotic pool of cells fated to become photoreceptors (photoreceptor precursors). Expression of NRL and its target NR2E3 determines rod photoreceptor cell fate, whereas their absence leads to cone fate. NRL/NR2E3-expressing rod precursors progress through multiple transition stages and become functional rod photoreceptors when rhodopsin and phototransduction protein synthesis occurs and outer segments are mature. Photoreceptor precursors that do not express NRL/NR2E3 progress toward the cone lineage. Upon downregulation of TRβ2 and RXRγ, cone precursors become S cone precursors and synthesize S-opsin. For M cone precursors to develop, S-opsin expression must then be repressed by the heterodimer TRβ2/RXRγ, and M-opsin synthesis initiated by another TRβ2-containing complex. S- and M-opsin expression followed by outer segment maturation complete cone differentiation. The current model supports the existence of a default S-cone pathway that requires active inhibition by NRL/NR2E3 and by TRβ2/RXRγ to allow differentiation of rods and M cones, respectively. The roles of other cell intrinsic and extrinsic factors are further described in the text. Arrows indicate active promotion and truncated lines indicate inhibition of a developmental stage. Dotted lines indicate tentative roles. See the text for explanation of abbreviations.

mutations are associated with retinal diseases, such as anophthalmia, microphthalmia, and coloboma.

At the molecular level, OTX2 is shown to activate the promoter of cone–rod homeobox (CRX) transcription factor, a closely related homeodomain transcription factor. The two transcription factors (OTX2 and CRX) appear to promote completion of photoreceptor differentiation programs (**Figure 2**). CRX does not contribute to photoreceptor cell specification, but is essential for terminal differentiation and maintenance. In *Crx-null* mice, despite normal photoreceptor genesis, morphogenesis is incomplete as outer segments fail to elongate, and photoreceptors do not produce a full complement of phototransduction proteins. These abnormal photoreceptors undergo synaptogenesis, but their synaptic endings appear malformed and eventually degenerate. Mutations in the human *CRX* result in retinopathies, including Leber congenital amaurosis (LCA), cone–rod dystrophy, and retinitis pigmentosa (RP).

Another protein suggested to participate in photoreceptor cell development is the basic helix-loop-helix (bHLH) transcription factor NeuroD1 (**Figure 2**). *NeuroD1* is expressed in developing and differentiated rod and cone photoreceptors. Its targeted deletion in the mouse, however, causes only a modest decrease in photoreceptor number. NeuroD1 acts in combination with another bHLH transcription factor, MASH1, which may contribute to regulating the timing of photoreceptor differentiation as its targeted deletion in mouse leads to delay in photoreceptor development.

Very early, at the time of photoreceptor specification, postmitotic precursor cells become committed toward rod or cone fates. The Maf family basic motif-leucine zipper transcription factor NRL and its target, the

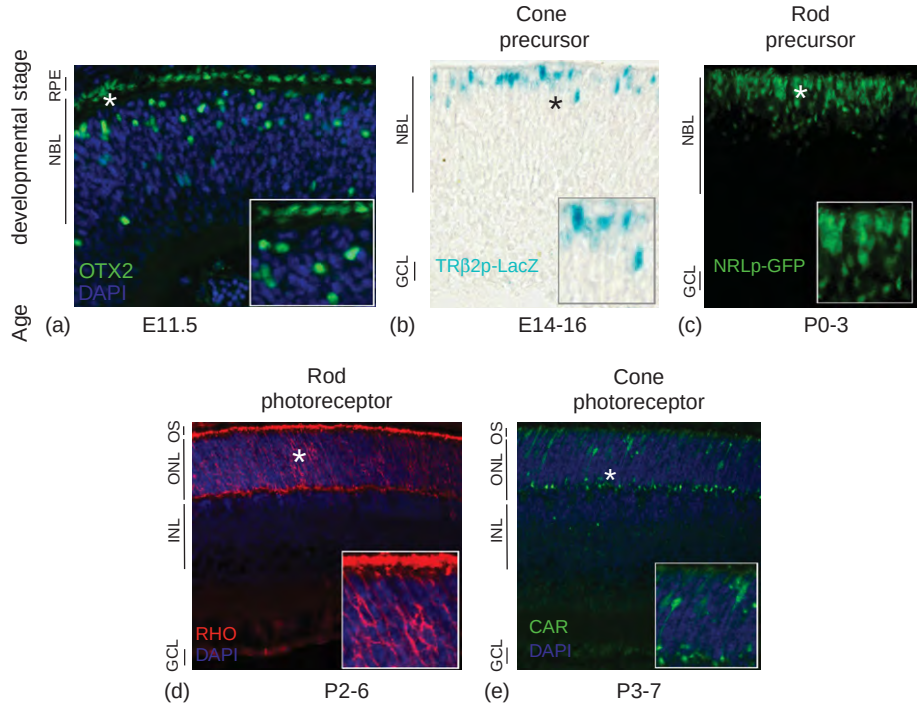

Figure 3 Stages of photoreceptor development in murine retina. Developmental stages are characterized by unique markers. Postmitotic photoreceptor precursors (a) can be detected by immunohistochemistry (IHC) with anti-OTX2 antibodies (green). Intermediate stages leading to cone or rod precursors are less delineated. However, cone precursors are characterized by the expression of TRβ2 and RXRγ, while rod precursors can be distinguished for NRL and NR2E3 expression. When the *lacZ* reporter gene driven by the *Trβ2* promoter is expressed in transgenic mice (b), cone precursors, normally expressing TRβ2, express LacZ (cyan). Similarly, rod precursors in a transgenic mouse expressing green fluorescent protein (GFP) under control of *Nrl* promoter (c) become fluorescent (green). Mature photoreceptors are identified by expression, at the RNA level first and protein level after, of their characteristic opsins and phototransduction proteins. Rod (d) and cone (e) photoreceptors are visualized by IHC with antirhodopsin (red) and anticone arrestin (green) antibodies, respectively. Areas labeled with an asterisk in (a)–(e) are enlarged in the inlets. Images are provided by Dustin Hambright ((a), (d), and (e)), Li Jia and Douglas Forrest (b), and Jerome Roger (c). RPE, retinal pigment epithelium; NBL, neuroblastic layer; GCL, ganglion cell layer; OS, outer segments; ONL, outer nuclear layer; INL, inner nuclear layer; E, embryonic day; P, postnatal day; DAPI, 4'-6-diamidino-2-phenylindole (nuclear staining); CAR, cone arrestin.

photoreceptor-specific orphan nuclear receptor NR2E3, are the primary determinants of rod versus cone cell-fate determination. It appears that S cone cell fate is specified as a default pathway and that inhibition of this pathway by NRL/NR2E3 is permissive to rod specification (**Figure 2**).

From Cone Precursor to Cone Photoreceptor

Cones are the first photoreceptor cell type to exit the cell cycle in all vertebrates (**Figure 1**). However, their differentiation takes a few days (mouse) to weeks (human) and is complete only after a majority of rods have become postmitotic. Cone precursors must go through an additional specification process that determines distinct cone subtypes (L, M, or S in humans, and M or S in mouse).

Studies of cone-photoreceptor-fate determination rely 8w?>on the detection of specific opsins at the mRNA or protein level, thus overlapping with studies on opsin gene regulation. In mouse and human cone precursors, S-opsin expression is detected first, followed by M-opsin expression (**Figure 1**). Variable numbers of photoreceptors go through a transitional state in which both opsins are expressed, before S-opsin is downregulated and M-opsin predominates. In the adult mouse retina, a prevalent population of photoreceptors coexpresses both pigments, whereas cone photoreceptors in the human retina express a single opsin.

In mice, onset of cone opsin expression is regulated by numerous factors; these include CRX, members of the nuclear receptor family, thyroid hormone nuclear receptor beta 2 isoform (TRβ2) and retinoid X nuclear receptor gamma (RXRγ), and of the retinoic acid (RA) receptor-related orphan receptor – RORα and RORβ2. RORα and RORβ2 are expressed in postmitotic cone-photoreceptor precursors and directly regulate S-opsin expression synergistically with CRX. Furthermore, RORα also appears to regulate the expression of M-opsin through direct binding to its promoter, highlighting a potentially more complex role in cone differentiation. Notably, *Rorβ2-null*

mice lack outer segments, suggesting RORβ2 plays an additional role in promoting photoreceptor maturation.

TRβ2 and RXRγ are also expressed in postmitotic cone precursors in the neonatal mouse retina (**Figures 2** and **3**) and act as transcriptional repressors of S-opsin expression. In fact, both receptors are downregulated concomitant with the initial onset of S-opsin expression and upregulated at a later stage in M cones in the dorsal retina to suppress S-opsin. Further evidence comes from studies of *Rxrγ-null* and *Trβ2-null* mice. Both nuclear receptors are necessary to repress S-opsin expression and probably act in concert on the S-opsin promoter. However, only TRβ2 is required for M-opsin expression, making it a key regulator of M cone differentiation. *Trβ2* gene appears to be regulated by a transcriptional complex containing NeuroD1. Although NeuroD1 alone is not sufficient to initiate *Trβ2* expression, it is required for sustained gene activation, thus supporting its role in M cone differentiation.

To date, there is no evidence involving RA in cone development in the mouse or human. On the other hand, TH has been suggested to regulate the ratio and patterning of cone-photoreceptor subtypes through changes in geographical distribution in the developing retina.

From Rod Precursor to Rod Photoreceptor

NRL is the master regulator of rod cell fate and serves as the unique defining signature of newborn rod photoreceptors (see **Figures 2** and **3**). NRL induces the expression of NR2E3. Following this, NRL and NR2E3 – together with CRX – lead to the expression pattern typical of mature rod photoreceptors (**Figure 2**). In mice *null* for the *Nrl* gene, all rods are converted to cones. Targeted deletion of *Nr2e3* in the mouse leads to enhanced S-cones with hybrid photoreceptors. Transgenic expression of *Nr2e3* in *Nrl-null* mice suppresses cone differentiation and leads to the generation of rod-like photoreceptors, yet NR2E3 is not sufficient to produce functional rods. These data support a model in which active induction by NRL and NR2E3 in CRX-expressing photoreceptor precursors is required for rod cell-fate determination with simultaneous inhibition of the cone pathway (**Figure 2**).

Mutations in NRL are associated with retinal degenerative diseases, including autosomal dominant and recessive RP, and retinopathies with varying phenotypes. Loss of NR2E3 in humans leads to enhanced S-cone syndrome, Goldmann–Favre syndrome, and similar retinopathies with increased S-cone function.

The retinoblastoma (*Rb*) gene appears to be an important intrinsic regulator of rod development. In the postnatal mouse retina, *Rb* is expressed in mitotic RPCs, where it regulates timely exit from the cell cycle, and in differentiating rod photoreceptors. When *Rb* is deleted, RPCs continue to proliferate and rod photoreceptors do not develop. Unlike *Nrl*- and *Nr2e3-null* mice, rod photoreceptors in *Rb-null* mice do not change their fate to cones (cone number remains unmodified). Rather, their development is arrested at the progenitor stage. It remains unclear from the current literature whether Rb is instructive or permissive for rod-photoreceptor cell fate.

Several extrinsic factors contribute to signaling for rod development (**Figure 2**). Cell–cell interaction mediated by Notch1 is known to sustain the undifferentiated and proliferating state of RPCs, repressing neuronal fate in general. Recently, Notch1 signaling has been shown to specifically inhibit photoreceptor fate, that is, cone in the embryonic and rod in the postnatal mouse retina. This function of Notch1 may allow differentiation of other neuronal cell types as light detection evolved from uniquely photoreceptor-based, in lower species, to multiple cell-type-mediated, in higher species. Other extrinsic factors inhibiting rod fate are leukocyte inhibitory factor (LIF), ciliary neurotrophic factor (CNTF), and epidermal growth factor (EGF).

Taurine, secreted by RGCs, is suggested to stimulate rod photoreceptor production through glycine (Gly) and gamma aminobutyric acid (GABA(A)) receptors. The hypothesis that taurine and its receptor GlyRα2 have a role in promoting rod cell fate awaits further validation.

Proper maturation and/or migration and integration of young rods into the outer nuclear layer (ONL) may require gradients of Indian Hedgehog (IHH) secreted by the retinal pigment epithelium (RPE), and Sonic Hedgehog (SHH) secreted by RGCs. IHH may also have a role in the specification of photoreceptor fate, possibly inducing *Nrl* in photoreceptor precursors. Similarly, fibroblast growth factor (FGF) family members – acidic FGF (FGF1) and basic FGF (FGF2) – are implicated in rod maturation and may induce NRL expression.

The role of RA in promoting rod photoreceptor differentiation is still unclear, though it can induce *Nrl* expression and RA-responsive sites are present in the *Nrl* promoter. However, retinoic acid receptor (*RAR*)β2/*RARγ*2 double *null* mutant mice contain a normal photoreceptor complement.

Activin A – a transforming growth factor beta (TGFβ)-like protein expressed by extraocular mesenchyme and RPE – promotes photoreceptor development *in vitro* and *in vivo*, and increases the number of photoreceptor cells in rat retinal cultures. *In vitro*, it causes RPCs to exit the cell cycle and biases them to become rods, but not cones. *In vivo*, mice with homozygous deletion of *activinA* show substantial decrease in the number of photoreceptors. Finally, growth differentiation factor 11 (GDF11) and related TGFβ family members control the competence of mitotic progenitors to acquire rod cell fate. *GDF11-null* retinas have more RGCs at the expense of photoreceptors.

Maturation of Photoreceptors

Cones are generated in mice during the prenatal period. Rod photoreceptor birth overlaps with the genesis of all retinal cell types, though most rods are born postnatally (**Figure 1**). Maturation of committed precursors to differentiated functional photoreceptors is a lengthy process and involves expression of cell-type-specific phototransduction genes, biogenesis of outer segments, and formation of synapses with specific interneurons. Expression of most photoreceptor-enriched genes depends on the synergistic or antagonistic actions of NRL, NR2E3, and CRX and their interaction with other regulatory proteins. In most instances, these proteins co-occupy the promoter/enhancer regions of their target genes. Mutations in the target genes of NRL and CRX are associated with retinal dysfunction.

Studies with transgenic and knockout mice, together with microarray and chromatin immunoprecipitation analysis, have yielded valuable information about gene-regulatory networks that guide photoreceptor differentiation and maturation. As NRL and its direct target nuclear receptor NR2E3 determine rod cell fate, these two transcription factors activate the expression of rod-specific genes and repress cone-gene expression. NRL, even in the absence of NR2E3, can activate all rod-specific genes (e.g., rhodopsin, PDE-α, PDE-β) but the repression of cone genes (e.g., S-opsin) is not efficient, leading to hybrid photoreceptors in mice expressing NRL but not NR2E3 (rd7 mice). NR2E3, on the contrary, can repress cone genes but it is unable to efficiently activate rod genes in the absence of NRL. Both NRL and NR2E3 interact with a multitude of regulatory proteins to accomplish transcriptional regulation. NRL is a highly phosphorylated protein and its function is modulated by several kinases. NRL also interacts with TATA-binding protein (TBP) and, presumably, brings the basal transcriptional machinery to target gene promoters. Recent studies have shown a key role for the protein inhibitor of activated STAT3 (PIAS-3) in the sumoylation of NR2E3, adding another level of control in gene expression and consequently rod differentiation. A combined action of NRL and NR2E3 is essential to generate functional rod photoreceptors.

CRX, on the other hand, acts as an enhancer of both rod and cone genes. While photoreceptors are produced even in the absence of CRX, these cells do not elaborate outer segments because of the low expression of most, if not all, phototransduction and structural proteins. CRX is, therefore, necessary to produce functional photoreceptors. CRX also interacts with coactivator proteins that possess histone acetyltransferase (HAT) activity and recruits HATs to promoter/enhancer regions to acetylate histone H3, thereby inducing and maintaining chromatin configurations that facilitate binding of NRL, NR2E3, and RNA polymerase II. These recently described molecular mechanisms underscore the importance of as yet poorly understood epigenetic factors in determining retinal photoreceptor cell fate and maturation.

Current Research in Photoreceptor Development

Cell interactions and intrinsic cellular mechanisms modulate gene expression and regulate photoreceptor differentiation. Among these, chromatin remodeling and small regulatory RNAs have attracted attention in recent years.

Histone methylation/acetylation are key epigenetic modifications that govern chromatin dynamics. The role of chromatin-modifying activities in directing tissue-specific development is an active area of investigation. Histone acetylation is emerging as an important mechanism in regulating photoreceptor development. Acetylation of histone H3 by HATs – recruited by CRX – appears important in maintaining chromatin configurations permissive to NRL/NR2E3 transcriptional activity in developing rods. Furthermore, histone deacetylase 4 (HDAC4) activity is shown to promote the survival of newly differentiated photoreceptors. More recently, the chromatin-remodeling complex Baf60c has been identified in differentiating, but not mature, retinal cells.

A family of three DNA methyltransferases, Dnmt1, Dnmt3a, and Dnmt3b, partially cooperate to establish and maintain genomic DNA methylation patterns. The presence of high levels of Dnmt3a and of Dnmt3b in the mouse rostral neural tube, including the optic grooves and cranial neural folds at E8.5, and in the area of evaginating optic vesicles at E9.5 is suggestive of the role Dnmts play in eye development. Epigenetic chromatin-remodeling mechanisms are also active in retinal neuroblasts undergoing cell-fate commitment, and are likely to contribute to retina-restricted patterns of gene expression. For example, hypomethylation is suggested to modulate interphotoreceptor retinoid-binding protein (IRBP) gene activation during photoreceptor genesis. Little is known about the influence of methylation on retinal cell fate, yet it is plausible that DNA methylation is actively involved in establishing RPC competence.

MicroRNAs (miRs) are short (18–24 nucleotides), noncoding, RNA sequences that modulate gene expression by binding the 3′ (and 5′) untranslated region (UTR) of their target RNAs, thus regulating their stability and translation. They originate as longer RNA transcripts that are processed and cleaved by the subsequent activity of two RNase III endonucleases – the Drosha-DGCR8 complex and Dicer. MiRs could play a gene-regulatory role in development (including retinal) that is comparable to that of transcription factors. For example, in the *Drosophila* eye,

miR-7 is activated by EGF-receptor (EGFR) signaling in cells undergoing the initial steps in photoreceptor differentiation. Furthermore, conditional *Dicer-null* mutation in the developing retina results in apparently normal retinal structure – albeit interspersed with rosettes and fated to progressive degeneration – pointing to the role of miRs in normal photoreceptor genesis and function. Further studies are warranted to fully elucidate the role of miRs in photoreceptors in general and in their development in particular.

Conclusions

When investigating cellular events and molecular mechanisms, the accuracy of models is only as good as the methods used to collect the data and the relevance to human retinal development of the animal model used. Future studies in other vertebrate species (e.g., zebrafish) and in human embryonic stem cells, with more sophisticated tools to dissect cell-fate specification/determination mechanisms, and the analysis of the vast amount of *omic* data available will permit integration of current photoreceptor development models to more closely represent the relevance to human disease. It is the authors' auspice that this article be read as the starting point to stimulate the reader's curiosity to further investigate the field of retinal developmental neurobiology for more in-depth understanding and up-to-date breakthroughs.

Photoresponse in Squid

J Mitchell and W Swardfager, University of Toronto, Toronto, ON, Canada

Glossary

Arhabdomeral lobe – The proximal segment of the photoreceptor cell containing the nucleus and other organelles.
Arrestin – A protein that binds to metarhodopsin and arrests phototransduction by inhibiting metarhodopsin activation of its target gaunine nucleotide-binding protein.
Calpain-like protease – An enzyme isolated from squid photoreceptors that, like calpain, requires millimolar concentrations of calcium for its proteolytic activity.
Metaretinochrome – The conformation of retinochrome when retinal has been photoisomerized to 11-*cis*-retinal.
Metarhodopsin – The light-activated conformation of opsin when bound to all-*trans* retinal.
Retinochrome – A photosensitive protein that binds all-*trans* retinal.
Rhabdomeral lobe – The distal segment of the photoreceptor cell containing the molecular machinery of phototransduction.
Rhabdomere – The collective surfaces of the distal segment composed of densely packed microvilli.
Rhodopsin kinase – An enzyme that adds phosphates onto serine or threonine residues in the carboxyl-terminus of metarhodopsin.

Introduction

Squid, like most invertebrates, have light-sensing organs. The visual systems of squid are composed of camera-type eyes. Incoming light passes through a single lens and an image is formed on the light-sensing cells of the retina in the anterior chamber of the eye. The retina consists of a single layer of photoreceptive neurons that are segmented in structure. The outer segment, also known as the rhabdomeral lobe, contains the protein machinery of phototransduction. The inner segment, or the arhabdomeral lobe, contains the cellular organelles involved in protein synthesis and the soma contains the cell nucleus. Axons arising from the soma of the photoreceptors comprise the optic nerve that projects to the squid brain (Figure 1).

The photoreceptor outer-segment membrane forms densely packed microvilli that greatly increase the surface area of the membrane available to capture incoming photons of light (see enlargement in Figure 1). Embedded in the membrane are the rhodopsin receptors containing light-sensitive chromophores. Light activation of rhodopsin sets off a cascade of molecular interactions that culminate in depolarization of the photoreceptor membrane (Figure 2). In recent years, many of the molecular components of the light-activated signaling system have been identified and a review of our current knowledge of these components is outlined here. Equally important to vision are the molecular mechanisms that inhibit signal transduction after transmission of the light signal (Figure 3). These mechanisms are not well understood; however, many of the components of the inactivation pathway have been revealed and these will also be discussed.

Molecular Components of Squid Visual Signal Transduction

The squid visual signal transduction system is composed of a light-sensitive receptor, rhodopsin, that transduces its activation signal via a heterotrimeric G protein (G_q) to a phospholipase C (PLC) enzyme. Activated phospholipases hydrolyze membrane phospholipids liberating soluble inositiol 1,4,5-trisphosphate (IP_3) and membrane-bound diacylglycerol (DAG). While it is still not clear how these second messengers stimulate membrane depolarization, it probably involves release of calcium from the submicrovillar tubules as a result of IP_3 stimulation of receptors on these organelles and perhaps direct stimulation of transient receptor potential (TRP)-like channels in the membrane by DAG. Together, these mechanisms raise intracellular calcium and increase membrane depolarization.

Squid Rhodopsin

Squid rhodopsin consists of a guanine nucleotide-binding protein-coupled receptor (GPCR) or opsin bound to a light-absorbing retinoid chromophore. Squid opsin genes have been cloned from *Loligo forbesi, Loligo pealei,* and *Todarodes pacificus*, and they share 45% sequence identity with other invertebrate and vertebrate opsins. However,

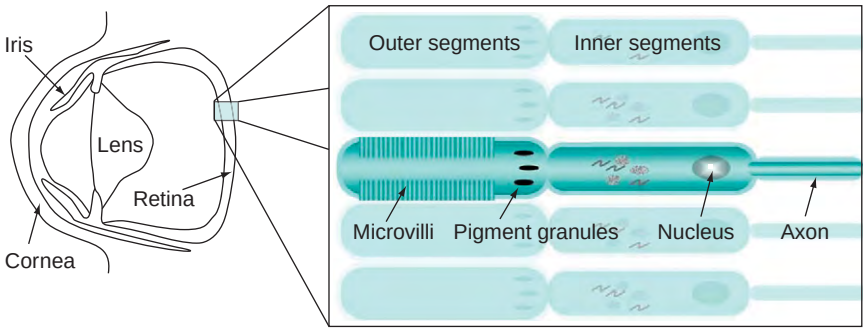

Figure 1 Structure of the squid eye and photoreceptors. Squid have camera-type eyes in which incident light enters the eye and an image is focused through a lens onto the retina in the anterior chamber of the eye. The enlargement on the right shows the orientation of the photoreceptors in the retina. The outer (rhabdomeral) segments contain the microvillar membranes in which rhodopsin and all of the photoreceptor proteins are embedded or associated. The inner (arhabdomeral) segments contain the cell organelles while the photoreceptor cell axons compose the optic nerve that extends to the brain.

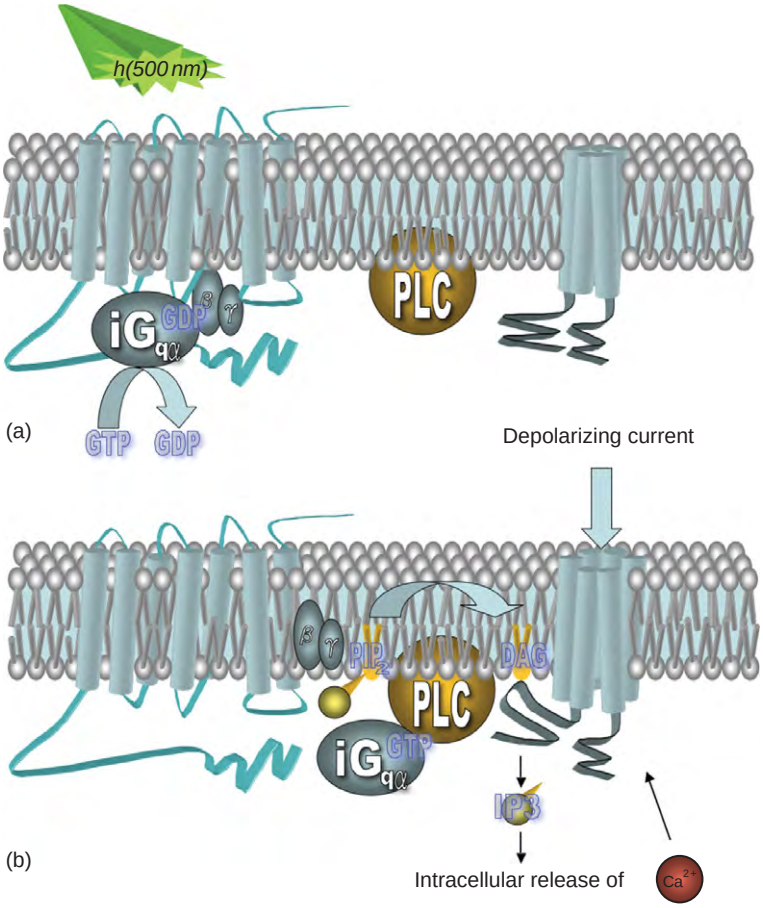

Figure 2 Activation of the squid visual system. (a) In the dark state, rhodopsin is likely coupled to an inactive (GDP-bound) invertebrate G_q (iG_q) protein. On absorption of a photon, 11-*cis*-retinal isomerizes to all-*trans*-retinal changing rhodopsin to metarhodopsin, which stimulates GDP–GTP exchange on the $iG_q\alpha$ subunit. (b) Activated $iG_q\alpha$-GTP changes conformation to interact with PLC stimulating the enzyme to hydrolyze phosphoinositol 4,5-bisphosphate (PIP_2) to inositol 1,4,5-trisphosphate (IP_3) and leaving DAG in the membrane. IP_3 stimulates the release of calcium (Ca^{2+}) from submicrovillar stores and, together with DAG, stimulates opening of an ion channel in the membrane. Membrane depolarization is transmitted to the optic lobe of the squid brain through the photoreceptor cell axons.

squid opsins are about 100 residues larger than those of vertebrates, primarily owing to the addition of a proline-rich carboxyl-terminal tail. Squid rhodopsins bear structural hallmarks of the GPCR superfamily, including amino-terminal sites of N-linked glycosylation, carboxyl-terminal sites of palmitoylation, a disulfide bridge between two extracellular loops, proline residues in the α-helices of the transmembrane domains, and a (D/E)R(Y/W)

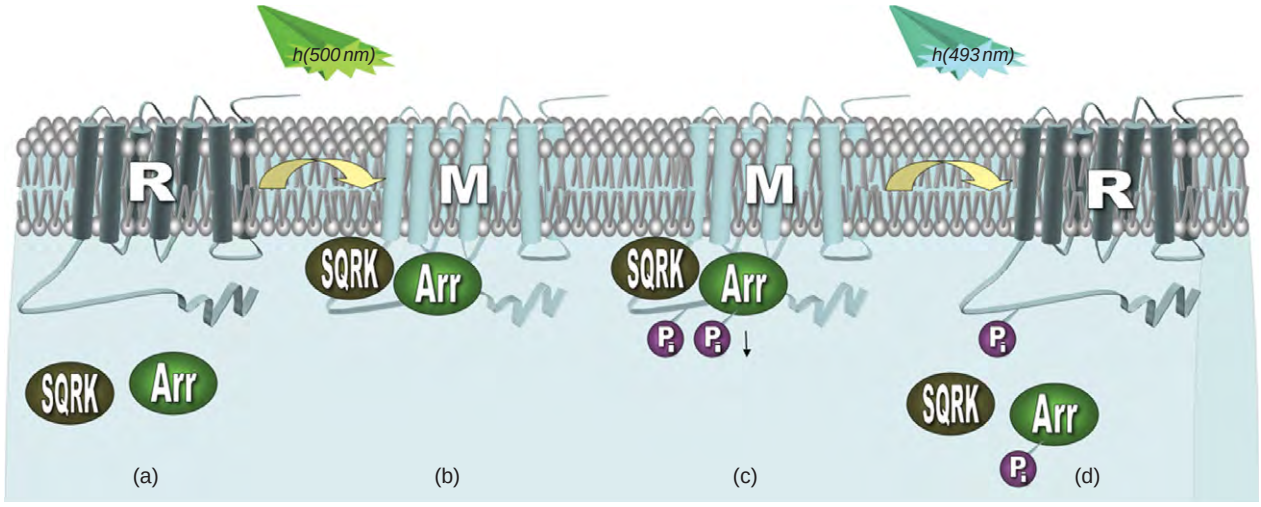

Figure 3 Inactivation of the squid visual system. (a) Rhodopsin (R) stimulation by light (*h* 500 nm) stimulates a conformational change to metarhodopsin (M). (b) SQRK and arrestin (Arr) both bind with high affinity to metarhodopsin. Arrestin binding obstructs further interaction of metarhodopsin with iG_q, uncoupling metarhodopsin from further stimulation of the signal transduction system. (c) SQRK phosphorylates metarhodopsin and following an increase in intracellular Ca^{2+} concentration, SQRK also phosphorylates arrestin. (d) A second light stimulus (*h* 493 nm) isomerizes all-*trans*-retinal back to 11-*cis*-retinal and converts metarhodopsin back to rhodopsin. Phosphorylation of arrestin and rhodopsin by SQRK may facilitate dissociation of the two proteins to return the system back to the dark state, which is primed to receive subsequent stimulation by light.

sequence in the third helix which is involved in G protein interactions.

The presence of a proline-rich carboxyl-terminal tail is unique to cephalopod rhodopsins. This motif consists of 9–10 repeats of the pentapeptide Pro–Pro–Gln–Gly–Tyr that may facilitate receptor trafficking and morphogenesis. Though unique among rhodopsins, tandem repeats of proline-rich sequences are found in other protein families, where they are often associated with protein–protein interactions. Rhodopsin–rhodopsin interactions may be of structural importance in the cephalopod rhabdomere, since rhodopsin networks form in the microvilli of the rhabdomeral lobe. In native membranes, electron microscopy has revealed both poorly ordered rhodopsin clusters of 4–10 molecules and ordered rhodopsin pentameres. Intermolecular interaction is mediated in part by the rhodopsin carboxyl-termini, which aggregate and extend intracellularly from the membrane surface. In contrast, when the carboxyl-terminal is cleaved, crystalline lattice formation is observed both in reconstituted membranes and in crystallized rhodopsin. These more highly ordered crystalline arrays may be favored by interactions between transmembrane domains of adjacent molecules. It has therefore been suggested that the proline-rich region may function, in part, to limit crystalline array formation in native membranes, contributing instead to the formation of less-ordered rhodopsin clusters that confer membrane superstructure. Unfortunately, technical considerations prevent the observation of the squid rhodopsin crystal structure with an intact proline-rich tail, precluding definitive structural analysis.

The majority of opsins are covalently linked to an 11-*cis*-retinal chromophore and squid rhodopsin employs the 4-hydroxy-retinal derivative. In the squid, retinal is attached via a protonated Schiff's base linkage to a lysine residue in transmembrane domain 7 (residue 303 in *Loligo* and 305 in *Todarodes*). In contrast to the mammalian opsins, however, where the Schiff's base is stabilized using a glutamic acid residue of transmembrane domain 3 as a counterion, the crystal structure of *Todarodes* reveals the counterion to be a glutamic acid at residue 180, which is located between transmembrane helices 3 and 4.

On absorption of a photon, 11-*cis*-retinal isomerizes to all-*trans*-retinal in a few hundred femtoseconds, which induces conformational changes in the opsin component. In invertebrates, the product of photoexcitation is an active metarhodopsin that is comparable in stability to inactivated rhodopsin. This contrasts the situation in vertebrates, where rhodopsin undergoes rapid sequential transitions between several unstable intermediate states. In vertebrates, all-*trans*-retinal is released during thermal relaxation of photoexcitation products and rhodopsin must be regenerated through subsequent recombination of opsin with another molecule of 11-*cis*-retinal. In the squid, however, the retinoid chromophore can remain attached to opsin throughout the rhodopsin activation cycle, and in a subsequent deactivating photoconversion event, invertebrate metarhodopsin can be converted to inactive rhodopsin by photon absorption. Thus, photobleaching may not be inevitable in the squid retina. The spectral sensitivities of squid rhodopsin and metarhodopsin differ by only a few nanometers (493 and 500 nm,

respectively) suggesting that the same visual stimulus could be both activating and inactivating. Due to the comparable stabilities and interconverting wavelengths of rhodopsin and metarhodopsin, it has been suggested that substantial populations of each could exist at steady state in the squid eye. However, retinas obtained from freshly caught squid are found to contain almost exclusively rhodopsin, a finding that suggests a highly efficient inactivation pathway.

In addition to rhodopsin, cephalopod photoreceptor cells contain retinochrome, a second photosensitive retinal-binding protein implicated in rhodopsin regeneration. Squid retinochrome from *Todarodes pacificus* has been cloned, revealing a 301-amino-acid protein. The structure of retinochrome resembles that of rhodopsin, but its retinoid occupancy is reversed; whereas rhodopsin binds 11-*cis*-retinal and produces all-*trans*-retinal on photoisomerization to metarhodopsin, retinochrome binds and photoisomerises all-*trans*-retinal to 11-*cis*-retinal in its conversion to metaretinochrome. Metaretinochrome then releases 11-*cis*-retinal, providing it to rhodopsin via a shuttling protein known as retinal-binding protein (RALBP). In the dark, metaretinochrome is localized in the arhabdomeral lobe, where it releases 11-*cis*-retinal and, subsequently, binds all-*trans*-retinal released from metarhodopsin. Soluble RALBP then shuttles 11-*cis*-retinal to the rhabdomeral microvilli, where it binds retinal-free opsin, which may have arisen as a photoproduct or by synthesis *de novo*, in order to generate rhodopsin. Light-dependent translocation of both rhodopsin and retinochrome has been documented. In the dark, rhodopsin and retinochrome colocalize at the base of the microvilli, while in the light rhodopsin redistributes along the entire area of the microvillar membrane, and retinochrome becomes more plentiful in the rhabdomeral lobe. Dynamic control of the availability of rhodopsin (and other light-absorbing pigments and signaling proteins) in signaling compartments may modulate the cascade and rhodopsin regeneration. Thus, the eye can adjust to dim or bright ambient light conditions, accurately perceive objects in each, and regenerate rhodopsin when necessary.

Squid Visual Guanine Nucleotide-Binding Protein, G_q

Squid rhodopsin couples to its effector enzyme, a PLC, via a heterotrimeric G protein belonging to the G_q subfamily. Like all G proteins in this family, squid G_q is composed of three nonidentical subunits, α, β, and γ. These subunits are associated with each other in the inactive state with GDP bound to the α subunit. In this state, the G protein is tightly bound to the rhabdomeric membrane, likely in association with rhodopsin. Upon 11-*cis*-retinal isomerization by light, a conformational change in the receptor causes a conformational change in the G protein subunits, which opens up the gunanine nucleotide-binding site on the α subunit allowing GDP to be exchanged for GTP. In the GTP-bound state, $G_q\alpha$ has a lower affinity for rhodopsin and its $\beta\gamma$ partners, but gains a higher affinity for its effector, PLC. PLC is recruited to the rhabdomeric membrane to interact with activated $G_q\alpha$ and its substrate phosphotidylinositol 4,5-bisphosphate. $G_q\alpha$ binding activates the PLC enzyme and at the same time the PLC stimulates the GTPase activity of $G_q\alpha$ resulting in hydrolysis of the terminal phosphate group on the bound GTP, thus rendering the G protein once again inactive in the GDP-bound state. Reassociation of the G protein subunits completes the cycle of activation and inactivation back to the basal state. The G protein is then ready to receive the next signal from rhodopsin.

G_q protein subunits have been purified and cDNA sequences encoding the proteins have been reported from *L. forbesi* and *L. pealei*. *Loligo* $G_q\alpha$ is similar in amino acid sequence to $G_q\alpha$ proteins of other species with a conserved guanine nucleotide-binding domain and three switch regions that are the major sites of conformational change in the protein when GDP is exchanged for GTP on the protein. The sites of interaction between a G protein α subunit and its receptor are primarily in the two ends of the protein. The carboxyl-terminus of squid $G_q\alpha$ is identical to that found in G_q proteins from other species; however, the amino-terminus of the protein in all invertebrates lacks a six-amino-acid extension found in mammalian $G_q\alpha$. Studies using *L. pealei* $G_q\alpha$ expressed in mammalian cells suggest that the modified amino-terminus found in invertebrate proteins increases the efficacy of G protein activation by receptors.

The amino-terminus is also the site of posttranslational addition of palmitic acid on one or more of the two cysteine residues at position 3 and 4 of the $G_q\alpha$ subunit. This lipid modification helps maintain membrane association of the G_q protein and is particularly important for keeping $G_q\alpha$ attached to the membrane following activation by the receptor when $G_q\alpha$ dissociates from the receptor and $G_q\beta\gamma$ subunits.

The $G_q\beta\gamma$ subunits have not been examined extensively. They appear to have similar functions to other G protein $\beta\gamma$ subunits in that they associate with the $G_q\alpha$ subunit when it is bound to GDP and dissociate when $G_q\alpha$ is bound to GTP. The $\beta\gamma$ subunits are tightly associated with the retinal membranes at all times and lipid modifications of the γ subunit may contribute to this localization. *Loligo* Gβ has a similar sequence to that of all other G protein β subunits, whereas *Loligo* Gγ is quite distinct from Gγ subunits of other species. $G_q\beta\gamma$ subunits do not activate purified PLC from squid eyes. Further studies will be required to determine if squid G protein $\beta\gamma$ subunits have any additional roles in visual signal transduction.

Squid Visual PLC

The protein stimulated by activated G_q in the squid visual system is PLC. The protein has been purified and the amino acid sequence determined from *L. pealei*. Immunoblot analysis of many squid tissues showed that the visual PLC is uniquely expressed in the photoreceptor membranes. Squid visual PLC is a 140 kDa protein that has significant sequence similarity and a domain structure that is common to phospholipase β enzymes; a PH domain that helps the protein bind to membranes, X and Y catalytic domains, and a C2 domain that is likely the site of calcium binding to the enzyme. In the absence of light stimulus to the photoreceptors, intracellular calcium concentrations are low and the PLC has very little catalytic activity. Upon activation of rhodopsin, the catalytic activity of the phospholipase is highly stimulated by the binding of activated $G_q\alpha$ to domains in the carboxyl-terminal end of the protein known as P and G boxes. The enzyme hydrolyzes membrane phospholipids with preference for phosphatidylinositol 4,5-bisphosphate, which is converted into inositol 1,4,5-trisphosphate (IP_3) and DAG. A network of submicrovillar tubules has been observed beneath the microvilli that may express IP_3 receptors and release stored calcium in response to IP_3 activation. A rapid rise in intracellular calcium may help to maintain PLC activity as these enzymes are stimulated in the presence of elevated calcium concentrations.

In addition to the role that calcium plays in visual signal transduction, high (millimolar) calcium concentrations can activate a calpain-like protease found in the squid retina. This protease can cleave several proteins in the visual signaling pathway. Calpain cleaves PLC near the carboxyl-terminus and renders the protein insensitive to $G_q\alpha$ activation. The protease can also cleave rhodopsin near its carboxyl-terminus removing the proline-rich repeat sequence from the rest of the molecule. Calcium activation of this protease may therefore play a role in freeing rhodopsin and G_q to allow for greater membrane turnover following prolonged light exposure.

Light-Activated Ion Channel

The final component in the visual signal transduction system is the channel regulated by PLC hydrolysis of membrane lipids. This component of the squid visual system has been characterized in only one report; an electrophysiological recording made from an isolated *L. pealei* photoreceptor. Light stimulation of the squid photoreceptor evoked an inward current with a peak amplitude greater than 1000 pA and channel activity was most frequently recorded when the patch electrode was placed near the apical tip of the cell where microvilli are present.

A squid photoreceptor channel has been identified and cloned from *L. forbesi* and it was found to be most homologous to that of the visual transient receptor potential (TRP) ion channels identified in *Drosophila*. TRP and an additional TRP-like channel have been shown to constitute the light-activated response in *Drosophila*. Analysis of the amino acid sequence of the squid channel suggests a protein with six or eight membrane spanning segments. The amino-terminus contains an ankyrin-like repeat sequence similar to that found in *Drosophila* TRP channels, and may account for the association of the protein with the cytoskeleton during purification. The carboxyl-terminus of the squid channel is considerably shorter than that found in the *Drosophila* TRP channel and lacks the proline-rich repeat sequence suggested to link TRP to intracellular Ca^{2+} stores. Expression of a peptide composed of the squid channel carboxyl-terminus bound to calcium-calmodulin *in vitro*. These studies suggest that the squid channel may be regulated differently from that of *Drosophila*, however, since the squid channel has not yet been characterized, its properties and the mechanisms by which it is regulated by the PLC signaling cascade remain speculative.

Desensitization of Visual Signal Transduction

Once rhodopsin has been activated, a series of protein–protein interactions occur within the photoreceptor cell to terminate signal transduction and restore the photoreceptor to its inactive state. Like most GPCRs, activated squid rhodopsin is phosphorylated by a G-protein-coupled receptor kinase (GRK) also called rhodopsin kinase. Light-activated rhodopsin also binds arrestin and biochemical studies using purified arrestin have demonstrated that this uncouples rhodopsin from activation of G_q.

Squid Rhodopsin Kinase

The squid visual system expresses a kinase that has sequence and functional similarity with other GRKs. The most extensively studied GRKs are the mammalian rhodopsin kinases (GRK1 and GRK7) and β-adrenergic receptor kinases (GRK2 and GRK3). Interestingly, molecular cloning of squid rhodopsin kinase (SQRK) revealed much higher sequence similarity to the mammalian β-adrenergic receptor kinase GRK2 (66%) than to GRK1 (33%), which terminates signaling in the mammalian visual system. This is a common theme among invertebrate rhodopsin kinases, as eye-specific GRK1 cloned from *Drosophila* and octopus rhodopsin kinase (ORK) also bear higher sequence identity to GRK2 than to GRK1. The structural similarities between SQRK and GRK2 include a central

serine/threonine kinase catalytic domain, a structurally conserved amino-terminal domain bearing an RGS domain, a conserved carboxyl-terminal sequence and a PH domain in the carboxyl-terminal. In GRK2, it has been established that a carboxyl-terminal region partially overlapping the PH domain associates with the G protein βγ subunits hence facilitating membrane localization in a stimulus-dependent manner. These structural similarities suggest that the phosphorylation of squid rhodopsin may more closely resemble the phosphorylation event of the mammalian β-adrenergic receptor than that of mammalian rhodopsin. SQRK structural motifs bearing high homology to the GRK2 Ca^{2+}/CaM-binding domain and the GRK2 clathrin box motif suggest that Ca^{2+} may have a role in regulating SQRK activity and that SQRK may also bind to the clathrin heavy chain and play a role in endocytosis. To date, functional characterization of SQRK has confirmed that purified SQRK is able to phosphorylate squid rhodopsin in rhabdomeric membranes in a light-dependent manner. SQRK phosphorylation of rhodopsin requires GTP and Mg^{2+} ion cofactors that may relate to the need to activate the G_q protein to allow SQRK access to rhodopsin.

Squid Visual Arrestin

Squid visual arrestin (sArr) has been cloned, purified, and characterized with respect to its functional interactions with rhabdomeric membranes. Squid arrestin from *L. pealei* is a 400-amino-acid protein with an estimated mass of 55 kDa that is expressed exclusively in eye tissue. Sequence identity between sArr and those from *Drosophila* and *Limulus* are 42% and 37%, respectively (sequence similarity including conservative substitutions is considerably higher, at 61% and 60%, respectively). Of the mammalian arrestins, visual arrestin from *L. pealei* shares highest identity with β-arrestins (44% identity and 64% similarity to β-arrestin1; 42% identity and 63% similarity to β-arrestin2). Squid visual arrestin is only 32% identical to mammalian visual arrestin, conservatively substituted to 49% similarity. This pattern of similarity parallels that between invertebrate rhodopsin kinase and mammalian β-adrenergic receptor kinases, and suggests that the functional interactions with invertebrate rhodopsin resemble those of the mammalian β-adrenergic receptor more closely than those of mammalian rhodopsin.

For many GPCRs, including mammalian rhodopsin, it has been demonstrated that receptor phosphorylation enhances high-affinity binding of arrestin. Accordingly, the primary structure of squid arrestin contains both conserved residues associated with both high- and low-affinity phosphate interactions. However, purified sArr does not seem to require rhodopsin phosphorylation to bind light-activated rhodopsin. This parallels biochemical studies in *Drosophila*, where purified Arr2 can bind to phosphorylated and unphosphorylated light-activated rhodopsin with comparable affinity. Further, light-dependent binding of Arr2 was equivocal in wild type and mutants where rhodopsin cannot be phosphorylated (both a truncation mutation lacking the phosphorylation site, and a serine to alanine point mutation that retains a similar structure but which cannot be phosphorylated). These findings are consistent with observations that the phosphorylation-deficient rhodopsin mutants display similar deactivation kinetics. Thus for invertebrates, the role of rhodopsin phosphorylation in arrestin binding is unclear, and light activation of rhodopsin may be sufficient.

Squid visual arrestin associates with the rhabdomeric membrane in a light-dependent manner and inhibits light-activated GTPase activity. This is consistent with the notion that recruitment and stoichiometric binding to the intracellular surface can uncouple G_q from the receptor and terminate signaling by a competitive mechanism. In the dark, squid arrestin also has appreciable affinity for the rhabdomeric membrane, an interaction which can be abrogated by inositol 1,2,3,4,5,6-hexakisphosphate (IP_6), a soluble analog of the membrane lipid phosphatidylinositol 3,4,5-triphosphate. This suggests that arrestin can also bind to membrane phospholipids, an interaction that studies in *Drosophila* suggest may mediate arrestin trafficking along an elaborate system of cytoplasmic structural components.

The primary structure of sArr includes five fingerprint motifs that correspond with domains of distinct functional importance conserved among the arrestin family; a region that recognizes receptor activation, a domain rich in hydrophobic interactions, a domain that recognizes receptor phosphorylation, a carboxyl-terminal regulatory domain, and a conserved amino-terminal domain. Overall, the arrestin molecule adopts a concave saddle-like conformation consisting of amino- and carboxyl-terminal domains rich in antiparallel β-sheets that hinge on a central polar core region of buried salt bridges that are disrupted when the molecule encounters the activated receptor. The primary sequence of sArr contains ^{26}Asp, ^{169}Arg, ^{293}Asn, ^{300}Asp, and ^{381}Arg, which are identical to bovine visual arrestin (except ^{293}Asn, which is a conservative substitution). These five essential conserved residues are contained within consensus sequences of five to eight identical or conservatively substituted amino acids that form the salt bridges buried in the polar core. Both the amino- and carboxyl-terminal domains mediate high-affinity binding to rhodopsin intracellular loops and these regions are located exclusively on the concave side of arrestin. Arrestin binding to rhodopsin thus occludes the binding of the G protein, preventing catalysis of GTP exchange, and uncoupling the receptor from its effector.

Interestingly, sArr can be phosphorylated by SQRK, a novel function among the GRK family. This contrasts the phosphorylation of *Drosophila* and *Limulus* visual arrestins, which are phosphorylated by Ca^{2+}/calmodulin-dependent kinase II. Phosphorylation of purified sArr requires SQRK, membranes, light-activated rhodopsin, and the presence of Ca^{2+}. Though the kinase is different, Ca^{2+} dependence is common to *Limulus* and *Drosophila*. Studies in *Drosophila* show that the kinetics of invertebrate visual arrestin phosphorylation are fast (seconds after illumination, 43% of *Drosophila* Arr2 is phosphorylated) and that arrestin phosphorylation can facilitate its release from rhodopsin once arrestin-bound metarhodopsin is photoconverted back to its inactive state. A similar role for squid arrestin phosphorylation has been found, as phosphorylated arrestin dissociates from dark-adapted membranes more readily than unphosphorylated arrestin.

Conclusion

Many of the molecular components of the squid visual system have been identified and characterized. Studies have suggested many similarities between the squid and other invertebrate visual systems. The strength of the squid system has been in the abundance of retinal tissue that makes protein purification and characterization feasible. These biochemical studies have complemented the power of genetic manipulations in the *Drosophila* system and the ease of electrophysiology in *Limulus*. Further studies are still required to determine the roles of rhodopsin and arrestin phosphorylations as well as identification of the many proteins involved in resetting the signaling components in the dark. We still know very little about how the activation of PLC results in membrane depolarization and the characteristics of the ion channels in the microvillar membranes. Future studies may eventually reveal all the molecular machinery of this fascinating visual system.

Glossary

Confocal fluorescence microscopy – An optical microscopy method that uses a focused laser spot to measure fluorescence within an extremely small volume.
Cytosol – The liquid portion of a cell's contents, or cytoplasm.
Depolarization – A positive-going change in the membrane potential of a cell.
Diacylglycerol (DAG) – A glyceride consisting of two fatty acid chains covalently bound to a glycerol molecule through ester linkages.
d-*myo*-Inositol (1,4,5) trisphosphate (IP_3) – An inositol derivative having three phosphate groups covalently bound to the inositol ring.
Guanine-nucleotide-binding protein (G protein) – A family of signaling proteins that are activated by the exchange of guanine triphosphate for guanine diphosphate bound to the protein.
On-cell patch clamp – An electrophysiological recording technique that uses a polished glass micropipette to measure currents flowing through a small patch of cellular plasma membrane containing ion channels.
Phosphoinositide – A phospholipid containing a polar inositol headgroup.
Smooth endoplasmic reticulum (SER) – A network of membrane sacs found in animal cells that, among other things, functions as a store of calcium ions.
Transient receptor potential (TRP) channels – A widespread family of ion channels. The light-activated channels of *Drosophila* are founding members of the family.

Arrangement of Eyes in *Limulus*

American horseshoe crabs (*Limulus polyphemus*) have 10 eyes. They have two large lateral compound eyes, each containing about 1000 clusters of photoreceptors or ommatidia. A small lens within each ommatidium focuses light from a small patch of visual space onto each photoreceptor cluster, which transmits information about local changes in light intensity to the brain through a nerve fiber. There are five additional eyes on the top side of its first (anterior) major body section, two median eyes, one endoparietal eye, and two rudimentary lateral eyes. Two ventral eyes are located on the underside of the animal above the mouth (Figure 1). Photoreceptors located on the telson (tail) constitute the 10th eye. Of these eyes, the lateral compound, median ocellar and ventral eyes have been extensively studied. All have microvillar photoreceptors, in which the visual pigment, rhodopsin, is embedded in the membrane of finger-like projections of the plasma membrane called microvilli (Figure 2). Each eye has allowed for a study of different aspects of invertebrate vision. The large compound eyes have been favorite preparations for the study of image processing by compound eyes, the biochemistry of visual transduction, and the circadian control of visual sensitivity. The medial eye has been studied for its sensitivity to ultraviolet (UV) light which has allowed the elucidation of the physiological consequences of the reversible photoisomerization of invertebrate rhodopsin. Lastly, the ventral eyes have played a role in the understanding of phototransduction in invertebrate photoreceptors.

The Microvillus is the Cellular Structure Mediating Visual Transduction

Central to the performance of each photoreceptor cell is the rhabdomere – an array of photoreceptive microvilli positioned so as to maximally absorb light entering the eye. Each microvillus is a cylindrical outgrowth of the plasma membrane, 50–80 nm in diameter and 0.5–2 μm in length (Figure 2). Electron micrographs often show an axial filament within each microvillus. The axial filament contains a bundle of actin filaments with their + ends directed toward the tip of the microvillus. The actin filaments appear to extend through the bottom of the microvillus into the cytoplasm, through fenestrations in submicrovillar cisternae (SMC) of smooth endoplasmic reticulum (SER). The actin cytoskeleton is responsible for the presence of an unconventional motor protein, myosin III, in the microvilli of *Limulus* lateral eye photoreceptors. The membrane of a typical microvillus contains 1000 or more particles, which are presumed to be mostly molecules of the visual pigment, rhodopsin, which absorbs light and initiates the physiological response of the photoreceptor. A photoreceptor might possess 10^5 microvilli, resulting in a total rhodopsin content of $\sim 10^8$ molecules, comparable to that of vertebrate retinal photoreceptors.

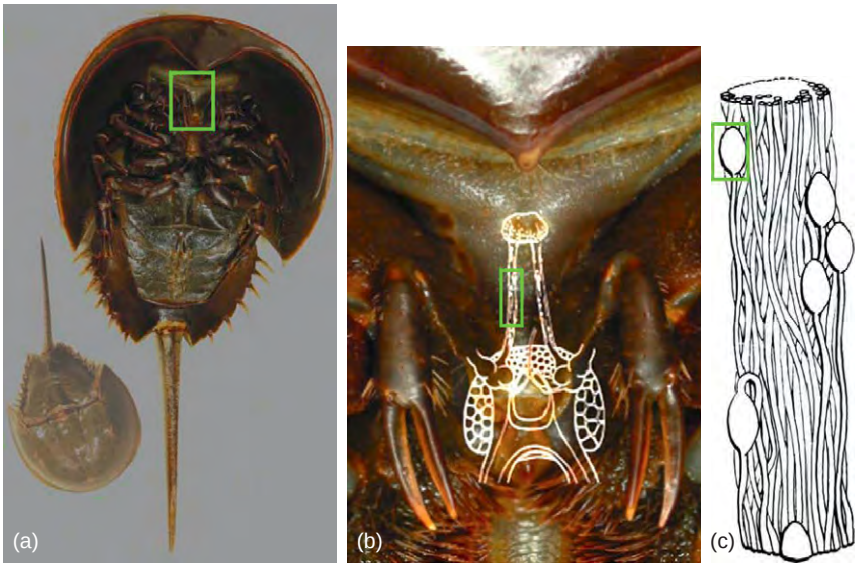

Figure 1 (a) Underside and top side (inset) of the Atlantic horseshoe crab (*Limulus polyphemus*). The green box shows the area enlarged in (b). (b) Enlarged view of the underside, just above the mouthparts. The drawn overlay shows the arrangement of the ventral nerves (green box, enlarged in (c)) and ventral eyes under the skin. The ventral nerves lead from the brain (just above the mouthparts at the bottom of the figure) to the ventral eyes above. Studies of Visual Transduction Using *Limulus* Ventral Photoreceptors

The *Limulus* ventral photoreceptor (**Figure 3**) is a highly polarized cell divided into two lobes, analogous to the inner and outer segments of vertebrate retinal photoreceptors. The rhabdomeral (R) lobe bears microvilli on its plasma membrane and is therefore light sensitive. The light-insensitive arhabdomeral (A) lobe contains the cell's nucleus. An axon projects from the A lobe toward the animal's central nervous system. Ventral photoreceptors were originally chosen as a model for invertebrate phototransduction because of their large size (>200 µm). This facilitates insertion of multiple electrodes and makes it possible to clamp the membrane potential of the cells, measure electrical current flow across the plasma membrane, and inject compounds of interest into the cytoplasm (**Figure 4**).

The essential electrical response to illumination is the activation of a very large flow of current into the cell, carried mostly by sodium ions (**Figure 4**). The result is a depolarization (positive-going change) of the cell membrane which is graded with light intensity, of up to 60 mV. The reversal potential of the light-sensitive current is between +10 mV and +20 mV and its dependence on extracellular ion concentrations indicates that this conductance is sodium- and potassium-, but not Ca^{2+}-permeable. This is in contrast to the light-activated transient receptor potential (TRP) channel conductance in the photoreceptors of the fruit fly, *Drosophila*, which is highly Ca^{2+} permeable.

The study of ventral photoreceptors has revealed that they have remarkable performance characteristics, most notably the very large amplification of the transduction process. Amplification refers to the amount of charge that is carried across the plasma membrane as a result of excitation by a single photon. In ventral photoreceptors, this gain can be directly measured because the single-photon response, termed a quantum bump, is easily recorded using glass micropipettes. In response to very dim illumination,

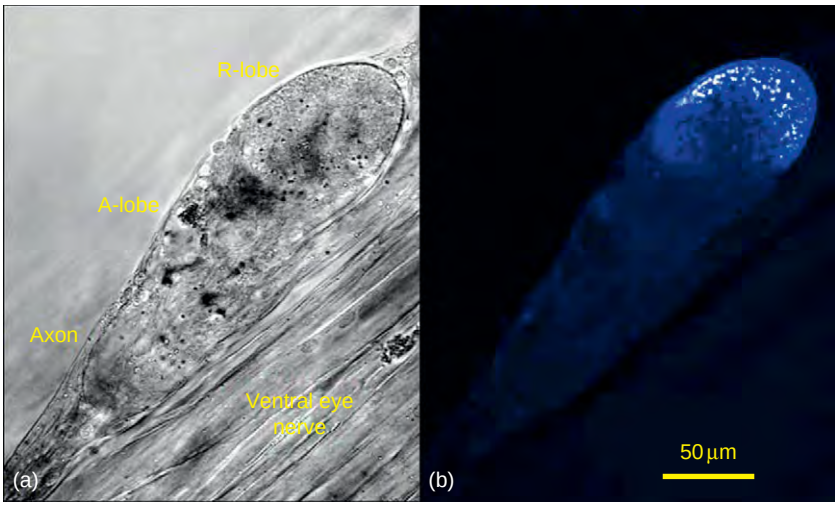

Figure 3 (a) Light micrograph of a ventral photoreceptor. R-lobe, rhabdomeral lobe; A-lobe, arhabdomeral lobe. (b) Immunolocalization (blue) of rhodopsin within the same photoreceptor cell. The ventral photoreceptor has two lobes, a light-sensitive rhabdomeral lobe (R-lobe), which bears rhodopsin-containing microvilli on its plasma membrane and is analogous to the outer segments of vertebrate photoreceptors, and a light-insensitive arhabdomeral lobe (A-lobe), which is analogous to the inner segment of vertebrate photoreceptors. From Battelle, B. A. et al. (2001). *Journal of Comparative Neurology* 435: 211–225. Copyright 2009 Wiley-Liss, Inc.

quantum bumps over 10 mV in amplitude occur randomly as individual photons are effectively absorbed by rhodopsin molecules. Under voltage clamp, the peak current across the membrane generated by an effectively absorbed photon can exceed 1 nA and appears to be generated over several square microns of membrane surface, containing hundreds of microvilli. The comparatively large currents flowing indicate that quantum bumps are caused by the passage across the plasma membrane of hundreds of millions of cations through ion channels. By contrast, in the smaller *Drosophila* photoreceptors or amphibian rods, a single-photon event involves a maximum current of less than 10 pA. *Limulus* photoreceptors achieve this large amplification in only 100–200 ms, faster than amphibian rods. A further remarkable feature of *Limulus* photoreceptors is their broad dynamic range. Whereas most vertebrate rods work over about a 4-log-unit range of light intensity before saturating, *Limulus* photoreceptors work over 8. They achieve this range through a strong adaptation process that reduces amplification at high light intensity. The large dynamic range of these cells obviates the need for the dual system of photoreceptors (rods and cones) used to achieve a large dynamic range in the vertebrate eye.

The Light-Sensitive Conductance Consists of the Summed Effect of Conventional Ion Channels

The glial cells that surround individual ventral photoreceptors can be removed, exposing the plasma membrane surface. This preparation allows On-cell patch-clamp

recording of single ion channels in the microvillar membrane. As expected, channels whose opening was triggered by light were recorded by this method, with single-channel conductance ranging from 18 to 50 pS. Identification of these channels as the light-activated conductance requires establishing a close correspondence between the properties of individual channel currents and those of photocurrents recorded from the whole cell. Depolarizing potentials applied in the dark did not open the channels; therefore the light-activated opening was not just a secondary consequence of the depolarizing receptor potential. Light-evoked single-channel activity was graded with light intensity, reduced by light adaptation, and the single-channel currents reversed in the same membrane potential range as the macroscopic photocurrent. While these characteristics are consistent with the recorded channels being those that carry the light-activated current, definitive molecular or pharmacological proof is still needed.

The Response of the Ventral Photoreceptor is Mediated by the Phosphoinositide Cascade

A large body of evidence now demonstrates that the phosphoinositide (PI) pathway links the absorption of light to the activation of ion channels in the plasma membrane of invertebrate microvillar photoreceptors (Figure 5). The PI pathway is a mechanism for releasing intracellular messengers upon the activation of a receptor protein, using inositol phospholipids as a substrate. In microvillar photoreceptor cells, the receptor protein is rhodopsin and the cascade is localized to the membrane of the microvilli that cover the plasma membrane of the light-sensitive R-lobe. Activated rhodopsin catalyzes the exchange of guanine triphosphate (GTP) for guanine diphosphate (GDP) bound to the alpha subunit of a heterotrimeric GTP-binding protein of the G_q subfamily ($G_{q\alpha}$), which in turn activates phospholipase C (PLC). PLC cleaves phosphatidylinositol 4,5 bisphosphate (PIP_2), a minor membrane phospholipid, into a lipid messenger, diacylglycerol (DAG), and the water-soluble messenger, d-*myo*-inositol 1,4,5 trisphosphate (IP_3). In support of this biochemical pathway, light-activated PIP_2 hydrolysis and/or IP_3 production has been reported in ventral photoreceptors of *Limulus*. $G_{q\alpha}$ has been amplified and sequenced from *Limulus* ventral eye tissue and immunolocalized to the rhabdomeral microvilli. Pharmacological agents that inhibit PLC, neomycin and U-73122, dramatically desensitize the light response of *Limulus* photoreceptors.

The PI Cascade Generates at Least Two Intracellular Messenger Molecules

The PI cascade generates two messenger molecules with very different properties (Figure 5) DAG is essentially confined to the plasma membrane, while IP_3 can diffuse into the surrounding cytoplasm. In addition, the decline of the precursor, PIP_2 may act as an additional signal within

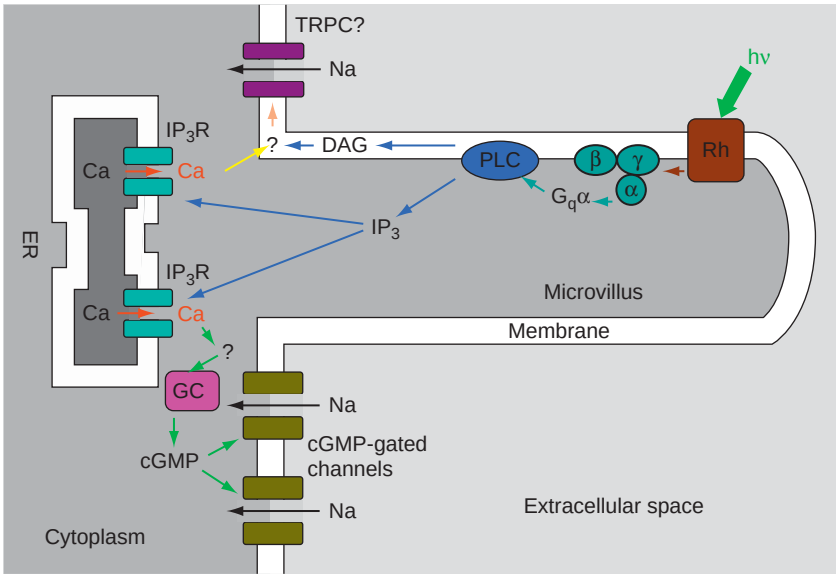

Figure 5 Diagram of mechanisms proposed to mediate phototransduction within a microvillus of the *Limulus* photoreceptor. cGMP, cyclic guanosine monophosphate; DAG, diacylglycerol; ER, endoplasmic reticulum; $G_q\alpha$, alpha subunit of a heterotrimeric GTP-binding protein of the G_q subfamily; β,γ, beta and gamma subunits of a heterotrimeric GTP binding protein of the G_q sub-family; GC, guanylate cyclase; IP_3, d-*myo*-inositol (1,4,5) trisphosphate; IP_3R, d-*myo*-inositol (1,4,5) trisphosphate receptor; PLC, phospholipase C; Rh, rhodopsin; TRPC, transient receptor channel C.

the membrane. The difficult task of assessing the relative roles of these messengers in activating the light-sensitive ion channels has dominated research on the invertebrate phototransduction cascade.

Roles of IP_3 and Intracellular Ca^{2+} Ions in Excitation of *Limulus* Ventral Photoreceptors

There is no evidence that IP_3 can itself activate the light-sensitive channels of ventral photoreceptors. The best-characterized alternative target of IP_3 is a Ca^{2+} channel, the IP_3 receptor protein (IP_3R), located in the membrane of endoplasmic reticulum (ER). IP_3 therefore releases Ca^{2+} from intracellular stores within the ER. In *Limulus* photoreceptors, suitable calcium stores are located close to the base of the rhodopsin-containing microvilli – the subrhabdomeral cisternae (SMC) of SER. Extensions of the SMC are juxtaposed less than 100 nm from the bases of the microvilli. The cytoplasm of both the R lobe containing the SER and, to a lesser extent, the A lobe are immunoreactive when probed with an anti-IP_3R antibody.

In darkness, ventral photoreceptors, like most cells, maintain a low free cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$) of 200–600 nM. Release of calcium from the SMC results in a very large elevation of $[Ca^{2+}]_i$ during the first few hundred milliseconds of the light response. Confocal fluorescent light microscopy has enabled the measurement of the light-induced elevation of $[Ca^{2+}]_i$ in ventral photoreceptors at spots within 4 μm of the microvillar membrane in the R lobe (**Figures 6** and **7**).

Following a very bright flash, $[Ca^{2+}]_i$ begins to rise after a latent period of approximately 20 ms. Thereafter, $[Ca^{2+}]_i$ rises at an initial rate of 1–2 mM s^{-1} to reach a peak of 100–200 μM within 200 ms. For less-intense flashes, the peak elevation of $[Ca^{2+}]_i$ is graded with flash intensity, increasing from 2 μM to more than 140 μM as light intensity increases from 10 effective photons to 10 000 effective photons. For the dimmest flashes so far investigated, these concentrations represent ~600 free Ca^{2+} ions per effective photon generated within the confocal measurement volume.

Very high levels of $[Ca^{2+}]_i$ are reached only transiently upon illumination. Following a dim or moderate-intensity light flash, $[Ca^{2+}]_i$ falls close to its resting value within 1 s, although a small lingering elevation may persist for up to a minute afterward. Even during sustained intense illumination, $[Ca^{2+}]_i$ falls within 5 s to a sustained plateau elevation of less than 20 μM. As expected, if calcium release from stores occurs, the light-induced rise in $[Ca^{2+}]_i$ is unaltered by removal and chelation of extracellular Ca^{2+}, but is severely reduced by pharmacological agents expected to deplete Ca^{2+} stores.

IP_3 Can Release Ca^{2+} from the SER

Microinjections of IP_3, or photolysis of caged IP_3, rapidly release Ca^{2+} from the R lobe in darkness (**Figure 8**). Photolysis of caged IP_3 by UV light delivered to a spot beneath the microvillar membrane results in local elevations of Ca^{2+} that are comparable in magnitude and rate

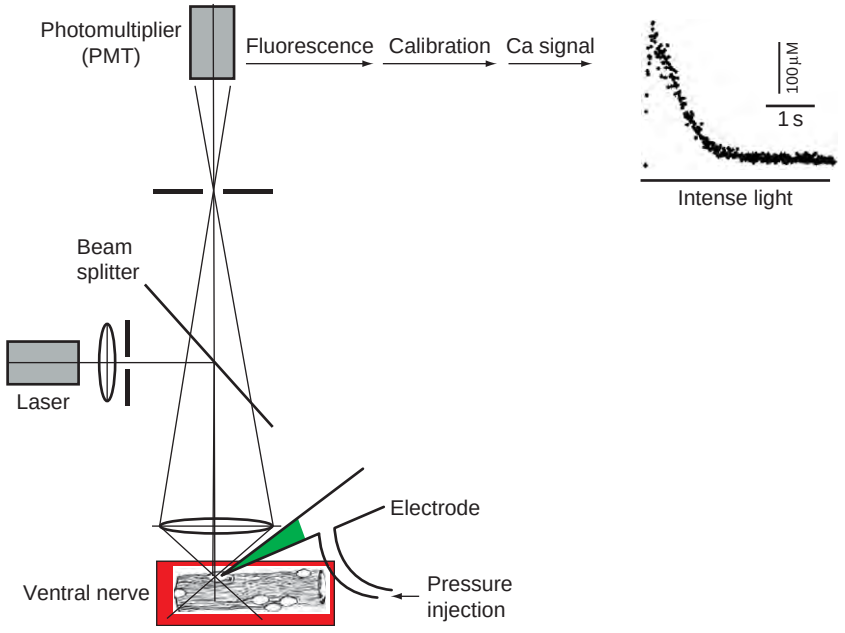

Figure 6 Diagram of confocal microscopy method (left) and recordings of light-activated Ca2+ signals (right) from a Ca^{2+}-sensitive fluorescent indicator dye (indicated in green) injected into the photoreceptor and recorded close to the microvillar membrane of the R-lobe.

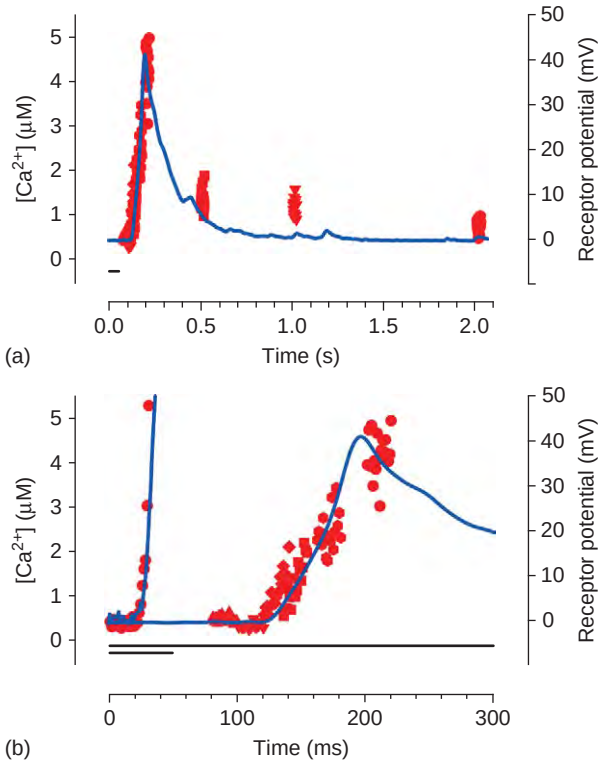

Figure 7 (a) Receptor potential (solid line) and reconstructed elevation of $[Ca^{2+}]_i$ (red symbols) recorded following a flash from an attenuated laser beam that delivered ~50 effective photons to a photoreceptor. The bar beneath the trace indicates the timing of the flash. (b) The responses to the dim flash used in (b) are shown on an expanded timescale on the right. On the left is shown the rising edge of the responses to a much brighter step of light produced by the unattenuated laser beam, delivering $\sim 10^8$ effective photons per second. The bars below the traces indicate the onset and duration of the stimuli. Adapted from Payne, R. and Demas, J. (2000). *Journal of General Physiology* 115: 735–748.

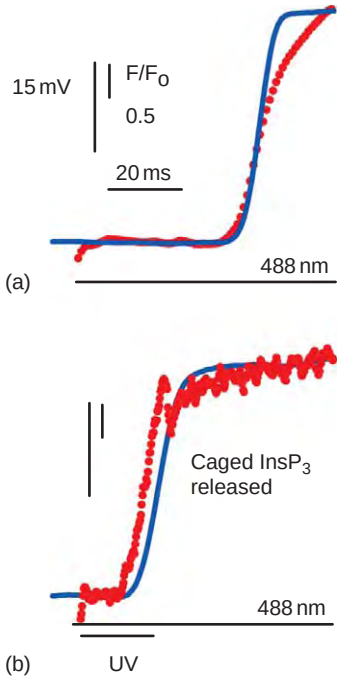

Figure 8 Timing of Ca^{2+} release by caged InsP3. Photoreceptors were loaded with caged IP_3 and the Ca^{2+} indicator dye fluo-3; 488 nm and UV laser beams were focused onto the edge of the R-lobe. As an indicator of $[Ca^{2+}]_i$, uncalibrated dye fluorescence is shown, expressed as a fraction of the background fluorescence during the latent period of the response (F/F_0). (a) Membrane potential (solid line) and fluo-3 fluorescence (red dots) recorded during illumination by the 488-nm laser alone, stimulating $Ca2^+$ release and depolarization through the photoisomerization of rhodopsin, that is, through the natural phototransduction pathway. Laser stimulation began at the beginning of the fluorescence trace. (b) Effect of superimposing a 20-ms duration UV flash and so releasing caged InsP3 into the cytoplasm of the cell, stimulating an earlier release of Ca^{2+} directly from the SER. Adapted from Ukhanov, K. and Payne, R. (1997). *Journal of Neuroscience* 17: 1701–1709.

of rise to those elicited by bright visible light. However, the latency of the Ca^{2+} signal that follows illumination by visible light is ~30 ms longer than that of the response to the release of caged IP_3 (compare **Figures 8(a) with 8(b)**), the difference being presumably the time required for light to activate the PI pathway. There is therefore convincing evidence that the light-induced release of Ca^{2+} from internal stores is mediated by the PI pathway acting on IP_3Rs in SER that are closely juxtaposed to the microvillar membrane.

Released Ca^{2+} Ions can Activate an Inward Current

Pulsed pressure injections of solutions containing 1–2 mM Ca^{2+} into the R lobe of ventral photoreceptors activates a current in the plasma membrane of up to 20 nA, with a similar reversal potential, sodium dependence, and outward rectification to that activated by light. Release of Ca^{2+} ions through IP_3 activates the same conductance, indicating that the $[Ca^{2+}]_i$ generated through the endogenous Ca^{2+} release pathway is sufficient. The current, typically 5–20 nA in amplitude following a pulse of 100 μM IP_3, generates a transient depolarization of the photoreceptor lasting for less than 1 s. The coupling between the elevation of $[Ca^{2+}]_i$ and the depolarization of the photoreceptor is rapid. Depolarization follows caged IP_3-induced Ca^{2+} release after 2.5 ± 3.3 ms (**Figure 8**), while photolysis of caged Ca^{2+} (*O*-nitrophenyl ethylene glycol tetraacetic acid (EGTA)) at the edge of the R lobe activates current within 1.8 ± 0.7 ms.

Light-Induced Ca^{2+} Release can be Detected before the Electrical Response

The above experiments indicate that micromolar $[Ca^{2+}]_i$, released from internal stores by IP_3, can activate an

inward current through the plasma membrane within a few milliseconds. It follows that if light-induced Ca^{2+} release is to act similarly, then a component of the photocurrent must be initiated a few milliseconds after $Ca2^{+}$ is released. Certainly, the onset of the two signals is highly correlated if measured confocally beneath the microvillar membrane. The time for $[Ca^{2+}]_i$ to exceed 2 μM is approximately equal to that for the receptor potential to exceed 8 mV (mean difference: 2.2 ± 6.4 ms). However, the question of which event occurs first is difficult to address, since two signals with different noise levels are compared (**Figure 7**). The detection of the Ca^{2+} signal lead the electrical response by up to 5 ms within about one-third of cells examined. The lag in other cells could indicate the presence of an early Ca^{2+}-independent component of the response present in some cells, but it is difficult to be sure of this because the placement of the confocal measuring spot relative to the microvillar membrane is critical. However, in any case, given the rapidity with which Ca^{2+} can elicit an inward current (1–3 ms; see above) and the fact that it takes the photocurrent 50 ms to rise to peak, this timing appears to be sufficient for released Ca^{2+} ions to contribute to the activation of the photocurrent during the rising edge of the response to light.

How Does IP_3-Induced Ca^{2+} Release Activate Inward Current and is this Current Flowing through the Light-Sensitive Conductance?

Given the detailed evidence above, it seems reasonable to propose that IP_3-induced Ca^{2+} release can activate the light-activated conductance in ventral photoreceptors (**Figure 5**). However, the molecular nature of the channel and the site of calcium's action are not yet known. An ideal preparation for electrophysiology, ventral photoreceptors do not have the advantage of molecular genetic approaches that have allowed the identification of the light-sensitive channels in *Drosophila* as members of the TRP family. Still, two hypotheses have been developed for the nature of the light-activated ion channels based on physiological and molecular evidence.

The first hypothesis is that the channels are not Ca^{2+}-gated, but are cyclic guanosine monophosphate (cGMP) gated. This seems a remote possibility at first, given the evidence that IP_3-induced Ca^{2+} release can rapidly activate a plasma membrane conductance in intact cells. However, the proposal that a further messenger exists downstream from Ca^{2+} is driven by the experimental inability of Ca^{2+} to directly activate ion channels when applied to the inside of patches of plasma membrane excised from the rhabdomeral lobe. Instead, application of cGMP activated channels in a minority of excised patches. The channel events activated during application of cGMP had a similar conductance to light-activated channels, similar reversal potential when bathed in media mimicking intracellular and extracellular ion concentrations and a similar increase in open probability upon membrane depolarization. Since intracellular injections of cGMP or its analogs depolarize the photoreceptor, it was proposed that cGMP might be a terminal messenger in the visual cascade in ventral photoreceptors, as well as in vertebrate rods and cones. A putative cGMP-gated channel has been sequenced from ventral photoreceptors and localized to the microvillar photoreceptors. However, to reconcile this hypothesis with the large body of evidence for the initiation of the light response by the PI pathway, some coupling mechanism must be found to link IP_3-induced Ca^{2+} release to the production of cGMP. There is some pharmacological evidence that a Ca^{2+}-activated guanylate cyclase (GC) might provide this link (**Figure 5**), but no biochemical or molecular evidence has so far been obtained for this hypothesis.

The second hypothesis is that *Limulus* channels are members of the TRP family which, unlike *Drosophila* TRP and TRPL, do not display a high Ca^{2+}- permeability (**Figure 5**). TRP channel homologs have been cloned from ventral photoreceptor messenger RNA (mRNA), and an established activator of some TRP-family channels, the synthetic lipid, 1-oleoyl-2-acetyl-*sn*-glycerol (OAG), activates a conductance with reversal potential similar to that activated by light. Activation of this conductance by OAG apparently requires the presence of free Ca^{2+} ions in the injection pipette, which may explain why extracellularly applied OAG has no effect and why there is a complete dependence of the light response on light-induced Ca^{2+} release from intracellular stores. The hypothesis of a *Limulus* homolog of the TRP channel provides a testable alternative to the proposed role of a cyclic nucleotide channel and may resolve the differences in phototransduction between *Limulus* and *Drosophila* photoreceptors.

Adaptation, a Decrease in the Sensitivity of the Visual Cascade, is Mediated by Small, Lingering Elevations of Ca^{2+}

The onset of prolonged illumination of ventral photoreceptors, or the huge elevations of $[Ca^{2+}]_i$ that occur following flashes of light are not sustained but fall back to the micromolar range within seconds. Concurrently, the photocurrent also falls from tens or hundreds of nA to a few nA. These declines are the result of a decrease in the photoreceptor's sensitivity that prevents saturation of the photoreceptors in bright light and so extends its dynamic range. The initial light-induced elevation of $[Ca^{2+}]_i$ therefore appears to function as a feedback signal that subsequently reduces the sensitivity of the visual cascade.

In support of this concept, slow injection of Ca^{2+} ions into the cytosol of ventral photoreceptors diminishes the sensitivity and latency of the light response, mimicking the effect of an adapting light. Injection of Ca^{2+} chelators, such as EGTA or 1,2-bis(o-aminophenoxy)ethane-N,N,N′,N′-tetraacetic acid (BAPTA), not only slows down and diminishes the initial photocurrent, but also blocks the decline of the light-induced current during prolonged illumination. The site of this feedback inhibition of the light response by Ca^{2+} could be at several points in the phototransduction cascade. For example, IP_3-induced Ca^{2+} release is known to be inhibited by lingering elevations of $[Ca^{2+}]_i$ in ventral photoreceptors. In addition, pharmacological activation of protein kinase C greatly reduces the sensitivity of the light-induced current, apparently acting upstream of IP_3-induced Ca^{2+} release.

Drosophila and *Limulus* Photoreceptors Operate Differently and Illustrate Two General Mechanisms Coupling the PI Cascade to an Electrical Response

The two most extensively studied microvillar photoreceptors, those of *Limulus* and *Drosophila*, have many aspects of their phototransduction mechanism in common. Both are thought to utilize the PI cascade to open non-selective cation channels and both exhibit large elevations of $[Ca^{2+}]_i$, which are necessary for signal amplification and speed, as well as light adaptation. However, there are also clear differences: *Limulus* photoreceptors utilize IP_3-induced Ca^{2+} release to elevate intracellular free Ca^{2+} ion concentrations, while *Drosophila* photoreceptors are thought to utilize DAG or derived products to open Ca^{2+}-permeable TRP channels that allow Ca^{2+} entry from the extracellular space. The photoreceptors of the two species are therefore specific examples of two general mechanisms in cells for coupling the PI pathway to $[Ca^{2+}]_i$ elevation. Why is there this difference? One explanation is the need in *Limulus* for the extra amplification provided by IP_3-induced Ca^{2+} release. One IP_3 molecule can release hundreds of Ca^{2+} ions from the ER through the IP_3R channel. These Ca^{2+} ions can then diffuse along the inner surface of the plasma membrane to activate downstream targets, such as the hundreds of channels required to open in order to produce a significant quantal event in these giant photoreceptors. The trade-off for this amplification is slower speed. The extra amplification step (Ca^{2+} release) required in the visual cascade may explain why *Limulus* photoreceptors are slower than fly photoreceptors to respond to light. This speed difference is entirely reasonable, given the animals' differing demands on their visual systems. Horseshoe crabs do not fly; rather they use their lateral eyes to find mates near moonlit beaches.

Extension of Phototransduction Mechanisms to other Microvillar Photoreceptor Types

Detailed knowledge of the mechanisms of both *Limulus* and *Drosophila* photoreceptors may outline general approaches used by other cell types to the problem of tailoring the outcome of the PI cascade to the need for either speed or amplification. An outstanding question is the extent to which other photoreceptor types utilize these mechanisms. It is apparent that light-induced Ca^{2+} release from intracellular stores occurs in photoreceptors of the file clam, leech, and honeybee. Furthermore, the light-sensitive channels that mediate the immediate electrical response in the file clam are relatively impermeable to Ca^{2+} ions, like those of *Limulus*, but not *Drosophila*. Barnacle photoreceptors, on the other hand, like those of *Drosophila*, display prominent light-induced Ca^{2+} influx. Thus, elements of the two mechanisms for coupling phototransduction to an elevation of Ca^{2+} seem to be scattered across the invertebrate phyla. Whether there is a functional or evolutionary rationale for these differences remains to be seen. Indeed, it is not known yet whether photoreceptors in the other eight eyes of *Limulus* function similarly to the much-studied ventral eye.

Phototransduction: Adaptation in Cones

T D Lamb, The Australian National University, Canberra, ACT, Australia

Glossary

Avoidance of saturation – The ability of cones (but not rods) to continue functioning in steady background illumination of arbitrarily high intensity.
Light adaptation – The rapid adjustment of sensitivity and kinetics (of the entire visual system, or of the photoreceptors) that occurs in response to altered ambient light intensity. The adjustment is rapid irrespective of whether the change is an increase or decrease in intensity, provided that the change is not too great.
Saturation – The failure of the photoreceptors (or of the visual system) to respond to incremental illumination in the presence of appropriately bright illumination. The rod photoreceptors saturate at a relatively low background intensity; in contrast, the cone photoreceptors avoid saturation by steady backgrounds, no matter how bright the light is.
Weber's law – The reduction in visual sensitivity that occurs in inverse proportion to the intensity of the ambient background illumination. This corresponds to a rise in visual threshold in direct proportion to the ambient illumination.

Performance of the Photopic (Cone) System

Workhorse of Vision

For human vision, the photopic cone system can be considered the workhorse of vision, because it is operational under almost all of the conditions that we (in a modern world) experience. Thus, it is our photopic system that provides our sense of vision under all lighting conditions, apart from exceptionally low levels such as starlight conditions. Under moonlight conditions, our scotopic and photopic systems are both functional, over an intensity range that is termed mesopic. If you are ever in doubt as to whether you are using your photopic system under twilight or nighttime conditions, there is a simple test: if you are able to detect any color in the scene, then your cones are active; your rods may also be active, but this is one test of whether there is any cone activity at that level of intensities. In addition, the photopic system remains functional at all higher intensities, up to the brightest sunlit conditions than we ever experience.

It is interesting to consider that, despite their enormous importance to our vision, cones make up perhaps only 5% of the population of photoreceptors over most of our peripheral retina. This relatively low proportion of cone photoreceptors in the peripheral retina is entirely adequate for our normal peripheral vision, which requires only relatively low spatial acuity. Even though the great majority of peripheral photoreceptors are rods, they are simply not used under most of the circumstances that we think of as vision – thus, they are only used at exceedingly low ambient lighting levels. The reason for the great numerical preponderance of rods is to be able to capture every available photon at those very low light intensities.

Rapid Response and Moderate Sensitivity

In survival terms, one of the greatest advantages of cones over rods is their much faster speed of response. The responses of our rods, even when they are light adapted, are much too slow to allow us to function visually at the speeds that are required to escape predators and to capture prey. Cones, instead, are specialized so as to permit extremely rapid signaling of visual stimuli to the brain.

Cones are often described as having much lower sensitivity than rods, but this view is misleading, especially when considered in terms of the rapidly changing visual stimuli that the cones are specialized for signaling. Although the peak sensitivity to a brief flash of light may be perhaps 30-fold lower in a cone than in a rod, the sensitivity to rapidly fluctuating stimuli is considerably higher in cones than in rods; thus, the slow response of the rods makes them quite insensitive to rapidly changing stimuli. When expressed in terms of the efficacy of activation within the G-protein cascade of phototransduction, the amplification in cones and rods appears to be essentially indistinguishable – the real difference is in the speed of inactivation.

Avoidance of Saturation

The second crucial feature of cones, in terms of survival advantage, is their amazing ability to avoid saturation no matter how intense the steady background illumination becomes. This property stands in stark contrast to the situation in rods, which are completely incapable of responding once the background exceeds a relatively low level (corresponding roughly to twilight illumination). One of the major challenges in photoreceptor research is

to provide a clear understanding of how it is that cones are able to avoid saturation at arbitrarily high light intensities, whereas rods succumb to saturation at very low light intensities. As will be described below, considerable advances have recently been made toward providing this understanding.

Light Adaptation of the Cones

Cone photoreceptors undergo light adaptation over an enormously wide range of intensities, and it is likely that almost all of the adaptation that is observed in the overall photopic visual system is mediated by these changes occurring at the level of the receptor cells. This section describes the adaptational effects that occur in the cone photoreceptors.

Flashes on Backgrounds: Desensitization and Acceleration

Figure 1 illustrates the responses of a cone photoreceptor to the same set of flashes presented under three different conditions; the flashes *A–F* were of progressively greater intensity from left to right, but were exactly the same in each of the three panels. In (a), the flashes were presented in darkness, and represent a standard dark-adapted flash family; in (b), the same flashes were presented shortly after a dim steady background had been turned on; and in (c), the same flashes were presented after the onset of a brighter background. In the presence of the background illumination, the amplitude of the responses to dim flashes was smaller. For example, for the second flash intensity, *B*, the response amplitude becomes markedly smaller from (a) to (b) to (c). In other words, backgrounds of increasing intensity progressively desensitized the cone's incremental

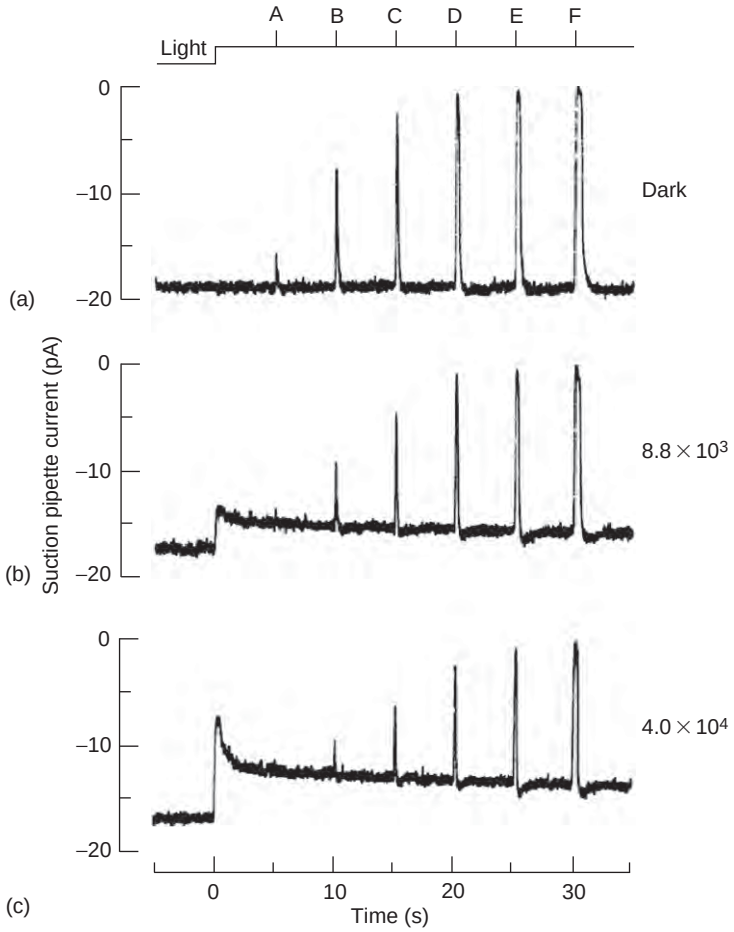

Figure 1 Circulating current of a salamander cone in response to flashes and steps of illumination. Timing of illumination is indicated by the marker trace at the top; flashes *A–F* increased in intensity by factors of ~4, and were the same intensity in each of (a)–(c). In (a), these flashes were presented in darkness; in (b) and (c) the same flashes were presented on steady backgrounds that had been switched on at time zero; the background in (c) was ~4 times brighter than in (b). Reproduced from Matthews, H. R., Fain, G. L., Murphy, R. L. W., and Lamb, T. D. (1990). Light adaptation in cones of the salamander: A role for cytoplasmic calcium concentration. *Journal of Physiology* 420: 447–469.

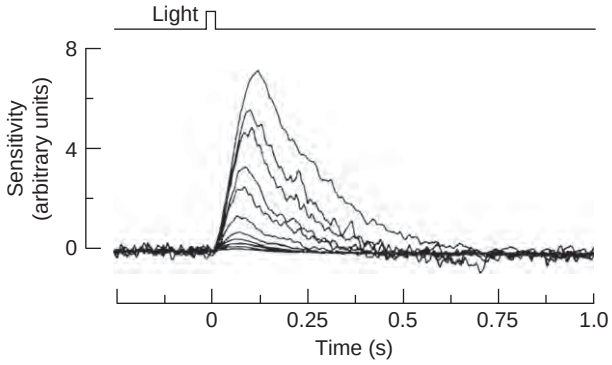

Figure 2 Incremental responses of a salamander cone to test flashes presented on backgrounds of increasing intensity. The largest trace is for a dim flash presented in darkness, while the other traces correspond to the same test flash presented on backgrounds. In fact, in the presence of brighter backgrounds, the test flash intensity was increased in order to obtain measurable responses, and the plotted traces have therefore been scaled as response divided by test flash intensity, so as to provide a direct measure of sensitivity. Reproduced with permission from Matthews, H. R., Fain, G. L., Murphy, R. L. W., and Lamb, T. D. (1990). Light adaptation in cones of the salamander: A role for cytoplasmic calcium concentration. *Journal of Physiology* 420: 447–469.

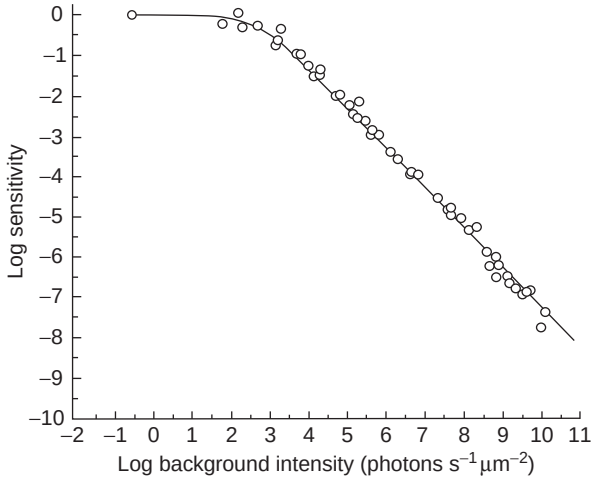

Figure 3 Cone sensitivity as a function of background intensity. Data are plotted in double logarithmic coordinates, and were obtained from intracellular measurements averaged from 15 cones in the turtle eyecup preparation. The experiments used laser illumination to achieve very high background intensities, and monitored step sensitivity rather than the more conventional flash sensitivity. The smooth curve plots Weber's law, given by eqn [1]. Reproduced from Burkhardt, D. A. (1994). Light adaptation and photopigment bleaching in cone photoreceptors *in situ* in the retina of the turtle. *Journal of Neuroscience* 14: 1091–1105.

response. Such behavior is very characteristic of photoreceptors, and these responses from cones are qualitatively similar to those obtained from rods.

The manner in which the response to a dim flash is modified by the presence of backgrounds of different intensity is illustrated in **Figure 2**. The largest trace is the response to a dim flash presented under fully dark-adapted conditions, while the other traces are for the same flash presented on backgrounds of progressively brighter intensity. (In fact, in order to maintain responses of measurable amplitude, the flash intensity was increased in the presence of backgrounds, and the traces actually plot response divided by flash intensity; i.e., the response sensitivity.)

The traces in **Figure 2** demonstrate that the effect of backgrounds of increasing intensity is to both desensitize and accelerate the response to an incremental dim flash. This behavior of cones is very similar to that exhibited by rods.

Dependence of Sensitivity on Background Intensity: Weber's Law

By plotting the peak amplitude of each of the traces in **Figure 2** as a function of the background intensity on which it was measured, one obtains a sensitivity versus background plot of the type illustrated in **Figure 3**.

The results plotted in **Figure 3** were obtained over an extremely wide range of background intensities by Dwight Burkhardt using a laser source of illumination. Importantly, the preparation was the intact eyecup (of the turtle), so that the photoreceptors remained in contact with the retinal pigment epithelium (RPE) and thereby experienced normal regeneration of visual pigment, in order that meaningful results could be obtained even at very high background intensities. (One methodological difference between the results plotted in **Figure 3** and the results that are more usually plotted is that step sensitivities rather than flash sensitivities are plotted; however, this does not, in practice, make much of a difference.)

For background intensities from 10^3 to 10^{11} photons $\mu m^{-2}\ s^{-1}$, the relationship between log sensitivity and log background intensity is a straight line with a slope of -1; in other words, over roughly 8 log units of background, the turtle cone's sensitivity declines inversely with background intensity. The curve plotted near the points in **Figure 3** represents Weber's law, described by:

$$\frac{S}{S_D} = \frac{1}{1 + (I/I_0)} \qquad [1]$$

where S is flash sensitivity, S_D is its dark-adapted value, I is the background intensity, and I_0 is the half-desensitizing intensity, also known as the dark-adapted equivalent background intensity. The good fit of the Weber's law expression shows, very importantly, that cone photoreceptors in the intact eyecup are able to completely avoid saturation, even at enormously high intensities of steady illumination. This feature represents a crucial distinction between the properties of cones and rods. The circulating current of rods is shut off at quite low background intensities, so that

the rods are unresponsive to superimposed stimuli, in the presence of background illumination of moderate intensity.

In the same set of experiments, Burkhardt measured the intensity at which 90% of the pigment was in the bleached state, and found this to be around 10^6 photons $\mu m^{-2}\ s^{-1}$. For all intensities above that level, the observed Weber's law behavior can be accounted for in terms of pigment bleaching. For each additional 10-fold increase in intensity, there will be a 10-fold reduction in the amount of pigment remaining available to absorb light, and hence there will necessarily be a 10-fold reduction in sensitivity in the absence of any other change of parameters of transduction in the outer segment. In other words, if the photoreceptor is able to avoid saturation up to intensities that cause substantial bleaches, then it will be able to exhibit Weber's law desensitization at higher intensities purely by means of pigment bleaching. Cones are able to function up to this critical intensity, whereas rods saturate at much lower intensities.

Extremely Rapid Recovery of Cone Photocurrent

In order to measure the performance of mammalian cones in the presence of extremely bright background illumination, it is necessary to use a preparation in which the cones are in contact with the RPE (as was the case in the experiments above with turtle cones). Accordingly, it is not appropriate to use suction-pipette experiments at very high intensities. On the other hand, experiments measuring the electroretinogram (ERG) in the intact eye are very suitable.

Results from an experiment designed to measure the kinetics of recovery of the circulating current of human cone photoreceptors, upon extinction of steady illumination that bleached 90% of the visual pigment, are illustrated in **Figure 4**. This Figure shows recordings of the a-wave of the human ERG, which monitors primarily the response of photoreceptors; and at these incredibly high intensities, only the cone photoreceptors are responding. The left panel shows the response to a bright flash superimposed on the intense steady background, while the right panel shows the response obtained at extinction of that background. As indicated by the right-hand pair of vertical scales, the bright flash responses established the zero level of circulating current, as well as the level of circulating current during the intense background (i.e., unity on the inner scale). Separate measurements (not shown) established the dark current (i.e., unity on the outer right-hand scale). Even during the presence of the intense steady background, the cone circulating current was roughly 50% of its original level in darkness.

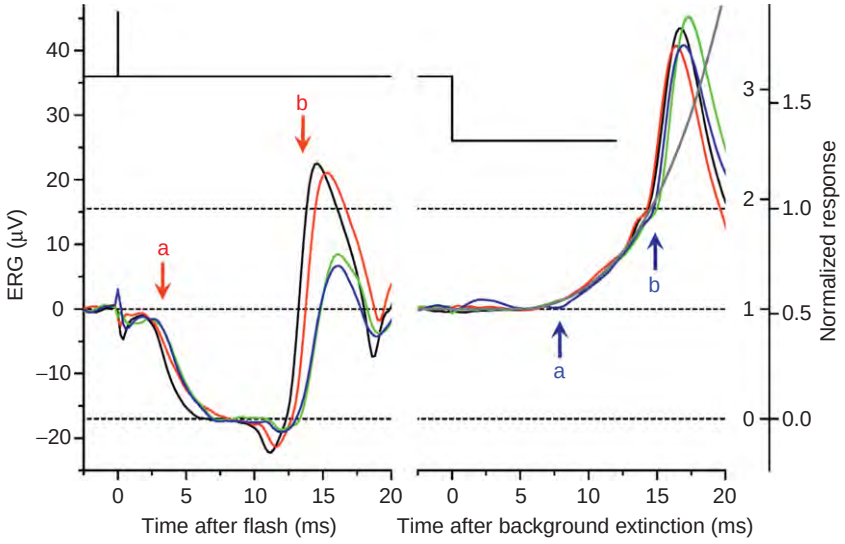

Figure 4 Extremely rapid recovery of human cone photocurrent upon extinction of intense illumination, measured with the ERG. The four colored traces plot ERG responses from two subjects, at two different flash intensities. The light stimulus is monitored by the black traces at the top. Left panel is for an intense flash presented on the intense steady background; right panel is for extinction of that background. The ON a-wave and b-wave elicited by the bright flash are indicated by the red arrows; the OFF a-wave and b-wave elicited by extinction of the background are indicated by the blue arrows. The b-wave is roughly similar in the two cases, and arises from postreceptoral activity. The OFF a-wave represents recovery of the cone circulating current, and begins around 7 ms after the intense background is turned off. Dashed horizontal lines represent the following levels of cone circulating current (from bottom): zero level, steady level during intense background, dark level, as indicated by the two normalized scales on the right. Reproduced from Kenkre, J. S., Moran, N. A., Lamb, T. D., and Mahroo, O. A. R. (2005). Extremely rapid recovery of human cone circulating current at the extinction of bleaching exposures. *Journal of Physiology* 567: 95–112.

The traces on the right show the ERG a-wave upon extinction of the intense background. Little change occurs for the first 7 ms, but thereafter a substantial upward response occurs, the OFF a-wave indicated by the blue arrow, until about 15 ms after extinction of the background; at this point, the a-wave is obscured by spike-like activity of the b-wave. There is compelling evidence that the a-wave traces for these subjects monitor the recovery of the cone circulating current. On this basis, the cone circulating current is essentially fully recovered within about 15 ms after extinction of illumination so intense that it bleaches 90% of the cone pigment. This is extremely rapid recovery, at least when compared with the time course of recovery following intense flashes delivered from darkness. The next section considers the speed that is required for the shut-off reactions of phototransduction, in order to be able to account for recovery of the circulating current as fast as is shown in **Figure 4**. The smooth gray curve near the measured traces in the right-hand panel of **Figure 4** was calculated from the model presented in the next section, using the short time constants listed in **Table 1**.

Extremely rapid recovery of cone circulating current, as inferred from the results of **Figure 4**, is also required in order to account for classical experiments on the flicker-fusion frequency of human subjects. Even at quite low photopic intensities, human subjects are able to detect square-wave flicker at a frequency of around 50 Hz using peripheral vision. However, at higher intensities, the flicker-fusion frequency increases to 100 Hz or more. At a frequency of 100 Hz, the illumination is being switched on and off at intervals of 5 ms each. Thus, in order for the flicker to be detectable, some degree of recovery of cone circulating current must have occurred within 5 ms. Hence, this finding is broadly consistent with the time course inferred from **Figure 4**.

Molecular Basis of Cone Light Adaptation

Reaction Steps Underlying Rapid Recovery of the Cone's Light Response

Figure 5 presents a schematic of the reaction steps underlying phototransduction in cones, where shut-off reactions and the lifetimes (or turnover times) of important intermediates are indicated in red.

For mammalian cones, the speed of the various shut-off reactions shown in the schematic of **Figure 5** has been estimated in a number of recent studies using intact preparations. In the case of monkey cones, the parameters were extracted through theoretical modeling of results obtained from intracellular recordings of horizontal cells in the retina–RPE–choroid preparation. In the case of human cones, the parameters were extracted through theoretical modeling of ERG results, including those of the type illustrated in **Figure 4**. The shut-off reactions have been found to be extremely rapid, and the parameters that have been reported are summarized in **Table 1**.

The collected estimates in **Table 1** are consistent with the notion that all four of the shut-off time constants in human cones are extremely short, with values in the range of 3–18 ms; in fact, it appears that three of the time constants could be around 5 ms or less, and one around

Table 1 Shut-off time constants estimated for mammalian cones and rods

	τ_R ms	τ_E ms	τ_{Ca} ms	$\tau_{cG} = 1/\beta$ (intense) ms	Preparation	Ref.
Cone		18			Human ERG	1
	5	13		4	Human ERG	2
	3	9	3	4	Monkey retina	3
	3	10	3	6	Human ERG	4
Rod	70	200			Mouse suction pipette	5

Estimates for the four shut-off time constants (τ_R, τ_E, τ_{Ca}, and τ_{cG}) obtained from recent experiments are tabulated.
Note that it is not usually possible to determine which is which for the two time constants τ_R and τ_E; however, in the case of the rod results, this identification was made using other experiments.
The time constants for cones are around 20 times faster than for rods.
The studies from which these results were obtained are as follows:

10–15 ms. (Note that the turnover time for cyclic guanosine monophosphate (cGMP), τ_{cG}, listed in Table 1 represents the value applicable during very intense illumination; under dark-adapted conditions, when the light-induced activity of the phosphodiesterase (PDE) is relatively low, this time constant is likely to be much longer.)

The shut-off time constants for the activated visual pigment (R*) and the activated G-protein/PDE (E*), τ_R and τ_E, are around 20-fold shorter in human cones than in mouse rods, with values of ~80 and ~200 ms having been reported in rods.

Cone Avoidance of Saturation

Work done in collaboration with Edward N. Pugh, Jr. has shown that the ability of the cones to avoid saturation is explicable in terms of the combination of these two 20-fold shorter time constants and the bleaching of cone visual pigment.

In human rod photoreceptors *in vivo*, the circulating current is halved at a steady intensity of ~70 scotopic trolands (600 R* s^{-1}), with complete saturation occurring at ~1000 scotopic trolands (~10^4 R* s^{-1}). If the activation gain of transduction is the same in human cones as in human rods, then the two very short cone time constants would elevate the intensities required for half and full saturation by some ~400×, to levels of ~240 000 and ~4 × 10^6 R* s^{-1} in cones. An additional factor is that the cGMP-gated channels of mammalian cones (in contrast to those of rods) show increased cGMP-binding affinity when Ca^{2+} falls, thereby further increasing the R* rate required for saturation.

How do these estimated rates of isomerization compare with the maximum rate at which the cone visual pigment can be bleached during steady illumination? At steady state, the rate of photoisomerization equals the rate of pigment regeneration, which is set by the delivery of 11-*cis* retinal to opsin. For human L/M cones, the maximal rate of regeneration has been measured as ~45% min^{-1}, or 0.75% s^{-1}. If the outer segment contains ~40 million pigment molecules, then the maximal rate of photoisomerization during intense steady light will be ~300 000 R* s^{-1}. This rate cannot be exceeded in the steady state because a higher rate of isomerization would lead to such a low level of cone pigment available to absorb light that the rate could simply not be maintained.

Hence, from the numbers in the preceding paragraphs, the rate of photoisomerization required to saturate the human cone current exceeds the highest rate of isomerization of cone pigment molecules (~300 000 R* s^{-1}) that can be elicited by a steady light of arbitrarily high intensity. Therefore, the human cone photoreceptor cannot be saturated by steady lights, no matter how bright they are. This is not to say that the cone can never be saturated; if an intense light is presented from dark-adapted conditions (when the cone initially has a full complement of visual pigment), then it will transiently be driven into saturation until bleaching reduces the amount of visual pigment to a suitably low level.

Modeling of Human Cone Light Adaptation

A computational model of human cone light adaptation has been developed by Hans van Hateren and Herman Snippe, which puts factors of the type described in the preceding section into a comprehensive theoretical/numerical model. They take a molecular description of the steps in cone phototransduction closely similar to that illustrated in Figure 5, including pigment bleaching, and

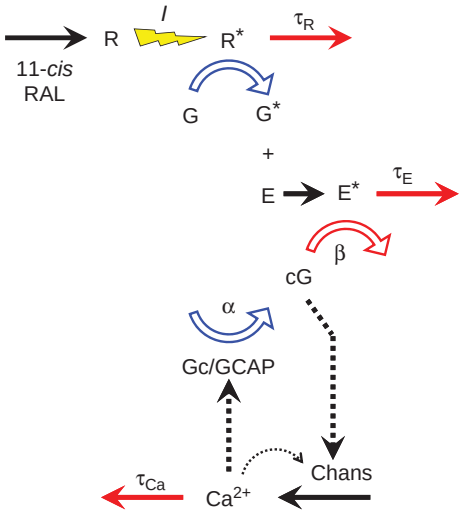

Figure 5 Reaction steps underlying the cone's rapid recovery. Visual pigment (R) is formed by delivery of 11-*cis* retinal (11-*cis* RAL). Light (of intensity *I*) activates the visual pigment, and the activated pigment (R*) is inactivated with a time constant τ_R. R* activates the guanine-nucleotide-binding G protein to G*, which then binds to phosphodiesterase (E) to form active G*–E* (E*). The active G*–E* complex (E*) has a lifetime τ_E. E* hydrolyzes cGMP (cG) with a rate constant β. The increase in β is proportional to steady intensity *I*, and to the product of the R* and E* lifetimes; that is, $\beta = \beta_{Dark} + (A/n_{cG})\,\tau_R\,\tau_E\,I$ (see Nikonov, S., Lamb, T. D., and Pugh, E. N., Jr. (2000). The role of steady phosphodiesterase activity in the kinetics and sensitivity of the light-adapted salamander rod photoresponse. *Journal of General Physiology* 116: 795–824). cGMP is formed by guanylyl cyclase (GC), under regulation by the Ca^{2+}-sensitive guanylyl-cyclase-activating proteins (GCAPs). When present, cG causes opening of ion channels (chans) in the plasma membrane, admitting Ca^{2+}. Ca^{2+} has a powerful negative-feedback action through GCAPs onto the rate α of cGMP synthesis. Ca^{2+} is removed from the cytoplasm with a time constant τ_{Ca}. Reproduced from Lamb, T. D. and Pugh, E. N., Jr. (2006). Avoidance of saturation in human cones is explained by very rapid inactivation reactions and pigment bleaching. *Investigative Ophthalmology and Visual Science* 47, E-Abstract 3714, with permission from the Association for Research in Vision and Ophthalmology.

they express the system in terms of differential equations. Their simulations predict that human cones will indeed conform to Weber's law over a very wide range of background intensities, and that they will not saturate with steady intensities of any level. Thus, there is now a comprehensive description of the process of light adaptation in human cones and, in particular, of the ability of human cones to avoid saturation.

Phototransduction: Adaptation in Rods

T D Lamb, Australian National University, Canberra, ACT, Australia

Glossary

Dark adaptation – The very slow recovery of visual sensitivity that occurs upon the return to darkness following exposure of the eye to extremely intense (and possibly prolonged) illumination. Full recovery of the human visual system takes about 45 min, after a total bleach of all the rhodopsin.

Light adaptation – The rapid adjustment of sensitivity and kinetics (of the entire visual system or of the photoreceptors) that occurs in response to altered ambient light intensity. The adjustment is rapid irrespective of whether the change is an increase or decrease in intensity, provided that the change is not too great.

Saturation – The failure of the photoreceptors (or of the visual system) to respond to incremental illumination in the presence of appropriately bright illumination. The rod photoreceptors saturate at a relatively low background intensity; in contrast, the cone photoreceptors avoid saturation by steady backgrounds, no matter how bright the light is.

Weber's law – The reduction in visual sensitivity that occurs in inverse proportion to the intensity of the ambient background illumination. This corresponds to a rise in visual threshold in direct proportion to the ambient illumination.

Vision over a Billion-Fold Range of Light Intensities

Our visual system operates effectively over an enormously wide range of intensities, of at least a billion-fold, from around 10^{-4} cd m^{-2} under shaded starlight conditions to around 10^{5} cd m^{-2} under intense sunlight. Changes in pupil area account for only about 1 log unit of this >9-log-unit range, since the pupil diameter changes from a maximum of 8 mm to a minimum of 2.5 mm, corresponding to a 10-fold reduction in area. Instead, the great bulk of the operational range is achieved by the combination of, first, a switch between the rod (scotopic) and cone (photopic) pathways in our duplex visual system and, second, the ability of each of these photoreceptor systems to operate over a range of 5 log units (100 000-fold) or more.

This ability of the visual system (or of any of its component parts, such as the photoreceptors) to adjust its performance to the ambient level of illumination is known as light adaptation; the adjustment typically occurs very rapidly (within seconds), whether the light intensity is increasing or decreasing. The term dark adaptation is reserved for the special case of recovery in darkness, following exposure of the eye to extremely bright and/or prolonged illumination that activates (bleaches) a substantial fraction of the visual pigment, rhodopsin. Dark adaptation occurs slowly, and the full recovery of the scotopic visual system after a very large bleach can take as much as an hour.

The changes that accompany light adaptation are beneficial to the possessor of the eye. At very low intensities, the sensitivity is increased to the utmost that is possible so that the rod photoreceptors reliably signal the arrival of individual photons and the scotopic visual system operates in a photon-counting mode. The ability of the scotopic system to operate at incredibly low intensities is enhanced by two deliberate trade-offs – of reduced spatial resolution (increased spatial summation) and reduced temporal resolution (increased temporal integration) – that permit more reliable detection of small signals in the presence of noise. Similar trade-offs are used in the photopic system so that as the ambient illumination decreases from daylight levels toward twilight levels, one's spatial and temporal resolution deteriorate; this is why, in cricket, bad light stops play.

In contrast, the changes that characterize dark adaptation are disadvantageous. To be essentially blind to dim stimuli, for some considerable time following intense light exposure, cannot in any way be useful to an organism. Indeed, for a caveman, entering a cave from bright sunshine, it may have been a serious handicap to have been unable to see well for tens of minutes. Why should such an apparently unsatisfactory situation have persisted? A possible reason could be because it represents an unfortunate downside that has somehow resulted from the enhancements that were needed in order to enable the scotopic system to detect individual photons, and thereby be able to function at incredibly low light levels.

Performance of the Scotopic (Rod) System

For the rod pathway, the dominant mechanisms of scotopic light adaptation result from alterations of signal processing at postsynaptic stages within the retina, and the

rods themselves adapt over only a modest range of intensities before being driven into saturation. This is illustrated in **Figure 1**, which compares the changes in sensitivity of the rod photoreceptors and of the overall visual system during scotopic light adaptation.

The blue symbols and curve plot the relative sensitivity of the overall visual system, measured psychophysically, while the red symbols and curve plot the relative sensitivity of primate rod photoreceptors. Importantly, the overall scotopic visual system begins desensitizing at intensities around 1000 times lower than those required to begin desensitizing the rod photoreceptors. This occurs because the postreceptoral scotopic system is able to integrate photon signals from large numbers of rod photoreceptors, thereby gaining increased sensitivity, while introducing the need to begin desensitizing at much lower background intensities in order to avoid saturation. Hence, the rod photoreceptors maintain their maximal sensitivity over several log units of the lowest intensity regime (up to ~10 isomerizations per second) where the visual system needs to exhibit gradual desensitization.

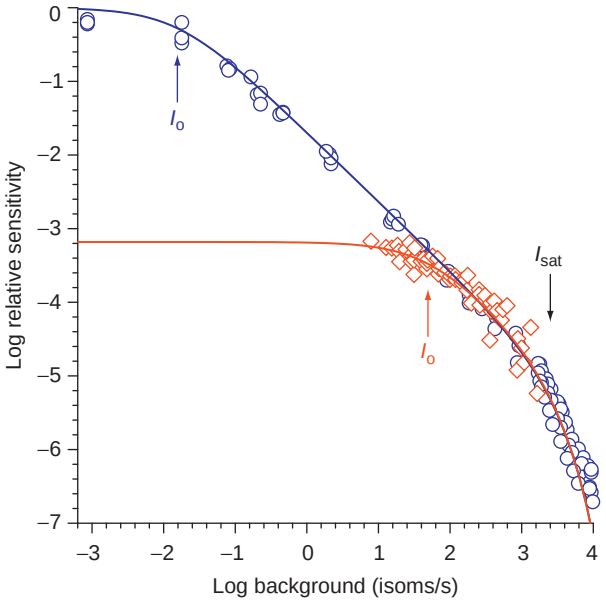

Figure 1 Sensitivity of the human scotopic visual system (blue) and of monkey rod photoreceptors (red) as functions of background intensity in double logarithmic coordinates. The blue symbols are from human psychophysical measurements and the blue curve plots Weber law desensitization in conjunction with saturation, as described by eqn [1], with parameters $I_0 = 0.016$ photoisomerizations per second (blue arrow) and $I_{sat} = 2500$ photoisomerizations per second (black arrow). The red symbols are from suction pipette measurements from isolated rod photoreceptors of monkeys (*Macaca fascicularis*); these symbols have been shifted vertically to align with the blue symbols in the upper intensity range. The red curve also plots eqn [1] with the same value of I_{sat}, but with $I_0 = 50$ photoisomerizations per second (red arrow). Data for the blue symbols are from Figure 3 of Aguilar, M. and Stiles, W. S. (1954). Saturation of the rod mechanism of the retina at high levels of stimulation. *Optica Acta* 1: 59–65. Their troland values were converted using a factor of $K = 8.6$ photoisomerizations per second per troland. Data for the filled symbols are from Figure 9A and Table III of Tamura, T., Nakatani, K., and Yau, K.-W. (1991). Calcium feedback and sensitivity regulation in primate rods. *Journal of General Physiology* 98: 95–130.

When the background intensity is reduced from relatively high scotopic intensities (moving from right to the left along the *x*-axis in **Figure 1**), the sensitivity of rods, and of the scotopic visual system, steadily rises. However, below the intensities indicated by the blue and red arrows, the sensitivity of, first, the rods and, second, the visual system fails to continue increasing, as if the respective mechanism were experiencing a phenomenon equivalent to light. Accordingly, the arrowed intensities for the rods and for the scotopic visual system have been referred to as equivalent background intensities. Clearly, the equivalent background for the scotopic system (around 0.016 photoisomerizations per second) is several log units lower than the equivalent background intensity for the rods (around 50 isomerizations per second).

The curves in **Figure 1** plot desensitization according to the combination of Weber's law with saturation at high intensities, as described by

$$\frac{S}{S_D} = \frac{1}{1 + (I/I_0)} \exp(-I/I_{sat}) \qquad [1]$$

where S is flash sensitivity, S_D is its dark-adapted value, and I is the background intensity. The first term on the right-hand side expresses Weber's law, where I_0 is the equivalent background intensity mentioned above. This first term indicates that, at low background intensities (when $I << I_0$) the sensitivity S approaches a constant level (its dark-adapted value, S_D), while for brighter backgrounds (when $I >> I_0$) the sensitivity declines inversely with background intensity.

At higher scotopic intensities, both the rods and the overall scotopic system exhibit saturation, characterized by a steep decline in sensitivity with increasing background intensity. This behavior is described by the second term on the right-hand side in eqn [1], where I_{sat} is termed the saturation intensity of around 2500 isomerizations per second. It is almost certain that saturation of the overall scotopic system results directly from saturation of the rods.

The span of intensities from I_0 (the equivalent background) to I_{sat} (the saturation intensity) is known as the Weber region and, in this range of background intensities, the sensitivity declines inversely with background intensity; that is, $S \propto 1/I$. Since the contrast in a visual stimulus is, likewise, inversely proportional to background intensity (i.e., contrast = $\Delta I/I$), this Weber region is characterized by a fixed level of contrast sensitivity; that is, a given level of contrast elicits a fixed size of response. Thus, an important feature of Weber's law light adaptation is that it provides automatic extraction of visual contrast.

For mammalian rods, the Weber region encompasses only 1–2 log units of intensity, though for the larger rods of lower vertebrates, it may encompass a slightly wider range of about 3 log units. On the other hand, for the overall scotopic system, the Weber region covers a much wider range of at least 5 log units (i.e., over 100 000-fold). In addition, for cone photoreceptors, it extends over an even wider range.

The Purpose of Light Adaptation: Optimization of Performance

The purpose of light adaptation is to permit the visual system (or any neuron within it) to provide the best performance possible at that particular level of illumination. However, it is not always clear what constitutes best. For example, for the rod photoreceptors, it is clear that at very low ambient levels of illumination, their sensitivity should be as high as possible. However, we cannot readily anticipate the time course of their response that will be optimal.

Avoidance of Saturation: Range Extension

As the ambient light intensity increases, it is important that the rod (or any other cell) should avoid saturating, or else it will be unable to signal. By preventing saturation, light adaptation permits a photoreceptor to extend the range of intensities over which it operates. Although the rods achieve light adaptation over a limited range of intensities, the cones excel, and are able to avoid saturation no matter how bright the steady illumination becomes. Why has evolution permitted the rods to be driven into saturation by relatively low intensities? In part, it is because the photopic (cone) system is functional at these intensities, so that there is no disadvantage if the rods saturate. Not only is there no disadvantage – in fact, there is a distinct advantage when the rods saturate, in conserving energy during daylight conditions. Maintenance of the rod circulating current, in darkness and at low light levels, represents an extremely high metabolic load on the cells, and the elimination of this load when the cones are functional provides a major benefit to retinal metabolism. From this perspective, the limited range of rod light adaptation is beneficial, whereas an extended range (as occurs in cones) would be detrimental.

Extraction of Contrast Information and Optimization of Response Kinetics

In addition to the very important function of extending the operating range of the photoreceptor, there are two other ways in which photoreceptor light adaptation optimizes the cell's response. First, as described above in relation to eqn [1], it permits the extraction of contrast in the visual scene, independent of the absolute level of illumination. Second, it provides real-time adjustment of the time course of the response to an incremental flash of light, in a manner that is presumed to be optimal for the visual system. Thus, at very low background intensities, the response is sluggish, and postreceptoral elements are able to integrate visual signals over relatively long times. At progressively higher background intensities, the response becomes progressively accelerated, thereby improving the time resolution of the system. However, we do not have sufficient information yet to be able to describe exactly how it is that kinetic changes of this kind are actually optimal for the visual system.

Light Adaptation of the Rod Photoreceptors: Range Extension, Desensitization, and Acceleration

In the presence of background illumination, it is not only the overall visual system that adapts, but also the rod photoreceptors themselves display light adaptation, characterized by an extension of their operating range and by desensitization and acceleration of the incremental flash response.

Prevention of Rod Photoreceptor Saturation: Range Extension

The response of a salamander rod to the onset of steady illumination at different intensities is illustrated in **Figure 2**. At the beginning of the step of light, the rod's response begins rising according to what is predicted from the time integral of the flash response, but very soon deviates, falling well below the linear prediction (upper panel). Characteristically, the response to such a step of light typically exhibits an early peak followed by a sag. This deviation from the simplest linear prediction is a crucial aspect of light adaptation – if this deviation did not occur, then the rod would be driven into saturation by lights of very low intensity. Such saturation can be induced by exposing the rod to a solution that clamps the cytoplasmic calcium concentration; in the presence of calcium-clamping solution (lower panel), the responses of the rod follow the predictions of the smooth theoretical curves, and a very low intensity (labeled 2) saturates the rod. This result shows that at least a part of the rod's ability to continue operating in backgrounds of moderate intensity (i.e., the extension of its operating range) is a consequence of changes in cytoplasmic calcium concentration; the molecular mechanisms that contribute to this will be discussed below.

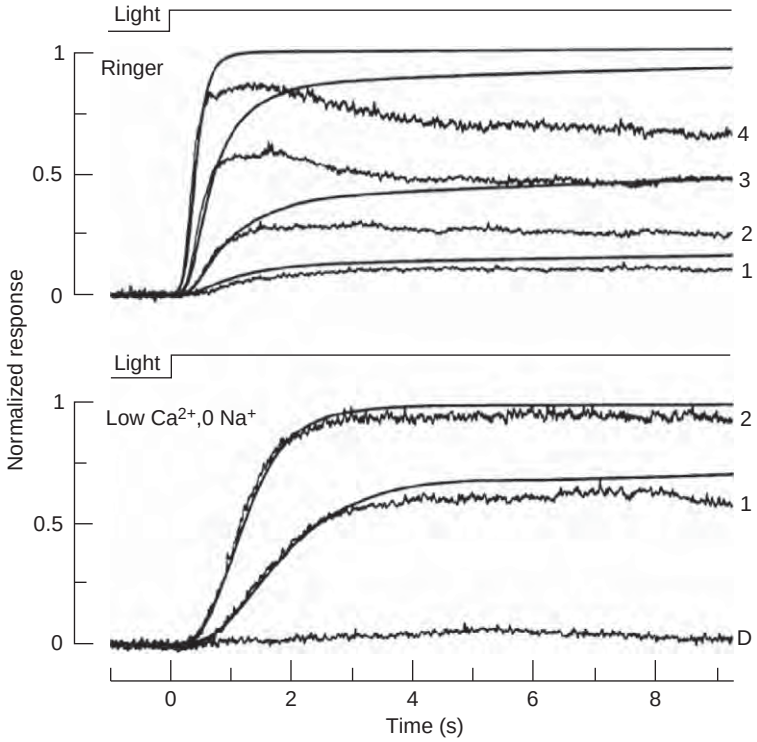

Figure 2 Responses of a salamander rod to onset of steps of light of different intensity. Upper panel: under control conditions (Ringer solution). Lower panel: in the presence of Ca^{2+}-clamping solution. The step intensities increased by factors of ~4 for traces labeled 1–4; D, darkness. The smooth curves are predictions obtained by integrating the measured dim flash response (not shown), and represent the step responses that are predicted in the absence of any adaptation. Reproduced from Fain, G. L., Lamb, T. D., Matthews, H. R., and Murphy, R. L. W. (1989). Cytoplasmic calcium as the messenger for light adaptation in salamander rods. *Journal of Physiology* 416: 215–243.

Desensitization and Acceleration

The manner in which background illumination modifies the rod's response to a dim test flash is illustrated in **Figure 3**. The uppermost trace is for a dim flash presented in darkness, while the remaining traces are for exactly the same flash presented on backgrounds of successively higher intensity. Characteristically, the flash response becomes progressively more desensitized and accelerated with backgrounds of higher intensity. Thus, the peak of the incremental flash response moves downward and leftward as the background intensity increases.

By plotting the peak amplitude of the flash response as a function of the background intensity upon which it was elicited, one obtains a plot of the kind indicated by the red symbols in **Figure 1**, where sensitivity declines according to Weber's law, given above in eqn [1].

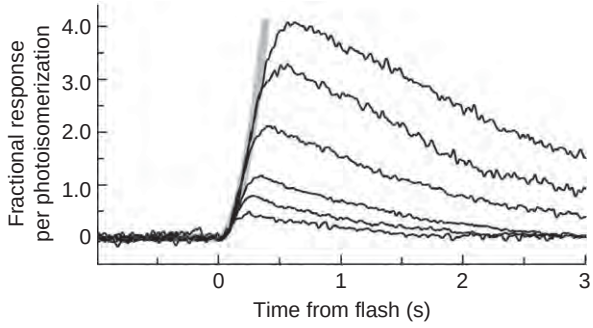

Figure 3 Dim flash responses of a salamander rod obtained in the dark (top trace) or in the presence of backgrounds of progressively higher intensity**.** Each trace was obtained by taking the raw response and dividing by the circulating current, and then dividing by the flash intensity. Reproduced from Pugh, E. N., Jr., Nikonov, S., and Lamb, T. D. (1999). Molecular mechanisms of vertebrate photoreceptor light adaptation. *Current Opinion in Neurobiology* 9: 410–418.

Unaltered Rising Phase, but Accelerated Recovery

For the incremental flash responses in **Figure 3**, the vertical scale has been adjusted to take account of changes in the level of circulating current remaining in the presence of the different background intensities. Thus, rather than plotting raw sensitivity (response per photoisomerization), **Figure 3** instead plots the fractional response

(i.e., the incremental response as a fraction of the circulating current at that background) per photoisomerization. This has been done in order to provide a direct measure of the level of activation of the guanine nucleotide-binding protein (G protein) cascade of phototransduction; thus, it can be shown that the level of cascade activation is best measured by the fractional channel opening, which in turn is measured by the incremental response expressed as a fraction of the existing circulating current. When plotted in this manner, the incremental responses in **Figure 3** demonstrate the remarkable property that the onset phase of the response is invariant; that is, the traces for different background intensities exhibit a common rise at early times, indicated by the smooth gray trace. This behavior indicates that the amplification parameter describing the activation steps in phototransduction is unaltered during light adaptation; in other words, light adaptation causes no change in the efficacy of the activation steps in phototransduction. Instead, it is clear that light adaptation causes a marked speeding up of the shut-off steps in the transduction cascade. The molecular identity of the steps that are accelerated is analyzed below.

Saturation of the Rod Photocurrent at Higher Background Intensities

At higher background intensities, the rod circulating current is completely suppressed. Thus, in the upper panel of **Figure 2**, intensities higher than those labeled 4 cause the response simply to rise to its maximum level (corresponding to the closure of all cyclic guanosine monophosphate (cGMP)-gated channels in the outer segment) and, as a result, incremental stimuli are unable to elicit any incremental response so that the cell's response is saturated. Typically, such saturation sets in exponentially with increasing background intensity, as described by the second term on the right of eqn [1].

Calcium-Dependent Mechanisms of Rapid Light Adaptation in Rod Photoreceptors

The mechanisms that contribute to light adaptation in photoreceptors (i.e., to the alteration in response properties of the photoreceptors upon exposure to background illumination) are closely associated with the mechanisms of response recovery. These mechanisms of adaptation can be classified broadly as (1) those that are calcium dependent and (2) those that do not involve calcium. Both categories are important; yet, the noncalcium-dependent mechanisms have frequently been overlooked.

Role of Calcium: Resensitization through Prevention of Saturation

When cGMP-gated ion channels in the outer segment are closed in response to light, the cytoplasmic concentration of calcium drops. This drop in Ca^{2+} concentration is vitally important to light adaptation, though it is crucial to emphasize that it does not cause the desensitization that characterizes photoreceptor light adaptation. Quite the contrary: the drop in Ca^{2+} concentration actually rescues the rod from the saturation that would otherwise be induced by light, and thereby prevents the onset of massive desensitization at relatively low intensities of background illumination. Thus, the light-induced drop in Ca^{2+} acts to increase the rod's sensitivity above the drastically reduced level that would occur either if the Ca^{2+} concentration did not alter or if the rod's calcium-dependent mechanisms were inoperative.

Powerful Negative-Feedback Loop Mediated by Calcium

Calcium is the cytoplasmic messenger for a very powerful negative-feedback loop that tends to stabilize the rod's circulating current. If ever the Ca^{2+} concentration drops (e.g., in response to light, or as a result of some other perturbation), then, as described below, a number of changes occur very rapidly. These changes are stimulated by the unbinding of Ca^{2+} from at least three classes of calcium-sensitive protein: (1) guanylyl cyclase activator proteins (GCAPs) 1 and 2, which activate guanylyl cyclase; (2) recoverin, which regulates the lifetime of activated rhodopsin; and (3) calmodulin, which modulates the opening of cGMP-gated channels. Calcium's action via each of these pathways leads to the opening of cGMP-gated channels, thereby increasing the circulating current and admitting Ca^{2+} ions from the extracellular medium. This influx of Ca^{2+} ions tends to counteract the initial reduction in Ca^{2+} concentration, thereby completing a negative-feedback loop.

Each of these molecular mechanisms contributing to the calcium negative-feedback loop contributes toward extending the rod's operational range of light intensities by helping prevent saturation of the circulating current. Thus, each of these three molecular mechanisms assists in rescuing the rod from saturation and hence increasing, rather than decreasing, the rod's sensitivity compared with the case that would exist if the mechanism were absent. Each of the three mechanisms is most effective over some range of calcium levels, and a corresponding range of light intensities. Overall, the most powerful of the three (at least in rods) is the GCAPs' activation of guanylyl cyclase.

Since the various components of the calcium negative-feedback loop act quite rapidly, they contribute to determining not only the photoreceptor's sensitivity in the

presence of background illumination, but also the kinetics of its response to an incremental flash presented on the background. The importance of altered Ca^{2+} concentration in setting the incremental flash response kinetics can be demonstrated by incorporating a calcium buffer (such as 1,2-bis(o-aminophenoxy)ethane-N,N,N′,N′-tetraacetic acid (BAPTA)) into the outer segment. Although the flash response begins rising exactly as in control conditions, it does not begin recovering as soon and, instead, rises to a substantially larger and later peak with slower final recovery (see also **Figure 4**).

Three Calcium-Sensitive Molecular Pathways

Guanylyl cyclase activation

In response to a drop in calcium concentration, Ca^{2+} will unbind from the GCAP proteins (GCAP1 and GCAP2), thereby activating guanylyl cyclase and stimulating the production of cGMP at a greatly increased rate, leading to the opening of cGMP-gated channels.

The cyclase activity increases roughly as the fourth power of the drop in Ca^{2+} concentration, and furthermore (as also applies for the other two routes considered below), the number of channels open increases approximately as the cube of the cGMP concentration. Because of the cascading of two such steep dependencies, any small fractional change in Ca^{2+} concentration stimulates a large and opposite fractional change in channel opening; that is, the fractional change in channel opening is opposite in sign to, and up to 12× the magnitude of, the originating fractional change in Ca^{2+} concentration. As a result, this molecular mechanism is the most potent of the three that contribute to the calcium negative-feedback loop and, hence, to setting the adaptational state in rods. It is especially dominant at relatively bright background intensities, corresponding to low Ca^{2+} concentrations, and is therefore the most important in extending the rod's operating range to high intensities.

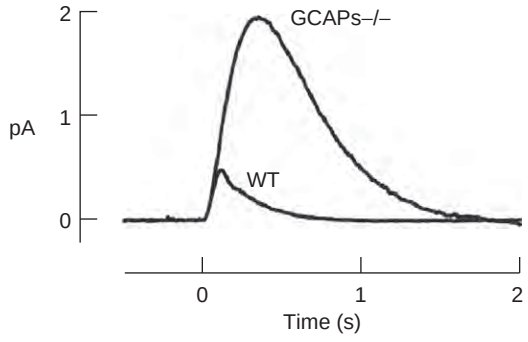

Figure 4 Single-photon responses from rods of wild-type (WT) and GCAPs knock-out (GCAPs−/−) mice. Suction pipette recordings from single rods, analyzed to extract the mean response to a single photoisomerization. Circulating current in rods of both strains averaged 12 pA. Reproduced from Burns, M. E., Mendez, A., Chen, J., and Baylor, D. A. (2002). Dynamics of cyclic GMP synthesis in retinal rods. *Neuron* 36: 81–91.

The role of the GCAPs/guanylyl cyclase component of the Ca^{2+} feedback loop in setting the waveform of the incremental flash response is illustrated in **Figure 4**, where averaged responses are shown for two classes of rod: rods from wild-type (WT) mice and rods from GCAPs knock-out mice. In a manner very similar to that seen in rods containing the calcium buffer BAPTA, the response in the GCAPs knockout case begins rising exactly as for the control (WT) case, but it does not recover as soon; therefore, the response continues rising and reaches a larger and later peak.

Shortened R lifetime*

Activated rhodopsin (R*) is inactivated by multiple phosphorylation steps mediated by rhodopsin kinase (GRK1) followed by binding of arrestin. It is generally assumed that the decline in R* activity follows exponential kinetics, and can therefore be described by a characteristic lifetime, τ_R; however, it is worth bearing in mind that there is no direct evidence for this assumption. It was established by Satoru Kawamura that GRK1's phosphorylation of R* is calcium dependent and that the effect is mediated by the calcium-binding protein recoverin. The molecular mechanism of this dependence is not entirely clear; however, some evidence suggests that the calcium-bound form of recoverin binds to GRK1, thereby preventing it from interacting with R*. In any case, it is proposed that a reduction in Ca^{2+} concentration leads to a shortened R* lifetime, τ_R.

The slowest time constant in the phototransduction cascade (the so-called dominant time constant, τ_{dom}) can be estimated from the steepness of the relationship between the duration that the rod is held in saturation by a bright flash and the flash intensity. Over the years, there has been considerable debate as to whether this dominant time constant is set by the R* lifetime, τ_R, or, instead, by the lifetime τ_E of the transducin–phosphodiesterase (PDE) complex (the effector). The situation may be species dependent; however, in mouse rods, it has now been clearly established by Marie Burns' group that, under dark resting conditions, the dominant time constant is that of transducin–PDE, with $\tau_E \approx 200$ ms, while the R* lifetime is shorter, with $\tau_R \leq 80$ ms. In the scenario where the R* lifetime is shorter than the transducin–PDE lifetime, further light-induced shortening of τ_R is likely to have very little effect on the response kinetics, but will instead cause a reduction in sensitivity because fewer molecules of transducin will be activated during the R* lifetime.

Although it remains difficult to establish the effectiveness of any individual mechanism in an intact rod with a functional calcium feedback loop, it appears that the recoverin-mediated reduction in R* lifetime plays a moderate role, especially at relatively low background intensities.

Channel reactivation

In response to a drop in calcium concentration, Ca^{2+} unbinds from calmodulin (in the case of the rods), leading to a lowered dissociation constant ($K_{½}$) for the binding of cGMP to the channels. The effect of the lowered $K_{½}$ is that any given concentration of cGMP will cause the opening of a larger fraction of the cGMP-gated channels, leading to an increase in circulating current and the influx of more calcium. However, the potency of this effect is low in rods, and the mechanism contributes only weakly to rod adaptation. In contrast, cones possess a much more powerful mechanism, mediated by a different calcium-sensitive protein.

Rod Photoreceptor Light Adaptation Independent of Calcium

There are at least three classes of noncalcium-dependent phenomena that represent mechanisms of light adaptation in rod photoreceptors, insofar as the properties of the response to light are altered in comparison with the dark-adapted state. First, there is response compression, whereby the reduced level of circulating current in the presence of steady background illumination reduces the size of the flash response. This phenomenon will not be discussed here, in part because it is both very well known and very simple and also because (in philosophical terms) it can be viewed as a failure of light adaptation; in comparison, cones cope much better and effectively avoid response compression by feedback mechanisms that maintain the circulating current. Second, there is pigment depletion. However, this is never relevant in rod light adaptation because the rods are driven into saturation even by very low levels of bleached pigment (see section titled 'Dark adaptation of the rods: Very slow recovery from bleaching'). Third, there is a direct effect of PDE activation, which is now considered.

Accelerated Turnover of cGMP

In a rod outer segment in darkness, the activity of the PDE is low; therefore, the turnover rate constant for cGMP (denoted β) is low, with a correspondingly long turnover time constant for cGMP, $\tau_{cGMP} = 1/\beta$, of around 1 s in amphibian rods and around 200 ms in mammalian rods. The magnitude of this parameter has a major effect on both the sensitivity and the kinetics of the rod's response to a flash. Thus, when the PDE activity increases in steady illumination, the shorter turnover time for cGMP contributes to both desensitization and acceleration of the photoresponse (compared with the case that would have applied, had the steady level of PDE activity not increased).

To provide an intuitive understanding of this mechanism, it is helpful to consider what we have referred to previously as the bathtub analogy. Imagine a container of water, such as a tall cylinder, and let the height of water in the cylinder represent the level (concentration) of cGMP in the outer segment. The rate at which water runs out of the cylinder, through a drain hole at the base, is proportional both to the height of water and to the size of the opening, representing the cGMP level and the PDE activity, β, respectively. Likewise, the rate at which water flows in to the cylinder through a tap at the top represents the activity of guanylyl cyclase, α. When a steady state is reached, the height of water will equal the rate of influx divided by the size of the drain hole; that is, $cGMP = \alpha/\beta$. Importantly, whenever the water level is perturbed from this steady-state level (e.g., upon a brief opening of an additional drain hole), the level will re-equilibrate with a time constant $\tau_{cGMP} = 1/\beta$ (provided that the rate of influx through the tap remains constant). Hence, if the drain hole is small (and the inflow via the tap correspondingly small), then any perturbation in water level elicited by a transient additional outflow will be corrected only slowly; if the drain hole is large (and the influx correspondingly large), then any perturbation will be rapidly corrected. Furthermore, though perhaps less intuitively, it can be shown that for a noninstantaneous perturbation, corresponding to the normal flash response, not only will the kinetics of recovery be faster, but the peak also will be smaller.

Hence, the effect of the increased PDE activity during steady illumination is both to accelerate the response kinetics and to reduce the peak amplitude (i.e., reduce the sensitivity) to an incremental flash. Calculations show that in rods the 20-fold increase in β during steady illumination provides the primary mechanism underlying the measured shortening of the time to peak and the decrease in flash sensitivity.

Slow Changes in Rods: Light Adaptation or Dark Adaptation?

In addition to the conventional features of rod photoreceptor light adaptation that occur extremely rapidly (on a subsecond time scale), other changes have been reported to occur over a time frame of minutes of exposure, in response to lights that saturate the cell's response. As the effects of these changes are very slow, and can only be observed in darkness when the adapting exposure is extinguished, there is a semantic issue as to whether these phenomena should be thought of as light adaptation or as dark adaptation.

Light-Induced Change in the Dominant Time Constant

It has recently been shown by Marie Burns' group that exposure of mouse rods to a just-saturating intensity of

around 1000 photoisomerizations per second, for 1 min or more, leads to a persistent speeding of the bright-flash response upon extinction of the background. The change did not involve any reduction in the activation phase of transduction, but instead involved a reduction in the dominant time constant of response recovery; typically, the dominant time constant τ_{dom} dropped from around 200 ms under dark-adapted conditions to around 100 ms immediately after extinction of the saturating light. The adaptational effect developed relatively slowly, building up over 60 s or so, and it required a rhodopsin bleach level of around 2% for full effect. The effect was relatively long lasting, declining with a time constant of around 80 s.

The molecular mechanism giving rise to this adaptational effect is not known, though some evidence suggests that it corresponds to a reduction in lifetime of the activated transducin–PDE complex. If so, it represents a phenomenon distinct from the actions of dimmer adapting lights.

Light-Induced Translocation of Proteins

The light-induced translocation of transducin, recoverin, and arrestin in photoreceptors is dealt with in detail elsewhere in this encyclopedia and, therefore, mentioned only briefly here. Movements of protein are elicited only at quite bright intensities (generally in the saturating range) and occur over a time scale of many minutes. In mouse rods, intensities above 3000 photoisomerizations per second for 30 min (which bleach a substantial fraction of the rhodopsin) trigger the movement of transducin from the outer segment to the inner segment, while slightly lower intensities of 1000 photoisomerizations per second or more trigger the movement of arrestin in the opposite direction; recoverin also leaves the outer segment in bright light.

Protein movements of these kinds may well affect the adaptational state of the rod, though this is yet to be established clearly. Since the movements are triggered only by saturating light intensities, the electrical effects cannot readily be observed during the illumination because the circulating current is completely suppressed. One possibility is that the protein translocation contributes to some form of conservation – for example, lowering the guanosine 5′-triphosphate (GTP) consumption involved in the continual (and maximal) activation of transducin during daylight conditions. Alternatively, it may be that the changes help prepare the rod for its return to lower intensities, as occurs around dusk. Interestingly, in one attempt that was made to detect any change in the amplification constant of human rods (using the electroretinogram (ERG)) following exposures to intensities that elicit transducin translocation in mouse rods, no change in amplification was detectable.

Dark Adaptation of the Rods: Very Slow Recovery from Bleaching

Following exposure of our eye to very intense illumination, our visual threshold is greatly elevated and may take tens of minutes to recover fully. Closely comparable effects can be measured in the overall visual system and at the level of the rod photoreceptors or the rod bipolar cells. The slow recovery of sensitivity is referred to as dark adaptation or bleaching adaptation; however, it should be noted that this use of the term adaptation is something of a misnomer. Adaptation normally refers to beneficial adjustments; yet, the changes that accompany intense illumination are distinctly disadvantageous – thus, there can be no advantage in being almost blind following exposure to intense light.

The recovery of visual threshold for a human subject is plotted in **Figure 5**, following the cessation of nine light exposures that bleached from 0.5% to 98% of the rhodopsin. For a bleach of 20%, the visual threshold was initially elevated by 3.5 log units. This indicates that the elevation of threshold is out of all proportion to the fraction of pigment remaining unbleached; even though 80% of the rhodopsin remained functional, the threshold was raised 3000-fold. Instead, there is overwhelming evidence that the phenomenon arises from the presence within the outer segment of unregenerated opsin (i.e., the presence of the protein part of the visual pigment, prior to its recombination with the regenerated 11-*cis* retinal).

Remarkably, the recovery of scotopic (rod-mediated) threshold exhibits a region of common slope across all the bleach levels, as indicated by the parallel red lines in **Figure 5**. This region is termed the S2 component of recovery, and has a slope $\Psi_{S2} = -0.24$ log unit min^{-1} that is characteristic of dark adaptation recovery in normal (young adult) human eyes; also characteristic is the nature of the rightward shift of the recovery traces as a function of increasing bleach level – the form of this shift is as expected for a rate-limited (zero-order) recovery process, as distinct from an exponential (first-order) recovery process.

From a detailed analysis of results of this kind, in combination with knowledge of the retinoid cycle, Trevor Lamb and Edward Pugh developed a cellular model that can account for human dark adaptation behavior. They postulated that (1) the presence of opsin (without chromophore) gives rise to a phenomenon closely equivalent to light, through activation of the G protein cascade of transduction and (2) the elimination of opsin via its reconversion to rhodopsin follows rate-limited kinetics because of a limitation in the supply of 11-*cis* retinal that results from the movement of this substance from a pool in the retinal pigment epithelium.

Application of this cellular model has provided an accurate account of (1) the regeneration of visual pigment

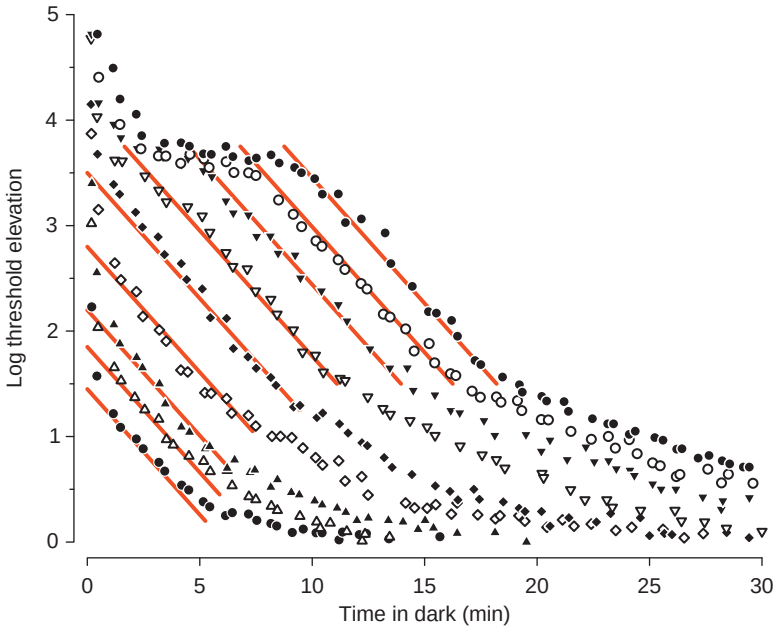

Figure 5 Human psychophysical dark adaptation. Recovery of log threshold elevation in a normal human observer is plotted as a function of time in darkness, after a wide range of bleaching exposures (from 0.5% to 98%). Parallel red lines represent component S2, with a slope of –0.24 decades min^{-1} (see text). The lateral shift between the lines is consistent with the rate-limited delivery of 11-*cis* retinal from the RPE to opsin in the outer segments. Reproduced from Lamb, T. D. and Pugh, E. N., Jr. (2006). Phototransduction, dark adaptation, and rhodopsin regeneration. The Proctor Lecture. *Investigative Ophthalmology and Visual Science* 47: 5138–5152, with permission of the Association for Research in Vision and Ophthalmology.

in humans and other mammals, measured by retinal densitometry; (2) normal human dark adaptation behavior (as in **Figure 5**); and (3) the slowed regeneration of pigment and the slowed dark adaptation that is characteristic of a number of diseases that affect the photoreceptors and/or retinal pigment epithelium.

Phototransduction: Inactivation in Cones

V V Gurevich and E V Gurevich, Vanderbilt University, Nashville, TN, USA

Glossary

Arrestin – A protein that selectively binds light-activated phosphorylated photopigment and blocks further signal transduction. Cones express two subtypes, arrestin1 and arrestin4 (often termed rod and cone arrestins, respectively).
Cone opsins – Light receptors, consisting of the protein part (opsin) and 11-*cis*-retinal covalently attached via Schiff base to a lysine in the seventh transmembrane domain. All opsins are members of superfamily of G-protein-coupled receptors (GPCRs), the largest family of signaling proteins in animals (mammals have ~1000 different GPCRs).
GCAP – Guanylyl cyclase activating protein is a member of the superfamily of EF-hand-containing calcium-binding proteins. Cones express two homologs, GCAP1 and GCAP2, which in the calcium-liganded form inhibit and in magnesium-liganded form enhance the activity of retinal guanylyl cyclase (retGC).
GRKs – G-protein-coupled receptor kinases that specifically phosphorylate active forms of their cognate receptors. Cones express rhodopsin kinase (systematic name: GRK1) and a cone-specific form GRK7. However, mice do not have GRK7; therefore, photopigments in mouse cones and rods are phosphorylated by a single isoform, GRK1.
Phosphodiesterase (PDE) – The photoreceptor-specific cyclic guanosine monophosphate (cGMP) PDE, PDE6. Cone PDE6 is a heterotetramer, consisting of two identical catalytic α'-subunits and two inhibitory γ-subunits. PDE rapidly hydrolyzes cGMP upon its activation by transducin, when its catalytic activity approaches the theoretical limit set by the rate of cGMP diffusion.
RetGC – Retinal guanylyl cyclase is structurally related to receptor guanylyl cyclases. Cones predominantly express RetGC1, in contrast to rods that express RetGC1 and RetGC2 at comparable levels.
RGS9-1 – Photoreceptor-specific short isoform of the regulator of G-protein signaling 9 expressed in both rods and cones. It interacts with the complex of the guanosine triphosphate (GTP)-liganded active α-subunit of transducin with PDEγ and facilitates its intrinsic GTPase activity, thereby directly inactivating transducin and indirectly PDE. Cones express much more RGS9-1 than rods.
Transducin – Photoreceptor-specific heterotrimeric G protein that couples to light-activated opsins. Its α-subunit belongs to Gi/o family. All types of cones express the same α-subunit that is different from the rod variant.

Rod photoreceptors are often described as a marvel of molecular engineering, which creates an impression that cones are just noisier and less-sensitive rods. In fact, as light sensors, cones are just as amazing: their adaptability gives cones a much wider dynamic range covering more than seven orders of magnitude of light intensity without saturation. Cones begin to function in the light of the full moon reflected from objects in the night and are still adequate for a direct look at the sun. Mostly for technical reasons, the biochemistry of cone photoreceptors, particularly the molecular mechanisms underlying adaptation, is not as well studied as the signaling in rods. The assumption that the signaling and shutoff mechanisms in cones and rods are qualitatively similar is often used to fill the gaps in our knowledge of cone biochemistry. To avoid repetition, here we emphasize known differences between the cone and rod inactivation mechanisms.

Cone Signaling Cascade

Cone opsins are closely related to rhodopsin and belong to the same branch of the G-protein-coupled receptor superfamily. Gene duplication events in early vertebrate evolution produced five groups of light receptors: rhodopsins and four classes of cone opsins. Mammals lost half of cone opsin classes, retaining only two. Light activates cone opsins via induced isomerization of 11-*cis*-retinal covalently attached to a lysine in the seventh transmembrane domain. Cone opsins use the same 11-*cis*-retinal as rhodopsin, but have very different spectral sensitivity, with maxima ranging from 360 nm (ultraviolet) to 575 nm (red). Spectral tuning of covalently linked retinal is achieved by changing its environment in the retinal-binding pocket of opsin. Light-activated cone opsins couple to cone transducin, which, in turn, activates the cone subtype of phosphodiesterase 6 (PDE6). Subsequently,

a decrease of cytoplasmic cyclic guanosine monophosphate (cGMP) reduces the influx of Na^+ and Ca^{2+} through the cone variant of cGMP-gated channels, resulting in cell hyperpolarization. Similar to rods, the decrease in Ca^{2+} concentration and consequent replacement of bound Ca^{2+} with Mg^{2+} converts guanylate cyclase activating proteins (GCAPs) from inhibitors to activators of retinal guanylate cyclase (RetGC). The latter replenishes cGMP lost during the light response, which opens the channels, thereby restoring cytoplasmic Ca^{2+} to the original levels. Thus, the activation and deactivation mechanisms employed by rods and cones are quite similar. However, subtle differences at every step of the pathway, including differences in the subtypes of signaling proteins involved, their expression levels, and the geometry of the cell, result in striking functional specialization of the two types of photoreceptors.

Shutoff of the Light-Activated Cone Opsins

As far as signaling is concerned, the key difference between rhodopsin and cone opsins is lower thermal stability of the latter. Because cone opsins spontaneously activate with much higher probability than rhodopsin and readily release retinal even in the dark, cones generate noise that is orders of magnitude higher than in rods. This rules out the detection of signals below the noise level (e.g., a few photons) and makes even completely dark-adapted cones pre-desensitized and ready to operate at light levels they can detect. Loose attachment of the retinal to opsin also results in a significantly faster spontaneous decay of the light-activated cone opsin. For example, mouse cone S-opsin transgenically expressed in rods lacking arrestin was estimated to decay ~40 times faster than rhodopsin coexpressed in the same cell. However, this spontaneous decay with a time constant of ~1.3 s is still much slower than the rate of recovery in cones.

Evolution equipped cones with a more elaborate (and presumably more efficient) photopigment shutoff machinery than that found in rods. The opsin inactivation is accelerated by pigment phosphorylation followed by arrestin binding. In most species, cones express two G-protein receptor kinase (GRK) subtypes: GRK1 (shared with rods) and cone-specific GRK7. It is likely that the co-expression of GRK7 with higher enzymatic activity accelerates opsin phosphorylation in cones. However, it should be noted that mice and rats are rare exceptions: these nocturnal rodents have only GRK1 in both types of photoreceptors. Cones also express two arrestin subtypes, arrestin1 and cone-specific arrestin4 (formerly known as rod and cone arrestins, respectively). Arrestin1 is present in cones at ~50-fold molar excess over arrestin4. A recent study in knock-out animals shows that both arrestins contribute comparably to the shutoff of the photopigment in cones. It is not entirely clear why cones express two arrestin subtypes, rather than a higher level of one subtype, especially considering that the cone opsin transgenically expressed in mouse rods is rapidly and efficiently deactivated by rod arrestin1.

Two functional differences between these arrestins provide some clues. Arrestin1 has high propensity to self-associate, cooperatively forming dimers and tetramers at physiological concentrations. Even in the dark-adapted rod, where the outer segment contains a small fraction of the total arrestin1, most of arrestin1 is a tetramer. It has been unambiguously shown that only monomeric arrestin1 is an active rhodopsin-binding species; therefore, oligomers appear to be storage forms. In contrast, cone-specific arrestin4 does not self-associate at physiologically relevant concentrations; therefore, the whole complement of arrestin4 present in cones is an active monomer. Recent estimates of their expression and arrestin1 self-association constants suggest that dark-adapted cones have in the outer segment ~60 μM of arrestin4 and ~30 μM (5% of the total) of monomeric arrestin1 ready to bind phosphorylated opsin at any time, in addition to a huge backup supply of arrestin1 oligomers.

The second important difference lies in the stability of the arrestin complex with phosphorylated opsin. Arrestin1 forms very stable complexes that take the bound molecule of phosphopigment out of the game for a long time. This is important in the rod to ensure the fidelity of the shutoff. In order to release completely inactive rhodopsin upon dissociation, arrestin1 must stay bound until metarhodopsin II (Meta II) slowly decays and likely until it is regenerated with 11-*cis*-retinal. In contrast, arrestin4 forms fairly transient complexes with phosphorylated cone opsins, likely to ensure the quick return of the opsin back into the active pool. This is important for cone photoreceptors that function at a high rate of pigment bleaching. Although we do not know with certainty why cones express both arrestin subtypes, one scenario appears to provide a plausible explanation. Given the concentrations of the two arrestins in cones, in moderately bright light arrestin4 likely has an advantage, so that the majority of phosphorylated cone opsin would be rapidly recycled to the signaling-competent pool. Increasing levels of illumination inducing massive pigment bleaching would force the cell to draw increasingly on the virtually inexhaustible supply of arrestin1, which forms long-lived complexes with the opsin. The recent finding that arrestin1 plays a more prominent role in cone recovery after very bright flashes is consistent with this model. The formation of arrestin1-opsin complexes would take larger and larger fraction of the pigment out of action for a relatively long time, possibly serving as one of the mechanisms of light adaptation. Even though a cone-specific visual cycle involving

Müller glia provides 11-*cis*-retinal faster than the canonical retinal pigment epithelium-based visual cycle supplying rods, very bright light bleaches cone pigment faster than it can be regenerated. This loss of functional opsin was proposed to reduce light capture, acting as a mechanism of adaptation. It is entirely possible that in bright light, both incomplete regeneration of opsin and its binding by arrestin1 cooperate to limit the active pool, thereby reducing light sensitivity of cones.

Overall, cones combine less-stable photopigment with more sophisticated machinery of its inactivation (**Figure 1**). These factors apparently contribute to faster shutoff at the opsin level and likely provide cone-specific mechanisms for light adaptation.

Inactivation of Transducin and PDE

It is generally accepted that the activation of cone transducin by cone opsins and that of cone PDE6 by the guanosine triphosphate (GTP)-liganded α-subunit of cone transducin proceeds in similar ways to corresponding processes in rods. All three subunits of cone transducin differ from their rod counterparts, but the significance of this specialization is uncertain. In fact, cone S-opsin transgenically expressed in mouse rods efficiently activates the signaling cascade coupling to rod transducin. Cone PDE6 is an $\alpha'_2\gamma_2$ heterotetramer, in contrast to the $\alpha\beta\gamma_2$ version in rods, but the functional significance of the use of different catalytic subunits remains to be elucidated. There is one biochemical difference that undoubtedly contributes to the much faster inactivation of transducin-PDE6 complex in cones: ~10-fold higher level of the regulator of G-protein signaling 9-1 (RGS9-1) expression. It has been convincingly shown that the deactivation at this step rate limits the recovery kinetics in rods, and that the level of RGS9-1, which accelerates self-inactivating GTPase of transducin α-subunit, sets the speed of transducin-PDE6 inactivation. Thus, the shutoff at the opsin and transducin-PDE6 level in cones is much faster than corresponding processes in rods; however, it is still not clear which step is rate limiting in cone recovery.

Restoration of cGMP and Intracellular Calcium Level

Similar to the situation in rods, cone activation results in a drop in the intracellular Ca^{2+} concentration due to the closure of the cGMP-gated channels mediating the bulk of Ca^{2+} entry. In order to return to the initial state after opsin and PDE6 are fully inactivated, cones need to restore cytoplasmic cGMP hydrolyzed by PDE6. Cones and rods use the same negative-feedback mechanism that translates the drop in Ca^{2+} resulting from the reduction in the cGMP level into a signal to make more cGMP. Ca^{2+} dissociates from GCAPs when its cytoplasmic concentration drops in the light. The replacement of lost Ca^{2+} by Mg^{2+} converts GCAPs from inhibitors to activators of RetGC. The generated cGMP opens the channels, and the consequent increase in cytoplasmic Ca^{2+} stops further cGMP synthesis. Cones apparently express the same combination of GCAP1 and GCAP2 (which differ in their Ca^{2+} sensitivity) as rods. The functional significance of the predominance of the RetGC1 isoform in cones (in contrast to similar levels of RetGC1 and RetGC2 in rods) is not clear.

Several important differences between rods and cones are known to be responsible for much faster cone recovery. First, the rate of recovery depends on the absolute amounts of cGMP and Ca^{2+} that need to be replenished. Here cones hold an obvious advantage due to the much smaller volume of their outer segments: the hydrolysis or synthesis of the same absolute amount of cGMP leads to a more significant change in its concentration. Similarly, the closure of the same fraction of cGMP-gated channels leads to a more profound drop in intracellular Ca^{2+} in cones. However, geometry is only part of the story. The channel expressed in cones has a different subunit composition and ion preference. About 35% of the inward current via the cone cGMP-gated channel is carried by Ca^{2+}, whereas in rods this fraction is only ~20%. Thus, the closure of the same fraction of channels upon PDE6 activation results in a substantially greater change in the absolute number of Ca^{2+} ions entering the cell. Increased Ca^{2+} influx in cones is balanced by its accelerated extrusion via Na^+/K^+–Ca^{2+}-exchanger, so that the turnover of Ca^{2+} in cone outer segments is more rapid. The combination of faster constitutive extrusion, larger fraction of the current carried by Ca^{2+} through cGMP-gated channels, and much smaller outer segment volume greatly increases the rate of Ca^{2+} drop in response to light stimulus, speeding up RetGC activation and cGMP resynthesis. High intracellular Ca^{2+} reduces the sensitivity of the channels to cGMP, so that when the intracellular Ca^{2+} drops, the channels become more sensitive to the cytoplasmic cGMP and therefore reopen faster. This mechanism operates in both types of photoreceptors, but it is more powerful in cones, further contributing to accelerated recovery.

Conclusions

Cone photoreceptors use essentially the same molecular mechanisms of signal shutoff at the opsin level as rods. At this step, cones achieve much higher speed of inactivation by employing, in addition to GRK1 and arrestin1

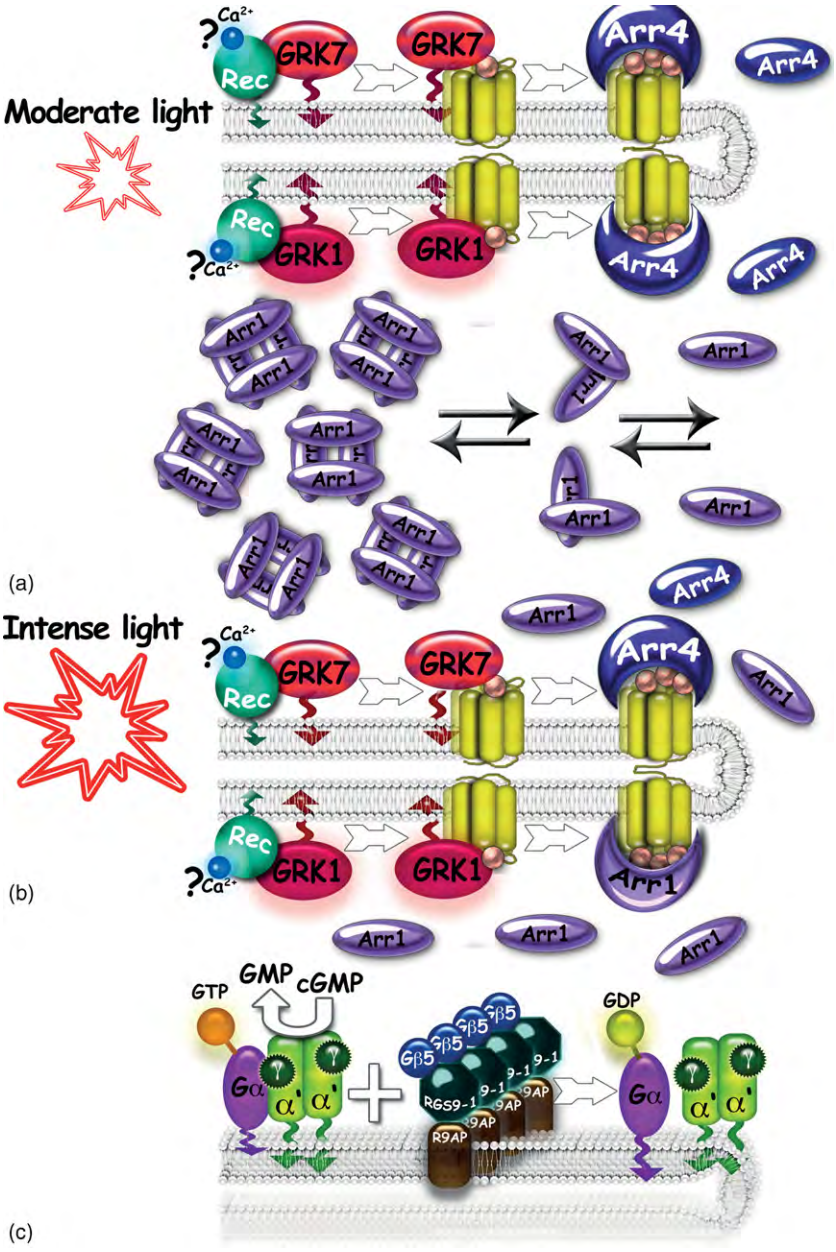

Figure 1 Biochemical mechanisms of rapid inactivation in cones. (a) Cone opsins are phosphorylated by both GRK1 and GRK7 coexpressed in cones of most vertebrates, including humans. At moderate light levels, the signaling by phosphorylated photopigment is largely quenched by constitutively monomeric arrestin4, which forms transient complexes with the receptor. (b) During massive opsin activation in very bright light, the amount of expressed arrestin4 becomes insufficient to quench all active opsins; therefore, cones increasingly use coexpressed arrestin1, which forms longer-lived complexes with phosphorylated cone opsins. The consumption of monomeric arrestin1 by the photopigment shifts its monomer–dimer–tetramer equilibrium toward dissociation of oligomers, which generates virtually inexhaustible supply of binding-competent monomer. (c) RGS9-1 is expressed at ~10-fold-higher level in cones than in rods, ensuring much faster inactivation of transducin and PDE. Cone opsin is shown as a bundle of seven transmembrane domains; opsin-attached phosphates are shown as spheres; lipid modifications anchoring recoverin, GRK1, GRK7, α-subunit of transducin, and catalytic α′-subunits of PDE are shown as membrane-imbedded arrows. Rec: recoverin, Arr1: arrestin1, and arr4: arrestin4.

used by rods, cone-specific GRK7 and arrestin4. The presence of two GRKs speeds up the phosphorylation of light-activated opsin, whereas the expression of two arrestin subtypes with very different functional characteristics likely results in a gradual switch from rapidly reversible arrestin4 interaction with phospho-opsin at moderate light levels to semi-irreversible binding of arrestin1 in very bright light. Inactivation at the transducin/PDE

level is accelerated by a 10-fold higher expression of RGS9-1 in cones. Two key features ensure faster recovery in cones than in rods. Faster Ca^{2+} turnover due to higher influx through cone-specific cGMP-gated channels and efflux via Na^{+}/K^{+}–Ca^{2+}-exchanger generate greater net changes in the number of Ca^{2+} ions in the outer segment when the same fraction of the channels is closed. Due to much smaller outer-segment volume, the same net change in the number of cGMP molecules or Ca^{2+} ions produces greater changes in the concentration of these second messengers. Rapid response and recovery gives cones better temporal resolution than rods. The high speed of activation and inactivation in combination with more powerful adaptation mechanisms (many of which still need to be elucidated at the molecular level) allows cones to function in a broad range of light levels without saturation.

Glossary

Arrestin (also known as S-antigen, 48-kDa protein, and rod or visual arrestin; systematic name: arrestin1) – A protein that selectively binds light-activated phosphorylated rhodopsin and blocks further signal transduction.

Guanylyl cyclase activating protein (GCAP) – A member of the superfamily of EF-hand-containing calcium-binding proteins. Rods express two homologs, GCAP1 and GCAP2, which in calcium-liganded form inhibit and in magnesium-liganded form enhance the activity of retinal guanylyl cyclase (retGC).

Phosphodiesterase (PDE) – Photoreceptor-specific cGMP phosphodiesterase, PDE6. Rod PDE6 is a heterotetramer, consisting of two nonidentical catalytic subunits (α- and β-) and two inhibitory γ-subunits. PDE6 rapidly hydrolyzes cyclic guanosine monophosphate (cGMP) upon its activation by transducin. In fully activated state, its catalytic activity approaches the limit set by the rate of cGMP diffusion.

RetGC – It is structurally related to receptor guanylyl cyclases. Rods express comparable levels of two homologs, RetGC1 and RetGC2.

Regulator of G-protein signaling 9 (RGS9-1) – Photoreceptor-specific short isoform of the regulator of G-protein signaling 9 expressed in both rods and cones. It interacts with the complex of the guanosine triphosphate (GTP)-liganded active α-subunit of transducin with PDEγ and facilitates its intrinsic GTPase activity, thereby directly inactivating transducin and indirectly PDE.

Rhodopsin – Light receptor, consisting of the protein part (opsin) and 11-*cis*-retinal covalently attached via Schiff base to a lysine in the seventh transmembrane domain. A member of the superfamily of G-protein-coupled receptors (GPCRs), also known as seven transmembrane domain receptors (7TMRs), the largest family of signaling proteins in animals (mammals have $\sim$1000 different GPCRs).

Rhodopsin kinase (RK) (systematic name: GRK1) – It is a member of the G-protein-coupled receptor kinase (GRK) family expressed in both rods and cones.

Transducin – Photoreceptor-specific heterotrimeric G protein that couples to light-activated rhodopsin. Its α-subunit belongs to Gi/o family.

As light sensors, vertebrate rod photoreceptors are a remarkable evolutionary achievement: rods yield amazingly low noise despite the presence of 10^8–10^9 molecules of the light receptor rhodopsin, and demonstrate single-photon sensitivity and a dynamic range of seven orders of magnitude of light intensity. This level of perfection is achieved through several unique structural and biochemical adaptations. The rod outer segment (OS) is a specialized signaling compartment containing rhodopsin molecules tightly packed in disks. It is separated from the inner segment (IS), which is a mitochondria-rich power station providing huge amounts of energy. Several soluble signaling proteins move between the two compartments depending on the illumination, ensuring their on-demand delivery to the OS. The OS concentrations of transducin (Td) and arrestin, the proteins that transmit and shut down rhodopsin signaling, respectively, change by at least 10-fold. An important functional feature of the rod is that every biochemical step in the pathway between photon capture and the change in synaptic output has its own dedicated shutoff mechanism.

What Needs to Be Inactivated: Overview of the Signaling Cascade

Rhodopsin activation by a photon of light is the first step in visual signaling. Due to extremely high concentration of its cognate G protein, Td, and rapid diffusion of both active rhodopsin (Rh*) and Td in the plane of the disk membrane, Rh* activates a molecule of Td every few milliseconds, generating 50–100 active Td (Td*) during its lifetime. These events occur in the two-dimensional space on the cytoplasmic surface of disk membranes. Each Td* binds the inhibitory γ-subunit of cyclic guanosine monophosphate (cGMP) phosphodiesterase (PDE6), turning the enzyme on. Each molecule of active PDE6 hydrolyzes several cGMP molecules per millisecond, producing a rapid drop in the cGMP concentration in the three-dimensional cytoplasmic space. This results in closure of cGMP-gated Na^+/Ca^{2+} channels on the

plasma membrane. In rods, light activation of a single rhodopsin translates into the hydrolysis of ~100 000 cGMP molecules. The channels are heterotetramers, with each subunit carrying a cGMP-binding site in its C-terminal domain. Highly cooperative cGMP binding to the four sites in the channel greatly increases its response to the change in cGMP concentration. The decrease of the inward current hyperpolarizes the rod, reducing neurotransmitter release in its output synapse.

Several features of the rod signaling machinery bring its light sensitivity within the range of its physical limit: the detection of single photons. First, the concentration of signaling molecules in the rod OS is orders of magnitude higher than in normal cells: ~3 mM rhodopsin (compared to low nanomolar concentrations of related receptors elsewhere), ~0.3 mM Td, ~60 μM PDE, and so on. Second, all three signaling proteins involved have much lower basal activity than their counterparts in other cells. This results in an incredibly low noise level, making signal-to-noise ratio favorable for the detection of even an extremely weak signal. Third, very efficient shutoff mechanisms at every step of the pathway rapidly terminate the signaling, allowing for an exquisite subsecond temporal resolution of mammalian rods.

Shutoff of the Light-Activated Rhodopsin

Rhodopsin is a prototypical G-protein-coupled receptor. In contrast to ~1000 other members of this superfamily, it has virtually no basal activity, because it is effectively suppressed by the covalently attached inverse agonist, 11-*cis*-retinal. Retinal is converted by light into the all-*trans* form, which is a potent agonist of rhodopsin. The fact that it remains covalently attached to the receptor (in contrast to other GPCRs where bound and free agonists are in dynamic equilibrium) ensures a powerful burst of signaling. Through a series of short-lived photoproducts, light-activated rhodopsin reaches the Metarhodopsin II (Meta II) state, which is an active form (Rh*) that couples to Td. Meta II is in equilibrium with the two other states, Meta I and Meta III, which are believed to be inactive, or at least considerably less active than Meta II. Ultimately, all-*trans*-retinal dissociates, yielding empty protein opsin, which has orders of magnitude lower ability to activate Td than Meta II. However, this spontaneous deactivation of rhodopsin is inadequate as a shutoff mechanism for two reasons. At physiological temperatures, rhodopsin decay takes about a minute, which would greatly compromise temporal resolution. Moreover, the activity of opsin, which is much higher than that of dark rhodopsin, would generate considerable noise, compromising rod sensitivity. Therefore, rods use a sophisticated two-step mechanism to achieve rapid and complete rhodopsin deactivation.

First, light-activated rhodopsin is phosphorylated by rhodopsin kinase (RK). Similar to Td, RK is activated by binding to Rh*. Therefore, it selectively phosphorylates the active form of rhodopsin. It should be noted that at low light levels, RK was reported to phosphorylate multiple rhodopsin molecules for each light-activated one, likely by targeting neighboring inactive rhodopsins in the crowded disk membrane. In mammals, RK activity is believed to be held in check by its interaction with Ca^{2+}-loaded recoverin. As a result, RK is fully unleashed only after a brief delay, which allows Td activation to continue until the Ca^{2+} concentration in the rod actually drops. However, low affinity of recoverin for Ca^{2+} ($K_D \sim 5$ μM) is the weak point of this model. Current estimates of the Ca^{2+} concentrations in the dark- and light-adapted mouse OS are ~250 nM and ~25 nM, respectively, so that only a very small fraction of recoverin would be Ca^{2+}-loaded in either. In addition, unlike RK, recoverin predominantly localizes in the inner segment. Still, rods express 50 molecules of recoverin for each RK, so a relatively small change in the Ca^{2+} occupancy of a fraction of recoverin present in the OS could conceivably play a role in RK regulation.

Phosphorylation *per se* reduces, but does not abolish the ability of rhodopsin to activate Td. In the next step, arrestin binds active phosphorylated rhodopsin (P-Rh*), shielding its cytoplasmic tip and precluding further Td interaction. Arrestin apparently remains bound until rhodopsin decays to opsin, and very likely even longer, until opsin is regenerated with 11-*cis*-retinal to the truly inactive dark rhodopsin. Arrestin has several dedicated phosphate-binding residues and other elements that specifically interact with light-activated rhodopsin independently of its phosphorylation state. These partial interactions mediate relatively low-affinity binding to dark P-Rh and unphosphorylated Rh*, respectively. Arrestin elements participating in these interactions also serve as sensors, allowing arrestin to test the functional state of the rhodopsin molecule it encounters and then quickly dissociate from its low-affinity targets, dark Rh, dark P-Rh, or Rh*. In contrast to all other forms, P-Rh* simultaneously engages both sets of elements. This turns the two sensors on at the same time, allowing the arrestin transition into a high-affinity rhodopsin-binding state. This transition involves a global conformational change in arrestin, which mobilizes additional arrestin elements for the interaction. Thus, arrestin works as a molecular coincidence detector, swinging into action only when the rhodopsin molecule it encounters is both active and phosphorylated. The model of sequential multisite interaction readily explains exquisite arrestin selectivity, that is, manifold difference in arrestin binding to Rh* and dark P-Rh on the one hand, and to its preferred target P-Rh* on the other. The salt bridge between positively charged Arg175 and negatively charged Asp296, which is one of the

intramolecular interactions holding arrestin in its basal state, was identified as the main phosphate sensor in arrestin. Rhodopsin-attached phosphates bind Arg175 and neutralize its charge, thereby breaking the salt bridge and facilitating arrestin transition into its active conformation. The reversal of either charge by targeted mutagenesis yields mutants with reduced need for rhodopsin-attached phosphates that bind Rh* with much higher affinity than wild-type protein.

Rhodopsin has multiple phosphorylation sites in its C-terminus. The issue of the number of rhodopsin-attached phosphates necessary for high-affinity arrestin binding was resolved only recently. Studies performed *in vitro* with rhodopsin carrying defined number of phosphates and *in vivo* with mice expressing rhodopsin mutants with different number of sites show that rhodopsin multi-phosphorylation is required. A single rhodopsin-attached phosphate does not appreciably increase arrestin affinity, two somewhat enhance the binding, and three phosphates are necessary for high-affinity interaction *in vitro* and for the rapid shutoff of photoresponse *in vivo*. Whereas arrestin binding does not further increase when Rh* has more than three phosphates, the presence of additional phosphorylation sites on Rh accelerates the shutoff of the photoresponse *in vivo*. This likely reflects the kinetic effect of the abundance of sites that remain available to RK on partially phosphorylated rhodopsin. For example, rhodopsin with three sites would have only one possible RK target left after the incorporation of two phosphates, whereas rhodopsin with six sites would still have four available targets at the same level of phosphorylation. Thus, supernumerary sites would ensure that the magic number of three phosphates per rhodopsin is achieved faster.

Inactivation of Td and PDE

Td is a prototypical heterotrimeric G protein consisting of α-, β-, and γ-subunits. In the inactive state, the αβγ-trimer has guanosine diphosphate (GDP) in the nucleotide-binding site of the α-subunit. In this state, lipid modifications of both α-(N-terminal myristoyl) and γ-(C-terminal farnesyl) subunits provide a fairly strong membrane anchor. This restricts the Td diffusion to the plane of the disk membrane and enforces the orientation favorable for Rh* interaction, thereby maximizing its chances of encountering active rhodopsin and being activated by it. The Td interaction with Rh* opens its nucleotide-binding pocket, whereupon GDP promptly falls out and is immediately replaced by GTP simply because the latter is much more abundant in the cytoplasm. The GTP-liganded α-subunit dissociates from Rh* and βγ-dimer. Tdα-GTP binds the inhibitory γ-subunit of cGMP PDE, greatly increasing PDE activity by relieving the inhibition. Importantly, the separation of the two parts of Td heterotrimer dramatically weakens their membrane anchoring, so that active Tdα-GTP can jump off the disk where it was generated by Rh* and activate PDE on neighboring discs, spreading the signaling in three dimensions. Due to its very high catalytic activity (kcat $\sim 2000\ s^{-1}$ per subunit), active PDE rapidly reduces cGMP concentration in its vicinity, which leads to the closure of cGMP-gated channels and hyperpolarization of the rod within milliseconds of rhodopsin activation by light (**Figure 1**).

Similar to other heterotrimeric G proteins, Tdα has GTPase activity, which serves as a built-in self-inactivation mechanism. However, the intrinsic GTPase of free Tdα is very slow. Interaction of Tdα with PDE γ-subunit increases the activity of its GTPase. The interaction of Tdα–GTP–PDEγ complex with rod-specific GTPase activating protein (GAP) increases the GTPase activity even further. GAP consists of the short isoform of RGS9, Gβ5 (homolog of G-protein β-subunits), and another protein that provides membrane anchor for the complex, RGS9 anchoring protein (R9AP). Low basal GTPase of Tdα gives it time to diffuse around searching for PDE to activate without losing the signal in the transmission. The dramatic acceleration of the GTPase activity of Tdα by the PDE and GAP ensures that the signal is terminated quickly after it is received by PDE, improving the temporal resolution of the photoreceptor cell. The recent finding that the expression of the GAP complex in rods increases the rate of the response shutoff in a dose-dependent manner convincingly demonstrated that the inactivation of Tdα–GTP–PDEγ complex is the rate-limiting step in this process. These elegant experiments also revealed that when this step is maximally accelerated, the recovery kinetics becomes dominated by some other process with the time constant of ~80 ms. This number sets the upper limit for the next slowest step, which could be one of the following: the average lifetime of active Rh*; the release of PDEγ from Tdα-GDP; reassociation of PDEγ with PDE catalytic subunits; or even the time free Tdα-GTP spends searching for PDE and/or docking to it.

Resynthesis of cGMP and Restoration of Calcium Level

Obviously, to return to its initial state and become ready to respond to the next photon with the same vigor, the rod photoreceptor needs to do more than just turn off Rh* and all Td and PDE molecules activated by it. The response leaves, in its wake, substantially reduced cytoplasmic cGMP concentration and very low intracellular calcium due to the closure of the cGMP-gated channels that are responsible for the bulk of Ca^{2+} entry into the OS. Photoreceptors are equipped with an

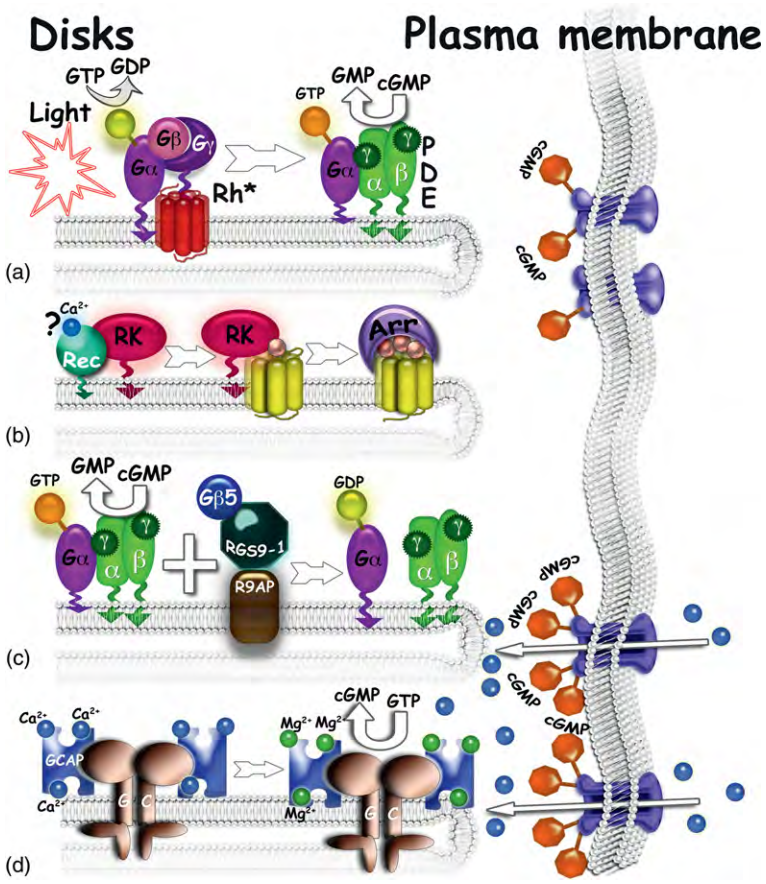

Figure 1 Biochemical mechanisms of signal inactivation in rods. (a) Visual amplification cascade. Light-activated rhodopsin (Rh*) catalyzes GDP/GTP exchange on visual G protein, Td, sequentially activating dozens of Td molecules. Inactive Td is an $\alpha\beta\gamma$-heterotrimer, whereas upon activation the GTP-liganded α-subunit dissociates from the $\beta\gamma$-dimer and binds the inhibitory γ-subunit of rod PDE (which is an $\alpha\beta\gamma_2$ heterotetramer). This activates PDE, which hydrolyzes massive amounts of cGMP (over 100000 molecules per one Rh*). The decrease in cytoplasmic cGMP closes cGMP-gated cation channels on the plasma membrane (right panel). Channel closure reduces the influx of Na^+ and Ca^{2+}, hyperpolarizing the cell up to 1 mV per one Rh*. (b) Rh* is phosphorylated by the rhodopsin kinase (RK, systematic name GRK1), which is expressed in rods and cones of all vertebrates. In the dark, RK may be kept away from rhodopsin via its interaction with Ca^{2+}-liganded recoverin (Rec). Multiphosphorylation prepares Rh* for arrestin (Arr) binding. Arrestin shields the cytoplasmic tip of rhodopsin, sterically blocking its interactions with transducin, thereby completing rhodopsin inactivation. (c) The intrinsic GTPase activity of the Td α-subunit serves as a built-in inactivation mechanism. Its interaction with PDEγ and RGS9-1 (which exists in constitutive complex with Gβ5 and membrane anchoring protein R9AP) greatly facilitates GTP hydrolysis, ensuring rapid inactivation of Td and PDE. (d) In the dark, retinal guanylyl cyclase (GC) is inhibited by Ca^{2+}-liganded GCAPs. Light-induced closure of the cGMP-gated channels results in the drop in cytoplasmic Ca^{2+}. Its replacement with Mg^{2+} on the metal-binding sites of GCAPs converts them into GC activators. GC replenishes the cytoplasmic cGMP and consequent opening of the channels restores cytoplasmic Ca^{2+}, thereby turning off GC. Rhodopsin is shown as a bundle of seven transmembrane domains; Rhodopsin-attached phosphates are shown as spheres; lipid modifications anchoring recoverin, GRK1, α- and γ-subunits of Td, and catalytic α- and β-subunits of rod PDE are shown as membrane-imbedded arrows. Arr, arrestin1; GC, gyanylyl cyclase; Rec, recoverin; Rh*, light-activated rhodopsin; RK, rhodopsin kinase.

ingenious negative-feedback mechanism that translates the drop in Ca^{2+} resulting from the reduction in cGMP level into a signal to replenish it. In photoreceptors, cGMP is synthesized by retinal guanylyl cyclases (retGCs). RetGCs are related to a family of hormone-regulated guanylyl cyclases, such as atrial natriuretic factor receptor, which have extracellular hormone-binding domain connected via a single transmembrane helix to the intracellular guanylyl cyclase domain. Similar to these receptors, retGCs are dimeric, with each monomer equipped with a catalytic domain and an extracellular domain. Interestingly, Mg^{2+} and GTP are bound by two different subunits forming the active catalytic site. As far as we know, the extracellular domain of retGCs neither binds any ligands nor participates in the enzyme regulation. Instead, the activity of retGCs is tightly regulated by their interaction via intracellular elements with GCAPs. GCAPs, as well as recoverin, are members of the neuronal calcium sensor protein branch of the superfamily of calcium-binding proteins containing EF hands (that includes calmodulin).

Similar to other members of this family, GCAPs have four EF hands, three of which actually bind divalent cations. Strictly speaking, GCAPs are Ca^{2+}–Mg^{2+}-binding proteins. The word activating in their name is a bit misleading: Mg^{2+}-liganded GCAPs activate retGCs, whereas Ca^{2+}-liganded forms actually inhibit cGMP synthesis. Thus, in dark-adapted rods with high free-Ca^{2+} concentrations (estimates range from 250 to 600 nM in different species), GCAPs keep the retGC activity at low level. This makes perfect sense, because high Ca^{2+} indicates that there is enough free cGMP ($\sim$2–5 μM) to keep the channels open. Light-induced decrease of intracellular Ca^{2+} (to 5–50 nM, based on different estimates) is the direct result of channel closure, reflecting reduced cGMP in need of replenishing. The loss of bound Ca^{2+} and its replacement by Mg^{2+} (which is always $\sim$1 mM in the cytoplasm) switches GCAPs from the inhibitory to the activating mode exactly when rapid cGMP synthesis is necessary to restore its level. Increasing cGMP opens more channels, thereby gradually restoring Ca^{2+}. Rising Ca^{2+} displaces Mg^{2+} on GCAPs, progressively reducing retGC activity, so that the cell returns to the initial state. After a dim flash, this process often overshoots, leading to a transient increase in the cGMP and Ca^{2+} concentration, likely because PDE is inactivated faster than retGC. The absence of GCAPs slows down cGMP resynthesis, so that light-induced PDE activity results in a more profound decrease of cGMP than in the normal rod. This results in closure of more channels and greatly increases the amplitude of single-photon response. This compromises temporal resolution, prolonging the rising and falling phase of the light response, and limits the working range of rods to lower light levels.

Interestingly, vertebrate photoreceptors express two isoforms of retGC, retGC1 and retGC2, and at least two GCAPs, GCAP1 and GCAP2. The presence of two isoforms of each protein in rods of all vertebrates, including fish, clearly indicates that the different isoforms have nonredundant functions. RetGCs are membrane proteins, suggesting that retGC1 and retGC2 may be localized to different membranes within the OS. RetGC1 was reliably detected in disks, and the possibility that a fraction may also be present in the plasma membrane remains open. The localization of RetGC2 was not studied with sufficient spatial resolution. Since retGC is a dimer, two isoforms of RetGC could give rise to three types of dimers, two homo- and one heterodimer. The fact that each subunit interacts with either GCAP1 or GCAP2 further expands the number of combinatorial possibilities. Definitive experiments, such as knockouts of individual isoforms of either protein, singly and in different combinations, are needed to fully elucidate the biochemistry of the Ca^{2+} feedback mechanism. A recent study of GCAP2 knockout mice revealed that although each GCAP is responsible for about half of the total retGC activation, the functions of the two proteins are quite distinct. Due to lower affinity for Ca^{2+}, GCAP1 switches to the activation mode as soon as the concentration of Ca^{2+} begins to fall, whereas GCAP2 responds later, when Ca^{2+} levels drop further. Thus, together the two GCAPs ensure graded increase in retGC activity in a wider range of Ca^{2+} concentrations than either one could have covered alone.

Another issue in need of clarification is the physiological role of a remarkable buffering capacity of the OS cytoplasm for both second messengers. According to current estimates, total cGMP in the OS is as high as $\sim$50 μM, with only 2–5 μM of it being free and the rest bound to the noncatalytic sites on PDE α- and β-subunits. The polycationic region of PDEγ appears to stabilize the interaction of cGMP with these sites. Reciprocally, the presence of cGMP in noncatalytic sites enhances the interaction of the α- and β-subunits with PDEγ. This mechanism implies that PDE activation by Td would release cGMP from noncatalytic sites. The role of this event in the photoresponse remains unclear. Similarly, free Ca^{2+} represents only a small fraction of the total Ca^{2+} in the OS cytoplasm, the rest being bound to several abundant proteins, such as recoverin, GCAPs, and calmodulin. Ca^{2+} binding by these proteins is a two-way street: on the one hand, it critically regulates their function, on the other hand, by soaking up Ca^{2+}, they significantly change its concentration, modulating the input they respond to. Obviously, Ca^{2+} and cGMP buffering cannot be separated by purely experimental means from other functional modalities of the proteins involved. Therefore, rigorous experimentation must be supplemented with detailed biochemically realistic mathematical modeling to distinguish between the effects of binding on protein activity and on the concentration of free second messenger in the cytoplasm, which is necessary to elucidate the exact biological roles of both.

Light-Dependent Protein Translocation and Rod Signaling

Arrestin localization to the OS in the light and to the IS in the dark was first described in 1985, before the role of this protein in signal termination was established. The subsequent discovery that Td also translocates in a light-dependent fashion, moving in the opposite direction, suggested an idea that translocation may underlie well-known adaptation of rods to different light levels. Preferential localization in the dark-adapted rod of a signal transducer to the rhodopsin-rich OS and a signal terminator to the IS could increase light sensitivity by slowing down shutoff. Conversely, the removal of Td from the OS and accumulation of arrestin in this compartment in the light could significantly reduce it by decreasing the number of Td molecules activated by

Rh* and speeding up rhodopsin inactivation. Subsequent studies showed that the fraction of recoverin, which presumably slows down rhodopsin phosphorylation by keeping RK away from Rh*, in the OS decreases dramatically from 12% in the dark to less than 2% in the light (the bulk of recoverin localizes to the IS in both conditions). The amplification constant in light-adapted rods was found to decrease ~10-fold, in line with the reduction of Td concentration in the OS. While these results support the idea that Td translocation plays a role in rod adaptation, by fully explaining the changes in sensitivity by Td movement alone, they effectively rule out any significant contribution of the translocation of other proteins. The recent finding that phosducin, which interacts with free βγ-dimer released upon Td activation and demonstrates robust translocation from the OS in the light, does not contribute to rod adaptation, supports this notion. The movement of Td, arrestin, phosducin, and recoverin in both directions is a relatively slow process that takes many minutes, which does not seem adequate to explain much faster photoreceptor adaptation. The translocation of arrestin in both directions is energy independent. It is driven in the dark by its low-affinity interactions with microtubules, particularly abundant in IS, and in the light by its binding to light-activated forms of rhodopsin. These findings suggest that the translocation of arrestin and other proteins is more likely to play a role in rod survival during daytime than in relatively fast light/dark adaptation. However, the translocation of different proteins may have distinct functions, which to a large extent remain to be elucidated.

Why Rods Do Not Have an Action Potential

In most neurons, extracellular Ca^{2+} enters presynaptic terminals during an action potential. A brief increase in its local concentration triggers transient exocytosis of neurotrasmitter-containing vesicles. In contrast, vertebrate rod photoreceptors work backward. In the dark, rods are partially depolarized (OS membrane potential is about −35 mV) due to massive influx of Na^+ and Ca^{2+} ions through cGMP-gated channels. This results in continuous release of the neurotransmitter (L-glutamate) from ribbon synapses. By virtue of closing cGMP-gated channels, light of increasing intensity induces progressive hyperpolarization of rods up to –60 mV (a change of ~25 mV). The activation of a single rhodopsin changes the membrane potential by as much as 1 mV. Thus, light intensity is encoded in the extent of hyperpolarization, which determines the magnitude of the decrease of neurotransmitter release. This mechanism makes the signaling graded, in contrast to the all-or-nothing type in neurons with a conventional action potential. It directly couples the change in membrane potential with synaptic activity, so that both the closure of the cGMP-gated channels upon light stimulation and their reopening upon signal termination described above immediately translate into corresponding changes in neurotransmitter release. The absence of thresholds ensures that the information is not lost in transmission, so that the brain can take full advantage of the single-photon sensitivity of the rod photoreceptors. In addition, this mechanism creates a natural ceiling: a full stop of neurotransmitter release is the maximum possible effect of the illumination of any intensity.

Conclusions

In many respects, rod photoreceptors are virtually perfect light sensors that combine single-photon sensitivity with a surprisingly wide dynamic range. Exquisitely timed and extremely efficient inactivation at every step of the signaling cascade between light absorption by rhodopsin and changes in the membrane potential plays an important role in their function. Not surprisingly, molecular errors in this complex multistep inactivation mechanism due to mutations in key proteins underlie a variety of congenital visual disorders in humans, ranging in severity from night blindness to retinal degeneration.

Phototransduction: Phototransduction in Cones

V J Kefalov, Washington University School of Medicine, Saint Louis, MO, USA

Glossary

Dark adaptation – The mechanism that allows photoreceptors to recover their sensitivity to dark-adapted levels following exposure to bright light.
Light adaptation – The mechanism that allows photoreceptors to reduce their sensitivity in the presence of steady light.
Phototransduction cascade – A series of reactions in the outer segments of photoreceptors through which the energy of a photon is converted into a change in the membrane potential of the cell.
Visual cycle – A series of reactions initiated by the activation of the visual pigment by light and terminating in resetting the pigment to its inactive, ground state. It involves the decay of the photoactivated visual pigment to free opsin and all-*trans* retinal, the recycling of chromophore from all-*trans* to 11-*cis* outside of photoreceptors, and the regeneration of the visual pigment molecule.
Visual pigment – A G-protein-coupled receptor consisting of protein, opsin, covalently linked to a chromophore, 11-*cis* retinal. The absorption of a photon by the visual pigment is the initial step in activating the phototransduction cascade.

Introduction

Cone photoreceptors mediate our vision during the day and provide us with fine spatial and temporal resolution as well as color perception. In most species, cones are located mostly in the central area of the retina where the image directly in front of the eyes is projected. Unlike rods, where the signal from hundreds of photoreceptors is integrated for optimized photon detection in low light conditions, signals from individual cones are relayed to the brain. As a result, the spatial resolution of our central vision, driven primarily by the cones, is excellent, whereas that of our peripheral vision, driven by the rods, is significantly lower. Color discrimination is achieved as each cone typically expresses a single type of visual pigment which conveys different spectral sensitivity to different cone types. While single photoreceptors cannot discriminate colors as the degree of photoactivation depends not only on the wavelength of the stimulus but also on its intensity, the visual system extracts that information by comparing the signals coming from the different cone types. An interesting exception to the one cell–one pigment rule is the mouse retina where green and ultraviolet cone visual pigments are coexpressed in the same cells. The functional significance of that arrangement is not clear.

Functional Properties of Cones

Cones use a phototransduction cascade, similar to the one well characterized in rods, to convert the energy of light into an electrical signal. In addition, cone phototransduction proteins are homologous, or sometimes even identical, to the ones found in rods. Yet, cones have functional properties that are distinct from those of rods and that are suited for their role as bright-light detectors. First, cones are significantly less sensitive than rods. The rod phototransduction cascade is tuned for high amplification which allows rods to achieve the maximal physically possible sensitivity and generate a detectable single photon response. As such enormous gain requires buildup of the reactions of the phototransduction cascade, the trade-off is the slow kinetics of rod responses. Cones, on the other hand, are 30- to 100-fold less sensitive than rods (**Figure 1**) and require the simultaneous activation of tens to hundreds of visual pigment molecules to generate a detectable response. As a result of the low amplification of their phototransduction cascade, cones are not sensitive enough to function under low light conditions, depriving us of color vision in dim light. Instead, the low cone phototransduction gain shifts their dynamic range toward brighter light conditions and enables cones to function during the day. The low signal amplification in cones is made possible by the rapid inactivation of their phototransduction cascade. This results in the second notable difference from rods, namely, that cone responses are typically several fold faster than rod responses. The rapid activation and subsequent inactivation of the cone phototransduction cascade reactions provides the basis for the high temporal resolution of cone-mediated vision (**Figure 1**). The rapid activation of cones results in short latency of detection, whereas their rapid inactivation enables discrimination of stimuli spaced closely in time. In contrast, the slower rod responses limit the temporal resolution of rod-mediated vision. Third, following exposure to bright light, cones fully recover their sensitivity within a few minutes. Rods, in contrast, experience a long

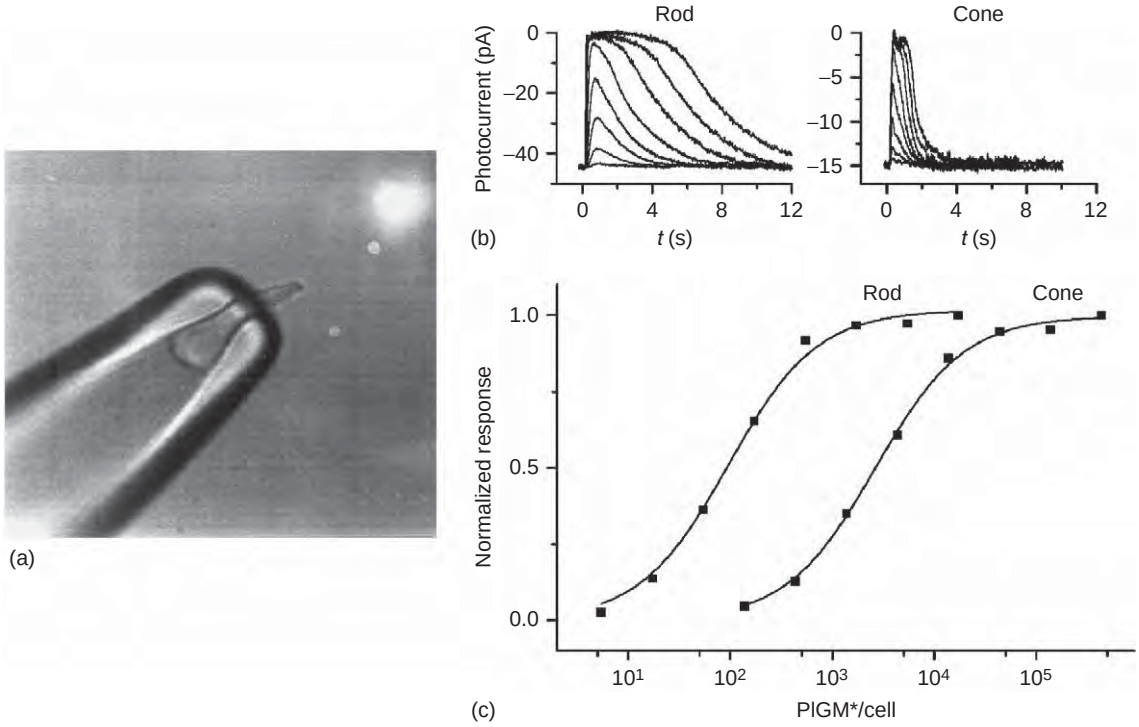

Figure 1 Comparison of rod and cone photoresponses. (a) Salamander red cone drawn in a suction pipet electrode with the outer segment protruding out. (b) Families of photoresponses from a salamander rod (left) and a red cone (right) to brief test flashes of increasing intensity delivered at $t = 0$. Note the significantly lower cone sensitivity compared to the rod sensitivity.

refractory period following exposure to bright light and can take up to an hour for a complete recovery of their sensitivity. This process, known as dark adaptation, prevents cones from becoming refractory and allows us to retain visual perception in a quickly changing light environment. Finally, cones have a remarkable ability to adjust their sensitivity over a very wide range and remain photosensitive even in extremely bright light. Rods, in contrast, saturate in even moderately bright light and remain nonfunctional during most of the day. This process, known as light adaptation, prevents cones from saturating in bright light and allows us to see throughout the day. With rods saturated, cones are responsible for most of the visual information reaching our brain during the day. In fact, with the introduction of artificial lighting, humans rely almost exclusively on cones both during the day and at night. This is why cone disorders, such as macular degeneration, the most common cause of blindness in the elderly, have a devastating effect on vision.

Obstacles for Studying Cone Phototransduction

The last several decades have seen a tremendous advance in our understanding of the function of photoreceptors. The development of electrophysiological tools for studying the function of single photoreceptors, together with biochemical and genetic tools have revealed the mechanism of phototransduction and provided quantitative description of the reactions involved in it. Unfortunately, these advances have been almost exclusively limited to rods. The great abundance of rods in most mammalian retinas (95% of all photoreceptors in human and 97% in mouse retinas) has facilitated the purification and biochemical study of rod phototransduction proteins. In contrast, the small fraction of cones and the homology between rod and cone phototransduction proteins have rendered comparable studies from cone proteins technically challenging. A further obstacle has been the fragility of mammalian cone photoreceptors, which has rendered physiological studies from cones also significantly more challenging than comparable rod studies. As a result, while mammalian rod phototransduction has been characterized in quantitative details, most of what we currently know about cone phototransduction is derived from studies of amphibian and fish photoreceptors. Based on the similarities in structure and transduction proteins between rods and cones, it has been assumed that phototransduction in cones follows the same set of reactions as phototransduction in rods. There exist, however, important quantitative phototransduction differences in

rods and cones pertinent to their function in dim and bright light, respectively. The phototransduction cascade in cones will be discussed here in the context of the much better understood rod phototransduction cascade.

In both, rods and cones, phototransduction takes place in specialized compartments, called outer segments, which consist of stacks of membrane disks, similar to a stack of coins. Unlike in rods, where these disks are surrounded by, but not connected to, the plasma membrane, in cones these disks are formed from invaginations of the plasma membrane. As a result, the plasma membrane of cone outer segment has significantly higher area, a factor possibly important for the rapid flow of molecules in and out of the cell. The transduction channels are cGMP-gated nonselective cation channels held open in darkness by the binding of free cGMP in the outer segment. Cone cGMP channels are homologous to those found in rods and in olfactory neurons and consist of two cyclic nucleotide-gated alpha 3 (CNGA3) and two cyclic nucleotide-gated beta 3 (CNGB3) subunits. In darkness, the influx of Na^+ and Ca^{2+} through these channels depolarizes the cells to about −40 mV, which results in the steady release of the neurotransmitter glutamate from the cone synaptic terminal. Photoactivation of the cell results in the hydrolysis of cGMP, closure of the transduction channels, hyperpolarization of the cell, and reduction in the release of neurotransmitter from the cone synaptic terminal.

Cone Visual Pigment and Phototransduction

Phototransduction in cones is initiated by the activation of cone visual pigments by the absorption of a photon. The cone visual pigments, similar to rod pigments, consist of protein, opsin, covalently attached to a chromophore, typically 11-*cis* retinal. Cone opsins have a moderate level (∼50%) of homology to rod opsins. The visual chromophore is a derivative of vitamin A (all-*trans* retinol), which is converted in the pigment epithelium into 11-*cis* retinal and then transported to the photoreceptor's outer segments where it combines with opsin to form the visual pigment. The visual pigment is expressed at very high levels in the disks of the outer segment (3.5 mM), so that a photon traveling along the outer segment has a ∼40% chance of activating a pigment molecule. Interestingly, the concentrations of rod and cone visual pigments in the outer segment as well as their extinction coefficients are similar. In addition, the probability that a pigment molecule will become activated once a photon has been absorbed (quantum efficiency) is also comparable between rod and cone pigments. Thus, with respect to the pigment distribution and optical properties, only the typically smaller size of the cone outer segment compared to that of the rod contributes to the lower sensitivity of cones.

Studies with amphibian photoreceptors indicate that the different stability of rod and cone pigments modulates their respective phototransduction cascades. First, studies of transgenic *Xenopus* rods expressing red cone opsin have allowed the direct observation of physiological responses to the activation of a single cone pigment molecule. This has made possible the determination of the rate of spontaneous thermal activation of red cone pigments, which produces a response identical to the activation by a photon. The molecular rate of thermal activation measured in this way is ∼10 000 times higher for red cone pigment than for rod pigment. As a result, amphibian red cones experience ∼200 pigment activations per second in darkness. This level of dark activity is comparable to the total dark noise measured from salamander red cones, indicating that most of the noise in these cells originates in the thermal activation of the pigment. This spontaneous activity acts as background light to induce adaptation and, therefore, desensitization and acceleration of the flash response. A second mechanism by which the stability of the visual pigment contributes to the differences between rods and cones is based on the covalent bond between opsin and retinal in their respective pigments. Both biochemical and physiological studies indicate that the formation of the covalent bond between opsin and chromophore is reversible in cones but not in rods. As a result, the visual pigment in cones, but not in rods, can spontaneously dissociate into free opsin and 11-*cis* retinal. The very low level of free 11-*cis* retinal in the outer segment (only ∼0.1% of the pigment content) shifts the equilibrium between free and chromophore-bound cone opsin so that even in dark-adapted cones, there is ∼10% free opsin. At this high level, the total catalytic activity of free opsin, though weak per single molecule, is sufficient to induce adaptation and further reduce the sensitivity and accelerate the kinetics of the cone flash responses.

The effects of cone pigment properties on mammalian photoreceptor function have not been well characterized. Interestingly, studies from transgenic mouse rods expressing cone pigments indicate that, though still significantly higher than that of rod pigment, the rate of thermal activation of cone pigment is not high enough to affect cone photosensitivity significantly. A possible explanation for the relatively low thermal activity of cone pigments in mammalian species compared to amphibians might be that they use a slightly different chromophore (11-*cis* retinal or A1) than most amphibian photoreceptors (11-*cis* 3-dehydroretinal or A2). The reversibility of cone pigment formation and its possible effect on cone function have not yet been examined in mammalian cones. Finally, differences in the properties of rod and cone visual

pigment also contribute to the very different rates of dark adaptation in rods and cones.

Activation of Cone Phototransduction

Once activated, the visual pigment binds to and activates a heterotrimeric G protein, called transducin (G_t). This triggers the exchange of GDP for GTP on the α-subunit of transducin ($G_{t\alpha}$) and the dissociation of $G_{t\alpha}$·GTP from $G_{t\beta\gamma}$. This represents the initial amplification step in phototransduction as one visual pigment molecule can activate multiple G_t molecules. Rod and cone transducins are closely related and the primary structures of their α-subunits are ~80% identical, with even higher identity in the region of interaction with the visual pigment. Biochemical studies indicate that rod and cone pigments have comparable binding affinities for rod transducin and that they activate rod transducin with similar kinetics. Furthermore, studies with transgenic animals coexpressing rod and cone visual pigments in the same photoreceptor have shown that rod and cone pigments produce comparable responses. Thus, cone pigments expressed in rods produce a response with rod-like amplification and kinetics and, conversely, rod pigments expressed in cones produce a response with cone-like amplification and kinetics. These results indicate that the activation of the phototransduction cascade by the visual pigment and the inactivation of the visual pigment are not determined by its properties but rather, by the downstream transduction reactions, including the activation of transducin. Indeed, biochemical studies of fish photoreceptors have shown that the activation of transducin is ~25 times less effective in cones compared to rods. This lower activation efficiency would contribute to the lower amplification of the signal and, therefore, to the lower sensitivity of cones. It is not clear yet whether the lower activation of transducin in cones is due to the properties of the cone isoform of transducin or due to the faster inactivation of pigment in cones compared to rods. An interesting recent observation is that exposure to bright light in rods triggers translocation of the subunits of activated transducin from the outer to the inner segment. In contrast, in cones, such translocation does not occur, possibly because transducin subunits are inactivated and re-form a trimer faster than in rods. The mechanism of this light-dependent translocation is still not well understood and is an active area of research.

Once activated by the visual pigment, $G_{t\alpha}$·GTP in turn activates cGMP phosphodiesterase (PDE) by binding to its inhibitory subunit PDEγ and removing its inhibition on the catalytic PDEαβ. The resulting hydrolysis of cGMP by PDE leads to the closure of cGMP-gated channels in the cone outer segment and the hyperpolarization of the photoreceptor to produce the light response. While cone PDE has 60% identity to rod PDE, biochemical studies of fish photoreceptors indicate that the activation of PDE by transducin might also be ~10 times less effective in cones compared to rods, contributing further to the lower cone sensitivity.

Inactivation of Cone Phototransduction

Response termination is achieved as the visual pigment, transducin, and PDE are inactivated and the concentration of cGMP is restored to its dark, preflash level. Though these reactions in cones are not well characterized, it is clear that, similar to their activation, quantitative differences in the inactivation of phototransduction reactions in rods and cones contribute to the lower sensitivity and faster response kinetics of cones. The activity of the visual pigment is initially partially quenched when it is phosphorylated by a G-protein receptor kinase (GRK). Phosphorylation of activated visual pigment is ~50 times faster in cones compared to rods. It appears that this faster phosphorylation is the result of two factors – higher expression of GRK in cones and higher efficiency of cone GRK (GRK7) compared to rod GRK (GRK1). While most species, including human, express GRK1 in rods and GRK7 in cones, the mouse retina is unusual as its rods and cones share the same kinase, GRK1. In this case, the faster pigment inactivation in cones is most likely due to the higher concentration of GRK1 and possibly also to differential modulation of that reaction by the calcium-binding protein recoverin.

Following phosphorylation, complete inactivation of the phosphorylated visual pigment is achieved by the subsequent binding of a protein called arrestin. The cone isoform of arrestin (Arr4) has about 50% identity to rod arrestin (Arr1). The mouse retina again represents an unusual case, as in addition to Arr4, mouse cones also express Arr1. Interestingly, the ratio of arrestin to visual pigment is 7 times higher in cones compared to rods. In dark-adapted rods, most of arrestin is in the inner segment and does not, therefore, contribute to the inactivation of rod visual pigment. As a result, the quantity of arrestin in the outer segments of rods is only a few percent of their visual pigment. Exposure to bright light triggers the translocation of arrestin from the inner to the outer segment for more efficient pigment inactivation. While arrestin also transloactes in cones, the total quantity of arrestin in their outer segments in darkness is comparable to that of their visual pigment. Recent studies from mouse cones lacking both rod and cone arrestins reveal that either arrestin is capable of inactivating cone visual pigment though Arr1 is much more abundant than Arr4 in cones. Studies with transgenic rods expressing cone S-opsin and either rod or

cone arrestin further demonstrate that rod arrestin is more efficient at inactivating cone pigment than cone arrestin. The relatively low expression of Arr4 in cones and its relative inefficiency suggest a possible additional role for this protein. The coexpression of two arrestins and their high concentration in cone outer segments would contribute to the rapid cone pigment inactivation and are consistent with the more rapid pigment inactivation and faster response termination in cones compared to rods.

$G_{t\alpha}$·GTP is inactivated as GTP is hydrolyzed into GDP. This reaction is catalyzed by PDEγ as part of a GTPase-activating protein (GAP) complex that consists, in addition, of regulator of G-protein signaling (RGS9), RGS9 anchoring protein (R9AP), and a G_β subunit ($G_{\beta 5}$). The rod and cone PDEγ have comparable potencies for inhibiting PDE and also for enhancing the hydrolysis of GTP by the GAP complex. In contrast, even though the identical RGS9 protein is present in rods and in cones, its concentration is more than 10 times higher in cones compared to rods. Deletion of RGS9 in the mouse greatly retards cone response inactivation, and mutations in RGS9 have been associated with slow cone deactivation in patients. Thus, while the extent to which the differences in GAP activity in rods and cones contribute to their functional differences is not well understood, RGS9 and the GAP complex clearly play an important role in the inactivation of cone phototransduction.

The final step in photoresponse termination involves the upregulation of synthesis of cGMP by guanylyl cyclase (GC) to restore the concentration of free cGMP in the outer segment and reopen the cGMP-gated channels. While rods express two isoforms of GC, that is, GC1 and GC2, cones appear to express predominantly, if not exclusively, GC1. The role of GC2 in rods is not clear as its deletion produces only a mild change in rod physiology. It is also not understood how modulation of GC by the pair of GC-activating proteins (GCAP1 and GCAP2) contributes to the unique functional properties of cones. Although the distribution of GCAPs between rods and cones in different species is ambiguous, it appears that GCAP2 is prevalent in rods, while GCAP1 is expressed at high levels in cones. The possible role of GCAPs in mediating light adaptation in cones is discussed below in the context of light adaptation.

Dark Adaptation of Cones

Quantitative differences between the phototransduction cascades of rods and cones not only contribute to the difference in sensitivity and kinetics of photoresponses as discussed above, but also play a role for the very different adaptation properties of rods and cones. The ability to recover their sensitivity rapidly following exposure to bright light, or dark-adapt, is critical for the function of cones as daytime photoreceptors. The absorption of a photon by the visual pigment not only triggers its activation, but also results in its eventual decay into free opsin and all-*trans* retinal. Dark adaptation of both, rods and cones, after exposure to bright light requires regeneration of the visual pigment from opsin and 11-*cis* retinal. However, the speed of pigment regeneration, and hence sensitivity recovery, is very different in rods and cones, with full recovery requiring less than 5 min in cones and up to an hour in rods (see **Figure 2**).

Several factors contribute to the rapid pigment regeneration in cones. First, the decay of the photoactivated pigment to free opsin and all-*trans* retinal occurs in seconds for cone pigments compared to minutes for rod pigments. Second, the reduction of all-*trans* retinal into all-*trans* retinol, which takes place in the outer segment and is catalyzed by retinol dehydrogenase (RDH), is also 10–40 times faster in cones compared to rods. The reduction reaction requires the cofactor nicotinamide adenine

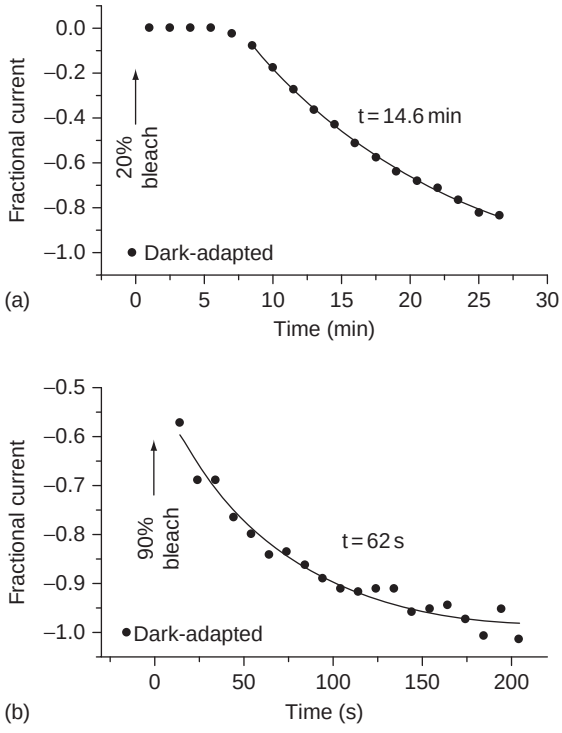

Figure 2 Comparison of rod and cone dark adaptation. Recovery of the circulating (dark) current in salamander rod (a) and red cone (b) measured with a suction electrode. Cells were exposed to bright light that activated (bleached) 20% of the rod pigment and 90% of the cone pigment. The recording was done in the presence of exogenous 11-*cis* retinal to enable pigment regeneration in the isolated cells. Current recovery is fit by a single exponential decay function (solid line). Note the significantly faster recovery of the current in cone compared to the current in the rod.

dinucleotide phosphate oxidase (NADPH). While it is possible that the faster reduction of all-*trans* retinal in cones is due to the different properties of rod and cone RDH enzymes, a more likely hypothesis is that the reduction reaction is limited by the supply of NADPH from the inner segment. Third, single-cell measurements from amphibian photoreceptors indicate that the clearance of all-*trans* retinol from the outer segment is ~25 times faster in cones compared to rods. However, the actual difference in these rates in the intact retina might be affected by factors such as the proximity to the pigment epithelium and the action of extracellular chromophore-binding proteins such as interphotoreceptor retinoid-binding protein (IRBP). Finally, the formation of the covalent bond between opsin and 11-*cis* retinal during pigment regeneration occurs in seconds in cones and minutes in rods. Together, these factors contribute to the faster turnover of cone visual pigment and the faster dark adaptation of cones compared to rods.

In addition to the effects of faster visual pigment decay and regeneration, cone dark adaptation is accelerated by the noncovalent interaction between opsin and 11-*cis* retinal. Pigment regeneration requires the initial binding of 11-*cis* retinal in the chromophore pocket of free opsin. While in rods, the noncovalent binding of retinal activates the opsin molecule and desensitizes the rods, in cones, this reaction has the opposite effect and inactivates cone opsin. As a result, the noncovalent binding of 11-*cis* retinal to opsin delays dark adaptation in rods but accelerates it in cones, as it allows cones to substantially recover their sensitivity even before the regeneration of their visual pigment.

Recent biochemical studies indicate that another mechanism contributing to the faster dark adaptation of cones compared to rods is based on the supply of recycled chromophore for pigment regeneration. The canonical visual cycle involves the pigment epithelium, where all-*trans* retinol is converted into 11-*cis* retinal via a series of enzymatic reactions and then transported back to the photoreceptors for incorporation into opsin. The rapid dark adaptation of cones and their ability to maintain adequate levels of pigment and remain light sensitive even in steady bright light require rapid pigment regeneration, hence rapid recycling of chromophore for cones. However, the slow rate of chromophore turnover in the pigment epithelium and the competition for recycled chromophore between cone opsin and overwhelming levels of rod opsin in most rod-dominant species indicate that the canonical pigment epithelium visual cycle might not be sufficient to meet the chromophore demand of cones. Indeed, recent biochemical studies from cone-dominant species have brought up the idea of a second, cone-specific pathway for recycling of chromophore located within the retina and possibly relying on the Müller cells. The role of this novel cycle in mammalian rod-dominant species is still controversial. However, recent physiological experiments with amphibian photoreceptors demonstrate the function of a retina visual cycle under physiological conditions in a rod-dominant retina. Importantly, the combined action of the pigment epithelium and the retina visual cycles is required for the rapid and complete dark adaptation of cones.

Light Adaptation in Cones

In contrast to rods, which saturate in moderate light and are not responsive during the day, cones have the ability to adapt their sensitivity and remain functional over a very wide range of light intensity. Studies with amphibian and fish photoreceptors indicate that, similar to the case of rods, cone adaptation is mediated by intracellular calcium, modulated by the activation of the phototransduction cascade. In the dark, the continuous current entering the outer segment through the cGMP-gated channels is carried in part by calcium, which is returned to the extracellular space via a $Na^+/(Ca^{2+}, K^+)$ exchanger. Following photoactivation and the closure of cGMP channels, calcium continues to be exported out of the cell through the $Na^+/(Ca^{2+}, K^+)$ exchanger until a new equilibrium is reached. As a result, activation by light causes a decline in the concentration of calcium in the outer segment of the cell. This triggers the calcium-mediated negative feedback on phototransduction, which in rods is required for eventually terminating the signal and for adapting the cell in response to light. Interestingly, calcium constitutes a larger fraction of the total ionic flux in and out of the outer segment of cones compared to rods. Thus, in cones of amphibians and fish, the fraction of photocurrent carried by calcium is about 35% compared to 20% in rods. As would be expected from the need to maintain a steady calcium concentration in darkness, the matching rates of extrusion of calcium via the $Na^+/(Ca^{2+}, K^+)$ exchanger are also higher in cones compared to rods. The combination of faster turnover of calcium in cones and their smaller volume compared to rods allows calcium in cones to decline several times faster upon light stimulation. In addition, their range of calcium concentrations from darkness to bright light is threefold wider than that in rods. These quantitative differences create the potential for more powerful modulation of phototransduction by calcium in cones compared to rods consistent with the ability of cones to adapt better and faster to various light conditions than rods.

The mechanisms by which calcium modulates the cone phototransduction cascade are not well understood. However, comparison between cone and rod phototransduction reveals several interesting points. One mechanism by which calcium modulates phototransduction in rods involves inactivation of the visual pigment via

phosphorylation by rhodopsin kinase. This reaction is modulated by the calcium-binding protein recoverin (also known as S-modulin). Recoverin is a member of the EF-hand superfamily and exerts its effect by inhibiting phosphorylation of rhodopsin by rhodopsin kinase at high calcium levels. In rods, inhibition of rhodopsin kinase by recoverin regulates phototransduction in darkness, in high calcium conditions, but has little effect during light adaptation, in low calcium conditions. The role of recoverin in modulating cone phototransduction in darkness and during light adaptation is not known. However, rods and cones share the same isoforms of recoverin and rhodopsin kinase. In addition, calcium modulates the sites and extent of pigment phosphorylation in cones but not in rods. Finally, unlike in rods, in cones, the calcium-dependent inactivation of cone visual pigment could be the rate-limiting step for the shutoff of the cone photoresponse.

Another mechanism by which calcium modulates phototransduction in rods involves the synthesis of cGMP by GC. As discussed above, this reaction is modulated by GCAP1 and GCAP2. GCAPs modulate GC in rods up to 20-fold as they inhibit it at high intracellular calcium levels and activate it at low calcium levels. While the simultaneous deletion of GCAP1 and GCAP2 delays the recovery of cone light responses, the extent to which GCAPs modulate cone phototransduction in darkness and during light adaptation is not known.

Finally, calcium is also believed to directly modulate the cGMP-gated channels in cones. The Ca^{2+}-dependent modulation of cGMP current is minimal in amphibian and undetectable in mammalian rods. In contrast, cone cGMP channels are directly modulated by Ca^{2+} both in fish and in mammalian retina. The molecular mechanism of cone channel modulation remains to be discovered. While calmodulin binds to and modulates heterologously expressed cGMP-gated channels, its role in the intact cone photoreceptor has been questioned.

Epilog

These are exciting times for studying cone phototransduction. Until recently, technical issues such as the low abundance of cone photoreceptors in rod-dominant retinas and the fragility of mammalian cone photoreceptors have held back the biochemical and physiological studies of cones. As a result, despite the crucial role of cones for our daytime vision, mammalian cone phototransduction has been poorly understood. Recent development of several genetically modified mice has turned the tables. One example is the Nrl knockout mouse. Nrl is a transcription factor required for rod photoreceptor differentiation and its deletion produces a retina populated exclusively by cone-like photoreceptors. This makes possible the purification and biochemical characterization of mammalian cone phototransduction proteins. The Nrl knockout retina has also been used recently for physiological studies of cone photoreceptors. Other examples of useful genetically modified mice include those lacking the rod visual pigment (rhodopsin knockout) and the rod $G_{t\alpha}$ subunit (transducin α knockout). The lack of functional rods in both of these retinas makes possible the physiological identification and study of cone photoreceptors. This approach was most recently used to investigate the role of Arr1 and Arr4 in the inactivation of mouse cone pigments. The combination of new genetic models and improved physiological tools provides promise for studies of mammalian cone photoreceptors using the full range of tools that have been so successful in characterizing the function of mammalian rods. This should allow not only quantitative characterization of the cone phototransduction cascade but also understanding the mechanisms for cone dark and light adaptation which make cones invaluable as our daytime photoreceptors.

Phototransduction: Phototransduction in Rods

Y Fu, Department of Ophthalmology and Visual Sciences, University of Utah, Salt Lake City, UT, USA

Glossary

Dark current – Also called circulating current. Current generated by constant influx of Na^+/Ca^{2+} into the rod outer segment through cGMP-gated channels, which is balanced by an outward current flowing across the inner segment membrane that mainly carried by potassium channels.
Dark light – Signals produced by thermal activation of rhodopsin in the dark, which adapt the visual system like real background light.
Phototransduction – The conversion of a light signal to an electrical signal in a photoreceptor cell.
Quantum efficiency – The ratio between the number of photoactivated molecules and the number of molecules that absorbed a photon.
Single-photon response – Electrical signal triggered by a single photon in a rod cell.
Suction-electrode recording – The recording of light-sensitive current of a single rod (or cone) by drawing its outer segment (or inner segment) into a suction electrode.

Introduction

Image-forming vision in vertebrates is mediated by two types of photoreceptors: the rods and the cones. Rods are specialized for dim-light (scotopic) vision while cones mediate vision in bright light (photopic). Great progress has been made in understanding rod phototransduction since the introduction of the suction-electrode recording technique in the late 1970s. The light-sensitive current of individual amphibian and mammalian (including primate) photoreceptors can be recorded with this method. Bovine retina, on the other hand, has been a favorite preparation for studying phototransduction by biochemists because of the abundance of tissue available. The mouse, however, has become an increasingly popular animal model for study in the past decade through the advent of gene-targeting techniques. When combined with electrophysiology, mouse genetics provides unmatched power in elucidating the *in vivo* functions of key phototransduction proteins, most of which have been knocked out, overexpressed, or mutated in rods, yielding a rich body of information on the mechanisms underlying the amplification, recovery, and adaptation of rod photoresponses. The details of the activation phase of rod phototransduction are now established. A quantitative description, the Lamb–Pugh model, is achieved that reproduces the activation kinetics of the rod response under physiological conditions. In this article, the focus is on the activation phase of rod phototransduction with particular emphasis on the molecular mechanisms underlying its high signal amplification feature.

Vertebrate Rods Are Highly Efficient Photon Detectors

Psychophysical experiments performed by Hecht, Schlaer, and Pirenne in 1942 suggested that human retinal rods can detect single photons. Thirty-seven years later, suction-electrode recordings from isolated toad rods by Baylor, Lamb, and Yau confirmed this remarkable ability of vertebrate rods (Figure 1). The amazing ability of vertebrate rods to detect single photons can be attributed to at least three factors: high quantum efficiency of photoactivation, low intrinsic noise, and a powerful signal amplification cascade. Two other factors greatly increase the photon capture ability of vertebrate rods, numerical dominance of rods over cones, and a highly specialized outer segment structure. The dense stack of disks of the rod outer segment ensures that virtually every photon traveling axially will be captured. In a sense, vertebrate rods can be viewed as sophisticated three-dimensional photon capture devices.

Phototransduction in Rods: A G-Protein-Signaling Pathway

Rod phototransduction is one of the best-characterized G-protein-signaling pathways. The receptor is rhodopsin (R), the G protein is transducin (G), and the effector is cyclic guanosine monophosphate (cGMP) phosphodiesterase (PDE or PDE6). Upon photon absorption, the rhodopsin molecule becomes enzymatically active (R^*) and catalyzes the activation of the G-protein transducin to G^*. Transducin, in turn, activates the effector PDE to PDE^*. PDE^* hydrolyzes the diffusible messenger cGMP. The resulting decrease in the cytoplasmic-free cGMP concentration leads to the closure of the cGMP-gated channels on the plasma membrane. Channel closure leads to localized reduction on the influx of cations into the outer segment, which results in membrane hyperpolarization, that is, the intracellular voltage becoming more negative (Figure 2).

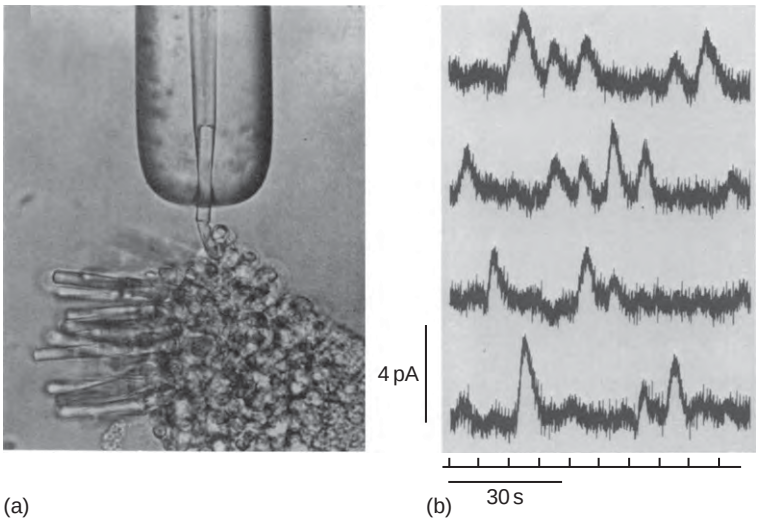

Figure 1 Suction-electrode recording on the membrane current of a single toad rod. (a) The outer segment of a rod projecting from a piece of retina was sucked in position in a suction electrode. Proximal end of cell remains attached to retina. Boundary between inner and outer segments is visible. (b) Response of rod outer segment to a series of 40 consecutive dim flashes, 20 ms flash delivering 0.029 photons μm^{-2} at 500 nm, flash timing monitored below. The rod showed no response to some flashes, or a small response of ~1 pA to others, and occasionally a larger response. This suggests that the flash response is quantized, as might be expected when on average very few photons are absorbed. With further analysis, the authors demonstrated that each quantal electrical event resulted from a single photo-isomerization with mean amplitude of ~1 pA – the single-photon response. Modified from Baylor et al. (1979) *Journal of Physiology*, 288: 589–611 (a) and 288: 613–634 (b), with permission from Blackwell Publishing.

This hyperpolarization decreases or terminates the dark glutamate release at the synaptic terminal. The signal is further processed by other neurons in the retina before being transmitted to higher centers in the brain.

Following light activation, a timely recovery of the photoreceptor is essential so that it can respond to subsequently absorbed photons, and signal rapid changes in illumination. This recovery from light requires the efficient inactivation of each of the activated components: R*, G*, and PDE*, as well as the efficient regeneration of rhodopsin (R) and the rapid restoration of the cGMP concentration. The termination rates of the activation steps set the time course of the photoresponse.

Although rod phototransduction is the best-characterized sensory transduction pathway, rods differ from other sensory cells in that light leads to hyperpolarization rather than depolarization. Rods respond to light with graded hyperpolarization whose amplitude increases monotonically as a function of flash intensity until saturation. One hallmark of rod phototransduction is the reproducibility of its single-photon response in both amplitude and kinetics. This is quite remarkable considering the fact that events generated by single molecules are stochastic in nature. The study on the underlying mechanisms has long been a hot topic in the vision field. Recent research pointed to two possible mechanisms: (1) Rhodopsin inactivation is averaged over multiple shutoff steps so that the integrated R* activity varies less than otherwise controlled by a single step. (2) Averaging over the deactivation of multiple G-protein molecules.

High Quantum Efficiency of Photoactivation

The quantum efficiency of photoactivation measures the probability that the adsorption of a photon initiates photoactivation. This probability is defined as the ratio between the number of photoactivated molecules and the number of molecules that absorbed a photon. Quantum efficiency of visual pigments is wavelength independent at ~0.7 in the spectrum of visible light. This suggests that every absorbed photon in the visible range can activate rhodopsin equally well. The quantum efficiency of 0.7 is very similar across all visual pigments. This high efficiency seems to be a common feature of most vertebrate visual pigments.

The Great Thermal Stability of Rhodopsin

Unlike chemosensory systems, phototransduction is not triggered by the binding of a chemical ligand to the receptor, rhodopsin. Instead, the chemical, 11-*cis*-retinal in birds and land-based animals (or 11-*cis*-3,4-dehydroretinal in aquatic animals), is prebound to rhodopsin. Photon absorption triggers the *cis*- to *trans*-isomerization of the retinoid. This isomerization rapidly converts the ligand from a powerful antagonist to a powerful agonist, leading to the formation of a series of spectrally distinct intermediates of rhodopsin in the order of bathorhodopsin, lumirhodopsin, metarhodopsin I (Meta I), and metarhodopsin II (Meta II) within a few milliseconds. Meta II is

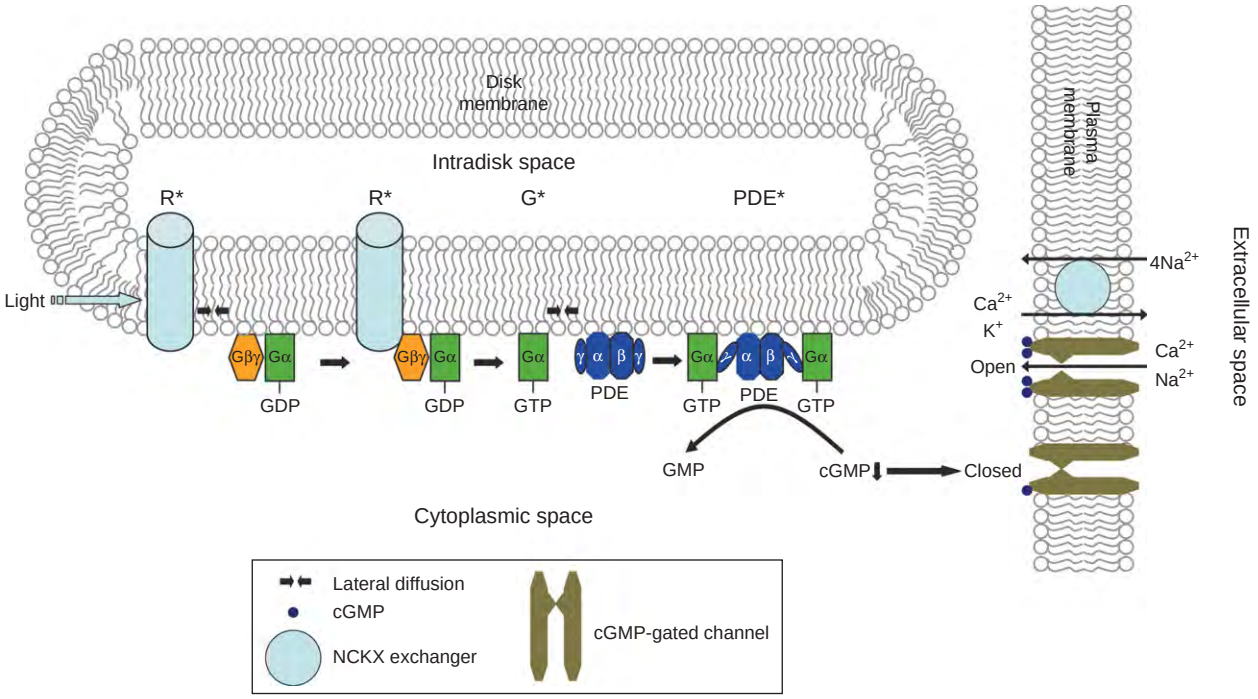

Figure 2 Schematic representation on the activation of vertebrate rod phototransduction. Following photon absorption, the activated rhodopsin (R*) activates the heterotrimeric G protein, catalyzing the exchange of GDP for GTP, producing the active Gα*-GTP. Two Gα*-GTPs bind to the two inhibitory γ-subunits of PDE, thereby releasing the inhibition on the catalytic α- and β-subunits, forming PDE*, which in turn catalyzes the hydrolysis of cGMP. The consequent decrease in the cytoplasmic-free cGMP concentration leads to the closure of the cGMP-gated channels on the plasma membrane and blockage of the influx of cations into the outer segment, which results in the reduction of the circulating dark current.

the active form of rhodopsin (R*), which in turn activates the downstream G protein, transducin. Because free opsin can weakly activate the transduction cascade, the antagonist role of 11-*cis*-retinal in the dark is important to keep the noise low in rods.

Even with 11-*cis*-retinal attached, rhodopsin occasionally undergoes spontaneous (thermal) activation in the dark, producing responses identical to those triggered by photons. This noise is often expressed as dark light because the noise adapts the visual system like real background light. This activity sets the limit on scotopic sensitivity, the visual sensitivity in darkness or dim light. To achieve the single-photon-detection sensitivity, rods not only need to have a high amplification system, but also need to have extremely low noise, or to be very quiet in the dark. This quietness can be partly attributed to the great thermal stability of rhodopsin. In a toad rod, the rate of thermal activation of rhodopsin was measured to be ~0.03 event s^{-1} rod^{-1} at 22 °C, corresponding to an average wait of 2000 years for the spontaneous activation of a given rhodopsin molecule to occur, based on a total of 2×10^9 rhodopsin molecules per cell. This great stability makes it possible for rods to pack many rhodopsin molecules to the rod disks to increase its photon-capture ability while keeping the dark noise low.

It should be mentioned that the question of dark noise in vision has had a long intellectual history from the point of view of psychophysics and system neuroscience. As early as 1940s and 1950s, Hecht and Barlow have estimated the amount of dark light in human rods based on psychophysical experiments. More than 30 years later, Baylor and colleagues used suction-electrode recording technique on primate rods to demonstrate that the very low quantal noise from rhodopsin, corresponding to ~0.01 event s^{-1} rod^{-1} in darkness, indeed matches the human psychophysical scotopic threshold. The quantitative agreement between the quantal noise measured from single rods and that measured in human psychophysics was considered a breakthrough in the vision field and a wonderful convergence between cell physiology and human psychophysics/system neuroscience – the goal of modern neuroscience after all.

The Activation of Transducin Constitutes the First Amplification Step

The second component of the rod phototransduction is the 81-kDa heterotrimeric G-protein, transducin (G_t, or $G\alpha_{t1}\beta_1\gamma_1$), which forms a subfamily of heterotrimeric G proteins. The molecular weight for α-, β-, and γ-subunits of rod transducin is approximately 39, 36, and 6 kDa, respectively. Transducin is present at ~10% the amount of rhodopsin in the disk membrane. Although transducin

subunits are soluble, the holo-transducin is firmly anchored to the disk membranes by a farnesyl lipid group that is post-translationally attached to the carboxy-terminal of the γ-subunit and an acyl group on the amino-terminal of the α-subunit. Therefore, photo-activated rhodopsin (R*) can only interact and activate transducin through lateral diffusion at the membrane surface.

Like many other G proteins, transducin exists in one of the two states: the GDP-bound inactive state and the GTP-bound active state. Binding of R* catalyzes the exchange of GTP for GDP on the α-subunit. The active Gα-GTP (G*) dissociates from R* as well as its native partner, Gβγ, and interacts with PDE to carry the signal forward. In the meantime, R* is able to activate additional molecules of transducin. Transducin activation by R* represents the first amplification step in the phototransduction cascade. The estimated rate of transducin activation by a single R* varied from 10 to over 3000 s^{-1} at room temperature. A rate of ~120 s^{-1} was later reported to be more consistent with biochemical, light-scattering, and electrophysiological measurements. The rate is roughly doubled in mammalian rods due to the higher body temperature. Until recently, it was believed that over a hundred transducins are activated during the lifetime of a single R* in mammalian rods. This number is now revised to be ~20 in mouse rods, based on the shorter life time of R* (80 ms) and activation rate of transducin by R* (240 s^{-1}).

The importance of transducin for conveying the signal from R* to PDE was manifested from animal models deficient in Gα and human patients carrying Gα mutations. It was found that rods of $G\alpha_{t1}$-null mice (*Gnat1*$^{-/-}$) lost all light sensitivity. In human, a mis-sense mutation in *Gnat1* (encoding the rod $G\alpha_{t1}$) is implicated in autosomal-dominant congenital stationary night blindness of Nougaret, caused by constitutive activation of rod phototransduction. The *gnat1*$^{-/-}$ mouse line has proven to be a valuable tool for blocking rod phototransduction to study cone phototransduction and circadian photoreception. It was also used successfully to delineate two apoptotic pathways in light-induced retinal degeneration. Bright light triggers apoptosis of photoreceptors through a mechanism requiring the activation of rhodopsin but not transducin signaling. In contrast, low-intensity light induces apoptosis that is predominantly dependent on transducin signaling.

The High Catalytic Power of PDE Accounts For the Second Amplification Step

PDE is the third component of rod phototransduction. It is a hetero-tetrameric protein consisting of two catalytic subunits, α- and β-, and two identical γ-subunits. PDE is anchored to the disk membrane by a hydrophobic isoprenyl group (compounds that are derived from isoprene, 2-methylbuta-1,3-diene, linearly linked together) post-translationally attached to the C-termini of the two catalytic subunits. As for transducin activation, PDE activation by G is through lateral diffusion on the rod disk membrane. Each catalytic subunit has two high-affinity noncatalytic binding sites and one catalytic binding site for cGMP. The noncatalytic sites were suggested to modulate the binding affinity between PDEγ and PDEαβ. The amount of PDE is ~1–2% of rhodopsin. Thus, the first three components of phototransduction are present in the ratio of 100R:10G:1PDE. In the dark, the two γ-subunits act as inhibitory subunits by binding to the two catalytic subunits and significantly reducing the hydrolysis of cGMP. In the light, Gα-GTP encounters PDEγ and sterically displaces the latter, therefore relieving its inhibitory effect on the catalytic subunits and permitting the hydrolysis of cGMP to proceed (**Figure 2**). Since each G* can only activate one PDEγ, two G*'s are required to fully activate a holo PDE. This is likely the scenario *in vivo* during light activation due to the excess amount of G over PDE and the presence of many molecules of G* activated by rhodopsin.

In contrast to the amplification achieved during transducin activation by R*, the activation of PDE by G* constitutes no gain, that is, with an efficiency approaching 1 (one G*, one activated PDE catalytic subunit) or 0.5 in terms of PDE holoenzyme. It is the catalytic power of PDE* that provides the second amplification step. It was reported that PDE* hydrolyzes cGMP at a rate close to the limit set by aqueous diffusion, with a K_m of ~10 μM and a K_{cat} of 2200 s^{-1}, making it one of the most efficient enzymes *in vivo*.

In addition to the noise produced by spontaneous activation of rhodopsin, spontaneous activation of individual catalytic PDE subunits produces the continuous noise, which accounts ~30–80% (depending on the species) of the total dark noise variance in rods. The basal spontaneous PDE activity balances constitutive guanylate cyclase activity in the dark, therefore maintaining a steady-free cGMP level. It also has the function of increasing the rate of cGMP turnover and consequently speeding up the dim flash response.

One might have expected that the deletion of PDEγ from mouse rods would unleash the full catalytic power of PDEαβ. However, it was found, in the absence of PDEγ that the PDEαβ dimer actually lacked catalytic activity, and the photoreceptors of the mutant mouse rapidly degenerated. Thus, the inhibitory PDEγ subunit appears to be necessary for the integrity of the catalytic PDEαβ subunits. The degeneration might be caused by an abnormally high cGMP concentration due to the lack of hydrolysis. A related example is the *rd* mouse, which is the oldest and one of the best-known models for retinal degeneration. The rod cells in the *rd* mouse begin to degenerate at about postnatal day 8, followed by cones;

by 4 weeks, virtually no rod photoreceptors are left. Degeneration in this mouse model is preceded by the accumulation of cGMP in the retina, correlated with deficient activity of the rod PDE due to a mutation in the PDEβ subunit. It is worth noting that the *rd* mouse was instrumental in suggesting that inner retinal neurons could mediate non-image-forming vision.

cGMP Is the Second Messenger Mediating Rod Phototransduction

By 1970, scientists generally believed that a second messenger was required to mediate the rod photoresponse based on several lines of evidence. First, light absorption occurs on the rod disk membrane, whereas the light-sensitive conductance is in the plasma membrane. Since rod disks are separate from the plasma membrane, a second messenger is required to connect the two. Second, the dim-flash response of rods lasts a few seconds, which is too long to be accounted by the open time of known membrane conductance. However, it took more than a decade before the identity of the second messenger was finally determined to be cGMP. The fierce battle was fought on the validity between two competing candidates, Ca^{2+} and cGMP. According to the Ca^{2+} hypothesis, which was first proposed by Hagins, the concentration of intracellular free Ca^{2+} is low in the dark and rises in the light to block light-sensitive current. The main supporting evidence is that reducing the concentration of external Ca^{2+} dramatically increases the dark current, suggesting that internal Ca^{2+} inhibits the dark current. On the other hand, the cGMP hypothesis proposed that the concentration of cGMP was high in the dark to maintain a cGMP-dependent conductance. Light led to the hydrolysis of cGMP and the subsequent closing of the conductance. The supporting evidence is that intracellular injection of cGMP increases the amplititude and latency of the photoresponse. Adding to the complexity is the finding that the free cGMP concentration varies inversely with the free Ca^{2+} concentration in rods, making it difficult to separate the effect of the two.

This debate was finally settled with the discovery of cGMP-gated channels in rods by Fesenko and colleagues in 1985. By using the patch-clamp technique, they showed that cGMP increased a cation conductance of inside-out patches of outer-segment plasma membrane without the need of ATP. The direct channel gating by cGMP is surprising because cyclic nucleotides were generally believed to act through cyclic-nucleotide-dependent kinases and protein phosphorylation on target proteins at that time. This dogma partially explained scientists' reluctance to embrace the cGMP hypothesis because protein phosphorylation was too slow. Another monumental work by Yau and Nakatani was published at the same year that helped the anointment of cGMP as the right candidate. An identical cGMP-gated cation conductance was found on a truncated rod outer segment with an intact plasma membrane. Most importantly, this conductance could be suppressed by light, suggesting that the long-sought light-sensitive conductance is the cGMP-gated conductance. The publications by Fesenko and Yau marked the end of the Ca^{2+} hypothesis.

The cGMP-Gated Channel Provides the Final Step of Signal Amplification

The cGMP-gated channel belongs to the family of cyclic-nucleotide-gated (CNG) channels, which are nonselective cation channels. The channel is located on the plasma membrane with a density of 400–1000 μm^{-2} and is the last component in the activation phase of phototransduction. Rod CNG channels consist of CNGA1 (or α1) and CNGB1 (or β1) subunits. CNGA1 subunit forms functional homomeric channels by themselves when heterologously expressed. Although CNGB1 does not form functional channels by themselves, it confers several properties typical of native channels when coexpressed with the CNGA1 subunit: flickery opening behavior, increased sensitivity to L-*cis*-diltiazem, (a CNG channel–specific inhibitor) and weaker block by extracellular calcium. For a long time, the rod channel was believed to be a hetero-tetramer consisting of two CNGA1 and two CNGB1 subunits. In 2002, a number of laboratories made the surprising discovery that the rod channel actually has a 3CNGA1:1CNGB1 subunit composition. In humans, mutations in CNGA1 cause retinitis pigmentosa. CNGB1 subunits were found to be crucial for the targeting of the native CNG channel in rods. Thus, only trace amounts of the CNGA1 subunit were found on the rod outer segments in CNGB1-null mice and the majority of rod photoreceptors failed to respond to light.

The gating of the rod channel by cGMP is cooperative with a Hill coefficient of ~3; therefore, the light-triggered suppression of the dark current is 3 times larger than the decrease in the intracellular cGMP concentration. This is the last step of signal amplification in rod phototransduction. The combined amplification provided by rhodopsin, PDE, and CNG channels is very high ($\sim 10^5$–10^6), ensuring the high sensitivity of rods, including the ability of rods to detect single photons.

In the dark, the concentration of free cGMP in the rod outer segment was estimated to be several μM, which is lower than the $K_{1/2}$ (~10–40 μM depending on Ca^{2+} concentration), the concentration of cGMP necessary to half-maximally activate the channel. As a result, only ~1% of the CNG channels are open! In other words, 99% of the channels are already closed in the dark and light can only suppress the remaining 1% channels. This explains

why current induced by cGMP injection is more than 10 times larger than the dark current.

The inward current through the cGMP channel is composed of ~85% Na^+ because Na^+ is the predominant external cation and the channel is nonselective to monovalent cations. The remaining current is mainly carried by Ca^{2+} with a minor contribution from Mg^{2+}. Extracellular Ca^{2+} actually partially blocks the channel to reduce its conductance under physiological conditions. The inward current is balanced by an outward current flowing across the inner-segment membrane, which is mainly carried by potassium channels. This circulating current is also called dark current in both rods and cones. Unlike other ligand-gated channels, the CNG channel does not desensitize to cGMP, which is important for rods to maintain a steady dark current ranging between 20 and 70 pA in vertebrate rods. The rod photoresponse is essentially a transient suppression of the circulating current. It was estimated that the dark current was carried by ~10 000 channels. The participation of large numbers of micro-channels averages out the channels noise, that is, reduces an otherwise substantial stochastic channel noise if the dark current were carried out by a few macro-channels. This feature improves the sensitivity of rods.

Two extrusion mechanisms are critical in maintaining ionic balance in rods. An energy-dependent Na–K ATPase at the inner segment pumped Na^+ out and K^+ into the cells. A Na/Ca,K exchanger (NCKX) in the outer-segment plasma membrane extrudes one Ca^{2+} and one K^+ outward in exchange for four Na^+ inward producing the net entry of one positive charge. The exchanger and the CNG channel were found to form a stable complex on the plasma membrane, likely as a way to control the stoichiometry between the two, which is critical for regulating Ca^{2+} concentration in the rod outer segment. During the light response, the influx of Ca^{2+} is reduced due to the closure of some CNG channels while the efflux of Ca^{2+} through the exchanger is maintained. The resulting Ca^{2+} decline triggers negative feedback to produce light adaptation.

Phototransduction: Rhodopsin

L P Pulagam and K Palczewski, Case Western Reserve University, Cleveland, OH, USA

Glossary

GPCRs – G protein-coupled receptors are membrane receptor proteins with a seven-transmembrane helical topology that are capable of activating G proteins.
G proteins – Heterotrimeric intracellular proteins so named because they bind to the guanine nucleotides, guanosine diphosphate in an inactive state and guanosine triphosphate in an active state.
GRK1 – G protein-coupled receptor kinase 1 (rhodopsin kinase) is a highly specific protein kinase that catalyzes phosphorylation of photoactivated rhodopsin thereby triggering its deactivation.
LCA – Leber's congenital amaurosis is an inherited degenerative disease of the retina that results in a severe loss of vision.
Photoisomerization – The structural change between chromophore geometric isomers (*cis* to *trans*) caused by photoexcitation. For rhodopsin, photoisomerization of its chromophore leads to activation of this receptor.
ROSs – Rod outer segments are the cylindrical outer portions of rod cells, each containing hundreds of membranous disks enveloped by the cellular (plasma) membrane.
RP – Retinitis pigmentosa is the name of a heterogeneous group of progressively blinding degenerations of the human retina caused by mutations in genes encoding photoreceptor proteins with an autosomal dominant (adRP), autosomal recessive (arRP), or X-linked pattern of inheritance.
Schiff base – A functional chemical group containing a carbon–nitrogen double bond. The retinylidene moiety is a chemical link between retinal and an amino group, for example, Lys^{296} of opsin.

Vision is an important biological sensing mechanism that involves conversion of light signals received by the eye into electrical nerve impulses transmitted to the brain by a process called phototransduction, consisting of a cascade of biological processes that occur in photoreceptor cells (rod and cone cells) of the retina. In the absence of light, photoreceptors are depolarized to a membrane resting potential of –40 mV. In the presence of light, the plasma membrane of the photoreceptor cells becomes hyperpolarized to –70 mV, resulting in a reduced amount of neurotransmitter released to downstream neurons. This article focuses on rhodopsin structure that relates to its function as a G protein-coupled receptor (GPCR).

Rod Cells and Rhodopsin

The vertebrate rod cell, a highly differentiated postmitotic neuron, is characteristically long, cylindrical, and primarily consists of an outer segment connected to an inner segment via a cilium (**Figures 1(a)** and **1(b)**). The rod outer segment (ROS) contains a stack of disk membranes enclosed by the plasma (cell) membrane, whereas the rod inner segment (RIS) contains the metabolic machinery for this cell. Rhodopsin is processed in the endoplasmic reticulum and transferred to the Golgi membranes of the RIS for additional processing of its carbohydrate moieties. Then rhodopsin-containing Golgi vesicles fuse with the apical plasma membrane of the inner segment and the rhodopsin molecules are transported through the rod cell cilium to the ROS where they form disk membranes. Mutations in the C-terminal region of rhodopsin inhibit transport of rhodopsin to ROS, indicating that this region is essential for recognition by the transport machinery.

A mammalian ROS consists of a stack of 1000–2000 disks enclosed by the plasma membrane. A cryo-electron tomography image of murine ROS (**Figure 1(c)**) also reveals that the thickness of a single disk membrane is 8 nm. Rhodopsin comprises >90% of all proteins in disk membranes and occupies 50% of the disk membrane volume. It is also present at a lower density in the plasma membrane of rod cells, and its expression is essential for ROS formation, which is absent in knock-out $Rho^{-/-}$ mice. In wild-type mice, there are approximately 8×10^4 rhodopsin molecules per disk and 3.96×10^{14} per eye. The power spectra of negatively stained disk membranes from bovine ROS (**Figure 1(d)**) reveals a diffuse diffraction ring at $\sim(45\,\text{Å})^{-1}$, indicating paracrystallinity of rhodopsin. Organization of the seven helices of rhodopsin was first ascertained by using a low-resolution imaging method called electron crystallography. Rhodopsin is unequally distributed in disk membranes. Electron tomographs of the ROS reveal both high- and low-density regions (**Figure 1(e)**). An atomic force microscopic image of native disk membranes showed that the average packing density of rhodopsin monomers is $48\,300 \pm 8000\,\mu m^{-2}$. Recent atomic force microscopic studies disclosing the arrangement of rhodopsin in native mouse disk membranes revealed that rhodopsin and opsin form structural dimers arranged in

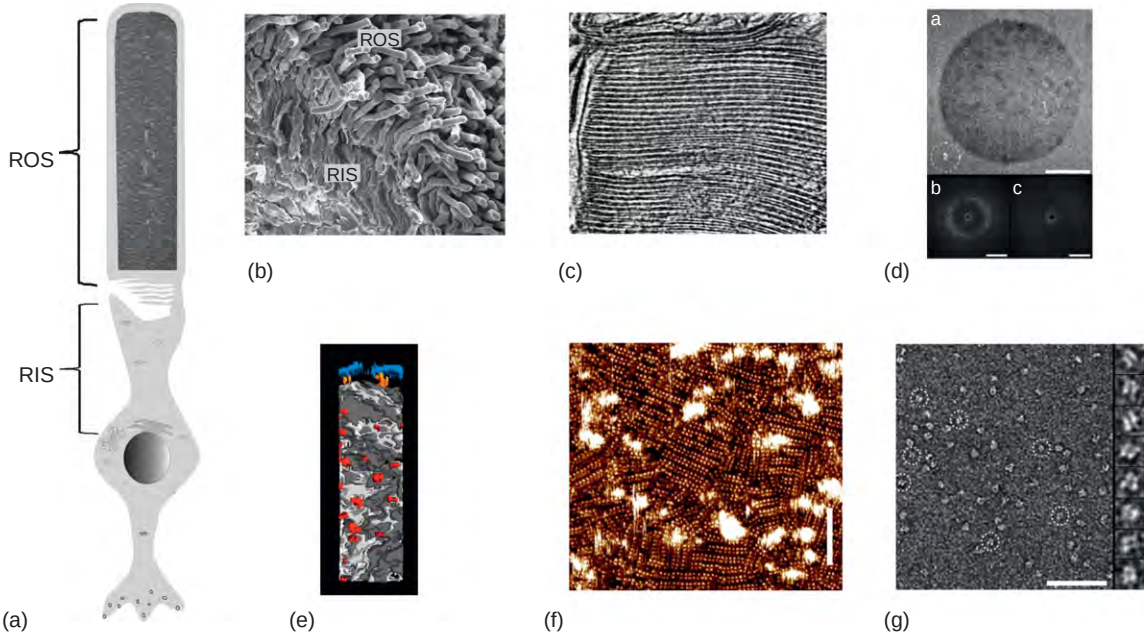

Figure 1 Vertebrate retina and rhodopsin. (A) Diagram of a rod cell. Vertebrate rod cells are postmitotic neurons with highly differentiated rod outer segments (ROSs) connected to rod inner segments (RISs) that generate proteins and energy to sustain phototransduction. ROSs consist of hundreds of stacked disk membranes enveloped by a plasma membrane. The main component of disk membranes is rhodopsin. Biochemical processes involving rhodopsin in the ROS allow rapid transduction of a light signal to graded hyperpolarization of the plasma membrane resulting from a decrease of light-sensitive conductance in ROS cGMP-gated cation channels. (B) Scanning electron micrograph of mouse retina. Rod cells comprise ~70% of all 6.4 million retinal cells, whereas cone cells represent <2%. (C) An *x–y* slice electron tomogram of vitrified mouse ROS. Disk membranes consist of a phospholipid bilayer studded with rhodopsin. (D) Transmission electron microscopy of negatively stained native disk membranes from mouse rod photoreceptors adsorbed on carbon film. (a) Morphology of a native bovine disk membrane. (b) Average of five power spectra calculated from broken circle outlined region shown inside the disk membrane in (a). A diffuse power diffraction signal is evident, indicating paracrystallinity of rhodopsin. (c) Average of five power spectra calculated from broken circle outlined region shown outside the disk membrane in (a). No power diffraction is evident. Scale bars: (a) = 2000 Å; (b and c) = 40 $Å^{-1}$. (E) The density of disk membranes is not uniform, indicating that rhodopsin is unevenly distributed in the mouse membrane. The distribution of high- (dark gray) and low- (light gray) density regions is shown in a top view of a single disk. Areas of low density (gray value < 0.33) represent 29% and areas of high density (gray value > 0.33) represent 71% of the disk volume. Gray values were obtained by computing the gray value for each voxel (three-dimensional pixel) in a disk membrane volume of 10 disks. Spacer proteins connecting two disks are colored red and the plasma membrane is colored blue. (F) Topograph obtained by using atomic-force microscopy shows the paracrystalline arrangement of rhodopsin dimers in the native disk membrane of mouse rod photoreceptors. Vertical brightness ranges: 1.6 nm. Scale bar = 50 nm. (G) Transmission electron microscopy of negatively stained disk membranes solubilized by n-dodecyl-β-D-maltoside. Rhodopsin dimers are clearly discerned on the carbon film. Magnified selected particles marked by broken circles are shown on the right. Scale bar = 500 Å. Frame size of the magnified particles in the gallery is 104 Å. (C and E) From Nickell et al. (2007). Originally published in *The Journal of Cell Biology*. (doi:10.1083/jcb.200612010). paracrystalline arrays of rows (Figure 1(f)). Previous studies also support the importance of dimerization/oligomerization as necessary for the function of many, if not all GPCRs. Negative staining of detergent (*n*-dodecyl-β-D-maltoside)-solubilized disk membranes shows bi-lobed, roughly conical structures with lengths of ~65 Å, and these lobes are separated from each other by ~32 Å (Figure 1(g)).

Structure of Rhodopsin

Rhodopsin is a transmembrane protein consisting of an apoprotein, the 348 amino acid residue-long opsin (Figure 2), linked to a chromophore, 11-*cis*-retinal. The chromophore is bound covalently via a protonated Schiff base to the Lys^{296}-containing side chain of the opsin. Bovine rhodopsin also is post-translationally modified. The N-terminal Met is acetylated, and Cys^{322} and Cys^{323} of the C-terminus are palmitoylated, which is very common in GPCRs. In addition, a disulfide bond exists between $Cys^{110\ (H\text{-}III)}$ and $Cys^{187\ (E\text{-}II)}$. Rhodopsin is glycosylated at Asn^{2} and Asn^{15} by the hexasaccharide sequence $(Man)_3Glc(Nac)_3$. The molecular mass of bovine opsin with its post-translational changes (palmitoylation, acetylation of the N terminus and glycosylation) is 42 002.

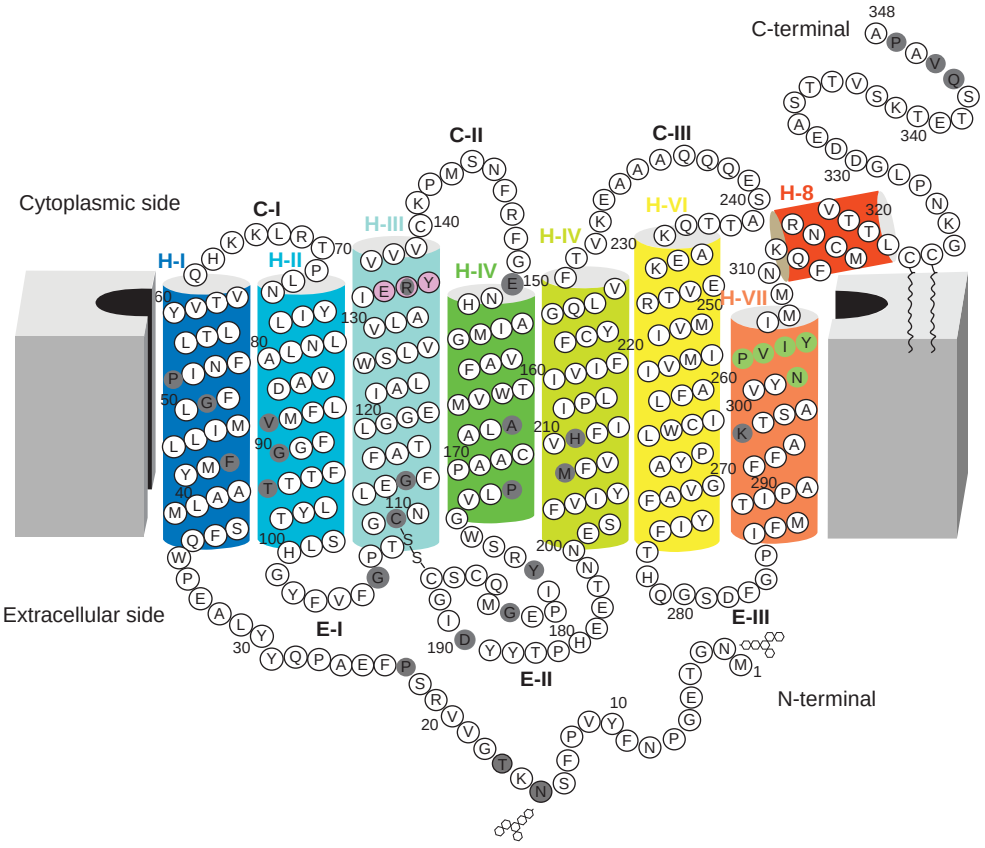

Figure 2 Two-dimensional representation of rhodopsin. Rhodopsin has seven transmembrane α-helices, C-I, C-II, and C-III depict its cytoplasmic loops, and E-I, E-II, and E-III represent the extracellular loops in this diagram. Stability of the helical segment is increased by the disulfide Cys^{110}–Cys^{187} bridge (shown as-S-S-), a highly conserved feature among many GPCRs. The chromophore, 11-*cis*-retinal, not shown here, is attached to Lys^{296} via a protonated Schiff base. Asn^{2} and Asn^{15} are sites of glycosylation by conserved glycans, Met^{1} is acetylated and Cys^{322} and Cys^{323} are palmitoylated. The predominant phosphorylation sites are Ser^{334}, Ser^{338}, and Ser^{343}. The whole C-terminal region is highly mobile but, as shown by using a model peptide, it may become more rigid when bound to arrestin. The highly conserved domains among GPCRs, (D/E)R(Y/W) (colored in pink) in helix 3 and NPXXY in helix VII (colored in green), are important for transforming the receptor from an inactive to a G protein-coupled conformation. Nonsense/missense mutations in rhodopsin leading to retinitis pigmentosa are colored in dark gray.

Rhodopsin was crystallized from detergent solutions. The three-dimensional structure of bovine rhodopsin at 2.8 Å, the first high-resolution structure reported for a GPCR, reveals the internal organization of this receptor molecule (**Figure 3**). Rhodopsin folds into seven transmembrane helices (H-I–H-VII) that vary in length from 20 to 33 amino acid residues, and one cytoplasmic helix (H-8). The transmembrane residues are irregular and tilted at various angles due to their Gly and Pro residues. Further advances in rhodopsin crystallization were recently reviewed.

The N-terminal region of rhodopsin is located intradiscally (extracellular) and the C-terminal region is cytoplasmic (intracellular), each region possessing three interhelical loops. The extracellular region consists of four distorted β-strands, three interhelical loops and the doubly glycosylated N-terminal domain. The extracellular region from residues 173–198 acts as a plug for the chromophore-binding pocket (**Figures 4(a)** and **4(b)**). The cytoplasmic surface contains 14 positively charged residues, whereas the extracellular side contains only three positively charged residues, an arrangement that agrees with the positive inside rule for multispanning eukaryotic membrane proteins. The intracellular/cytoplasmic region of rhodopsin is essential for its vectorial transport from the site of synthesis to the ROS and it also plays important roles in G protein activation and photoactivated rhodopsin desensitization.

A highly conserved (D/E)R(Y/W) motif in the GPCR A family is formed by the tripeptide, Glu^{134}-Arg^{135}-Tyr^{136}, located in the cytoplasmic region of bovine rhodopsin (**Figure 4(a)**). The carboxylate group of Glu^{134} forms a salt bridge with Arg^{135}, a highly conserved residue among GPCRs, and Arg^{135} also interacts with Glu^{247} and Thr^{251} in H-VI. The ionization state of Glu^{134} is sensitive to its environment, such that protonation of this residue causes rhodopsin activation (from meta IIa to meta IIb). This motif plays an important role in conformational changes in the structure of GPCRs that lead to their activation.

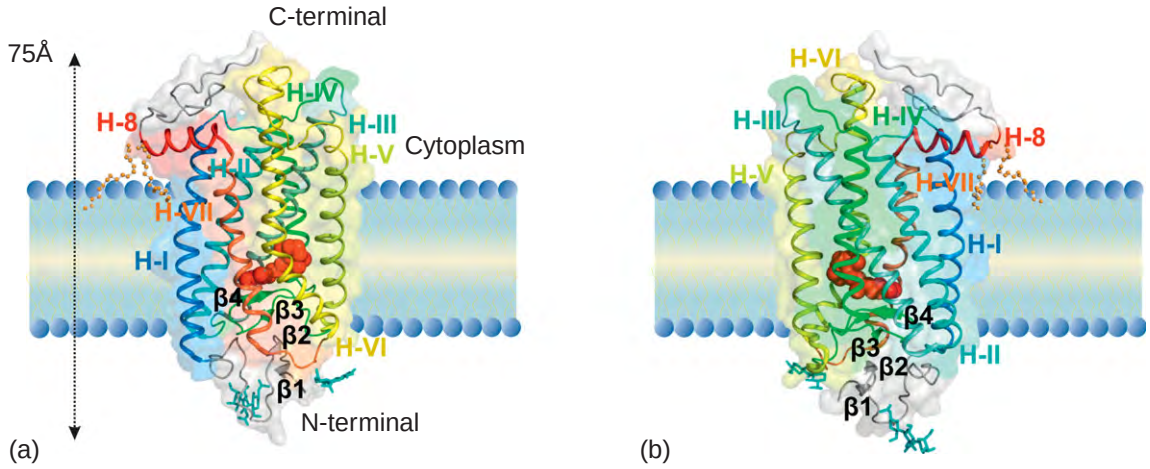

Figure 3 Structure of rhodopsin. (a) Rhodopsin has seven transmembrane helices (H-I to H-VII) and one peripheral helix (H-8). The transmembrane segments are α-helical, but these helices are highly distorted and tilted. Helices are displayed as ribbons and colored from blue (H-I) to red (H-8), as in the visible light spectrum. Helix labels are shown in the same color as their respective helices. N-terminal and C-terminal ends are colored gray. A palmitoyl group (orange-colored ball and stick representation) is attached to each of the two Cys residues at the end of helix H-8. Removal of this group has only a minor effect on phototransduction. β_1–β_4 are distorted β strands. The carbohydrate moieties (cyan-colored stick representation) are at Asn^2 and Asn^{15}. The Gly^3 to Pro^{12} region forms the first β-hairpin that runs parallel to the expected plane of the membrane. Arg^{177} to Asp^{190} leave helix H-4 to form a second twisted β-hairpin on the extracellular side. Rhodopsin is represented in a space-filled background and the plane of the lipid bilayer is shown. (b) Opposite side of rhodopsin shown in **Figure 2(a)**. (pdb code: 1U19.pdb)

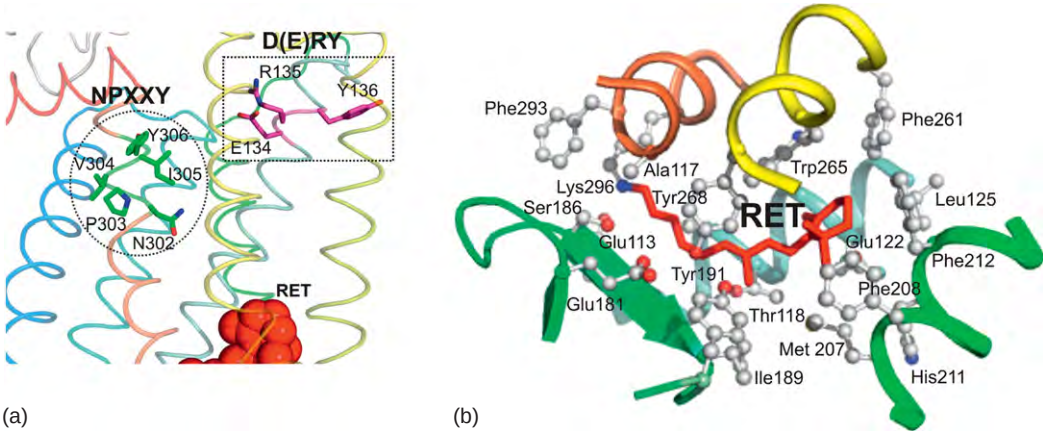

Figure 4 Functional regions of rhodopsin. (a) Conserved NPXXY and (D/E)R(Y/W) motifs in rhodopsin. Amino acid residues of these motifs are rendered as sticks, retinal (RET) is shown in the CPK color scheme as red, and helices are displayed as ribbons. (b) Retinal (RET)-binding site. Amino acid residues within about 5 Å are displayed to show the side chain environment surrounding the 11-*cis*-retinylidene group. Residues are represented as balls and sticks and retinal is shown in stick form (red). See text for explanation/discussion. Helices are colored as in **Figure 3**.

Another highly conserved NPXXY (Asn-Pro-Xaa-Xaa-Tyr) motif located at the end of helix VII and the beginning of H-8, is also close to the cytoplasmic region. Both the D(E)RY and NPXXY regions control the meta II (active) state of rhodopsin, and the NPXXY sequence is likely to be involved in G protein coupling (**Figure 4(a)**). The greatest distortion in H-VI is imposed by Pro^{267} (a highly conserved residue among GPCRs) and H-VII is elongated due the presence of Pro^{291} and Pro^{303} (parts of NPXXY) located in close proximity to Lys^{296}, the retinal-binding residue. Highly conserved Glu^{122} and His^{211} are located at the Zn^{2+}-binding site. The interaction between the β ionone ring and H-III occurs at Glu^{122}, one of the residues that determine the rate of meta II decay (**Figure 4(b)**).

Chromophore-Binding Site

Visual pigments of both rod and cone cells contain the chromophore, 11-*cis*-retinal, bound covalently to a Lys side chain (Lys^{296} in bovine rhodopsin) via a protonated Schiff base. The absorption maximum (λ_{max}) of free

solubilized 11-*cis*-retinal is about 380 nm. When this chromophore binds to opsins, its λ_{max} shifts toward longer wave lengths (a red shift) ranging from 435 nm (frog rods) to 560 nm (human cones). The protonated Schiff base linkage is responsible for about 70 nm of this shift. A further red shift results from the retinal-binding-pocket environment, especially its counter ion, which is Glu113 in vertebrate rhodopsins. In bovine rhodopsin, the λ_{max} of mutant E113Q (Glu to Gln) is dramatically shifted from 498 nm to ~380 nm. The absorption maximum also varies according to the interaction sites of the opsin molecule with the chromophore, especially dipolar interactions near the β ionone ring. Therefore, the λ_{max} absorption of visual pigments varies from species to species that differ with respect to their opsin protein sequences.

The chromophore in rhodopsin is located in the core of the seven transmembrane helices, closer to the extracellular side of the disk membrane. 11-*cis*-Retinal helps maintain rhodopsin in an inactive state (**Figure 4(b)**). The retinal-binding pocket is formed by helices H-III, H-V, H-VI, and H-VII and the antiparallel β sheet of the N-terminal plug, part of extracellular loop II (E-II in **Figure 2**). Although the retinal-binding site is very hydrophobic (**Figure 4(b)**), four charged residues, specifically $Glu^{113\ (H\text{-}III)}$, $Glu^{122\ (H\text{-}III)}$, $Glu^{181\ (\beta\ sheet)}$, and $Lys^{296\ (H\text{-}VII)}$, are located near the chromophore. $Lys^{296\ (H\text{-}VII)}$ donates an amino group to form a protonated Schiff base and $Glu^{113\ (H\text{-}III)}$, which is 3.6 Å away from the Schiff base, acts as a counter ion for this linkage. The positive charge on the protonated Schiff base is energetically unstable in the hydrophobic protein core but the $Glu^{113\ (H\text{-}III)}$ counter ion stabilizes the base by shifting its pK_a from neutral to alkaline. Highly conserved among all known vertebrate visual pigments, $Glu^{113\ (H\text{-}III)}$ plays three important roles: (1) It keeps rhodopsin in its resting state by participating in the salt bridge with the Schiff base. Disruption of this bridge allows the H-VI motion that occurs upon photoactivation. (2) It prevents spontaneous hydrolysis of the Schiff base by stabilizing the protonated Schiff base via increasing its K_a by as much as 10^7. (3) It causes a major bathochromic (longer wavelength) shift in the maximum wavelength absorption of visual pigments. Longer wavelength absorption is essential because the front of the eye in most animals does not allow ultraviolet (UV) light to reach the retina. Steric hindrance, resulting either from mutating $Gly^{121\ (H\text{-}III)}$ or substituting larger R groups at the C9 position, causes transducin (G_t) activation in the dark whereas lack of the C9 methyl group impedes photoactivation.

Opsin reacts within minutes with 11-*cis*-retinal to form rhodopsin. Similarly, 7-*cis* and 9-*cis* retinal also form visual pigments. In contrast, all-*trans*-retinal and 13-*cis*-retinal cannot regenerate opsin. The crystal structure of rhodopsin reveals that the chromophore-binding pocket is well defined, suggesting that the binding pocket has high specificity for the Schiff base and the β ionone ring. The exact location of these two components restricts the length of the chromophore-binding site. Therefore, 7-*cis*, 9-*cis*, and double and triple *cis* retinal analogs that have similar lengths and structures can regenerate the opsin, whereas chromophore analogs that are either shorter or longer than 11-*cis*-retinal cannot.

Rhodopsin Cycle – Retinal Isomerization

Inactive rhodopsin is activated upon light absorption, which induces a *cis–trans* isomerization that converts 11-*cis*-retinal to all-*trans*-retinal. The activation process can be divided into three phases (**Figure 5**).

1. Light-induced *cis–trans* isomerization of the retinylidene.
2. Thermal relaxation of the retinylidene–protein complex.
3. Hydrolysis of the Schiff base linkage, leading to formation of rhodopsin's active meta II state.

Light absorption induces isomerization of 11-*cis*-retinylidene to all-*trans*-retinylidene, resulting in a transient intermediate called photorhodopsin, formed by the fastest chemical reaction (200 fs) in the rhodopsin cycle. Photorhodopsin is converted first into a thermally stable and high-energy intermediate product called bathorhodopsin. About 60% of the incident photon energy is stored in bathorhodopsin and then used to drive further conformational changes. In this state, the chromophore is in an 11-*trans*-15-*anti* conformation, a distorted all-*trans* conformation that results from steric restriction caused by the polyene chain of the retinal and the protein side chains. The β ionone ring and Schiff base are located in a conformation similar to that of rhodopsin in the dark, but Thr^{181} and Glu^{113} are slightly moved. Then the blue-shifted intermediate (BSI) is produced during the thermal relaxation of bathorhodopsin, but BSI can be observed only by time-resolved measurements during subsequent formation of lumirhodopsin. The distorted all-*trans*-retinal in bathorhodopsin relaxes by dislocation of the β ionone ring in lumirhodopsin. Displacement of this ring reflects the movement of helix III aided by interactions between other helices, that result in a slightly disordered structure during the transition from the dark state to lumirhodopsin. In particular, Thr^{181} and Glu^{122} (which are moved slightly in bathorhodopsin) become significantly moved due to the β ionone ring displacement. Lumirhodopsin then relaxes further into meta I. Although the conformation of the chromophore in meta I closely resembles that in lumirhodopsin and the Schiff base proton is still hydrogen bonded, the overall structure is similar to rhodopsin. Meta I is further converted to meta II in two steps that can be separated by 20 ms in detergent-solubilized samples: (1) Conversion of meta I to meta IIa, accompanied by proton transfer from the Schiff base to the counterion Glu^{113}. (2) Subsequent uptake of a proton from the cytoplasm leading to meta IIb formation. The proton acceptor here is $Glu^{134\ (H\text{-}III)}$, thus meta IIa and meta IIb are in a pH-dependent equilibrium regulated by proton uptake

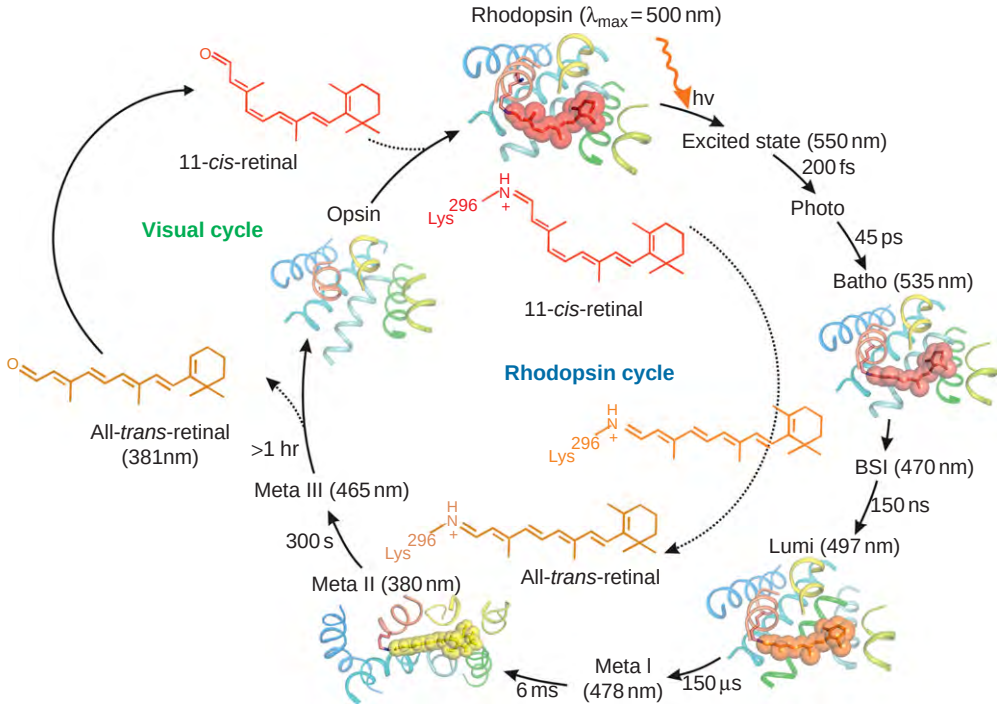

Figure 5 Schematic illustration of the rhodopsin cycle. Rhodopsin consists of an apoprotein called opsin and the bound chromophore, 11-*cis*-retinylidene, a geometric isomer of vitamin A in aldehyde form that imparts a red color to this protein. Upon light activation, rhodopsin transforms into opsin via many intermediate states. In the dark, rhodopsin contains the 11-*cis*-retinal chromophore attached to Lys^{296} (rendered as sticks) of helix H-VII in a protonated Schiff base linkage. Upon absorption of a photon, the chromophore is isomerized with ~65% probability from a *cis* C^{11}–C^{12} double bond to a *trans* conformation. In addition, with light activation, rhodopsin transforms into the photointermediate, bathorhodopsin (Batho), which thermally relaxes to BSI followed by lumirhodopsin (Lumi), which then changes to Meta I. During the transition of meta I to meta II, the all-*trans*-retinylidene Schiff base becomes deprotonated. Meta II, the signaling state capable of G protein activation, ultimately decays to free all-*trans*-retinal and opsin. The released photoisomerized chromophore, all-*trans*-retinal, is reduced to an alcohol by short chain alcohol dehydrogenases, such as prRDH, retSDR, and RDH12. The all-*trans*-retinal then diffuses into the retinal pigmented epithelium. There it undergoes enzymatic transformation back to 11-*cis*-retinal in a metabolic pathway known as the visual cycle. The replenished 11-*cis*-retinal then combines with opsin to form rhodopsin, thereby completing the rhodopsin cycle. The λ_{max} in nm as well as the duration (fs-s) of the various components are shown.

at Glu^{134} (part of E/DRY motif). However, only meta IIb can trigger G_t activation. Deprotonation of the Schiff base is characterized by a large UV shift of the absorption maximum from 478 nm in meta I to 380 nm in meta II. A low-resolution crystal structure of a bovine-deprotonated Schiff base meta II-like rhodopsin has been elucidated. Finally, meta II decays into opsin and all-*trans*-retinal. Free opsin exhibits the largest conformational changes as compared to dark-state rhodopsin (Figure 5).

Visual Cycle – Rhodopsin Regeneration

The visual cycle consists of a series of reactions by which all-*trans*-retinal released from opsin isomerizes back into 11-*cis*-retinal that again binds to the opsin (Figure 5). This cyclic process does not require light. The released all-*trans*-retinal is transformed first to all-*trans*-retinol by a retinal dehydrogenase (RDH) in the ROS. The all-*trans*-retinol is transferred to the retinal pigment epithelium (RPE) where it is esterified by lecithin:retinol acyltransferase (LRAT), and later isomerized to 11-*cis*-retinol by a retinol isomerase. 11-*cis*-RDH then converts 11-*cis*-retinol back to 11-*cis*-retinal, which leaves the RPE to regenerate the opsin in the ROS.

Vertebrate versus Invertebrate Rhodopsins

Enzymatic regeneration of rhodopsin does not occur in invertebrate visual systems where rhodopsin and metarhodopsin are photoconvertible. Upon photon absorption, 11-*cis*-retinal (or its analogs) of rhodopsin is converted into all-*trans*-retinal of metarhodopsin, and then irradiation of metarhodopsin changes the all-*trans*-retinal back to 11-*cis*-retinal by a process called photoregeneration.

Notably, invertebrates differ from vertebrates in the photoactivation of rhodopsin. Absorption of a photon by

invertebrate rhodopsin leads to a stable meta II, but retinal remains in the retinal-binding pocket. This contrasts to vertebrate rhodopsin where retinal leaves the meta II-binding pocket. Invertebrate phototransduction also involves an inositol-1,4,5-triphosphate signaling cascade (cyclic-guanosine monophosphate (GMP) in vertebrates) and a G_q-type G protein (G_t in vertebrates) that is stimulated by photoactivated rhodopsin.

Three-dimensional structures of bovine (vertebrate) rhodopsin and squid (invertebrate) rhodopsin show structural similarities in the arrangement of their transmembrane helices (Figure 6). Squid rhodopsin is a 50-kDa protein composed of 488 amino acid residues. A proline-rich 10-kDa C-terminal extension compared with bovine rhodopsin is important for intracellular trafficking of this rhodopsin, and its deletion does not affect G protein activation. Like other GPCRs, squid rhodopsin forms a disulfide bridge between Cys^{108} and Cys^{186} for proper folding of the E-II loop. The NPXXY and (D/E)R(Y/W) regions of squid rhodopsin are similar to those of bovine rhodopsin. However, Val in the NPXXY motif, and Glu in the (D/E)R(Y/W) motif of bovine rhodopsin are replaced by Met and Asp, respectively, in squid rhodopsin (Figure 6(b)). Their structural similarity implies that the functional difference between vertebrate and invertebrate rhodopsins might be due to specific interactions between

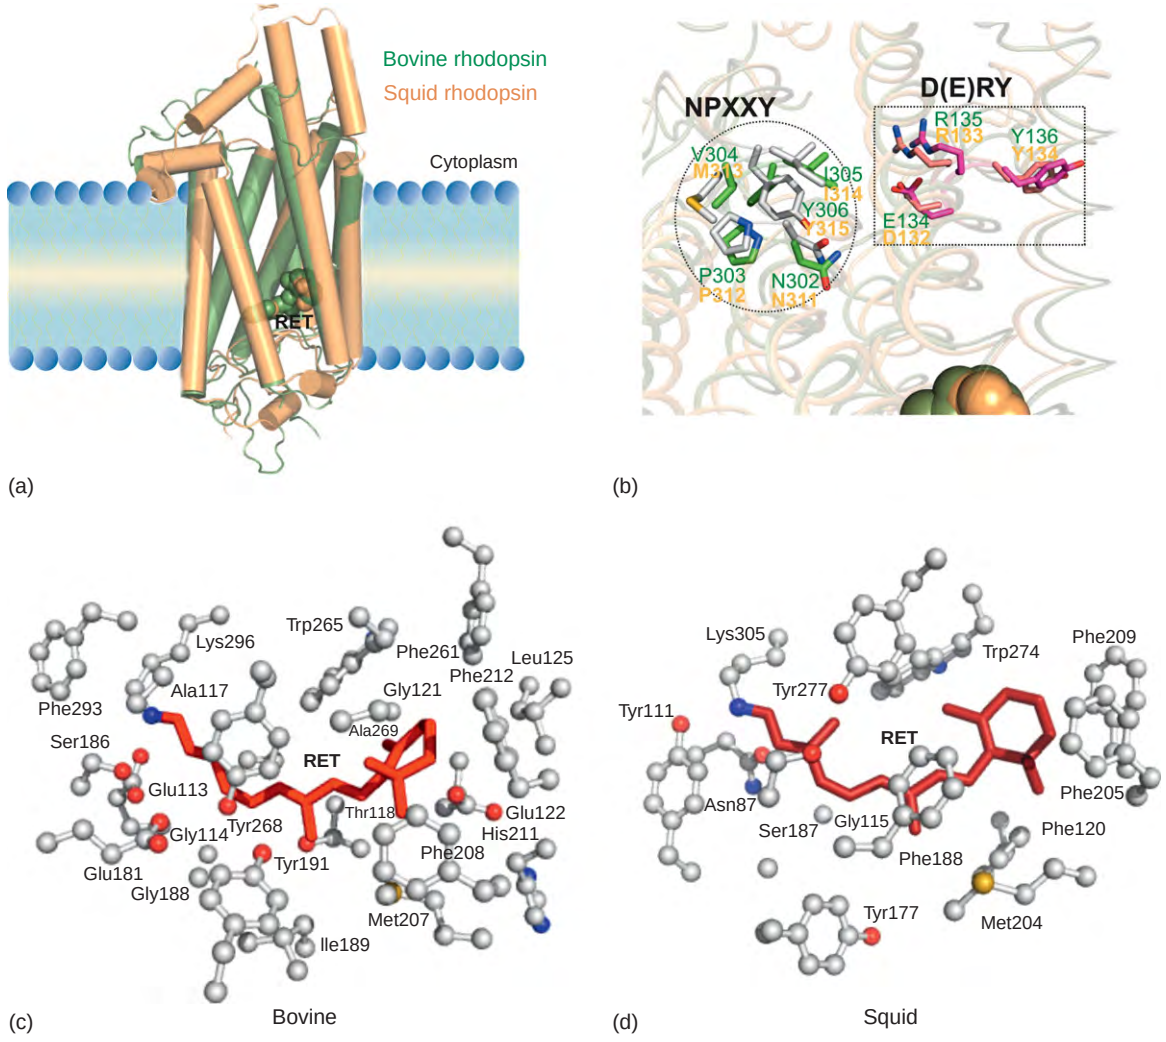

Figure 6 Bovine rhodopsin vs. squid rhodopsin. (a) Superimposition of bovine and squid rhodopsin structures. Helices are displayed in cartoon style, retinal (RET) is rendered as CPK balls, and the planar lipid bilayer is shown. (b) Conserved NPXXY and (D/E)R(Y/W) motifs of both bovine (green) and squid (yellow) rhodopsins are compared. Amino acids of these motifs are rendered as sticks, retinal is rendered as CPK balls, and helices are displayed as ribbons. (c) Retinal-binding site of bovine rhodopsin. Amino acid residues within about 5 Å are displayed to show the side-chain environment surrounding the 11-*cis*-retinylidene group. Residues are rendered as balls and sticks and retinal is shown in stick form (red). (d) Retinal-binding site of squid rhodopsin. Amino acid residues within about 5 Å are displayed to reveal the side-chain environment surrounding the 11-*cis*-retinylidene group. Residues are rendered as balls and sticks and retinal is shown in stick form (red). See text for explanation/discussion.

retinal and the amino acid sequence of the retinal-binding site. These binding sites are compared in Figures 6(c) and 6(d). In squid rhodopsin, the highly conserved Glu^{180} is too far away from the retinal-binding pocket and Asn^{185} is located between Glu^{180} and the Schiff base. Asn^{185} is assumed to move after photoisomerization of retinal, to mediate an indirect interaction between Glu^{180} and the retinal Schiff base. In the dark state, either Asn^{87} or Tyr^{111}, which is highly conserved among all invertebrates, might act as a hydrogen-binding partner (counter ion) for the Schiff base. These residues are replaced by Gly^{89} and Glu^{113} in bovine rhodopsin.

Signaling Cycle

After photoactivation, an active meta II state of rhodopsin triggers the activation of transducin (G_t protein). This form of rhodopsin is capable of activating G_t proteins during the relatively prolonged period of its activation. Accordingly, rhodopsin activity is regulated by its phosphorylation, a common feature among many GPCRs. This regulatory process is also important for rod cells to recover their responsiveness during dark adaptation. Desensitization of rhodopsin involves two steps: (1) phosphorylation of meta II, reducing the rate of transducin activation and (2) binding of arrestin to meta II, completely ending transducin activation by rhodopsin (Figure 7). This phosphorylation is carried out by rhodopsin kinase, a specific kinase also known as GRK1. Rhodopsin kinase phosphorylates specific serines in the rhodopsin C-terminal sequence. However, upon light illumination, GRK1 is released from recoverin and phosphorylates rhodopsin at multiple sites. Ser^{343}, Ser^{338}, and Ser^{334}, located in the C terminal domain on the cytoplasmic side of rhodopsin, are the main sites for this phosphorylation. Some threonine residues in this domain are also phosphorylated. Phosphorylation of this cytoplasmic domain reduces the ability of the G_t protein to bind to meta II, but it does not completely stop G_t activation. By binding to phosphorylated-meta II, arrestin prevents the interaction of G_t with meta II, and thus completely terminates G_t activation. At least three phosphorylated sites are required for high-affinity binding of the rhodopsin–arrestin complex. Arrestin dissociates from rhodopsin as meta II decays and loses all-*trans*-retinal. Then phosphorylated opsin is dephosphorylated by protein phosphatase 2A (PrP2A). The resulting free opsin is readily regenerated by 11-*cis*-retinal and continues recycling through the signaling cascade. A fraction of meta II directly dissociates into all-*trans*-retinal and opsin.

Rhodopsin Interaction with Other Proteins

According to X-ray crystallographic models and atomic force microscopic studies, H-IV–H-V of rhodopsin contact

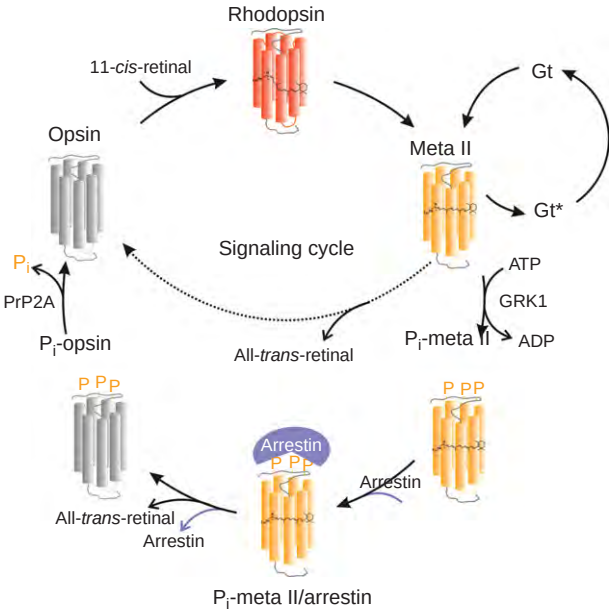

Figure 7 Interaction of rhodopsin with partner proteins. Phototransduction starts with the absorption of light by rhodopsin that causes photoisomerization of 11-*cis*-retinal to all-*trans*-retinal. Photoisomerization of this chromophore induces conformational changes in rhodopsin leading to formation of meta II, the signaling state of rhodopsin. Meta II binds and activates a large number of photoreceptor-specific G protein molecules, transducins (Gt), by catalyzing the exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) on transducin's α-subunit, Gtα. Deactivation of meta II and consequent Gt-mediated signaling starts with binding of the GPCR kinase called GRK1 (or rhodopsin kinase) that catalyzes subsequent phosphorylation of Ser and Thr residues in the C-terminus of rhodopsin. Phosphorylated rhodopsin then is capped by binding to arrestin, which prevents any residual Gt activation by meta II. The complex of phosphorylated rhodopsin–arrestin loses all-*trans*-retinal and then arrestin, after which the phosphorylated opsin is dephosphorylated by the action of protein phosphatase 2A (PrP2A). All-*trans*-retinal is transformed, through a series of steps, to 11-*cis*-retinal, which rebinds to opsin (as shown in Figure 4), thereby continuing rhodopsin signaling. A fraction of meta II loses all-*trans*-retinal (without phosphorylation) and directly transforms to opsin.

each other in a rhodopsin dimer. The sizes of G_t, GRK1, and arrestin proteins also favor the hypothesis of their interaction with the rhodopsin dimers. Previously reported models of rhodopsin with these proteins are discussed below. These complexes have yet to be resolved by crystallography.

Rhodopsin–G_t

In its inactive state, G_t is a membrane-associated protein that consists of α, β, and γ subunits with one guanosine diphosphate (GDP) noncovalently bound to the α-subunit. Post-translational modification of the α-(myristoylation) and γ-(farnesylation) subunits help this protein to associate with the membrane. A model for the rhodopsin–G_t complex has been reported (Figure 8(a)). Spectroscopic,

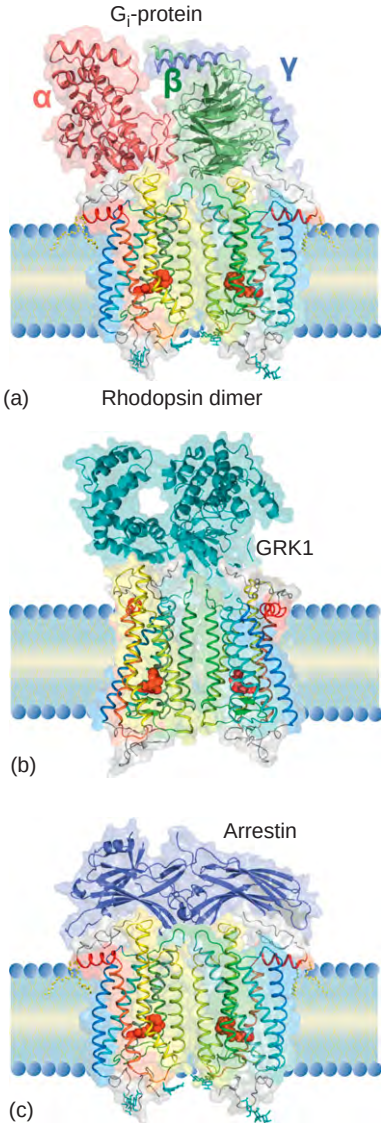

Figure 8 Conceptual models of rhodopsin dimers interacting with Gt, GRK1 and arrestin. (a) Rhodopsin dimer bound to one heterotrimeric Gt. Gtα is colored red, Gtβ is colored green, and Gtγ is colored blue. Gt occupies a single rhodopsin dimer, with only one rhodopsin monomer requiring activation. Helices of rhodopsin are colored as in **Figure 2**. (b) A rhodopsin monomer is modeled such that its third cytoplasmic loop (C-III) lies close to the proposed receptor-docking site for GRK1. This allows the GRK1 active site to have easy access to the C-tail of activated rhodopsin or of a neighboring unactivated rhodopsin in the same membrane plane, thereby allowing high gain phosphorylation of the ROS. (c) This theoretical model reflects the interaction of one arrestin molecule with a rhodopsin dimer. Molecules are represented in a space-filled background and the plane of the lipid bilayer is shown. No structural optimization was performed.

biochemical, and peptide competition experiments reveal that cytoplasmic loops II, III, H-8, and the C-terminal tail of rhodopsin interact with transducin. The interacting sites of transducin are the C-terminal tail, N-terminal helix, the α4–β6–α5 region of the α-subunit, and the farnesylated C-terminal region of the γ-subunit.

Rhodopsin–GRK1

GRK1 phosphorylates multiple sites on the C-terminal tail that is freely accessible in both active and inactive states of rhodopsin (**Figure 8(b)**). A single activated rhodopsin (meta II) molecule can induce the phosphorylation of hundreds of other rhodopsins. Cytoplasmic loops II and III of rhodopsin are the most important sites for binding of GRK1, and the N-terminal 30 residues of GRK1 are important for this interaction. Inactivating mutations in GRK1 are found in human patients with Oguchi disease, a stationary form of night blindness characterized by a substantial delay in recovery of dark vision after photobleaching.

Rhodopsin–Arrestin

Arrestin binds to photoactivated-phosphorylated rhodopsin (**Figure 8(c)**). Biochemical analysis of the arrestin–rhodopsin complex reveals that several domains of arrestin are essential for this interaction. In particular, the region from residues 163 to 189 is essential for binding to activated-phosphorylated rhodopsin, but not to unphosphorylated rhodopsin. Lysine and arginine residues of arrestin are also very important for specific binding, but only to phosphorylated rhodopsin.

Mutations in Rhodopsin and Retinal Diseases

Mutations in the genes encoding many proteins involved in phototransduction and the visual and signaling cycles have been implicated in causing blinding diseases of humans such as Leber's congenital amaurosis (LCA), Stargardt macular degeneration, congenital cone–rod dystrophy, and retinitis pigmentosa (RP). More than 100 rhodopsin mutants resulting in human eye diseases have been identified (**Figure 2**). Some mutations result in degeneration of rod cells, while some affect the function of rhodopsin. Mutations at the C-terminal tail impair rhodopsin trafficking from RISs to the ROSs. Mutations, for example Pro^{23} to His, which lead to rhodopsin misfolding will not allow the protein to reach disk membranes of ROS. Nonetheless, the ROSs degenerate and finally cause blindness. The Lys^{296} mutant is unable to bind chromophore, thereby compromising rhodopsin function. Mutations, for example Ala^{292} to Glu, which lead to human congenital night blindness do not involve ROS degeneration but rather compromise human vision under dim light. Mutations of proteins in the visual cycle also cause eye diseases. For example, inactivating mutations in the *LRAT* gene cause LCA. The $Lrat^{-/-}$ knock-out mouse with *LRAT*-mediated retinal dystrophy evidences only traces of retinoid compounds in ocular tissues, resulting in impaired vision from birth. The ROS are shortened in $Lrat^{-/-}$ mice, and photoreceptors degenerate very slowly. This disease can be treated by

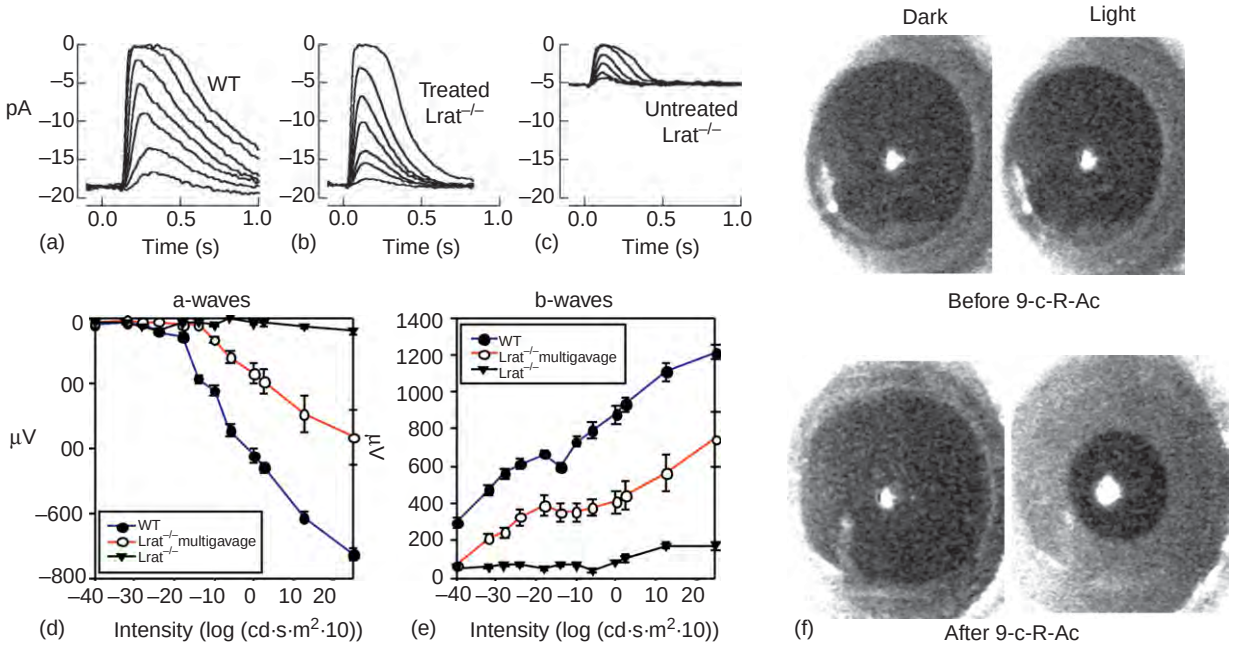

Figure 9 Rescue of visual responses measured by single-cell recording and ERG responses of single *WT* and *Lrat*$^{-/-}$ mouse rod cells. (a) Flash families measured for a *Lrat*$^{+/+}$ mouse (WT) rod, (b) a *Lrat*$^{-/-}$ rod from a mouse that had received a single gavage with 9-*cis*-R-Ac (9-*cis*-retinyl acetate), and (c) a control *Lrat*$^{-/-}$ mouse rod. Rods were obtained from 8-week-old mice. Each panel superimposes averaged responses to 5–20 repeats of a flash; flash strength was increased by a factor of 2 to produce each successively larger response. (d and e) Comparisons of scotopic single-flash ERG recordings from *Lrat*$^{+/+}$ (WT) control mice, 9-*cis*-R-Ac gavaged *Lrat*$^{-/-}$ mice and *Lrat*$^{-/-}$ untreated mice. *Lrat*$^{-/-}$ mice were gavaged 9 times with 5 μmol of 9-*cis*-R-Ac during a 1-month period. (f) Light-induced pupillary constriction of *Lrat*$^{-/-}$ mice before and after treatment with 9-*cis*-R-Ac. All together, these experiments show that 9-*cis*-retinyl acetate restored retinal function in this animal model of LCA. Adapted from figures 4 and 6 in Batten M. L. (2005). Pharmacological and rAAV gene therapy rescue of visual functions in a blind mouse model of Leber congenital amaurosis. *PLOS Medicine* 2(11): e333.

dietary intake of active chromophores or their 9-*cis*-precursors. Oral supplementation of *Lrat*$^{-/-}$ mice with 9-*cis*-retinyl acetate restored retinal function (**Figure 9**).

Phototransduction: The Visual Cycle

G H Travis, UCLA School of Medicine, Los Angeles, CA, USA

Glossary

Lipofuscin – Fluorescent pigment granules found within cells of the RPE. Lipofuscin contains oxidized fatty acids and condensation of products of retinaldehyde with phosphatidylethanolamine, such as A2E. Lipofuscin is thought to arise from the incomplete digestion of phagocytosed outer segments. Components of lipofuscin, including A2E, are cytotoxic and thought to play a role in the etiology of macular degeneration.

Opsin visual pigment – Opsin pigments are light-sensitive complexes containing a protein and an 11-*cis*-retinaldehyde chromophore.

Outer segment – An elongated light-sensitive structure attached to the connecting cilium of rod and cone photoreceptors. The outer segment comprises a stack of approximately 1000 membranous disks. These disks are loaded with rhodopsin or cone opsin visual pigments.

Retinyl ester – A conjugate of vitamin A (retinol) with a fatty acid. Retinyl esters represent stable, nontoxic, and water-insoluble storage forms of retinol. Retinyl esters are also the substrate for Rpe65-isomerase in RPE cells.

Retinaldehyde – An oxidized form of retinol. Retinaldehydes are highly reactive and potentially cytotoxic. The 11-*cis* isomer of retinaldehyde (11-*cis*-RAL) is the light-sensitive chromophore in rhodopsin and cone-opsin visual pigments.

Schiff base – It is also called an imine. Results from the reaction of a primary amine (as in lysine or phosphatidylethanolamine) with a carbonyl group (as in retinaldehyde) to form a carbon–nitrogen double bond with loss of a water molecule. Formation of a Schiff base is reversible.

The vertebrate retina contains two classes of light-sensitive cells, rods and cones. Both cell types contain a membranous structure called the outer segment (OS), which are loaded with rhodopsin or cone-opsin visual pigments. These pigments are members of the G-protein-coupled receptor superfamily. Each rod OS contains approximately 10^8 rhodopsin pigments. The ligand for these pigments is 11-*cis*-retinaldehyde (11-*cis*-RAL), which is covalently coupled to a lysine in the opsin protein through a Schiff-base linkage. Absorption of a photon by an opsin pigment induces photoisomerization of the 11-*cis*-RAL chromophore to all-*trans*-retinaldehyde (all-*trans*-RAL). This isomerization converts the pigment to active metarhodopsin II, which stimulates the visual-transduction cascade. After a brief period, metarhodopsin II is inactivated by rhodopsin kinase-mediated phosphorylation and subsequent capping by arrestin. Next, all-*trans*-RAL dissociates from the inactivated opsin pigment. To restore light sensitivity, the bleached apo-opsin recombines with another 11-*cis*-RAL, forming a new rhodopsin or cone-opsin pigment. To maintain continuous vision in light, the all-*trans*-RAL released by bleached pigments must be converted back to 11-*cis*-RAL. This process is carried out by a multistep enzyme pathway called the visual cycle (**Figure 1**). The first two catalytic steps of this pathway occur in photoreceptors, while the remaining steps take place in cells of the retinal pigment epithelium (RPE). The RPE is an epithelial monolayer adjacent to the photoreceptors. Apical processes of RPE cells interdigitate with the photoreceptor OS. The regeneration of visual chromophore is one of the several collaborations between photoreceptors and RPEs; and cone opsins may have access to an alternative source of 11-*cis*-RAL chromophore. This alternative retinoid pathway is present in Müller glial cells.

Clearance of All-*trans*-RAL from OS Disks

Following photoactivation and subsequent deactivation of the opsin pigment, all-*trans*-RAL probably exits between transmembrane (TM) helices, TM1 and TM7, into the lipid bilayer. The all-*trans*-RAL diffuses within the bilayer until it encounters the amine headgroup of a phosphatidylethanolamine, which may condense with the all-*trans*-RAL to form the Schiff base, *N*-retinylidene-phosphatidylethanolamine (*N*-ret-PE). This condensation reaction is reversible. On the cytoplasmic surface of the OS disk-membrane, all-*trans*-RAL is reduced to all-*trans*-retinol (all-*trans*-ROL), driving dissociation of *N*-ret-PE (see below). However, all-*trans*-RAL can be temporarily trapped as *N*-ret-PE on the intradiscal surface. An adenosine triphosphate (ATP)-binding cassette transporter called ABCA4 (also ABCR or rim-protein) is present in the disks of rod and cone OS. Mice with a knockout mutation in the *abca4* gene show delayed clearance of all-*trans*-RAL and elevated *N*-ret-PE in the retina following exposure to light. *In vitro* studies suggest that ABCA4 is an outwardly directed flippase for

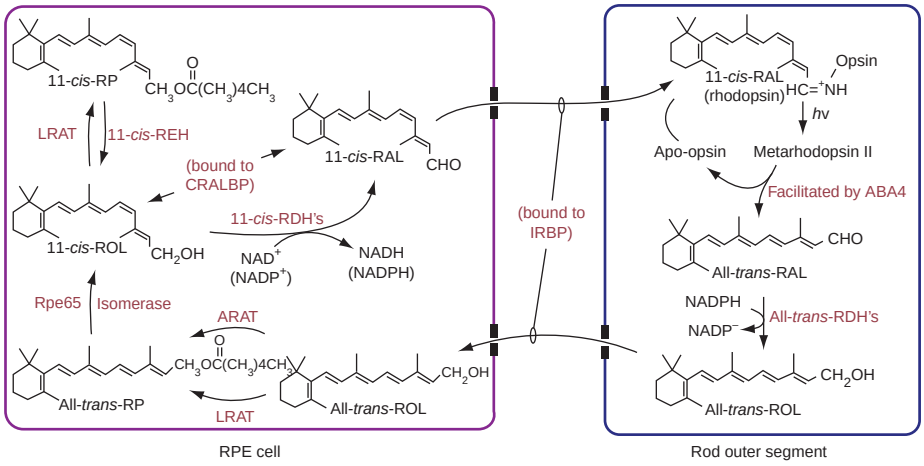

Figure 1 Visual cycle. Following absorption of a photon ($h\nu$), 11-*cis*-RAL Schiff base in rhodopsin is isomerized to all-*trans*-RAL, converting the receptor to active metarhodopsin II. Subsequently, the all-*trans*-RAL dissociates from apo-opsin. ABCA4 transports all-*trans*-RAL (as *N*-ret-PE) across the disk bilayer from the interior to the cytoplasmic leaflet. The all-*trans*-RAL is reduced to all-*trans*-ROL by one or more all-*trans*-RDH's that use NADPH as a cofactor. The all-*trans*-ROL is released by the OS to IRBP in the IPM. The all-*trans*-ROL is carried by IRBP to the apical RPE, where it is taken up and esterified by LRAT or ARAT to yield an all-*trans*-RE such as all-*trans*-RP. The all-*trans*-RP is isomerized and hydrolyzed by Rpe65 to yield 11-*cis*-ROL. The 11-*cis*-ROL may be oxidized by one or more 11-*cis*-RDH to yield 11-*cis*-RAL chromophore. Alternatively, the 11-*cis*-ROL may be secondarily esterified by LRAT or ARAT to yield an 11-*cis*-RE, such as 11-*cis*-RP, representing a preisomerized storage form of chromophore precursor. When needed, the 11-*cis*-RP is hydrolyzed by 11-*cis*-REH to yield 11-*cis*-ROL. 11-*cis*-ROL and 11-*cis*-RAL are bound to CRALBP in RPE cells. The 11-*cis*-RAL is released by the RPE into the IPM where it binds to IRBP. Finally, the 11-*cis*-RAL is delivered to the OS where it recombines with apo-opsin to form a new visual pigment.

N-ret-PE, consistent with the biochemical phenotype in *abca4*$^{-/-}$ mice. Thus, ABCA4 appears to facilitate the removal of all-*trans*-RAL from disk membranes for subsequent reduction to all-*trans*-ROL. Mutations in the human *ABCA4* gene cause Stargardt macular degeneration and a subset of recessive cone–rod dystrophy in humans. Stargardt patients and *abca4*$^{-/-}$ mice accumulate toxic lipofuscin pigments in RPE cells. Buildup of these fluorescent pigments is important in the pathogenesis of photoreceptor degeneration in Stargardt's disease.

Reduction of All-*trans*-RAL to All-*trans*-ROL

This reaction is carried out in photoreceptor OS by a member of the short-chain dehydrogenase/reductase family called photoreceptor retinol dehydrogenase (prRDH) or RDH8. RDH8 uses nicotinamide adenine dinucleotide phosphate oxidase (NADPH) as a co-factor. In *rdh8*$^{-/-}$ knockout mice, reduction of all-*trans*-RAL to all-*trans*-ROL is slowed but not halted, suggesting that RDH8 function is complemented in photoreceptors by at least one other retinol dehydrogenase. Photoreceptors contain a second retinol dehydrogenase called RDH12 that also catalyzes NADPH-dependent reduction of all-*trans*-RAL to all-*trans*-ROL. Mice with a knockout mutation in the *rdh12* gene show mildly slowed reduction of all-*trans*-RAL to all-*trans*-ROL, and protection from light-induced photoreceptor degeneration. Unlike RDH8, which is expressed in photoreceptor OS, RDH12 is expressed in photoreceptor inner segments. This distribution is unexpected given that all-*trans*-RAL is released following light exposure into the OS. RDH12 may play a detoxifying role in the inner segment by reducing all-*trans*-RAL that escaped reduction by RDH8 in the OS. Mutations in *RDH12* cause a severe recessive blinding disease called Leber congenital amaurosis (LCA). No mutations in *RDH8* have been associated with a retinal dystrophy in humans. Mice with a knockout mutation in the *rdh8* gene show normal kinetics of rhodopsin regeneration and delayed recovery of sensitivity following exposure to bright light. An identical pattern is seen in *abca4*$^{-/-}$ mice. ABCR and all-*trans*-ROL dehydrogenase act sequentially in the visual cycle to remove all-*trans*-RAL following a photobleach (**Figure 1**). Delayed dark adaptation in *rdh8*$^{-/-}$ and *abca4*$^{-/-}$ mice is probably due to noncovalent reassociation of all-*trans*-RAL with apo-opsin to form a noisy photoproduct that activates transducin.

Transfer of All-*trans*-ROL from Photoreceptors to the RPE

Interphotoreceptor retinoid-binding protein (IRBP) is secreted by photoreceptors and present at a high concentration in the extracellular space. Besides IRBP, this space is filled with extracellular matrix material and is called the

interphotoreceptor matrix (IPM). IRBP contains binding sites for both 11-*cis*- and all-*trans*-retinoids. IRBP has been shown to accelerate the removal of all-*trans*-ROL from bleached photoreceptors. The uptake of all-*trans*-ROL by IRBP may involve a receptor on the OS plasma membrane. Retinoids bound to IRBP are protected from oxidation and isomerization during transit through the IPM. Mice with a knockout mutation in the *irbp* gene show accumulation of all-*trans*-ROL in the retina, and reduced all-*trans*-REs in the RPE following light exposure. These mice also show accumulation of 11-*cis*-RAL in the RPE and reduced 11-*cis*-RAL in the retina following light exposure. These results suggest that IRBP functions to extract all-*trans*-ROL from bleached photoreceptors, and 11-*cis*-RAL from RPE cells. Mutations in the *RBP3* gene for IRBP cause the inherited blinding disease, recessive retinitis pigmentosa in a small subset of cases.

Another all-*trans*-ROL-binding protein, cellular retinol–binding protein type-1 (CRBP1), is present in RPE cells. CRBP1 is a soluble protein that binds all-*trans*-ROL with 100-fold higher affinity than does IRBP. This difference in affinity drives the uptake of all-*trans*-ROL from the IPM into RPE cells. Compared with wild-type mice, $crbp1^{-/-}$ knockout mice contain reduced all-*trans*-REs in the RPE and higher all-*trans*-ROL in the retina following light exposure. This biochemical phenotype is similar to the phenotype in $irbp^{-/-}$ mice.

Synthesis of Retinyl Esters

The major retinyl-ester synthase in RPE cells is lecithin: retinol acyl transferase (LRAT), which catalyzes the transfer of a fatty-acyl group from the *sn*1 position in phosphatidylcholine to all-*trans*-ROL (see **Figure 1**). The resulting all-*trans*-retinyl esters (all-*trans*-REs) are water-insoluble, and represent a stable and nontoxic storage form of vitamin A. Mice with a knockout mutation in the *lrat* gene contain virtually no all-*trans*-REs or other visual retinoids in their ocular tissues. Accordingly, $lrat^{-/-}$ mice are totally blind. Mutations in the human *LRAT* gene are yet another cause of recessive LCA.

Another retinyl-ester synthase activity, called acyl-CoA: retinol acyltransferase (ARAT), is present in RPE cells. Unlike LRAT, ARAT uses palmitoyl coenzyme A (palm CoA) as an acyl donor. Two enzymes have been shown to posses ARAT activity. Diacylglycerol acyltransferase type-1 (DGAT1), which catalyzes palm CoA-dependent synthesis of triglycerides from diacylglycerol, also catalyzes palm CoA-dependent synthesis of all-*trans*-REs from all-*trans*-ROL. Multifunctional *O*-acyltransferase (MFAT) also possesses ARAT catalytic activity. The very low level of all-*trans*-REs in the RPE of $lrat^{-/-}$ mice despite the presence of ARAT activity is due to the 10-fold higher K_M for all-*trans*-ROL substrate of ARAT versus LRAT. ARAT preferentially uses free all-*trans*-ROL as a substrate in contrast to LRAT, which uses holo-CRBP1.

Retinoid Isomerization

Conversion of a planar all-*trans*-retinoid to the strained 11-*cis* configuration is energetically unfavorable. Rpe65-isomerase uses all-*trans*-REs as substrate and catalyzes two reactions: hydrolysis of the carboxylate ester, and *trans* to *cis* isomerization of the C11–C12 double bond in the retinoid. Accordingly, the energy released by ester hydrolysis (−5.0 kcal $mole^{-1}$) is used to drive isomerization (+4.1 kcal $mole^{-1}$). Rpe65 is homologous to β-carotene oxygenase in mammals and apocarotene oxygenase (ACO) in cyanobacteria. The X-ray diffraction analysis showed that ACO has a seven-bladed β-propeller structure, with a Fe^{2+}-4-His arrangement at its axis. The four His residues that define the Fe^{2+}-binding site are conserved in all members of the ACO family including Rpe65. Rpe65 was shown to bind Fe^{2+}, which is required for its catalytic activity. Rpe65 is strongly associated with membranes but contains no membrane-spanning segments. Mice with a knockout mutation in the *rpe65* gene contain high levels of all-*trans*-REs in the RPE and no detectable 11-*cis*-RAL. Accordingly, $rpe65^{-/-}$ photoreceptors contain only apoopsin, and the mice have no detectable visual function. Despite blocked synthesis of visual chromophore, photoreceptor morphology is nearly normal in $rpe65^{-/-}$ mice. Visual function has been restored in $rpe65^{-/-}$ mice and dogs by administering exogenous visual chromophore. Injection of recombinant adeno-associated virus (AAV) containing a wild-type *rpe65* gene into the subretinal space (between RPE cells and photoreceptors) of $rpe65^{-/-}$ mice partially rescued the blindness phenotype. More recently, patients with *RPE65*-mediated LCA received subretinal injections of a similar *RPE65*-containing AAV. Encouragingly, these blind patients partially recovered visual function with expression of wild-type Rpe65 in their RPE.

The 11-*cis*-ROL synthesized by Rpe65 binds to cellular retinaldehyde-binding protein (CRALBP) in RPE cells. CRALBP also binds 11-*cis*-RAL. Mutations in the gene for CRALBP (*RLBP1*) cause several inherited retinal dystrophies including recessive retinitis pigmentosa. A newly synthesized molecule of 11-*cis*-ROL has two potential fates. As discussed below, it can be oxidized to 11-*cis*-RAL for use as visual chromophore. Alternatively, it can be esterified by LRAT to form an 11-*cis*-RE. 11-*cis*-REs represent a storage form of preisomerized chromophore precursor. Hydrolysis of 11-*cis*-REs is catalyzed by 11-*cis*-retinyl ester hydrolase (11-*cis*-REH) in the plasma membrane of RPE cells. The protein responsible for 11-*cis*-REH activity in RPE cells has not yet been identified.

Synthesis of 11-*cis*-RAL Chromophore

The final step in the visual cycle is oxidation of 11-*cis*-ROL to 11-*cis*-RAL. This reaction is catalyzed by 11-*cis*-ROL-dehydrogenase type-5 (RDH5), which uses NAD^+ as a cofactor. Mice with a knockout mutation in the *rdh5* gene show accumulation of 11-*cis*-ROL and 11-*cis*-REs in the RPE, and delayed recovery of rod sensitivity following light exposure. 11-*cis*-RAL is synthesized in *rdh5* $^{-/-}$ mice, albeit at a reduced rate, suggesting that RPE cells express at least one other 11-*cis*-ROL-dehydrogenase. RDH11 catalyzes $NADP^+$-dependent oxidation of 11-*cis*-ROL to 11-*cis*-RAL in the RPE. Surprisingly, *rdh5* $^{-/-}$, *rdh11* $^{-/-}$ double-knockout mice also synthesize 11-*cis*-RAL, although more slowly than in *rdh5* $^{-/-}$ or *rdh11* $^{-/-}$ single-knockout mice, and much more slowly than in wild-type mice. Thus, extensive functional redundancy exists for the oxidation of 11-*cis*-ROL in RPE cells, similar to the functional redundancy for reduction of all-*trans*-RAL in photoreceptors. 11-*cis*-RAL is strongly bound to CRALBP in RPE cells. CRALBP has been shown to interact with a protein complex on the cytoplasmic surface of the apical plasma membrane. From this position, 11-*cis*-RAL is transferred across the plasma membrane to bind IRBP in the IPM. This process may involve a receptor for IRBP on RPE cells.

Regeneration of Rhodopsin or Cone Opsin

The final step in the visual cycle is regeneration of a visual pigment from an apo-opsin and 11-*cis*-RAL. The mechanism whereby 11-*cis*-RAL is transferred from IRBP in the IPM to apo-opsin in the OS disk is unknown. It may involve an IRBP receptor on the OS plasma membrane, or simple diffusion of the 11-*cis*-RAL. No retinoid-binding protein has been identified in OS. The interaction of 11-*cis*-RAL with an apo-opsin involves a two-step process. First, a weak noncovalent complex is formed with 11-*cis*-RAL binding to a hypothesized entrance site on the opsin. Second, the 11-*cis*-RAL moves into the hydrophobic pocket and forms a Schiff base. This step is virtually irreversible in the case of rhodopsin. Once formed, rhodopsin is extremely quiet, with a spontaneous thermal-activation rate of one isomerization every 2000 years. In contrast to rhodopsin, recombination of 11-*cis*-RAL with the apo-cone-opsins is less favorable thermodynamically. Unlike rhodopsin, 11-*cis*-RAL freely dissociates from cone-opsins. For example, a dark-adapted red cone contains approximately 10% apo-cone-opsin due to spontaneous dissociation of chromophore. This effect contributes to the higher noise and much lower sensitivity of cones versus rods. It is also explains the tendency of rods to steal visual chromophore from cones when the availability of 11-*cis*-RAL is limited.

Regulation of the Visual Cycle

In the dark, photoreceptors stop releasing all-*trans*-ROL. Residual all-*trans*-ROL is esterified by LRAT. The major retinoids present in a dark-adapted eye are all-*trans*-REs in the RPE and 11-*cis*-RALs in photoreceptor visual pigments. How does the visual cycle know to stop converting all-*trans*-REs into 11-*cis*-RAL chromophore in the dark? One mechanism is the strong inhibition of Rpe65 by its product, 11-*cis*-ROL. When rhodopsin is fully regenerated and CRALBP is saturated, further synthesis of 11-*cis*-ROL by Rpe65 is inhibited.

A second mode of visual-cycle regulation involves an opsin protein called RPE-retinal G-protein receptor (RGR) opsin, expressed in RPE cells. Within RPE cells, all-*trans*-REs are stored in two compartments, internal membranes and oil droplets. Rpe65 associates with internal membrane but not lipid droplets. Hence, RPE internal membranes contain a pool of all-*trans*-REs available as substrate for isomerization, while lipid droplets contain a storage pool of all-*trans*-REs. This storage pool is potentially much larger than the isomerase pool in membranes. RGR opsin mediates light-dependent transfer of all-*trans*-REs from the storage compartment to the membrane compartment for isomerization. In light, where the requirement for visual chromophore is high, RGR opsin stimulates synthesis of 11-*cis*-ROL by increasing substrate availability to Rpe65. Consistently, mice with a knockout mutation in the *rgr* gene synthesize less 11-*cis*-RAL in the light and accumulate all-*trans*-REs. Mutations in the human *RGR* gene cause autosomal dominant retinitis pigmentosa.

Physiological Anatomy of the Choroidal Vasculature

S S Hayreh, University of Iowa, Iowa City, IA, USA

Glossary

Choriocapillaris – A network of choroidal capillaries with a lumen of 10–50 μm and many fenestrations (openings) in its wall.
Fluorescein fundus angiography – A technique for examining the circulation of the retina using injection of sodium fluorescein into the systemic circulation. The angiogram is obtained by photographing the fluorescence emitted after illumination of the retina.
Ischemia – Restriction of blood supply with resultant damage or dysfunction of tissue.
Watershed zone – The border between the territories of distribution of any two end arteries.

The posterior part of the wall of the eyeball consists of three layers, which are, from the outside inward: the sclera, choroid, and retina. The choroid essentially consists of a thick layer of blood vessels, with some pigment. The blood vessels in the choroid are arranged, from the outside inward, in three ill-differentiated layers: (1) a layer of large vessels, (2) a layer of small vessels, and (3) the choriocapillaris. In the perichoroidal space, there are branches of the ciliary nerves, which form complex plexuses in the vascular layer so that the choroid has a rich nerve supply.

Unlike the neighboring retina, the importance of the choroid has until recently been ill-understood, despite the fact that it has many unique and important features, including the following:

1. Approximately 85% of the total ocular blood flow is in the choroid.
2. Choroidal blood flow is 20 times greater than that of retina.
3. Choroidal blood flow is the highest of any system in the body.
4. The choroidal circulation supplies 80% of the retina (outer 130 μm – up to the outer part of the inner nuclear layer), while the retinal vessels supply only 20%. When an eye has a cilioretinal artery, the choroid supplies the entire thickness of the retina in the area supplied by the cilioretinal artery.
5. Oxygen of the choroidal venous blood is 95% of that in the choroidal arterial blood.
6. Unlike capillaries elsewhere in the eye, the choriocapillaris has a lumen of 10–50 μm.
7. The choriocapillaris has many fenestrations in its wall. Therefore, there is no blood–ocular barrier in the choroid.
8. The peripapillary choroid is the main source of blood supply to the optic nerve head.

Blood Supply of the Choroid

Arterial Supply

The choroid is entirely supplied by the posterior ciliary arteries (PCAs). There is a good deal of confusion as to the nomenclature, number, origin, and distribution of the PCAs in humans. Based on our anatomical study of 59 human ophthalmic arteries and their branches, the following PCA types can be identified.

Posterior ciliary arteries

These arteries arise from the ophthalmic artery (**Figures 1(a)** and **1(b)**). In humans, the ophthalmic artery gives out one (in 3%), two (in 48%), three (in 39%), four (in 8%), or five (in 2%) PCAs. Usually, two or three PCAs supply an eye; when there are more than three PCAs, the additional arteries are usually small in size. The PCAs usually enter the eyeball medial and lateral to the optic nerve and occasionally at other sites. The PCAs are named according to their relationship to the optic nerve at their site of entry into the eyeball:

Medial PCA. This lies medial to the optic nerve and may be one (in nearly 70%) or two (in nearly 30%) in number.

Lateral PCA. This lies lateral to the optic nerve, and there may be one (in nearly 75%), two (in nearly 20%), or none (in nearly 3%).

Superior PCA. This is seen in only 9% and may be one (in 7%) or two (in 2%); and is usually small in size.

Branches of the main PCAs

After their origin from the ophthalmic artery, the various PCAs run forward (**Figure 2(a)**), divide into a large number of small branches, and pierce the sclera near the optic nerve (**Figure 2(b)**). They have the following branches:

1. *Long PCAs.* They are two long PCAs – one on the medial and the other on the lateral side. They run forward horizontally.

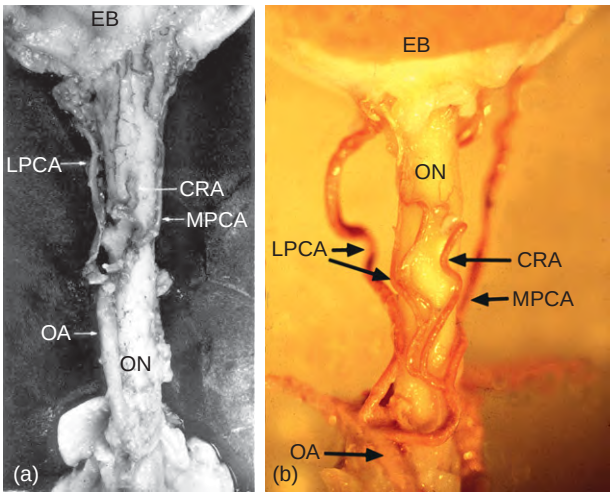

Figure 1 Photographs of inferior surface of the intraorbital part of the optic nerve (ON) and adjacent eyeball (EB) of (a) human and (b) rhesus monkey, showing ophthalmic artery (OA) with its lateral (LPCA) and medial (MPCA) posterior ciliary arteries and central retinal artery (CRA). Note a common trunk of origin of MPCA and CRA from the ophthalmic artery. (a) Reproduced from Hayreh, S. S. (1970). *British Journal of Ophthalmology* 54: 289–311.

2. *Short PCAs (SPCAs)*. There may be up to 20 SPCAs. They are further subdivided into two subgroups:
   (a) Paraoptic SPCAs enter the eyeball closest to the optic nerve (**Figure 2(b)**). Available evidence suggests that the optic nerve head is mostly supplied by the paraoptic SPCAs.
   (b) Distal SPCAs: The majority of the short PCAs are distal; they enter the eyeball midway between the paraoptic SPCAs and long PCAs on either side of the optic nerve (**Figure 2(b)**). They mainly supply the choroid.

From this account it is evident that there may be one to five PCAs and then three sets of branches of the PCAs supplying three different areas. It is inaccurate to use the term PCA loosely and as a generic term, covering all types of PCA and their branches.

Ocular supply by the PCAs

The short PCAs supply the following (**Figure 3**): (1) the choroid as far as the equator, and (2) the overlying retina to a depth of about 130 µm, including the retinal pigment epithelium and up to the outer part of the inner nuclear layer. If a cilioretinal artery is present, then the entire thickness of the retina is supplied in the distribution of the cilioretinal artery. (3) The PCA circulation is the main source of blood supply to the optic nerve head and the adjacent retrolaminar part of the optic nerve.

Each long PCA supplies a sector of the choroid, starting almost immediately from the point where it joins the choroid temporal to the macular region after having pierced the sclera, and extending forward to the ciliary body and iris. It also supplies the corresponding segment of the anterior uvea.

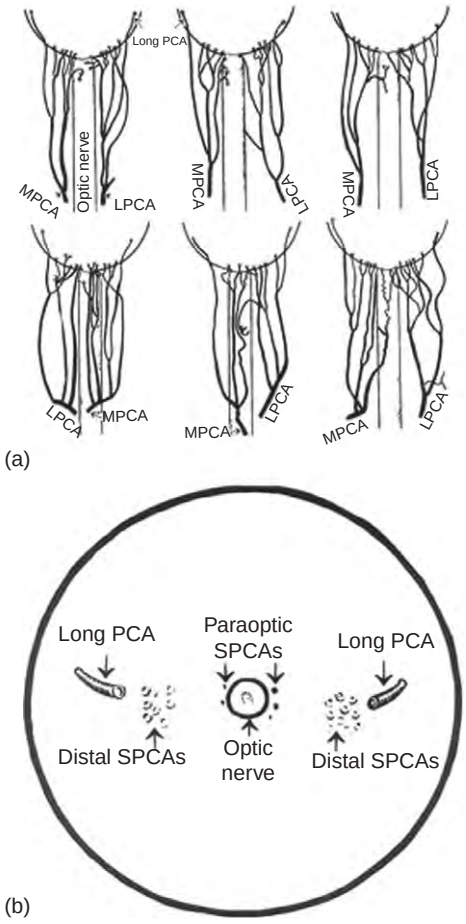

Figure 2 Diagrammatic representation of (a) the actual branching pattern of medial and lateral PCAs in six eyes, and (b) the site of entry of the various long and short PCAs, as seen on the back of the eyeball. Reproduced from Hayreh, S. S. (1999). *Current Concepts on Ocular Blood Flow in Glaucoma*. Pillunat et al. (eds.) pp. 3–31. The Hague: Kugler.

Venous Drainage

Vortex veins

The choroid has a large number of thin-walled veins, which finally drain into the vortex veins. There are usually four vortex veins (**Figure 4**). Each drains the veins not only from the corresponding quadrant of the choroid but also from the same quadrant of the iris and ciliary body.

Choriovaginal vein. In addition to the vortex vein, in some eyes, a vein may be seen which passes from the choroid through the sclera closely adjacent to the optic nerve head (**Figure 5**). It drains into the venous plexus of the pial sheath of the optic nerve. This choriovaginal vein occurs more frequently in highly myopic eyes than others.

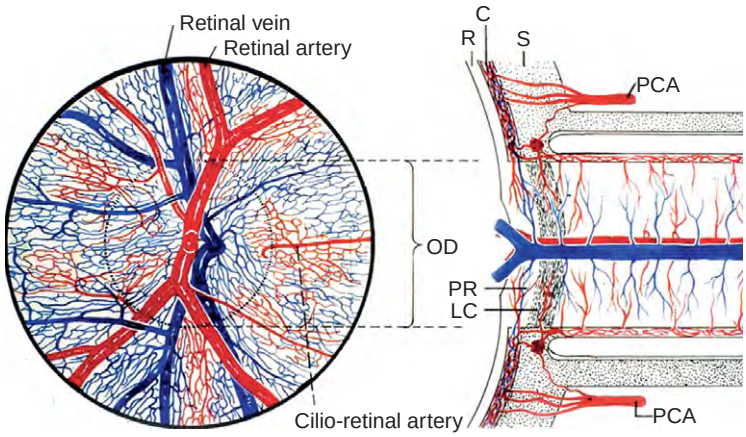

Figure 3 Schematic representation of blood supply of the optic nerve head by the PCA and retinal vasculature with a cilioretinal artery. Figure 5 Fundus photograph of left human eye showing the choriovaginal vein (arrow).

Since 1755, when Johann Gottfried Zinn, based on his studies, first described the anatomy of the choroidal vascular bed in *Descriptio Anatomica Oculi Humani*, extensive anatomical studies of the choroidal vascular bed have been conducted, mostly by studying casts prepared by the postmortem injection of a variety of materials and lately by studying the casts by scanning electron microscopy. These studies have formed the basis for the classical anatomical textbook description of the choroidal vasculature. According to most of these descriptions:

1. Extensive anastomoses exist between the various branches of all the SPCAs.
2. The SPCAs anastomose with the anterior ciliary arteries at the equator of the eye.
3. The choriocapillaris is arranged in one plane as a single continuous layer of wide lumen capillaries and they form a continuous anastomotic network over the entire choroid (**Figure 6**).
4. The choroidal veins communicate freely and the vortex veins have no segmental distribution (**Figure 4**).

Thus, postmortem cast studies of the choroidal vascular bed have consistently led to the conclusion that (1) there is NO segmental distribution in it, (2) the choroidal vessels anastomose freely with one another (**Figures 4** and **6**),

(3) PCAs anastomose with anterior ciliary arteries, and (4) there are interarterial as well as arteriovenous anastomoses. The casts have also suggested that the choriocapillaris forms a continuous vascular network and choroidal veins anastomose freely (**Figure 6**). However, it is well known that inflammatory, metastatic, ischemic, and degenerative lesions in the choroid are usually localized. Moreover, a number of clinical and experimental observations reported in the literature suggest that the PCAs have a segmental supply to the choroid. To resolve this controversy, the normal *in vivo* circulation and physiological anatomy of the choroidal vascular bed have been investigated experimentally in rhesus monkeys and clinically in humans by means of fluorescein fundus angiography (since 1969). These angiographic studies have virtually revolutionized our concept of the choroidal vascular bed, demonstrating its segmental nature (see above), and helping to explain the pathogeneses of some obscure fundus lesions. The following account represents our current knowledge on the subject.

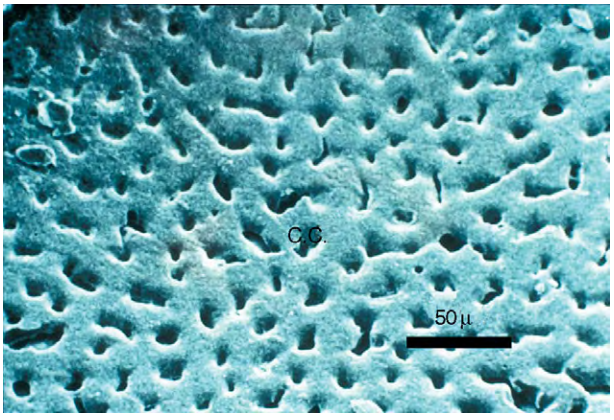

Figure 6 A plastic cast of choriocapillaris vascular bed of macaque monkey. Reproduced by courtesy of Professor Koichi Shimizu.

Normal *In Vivo* Circulation and Physiologic Anatomy of the Choroidal Vascular Bed

Experimental and clinical fluorescein fundus angiographic studies have demonstrated that the choroidal vascular bed is an end-arterial, segmental vascular system, almost similar to that seen in the retinal vasculature.

Posterior ciliary arteries

In the human, each PCA supplies the corresponding segment of the choroid. However, there is marked interindividual variation in the area supplied by each PCA.

The medial PCA

This may supply the entire nasal choroid up to the level of the fovea (**Figure 7(a)**), including the entire optic nerve head, or a part of the optic nerve head (**Figures 7 (b)** and **7(c)**) or its supply may stop short nasal to the nasal peripapillary choroid, so that it may take no part in the blood supply of the optic nerve head; or there may be any variation between these two extremes.

The lateral PCA

This supplies the area of the choroid not supplied by the medial PCA or vice versa. When there are more than one medial or lateral PCAs, the area supplied by each may correspond to only one quadrant or to only a sector.

The superior PCA

When present, this supplies a superior sector (**Figure 8**).

With the interindividual variation in number of PCAs and their distribution (see above), there may be an extremely variable pattern of distribution in the choroid from eye to eye. Clinical and experimental studies have shown that the various PCAs have a segmental supply and

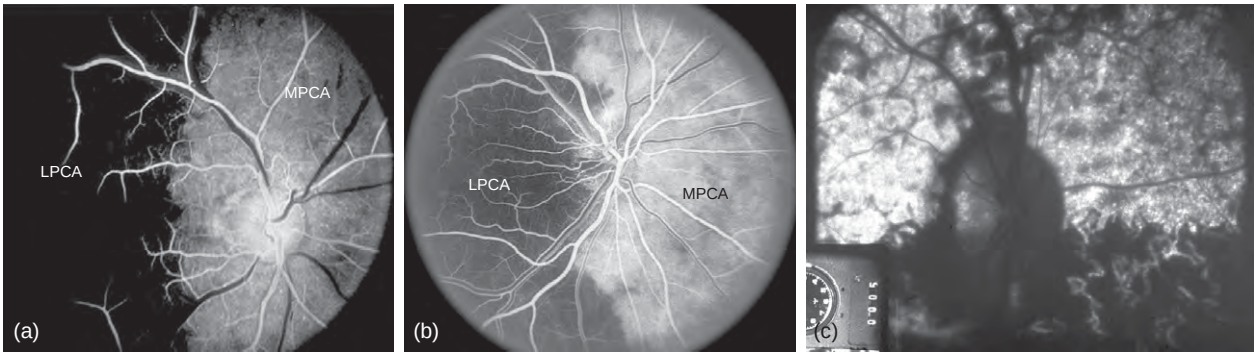

Figure 7 Fluorescein fundus angiograms of two human eyes (a, b) showing two examples of variations in the areas of supply in the choroid and the optic disk by the medial and lateral posterior ciliary artery (MPCA and LPCA, respectively) in different eyes. S. (1970). *British Journal of Ophthalmology* 54: 289–311.

do not anastomose with one another; each behaves like an end artery.

The SPCAs

These supply segments of the choroid extending radially from the posterior pole to the equator; each segment varies greatly in shape, size, and location and has irregular borders (**Figures 9** and **10(a)–10(c)**). Smaller subdivisions of the short PCAs supply still smaller segments of irregular shape and size, having a geographic pattern. Ultimately, each terminal choroidal arteriole supplies a lobule of choriocapillaris. There may be a marked spatial variation in the filling of the various choroidal segments, which explains the well-defined geographical filling defects commonly seen on fluorescein angiography in the normal choroid. These physiological choroidal filling defects have often been mistaken for pathological filling defects. Our criterion to differentiate normal from abnormal filling defects in the choroid is to correlate the filling defects with the normal retinal vascular filling. If the choroidal filling defect disappears when the major retinal veins start to fill, it is normal, but if it is delayed then it is usually abnormal.

Long PCAs

These supply a wedge-shaped sector of the choroid, with its apex posteriorly, extending radially and temporally from the temporal border of the macular region (**Figures 9** and **11**).

Choriocapillaris

Fluorescein angiographic studies have shown that each terminal choroidal arteriole supplies an independent segment (lobule) of choriocapillaris, with the arteriole joining the segment in its center and the draining venules lying around the periphery of this segment (**Figures 12** and **13**). Each lobule of the choriocapillaris is an independent unit (of a polygonal shape in the posterior fundus), with no anastomosis with the adjacent segments *in vivo*. The lobules are arranged like a mosaic, the borders of the mosaic being formed by the venous channels. The size of each lobule of the choriocapillaris varies, and in our studies, it was usually about one-quarter of the disk diameter or less. The choriocapillaris is most densely packed at the posterior pole and progressively become less densely arranged toward the periphery. Unlike the retinal capillaries, the choriocapillaris have no blood barrier in the choriocapillaris because their endothelial fenestrations make them highly permeable.

Vortex veins

Experimental occlusion of the various vortex veins has shown that *in vivo* there is poor communication between the adjacent veins (**Figure 14**).

Choroidal anastomoses

The presence of interarterial and arteriovenous anastomoses in the choroid has been well documented in all the postmortem injection studies. Likewise, interarterial anastomoses between the branches of the PCAs and the anterior ciliary arteries have been documented in those studies. Nonetheless, no *in vivo* experimental or clinical studies, involving acute occlusion of the PCAs or their

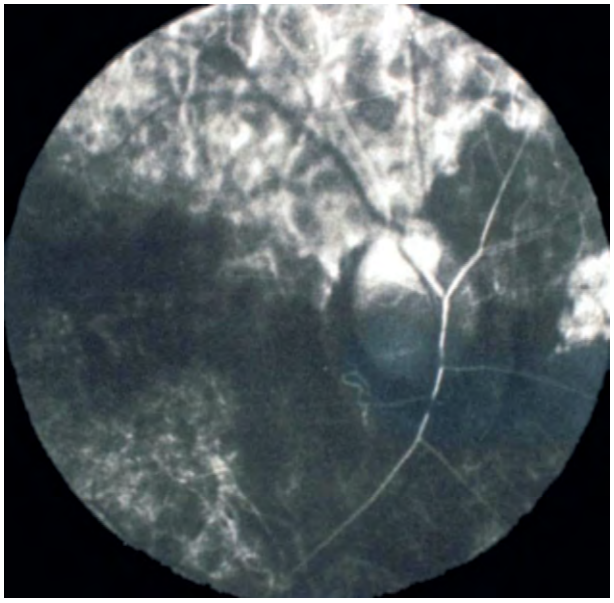

Figure 8 Fluorescein fundus angiogram, of a normal human right eye, shows filling of the superior PCA and corresponding part of the optic disk. Reproduced from Hayreh, S. S. (1974). *British Journal of Ophthalmology* 58: 955–963.

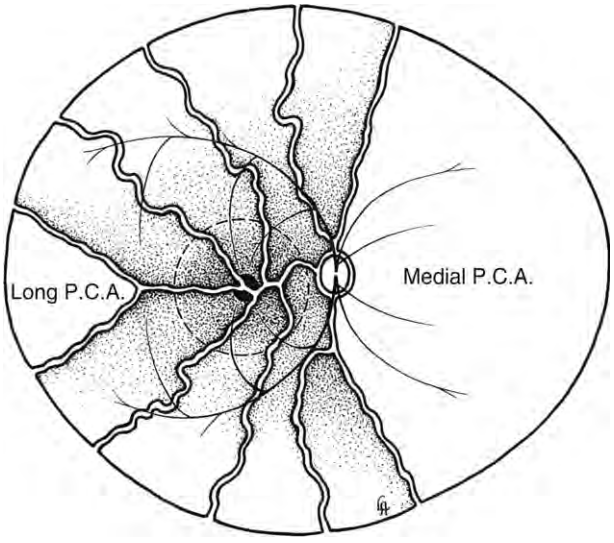

Figure 9 Diagrammatic representation of distribution by various temporal short PCAs and their watershed zones in the posterior part of the fundus. Dotted circle in the region of distribution of the temporal short PCAs represents the macular region. Areas of supply by the medial PCA and the temporal long PCA are also shown. Reproduced from Hayreh, S. S. (1974). *Graefe's Archive for Clinical and Experimental Ophthalmology* 192: 181–196.

smaller divisions, have shown any evidence at all of the presence of such anastomoses.

Segmental Nature of the Choroidal Vascular Bed

Fluorescein angiography clearly shows that blood flow in the choroidal arterial, choriocapillaris, and choroidal venous beds is strictly segmental, with no anastomoses between the adjacent segments at any level. The PCAs and choroidal arteries, right down to the terminal choroidal arterioles, are end arteries. These findings totally contradict the old concept, based on postmortem injection studies, that the entire choroidal vascular bed is one continuous, freely communicating system. Clearly, there is a serious disparity between the postmortem injection and the *in vivo* studies – the former misled us badly for more than two centuries. The reason for this discrepancy is that when the cast material is injected under pressure in the postmortem studies, the vessels fill from all sources, irrespective of the normal blood flow pattern, and, therefore, give information about the morphological conduits only, while the *in vivo* studies with fluorescein angiography reveal the actual pattern of the blood flow in those channels. It is also possible that in the living eye the neural supply to the potential anastomotic channels, seen on postmortem injection studies, may influence the pattern of blood flow; however, as yet, we have no definite explanation for this important disparity. In any case, what matters clinically, in explaining different vascular disorders, is the *in vivo* circulatory pattern.

Watershed Zones in the Choroidal Vascular Bed

When a tissue is supplied by two or more end arteries, the border between the territories of distribution of any two end arteries is called a watershed zone. The occurrence of such watershed zones between the various cerebral arteries is well known, as is also the case in some other organs having end-arterial systems. The significance of the watershed zones is that in the event of a fall in the perfusion pressure in the vascular bed of one or more of the end arteries, the watershed zone, being an area of comparatively poor vascularity, is most vulnerable to ischemia. The development of watershed infarcts in the cerebral cortex is well known.

From the foregoing discussion, it is evident that PCAs and their subdivisions, right down to the terminal choroidal arterioles, are end arteries. The choroidal vascular bed, therefore, has watershed zones. These zones are

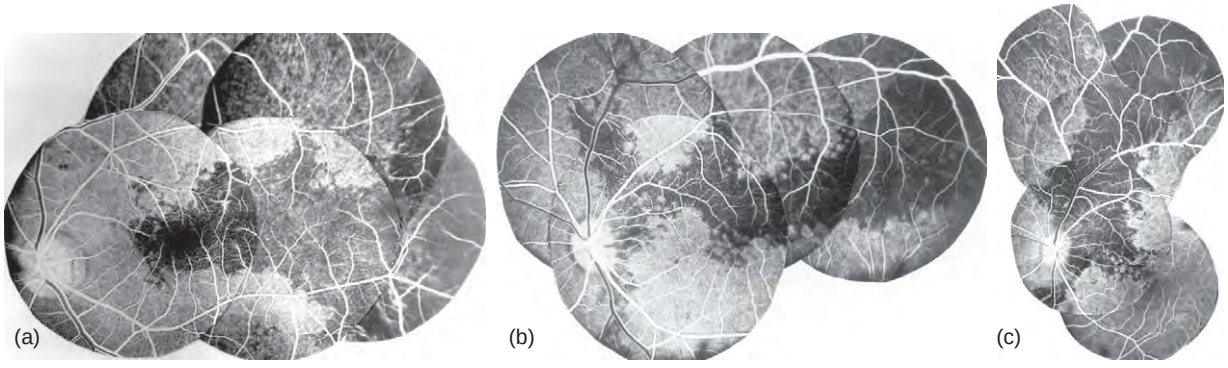

Figure 10 Fluorescein fundus angiograms of 3 (a–c) rhesus monkey eyes after experimental occlusion of different short PCAs, showing the variability in the areas of supply by the 3 different occluded arteries (dark areas). Reproduced from Hayreh, S. S. (1974). *Graefe's Archive for Clinical and Experimental Ophthalmology* 192: 181–196.

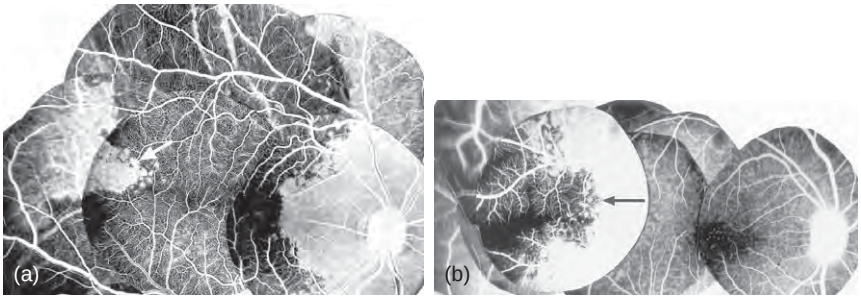

Figure 11 Fluorescein fundus angiograms of two eyes of rhesus monkey showing the area of supply by the long PCA (arrow). (a) After experimental occlusion of all short PCAs but leaving a normal long PCA. (b) After experimental occlusion of long PCA only. Reproduced from Hayreh, S. S. (1974). *Graefe's Archive for Clinical and Experimental Ophthalmology* 192: 197–213.

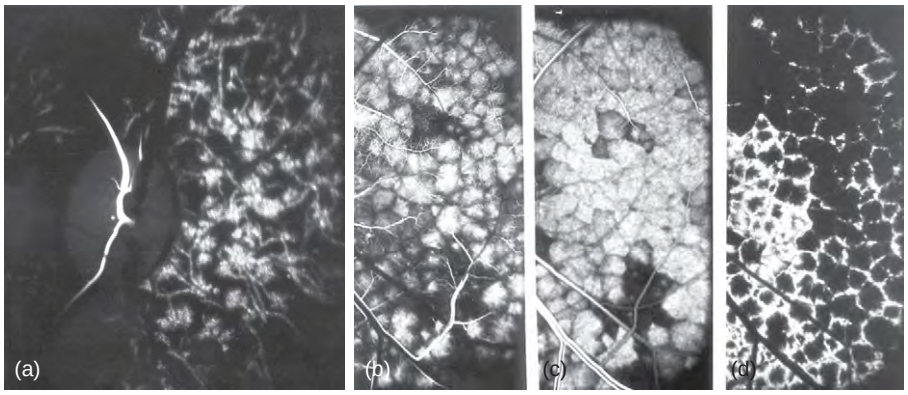

Figure 12 Fluorescein fundus angiograms of a rhesus monkey eye at the posterior pole, showing different phases in choriocapillaris filling. (a) Very early filling phase, where the choriocapillaris is seen as bunches of tiny fluorescent spots at the ends of terminal choroidal arterioles. (b) The early arterial filling phase of the choriocapillaris, showing each lobule of the choriocapillaris (supplied by the terminal choroidal arteriole) forming a big fluorescent spot. Each spot is surrounded by a polygonal unfilled zone, producing a mosaic pattern in the choriocapillaris. (c) Peak arterial filling phase. Note the extraordinarily well-defined mosaic pattern, in which each unit of the mosaic is an independent entity. Some isolated lobules remain unfilled or fill slowly. This suggests that there is no communication between adjacent lobules. (d) Venous phase of the choriocapillaris filling, showing a honeycomb pattern; the fluorescent pattern is the reverse of that seen in figure (b), that is, the fluorescent areas are nonfluorescent and vice versa. Reproduced from Hayreh, S. S. (1974). The choriocapillaris. *Graefe's Archives for Clinical and Experimental Ophthalmology* 192: 165–179.

located (1) between the PCAs, (2) between the SPCAs, (3) between anterior ciliary arteries and SPCAs, and (4) between adjacent vortex veins.

Between PCAs

Fluorescein fundus angiographic studies have clearly shown the presence of watershed zones between the various PCAs (**Figure 15**).

When there are two (medial and lateral) PCAs

As discussed above, the area of the choroid supplied by the medial and lateral PCAs shows marked interindividual variation, which must result in a wide variation in the location of the watershed zone between the two (**Figure 16**).

Figure 14 Fluorescein fundus angiogram of right eye of a rhesus monkey after occlusion of superior nasal and inferior temporal vortex veins, showing normal filling of superior temporal and inferior nasal quadrants of the choroid but incomplete filling of the quadrants with the occluded veins, and sharp borders between the complete and incomplete filling quadrants. Reproduced from Hayreh, S. S. (1973). *British Journal of Ophthalmology* 57: 217–238.

Figure 17 is a diagrammatic representation of some common locations of the watershed zone between the medial and lateral PCAs. The watershed zone may be situated temporal to the peripapillary choroid, or pass through the temporal

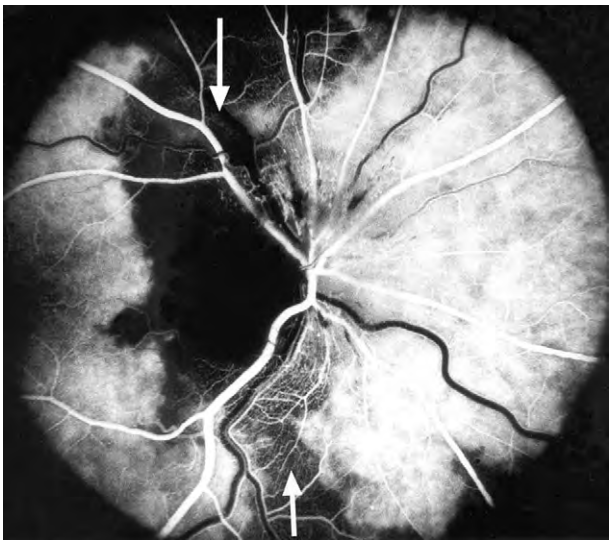

Figure 15 Fluorescein fundus angiogram of right human eye showing nonfilling of the choroidal watershed zone (arrows, vertical dark band) between the lateral and medial PCAs and of the temporal part of optic disk. Reproduced from Hayreh, S. S. (1985). *Documenta Ophthalmologica* 59: 217–246.

peripapillary choroid, one or the other part of the optic disk or medial peripapillary choroid, or the entire optic disk may lie in the watershed zone. There may even be various combinations of the above.

In our fluorescein fundus angiographic studies in eyes with glaucomatous optic neuropathy, where we could outline the watershed zone, we found the incidence of the various locations of the watershed zone as shown in Figure 18; the most common (60%) site was the temporal part of the optic disk and the adjacent peripapillary choroid.

When there are three or more PCAs

The location of the watershed zones varies according to the number of the PCAs and their locations. Figure 19 shows diagrammatically the various combinations of watershed zones, which can occur when an eye has more than two PCAs. The watershed zone filling defect may involve only the upper (Figure 20(a)) or the lower half (Figure 20(b)) of the vertical watershed zone.

Between SPCAs

Figures 9 and 21 are a diagrammatic representation of the watershed zones between the various SPCAs, as revealed by our fluorescein angiographic studies in experimental occlusion of the temporal SPCAs in rhesus monkeys. The area supplied by each SPCA has a well-defined margin, with watershed zones situated between adjacent SPCAs. All the temporal SPCAs enter the eyeball in the macular region and spread out radially to the periphery of the fundus to supply the temporal half of the choroid (Figure 21). It is, therefore, natural that most of the segments of the choroid supplied by the temporal SPCAs and their watershed zones meet in the macular region (Figures 9 and 21). This was a consistent pattern in our studies. It is well established that an area where numerous watershed zones meet is usually an area of comparatively poor vascularity and in the event of circulatory insufficiency, most vulnerable to ischemia.

Between the Anterior Ciliary and SPCAs

This is located in the equatorial region of the choroid (Figure 21). Experimental and clinical studies showed no anastomoses between SPCAs and anterior ciliary arteries. This is because (1) there is no choroidal filling from anterior ciliary arteries when there is PCA occlusion, and (2) when there is anterior ciliary artery occlusion, the normal blood flow in the PCAs does not prevent the development of anterior segment ischemia. Reticular pigmentary degeneration in the location of this watershed zone is not uncommon in elderly patients with severe carotid artery disease, arteriosclerosis, and other conditions associated with vascular insufficiency.

Between the Vortex Veins

Experimental studies on vortex vein occlusion in rhesus monkeys have revealed that the various vortex veins show no free anastomoses (Figure 14), and that the watershed zones between the four vortex veins extend antero–posteriorly through the entire length of the uveal tract – a horizontal watershed zone between the upper and lower vortex veins passes through the optic disk and macular region, while a vertical watershed zone between the temporal and nasal vortex veins passes between the optic disk and macular region (Figure 23).

What then is the clinical significance of all this information about the watershed zones of the PCAs and SPCAs?

Clinical Importance of Watershed Zones Between the PCAs

Role of the watershed zone in relation to the optic disk in the production of anterior ischemic optic neuropathy and other ischemic disorders of the optic nerve head. Since the PCA circulation is the main source of blood supply to the optic nerve head, the location of the watershed zone between the PCAs is crucial in ischemic disorders of the optic nerve head. Our studies indicate that the location of the watershed zone contributes toward the vulnerability of the corresponding part of the optic nerve head to ischemia. If the watershed zone is located away from the optic disk (Figure 16(a)), the optic nerve head is comparatively less

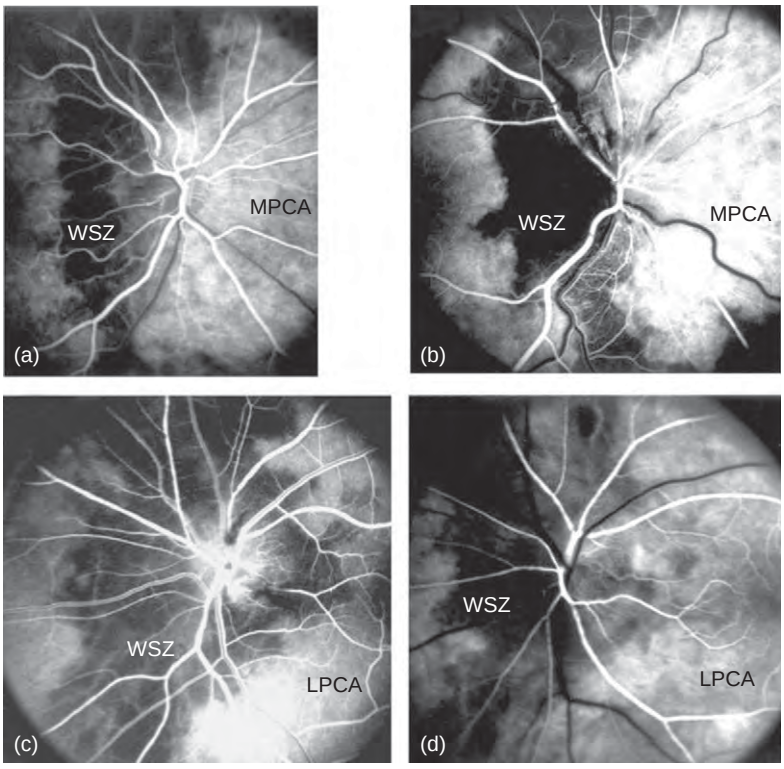

Figure 16 Fluorescein fundus angiograms of four human eyes, showing different locations of the watershed zone (WSZ, vertical dark bands) in relation to the optic disk. Watershed zone lying temporal to the optic disk in (a), passing through the temporal part of the optic disk and adjacent peripapillary choroid in (b), and passing through the nasal part of the disk and adjacent peripapillary choroid in (d), and with the optic disk lying in the center of the watershed zone in (c). vulnerable to ischemia than if the watershed zone passes through it (**Figures 16(b)** and **16(d)**). Conversely, the part of the optic disk that lies in the watershed zone is more vulnerable to ischemia than the part that does not. Furthermore, when the entire optic disk lies in the center of a watershed zone (**Figure 16(c)**), that disk is particularly vulnerable to ischemia. The marked variation in the location of the watershed zone in relation to the optic disk produces a marked interindividual variation in the susceptibility to ischemia of optic nerve head.

Importance of the location of multiple watershed zones of the SPCAs in the macular choroid and its possible role in production of various macular ischemic lesions. As discussed above, all the temporal SPCAs pierce the sclera and join the choroid in the macular region, and then run radially toward the equator (**Figures 21** and **22**), so that the apical parts of the various segments supplied by the SPCAs meet each other in the center of the macular region (**Figures 9, 10** and **21**). Therefore, the watershed zones between the several SPCAs meet in the macular region. As already noted, an area

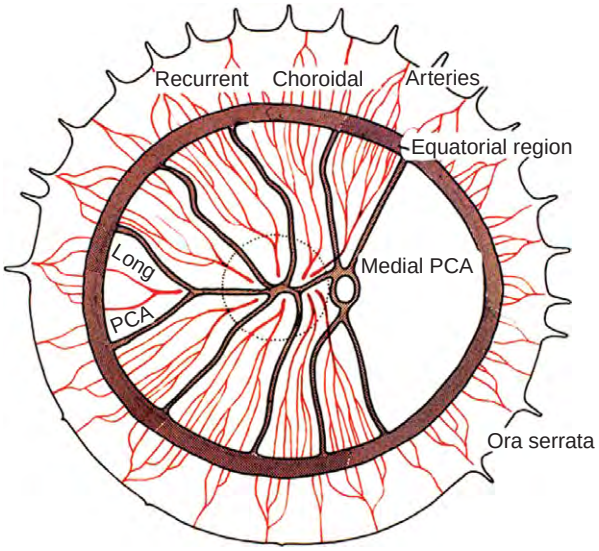

Figure 21 Diagrammatic representation of the distribution by the various ciliary arteries in the choroid and their watershed zones. The choroid posterior to the equator is supplied by the medial and lateral PCAs. In the area supplied by the lateral PCA, the segments supplied by the various short PCAs and the one by the long PCA are shown, with the watershed zones between them (dotted circle in this area indicates the macular region). Recurrent choroidal arteries from the anterior ciliary arteries and supposedly the greater arterial circle of the iris supply in front of the equator. The watershed zone between the anterior and posterior choroidal arteries lies in the equatorial region. Reproduced from Hayreh, S. S. (1981). *Ophthalmologica* 183: 11–19.

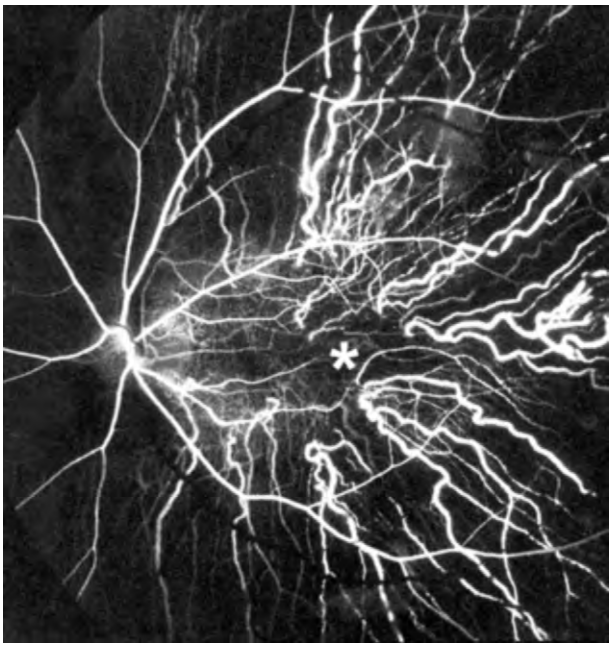

Figure 22 Fluorescein fundus angiogram of a normal human eye, showing the sites of entry of the short PCAs and their radiating course in the choroid. Star marks the center of the macular region. Note that no artery lies in the center of the macular region. Reproduced from Hayreh, S. S. (1983). Physiological anatomy of the choroidal vascular bed. *International Ophthalmology* 6: 85–93.

where multiple watershed zones meet is an area of poor vascularity and most vulnerable to ischemic disorders. There is further evidence suggesting that the macular choroid is more vulnerable to ischemic disorders than other parts of the choroid. For example:

1. In experimental studies on malignant arterial hypertension in rhesus monkeys, choroidal ischemic lesions were most prominent in the macular region and fluorescein fundus angiography revealed a marked, selective delayed filling of the macular choroid, particularly its central part (**Figures 24(a)** and **24(b)**).
2. In experimental studies in rhesus monkeys, when the perfusion pressure in the ocular vessels was reduced, fluorescein angiography revealed delayed filling of the watershed zones in the macular choroid, and of the central choriocapillaris (**Figure 25**).
3. There have been reports of selective localized senile atrophy of the choriocapillaris and in some cases even of large choroidal vessels, in the macular choroid.

In the light of all this information, it is quite logical that in eyes with marked generalized atherosclerosis and arteriosclerosis of the choroidal vessels, the macular choroid would be most vulnerable to ischemic disorders, by virtue of the numerous watershed zones meeting in that location. Similarly, eyes with generalized chronic choroidal ischemia often display a reticular pigmentary degeneration in the equatorial region (the region of the equatorial watershed zone between the anterior and posterior ciliary circulation; **Figure 26**), particularly on the nasal side.

In conclusion, watershed zones may play an important role in making that part of the choroid or the optic nerve head more vulnerable to ischemic lesions. The clinical importance of this is that watershed zone(s) between the PCAs may play a role in ischemic disorders of the optic nerve head, for example, anterior ischemic optic neuropathy and glaucomatous optic neuropathy. Watershed zones between SPCAs may play a role in some macular lesions, for example, macular involvement by hypertensive choroidopathy and probably age-related macular degeneration.

Submacular Choroid

Because of the well-known localized involvement of the macular region in a large number of conditions, a good deal of interest has centered on the submacular choroid. In spite of some claims that there may be a special macular artery, all the available evidence is against the existence of any such artery. All the temporal SPCAs enter the eyeball in the macular region and each artery then radiates toward the periphery, similar to the spokes of a wheel

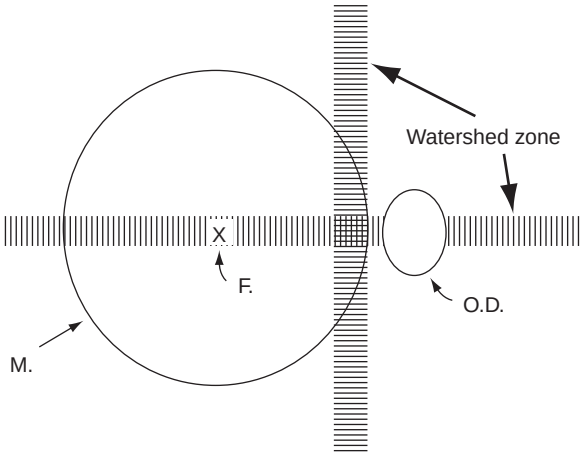

Figure 23 Diagrammatic representation of vertical and horizontal watershed zones between the various vortex veins in rhesus monkeys. F and X, foveola; M, macular region; OD, optic disk. Reproduced from Hayreh, S. S. (1974). Submacular choroidal vascular pattern. *Graefe's Archives for Clinical and Experimental Ophthalmology* 192: 181–196.

(**Figures 21** and **22**); each one of the SPCAs in the macular region gives branches to the submacular choriocapillaris. The sites of entry of the various SPCAs are usually situated some distance away from the center of the macular region (**Figure 22**), and each artery, near its site of entry, gives recurrent centripetal macular branches, which together supply the macular region. Each temporal SPCA supplies a segment of the choroid, with no anastomoses between adjacent segments (**Figures 10(a)–10(c)**). Most of the segments and their watershed zones meet in the macular region (**Figures 9** and **21**). Similarly, the four quadrants of the uveal tract drained by the four vortex veins and their watershed zones meet in the macular region (**Figure 23**). It has been consistently stated that the submacular choroid has a more abundant arterial supply than other parts of the choroid. This impression is based essentially on the fact that the submacular choroid is much thicker than elsewhere. This is because all the temporal SPCAs pierce the sclera in the macular region to join the choroid in the submacular choroidal region (**Figure 22**), and are thus

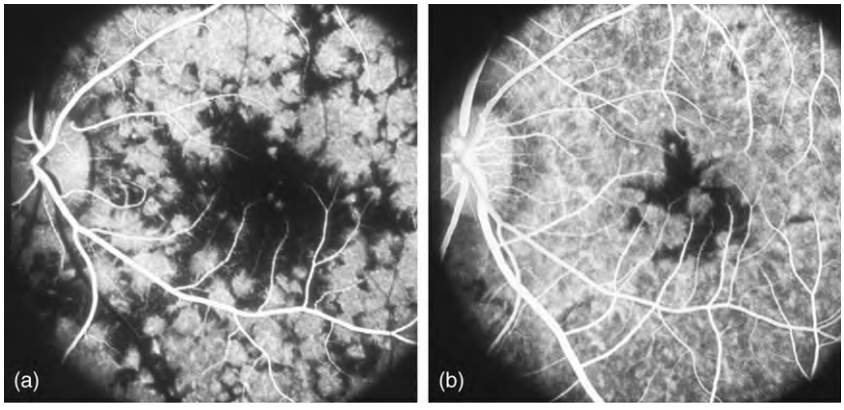

Figure 24 Fluorescein fundus angiograms of left eye of a rhesus monkey with malignant arterial hypertension, during (a) arterial and (b) late venous phases, showing marked delay (dark area) in filling of the submacular choroid. (1981). *Ophthalmologica* 183: 11–19.

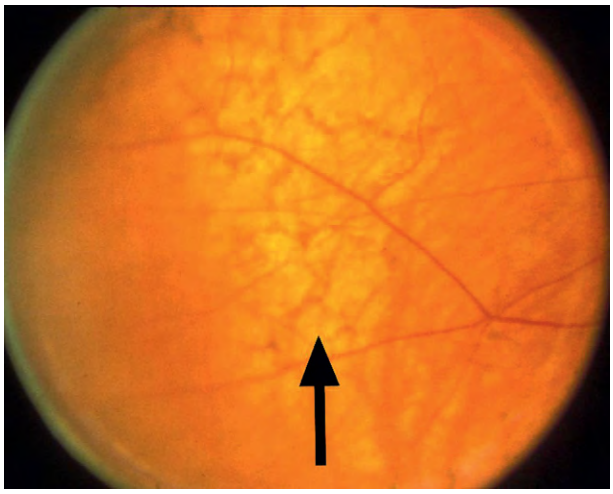

Figure 26 Reticular pigmentary degeneration (arrow) in the equatorial region of a patient with age-related macular degeneration. The pigment accumulates in lines forming irregular polygons. Reproduced from Hayreh, S. S. (1981). *Ophthalmologica* 183: 11–19.

aggregated together in this region. A mere increase in the number of arteries in the submacular choroid does not increase the blood supply and nutrition to that area. Terminal choroidal arterioles supplying the macular choriocapillaris are usually short, vertical, and enter the choriocapillaris perpendicularly and abruptly as compared to those going to the choriocapillaris in the peripheral choroid. This anatomical peculiarity of the submacular terminal choroidal arterioles would make the macular choriocapillaris much more vulnerable to embolism than the peripheral choriocapillaris.

Peripapillary Choroid

The peripapillary choroid is a very important part of the choroidal vascular bed since it is the main source of blood supply to the prelaminar and retrolaminar parts of the optic nerve (**Figure 3**). The branches supplying the optic nerve head arise essentially from the arteries in the peripapillary choroid and not from the choriocapillaris which stop abruptly at the disk margin. The peripapillary choroid is supplied by branches from the SPCAs. Similar to the rest of the choroid, postmortem cast studies have consistently shown free anastomoses in the peripapillary choroidal arteries so as to form a continuous vascular network. Experimental and clinical *in vivo* fluorescein fundus angiographic studies, however, have clearly demonstrated the segmental nature of the peripapillary choroid (**Figures 16(b)–16(d)** and **20(a)** and **20(b)**), which explains the segmental occurrence of anterior ischemic optic neuropathy.

Physiological Anatomy of the Retinal Vasculature

S S Hayreh, University of Iowa, Iowa City, IA, USA

Glossary

Blood flow autoregulation – The property of a tissue or an organ (i.e., retina) to maintain constant blood flow during changes in perfusion pressure.
Blood–retinal barrier – The system of occluding cellular junctions in the retinal pigmented epithelium and retinal vascular endothelium that prevents free movement of fluid and macromolecules from the blood into the retina.
Cilioretinal artery – A retinal artery which arises from the choriod or the posterior ciliary artery, and is found as a variant in some individuals.
Cotton wool spots – White patches on the retina observed on fundus examination and are caused by local obstruction of the tiny arteries supplying that area.
Fluorescein fundus angiography – Fundus photographs taken in rapid sequence following injection of the fluorescent dye, fluorescein. This provides important information about blood flow as the dye reaches the retinal and choroidal vasculature.

The retina has a dual blood supply; the retinal vasculature supplies only the inner retinal layers up to the inner part of the inner nuclear layer (**Figure 1**), while the choroidal vascular bed supplies the outer 130 μm – up to the outer part of the inner nuclear layer, so that retinal vessels supply only 20% of the retina while the choroid supplies 80%. In this article, the discussion is restricted to the retinal component.

Arterial Supply of the Retina

The main arterial supply of the retina is by the central retinal artery (CRA). In some eyes, another artery, called the cilioretinal artery, may supply a highly variable part of the retina.

Central Retinal Artery

The CRA is usually the first branch of the ophthalmic artery, arising as an independent branch or in common with one of the posterior ciliary arteries (**Figure 2**). Its course can be divided into three distinct parts: (1) intra-orbital (lying below the optic nerve (ON) – (**Figure 2**)), (2) intravaginal (lying in the space between the ON and its sheath), and (3) intraneural (lying in the ON) (**Figure 3**). It enters the ON about 10 mm posterior to the eyeball (**Figures 2** and **3**). A variable number of branches arise from each of its three parts, which anastomose with the surrounding branches from other arteries, mostly in the pial plexus of the ON (**Figure 3**). At the optic disk, the CRA usually first divides into two and then each of them further divides into its various branches (**Figure 4**). The lumen of the intraneural part of the CRA is approximately 200 μm.

Cilioretinal Artery

The cilioretinal artery is either a direct branch of one of the posterior ciliary arteries or arises from the peripapillary choroid and enters the retina by hooking around the Bruch's membrane at the disk margin – usually on the temporal side (**Figures 3** and **5**). Based on ophthalmoscopy, the incidence of the occurrence of the cilioretinal artery reported by different authors varies from 6% to 25%. However, fluorescein fundus angiography provides the most reliable data because the cilioretinal artery fills synchronously with the choroidal filling, which usually starts to fill before the retinal circulation (**Figure 6(a)**). An artery which, on ophthalmoscopy, may look similar to a cilioretinal artery may in fact be an intraneural branch of the CRA emerging at the optic disk – not a true cilioretinal artery. A fluorescein fundus angiographic study of 2000 eyes showed one or more cilioretinal arteries in 32% of the eyes and in both eyes in 15% of persons. There is great variability in size, number, and distribution of the cilioretinal arteries. The area of the retina supplied by the cilioretinal arteries varies markedly, from a tiny region to a large sector of the retina. Eyes where one-fourth to half of the retina is supplied by a cilioretinal artery have been observed (**Figure 6(a)**). Rarely, the CRA is missing and the entire retina is supplied by the cilioretinal artery (**Figure 6(b)**). The outer part of the entire retina is always supplied by the posterior ciliary artery. When a cilioretinal artery is present, in the part of the retina supplied by it, the entire thickness of the retina receives its blood supply from the posterior ciliary artery.

The blood flow in the retinal vascular bed depends upon the perfusion pressure, which is equal to the difference

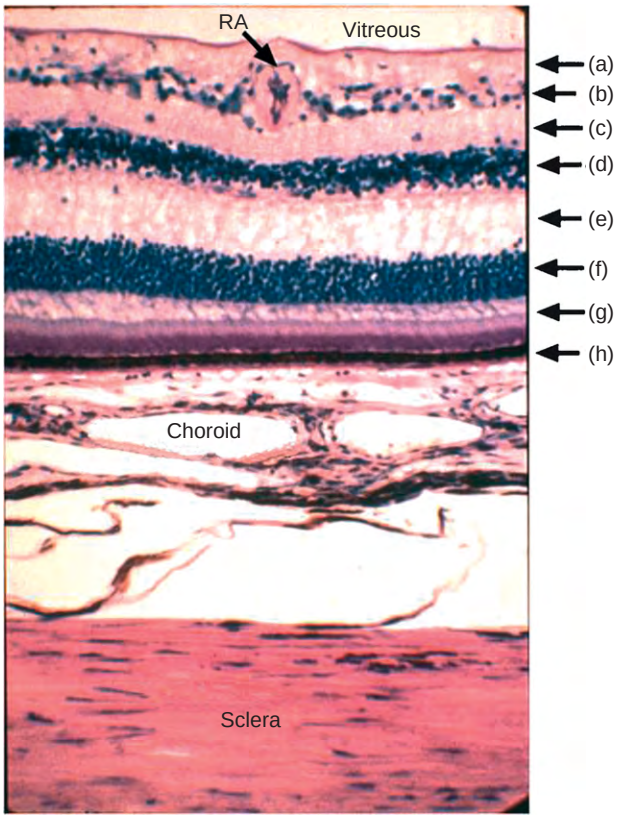

Figure 1 Light micrograph of the retina, choroid, and sclera. The retinal layers are identified as: (a) nerve fiber layer; (b) ganglion cell layer; (c) inner plexiform layer; (d) inner nuclear layer; (e) outer plexiform layer; (f) outer nuclear layer; (g) rod and cone layer; and (h) retinal pigment epithelial layer. RA, retinal arteriole.

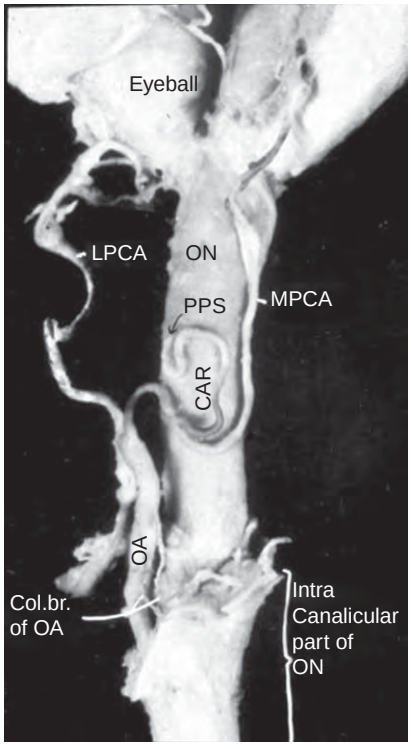

Figure 2 View from under surface of the human eyeball and optic nerve (ON) showing central artery of the retina (CAR) and its site of penetration into the optic nerve sheath (PPS), medial (MPCA) and lateral (LPCA) posterior ciliary arteries, and ophthalmic artery (OA). between the retinal arterial and venous pressures. The CRA and cilioretinal artery belong to two arterial systems with different physiological properties. This raises an important physiological issue in eyes with a cilioretinal artery when that eye develops central retinal vein occlusion in which the retinal venous pressure rises suddenly to a high level. The CRA arises directly from the ophthalmic artery and the retinal vascular bed supplied by it has an efficient blood flow autoregulation (see below), so that when there is a fall in perfusion pressure in the retinal arterial bed, caused by a rise in the retinal venous pressure, the autoregulatory mechanism in the central retinal arterial vascular bed kicks in trying to maintain retinal circulation. By contrast, the cilioretinal artery belongs to the choroidal vascular system, which has no autoregulation, so that when the venous pressure rises, there is no corresponding compensatory autoregulatory mechanism. Moreover, the perfusion pressure in the choroidal vascular bed normally is lower than that in the CRA, and there is no corresponding rise of pressure in the choroidal venous bed. In view of all these factors, the following scenario occurs in an eye with cilioretinal artery developing central retinal vein occlusion: sudden occlusion of the central retinal vein results in a marked rise of intraluminal pressure in the entire retinal capillary bed; when that intraluminal pressure rises above the pressure in the cilioretinal artery, the result is a hemodynamic block in the cilioretinal artery, producing cilioretinal artery occlusion (**Figure 7**).

Intraretinal Branches of the CRA

Each of the two main branches (superior and inferior) of the CRA at the optic disk usually divides into temporal and nasal branches, which supply the four quadrants of the retina (**Figure 4**); however, there is marked variation in their vascular pattern. In the retina, the arrangement of the branches and their subdivisions is highly variable, so much so that each eye has a different pattern (**Figures 4** and **7**). It has been suggested that the pattern could be used for personal identification like a finger print. Usually, there is a dichotomous or right-angle branching pattern. The various branches, by multiple divisions, finally end in terminal or precapillary arterioles, which are usually not visible on ophthalmoscopy. Terminal arterioles play an important role in the regulation of retinal blood flow by constriction or dilatation.

There has been a controversy about the true nature of the arteries in the retina. According to some accounts these are small arteries. Others, however, consider them as arterioles after the first branching in the retina because they possess the following anatomic properties, typically seen in arterioles: (1) the widest part of the lumen of the retinal arterioles is near the optic disk and there its diameter is about 100 µm, which is typically the diameter of an arteriole; and (2) unlike arteries, they possess neither an internal elastic lamina nor a continuous muscular coat. This differentiation from the arteries is important in understanding their pathological involvement in some diseases, such as giant cell arteritis. In the retina, there are no interarterial or arteriovenous anastomoses, so that the retinal vascular bed is an end-arterial system.

These intraretinal arterial branches mainly lie in the nerve fiber and ganglion cell layer, usually under the internal limiting membrane (**Figure 1**); however, at the arteriovenous crossing they may extend down to the inner nuclear layer.

Figure 4 Normal human fundus – left eye.

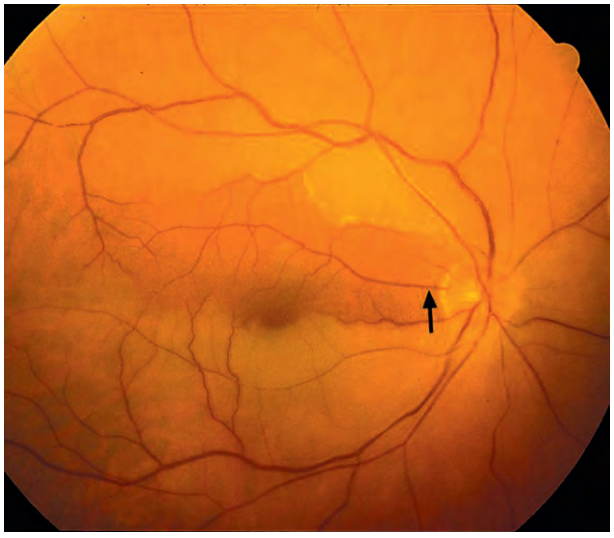

Figure 5 Ophthalmoscopic appearance of right eye with central retinal artery occlusion (pale retina) and a normal cilioretinal artery in the area of normal retina (arrow).

Retinal Capillary Bed

Each terminal arteriole gives out a plexus of 10–20 interconnected capillaries (**Figure 8**). Capillaries lie between the feeding arterioles and venules (**Figure 8**). Around the retinal arteries, there is a capillary-free zone (**Figure 8**). The retinal capillaries are arranged in two layers (**Figure 9**): (1) a superficial layer in the ganglion cell and nerve fiber layers, and (2) a deeper layer in the inner nuclear layer which is denser and more complex than the superficial layer. However, in the posterior retina, there may be three layers in the peripapillary region and there is only one layer in the perifoveal region. Furthermore, in the peripheral retina the deep layer disappears and only the superficial layer is left, with a wider network. At the extreme periphery of the retina, there is an avascular zone about 1.5 mm width.

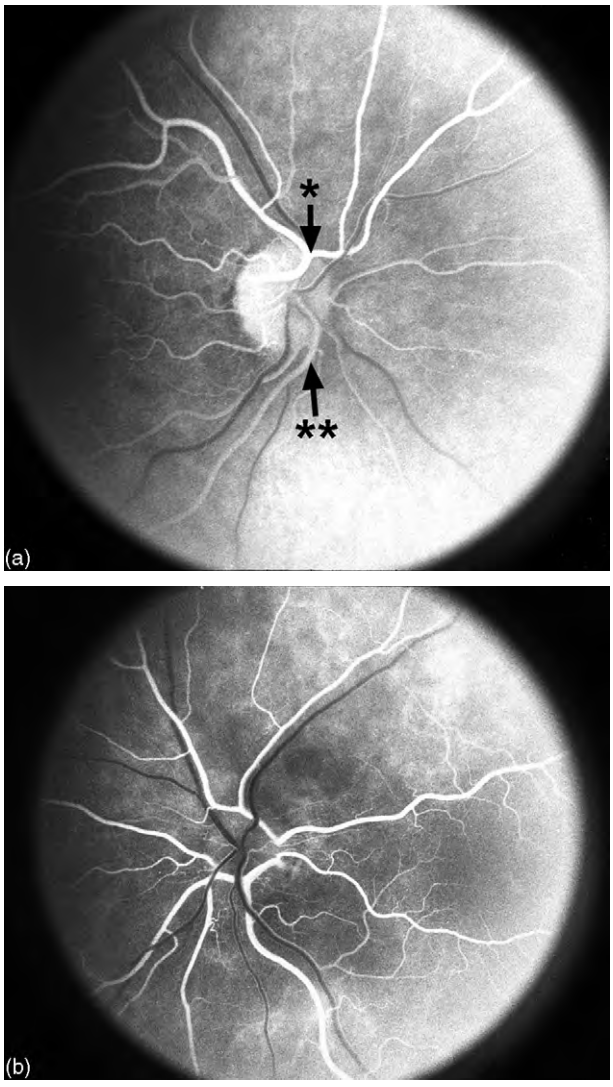

Figure 6 Fluorescein fundus angiograms of (a) right and (b) left eyes of a person. (a) The right eye has one large cilioretinal artery (one asterisk) supplying the superior one-third of the retina that starts to fill before the central retinal artery (two asterisks) which supplies the rest of the retina. (b) The left eye has two large branching cilioretinal arteries (white) – the one above branches in the upper half and the other below branches in the lower half. This eye lacks a central retinal artery.

Figure 7 Fundus photograph of right eye with nonischemic central retinal vein occlusion associated with cilioretinal artery occlusion (arrow).

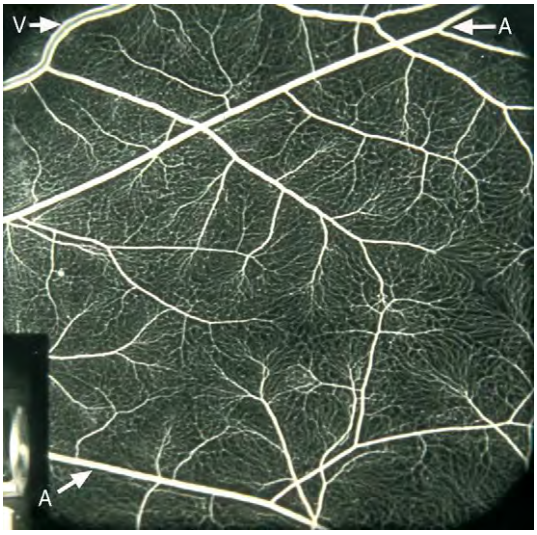

Figure 8 Fluorescein fundus angiogram showing retinal vessels and capillary network. A, retinal arteriole; V, retinal vein.

In addition to the retinal capillary bed described above, there is a distinct retinal capillary bed called the radial peripapillary capillaries, which were first described in 1940 (**Figures 9** and **10**). They have the following special characteristics compared to other retinal capillaries:

1. They are long, straight capillaries, measuring several hundred microns to several millimeters.
2. They form the most superficial layer (**Figure 9**) lying among the superficial nerve fibers, along the superior and inferior temporal arcades of retinal vessels and the peripapillary region (**Figure 10**).
3. They rarely anastomose with one another.
4. They arise from the peripapillary retinal arterioles lying deeper in the retina, and drain into retinal venules or veins on the optic disk (**Figure 3**).

Because of these characteristics, the radial peripapillary capillaries assume importance in the development of several lesions. For example, cotton wool spots are often located in the distribution of the radial peripapillary capillaries, which indicates that the latter may play a role in the pathogenesis of cotton wool spots. In addition, in chronic optic disk edema these capillaries become dilated and develop microaneurysms and hemorrhages.

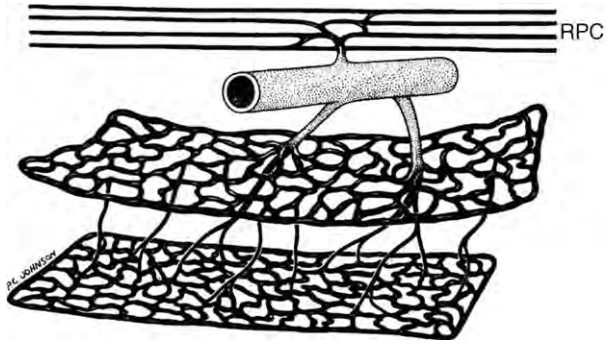

Figure 9 Schematic representation of two layers of the retinal capillaries and radial peripapillary capillaries (RPC). Reproduced with permission from Henkind, P. (1969). Microcirculation of peripapillary retina. *Transactions of the American Academy of Ophthalmology and Otolaryngology* 73: 890–897.

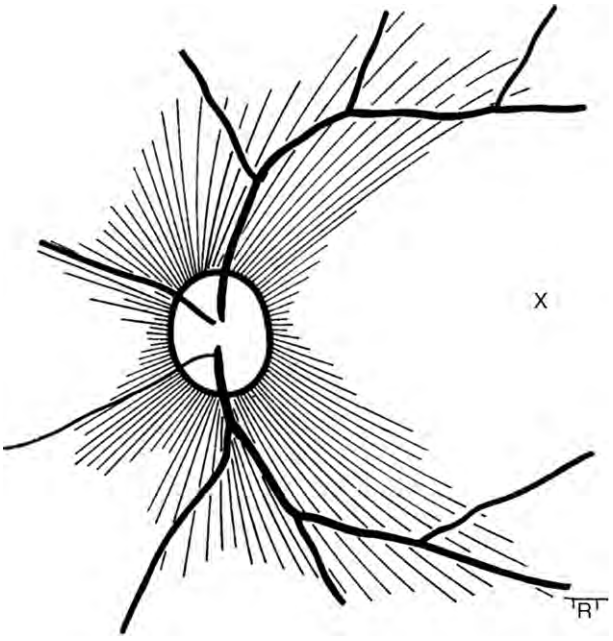

Figure 10 Schematic representation of radial peripapillary capillaries. Site of foveola (X). Reproduced with permission from Henkind, P. (1967). Radial peripapillary capillaries of the retina: I. Anatomy: Human and comparative. *British Journal of Ophthalmology* 51: 115–123.

In the macular region, the capillaries are supplied by arterioles arising from the superior and inferior temporal arteries (**Figure 4**). Their thickness decreases toward the center of the macula where they are arranged in a single layer. The capillaries are absent in the foveal region, with a capillary-free zone of about 400–500 μm in diameter (**Figure 11**).

The wall of the retinal capillaries consists of endothelial cells, pericytes, and basement membrane. Their diameter varies from 3.5 to 6 μm. The endothelial cells have

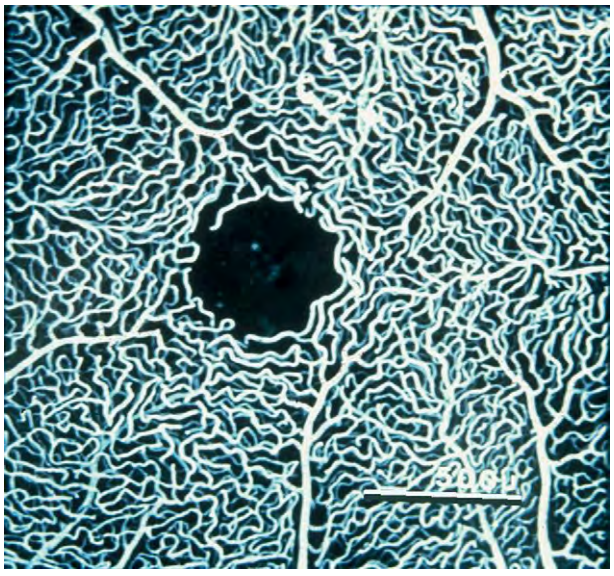

Figure 11 A cast of retinal capillaries in the macular region of a monkey showing the foveal avascular zone in the center. Courtesy of Professor Koichi Shimizu.

tight-cell junctions, which constitute a blood–retinal barrier (see below). In addition to the endothelial cells, there are also pericytes which form a discontinuous layer within the basement membrane of the capillaries. They have a contractile property, by virtue of which they may play a role in regulating blood flow in the capillaries and autoregulation of blood flow (see below). Pericytes are lost preferentially in diabetes so that they may have a role in diabetic retinopathy; it is suggested that diabetic pericyte loss is the result of their migration. Migration of pericytes is also involved in the regulation of angiogenesis.

Retinal Venous Drainage

The postcapillary venules drain the blood from the capillaries but, occasionally, capillaries may join a major vein directly. The terminal arterioles and postcapillary venules are situated in an alternating pattern, with the capillary bed in between the two (**Figure 8**). The postcapillary venules drain into bigger venules and finally into the branch retinal veins. The lumen of the major branch retinal veins, just before they join to form the central retinal vein, is about 200 μm. In the central part of the retina, the branch retinal veins and arteries usually run in close association and at places cross one another (**Figures 4, 5,** and **7**). On the other hand, in the peripheral retina, the veins do not follow the course of the arteries. Various retinal arteries and veins in the retina cross each other at arteriovenous crossings (**Figures 4, 5,** and **7**). In a study of 189 normal eyes, at the sites of arteriovenous crossing, the artery crossed over the vein in 68% and was the reverse

in the remainder. However, in eyes with branch retinal vein occlusion, the artery crossed over the vein at the site of occlusion in 98% of the cases, indicating that pattern of arteriovenous crossing plays a role in the development of branch retinal vein occlusion. At the site of arteriovenous crossing, the artery and vein share a common fibrous coat and are separated by only a thin endothelial lining and basement membrane.

The superior branch veins usually join to form a superior trunk and the inferior branch veins, an inferior trunk. These superior and inferior trunks join on the optic disk to form the central retinal vein (**Figure 3**). However, in 20% of eyes, the superior and inferior trunks do not join together at the disk but enter the optic disk as two separate trunks; this represents a congenital anomaly (**Figure 12**). During the third month of intrauterine life, there are always two trunks of the central retinal vein in the ON, one on either side of the CRA (**Figure 13**), and one of the two trunks usually disappears before birth; however, in 20% of eyes, a dual-trunked central retinal vein persists into adult life. In such eyes, only one of the two trunks may develop occlusion in the ON, resulting in development of the clinical entity called hemi-central retinal vein occlusion (**Figure 12**).

The central retinal vein travels in the ON temporal to the artery, where the central retinal vein and artery lie in the center of the ON, surrounded by a fibrous tissue envelope (**Figure 14**). During its intraneural course, the vein receives many tributaries (**Figure 3**). The central retinal vein exits the ON and its sheath (**Figure 15**), and finally drains into either the superior ophthalmic vein or directly into the cavernous sinus.

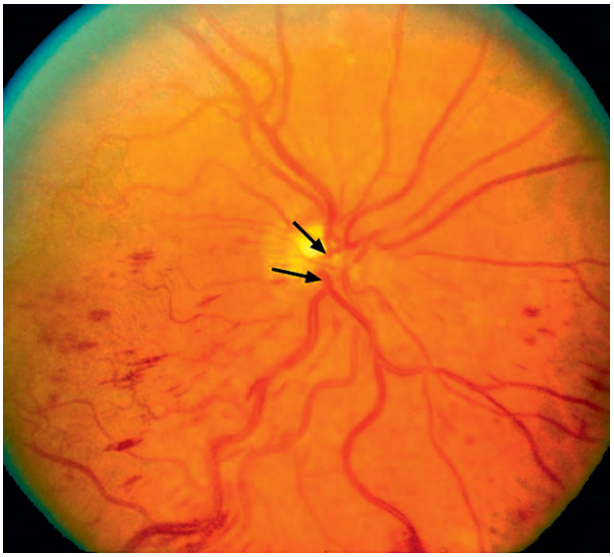

Figure 12 Fundus photograph of an eye with inferior hemicentral retinal vein occlusion, involving the lower trunk of the central retinal vein. Two trunks (arrows) of the central retinal vein enter the optic disk separately above and below.

Nerve Supply

The intraorbital and intraneural portions of the CRA have an adrenergic nerve supply from a sympathetic nerve called the nerve of Tiedemann (**Figure 16**); however, the retinal branches of the CRA have no adrenergic nerve supply. Therefore, there is no autonomic innervation of the retinal vascular bed.

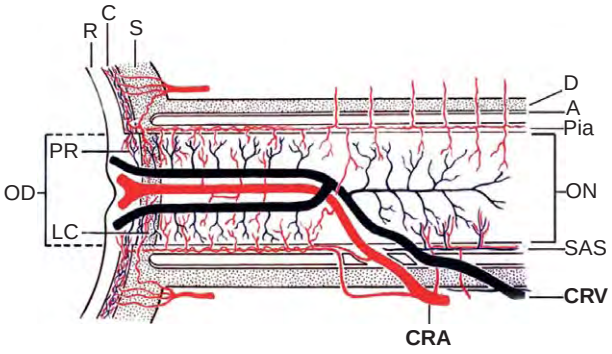

Figure 13 Schematic representation of two trunks of the central retinal vein in the anterior part of the optic nerve. A, Arachnoid; C, choroid; CRA, central retinal artery; Col. Br., collateral branches; CRV, central retinal vein; D, dura; LC, lamina cribrosa; OD, optic disc; ON, optic nerve; PCA, posterior ciliary artery; PR, prelaminar region; R, retina; S, sclera; SAS, subarachnoid space.

Blood–Retinal Barrier

The retina has two types of blood–retinal barriers.

Inner blood–retinal barrier. This lies in the retinal vessels. It is produced by the tight cell junctions between the endothelial cells of the vessels (due to the presence of extensive zonulae occludentes). The tight interendothelial cell junctions block movement of macromolecules from the lumen toward the interstitial space. Pericytes, Müller cells, and astrocytes also contribute to the proper functioning of this barrier.

Outer blood–retinal barrier. Tight cell junctions between the retinal pigment epithelial cells (**Figure 1**) also produce a blood–retinal barrier, preventing the leakage of fluid from the choroid into the retina. This barrier breaks down when the retinal pigment epithelial cells are destroyed or subjected to ischemia, as in hypertensive choroidopathy.

The blood–retinal barrier plays an important role in the regulation of the microenvironment in the retina. An intact blood–retinal barrier is essential for maintaining retinal structure and function. Breakdown of this barrier results in increased vascular permeability of the capillaries, which causes retinal edema, as seen in a variety of retinopathies. Breakdown of the inner blood–retinal barrier may be caused by acute distension of the vessel walls, ischemia, chemical influences, defects in the endothelial cells, or failure of the active transport system.

The retinal tissue itself has no barrier in its stroma, therefore fluid may diffuse from one part to the adjacent areas.

Autoregulation of Retinal Blood Flow

The object of blood flow autoregulation in a tissue is to maintain relatively constant blood flow during changes in perfusion pressure. This is an important mechanism to regulate blood flow. The retinal circulation has efficient autoregulation. The exact mechanism and site of autoregulation are still unclear except that it most probably operates by altering the vascular resistance. It is generally considered as a feature of the terminal arterioles; so with the rise or fall of perfusion pressure beyond normal levels, the terminal arterioles constrict or dilate, respectively, to regulate the vascular resistance and thereby the blood flow. Recent studies have suggested that pericytes in the retinal capillaries play a role in autoregulation as well because of their contractile property. The metabolic needs of the tissue also regulate the autoregulation. Autoregulation works within a critical range of perfusion pressure, and it breaks down with any rise or fall of the perfusion pressure beyond the critical autoregulatory range.

The vascular endothelium plays an active role in the vasomotor function of both macro- and microvasculatures, including maintenance of vascular tone and regulation of blood flow. Recent studies suggest that vascular-endothelial-derived vasoactive agents (e.g., endothelin-1, thromboxane A_2, and prostaglandin H_2 – vasoconstrictors; and nitric oxide – a vasodilator) profoundly modulate local vascular tone and, thereby, may also play a role in autoregulation. Mechanical stretching and increases in arteriolar transmural pressure induce the endothelial cells to release contracting factors affecting the tone of arteriolar smooth muscle cells and pericytes. Therefore, damage to vascular endothelium (as in arteriosclerosis, atherosclerosis, hypercholesterolemia, aging, diabetes mellitus, ischemia, and possibly from other causes) may be associated with abnormalities in the production of endothelial vasoactive agents, and consequent autoregulation abnormalities.

Physiology of Photoreceptor Synapses and Other Ribbon Synapses

W B Thoreson, University of Nebraska Medical Center, Omaha, NE, USA

Glossary

Ca^{2+} microdomains – Local submembrane regions of elevated intracellular Ca^{2+} caused by the influx of Ca^{2+} through nearby Ca^{2+} channels.
Calcium-induced calcium release (CICR) – Release into the cytoplasm of Ca^{2+} ions stored in the endoplasmic reticulum that is triggered by the Ca^{2+}-dependent activation of ryanodine receptors.
ERG b-wave – The electroretinogram (ERG) is a massed electrical response of the retina to light that can be recorded by electrodes on the surface of the cornea. ON bipolar cells provide the source of the b-wave of the ERG. A selective reduction in the b-wave indicates a reduction in signaling between photoreceptors and ON bipolar cells.
L-type calcium currents – Currents from high-voltage-activated CaV1.1 (alpha 1S), CaV1.2 (alpha 1C), CaV1.3 (alpha 1D), or CaV1.4 (alpha 1F) calcium channels which show sustained activation and can be selectively blocked by dihydropyridine antagonists.
OFF bipolar cells – Second-order retinal bipolar cells which exhibit a hyperpolarizing response to light mediated by non-NMDA ionotropic glutamate receptors.
ON bipolar cells – Second-order retinal bipolar cell subtypes which exhibit a depolarizing response to light mediated by mGluR6 metabotropic glutamate receptors.
Readily releasable pool – A pool of synaptic vesicles primed for rapid release by elevation of intracellular calcium.
SNARE proteins – SNAP and NSF attachment receptors are a family of proteins participating in vesicle fusion. They can be subdivided into vesicle SNAREs (v-SNAREs), which attach to vesicles, and target SNAREs (t-SNAREs), which associate with the plasma membrane.
Synaptic ribbon – An electron dense presynaptic structure that tethers synaptic vesicles in nerve terminals of sensory neurons including photoreceptors, retinal bipolar cells, hair cells, pinealocytes, and electroreceptors.
Total internal reflectance (TIRF) microscopy – By taking advantage of the subwavelength evanescent field of light created by reflections at the interface between a cell and coverslip, TIRF microscopy can be used to visualize subwavelength structures such as synaptic vesicles.

Anatomy of the Ribbon Synapse

Structures of the electron dense ribbons found at the synapses of retinal photoreceptors and bipolar cells differ depending on cell type. In cross section, photoreceptor ribbons appear as ~35 nm thick bars, but in three dimensions they form flat, ribbon-like structures. Mammalian rods have one to two ribbons that can be up to 2 μm in length and extend up to 1 μm into the cytoplasm. Each wraps around the synaptic ridge to form crescent or horseshoe shapes. The ribbons in mammalian cone are smaller, typically less than 1 μm long and extend only a few hundred nanometers into the cytoplasm. They are shaped like surfboards, and typically a dozen or more ribbons are in each cone terminal. Sitting just below the photoreceptor ribbon is a trough-like arciform density. Ribbons in bipolar cells are planar, like those in rods, but they are smaller than both rod and cone ribbons.

The focus of this review is on ribbon synapses in retina; however, ribbon synapses are not unique to retina. They are present in other sensory neurons, including pinealocytes, electroreceptors in the lateral line organ of fishes, and hair cells of the cochlea and vestibular apparatus. Again, the ribbons in the synapses of these cells have different structures depending on cell type. For example, hair cell ribbons are small spheres.

The ribbon synapses of photoreceptor terminals contain many more synaptic vesicles than conventional synapses. Conventional synapses have 10–100 vesicles near each presynaptic density compared to the synaptic terminal of a lizard cone, which contains ~170 000 vesicles or 7000 vesicles per ribbon. Furthermore, ~85% of the vesicles at ribbon synapses are freely mobile and readily participate in release compared to ~20% of vesicles at conventional synapses. The expanded mobility of vesicles at ribbon synapses may be due to the absence of synapsins which have been proposed to tether synaptic vesicles at conventional synapses. The small subset of vesicles in photoreceptor terminals that are tethered to synaptic ribbons are attached by fine filaments (**Figure 1**).

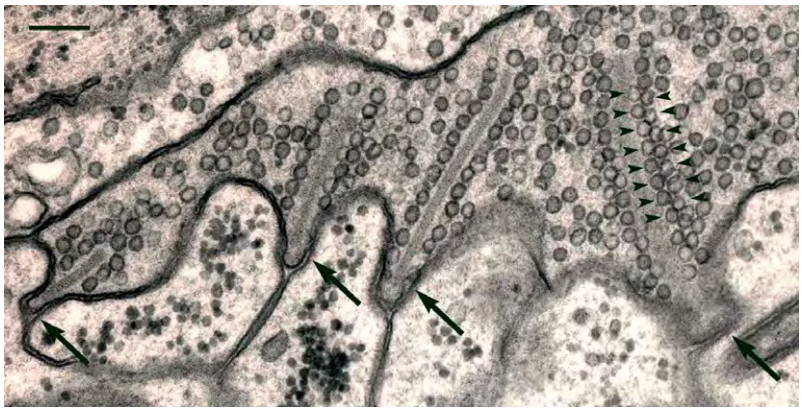

Figure 1 Ribbon-style active zones (arrows) in a salamander rod photoreceptor. A tangential section through the ribbon at right shows the hexagonal packing of vesicles on the ribbon (arrowheads). Scale = 200 nm. Adapted from Thoreson, W. B., Rabl, K., Townes-Anderson, E., and Heidelberger, R. (2004) A highly Ca^{2+}-sensitive pool of vesicles contributes to linearity at the rod photoreceptor ribbon synapse. *Neuron* 42: 595–605, with permission from Elsevier.

Vesicle Pools and Vesicular Release at Synaptic Ribbons

Newly tethered vesicles can be found throughout the ribbon, indicating that vesicles either freely enter the ribbon at any position or redistribute rapidly about the ribbon face after attachment. However, once attached to the ribbon, vesicles exit only from the base. Vesicles tethered on the bottom first to third rows of the ribbon contact the plasma membrane along the synaptic ridge. These vesicles constitute a pool that can be released rapidly in response to increased Ca^{2+} levels. In bipolar cells, the fastest component of vesicular release equals the number of vesicles tethered along the bottom row of the ribbon, and maintained depolarization stimulates release of the total number of vesicles lining the entire ribbon. Similarly, the total releasable pool in rod photoreceptors equals the number of vesicles tethered to the entire ribbon (~700 vesicles in amphibian rods), and there is an ultrafast component similar to the number of vesicles tethered at the ribbon base (~30 vesicles). Because of their smaller size, cone ribbons have a smaller releasable pool than rod ribbons.

In contrast with bipolar and photoreceptor cells, the ultrafast release component in hair cells exceeds the number of vesicles lining the bottom row by nearly 10-fold, and the total releasable pool exceeds the number of vesicles lining the ribbon six- to eightfold. The large ultrafast or rapidly releasable pool could be explained by compound fusion between adjacent vesicles as discussed later. The large size of the total pool suggests that vesicles released from the ribbon are replenished rapidly from the surrounding cytoplasm.

Vesicular transmitter release clearly occurs at the ribbons in ribbon synapses, but the ribbons may not be the only site of transmitter release. Photoreceptors also contact bipolar cell dendrites at flat or basal junctions identified by pre- and postsynaptic membrane densities. In mammalian retina, the basal junctions of cones only contact OFF-type bipolar cells and the dendrites of many OFF-type bipolar cells are not directly apposed to synaptic ribbons. In salamander retinas, the architecture of photoreceptor input to bipolar cells is different, and OFF bipolar cells receive ~80% of their contacts from ribbon synapses and only ~20% from basal junctions. On the other hand, salamander ON-type bipolar cells receive ~ 20% of their contacts from ribbons synapses and ~80% from basal junctions.

Basal junctions lack the vesicle clusters which typify conventional synapses; however, the absence in mammals of direct ribbon contacts onto many OFF bipolar cells led to the suggestion that they necessarily receive synaptic input from basal junctions. This idea was tested in experiments that compared synaptic events recorded simultaneously from two OFF bipolar cells – one that contacted photoreceptors only at basal junctions and a neighbor whose dendrites approach the ribbon. These studies showed that glutamate released at a synaptic ribbon can diffuse rapidly to bipolar cell processes at basal junctions. This finding shows that glutamate released at the ribbon can reach basal junctions, although it does not exclude the possibility of additional nonribbon release events.

The question of whether nonribbon release events occur in ribbon synapses has been addressed further by using total internal reflectance (TIRF) microscopy to visualize single-vesicle fusion events. Studies of release from bipolar cells indicate that up to 1/3 of fusion events occur at ectopic sites away from the ribbon including much of the release during sustained depolarization. Studies on hair cells from mice with disrupted ribbon anchoring also suggest a role for nonribbon sites in sustained release by showing that sustained release is unchanged although fast release is diminished. However,

in photoreceptors, as discussed later, there is evidence suggesting that sustained release occurs predominately at the ribbon.

Role of the Ribbon in Release

The functions of the ribbon in release are not fully understood. It has been widely suggested that the ribbon may operate like a conveyor belt, acting as a molecular motor to accelerate delivery of vesicles to their release sites. Consistent with this possibility is the presence of a kinesin motor protein, KIF3A, at the ribbon. However, release of vesicles attached to the ribbons does not require ATP, although ATP is needed for subsequent replenishment and priming of vesicles. Ribbons are also not necessary for sustaining high-frequency release since it can be observed at conventional central nervous system (CNS) synapses without ribbons. In fact, during sustained release from photoreceptor ribbons, the delivery of vesicles to the base of the ribbon is actually slower than the rate predicted from delivery by simple diffusion. Thus, rather than accelerating release, synaptic ribbons in cones appear to slow the rates of sustained release by constraining the rate of vesicle delivery to the base. By making release more regular, such a mechanism could improve the ability to detect small intensity changes that produce small changes in release rate.

Another hypothesis of ribbon function is that it may operate as a vesicle trap. In this scenario, vesicles moving about the terminal by Brownian motion occasionally collide with the ribbon face where they are captured like flies to fly paper and then delivered to the base for release.

Ribbons may assist in vesicle priming. The match between releasable pool size and the number of vesicles tethered to rod or bipolar cell ribbons indicates that tethered vesicles are primed for release. Furthermore, members of the RIM family of proteins involved in vesicle priming localize to the ribbon. RIM proteins are synaptic proteins required for normal neurotransmitter release.

Another proposed role for the ribbon is to facilitate compound fusion during depolarization by promoting fusion between neighboring vesicles on adjacent rows of the ribbon. Compound fusion could explain the finding in hair cells that many more vesicles fuse rapidly after stimulation than are anchored at the base of the ribbon. The possibility of compound fusion in hair cells is supported by statistical properties of fluctuations in postsynaptic currents and presynaptic exocytotic capacitance changes. There is also ultrastructural and electrophysiological evidence for compound or coordinated fusion of multiple vesicles at bipolar cell synapses.

Ribbons may perform more than one of these functions. They may capture vesicles, prime them for release, regulate their delivery to release sites, and facilitate compound fusion. To sort out the unique functions of ribbons and ribbon synapse, the biochemistry and electrophysiological properties of ribbon synapse are being studied in detail.

Synaptic Proteins

Ribbon synapses contain many of the same proteins as conventional synapses. For example, conventional and ribbon synapses both employ SNARE proteins in vesicle fusion: synaptobrevin (VAMP1 and 2), SNAP-25, and syntaxin. Ribbon synapses also possess Munc 18-1, Munc 13-1, RIM, and rab3A proteins which assist with assembly of the SNARE complex and vesicle priming. RIM1 is distributed across the ribbon, whereas RIM2 localizes to the ribbon base, suggesting that they may have different roles.

In addition to many similarities, there are also differences among the proteins at ribbon and conventional synapses. In place of syntaxin-1 found at many conventional synapses, ribbon synapses utilize syntaxin-3b. In place of complexins 1 and 2 that interact with the SNARE complex at many synapses, ribbon synapses possess complexins 3 and 4. Ribbon synapses lack synapsins. The functional consequences of these differences remain to be explained.

As in conventional synapses, a rise in intracellular free Ca^{2+} is required for neurotransmitter release, but the identity of the calcium sensor(s) at ribbon synapses is unsettled. Synaptotagmin I is the principal calcium sensor at most conventional synapses. Antibodies to synaptotagmin I/II label photoreceptor and bipolar cell ribbon synapses in mouse and bovine retina but do not label these synapses in goldfish and salamander retina, which are instead labeled by antibodies to synaptotagmin III. In hair cells, it has been proposed that otoferlin, not synaptotagmin, is the principal calcium sensor for exocytosis.

The most conspicuous difference between ribbon and conventional synapses is the presence of the ribbon-specific protein, ribeye. Ribbons are constructed from interdomain interactions between adjoining ribeye molecules. Each bipolar cell ribbon is formed from ~4000 ribeye molecules and the 10-fold greater surface area of rod ribbons suggests that they are built from ~40 000 ribeye molecules. Ribeye is an alternative transcript of the gene for transcriptional repressor C-terminal-binding protein 2 (CtBP-2) with a unique ribbon-specific A domain and an enzymatic B domain. Interactions between ribeye molecules are regulated by NAD and NADH levels, suggesting a mechanism by which changes in the metabolic state of the terminal could contribute to observed circadian changes in ribbon structure.

As mentioned above, the kinesin KIF3A is located at the ribbon, but since ATP-driven molecular motors are

not needed for vesicle release from the ribbon, the role of KIF3A at the ribbon is unclear. However, kinesin motor proteins interact with plant homologs of CtBP, indicating that the interaction of kinesins with the major structural protein in ribbon synapses is highly conserved. It has also been proposed that KIF3A may assist with circadian changes in ribbon structure.

Interactions among synaptic proteins help maintain the structure of the ribbon. Interactions between ribeye and the cytomatrix scaffold protein bassoon anchor ribbons to the active zone. Bassoon also tethers ribbons in hair cells and pinealocytes. Bipolar cells lack bassoon but possess a related protein, piccolo. In photoreceptors, piccolo is located further up the ribbon than bassoon.

Interactions between cytoskeletal proteins, membrane-spanning dystroglycan proteins, and extracellular matrix pikachurin proteins are important for maintaining contacts between photoreceptor ribbon synapses and their postsynaptic targets. Disrupting these interactions leads to reductions in the electroretinogram (ERG) b-wave (indicating a reduction in ON bipolar cell responses) in patients with muscular dystrophy.

Interactions between ribeye and Unc119, a protein that is highly expressed in photoreceptors, may help localize Ca^{2+} channels to the base of the ribbon. Unc 119 can bind to both ribeye and the calcium-binding protein CaBP4. CaBP4 binds in turn to Ca^{2+} channels in photoreceptor terminals. Mutations in Unc 119 lead to cone/rod degeneration.

Photoreceptor Calcium Channels

Glutamate release from photoreceptors requires an influx of Ca^{2+} through Ca^{2+} channels. However, unlike conventional synapses that use N- and P-type calcium channels, photoreceptors and other ribbon synapses rely on dihydropyridine-sensitive, L-type calcium channels. L-type calcium channels are classified by their α1 pore forming subunits into CaV1.1-CaV1.4 subtypes. Mutations in CaV1.4 (also known as α1F) cause incomplete congenital stationary night blindness and antibodies to CaV1.4 label mammalian rod terminals, suggesting that CaV1.4 is the principal subtype in rods. Rods and long-wavelength sensitive cones also appear to possess CaV1.3 channels but CaV1.3 antibodies do not label short-wavelength-sensitive cones, suggesting that they possess a different channel subtype.

Calcium channels cluster beneath the ribbon. Freeze fracture electron micrographs from mammalian cones show clusters of ~500 polyhedral transmembrane particles, each with a central dimple, beneath the arciform density of each ribbon. Sites of calcium influx co-localize with ribeye-binding peptides and antibodies to L-type calcium channels co-localize with antibodies to bassoon and ribeye.

Properties of single-calcium channels recorded from amphibian rod photoreceptors are similar to those of L-type calcium channels in other tissues. Single-CaV1.4 channels expressed in HEK293 cells showed a tiny single-channel conductance and extremely low open probability. However, it is unlikely that these properties are retained *in vivo* since they imply an unrealistically large number of channels per ribbon (>15 000).

Photoreceptor calcium currents (I_{Ca}) exhibit a sigmoidal voltage dependence (**Figure 2**). When measured under the same experimental conditions, the voltage dependence of I_{Ca} (calcium current) in rods and cones of different species are remarkably similar. Typically, photoreceptor I_{Ca} activates above −60 mV and is fully activated around −20 mV. I_{Ca} attains about a third of its

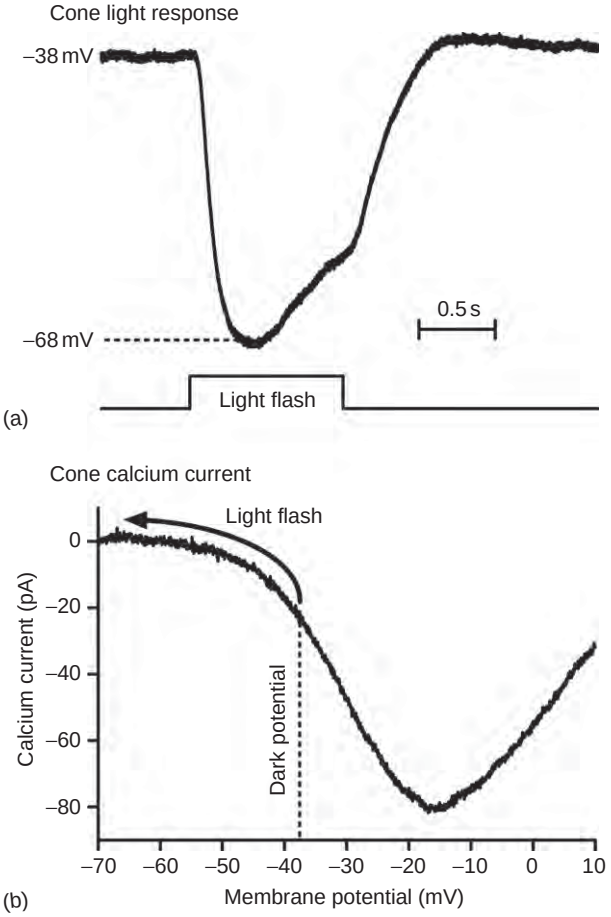

Figure 2 Influence of light-evoked changes in membrane potential on cone calcium currents. (a) Response of a salamander cone to a bright flash of light. (b) Calcium current averaged from eight salamander cones evoked by a ramp voltage protocol (0.5 mV ms^{-1}). By convention, the influx of positively charged Ca^{2+} ions into cones is shown as negative or inward current. The dark potential of the cone in (a) is denoted by the dashed line and the reduction in I_{Ca} caused by the hyperpolarizing light response is shown by the arrow.

peak amplitude at the dark resting potential (ca. –40 mV). The hyperpolarizing light response of a rod or cone photoreceptor diminishes I_{Ca} and thereby diminishes Ca^{2+}-dependent release. The sigmoidal voltage dependence of I_{Ca} contributes to response compression at higher intensities. As illustrated in **Figure 2**, the first 10 mV of membrane hyperpolarization during a cone light response causes a much greater decrease in I_{Ca} than the next 10 mV. This diminished responsiveness at more hyperpolarized potentials is sufficiently pronounced at rod synapses that it has been described as response clipping. There is evidence that Ca^{2+} influx through cGMP-gated cation channels can stimulate synaptic release from cones but the role that these channels play in release under normal physiological conditions is not clear.

Photoreceptor I_{Ca} shows limited and slowly developing inactivation involving both voltage- and calcium-dependent mechanisms. Limited inactivation is important for sustaining synaptic release in darkness when photoreceptors are continuously depolarized. Although the amplitude of I_{Ca} declines slowly in darkness, changes in I_{Ca} produced by brief changes in illumination mirror the sigmoidal voltage dependence of I_{Ca}.

Along with pore-forming α1 subunits, calcium channels possess accessory β and α2/δ subunits. Knockout of β2 subunits almost completely abolishes both the ERG b-wave and staining for CaV1.4 in the outer plexiform layer indicating that β2 subunits are the predominant subtype at photoreceptor synapses. Mutations in α2/δ type 4 subunits lead to disordered ribbons, reduced scotopic b-waves, absent photopic b-waves, and a human cone dystrophy, suggesting that this accessory subunit is associated with calcium channels in photoreceptors, particularly cones.

The calcium-binding protein, CaBP4, is closely associated with photoreceptor calcium channels. When heterologously expressed in the presence of CaBP4, the voltage dependence of CaV1.3 and CaV1.4 I_{Ca} is shifted to more negative potentials, similar to the voltage dependence of I_{Ca} in photoreceptors. By shifting activation to more positive potentials, mutations in CaBP4 reduce the amplitude of I_{Ca} in the normal physiological range and thereby reduce synaptic output from photoreceptors. The reduction in rod output accompanying CaBP4 mutations causes congenital stationary night blindness.

Role of Intracellular Ca^{2+} in Release

Free calcium levels in the photoreceptor synapse are tightly regulated by a variety of mechanisms to maintain synaptic output and prevent calcium overload during the continual influx of Ca^{2+} in darkness.

One way to remove Ca^{2+} from the cytoplasm is to pump it into the endoplasmic reticulum using sarco- and endoplasmic reticulum ATPases (SERCA). SERCA 2A predominates in photoreceptor terminals. The release of calcium from these sequestered stores by calcium-induced calcium release (CICR) can amplify calcium entry through L-type calcium channels. CICR in retina is mediated by a retina-specific variant of the type 2 ryanodine receptor. In rods, CICR amplifies synaptic release and increases the likelihood of the simultaneous fusion of multiple vesicles. CICR also contributes to synaptic release from ribbon synapses in vestibular hair cells. Calcium imaging studies show evidence for CICR in cone cell bodies but it does not appear to contribute to synaptic release. Immunohistochemical studies suggest IP3 receptors, which mediate the release of intracellular Ca^{2+} in many cell types, may be present in cone terminals. However, there is no physiological evidence for IP3-mediated release of calcium in photoreceptors.

Depletion of calcium from intracellular stores triggers the opening of calcium-permeable channels in the plasma membrane to facilitate store refilling. Store-operated calcium entry can influence synaptic release by regulating basal calcium levels in photoreceptor terminals.

Calcium can also be removed from the cytoplasm by pumping it out of the cell. Calcium is removed from outer segments by a Na/Ca exchanger whereas extrusion from inner segments and synaptic terminals rely more on plasma membrane calcium ATPases (PMCA). PMCA2 antibodies label photoreceptor terminals and PMCA2 knockout mice show significant reductions in rod-driven responses, suggesting that this subtype is particularly important in regulating calcium levels in rod terminals.

Calcium buffering by cytoplasmic proteins provides a much more rapid way to reduce free calcium levels than extrusion. The principle calcium buffers are calbindin, calretinin, and parvalbumin although many signaling proteins (e.g., calmodulin, synaptotagmin, and CaBP4) also bind calcium. There is considerable species variability, but cones typically possess the fast, low mobility buffer calbindin whereas the higher mobility buffers calretinin and parvalbumin are less common in photoreceptors.

Supplementing these mechanisms, large calcium increases in rods and cones can be buffered by mitochondrial uptake.

Physiology of Release at Photoreceptor Synapses

Photoreceptors hyperpolarize to light and decreases in light intensity cause photoreceptors to depolarize. Depolarization increases the open probability of Ca^{2+} channels clustered beneath the ribbon. The opening of Ca^{2+}

channels increases $[Ca^{2+}]_i$, stimulating fusion of vesicles at the base of the ribbon. The calcium sensors in bipolar and hair cells have a low affinity for calcium requiring $>10\,\mu M$ calcium to stimulate exocytosis. Release from bipolar cells and most other CNS neurons exhibits high cooperativity consistent with the binding of as many as five Ca^{2+} ions required for release. The release mechanism employed by photoreceptors differs from these synapses by showing a much higher affinity for Ca^{2+} whereby submicromolar calcium levels can stimulate release. This high affinity is consistent with the possible involvement of synaptotagmin III, which has a higher affinity for calcium than synaptotagmin I or II. In addition to higher Ca^{2+} affinity, release from photoreceptors shows lower cooperativity for Ca^{2+} binding ($N \leq 3$).

Ca^{2+} channels are close to the ribbon and thus opening of a channel will expose nearby release sites to high $[Ca^{2+}]$. Opening only a few channels is sufficient to stimulate fusion of a vesicle. Increasing the number of active Ca^{2+} channels increases the number of active Ca^{2+} microdomains and this in turn increases the number of active release sites. Because the number of active release sites increases linearly with I_{Ca} amplitude, there is a linear relationship between I_{Ca} and release at hair cell synapses. This mechanism may also contribute to linearity between I_{Ca} and release at photoreceptor synapses although linearity at this synapse is also promoted by use of a sensor with a low cooperativity for calcium binding ($N \leq 3$).

Synaptic release at ribbon synapses involves two components: a transient burst of release stimulated by abrupt membrane depolarization and the slower, sustained release that accompanies maintained depolarization. In bipolar cells, as with many other neurons, fast release requires very high levels of Ca^{2+} whereas slow sustained release is triggered by low Ca^{2+} levels. The separate control of fast release by low Ca^{2+} affinity sensors and slow release by high Ca^{2+} affinity sensors is consistent with the idea that fast and slow release in bipolar and hair cells may occur at ribbon and nonribbon sites, respectively.

Unlike bipolar cells, fast and slow release from photoreceptors exhibit the same high affinity for Ca^{2+}, suggesting that both components of release occur at the same site. Thus, sustained release from photoreceptors appears to be predominately due to continued release of vesicles from the ribbon, albeit at lower rates than those attained during fast transient release. Because of the high affinity for Ca^{2+} exhibited by the release apparatus in photoreceptors, micromolar levels of Ca^{2+} present at the base of the ribbon in darkness are sufficient to stimulate fusion of vesicles at the base of the ribbon almost immediately after docking. As a consequence, the base of the cone ribbon is largely devoid of vesicles in darkness. This means that in darkness, calcium channel openings often occur beneath empty release sites. The rate of sustained release in darkness is therefore not directly controlled by the stochastic opening of individual Ca^{2+} channels, but by the rate at which vesicles are delivered and readied for release at the base of the ribbon.

Release rates decline when photoreceptors hyperpolarize, allowing vesicles to be replenished at release sites along the base of the ribbon. With a sufficiently long and bright flash of light, the entire readily releasable pool of vesicles can be replenished. When the cone depolarizes at light offset, the rapid release of this replenished pool of vesicles can evoke a large off response in second-order neurons.

Photoreceptors release vesicles continuously at a rate of ~10–20 vesicles per ribbon per second in darkness. Cones can respond to light intensities spanning a 10 000-fold range, but this sustained release rate can encode only 10–20 distinguishable levels of steady light if synaptic release exhibits Poisson release statistics. If sustained release is controlled by the rate of vesicle delivery down the ribbon rather than the stochastic openings of individual calcium channels, this will make the rate of sustained release more regular. Regularization allows discrimination of a greater number of light levels than predicted for a Poisson release process. The high rates of release from cones that can be attained at light offset allow for the encoding of up to 100 distinguishable light decrements. This may account for psychophysical results showing a greater sensitivity to decrements than increments of light.

Rods exhibit slower release kinetics than cones, roughly matched to the slow kinetics of rod light responses. Rod and cone synapses have similar ribbons, I_{Ca} with similar properties, and similarly rapid, high affinity calcium sensors, suggesting that differences in Ca^{2+} handling and buffering may be responsible for rod/cone differences in release kinetics.

The continuous release of vesicles from photoreceptor synapses in darkness is balanced by compensatory endocytosis of vesicles. Photoreceptors rely largely on clathrin-mediated endocytosis whereas bipolar cells and hair cells rely more on bulk retrieval of large endosomes. Visualization of single vesicles at bipolar cell terminals by TIRF microscopy show that the vast majority of vesicles undergo full collapse during fusion indicating that kiss-and-run retrieval of fully formed vesicles is minimal at this synapse.

Disease-Related Mutations in Synaptic Proteins at the Photoreceptor Synapse

Given that all visual information must pass through the photoreceptor synapse, it is not surprising that mutations in synaptic proteins of photoreceptors can produce visual deficits. For example, rod–cone dystrophies can be caused by mutations in Rab3 interacting protein (RIM1),

UNC-119, or Ca^{2+} channel $\alpha 2/\delta$ subunits. Congenital stationary night blindness can be caused by mutations in the rod CaV1.4 Ca^{2+} channel or CaBP4. Misregulation of glutamate release by photoreceptors and bipolar cells may also contribute to excitotoxic damage in neurodegenerative diseases of the retina.

Pigment Dispersion Syndrome and Pigmentary Glaucoma

R Ritch, The New York Eye and Ear Infirmary, New York, NY, USA

Glossary

Krukenberg spindle – Typical spindle-shaped pigment deposition on the cornea of patients with pigment dispersion syndrome.
Pigment dispersion syndrome – An autosomal dominant disorder in which iridozonular friction mechanically disrupts the iris pigment epithelium dispersing pigment granules throughout the anterior eye segment.
Pigmentary glaucoma – Form of glaucoma that may develop in patients with pigment dispersion syndrome.
Reverse pupillary block – A condition in which the extend of iridolenticular contact is greater than normal, reducing the ability of aqueous humor to equilibrate between the anterior and posterior chambers, and leading to increased pressure in the anterior chamber that pushes the iris posteriorly.

History

In 1899, Krukenberg described spindle-shaped pigment deposition on the cornea. Two years later, von Hippel suggested that pigment obstructing the aqueous outflow system could lead to elevated intraocular pressure (IOP). Levinsohn first suggested that pigment in the anterior chamber angle of patients with glaucoma originated from the iris pigment epithelium (IPE). A cause and effect relationship between pigment and glaucoma found both support and opposition.

In 1949, Sugar and Barbour described two young, myopic men with Krukenberg spindles, trabecular hyperpigmentation, and open angles, whose IOP increased with mydriasis and decreased with pilocarpine. They identified the disorder as a rare, distinct form of glaucoma, which they termed as pigmentary glaucoma (PG). More patients were subsequently reported, and in 1966 Sugar reviewed 147 cases in the literature, describing several additional features, including bilaterality, frequent association with myopia, greater incidence in men than in women, and a relatively young age of onset. These features were confirmed by Scheie and Cameron.

In the 1950s, the discovery of iris transillumination defects led to the concept that the trabecular pigment originated from the IPE and perhaps the ciliary body. Congenital atrophy or degeneration of the IPE was suggested as a cause of loss of iris pigment. In 1979, Campbell proposed the pathogenesis to involve mechanical damage to the IPE during rubbing of the posterior iris against the anterior zonular bundles during physiologic pupillary movement. Karickhoff presented the concept of reverse pupillary block, in which abnormally extensive iridolenticular contact in eyes with PDS prevents equilibration of aqueous between the anterior and posterior chambers (**Figure 1**). Ritch and colleagues found PDS in 2.45% of the Caucasians in a mass screening, extending the concept of the prevalence of this entity by an order of magnitude. Subsequently, the autosomal dominant inheritance, natural history, reversibility, and more precise therapeutic approaches have become increasingly delineated. Ultrasound biomicroscopic studies have revealed new insights into the pathophysiology of PDS (**Figure 2**).

Pathophysiology

In 1958, Scheie and Fleischauer described iris transillumination defects associated with PDS and noted a pale and waxy appearance of the ciliary body in a few patients, attributing their findings to congenital IPE atrophy. Fine and colleagues examined the eyes of a 55-year-old man who had been found to have PDS without glaucoma at age 43. In the iris mid-periphery, there was an abrupt transition from normal to abnormal IPE, accompanied by hyperplasia of the iris dilator muscle with marked hyperplasia of the muscle spur of Grunert at the iris root. Rodrigues and colleagues, in contrast, reported a focally thickened dilator muscle with thinning in the areas of epithelial atrophy and found an increased number of immature melanosomes, suggesting a developmental defect.

Kupfer and colleagues believed the primary lesion in PDS to be epithelial in origin. The dilator fibers of the inner IPE appeared to be hypertrophic and hyperplastic, resembling the sphincter muscle, and were associated with degenerated neural elements. They hypothesized that the primary defect in the inner IPE could be the result of interruption of sympathetic innervation. The relevance of dilator muscle hyperplasia and nerve fiber degeneration to the disease process remains unknown; however, epinephrine compounds, alone or in combination with other agents, have been suggested to be more effective in patients with PG than in those with primary open-angle glaucoma (POAG).

The theory that posterior bowing of the iris brings it into contact with the anterior zonular bundles was proposed by Campbell. The location and number of the transillumination defects correlated with the position and number of the

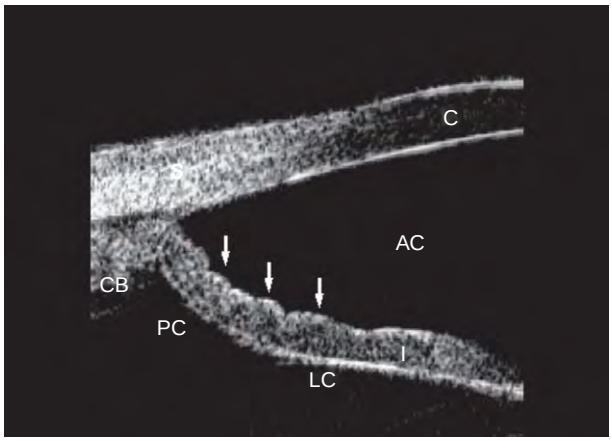

Figure 1 Typical UBM appearance of an eye with pigment dispersion syndrome. The extent of iridolenticular contact is greater than normal, reducing the ability of aqueous to equilibrate between the anterior (AC) and posterior (PC) chambers, leading to increased pressure in the anterior chamber pushing the iris posteriorly (arrows), resulting in reverse pupillary block. Liebmann, J. M. and Ritch, R. (2000). Pigment dispersion syndrome and pigmentary glaucoma. In: Fingeret, M. (ed.) *Primary Care of the Glaucomas*, 2nd edn., pp. 427–442. Philadelphia: McGraw-Hill.

underlying zonular bundles. He hypothesized that iridozonular friction during pupillary movement disrupts the IPE, releasing pigment into the posterior chamber, noting that hyperplasia of the iris dilator muscle was localized to areas of iridozonular contact. Scanning electron microscopic observations supported this hypothesis, which is now accepted as the underlying mechanism of PDS.

There is debate, however, over whether posterior bowing of the iris with iridozonular contact is sufficient in itself to cause PDS. Ultrasound biomicroscopy (UBM) performed during accommodation or exercise reveals accentuation of the iris concavity not only in patients with PDS, but also in normals, particularly myopes. It is possible that a predisposing factor in addition to iridozonular contact, perhaps congenital, is required to allow disruption of the pigment epithelium. Scuderi and colleagues found psychophysical evidence of decreased retinal pigment epithelial function in eyes with PDS by electro-oculography, suggesting primary involvement of the retinal pigment epithelium in PDS. In another study, the mean ratios of the light-peak amplitude to dark-trough amplitude of patients with PDS and PG were found to be significantly lower than the mean ratios of normal controls and patients with POAG, respectively. The pigment epithelium of the iris is continuous with those of the ciliary body and retina. Retinal pigment epithelial dystrophies have rarely been associated with PDS.

Ultrasound Biomicroscopy

UBM has enabled us to elucidate a number of facets of the pathophysiology of PDS. The size of the iris appears overly large relative to that of the anterior segment. This may be the basic anatomic cause of the mid-peripheral iris concavity predisposing to iridozonular contact. Iridolenticular contact is greater in eyes with PDS than in normal eyes and decreases after laser iridotomy is performed to eliminate reverse pupillary block (**Figure 3**). Mathematical modeling, treating the aqueous humor as a Newtonian fluid and the iris as a linear elastic solid, suggests that passive iris deformation can produce the iris contours observed using UBM. Sokol and colleagues compared patients with PDS to age-, sex-, and refraction-matched controls and found a greater mean iris-trabecular meshwork distance in the PDS group (**Figure 4**). Thus, iridozonular contact appears to be facilitated by a congenitally more posterior iris insertion.

The question has again been raised as to whether posterior bowing of the iris and iridozonular contact is sufficient in itself to cause PDS. UBM performed during accommodation reveals accentuation of the iris concavity, not only in patients with PDS but also in normals, particularly myopes. This accentuation also occurs in both normals and PDS patients after exercise. It is possible that many people have iridozonular contact, but that a predisposing factor is required to effect disruption of the IPE.

UBM has shown iridozonular and iridociliary contact in PDS. While iridociliary contact has not been proven to liberate pigment, the occasional extension of transillumination defects into the periphery of the iris, creating an appearance similar to that of an exclamation point, suggests that contact between the two surfaces may damage the pigment epithelium of both and may account retrospectively for the observation of Scheie and Fleischauer regarding the pale and waxy appearance of some ciliary processes.

Electron Microscopy

Trabecular cells are filled with pigment and show various stages of degeneration. Electron microscopic examination

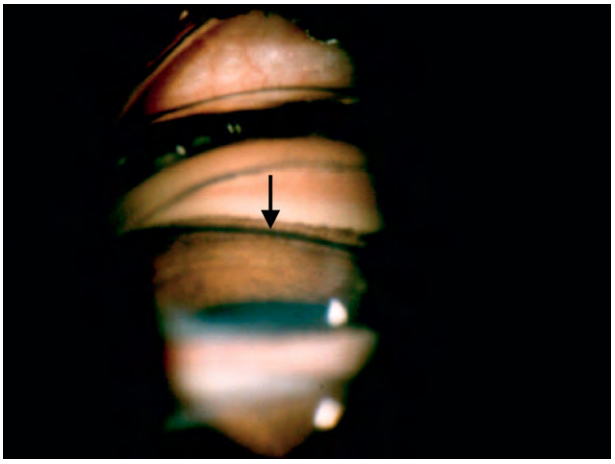

Figure 4 Dense, homogeneous pigmentation (arrow) of the trabecular meshwork in a 35-year-old man with pigment dispersion syndrome. Liebmann, J. M. and Ritch, R. (2000). Pigment dispersion syndrome and pigmentary glaucoma. In: Fingeret, M. (ed.) *Primary Care of the Glaucomas*, 2nd edn., pp. 427–442. Philadelphia: McGraw-Hill.

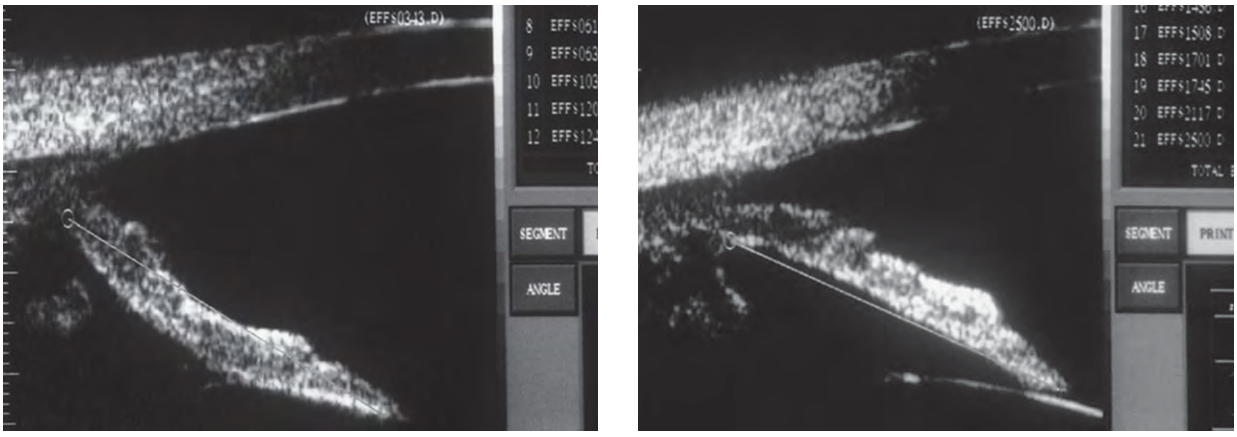
of the trabecular meshwork shows cells lining the trabecular beams lifting off and disintegrating. There is trabecular cell loss, loss of intertrabecular spaces, fusion of lamellae, and an increase in extracellular material under the inner wall of Schlemm's canal, while the intertrabecular spaces contain cellular debris, but not pigment. These observations suggest that plugging of the trabecular spaces by pigment and cell debris together with fragmentation and collapse of trabecular sheets contribute to the decrease in the facility of outflow that occurs in PG. It is possible that failure or breakdown of endothelial phagocytic function may be involved as well. When eyes with PDS with elevated IOP are compared to normal eyes, the aqueous humor dynamics are similar between the two groups, indicating that a reduction in outflow facility alone is responsible for elevated IOP.

Blinking

When eyelid blinking is prevented in PDS patients, aqueous humor builds up in the posterior chamber and the iris assumes a planar and even a convex configuration. As the volume of the posterior chamber increases relative to that of the anterior chamber, the iris gradually flattens, iridolenticular contact diminishes, and iridozonular and iridociliary process distances increase. In the most pronounced cases, iridolenticular contact disappears, the iris sphincter lifting completely off the surface of the lens without the posterior chamber losing its expanded volume (**Figure 5**). When PDS patients are permitted to blink and are then rescanned, the concave iris configuration is restored.

The mechanism by which blinking affects the anatomy of the anterior segment appears to be a mechanical one. Campbell proposed that a blink initially deforms the cornea, transiently increasing IOP and pushing the iris posteriorly against the lens. Chew and colleagues demonstrated that during blinking of the nictitating membrane in the chick eye, the cornea indents in a wave from the periphery to the center and that anterior chamber depth similarly decreases. Extrapolating this finding to humans, we have hypothesized that blinking acts as a mechanical pump to push a bolus of aqueous humor from the posterior chamber to the anterior chamber. A pressure wave is created, pushing the iris posteriorly toward the zonules. This wave begins at the iris periphery and moves centrally, pushing aqueous before it into the anterior chamber and emptying the posterior chamber.

Abnormally extensive iridolenticular contact in eyes with PDS prevents equilibration of aqueous between the anterior and posterior chambers (reverse pupillary block). The now increased volume of aqueous in the anterior chamber helps to maintain the mid-peripheral iris concavity. As aqueous leaves the eye through the trabecular meshwork and enters through ciliary secretion, the volume of the anterior chamber decreases while the volume



(a) (b)

Figure 5 (a, b) Inhibition of blinking for several minutes causes the iris concavity to disappear as the posterior chamber fills with aqueous, and the iris contour eventually becomes convex.

of the posterior chamber increases, until the next blink starts the cycle once again. Interestingly, increasing myopia is also a predictor of increasing iridolenticular contact, independent of the presence of PDS. This may explain why myopia enhances the phenotypic expression of the genetic abnormality underlying PDS. It also raises the question as to whether decreased trabecular function and reduction of the aqueous outflow coefficient might serve to accentuate the iris concavity.

Accommodation

Accommodation in normal, young individuals and in PDS patients may affect iris contour. Accommodation in normal eyes causes an iris concavity indistinguishable from that in PDS, but recent evidence shows that this effect is lessened with age. Contraction of the ciliary ring allows shallowing of the anterior chamber, anterior lens movement, and increased iridolenticular contact. Aqueous in the anterior chamber is forced into the angle recess and the peripheral iris becomes more concave. As accommodation is relaxed, the iris resumes its initial configuration.

Accommodation might enhance pigment liberation in two ways. In addition to posterior iris bowing during accommodation, the pupil constricts. Relaxation of accommodation accompanied by pupillary dilation might result in additional iridozonular friction. UBM during accommodation in eyes with PDS shows iridozonular contact at the lens margin, consistent with the usual position of iris transillumination defects. The magnitude of the posterior iris bowing is a function of the amount of accommodation exerted.

Scanning following administration of pilocarpine shows resolution of the iris concavity and iridozonular contact in all eyes. Pilocarpine produces a convex rather than a planar configuration. Laser iridotomy relieves reverse pupillary block by allowing aqueous to flow from the anterior to the posterior chamber and produces a planar iris configuration. Iridotomy appears to prevent the accentuation of the iris concavity which accompanies accommodation.

Exercise

Some PDS patients may experience pigment-induced IOP elevation after exercise or with pupillary dilation. This is most commonly associated with activities that include bouncing, such as jogging or playing basketball. However, bicycle exercise increased the iris concavity by UBM both in normals and in eyes with PDS, an effect which was eliminated in the latter by laser iridotomy. Vibration-induced increased trabecular pigmentation has also been reported in rock drillers. The exercise-induced release of pigment and elevation of IOP can be completely blocked by pilocarpine, but iridotomy does so incompletely. A rise in IOP after dilation may be delayed by hours, and patients with PDS should always have IOP measured and the anterior chamber examined for pigment dispersion after dilation. If IOP is elevated or there is extensive pigment liberation, this phenomenon should be kept in mind.

Clinical Findings

Anterior segment

Loss of iris pigment appears clinically as a mid-peripheral, radial, slit-like pattern of transillumination defects seen most commonly inferonasally and most easily in eyes with blue irides. The defects can sometimes be seen by retroillumination, but infrared videography provides the most sensitive method of detection and may be more helpful in black patients. Pigment particles tend to aggregate in the furrows of the iris surface (**Figure 6**). Rarely, dense,

asymmetric pigment on the iris face can cause heterochromia when involvement is asymmetric.

Asymmetric involvement may lead to anisocoria, with the larger pupil found in the eye with greater pigment loss from the iris. Alward and Haynes suggested the presence of an efferent defect in the eye with the larger pupil. The pupil may be distorted in the direction of maximal iris transillumination, possibly as a result of hyperplasia of the iris dilator muscle (see below).

Corneal endothelial pigment generally appears as a central, vertical, brown band of pigment on the corneal endothelium, the shape being attributed to aqueous convection currents. The pigment is phagocytosed by endothelial cells, but endothelial cell density and corneal thickness remain unchanged compared to controls. Coincident PDS and megalocornea has been reported, in one study involving four of eight boys referred for megalocornea and elevated IOP. Anterior megalophthalmos with megalocornea has been reported in two sisters with PG.

In PDS, the anterior chamber is deeper both centrally and peripherally than can be explained by sex, age, or refractive error. Davidson and colleagues compared the central and peripheral anterior chamber depths of patients with PDS to controls and found the anterior chamber to be deeper and the anterior chamber volume greater in the PDS group, more so inferiorly. In patients with unilateral PDS the anterior chamber was deeper and the lens flattens in the involved eyes. Patients with PDS have flatter corneas than myopic age- and refraction-matched controls, but no difference in axial length. Quantification of aqueous melanin granules in the anterior chamber yields a positive correlation with IOP.

The angle is characteristically widely open, with a homogeneous, dense pigmented band on the trabecular meshwork. Pigment may also be deposited on Schwalbe's line and on the corneal shelf anterior to it, distinguishable from a Sampaolesi line by the presence of finer and darker particles. The iris insertion is posterior and the peripheral iris approach is often most concave in the mid-periphery. In younger patients, the scleral spur may be poorly demarcated, blending with the ciliary face due to pigment deposition on these structures. Pigment may be deposited on the zonules (**Figure 7**), on the posterior capsule of the lens, where it is apposed to the anterior hyaloid face at the insertion of the posterior zonular fibers (Zentmayer ring, **Figure 8**), on the posterior lens central to Weigert's ligament (**Figure 9**), and on the anterior vitreous face when that has separated from the lens (**Figure 10**).

Posterior segment

Investigators have found no differences between PG and primary open-angle glaucoma in terms of the size and shape of the optic disk, configuration of the neuroretinal rim, depth of the optic cup, area of the alpha zone of parapapillary atrophy, diameter of retinal vessels at the disc border, and frequency of disc hemorrhages and localized retinal

nerve fiber-layer defects. A recent study by scanning laser polarimetry in patients with PDS found the retinal nerve fiber layer thickness to be between that of patients with PG and normals.

PDS is associated with a high incidence of retinal detachment. Most detachments occur in phakic men who are not highly myopic. Miotics have been incriminated in precipitating these. It is significant that the incidence of retinal detachment in PDS is 6–8% independent of miotic treatment, and when detachment is associated temporally with miotics, a pre-existing lesion was most likely present. Lattice degeneration is commonly found in myopes and may be hereditary. Its incidence appears to be higher for all degrees of myopia in patients with PDS than in the general population. Despite the fact that comparable prevalences of lattice degeneration in blacks and whites have been demonstrated at autopsy, PDS and retinal detachment are both uncommon in blacks.

Demographics of Pigment Dispersion Syndrome

Heredity

Occasionally families with Krukenberg spindles were reported prior to the 1980s, with subsequent reports describing familial PDS. McDermott and colleagues examined relatives of 21 probands and found involvement in 36% of parents and 50% of siblings, but none in children under the age of 21 years. This suggested a strong pattern of autosomal dominance, with phenotypic onset beginning in the mid-20s. That Caucasians are almost exclusively affected is also consistent with a genetic origin.

Loci for PDS have been reported at chromosome 7q35-36 and 18q, suggesting genetic heterogeneity. The gene for phenylthiocarbamide tasting is located in this region and was once associated with primary open-angle glaucoma. A re-examination of this phenomenon showed no difference between patients with PDS, PG, and juvenile POAG.

Gender

Men and women are equally affected by PDS, but men develop PG about 3 times as often as women and at a younger age. Since the prevalence of myopia in the United States is similar between men and women, refractive error differences cannot explain this observation.

Race

PDS is found almost exclusively in Caucasians. PDS has been reported in African-Americans, but African-American patients with PDS reported a significantly greater percentage of Caucasian ancestry and were more lightly complected than controls. Rare cases have been reported in Asia.

Refractive error

About 60–80% of the patients with PDS and PG are myopes and 20% are emmetropes. Eyes with PG are significantly more myopic than those with PDS and refractive error is correlated with the age of onset of glaucoma.

Asymmetric involvement

Since PDS is a bilateral disorder, asymmetric involvement requires explanation and may be informative of the disease pathogenesis. A second disorder may make one eye worse. The most common cause in older patients appears to be the development of exfoliation syndrome in one eye in patients who had had PDS or PG in earlier life. This combination is an example of an overlap syndrome. Angle recession in one eye has also been reported.

It is also possible for one eye to have a second disorder which reduces the severity of PDS, such as unilateral traumatic cataract extraction in youth prior to the onset of pigment dispersion or development of unilateral cataract during the pigment dispersion phase, which decreases iridozonular contact by causing pupillary block. Trauma resulting in an iridectomy and an iris coloboma leading to protection against PDS has been reported. Horner's syndrome may have a protective effect, while Adie's pupil has been associated with PDS in the same eye.

In other cases, mild to marked asymmetry may exist without any other evident process. Kaiser-Kupfer and colleagues reported four normotensive patients with markedly asymmetric involvement and no obvious cause for asymmetry. Three had anterior chamber depths 0.2 mm greater in the affected eye. UBM has revealed that in all cases of PDS where asymmetric pigment dispersion is present there is either increased relative pupillary block in the less-involved eye (reducing peripheral iridozonular contact) or greater iridozonular contact in the more-involved eye. There is greater iridolenticular contact and a more posterior iris insertion in the more-involved eye.

Clinical Course

Active phase

The mean age of onset of PDS is probably in the mid-20s, when patients enter the pigment liberation phase. Patients in their early teens have been reported. Early in the disease, pigment liberation in the anterior chamber and the characteristic peripheral iris concavity may be the only detectable signs. Neither any pigment has collected on the corneal endothelium nor have iris transillumination defects developed. The youngest patients reported have been aged 12, 14, and 15. McDermott and colleagues found no children of probands with PDS under age 21; however, further studies are warranted.

The phenotypic expression of PDS varies widely, and is difficult to detect early in the disease process. It is not known whether the variability in phenotypic expression is hereditary, environmental, or a combination of both. For instance, the concavity due to iris position and size (genetic) could be affected by the cumulative amount of accommodation (environmental).

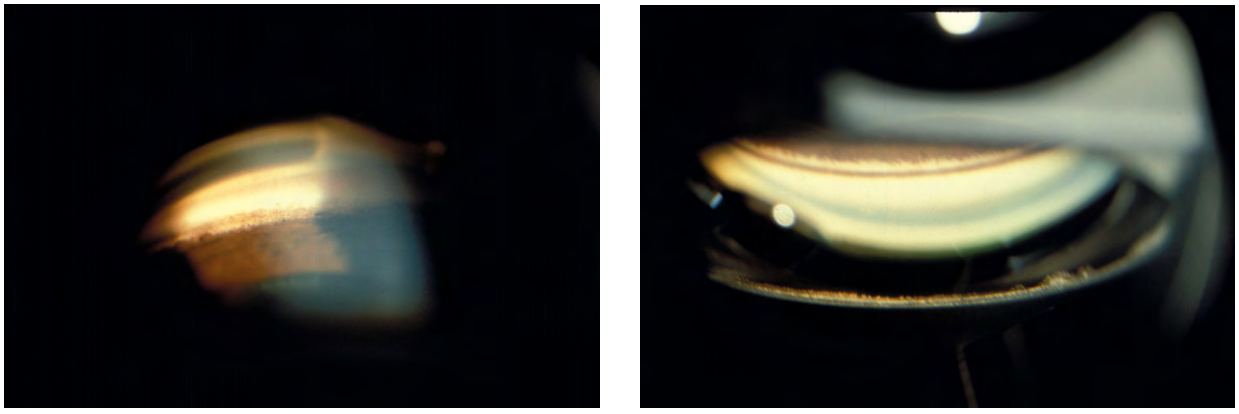
Regression phase

Loss of accommodation with the onset of presbyopia and development of relative pupillary block secondary to increased lens thickness with age presumably lead to the cessation of pigment liberation in middle age. Older patients with PDS as well as normals develop little or no accentuation of the iris concavity with accommodation. The severity of involvement of both PDS and PG decreases in middle age when pigment liberation ceases presumably because pigment can pass out of the trabecular meshwork with age. Transillumination defects may disappear and the IOP may return toward normal. Some patients treated with long-term miotic therapy have been able to reduce or discontinue treatment for glaucoma. Older patients presenting with glaucoma may have only very subtle manifestations, if any, of PDS, and may be misdiagnosed as primary open-angle glaucoma or normal-tension glaucoma. That remission of PG occurred in a young patient following lens subluxation provided early confirmation of Campbell's hypothesized mechanism for pigment liberation.

Trabecular pigmentation is initially dense and homogeneous for 360°. During the regression phase, it becomes lighter and more localized to the filtering portion of the meshwork. When the trabecular meshwork begins to recover, the normal pigment pattern reverses and the pigment band becomes darker superiorly than inferiorly. We have termed this the pigment reversal sign and in older patients, it may be the only finding suggestive of previous PDS (**Figure 11**). Although it cannot be regarded as diagnostic, examination of the patient's offspring may be confirmatory. The pigment reversal sign may also be found in patients after long-term miotic therapy in patients with PDS/PG.

Conversion to Glaucoma

The frequency with which PDS converts to PG has probably been greatly overestimated. The three studies which have examined patients longitudinally suggest that up to 50% will eventually develop glaucoma. However, the true rate of PDS in the general population may be an



(a) (b)

Figure 11 (a, b) Pigment reversal sign.

order of magnitude greater than had previously been suspected. Wilensky and colleagues found only 2 of 43 patients with Krukenberg spindles developed visual field loss during a mean of 5.8 years of follow-up. In a retrospective community-based study of 113 patients with PDS followed for 24 years, nine developed PG or elevated IOP requiring therapy. The probability of converting to PG was 10% at 5 years and 15% at 15 years.

Differential Diagnosis

Other disorders can produce abnormal pigment dispersion. Exfoliation syndrome may produce dense trabecular pigmentation. A typical Krukenberg spindle does not develop; rather, a more evenly distributed flecking of pigment develops on the posterior surface of the corneal endothelium. The diagnosis is made by discerning the typical pattern of exfoliation material within the eye in association with pigment dispersion. Patients who have had PDS can develop exfoliation syndrome in later life. We are finding this combination increasingly common as patients with known PDS have been followed into middle age. Secondary pigment dispersion has also been reported associated with iris pigment epithelial cysts, iris nevus, and melanocytoma of the ciliary body. Iris, ciliary body, or even posterior segment melanomas (if the anterior hyaloid face is disrupted) can be associated with dispersed pigment. Pigmented tumor cells or pigment-laden macrophages may cause considerable darkening of the anterior and posterior chambers. The typical signs of PDS/PG are absent: there is no Krukenberg spindle; there are no transillumination defects; and the tumor is usually readily apparent. Inflammation involving the posterior surface of the iris can occasionally disperse a moderate amount of pigment often clumped in the inferior angle.

A secondary form of PDS capable of causing glaucoma has been described following implantation of a posterior chamber intraocular lens and after penetrating keratoplasty with a posterior chamber intraocular lens. In this situation, ongoing postoperative contact between the iris and the abnormally positioned lens causes release of pigment. Posterior chamber phakic refractive lenses have also been reported to induce PDS through contact between the lens and the iris, as has piggyback lens implantation.

Pigmented long anterior zonules (PLAZ), originally described as retro-iridial lines of Vogt, is a bilateral disorder in which abnormally long and anteriorly inserted zonules are present on the face of the anterior lens capsule (Figure 12). This creates a type of pigment dispersion as the zonules rub against the posterior surface of the iris, liberating pigment into the anterior chamber. Krukenberg spindles, densely pigmented trabecular meshwork, and pigmented zonules may be seen. Iris transillumination defects are not found. Unlike PDS, PLAZ is common in black patients, and its incidence increases with hyperopia, age, and female gender. In some cases, PLAZ is associated with a CTRP5 mutation and late-onset macular degeneration.

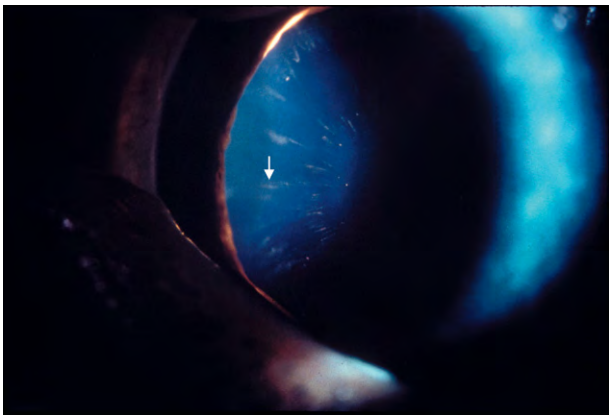


Figure 12 Pigmented long anterior zonule syndrome.

Treatment

While PG is often treated identically with POAG, the unique mechanism of development of elevated IOP in PDS warrants a very different approach to therapy. Miotics both constrict the pupil, eliminating iridozonular contact, and increase aqueous outflow, lowering IOP, thus allowing the pathophysiologic process to begin to reverse, and should be in principle the drug of choice to initiate therapy. Miotics may prevent progression of the disease and the development of glaucoma by both inhibiting iris pigment release and by enhancing clearance of the pigment through the trabecular meshwork. The peripheral retina should be examined carefully and appropriate steps taken if lattice is present. Miotic drops are poorly tolerated because of accommodative spasm and induced myopia in young patients, causing difficulty functioning in work-related situations and activities such as sports and driving, particularly at night. Pilocarpine Ocuserts were the best delivery system for pilocarpine, and we had excellent success with them. Unfortunately, their manufacture was discontinued.

Prostaglandin analogs, which increase uveoscleral outflow, produce an excellent IOP response in patients with PDS and are now our first line choice of drug. In a prospective, randomized, double-masked study, Latanoprost 0.005% qhs was more effective at lowering IOP than timolol bid, which also produced a significant reduction in heart rate. We have found prostaglandin analogs to be effective as monotherapy, and their IOP-lowering effects are also additive in patients already on miotic therapy.

Aqueous suppressants have theoretical disadvantages compared with cholinergic agonists for PG. They decrease IOP by reducing aqueous flow, which could diminish the rate of clearance of the pigment from the trabecular meshwork and conceivably exacerbate the disease process.

Furthermore, reduced aqueous flow into the posterior chamber may exacerbate reverse pupillary block, allowing for more rubbing of the posterior iris surface against the zonules and more pigment release. Furthermore, nonselective beta blockers are likely to suppress younger patients' exercise-induced tachycardia and interfere with exercise tolerance.

Just as argon laser iridotomy is used to eliminate relative pupillary block, it has been advocated for the treatment of PDS as a means of eliminating reverse pupillary block (**Figure 13**). In relative pupillary block, iridotomy results in opening of the angle and increased iridolenticular contact, while in reverse pupillary block, it produces narrowing of the angle and decreased iridolenticular contact. Neodymium-YAG laser iridotomy has been reported to cause a significantly greater postoperative elevation in IOP after iridotomy when performed on eyes with PDS compared to eyes with relative occludable angles. Flattening of the iris contour both clinically and on UBM occurs after iridotomy, although perhaps not in all cases. A reduction of IOP has been reported to correlate with loss of the iris concavity. The number of melanin granules in the anterior chamber is decreased after iridotomy. In one study, 21 patients with PDS underwent unilateral iridotomy and a rise in IOP of more than 5 mmHg was reported in 11/21 untreated other eyes during a 2-year follow-up. No other study of PDS has reported this much high proportion of rise in IOP in normotensive eyes with PDS in such a short time, nor have we observed such rises in our patients. In a review of 23 patients with PDS and elevated IOP with no or mild glaucomatous damage having undergone laser iridotomy, Wang and colleagues found no significant long-term IOP reduction in the lasered eyes compared to the medically treated other eyes. Reistad reported 60 patients collected from American Glaucoma Society members who underwent unilateral laser iridotomy for PG. While the lasered eye had a greater IOP reduction after a minimum of 2 years of follow-up, the magnitude of the effect was explained by a higher baseline IOP in the treated eye, and the study was deemed inconclusive.

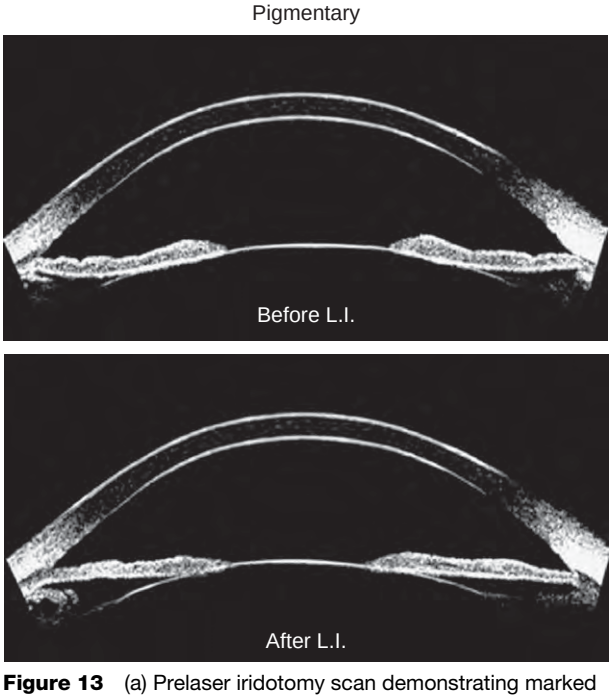

Figure 13 (a) Prelaser iridotomy scan demonstrating marked iris concavity and central iris contact with anterior lens capsule and zonules. (b) Postlaser iridotomy scan shows resolution of iris concavity and decreased length of iris contact with anterior lens capsule.

Patient selection for laser iridotomy is important. By preventing pigment liberation from the iris, the meshwork should theoretically have time to clear itself of pigment already deposited and reduce or eliminate further deposition. Therefore, patients should still be in an early stage of the disease, such as the pigment liberation stage. If pigment is liberated into the anterior chamber with pupillary dilation, it is suggestive that the patient is still in this stage. Patients who have uncontrolled glaucoma and are facing surgery are also poor candidates for laser iridotomy, since perhaps years are required to achieve functional reconstitution of the trabecular meshwork. Generally, we have restricted iridotomy to patients under 45 years of age who have elevated IOP with no damage or early glaucomatous damage. Since not all patients with PDS go on to develop elevated IOP, and since the iridotomy procedure itself results in significant pigment liberation, we do not advocate treating normotensive eyes.

The success rate of argon laser trabeculoplasty (ALT) in PG is greater in younger patients than in older ones and decreases with age. Pigment in younger patients is largely in the uveoscleral and corneoscleral meshworks, whereas in older patients, it is primarily localized to the juxtacanalicular meshwork and the back wall of Schlemm's canal. A larger portion of patients fail within a shorter period of time compared to POAG patients. Initially successful trabeculoplasty may be followed by a sudden, late rise in IOP, similar to that seen in exfoliative glaucoma. Patients in the pigment liberation stage who undergo ALT should be maintained on miotics or undergo laser iridotomy after ALT to prevent further contact between the iris and zonules.

Selective laser trabeculoplasty should be approached with caution at this point. Severe, irreversible IOP rises have been reported after this procedure. We advocate using low-power applications over 180° of trabecular meshwork and repeating the procedure as necessary.

Polarized-Light Vision in Land and Aquatic Animals

T W Cronin, University of Maryland Baltimore County, Baltimore, MD, USA

Glossary

Chromophore – As used here, a small molecule that when bound to a protein causes the complex to absorb light at visible or near-visible wavelengths. The chromophore for visual pigments, in which the protein component is opsin, is either 11-*cis* retinal or a very similar molecule.

Circular polarization – As used here, a type of polarization of light in which the electric vector, or *e*-vector, rotates one full circle for each wavelength traveled by the light, thus describing a circle as seen from the wave front or a helix as seen from the side. Circular polarization can be either right-handed or left-handed, depending on the direction of rotation.

Dichroism – The property of a substance to absorb polarized light of one *e*-vector orientation more strongly than of other orientations, thus transmitting linearly polarized light.

Dielectric – Refers to chemical compounds or substances that do not conduct electricity. Water and most biological molecules are dielectric.

***e*-Vector** – The electrical vector of an electromagnetic wave. For polarized light, the *e*-vector orientation is usually taken to be the plane of polarization.

Linear polarization – Sometimes called plane polarization. Refers to light in which the *e*-vectors of the constituent photons are all oriented on the same axis, or in the same plane.

Microvillus – A membranous protrusion from a cell surface shaped like a tiny tube, typically only a few cell membrane thicknesses in radius.

Polarized light – The light in which the *e*-vector lies in a plane (for linearly polarized light) or rotates through a full circle once for each wavelength (circularly polarized light).

Rayleigh scattering – A type of scattering of electromagnetic energy caused by interactions of the energy with particles much smaller than the wavelength of the energy. Rayleigh scattering produces the blue color of the sky and also produces a celestial polarization pattern by scattering of sunlight.

Specular reflection – Reflection as from a mirror, where the reflected ray leaves the surface at the same angle that the incident ray arrived. Specular reflection is typical of shiny surfaces; examples in nature include shiny leaves, insect cuticle, wet skin, or the surface of smooth water.

Light is made up of streams of photons, the elementary particles that carry electromagnetic energy. Each of these photons can be thought of as a miniature electromagnetic wave, which has a single wavelength related to the energy it carries (the distance the photon travels from one energy maximum to the next, inversely proportional to the photon's frequency) and a single plane within which the electrical energy vibrates – the polarization angle, properly called the *e*-vector (for electrical vector) angle. Note that since the energy is electromagnetic, there are both electrical vectors and magnetic vectors present, normal to each other. For consistency, throughout this article reference is made only to the *e*-vector. Therefore, a beam of light, containing countless photons, is characterized by its intensity (the number of photons delivered per unit time), its spectrum (the distribution of wavelengths of all the photons in the beam), and its polarization (the distribution of the planes of vibration, or *e*-vector angles, of all the photons in the beam).

The most common form of polarization, linear (or plane) polarization, has two descriptors: the overall *e*-vector angle, which is the mean angle of all planes of vibration of the constituent photons, and the degree of polarization, which is the fraction of energy of all photons vibrating within the plane of the *e*-vector angle. Of course, in a typical beam consisting of photons of mixed wavelengths, these polarization parameters generally vary with wavelength, creating a polarization spectrum. In this article, only linearly polarized light is discussed unless otherwise noted.

Like many vertebrates, humans are not generally aware of light's polarization properties, but the visual systems of most animals perceive light's polarization and use this ability to regulate their behavior. To help us understand what visualizing polarization would be like, the polarization properties of light can be analogized to its color properties. The spectrum of light produces the sensation of color, with a perceived hue (the predominant wavelength of constituent photons) and purity or saturation (the overall distribution of wavelengths around that of the hue itself). Hue is therefore analogous to the *e*-vector (the predominant angle of polarization of constituent photons) and saturation to the degree of polarization (the distribution of angles around this). In fact, polarization fields are often portrayed as images using false colors where angle is coded into hue and degree of polarization into saturation. Such a display can also include the coding of overall brightness as the intensity at each point, to provide a complete description of the polarized-light field.

Polarized Light in Nature

There are no natural sources of polarized light of known biological significance. Nevertheless, linearly polarized light is abundant in natural scenery. Light can become polarized in many ways, but the most important processes in nature are through differential absorption, differential reflection, or differential scattering (**Figure 1**).

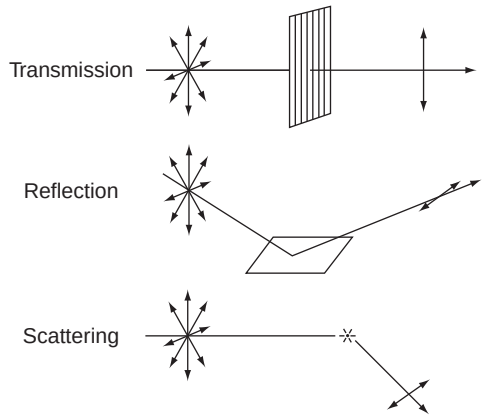

Figure 1 The three most common ways by which linearly polarized light is created either in nature or in the laboratory. At the top part of the figure, the polarization is produced by transmission through some dichroic material, with its preferential plane of transmission symbolized by the vertically parallel lines. Light emerging from a perfect dichroic material becomes fully linearly polarized. Dichroic polarizers are relatively rare in nature, and account for only a minor fraction of the polarized light observed in natural light fields. The middle part of the figure illustrates polarization by reflection from a smooth, dielectric surface. At a particular angle, known as Brewster's angle, the reflected light is fully polarized parallel to the surface. Most biological surfaces are dielectric, as is the surface of water, so much light reflected from shiny natural surfaces is highly polarized. The bottom section of the figure illustrates polarization induced by scattering. When the scattering angle is orthogonal to the axis of the ray being scattered, the scattered light is fully polarized at an *e*-vector angle perpendicular to the plane containing the original ray and the scattered ray.

Some natural or artificial transparent materials preferentially transmit one *e*-vector plane while absorbing others, usually because of aligned molecules within the material. This property, known as dichroism, is not particularly common in biological systems, but there are important exceptions, including the inherent dichroism of visual pigment molecules described later. Reflection of light from dielectric surfaces produces polarization parallel to the surface (**Figure 1**). Therefore, bodies of water and many surfaces in natural scenery reflect horizontally polarized light. Rayleigh scattering from molecules and suspended particles in air produces a well-known pattern of polarization in the sky. Scattering-induced polarization varies with the scattering angle, being greatest (often near 100% polarization) for scattering perpendicular to the axis of the incoming ray (**Figure 1**). As a result, skylight polarization reaches its maximum in a band that stretches across the sky at 90° to the sun. The axis of the *e*-vector of the scattered ray is perpendicular to the plane defined by the incoming ray and the scattered ray, such that the band of maximum sky polarization has its *e*-vectors oriented tangentially to the great circle 90° from the sun's position. At dawn or dusk, this band stretches vertically across the celestial hemisphere (**Figure 2**). Since Rayleigh scattering is most effective at short wavelengths, skylight polarization is strongest in the ultraviolet. Scattering from water molecules and very small particles suspended in natural waters also produces polarization (**Figure 3**), although it rarely reaches the very high degrees of polarization seen in the sky. Light scattering in water is optically different from the processes

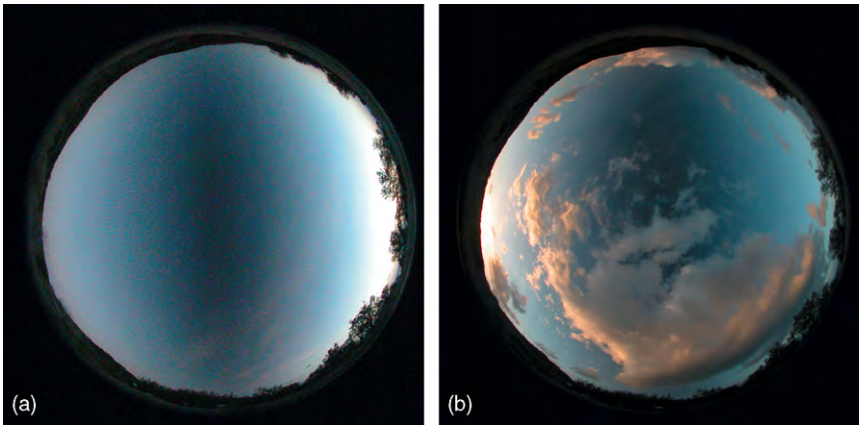

Figure 2 Polarization in the sky at twilight produced by Rayleigh scattering, imaged through a fisheye lens fitted with a linear polarizer with the transmission axis oriented to the right and left. Thus, vertically polarized light is not transmitted to the camera and shows as a dark band in the sky. In these photographs, taken at the same location and not enhanced or retouched in any way, North is to the top and West to the right. (a) Polarization in a clear sky at dusk. Note the clearly visible band of strong polarization passing from North to South through the zenith. (b) Polarization in a partly cloudy sky at dawn. The polarization is still clearly visible, but the presence of clouds depolarizes the skylight.

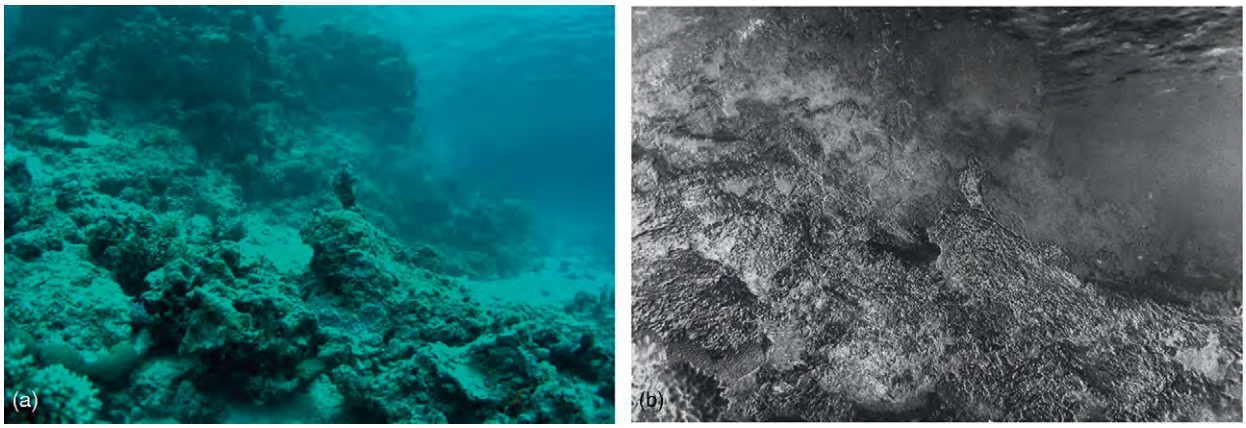

Figure 3 Polarization of light underwater produced by scattering from water molecules and suspended particles. (a) An unaltered image of an underwater scene at a depth of about 7 m, showing coral reef and rubble. (b) The same scene shown as a polarization image, with the degree of polarization encoded by brightness. The maximum degree of polarization in this scene is about 50%. Note that the parts of the scene that are fairly near the camera and that appear darkest in the normal photograph are most polarized. This occurs because the water between these dark regions and the camera scatters mostly horizontally polarized light.

operating in air, and polarization in water typically reaches its maximum value at blue-green wavelengths.

Thus, in the sky and underwater, scattering of incoming light produces partial polarization that varies with solar position and direction of view, and reflection of light from the air–water interface or from shiny surfaces (e.g., leaves, wet surfaces, animal skin, scales, or cuticle) produces strong polarization in geometrically favorable circumstances. If a terrestrial animal has polarized-light vision, the sky presents a reliable pattern useful for navigation, but in contrast, the chaotic and unpredictable pattern of polarized-light reflection produces false, pointillistic images that can mask or taint the true colors and locations of objects. Consequently, as described later, photoreceptors in animals that would normally be sensitive to the polarization of light are sometimes structurally modified to destroy polarization sensitivity.

The situation is almost always simpler in water than in air, particularly at depths greater than a few meters. Due to refraction at the air/water interface, illumination from the sun or moon is confined to within 46° of overhead position. The resulting polarization field, while variable to some extent, has horizontally oriented *e*-vectors much of the time, and the degree of polarization is almost always lower than in air. The pointillistic reflection of polarized light from objects is virtually gone underwater, as the refractive index gradient between water and most natural objects is much lower than in air, such that there is little specular reflection of light (required to produce polarization from dielectric surfaces). The predictable surround, typically low degree of polarization, and minimal polarized-light reflective noise would seem to make polarization vision in water of little utility, yet many aquatic animals have excellent polarization sensitivity. Currently, it is not always clear what biological advantages are provided by such visual abilities.

Polarization Sensitivity and Polarization Vision

Polarization Responses of Photoreceptor Cells

Light is absorbed in visual photoreceptors of all animals by molecules of visual pigment, which consist of a chromophore (derived from vitamin A or a close chemical analog) linked to a protein, termed opsin. Just as each visual pigment molecule has its characteristic absorption spectrum, which ultimately determines the spectral sensitivity of the photoreceptor within which it resides, it also has an inherent polarization sensitivity. This exists because the chromophore itself is dichroic, absorbing preferentially when the *e*-vector of an incident photon is parallel to the long axis of the molecule. Since the chromophores of visual pigment lie nearly parallel to the membranes of photoreceptors, when light arrives perpendicular to these membranes the incident photons are likely to be polarized parallel to the absorption axes of some of the visual pigment chromophores. The way in which these chromophores are aligned within the photoreceptor cell as a whole determine whether or not the receptor responds differentially to polarized light, and thus whether it has inherent polarization sensitivity (**Figure 4**).

In the rod and cone photoreceptors of vertebrate retinas, photoreceptive membranes are arranged in a series of parallel layers, either in flattened disks (rods) or lamellae formed from folded membrane sheets (cones). Since light generally strikes these layers normal to their surfaces, it encounters visual pigments that are arrayed at

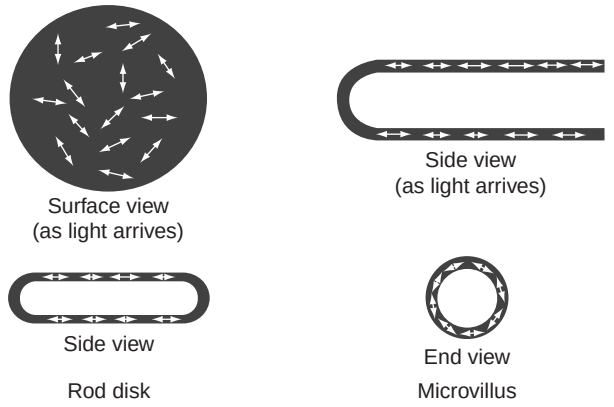

Figure 4 An illustration to show absorption of polarized light by vertebrate rod photoreceptors (left; cone photoreceptors would have similar properties) and by microvillar photoreceptors like those of arthropods or cephalopod mollusks (right). In life, light arrives normal to the flat surfaces of rod disks and encounters randomly oriented chromophores of visual pigment lying within the disk membrane (symbolized by double-headed arrows to indicate the preferred axis of polarization for best absorption). Since the orientation is fully random, there is no preferential absorption of any given *e*-vector angle. If light were to arrive from the side of the disk, it would encounter chromophores that are restrained to angles near that of the membranes themselves, favoring the absorption of horizontally polarized light. In microvillar photoreceptors (right), light arrives orthogonal to the long axis of each microvillus, and encounters visual pigment chromophores that are oriented roughly parallel to the axis of the microvillus. Thus, the microvillus as a whole preferentially absorbs light polarized parallel to its axis. If light were to impinge on the microvillus from the end, it would encounter chromophores arrayed at all possible angles around the circumference of the microvillus, and no preferred absorption orientation would exist.

all possible orientations (Figure 4, top-left). Consequently, rods and cones rarely have an overall polarization response, even though the individual molecules of visual pigment are dichroic. The situation would be very different if light impinged on rods or cones from the side (i.e., normal to the long axes of their outer segments). It would then meet chromophores lying in the planes of the membrane layers, and all chromophores would preferentially absorb light polarized nearly parallel to the membrane. Note that while the individual chromophores have random arrangements in the membrane's plane, and thus absorb light from this direction with varying effectiveness (suggested by the variable lengths of the double-headed arrows), they always absorb light polarized in the membrane's plane most effectively.

The photosensitive membranes of photoreceptor cells of arthropods (crustaceans, insects, etc.) and cephalopods (octopus, squid, and cuttlefish) are constructed from bundles of microvilli. In each microvillus, for reasons that are not yet fully understood, the molecules of visual pigments are arranged such that their chromophores are roughly parallel to the axis of the microvillus. The microvilli typically extend out perpendicular to the axis of the receptor cell as a whole, such that light arrives perpendicular to each microvillus. In this orientation, each microvillus preferentially absorbs light polarized parallel to its axis, such that if microvilli are arranged parallel throughout the receptor as a whole, the cell will be polarization-sensitive. Note that this property requires no other cellular specializations, and as a result, almost all microvillar photoreceptor cells have some level of polarization sensitivity.

Polarization sensitivity

Having receptor cells that respond differentially to polarized light is only the first requirement for polarization sensitivity at higher levels of neural analysis. For the nervous system to be able to analyze light's polarization, sets of photoreceptors with different preferred polarization orientations must be compared, typically through opponent processing. This type of analysis is like that of color vision, where sets of photoreceptors with differential spectral sensitivity are compared for color processing. Recall that polarization of light has three attributes: intensity, degree of polarization, and polarization angle. Thus, for full awareness of light's polarization at a given point in the visual field, independent inputs from three receptor sets must be analyzed. Interestingly, few animals do this; in almost all cases, only two receptor sets with orthogonal microvilli are compared. This is reasonably effective in practice, because natural polarization tends to be predictable, such that if the receptor sets are appropriately oriented, the polarization is well analyzed. Two-channel polarization analysis can be extended to full polarization sensitivity if the receptors are rotated relative to the stimulus, although this has rarely been observed in practice.

The animal groups for which the mechanisms of polarization sensitivity are best understood are the insects, the crustaceans, and the cephalopod mollusks (octopus and squid). All of these have microvillar photoreceptors, and in most species the receptors are arranged orthogonally. Crustaceans and insects have compound eyes that are particularly well designed for analyzing polarized light. Each unit of the eye contains a group of photoreceptor cells, such that each unit of the compound eye can potentially serve as an independent polarization detector. For two-axis polarization sensitivity, subsets of receptors in each group have orthogonal microvilli. In insects, these subsets often extend into a central, fused photoreceptor from four sides, with microvilli entering from opposite sides abutting near the center. Viewed from the tip of the receptor group, the overall arrangement ends up having two cell sets with horizontal microvilli and two with vertical microvilli (Figure 5). Crustaceans have a similar system, but here the orthogonal sets of microvilli exist in successive layers, making the entire composite

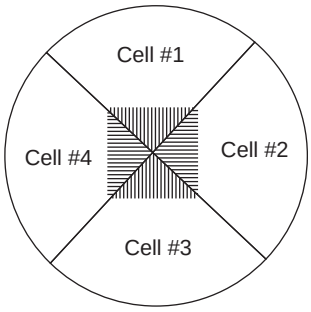

Figure 5 A schematic diagram of the structure of typical polarization-sensitive photoreceptors such as would be found in the compound eyes of insects. The receptor is viewed in a section as seen on the axis of the photoreceptor group. In life, these receptors would form a bundle of cells arranged in a circle and together forming a tall cylinder with the microvilli arranged in a smaller cylinder running down its middle. Each cell forms a section of the overall receptor (a single cell in this diagram can represent either one receptor cell or two cells lying side-by-side with parallel microvilli). Note that cells on opposite sides of the receptor extend parallel microvilli toward the junction in the center, and thus have parallel polarization sensitivity. Since two sets of receptors exist, with either horizontally oriented or vertically oriented microvilli, the receptor group as a whole can provide information for two-axis polarization analysis. Receptors of crustaceans are similar to this, but each layer of the joint photoreceptor contains microvilli from only one subset of cells, with either horizontally arrayed or vertically arrayed orientations. Successive layers of the receptor contain microvilli from the other subset of cells, and thus the receptor cylinder has stacks of mutually orthogonal microvillar layers which can contribute to two-axis polarization analysis. Photoreceptors of cephalopods are somewhat different from these, since they are arrayed continuously side-by-side throughout a retina, but each junction of four cells forms a set of microvilli organized like those in the center of the diagrammatic insect photoreceptor illustrated here. Cephalopod receptor cells also form parallel microvilli on the opposite side of each cell. Consequently, each cell contributes to two junctions of microvilli, one on each side of the cell. Again, with two primary axes of orientation of microvilli, separate cells can contribute to two-axis polarization sensitivity.

photoreceptor like a pile of a large number of circular segments, each having microvilli orthogonal to the segments immediately above and below. Finally, the cephalopods (which do not have compound eyes, but instead have a single lens eye structured much like a vertebrate camera eye) arrange their microvillar receptors such that each cell has microvilli on two opposing sides (like a two-sided toothbrush). The mosaic of cells forms junctions similar to what is pictured in the center of Figure 5, except that each of the four cells in this figure would form another junction on the opposite side with yet other cells. In all these cases, the cells with parallel microvilli viewing one point in space join to form one polarization channel, and those with microvilli orthogonal to these join for the opponent channel.

Vertebrate polarization sensitivity is more difficult to explain, and it is fair to say that we are still not able to account for it satisfactorily. Nevertheless, there is no doubt at all that some vertebrates sense light's polarization. Recall that end-on stimulation of rods and cones is unlikely to produce any differential sensitivity to the plane of polarization, because chromophores are randomly oriented for such light (Figure 4). If vertebrate photoreceptor cell outer segments were slanted relative to the axes of impinging rays of light, this would confer some polarization sensitivity. It appears that in at least some fishes, the outer segments of some classes of cones lie on their sides, tilting their lamellae vertically in the retina. If all cones of a given class lay parallel, or were organized into orthogonal classes, this could permit the retina as a whole to achieve an overall polarization sense. There is recent evidence that some rod or cone classes are measurably dichroic to end-on illumination. The origin of this dichroism is unclear, but it could be caused by parallel tilting of the rod disks or cone lamellae.

Polarization vision

If an animal has polarization sensitivity, it can obviously respond in some way to a polarization stimulus. As described later, these responses are frequently hard-wired and inflexible, and the polarization sense that drives them does not correspond to what is normally conceived of as vision, which implies a perception of space, form, and individual objects. The term polarization vision refers to a polarization sense analogous to color vision, whereby animals visualize polarization attributes of features within the overall field of view and use polarization variations to enhance the visibility, contrast, or features of particular objects. In principle, an animal that is capable of polarization vision perceives the visual world as a pattern varying in polarization features among receptive fields. While polarization sensitivity is most useful for orientation or for organizing simple responses, polarization vision offers the potential to direct complex behavior such as predation, camouflage generation or breaking, and signal detection. There is only weak evidence of this ability in some vertebrates, but many species of both arthropods and cephalopods probably use true polarization vision in ways that are discussed later.

Disentangling polarization and color sensitivity

Many – perhaps most – animals that are sensitive to polarized light also have color vision. This presents both perceptual and sensory-processing challenges, as it is generally not desirable to mix these visual modalities. For example, if a receptor cell that contributes to a perceptual color channel has some residual polarization sensitivity, color appearance will be altered by stimuli that contain polarized light. This is most often a problem for

animals with microvillar photoreceptors due to their inherent polarization bias. The cephalopods have firmly dealt with this issue by discarding color vision entirely – the great majority of octopuses, squids, and cuttlefishes have only a single spectral receptor class in their retinas, restricting vision entirely to the intensity and polarizational domains. Many crustaceans have reached a similar solution, devoting nearly all of their receptors to polarized-light reception. Some crustacean species, however, separate color and polarization processing, using a single spectral class for polarization analysis while reserving a set of other polarization-insensitive classes for color vision. This solution is used, for example, by stomatopod crustaceans, also known as mantis shrimps. Insects also commonly separate color-sensitive from polarization-sensitive receptors, isolating their polarization receptors to just one part of the visual field and often using only ultraviolet receptors for polarization analysis. Some insect species destroy polarization sensitivity in photoreceptors by twisting the entire receptor group around its long axis. In a few cases, surprisingly, insects unify polarization and color perception in the same receptor cells, interpreting some stimuli by combining these two modalities into a single signal. Some butterfly species, for instance, examine potential ovoposition sites in this way. In vertebrates, however, as with other aspects of polarized-light photoreception, it is unknown how (or even if) polarized-light processing is kept separate from color processing. This could be a difficult problem, as it is thought that some vertebrates use different spectral types of cones to sense different polarization planes, a technique that immediately must mix color and polarization information at the first level of light detection.

The Contributions of Polarized-Light Perception to Behavior

Sensing polarized light seems strange to us, but for most animals it is as fundamental to their visual perception as color vision is to humans. Indeed, as will be described shortly, in many animals polarized-light perception plays similar roles to those assumed by color vision, and it can even work together with color vision to improve visual interpretation of stimuli. However, there are many situations where polarized light is used for special purposes unique to this modality. Among these are water surface detection and skylight navigation.

Water surfaces reflect horizontally polarized light, as illustrated in **Figure 1**. This is why sunglasses with polarizing lenses make it easier for fisherman to see fish – the lenses are oriented to block horizontally polarized light, reducing the glare from the water's surface and clarifying the visibility of objects in the water itself. Many flying insects, including adult water beetles and mayflies, use the reflected polarization in the opposite way – their eyes are adapted to respond strongly to large expanses of horizontal polarization below the horizon, which in nature invariably correspond to water surfaces. The insects respond by diving into the water, or by alighting on its surface to ovoposit. This simple response is extremely reliable in nature, but can lead to disastrous consequences for the insects today, when many shiny, horizontal surfaces are man-made. Parking lots, oil ponds, and even the painted surfaces of cars and other manufactured objects induce the same response, which in these cases is frequently lethal.

Scattering of sunlight in the clear sky produces a highly reliable pattern of polarization (**Figure 2**), recognized by the visual systems of many insects (including bees, ants, and crickets) as well as by other arthropods including some spiders and crustaceans. The pattern is used for navigation, as it is a perfect indicator of the current position of the sun, persisting even when the sun is not visible behind an obscuring object or landscape feature, or when the sun is hidden by clouds. Thus, navigation is possible even on quite cloudy (but not wholly overcast) days. Most insects that navigate using skylight polarization devote a small region of the compound eye, called the dorsal rim, to perceiving the pattern, and most require only a small patch of clear sky to orient. Navigation using the location of the sun or skylight polarization patterns is not simple, as the solar position drifts through the sky with changing dynamics throughout the seasons, and insects must be able to compensate for these changes each day as they manage their foraging excursions. Some insects, including dung-foraging scarab beetles, use skylight polarization created by moonlight to navigate during their nocturnal rambles. In an interesting vertebrate example, migrating birds are thought to use skylight patterns of polarization at twilight to calibrate their magnetic compasses.

The tasks described so far are analogous to map senses, simple reflexes, or other perceptual abilities that are not strictly visual in the sense that we humans understand it. In other words, these types of abilities do not examine features or objects in the outside world except in very general ways. However, there are animals that actually see patterns of polarization in a fashion that is quite analogous to the way that we perceive the external world – they use polarization vision to recognize objects, to enhance contrast of prey, or to see signals of conspecific animals. Some animals, in fact, can be trained to discriminate objects that we see as identical but that differ in the patterns of polarization that they reflect or transmit. Octopus and mantis shrimps learn such tasks.

Near the water's surface, the skylight polarization pattern penetrates and is therefore available as an orientation cue. Deeper than this, underwater polarization is only rarely usable for navigation (although it can be used to orient vertical migration) because it is frequently weak,

often oriented near the horizontal plane, and quite variable depending on the background (Figure 3). Nevertheless, the background polarization can be used to enhance the contrast of the visual world and make midwater objects more visible. Squids take advantage of this, making them more effective predators on fishes and transparent planktonic prey against a polarized background than against a depolarized one. Presumably, they use their polarized-light sense to detect differences in polarization between the prey and the background, making objects of similar overall brightness appear distinguishable.

If squids and cuttlefishes can distinguish objects based on polarization, it should not be surprising that they also have body patterns that reflect polarized light, undetectable by many marine animals, and apparently employ these patterns to communicate with each other. The polarization patterns are actively controlled by the animal producing them and can appear and disappear in fractions of seconds. When displayed, the polarization reflections remain highly visible to a conspecific individual even as the signaler changes its posture or moves its arms about.

Two other groups of animals, one marine and one terrestrial, are currently known to recognize and respond to polarization signals. Mantis shrimps produce an abundance of signals based on patterns of polarized light reflected from their carapace (Figure 6), and use these signals during mating and aggressive displays. Like the cephalopods, of course, they are marine invertebrates and conduct their diplays underwater. One group of insects, however, uses polarized-light signals in the open air. Many species of tropical butterflies find mates in the diffuse light under the rainforest canopy. Here, the background polarization is relatively weak, and the strong polarization pattern of the sky is rarely visible. Thus, the polarization produced by reflection from scales on butterfly wings can act as an unusually strong, visible signal.

Sensitivity to Circularly Polarized Light

This discussion of polarized-light sensitivity would not be complete without mention of a recently discovered visual modality, sensitivity to circularly polarized light. Circular polarization differs from linear polarization, the type discussed exclusively until now, in that the *e*-vector does not remain within a single plane, but instead rotates around the axis of the beam of light. Circularly polarized light is not common in nature, and its presence cannot be detected with standard polarization-sensing systems. Despite this, one group of animals, the mantis shrimps, perceives circularly polarized light and produces circularly polarized signals by reflection. This ability is particularly unexpected because there is no known source of circular polarization underwater other than signals from other mantis shrimps, so it is difficult to explain how and why the ability originally arose. It is possible that circular polarization sensitivity in these animals first appeared as an accidental epiphenomenon related to the unusual way in which their linear polarization system is assembled, and that this led to the elaboration of signals based on circularly polarized light. See the suggested reading for a more detailed account of this unusual finding.

Summary

The ability to perceive and respond to linearly polarized light is widespread among animals, occurring in many vertebrates and invertebrates. Some of these species use polarization for general tasks that do not require precise imaging, such as finding water or navigating using patterns of scattered polarized light in the sky. Others truly see polarized objects and use this imaging ability to detect prey and recognize signals from conspecifics. Our poor understanding of the biology of polarized-light sensitivity

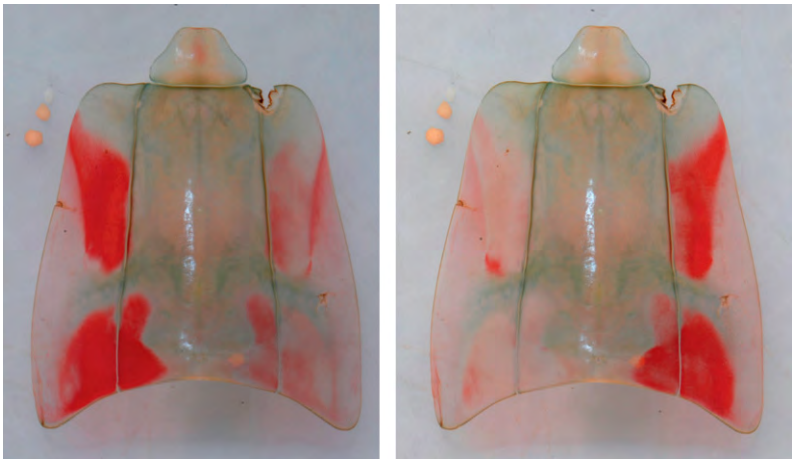

Figure 6 Polarization signals reflected from the shed carapace (or molt) of the stomatopod crustacean, or mantis shrimp, *Odontodactylus cultrifer*. These patterns of polarization are visualized through a linearly polarizing filter rotated to two orientations at 90° to each other. Signals like these are used during aggressive or mating displays of mantis shrimps. Photograph by T. H. Chiou.

in vertebrates, and the recent discovery of circular polarization sensitivity in mantis shrimps, suggest that there are other aspects to polarized-light sensitivity and to polarization vision that still remain to be revealed.

Post-Golgi Trafficking and Ciliary Targeting of Rhodopsin

D Deretic, University of New Mexico, Albuquerque, NM, USA

Glossary

Cell polarity – The asymmetry in cell shape, protein distributions, and cell functions.

Golgi complex – A biosynthetic organelle comprised of a stack of membranous cisternae that are involved in protein modifications, such as processing of N-linked sugars as well as sorting and transport of membrane proteins. Newly synthesized membrane and secretory proteins enter the stack through the *cis*-Golgi, progress through the medial cisternae and exit at the *trans*-Golgi.

Phosphatidylinositol-4,5-bisphosphate ($PI(4,5)P_2$) – An essential second messenger as well as lipid regulator of membrane trafficking. Along with its precursor phosphatidylinositol-4-phosphate (PI(4)P), it regulates Arfs and is regulated by them, providing a positive-feedback loop that regulates membrane trafficking.

Post-Golgi transport carriers (TCs) – The post-Golgi vesicles that carry cargo to the plasma membrane. It is now clear that these carriers are large pleiomorphic structures, rather than small vesicles, as previously believed, thus the term vesicles has been replaced with transport carriers.

Small GTPases – The members of the low-molecular-weight (20–25 kDa) Ras super family of guanosine-triphosphate (GTP)-binding proteins comprised of at least four large families, including the Arfs and the Rabs. Small GTPases function by providing directionality to membrane traffic through the molecular switch whose ON and OFF states are triggered by binding and hydrolysis of GTP. The nucleotide-bound state determines the affinity of interactions with regulatory proteins and the downstream effectors of small GTPases.

SNARE proteins – The soluble N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) proteins are major components of the intracellular machinery responsible for targeted membrane delivery. SNAREs were identified as membrane receptors for the soluble N-ethylmaleimide-sensitive factor (NSF) attachment protein (SNAP) in the cell-free system that reconstituted intra-Golgi trafficking. SNARE proteins form complexes, which are generally composed of a four helical bundle that bridges opposing membranes and brings them into close proximity to initiate fusion.

The *trans*-Golgi network (TGN) – A tubular network in the close proximity to the *trans*-Golgi cisternae that represents the central sorting station of the cell, where proteins and lipids destined for different subcellular domains are segregated from each other and sorted into post-Golgi TCs.

Introduction

Retinal rod photoreceptors are exquisitely complex polarized cells that carry photon detection and visual transduction that are essential as the first step in vision. Following the final cell division of their precursors, photoreceptors attain a level of polarity that is nearly unmatched in other cells of the body. Maintaining this organization throughout the lifetime of the organism is a prerequisite for vision. Proper targeting and retention of the macromolecular complexes involved in the visual transduction cascade are accomplished by the highly coordinated action of protein and lipid regulators that together constitute the membrane trafficking machinery. Specific components of this machinery involved in the directed delivery of rhodopsin and its associated proteins and lipids are only beginning to emerge.

Photoreceptor Polarity

Rod photoreceptors are modified neurons with specialized light-sensing organelle, the rod outer segment (ROS). The ROS is filled with membranous disks housing the phototransduction machinery that converts photon absorption by rhodopsin into changes in neurotransmitter release, thus transmitting photosensory information to the visual cortex. The light-sensing machinery is comprised of peripheral and integral membrane proteins of the ROS. It is continuously replenished through ROS disk membrane renewal, followed by its removal through daily shedding and phagocytosis by retinal pigment epithelial (RPE) cells.

The ROS disk membrane proteins are embedded in a low-viscosity lipid bilayer milieu comprised of unsaturated long-chain phospholipids highly enriched in omega-3 docosahexaenoic acid (DHA, 22:6(n-3)), which is essential for sensory membrane function and for cell

survival. The exceptionally high content of polyunsaturated DHA phospholipids renders ROS membranes highly susceptible to light and oxidative damage.

ROSs initially form from primary cilia, and a short 9+0 (nonmotile) connecting cilium remains in the adult as the only path of communication between the ROS and the photoreceptor rod inner segment (RIS). The RIS houses mitochondria and biosynthetic membranes involved in oxidative metabolism and membrane protein and lipid biosynthesis, respectively. The photoreceptor-connecting cilium corresponds to the transition zone of primary cilia, which is considered a gateway for the admission of specific proteins to this privileged intracellular compartment.

The primary cilium is the site of assembly of large molecular complexes involved in intraflagellar transport (IFT). IFT protein 20 (IFT20) subunit links mammalian IFT complex with the microtubule motor, kinesin II. The base of the cilium is a region of particularly high lipid ordering, separating the ciliary membrane from the surrounding plasma membrane due to high cholesterol content and glycosphingolipid products of the phosphatidylinositol 4-phosphate (PI(4)P)- and Arf-dependent effector four-phosphate-adaptor protein 2 (FAPP2). Cholesterol rings have also been reported to surround the photoreceptor connecting cilium. Lipid ordering might be important for the docking of the basal body to the plasma membrane or the extension of the ciliary axoneme, both essential processes in ciliogenesis.

The RIS is separated from the nuclear and synaptic domains by adherens junctions (AJs) that comprise a continuous adhesion belt, the outer limiting membrane (OLM). Interestingly, this junctional region lacks tight junctions that normally confine plasma membrane proteins to their respective domains. Nonetheless, rod membrane proteins are strictly confined to their specialized domains and the maintenance of polarity is essential for the cell's function and survival. The photoreceptor synaptic terminal contains specialized ribbon synapses that are responsible for the tonic release of neurotransmitters, which is interrupted by photon capture.

Photoreceptor cytoskeletal networks and molecular motors play a major role in the cell polarity. Microfilaments provide structural support by encircling the RIS beneath the plasma membrane and are anchored at the AJs. Other polar dynamic actin networks and filaments are also dispersed through the cell, most notably in the distal portion of the cilium, at the sites of ROS disk formation where they regulate the growth of nascent disks. Actin-based motility through the cilium is thought to be mediated by myosin VIIa, the product of the Usher syndrome (USH) 1B (Usher1B) gene. An array of microtubules radiates into the RIS from the microtubule-organizing center nucleated by a pair of centrioles located below the cilium. Microtubules generate polar networks that generally determine the position of membrane organelles and allow intracellular motility. Heterotrimeric molecular plus end-directed motor kinesin-II and homodimeric KIF17 mediate microtubule-dependent trafficking into the ROS. The absence of KIF3A subunit of kinesin-II causes membrane accumulation in the RIS and cell death. Cytoplasmic dyneins 1 and 2 mediate retrograde trafficking to the centrosome from the RIS and the ROS, respectively.

Photoreceptor Biosynthetic Membrane Trafficking: Endoplasmic Reticulum, Golgi, and Post-Golgi Transport Carriers

ROS integral membrane proteins are synthesized on the rough endoplasmic reticulum (ER), pass through the Golgi apparatus, and are then incorporated into post-Golgi vesicles or, in current terminology, rhodopsin transport carriers (RTCs) that bud from the *trans*-Golgi network (TGN), the central membrane sorting station of the cell, and are transported to a docking site near the base of the cilium. Along with rhodopsin, DHA phospholipids are co-transported on RTCs, which fuse with the specialized domain separating the ciliary membrane from the surrounding RIS plasma membrane, thereby regulating the replenishment of light-sensitive ROS membranes. Rhodopsin represents 90% of the newly synthesized protein in rod photoreceptors, and its biosynthetic pathway is best understood. In the 1980s, the laboratories of David S. Papermaster and Joseph C. Besharse combined electron microscope (EM) immunocytochemistry, autoradiography, and freeze-fracture analysis and demonstrated that newly synthesized rhodopsin is transported vectorially to the base of the cilium on membranous carriers. Membrane biosynthesis was also studied by pulse–chase experiments that established the kinetics of movement of newly synthesized rhodopsin through membrane compartments separated by subcellular fractionation. This methodology was subsequently refined by Deretic and Papermaster to incorporate high-resolution linear sucrose gradients, which separated the low-density post-Golgi carriers from other subcellular organelles, including the Golgi, TGN, plasma membrane, and synaptic vesicles.

Successful isolation of post-Golgi RTCs provided not only insight into their molecular composition, but was also the basis for the development of the retinal cell-free assay that reconstitutes RTC budding *in vitro*. The development of this assay in our laboratory led to the discovery that rhodopsin contains a sorting signal within its five C-terminal amino acids that regulates its incorporation into RTCs as they bud from the TGN. Abundant evidence points to the role of the amino acid sequence valine-x-proline-x (VxPx motif) in rhodopsin's C-terminal domain as a sorting signal into RTCs and delivery to the cilium and the ROS. In our retinal cell-free system a monoclonal antibody, whose antigenic site is within the five C-terminal

amino acids of rhodopsin, and synthetic peptides corresponding to the C-terminus of rhodopsin inhibit RTC budding from the TGN. Studies in a number of laboratories employing transgenic animals expressing rhodopsin lacking the sorting signal, or rhodopsin–C-terminal fusion proteins carrying autosomal dominant retinitis pigmentosa (adRP) mutations, confirmed that the absence of the correct sorting information results in the targeting to the RIS plasma membrane and the synapse *in vivo*.

Because of the exceptionally high membrane turnover, photoreceptors are vulnerable to mutations that affect membrane trafficking. Among the rhodopsin mutations with the most severe phenotypes are those that alter the rhodopsin C-terminal VxPx targeting motif. Rhodopsin C-terminal mutations cause rapid photoreceptor cell death, retinal degeneration, and blindness in adRP. Within the VxPx targeting motif, V345 and P347 are the primary sites of C-terminal adRP mutations involving single amino acid substitutions.

To dissect the sorting machinery that regulates RTC budding, targeting, and fusion, it was essential to identify the resident proteins of this organelle. These studies indicated a succession of binding on RTCs of members of the small guanosine triphosphate (GTP)-binding protein families (G proteins or small GTPases) that are the known regulators of membrane trafficking.

Small GTPases of the Rab and Arf Families and Their Regulators in Rhodopsin Trafficking

Rabs

Directed delivery of membrane cargo is mediated through vesicular transport regulated by the small GTPases of the Rab and Arf families, which play a central role in organizing intracellular membrane trafficking. All GTPases function by providing a universal molecular switch whose ON and OFF states are triggered by binding and hydrolysis of GTP. Small GTPases are in a dynamic equilibrium between the cytosol and the membranes maintained by the interactions with a number of regulatory proteins, including nucleotide exchange factors (GEFs), GTPase-activating proteins (GAPs), and their downstream effectors, and the affinity of these interactions is determined by the nucleotide-bound state. The Rab family of small GTPases includes over 60 members that are generally designated numerically (i.e., Rab6, Rab8, and Rab11). Upon GTP binding, activated Rabs recruit a multitude of effectors that organize membrane domains involved in the tethering of membranes to other membranes and to cytoskeletal elements, thus conferring directionality to membrane traffic. Macromolecular complexes organized by Rabs provide a unique identity to membrane microdomains within cellular organelles. Consequently, a change in Rabs, termed Rab conversion, changes the membrane identity and accompanies cargo progression through intracellular compartments.

Rab6 regulates retrograde transport between the Golgi and the ER, but in cells with hypertrophied synthesis of simple membranes it also associates with post-Golgi carriers. In photoreceptor cells, Rab6 is associated with the Golgi, TGN, and RTCs. It was demonstrated in *Drosophila* that Rab6 regulates rhodopsin trafficking, and that the expression of the GTPase-deficient mutant of Rab6 leads to retinal degeneration.

Rab11 has been localized to both the Golgi and the recycling endosomes, which are involved in return of plasma membrane receptors to the cell surface through endocytosis. However, the Golgi-associated function of Rab11 is less well understood. The specific functions of Rab11 in apparently divergent cellular processes are probably based on its ability to interact with different effector molecules that belong to the family of Rab11-interacting proteins (FIPs), which are localized in different trafficking pathways. Rab11 is associated with photoreceptor TGN and RTCs where it interacts with FIP3. At the TGN, Rab11 and FIP3 are incorporated into a ciliary targeting complex regulated by the small GTPase Arf4, described below. Sustained presence of Rab11 on RTCs suggests that Rab11 might also interact with the conserved octameric Sec6/8 complex, also known as the exocyst in yeast. The Sec6/8 complex tethers the Rab11/FIP3-positive membranes and is involved in tethering RTCs to the RIS plasma membrane. Exocyst complex localizes to the cilia in polarized epithelial cells, and we also find it at the base of the photoreceptor cilium. In *Drosophila*, interaction of the Sec6/8 complex with Rab11 plays a role in the tethering of membranes carrying rhodopsin. Rab11 may also cooperate with another RTC-associated Rab, Rab8. A handover from Rab11 to Rab8, or Rab conversion, may occur at the base of the cilium to couple the final stages of traffic along the ciliary pathway.

Rab8 regulates polarized trafficking in epithelial cells and neurons through its activity on cytoskeleton remodeling necessary for membrane outgrowth and the formation of cellular protrusions. It has recently emerged as a major player in ciliogenesis. In retinal photoreceptors, Rab8 regulates RTCs fusion and ROS biogenesis. It acts at the base of the cilium in conjunction with another small GTPase (Rac1), phosphatidylinositol-4,5-bisphosphate ($PI(4,5)P_2$), actin and the phosphoinositide- and actin-binding protein moesin. In addition, Sec6/8 complex is also likely to function as one of Rab8 effectors in ciliogenesis. Transgenic *Xenopus* with photoreceptor-specific expression of GFP-Rab8Q67L dominant-active mutants show normal photoreceptor cell morphology, but cause slow retinal degeneration, whereas GFP-Rab8T22N GTPase-deficient dominant-negative mutants show a defect in membrane tethering and accumulate RTCs in

the vicinity of the cilium, leading to rod cell death and rapid retinal degeneration. Emerging evidence points to Rab8 as a central regulator of the biogenesis of primary cilia, suggesting that its regulation of rhodopsin trafficking may be a part of a broad and more general role for Rab8 in the regulation of ciliogenesis.

Mutations that affect regulatory proteins of small GTPases and their interacting proteins have been found to cause X-linked retinitis pigmentosa (RP), autosomal recessive Leber congenital amaurosis (LCA), and choroideremia. Rab escort protein 1 (Rep1), encoded by the choroideremia gene is a subunit of geranylgeranyl transferase, the enzyme that isoprenylates Rab proteins. Rab8-interacting proteins, Optineurin and Huntingtin, are also linked to the neurodegenerative diseases primary open-angle glaucoma (POAG) and Huntington's disease, respectively. Rab8, Optineurin, and Huntingtin are collectively involved in the linkage of membrane organelles to the cytoskeleton, suggesting that the breakdown of this linkage may be a common theme in retinal degeneration and in other neurodegenerative diseases.

Arfs

The Arf family of small GTPases includes three different groups of proteins: the Arfs, Arf-like proteins (Arls), and SARs. Arfs were originally discovered as ADP-ribosylation factors, but in 2006 the new nomenclature for the human Arf family of GTP-binding proteins, formerly known as ARF, ARL, and SAR proteins, has been established. Arfs are no longer called ADP-ribosylation factors (ARFs), since ADP-ribosylation appears unrelated to their physiological function. Arf family members regulate membrane trafficking, lipid metabolism, organelle morphology, and cytoskeleton dynamics. These functions were elucidated for the abundant class I Golgi Arfs, Arf1 and Arf3, and the plasma membrane-associated Arf6. The loss of a single class I or class II Arf has little effect on membrane trafficking, but the deletion of pairs of Arfs causes distinct defects. This suggests a pair-wise engagement of Arfs and a certain redundancy in their function. Arf function depends on GTP hydrolysis mediated by Arf GAPs, which are essential for coupling the proofreading of cargo incorporation to the budding of membrane carriers and are often incorporated into protein coats.

The selection and packaging of sensory receptors and membrane cargo targeted to the primary cilia and cilia-derived sensory organelles are critical to replenish the ciliary membrane, yet it remains poorly understood. Our recent studies have demonstrated that rhodopsin C-terminal VxPx targeting signal binds Arf4 to regulate incorporation of rhodopsin into RTCs at the TGN. The function of the class II Golgi-associated Arfs, Arf4 and Arf5, is least understood, yet the direct and specific binding of the VxPx-targeting motif to Arf4 suggests a distinct role for this particular Arf in the generation of RTCs. The targeting VxPx motif binds Arf4 and recruits it to the TGN, leading to assembly of a ciliary targeting complex. This complex is comprised of two small GTPases, Arf4 and Rab11, the Rab11/Arf effector FIP3, and an Arf-GAP/effector ASAP1. The localization of the ciliary targeting complex in photoreceptors is illustrated in **Figure 1**. ASAP1 catalyzes phosphatidylinositol 4,5-bisphosphate (PIP_2)-dependent GTP hydrolysis on Arf4. Transgenic frogs expressing an Arf4 mutant impaired in ASAP1-mediated GTP hydrolysis, display dysfunctional rhodopsin trafficking and cytoskeletal and morphological defects, resulting in retinal degeneration. FIP3, which binds Arf4, also forms a ternary complex with Rab11 and ASAP1 and stimulates Arf GAP activity of ASAP1. Emerging evidence points to the role of ASAP1 and FIP3 as a functional module that provides temporally and spatially restricted hydrolysis of GTP bound to Arf4 at the TGN. Since ASAP1 and FIP3 act as homodimers, they may oligomerize to form a protein coat that regulates ciliary targeting, a specialized form of the TGN-to-plasma membrane trafficking.

Rhodopsin provides the spatial control for the ciliary targeting module by recruiting Arf4 to the carrier budding sites at the TGN through its VxPx targeting signal. Surprisingly, the VxPx motif is not unique to rhodopsin, but is present in other membrane proteins targeted to primary cilia such as polycystins 1 and 2, and the cyclic nucleotide-gated channel CNGB1b subunit. The VxPx from polycystin-2 also binds Arf4, suggesting that the targeting complex recruited through Arf4 is a part of conserved machinery involved in the selection and packaging of the cargo destined for delivery to the cilium.

SNAREs and their Regulators in Rhodopsin Trafficking

In addition to GTPases and their effectors, the soluble N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) proteins are major components of the intracellular machinery responsible for targeted membrane delivery. SNAREs are considered to be directly involved in membrane fusion. After the tethering step, SNAREs are activated on the opposing donor and target membranes to form a complex that bridges the two membranes and brings them into close proximity to initiate fusion. Although SNARE pairing alone is not sufficient to determine the specificity of organelle fusion, cognate SNAREs are correctly paired in biological membranes, based on proofreading and polarized distribution leading to their relative enrichment at the appropriate fusion sites. Rabs also function by concentrating and activating SNAREs, accessory proteins and lipids, at the sites of membrane fusion and are thus required for carrier docking and fusion with the target organelle.

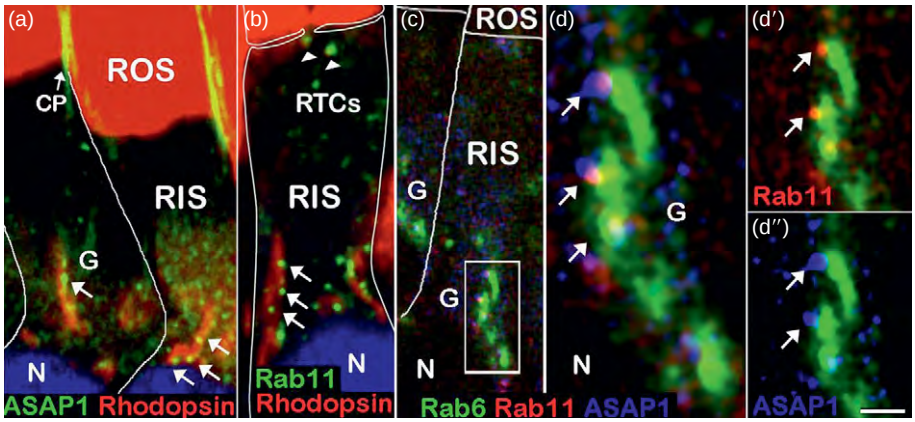

Figure 1 The Arf GAPASAP1 co-localizes with Rab11 on nascent RTCs at the *trans*-Golgi network (TGN). (a) A confocal optical section (0.7 μm) of frog retina labeled with anti-rhodopsin C-terminal mAb 11D5 (red) and anti-ASAP1 (green). Anti-rhodopsin antibody labels the rod outer segment (ROS) and the Golgi (G) in the rod inner segment (RIS), where ASAP1-positive puncta (yellow, arrows) line up with regular periodicity. ASAP1 is also detected in calycal processes (CP) that evaginate from the RIS and surround the base of the ROS. Nuclei (N) are stained with TO-PRO-3 (blue). (b) A confocal optical section labeled with anti-rhodopsin C-terminal mAb 11D5 (red) and anti-Rab11 (green). Rab11-positive puncta (yellow, arrows) aligned with rhodopsin-laden Golgi. Rab11 is also present on RTCs (arrowheads). Nuclei (N) are stained with TO-PRO-3 (blue). (c) ASAP1 (blue) and Rab11 (red) colocalize in the bud-like profiles at the tips of the *trans*-Golgi (Rab6, green) (boxed area magnified in (d). (d) Magnified *trans*-Golgi area from panel C, with ASAP1- and Rab11-positive buds (arrows), which likely represent the TGN. (d′ and d″). Rab11 (red) and ASAP1 (blue) are shown separately. Scale bar = 3 μm in (a)–(c), 0.7 μm in (d), 1 μm in (d′) and (d″). Modified from Mazelova, J., Astuto-Gribble, L., Inoue, H., Tam, B. M., Schonteich, E., Prekeris, R., Moritz, O. L., Randazzo, P. A., and Deretic, D. (2009). Ciliary targeting motif VxPx directs assembly of a trafficking module through Arf4. *EMBO J* 28: 183–192.

SNARE complexes are generally composed of a four-helical bundle bridging opposing membranes and bringing them into close proximity to initiate fusion. Fusion with the plasma membrane requires formation of a complex between syntaxins (Qa SNAREs) and VAMPs (R-SNAREs), each contributing one helix to the four-helix SNARE bundle, and Qbc SNAREs, either neuronal SNAP-25 or non-neuronal SNAP-23, which provide two helices to the central layer of the core complex. SNAREs are targeted to appropriate membrane domains based on specific sequences. The polarized distribution of Qa SNAREs is likely to contribute additional specificity of membrane targeting by promoting fusion with only certain target membranes. Recent evidence suggests that the local lipid environment, particularly phospholipids enriched in omega-3 and omega-6 fatty acids, also contributes to regulate SNARE function.

The membrane fusion event through which RTCs deliver rhodopsin to the cilium is mediated by a SNARE complex. Syntaxin 3 and SNAP-25 are the Q-SNAREs for the fusion of incoming RTCs with the RIS plasma membrane and, therefore, regulators of ROS biogenesis in photoreceptors. The distribution of these SNAREs in photoreceptors is illustrated in Figure 2. Remarkably, omega-3 DHA enhances syntaxin 3 incorporation into SNARE complexes at RTC fusion sites and promotes ciliary membrane expansion and ROS biogenesis. Microtubules direct the restricted distribution of syntaxin 3, consistent with the membrane cytoskeleton playing an essential role in concentrating RTC fusion regulators around the cilium. Syntaxin 3 is the major partner for SNAP-25 in photoreceptor cells; however, SNAP-25 pairing with syntaxin 1A, or 1B, may regulate a distinct trafficking pathway in the RIS. Interestingly, Syntaxin 3 is also found at the base of mouse ROS, suggesting an additional role for this SNARE in rodent rods.

ROS is a Modified Primary Cilium

Almost all cells possess primary cilia that house an array of signal transduction modules. Long underappreciated, the cilium has recently received a great deal of attention due to the ciliary involvement in a wide range of human diseases, including retinal degeneration, polycystic kidney disease (PKD), Bardet–Biedl syndrome (BBS), and neural tube defects. Many cilium disease proteins were detected in the mouse photoreceptor ciliary proteome. Ciliary involvement in a wide range of retinal diseases has come into sharp focus in the past several years, with the molecular mechanism underlying these diseases being rapidly elucidated. Several human syndromes, including Senior–Loken syndrome, Jeune syndrome, and BBS, are also characterized by both cystic kidneys and retinal degeneration, which are often found in combination with skeletal defects or other abnormalities such as obesity, polydactyly, hypogenitalism, and developmental delay that might also be caused by defects in cilia. The organization of the small GTPases,

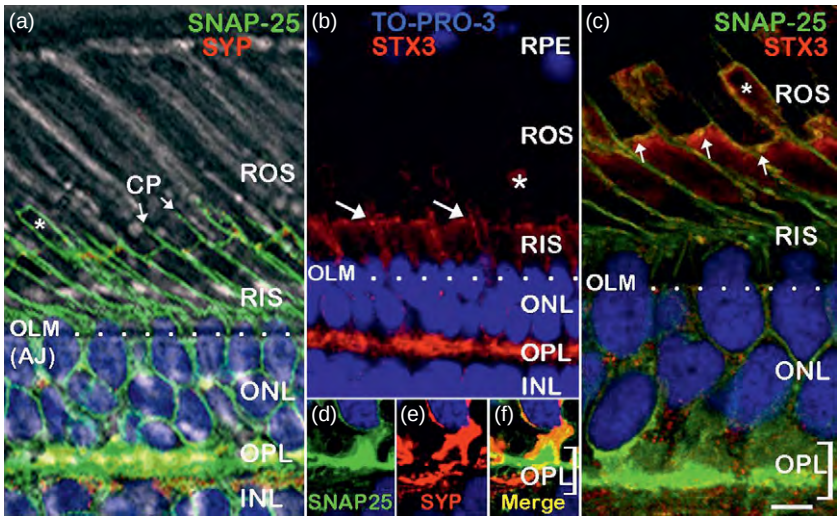

Figure 2 SNAP-25 is a photoreceptor RIS plasma membrane (PM) and synaptic SNARE, whereas syntaxin 3 is concentrated in the RIS PM. (a) A confocal optical section (0.7 μm) of frog retina labeled with anti-SNAP-25 N-terminal mAb (green) and anti-syntaxin 3 (STX3, red). Nuclei are stained with TO-PRO-3 (blue). Anti-SNAP-25 (green) outlines the photoreceptor PM. The calycal processes (CP), which are in continuum with the RIS PM, also contain SNAP-25. The ROS, which are visible by DIC, are completely devoid of this SNARE. AJ, adherens junctions that form the outer limiting membrane (OLM, dotted line). The retinal layers are: ONL-outer nuclear, OPL-outer plexiform, INL-inner nuclear. SNAP-25 co-localizes with synaptophysin (SYP, red) in the OPL, which encompasses the synapses of rods and cones with the rod bipolar, cone bipolar, and horizontal cells. Asterisks indicate the protruding RIS of green rods, a minor subpopulation that accounts for ~5% of total rods. (b) A confocal optical section labeled with anti-syntaxin 3 (STX3, red), which is highly concentrated in the RIS PM (arrows), but is absent from the ROS, and from the RPE. Syntaxin 3 is also abundant in the OPL. Nuclei are stained with TO-PRO-3 (blue). (c) SNAP-25 and syntaxin 3 co-localize (yellow) in the RIS at the RTC fusion sites in the vicinity of cilia (arrows). Syntaxin 3 is also abundant in the inner (lower) half of the OPL (large bracket), where bipolar and horizontal cells are localized, but not in the outer (upper) half where photoreceptor synapses are localized. (d–f). SNAP-25 (green in (d)) co-localizes with synaptophysin (red in (e)) in the photoreceptor synapses (yellow in (f)). However, SNAP-25 is abundant in the bipolar and horizontal cell processes in the OPL (green in (f)), where synaptophysin is not detected. Scale bar = 8 μm in (a), 10 μm in (b), 7 μm in (c)–(f). Modified from Mazelova, J., Ransom, N., Astuto-Gribble, L., Wilson, M. C., and Deretic, D. (2009). Syntaxin 3 and SNAP-25 pairing, regulated by omega-3 docosahexaenoic acid (DHA), controls the delivery of rhodopsin for the biogenesis of cilia-derived sensory organelles, the rod outer segments. *Journal of Cell Science* 122: 2003–2013.

SNAREs and their regulators involved in the ciliary targeting of rhodopsin is schematically illustrated in **Figure 3**.

Twelve BBS genes have been identified. A complex composed of seven BBS proteins, the BBSome, localizes to the base of the cilium and is required for ciliogenesis. BBS3, which is not a part of BBSome encodes the Arf family GTPase Arl6. Strikingly, Rabin8, the GDP/GTP exchange factor that activates Rab8, localizes to the basal body and contacts the BBSome. In cultured epithelial cells, activated Rab8 enters the primary cilium and promotes extension of the ciliary membrane. This explains the accumulation of RTCs below the cilium in photoreceptors expressing mutant Rab8. Strikingly, activated Rab8, in its GTP-bound form interacts with another centrosomal/ciliary protein CEP290/BBS14/NPHP6, which is not a part of the BBSome. Thus, BBS may be caused by defects in Rab8-mediated vesicular transport to the cilium.

An extraordinary array of retinopathy-associated ciliary proteins includes X-linked RP1, which is localized to the proximal cilium and involved in disk morphogenesis, and RP2, which was recently identified as a GAP for the Arf family GTPase Arl3 that is involved in kidney and photoreceptor development. A major player in ciliary morphogenesis is retinitis pigmentosa GTPase regulator (RPGR), which is homologous to RCC1, the nucleotide exchange factor for the small GTPase Ran. Mutations in the retina-specific ORF15 isoform of RPGR (RPGR (ORF15)) were found in X-linked RP3, which is associated with 10–20% of RP. RPGR appears to be a part of a ciliary and basal body protein network that, when disrupted, can result in Leber congenital amaurosis, Senior–Loken syndrome, nephronophthisis, or Joubert syndrome. RPGR (ORF15) co-localizes with RPGRIP1 at centrioles and basal bodies and interacts with nucleophosmin. RPGRIP1, which is affected in patients with LCA, anchors RPGR to the photoreceptor connecting cilium and participates in disk morphogenesis. RPGR also interacts with calmodulin and nephrocystin-5, a ciliary IQ domain protein, which is mutated in Senior–Loken syndrome, and with the centrosomal/ciliary protein CEP290/BBS14/NPHP6, which is truncated in early-onset retinal degeneration in the rd16 mouse. In addition,

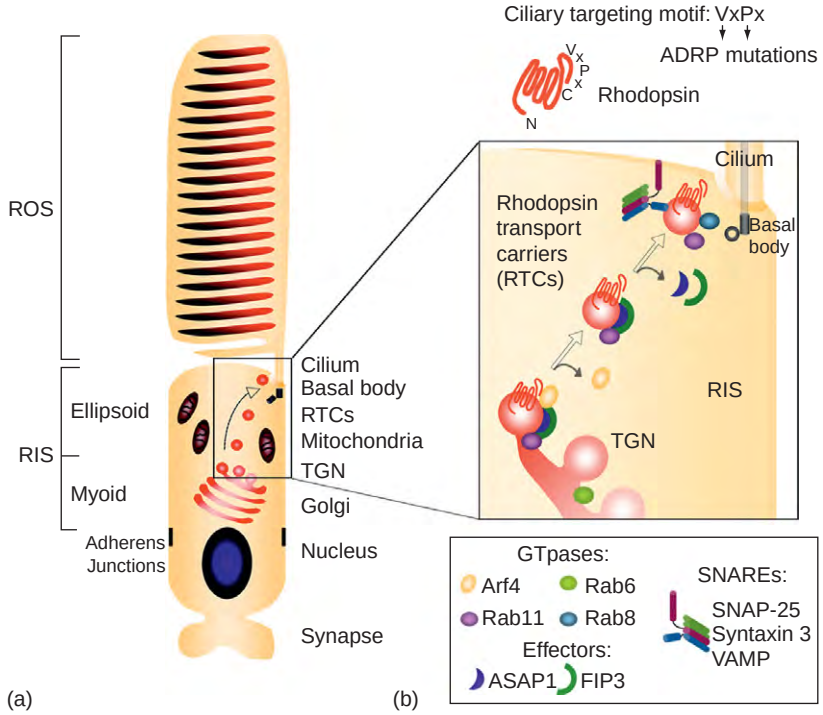

Figure 3 Post-Golgi trafficking and ciliary targeting of rhodopsin (a) Diagram of the rod photoreceptor cell. Cilium protrudes from the cell body (RIS) and elaborates the ROS filled with membranous disks containing photopigment rhodopsin and associated phototransduction machinery. Following synthesis in the RER, newly synthesized rhodopsin traverses the Golgi and the TGN, localized in the myoid region of the RIS, where it is incorporated into transport carriers (RTCs). RTCs travel from the TGN, though the mitochondria-laden ellipsoid region of the RIS, to the base of the cilium where they fuse with the RIS PM. Adherens junctions separate the RIS from the synapse. Little is known about membrane targeting to the RIS PM and the synapse. (b) Polarized trafficking of post-Golgi RTCs is dependent on the rhodopsin C-terminal VxPx ciliary targeting motif. ADRP mutations in the VxPx motif are indicated. Selected proteins involved in the recognition of the VxPx motif, sorting of rhodopsin into the RTCs and their targeting to the cilium are shown in the enlarged area of the RIS. Rhodopsin C-terminal binds to, and recruits Arf4 to the TGN membrane, leading to assembly of a ciliary targeting complex. This complex is comprised of two small GTPases Arf4 and Rab11, the Rab11/Arf effector FIP3, and an Arf-GAP/effector ASAP1. The small GTPases Rab6 regulates trafficking through the Golgi, whereas Rab8 regulates RTC fusion. Syntaxin 3 and SNAP-25 are a part of the SNARE complex that catalyzes RTC fusion at the base of the cilium.

mutations in the gene encoding the basal body protein RPGRIP1L (RPGRIP-like), a nephrocystin-4 interactor, cause Joubert syndrome.

Another ciliary and basal body protein network linked to myosin VIIa is disrupted in human USH, the most frequent cause of combined deafness–blindness. USH is genetically heterogeneous with three clinical types, USH1–3. The scaffold protein harmonin (USH1C) integrates USH1 and USH2 molecules into protein networks. The Usher protein network is organized by the scaffold proteins SANS (USH1G), which provides a linkage to the microtubule transport machinery, and whirlin (USH2D), which anchors USH2Ab and very large G-protein-coupled receptor 1b (VLGR1b). Remarkably, the USH protein network is also a part of the periciliary ridge complex (PRC), a specialized membrane domain for docking and fusion of RTCs in Xenopus photoreceptors. Finally, the Usher protein network is linked to the Crumbs polarity complex in the retina and mutations in Crumbs cause retinitis pigmentosa (RP12).

Conclusions and Summary

Numerous diseases arise from defects in proteins that participate in membrane protein trafficking, vectorial transport, and assembly of outer segment membranes. Thus, maintenance of photoreceptor cell polarity is of utmost importance for their health and survival, and ultimately for vision.

Posterior Capsule Opacification

I M Wormstone, University of East Anglia, Norwich, UK

Glossary

Capsulotomy or Nd:YAG capsulotomy – An opening made in the posterior capsule, usually with a Nd:YAG (neodymium-doped yttrium aluminum garnet) laser, which is intended to remove opacified tissue from the visual axis.

Epithelial-mesenchymal transition – The transformation of epithelial cells to a cell type that resembles mesenchyme. This process is associated with loss of the tight cell adhesions between epithelial cells, the onset of cell migration, and the synthesis of large amounts of a collagenous extracellular matrix.

Rhexis or capsulorhexis – The opening that is made in the anterior capsule through which the opaque fiber cells are removed during cataract surgery.

General Background

Cataract is a general term, describing any opacity of the lens. It appears in many forms and affects the sight of tens of millions of people throughout the world. At present, there is no cure for cataract; therefore, surgical intervention is required to alleviate this problem. With the development of modern cataract surgery, hopes were high that the problem of cataract had been resolved. This surgical procedure involves creating a circular window in the anterior capsule, which provides access to the fiber mass, the most common site of opacity. The fiber cells can then be removed. Some residual fiber cells remain and these can also be removed using irrigation and aspiration. The product of this operation is known as a capsular bag (Figure 1). The capsular bag serves a number of purposes in that it maintains separation of the anterior and posterior chambers and importantly can house an artificial lens commonly known as an intraocular lens, which provides refractive power. Initially, this procedure is extremely effective, but secondary visual loss can result. Despite the rigors of surgical manipulation, a number of lens epithelial cells remain and a wound-healing response is initiated by these cells. The remaining population of lens epithelial cells re-colonize the denuded regions of the anterior capsule, grow onto the outer surface of the anterior capsule, and migrate onto the intraocular lens surface. Most critically, they begin to colonize the previously cell-free posterior capsule and, consequently, encroach upon the visual axis. These cells can then transform in to several different cell phenotypes, which can lead to altered refractive indices within the bag through increased matrix deposition, fiber cell differentiation, bladder cell formation, and matrix deformation (wrinkling/contraction). This condition is known as secondary cataract, after-cataract, and most commonly posterior capsule opacification (PCO; Figure 1). Ultimately, PCO can cause a significant reduction in visual quality and necessitates a secondary procedure to treat posterior capsule opacification. This typically involves the use of a neodymium-doped yttrium aluminium garnet (Nd:YAG) laser to ablate the cells and central posterior capsule of the patient in order to restore a clear path of light through the visual axis.

The original concept of modern cataract surgery was formed in the 1940s by Sir Harold Ridley, but it was not commonly employed until the 1980s. While this procedure is infinitely superior to its predecessor, which involved the complete removal of the lens, the problem of PCO has continued to affect the long-term outcome of modern cataract surgery. While the importance of PCO is often dismissed by surgeons as resolved or insignificant, this notion is not supported by the available literature. A more balanced view is that, through an evolutionary process, cataract surgery and intraocular lense (IOL) design have improved to such an extent that PCO within 2 years of surgery, determined by Nd:YAG capsulotomy rates, has fallen from ~30% to ~10%. This is a significant achievement, but we must consider that 10% of cataract patients is still >1 million people per annum and that more will develop visually deteriorating PCO at stages later than 2 years. In addition, virtually all patients undergoing cataract surgery will develop PCO to some extent, which may still affect vision. PCO therefore is not a problem that should be dismissed and requires even greater efforts to further reduce the rate of incidence. This idea is given even greater support because of the ambition to introduce accommodating lenses as a routine part of cataract surgery. At present, these lenses have very high rates of PCO. Unless this issue can be addressed, their introduction will be limited.

Regulatory Systems and Management of PCO

In this section, the factors that can influence PCO will be discussed. In order to improve the treatment of PCO, it is important to understand the systems which control its development. Consequently, the biological factors that

have been identified will be covered here along with surgical advances, including IOL design, which are, in effect, physical methods designed to overcome or suppress a biological response. It is important to consider the biological processes that contribute to PCO (**Figure 2**). In essence one can consider these to be cell migration, cell division, differentiation into fiber cells, transdifferentiation from an epithelial cell type to a myofibroblast, matrix deposition, and matrix contraction. In order to understand the problem of PCO, one needs to have knowledge of the factors that drive these processes. Through identification of regulatory systems, specific components can be identified and used as therapeutic targets or a physical mechanism can be used to prevent a specific event occurring (e.g., by IOL design). The understanding of the condition and the development of treatment are integrally linked. In due course, putative therapeutic approaches will be discussed, but when considering an approach to prevent PCO there are several options. One method is to kill the entire population of lens epithelial cells within the bag, a second is to prevent proliferation/migration and thus prevent any cell encroachment on the visual axis, while another option is to prevent matrix contraction/fibrosis on the posterior capsule. There are arguments and counter-arguments for each of these strategies. With regard to complete removal of the epithelial cell population, it is possible that a naked capsule will either

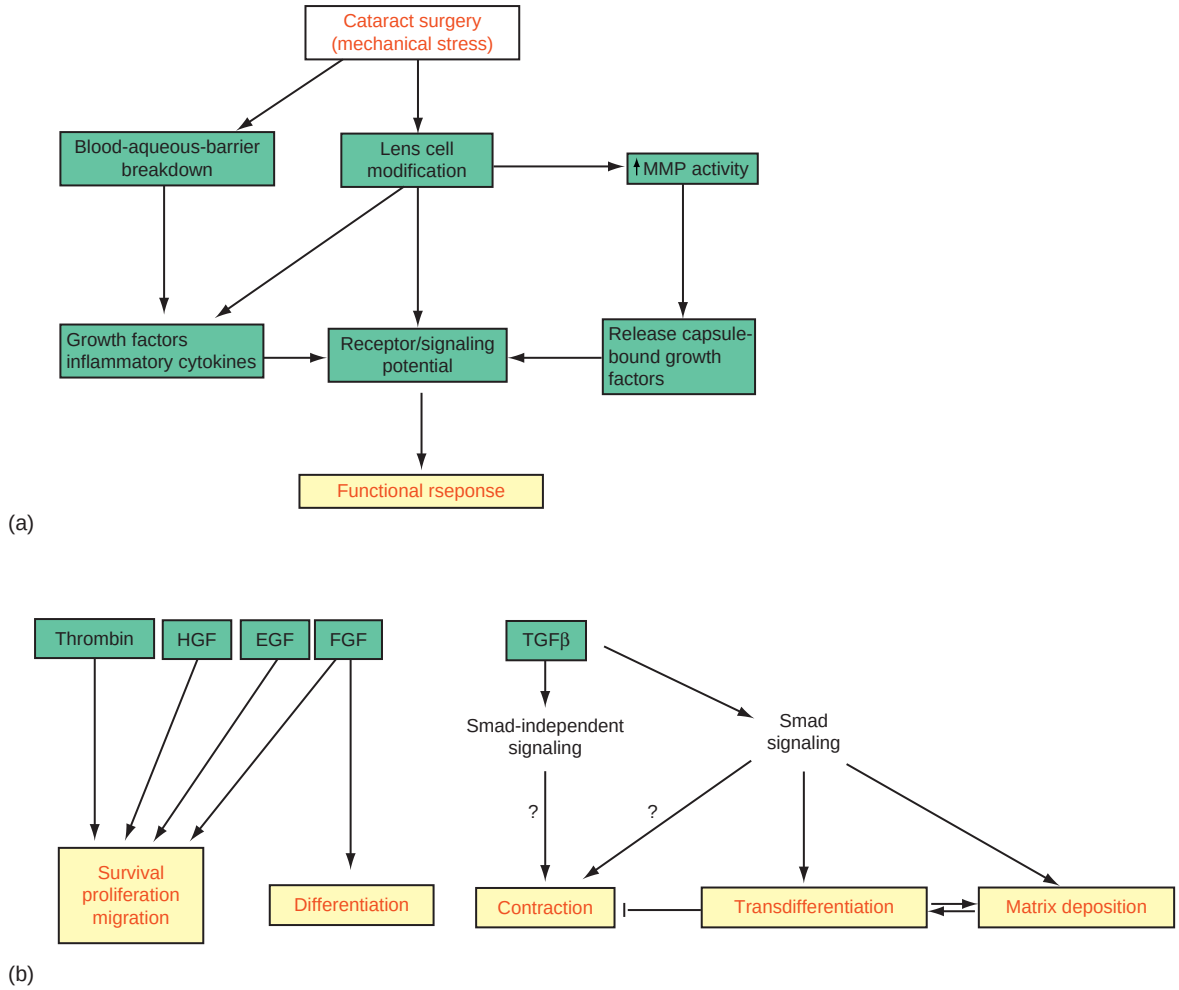

Figure 2 A schematic overview of (a) the wound-healing events following cataract surgery that will ultimately give rise to PCO and (b) the relationship between growth factors and functional events associated with PCO. degenerate, for example, through the action of matrix degrading enzymes or, with the absence of cellular maintenance, become altered, such that it occludes the visual axis. It may, however, continue to permit light to pass along the visual axis unaffected. In relation to the prevention of proliferation, migration, and fibrosis, it could be argued that maintaining the cell population is attractive, but there are still concerns about the period for which effective therapy can be sustained. In all cases, if an agent is used to achieve an effect, it is important that its actions are exclusive to lens epithelial cells; damage to other tissues would render any treatment unsuitable for clinical use. Consequently, the method of drug delivery is also of great importance when considering a pharmacological solution to PCO.

Surgical Factors

The incidence of PCO can be affected by the quality of surgery, for example, maintaining the entire rhexis edge in contact with the anterior IOL optical surface has been shown to significantly reduce PCO rate. However, significant efforts have been made to change surgical practice. In pediatric cases surgeons have employed for some time a double rhexis approach, such that in addition to the standard capsulorhexis on the anterior capsule, a capsulorhexis is also carried out on the posterior capsule before implanting an IOL. The theory behind this being that without a matrix the cells cannot encroach on the visual axis. This procedure has now been adapted further and is known as the bag-in-the-lens technique and involves placing the rhexis edges in a groove along the IOL perimeter. The clinical results from this method are promising, such that no Nd:YAG laser treatment was performed on a study cohort within 1 year of cataract surgery. This method may be viewed as technically difficult, but it does provide a valid surgical approach to manage PCO.

From a number of clinical trials studying different materials, construction, and design of IOLs, the greatest

benefit appears to result from a square design at the optic edge or from capsular tension rings. This helps prevent PCO through a physical characteristic and is reported to create a barrier that suppresses the movement of cells onto the posterior capsule. This improved design is undoubtedly beneficial. Nevertheless, Nd:YAG capsulotomy is still carried out in approximately 10% of patients who have been implanted with these lenses. A patient implanted with a fixed focus IOL will have refractive power, but glasses or other corrective lenses are still often required because of limited ability to accommodate. The future area of development lies with focusable (accommodating) IOLs. However, with these lenses the barrier provided by the square-edge, fixed focus IOLs is no longer effective. Recently, it has been reported that 50% of patients implanted with a 1CU accommodating lens required Nd:YAG capsulotomy 2 years following surgery. In addition, the changes observed with posterior capsule opacification prevent the focus-shift mechanism of accommodating IOLs to function, thus stopping the IOL from moving forward with accommodative effort. If this next-generation IOL technology is to be introduced, PCO needs to be effectively managed.

Biological Factors

There are two basic levels of regulation of lens cells following cataract surgery. The first can be termed paracrine factors, which are often introduced following a breach of the blood aqueous barrier and an inflammatory response. The second is autocrine factors that are synthesized by the lens. PCO is not an instant problem; it can progress over weeks and years. Therefore, to understand the nature of PCO development it is important to understand the relative contributions of both paracrine and autocrine control. In the days following cataract surgery, protein levels in the aqueous humour are high. This allows many blood proteins to reach the remaining lens epithelial cells and, through activation of receptors, initiate a functional response that could contribute to PCO. However, these elevated protein levels are relatively short-lived and return to baseline within a few weeks or months, whereas PCO often becomes a clinical problem years after surgery. This slow, but persistent progression is most likely explained by the autocrine regulation of lens cells. Previous work has shown that lens cells can survive and synthesize proteins in serum-free medium, provided they remain attached to the lens capsule. Moreover, it has also been shown that the majority of the survival protein, transferrin, within the aqueous humor is synthesized by the lens. This survival response, therefore, exists within lens cells. Thus, PCO can be considered as a two-phase process. In the first phase, the response dominated by the introduction of paracrine factors. It is followed by a second slow, but persistent phase, resulting largely from the independent behavior of lens cells. A number of molecules have been identified that can act as paracrine or autocrine factors or both.

Survival, proliferation, migration, and differentiation

The normal lens requires specific functional tasks to take place in specific places. Proliferation, migration, and differentiation are normal events in the lens and, consequently, a number of the factors regulating these processes have been identified. In relation to PCO, the rate of change is increased, but the regulatory principles still apply. Proliferation, in association with migration, is an important aspect of wound healing and PCO. In one study, it has been shown that creating a small capsulorhexis can increase the rate of proliferation in the lens when compared to the intact lens; removal of fibers increased this rate further. Human capsular bags cultured for 3 days in serum-free medium also exhibited a higher number of positive cells, which were largely situated at the equatorial zone, the natural site of cell division. Addition of serum increased the dividing population, again predominantly at the equator. Fiber differentiation also occurs in the peripheral regions of the capsular bag and is often known as Soemerring's ring. While this does not usually encroach on the visual axis, it can provide peripheral glare and cause the IOL to become displaced.

One protein associated with proliferation, migration, and differentiation is fibroblast growth factor (FGF). Using rat lens epithelial explants as an experimental model, McAvoy and Chamberlain showed that basic FGF could give rise to peak rates of proliferation, migration, and differentiation at 0.15, 3, and 40 ng ml^{-1} respectively. Acidic FGF also induced the same effects in a similar pattern, but the concentrations required were an order of magnitude greater. Similarly, human primary cells also demonstrated 10-fold higher sensitivity to basic FGF over acidic FGF. Basic FGF and FGF receptor 1 (FGFR-1), the elements of a potential autocrine pathway, were identified using reverse ranscriptase polymer chain reaction (RT-PCR) in cultured human lens capsular bags. Basic FGF was also detected using enzyme-linked immunosorbent assay (ELISA). Interestingly, the degree of messenger RNA for the ligand and receptor appeared to be greater in cultured bags compared with native human lens epithelium. Moreover, capsular bags removed from donors who had previously undergone cataract surgery also exhibit RNA encoding FGF and FGFR-1. The levels detected were similar to cultured capsular bags. The functional role of this autocrine system was tested by blocking FGFR-1 using a specific inhibitor, SU5402, which caused a retardation of growth. In addition, the affinity of lens cells for FGF has been exploited as a strategy to prevent PCO by using an FGF–saporin complex bound to a heparin surface-modified IOL. The basis of this approach is that when FGF binds to the appropriate receptors on the epithelial cells, internalization of the complex occurs,

including the saporin, which will then lead to cell death. Unfortunately, this particular system produced some side effects, including transient corneal oedema and iris depigmentation.

Epidermal growth factor (EGF) when applied to lens cell cultures has also been shown to induce proliferation. Using human capsular bag cultures, it has been shown that 10 ng ml^{-1} EGF can increase growth across the posterior capsule; moreover, inhibiting the EGF receptor, using the selective inhibitor AG1478, significantly slowed growth rate. The ability of EGF to induce differentiation of epithelial cells to fibers has also been demonstrated by the capacity to form lentoid bodies that express gamma crystallin.

Hepatocyte growth factor (HGF) has been identified in capsular bags removed from donors who had previously undergone cataract surgery. Cells growing on both the anterior and posterior capsules showed increased c-met (HGF receptor) expression in response to surgical trauma, when compared to native epithelium. In addition, HGF was detected in the medium in the first few days of culture and declined with time. Employing the capsular bag model, application of c-met antibody retarded the rate of growth across the posterior capsule.

Application of thrombin, which is typically associated with the blood coagulation cascade, to the human lens cell line FHL 124 resulted in the activation of the extracellular-regulated kinase (ERK) cascade, a rise in intracellular calcium, and enhanced phosphorylation of Akt. Moreover, in capsular bag experiments, an increased rate of growth across the posterior capsule was observed in response to thrombin. The receptor mediating these events is PAR1, which was determined by the use of specific activating peptides for the four PAR members and detection of message using RT-PCR. Disruption to the blood aqueous barrier, as a consequence of surgery, introduces blood proteins, including thrombin, and is, therefore, likely to affect lens cell behavior.

Many growth factors activate shared signaling pathways. Consequently, signaling components and pathways are a source of great interest to the PCO field. Application of U0126, a mitogen-activated protein kinase kinase (MEK) inhibitor that disables MAP kinase signaling to capsular bag cultures, caused a retardation of growth, but not complete growth arrest suggesting that multiple signaling pathways are involved. Using a chick capsular bag model, the role of Src family kinases (SFKs) has been investigated. Application of PP1 an SFK inhibitor was capable of inhibiting migration on to the posterior capsule. In addition, application of the proteosome inhibitor, MG132, to the human lens epithelial cell line, HLE B-3, caused a reduced rate of proliferation in the presence of different growth stimuli. In addition, cell cycle regulatory proteins p21 and p27 were increased in association with growth inhibition. Intracellular calcium signaling is also a key mechanism in the regulation of lens cells. It has been shown that the application of thapsigargin, a calcium ATPase inhibitor that effectively ablates calcium signaling, results in reduced protein synthesis, proliferation, and increased apoptosis. When directly coated onto an IOL, thapsigargin successfully killed all cells within the capsular bag. However, this coating was too basic and did not account for the physical stress associated with entry through the corneal/scleral tunnel. Recent advances in drug delivery can overcome some of these problems. The Perfect Capsule system is one method that has been investigated in the clinic and laboratory and seems to be a promising approach. This is a means to thoroughly perfuse the capsule with a solution or drug prior to the introduction of an IOL. Human capsular bags prepared *in vitro* were cultured following a 2 min application of 100 μM thapsigargin, which caused complete ablation of the lens epithelial cell population. Interestingly, other agents were also applied to capsular bags in this fashion. Distilled water appeared to cause cell death in the short term, but at the end-point of the study, cell growth was similar to untreated controls. Three molar of NaCl and 250 μg ml^{-1} 5-fluorouracil (5-FU), a drug that interferes with cell growth, had some inhibitory effect, but growth on the posterior capsule was still extensive. Higher doses of 5-FU did cause a significant reduction in coverage of the central posterior capsule, but at day 28 it was evident that viable cells remained on the anterior capsule and on the peripheral posterior capsule. Therefore, it is predicted that 5-FU would retard PCO development, but not prevent it. Interestingly, direct comparison between *in vitro* capsular bag data and the clinic can now be made. Application of distilled water, using the Perfect Capsule system, has been performed in patients. The data from the human capsular bags predicted that distilled water would be ineffective and this proved to be the case clinically. Moreover, the role of the capsular bag model to predict pharmacological responses was strengthened recently. The profile of sensitivity to the agents described earlier differed in human and rabbit *in vitro* capsular bag cultures, such that thapsigargin was ineffective in the rabbit and 5-FU was the most effective at inhibiting growth. Both thapsigargin and 5-FU have also been studied using an *in vivo* rabbit system. The drugs were again delivered using the Perfect Capsule device. As with the *in vitro* results, thapsigargin was ineffective, while 5-FU was successful. This collection of data is important; as it shows that the pharmacological profile in rabbits differs from humans and that the *in vitro* model strongly predicts the pharmacological response *in vivo* for a given species.

Transdifferentiation, matrix contraction, and matrix deposition

A single monolayer of cells would not significantly disturb the light path. Light scatter that we associate with PCO is actually associated with changes in refractive index caused

by matrix contraction, that is, a wrinkling of the posterior capsule along with cell aggregation and matrix deposition. These are, in effect, fibrotic events and are common in pathologies throughout the body. With respect to fibrosis, epithelial–mesenchymal transition or transdifferentiation is often implicated. In the case of lens cells, a transformation from an epithelial cell phenotype to a myofibroblast is often described and is identified by expression of the marker protein, α-smooth muscle actin (α-SMA). Analysis of post-mortem material has shown that, in cases with PCO, there is evidence of contraction, cell aggregation, and matrix deposition in association with α-SMA expressing cells. The most likely candidate to cause this response is the cytokine, transforming growth factor-β (TGFβ). Understanding the role of TGFβ in lens fibrosis has become a major area of investigation. *In vitro* studies using rat explants, cell lines, and the human capsular model have demonstrated that the addition of TGFβ can induce marked transdifferentiation, matrix deposition, and cause matrix contraction.

Levels of active TGFβ are known to increase following injury, which arises from increased production and activation of a latent form of the cytokine, due to proteolytic cleavage of TGFβ binding proteins. The major isoform found in the eye is TGFβ2, but TGFβ1 and TGFβ3 can also be introduced following a breakdown of the blood-aqueous barrier. It has been reported that TGFβ-regulated Smad signaling proteins are present in the nuclei of cells in capsular bags following cataract surgery and wound healing responses can be suppressed by TGFβ antibodies. Therefore, TGFβ is available to lens cells following surgery and is capable of inducing the responses observed *in vivo*.

Post-mortem analysis of a capsular bag received from a donor 1 month following cataract surgery provided evidence of matrix contraction/wrinkling of the posterior capsule and transdifferentiation. Importantly, addition of TGFβ2 to *in vitro* human capsular bags replicated these events over a similar time frame. These effects could be produced after exposure to 10 ng ml^{-1} TGFβ for the first 2 days of culture or after exposure for the complete 28 day culture duration. The fact that significant long-term changes can result from a relatively short exposure to TGFβ is important because the level of active TGFβ in the aqueous humor of patients is likely to be highest within the first week following surgery; the results observed *in vitro* therefore support the idea that this increase is sufficient to provide a long-term contribution to PCO development. There are two possible mechanisms by which this could be achieved: first, through a positive feedback TGFβ level can be increased following TGFβ exposure and second TGFβ can bind to the lens capsule. One substrate with which TGFβ is reported to associate is collagen type IV, which constitutes the bulk of the lens capsule.

A commonly held view is that transdifferentiation of lens epithelial cells into the myofibroblast phenotype is a prerequisite for matrix contraction to occur. This notion is based on the assumption that α-SMA forms an integral part in the formation of contractile apparatus. Much of the evidence to support this theory is circumstantial based on the observation that α-SMA is expressed and matrix contraction occurs in response to TGFβ; on the face of it, this seems plausible. However, it has recently been shown, using the FHL 124 human lens cell line, that transdifferentiation does not appear to drive TGFβ-mediated matrix contraction. This argument is based on a number of results. A comparative study of TGFβ1 and TGFβ2 showed that the latter was a more potent inducer of transdifferentiation, but with respect to matrix contraction TGFβ1 was more potent. Moreover, through the use of siRNA targeted against α-SMA, TGFβ-induced α-SMA expression was suppressed, but matrix contraction was enhanced. In addition, using Arg-Gly-Asp-Ser (RGDS) peptide to block fibronectin/fibronectin receptor (α5β1 integrin) interaction, which is a process also reported to mediate transdifferentiation, leads to an enhanced rate of contraction. Therefore, TGFβ is capable of stimulating cells to undergo both transdifferentiation and matrix contraction, but the signaling pathways driving these events are different.

In terms of putative prevention of PCO, attempts to maintain a lens cell phenotype have been investigated. Application of lithium chloride (LiCl) to rat explant cultures successfully maintained the epithelial cells in a polarized state. In maintaining this phenotype, proliferation and migration were inhibited. Moreover, treatment with LiCl also prevented TGFβ-induced transdifferentiation, such that α-SMA expression was significantly suppressed. TGFβ has also been blocked directly, using a fully human monoclonal anti-TGFβ2 antibody. This antibody neutralizes the effects of TGFβ in a human lens cell line and *in vitro* human capsular bag model. A 2-day period of exposure to an *in vitro* capsular bag was sufficient to suppress TGFβ-induced matrix contraction, α-SMA expression, and Smad signaling for extended periods. The antibody is adsorbed by the lens capsule, which extends the longevity of its actions. However, it is important to note that neutralization of a single TGFβ isoform is probably insufficient to yield a positive therapeutic effect, due to the availability of other TGFβ isoforms following surgery; inhibition of all TGFβ isoforms could be a more productive route.

Summary

While improved IOL design has reduced the incidence of PCO, the problem still remains. Moreover, PCO is

impeding the introduction of accommodating lenses as a routine part of surgery. We are gaining a greater understanding of the biological mechanisms underpinning PCO development. Targeted inhibition of these mechanisms is likely to be of benefit to patients. It is important that both surgical and biological approaches are developed in concert to manage PCO and, as a result, improve the quality of life of millions.

Posterior Subcapsular and Anterior Polar Cataract

C-K Joo, J-C Choi, and H-G Kwan, Catholic University, Seoul, South Korea
H Kim, Baekseok University, Cheonan, South Korea

Glossary

Amblyopia – Visual impairment resulting, in most cases, from an opacity or refractive error early in life, when the visual maps in the brain are undergoing functional refinement.
Curvilinear capsulorhexis – A surgical technique by which the anterior lens capsule and associated lens epithelial cells are removed at the beginning of modern cataract surgery. In the case of lenses with anterior polar cataracts, most or all of the opacity is removed in this process.
Fibrosis – A cellular response to injury involving the accumulation of excessive amounts of extracellular matrix materials. The excessive matrix interferes with the normal function of the tissue. In the case of lens fibrosis, the lens epithelial cell moves out of the epithelial cell layer but scattering light does not occur. The epithelial cells that moved are transformed by fibrosis and then the normal lens structure is broken down in the fibrosis zone.
Transdifferentiation – The conversion of one differentiated cell type to another. In this case, the conversion of lens epithelial cells to a myofibroblast-like cell.

Prevalence

Posterior subcapsular and anterior polar cataracts are often seen in patients younger than those presenting with nuclear, cortical, or mixed cataracts.

The prevalence of posterior subcapsular cataract was 10.2% in an Australian urban population over 40 years of age. In a population-based, cross-sectional study of elderly Chinese, the prevalence of posterior subcapsular cataract was 4.3%. The proportion of these cataracts in subjects in the age range of 40–49 years and 50–59 years was 1.2% and 4.1%, respectively. The proportion of female patients with incident posterior subcapsular cataracts has been reported to be 57.7%, suggesting that, like other age-related cataracts, females may be more susceptible to the condition.

Although the prevalence of anterior polar cataracts has not been reported in population-based studies, the prevalence of anterior polar cataracts as a fraction of total cataract patients is generally agreed to be quite low. However, in Korea, the prevalence of anterior polar cataract in total cataracts was high in comparison to the experience in other countries. In a hospital-based study, of the total percentage of all patients presenting for cataract surgery, 6.02% had anterior polar cataracts; of these, 87.0% were male. The mean age of patients with anterior polar cataract was 52.7 years; 38.9% were younger than 50 years of age, 42.6% were in their 50s, 14.8% in their 60s, and 3.7% in their 70s. The unusual geographic, age, and sex distribution of these opacities has not been explained.

Mechanisms

Cataractogenesis and Lens Epithelial Cells

The lens epithelium is the first site in the lens that is exposed to an insult coming through the cornea or in the aqueous humor that may result in cataract. Although lens epithelial cells have the machinery to combat cataractogenic insults, any damage to these cells may lead to cataract. Aging, stress, ultraviolet radiation, hydrogen peroxide, and cytokines are cataractogenic factors that may activate lens epithelial cell proliferation, migration, extracellular matrix (ECM) accumulation, and epithelial–mesenchymal transition (EMT), leading to cataract formation.

Anterior Polar Cataract

Anterior polar cataract is caused by the transdifferentiation and abnormal proliferation of lens epithelial cells and the accumulation of an abnormal ECM that is secreted by these cells.

Epithelial–Mesenchymal Transition

During the formation of anterior polar cataracts, lens epithelial cells transdifferentiate into large plaques of spindle-shaped, contractile cells, called myofibroblasts, by the process of epithelial–mesenchymal transition (EMT). EMT is a highly conserved, fundamental process that occurs during many phases of embryonic development in multicellular organisms. In mammals, EMT first occurs at the blastula stage, during the formation of the parietal endoderm, which later contributes to the formation of extraembryonic tissues. EMT is, later, involved in gastrulation, the formation of neural crest cells, and many other developmental processes. EMT or EMT-like processes also occur in a variety of disease mechanisms, including renal fibrosis, liver cirrhosis, and cancer metastasis.

Pathological fibrosis in various tissues involves modulation of the interaction between the cells and molecules of the ECM. Transforming growth factor-beta (TGF-β) has been implicated as a strong inducer of fibrotic diseases in many cell types. It is one of the well-characterized cytokines driving the transformation and pathological fibrosis of lens epithelial cells. When the monolayer lens epithelium is treated with TGF-β, the cells lose contacts with their neighbors and acquire a bipolar, elongated shape, bundles of microfilaments, and enriched rough endoplasmic reticulum. These are changes typical of EMT. Therefore, exposure to increased levels of TGF-β is a risk factor in the formation of anterior polar cataracts.

The accumulation and rearrangement of the ECM in anterior polar cataracts suggest that these cataracts involve alterations in the synthesis and/or degradation of matrix proteins. Many researchers have reported that ECM accumulates in anterior polar cataract tissue, including collagen types I and III, and fibronectin. These matrix components are also found in postoperative capsule opacification and are considered to be produced by fibroblast-like lens epithelial cells. Studies have also reported on the role of matrix metalloproteinases (MMPs) in cataract. The secretion of MMP-2 and MMP-9 was stimulated by the TGF-β or hydrogen peroxide in lens epithelial cells and MMP secretion induced transformation of lens epithelial cells. Inhibitors of MMPs have been reported to inhibit the formation of fibrotic plaques in cultured lenses.

It has been suggested that various growth factors may be involved in regulating matrix macromolecule production. TGF-β and fibroblast growth factor-2 (FGF-2) are the most likely candidates. Members of the FGF family are present in a gradient from anterior to posterior in the eye. FGFs regulate epithelial cell proliferation, migration, and differentiation. Both the mitogen-activated protein kinase (MAPK) and phosphoinositide 3-kinase (PI3K) signaling pathways have been implicated as downstream mediators of FGF-induced proliferation and differentiation. Members of the TGF-β and Wnt families of growth factors – which are involved in various stages of lens development – can also regulate the ability of lens epithelial cells to undergo EMT.

Steroid-Induced Cataract

Chronic treatment of patients or animals with steroids may induce a posterior subcapsular opacity in the lens. Steroid-induced posterior subcapsular cataracts occur bilaterally and are easily differentiated from the more common senile nuclear or cortical cataract and some other forms of posterior subcapsular cataract. At the cellular level, steroid-induced cataracts are associated with nucleated epithelial cells that migrate from the equatorial region to the posterior region of the lens.

Glucocorticoid

Glucocorticoids are highly effective anti-inflammatory agents for allergy, asthma, rheumatoid arthritis, and other autoimmune diseases. However, a significant risk exists for the development of complications when glucocorticoids are administered for an extended period at relatively high doses. One of the ocular complications of steroid treatment is the development of cataracts – specifically posterior subcapsular cataracts (PSCs). Despite studies of steroid-induced cataracts, the precise molecular mechanisms involved are unclear, partly because it is difficult to procure human samples.

A few animal models have been developed to examine the effects of glucocorticoids on the lens. After an intravitreal injection of glucocorticoid, opacification appeared in the rabbit lens beneath the posterior capsule. Long-term administration of steroids to rats also induced cataracts, in rats, that were similar to human steroid-induced cataracts. However, it takes more than 8 months to produce phenotypic changes with the *in vivo* model system. One of the mechanisms suggested for posterior subcapsular capsules formation is the inhibition of Na-K-ATPase by corticosteroids. This would increase intracellular sodium concentrations and decreases potassium levels, which leads to the accumulation of water within lens fiber cells.

Lens Epithelial Cell Migration

E-cadherin is a cell-adhesion protein that is normally expressed by lens epithelial cells. Decreased expression of E-cadherin protein followed the administration of steroids. This may account for the abnormal migration of epithelial cells along the capsule. Because the abnormal cells may have been impeded in their differentiation into fiber cells, it is possible that the adhesion of fiber cells to the posterior capsule or the interaction between fiber cells was disrupted. Therefore, the opacity may be caused by the abnormal migration of lens epithelial cells.

Additionally, the posterior capsular opacity by steroid requires signaling mediated by the glucocorticoid receptor. Glucocorticoids may induce new-gene expression including genes involved in signal transduction, transcription factor activity, cytoskeleton, ECM, cell adhesion, membrane transport, and cell cycle in the lens epithelial cells.

Clinical Aspects

Even though anterior polar cataracts and posterior subcapsular cataract involve the same mechanism of visual disturbance and both occur in the visual axis, patients experience more severe visual symptoms with posterior subcapsular opacities. Patients may have relatively little visual impairment with anterior polar cataracts, but may

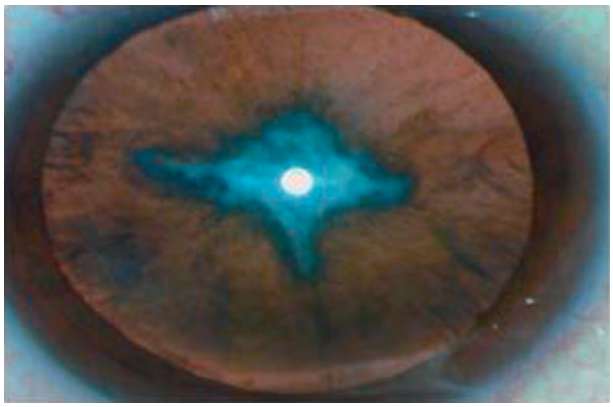

Figure 1 Anterior polar cataract. Courtesy of Choun-Ki Joo MD PhD.

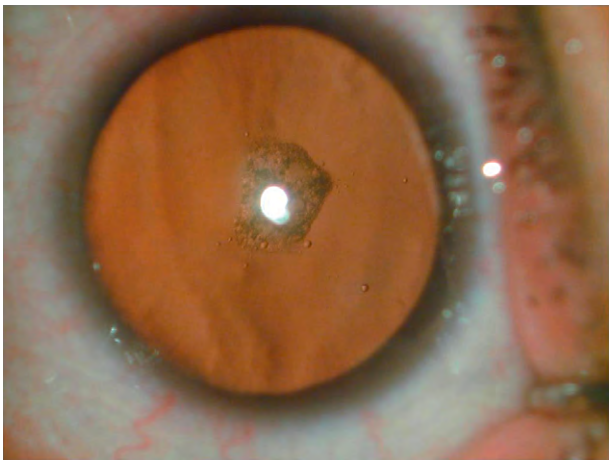

Figure 2 Posterior subcapsular cataract. Courtesy of Choun-Ki Joo MD PhD.

be severely impaired by PSCs. During cataract surgery, the anterior polar-type cataract may be removed easily after continuous curvilinear capsulorhexis, followed by phacoemulsification.

Anterior polar cataracts may present as a congenital (autosomal dominant inherited) or acquired opacities, secondary to uveitis or trauma. In the slit-lamp examination, anterior polar cataract usually has a star shape. It can lie flat on the lens surface or protrude forward from the lens as a small pyramid. However, the cause of most anterior polar cataracts is unknown in the Korean medical literature (**Figure 1**).

Anterior polar cataracts are divided into two groups. Opacities associated with the lens capsule and cataracts also involve the anterior lens fiber cells. Several theories may explain the mechanism of congenital anterior polar cataract. One suggests that the opacity may develop from an intrauterine infection, causing the transformation of epithelial cells. According to another theory, normal nutrition of the lens may be adversely influenced by a persistent vascular tunica that can lead to lens opacity.

Generally, anterior polar cataracts do not affect visual acuity as severely as those at the posterior pole. Traditionally, it has been thought that anterior polar cataracts <2 mm in size are unlikely to interfere with vision sufficiently to induce amblyopia. However, Jaafar and Robb noted a surprisingly high incidence of visual morbidity in 63 patients with anterior polar cataracts. More than one-third of patients were found to have strabismus, anisometropia, or amblyopia. They found that amblyopia did not result from enlargement of anterior polar opacities but occurred secondary to strabismus, anisometropia, and the presence of asymmetrically shaped opacities. Wheeler and colleagues also reported a high incidence of amblyopia. Amblyopia was related to three probable causative factors: (1) size of the opacity, (2) asymmetry of the opacity, and (3) superimposition of cortical changes.

Posterior subcapsular cataracts (**Figure 2**) occur at the posterior pole of the lens and are most often related with the aging process. They are mainly due to posterior migration of lens epithelial cells from the equator. These epithelial cells cluster, form balloon cells, and interdigitate with adjacent lens fibers and the deeper cortical fibers, breaking them down. The result is the lacy, granular, iridescent appearance of PSCs.

Patients with PSCs tend to have relatively good distance-acuity in low-light conditions, but markedly reduced near vision with glare in bright light or with night driving. The reason for this is that the reduced aperture in brighter light prevents the entrance of the more peripheral light rays, resulting in more light passing through the opacity. In PSCs, the opacity is also closer to the nodal point of the eye. It has been suggested that this is the reason that the PSC decreases visual acuity more significantly than does anterior polar cataract, although this remains a controversial explanation.

Posterior subcapsular cataract is the typical cataract type seen with different intraocular diseases (high myopia, retinitis pigmentosa, diabetes mellitus, uveitis, etc.), trauma, or drugs (corticosteroids, antimalarial agents, etc.). However, the cause of the cataract cannot be established from only the ocular appearances. PSCs may develop as isolated entities or may be associated with other types of lens opacities. Often, some granules and vacuoles are found in front of the posterior opacity.

The PSC is one of the most difficult challenges for the cataract surgeon because of the increased tendency for rupture of the posterior capsule during cataract removal. Osher and colleagues reported a 26% incidence of capsule rupture in a series of 31 cases, and Vasavada and Singh reported a 36% incidence in a series of 22 cases. Das and colleagues reported that posterior capsule rupture occurred in 25 (31%) eyes, and was more common in young patients (<40 years). These authors reported that posterior capsule rupture was more common in extracapsular cataract extraction with phacoemulsification. Many

Table 1 Comparison of the main features of anterior polar and posterior subcapsular cataracts

Cataract type	*Anterior polar cataract*	*Posterior subcapsular cataract*
Location	Anterior visual axis	Posterior visual axis
Causes	Congenital, uveitis, trauma	Aging, intraocular disease, drugs (steroids), ionizing radiation
Effect on visual acuity	In congenital cases, little effect or increased risk of amblyopia. In acquired cases, effect mostly in early stages	Impairment, even in early stages; glare and decreased visual acuity, especially in bright sunlight or when driving at night; vision better in dim illumination
Surgical outcome	Easily removed after continuous curvilinear capsulorhexis and standard cataract surgery	High incidence of posterior capsular rupture

techniques have been introduced to protect the posterior capsule during cataract surgery. Howard Fine and colleagues placed emphasis on avoiding pressure on the posterior capsule and stated that careful viscodissection of lens material will help the surgeon successfully meet this challenge. A comparison of anterior polar cataract and PSC is presented in Table 1.

Presbyopia

A Glasser, University of Houston, Houston, TX, USA

Glossary

Accommodation – The dioptric change in optical power of the eye to focus at near. In the young phakic eye, this occurs through an increase in the lens anterior and posterior surface curvatures.
Cataract – An optical opacification of the natural lens that most often occurs through the natural process of aging, but can also result from injury to the lens. A cataract can ultimately reduce the quality of vision if the cataract develops within an area of the lens through which light normally passes to reach the retina.
Depth of field – The range of movement of an object in object space over which there is no perceptible change in focus of the image.
Depth of focus – The range of movement of the image in image space over which there is no perceptible change in focus of the image.
Emmetropia (or an emmetropic eye) – An eye without a refractive error (i.e., without hyperopia or myopia). An unaccommodated emmetropic eye would be normally focused for infinity.
Far point – The point of focus of the eyes when accommodation is relaxed. For an emmetropic eye, this is optical infinity.
Hyperopia (referred to as far-sighted) – A refractive error of the eye in which, technically, the eye is in focus for a virtual object behind the retina, that is, the far point of a hyperopic eye is behind the retina. For a hyperopic eye, there is no distance in front of the eyes at which an object can be positioned so that the image is in focus on the retina when accommodation is relaxed.
Myopia (referred to as near-sighted) – A refractive error in which the eye is focused for an object that is closer to the eye than optical infinity, that is, the far point of the eye is at a closer distance to the eye than optical infinity.
Near point – The closest point of focus of the eyes when the eyes are maximally accommodated.
Phakic eye – An eye that still retains the natural lens.
Presbyopia – The age-related loss of accommodative amplitude which is primarily due to a loss in the ability of the lens to undergo accommodative optical changes. Ultimately, by about 55 years of age the human eye completely loses the ability to accommodate.
Pseudo-accommodation – Some degree of functional near vision that can be attained through nonaccommodative means such as due to ocular aberrations, multifocal optics (such as from a contact lens or an intraocular lens (IOL)), or an increased depth of field of the eye.
Pseudophakic eye – An eye in which a cataract surgical operation has been performed to remove the natural phakic lens to replace it with an artificial IOL.

Accommodation

Accommodation is defined as a dioptric change in power of the eye with an effort to focus at near. In the natural young phakic eye, accommodation is due to an increase in the optical power of the lens. The increase in the optical power of the lens comes about through an increase in the lens anterior and posterior surface curvatures. An effort to focus on a near object results in a contraction of the ciliary muscle, an inward movement of the inner apex of the ciliary body toward the axis of the eye. This results in a relaxation of zonular tension around the lens equator to allow the elastic capsule surrounding the lens to mold the young lens into a more spherical and accommodated form. Accommodation is not simply the ability of a distance-corrected eye to see clearly at near. For example, in a complete presbyope with no accommodation, some degree of functional near vision can be achieved by placing a multifocal contact lens on the cornea. The multifocal contact lens may permit the presbyopic eye some degree of simultaneous focus at both near and distance. This is not an active process but is due to the multifocal optics of the contact lens. The ability of an eye to achieve some degree of functional near visual acuity without active accommodation is called pseudo-accommodation. Many factors can contribute to pseudo-accommodation including an increased depth of field of the eye due to multifocal optics, a small pupil diameter which results in an increase in depth of field, or the presence of ocular optical aberrations such as astigmatism, spherical aberration, or coma. Further, if vision is available to both eyes, some degree of simultaneous near and distance vision can be achieved with one eye corrected for distance and the other corrected for near. This is monovision and as with pseudo-accommodation it can provide some relief to the

symptoms of presbyopia to allow a patient to see at both distance and near, but it is clearly very different from the active optical change in power of the eye that occurs with accommodation.

Presbyopia

Presbyopia is defined as the gradual and progressive age-related loss of accommodative amplitude and is ultimately due to an age-related loss in the ability of the lens to undergo accommodative optical changes (**Figure 1**). Presbyopia is ubiquitous in that every person who lives to beyond 50–55 years of age will ultimately and inevitably, completely lose the ability to accommodate. The impact and symptoms of presbyopia are felt most strongly by emmetropes and uncorrected hyperopes. An emmetropic eye, with a far point at optical infinity, must accommodate to focus clearly on objects at any distance closer to the eyes than optical infinity. The hyperopic eye, with a far point behind the eye, must accommodate to focus clearly on an object at any distance in front of the eye, including for an object at optical infinity. This is only possible if the hyperopic eye has sufficient amplitude of accommodation

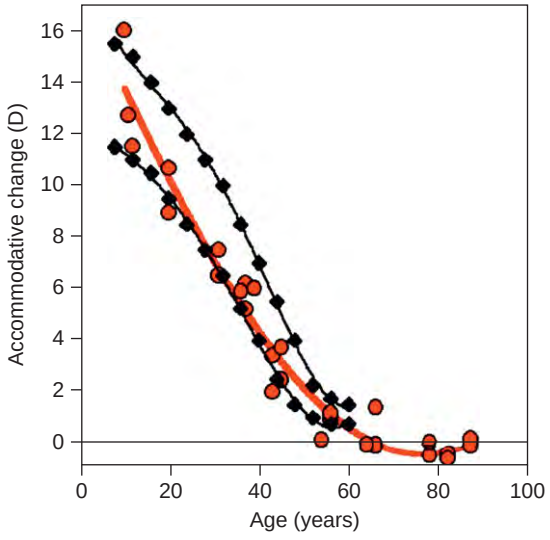

Figure 1 Mechanical stretching studies on human eye bank eyes (red circles) ranging from 10 to 86 years of age show that young human lenses are able to undergo about 12–16 D of accommodative change and that by the age of about 60 years the same amount of mechanical stretching fails to produce any systematic accommodative change in optical power of lenses over 60 years of age. The data from enucleated human eyes are plotted together with the range of subjectively measured accommodative amplitudes from more than 1000 human subjects (black diamonds) taken from Duane (1912). Reproduced from Glasser, A. and Campbell, M. C. W. (1998). Presbyopia and the optical changes in the human crystalline lens with age. *Vision Research* 38: 219, with permission from Elsevier.

to overcome the hyperopic defocus as well as the vergence due to the near object. Myopes suffer the symptoms of presbyopia to a lesser degree than emmetropes and hyperopes. The far point of the uncorrected myopic eye is at a distance in front of the eye closer than optical infinity and therefore myopes can focus on objects at this distance without the need to accommodate by simply removing their distance correction.

Presbyopia represents a complete failure of the normal physiological function of accommodation roughly two-thirds of the way through the normal human life span. The progression of presbyopia actually begins early in life (**Figure 1**) and results in a gradual and progressive decrease in objectively measured accommodative amplitude from about 10 D around 10 years of age ultimately to 0 D by about 55 years of age. The word presbyopia (Greek, *presbys* meaning an aged person and *opsis* meaning vision) possibly derives from Aristotle's use of the term presbytas to describe those who see well at distance, but poorly at near. Historically, the term presbyopia was used to describe the condition where the near point has receded too far from the eye for normal near-vision tasks due to a loss of accommodation. Since the accommodative mechanism was first described by Helmholtz and Gullstrand, it has generally been understood that presbyopia results from an age-related loss of accommodation due to an increase in stiffness of the lens. Normal, emmetropic individuals start to experience the symptoms of presbyopia by about 40–45 years of age. These symptoms include blurred vision at near, visual fatigue or headache after attempting to read at near for prolonged periods, or an inability to sustain clear vision at a normal reading distance. These symptoms usually occur when the amplitude of accommodation decreases to below about 3–4 D. For patients first experiencing the symptoms of presbyopia, it often appears that presbyopia is of sudden onset. However, presbyopia progresses gradually for many years and it is only by about 40–45 years of age that patients for the first time start experiencing the symptoms of not having sufficient accommodation to adjust the focus of their eyes for the habitual reading or working distance.

Our current understanding of the accommodative mechanism and the age-related changes in the eye comes from studying human eyes as well as the eyes of rhesus and cynomolgus monkeys. The anatomy of the accommodative apparatus of the rhesus monkey eye is similar to that of humans. Young rhesus monkeys have high accommodative amplitudes and rhesus monkeys are the only animal species known to experience the same age-related loss of accommodation as humans. Although the life span of rhesus monkeys is shorter than that of humans, they develop presbyopia with a similar relative age-course as humans when adjusted for life span. Presbyopia may be a symptom of outliving the functional life span of the

accommodative system due to increased longevity. Few tissues in the body continue to grow throughout life. Among those that do are nails, hair, and the lens. There are no adverse consequences to continued growth of nails and hair and failure of the primary physiological function of essential organs, such as the heart and liver, would ultimately be incompatible with life; however, in the case of the lens, continued growth ultimately results in a loss of one of its primary functions, that is, accommodation. Loss of accommodation may simply represent the organism outliving one of the physiological functions of the lens. For humans who might once have had a life span less than 40 years, presbyopia would never have become symptomatic. In monkeys in the wild in which life span is shorter than in captivity, reduced life span may be exacerbated by a loss of normal visual function, including accommodation. However, it has also been suggested that from an evolutionary perspective, presbyopia may be adaptive in the hierarchy of monkeys where time spent by the alpha male and other elders on the lookout, scanning the distance for predators rather than performing near-vision tasks requiring accommodation may serve as an important survival strategy for the troop. The modern-day near-obsession with presbyopia may be as much due to suffering the symptoms longer as it is due to the perceived negative connotations or cosmetic insult attributed to reading glasses.

Age-Related Changes in the Eye

There are a myriad of age-related changes in the various anatomical components of the eye involved in the accommodative mechanism that could possibly contribute to the loss of accommodation. For accommodation to occur, there must be a fine balance of forces between the stiffness of the lens nucleus and cortex, the elasticity of the lens capsule and the zonular fibers, and the ciliary muscle and ciliary body. Any disruption to this balance of forces could contribute to a loss of accommodation. Age-related changes have been reported in just about every aspect of the accommodative anatomy and potentially any of these age-related changes could contribute to the loss of accommodation. The most important aspects of the accommodative system are the ciliary muscle which serves as the engine that drives accommodation, the zonular fibers that extend from the ciliary body to insert around the lens equator and in the unaccommodated eye apply an outward-directed tension to maintain the lens in a relatively flattened and unaccommodated state, the lens capsule surrounding the lens that provides the force to change the shape of the lens, and the lens nucleus and cortex that must undergo a change in shape to allow accommodation to occur. Age-related changes have been described in all these tissues. For example, there is a progressive age-related decrease in area and length of the ciliary muscle as well as a change in the configuration of the ciliary muscle (**Figure 2**). There is a decrease in area of the longitudinal and reticular fibers of the ciliary muscle and an increase in area of the circular fibers of the muscle. With increasing age in the unaccommodated eye, the ciliary muscle appears more like an accommodated ciliary muscle with a progressive forward and inward movement of the inner apex of the ciliary muscle and ciliary body. This may occur in part due to the ciliary body being gradually pulled inward by increasing tension on the zonular fibers inserting around the lens equator

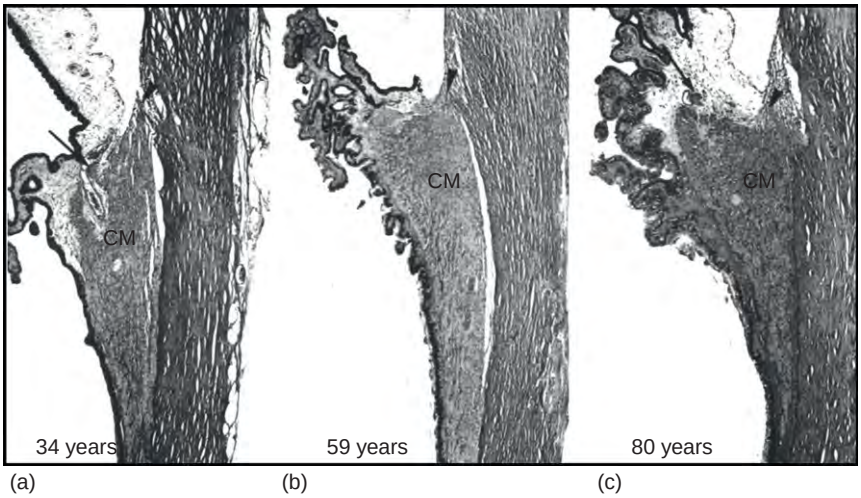

Figure 2 With increasing age the unaccommodated, atropinized human ciliary muscle shows a configurational change such that the older ciliary muscle appears more like an accommodated ciliary muscle with the inner apical region advancing forward of the scleral spur. Reproduced from Tamm, S., Tamm, E., and Rohen, J. W. (1992). Age-related changes of the human ciliary muscle. A quantitative morphometric study. *Mechanisms of Ageing and Development* 62: 217, with permission from Elsevier.

(see below), or simply due to growth-related changes in the ciliary muscle. There are also age-related changes in the relative distribution of ciliary muscle fibers within the ciliary muscle and other morphological changes in the ciliary muscle. The age-related configurational change of the ciliary muscle results in a decrease in the circumlental space with increasing age. In rhesus monkeys, there is an age-related loss of compliance of the posterior attachment of the ciliary which may serve to reduce the ciliary muscle motility; however, there is no age-related loss of contractility of the isolated rhesus monkey ciliary muscle. In spite of the age-related changes in the ciliary muscle, it still remains active with an accommodative effort even in complete presbyopes. The ciliary muscle is, like the iris, an intraocular muscle. The iris is known to continue to contract throughout life in response increased illumination to constrict the pupil. Similarly, the ciliary muscle is unlikely to become quiescent even in complete presbyopes. Convergence, pupil constriction, and accommodation are neurologically coupled in the brain. Every attempt to focus at near or even to converge the two eyes to achieve single, binocular vision on a near object will result in a neuronal stimulus to the ciliary muscle to cause a contraction even in the presbyopic eye. Accommodative contraction of the ciliary muscle occurs with an effort to focus at near in presbyopes even in the absence of any accommodative changes in lens thickness or lens diameter, thereby demonstrating that the ciliary muscle moves even though no accommodative optical change occurs in the lens or eye. Similarly, in rhesus monkeys, irrespective of age, accommodative movements of the ciliary body are always greater than the accommodative movements of the lens. This shows that accommodative movements of the lens limit accommodation through all ages and that at its end point, presbyopia is not due to a loss in contractility of the ciliary muscle.

Age-Related Changes in the Lens

The lens is surrounded by the thin, elastic lens capsule. Lens epithelial cells line the anterior surface of the lens under the capsule. These epithelial cells, like epithelial cells in the rest of the body (such as on the skin and those lining the gut), continue to proliferate throughout life. However, unlike the epithelial cells on the skin and lining the gut which can slough off, because the lens is surrounded by the capsule, lens epithelial cellular proliferation results in a continued age-related increase in mass, size, and volume of the lens. The mass of the isolated human lens increases linearly with age after adolescence (**Figure 3**). Lens axial thickness increases linearly with age, but without a systematic increase in lens diameter (**Figure 4**). The increased volume and axial thickness without a systematic increase in equatorial diameter

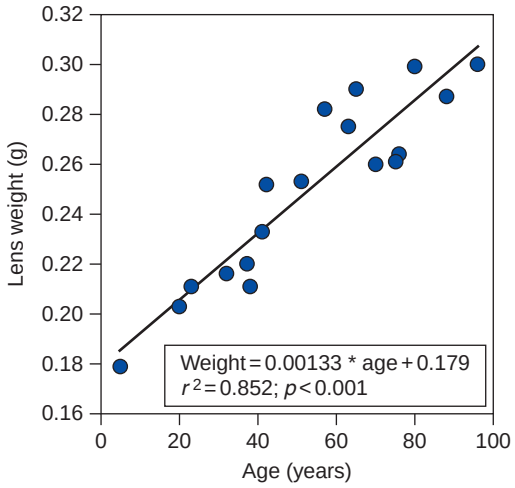

Figure 3 Wet weight of isolated human lenses from donor eyes aged 5–96 years of age increases linearly reflecting the increased growth of the lens. Reproduced from Glasser, A. and Campbell, M. C. W. (1999). Biometric, optical and physical changes in the isolated human crystalline lens with age in relation to presbyopia. *Vision Research* 39: 1998, with permission from Elsevier.

result in an increase in the lens anterior surface curvature. Posterior lens surface curvature does not change systematically with increasing age. The continued growth of the lens results in a decrease in anterior chamber depth of the eye and an increase in anterior segment length (the distance from the cornea to the posterior lens surface). The anterior most zonular fiber insertion into the capsule undergoes an anterior shift with increasing age. This may result in an increased zonular tension around the lens equator and could be partially responsible for the configurational changes observed in the ciliary muscle (described above). In addition, there are internal changes in the lens. Optically evident so-called zones of discontinuity observed with slit-lamp illumination are thought to represent visible boundaries between the nucleus and cortex. These visible zones of discontinuity show that there is a greater increase in axial thickness of the cortex of the lens than of the nucleus with increasing age.

The age-related increases in lens anterior surface curvature and axial thickness may make the older lens appear to be in a more accommodated form and might therefore be expected to result in a progressive age-related increase in optical power of the unaccommodated lens resulting in a myopic progression of the eye. However, presbyopia is characterized by a loss of near vision, rather than a myopic progression with increasing age. This leads to what has been referred to as the lens paradox, that is, how it is that the eye progressively loses near vision despite changes in the lens that might be expected to increase the power of the lens and eye, leading to a more myopic eye. The resolution to this paradox resides in the fact that there is a progressive age-related decrease

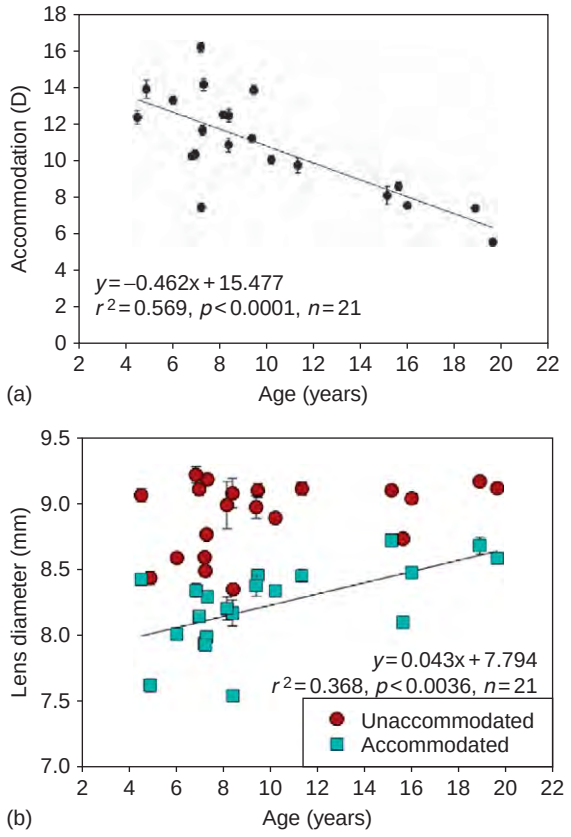

Figure 4 (a) Age-related loss of pilocarpine-stimulated accommodation in 21 rhesus monkeys ranging in age between 5 and 20 years of age. (b) Unaccommodated lens equatorial diameter (circles) as a function of age show no systematic change with increasing age. Pilocarpine-stimulated accommodation causes a decrease in lens diameter (squares) with the accommodative change in lens diameter decreasing with increasing age. Reproduced from Wendt, M., Croft, M. A., McDonald, J., et al. (2008). Lens diameter and thickness as a function of age and pharmacologically stimulated accommodation in rhesus monkeys. *Experimental Eye Research* 86: 751, with permission from Elsevier.

in the overall refractive index of the nucleus. The lens has a gradient refractive index with a greater refractive index at the center of the lens than at the periphery. This gradient refractive index adds additional refractive power to the lens. The refractive index of the surface of the lens does not change systematically with increasing age. The age-related decrease in refractive index of the nucleus can be explained by the observed aggregation, insolubilization, and precipitation of lens proteins (the lens crystallins) and a resulting increase in free water content of the aging lens nucleus. In spite of the age-related increase in anterior lens surface curvatures, which would tend to increase lens power, the increased lens thickness and the reduced nuclear refractive index actually result in a slight overall age-related decrease in lens power in the unaccommodated eye.

Age-Related Changes in the Capsule

The elasticity of the lens capsule produces the accommodative change in shape of the young lens and as such, age-related changes in the properties of the capsule may influence the ability of the capsule to mold the lens. In a young eye, zonular tension around the lens equatorial region holds the lens in a relatively flattened and unaccommodated state. If these zonular fibers are cut, the young lens is molded into a maximally accommodated form by the capsule. If the lens capsule is then carefully cut and removed from the young lens, the isolated, decapsulated lens substance returns to an unaccommodated form. This means that the resting state of the young isolated, decapsulated lens is maximally unaccommodated, whereas with the capsule on, but without zonular tension, the lens is maximally accommodated. The change in shape of the lens substance from the accommodate to the unaccommodated form with decapsulation progressively decreases with increasing age to the point that removing the capsule from a presbyopic lens results in no change in shape of this older lens. The implications of this are that in the older eye, either the capsule has lost the elasticity to mold the presbyopic lens or the presbyopic lens has become too stiff for the capsule to mold it or both changes have occurred with increasing age. Mechanical stretching studies of isolated rings from the anterior surface of human lens capsules show that the elastic modulus increases with increasing age up to about 35 years of age with no significant change thereafter (**Figure 5**). Thus, the capsule may actually become increasingly effective at transmitting accommodative forces to the lens with increasing age during the pre-presbyopic years.

Increased Stiffness of the Lens

The progressive age-related increase in stiffness of the lens is now widely regarded as the primary cause of the age-related loss of accommodation. The lens substance growing in size and mass within the confines of the capsule becomes progressively more compacted and undergoes an exponential increase in stiffness (**Figure 6**). This results in an over fourfold increase in stiffness between approximately 5 and 100 years of age. In the young lens, the nucleus is softer than the cortex. With increasing age, the stiffness of both the nucleus and cortex increases but there is a greater increase in stiffness of the nucleus than the cortex (**Figure 7**). At about 35 years of age, the stiffness of the nucleus and cortex is approximately the same, but after this age the nucleus becomes progressively stiffer than the cortex. This represents a change in the stiffness gradient of the lens with a relatively greater increase in stiffness at the center of the lens and a smaller increase in stiffness

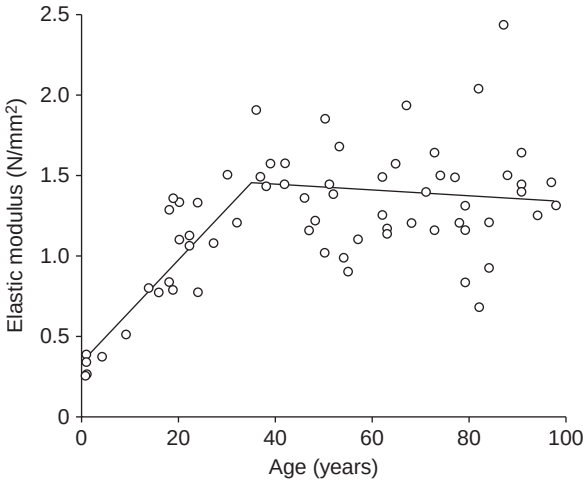

Figure 5 For low strains representing the range that might be expected to occur with accommodation (0–10% of breaking strain) there is an age-related increase, up to age 35, in the elastic modulus of capsular rings cut from the anterior surface of human lens capsules. After the age of 35, there is no systematic change in anterior capsular ring elastic modulus. These data suggest that the human lens capsule actually becomes increasingly effective at transmitting the forces to the lens that are required for accommodation to occur. Reproduced from Krag, S. and Andreassen, T. T. (2003). Mechanical properties of the human lens capsule. *Progress in Retinal and Eye Research* 22: 757, with permission from Elsevier.

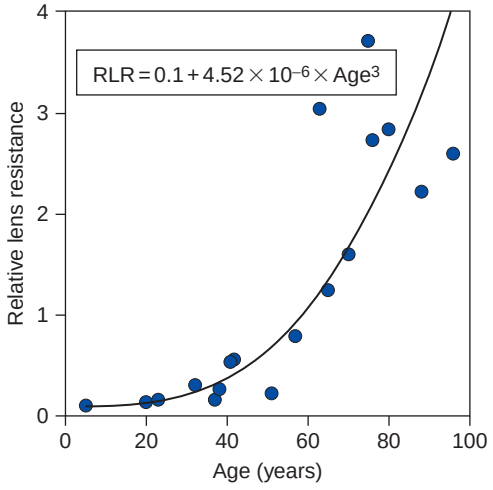

Figure 6 Mechanical squeezing of isolated, intact human lenses shows an exponential increase in resistance of the human lens between 5 and 96 years of age. Reproduced from Glasser, A. and Campbell, M. C. W. (1999). Biometric, optical and physical changes in the isolated human crystalline lens with age in relation to presbyopia. *Vision Research* 39: 2006, with permission from Elsevier.

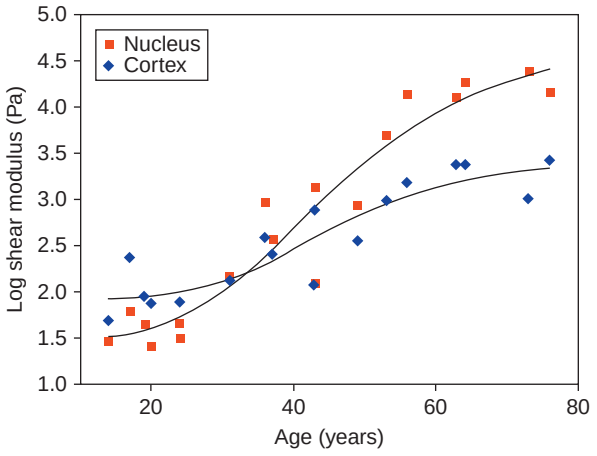

Figure 7 A probe inserted into different regions of equatorially sectioned human lenses shows that in the younger lenses the sheer modulus of the nucleus is less than the cortex, but with increasing age there is a greater increase in the sheer modulus of the nucleus than the cortex. Reproduced from Heys, K. R., Cram, S. L., and Truscott, R. J. (2004). Massive increase in the stiffness of the human lens nucleus with age: The basis for presbyopia? *Molecular Vision* 10: 959, with permission from Molecular Vision.

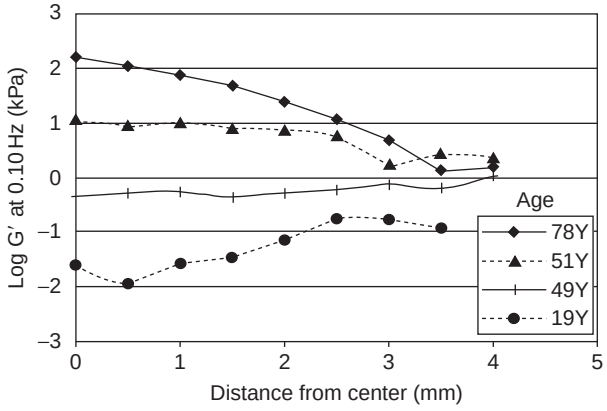

Figure 8 Sheer modulus values determined from inserting a probe into four equatorially sectioned human lenses. In the youngest lens, the sheer modulus is lowest at the center of the lens and increases progressively toward the cortex, whereas in the oldest lens, the sheer modulus is greatest at the cortex and decreases toward the cortex. Both the nucleus and the cortex undergo an increase in sheer modulus with increasing age, with a relatively greater increase toward the center of the lens than toward the periphery. This represents not only an increase in stiffness of the lens, but also a relative increase in the stiffness gradient. Reproduced from Weeber, H. A., Eckert, G., Pechhold, W., and van der Heijde, R. G. L. (2007). Stiffness gradient in the crystalline lens. *Graefe's Archives for Clinical and Experimental Ophthalmology* 245: 1362, with kind permission of Springer Science + Business Media.

progressively further from the center of the lens toward the surface (**Figure 8**). Although accommodation is essentially completely lost by age 55, the increase in stiffness of the lens continues throughout life. This suggests that the age at which accommodation is lost simply represents a time point in the continuum of age-related changes occurring in the lens. It is likely that as the stiffness of the lens nucleus and cortex progresses, there is a progressive change in the fine

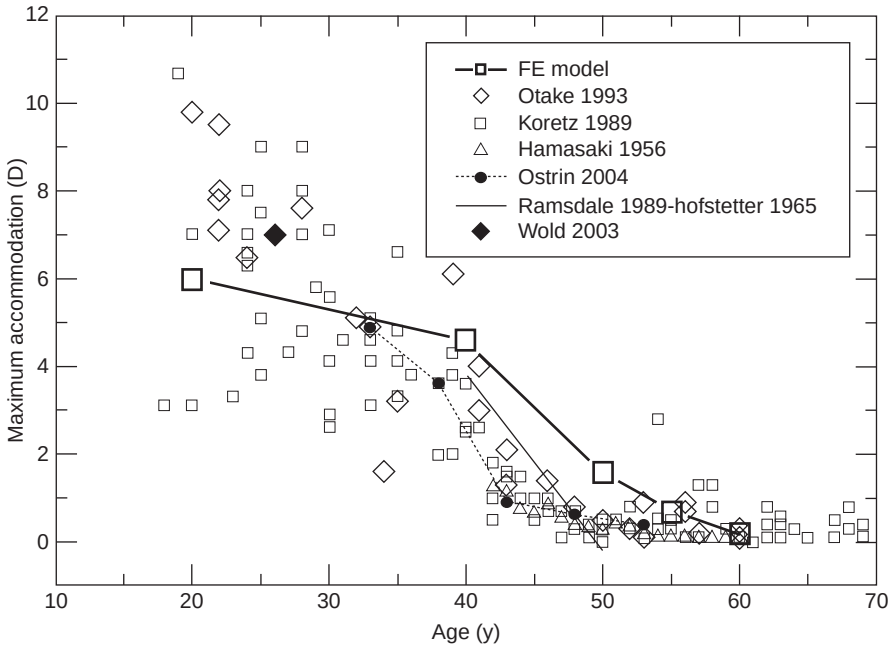

Figure 9 The age-related decrease in the accommodative response in a finite element (FE) model of accommodation (FE model) of a 40-year-old lens in which the only age-dependent parameter modeled was the empirically measured age-related change in stiffness gradient of the lens. The response from the model is compared with objectively measured accommodative response amplitudes from a variety of different human clinical studies. The FE model incorporating an age-dependent stiffness gradient in the lens is able to capture most of the age-related decrease in accommodative amplitude observed in human clinical studies. Reproduced from Weeber, H. A. and van der Heijde, R. G. (2007). On the relationship between lens stiffness and accommodative amplitude. *Experimental Eye Research* 85: 605, with permission from Elsevier.

balance of forces within the lens substance, capsule, and zonules such that ultimately a point is reached when the accommodative forces that can be generated on the lens by the capsule is insufficient to overcome the resistance of the stiffer lens. In the young eye, accommodation results in an increase in thickness of the nucleus but without a change in thickness of the cortex. It is therefore the cortex surrounding the lens that may be molding the lens to allow the lens to undergo the changes in shape required for accommodation to occur. This system may be effective at producing changes in shape of the nucleus when the nucleus is less stiff than the cortex as in the young lens, but this process may become increasingly ineffective as the nucleus becomes stiffer than the cortex. Finite element modeling shows that the age-related loss of accommodation can be relatively accurately predicted by incorporating the age-related change in stiffness gradient of the lens without incorporating age-related changes in other parameters of the model (such as lens size and surface curvatures) (**Figure 9**). Modeling an overall increase in stiffness of the lens as opposed to the stiffness gradient is less predictive of the age-related loss of accommodation. This further suggests that the fine balance of forces between the lens nucleus and cortex is important to allow accommodation to occur and that this fine balance of forces is also ultimately lost by the progressive age-related changes that occur in the lens.

Primary Open-Angle Glaucoma

D Spiegel, University of Regensburg, Regensburg, Germany

Glossary

Bjerrum's area – An arc-shaped area from 5° to 30° in the central visual field, it is the site of typical visual defects in primary open-angle glaucoma.
Chamber angle – The angle between the cornea and the iris.
Gonioscopy – Method to gain a view of the iridocorneal angle by means of a goniolens or gonioscope in conjunction with a slit lamp or operating microscope.
Iridocorneal angle – Angle between the iris and cornea at the periphery of the anterior chamber.
Laser trabeculoplasty – Laser treatment in primary open-angle glaucoma which increases the aqueous humor outflow through the trabecular meshwork.
Myopia – Visual defect where light is focused in front of the retina rather than on it.
Perimetry – A method used to detect visual field defects in glaucoma.

Introduction

Primary open-angle glaucoma (POAG) is characterized by an open anterior chamber angle without any gonioscopic abnormalities. A relatively elevated intraocular pressure (IOP) is considered to cause damage and loss of retinal ganglion cells, which results in typical glaucomatous alterations of the optic nerve head. The loss of ganglion cells corresponds to the loss of visual field in a clinical pattern typical for glaucoma. Consecutively, this will lead to blindness in untreated aggressive cases.

Most of the patients affected with POAG do not recognize any symptoms before a substantial loss of ganglion cells occurs, which causes an advanced irreversible visual field defect. Therefore, POAG is still the second most common cause (12.3%) for blindness in the world (2002 WHO).

The main risk factors for developing and worsening of glaucoma have been identified as age, IOP, family history, myopia, and diabetes mellitus. These factors play an important role in the diagnosis and treatment of the disease.

Definition

Primary open-angle glaucoma is defined as an acquired optic neuropathy, based on a chronic progressive loss of retinal nerve fibers and retinal ganglion cells. These ganglion cell losses are responsible for a typical glaucomatous pattern of visual field defects. In POAG, the iridocorneal angle must be open and there should be no secondary etiology.

Clinically, the signs for glaucoma include: a relatively elevated IOP, glaucomatous optic disk damage, nerve fiber bundle losses seen in the red free retinal image, and visual field defects in a pattern that is typical of glaucoma.

Pathophysiology

To date, the pathogenesis of POAG is still not fully understood. It is believed that the relatively elevated IOP results from increased resistance within the aqueous drainage system. Changes in the trabecular meshwork are considered to be responsible for the outflow restriction. Other reasons for optic neuropathy may include mechanical theories – based on direct pressure-induced damage to the retinal ganglion cell axons at the level of the lamina cribrosa. On the other hand, vascular theories propose microvasculatory changes that result in ischemia in the optic nerve head.

Risk Factors

The term risk factor refers either to risk factors for an increase of prevalence and incidence or for the worsening of POAG.

The prevalence and incidence of POAG increase with higher IOP, older age, Afro-Caribbean race, positive family history, myopia, and diabetes mellitus – the last two are still under debate. Elevated IOP of over 26 mmHg has a 13-fold risk for glaucoma. Age is the second most important risk factor. The prevalence of POAG is 2.1% for individuals over the age of 40. Hereby, the range of prevalence is found to be 0.3% at 40, 3.3% at 70, and over 10% in humans over 80 years of age. The Afro-Caribbean race tends to have a 3.8-fold higher incidence of glaucoma than the white population. Individuals with a family history of glaucoma have a 3.14-fold higher relative risk of developing glaucoma. The highest association is found in siblings of glaucomatous patients. Some of the studies demonstrated that patients with diabetes mellitus have a 1.93-fold, and those with myopia have a 1.88-fold, higher risk of POAG.

The risk factors for worsening of the glaucomatous disease are: IOP above the target pressure, disk hemorrhages, stage of glaucomatous damage, age, perfusion

pressure, history of cardiovascular diseases, and reduced central corneal thickness.

Intraocular Pressure

In the last century, the search for the upper limit of a normal pressure was based on a Gaussian distribution of the IOP in the normal population, in which the readings of the pressure in excess of two standard deviations was 20.5 mmHg, resulting in a fixed pressure value of −21 mmHg. Since elevated IOP has been dropped from the modern definition of glaucoma, this definition (IOP > 21 mmHg) is no longer acceptable. As of now, it is more important to determine the target pressure in each individual patient, considering the increased IOP as a risk factor for developing – and worsening of – glaucoma. Therefore, the target pressure is defined as a level of IOP under which the disease of glaucoma in the individual patient does not progress. To assess the target pressure, several nonevidence-proofed suggestions are made based on the stage of glaucoma and the results of the latest large glaucoma studies with regard to the treatment and natural course of glaucoma (see **Table 1**).

The golden standard for IOP measurement is taken by the Goldmann applanatory tonometer (GAT). Other methods used include noncontact air pulse tonometry, Tono-Pen, or dynamic contour tonometry.

The GAT measurements are influenced by the central corneal thickness. A thicker cornea (above 550 µm) leads to false higher readings and a thinner cornea to false lower IOP measurements. Edema in the cornea causes false lower IOPs. Following refractive corneal surgery, the IOP measured is also substantially lower. Therefore, this needs to be taken into consideration in diagnosis and treatment of glaucoma as well.

The IOP increases with age. From birth to the age of 12 years, the IOP slowly increases from 7 to 12 ±3 mmHg. In healthy adults, the IOP ranges from 10 to 21 mmHg.

Optic Disk Appearance in POAG

The most important objective signs for detecting glaucoma are changes of the optic nerve head (optic disk), which can be detected by direct ophthalmoscopy on slit-lamp examination. The leading clinical signs for glaucoma can be divided into qualitative and quantitative changes at the optic disk. The qualitative signs can again be classified into signs that are found nearly in all eyes with glaucoma only and signs that are also found in up to 50% of healthy eyes.

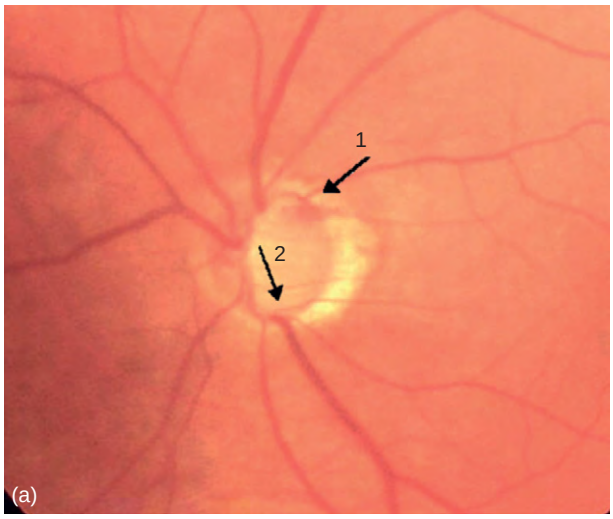
Definitive qualitative signs for glaucoma at the optic disk are baring of vessels, notches in the optic nerve-head rim, disk hemorrhages, and a peripapillary atrophy zone-β. Less certain signs at the optic disk for glaucoma are bayoneting vessels, nasal cupping of the optic disk, and a bare lamina cribrosa (see **Figure 1(a–c)**).

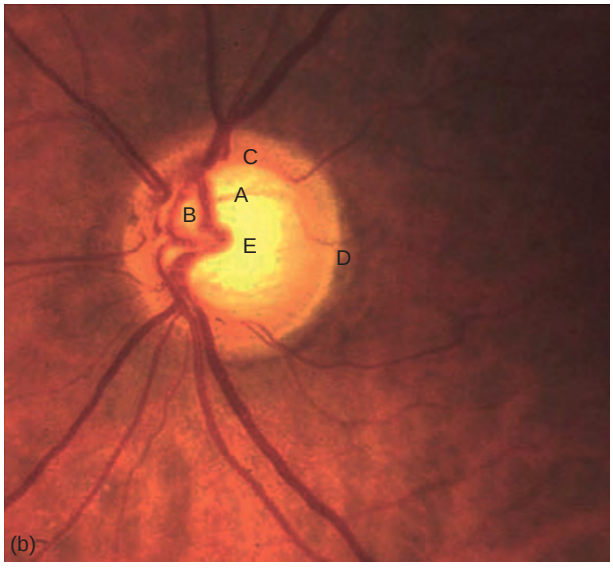
The baring of vessels develops after the loss of nerve tissue at the optic rim. Once the nerve tissue is reduced, the vessel is left hanging over the lamina cribrosa similarly to a bridge. Afterward, the vessel will slide down to the floor of the bottom of the lamina cribrosa. This entity is only seen in damaged disks. Circumscriptive sectional loss of healthy optic rim results in so-called notches. These notches of the optic nerve-head rim are located most commonly in the upper temporal and lower temporal rim. Peripapillary chorioidal atrophies slowly increase in eyes affected by glaucoma. There are two zones distinguished: zone-β – which is adherent to the disk – and zone-α – which is located temporal to zone-β. While zone-α is frequently seen in healthy eyes, zone-β is found in 62% of glaucomatous eyes and in only 22% of healthy eyes. Bayoneting vessels are retinal vessels which have the form of a bayonet when leaving the optic nerve head. Due to the nerve tissue loss, the excavation of the disk is so extensive that the vessel is hidden under the rim. With the progression of the glaucoma, this sign becomes more pronounced. Nasal cupping is seen when the rim loss of the nerve head can be noticed nasal to the main retinal vessel trunk. In summary, all qualitative signs, except disk hemorrhage, can be directly related to the loss of nerve tissue at the optic disk.

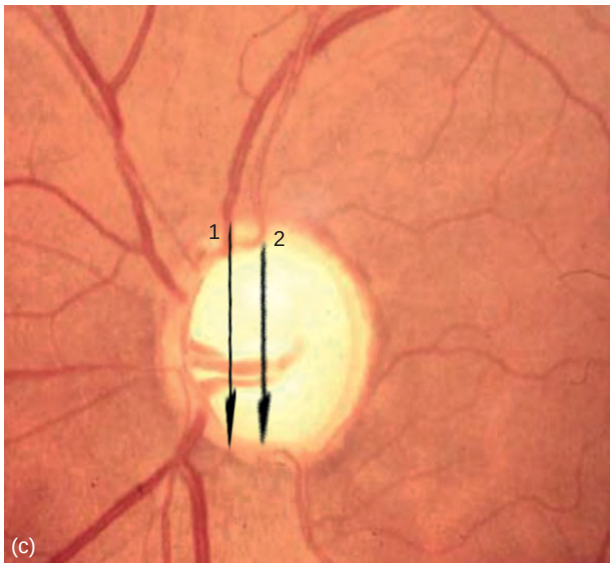
The quantitative signs for glaucoma are the cup-to-disk ratio (CDR) and the nerve-fiber thickness. The CDR is the equation of the optic disk size to the healthy optic rim. In glaucoma-damaged eyes, the vertical CDR is larger than the horizontal CDR. It is believed that the optic nerve head at the lamina cribrosa is more vulnerable

Table 1 Delphi panel recommendations for initial target pressures

Patients with elevated IOP	*Target pressure (mm Hg)*	*Range (mm Hg)*	*Minimum % IOD reduction*
Early glaucoma damage	18	16–21	25%
Moderate glaucoma damage	16	14–18	30%
Advanced glaucoma damage	12	10–14	35% (40%)
Glaucoma suspect	22	18–24	20%
Normal tension glaucoma (early)		30%	
Normal tension glaucoma		35%	Hawai 2002







to raised IOP in the inferior and superior cups. In a normal disk, the healthy rim on average is broadest in the inferior temporal sector followed, in a declining fashion, by the superior temporal, nasal, and temporal sector; this is described as the "isn't" rule. The nerve-fiber-bundle loss can be seen at the level of the retina ophthalmoscopically in red-free light.

For a long time, a CDR >0.5 was considered suspicious for glaucoma. However, in larger disks the CDR will be greater than in smaller disk, since the retinal fibers are quite constant in numbers and, thus, a greater CDR would be mistaken for glaucomatous cupping in a larger disk. On the other hand, in a smaller disk the cupping might be underestimated and glaucomatous damage overlooked.

For documentation of the optic nerve head and/or the nerve-fibre layer, methods such as colored fundus photos, scanning images with laser light (Heidelberg Retinal Tomography (HRT)), nerve fiber analyzer (GDx), or optic coherence tomography (OCT) are currently in use. These methods allow a quantification of the nerve tissue or layer and are used for the detection of slow progression of nerve-tissue loss typical in glaucoma.

Visual Field

Visual field defects demonstrate the functional impairment as a result of nerve-fiber loss and localized nerve-fiber-bundle defects. To definitely determine the presence of glaucomatous damage, the detection of visual field defects is necessary; however, this requires the subjective test of perimetry. Since the testing of the visual field needs concentration and good compliance from the patient, a learning curve can be observed in visual field testing. Thus, the first visual field taken from a patient is usually not valid.

The conventional standard method to detect visual field defects attributable to glaucoma is the static computerized perimetry, known as standardized automated perimetry (SAP). Different types of perimeters from different companies are in use, all of which fulfill the standards of testing for glaucoma patients. However, the testing conditions are not the same in each of these instruments (e.g., background illumination) and the numbers representing loss of light sensitivity are not comparable between different instruments. Therefore, the detection of glaucomatous defects and worsening of the functional impairment need the same kind of perimeter with the same testing program.

Figure 1 (a) Optic disk hemorrhage in glaucoma (arrow 1) and notch (arrow 2). (b) Signs for glaucoma on a disk. A: baring vessel, B: nasal cupping, C: bayoneting of vessels, D: parapapillary atrophy (zone-β), and E: bare lamina cribrosa, vertically pronounced CDR. (c) Advanced glaucomatous disk cup (arrow 2)-to-disk (arrow 1) ratio of 0.9.

Nonconventional perimetric methods are developed and utilized in order to detect defects in glaucoma earlier. These methods include short-wavelength automated perimetry (SWAP) or blue/yellow-perimetry, frequency-doubling technology (FDT), high-pass resolution perimetry (HRP), and flicker perimetry. The value of these methods for early detection of glaucomatous defects is still under debate and, in the future, longitudinal studies are warranted. At present, SAP is the standard method for diagnosis and assessment for treatment in glaucoma.

To detect typical visual defects in glaucoma, the central 30° visual field – which requires up to 20 min of testing – is sufficient. To avoid patient fatigue, 24° programs are in use, which reduce the testing time from 8 to 13 min.

Since the beginning of the last century, a typical pattern of visual defects could be found in patients having glaucoma. These patterns help to diagnose glaucoma and to detect the disease at the earliest. The breakthrough in the early detection of defects in glaucoma was the work of Jannik Petersen Bjerrum, at the University of Copenhagen, who found small paracentral defects in the central 30° visual field. Since then, glaucomatous defects have been defined systematically.

The typical visual defects in glaucomatous patients include nasal steps, small localized defects (scotomas) in Bjerrum's area (an arc-shaped area from 5° to 30° in the central visual field but sparing a central island of fixation), enlarged blind spots, and small sector-shaped temporal defects. Most often, the defects occur in the upper central area and in the lower nasal step area. However, glaucomatous visual defects can also occur in any location of the upper or lower Bjerrum's area. The progressing visual field is characterized by scotomas increasing in size and depth – mainly in an episodic manner – by fresh scotomas or sector-shaped defects, or by generalized loss of retinal sensitivity. The progression can occur suddenly but, often, is more gradual. The disease is usually asymmetrically present in both eyes and can lead to a compensation of visual impairment resulting in one normal field for the patient. This might be the main reason for the late subjective recognition of the disease. The late stage of visual impairment is characterized by subtotal loss of the peripheral and paracentral visual field, in which the central island and a temporal peripheral field is spared (see **Figure 2**).

Treatment

At present, the treatment of glaucoma comprises of lowering of the IOP to below a certain target pressure, below which the disease is considered to be nonprogressive. The quality of life of the patient should be taken into consideration when choosing the therapeutic options in terms of side effects of the treatment.

There are two possible physiological ways of lowering the IOP: to reduce the production of aqueous humor and/or to increase the aqueous humor outflow through the trabecular meshwork or into the suprachorioidal space.

These can be achieved by local medications – in the form of eye drops – by laser surgery and/or surgical interventions.

Medical Treatments

There are six different medical treatment groups: β-blockers, α_2-selective adrenergic agonists, prostaglandin derivates, carbonic anhydrase inhibitors, pilocarpine, and dipiverin/epinephrine.

β-blockers, α_2-selective adrenergic agonists, and carbonic anhydrase inhibitors reduce the aqueous humor production, whereas pilocarpine increases the aqueous humor outflow through the trabecular meshwork. Dipiverin and epinephrine are nonselective adrenergic agents, which reduce aqueous humor production and increase the aqueous humor outflow simultaneously. In contrast, prostaglandin derivatives increase the outflow of aqueous humor only through the subchorioidal space. The range of IOP reduction is different for each group and varies on average from 15% to 33% according to different studies, depending on the baseline pressures. Prostaglandins have proven to have the best effect in lowering IOP – up to 33%. The use of combined medications may lead to an additional effect and reaches 50% IOP reduction. Due to the half-life of each different medication, the frequency of application varies from once daily to 4 times a day. The higher frequency of application of eye drops can result in a reduced effectiveness of medical treatment because of the variability subject to patient compliance.

Laser Treatments

Argon laser trabeculoplasty (ALT) and selective laser trabeculoplasty (SLT) are laser treatments used in POAG that increase the outflow at the site of the trabecular meshwork. The production of the aqueous humor can be reduced by laser coagulation of the ciliary body with cyclophotocoagulation (CPC).

Both ALT and SLT are applied gonioscopically at the anterior chamber angle where the trabecular meshwork can be located. Individual spots are circumferentially applied on to the trabecular meshwork. The results of both methods do not appear to be substantially different. A pressure reduction of about 30% can be achieved; however, the effect diminishes across 5 years and repeated application has been demonstrated to have a much lower effect. Both methods are used to achieve a reduction in medications or as a procedure for gaining time to delay surgical intervention in patients with less aggressive glaucomatous disease. On the other hand, CPC can reduce the

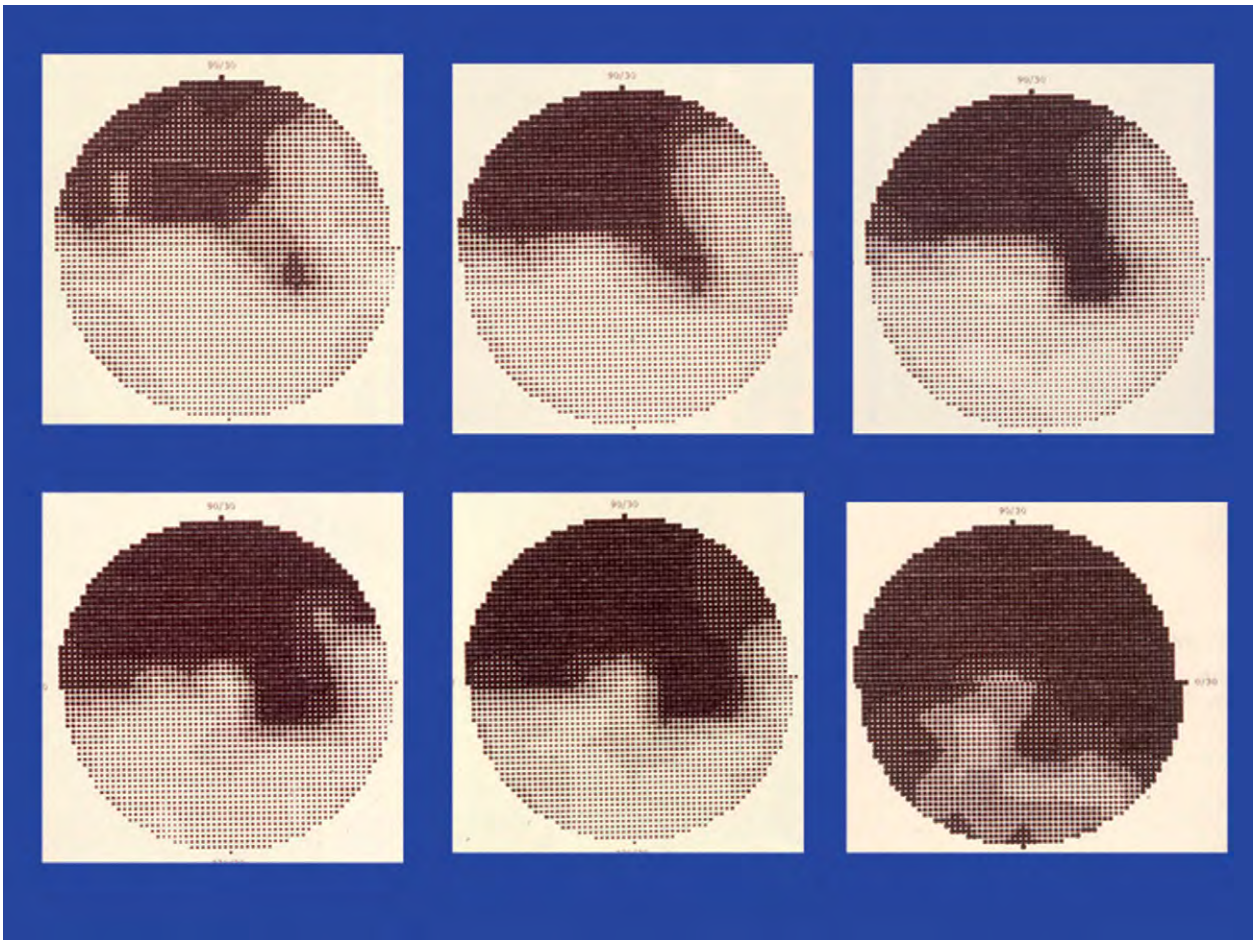


Figure 2 Natural course and field progression observed in a patient who refused treatment.

production of aqueous humor. In CPC, a diode laser is trans-sclerally applied to coagulate the tissue of the ciliary body. Conventionally, the method was applied to eyes in which other surgical methods were less successful. Side effects such as inflammation and hypotony (low IOP) can occur. CPC is safer and has fewer complications in comparison to freezing techniques (cyclocryo) that were commonly used previously.

Surgical Treatment

The most commonly performed surgical procedures are trabeculectomy with or without antimetabolites (mitomycin C or 5-fluorouracil) and implantation of shunts such as the Baerveldt, Molteno, Krupin Implants (without a valve mechanism) and the Ahmed valve (with a valve mechanism). All of these surgical procedures create a fistula that connects the anterior chamber to the subconjunctival space. Thus, they are categorized as fistulating penetrating procedures. These procedures can lower the IOP to 50% or more, independent of the baseline pressure. However, the short- and long-term side effects and complications must be carefully taken into consideration based on the needs and the situation of the individual patient.

Nonpenetrating procedures (canaloplasty, viscocanaloplasty, deep sclerectomy, etc.) and procedures that connect the anterior chamber with Schlemm's canal (trabeculotomy, i-stent) have lesser side effects. However, the long-term pressure reduction is less than what is seen in fistulating penetrating procedures.

The decision of a therapy regimen for POAG includes medical treatment, laser treatment, surgical procedures, and a combination of any/or all of the above-mentioned treatments and is based upon the required target pressure, the side effects of the chosen treatment, the anatomy of the eye, and the individual situation and needs of the patient.

Primary Photoreceptor Degenerations: Retinitis Pigmentosa

M E Pennesi, P J Francis, and R G Weleber, Oregon Health and Sciences University, Portland, OR, USA

Glossary

Allied disorders – Retinitis pigmentosa (RP) is often grouped with a class of more stable, inherited retinal disorders collectively referred to as RP and allied disorders. Some of these allied disorders cause similar clinic findings as RP, e.g., nyctalopia (night blindness), but usually do not show progression and deterioration with time. An example is congenital stationary night blindness (CSNB), which can present with nyctalopia and decreased rod and cone function on the electroretinogram (ERG). Unlike RP, most patients with CSNB have stable visual function. X-linked CSNB is caused by mutations in nyctalopin (NYX) and L-type voltage dependent calcium channel (CACNA1F). Although the majority of mutations of rhodopsin causes typical RP, rare mutations, such as G90D in rhodopsin, produce night blindness with such mild progression late in life that they have been called stationary night blindness. Another allied disorder is achromatopsia, which is caused by mutations in cyclic nucleotide-gated channel subunits (CNGA2, CNGB3) or guanine nucleotide alpha-binding protein 2 (GNAT2). Achromatopsia is associated with severely decreased central and color vision, photophobia, and nystagmus. These symptoms are similar to those that can be seen with some cone–rod dystrophies. Indeed, later in life some modest foveal atrophy can occur and cases of progressive cone–rod dystrophy have been associated with mutations of some of the achromatopsia genes. However, unlike cone–rod dystrophies, which invariably progress, achromatopsia is, in the vast majority of cases, stationary.

Cone dystrophy – Cone photoreceptors are affected and rod photoreceptors are minimally affected or spared in cone dystrophy. Many cases of early cone dystrophies with time will develop significant rod abnormalities.

Cone–rod dystrophy – Cone-rod dystrophy, as a group, involves both photoreceptors with cones affected more than rods. Certain forms of RP present with greater cone than rod involvement on ERG and these patients have been termed to have cone–rod RP. However, in cone–rod dystrophies as a group the primary defect lies in cones and secondaryrod loss occurs with time. Most investigators consider primary cone–rod dystrophy separate from RP.

Extrinsic factor – An agent external to the organism that contributes to or is causative of a disease state. This can include drugs, foods, normal nutrients (excess or deficiency), toxins, inhaled chemicals, infectious agents, and exposures to radiation such as light, sound, and high-energy particles.

Intrinsic factor – An agent that is inherent to the organism that contributes to or is causative of a disease state.

Mixed intrinsic and extrinsic etiology for a secondary photoreceptor degeneration – This occurs when a person has a genetic variant that creates a toxic metabolite in the presence of an extrinsic molecule that would normally not be encountered.

Mixed model of primary and secondary photoreceptor degeneration – This is considered when a genetic alteration within the photoreceptors is insufficient to cause photoreceptor degeneration by itself, but predisposes to degeneration in the presence of an extrinsic or intrinsic agent. A second mode of combined primary and secondary photoreceptor degeneration is when one group of photoreceptors, such as the rod photoreceptors, undergoes a primary degenerative process that is due to a mutation in a gene that is expressed in those photoreceptors and precipitates apoptosis, which leads to a secondary degenerative process, in this example cones, due to alterations in the cellular environment induced by death of neighboring cells.

Primary retinal degeneration – This occurs when cells in the retina, usually photoreceptors, die secondary to a process that originates within the retina itself. An example of a primary retinal degeneration is RP, which is caused by mutations in genes that encode proteins important for retinal function. A disease can be classified as a primary retinal degeneration if the genetic defect is such that correction of expression of the normal gene product in the photoreceptors is required to correct the abnormality and arrest the degeneration.

Primary retinal degeneration with secondary photoreceptor degeneration – This occurs when photoreceptor degeneration is the result of mutation(s) of a gene that exists in other retinal cells, for example,

retinal pigment epithelial (RPE) cells. Correction of the genetic defect would require modification of the effects of those other retinal cells (e.g, RPE cells).

Retinal atrophy – A broad term encompassing not only processes that occur with retinal degenerations, but also abnormal retinal tissue or cellular loss due to developmental defects and malnutrition.

Retinal degeneration – A process whereby cells in the retina undergo cell death by apoptosis. Most retinal degenerations affect both rod and cone photoreceptors, but some disorders reflect damage that occurs principally in other cell types, e.g., the RPE in Stargardt's disease and other ABCA4-related retinopathies. Secondary degeneration of the RPE is also common. Transsynaptic degeneration of higher-order cells, bipolar and ganglion cells, can also occur. The general term retinal degeneration should be distinguished from the more specific term, photoreceptor degeneration.

Retinal dystrophy – A broad term that not only encompasses retinal degenerations, but also includes abnormal retinal function due to developmental defects and malnutrition.

Retinitis pigmentosa (RP) – A heterogeneous group of diseases that result in degeneration of the rod and cone photoreceptors and secondarily the RPE. This degeneration usually leads to a loss of night vision due to the early degeneration of rods, constricted visual fields, decreased responses on ERG, and ultimately a decrease in visual acuity once macular cones begin to degenerate. Typical fundus findings include midperipheral atrophy of the pigment epithelium, bone spicule pigments, retinal vessel attenuation, and waxy pallor of the optic nerve. The term RP usually refers to only rod-cone dystrophies; however, cone-rod dystrophies and cone dystrophies are sometimes grouped under this term.

Rod–cone dystrophy – A retinal dystrophy in which the rod photoreceptors are affected more than the cones. Most forms of RP manifest as rod–cone dystrophies.

Secondary photoreceptor degeneration of the extrinsic type – A secondary photoreceptor degeneration of the extrinsic type exists if, despite the underlying molecular defect, one could avoid the photoreceptor degeneration by preventing an individual's exposure to an extrinsic agent or condition (e.g., toxin, drug, infectious agent, light, and trauma).

Secondary photoreceptor degeneration of the intrinsic type – If one can prevent photoreceptor degeneration by correcting or reversing a systemic or ocular metabolic or immune process, then it is a secondary photoreceptor degeneration of the intrinsic type.

Background

Retinitis pigmentosa (RP) is caused by a large number of genetic defects that result in a characteristic pattern of degeneration of the rod and cone photoreceptors and the retinal pigment epithelium (RPE). This degeneration usually leads to a loss of night vision due to the early degeneration of rods, constricted visual fields, decreased responses on electroretinogram (ERG), and ultimately a decrease in visual acuity once macular cones begin to degenerate. The typical fundus exam in RP reveals midperipheral atrophy of the pigment epithelium, bone spicule pigmentation, retinal vessel attenuation, and waxy pallor of the optic nerve (Figure 1).

RP was first named by the Dutch ophthalmologist, Frans Cornelius Donders, in the mid-nineteenth century, although earlier clinical descriptions of the disease exist. The term retinitis pigmentosa is somewhat of a misnomer because inflammation is not thought to be the primary pathological mechanism. Rather, mutations in over 100 genes have been shown to cause RP and its allied disorders, and there still remain a significant number of genes yet to be identified. To keep track of the ever-growing list of genes implicated in this disease, a comprehensive online database, Retnet, has been established by Dr. Stephen Daiger.

One of the most fascinating aspects of RP is that mutations in genes that encode functionally distinct

Figure 1 Classic fundus appearance in retinitis pigmentosa demonstrating bone spicule pigmentation, vascular atrophy, retinal pigment epithelium atrophy, and waxy pallor of the optic nerve. From Weleber, R. and Evan, K. G. (2006). Retinitis pigmentosa and allied disorders. In: Ryan, S. J. (ed.) *The Retina*, 4th edn., vol. 1, chap. 17, pp. 395–498. Philadelphia, PA: Elsevier.

proteins result in a common degenerative pathway. Some of the many examples include genes involved in the structural integrity of the photoreceptors and cilia, the retinoid cycle, the phototransduction cascade, the extracellular matrix, cellular metabolism, intracellular trafficking, and RNA processing.

Prevalence

The worldwide prevalence for all forms of RP has been reported to be approximately 1:4000. While most studies have focused on the prevalence in European/Caucasian populations, the occurrence of RP has been reported throughout the world.

Inheritance

All forms of Mendelian inheritance have been reported but autosomal dominant, recessive, and X-linked traits are most frequently seen. Rarely RP is inherited as a digenic disorder or through the maternal line as a mitochondrial disease.

Autosomal Recessive

RP patients with a family history of similarly affected relatives are called multiplex, whereas those with no family history are classified as simplex. Simplex individuals are usually assumed to represent autosomal recessive inheritance, although some of these cases may be *de novo* dominant mutations or unrecognized X-linked inheritance. When simplex cases are included, autosomal recessive cases of RP have been reported to account for approximately 50–60% of all cases, with the exact percentage varying from country to country. Some of the most commonly affected genes are usherin (*USH2A*), a gene that is involved in both Usher syndrome and autosomal recessive RP, and the phosphodiesterase beta subunit (*PDE6B*), a gene involved in phototransduction.

X-Linked RP

X-linked RP results from mutations of genes on the X chromosome and represents approximately 5–15% of patients with RP. To date, six genes that cause retinal degeneration have been linked to the X chromosome. Two genes, retinitis pigmentosa GTPase regulator (*RPGR*) and retinitis pigmentosa 2 (*RP2*), are known, and several genes remain to be identified.

Males with X-linked RP typically have more severe retinal degeneration compared to autosomal recessive and dominant forms of the disease. The actual rate of degeneration is likely similar to the other forms, but the age of onset appears to be earlier.

Female carriers are thought to have a mosaic retina in which some of the cells express the normal allele, while others express the mutant allele. The fundus findings in female carriers of X-linked RP can vary from very subtle changes, such as mottling of the RPE, to more severe disease with some patients showing the classic bone spicule pigmentation. Even in the cases of female carriers with a normal appearing fundus, changes are usually apparent on the ERG.

Autosomal Dominant

Patients with autosomal dominant RP often have a family history of the disease, although there are cases of incomplete penetrance and *de novo* mutations. Autosomal dominant mutations account for approximately 30–40% of patients with RP. In general, patients with autosomal dominant RP tend to be less affected than patients with X-linked or autosomal recessive RP. Some of the most commonly mutated genes include rhodopsin (*RHO*) and retinitis pigmentosa 1 (*RP1*).

Nonsyndromic versus Syndromic Retinal Degeneration

Most cases of RP are nonsyndromic and the pathology is limited to the eye. However, RP can also be associated with dysfunctions in other organ systems, with many of these cases comprising defined syndromes.

The most common syndromic association with RP is Usher syndrome, which is an autosomal recessive disorder and is divided into three subtypes based on clinical findings. Patients with type I Usher syndrome present with severe, but nonprogressive congenital hearing loss, balance problems, and RP. In type II Usher syndrome, patients have less severe hearing loss, RP, and normal balance. Patients with type III Usher syndrome, start with symptoms similar to type II but later progress to type I. The retinal findings in Usher syndrome are indistinguishable from those characteristic of nonsyndromic autosomal recessive RP. Eleven genes have been found to cause Usher syndrome. Considering the presumed shared evolutionary ancestry of photoreceptors and cochlear hair cells, it is likely that some of these genes share similar functions.

Bardet–Biedl syndrome (BBS) is an autosomal recessive disorder in which RP is a universal finding. Other commonly associated features include postaxial polydactyly, truncal obesity, abnormalities of cognition, and renal disease. Mutations in 12 genes have been implicated in BBS. Many of these genes encode proteins that are important for the formation or function of the cilia (**Figure 2**).

Some other syndromes that can present with RP include: abetalipoproteinemia (Bassen–ornzweig disease), Alström

Figure 2 (a) Fundus photos of patient with Bardet–Biedl syndrome (BBS), demonstrating the classical changes of RP that include bone spicule pigmentation, vascular attenuation, and waxy pallor of the optic nerve. (b) Scars on the foot of a patient with BBS from removal of an extra digit. (c) Similar scars on the hand.

syndrome, chronic progressive external ophthalmoplegia (CPEO), Friedreich's ataxia, incontinentia pigmenti (Bloch–Schulzberg syndrome), Joubert syndrome, Kearns–Sayre syndrome, mucopolysaccharide disorders, neuronal ceroid lipofuscinoisis (Batten disease), Refsum disease (infantile and adult), Senior–Loken syndrome, and spinocerebellar ataxia type 7.

Classification of RP

One often confounding feature of RP is the many different ways in which the disease can be classified. RP can be classified by its mode of inheritance, age of onset, fundus appearance, pattern of functional vision loss, or by genetic mutation.

As mentioned previously, RP is often characterized by its pattern of inheritance. With the advent of genetic testing, patients are increasingly being tested and classified according to which genes are mutated (see **Table 1** for the most common mutations and **Table 2** for description of genes). The phenotype and course of the disease can show significant variation with different mutations in the same gene. Likewise, there can also exist significant phenotypic variations between two people who harbor the same mutation. Ultimately, classification by genetic defects will likely prove to be the most useful way to segregate and treat patients with RP. However, many genes remain to be discovered and genetic testing is not yet universally available to test for all mutations in known genes. For these reasons, it is useful to examine the ways in which RP has been categorized in the past.

Table 1 Most common genes causing retinitis pigmentosa by inheritance

	Most common genes causing retinitis pigmentosa
Autosomal recessive RP (including Usher syndrome)	*USH2A, PDE6B, PDE6A, MYO7A, CRB1, RGR, CNGB1, RPE65*
Autosomal dominant RP	*Rho* (rhodopsin), *RP1, PRPF31, PRPF3, RDS/ROM*
X-linked RP	*RPGR, RP2*

Classification by Age of Onset

Severe forms of RP that manifest before the first year of life are referred to as Leber congenital amaurosis (LCA). The forms of RP occurring between 1 and 5 years have been termed juvenile RP or severe early childhood-onset retinal dystrophy (SECORD). LCA is characterized by

Table 2 Genes, protein, diseases, and function

Gene symbol	*Protein*	*Diseases*	*Function*
ALMS1	Alström syndrome protein 1	Alström syndrome	Exact function unknown, may play a role in ciliogenesis
CACNA1F	Calcuim-channel, voltage-dependent, alpha 1F subunit	Incomplete CSNB, AIED, and other X-linked CRD (CORDX3, Maori disease, CSNB with retinal and optic atrophy)	Acts as a subunit in the major voltage-sensitive calcium channel in rod and cone photoreceptor terminals. Required for the calcium flux into photoreceptors (rods and cones) that is needed for sustaining the tonic neuro-transmitter release from presynaptic terminals. Required for formation/ maintenance of ribbon synapses
CEP290	Centrosomal protein CEP290	Joubert syndrome, LCA	Localizes to cilium, may mediate G-protein trafficking
CHM	Rab escort protein 1 (REP-1)	Choroideremia	Participates in post-translational lipid modifications of proteins to enable membrane attachments that are essential in membrane trafficking. Acts as a geranylgeranyl transferase and appears required for specific Rab pathways.
CNGA2	Cyclic nucleotide-gated channel – subunit alpha 2	Achromatopsia	Codes for the alpha subunit of the cyclic nucleotide-gated channels in cones
CNGB1	Cyclic nucleotide-gated channel – subunit B1	arRP	Codes for the beta subunit of the cyclic nucleotide gated channels in rods
CNGB3	Cyclic nucleotide gated channel – subunit beta 1	Achromatopsia	Codes for the beta subunit of the cyclic nucleotide-gated channels in cones
CRB1	Homolog of crumbs	arRP, LCA	Homologous to crumbs in the *Drosophila*, where it plays a role in cell–cell interactions and photoreceptor polarity
GNAT2	Transducin alpha 2	Achromatopsia	Plays a role in the photoreceptor phototransduction cascade. Forms a complex with the beta and gamma subunits and acts to convert cGMP to GMP
MYO7A	Myosin-VIIA	Usher syndrome type IA	May play a role in trafficking of ribbon-synaptic vesicle complexes and renewal of the outer photoreceptors disks
NYX	Nyctalopin	CSNB	Predicted secreted protein important for development of ON bipolar cell signaling pathways
OAT	Ornithine-∂-aminotransferase	Gyrate atrophy	Catalyzes the conversion of L-ornithine and a 2-oxo acid to L-glutamate 5-semialdehyde and an L-amino acid
PDE6A	Phospodiesterase alpha subunit	arRP	Plays a role in the photoreceptor phototransduction cascade. Forms a complex with the beta and gamma subunits and acts to convert cGMP to GMP
PDE6B	Phospodiesterase beta subunit	arRP	Plays a role in the photoreceptor phototransduction cascade. Forms a complex with the alpha and gamma subunits and acts to convert cGMP to GMP
PHYH	phytanoyl-CoA 2-hydroxylase	Refsum disease	Catalyzes the first step in the alpha-oxidation of phytanic acid
PRPF3	PRPF3	adRP	Forms part of a spliceosome complex for mRNA processing
PRPF31	PRPF31	adRP	Forms part of a spliceosome complex for mRNA processing
RDH5	11-*cis* retinol dehydrogenase	Fundus albipunctata	11-*cis* RDH is found in the RPE, where it catalyzes the final step in the biosynthesis of 11-*cis* retinaldehyde, the visual chromophore for both rods and cones
RDS	Peripherin	RP, pattern dystrophy	Interacts with Rom-1 as the major morphogen for disk formation and to stabilize photoreceptor disks
RGR	Retinal g-protein-coupled receptor	arRP, adRP	Expressed in the RPE and Müller cells and plays a role in retinoid recycling
RHO	Rhodopsin	adRP, arRP CSNB	Mediates the detection of photons through light-induced isomerization of 11-*cis* to all-trans retinal, which triggers a conformational change leading to G-protein activation and release of all-trans retinal

Continued

Table 2 Continued

Gene symbol	*Protein*	*Diseases*	*Function*
RLBP1	Cellular retinaldehyde-binding protein 1-like protein 1	arRP, retinitis punctata albescens, Bothnia dystrophy, Newfoundland rod–cone dystrophy	Plays a role in visual pigment regeneration: carrier for endogenous 11-*cis*-retinol and 11-*cis*-retinal, major 11-*cis*-retinol acceptor in the isomerization step of the rod visual cycle, stimulating isomerization of all-*trans*- to 11-*cis*-retinol, facilitates oxidation of 11-*cis*-retinol to 11-*cis*-retinal by 11-*cis*-retinol dehydrogenase (RDH5)
ROM	Rom-1	Digenic RP	Interacts with peripherin to stabilize photoreceptor disks
RP1	RP1	adRP	Localizes to photoreceptor cilium, may play a role in transport of proteins between inner and outer segments
RP2	RP2	xlRP	Exact function unknown. Stimulates GTPase activity of tubulin and may function to link cell membrane with cytoskeleton
RPE65	RPE65	arRP, LCA	Expressed in the RPE and acts in retinoid metabolism to isomerizes all-trans-retinal ester to 11-*cis* retinol
RPGR	Retinitis pigmentosa GTPase regulator	xlRP	Exact function unknown. Localizes to cilium and may act to maintain protein polarization across the cilium
USH2A	Usherin	Usher syndrome type II, arRP	Exact function unknown, Interacts with collagen IV and fibronectin and may be required for stable integration into the basement membrane

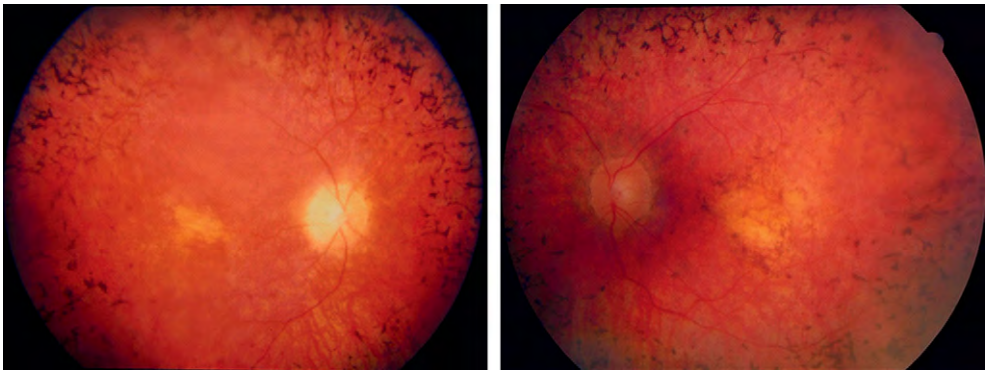

Figure 3 Fundus photographs of a 16-year-old patient with Leber congenital amaurosis. There is waxy pallor of the optic nerve, severe vascular attenuation, RPE atrophy most notable in the macula, and bone spicule pigmentations.

severe vision loss, nystagmus, unrecordable ERGs, and poorly responsive pupils (amaurosis). Mutations in at least 16 genes have been found to cause LCA and most of these are inherited in an autosomal recessive fashion. Juvenile RP/SECORD is thought to be caused by less severe mutations in the same set of genes as LCA, and more mild mutations in some of these genes have been implicated in recessive RP (Figure 3).

Classification by Fundus Appearance

The classic fundus appearance in RP is described below (see the subsection titled 'Fundus findings'). Deviations from this classic fundus appearance have given rise to several alternative terms for pigmentary retinopathies including: inverse RP, concentric RP, sector RP, retinitis punctata albescens, fundus albipunctatus, RP with preserved peri-arteriolar RPE, pigmented perivenous retinochoroidal atrophy, and retinitis sine pigmento. Some of these terms are falling out of usage as genetic characterization of the disease is becoming more common.

There have been many cases of unilateral RP described and it has been proposed that this could be caused by a somatic mutation. However, there is yet to be a histologically confirmed case of RP caused by a somatic mutation. Most of these cases likely represent other diseases that can mimic RP and cause a pigmentary retinopathy.

Classification by Functional Loss

Historically, adult RP was categorized as either type I (rod dysfunction) or type II (rod and cone dysfunction) based on psychophysical testing. These classifications were further refined on the basis of electrophysiological findings to include the categories: rod–cone dystrophy, cone–rod dystrophy, or cone dystrophy. Most forms of RP are rod–cone dystrophies in which rod photoreceptor death occurs first and is later followed by subsequent cone photoreceptor death. This article will use the term RP to describe the most common form, namely rod–cone dystrophy. The forms of RP that cause cone and cone–rod dystrophy will be denoted accordingly.

Mechanism of Disease

RP and its allied disorders are caused by mutations in over 100 genes and likely the same number remains to be elucidated. Ultimately, these mutations lead to photoreceptor death by apoptosis. It is still not fully understood how mutations in genes, which code for an array of functionally different proteins, result in a common pathway to photoreceptor death.

Mutations can result in decreased expression of a given protein, cause loss of function of that protein, or imbue a gain of function. In autosomal recessive forms of RP, there is a loss of expression or function when both copies of a given gene are mutated. In contrast, autosomal dominant forms of RP are thought to be caused by gain-of-function mutations, where the mutated protein becomes toxic or interferes with the function of the remaining normal forms of that protein (dominant negative effect). In autosomal dominant RP, the most common mutations are found in *RHO*. These dominant mutations can lead to forms of *RHO* that do not inactivate properly or are not transported to the outer segment.

An example of one well-studied mutation that causes autosomal dominant RP is the P23H mutation in the *RHO* gene. This mutation results in misfolding of the protein such that it is sequestered in the endoplasmic reticulum and is never transported to the outer segment. The misfolded proteins accumulate creating aggregations that activate an unfolded protein response. Dysregulation of these responses may lead to photoreceptor death although the exact mechanism has yet to be determined.

Clinical Presentation

Symptoms

Most frequently, the earliest symptom of RP is night blindness that precedes visual-field change and, in some, retinal pathology. In children, parents may comment that their child is afraid or becomes distressed in the dark. Older children often comment on poor vision compared with their fully sighted peers. In adults, difficulties with night driving are frequent. The second cardinal symptom of RP is progressive peripheral visual-field loss. Since central vision is spared early in the course of the disease, some patients do not notice this loss of visual field until the degeneration has become quite advanced.

Another common symptom of RP is problems with dark adaptation, such as difficulties adjusting to dim illumination when entering a movie theater. Additionally, as the disease progresses, patients can develop photophobia. Color vision is typically normal early in the disease but with progression, blue–yellow defects become apparent. Flashes of light, or photopsias, are experienced by most patients.

Patients with cone and cone–rod dystrophies can present with early photophobia, decreased central vision, and impaired color vision. These patients will typically have worse visual acuity than patients with rod–cone dystrophies due to earlier involvement of macular cones.

Refraction

Refractive errors in patients with RP have been studied and, on average, these patients are more myopic and have a greater degree of astigmatism than those in the general population. By contrast, patients with early-onset forms of RP, such as LCA or SECORD, tend to have hyperopic refractions.

Anterior Segment and Cataract

The external ocular exam and anterior segment are typically unremarkable in nonsyndromic forms of RP. However, there does appear to be a higher rate of keratoconus and glaucoma in patients with RP. Posterior subcapsular cataracts are common and often can become visually significant. Cataract extraction is beneficial in patients with RP if the cataract is thought to be the vision-limiting factor.

Fundus Findings

The characteristic signs on fundus examination include midperipheral atrophy of the pigment epithelium, intraretinal pigment accumulation (bone spicules; **Figure 1**), retinal vessel attenuation, and waxy pallor of the optic nerve. A yellowish ring of peripapillary atrophy is sometimes seen in patients with RP as well as with optic nerve head drusen. A minor number of vitreous cells are commonly observed in patients with RP. Cystoid macular edema is common in patients with RP and can often result in significantly decreased vision. Rarely, patients can develop a Coats-like retinopathy.

Diagnostic Tests for RP

Dark Adaptation

Dark adaptation can be a useful test in patients with RP. Patients who manifest with a rod–cone dystrophy will usually have a detectable increase in final dark-adapted thresholds and show delayed dark-adaptation curves. Prolonged dark adaptation is especially common among patients with *RHO* mutations. Elevations of the early cone segment of the dark-adaptation curve may be particularly noticed by patients, more so than elevations of the rod segment (Figure 4).

Visual Fields

Visual fields are not only useful for making the diagnosis of RP, but are also one of the most useful objective methods for monitoring progression of the disease. Decreased visual-field sensitivity results from photoreceptor loss (Figure 5).

The earliest change seen as measured by kinetic perimetry is concentric constriction or decreased sensitivity with static perimetry in diffuse disease and relative midperipheral scotomas seen in the in regional disease. As these midperipheral scotomas or regions of decreased sensitivity enlarge and deepen, severe tunnel vision results. Eventually, macular function fails and visual field becomes difficult or impossible to measure by conventional perimetry. Although visual function may be reduced to light perception only, it is rare for patients to become completely blind. With the exception of female carriers in X-linked RP, visual-field loss is usually symmetrical. Marked asymmetry should raise concern for diseases that mimic RP (Figure 6).

The rate of visual-field loss has been shown to be exponential. This rate is thought to be similar for the different forms of inheritance once correction has been made for the critical age of onset. Massof and Finkelstein found that patients lost about 50% of their visual field every 4.5 years. The superior visual field, which corresponds to the inferior retina, is often more affected than inferior visual fields. Based on this finding, it has been suggested that increased levels of light may play a role in accelerating retinal degeneration and this in turn may play a role in the forms of RP with greater damage in the inferior retina.

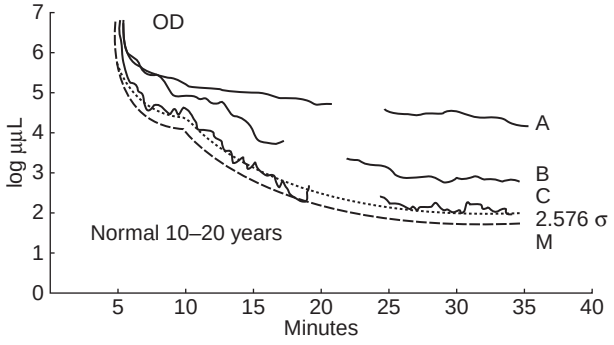

Figure 4 Example of dark-adaptation curves in a normal subject (dashed lines represent the mean normal response, dotted lines represent the upper limit of normal) and patients with retinitis pigmentosa (solid lines). From Weleber, R. and Evan, K. G. (2006). Retinitis pigmentosa and allied disorders. In: Ryan, S. J. (ed.) *The Retina*, 4th edn., vol. 1, chap. 17, pp. 395–498. Philadelphia, PA: Elsevier.

Electroretinograms

ERGs play a crucial role in the diagnosis of RP because these electrophysiological recordings are sensitive enough to detect decreased photoreceptor function early in the disease when fundus findings and visual fields may be minimally altered. In addition, ERGs are particularly

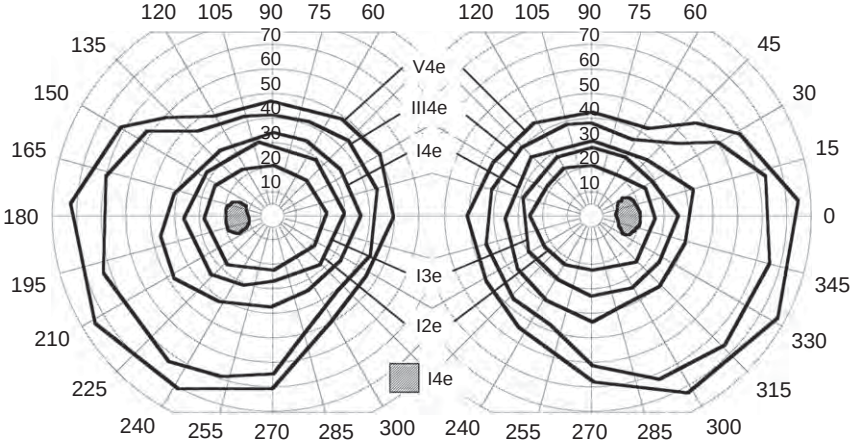

Figure 5 Example of a mildly abnormal kinetic visual field in a patient with early retinitis pigmentosa demonstrating the responses to different-sized targets. The gap between the size III4e and size I4e isopters is greater than normal, indicating loss of sensitivity in this region. The blind spot (region containing the optic nerve head and therefore no photoreceptor cells) is plotted in each eye just temporal to the fovea.

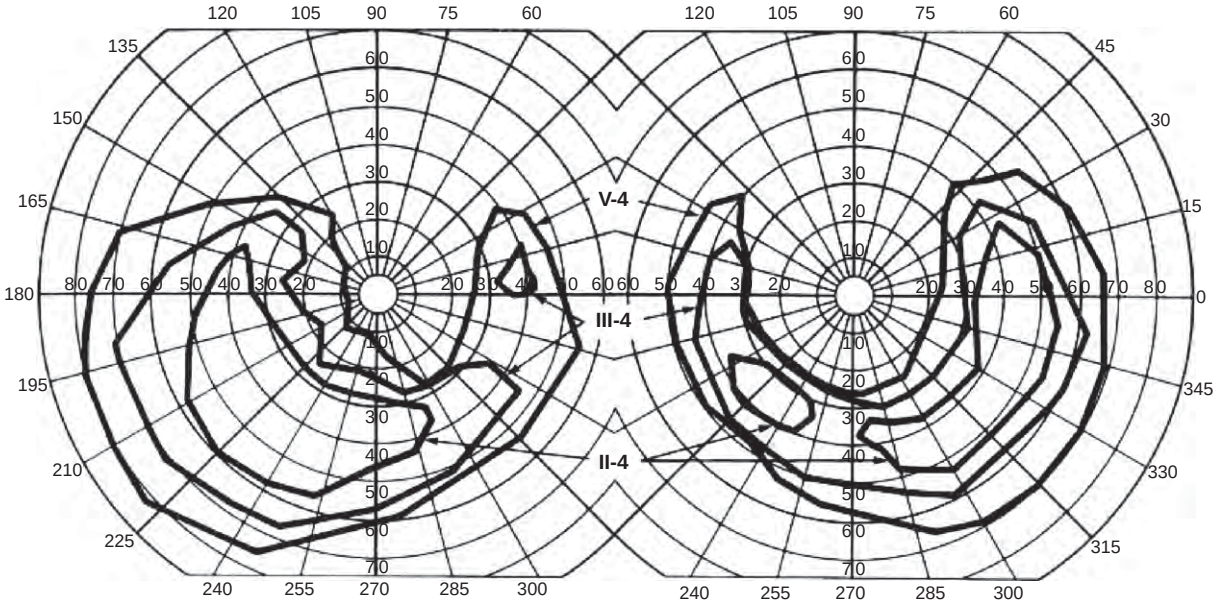

Figure 6 Kinetic visual fields obtained from patient with retinitis pigmentosa. Note the relative preservation of inferior fields, which correlated with preserved superior retina. From Weleber, R. and Evan, K. G. (2006). Retinitis pigmentosa and allied disorders. In: Ryan, S. J. (ed.) *The Retina*, 4th edn., vol. 1, chap. 17, pp. 395–498. Philadelphia, PA: Elsevier.

useful to assess visual function in preverbal infants and children. Almost all patients with symptomatic RP will have detectable changes on the ERG at the time of diagnosis. While the ERG is useful for the diagnosis of RP, visual fields are better for monitoring of the course of the disease. In severe cases of RP, such as LCA, the ERG may be not recordable.

Patients with RP can show decreased amplitude and timing of the major components of the ERG. Caution must be taken when interpreting decreases in the amplitude of an ERG because poor contact of the electrodes, deviations of the eye, and high myopia can affect the amplitude of the signal. When present, delayed timing tends to be a more robust indicator of dysfunction.

By analyzing the different components of the ERG, different forms of RP can be classified. Degeneration of the rod and cone photoreceptors leads to a decrease in the amplitude of different waveforms of the ERG and can also increase the timing or latency of the peaks of these waveforms. The most common forms of RP manifest as a rod–cone dystrophy and the first detectable changes will be apparent on the scotopic ERG. Decreases in the b-wave amplitude and timing of the peak of the b-wave are indicative of early rod photoreceptor death. Further loss of rod cells leads to further decreases in the b-wave amplitude and decreased amplitude of the a-wave responses at higher intensities. Patients with a cone–rod dystrophy have normal, or lesser defect of b-wave responses to dim scotopic stimuli, but typically have more markedly abnormal ERGs to 30-Hz flicker or single-flash stimuli measured under photopic conditions (**Figures 7–9**).

Fundus Photography/Fluorescein Angiography

Documentation by fundus photography can assist in monitoring changes in patients with RP. Fluorescein angiography in patients with RP will demonstrate hyperfluorescence in areas of RPE atrophy and can highlight areas of cystoid macular edema. However, fluorescein angiography has largely been supplanted by optical coherence tomography (OCT) for detecting cystoid maculopathy. In addition, concerns about light exposure accelerating certain forms of RP in animal models have prompted many ophthalmologists to exercise caution in obtaining excessive photographs.

Optical Coherence Tomography

OCT provides a noninvasive cross-sectional image of the retina. It is very useful in patients with RP when there is a question of cystoid macular edema. The ability to detect cystoid macular edema by OCT often obviates the need to get a fluorescein angiogram.

Differential Diagnosis

It is important to realize that RP is not the only cause of a pigmentary retinopathy but many other diseases can mimic RP. Significant asymmetry or the onset of symptoms in an elderly patient should raise suspicion for one of the diseases that mimics RP.

Trauma to the eye can disrupt the retina and result in pigment migration of the RPE into the retina with the formation of bone spicules. By a similar mechanism,

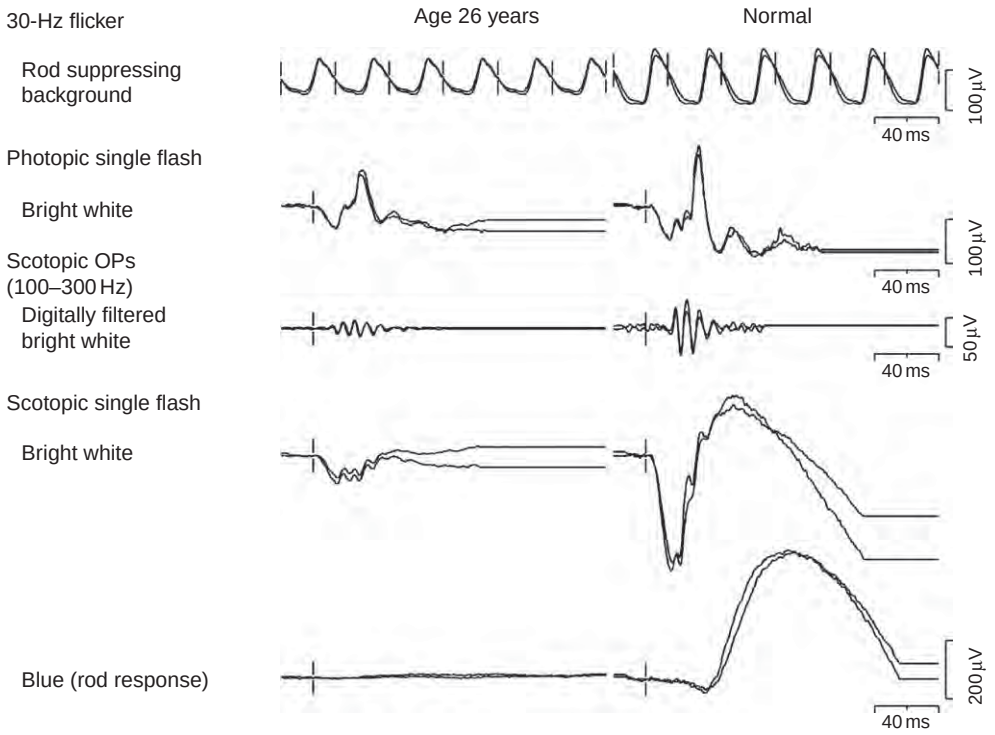

Figure 7 ERGs recorded from a patient with autosomal recessive RP (left column) compared to a control patient (right column). This patient is demonstrative of a rod–cone dystrophy. There is a flat response to the dim blue flash under scotopic conditions, which specifically stimulates rods. The bright flash under scotopic conditions normally elicits mixed responses from both rods and cones. In this case, the response is severely attenuated and the small amount of signal is likely coming from the cone system. Under light-adapted conditions (photopic single flash and 30-Hz flicker), which selectively stimulate the cones, the response is only slightly decreased consistent with the categorization of a rod–cone dystrophy.

ophthalmic artery occlusions and old retinal detachments can present with a pigmentary retinopathy.

Additionally, infections caused by syphilis, toxoplasmosis, and herpes viruses can lead to a pigmentary retinopathy. Congenital rubella infection can often be misdiagnosed as RP or Usher syndrome because these patients present with deafness and a fine, speckled pigmentary retinopathy. The key to differentiating patients with rubella from those with RP is that patients with rubella retinopathy will have normal or near normal responses by ERG (**Figure 10**).

Diffuse unilateral neuroretinitis (DUSN) is caused by a chronic infection with a nematode. In the early stages, this disease can be distinguished due to the appearance of crops of yellowish, deep choroidal infiltrates, neuroretinitis, and sometimes, visualization of the worm itself. However, late in the disease, with the exception of being unilateral, the fundus appearance is identical to RP with the fundus showing bone spicules, vascular attenuation, and optic atrophy (**Figure 11**).

Inflammatory diseases that cause a posterior uveitis can cause chronic changes that mimic the pigmentary changes of RP. Some examples include sarcoidosis, birdshot chorioidoretinopathy, serpiginous retinopathy, Behcet disease, and acute zonal occult outer retinopathy (AZOOR).

Certain drugs can cause pigmentary retinopathies and their usage must be excluded prior to making a diagnosis of RP. One example is thioridazine (Mellaril), an antipsychotic drug, which mimics RP by causing decreased night vision, RPE atrophy, and a pigmentary retinopathy. Hydroxychloroquine (Plaquenil) is used to treat systemic lupus erythematous and rheumatoid arthritis and when taken for extended period of time or at higher doses can lead to central vision loss. Other drugs that have been found to cause pigmentary retinopathies include chlorpromazine, chloroquine, and quinine.

Autoimmune retinopathy is an incompletely understood disease resulting from antibodies to retinal antigens and can present with many of the same features of RP, such as decreased vision, visual-field loss, and decreased ERGs. Unlike the other diseases that mimic RP, autoimmune retinopathy does not present with a pigmentary retinopathy and, in many cases, the fundus appearance can be normal or only show vascular attenuation. A subset of cases of autoimmune retinopathy is associated with carcinomas in other parts of the body. Two examples of this entity are cancer-associated retinopathy (CAR), which often arises from small cell carcinoma of the lung and melanoma-associated retinopathy (MAR). CAR patients may test positive for antibodies directed against retinal

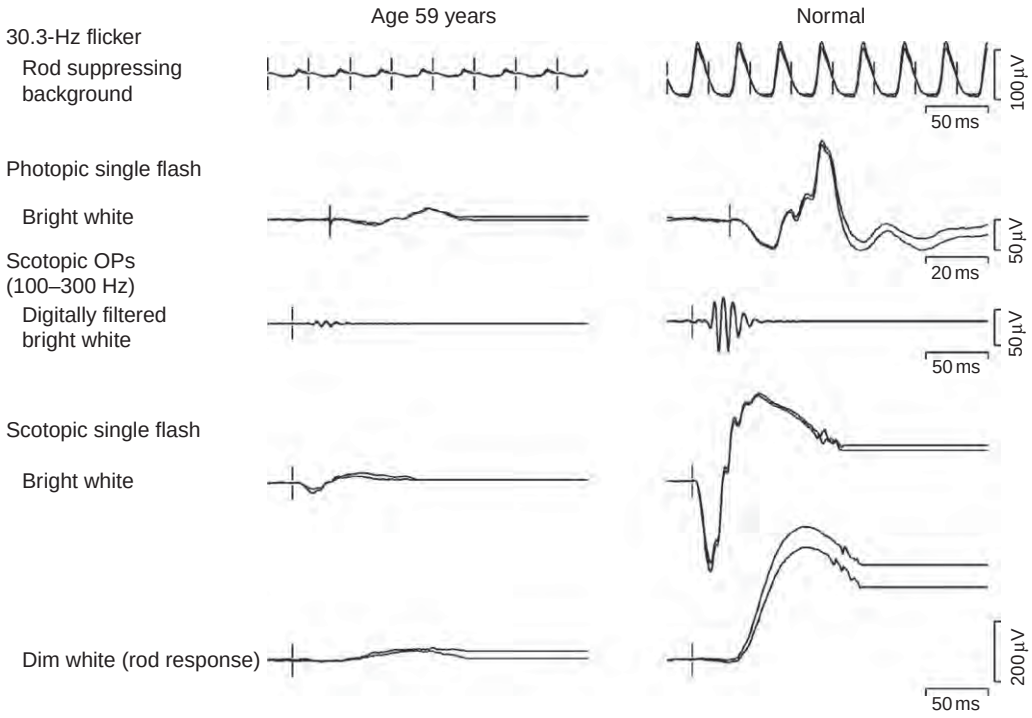

Figure 8 ERGs recorded from a patient with peripherin/*RDS* null mutation (left column) compared to a control patient (right column). This patient is demonstrative of a rod–cone dystrophy where the rods and cones are equally affected. It is of importance that peripherin is expressed in both rods and cones. There is a severely diminished response to the dim white flash under scotopic conditions, which specifically stimulates rods. The bright flash under scotopic conditions normally elicits a mixed response from both rods and cones. In this case, the response is severely attenuated. Under light-adapted conditions (photopic single flash and 30-Hz flicker), which selectively stimulate the cones, the response is also severely decreased consistent with the categorization of an equal rod–cone dystrophy.

antigens, such as anti-recoverin or anti-enolase, while MAR patients may test positive for antibodies directed against bipolar cells.

Prognosis in RP

It is uncommon for a patient with RP to lose all light perception. A study by Grover et al. in 1999 showed that only 0.5% of patients over the age of 45 had no light perception and 50% retained vision better than 20/40. In the typical rod–cone dystrophies, visual loss usually starts in the midperiphery with central visual acuity being spared for many years. Most patients will eventually qualify as being legally blind, often secondary to decreased visual fields prior to being disqualified on the account of decreased central visual acuity. RP is a slowly progressive disease and many patients will eventually experience decreased central acuity, most often from decrease in cone photoreceptor density, macular edema, epiretinal membranes, or retinal pigment defects. However, when there is an unexpected decrease of central acuity, the development of cataracts or cystoid macular edema should be suspected because these sequelae are more amenable to treatment.

Current Treatments

Currently, there is no known cure for most forms of RP, although some treatments have been shown to slow down the progression of the disease and future therapies are promising.

Treatable Forms of RP

A few rare forms of RP are amenable to specific treatments. It is important to rule out these treatable forms of RP because prompt therapy can prevent further damage. The treatable forms of RP include abetalipoproteinemia and adult Refsum disease.

Resources/Support for Patients with RP

The diagnosis of RP can be both frightening and confusing to patients. In addition to having their questions answered by the physician, patients can benefit by meeting with a genetic counselor who can take a detailed family history and answer questions about heritability. Patients should be referred to the many organizations or websites dedicated to providing support for this disease, such as the Foundation Fighting Blindness.

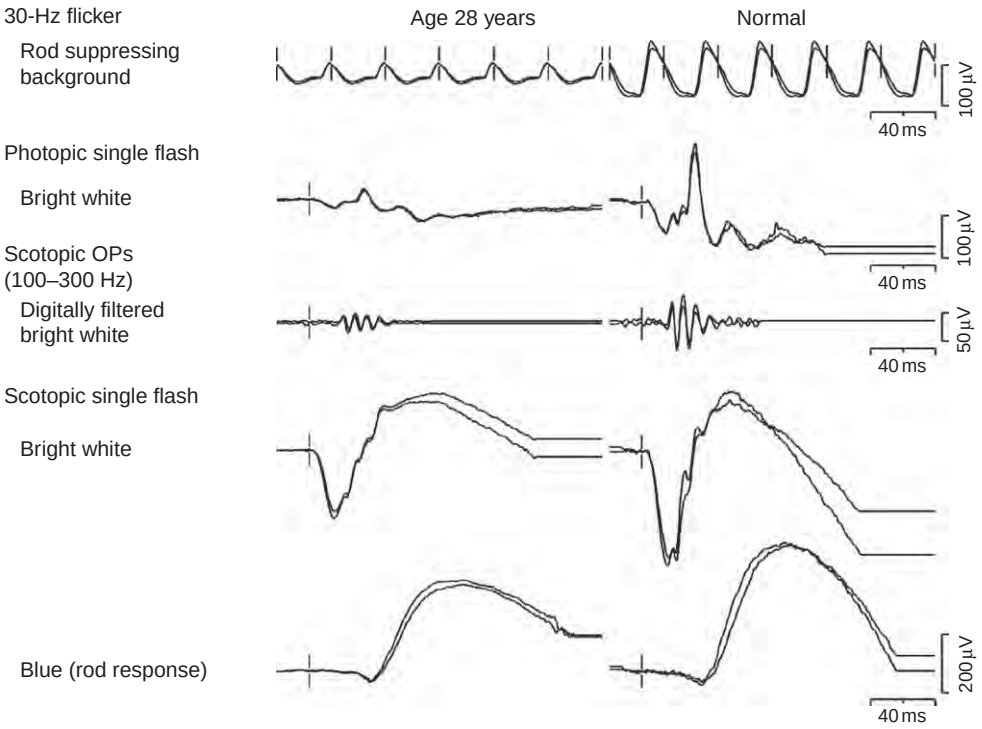

Figure 9 ERGs recorded from a patient with autosomal recessive RP (left column) compared to a control patient (right column). This patient is demonstrative of a cone–rod form of RP. There is a mildly diminished response to the dim blue flash under scotopic conditions, which specifically stimulates rods. The bright flash under scotopic conditions normally elicits a mixed response from both rods and cones. In this case, the response is only moderately attenuated. Under light-adapted conditions (photopic single flash and 30-Hz flicker), which selectively stimulate the cones, the response is severely decreased consistent with the categorization of a cone–rod dystrophy.

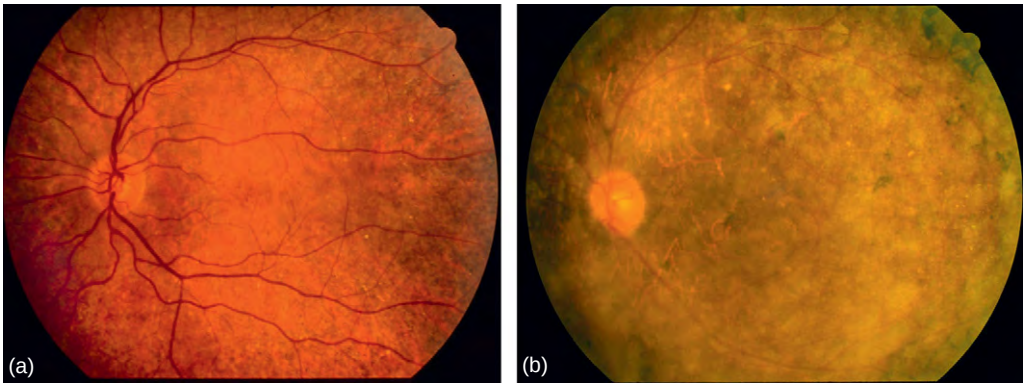

Figure 10 (a) An example of rubella retinopathy. Note the fine, mottled pigmentary changes and normal-appearing nerve and vessels. Unlike RP, ERG testing in this patient would be expected to be normal. (b) Example of a pigmentary retinopathy caused by syphilis.

Optimizing Remaining Vision

It is important that patients with RP have an up-to-date refraction to optimize remaining vision. Patients with significantly decreased visual acuity greatly benefit from a referral to low vision services. A variety of different magnifying devices are available to assist patients with RP. For example, night-vision devices can assist with navigation in dim conditions, although a bright, wide, beam flashlight may be a more cost-effective solution. Various magnifiers and closed-circuit televisions (CCTVs) are available to enhance reading vision.

Cataractogenesis is frequent in patients with RP. Functional visual improvement can be achieved by cataract surgery in carefully selected individuals with suitable remaining retinal function. The risks of surgery are increased in these individuals who should be counseled specifically regarding the risks of postoperative cystoid macular edema.

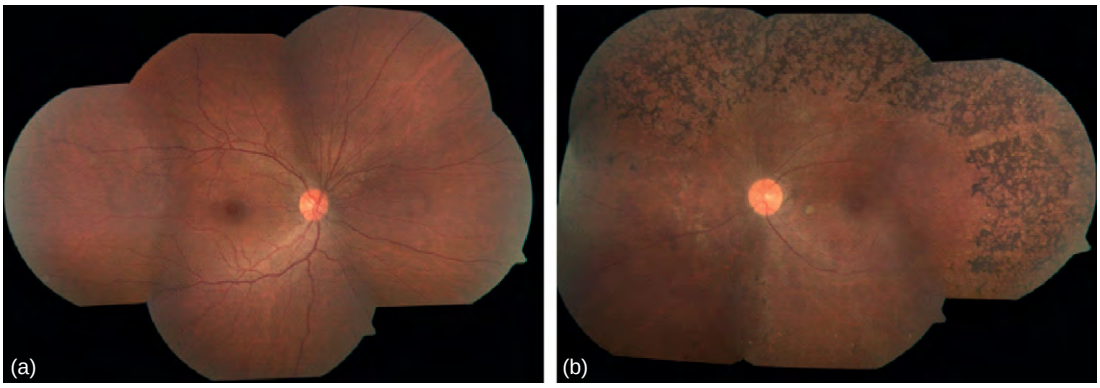

Figure 11 (a) Normal fundus from a patient with diffuse unilateral subacute neuroretinitis (DUSN). (b) The affected eye in the same patient. Note that appearance is identical to RP, demonstrating waxy pallor of the nerve, vascular attenuation, bone-spicule pigmentation, and RPE atrophy.

Cystoid macular edema in RP has been treated with carbonic anhydrase inhibitors such as oral acetazolamide (Diamox) or topical dorzolamide (Trusopt). These medicines can improve vision in some RP patients with cystoid macular edema; however, their efficacy can decrease with time and many patients cannot tolerate the side effects induced by these medicines.

Vitamin A

Observational studies of patients with RP taking vitamin A and vitamin E supplementation demonstrated a slower decline in cone ERGs than expected and led to a randomized, controlled, double-masked trial, to assess if these supplements could slow down retinal degeneration. Additional subgroup analyses in this study suggested that oral supplementation with 15 000 IU of vitamin A modestly slowed down the loss of ERG amplitude over a 5-year period in certain individuals with RP. Currently, vitamin A supplementation is frequently recommended but its use is not universal. High doses of vitamin A supplementation have also been associated with elevated liver enzymes, elevated triglycerides, and an increased risk of osteoporosis. It seems prudent to check annual liver function tests and triglyceride levels for all patients and bone density scans in older patients taking vitamin A supplementation. Vitamin A should be avoided in children, pregnant women, and those with decreased liver function.

Additionally, from a mechanistic disease perspective, vitamin A should be avoided in forms of RP caused by mutations in the gene *ABCA4* due to evidence in animal models of accelerated retinal degeneration. *ABCA4* codes for the ABCR protein, which is important for transport of vitamin A-derived all-trans-retinal from the disk to the photoreceptor cytoplasm. Mutations in this gene are responsible for Stargardt macular dystrophy and rarely can also cause autosomal recessive RP.

Docosahexanoic Acid

Docosahexanoic acid (DHA) is an important omega-3 fatty acid that comprises 30–40% of fatty acids in the retina. The exact role of DHA is not known, but it has been proposed to play a role maintaining membrane fluidity, mediating 11-*cis* retinal transport, and acting as a precursor for neuroprotective factors. Studies in patients with X-linked RP suggested that decreased levels of DHA correlate with decreased ERG responses and have prompted studies to evaluate if supplementation with DHA might slow down retinal degeneration. Two prospective, randomized, double-masked studies (one in patients with X-linked, the other in patients with all forms of RP) failed to show a significant benefit of DHA. However, considering the low risk of adverse effects, many centers do recommend DHA supplementation to patients with RP.

Neuroprotection/CNTF

A relatively new strategy for the treatment of RP is to prevent photoreceptor loss by the delivery of neuroprotective factors. Numerous studies in animal models have documented the successful rescue of photoreceptor degeneration by neurotrophic factors. A delivery system for one of these factors, human ciliary neurotrophic factor (CNTF), has been developed using encapsulated cell technology. These devices use RPE cells that have been transfected to express CNTF and are enclosed by a semipermeable membrane which allows nutrients to diffuse in, but prevents immune attack on the cells. Phase I studies, implanting this device in patients with RP, have been completed without any major adverse events. Phase II studies, which will be able to better assess any visual improvement, are underway.

Gene Therapy

Replacement of defective genes in autosomal recessive forms of RP holds much promise. Currently, three groups

have used an adeno-associated viral vector to deliver normal copies of the all-trans-retinol isomerase (*RPE65*) in patients with LCA. The treatment has thus far been well tolerated and some patients have demonstrated improvement in subjective vision and to some more objective tests such as pupillary reflexes. Gene therapy holds much promise for treating RP, but several challenges remain. RP and its allied disorders are caused by mutations in over 100 genes. Designing a multitude of vectors for each of these genes poses an arduous challenge.

Autologous RPE Transplantation

Replacement of RPE cells has been attempted using suspensions or sheets of cultured RPE cells or autologous grafts. Engraftment of these injected cells has been demonstrated in animal models. Rescue of photoreceptor degeneration has been achieved suggesting that transplanted RPE cells may modulate photoreceptor death. However, in spite of early photoreceptor rescue in these animal models, long-term restoration of vision has been disappointing.

Stem-Cell-Based Therapies

Cell-based therapy using stem cells is currently being intensely explored for rescuing vision. There are two fundamentally different strategies: one is to limit the progress of photoreceptor loss by introducing cells before such loss has progressed too far; the other is to replace lost photoreceptors. Stem cells are multipotent cells capable of self-renewal and have the potential to develop into many specific cell types. Their capacity for proliferative expansion to a large scale and their ability to produce a number of growth factors make them attractive candidates to be used to replace or repair damaged cells in adult organisms.

Microelectrode Implants

One novel concept for treatment of RP is to bypass the loss of the photoreceptors by electronically stimulating the retina, optic nerve, or visual cortex using microelectrode implants.

Expression of Photosensitive Proteins

A very recent approach for treating RP has been the strategy to bypass photoreceptor loss by using viral vectors to express light-sensitive proteins, such as channel rhodopsin, into postreceptor ganglion cells. Early experiments in small animals have demonstrated successful responses from ganglion cells using this strategy. Much work remains to be done, including how to obtain high enough expression to provide adequate sensitivity for useful vision.

Conclusions

RP is a significant cause of vision loss in adults and children. Diagnosis is best made by careful history and clinical examination combined with retinal electrophysiology and psychophysical testing. For some individuals, genetic testing can identify causative mutations. While there is currently no cure for RP, many treatment options are emerging and future therapies are promising.

Primary Photoreceptor Degenerations: Terminology

M E Pennesi, P J Francis, and R G Weleber, Oregon Health and Sciences University, Portland, OR, USA

Glossary

Allied disorders – Retinitis pigmentosa (RP) is often grouped with a class of more stable, inherited retinal disorders collectively referred to as RP and allied disorders. Some of these allied disorders cause similar clinic findings as RP, e.g., nyctalopia (night blindness), but usually do not show progression and deterioration with time. An example is congenital stationary night blindness (CSNB), which can present with nyctalopia and decreased rod and cone function on the electroretinogram (ERG). Unlike RP, most patients with CSNB have stable visual function. X-linked CSNB is caused by mutations in nyctalopin (NYX) and L-type voltage dependent calcium channel (CACNA1F). Although the majority of mutations of rhodopsin causes typical RP, rare mutations, such as G90D in rhodopsin, produce night blindness with such mild progression late in life that they have been called stationary night blindness. Another allied disorder is achromatopsia, which is caused by mutations in cyclic nucleotide-gated channel subunits (CNGA2, CNGB3) or guanine nucleotide alpha-binding protein 2 (GNAT2). Achromatopsia is associated with severely decreased central and color vision, photophobia, and nystagmus. These symptoms are similar to those that can be seen with some cone–rod dystrophies. Indeed, later in life some modest foveal atrophy can occur and cases of progressive cone–rod dystrophy have been associated with mutations of some of the achromatopsia genes. However, unlike cone–rod dystrophies, which invariably progress, achromatopsia is, in the vast majority of cases, stationary.

Cone dystrophy – Cone photoreceptors are affected and rod photoreceptors are minimally affected or spared in cone dystrophy. Many cases of early cone dystrophies with time will develop significant rod abnormalities.

Cone–rod dystrophy – Cone–rod dystrophy, as a group, involves both photoreceptors with cones affected more than rods. Certain forms of RP present with greater cone than rod involvement on ERG and these patients have been termed to have cone–rod RP. However, in cone–rod dystrophies as a group the primary defect lies in cones and secondaryrod loss occurs with time. Most investigators consider primary cone–rod dystrophy separate from RP.

Extrinsic factor – An agent external to the organism that contributes to or is causative of a disease state. This can include drugs, foods, normal nutrients (excess or deficiency), toxins, inhaled chemicals, infectious agents, and exposures to radiation such as light, sound, and high-energy particles.

Intrinsic factor – An agent that is inherent to the organism that contributes to or is causative of a disease state.

Mixed intrinsic and extrinsic etiology for a secondary photoreceptor degeneration – This occurs when a person has a genetic variant that creates a toxic metabolite in the presence of an extrinsic molecule that would normally not be encountered.

Mixed model of primary and secondary photoreceptor degeneration – This is considered when a genetic alteration within the photoreceptors is insufficient to cause photoreceptor degeneration by itself, but predisposes to degeneration in the presence of an extrinsic or intrinsic agent. A second mode of combined primary and secondary photoreceptor degeneration is when one group of photoreceptors, such as the rod photoreceptors, undergoes a primary degenerative process that is due to a mutation in a gene that is expressed in those photoreceptors and precipitates apoptosis, which leads to a secondary degenerative process, in this example cones, due to alterations in the cellular environment induced by death of neighboring cells.

Primary retinal degeneration – This occurs when cells in the retina, usually photoreceptors, die secondary to a process that originates within the retina itself. An example of a primary retinal degeneration is RP, which is caused by mutations in genes that encode proteins important for retinal function. A disease can be classified as a primary retinal degeneration if the genetic defect is such that correction of expression of the normal gene product in the photoreceptors is required to correct the abnormality and arrest the degeneration.

Primary retinal degeneration with secondary photoreceptor degeneration – This occurs when photoreceptor degeneration is the result of mutation(s) of a gene that exists in other retinal cells, for

example, retinal pigment epithelial (RPE) cells. Correction of the genetic defect would require modification of the effects of those other retinal cells (e.g, RPE cells).

Retinal atrophy – A broad term encompassing not only processes that occur with retinal degenerations, but also abnormal retinal tissue or cellular loss due to developmental defects and malnutrition.

Retinal degeneration – A process whereby cells in the retina undergo cell death by apoptosis. Most retinal degenerations affect both rod and cone photoreceptors, but some disorders reflect damage that occurs principally in other cell types, e.g., the RPE in Stargardt's disease and other ABCA4-related retinopathies. Secondary degeneration of the RPE is also common. Transsynaptic degeneration of higher-order cells, bipolar and ganglion cells, can also occur. The general term retinal degeneration should be distinguished from the more specific term, photoreceptor degeneration.

Retinal dystrophy – A broad term that not only encompasses retinal degenerations, but also includes abnormal retinal function due to developmental defects and malnutrition.

Retinitis pigmentosa (RP) – A heterogeneous group of diseases that result in degeneration of the rod and cone photoreceptors and secondarily the RPE. This degeneration usually leads to a loss of night vision due to the early degeneration of rods, constricted visual fields, decreased responses on ERG, and ultimately a decrease in visual acuity once macular cones begin to degenerate. Typical fundus findings include midperipheral atrophy of the pigment epithelium, bone spicule pigments, retinal vessel attenuation, and waxy pallor of the optic nerve. The term RP usually refers to only rod–cone dystrophies; however, cone–rod dystrophies and cone dystrophies are sometimes grouped under this term.

Rod–cone dystrophy – A retinal dystrophy in which the rod photoreceptors are affected more than the cones. Most forms of RP manifest as rod–cone dystrophies.

Secondary photoreceptor degeneration of the extrinsic type – A secondary photoreceptor degeneration of the extrinsic type exists if, despite the underlying molecular defect, one could avoid the photoreceptor degeneration by preventing an individual's exposure to an extrinsic agent or condition (e.g., toxin, drug, infectious agent, light, and trauma).

Secondary photoreceptor degeneration of the intrinsic type – If one can prevent photoreceptor degeneration by correcting or reversing a systemic or ocular metabolic or immune process, then it is a secondary photoreceptor degeneration of the intrinsic type.

Histological and Fundus Features of Retinitis Pigmentosa

The fundus exam in retinitis pigmentosa (RP) reveals mid-peripheral atrophy of the pigment epithelium, bone spicule pigments greater in the periphery than centrally, retinal vessel attenuation, and waxy pallor of the optic nerve.

Bone Spicule Pigmentation

Bone spicules are intraretinal accumulations of melanin pigment that result from the migration of retinal pigmented epithelial (RPE) cells into the retina after photoreceptor death. These spicules are commonly found in a perivascular pattern and may encircle and occlude these vessels, and are a typical feature of RP. However, there are cases of RP that do not present with bone spicules as well as other disease processes, such as trauma and infection, can result in an appearance that mimics RP by presenting with bone spicules (**Figure 1**).

Waxy Pallor of the Optic Nerve

Much as the name implies, waxy pallor of the optic nerve refers to the funduscopic appearance of the optic nerve seen in many patients with RP. When retinal photoreceptors die, Müller cells and astrocytes in the retina undergo gliosis to form scar tissues. It is thought that this process may lead to the waxy pallor of the optic nerve (**Figure 2**).

Peripapillary/Optic Nerve Head Drusen

Peripapillary drusen/optic nerve drusen are found more commonly in patients with RP. Peripapilliary drusen are histologically different from the drusen found in macular degeneration and are found near or within the optic nerve head. They are thought to result from accumulations of materials in the axons of ganglion cells by axoplasmic stasis and can become calcified with time. Such drusen can cause isolated and asymmetrical visual-field defects, which can be slowly progressive (**Figure 3**).

Bull's Eye Maculopathy

A bull's eye maculopathy results from photoreceptor loss and retinal thinning in a parafoveal distribution. It is often apparent on color fundus photos, but can be visualized on

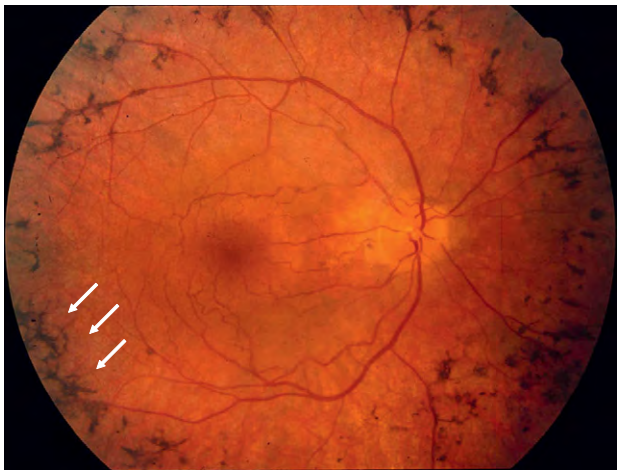

Figure 1 A fundus photo of a patient with retinitis pigmentosa demonstrating intraretinal pigment accumulations (white arrows), also known as bone spicules, which are a common finding in retinitis pigmentosa. They are caused by the migration of retinal pigment epithelial cells into the retina after photoreceptor degeneration. Modified from Weleber, R. and Evan, K. G. (2006). Retinitis pigmentosa and allied disorders. In: Ryan, S. J. (ed.) *The Retina*, 4th edn., vol. 1, chap. 17, pp. 395–498. Philadelphia, PA: Elsevier.

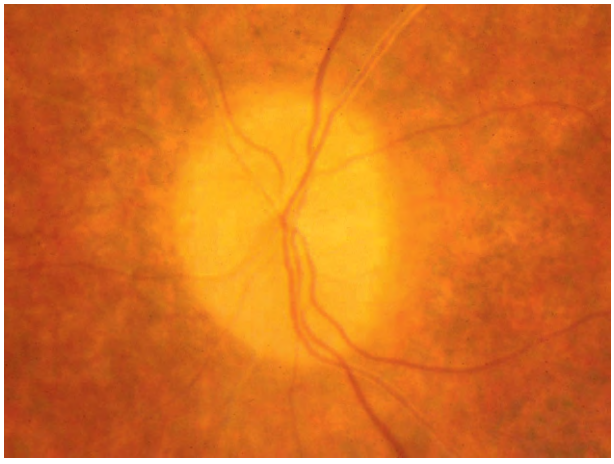

Figure 2 An example of the waxy nerve pallor seen in patients with RP. Also note the vascular attenuation and sheathing.

fluorescein angiography as well. Bull's eye maculopathies are most commonly not only seen in cone–rod dystrophies, but can also be seen in other diseases such as Stargardt's macular dystrophy, Batten's disease, and with hydroxychloroquine (Plaquenil) toxicity (**Figure 4**).

Coats-Like Response

Coats disease is characterized by peripheral retinal telangiectasias, which are dilations of retinal blood vessels, and is usually seen in young males. Rarely, patients with RP can develop localized areas of vascular telangiectasias with exudation similar to those seen in Coats disease. Extravasation of fluid from these vessels can lead to an exudative retinal detachment. This process is termed a Coats-like response (**Figure 5**).

Classification of RP by Fundus Pattern

Classic Pattern for RP

The classic pattern on fundus exam in RP reveals mid-peripheral atrophy of the pigment epithelium, bone spicule pigments in the periphery greater than centrally, retinal vessel attenuation, and waxy pallor of the optic nerve (**Figure 6**).

Inverse RP

The term inverse RP refers to a funduscopic pattern where the central retina exhibits more pigmentary changes and RPE atrophy than the periphery. This term is falling out of favor, as it is now understood that this pattern is often seen with advanced cone and cone–rod dystrophies, as well as some instances of secondary pigmentary retinopathies.

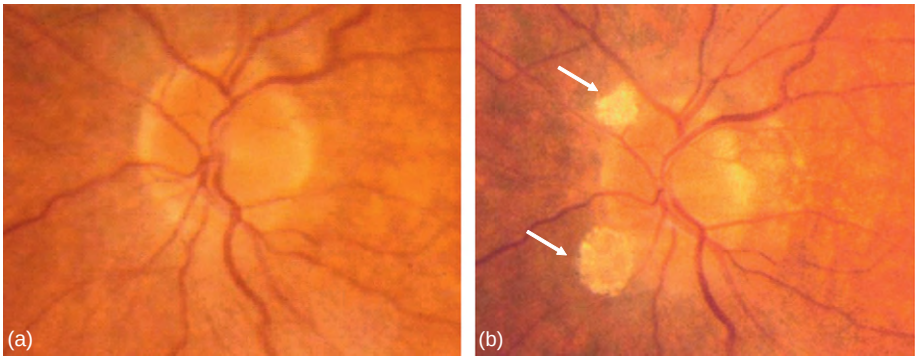

Figure 3 (a) Patient with retinitis pigmentosa – note the lack of a normal physiological cup, which raises the concern for buried drusen. (b) The same patient seen years later who demonstrates peripapillary drusen (arrows).

Concentric RP

Concentric RP is a defined by a subgroup of patients who show a consistent pattern of centripetal vision loss from the far periphery toward the center. This distinguishes it from the classic pattern of RP, which starts in the mid-periphery and progresses both outward and inward. Histological studies have shown an abrupt transition between diseased and normal areas of retina.

Sector RP

Sector RP is a term that refers to the fundus appearance where abnormal pigmentation and atrophy is confined to only one area of the retina, usually an arc inferior to the macula. Debate exists whether this term is specific for certain gene defects or is a stage in evolution of what will become a more generalized process with time. Autosomal recessive or autosomal dominant regional disease can be characterized by such a sectorial pattern at least in early disease. The pattern is usually symmetrical between the two eyes. Mutations in rhodopsin (*RHO*) have been associated with sector RP. These patients are often less symptomatic and their electroretinograms (ERGs) are much less reduced than patients with diffuse or more widespread RP. Early generalized RP can mimic sector RP and, therefore, the diagnosis of sector RP must remain provisional for at least 10 years (**Figure 7**).

Figure 4 A fundus photo demonstrating a Bull's eye maculopathy (dark surrounded by light area).

RP Sine Pigmento

The term RP sine pigmento is applied to the early stages of RP where the classical findings of visual-field loss, decreased ERGs, and vascular attenuation may be present, but there is a lack of bone spicules on the fundus exam. This is thought to represent an early manifestation of the disease and most patients will eventually develop bone spicules, although often not until later stages. Another term in use is pauci-pigmentary retinopathy. In the case of patients who develop symptoms later in life and have a normal, or minimally abnormal, fundus appearance, a work-up for autoimmune retinopathy should be considered.

Tapetal-Like Reflex/Sheen

Tapetal-like sheen is a yellowish-white metallic reflex that can be seen in young males with X-linked RP, women who are carriers of this disease, and patients with cone–rod dystrophy. As the disease advances and RPE atrophy progresses, this reflex can fade. This finding is not pathognomonic of RP because it can be seen in other allied disorders (**Figure 8**).

RP with Preserved Peri-Arteriolar RPE

RP with preserved peri-arteriolar RPE (PPARPE) has been found in families with mutations in the crumbs

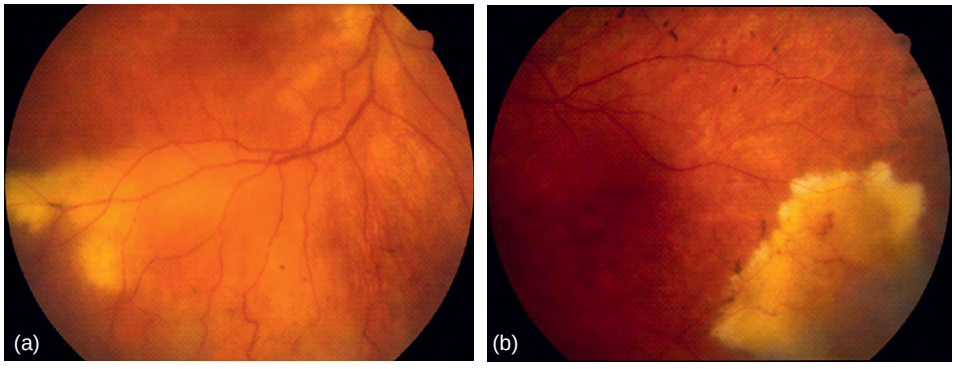

Figure 5 Both (a) and (b) show fundus photos from a patient with RP and a Coat's-like response. Note the yellowish subretinal exudates.

homolog 1 gene (*CRB1*). These patients present with the typical findings of RP, but for reasons not understood, have preservation of the RPE near arterioles.

Pigmented Paravenous Retinochoroidal Atrophy

In pigmented paravenous retinochoroidal atrophy (PPRCA), degeneration and accumulation of bone spicules are limited to the areas around the retinal veins. These patients are often asymptomatic, but with careful testing, scotomas corresponding to the areas of degeneration can be identified. Typically, the ERG is minimally reduced and disease is thought to be, at most, slowly progressive. Although PPRCA has been thought not to be inherited, mutations in the *CRB1* gene have been found in families demonstrating dominant inheritance (**Figure 9**).

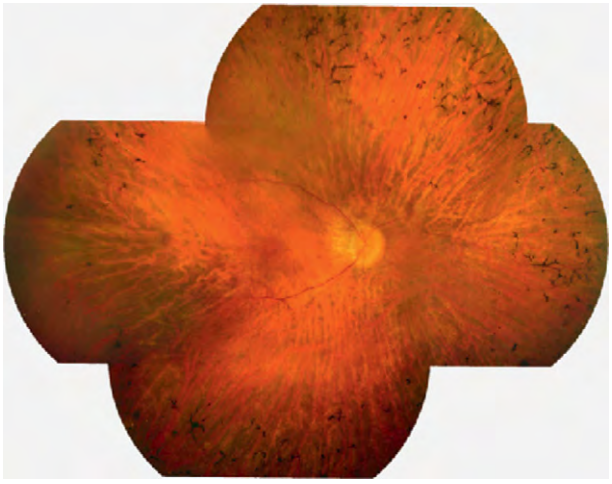

Figure 6 Fundus photo of a typical patient with RP. Note the pallor of the optic nerve, the vascular attenuation, atrophy of the pigment epithelium, and bone-spicules. Reproduced from Weleber, R. G., Butler, N. S., Murphey, W. H., Sheffield, V. C., and Stone, E. M. (1997). X-linked retinitis pigmentosa associated with a two base-pair insertion in codon 99 of the RP3 gene RPGR. *Archives of Ophthalmology* 115: 1429–1435.

Fundus Albipunctata

Fundus albipunctata is an autosomal recessive disease that does not result in a retinal degeneration like RP, but can cause a congenital stationary night blindness. It is more accurately classified as an allied disorder. It is caused by mutations in the retinol dehydrogenase 5 gene (*RDH5*), which results in problems regenerating visual pigment. As a result, these patients have severely decreased rod recovery with prolonged dark adaptation. The fundus exam shows many discrete yellowish-white dots at the level of the RPE. Atrophic lesions in the macula can occur in many patients in later years (**Figure 10**).

Retinitis Punctata Albescens

Retinitis punctata albescens is an autosomal recessive disease caused by mutations in the retinaldehyde-binding protein 1 gene (*RLBP1*). Similar to fundus albipunctata, this disease presents with severe night blindness and small, discrete, yellowish-white lesions in the fundus, but can have a pigmentary retinopathy as well. Later stages of RPA may develop diffuse disease similar to advanced RP.

Gyrate Atrophy

Gyrate atrophy is an autosomal recessive form of diffuse choroidal atrophy caused by mutations of the gene (*OAT*) for ornithine-∂-aminotransferase (OAT). The deficiency of this enzyme results in elevated plasma and tissue levels of ornithine, which exert a cytotoxic effect on the RPE, possibly by endpoint inhibition of a common intermediate for proline synthesis, L-Δ^1-pyrroline-5-carboxylic acid (P5C), which is normally formed from ornithine by OAT and from glutamic acid by P5C synthase. The early stage of gyrate atrophy is associated with sharply demarcated areas of peripheral chorioretinal atrophy. Later stages develop more diffuse and generalized total vascular choroidal atrophy. Dietary restriction of arginine, the precursor for ornithine, can be beneficial. Additionally, a rare subset of patients has been shown to respond with lowered

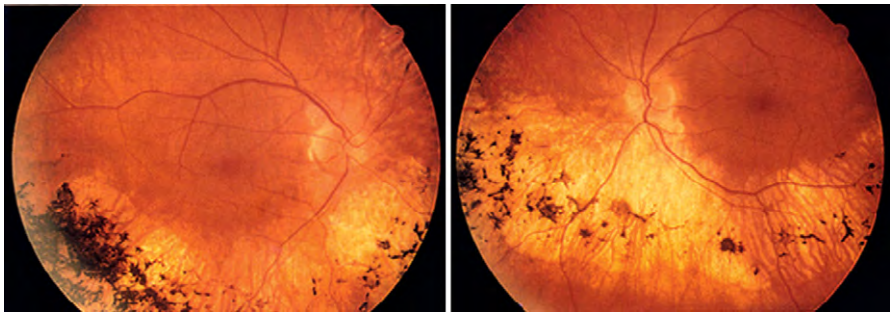

Figure 7 An example of sector RP. From Weleber, R. and Evan, K. G. (2006). Retinitis pigmentosa and allied disorders. In: Ryan, S. J. (ed.) *The Retina*, 4th edn., vol. 1, chap. 17, pp. 395–498. Philadelphia, PA: Elsevier.

ornithine levels to treatment with vitamin B6 (pyridoxine HCL), which acts as a co-factor for the defective enzyme. Disorders such as gyrate atrophy blur the distinction between primary and secondary retinal degenerations leading to the realization that it is difficult to draw the line between RP and allied diseases (**Figure 11**).

Choroideremia

Choroideremia is an X-linked disease, which is caused by a mutation in the *CHM* gene and leads to progressive degeneration of the retina, RPE, and choroid. The *CHM* gene encodes the homolog of the Rab escort protein 1 (REP1) which is thought to be important in the function of a Rab geranylgeranyl transferase. Choroideremia can often be mistaken for X-linked RP, as the two diseases can share several features including: nyctalopia, retinal RPE atrophy, pigmentary changes, and decreased ERGs and X-linked inheritance. Unlike the waxy nerve pallor seen in RP, patients with choroideremia will often have a normal-appearing nerve and relative preservation of the macula and peripapillary retina (**Figure 12**).

Syndromic Forms of RP

Abetalipoproteinemia

Also known as Bassen–Kornzweig syndrome, abetalipoproteinemia results from a deficiency of beta lipoproteins, which are necessary for normal absorption of fat-soluble vitamins from the gut, leading to poor absorption of vitamins A, D, E, and K. The syndrome is characterized by low levels of fat-soluble vitamins, ataxia, acanthocytosis,

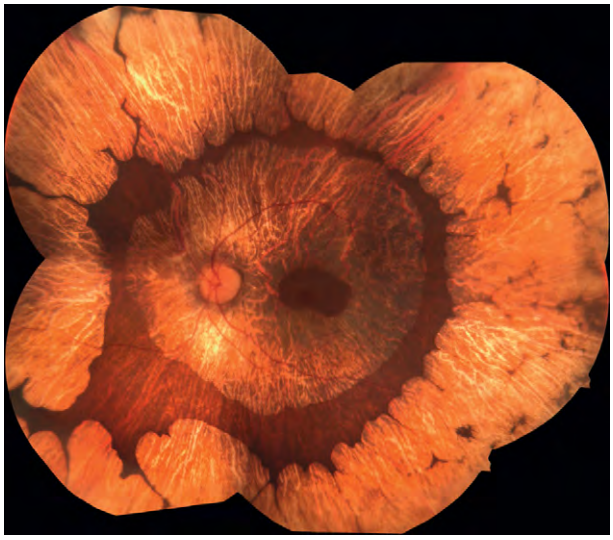

Figure 11 Gyrate atrophy. Note the scalloped peripheral areas of chorioretinal degeneration as well as central atrophy.

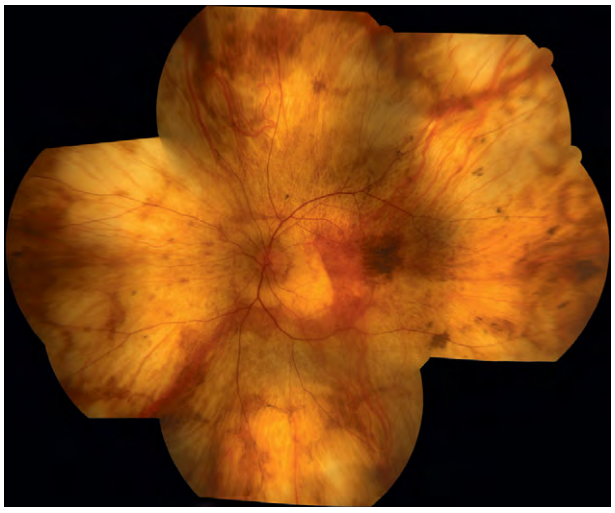

Figure 12 An example of choroideremia demonstrating large areas of chorioretinal atrophy with some macular sparing.

and RP. Treatment with combined vitamin A and vitamin E has been shown to prevent or slow retinal degeneration and, in rare patients, reverse the dark adaptation and ERG defects.

Alström Syndrome

Alström syndrome is an autosomal recessive disease characterized by deafness, obesity, diabetes, cardiomyopathy, and RP. This syndrome shares many overlapping features with Bardet–Biedl syndrome (BBS) and, indeed, much like the genes implicated in BBS, the gene involved in this syndrome, Alström syndrome 1 (*ALMS1*), is thought to play an important role in the structure and function of the cilium.

Bardet–Biedl Syndrome

The details on Bardet–Biedl syndrome are discussed elsewhere in this encyclopedia.

Chronic Progressive External Ophthalmoplegia/ Kearns–Sayre Syndrome

Chronic progressive external ophthalmoplegia (CPEO) and Kearns–Sayre syndrome are mitochondrial myopathies that cause progressive muscle paralysis and pigmentary retinal degeneration. Kearns–Sayre syndrome is associated with sudden cardiac death.

Friedreich's Ataxia

This is an autosomal recessive neurodegenerative disease caused by a trinucleotide repeat expansion in an intron of the frataxin gene (*FXN*), leading to silencing of the gene's protein product, frataxin. The resulting disease causes muscle weakness, ataxia, cardiac hypertrophy, deafness, and retinal degeneration.

Vitamin E Deficiency

Mutations in the alpha-tocopherol transferase protein gene lead to vitamin E deficiency and cause a Friedreich-like ataxia associated with RP. Treatment with oral vitamin E has been shown to halt both the neurological and visual manifestations of this disease.

Incontinentia Pigmenti (Bloch–Schulzberg Syndrome)

Incontinentia pigmenti (Bloch–Schulzberg syndrome) is an X-linked dominant disorder caused by mutations in the nuclear factor kappa-light-chain-enhancer of activated B cells (NFκB) essential modulator gene, *NEMO*, and is usually lethal in males. Affected females demonstrate abnormal teeth and nails, hyperpigmentation of the skin, and central nervous system defects. Retinal findings in these patients include peripheral telangiectasias, hypopigmentation of the fundus, and a pigmentary retinopathy.

Joubert Syndrome

Also known as cerebellooculorenal syndrome, Joubert syndrome is an autosomal recessive disease caused by mutations in 11 different genes. One causative gene, the centrosomal protein 290 (*CEP290*), has also been associated with Senior–Loken syndrome and nonsyndromic Leber congenital amaurosis. Patients with Joubert syndrome have hypoplasia of the cerebellar vermis, and also renal problems and retinal dystrophy. The hypoplasia of the cerebellar peduncles of the midbrain creates a characteristic radiological finding on CT scans termed the molar tooth sign.

Mucopolysaccharide Disorders

Mucopolysaccharide (MPS) disorders can also present with a pigmented retinopathy, some examples of which are Hurler syndrome (MPS type IH), Scheie syndrome (MPS type IS), and Hunter syndrome (MPS type II).

Neuronal Ceroid Lipofuscinosis (Batten Disease)

Neuronal ceroid lipofuscinosis (Batten disease) is a group of autosomal recessive neurodegenerative diseases that result from the accumulation of lipofuscin. This disease is characterized by vision loss, seizures, progressive motor and cognitive dysfunction, and retinal degeneration. Eight genes (*CLN1–CLN8*) have been associated with this disease.

Infantile Refsum Disease

This disease is caused by defective peroxisomes and patients with this disease present with RP, hearing loss, hepatomegaly, and mental retardation. Unlike the adult form of the disease where specific peroxisomal enzymes are defective, the infantile form is characterized by a complete defect in perixosomal biogenesis. Levels of phytanic acid, very long chain fatty acids, and pipecolic acids are elevated. The disease is ultimately fatal.

Adult Refsum Disease

This disease is an autosomal recessive peroxisomal disorder characterized by elevated levels of phytanic acid, which lead to RP, anosmia, deafness, ataxia, cardiac arrhythmias, skeletal anomalies, and polyneuropathy. Mutations in the gene *PAHX*, which encodes phytanoyl-CoA 2-dydroxylases, have been shown to be responsible for some cases of adult Refsum disease. Treatment for adult Refsum disease includes plasmapheresis and dietary restrictions of phytanic acid and its precursors.

Senior–Loken Syndrome

This syndrome is an autosomal recessive disease that also falls under the umbrella of ciliopathies and can share some of the same features as Joubert syndrome (see the section titled 'Syndromic forms of RP'). This disease is characterized by Leber's congenital amaurosis and nephronophthisis (cystic kidneys).

Spinocerebellar Ataxia Type 7

This is an autosomal dominant neurodegenerative disease caused by a trinucleotide expansion in the ataxin 7 gene (*ATXN7*). The disease is characterized by cerebellar ataxias, dysphagia, dysarthria, and a cone–rod dystrophy.

Usher Syndrome

The details of Usher Syndrome are discussed elsewhere in this encyclopedia.

Visual Testing in RP

Terminology of Light Adaptation

The retina can respond to an astonishing 9 log units of light. Rods and cones differ in their sensitivity, temporal characteristics, and response to background lights. Depending on the intensity of a stimulus and background light present, different classes of cells respond. Scotopic refers to conditions under which only rods are functional. Mesopic refers to conditions under which both rods and cones are functional. Photopic refers to conditions under which only cones are functional.

Dark Adaptation

Dark adaption is measured with a Goldmann–Weekers dark adaptometer. Each eye is tested separately by first bleaching the rod and cone photopigments with an intense light and then measuring the brightness of a second light needed to achieve a threshold response. A dark adaptation curve can be drawn by repeating this threshold measurement over time after the bleaching light has been turned off. The normal recovery curve can be separated into two segments. The first segment occurs as cones recover from the bleaching light. The rods are much slower to recover and contribute to the second segment of the curve.

Visual Fields

The details on visual fields are discussed elsewhere in this encyclopedia.

ERG Terminology

The ERG is a fundamentally important test for studying RP and allied disorders. Different forms of RP can be classified based on the ERG response. Just as the electrocardiogram (EKG) measures the electrical activity of the heart through surface electrodes placed on the chest, the ERG measures the electrical activity generated by the retina to flashes of light through electrodes placed on the eye. The standard ERG is most commonly measured using an electrode embedded in a contact lens. Reference electrodes are placed on the forehead and ears. The International Society of Clinical Electrophysiology in Vision (ISCEV) has developed standardized methods for eliciting and recording the ERG.

Full-Field ERG

With the full-field ERG, flashes of light are delivered into a Ganzfeld diffuser, which ensures a uniform distribution of the light to the retina. It is important to realize that the full-field ERG measures a summed response from all of the cells in the retina. Therefore, the visual acuity and the ERG response may not correlate. For example, a patient could have a small scar in the center of the fovea that significantly decreases the vision, but the recordings of the ERG could be normal; the opposite can also be true. A patient could have an extinguished ERG due to peripheral degeneration, but still maintain 20/20 visual acuity due to preservation of the central fovea. For this reason, it is important to correlate visual acuity and ERG recordings along with visual-field results.

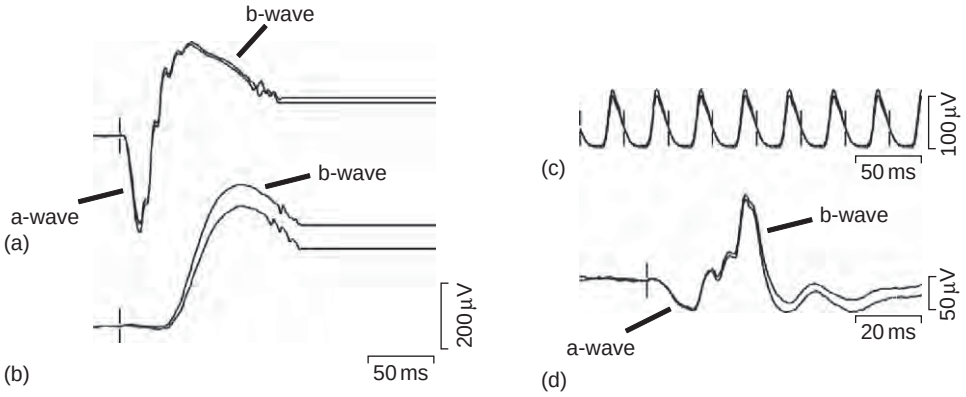

Figure 13 Components of a normal ERG. (a) Scotopic response to bright flash, which stimulates both rods and cones. Note the mixed a-wave, b-wave, and oscillatory potentials (superimposed on b-wave). (b) Scotopic response to a dim white flash, which stimulates only the rods. Note the rod-driven b-wave. (c) Photopic response to a 30-Hz flash, which isolates cones. (d) Response to a single flash under photopic conditions, which also isolates cones. Note the cone a-wave, b-wave, and oscillatory potentials (superimposed on b-wave).

Multifocal ERG

The full-field ERG can demonstrate a large disparity between the ERG signal and the visual acuity. To better detect localized retinal dysfunction in the macula, the multifocal ERG (mfERG) is very useful. The mfERG uses an m-sequence-derived check board pattern to selectively stimulate and isolate electrical activity from the retina. Specifically, the mfERG tests the macula under mesopic or photopic conditions, and therefore is primarily indicative of macular cone function.

Rod-Isolated ERG Response

The ERG can be recorded under dark-adapted (scotopic) conditions or light-adapted (photopic) conditions. When dim flashes are delivered under scotopic conditions, only the rod photoreceptors are stimulated. Such a flash elicits a positive electrical potential termed the b-wave. The scotopic b-wave arises from responses elicited by the rod bipolar cells. As the intensity of the flash increases, the b-wave grows in amplitude and, at higher intensities, a negative potential generated by the rod photoreceptors emerges and is termed the a-wave. Oscillations imposed on the b-wave are generated by higher-order retinal circuitry and are termed the oscillatory potentials.

Mixed Rod–Cone ERG Response

At even higher intensities, both the rod and cone photoreceptors are stimulated to generate a mixed scotopic response. Contributions from the cones contribute to the growing a-wave, while activity of the cone bipolar cells contributes to the b-wave. Once the intensity of the light has become intense enough to saturate the photoreceptors, the a-wave will cease to increase in amplitude. The amplitude from baseline to the peak of the a-wave is termed the saturated a-wave amplitude and the time to the peak of the a-wave is the implicit time. The b-wave amplitude is measured from the trough of the a-wave to the peak of the b-wave.

Cone-Isolated ERG Response

The electrical activity of the cone photoreceptors can be isolated in two ways. The first is to measure the response to 30-Hz flicker flashes for which the cones have sufficient time to recover but the rods do not. The repetitive stimulus elicits a sinusoidal-like response. The peak-to-peak amplitude and the time to peak of this response relative to the stimulus can both be measured. The second method is to turn on a background light, which saturates the rod photoreceptors but minimally affects the cones (photopic conditions). Flashes under these conditions will elicit a cone-driven a-wave and b-wave as well as oscillatory potentials (**Figure 13**).

Glossary

Cytokeratins – A family of proteins found in the cytoskeleton (intermediate filaments) of epithelial cells.
Glial fibrillary acidic protein – A protein found in the cytoskeleton (intermediate filaments) of glial cells.
Immunohistochemistry – The localization of antigens, especially proteins, in tissue sections by antigen-antibody reactions. The reaction sites are visualized by a label such as a chromogen (typically a brown or red dye).
Myofibroblast – A fibroblast-like cell with some of the features of smooth muscle, including contractile properties.

Introduction

In 1983, the Retina Society Terminology Committee published a landmark paper in which the term proliferative vitreoretinopathy (PVR) was proposed for a condition that had been recognized as the major cause of failure of retinal detachment surgery. Previous names for this disease included preretinal organization, massive vitreous retraction (MVR), massive preretinal retraction (MPR), and massive periretinal proliferation (MPP) – terms that highlighted some of the main clinical features of the disorder.

In this condition, following a retinal detachment, cells leave their normal location in the retina and migrate to the retinal surfaces. Here, the cells proliferate to form membranes. Although many of these membranes consist of only a thin layer of (glial) cells and produce no clinical problems or symptoms, in about 10% of retinal detachment patients the membranes develop into thicker scar-like tissues that are able to contract. It is this ability of the membranes to contract that leads to the clinical picture of PVR.

Definition

PVR is strictly defined as a complication of rhegmatogenous retinal detachment that is characterized by the formation of membranes on both surfaces of the detached retina and on the posterior surface of the detached vitreous gel.

Location of PVR Membranes

The membranes on the vitreous surface of the retina are usually called epiretinal membranes and these are the most common membranes of PVR. Membranes that form beneath the detached retina (i.e., between the neuroretina and the retinal pigment epithelium) are termed sub- or retro-retinal membranes. Membranes on the posterior surface of the vitreous gel are known as posterior hyaloid membranes and typically are continuous with epiretinal membranes in PVR (hence they tend to have a similar composition). The expression periretinal membrane is sometimes used to encompass all membranes around the retina.

In addition, membranes can extend into the vitreous base and anteriorly over the pars plicata to the back of the iris: a condition known as anterior PVR. There is also evidence that PVR can have a distinct component within the neuroretina itself – a situation that may be called intraretinal PVR (iPVR).

It is clear that cellular proliferation can occur at several of the above sites in the same eye. It is also important to recognize that membrane formation can occur in a wide variety of diseases other than retinal detachment. For example, the ischemic retinopathies can also lead to epiretinal and posterior hyaloid membranes although the membranes in these conditions are usually heavily vascularized and thus differ from PVR membranes (see below).

The Significance of Membrane Formation in PVR

In PVR, the membranes may contract so that they exert traction on adjacent tissues. Epiretinal membranes tend to produce tangential traction on the retinal surface. The effect of this retinal traction is to cause retinal folding and/or (re)detachment of the sensory retina (**Figure 1**). Such an effect can be localized, as for example when an epiretinal membrane over the macular (epimacular membrane) causes folding of the macular (macular pucker) or in a peripheral membrane causes a star fold (**Figure 2**). On the other hand, epiretinal membranes may be diffuse, rather than localized, covering much of the retinal surface.

The traction from epiretinal membranes can be mild, causing no more than subtle surface wrinkling of the inner retina. Moderate traction can cause marked folds of the retina. Severe traction can be associated with

displacement of retinal vessels and ectopia of the fovea. The effect of the traction is, however, not just two dimensional (2-D). The newer generation of Optical Coherence Tomography systems provides high-resolution cross-sectional views or reconstructed 3-D images of the retina (Figure 2). These images clearly show that the traction may be superficial but sometimes the whole thickness of the retina is involved. Thus, these signs can indicate the development of PVR.

Clinically, we often see the effect of traction rather than the epiretinal membranes themselves: on the attached retina, epiretinal membranes can be difficult to visualize (Figure 1). Nonetheless, the epiretinal membranes are present and exerting isometric' traction on the retina. The effect of this traction may only become apparent once the retina becomes detached, at which point one may observe star folds or retinal breaks with rolled edges when the traction in the tissue is focal. In addition, when the epiretinal membrane is diffuse, the detached retina will appear to have reduced mobility. Anterior PVR membranes will draw the pre-equatorial retina anteriorly toward the ciliary processes, whereas epiretinal membranes in the post-equatorial retina tend to contract the retina into a cone configuration. The combination of the anterior and posterior traction systems on a totally detached retina will give rise to a so-called closed funnel (Figure 3).

Subretinal membranes, particularly in the form of bands, are apt to elevate the neuroretina like a sheet on a washing line or, in the case of a circular band, like a napkin in a napkin ring. Posterior hyaloid membranes can produce circumferential or, if the vitreous base is involved, anteroposterior traction.

Particularly in eyes that have undergone previous vitrectomy or trauma, proliferative tissue can extend into the vitreous base and anteriorly toward the pars plicata of the ciliary body, the iris and even as far as the pupil margin. Traction in this latter situation may lead to traction on the ciliary body (hypotony can result) and posterior displacement of the iris.

The Cells Involved in PVR

It is now accepted that PVR combines reaction to damage by astrocytes of the central nervous system (gliosis) with fibrosis. In this context, the gliosis involves Müller cells and retinal astrocytes, while the fibrosis includes metaplasia or transdifferentiation of the retinal pigment epithelial (RPE) cells. Although retinal glia and RPE cells are thus major players in PVR, it is also apparent that a variety of other cell types are involved in the disease.

Figure 3 Section through an eye with PVR and a closed-funnel retinal detachment. Retinal folds can be seen. The eye is aphakic and there are anterior PVR membranes that also involve the iris.

Glial Cells

There is compelling evidence from a variety of morphological, immunohistochemical, *in vitro*, and experimental studies that astrocytes and Müller cells are involved in PVR membranes, particularly in epiretinal and, to a lesser extent, subretinal membranes.

Within PVR epiretinal membranes, glial cells often form layers in the tissue (**Figure 4**). These layers are adherent to fibrous components of the membranes and, in both human and experimental PVR, the cells can sometimes be traced through defects in the retinal inner limiting lamina into the retina itself. These observations

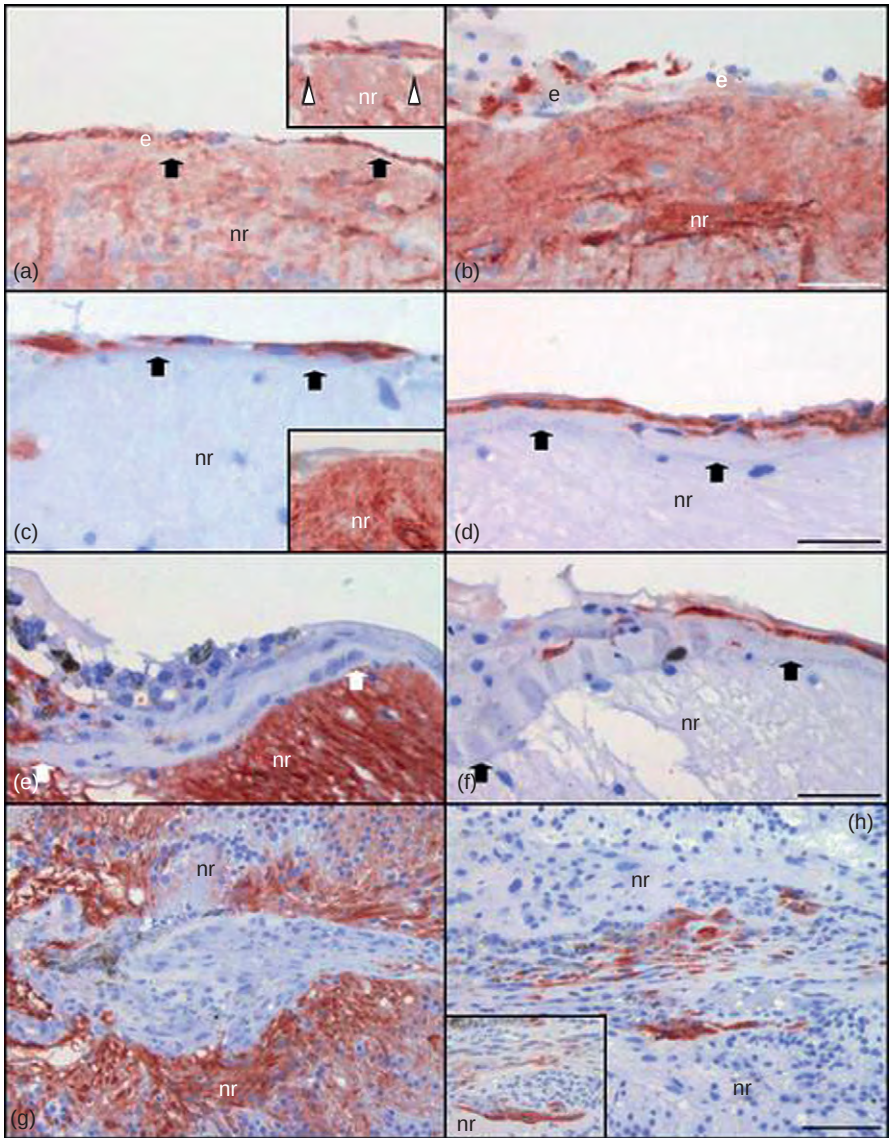

Figure 4 (a–h) Sections through neuroretina (nr) with PVR membranes in enucleated eyes. The sections have been stained with the immunohistochemical method for glial elements with an antibody to glial fibrillary acidic protein (see insets in (a–c) , and also (e) and (g)) or for RPE elements with antibody to cytokeratin 7 ((c), (d), (f), and (h)) or to a range of cytokeratins (inset in (h)): red-brown reaction product, hematoxylin counterstain. (a) The retina is gliotic and there is an epiretinal membrane 'e' composed of a glial monolayer. The internal limiting lamina is marked (arrows). Inset: this epiretinal membrane is composed of a double layer of glia and there is some distortion of the internal limiting membrane (arrowheads). (b) The epiretinal membrane 'e' is composed of glial and nonglial cells. Again, the underlying retina is gliotic. (c and d) Epiretinal RPE cells are seen. The subjacent retina is gliotic (inset in (c)). The internal limiting lamina is marked (arrows). Parts (e) and (f) show the same area of the same specimen: the epiretinal membrane contains both glial (e) and RPE (f) components. The internal limiting lamina is marked (arrows). Parts (g) and (h) show the same area of the same specimen: the retina is folded, disorganized, and gliotic. There is a PVR membrane containing fibroblastic RPE cells and a few glia. Some of the fibroblast-like cells do not label for glial or RPE markers, even with an antibody that reacts with a range of cytokeratins (inset in (h)): their origin is unclear. Scale bars: (a–f) 50 μm; (g and h) 100 μm.

have led to the concept that glial cells traversing the vitreoretinal interface serve to anchor the epiretinal membrane to the retina and that the epiretinal glia may form a substrate or scaffold that other cells might use to produce the rest of the epiretinal tissue. In support of this notion, experimental models have demonstrated that glial cells can break through the retinal inner limiting lamina early in the formation of epiretinal membranes and spread across the retinal surface to form sheets that other cells may adhere to. Failure of glial sheets to become populated by other cells may account for arrest of the disease process at an early stage and the production of asymptomatic or nonproblematic subtle membranes on either surface of the neuroretina.

RPE Cells

The same sorts of methods that were used to detect glia in PVR membranes have been employed to demonstrate RPE cells. Indeed, it is now widely accepted that RPE cells are major components of PVR membranes and the presence of large numbers of RPE cells in epiretinal membranes is one of the distinguishing factors between PVR membranes and epiretinal membranes caused by other diseases. Early in the development of PVR, RPE cells leave their normal location at the chorioretinal interface and either migrate or are swept with subretinal fluid movements to the surfaces of the detached retina. Here, the cells may attach to early membranes (**Figure 4**). In the case of epiretinal membranes, RPE cells may adhere to glia that have already arrived, while in subretinal membranes it has been suggested that the cells may in addition settle on fibrin deposits. Some RPE cells may also migrate into or through the neuroretina.

RPE cells have a remarkable propensity to undergo metaplasia or transdifferentiation. As a result, an RPE cell may change from a polarized, sedentary pigmented cuboidal epithelial cell to a nonpigmented fibroblastic cell, a migratory macrophage-like cell, a cell in a gland-like structure or even a bone-forming cell (**Figure 4**). In PVR membranes, RPE cells most often adopt fibroblastic or macrophagic phenotypes, though they may attempt to (re-)form a polarized monolayer as well.

Fibroblastic Cells

PVR membranes often have a substantial fibrous element that consists of fibroblastic cells in extracellular matrix. Many of these cells are of RPE origin (**Figure 4**). Others may be derived from perivascular sources such as adventitial cells of larger retinal vessels.

There has been much interest in the role of fibroblastic cells in PVR membranes for two reasons. First, they are believed to be responsible for generating most of the tractional forces within the tissue. Second, the cells are thought to be responsible for the production of the bulk of the extracellular matrix in the membranes. There is still debate about how these cells may produce traction: theories include smooth muscle-like contraction of the (myofibroblastic) cells and cell–matrix interactions that cause shortening of matrix elements.

Macrophages

In addition to macrophagic RPE cells, macrophages of hematogenous origin are involved in PVR. Macrophages are especially abundant in membranes arising in the presence of some tamponade agents (see below).

Irrespective of their origin, macrophages are believed to have a number of important roles in PVR. In the early stages of the disease, they produce mitogens, chemotactic agents, and growth factors that probably have a role in cell recruitment to and proliferation in the membranes. Growth factors and enzymes produced by macrophages later in the disease process may be involved in matrix synthesis and remodeling.

Vascular Elements

Blood vessels are found in around 10–20% of PVR membranes but, in contrast to periretinal membranes of conditions such as central retinal vein occlusion and proliferative diabetic retinopathy, blood vessels usually do not form a major component of the tissue. However, vessels are probably more abundant in anterior PVR membranes (**Figure 5**).

Other Cells

T lymphocytes, including CD4 and CD8 positive cells, have been found in PVR membranes. Some of these cells express interleukin-2 receptor, suggesting that they are activated and capable of promoting the cellular events in the tissue. Ciliary body epithelial cells have been reported in the membranes of anterior PVR (**Figure 5**). Hyalocyte-like cells have been described in epiretinal membranes generally and it has been suggested that hyalocytes may give rise to some of the fibroblastic and macrophagic cells in the epiretinal tissues. Recently, ganglion cell neurites have been observed in experimental and human epi- and subretinal membranes. They are co-localized with glia, suggesting active outgrowth into the periretinal tissues.

The Extracellular Matrix in PVR Membranes

PVR membranes contain a matrix that, in terms of composition, is similar to the one seen in a healing skin wound (**Figure 6**). These components include structural proteins

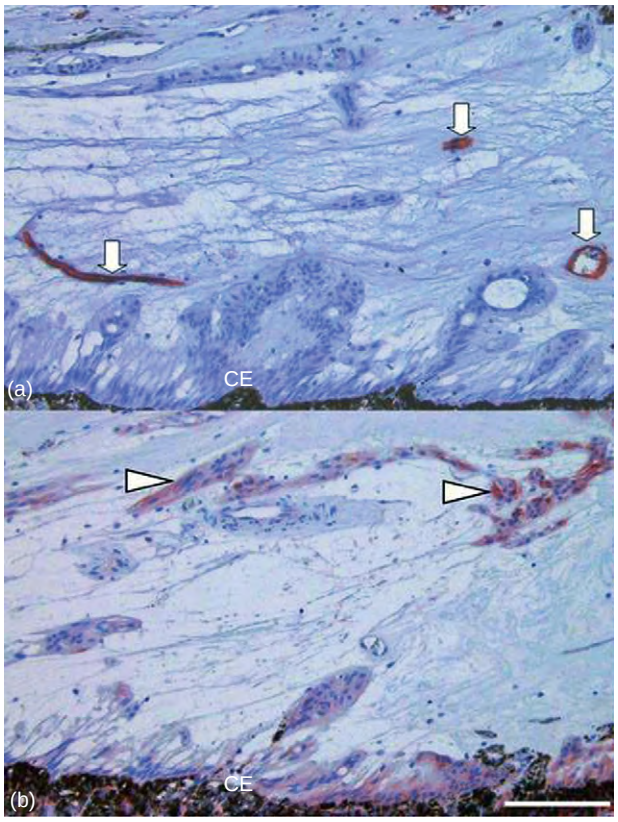

Figure 5 Anterior PVR membrane extending over distorted ciliary epithelium (CE) in an enucleated eye. (a) Stained with the immunohistochemical method for the endothelial marker CD34: note that there are blood vessels in the membranes (arrows). (b) Stained with the immunohistochemical method for cytokeratins: note that in addition to cells in the membranes (arrowheads), the CE normally expresses cytokeratins too. Thus, it is possible that at least some of the epithelial cells in anterior PVR membranes are of CB rather than RPE origin (hematoxylin counterstain, scale bar: 200 μm).

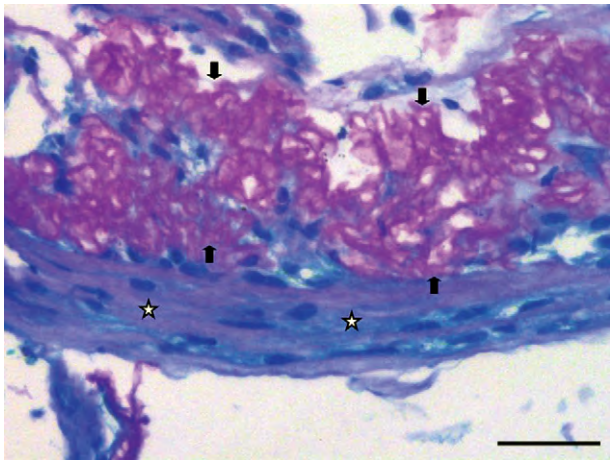

Figure 6 Section through a surgically excised PVR epiretinal membrane. The tissue contains a fibrous element (stars). Convoluted retinal internal limiting membrane is also present (arrows). Periodic acid Schiff reagent, hematoxylin counterstain. Scale bar: 50 μm.

such as collagens and elastic fiber precursors, adhesive glycoproteins like fibronectins and laminins, glycosaminoglycans, matricellular proteins such as tenascins and thrombospondins, and matrix enzymes like matrix metalloproteinases together with their inhibitors.

Much of the matrix in PVR is produced locally by the membrane cells themselves, though there is evidence that some components enter from elsewhere. For example, some blood derivatives like plasma fibronectin are found in PVR membranes. Irrespective of origin, the extracellular matrix in PVR membranes increases with time and there is a corresponding decrease in cellularity of the tissue. Indeed, this change in cellularity together with the contractile nature of the tissue and the presence of fibroblastic cells in matrix gave rise to comparisons between PVR membranes and healing wounds.

As in healing wounds generally, the matrix is more than a passive space filler: there is good evidence that PVR matrix is an important regulator of cell behavior (notably migration and proliferation) in the tissue. For example, there have been a number of reports demonstrating that cells in PVR membranes express a range of cell-surface receptors for the various matrix components around them (e.g., integrins) and experimental studies implicating the importance of such receptors in contraction in PVR models. Moreover, early matrix may have adhesive properties that aid cohesion of the developing tissue. There is also evidence of matrix remodeling in more established membranes. Longstanding PVR membranes are often densely fibrous. It is also worth noting that, when surgically excised, PVR membrane specimens often contain internal limiting membrane from the retina. This material tends to become convoluted in the tissue (**Figure 6**), presumably as a result of tractional forces upon it.

Pathogenesis and Natural History

Although the pathogenesis of PVR is not fully elucidated, our understanding of the disease is at the point where logical therapies can be designed and implemented.

Fundamental to the development of PVR is retinal detachment, itself dependent upon degenerative changes in the vitreous and retina. Vitreous degeneration (syneresis) is a normal aging process that can be accelerated by conditions such as myopia or trauma and results in the formation of fluid and formed components. Attachments between formed vitreous and retina may permit rotational tractional forces, such as dynamic traction from saccadic eye movements, to be transmitted between the two structures. In turn, a retinal tear may form and fluid vitreous pass through the hole in the retina to give rise to a (rhegmatogenous) retinal detachment.

There is experimental evidence that some changes associated with PVR can occur within a day of retinal

detachment. In retinal detachment, together with entry of fluid vitreous to the subretinal space, there is breakdown of the blood–retina barrier with accumulation of plasma proteins in the vicinity of the retina and influx of blood-borne inflammatory cells. Thus, there is aggregation of hematogenous and locally derived proteins and cytokines, including plasma glycoproteins, and growth and differentiation factors. Many of the components of this collection have chemotactic and/or mitogenic properties for RPE and glial cells. In fact, RPE cells can be observed to detach from Bruch's membrane and may be transported to the surfaces of the detached retina while glia may breech the retinal inner limiting lamina (see above) in retinal detachment.

The above reaction to retinal detachment might set the scene for PVR formation, as we have seen only a minority of retinal detachment patients develop the condition. It thus appears that additional factors are required and, indeed, a number of clinical risk factors have been identified (see below). These include factors that would be expected to elevate the concentrations of chemotactic and mitogenic chemical mediators and increase the influx of inflammatory cells to the retinal surfaces, such as hemorrhage, multiple surgical interventions, and large surface area of RPE cells exposed to detachment.

Cells displaced to the surfaces of the detached retina can be seen to adhere to each other as well as the retinal surface. These very early membranes lack matrix but they do possess adhesive glycoproteins like fibronectins. Moreover, a number of matricellular proteins including thrombospondin 1 are also present. It has been hypothesized that fibronectin and thrombospondin 1 can form a provisional matrix in healing wounds. Thus, it is possible that they provide some integrity to developing PVR membranes as well as an adhesion substrate for the cells.

Once in the developing membranes, the cells proliferate. Proliferation is assumed to increase the amount of membrane tissue and it can be detected as long as a year after the onset of the disease. In this respect, PVR differs from skin wounds where proliferation is restricted to a short wave early in the process. It is thought that cells also migrate along the retinal surfaces toward developing membranes, perhaps in response to local chemotactic agent production in the new tissue.

In addition to cell recruitment, cell migration in PVR membranes might also be a mechanism by which tractional forces are generated (motile cells impart a force on their substrate). Thus, it may be that cell migration, myofibroblastic contraction, and cell–matrix interactions (see above) can all be involved in membrane contraction.

The buildup of extracellular matrix with time in PVR membranes is matched by a reduction in cellularity of the tissue (**Figure 6**). Cell loss in PVR membranes probably occurs through apoptosis and nonapoptotic pathways. Ultimately, untreated PVR membranes become paucicellular and fibrous in nature.

Intraretinal PVR

The concept that retina-shortening cellular changes may occur within the neuroretina itself in PVR is relatively recent. Nevertheless, it is now clear that several cell types, including Müller cells and astrocytes, not only become reactive but also do replicate in the retina in PVR and it is thought that this gliosis contributes to retinal shortening. RPE cells are also involved in this process, although their numbers appear to be small compared to the numbers in periretinal membranes. Moreover, gliosis, with or without epiretinal and/or subretinal membranes, can cause marked retinal distortion and localized retinal thickening that can lead to the formation of a focal mass (**Figure 7**). Indeed, similarities in the microscopic appearances of localized PVR masses and vasoproliferative tumors of the retina, including the presence of RPE cells in both lesions (**Figure 8**), have led to speculation that some vasoproliferative tumors may be part of the spectrum of PVR.

Incidence and Risk Factors

It is often stated that PVR afflicts around 10% of all patients with retinal detachment. However, it is clear that some patients are at much greater risk of developing the condition than others. The most important risk factor for postoperative PVR seems to be preoperative PVR. A variety of clinical risk factors have been identified or suggested, including size and number of retinal holes, extent and duration of the detachment, the presence of blood and/or intraocular inflammation, aphakia, preoperative choroidal detachment, early stages of the disease or poor visual acuity prior to initial surgery, and

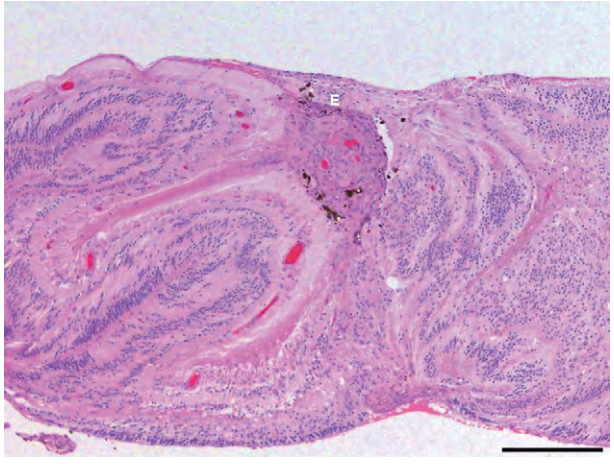

Figure 7 Gliotic, disorganized, thickened retina that has full-thickness folds in association with epiretinal membrane (E), in a section of an eye removed for complications of PVR. The retinal changes give rise to the formation of a localized mass (hematoxylin and eosin; scale bar: 500 μm).

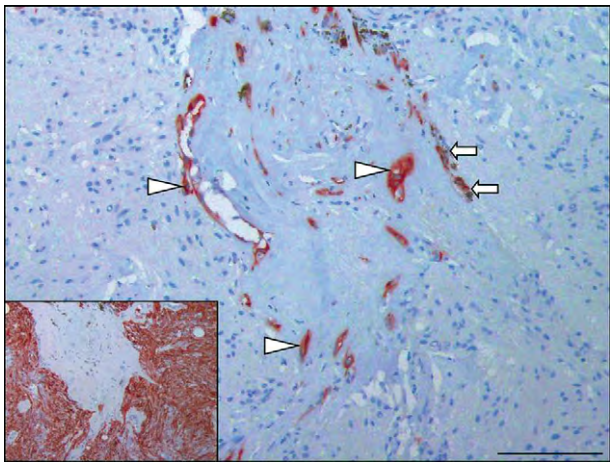

Figure 8 Section showing part of a vasoproliferative tumor (reactive retinal glioangiosis) in an eye removed for complications of retinal detachment. The lesion contains scattered RPE cells (arrowheads), revealed (red) by immunohistochemical staining for cytokeratin 7 (hematoxylin counterstain). A few of these cells contain melanin pigment (*arrows*). Staining of the lesion for glial cells (*inset*: immunohistochemical staining red, hematoxylin counterstain) confirms that the retinal tissue is gliotic and disorganized. Scale bar: 200μm

multiple previous attempts at re-attaching the detached retina. Methods employed during the primary retinal detachment surgery may also increase the risk of PVR. Thus, there is evidence that cryopexy, choice of tamponade agent, and vitrectomy impact on the risk of developing PVR.

Clinical Classification of Proliferative Vitreoretinopathy

There are several attempts to classify PVR according to the clinical features of the retinal detachment. These classifications are descriptive and help surgeons communicate, especially with regard to surgical approaches in the management of the condition. Thus, they are useful for surgical planning and are not based on pathobiology. PVR classifications are also not prognostic. They do not correlate well with visual prognosis or anatomical success with treatment. The classification is also not related to the stages of the disease. It is just the clinical picture at one snapshot in time. Despite their many shortcomings, clinical PVR classifications are widely used in clinical trials and for clinicopathological correlates.

Several classifications have been suggested, based on the clinical manifestations of the disease. For the most part, there is commonality between these systems with regard to the earlier or milder stages of the disease, whereas the schemes tend to diverge in their classification of later or more advanced stages of PVR.

Within these systems, stage A (minimal) is usually regarded as the presence of vitreous haze and pigment clumps, whereas stage B (moderate) is typically recognized as wrinkling of the retinal surface, decreased vitreous mobility, and increased retinal stiffness.

With respect to the more severe or later stages of PVR, some schemes separate the advanced stages by the number of quadrants of the retina involved. Thus, for example, the Retina Society Terminology Committee classification of 1983 associates stage C (marked) disease with fixed retinal folding and adds a number to reflect the number of quadrants involved (e.g., C-3 is fixed folds involving three quadrants of retina). In this system, stage D (massive) reflects the involvement of all four retinal quadrants. In addition, stage D is graded 1–3 depending on how extensive the folding of the retina is (D-1 being an open funnel of totally detached retina, D-3 being a closed funnel so that the optic nerve head cannot be seen: **Figure 3**).

Other schemes classify the more severe stages of PVR into anterior and posterior groups, according to the location of the disease with reference to the retinal equator. In these systems, the number of retinal quadrants involved by the disease is again used so that PVR involving fixed folds in, say, two quadrants of retina posterior to the equator would be classed P2 or CP2 (stage D is generally discarded in these schemes). The schemes employing anterior and posterior also add a contraction type, depending on the extent of epiretinal membrane (focal or diffuse), the presence of subretinal membrane, or posterior hyaloid/vitreous base proliferation.

Management

There is much interest in preventing proliferation of membranes after retinal detachment surgery by treating high-risk patients with combinations of agents. One such combination is the antiproliferative drug 5-fluorouracil and low-molecular-weight heparin (which binds growth factors). This combination has been shown to reduce the incidence of PVR in high-risk retinal detachment patients undergoing vitrectomy.

Once established, PVR membranes are removed by microsurgery so that the retina can be reattached. Again, there is much interest in the use of pharmacological measures to stop membrane recurrence after PVR surgery. For example, there is evidence that daunomycin used preoperatively can reduce the requirement for repeat surgery in these patients.

Tamponade agents to maintain retinal attachment are frequently employed during and after surgery for retinal detachment and PVR. These agents incorporate gases (e.g., air) and liquids (e.g., silicone oil). Liquids have a tendency to emulsify in the eye, particularly if they are

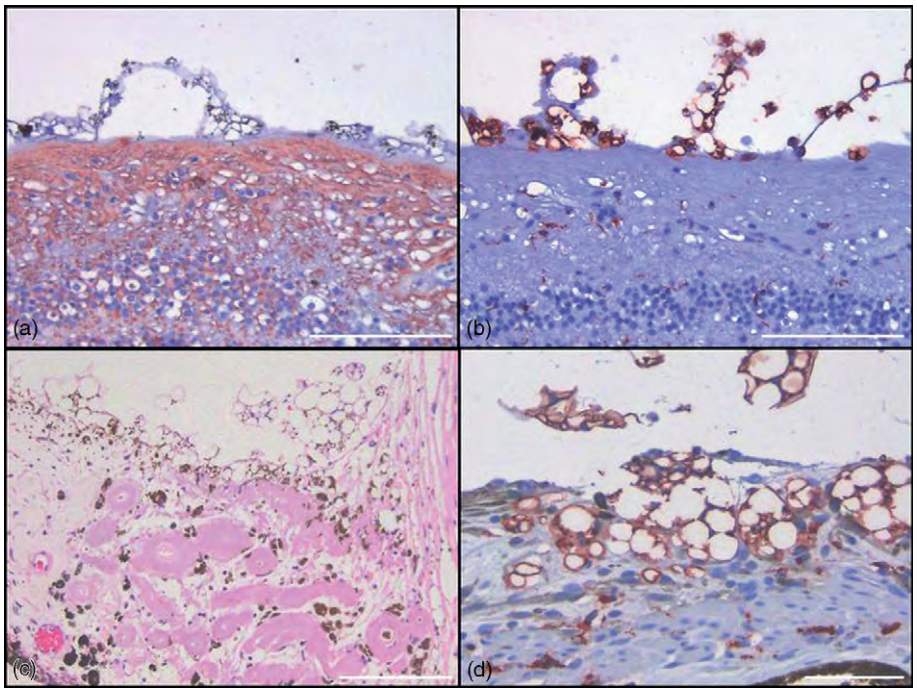

Figure 9 Photomicrographs from sections of an eye removed following liquid tamponade use in the treatment of PVR. Parts (a) and (b) show the vitreoretinal interface with numerous vacuolated cells that label for the macrophage marker CD68 (b), but not the glial marker glial fibrillary acidic protein (a). Similar cells are seen in the drainage angle (c) and in the anterior chamber and iris (d). The features are consistent with macrophage reaction to emulsified liquid tamponade agent (hematoxylin and eosin (c); immunohistochemical staining, red reaction product (a), (b), and (d); scale bars (a), (b), and (d): 100 μm; (c) 200 μm).

of low viscosity. The result is the formation of droplets of various sizes in the vitreous cavity or even elsewhere in the eye (such as in the aqueous if tamponade gains access to the anterior chamber: **Figure 9**). Thus, emulsification of tamponade agent may impact on the pathology of PVR membranes. It appears that the droplets can stimulate a foreign body-type reaction and attract macrophages to the retinal surface (**Figure 9**). New membranes may develop and these tissues characteristically have the microscopic appearances of PVR membranes containing granulomata to emulsified oil.

Outcomes

Successful treatment in PVR has often been measured in terms of final retinal reattachment rates. The assumption is that effective anti-PVR therapy would lead to an increased rate of successful reattachment. This assumption may or may not hold true. It is often missed or untreated holes that lead to retinal redetachment and not necessarily PVR, which may or may not be controlled by the anti-PVR drugs. Indeed, a totally ineffective anti-PVR treatment may be compatible with anatomical success so long as the epiretinal membranes do not act on the retina to produce another retinal break or cause tractional retinal detachment. Hence, anatomical success rate is a poor proxy for PVR control. Another important point is that anatomical success does not guarantee visual recovery. The advancement of surgery in the last few years has greatly increased the final anatomical success rate. Disappointingly, this success rate has not been translated into visual improvement. In retinal detachment patients, the fellow eye is also likely to be involved in sight-threatening pathology so that many PVR patients end up with visual impairment in both eyes.

Conclusions

Despite intense research over the last 25 years that has improved our understanding of the condition, PVR remains the major cause of failure after retinal detachment surgery. Nevertheless, continuing advances in both surgical and pharmacological manipulation of the disease, based on an expanding knowledge of PVR pathobiology, can be expected to reduce the impact of the disease in the future.

Properties and Functions of the Vessels of the Ciliary Body

E L van der Merwe and S H Kidson, University of Cape Town, Cape Town, South Africa

Glossary

Fenestrations – Derived from fenestra, the Latin word for window, 60–80 nm pores in the endothelium spanned by a diaphragm of radially oriented fibrils that regulate the diffusion of small molecules and amounts.
Occludin – A 65-kDa integral plasma-membrane protein that is a major constitutent of tight junctions.
Ora serrata – Junction between the retina and the ciliary body that marks the transition from the simple nonphotosensitive area of the retina to the complex, multilayered photosensitive region.
Pars plana – Part of the ciliary body just beyond the ora serrata is smooth.

Arterial and Venous Supply of the Ciliary Body

The ciliary body (CB) forms part of the anterior segment of the eye and is composed of the ciliary processes and the ciliary muscle. It extends from the iris root anteriorly to the ora serrata posteriorly. The CB is divided into two regions: the pars plana and the pars plicata. The pars plicata consists of ciliary muscles and ciliary processes. The ciliary processes are organized in a radial pattern, with alternating major and minor processes. Each process is composed of two epithelial layers encapsulating a capillary network embedded in a loose connective tissue. The large surface area of the CB enables the secretion of components of the aqueous humour and glycoproteins of the vitreous body. The CB connects to the lens by zonula fibres, thus enabling accommodation.

The CB has the highest density of blood vessels in the eye, and its vascular organization is extremely complex (Figure 1). This complexity, density, and redundancy ensures consistent perfusion of the anterior segment, even following interruption of arteriole supply routes, and thus facilitates homeostatic control of aqueous humor production. The CB has two main blood supplies: the anterior ciliary arteries, and the medial and lateral long posterior arteries which traverse the interior. Superficially, the anterior ciliary arteries arise from the muscular arteries supplying the four recti (superior, lateral, medial, and inferior). These arteries are derived from the ophthalmic artery. The anterior ciliary arteries continue anteriorly and branch at or just before the limbus. One branch supplies the episcleral arterial circle and conjunctiva in the superficial limbus while the other penetrates the limbus and enters the vascular bed of the ciliary muscle. Arterioles that branch off the penetrating anterior ciliary artery undergo further divisions where they interconnect with the capillary bed of the ciliary muscle (Figure 2). These vessels also anastomose with those that arise from the long posterior ciliary arteries to form the intramuscular circle of the CB that lies within the outer portion (exterior regions) of the ciliary muscle. This anastomotic ring artery supplies the superficial (outer) and posterior region of the ciliary muscle.

The other source of blood to the CB is via the major arterial circle (MAC) of the iris (also called the circulus iridis major (Figure 3) which lies between the ciliary muscle and the ciliary process and is located near the root of the iris). According to some reports, in the human eye the MAC is formed mainly from vessels that arise from the medial and lateral long posterior arteries that have bifurcated near the anterior choroid, and, which are orientated in the circumferential plane. Others report that branches of the intramuscular circle form the MAC. In addition, within this region, anastomoses are formed between branches of the anterior ciliary artery and the long posterior ciliary artery. The supply to the anterior and inner regions of the ciliary muscle is derived from arterioles that branch off the MAC.

In the human and primate eye, each ciliary process receives blood from an anterior and posterior arteriole that branch off the MAC. The anterior branches supply the anterior portion of the ciliary process which includes the marginal region and the lateral branching capillaries which supply the anterior portion of the neighboring processes. Thus, intercommunication between ciliary processes occurs through the lateral branching capillaries supplied by the anterior arteriole. The posterior arteriole supplies the inner, basal, and posterior portion of the process and to the minor ciliary processes. In ungulates, rodents, and carnivores, all ciliary processes receive blood solely from the posterior arteriole that arises from the MAC. Venous drainage is via the pars plana into the choroidal veins. Whereas the anterior arterioles have focal constrictions, the posterior arterioles are devoid of these.

The pars plana lies posterior to the ciliary processes and therefore has several sources of vessels. One is from the iris in the form of tributaries, another is from the basal capillaries/venules that lie within the first and third

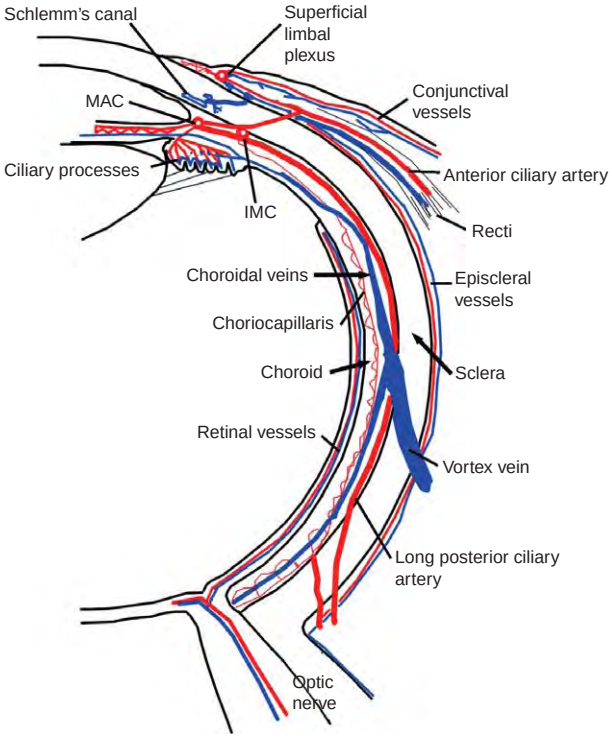

Figure 1 Schematic depicting the arterial supply to and the venous drainage from the anterior segment and ciliary body. The anterior ciliary arteries arise from the vasculature of the external ocular muscle (recti). One branch penetrates the sclera posterior to the limbus. The long posterior ciliary arteries penetrate the sclera near the optic nerve and traverse between the sclera and the choroid. Details of the blood supply to the ciliary body are shown in **Figures 2–4**. Blood drains from the ciliary body into the choroidal veins which converge into the vortex vein to leave the eye. Drawing adapted from Figure 10.25a in Bron, A. J., Ramesh, C., Tripathi, R. C., and Tripathi, B. J. (1997). The posterior chamber and ciliary body. In: *Wolff's Anatomy of the Eye and Orbit*, 8th edn., ch. 10. London: Chapman and Hall Medical. Leber, T. (1872) in Albrecht von Graefe's Archives (for clinical and experimental) Ophthalmology. Berlin: Springer Verlag.

territories (not the marginal capillaries), and the third source is from the venules arising from the marginal capillaries of the processes. These arterioles/capillaries drain into the choroidal veins which pass through the pars plana and drain into the vortex veins. The vortex veins exit the eye through the sclera just posterior to the equator of the globe.

Vascular Organization of the CB

The angioarchiteture of the ciliary process and vasculature is very complex. The vasculature and ciliary processes develop concommittantly, and it would appear that the patterning of the ciliary capillaries dictates the final pattern and organization of the processes. In the human and primate eye, the angioarchitecture is organized into different territories (**Figure 4**). The first territory includes vessels at the anterior end of the major processes at the crests of the processes. This region consists of the short anterior arterioles (precapillary) that branch off the MAC to feed the lateral branches. These lateral branches do not feed into the marginal capillaries but drain into isolated venules that run posteriorly without further connections to the rest of the vasculature in the ciliary processes. The second vascular territory includes the marginal vessels in the anterior end and also the center portion and basal regions of the major processes. The third territory comprises the vasculature of the minor processes. The angioarchitecture of the ciliary muscle is organized into a densely packed network of capillaries that are orientated in parallel to the longitudinal axis of the muscle fibers. Within the anterior portion of the pars plana, the vessels interconnect with the vessels located in the valleys between the ciliary processes, and with those from the anterior portion of the ciliary muscle. Posterior to this, the vessels are arranged in parallel rows orientated in the anterior–posterior plane. The vessels are large and flat with few interconnections with neighboring vessels. In the most posterior portion of the pars plana, the vessels are organized into a connecting meshwork similar to that seen in the choriocapillaris.

Characteristics and Properties of the CB Capillaries

The blood vessels of the ciliary processes have a number of unique properties that relate to the production and regulation of aqueous humor. There are two types of blood capillaries in the CB: those in the stroma of the processes are fenestrated, a property necessary for the production, and regulation of aqueous humor. The short ciliary arterioles that feed into the marginal capillaries (precapillary arterioles) are surrounded by two to three layers of smooth muscle. They characteristically have constrictions at their distal portions before they join to the marginal capillaries. In the rat, the arterioles that branch off MAC, the smooth muscle cells become less dense toward the more distal regions of these arterioles. The smooth muscle cells are replaced by pericytes (more stellate-like cells) in this region and are orientated in the circular plane around the vessel acting as a sphincter. This formation is thought to assist with regulating flow into the marginal capillaries. In the mouse eye, these constrictions are not present, and instead one sees constrictions/strangulations in the posterior portion (distal region) of the marginal capillaries.

The most marked characteristic of the vessels in the ciliary processes is the large irregularly dilated marginal capillaries. They have wide dilated lumens between 15 and 30 μm in diameter. These capillaries are lined by fenestrated endothelium where fenestrations are present throughout the entire capillary, a feature that ensures maximal area for aqueous humor production. In the rat eye, the marginal capillaries are surrounded by an open

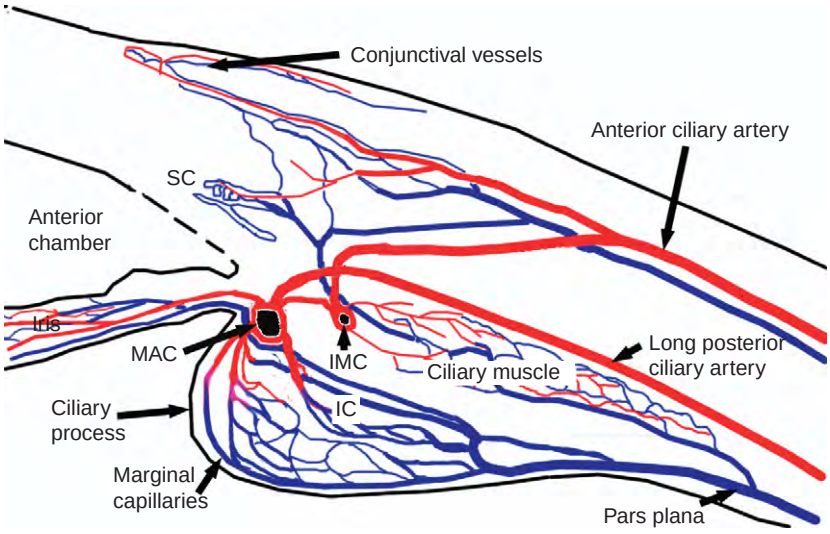

Figure 2 Schematic showing the arterial supply to and venous drainage from the ciliary body. The ciliary body receives its blood supply from the intramuscular arterial circle of the ciliary body (IMC) and the major arterial circle of the iris (MAC). These circular arteries are supplied by seven anterior ciliary arteries and the medial and lateral long posterior ciliary arteries. The anterior ciliary artery sends a branch through the sclera which gives off several branches that feed the ciliary muscle. The MAC is formed from the bifurcations of the medial and lateral long posterior arteries, but is also thought to have its origin in the arterioles that arise from the IMC. The ciliary processes receive their blood supply via the MAC. Blood drains from the ciliary processes and ciliary muscle into the pars plana. SC = Schlemm's canal which drains into aqueous vessels. Adapted from an original drawing from Lauber H., after Maggiore, L. in Bron, A. J., Ramesh, C., Tripathi, R. C., and Tripathi, B. J. (1997). *Wolff's Anatomy of the Eye and Orbit*, 8th edn. London: Chapman and Hall Medical. Lauber, H. (after Maggiore) (1936) in Der Strahlenkörper (Corpus ciliare). D. Die Nerven des Strahlnekörpers, in Handbuch der mikrsopischen Anatomie (ed. W. Von Mollendorf), Berlin: Springer.

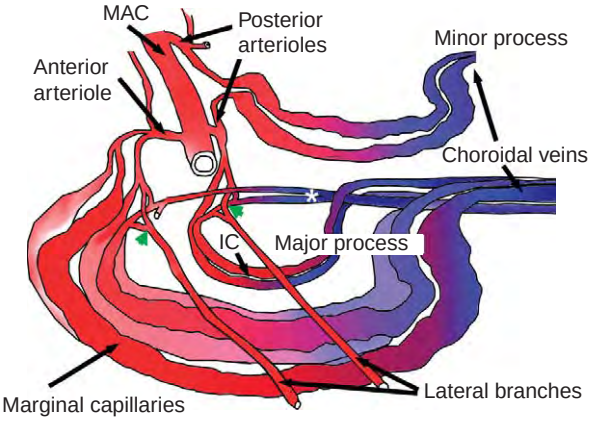

Figure 3 Drawing depicting the general vascular organization and the arterial feeds of the major and minor ciliary processes. The anterior and posterior arterioles that branch off the major arterial circle of the iris (MAC), supply the capillaries of the major and minor processes, respectively. Several smaller vessels that arise from the anterior arteriole feed into the marginal capillaries of the major process. Branches of the posterior arteriole feed the internal capillaries (IC) of the major process. Blood supply to the capillaries of the minor processes is derived from more than one posterior arteriole. Anastomoses (green arrowheads) occur between the lateral branches, some marginal or central capillaries of the major processes and the basally located capillaries that extend posteriorly (white star). Modified from Morrison, J. C. and van Buskirk, E. M. (1984). *American Journal of Ophthalmology* 97: 372–383 in Figure 10.28b in Bron, A. J., Ramesh, C., Tripathi, R. C., and Tripathi, B. J. (1997). The choroid and uveal vessels. In: *Wolff's Anatomy of the Eye and Orbit*, 8th edn, ch. 11. London: Chapman and Hall Medical.

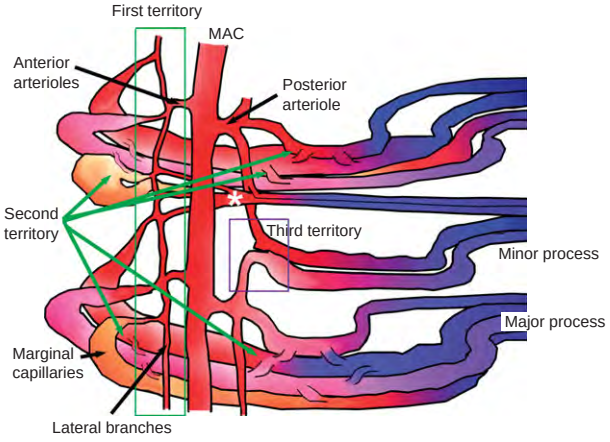

Figure 4 Schematic depicting the vascular territories of the ciliary processes. The first terroritory (outlined in the green box) includes the anterior arterioles, the lateral branches and the vessels arising from the latter that drain into the basally located venules (white star). The second territory (indicated by the green arrows), includes the marginal capillaries and the capillary network (shown as short connections) that connect to these and the internal capillaries (IC) of the major process. The third territory (outlined in the purple box) includes the capillaries that arise from the posterior arterioles, and the vasculature of the minor processes. According to some authors the vessels in the posterior third of the major processes also fall within the third vascular territory. Modified from Morrison, J. C. and van Buskirk, E. M. (1986). *Transactions of Ophthalmological Society of the United Kingdom* 105: 13 in Figure 11.25f in Bron, A. J., Ramesh, C., Tripathi, R. C., and Tripathi, B. J. (1997). The posterior chamber and ciliary body. In: *Wolff's Anatomy of the Eye and Orbit*, 8th edn., ch. 10. London: Chapman and Hall of Medical.

network of pericytes with their processes aligned along the longitudinal and circumferential planes. The processes of these pericytes are irregular and contain spines and are thought to play a role in regulating the permeability of the capillaries. A possible mechanism here may be to cover the fenestrations or constricting their diameters. In the mouse eye, blood vessels in the ciliary processes do not express tight junction proteins ZO-1 or occludin. Thus, movement of plasma constituents can move freely from the intravascular compartment through the paracellular route to the interstitial space. In contrast, blood vessels located near the base of the processes express ZO-1 and occludin, thus indicating different functional territories within the processes. Interestingly, an endothelial barrier protein which is expressed in the capillary endothelium of barrier vessels such as the retinal and iris vessels (also in nonfenestrated vessels in the brain) is highly expressed by the endothelium of the marginal capillaries in those within the CB of the rat. In contrast, these proteins are not expressed in capillaries located in the basal regions. Although the function in the CB is unknown, loss of this antigen is associated with increased vascular permeability in the brain. In particular, its association with an unmistakenly permeable endothelium is not clear.

It appears that the intravascular pressure within the CB is achieved by autoregulatory mechanisms in order to continue perfusion of aqueous humour under variable physiological conditions. Evidence for this is the presence of adrenergic and cholinergic nerve endings that are associated with the vasculature in the ciliary processes seen in several species, including humans. By stimulating the sympathetic and parasympathetic neural systems, studies have shown reduced and increased flow through the ciliary processes, respectively.

The diameter of the vessels of the ciliary muscle is small and the endothelium lining of these vessels is thicker than those of the capillaries in the ciliary processes. Fenestrations are few or absent in capillaries of the ciliary muscle. Capillaries of the pars plana are likely to be similar to that of the choriocapillaris which is fenestrated.

Comparative Angioarchitecture of the Ciliary Processes in Other Species

The vascular organization within the ciliary processes differs widely between rodents, ungulates, carnivores, and primates. The latter is similar to humans. Constrictions in the precapillary arterioles are present in all species but differ in their location along the arteriole. In rabbits, ungulates, rodents, and carnivores, the sole source of blood to the CB is via the MAC, whereas in primates and humans, the ciliary processes receive blood from both anterior and posterior arterioles that branch off the MAC. In rodents each arteriole that branches off the MAC gives rise to further branches which then supply a number of ciliary processes. In carnivores (dogs and cats), each ciliary process is supplied from individual arterioles that branch off the MAC. In ungulates, the branches off the MAC branch extensively over the iris root to form a plexus from which large ciliary process arterioles arise to supply each process. The internal organization of the ciliary processes differs widely between species, with rodents having a similar organization but simpler to that of primates and humans.

Pseudoexfoliation Syndrome and Glaucoma

U Schlötzer-Schrehardt, University of Erlangen-Nürnberg, Erlangen, Germany

Glossary

Cross-linking – The lateral linking of protein strands to one another via covalent bonds, resulting in a polymer network that becomes stronger and more resistant to degradation.
Elastic fibers – The bundles of stretchable proteins found in the extracellular matrix of connective tissue and produced by fibroblasts and vascular smooth-muscle cells. Elastic fibers are formed by elastic microfibrils and amorphous elastin.
Elastic microfibrils – The macromolecular assemblies of the extracellular matrix, which have unique extensible properties. They are heterogenous in composition and may consist of fibrillins, latent transforming growth factor-β-binding proteins, fibulins, emilins, microfibrillar-associated glycoproteins, and microfibril-associated proteins. They occur as isolated bundles devoid of elastin (e.g., zonules) or act as a template for elastin deposition within elastic fibers.
Elastosis – The degenerative changes in connective tissues resulting from breakdown of elastic fibers and accumulation of increased amounts of abnormal elastotic material.
Extracellular matrix – A complex structural entity surrounding and supporting cells within animal tissues, which includes the interstitial matrix and the basement membrane. It consists of structural proteins (e.g., collagen and elastin), glycoproteins (e.g., fibronectin and laminin), and proteoglycans.
Lysyl oxidase-like 1 (LOXL1) – A member of the lysyl oxidase family of enzymes that catalyzes the covalent cross-linking of collagen and elastin in connective tissues through oxidative deamination of lysine or hydroxylysine side chains.
Pseudoexfoliation (PEX) syndrome – A generalized disorder of the extracellular matrix, often leading to glaucoma. The term pseudoexfoliation syndrome results from dandruff-like deposits on the surface of the lens, as if the lens capsule has exfoliated. It is also called exfoliation syndrome.
Single nucleotide polymorphisms (SNPs) – The DNA sequence variations occurring when a single nucleotide – A, T, C, or G – in the genome differs between members of a species (or between paired chromosomes in an individual).

Pseudoexfoliation Syndrome

Definition

Pseudoexfoliation (PEX) syndrome is a common, age-related systemic disorder of the extracellular matrix characterized by pathologic accumulation of an abnormal fibrillar material in various intra- and extraocular tissues. It is clinically diagnosed by observation of dandruff-like white flakes deposited on ocular structures that line the aqueous-bathed surfaces of the anterior segment, particularly the anterior lens surface and the pupillary border of the iris. The terms pseudoexfoliation or exfoliation syndrome have been widely used for this entity, although the process does not represent a true exfoliation of the lens capsule, like in infrared (glass-blower's) cataract.

Epidemiology

PEX syndrome was first described in Finland by Lindberg in 1917, and at one time was considered to be much more common throughout Scandinavia than elsewhere. It has, however, been realized, that PEX syndrome occurs in all geographic regions worldwide with reported prevalence rates averaging about 10–20% of the general population over the age of 60. In all populations, the frequency rises with increasing age, with its incidence doubling every decade after the age of 50, and females are more frequently affected in most series. Despite its worldwide distribution, there is a clear tendency for the condition to cluster geographically and in certain racial or ethnic subgroups. There is a high prevalence of PEX syndrome in Finland, Lapland, Iceland, Norway, and Northern Russia, where it affects 10–13% of persons aged 50–69 years and 21–35% those over 70 years of age. Similar figures apply to Saudi Arabia, Mediterranean and Baltic countries, and among the Navajo Indians in the United States of America and Australian Aborigines. Recent reports suggest that it is equally common in Ethiopia and South Africa, and The Gambia in West Africa. In contrast, PEX syndrome occurs in only 3–10% of persons over 60 years of age in most European populations and in parts of the United States. Although common in Japan and Mongolia, it is rare in southern China and in the Malay population.

Etiology and Pathogenesis

Genetics

The reasons for true differences in prevalence rates between age-matched geographical and ethnic populations

remain unknown, but appear to be mainly related to genetic variability. Both population-based and pedigree-based studies have shown that genetic factors contribute to the pathogenesis of PEX syndrome, which has been suggested to be inherited as an autosomal dominant trait with late onset and incomplete penetrance. In the past, several chromosomal regions have been tentatively associated with PEX, including the putative gene loci 2p16, 2q35-36, and 3q13-q21. A recent genome-wide scan of 1000 microsatellite markers in a Finnish family suggested a strong linkage to 18q12.1-21.33 and a weaker linkage to chromosomes 2q, 17p, and 19q, which are possible regions of linkage to primary open-angle glaucoma (POAG). Apolipoprotein E gene variants and the ε2 allele were also found to be associated with an increased risk of developing PEX in a Turkish population, whereas the ε3 allele was found to be protective.

In a recent landmark study, the genetic etiology of PEX syndrome and glaucoma has been further specified. Performing a genome-wide association study, Thorleifsson and coworkers detected three common sequence variants or single-nucleotide polymorphisms (SNPs) in the *LOXL1* gene on chromosome 15q24.1 to be strongly associated with both PEX syndrome and PEX glaucoma in Scandinavian populations from Iceland and Sweden. Strikingly, these disease-associated polymorphisms accounted for virtually all PEX cases within the populations studied and appeared to confer risk of glaucoma mainly through PEX. A high-risk haplotype (G–G), that is, a combination of alleles on one chromosome, formed by two nonsynonymous coding SNPs, rs1048661 (R141L), and rs3825942 (G153D), in exon 1 of *LOXL1* increased the risk for PEX by factor 27. Individuals carrying two copies of this high-risk haplotype on both corresponding homologous chromosomes, that is, the high-risk diplotype, would have a 700 times increased risk of developing PEX than those carrying the low-risk haplotype. Compared with the general population, the risk of developing PEX is about 2.5-fold, because approximately 25% of the unaffected controls were also found to carry the high-risk diplotype. Following this discovery, several replication studies in populations from the United States, Australia, Europe, Japan, and India confirmed genetic susceptibility of *LOXL1* polymorphisms to PEX syndrome/glaucoma and verified the *LOXL1* gene as a major genetic risk factor for this condition worldwide. In most study populations, SNP rs3825942 (G153D) has been reported to be the primary risk-associated variant, whereas SNP rs1048661 (R141L) showed a different allele frequency in Japanese patients with PEX or was not significantly associated with PEX in other populations at all. However, because many individuals that carry the *LOXL1* risk alleles do not have PEX, there may be limited usefulness in genetic testing for these variants.

LOXL1 is a pivotal enzyme in extracellular matrix formation. It is a member of the lysyl oxidase family of enzymes that catalyze the covalent cross-linking of collagen and elastin in connective tissues through oxidative deamination of lysine or hydroxylysine side chains. They comprise five characterized members: lysyl oxidase (LOX) and lysyl oxidase-like 1–4 (LOXL1–4). LOXL1 seems to be specifically required for tropoelastin cross-linking and has been shown to be involved in elastic fiber formation, maintenance, and remodeling, particularly during dynamic processes such as tissue injury, fibrosis, cancer, and development. In order to fulfill its cross-linking function, the LOXL1 pro-peptide is selectively targeted to elastic microfibrils at sites of elastogenesis by binding to both tropoelastin and fibulin-5. Following attachment to the scaffolding structure, the pro-peptide is cleaved off by the endo-metalloproteinase procollagen-C-terminal proteinase (bone morphogenetic protein 1) for catalytic activation of the enzyme. Both PEX-associated coding SNPs of *LOXL1* reside in exon 1, which encodes the unique N-terminal domain that is required both for proper enzyme activation and for substrate recognition and binding. The available data suggest that LOXL1 is upregulated in the early phase of PEX fibrogenesis together with elastic fiber components, such as tropoelastin, fibrillin-1, and fibulin-2, and participates in the formation of the aberrant fibrillar aggregates accumulating in tissues of PEX patients.

However, a number of nongenetic factors, including ultraviolet light exposure, dietary factors, autoimmunity, infectious agents, and trauma, have also been hypothesized to be involved in pathogenesis, but have not been proven. Interestingly, the exceptional diagnosis of PEX in younger patients under the age of 40 seems to be generally preceded by prior intraocular surgery or trauma to the anterior segment, particularly to the iris, or to occur after corneal transplantation with grafts from elderly donors. These events may serve as a trigger for the premature development of PEX in a predisposed individual or even point to the possibility of a transmissible etiology. Altogether, it appears that PEX syndrome represents a complex, multifactorial, late-onset disease, involving both genetic and nongenetic factors in its etiopathogenesis.

Pathogenesis

The specific pathogenesis of PEX syndrome and the exact chemical composition of PEX material are still not known. However, the pathologic process is characterized by the chronic accumulation of an abnormal fibrillar matrix product, which is either the result of an excessive production or insufficient breakdown or both, and which is regarded as pathognomonic for the disease, based on its unique light microscopic and ultrastructural criteria.

By light microscopy, PEX material usually appears as periodic acid-Schiff (PAS)-positive, bush-like, nodular, or feathery aggregates on the surfaces of anterior-segment tissues. Transmission electron microscopy shows the

aggregates to be composed of randomly arranged, electron-dense, fuzzy fibrils, 25–50 nm in diameter, frequently with 20–25- or 45–50-nm crossbanding (Figure 1).

These composite fibers are generally associated with microfibrils, 8–10 nm in diameter, which resemble elastic microfibrils and which appear to aggregate laterally into mature PEX fibrils. However, the microfibrillar core of the complex fibers is usually hidden by an apparent coating with electron-dense amorphous material.

Immunohistochemical studies have shown PEX material to represent a complex glycoprotein/proteoglycan structure bearing epitopes of the basement membrane and elastic fiber system. The characteristic fibrils contain predominantly epitopes of elastic fibers, such as elastin, tropoelastin, amyloid P, vitronectin, and components of elastic microfibrils, such as fibrillin-1, microfibril-associated glycoprotein (MAGP-1), and latent transforming growth factor-beta (TGF-β)-binding proteins (LTBP-1 and

H., Holbach, L., and Kruse, F. E. (eds.) *Applied Pathology for Ophthalmic Microsurgeons*, 1st edn., p. 356, figure 6.3.1, Berlin: Springer, with permission from Springer.

LTBP-2). Abundantly associated glycosaminoglycans (heparin sulfate, chondroitin sulfate, hyaluronan, etc.) are indicative of excessive glycosylation processes. A direct analytical approach by using liquid chromatography coupled with tandem-mass spectrometry (LC–MS/MS) has confirmed PEX material to consist of the elastic fiber components fibrillin-1, fibulin-2, vitronectin, and amyloid P-component, the basement membrane components laminin and fibronectin, the proteoglycans syndecan-3 and versican, metalloproteases of the a disintegrin and metalloprotease (ADAM) family, the extracellular chaperone clusterin, and complement factor C1q. Together, these findings support the notion that PEX material represents an elastotic material arising from abnormal aggregation of elastic microfibril components interacting with multiple ligands.

A variety of unrelated epithelial and mesenchymal cell types participate in the excessive and disordered synthesis of the fibrillar PEX material at multiple intra- and extraocular sites. In the eye, PEX fibers have been demonstrated in close association with the pre-equatorial lens epithelium, the nonpigmented ciliary epithelium, the iris pigment epithelium, the trabecular endothelium, the corneal endothelium, and virtually all cell types in the iris stroma. Passive distribution of PEX material by the aqueous humor seems to be responsible for abnormal deposits on the central anterior lens capsule, the zonules, the anterior hyaloid surface, and artificial lenses, if present. In extraocular locations, PEX fibers could be identified in close proximity to connective tissue fibroblasts, vascular wall cells, smooth and striated muscle cells, and heart muscle cells. Therefore, the abnormal matrix process virtually affects all anterior segment tissues as well as vessel walls, muscle tissues, and connective tissue portions of skin and visceral organs throughout the body.

Molecular pathophysiology

Gene expression analyses revealed a set of genes differentially expressed in anterior-segment tissues of PEX eyes, which were mainly involved in extracellular-matrix metabolism and in cellular stress. One set of genes consistently upregulated in anterior segment tissues from different PEX patients comprised the elastic microfibril components fibrillin-1, LTBP-1, and LTBP-2, the cross-linking enzyme transglutaminase (TGase)-2, tissue inhibitor of matrix metalloproteinase (TIMP)-2, TGF-β1, several heat-shock proteins (Hsp 27, Hsp 40, and Hsp 60), proinflammatory cytokines, apolipoprotein D, and the adenosine receptor (AdoR)-A3. Genes reproducibly downregulated in PEX tissues included TIMP-1, the extracellular chaperone clusterin, the antioxidant defense enzymes glutathione-S-transferases (mGST-1, GST-T1), components of the ubiquitin–proteasome pathway (ubiquitin-conjugating enzymes E2A and E2B), several DNA repair proteins (ERCC1, hMLH1, and GADD 153), the transcription factor Id-3, and serum amyloide A1.

Apart from increased concentrations of various growth factors (bFGF, HGF, CTGF, and TGF-β1) in the aqueous humor of PEX patients, the growth factor TGF-β1, which is a major modulator of matrix formation in many fibrotic diseases, is considered a key mediator in the fibrotic PEX process. It is significantly increased in the aqueous humor of PEX patients, both in its latent and active form, it is upregulated and actively produced by anterior segment tissues, and it is known to regulate most of the genes found to be differentially expressed in PEX eyes, for example, fibrillin-1, LTBP-1 and-2, TGase-2, and clusterin. Binding of TGF-β1 to PEX material via the TGF-β-binding proteins LTBP-1 and-2 may represent a mechanism of regulation of growth-factor activity in PEX eyes. Whereas the TGF-β3 isoform was also reported to be significantly increased in aqueous humor of PEX patients, levels of TGF-β2 were significantly higher in the aqueous humor of POAG patients but not of PEX patients.

Changes in the local matrix metalloproteinase (MMP)/TIMP balance and reduced MMP activity in aqueous humor and tissues may further promote the abnormal matrix accumulation in PEX syndrome. Significantly increased concentrations of MMP-2, MMP-3, TIMP-1, and TIMP-2 were detected in aqueous humor samples from PEX patients with and without glaucoma compared to control patients with cataract. However, the levels of endogenously active MMP-2, which is the major MMP in human aqueous humor, were significantly decreased as was the ratio of MMP-2 to TIMP-2, resulting in a molar excess of TIMP-2 over MMP-2 in PEX samples. An imbalance of MMPs and TIMPs has been also reported on the tissue level, particularly in trabecular meshwork specimens from PEX glaucoma patients.

Moreover, there is increasing evidence that cellular stress conditions, such as oxidative stress and ischemia/hypoxia, constitute major mechanisms involved in the pathobiology of PEX syndrome. Significantly reduced levels of antioxidative protective factors (e.g., ascorbic acid and glutathione) and increased levels of oxidative stress markers (e.g., 8-isoprostaglandin-F2α and malondialdehyde) in aqueous humor, serum, and tissues are indicative of a faulty antioxidative defense system and increased oxidative stress in the anterior chamber of PEX eyes. PEX is also associated with ocular ischemia, particularly iris hypoperfusion and anterior chamber hypoxia, and with a reduced ocular and retrobulbar micro- and macrovascular blood flow occurring in PEX patients with or without glaucoma. The vasoactive peptide endothelin-1 has been shown to be significantly increased in the aqueous humor of normotensive PEX patients compared with that of age-matched controls, while levels of nitric oxide, a potent physiological vasodilator, were decreased in a small number of PEX patients. This dysbalance may play a role in the

obliterative vasculopathy of the iris causing local ischemia early in the disease process. Elevated homocysteine levels in the aqueous humor of patients with PEX may further contribute to ischemic alterations, such as endothelial dysfunction, oxidative stress, enhancement of platelet aggregation, reduction of nitric oxide bioavailability, and abnormal perivascular matrix metabolism.

Pathogenetic concept

Immunohistochemical, biochemical, and molecular biologic data support the current pathogenetic concept of PEX syndrome as a type of stress-induced elastosis, an elastic microfibrillopathy, associated with the excessive production of elastic microfibril components and their aggregation into typical mature PEX fibrils by a variety of potentially elastogenic cell types. Growth factors, particularly TGF-β1, increased cellular and oxidative stress, a dysfunction of the cellular protection and proteasome system, low-grade inflammatory processes, and genetic variations in the *LOXL1* gene coding for a key enzyme of elastogenesis appear to contribute to the stable accumulation of the elastotic PEX material in the course of this fibrotic matrix process. Due to a proteolytic imbalance between MMPs and TIMPs and extensive cross-linking processes involved in fiber formation, the pathologic material is not properly degraded but progressively accumulates within the tissues over time.

Clinical Findings

Diagnosis

The most important diagnostic criteria of PEX syndrome are the whitish flake-like deposits of PEX material on anterior-segment structures, particularly on the anterior lens surface and the pupillary margin, occasionally also on the posterior surface of the cornea, the anterior surface of intraocular lens implants, and the anterior vitreous face in aphakic eyes. However, the majority of intraocular PEX deposits cannot be observed by direct biomicroscopy, and the accumulations on zonules, ciliary processes, and trabecular meshwork may be only detected by gonioscopy or high-resolution ultrasound biomicroscopy.

The characteristic target-shaped pattern of PEX material accumulation on the lens, consisting of a rather homogenous central disk, an intermediate clear zone, and a peripheral granular zone with nodular vegetations, can be only seen after pupillary dilation. In routine examinations without pupillary dilation, the diagnosis may be easily missed, because the central disk, corresponding to the size of the pupil, may be very subtle or even absent in 20–50% of cases. In addition to PEX material deposits, several other mostly pigment-related clinical signs aid in the diagnosis, including pigment dispersion in the anterior chamber after pupillary dilation, peripupillary atrophy producing a characteristic moth-eaten transillumination pattern, pupillary ruff defects, and pigment deposition on anterior-chamber structures, such as the iris sphincter region, corneal endothelium, and trabecular meshwork. Pigment is also characteristically deposited on or anterior to Schwalbe's line forming one or more undulating lines of pigment in the peripheral cornea (Sampaolesi's line). Pigment dispersion is caused by mechanical friction of the peripupillary iris against the rough anterior lens surface during pupillary movement. Further PEX-associated clinical signs that can alert the clinician to the presence of PEX include phacodonesis, iris stroma atrophy, iris hemorrhages after pupillary dilation, increased aqueous flare values, posterior synechiae, elevated intraocular pressure (IOP), and insufficient pupillary dilation, particularly if asymmetrically present.

However, the classical picture of lens deposits represents a very late stage of the disease, which is preceded by a long, chronic, preclinical course of several years. By thorough biomicroscopic examination, a diffuse-matte grayish film on the entire surface of the anterior lens capsule can be observed prior to the formation of typical PEX deposits. This layer is thought to represent a precursor of PEX material which is initially diffusely deposited on the lens surface from the aqueous humor. As this precapsular layer becomes thicker, focal defects begin to form in the midperipheral zone by abrasive movements of the iris, which further enlarge and become confluent to form the classical picture of manifest PEX syndrome. Ancillary clinical signs, which define patients as PEX suspects, comprise peripupillary atrophy, anterior-chamber pigment dispersion, and deposition on anterior-segment structures, and poor mydriasis. In addition, examination by high-resolution ultrasound biomicroscopy has been shown to be useful for detecting early deposits of PEX material on zonules, particularly in cases with inadequate pupillary dilation or opaque media.

Asymmetry of involvement

PEX patients can present with either unilateral or bilateral involvement, which may be markedly asymmetric. In several large series, PEX syndrome was unilateral at the time of diagnosis in about 50–70% of patients and the conversion rates to bilaterality were found to vary from 15% to 40% within 5 years. Clinically, the involved eye often has a poorer visual acuity, more advanced lens opacity, higher IOP, a smaller pupil, and a more pronounced trabecular pigmentation than the noninvolved fellow eye. However, in the majority of clinically unilateral cases, there are subtle histopathological changes, such as PEX deposits in the conjunctiva and in the iris, particularly in the dilator muscle and blood-vessel walls, of the clinically uninvolved fellow eyes. Therefore, PEX syndrome can be diagnosed prior to the clinically visible appearance of classic PEX material on the lens surface by electron microscopy of conjunctival biopsies. These

early changes support the concept of PEX syndrome as a generalized, basically bilateral disorder with a clinically marked asymmetric presentation. The reasons for this asymmetric involvement remain unknown.

Ocular manifestations and complications

All anterior-segment structures are involved in the PEX process leading to characteristic tissue alterations, which predispose to a broad spectrum of potential intraocular complications:

1. The zonules are affected early in the course of the PEX process and may undergo degeneration and separation from their attachments to the ciliary body and lens. In the pre-equatorial lens capsule, corresponding to the proliferative zone of the lens epithelium and the zone of zonular anchorage, bundles of PEX fibrils appear to originate from the adjacent lens epithelial cells, disrupt the capsule proper, and invade the zonular lamella, resulting in separation of the zonules from their insertion onto the capsule. Similarly, at their origin and anchorage in the nonpigmented ciliary epithelium, the zonular bundles are separated from their connection to the disrupted epithelial basement membrane by intercalating PEX fibers. These alterations are usually not visible on clinical examination, being hidden behind the iris, but give rise to a marked instability of the zonular apparatus producing a characteristic phacodonesis or inferior displacement of the lens. Anterior lens movement can occur, particularly under miotic therapy, resulting in pupillary or even ciliary block-angle-closure glaucoma, which is more common in eyes with PEX.
2. Iris changes are an early and consistent feature of PEX eyes and involve all iris structures and cell types. Clinically, the iris of PEX patients is characteristically rigid with reduced dilating properties, which has been attributed to a combination of PEX fiber deposition in the stroma and muscle tissues along with degenerative changes of the stroma, including sphincter and dilator muscles. The posterior iris pigment epithelium exhibits marked degenerative changes with focal-membrane ruptures and liberation of pigment granules resulting in the diagnostically important moth-eaten pattern of peripupillary atrophy accompanied by a characteristic dispersion of pigment granules following pharmacological dilatation. Involvement of the iris stromal vessels has major functional consequences. Iris blood vessels may become degenerated or obliterated resulting in iris hypoperfusion and reduced partial pressure of oxygen in the anterior chamber. On fluorescein or indocyanine green angiography, changes including iris-vessel dropout and dye leakage may be seen. Spontaneous intrastromal hemorrhages, without rubeosis iridis, after mydriasis indicate significant vascular damage. Another important consequence of the iris vasculopathy is a chronic breakdown of the blood-aqueous barrier in eyes with PEX syndrome, which manifests clinically as a pseudouveitis with elevated aqueous flare values. Blood–aqueous barrier dysfunction is compromised to a greater extent in eyes with PEX compared to eyes without PEX following intraocular surgery, including cataract surgery, trabeculectomy, and laser trabeculoplasty.
3. In eyes with advanced PEX syndrome, focal retrocorneal flakes of PEX material can be clinically observed adhering to the corneal endothelium. Ultrastructural evidence suggests focal *in situ* production of PEX fibers by corneal endothelial cells. Associated with these specific changes, the corneal endothelium shows focal degeneration, phagocytosis of melanin granules, and abnormal extracellular matrix production, resulting in an irregular thickening of Descemet's membrane. Combination of clinical and histopathological observations leads to the concept of a specific PEX-associated keratopathy. The damaged and dysfunctional corneal endothelium in PEX eyes increases the risk of early corneal endothelial decompensation with normal or after moderate rises in IOP, for example, after mydriasis, or after minor intraoperative trauma. It can even result in irreversible corneal endothelial decompensation requiring penetrating keratoplasty.
4. Lens opacification, most commonly of a nuclear type, is long known to be associated with PEX syndrome and is the most common cause for PEX patients to require surgical intervention. Cataract development may be causally linked to the presence of ocular ischemia, aqueous hypoxia, increased growth-factor levels, or reduced protection against ultraviolet radiation by lower levels of ascorbic acid in the aqueous humor of PEX eyes. Traditionally, cataract surgery in eyes with PEX has been considered a challenge because of weakened zonules and reduced pupillary diameter. Intraoperative and postoperative surgical complications, such as zonular ruptures, vitreous loss, blood–aqueous barrier breakdown, anterior capsule fibrosis/contraction, secondary cataract, and decentration or dislocation of the lens implant, have been reported to be more common and more serious than in eyes without PEX. Today, the common use of phacoemulsification with anterior capsulorhexis by experienced surgeons has provided significantly better results with a lower rate of intraoperative complications compared with the conventional extracapsular cataract-extraction technique. However, this has been replaced by a growing number of case reports on late intraocular lens displacement/dislocation after uneventful phacoemulsification due to progressive postoperative zonular weakening.

Systemic manifestations

Aggregates of PEX material were identified by electron microscopy in autopsy specimens of heart, lung, liver, kidney, gall bladder, and cerebral meninges in patients with PEX. In these extraocular locations, PEX material was primarily found in connective tissue portions of visceral organs, often in the periphery of blood vessels. These findings suggested that ocular PEX syndrome is part of a general disorder of the extracellular matrix and that patients with PEX may suffer from increased comorbidity. Subsequently, many studies have examined potential clinical consequences of these deposits and attempted to establish an association between PEX syndrome and systemic diseases. In the meantime, a growing number of small-scale studies are part of an emerging clinical spectrum in which PEX syndrome appears to be associated with cardiovascular and cerebrovascular diseases. These include transient ischemic attacks, a history of angina pectoris, arterial hypertension, myocardial infarction, or stroke, aneurysms of the abdominal aorta, asymptomatic myocardial dysfunction, ischemic white-matter lesions in the brain, Alzheimer's disease, and sensorineural hearing loss. A more recent study retrospectively investigating 1150 patients with either PEX glaucoma or POAG found a significantly higher frequency of chronic cerebral disorders (e.g., senile dementia and cerebral ischemia) and acute cerebrovascular events (e.g., thromboses, embolies, and hemorrhages) in the PEX group. The prevalence of mild-to-moderate hyperhomocysteinemia, which may be related to significantly decreased plasma levels of vitamin B6, B12, and folate, has been suggested as one possible cause for an increased vascular risk in PEX patients. However, the mortality rate appears not to be increased in PEX patients. Therefore, prospective, randomized multicenter studies are indicated to finally resolve these issues.

Pseudoexfoliation Glaucoma

The most serious known complication of PEX syndrome is secondary open-angle glaucoma, affecting 20–60% of patients in different series. PEX-associated open-angle glaucoma accounts for approximately 20–25% of all open-angle glaucomas and currently represents the most common identifiable cause of glaucoma overall. In some populations (e.g., Baltic, Mediterranean, and Arabian), the frequency of PEX-associated secondary glaucoma may reach a higher percentage of the population than the primary form of the disease. The probability of PEX eyes to develop glaucoma has been reported to vary from 5% to 35% within 5 years and from 15% to 40% within 10 years. Patients with PEX are twice as likely to convert from ocular hypertension to glaucoma as those without PEX. Factors associated with conversion to PEX glaucoma were initial IOP, degree of pupil dilation, and difference in IOP between the fellow eyes. Accordingly, the frequency of PEX syndrome is usually high among glaucoma patients and has been reported to range from 10% to 30% in the United States and from 50% to 60% in Northern Europe.

Clinical Characteristics

Compared to POAG, PEX glaucoma has a more serious clinical course and worse prognosis. It is typically associated with higher mean IOP levels, greater diurnal pressure fluctuations, marked pressure spikes, higher frequency and severity of optic nerve damage, more rapid visual-field loss, poorer response to medications, and more frequent necessity for surgical intervention. PEX glaucoma further differs from POAG by a more frequent asymmetry of manifestation, more pronounced chamber-angle pigmentation, and acute pressure rises after mydriasis. In contrast to patients with POAG, patients with PEX glaucoma behave like normal persons after steroid application, that is, only one-third respond with a distinct pressure rise. There is a greater rate of conversion of ocular hypertensive patients to PEX glaucoma than to POAG and damage progresses more rapidly in patients with PEX glaucoma than in patients with POAG. In the Early Manifest Glaucoma Trial, the presence of PEX was the most important independent risk factor for progression. The percentage area of optic-disk pallor was shown to be significantly greater in PEX eyes than in control eyes and the mean disk area has been reported to be significantly smaller in eyes with PEX, with or without glaucoma, than in POAG eyes and normal control eyes. A significant correlation between the IOP level at the time of diagnosis and the mean visual-field defect as well as between diurnal IOP fluctuations and retinal-nerve-fiber-layer thickness could be only established in patients with PEX glaucoma, but not with POAG. These findings suggest that glaucomatous damage in PEX patients may be more directly related to IOP than in POAG patients.

Patients with PEX are also at increased risk for developing significant but transient IOP rises following diagnostic pupillary dilation due to dispersion of pigment granules and PEX material in the anterior chamber. The maximum of pigment liberation and pressure elevation, which can rise up to 30 mmHg above baseline IOP, may peak only 2–3 h post dilation and go back to normal levels after 10–15 h. Such pressure peaks can even mimic an acute glaucoma including pain, a red eye, corneal edema, and pressure rises over 50 mmHg.

Glaucoma in PEX syndrome usually occurs in the presence of an open chamber angle, but an association between PEX and angle-closure glaucoma is not rare either. As eyes with PEX syndrome often have narrowed chamber angles and smaller anterior chamber volumes in the presence of a weak zonular apparatus, a minimal

anterior subluxation of the lens predisposes to the development of angle-closure glaucoma through a pupillary block mechanism. Further features of PEX eyes that may predispose to the development of pupillary-block-angle-closure glaucoma include the formation of posterior synechiae, an increased iris rigidity and decreased iris motility, an impairment of the blood–aqueous barrier, and increased protein concentrations of aqueous humor. Miotics may aggravate both pupillary block and forward movement of the lens–iris diaphragm. In extreme and rather rare cases with marked zonular laxity, anterior displacement of the lens may be so pronounced that a ciliary block-angle-closure glaucoma (malignant glaucoma) is induced by contraction of the ciliary muscle. Secondary-angle-closure glaucoma following central retinal vein occlusion with rubeosis iridis (neovascular glaucoma) may also occur in PEX eyes, because retinal vein occlusion appears to be more common in patients with PEX syndrome/glaucoma.

Pathomechanisms of Glaucoma Development

Progressive accumulation of abnormal PEX deposits in the outflow structures is presumed to account for the increased outflow resistance in the trabecular meshwork and in the uveoscleral outflow pathways. In fact, PEX deposits can be observed throughout both outflow pathways, mainly in the anterior portions of the ciliary muscle, on the inner surface of the trabecular meshwork, beneath the inner and outer wall of Schlemm's canal, in the periphery of intrascleral aqueous collector channels, aqueous veins and episcleral veins, and in the suprachoroidal space. The focus of PEX material accumulation and pathological alterations is the juxtacanalicular tissue beneath the inner wall of Schlemm's canal, the site of greatest resistance to aqueous outflow. This critical area becomes thickened through gradual deposition of PEX material, which appears to be locally produced by the endothelial cells lining Schlemm's canal. The amount of PEX material accumulating in the outflow pathways has been shown to correlate with the IOP level and severity of optic-nerve damage, indicating a direct causative relationship between the matrix alterations in the meshwork and glaucomatous optic-nerve damage. There seems, however, no significant correlation between the clinically visible PEX material on the anterior lens capsule and IOP or glaucoma severity. Accumulation of PEX material in the juxtacanalicular region of the meshwork is also associated with a disruption of the normal elastic fiber network surrounding Schlemm's canal and may result in a progressive destabilization and disorganization of the normal tissue architecture leading to narrowing and focal collapse of the canal lumen in more advanced cases.

Abnormal matrix metabolism in the outflow structures may be associated with cellular dysfunction. Phospholipase A2, a housekeeping enzyme in phospholipid remodeling and removal of oxidized phospholipids from cell membranes, was significantly decreased in the trabecular meshwork of eyes with PEX glaucoma when compared to normal controls or patients with POAG. These observations may indicate abnormal physiological functions, decreased structural stability, and reduced protection against oxidative stress in trabecular meshwork cells of PEX eyes.

Increased trabecular meshwork pigmentation is a prominent and early clinical sign of PEX eyes, the pigment probably deriving from the degenerate iris-pigment epithelium. Although there seems to be a positive correlation with IOP level, the degree of chamber-angle pigmentation did not correlate with the degree of glaucomatous disk damage in most studies, arguing against a decisive role of pigment dispersion in chronic pressure rise. Pigment dispersion and deposition in the trabecular meshwork may, however, lead to acute and transient pressure rises after pupillary dilation. By electron microscopy, pigment granules are invariably present within trabecular endothelial cells, preferably in the innermost uveal portions of the meshwork, and are therefore rapidly cleared from the outflow pathways through phagocytosis by endothelial cells.

Although PEX glaucoma is characteristically a high-pressure disease with a predominant mechanical component of optic-nerve damage, pressure-independent risk factors, such as an impaired ocular and retrobulbar perfusion and structural alterations of the lamina cribrosa, may be present and further increase the individual risk for glaucomatous damage. A prospective study showed that in normotensive PEX patients with clinically unilateral involvement, in whom IOP was equal throughout the follow-up period, disk changes took place only in the involved eye, suggesting that the PEX process itself may be a risk factor for optic-disk changes. In fact, a pronounced elastosis can be observed in the connective tissue sheets of the lamina cribrosa of PEX eyes, which may adversely affect tissue elasticity and increase the susceptibility of optic-nerve fibers toward mechanical and vascular damage. Moreover, accumulations of elastotic and PEX materials are detected in the walls of various retrobulbar vessels, for example, the posterior ciliary arteries and retinal arteries, which may adversely affect vessel elasticity and perfusion parameters.

Therapeutic Aspects

In the management of PEX glaucoma, the stepwise approach from medical to surgical therapy is currently similar to that followed in POAG, but has to be complied with more consistently. In this regard, the importance of early recognition and accurate diagnosis of the pathologic features, rigorous reduction and stabilization of mean and diurnal 24-h IOP, careful examinations at narrow intervals, expectations of a higher complication rate during surgery,

and close attention to postoperative follow-up have to be emphasized. Konstas and coworkers demonstrated the benefit of IOP reduction and suggested a target IOP of <17 mmHg and lower to prevent or slow progressive damage. As peak levels of IOP are usually found in the early morning outside office hours, single IOP measurements are not sufficient for assessing mean IOP levels in PEX patients. PEX has been shown to be an important independent risk factor for glaucoma development in patients with ocular hypertension, implying that patients with PEX and ocular hypertension should receive medical treatment.

Medical therapy

In many PEX glaucoma cases, it is more difficult to reach the target IOP with monotherapy, and combination therapy, along with diurnal pressure monitoring and examinations at shorter intervals, is often required. Any therapy should, however, aim to reduce both mean IOP and 24-h IOP fluctuations.

To date, there are few comparative studies with respect to the efficacy of medications in controlling IOP in PEX glaucoma patients. Prostaglandin derivatives are more effective than beta-blockers in lowering mean and diurnal IOP in eyes with PEX glaucoma, but no significant differences between latanoprost and a fixed combination of timolol and dorzolamide have been reported. Comparing the effect of latanoprost versus bimatoprost on the diurnal IOP in patients with PEX glaucoma in a prospective, three-center, crossover study, mean diurnal IOP was significantly lower with bimatoprost than with latanoprost. In another prospective crossover comparison, latanoprost and travoprost both significantly reduced the 24-h IOP in patients with PEX glaucoma, but travoprost demonstrated a greater hypotensive efficacy in the late afternoon. In another prospective study of patients with hypertensive PEX syndrome receiving latanoprost, travoprost, or bimatoprost therapy, the mean 24-h range of IOP was significantly lower with travoprost. Unoprostone was also reported to provide a clinically significant IOP-lowering effect for patients with PEX glaucoma.

Despite good pressure-lowering effects and several potential benefits of miotic agents, for example, reduction of pupillary movement, there are some hazards of miotic use in PEX patients. Aggravation of blood–aqueous barrier breakdown, reduced pupillary movement promoting the formation of posterior synechiae, aggravation of lens opacities, and induction of pupillary or ciliary block glaucoma in eyes with marked zonular instability, may complicate management. Aqueous suppressants result in decreased aqueous flow through the trabecular meshwork, and this may conceivably lead to worsening of trabecular function and further compromise the degenerative ciliary epithelium.

Laser therapy

Argon laser trabeculoplasty (ALT) often has an immediate pressure-lowering effect, with reported initial success rates up to 80%, perhaps by easier heat absorption due to increased trabecular pigmentation. However, the success rates decrease with time and by 3 years, there is a substantial failure rate averaging 50% in both POAG and PEX eyes. Primary ALT seems to be a good first-line therapy in PEX glaucoma patients, as it can delay the use of medical therapy for up to 8 years in a significant proportion of these patients. Postlaser complications are more common in PEX eyes and comprise inflammatory reactions and IOP spikes, requiring careful follow-up together with anti-inflammatory therapy and pressure control in the early postoperative phase.

Selective laser trabeculoplasty (SLT) may be an effective and safe alternative to ALT in the treatment of PEX glaucoma.

Surgical therapy

As long-term effects of medical therapy and laser treatment are often unsatisfactory in patients with PEX glaucoma, surgical intervention may be earlier and more frequently necessary than in other forms of glaucoma. In cases of extremely high IOP fluctuations, a primary filtration surgery may be considered. Whereas routine trabeculectomy is most often applied, a relatively new surgical approach to improve chamber-angle facility by aspiration of debris and PEX material on the inner surface of the meshwork has been specifically developed for treating PEX glaucoma. Although efficacious in decreasing IOP in the early course, the effect of this trabecular aspiration technique appears to regress by time, being often limited to a few weeks only – possibly due to disregard of the juxtacanalicular region of the trabecular meshwork, where the bulk of PEX material is deposited. Successful results for IOP reduction in PEX glaucoma were also reported for sclerocanalectomy and for nonpenetrating deep sclerectomy. Whatever technique selected, antifibrotic agents may be used in order to limit the risk of postoperative scarring.

Filtration surgery combined with phacoemulsification does not seem to adversely influence the success rate, but has been reported to reduce the frequency and magnitude of postoperative pressure elevation. Cataract extraction alone may also improve IOP control in hypertensive patients with PEX syndrome and appears to be more effective than in POAG and cataract patients.

Peri- and postoperative surgical complications, such as inflammatory responses, fibrin reactions, formation of synechiae, and IOP spikes, are more common and more serious in PEX eyes than in eyes without PEX and can be directly attributed to the exaggerated and prolonged breakdown of the blood–aqueous barrier and anterior-segment hypoxia. The presence of abnormal iris vessels

can lead to intraoperative hemorrhage during iridectomy and postoperative hyphema. Weakened zonular support may allow vitreous loss, intraoperative lens movement, or even subluxation. Preoperative treatment with corticosteroids may therefore be beneficial along with more intensive and prolonged postoperative anti-inflammatory therapy and IOP control.

Pupil

P D R Gamlin and D H McDougal, University of Alabama at Birmingham, Birmingham, AL, USA

Glossary

Accommodation – A change in the refractive power of the crystalline lens of the eye.
Intrinsically photosensitive retinal ganglion cells (ipRGCs) – The ganglion cells expressing a photopigment, melanopsin, that is intrinsically light sensitive.
Miosis – Pupillary constriction.
Mydriasis – Pupillary dilation.
Pupillary light reflex (PLR) – The constriction of the pupil that is elicited by an increase in illumination of the retina.

Advantages of a Mobile Pupil

The normal human pupil can change diameter from 8 to 1.5 mm, which corresponds to approximately a 30-fold change in area and almost a 1.5-log unit change in retinal irradiance. Although the visual system can operate over a 10-log unit range of lighting levels through the process of adaptation, it can take several minutes for optimum sensitivity to return after an abrupt increase or decrease in retinal illumination. The rapid control of retinal irradiance by the iris allows the visual system to more quickly regain optimal sensitivity by dampening fast changes in ambient lighting levels and by requiring less retinal adaptation for a given change in environmental lighting levels.

However, changes in pupil size affect not only retinal illumination, but also diffraction, optical aberrations, and depth of focus of the eye. These factors differentially affect visual performance and, given changing environmental lighting conditions and visual tasks, the nervous system continuously modulates pupil diameter for optimal visual performance.

The diffraction of light rays by an aperture is a major limiting factor in the resolution of an image in any optical system. The amount of disruption in image quality caused by diffraction at a circular aperture decreases as the size of the opening increases. Therefore, as pupil diameter increases, there is decreased degradation in retinal image quality caused by diffraction. In contrast to diffraction, the image-degrading effects of optical aberrations increase as aperture diameter increases. Therefore, as pupil diameter increases, the degradative effects of optical aberrations also increase, and offset the benefits gained by reduced diffraction at larger pupil diameters. Over the normal range of pupillary diameter, diffraction impacts image quality less than optical aberration, and the optimal pupil diameter is therefore approximately between 2 and 4 mm.

Along with diffraction and optical aberrations, defocus is an important determinate of retinal image quality. Although the pupil does not refract or focus light, it influences the depth of field of the eye. Depth of field is the range of distance in depth in which objects appear to be in focus. For example, when one reads a book, the power of the crystalline lens of the eyes changes in order to bring the text on the page into focus through a process called accommodation. With the eyes accommodated on the book, all objects within a range in front of and behind the book will also appear in focus. This range is called the depth of field and it is primarily dependent both on viewing distance and pupil diameter. When the viewing distance is held constant, the depth of field increases with decreases in pupil diameter, and therefore the pupil diameter can affect the focus of the retinal image.

Clearly, a mobile pupil allows the nervous system to optimize retinal irradiance, diffraction, ocular aberrations, and depth of focus despite differing conditions and visual tasks. For example, across a range of daylight (photopic) luminances, pupil size corresponds to that required for the highest visual acuity, and the maximal information capacity of the retinal image. On the other hand, under low light (scotopic) conditions in which poorer retinal image quality can be tolerated due to the lower resolution of rod photoreceptors, the pupil dilates sufficiently to maximize the retinal illumination. Further evidence for the optimization of pupil diameter for differing visual tasks is evident in the pupillary near response (PNR). When the viewing distance changes from far to near, the pupils constrict to increase the field of view and reduce the retinal image defocus. This compensates for the decrease in the effective field of view that naturally occurs when viewing distance decreases (see the section titled 'Pupillary near response' for more details).

Overview of the Pathways Controlling Pupil Diameter

A summary diagram of the afferent, central, and efferent pathways controlling pupil diameter is shown in **Figure 1**. This figure shows the iris musculature innervated by autonomic efferents from both the parasympathetic and sympathetic components of the autonomic nervous system

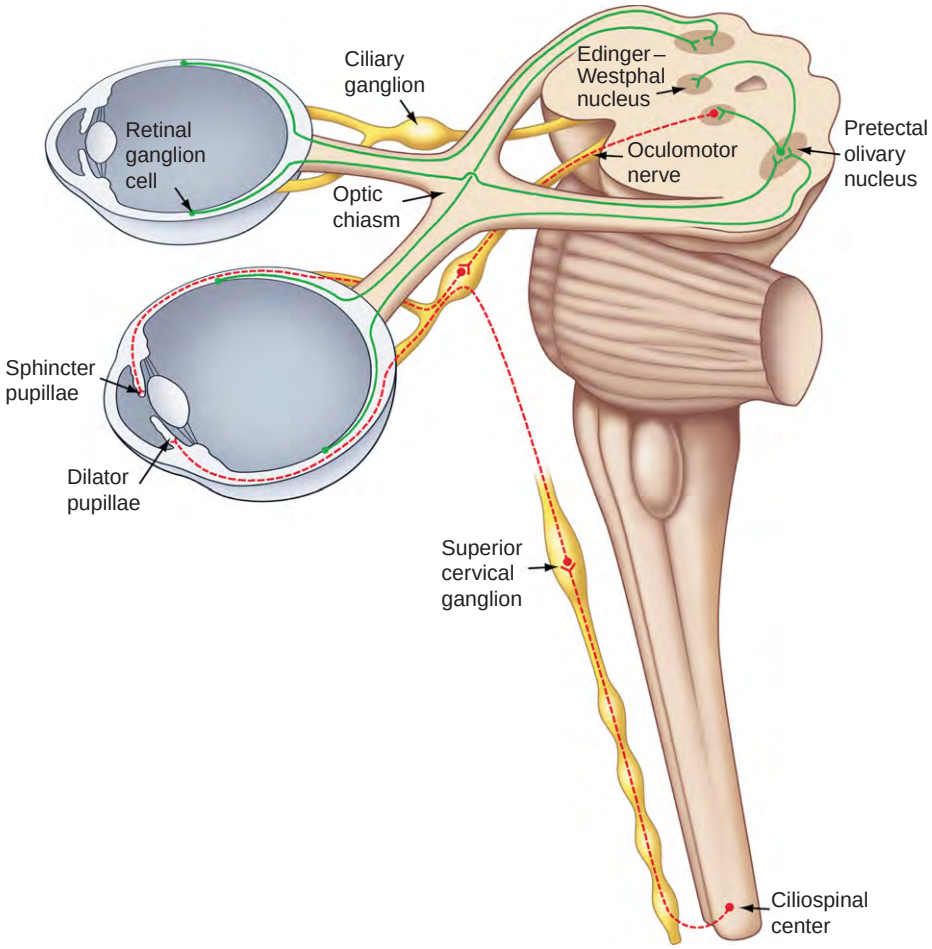

Figure 1 Anatomical drawing showing the direct and consensual pupillary light reflex (PLR) pathways and the parasympathetic and sympathetic innervation of the iris in primates. The bilateral projection from the retina to the pretectum is also shown. The pretectal olivary nucleus receives input from the temporal retina of the ipsilateral eye and the nasal retina of the contralateral eye. The pretectal olivary nucleus projects bilaterally to the Edinger–Westphal (EW) nucleus, which contains parasympathetic, preganglionic, and pupilloconstriction neurons. The axons of these preganglionic neurons travel in the third cranial nerve to synapse upon postganglionic pupilloconstriction neurons in the ciliary ganglion. The axons of these postganglionic neurons leave the ciliary ganglion and enter the eye through the short ciliary nerves, and travel through the choroid to innervate the sphincter muscle of the iris. The sympathetic preganglionic pupillodilation neurons are found at the C8-T1 segmental levels of the spinal cord. The axons of these neurons project from the spinal cord through the dorsal roots and enter the sympathetic trunk, and then project rostrally to the superior cervical ganglion where they synapse with the postganglionic neurons. These postganglionic neurons project from the superior cervical ganglion through the neck and carotid plexus, and into the orbit of the eye. These fibers enter the eye either by passing through the ciliary ganglion and entering the short ciliary nerves, or bypassing the ciliary ganglion and entering via the long ciliary nerves (for clarity, only one of these alternative pathways is shown). Upon entering the eye, these axons travel through the choroid and innervate the dilator muscle of the iris. From McDougal, D. H. and Gamlin, P. D. R. (2008). Pupillary control pathways. In: Basbaum, A. I., Kaneko, A, Shepherd, G. M., et al. (eds) *The Senses: A Comprehensive Reference*, *Vol 1: Vision 1*, pp. 521–536. San Diego, CA: Academic Press.

(ANS). The parasympathetic component of the ANS innervates the sphincter pupillae muscle of the iris. The preganglionic parasympathetic fibers controlling the sphincter pupillae originate from neurons in the Edinger–Westphal (EW) nucleus, the autonomic subdivision of the third cranial nerve nucleus, and travel through the third cranial nerve to the ciliary ganglion, which is located within the orbit of the eye (see **Figure 1**). Within the ciliary ganglion, the preganglionic pupilloconstriction neurons form cholinergic, nicotinic synapses with the postganglionic neurons. The axons of these postganglionic neurons leave the ciliary ganglion to enter the eye through the short ciliary nerves and travel to the iris. Here, they release acetylcholine, which acts on the muscarinic receptors of the sphincter pupillae (see **Figure 2**).

The sympathetic component of the ANS innervates the dilator pupillae muscle. The preganglionic sympathetic neurons, which control pupillary dilation, are located in the C8-T1 segments of the spinal cord, a region termed the ciliospinal center of Budge (and Waller). The

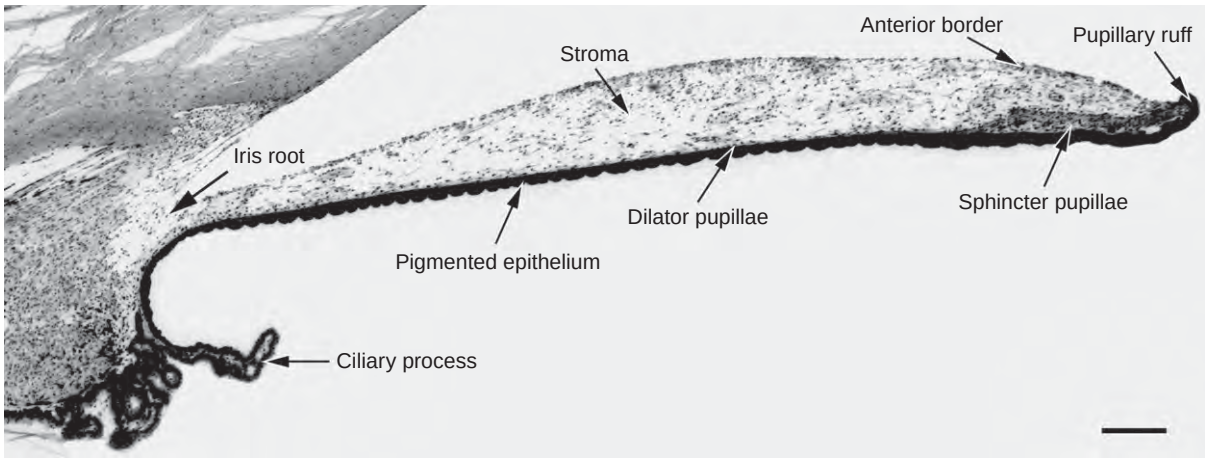

Figure 2 Low-power photomicrograph of a cross section of the macaque iris. Scale = 200 μm. From McDougal, D. H. and Gamlin, P. D. R. (2008). Pupillary control pathways. In: Basbaum, A. I., Kaneko, A, Shepherd, G. M., et al. (eds.) *The Senses: A Comprehensive Reference*, *Vol 1: Vision 1*, pp. 521–536. San Diego, CA: Academic Press.

axons of these preganglionic neurons project to the sympathetic chain and travel in the sympathetic trunk to the superior cervical ganglion. Within the superior cervical ganglion, the preganglionic axons form nicotinic, cholinergic synapses with postganglionic pupillodilation neurons. The axons of these postganglionic neurons project from the superior cervical ganglion to the orbit, where they enter the eye through the short and long ciliary nerves and travel to the iris (see **Figure 1**). Here, they release norepinephrine, which acts on the adrenoreceptors of the dilator muscle (see **Figure 2**).

Iris Musculature

In a cross-section of the iris, the sphincter pupillae can be seen as an annular band of smooth muscle (100–170 μm thick; 0.7–1.0 mm wide) encircling the pupil (**Figure 2**). The sphincter, which is located in the posterior iris immediately anterior to the pigmented epithelium, interdigitates with the surrounding stroma and connects to the dilator muscle fibers. The smooth muscle cells of the sphincter are clustered in small bundles and connected by gap junctions. These gap junctions ensure synchronized contraction of the sphincter muscle. The sphincter receives muscarinic, cholinergic innervation from the short ciliary nerves – parasympathetic, postganglionic fibers arising from the ciliary ganglion.

The dilator pupillae is composed of radially oriented smooth muscle fibers that are myoepithelial in origin. Individual fibers are approximately 50 μm long and 5–7 μm wide. In the pupillary zone, dilator muscle processes fuse with the sphincter pupillae, while peripherally, their processes attach to the ciliary body. Contraction of the dilator muscle pulls the pupillary margin toward the ciliary body.

Pupillary Light Reflex

Description

The pupillary light reflex (PLR) is the constriction of the pupil that is elicited by an increase in illumination of the retina. The direct PLR, present in virtually all vertebrates, is the constriction of the pupil in the same eye as that stimulated with light. The consensual PLR is the constriction of the pupil in the eye opposite to the eye stimulated with light. In mammals with laterally placed eyes, such as the rat and rabbit, the direct PLR is more pronounced than the consensual PLR. However, in those mammalian species with frontally placed eyes, such as humans and monkeys, the direct and consensual PLRs are essentially equal. An example of a human consensual PLR produced by two different wavelengths of light is shown in **Figure 3**. The PLR has traditionally been divided into two separate pathways based on the clinical manifestations of the defects in this reflex. The afferent pathway is composed of both the retinal cells that project to the pretectum as well as their recipient neurons, which project bilaterally to the EW nucleus (**Figure 1**). The efferent pathway is composed of the preganglionic pupilloconstriction fibers of the EW nucleus and their postganglionic recipient neurons in the ciliary ganglion, which project to the sphincter muscle of the iris (**Figure 1**).

Afferent Pathway

The first neurons in the afferent pathway of the PLR are retinal ganglion cells. It has recently been recognized that this reflex in rodents and primates is driven predominantly by a unique subset of intrinsically photosensitive retinal ganglion cells (ipRGCs) which project to the pretectal olivary nucleus (PON), a small nucleus in the

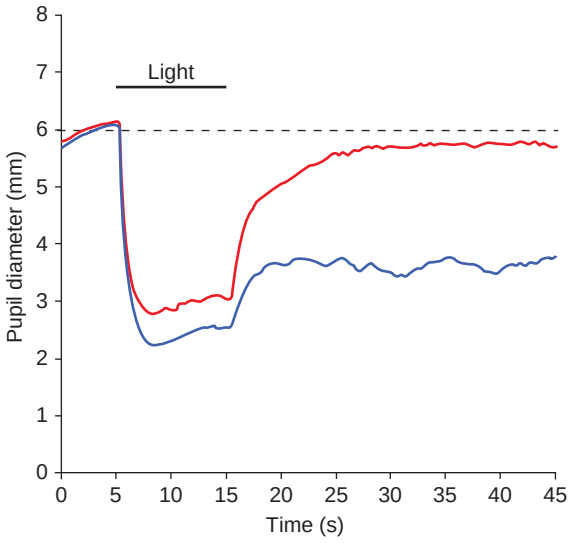

Figure 3 Pupilloconstriction elicited by a 10-s light stimulus of 493-nm wavelength light at 14.0 log quanta cm^{-2} per second irradiance (blue trace), and 613-nm wavelength light at 14.1 log quanta cm^{-2} per second irradiance (red trace). Note that a 473-nm stimulus, which effectively activates the intrinsic photoresponse of intrinsically photosensitive retinal ganglion cells (ipRGCs), drives a larger pupillary response than the 613-nm stimulus (red trace), which does not effectively activate the intrinsic photoresponse of ipRGCs at this irradiance level. Note that the pupilloconstriction induced by the 473-nm light is maintained following stimulus offset. From McDougal, D. H. and Gamlin, P. D. R. (2008). Pupillary control pathways. In: Basbaum, A. I., Kaneko, A, Shepherd, G. M., et al. (eds.) *The Senses: A Comprehensive Reference*, *Vol 1: Vision 1*, pp. 521–536. San Diego, CA: Academic Press.

pretectum; the pretectum is located in the dorsal lateral aspect of the midbrain at the level of the superior colliculus (see **Figure 1**).

Intrinsically photosensitive retinal ganglion cells

Prior to 2000, it was assumed that the PLR was driven by retinal ganglion cells which received light signals exclusively from rod and cone photoreceptors, which up to that time were the only known photoreceptive cells in the retina. However, recent studies have demonstrated that the PLR is driven predominantly by retinal ganglion cells which, unlike any other retinal ganglion cell class, are intrinsically photosensitive. The intrinsic photoresponse of these neurons, which is mediated by the photopigment melanopsin, presumably compensates for the adaptation of rod and cone photoreceptors, and serves to maintain pupilloconstriction during steady-state exposure at all photopic (daylight) illuminance levels. In addition to their intrinsic light-driven signal, it is clear that ipRGCs receive rod and cone inputs. In response to a pulse of light, intracellular recordings from these cells show a characteristic transient burst of neural activity at stimulus onset, which rapidly decays to a plateau of sustained activity that often extends well past stimulus offset. The initial burst of neural activity is mediated by a rapidly adapting cone-mediated photoresponse, while the sustained activity is driven predominantly by the intrinsic response of these cells, although there is growing evidence for a rod contribution to this sustained activity under steady-state lighting conditions.

IpRGCs project to the PON of rodents and primates, and they play a major role in pupillary responses. Monkeys and rodents with nonfunctional rod and cone photoreceptors but functional melanopsin-containing ipRGCs display a PLR; however, the reflex has a higher irradiance threshold than normal. Mice with ipRGCs lacking melanopsin also display PLR, but their pupils fail to constrict maximally in bright lights. Taken together, these results show that both the intrinsic photoresponse of ipRGCs and their classical photoreceptor inputs provide signals of retinal irradiance that drive the PLR. Additional studies further suggest that the influence of rod and cone photoreceptors on the pupillary light reflex is mediated exclusively through their inputs to ipRGCs.

The intrinsic photoresponse of ipRGCs can also affect pupillary behavior in the absence of ongoing light stimulation. As noted above, ipRGCs encode stimulus irradiance through an elevation of firing rate that continues well beyond stimulus offset. Indeed, bright light stimuli can produce a prolonged pupillary constriction in humans that can persist up to 20 min after the light has been extinguished (see **Figure 3**). Experiments in primates, including humans, demonstrate that this prolonged pupillary constriction in darkness is mediated almost entirely by the intrinsic photoresponse of ipRGCs.

Pretectal olivary nucleus

The first relay in the afferent pathway of the PLR consists of luminance neurons within the PON, which receives direct retinal input. PON luminance neurons are characterized by tonic firing rates that increase with increases in retinal illuminance. In primates, these neurons exhibit a transient burst of activity followed by sustained tonic activity in response to increases in retinal illuminance. In addition, the tonic firing rate of these cells is proportional to retinal illuminance over at least a 3 log unit range of stimulus intensities in primates and in rats. Electrical microstimulation of the PON in rats and monkeys elicits pupilloconstriction at short latencies, and lesions of the PON in rats produce deficits in pupillomotor function. These results strongly suggest that luminance neurons within the PON mediate the PLR. In addition to retinal afferents, the PON also receives significant cortical, ventral thalamic, and midbrain inputs which may also have an influence on the PLR or other pupillary movements. Owing to its importance for the PLR, the best-described efferent projection of the PON is to the EW nucleus. However, the PON has been shown to project to a number

of other targets, such as the hypothalamus, pons, and medulla that may also influence pupillary behavior.

Efferent Pathway

The efferent leg of the PLR begins with preganglionic pupilloconstriction neurons of the EW nucleus that project through the third cranial nerve to the ciliary ganglion (see **Figure 1**).

The EW nucleus is a distinct nucleus of the midbrain, lying immediately dorsal to the oculomotor complex. It is located just ventral and lateral to the cerebral aqueduct at the level of the superior colliculus (see **Figure 1**). Evidence for the course of the efferent parasympathetic pupillary pathway and the importance of the EW nucleus in pupilloconstriction comes from electrical stimulation studies in the vicinity of EW nucleus that elicit pupilloconstriction in a variety of animal models. Within the ciliary ganglion, which is approximately 3 mm in size, and located 2–3 mm posterior to the globe and lateral to the optic nerve, the axons of the preganglionic neurons synapse with the postganglionic pupilloconstriction neurons. The axons of these postganglionic neurons leave the ciliary ganglion to enter the eye via the short ciliary nerves to innervate the sphincter muscle of the iris.

Sympathetic Influences on the PLR

It is generally agreed that the parasympathetic pathway discussed above is the primary route of pupillary constriction associated with the PLR. However, there is some evidence that increases in retinal illumination may cause a reduction in the tone of the dilator muscle of the iris through the sympathetic pathway outlined in **Figure 1**, and thus enhance the PLR. Studies in cats have shown a light-induced inhibition of postganglionic pupillodilation fibers at the level of the long ciliary nerves, and preganglionic, pupillodilation fibers at the level of the cervical sympathetic nerve. These studies found that the pupillodilation fibers were inhibited by light in an intensity-dependent manner, that is, a more intense light brought about a greater inhibition in firing rate. However, these findings have not been replicated in primates, in which the evidence suggests that the sympathetic system does not contribute to the dynamics of the PLR and only contributes to tonic modulation of pupil diameter.

The Pupillary Near Response

Description

The PNR is the pupillary constriction associated with a change in viewing distance from far to near that occurs in primates including humans. When the eyes move from viewing a far object to viewing a near object, three oculomotor responses occur. The eyes converge to bring the image of the object onto the fovea of each retina, the refractive power of the crystalline lens is adjusted to bring the image of the object into focus on the retina, and the pupil constricts. These collective processes are classically referred to as the near response or the near triad.

Efferent Pathway of the PNR

The PNR is thought to be driven solely by an increased drive to the sphincter muscle of the iris through the parasympathetic efferent pathway. Therefore, the neural control pathway of the PNR shares a common efferent pathway with the PLR, although the afferent inputs responsible for the PNR are more complex. The neural signals driving these two reflexes most likely converge at the EW nucleus, since the activity of PON luminance neurons is not correlated with pupil constriction during near viewing. Further, certain clinical neurological conditions are characterized by an intact PNR despite the absence of the PLR (light-near dissociation).

It is generally accepted that preganglionic neurons in the EW nucleus drive the PNR as well as the PLR. However, it has not been determined if separate subpopulations of neurons exist in EW nucleus devoted exclusively to either the PLR or the PNR, or whether the same population of neurons drives pupillary constriction in both reflexes, although the latter seems most likely.

Afferent Influences on the PNR

Early investigations attempted to determine whether the PNR was driven primarily by ocular convergence or accommodation, the other two components of the near triad. Some studies found that the PNR was more closely associated with accommodation than with convergence. Other studies found a greater association with convergence, and even reported that the PNR was totally absent during some blur-driven accommodative responses. These conflicting results are likely a product of an incomplete disassociation between the convergence and accommodation systems during these experiments, as these two systems have been shown to be highly interdependent. A more modern view of the afferent influences controlling the PNR has recently emerged. In this view, the PNR is not seen as resulting from either accommodation or convergence alone, but as a separate output of the neural pathways that drive both accommodation and convergence.

A number of brain areas play a role in controlling the near triad. These include cortical areas, such as extrastriate cortex, parietal cortex, frontal eye fields, as well as the cerebellum and the midbrain. Of particular interest to the PNR, is the supraoculomotor area of the midbrain, which lies just dorsal and lateral to the oculomotor nucleus. The supraoculomotor area contains near response cells which

are modulated by both vergence and accommodation. These cells project to medial rectus motoneurons, and thus contribute to vergence eye movements. It seems likely that these cells also project to EW nucleus and are responsible for carrying the signal from the accommodation and convergence controller to the preganglionic, pupilloconstrictor neurons.

Additional Cortical Influences on Pupillary Responses

In addition to cortical afferents mediating the PNR, the pupil is also influenced by both visual and nonvisual cortical regions. These afferents manifest themselves as small changes in pupil diameter during presentation of visual stimuli such as colored stimuli and gratings, as well as nonvisual stimuli such as auditory tones, and even during higher-order cortical functions such as problem solving. These observations provide clear evidence that cortex exerts an influence on pupillary behavior, which therefore cannot be thought of as entirely reflexive in nature.

Visually Mediated Cortical Influences on Pupillary Behavior

Small pupillary constrictions have been shown to occur in both human and monkeys with the presentation of complex visual stimuli, even when the stimuli do not involve a change in viewing distance or retinal illuminance. Changes in stimulus attributes such as color, spatial frequency, or apparent motion produce such cortically mediated pupillary responses. Deficits in these pupillary responses are observed in humans with lesions to cortical areas involved in processing one or more of these stimulus characteristics. In addition, lesions of rostral inferior temporal cortex but not V4 in macaques abolish pupillary responses to chromatically modulated gratings.

Task-Evoked Pupillary Responses

In the early 1960s, Hess and colleagues published a series of papers which reported modulations in human pupillary diameter associated with complex cognitive processes such as subjective attitudes or mental activity. Later studies failed to replicate the findings relating pupillary dynamics to subjective attitudes, although the findings related to mental activity have been replicated and extensively studied. The small pupillary dilations associated with increased mental activity, or task-evoked pupillary responses (TEPRs), have now become a well-established tool of cognitive psychology. These pupillary responses are generally reported to vary in magnitude from 0.2 to 0.7 mm, and have been shown to correlate with cognitive load across diverse functions, such as sensory perception, memory, language, and attention. TEPRs have been repeatedly shown to monotonically vary with the degree of mental activity required by a task as measured by other objective criterion such as reaction time and the extent of cortical activation indicated by positron emission tomography (PET) scan, and this has allowed TEPRs to be utilized successfully to empirically test theories of language processing and intelligence.

Although the behavioral phenomenon of TEPRs has been extensively studied and quantified, little is known of the underlying neurophysiology that drives these responses. It has been suggested that they may be driven by noradrenergic projections from the locus ceruleus since the activity of neurons in this nucleus has been show to correlate with both pupil diameter and task-related events.

Influence of Alertness on Pupillary Behavior

Since the muscles of the iris are controlled by the ANS, environmental or physiological conditions which cause changes in overall autonomic function can have a significant effect on pupillary behavior. Even though the environment or physiological conditions which produce the change in autonomic tone may not have a direct influence on the visual system, they may still manifest themselves through an affect on pupil diameter.

Arousal

Situations or stimuli which produce an emotional or startle response often produce a profound pupillary dilation. This effect is mediated through the hypothalamus, the brain area responsible for the integration of autonomic function. This integration allows for the coordination of the various functions of the ANS and often leads to global changes in the balance between the sympathetic and parasympathetic branches of the ANS. For example, an unexpected loud noise may produce a startle response which is characterized by increases in heart rate, respiratory rate, and pupil diameter; it is caused by a systemic increase in sympathetic tone mediated through the hypothalamus. This global increase in sympathetic tone can affect pupil diameter via activation of the pupillodilation centers of the spinal cord and inhibition of the pupilloconstriction neurons of EW nucleus. Neurons within the hypothalamus project to the sympathetic preganglionic pupillodilation neurons of the thoracic spinal cord. This direct effect of hypothalamic activation on pupil diameter can be shown through microstimulation of the posterior hypothalamus, which often causes rapid pupil dilation. Increase in sympathetic tone can also produce inhibition

of pupilloconstriction neurons of EW nucleus via the influence of ascending neuromodulatory pathways.

The hypothalamus is also the site at which autonomic function is regulated by the central nervous system through connections with the limbic system and cortical structures. The limbic system of the brain, which is responsible for emotions and short-term memory, has a direct connection to the hypothalamus and therefore can have significant effects on autonomic balance. Situations or stimuli which produce an intense emotional response are often accompanied by pupillary dilation, which is certainly mediated through limbic connections to the hypothalamus. In addition, cortical influences on the hypothalamus allow a wide variety of stimuli to effect autonomic tone and thus pupil diameter.

Sleep

Sleep has a pronounced effect on the ANS, specifically a reduction in sympathetic outflow and an increase in parasympathetic outflow. Given this overall trend, it is not surprising that pupillary behavior during sleep is characterized by prolonged constriction of the pupil. It has been shown that sleep-induced pupillary constriction persists in animals with lesions of the preganglionic sympathetic pupillodilation fibers. This suggests that the sleep-induced pupillary changes are mediated by an activation of the preganglionic parasympathetic pupilloconstriction fibers of the EW nucleus.

Ascending Neuromodulatory Systems

The ascending neuromodulatory systems of the midbrain and brainstem can have a variety of effects on pupillary behavior. These nuclei are the origin of neuromodulatory fibers which release dopamine, norepinephrine, histamine, and serotonin at a number of brain areas implicated in pupillary control. These neuromodulatory systems appear to be critical in the regulation of sleep and arousal, as well as autonomic regulation and cortical plasticity. In addition to these global neuromodulatory effects, all or some of which could have a profound influence on pupillary behavior, there is some evidence for a direct inhibition of pupilloconstriction neurons in the EW nucleus by adrenergic neurons originating from the locus ceruleus in a number of animal models. However, other studies in humans and rabbits have failed to find this direct noradrenergic inhibition of EW nucleus pupilloconstriction neurons and it has been suggested that this effect might be mediated by dopaminergic neurons in these species. Drugs which agonize or antagonize these neuromodulatory neurotransmitters have been found to differentially affect pupillary behavior in a wide range of animal models and human studies. These differential effects are most likely due to the both interspecies variability in the projections of these neuromodulatory fibers, as well as the differential activation of multiple brain areas implicated in pupillary behavior due to the extensive projections of these neuromodulators.

Glossary

Aberrations – Phase deviations from the ideal wave front measured at the pupil plane. Aberrometers measure local ray deviations, which are fitted to the derivatives of the wave aberration, usually expressed as a Zernike polynomial expansion. A relevant aberration in the human eye (and particularly after standard refractive surgery) is spherical aberration (which results in peripheral rays converging on a different plane than central rays). A common optical quality metric derived from the wave aberration is the root mean square (RMS) wave-front error.

Ablation profile – Corneal tissue that needs to be removed at each location to produce the desired change in corneal power. Generally, the ablation-profile equation is converted into the number of laser pulses to be applied at each location.

Asphericity – Parameter used to describe the deviation of the anterior corneal surface from a sphere. The corneal surface can be fitted to a conic section using the apical radius of curvature and the eccentricity e (variation of this curve with distance from the apex). Asphericity Q is defined as $-e^2$, with the surface represented by the following equation: $(X^2+Y^2)+(1+Q)Z^2-2ZR=0$. For a sphere $Q=0$, a typical cornea shows an asphericity $Q=-0.26$; a surface with zero spherical aberration should have an asphericity $Q=-0.52$; an oblate surface (exhibiting positive spherical aberration) will have $Q>0$; and a prolate surface (exhibiting low positive spherical aberration or negative) will have $Q<0$.

Beer–Lambert law – Law governing the photoablation of the corneal tissue by excimer laser. The depth of ablated material is proportional to the logarithm of the laser fluence (relative to the ablation threshold).

Contrast-sensitivity function (CSF) – The contrast-sensitivity function represents the minimum subjectively discernible contrast as a function of spatial frequency. It typically has an inverted-U shape, peaking at around 4 cycles per degree (c/deg), with sensitivity decreasing on either side of the peak. The shape of the CSF is determined by the properties of the visual neurons and the optical aberrations of the eye. Other factors affecting the CSF are pupil diameter and luminance. CSF is a more sensitive measure of changes in visual quality following a change in the optics (such as that produced by refractive surgery) than visual acuity.

Excimer laser – Laser producing stimulated emission after electrical discharge forming dimers or complexes, emitting typically ultraviolet (UV) light. Lasers applied in refractive surgery use a combination of Argon (as inert compound) and fluorine (reactive gas) and emit at 193 nm. The excimer lasers are well suited to remove exceptionally fine layers of surface material (particularly, biological matter and organic compounds) by disrupting the molecular bonds of the tissue, through ablation rather than burning, leaving the remainder of the material almost intact. Lasers used in refractive surgery have fluences typically ranging between 120 and 400 mJ cm^{-2}.

Laser-assisted *in situ* keratomileusis (LASIK) – Corneal refractive surgery technique which involves the creation of a thin flap on the cornea, folding it to enable remodeling of the tissue underneath with laser and repositioning the flap back after the corneal ablation has been performed.

Modulation-transfer function (MTF) – Optical function representing the contrast degradation by an optical system as a function of spatial frequency. Factors affecting the MTF are diffraction (pupil size),

optical aberrations, scattering, and wavelength. The ocular MTF is a low-pass function, with a cut-off frequency at around 70 c/deg.

Munnerlyn formula – Equation on which standard ablation algorithms for corneal refractive surgery are based. The corneal tissue to be removed is a lenticule with an anterior radius of curvature equal to the preoperative corneal radius and the posterior radius of curvature equal to the postoperative corneal radius (easily related with the attempted correction). A parabolic approximation of the Munnerlyn formula states that the depth of the ablation (in microns) per diopter of refractive change is equal to the square of the optical ablation zone measured in millimeters, divided by 3.

Optical zone – Area of the cornea where the ablation algorithm is applied. For the same attempted correction, smaller optical zones require less ablation depth. However, small optical zones can severely compromise vision if they are smaller than pupil diameter. A transition zone around the optical zone is created to avoid an abrupt step between treated and untreated areas.

Short Historical Background of Corneal Refractive Surgery

Corneal refractive surgery has become, in recent years, a popular surgical approach to correct ametropia. Table 1 depicts highlights of refractive surgery history in chronological order. The first surgical procedure that achieved a change in corneal power by relaxation through corneal incision was radial keratotomy (RK). First attempts of incisional corneal surgery date from 1885 onward. The technique evolved through the 1930s and 1940s to the early 1980s when Fyodorov developed a systematic and more predictable RK procedure that he applied to thousands of patients. In the 1960s, Barraquer invented keratomileusis – the first lamellar surgical technique. This technique consisted of separating a thin layer of the superficial corneal tissue using a microkeratome, removing a small piece of cornea, which was frozen and then reshaped using a lathe, and suturing it back into place. However, it was only in the late 1980s, when excimer lasers were developed at IBM, that their excellent properties for micromachining of biological tissue and organic materials were identified by Srinivasan. In the 1980s, Stephen Trokel applied, for the first time, an argon-fluoride excimer laser to remove tissue in bovine corneas, following previous mechanical removal of the outer layer of the cornea (corneal epithelium) to treat ametropia, thus giving birth to photorefractive keratectomy (PRK).

Table 1 Chronology of corneal refractive surgery

1898	The basic principles of radial keratotomy are laid up by Dr. Lans (the Netherlands)
1930	Pioneering work on corneal incisions is performed by Dr. Tsutomu Sato (Japan)
1948	The first surgical techniques to reshape the cornea (freezing a corneal flap, reshaping it on a lathe and placing it back) are performed by Dr. José Barrarquer (Colombia)
1960s	Radial keratotomy is developed by Dr. Fyodorov (Russia)
1978	Radial keratotomy is introduced in the US by Dr. Leo Bores
1975–79	Excimer Laser Technology is developed. Dr. Srinavasan (IBM Laboratories, USA) foresees the potential of the interactions of laser and biological tissue
1983	The use of excimer laser to remove corneal tissue is described by Dr. Stephen Trokel (USA)
1988	The first excimer treatment on a human eye is performed by Dr. Teo Seiler (Germany)
1989	The benefits of performing PRK after a flap was removed were theorized and experimented by Dr. Pallikaris (Greece) and Lucio Buratto (Italy)
1991	The first LASIK procedure is performed by Dr. Stephen Brint in the United States
1995	FDA approves excimer laser for refractive surgery (PRK) to correct myopia
1999	First excimer lasers approved to perform LASIK surgery
1999	LASEK (a surface ablation procedure in which the epithelium is removed with alcohol) is introduced by Dr. Massimo Camellin (Italy)
2000	FDA approves LASIK surgery for hyperopia
2002	Wavefront-guided LASIK approved for custom correction
2002	Femtosecond laser flap removal approved by FDA
2003	First Epi-LASIK (epithelium mechanically removed) procedures performed by Dr. Pallikaris (Greece)

However, PRK was limited by unpredictability in higher ranges of refractive error and higher risk of corneal haze after surgery. In the 1990s, Pallikaris combined these two techniques (keratomileusis and PRK), creating the laser-assisted *in situ* keratomileusis (LASIK), which has become the most popular refractive surgery technique (see the section titled 'The LASIK procedure'). Today, faster lasers, larger spot areas, bladeless flap creation, intraoperative pachymetry, and wave-front-optimized and wave-front-guided techniques have significantly improved the reliability of the procedure compared to that of 1991. Nonetheless, the fundamental limitations of excimer lasers, the limited corneal thickness (particularly in the presence of the flap), and undesirable destruction of corneal nerves have spawned research into many alternatives to standard LASIK, including laser-assisted subepithelial keratomileusis (LASEK) or Epi-LASIK, which aim at combining the advantages of surface ablations such as PRK with those of LASIK surgery. Although safety and efficacy, and refraction predictability of PRK and LASIK are high, complaints of decreased vision and glare in mesopic and

scotopic light levels, that is, night-vision problems, exist. Haze, halos, and increased optical aberrations are attributed to cause visual degradation, particularly in eyes that had undergone high refraction corrections. Several questions are still open today: proper transfer of the ablation profile to the cornea, wound healing, biological response, corneal biomechanics, microstructural stromal changes, and long-term healing. The implementation of aberrometry in refractive surgery has meant a turning point in the history of laser refractive surgery since – along with other technological advances including improvements in surgical lasers (such as flying spot lasers), ablation algorithms, and eye-tracking – the measurement of ocular wave aberrations has opened the potential for improved refractive surgery, aiming not only at correcting refractive errors but also to minimize optical aberrations of the eye.

The LASIK Procedure

Figure 1 illustrates a LASIK procedure. In this technique, a hinged flap is created by means of a microkeratome, and folded back to leave the stroma exposed. To create the flap, a corneal suction ring is applied to the eye, holding the eye in place. Once the eye is immobilized, the flap is created. This process is achieved with a mechanical microkeratome using a metal blade, or more recently a femtosecond laser microkeratome. A hinge is left at one end of this flap. The flap is folded back, revealing the stroma, the middle section of the cornea. An excimer laser is then used to photoablate the stroma. For treatment of myopia, the central cornea is flattened and experiences a deeper ablation than the periphery. For a hyperopic treatment, the outer area of the optical zone experiences deeper ablation than the central area resulting in a cone-like corneal profile. After the laser has reshaped the stromal layer, the LASIK flap is carefully repositioned over the treatment area by the surgeon and checked for the presence of air bubbles, debris, and proper fit on the eye. The flap remains in position by natural adhesion until healing is completed.

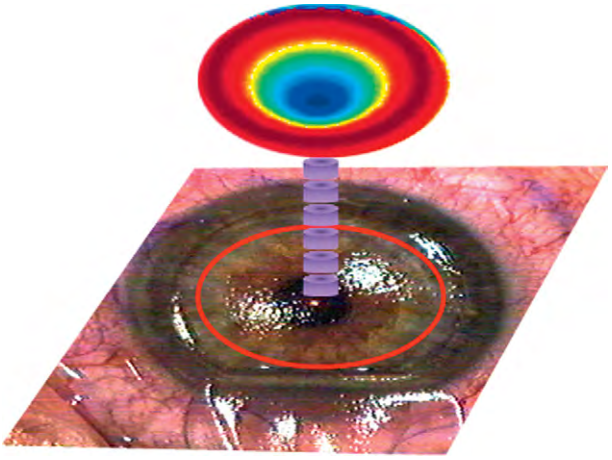

Figure 1 Illustration of a LASIK procedure. A flap is lifted and the exposed stroma ablated with excimer laser pulses according to the programmed ablation profile following which the flap is repositioned.

Corneal Refractive Surgery, Wound Healing, and Haze

The corneal response to laser refractive surgery induces keratocyte apoptosis immediately following the procedure. Proliferation and migration of keratocytes begins within 12–24 h, giving rise to activated keratocytes and myofibroblasts, which are critical components in the wound-healing cascade. Myofibroblasts and newly synthesized extracellular matrix play a major role in haze formation and regression due to stromal remodeling. The timing, intensity, and spatial distribution of wound healing vary significantly between LASIK and PRK. PRK involves injury on a broader area and removal of the epithelium, epithelial basement membrane, Bowman's layer, and a portion of the anterior stroma, while LASIK leaves these structures relatively undisturbed, except at the flap margin. Figure 2 depicts immunohistology microscopic images of excised corneas in an avian model following PRK (5, 15, and 30 days following surgery), showing the distribution of myofibroblasts.

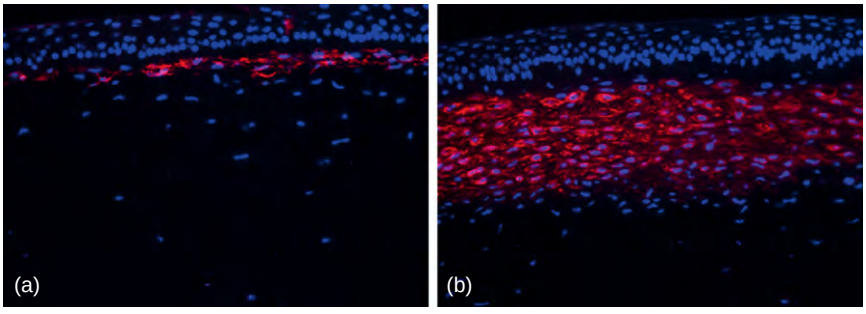

Figure 2 Immunohistology of chicken corneas following PRK, stained for alpha smooth muscle myosin (α-SMA) as a marker for myofibroblasts ((a) 6 days and (b) 30 days). Magnification 200×. From Merayo-Lloves, J., Yañez, B., Mayo, A., Martín, R., and Pastor, J. C. (2001). Experimental model of corneal haze. *Journal of Refractive Surgery* 17: 696–699.

Refractive regression is a major challenge following PRK for myopia, hyperopia, and astigmatism, especially for high levels of correction, and is both more common and more pronounced than the regression following LASIK. The source of regression is attributed to differential changes in the thickness of the cornea due to a combination of stromal remodeling and epithelial hyperplasia. The intensity of the corneal response is related to the magnitude of attempted treatment.

Corneal Refractive Surgery, Optical Aberrations, and Visual Quality

One of the most important side effects of standard refractive surgery is the induction of higher-order aberrations. Early studies based on corneal topography showed that while defocus or astigmatism are generally successfully corrected, refractive surgery (RK, PRK, and LASIK) increased the amount of corneal aberrations. In addition, the distribution of aberrations changed from the third-order dominance found in normal subjects, to fourth-order dominance. This increase in corneal aberrations correlates well with the decrease found in contrast sensitivity. Seiler and colleagues, in standard myopic PRK (15 eyes, mean preoperative spherical error = −4.8 D), and Moreno–Barriuso and colleagues, in standard myopic LASIK (22 eyes, mean preoperative spherical error = −6.5 D), measured, for the first time, the changes in the total aberration pattern induced by either type of surgery. Both studies found a significant increase in third- and higher-order aberrations (by a factor of 4.2 and 1.9 in the root mean square (RMS), respectively). The larger increase occurred for spherical and third-order aberrations. The changes of total spherical aberrations are not fully accounted by changes in the anterior corneal surface. In all eyes, total spherical aberration increased slightly less than corneal aberrations, likely due to significant changes in the posterior corneal shape (shifting toward more negative values of spherical aberration). The increase in the total spherical aberration is highly correlated to the amount of spherical error corrected, and it is associated with an increase in corneal asphericity.

Changes of corneal and total aberrations with LASIK surgery for hyperopia are even higher than those for LASIK surgery for myopia. While spherical aberration becomes more positive following myopic LASIK, it shifts toward negative values following hyperopic LASIK. For the same absolute amount of correction, the absolute increase of corneal spherical aberration is larger with hyperopic LASIK. **Figure 3** shows wave pre- and postoperative high-order aberration patterns in patients that had undergone myopic LASIK and hyperopic LASIK. **Figure 4** compares the induced aberration (total and corneal) following myopic and hyperopic LASIK, respectively.

Modulation-transfer functions (MTFs) can be computed from the measured wave aberrations, and the optical changes can be compared to the visual changes (measured in terms of contrast-sensitivity function (CSF)). Marcos and colleagues found that the decrease in the MTF (between 3 and 18 cycles per degree (c/deg)) was 1.38 – similar to the decrease in the CSF, by a factor of 1.51 (in the same spatial frequency range) – on average in a group of 22 eyes that had undergone LASIK surgery for myopia. This indicates that the increase in optical aberrations plays a major role in the decrease of visual quality following LASIK. **Figure 5** shows pre- and postoperative MTF and CSF, for 3-mm pupils, and the pre/post contrast ratio as a function of spatial frequency.

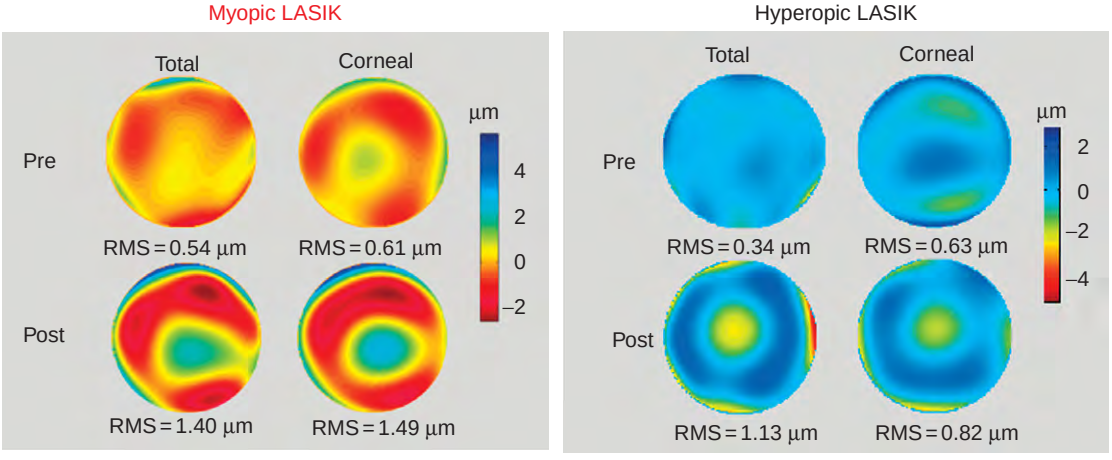

Figure 3 Examples of corneal and total wave aberrations (third- and higher-order aberrations) before and after LASIK surgery for myopia (left panel) and hyperopia (right panel). The increase in aberrations is indicated by the increased RMS. Following surgery, the total aberration map is dominated by the corneal contribution, primarily by positive spherical aberration following myopic LASIK and by negative spherical aberration following hyperopic LASIK. From Marcos, S., Barbero, B., Llorente, L., and Merayo-Lloves, J. (2001). Optical response to LASIK for myopia from total and corneal aberrations. *Investigative Ophthalmology and Visual Science* 42: 3349–3356.

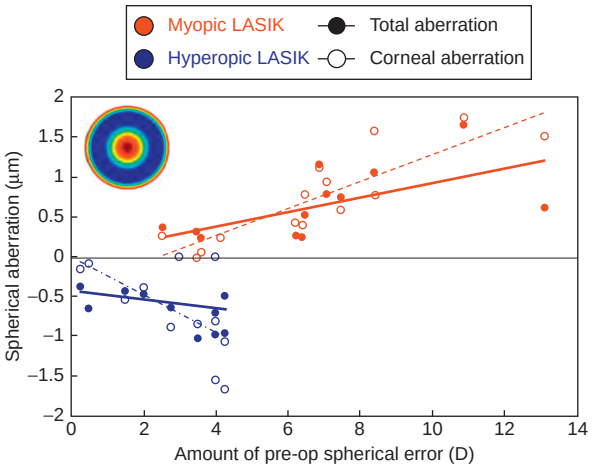

Figure 4 Induced spherical aberration vs. spherical correction (positive for hyperopia and negative for myopia). Corneal spherical aberration increases at a rate of 0.17 μm D^{-1} in myopic LASIK and –0.23 μm D^{-1} in hyperopic LASIK. Total spherical aberration increases at a rate of 0.09 μm D^{-1} in myopic LASIK and –0.06 μm D^{-1} in hyperopic LASIK. The inset depicts the fourth-order spherical-aberration Zernike term. From Llorente, L., Barbero, B., Merayo, J., and Marcos, S. (2004). Changes in corneal and total aberrations induced by LASIK surgery for hyperopia. *Journal of Refractive Surgery* 20: 203–216.

Causes for Spherical Aberration Increase Following Corneal Refractive Surgery

The causes for the increase of spherical aberration (and corneal asphericity) are still not well understood. Computer simulations of the postoperative corneal shape following subtraction of the standard ablation pattern (Munnerlyn equation) performed on real preoperative corneal elevation maps do not show the increased corneal asphericity found clinically. A parabolic approximation of this equation induces a slight increase of corneal asphericity, but much less than is found experimentally. It is likely that much of the discrepancy is due to the fact that the energy is not properly transferred onto the cornea, due to changes in laser efficiency across the corneal surface. Several authors have derived theoretical expressions (based on the Beer–Lambert law and Fresnel equations) to account for the laser-energy losses from the center to the periphery of the cornea. **Figure 6** depicts average results on 13 patients of postoperative corneal asphericities following computer simulation of the Munnerlyn ablation pattern (and its parabolic approximation), directly or considering laser-efficiency changes across the cornea (based on the equations proposed by Jiménez and colleagues), in

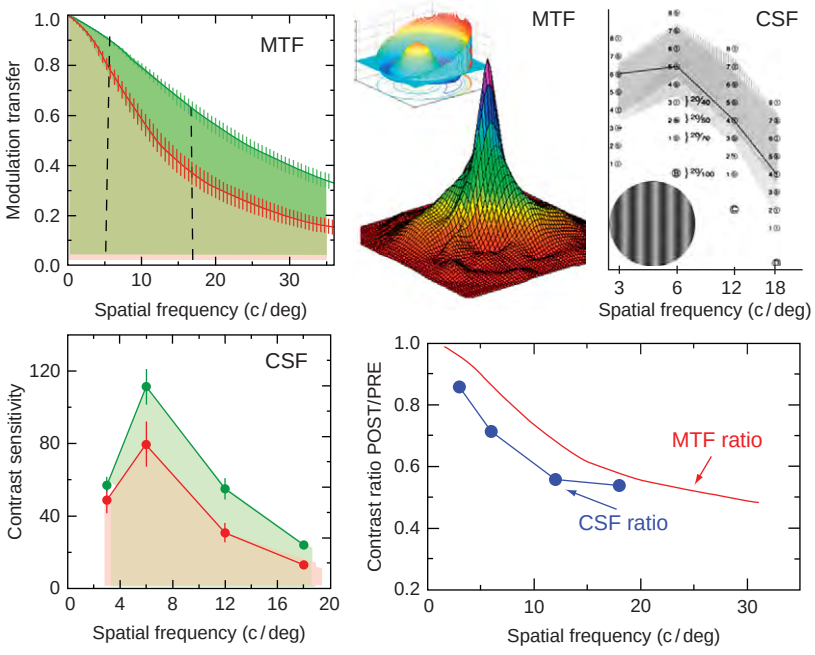

Figure 5 Illustration of the estimation of the MTF from the measured wave aberration, and of the measured CSF, using a clinical gold standard (CVS1000, Vectorvision), in the upper-right panel. Average preoperative MTF (in green) and postoperative MTF (in red), horizontal sections, in the upper-left panel. Average preoperative CSF (in green) and postoperative MTF (in red) for vertical gratings, in the lower-left panel. The area under the curve (shaded in green and red, respectively) between 3 and 18 c/deg was used as a metric for optical quality. The ratio of the area under the MTF decreased by a factor of 1.38, and under the CSF by a factor of 1.51 – indicating that the optical changes have a similar visual impact. The lower-right panel shows the ratio of the MTF and the CSF post/pre as a function of spatial frequency. The drop in contrast follows the same trend for both the MTF and the CSF. Data are average of 22 eyes that had undergone refractive surgery for myopia (between –2.5 and –13 D spherical correction), for undilated pupils. Marcos, S. (2001). Aberrations and visual performance following standard laser vision correction. *Journal of Refractive Surgery* 17: 596–601.

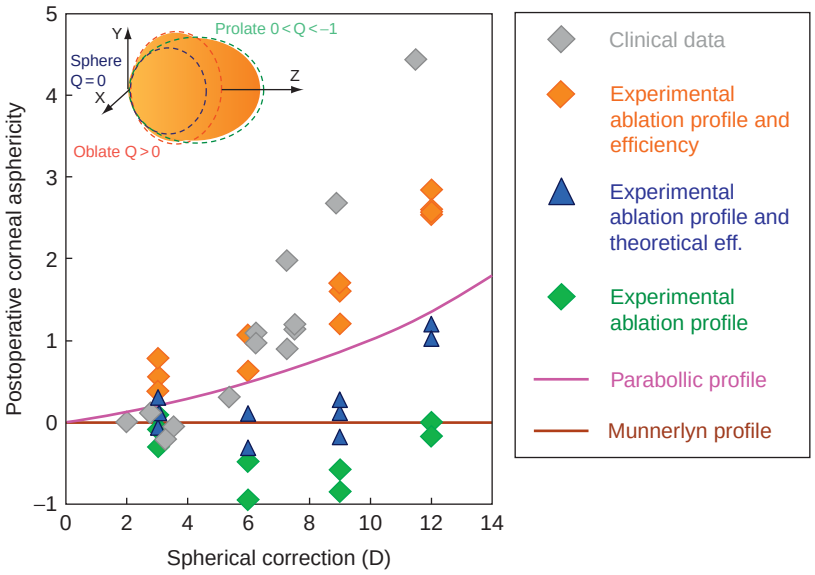

Figure 6 Postoperative corneal asphericity following LASIK surgery for myopia as a function of preoperative spherical error. The graph shows experimental postoperative data from patients – estimations from a virtual surgery using the experimental ablation profile measured on PMMA flat surfaces (and a conversion factor from PMMA to cornea) and an experimentally measured laser-efficiency factor (which takes into account the energy loss from the center to the periphery), estimations from a virtual surgery using the experimental ablation profile and a theoretical laser-efficiency factor, estimations from the experimental ablation profile, the Munnerlyn profile, and its parabolic approximation without considering laser-efficiency losses. From Cano, D., Barbero, B., and Marcos, S. (2004). Comparison of real and computer-simulated outcomes of LASIK refractive surgery. *Journal of the Optical Society of America A* 21: 926–936. and Dorronsoro, C., Cano, D., Merayo, J., and Marcos, S. (2006). Experiments on PMMA models to predict the impact of corneal refractive surgery on corneal shape. *Optics Express* 14: 6142–6156.

comparison with average preoperative asphericities and real postoperative asphericities in the same eyes.

An interesting approach to the understanding of the induction of spherical aberration is the ablation of plastic spherical surfaces, which are subject to geometrical effects but not biomechanical response. Ablation of poly(methyl methacrylate) (PMMA)-model eyes produces an increase in spherical aberration, similar to the increase found in real corneas. In addition, a comparison of the ablation profile of flat and spherical surfaces allows direct estimation of the laser-efficiency losses on PMMA, which can be extrapolated to corneal tissue, without relying on the exact knowledge of the ablation profile programmed into the laser system, and without the approximation of the theoretical approaches. Figure 6 shows estimated postoperative corneal asphericities following direct subtraction of the ablation profile obtained experimentally from profilometry of flat plastic surfaces and also considering the experimental efficiency factor.

Corneal Biomechanical Effects in Refractive Surgery

Although not fully understood, it seems clear that the biomechanical properties of the cornea change following refractive surgery. RK relied fully on the mechanical relaxation of the cornea following incisions. During PRK, LASIK, or any other procedure involving central ablation, corneal lamellae are severed. In a simple elastic shell model, if considered alone, this would result in corneal steepening. However, it has been suggested that a lamellar tension relaxation in the peripheral stroma occurs which produces a compression of the anterior cornea and central flattening. The elastic modulus of the residual stromal bed and the corneal shear strength likely change following surgery, as the cohesive forces among lamellae, stromal swelling pressure, are affected by the procedure. These effects have a potential relevance in the pathogenesis of ectasia, characterized by a progressive thinning and a progressive central and inferior steepening of the cornea, affecting 0.3% of the LASIK patients, although a careful identification of patients with preexisting corneal pathology (keratoconus) and reducing the risk of mechanical instability by leaving a minimal residual stromal thickness (of 300 μm or more) has proved to reduce the occurrence of corneal ectasia greatly. The change in the dynamical response of the cornea, inherent to its biomechanical properties, also affects the measurement of intraocular pressure with standard tonometers, which assume normalized values of corneal elasticity.

Other Side Effects and Complications of PRK and LASIK

Apart from the indicated increased aberrations (resulting in halos and ghost images), haze and loss of best-corrected

contrast sensitivity, other potential complications may occur during or following surgery. The most common side effect from refractive surgery is dry eye (occurring in 36% of patients), diffuse lamellar keratitis (2.3%), flap complications including slipped flap, debris or growth under flap and flap striae (0.244%), infection (0.4%), epithelial ingrowth (0.1%), glare, and light sensitivity.

Safety, Efficacy, and Satisfaction of LASIK

An average of 700 000 patients in the US undergo LASIK annually. To date, more than 28.3 million LASIK procedures have been performed worldwide. Collectively, 7830 patients (representing 16 502 eyes) participated in clinical trials from 1993 to 2005. In April 2008, the Food and Drug Administration (FDA) reaffirmed the safety and efficacy of the LASIK procedure. Although the number of patient complaints has increased in the last few years, the postoperative visual outcomes have improved in the most recent studies. In FDA studies recruiting patients that had undergone surgery prior to 2000, 1.4% of patients lost two lines or more of best spectacle-corrected visual acuity (BSCVA) versus 0.6% in studies after 2000. Prior to 2000, 1.68% of patients with a preoperative BSCVA 20/20 or higher had a postoperative BSCVA 20/25 or higher, compared with 0.16% after 2000. The surveys determining patient satisfaction with LASIK have found most patients satisfied, with satisfaction ranging between 92% and 98%. A meta-analysis – dated March 2008, performed by the American Society of Cataract and Refractive Surgery over 3000 peer-reviewed articles published over the past 10 years in clinical journals from around the world, including 19 studies comprising 2200 patients – that looked directly at satisfaction, revealed a 95.4% patient satisfaction rate among LASIK patients worldwide.

Toward an Optimization of the Corneal Refractive Surgery Procedure

Recent technological advances in refractive surgery include high-frequency eye-tracking, improved laser-delivery systems, and flap creation by femtosecond lasers. The availability of clinical aberrometers, and flying spot technology, led to the development of wave-front-guided ablation profiles – aiming not only at correcting defocus and astigmatism, but also the eye's high-order aberrations. However, major efforts must still focus on preventing the induction of high-order aberrations (particularly spherical aberration) by the procedure, particularly as these are not necessarily

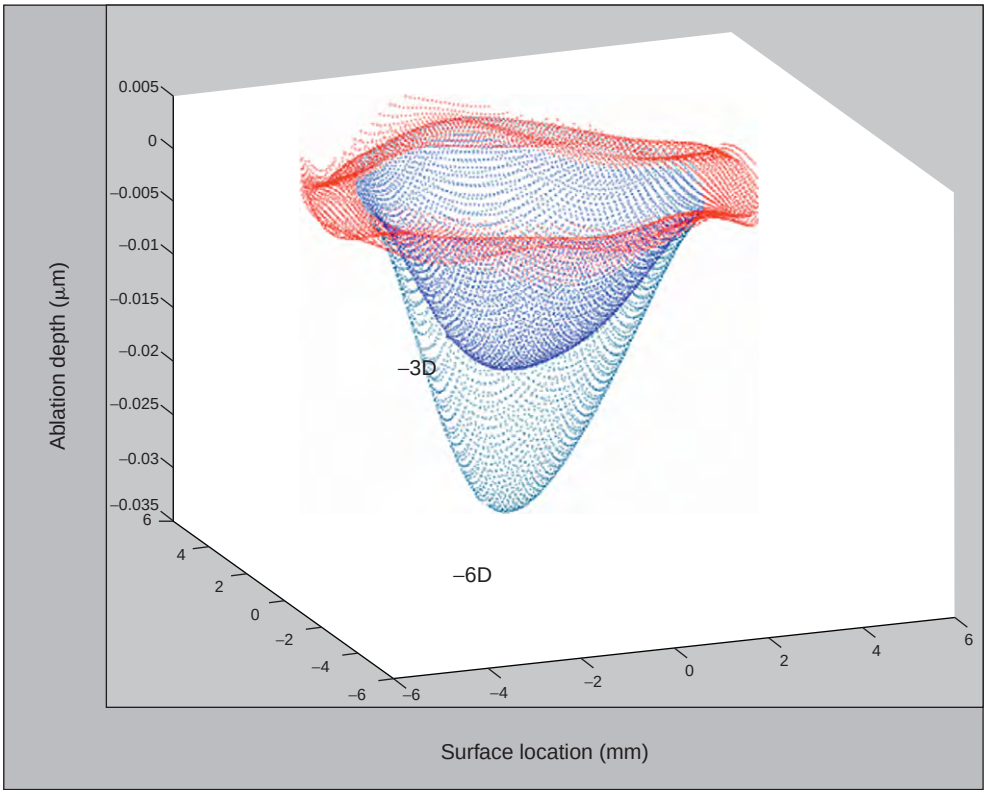

Figure 7 Ablation profiles –6 and –3 D spherical corrections measured experimentally by subtraction of pre- and postablation corneal topographies of PMMA corneal models. From Dorronsoro, C., Cano, D., Merayo, J., and Marcos, S. (2006). Experiments on PMMA models to predict the impact of corneal refractive surgery on corneal shape. *Optics Express* 14: 6142–6156.

inherent to ablation algorithm (despite its simplicity, the standard Munnerlyn algorithm does not induce spherical aberration). Approaches range from theoretical correction of the ablation profile to empirical adjustment of the attempted corneal asphericity. Undoubtedly, a proper characterization of the ablation algorithm, and a calibration of the ablation pattern created by the laser is critical to achieve the desired postoperative corneal shape. Plastic models (in PMMA, and, more recently, a semi-rigid contact lens material – Filofocon A) have been proposed as calibration models for refractive surgery, and their ablation properties have been thoroughly studied. **Figure 7** shows an example of the ablation profile recorded on a plastic material and measured using noncontact profilometry. To date, empirical adjustments of the ablation normogram have – based on population average data – compensated for deviations from ametropia systematically found following surgery. However, customized corrections require a deeper knowledge of ablation, physical effects of the role of corneal hydration, and of the contribution of corneal biomechanical effects and their inter-individual variations on the refractive and high-order aberration outcomes. A fine control of the ablation profile and the biomechanical response will likely expand the range of applications of refractive surgery into presbyopic treatments. As an emerging technology, corneal collagen cross-linking is starting to be applied following refractive surgery as a way to control corneal ectasia by increasing corneal stiffness.

Other technologies further in the track include solide-state ultraviolet (UV) lasers and femtosecond lasers. Diode-pumbed UV laser, using a solide-state laser crystal as the laser medium and nonlinear crystals for frequency conversion instead of the high-voltage gas discharge of excimer lasers, are a safer, more stable, compact, and less expensive alternative to gas-operated excimer lasers. On the other hand, femtosecond lasers use ultrashort pulses (as opposed to pulse durations in the range of nanosecond or picosecond in excimer lasers) which allow laser–tissue interactions characterized by significantly smaller and more deterministic photodisruptive energy thresholds, as well as reduced shock waves and smaller cavitation bubbles, which result in smoother surface quality. Lamellar procedures (keratomileusis) as well as lenticule removal are envisaged with this procedure.

Refractive Surgery and Inlays

R M M A Nuijts, M Doors, N G Tahzib, and L P J Cruysberg, University Hospital Maastricht, Maastricht, The Netherlands

Glossary

Astigmatism – A refractive defect in which vision is blurred due to the inability of the optics of the eye to focus a point object into a sharp, focused image on the retina due to an irregular or toric curvature of the cornea or lens.
Cycloplegic refraction – A measurement of the refractive state of the eye without the effects of accommodation. A cycloplegic drop is used to temporarily paralyze the accommodation muscle.
Corneal ectasia – A serious complication involving a cone-like bulging of the cornea following its weakening during laser *in situ* keratomileusis (LASIK).
Diffuse lamellar keratitis – Noninfectious inflammatory complication of LASIK.
Form fruste keratoconus – An abortive form of bulging of the cornea.
Hyperopia – Refractive defect caused by an eye that is too short or a cornea that is too flat, so that images focus at a point behind the retina. It is also called farsightedness.
Intracorneal ring (IRC) – Small ring inserted into the periphery of the cornea to change its shape and correct nearsightedness.
Laser-assisted subepithelial keratectomy (LASEK) – A refractive surgery where only the corneal epithelia is cut to reshape the cornea.
Laser *in situ* keratomileusis (LASIK) – A refractive surgery where the corneal epithelia and stroma is cut to reshape the cornea.
Manifest – Easily seen.
Myopia – Refractive defect of the eye where the light focuses in front of the retina rather than on the retina. It is also called nearsightedness.
Photorefractive keratectomy (PRK) – A refractive surgery where the corneal epithelia is removed to reshape the cornea.
Presbyopia – Reduced ability to see near objects caused by loss if the elasticity of the lens.
Radial keratotomy (RK) – Surgical procedure to correct myopia where radial incisions are made into the cornea at precise depths allowing the sides of the cornea to bulge out and flatten the central cornea.

Introduction

Corneal refractive surgery offers the patient the possibility of becoming independent of spectacles and/or contact lenses. The attainment of this treatment goal is of particular importance to individuals who are restricted in their professional and social life by their contact lens or spectacle intolerance. The developments and outcomes of various refractive surgery techniques have received increasing attention in the medical literature and public media. This phenomenon is mainly related to the numerous success stories and the dramatic changes achieved by correction of the refractive error and the resultant independence of spectacles and contact lenses.

Numerous corneal refractive surgery techniques are available for the correction of refractive errors, with the majority of treatments consisting of myopic and myopic–astigmatic corrections. The field of refractive surgery has greatly evolved since the commencement of excimer laser treatments and surgical implantations of corneal inlays. The techniques have been refined and are continually evolving to be more specifically directed toward the individual optical design. The optical system can differ greatly between individuals and depends on various factors, such as the amount of the refractive error and the degree of optical aberrations. Therefore, laser-ablation techniques have changed from the standard correction of the refractive error to personalized and optimized laser treatments and from broad-beam to scanning-spot or flying-spot devices.

This article presents an overview of the available corneal refractive procedures and their outcomes.

Radial Keratotomy

Prior to the popularity of excimer photoablative refractive surgery, the technique of radial keratotomy (RK) was among the most widely used surgical techniques for the correction of myopia. RK involves making deep radial incisions in the paracentral and peripheral anterior cornea using a diamond blade knife. The technique results in the flattening of the central corneal curvature and steepening of the peripheral area, which reduces the degree of myopia.

The number of RK incisions, diameter of the optic zone, and patient age determine the refractive outcome after RK. Incision direction was shown to be another predictor, with

the centripetal (vs. the centrifugal) incision decreasing myopia to a higher degree.

Although the treatment by RK initially resulted in satisfactory refractive results, it appeared not to be as predictable as current refractive surgery techniques. The Prospective Evaluation of Radial Keratotomy (PERK) study was a nine-center clinical trial which analyzed the long-term (10-year) effects and stability of myopic RK (with a range of −2.00 to −8.75 diopters (D)). They showed that 53% of eyes achieved an uncorrected visual acuity (UCVA) ≥20/20, and 85% of eyes achieved UCVA of ≥20/40. They also showed that 38% of eyes had a refractive error within ±0.50 D and 60% ± 1.0 D of the intended correction.

A common and challenging side effect of RK was the development of secondary and progressive hyperopia. This hyperopic shift occurred in 43% of reported cases, with an additional incidence of 1–2% annually. A less common side effect following RK is the development of irregular astigmatism, which can be induced by the intersection of the incisions with the visual axis or by the eccentricity of the optical zone. Some other side effects are fluctuating vision and glare.

Apart from treating myopia, RK has also been used for the correction of astigmatism (also known as arcuate keratotomy), although the predictability of this technique is known to be slightly less than that for the correction of myopia. The procedure has been shown to be an effective and safe method for correcting moderate to severe naturally occurring astigmatism.

The popularity of RK has declined since the approval of the excimer laser in 1995, due to the superior outcomes of photorefractive keratectomy (PRK) and LASIK. However, keratotomy techniques (arcuate keratotomy and limbal relaxing incisions) are still used for the treatment of astigmatism in cataract surgery and in postsurgical patients.

Photorefractive Keratectomy

In the early 1990s, PRK was the main treatment for low-to-moderate myopia. This technique went through various developments, varying from laser systems, to treatment algorithms, to the choice of transition and ablation zones. The treatment involves the use of a far-ultraviolet (193-nm) argon fluoride excimer laser, which permanently removes the most anterior portion of the corneal stromal tissue in a very precise manner. The ablation occurs with minimal damage to the adjacent corneal tissue. Prior to the performance of the laser-ablation procedure, the corneal epithelium is removed – either manually with a blade or a rotating brush or after alcohol administration. Afterward, a bandage contact lens is applied on the treated corneal surface.

Short-term problems following PRK include discomfort in the first 24 h; a delay in visual recovery lasting 3–5 days during epithelial healing; and a loss of corneal transparency – also called haze – lasting weeks to months following the procedure. PRK ablations often show an immediate postoperative hyperopic shift, due to a thinner epithelium. The hyperopic shift is often compensated by a period of regression that stabilizes between 1 and 6 months. Refractive stability after PRK is generally achieved after 6 months to 1 year and is maintained for up to a period of 5 years.

Long-term studies on the outcome of PRK found no evidence of progressive time-dependent hyperopic shift or late regression, with trace haze in 4% after 12 years with no loss of best-corrected visual acuity (BCVA). In general, corneal haze was transient and decreases rapidly 1 year after treatment.

Laser *in situ* Keratomileusis

The technique of LASIK was first described in 1991. The surgical technique includes the creation of an epithelial-stromal flap using a microkeratome. The flap is attached to the periphery of the cornea by a hinge of uncut tissue and has a diameter of 8–10 mm. When using the mechanical microkeratome, the thickness of the flap ranges between 130 μm (with the newest microkeratomes) and 180 μm (with the older microkeratomes). Subsequently the flap is peeled back and ablation of the corneal stroma is performed using an excimer laser. Following the photoablation, the flap is repositioned on the treated corneal stroma (**Figure 1**). The introduction of this technique meant a major change in the field of refractive surgery. The side effects associated with PRK made LASIK treatment the leading procedure in refractive surgery. The popularity of LASIK is related to the relatively fast visual recovery time, minimal discomfort immediately following treatment, and the minimal incidence of haze.

For low-to-moderate myopia (less than 6 D), LASIK has proven to be very effective, predictable, and safe – achieving an UCVA of 20/40 or more in 86–100% of eyes and an UCVA of 20/20 in 45–94% of eyes. The technique has shown to achieve a very accurate correction, with 71–96% of eyes achieving a refractive error within ±0.50 D of the intended correction and 88–100% of eyes within ±1.00 D of the intended correction. For moderate-to-high myopia (>−6.0 D), the results show more variation.

Since PRK and LASIK candidates typically have healthy eyes, achieving and maintaining high levels of (subjective) satisfaction after surgery are very important. In 2005, a clinical study showed that the overall patient satisfaction

Figure 1 Schematic LASIK-procedure: first the creation of the flap after which the flap is peeled back, then eximer laser ablation of the corneal stroma, and third repositioning of the flap on the treated corneal stroma.

following LASIK treatment was 4.10 ± 0.71 (a score of 5 meaning that the patient was totally satisfied). Patients are generally very satisfied with their uncorrected vision, visual recovery, and quality of life following LASIK treatment, with the majority of patients reporting that they would have the surgery again (92.3%), if required.

Myopic regression is a condition that can occur after LASIK. The risk of myopic regression increases with the degree of preoperative myopia and patient age. Long-term studies on LASIK for treatment of moderate and extreme myopia showed a trend toward myopic regression, changing from 52–96% of eyes within ±1.0 D of the attempted correction after 1 year to 46–91% after 5–6-years follow-up. In contrast, LASIK studies with lower degrees of preoperative myopia (<−6.0 D) show stable visual results during long-term follow-up.

Although the risks associated with LASIK are considered to be low, intraoperative and postoperative flap-related complications are sight threatening and have resulted in a permanent loss of BCVA. The overall incidence of intraoperative LASIK-flap complications – such as incomplete flaps, buttonholes, free caps, and torn flaps – is approximately 4%. Postoperative flap-related complications include diffuse lamellar keratitis, infection, spontaneously or trauma-related flap displacement, and epithelial ingrowth.

Furthermore, LASIK may cause (transient) dry eyes, which may be related to the neurotrophic effects of cutting the nerves during the creation of the flap. It tends to resolve 6–9 months following LASIK treatment, as the nerves grow back into the flap.

Despite the aim of many surgeons to keep the residual corneal thickness of the stromal bed at least 250 μm, postoperative corneal ectasia (dilation) may occur following LASIK treatment. This rare, but important, complication seems to be related to biomechanical changes in the cornea after treatment and occurs at rates much lower than 1%. Risk factors that might contribute to the development of ectasia following LASIK have been suggested to be: high intraocular pressure, irregular topography, thin corneas, thin remaining corneal beds, forme fruste keratoconus, thick corneal flaps, large optical zones, and, possibly, high myopia.

Laser-Assisted Subepithelial Keratectomy

LASEK aims to preserve the original anatomy of the cornea and to avoid potential risks posed by the creation of a LASIK flap. The treatment is, in fact, a blend of PRK and LASIK, aiming to decrease the potential complications of the two treatments. In LASEK treatment, diluted ethanol solution is applied to loosen the corneal epithelium, following which the epithelium is partially removed from Bowman's layer, leaving it connected only at a hinge. Laser treatment is applied directly to Bowman's layer, and afterwards the epithelial sheet is placed back over the treated stroma. The eye is covered by a bandage contact lens to prevent movement of the epithelial flap due to blinking and eye movements.

LASEK does not have the risk of flap-related complications such as with LASIK, because LASEK can easily be converted to the PRK procedure if the epithelial flap tears or breaks. Furthermore, a larger residual bed is created – which retains the cornea's biomechanical strength and reduces the risk of corneal ectasia associated with LASIK. One of the main therapeutic advantages of LASEK is that it can be performed in cases in which LASIK may be contraindicated. These include eyes with thin, steep, and flat corneas; epithelial basement-membrane dystrophy; large pupils (requiring wider and, therefore, deeper ablations); higher myopia; and deep-set eyes or tight orbits.

Reports have shown that LASEK is a safe, effective, and predictable treatment, which can be seen as a good alternative to LASIK and PRK for the surgical correction of myopia. A major review of the literature showed that 95% of eyes achieved an UCVA ≥ 20/40 and 74% ≥20/20. Seventy-four percent of eyes achieved a refraction within ±0.5 D of the desired refraction and 90% of eyes were within ±1.0 D of the desired refraction. Loss of two or more lines of BCVA was demonstrated in 2% of eyes.

Comparing LASEK with PRK and LASIK, it has been indicated that the recovery period following LASEK is shorter than that following PRK, but might be somewhat slower than that following LASIK. Discomfort following LASEK seems to be less than after PRK, which is probably

related to the fact that the epithelial flap acts as a biological therapeutic lens that protects the ablated stroma. However, other studies have demonstrated that the epithelial flap is probably not viable, is replaced by regenerated epithelial cells, and, as such, does not provide advantages in comparison to PRK.

The biological properties of the epithelium might inhibit haze formation following the LASEK treatment. Furthermore, the procedure can be combined with the use of mitomycin-C (MMC) – a cytostatic drug known to inhibit proliferating cells and can be used to prevent postablation corneal haze in high-risk cases, such as in patients requiring retreatment.

Epithelial Laser *in situ* Keratomileusis (epi-LASIK)

Epi-LASIK uses a modified microkeratome (epikeratome) to create a thin corneal epithelial flap before surface ablation is performed. The blade and the angle of cutting of the epikeratome are optimized for a subepithelial dissection, which does not disrupt the corneal stroma such as the LASIK microkeratome. The difference between epi-LASIK and LASEK is that the separation of the epithelium is obtained mechanically without the use of alcohol. Epi-LASIK has been proposed as a safe alternative to LASIK and is especially suitable for patients with low-to-moderate myopia and myopic astigmatism, thin corneas, and in individuals with steeper or flatter corneas, where the cutting of a LASIK flap could potentially impose flap-related complications. The healing period and visual recovery tends to be slower than traditional LASIK. Postoperative discomfort usually occurs within the first 48 h after surgery.

A recent study presented the 1-year results of epi-LASIK and stated that this technique is a safe and efficient method for the correction of low and moderate myopia, demonstrating that all of the eyes treated reached an UCVA of 20/40 or better and 86% an UCVA of 20/20 or better. More than 80% of eyes were within 0.5 D of the attempted correction and 97% were within 1 D of the attempted correction.

In comparison with LASEK, it has been suggested that the incidence of haze following ablation of the cornea is lower with epi-LASIK. Longer-term clinical studies are needed to confirm the reported results on epi-LASIK.

Femtosecond Laser *in situ* Keratomileusis (FS-LASIK)

At the beginning of this century the femtosecond laser, which creates a corneal flap by vaporizing small volumes of tissue using micro-photodisruption at a predetermined depth, was introduced. Furthermore, when using the femtosecond laser, the flap thickness is much more accurate and thinner (between 90 and 110 μm) than with the excimer laser. The corneal flaps can also be customized with a variable flap thickness and diameter based on the requirements of the patient.

The greatest benefit of these thinner femtosecond-created flaps is that they result in a greater stability of the cornea when compared to mechanically created flaps. It has been described that the greatest strength of the cornea lies within the first 150 μm of the cornea. Thus, thinner flaps will help to protect the integrity of the cornea and will lead to thicker residual stromal beds, which results in a decreased risk of corneal ectasia. Studies have shown that flaps created with a femtosecond laser provide better visual results than flaps created with a microkeratome. Furthermore, FS-LASIK demonstrates better visual outcomes than PRK in the first 6 months of follow-up. Following this period, both treatments show similar visual results. As for epi-LASIK, long-term follow-up studies are required to demonstrate the efficacy and safety of FS-LASIK.

Potential limitations of the femtosecond laser include increased costs of the procedure, increased surgical time, and a higher incidence of diffuse lamellar keratitis. The use of topical corticosteroids keeps the last complication at manageable levels. Furthermore, the newer high-frequency femtosecond lasers will probably diminish the incidence of diffuse lamellar keratitis.

Treatment of Hyperopia

Photorefractive keratectomy, LASIK, and LASEK can also be applied for the treatment of low hyperopia (<2 D). In hyperopic treatments, most of the laser ablation is located at the periphery of the treatment zone. Mechanical weakening of the peripheral cornea might lead to a forward-bowing of the central cornea, which increases the intended laser effect. These biomechanical changes and a different wound healing cause increased levels of regression following the hyperopic treatment. Therefore, only low levels of hyperopia can be treated using laser refractive surgery.

The Food and Drug Administration (FDA)-approved studies investigating the treatment of low hyperopia using LASIK showed that 90% of eyes achieved a UCVA $\geq$ 20/40 and only 63% a UCVA $\geq$ 20/20. Sixty-seven percent of eyes achieved a refraction within $\pm$0.5 D of the desired refraction and 90% of eyes were within $\pm$1.0 D of the desired refraction. Loss of two or more lines of BCVA was demonstrated in almost 2% of eyes after more than 3 months of follow-up. Hyperopic PRK and LASEK treatments show similar clinical results when compared to hyperopic LASIK treatments.

General Side Effects of Laser Refractive Surgery

Although many developments in keratorefractive surgical techniques have improved the clinical outcome and have shown great success rates, several quality-of-vision problems have been reported. Qualitative visual disturbances can affect patients' daily activities and include subjective complaints such as glare, halos, and difficulty with night driving. These complaints are more likely to occur with laser corrections of more than 7–8 D of myopia or more than 2–3 D of hyperopia and often diminish after the first six postoperative months. Glare, halos, and night-vision complaints may be attributed to a loss of contrast sensitivity or low-contrast visual acuity. These complaints have been described after all refractive surgery techniques, varying in degrees of incidence.

Reports on patient satisfaction following LASIK treatment showed that predictors for night-vision complaints can include:

- preoperative high levels of myopia (more than 5 D),
- advanced age,
- a flatter preoperative corneal curvature,
- surgical enhancements,
- optical zones <6 mm,
- postoperative residual refractive error >0.5 D from emmetropia (normal refraction), and
- postoperative residual cylinder – a type of higher-order aberration (HOA) of the cornea.

Remarkably, pupil size was not shown to be a significant predictor of night-vision complaints in any of these studies. There is variable evidence in the literature on excluding patients based on large pupil size. It has been suggested in the past that a large pupil, in combination with a small optical zone, is a dominant factor leading to increased night-vision complaints. However, other recent studies demonstrate that the correlation between pupil size and night-vision complaints or between night-vision complaints and the pupil–optical zone disparity is much less critical than previously thought. Pupil size seems to indeed be a significant predictor of glare and halos following LASIK, especially in the first postoperative month, yet it was demonstrated that pupil size is not a significant variable 6 or 12 months following treatment. Postoperative remodeling of the corneal shape by the epithelium may be responsible for these findings.

Other common complications of laser refractive surgery include under- and overcorrection (30%), irregular astigmatism (30%), and dry eyes (4–30%, depending on the type of refractive treatment).

Wave front and Laser Refractive Surgery

When applying conventional laser refractive surgery, the ablations are calculated using the data obtained during manifest and cycloplegic refractions. However, HOAs can cause glare and halos and lead to decreased quality of vision. Wave front technology was developed to categorize and limit the amount of HOA induced by refractive surgery. The wave front sensor measures defocus, astigmatism, and total and individual HOA. Customized wave front-guided corneal ablation combines wave front sensing and wave front correction and, therefore, corrects refractive errors beyond spherical and cylindrical errors.

Over the last decade, several clinical reports have studied HOAs in refractive surgery patients. Some of these studies have shown an increase in patient satisfaction, reduced night-vision complaints, and a lower increase of HOA following wave front-guided treatments, compared to conventional ablation; however, more and larger randomized studies are needed to further analyze and validate the results of these treatments. At the present time, it is not clear whether the excellent results are due to an improved postoperative asphericity profile or the consequence of treating the preexistent HOAs.

Corneal Inlays

The use of corneal inlays as a refractive procedure involves the insertion of a synthetic or biological material into the cornea, which changes the refractive power of the eye by either altering the anterior corneal curvature, or the refractive index of the inlay material, or a combination of these two mechanisms. These inlays can be placed in the stroma or beneath the epithelium of the cornea. The main advantage of this technique over the above-mentioned laser refractive treatments is the reversibility of the procedure.

The inlay material has to meet various physical and biological characteristics in order to minimize complications. Biological materials have shown to be biodegradable and insufficiently permeable to maintain a healthy cornea. Furthermore, hydrogel inlays have been demonstrated to be biocompatible but have insufficient porosity to maintain optimal nutrient flow. Many complications, including corneal haze, epithelial thinning, inlay encapsulation, epithelial opacification, corneal vascularisation, inlay decentration, and fibrosis, have been reported following the implantation of corneal inlays.

At present, a phase 1 trial is being conducted using a synthetic corneal inlay made of a polymer of perfluoropolyether, which is placed into the stroma following the creation of a corneal flap with a microkeratome. The study involves implantation of the inlays in unsighted eyes. Despite the experimental phase of these synthetic inlays, it is believed that they might meet all the required physical and biological characteristics which will help minimize the above-mentioned complications.

Corneal inlays have been developed not only to correct myopia and hyperopia, but also to correct presbyopia.

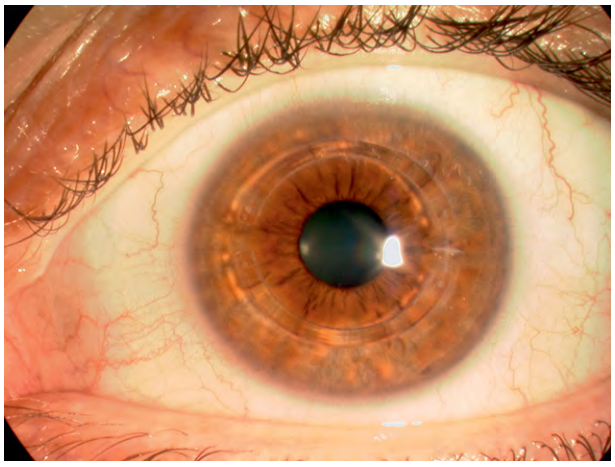

Figure 2 Patient with two intracorneal ring segments (Intacs).

These presbyopic inlays are designed to be implanted in the nondominant eye and have a pinhole optic, which increases the depth of focus. They are currently under investigation in the United States and Europe.

Intracorneal Rings (ICR)

Since 1999 the use of ICR segments, also known as Intacs, has been approved by the United States FDA for the correction of low myopia (less than 4 D) and low astigmatism ($\leq$1 D). These ring segments are curved and made of polymethylmethacrylate. They can be inserted into the peripheral cornea through corneal channels, which are created by a microkeratome or by a femtosecond laser, at about 70% of the corneal depth (**Figure 2**). They aim to expand and flatten the corneal surface.

ICR have some important advantages over laser refractive surgery: there is no abrasion of the cornea, less risk of corneal haze or scarring, the visual axis is spared from treatment, there is no flap creation and, therefore, no flap-related complications, and the procedure is reversible.

Complications following ICR implantation include induced astigmatism – which is the most common complication – extrusion of the ring, dry eye syndrome, and infectious keratitis.

In the treatment of low myopia, the visual results of ICRs seem to be similar to the results following laser refractive surgery. However, ICRs are mainly used to improve visual outcomes in patients with keratoconus, post-LASIK ectasia, or other ectatic disorders.

Conclusion

In conclusion, for the treatment of patients with low-to-moderate myopia, PRK, LASIK, and LASEK have all shown to produce stable and predictable results with an excellent safety profile. Patient selection is crucial to ensure high postoperative patient satisfaction and to diminish the risks of adverse effects. LASIK has the advantage of rapid visual recovery and minimal discomfort and, therefore, has become the most widely performed refractive surgery technique, associated with high patient satisfaction. However, mechanical microkeratome-assisted LASIK displays more complications due to the creation of a flap and might cause more induced HOAs, which is why some surgeons have switched to PRK or LASEK. In the near future, FS-LASIK might become the recommended treatment, but a longer follow-up is needed to ensure long-term stability and safety.

Regulation of Corneal Endothelial Cell Proliferation

Q Lu, T A Fuchsluger, and U V Jurkunas, Schepens Eye Research Institute, Boston, MA, USA

Glossary

Cell cycle – Series of events that occur in order for a cell to divide. This cycle is divided into phases where the G0 (gap 0) is resting or quiescent phase; G1 (gap 1) is the synthesis of enzymes necessary for DNA replication; S phase is when DNA synthesis occurs; G2 (gap 2) phase involves the production of microtubules; M phase is the division of the cell into daughter cells.
Corneal dystrophies – Conditions in which the cornea is altered without the presence of any inflammation, infection, or other eye disease.
Cyclins and cyclin-dependent kinases (CDKs) – Cyclins act as the regulatory subunits while CDKs act as the catalytic subunits of an activated heterodimer. Neither cyclins nor CDKs are active in the absence of one another. CDKs are constitutively expressed in cells, whereas cyclins are synthesized at specific stages of the cell cycle, in response to various molecular signals.
Descemet's membrane – A specialized form of extracellular matrix separating corneal endothelial cells from corneal stroma.
E2F – A group of genes that encodes a family of transcription factors.
Epidermal growth factor (EGF) – Compound that promotes cell growth and differentiation.
Mitogen – A chemical substance that induces cell division.
Retinoblastoma gene – A gene whose protein is dysfunctional in many types of cancer.
Tight junction – A junction between two cells composed of the junctional membrane. This acts as a selective barrier to small molecules and as a total barrier to large molecules.
Transforming growth factor (TGF) – Used as a polypeptide growth factors, TGF is produced in many cell types and is involved in cellular development.

Background

Mammalian corneal endothelial cells (CECs) are derived from neural crest cells of mesenchyme and form a monolayer in the inner portion of the cornea (**Figure 1**). The corneal endothelium is attached to the Descemet's membrane (DM) and is in direct contact with the aqueous humor. Its main function is to maintain corneal transparency by regulating corneal hydration. CECs contain numerous Na^+–K^+-adenosine triphosphatases (ATPases) that pump fluid out of the stroma to counteract the corneal tendency to swell. In addition, tight junctions between the CECs provide a barrier that prevents the influx of fluid from aqueous humor into the stroma. CEC number gradually declines with age (**Figure 2**). Since CECs do not proliferate *in vivo* and have a limited ability to regenerate, the loss of endothelial cells is permanent. Certain corneal pathologies, such as dystrophies, infections, and trauma, can lead to an accelerated loss of CECs and a compromise in the endothelial cell layer integrity. As a result, the cornea is unable to maintain its water balance and corneal edema ensues, clinically resulting loss of clarity and a decline in visual acuity.

Cell Cycle Progression, G1/S Transition and its Cell Cycle Regulators

Mammalian cell cycles can be divided into four phases, including G1 phase (gap phase 1), S phase (DNA synthesis), G2 phase (gap phase 2), and M phase (mitosis). The entire process of cell cycle progression is controlled by a variety of regulatory proteins (**Figure 3**). Among them, cyclin-dependent kinases (CDKs) are the engine cores that promote cell cycle progression. CDKs generally remain at a constant level throughout the cell cycle, while their binding partners, cyclins, and post-translational modifiers, kinases and phosphatases, undergo periodic fluctuations throughout the cell cycle. During this process, negative regulatory protein cyclin-dependent kinase inhibitors (CDKIs) also play an important role in cell cycle progression.

During the G1/S transition (**Figure 3**), CDKs 2, 4, 6 and their regulators control the cell transition to the S-phase. Association of CDK4 or CDK6 with D-type cyclins (Cyc D) is critical for G1 phase progression, whereas the association of CDK2 and cyclin E (Cyc E) fosters the initiation of the S phase. Both complexes, Cyc D–CDK4/6 and Cyc E–CDK2, are involved in phosphorylation of retinoblastoma gene (Rb) and a subsequent G1/S transition. During this process, two main families of CDKIs play an important role in regulating G1/S transition: inhibitor of CDK (INK) and CDK-interacting protein/cyclin-dependent kinase inhibitory protein (CIP/KIP). The INK protein, p16, is a

competitive inhibitor of CDK4/6-Cyc D complex, while the CIP/KIP proteins, p21 and p27, serve as competitive inhibitors of CDK2–Cyc E complex. The G1/S phase transition features two consecutive steps: (1) Early G1 progression involves mitogen-dependent accumulation of cyclin D, sequestration of p21, and cyclin D-dependent phosphorylation of retinoblastoma gene (Rb) (2) Late G1 progression depends on phosphorylation and degradation of p27 and additional phosphorylation of Rb by Cyc E/CDK2. Full phosphorylation of Rb leads to its dissociation from E2F and ultimately activation of E2F, which is a main transcription factor involved in the G1/S transition (**Figure 3**).

G1 Phase Cell Cycle Arrest in CECs *in vivo*

Human corneal endothelial cells (HCECs) do not divide *in vivo* sufficiently to replenish lost cells due to aging, trauma, or disease. HCECs exhibit no positive staining with Ki67, a marker of actively cycling cells. However, HCECs exhibit *in situ* staining with the key cycle cell regulators, such as cyclins D, E, and A. Such staining pattern which is similar to the one seen in limbal epithelium known to contain slow-cycling stem cells, points to the fact that CECs are arrested in the G1 phase rather than having permanently exited from the cell cycle. Possible mechanisms accounting for such G1 phase cell cycle arrest are contact inhibition, interaction with the extracellular matrix (ECM), and presence of transforming growth factor (TGF)-β2 in the aqueous humor (**Figure 4**).

Cell–Cell Contact Inhibition

Contact-dependent inhibition of cell proliferation is a well described phenomenon. In corneal endothelium, majority of studies on cell–cell contact inhibition have been performed in neonatal rats, since rats have an immature corneal endothelium at birth, unlike the other species. In neonatal rats, the number of CECs staining positively for bromo-deoxyuridine (BrdU), an S-phase marker, gradually decreased between postnatal days 1 and 13. After postnatal day 13, positive BrdU staining was no longer detectable. Stable cell–cell and cell–substrate contacts gradually formed, and monolayer maturation was complete between postnatal days 14 and 21. These studies showed a correlation between decreased proliferation and increased monolayer formation, underlying the importance of cell–cell contact inhibition in the maturation of endothelial monolayer.

Consistent with these findings, treatment of corneal endothelial monolayer with ethylenediaminetetraacetate (EDTA), a calcium chelator which releases cells from

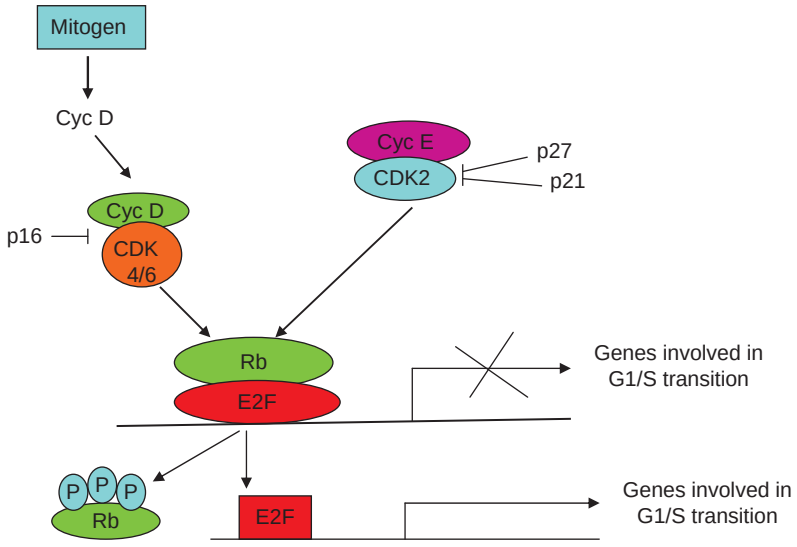

Figure 3 Cell cycle regulators involved in G1/S transition.

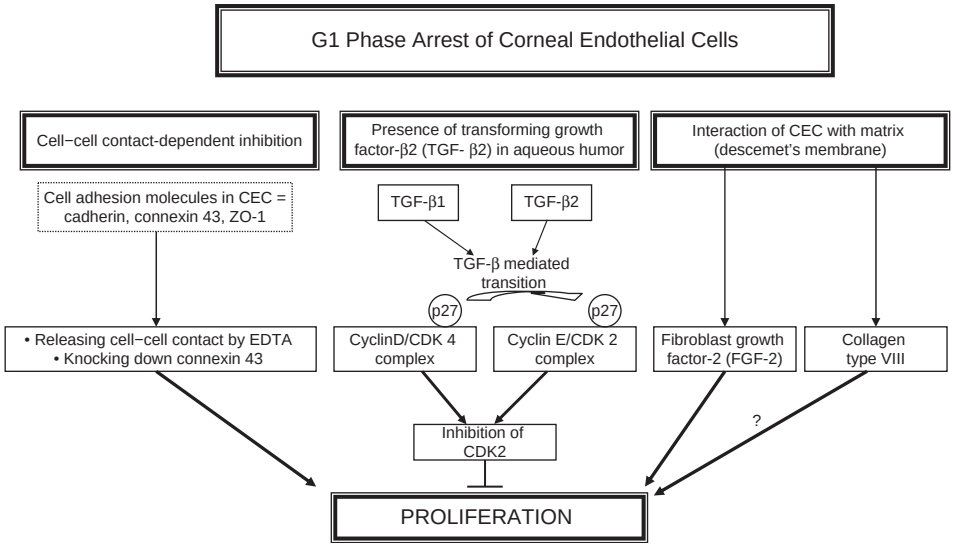

Figure 4 Possible mechanisms involved in G1 phase cell cycle arrest of corneal endothelial cells.

cell–cell contact, has been shown to promote cell proliferation. CEC proliferation can be regulated by calcium levels due to the presence of several cell adhesion proteins that are calcium sensitive and maintain cells in the state of contact inhibition. The main cell adhesion molecules involved in CEC physiology are cadherins, zonula occludens, and connexins (Cx). Exposure of CECs to calcium-free medium resulted in loosening of apical junctions, loss of barrier function, and corneal edema. This effect was reversible by exposing the endothelial cells to calcium. The attempts to break these intercellular interactions have been successful in promoting endothelial cell proliferation, and providing promise to regenerating CEC in traumatic and degenerative situations. These findings indicate that cell–cell contact inhibition may play an important role in the growth arrest status of CECs.

It was demonstrated that knocking down one of the major connexins, Cx43 resulted in a significant increase in the number of actively proliferating CECs. Using the rat model, corneal endothelial scrape injuries were simultaneously applied with Cx43 antisense oligodeoxynucleotide, small interfering RNA, or adenovirus (CMV–Cx43–mRFP1) into the anterior chamber. Changes in Cx43 expression were analyzed by immunolabeling (ZO-1, alpha-smooth muscle actin (SMA), Cx43). While, the endothelial–mesenchymal transition/transformation

after injury was inhibited, Cx43 knock-down induced proliferation of the corneal endothelium.

DNA-binding transcription factors, including the members of the BTB/POZ-zinc finger protein family, might be involved in the signaling pathway of cell–cell contact-induced growth inhibition as well. Among the family members, the promyelocytic leukemia zinc finger protein (PLZF) gene specifically inhibits the transcription of genes involved in G1/S transition, such as cyclin A2 and c-myc. The expression of PLZF is closely related with cell–cell contact. Its expression is high in confluent cells, and treatment with EDTA to disrupt cell–cell contact decreases PLZF messenger RNA (mRNA) levels. Similarly, overexpression of PLZF has been found to inhibit cell proliferation. N-Cadherin is thought to be a potential upstream signaling molecule that regulates PLZF mRNA levels.

Studies showed that p27, a CDKI-type protein, is also involved in the mediation of cell cycle arrest induced by cell–cell contact. Increased expression of p27 in the developing corneal endothelium is well correlated with the cessation of the proliferation in wild-type mice. On the other hand, p27 knock-out mice show prolonged postnatal period of CEC proliferation when compared with their wild-type counterparts. These data indicate that p27 plays an important role in contact-inhibition-mediated growth arrested in CEC.

The Presence of Antiproliferative TGF-β2 in the Aqueous Humor

In many cell types, TGF-β2 inhibits proliferation by inducing G1-phase arrest. CECs are in direct contact with aqueous humor containing TGF-β2. Both exogenous TGF-β2 and active TGF-β2 in rat aqueous humor inhibit S-phase entry in rat CECs. The effect of TGF-β2 may be mediated by CDK4 and p27. In CECs treated with TGF-β2, CDK4 synthesis is inhibited and p27 is mobilized from the cyclin D-CDK 4 complex into the cyclin E-CDK 2 complex to inhibit CDK 2 activity. Furthermore, TGF-β2 prevents phosphorylation of p27 and maintains p27 in an active form.

The Interaction Between CECs and Extracellular Matrix

ECM provides an important microenvironment for cell adhesion, migration, growth, differentiation, and signal transduction. DM is a specialized form of ECM separating CECs from corneal stroma. One difference between infant and adult human corneal DM is that collagen VIII, the major component of DM, shifted from the endothelial face of DM in infant to the stromal side of the DM in the adult. It is not fully understood whether compositional differences of collagen VIII are responsible for the differences in CECs growth potential from young and adult humans. In a mouse model, the complete lack of type VIII collagen leads to dysgenesis (abnormal development) of the anterior ocular segment and enlarged CECs with reduced cell density. Hence, collagen VIII may serve as an important component of matrix that stimulates CEC growth during embryonic development. It is possible that adult DM has structural differences that foster endothelial growth arrest, associated with adult corneas. Proteomic analysis revealed that there is an age-related increase in TGFβ-induced protein content and proteolytic processing of the human corneal endothelium and DM complex.

What Do We Know From Primary and Subcultured CECs

Human and other mammalian CECs can be isolated and subcultured *in vitro*, indicating that endothelium still retains some replicative capacity. Such studies may provide better understanding of the regulatory mechanisms involved in CECs proliferation. Age-related decrease in sensitivity to mitogen or growth factors has been observed in cultured HCECs. It is still controversial whether the corneal periphery has more replicative capacity compared to central region. E2F is a key transcription factor involved in the G1/S transition of CECs, and overexpression of one of its isoforms E2F2 has been shown to promote proliferation. Various upstream signals including protein kinase C (PKC) and fibroblast growth factor (FGF)-2 might also play an important role in the proliferation of cultured CECs.

Age-Related Decrease in Sensitivity to Mitogen or Growth Factors in Cultured HCECs

Donor age negatively affects the proliferative capacity of cultured HCEC. In cultured HCEC a decrease in proliferative capacity is accompanied by changes in morphology and cell density. CECs cultured from older donors show an increase in cell size and a decrease in overall cell density. Different expression levels of cell cycle regulators were studied in cultured HCEC from younger and older donors. Increased expression of CDKIs such as p21 and p16 were seen in HCEC from older donors when compared with those from younger donors. On the other hand, transfection of p27 siRNA was sufficient to promote proliferation in confluent cultures of HCECs from younger (<30 years old), but not from older donors (>60 years old). This suggests that inhibition of proliferation in older donors is regulated by other mechanisms in addition to p27. It is known that an age-dependent increase in expression of negative cell cycle regulators p21 and p16 might be among those mechanisms.

Protein tyrosine phosphatase (PTP) plays a negative role in regulating epidermal growth factor (EGF) signaling pathway. PTP1B is a widely expressed nonreceptor PTP originally identified in placentas. It downregulates the EGF signaling pathway by dephosphorylating epidermal growth factor receptor (EGFR) and inhibition of PTB1B promotes S phase entry. Increased PTP1B activity was detected in HCECs from older donors and reduced proliferative activity in response to EGF in those cells is partly due to increased PTP1B activity.

Comparison of Proliferative Capacity of HCECs from Central and Peripheral Regions

It is still controversial whether the peripheral endothelium has more potential for cell division than the central endothelium. p53 is a negative cell cycle regulator; it inhibits cell division primarily through a p21 pathway. It was found that p53 and its family member TAp63 are highly expressed in central rather than in peripheral endothelium, supporting that there is a greater potential for cell proliferation in the peripheral. However, studies by other group have shown that HCECs cultured from both the central and peripheral areas are capable of cell division in response to serum and their proliferation rates are same.

Overexpression of E2F2 Promotes Proliferation of CEC

E2F family proteins are key transcription factors for genes involved in the cell cycle progression. Three isoforms of this family (E2F1, E2F2, and E2F3) play an important role in G1/S transition. Overexpression of E2F2 promotes cell proliferation in rabbit CECs by increasing the proliferation marker ki67 and cylin B (G2 phase cell cycle regulator).

PKC Signaling Pathways in Regulating Proliferation of CECs

PKC comprises a family of serine/threonine protein kinases, which play an important role in regulating proliferation in many cell types. Several PKC isoforms, including PKC-alpha, -betaII, -delta, -epsilon, -iota, -eta, -gamma, and –theta, were detected in CECs. PKC activity, in particular PKC-alpha and -epsilon activity, is important in promoting CEC proliferation. Inhibition of PKC activity prohibits G1/S-phase progression and reduces cyclin E protein levels in cultured rat CECs.

FGF-2 Signaling Pathway

FGF-2 is a component of DM. As a member of the FGF family, it is a multifunctional regulator of cell development, differentiation, regeneration, senescence, proliferation, and migration. The biological actions of FGF-2 are mediated through transmembrane cell surface receptors that possess tyrosine kinase activity. There are four isoforms of FGF-2. Only the 24-kDa nuclear FGF-2 isoform induced by corneal endothelium modulation factor (CEMF) may be involved in cell proliferation. Phospholipase C gamma (PLC-gamma) or phosphoinositide 3-kinases (PI3 kinase) serve as a downstream signaling pathway in FGF-2-mediated proliferation of rabbit CEC proliferation. Both PLC-gamma and PI3 kinase may utilize Cdk4 and p27 while exerting the mitogenic signal.

Summary

Understanding of the regulatory mechanisms involved in CEC proliferation is important in the context of regenerative medicine. Since corneal endothelium does not divide *in vivo*, manipulation of the factors involved in this cell cycle can be used to expand endothelium for regenerative purposes. Such developments would bring a great promise to the development of the treatment strategies for both exogenous and endogenous corneal endotheliopathies, hopefully bypassing the need for allogeneic corneal transplantation.

Regulation of Corneal Endothelial Function

J A Bonanno and S P Srinivas, Indiana University, Bloomington, IN, USA

Glossary

Aquaporins – The water channels that facilitate water movement across the plasma membrane.
Deturgescence – The removal of water from the cornea stroma to counteract edema.
Guttata – Excresances of Descemet's membrane (basement membrane of the corneal endothelium) produced by abnormal endothelial cells.
Peri-junctional actomyosin ring (PAMR) – A Dense band of actin cytoskeleton found proximal to the apical junction complex.
Pump-leak mechanism – The maintenance of corneal deturgescence in which endothelial active fluid transport (the pump) exactly counters the passive leak directed into the stroma.
Tight junctions – The intercellular junctions at the apical domain of endothelial cells which occlude the paracellular space.
Transendothelial electrical resistance (TER) – Dependent on the integrity of the tight junctions.

Corneal Endothelial Function

Stromal Swelling Pressure and Maintenance of Transparency

The transparency of the cornea stroma is dependent on the tissue hydration. The stroma is composed of 200 or more lamellae, 2-μm thick with widths varying from 10 to 250 μm that span from limbus to limbus and overlap each other at varying orientations. The total thickness of the human stroma varies from 450 to 550 μm. Each lamella is composed of parallel strands of collagen (type I) and associated glycosaminoglycans (GAGs). Between the layers of overlapping lamellae are the keratocytes – a very flat, stellate-shaped cell that is responsible for producing collagen and GAGs and maintaining the stromal structure. The GAGs act as spacers between the collagen fibers. At normal stromal hydration, this space is ~30 nm and is very uniform. Because the refractive index of collagen and the GAGs ground substance are significantly different, a random orientation of collagen fibers and varying fiber diameter (which is characteristic of the sclera) would produce an opaque tissue. However, because there is almost no variation in fiber diameter and the spacing between fibers is uniform, light scattered off-axis through the stroma is <10%. GAGs, however, are very hydrophilic and exert a swelling pressure leading to imbibition of water across the relatively leaky endothelium at the posterior surface. Thus, if a bare piece of stroma is placed in saline, it will swell to many times the normal thickness. This stromal edema produces large variations in collagen-fiber spacing and consequentially increased light scatter, corneal haze, and *in vivo* produces diminished visual acuity. Loss of endothelial cells from surgical trauma or disease, for example, Fuchs' endothelial dystrophy, results in corneal edema. These observations together with *in vitro* physiological studies indicate that the maintenance of stromal hydration is primarily dependent on the corneal endothelium.

The pioneering work of David Maurice first showed that the corneal endothelium actively pumps water from stroma to anterior chamber. This pump exactly counterbalances the leak into the stroma, which is driven by the GAG-dependent swelling pressure. Therefore, the stromal hydration is maintained relatively constant and stromal transparency is preserved. This is often called the Pump–Leak hypothesis for maintenance of corneal hydration and is illustrated in Figure 1.

Endothelial Barrier Function

The tight junctions (TJs) of the corneal endothelium, although leaky (trans-endothelial resistance (TER) ~ 25 Ω cm^{-2}), restrain fluid leak into the stroma. This constitutes the barrier function of the endothelium, and complements fluid-pump function in the regulation of stromal hydration. Despite the leakiness of the endothelium, breakdown of its TJs in the absence of an increase in fluid-pump activity results in corneal edema. In addition to this direct effect, edema could be enhanced further by the fact that TJs also influence the fluid pump function through two indirect mechanisms. First, intact TJs prevent dissipation of local osmotic gradients across the endothelium set up by ion-transport mechanisms by restraining solute back-flux through the paracellular space (i.e., gate function of TJs). Secondly, intact TJs are indispensable for the maintenance of apical-basal polarity of the ion-transport proteins. This is achieved by limiting their lateral diffusion of the membrane proteins (i.e., fence function of TJs). When the polarity of the transport mechanisms is compromised, a vectorial ionic movement and hence fluid transport cannot occur. Thus, the TJs of the endothelium not only restrain fluid leak into the stroma, but also form a principal determinant of the endothelial fluid-pump activity (Figure 2).

Nutrition/Waste Removal

One requirement for corneal transparency is the absence of blood and blood vessels. As such, corneal nutrition must come from the tears, the limbus, and/or the anterior chamber. The stratified squamous epithelium is a very tight barrier, and there are no transporters for nutrients such as glucose. However, the epithelium is permeable to hydrophobic nutrients such as oxygen and wastes, for example, carbon dioxide (CO_2). Because of the long diffusion distances from the limbus, its contribution to overall corneal nutrition is minimal. Therefore, most of the nutrition and removal of wastes – for example, lactic acid – occurs across the endothelium. The corneal endothelium expresses glucose transporters to facilitate uptake into the stroma to nourish keratocytes and the corneal epithelium. Similarly, the endothelium expresses lactic acid transporters to remove this end product of anaerobic glycolysis. Approximately 85% of the glucose consumed by the cornea goes through anaerobic glycolysis because of the relative paucity of mitochondria in the epithelial cells and keratocytes. The relative lack of mitochondria is presumably another strategy to minimize light scatter and enhance transparency.

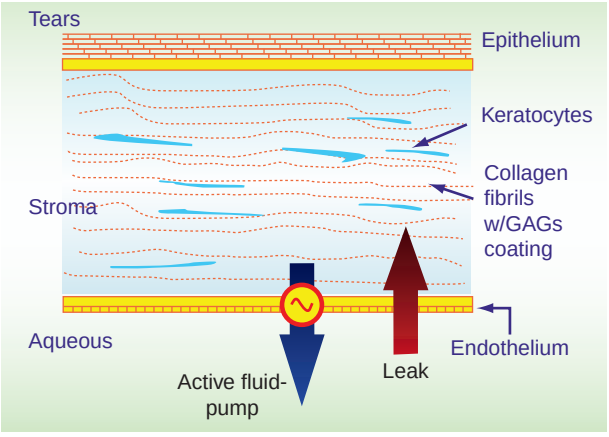

Figure 1 Pump–Leak hypothesis for maintenance of corneal hydration. Stromal glycosaminoglycans (GAGs) are negatively charged hydrophilic molecules that exert a swelling pressure that draws water across the limiting layers (epithelium and endothelium). This is the tissue leak. The endothelial pump must exactly counterbalance the leak so that stromal hydration and transparency are maintained.

Corneal Endothelial Transport

Active Transport

Following discovery that the endothelium was responsible for maintaining stromal hydration, it was shown that the endothelial pump was dependent on active transport. In contrast to corneal epithelial cells and keratocytes, endothelial cells have a very high mitochondrial density. Poisoning the mitochondria reduces the pump activity indicating that it is dependent on the availability of adenosine triphosphate (ATP). Furthermore, exposure of endothelium to the cardiac glycoside ouabain – which blocks the membrane Na^+,K^+-ATPase – also inhibits the pump activity. The Na^+,K^+-ATPase provides the ion gradients across cell membranes that drive secondary transporters, for example, Na^+:K^+:$2Cl^-$ cotransport, Na^+/H^+ exchange, and $Na^+ : 2HCO_3^-$ cotransport, and anion channels that may participate in ion-coupled fluid secretion. A classic fluid-transport mechanism might include basolateral cotransporters and apical anion channels providing a pathway for vectorial ion fluxes that could be osmotically coupled to water transport.

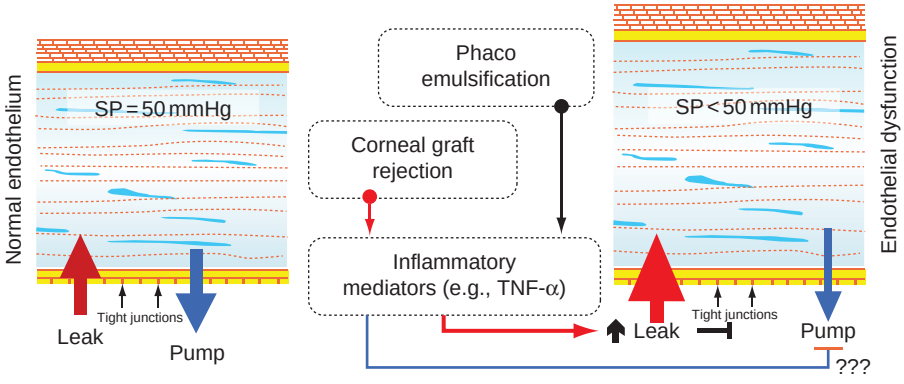

Figure 2 Barrier integrity is essential for stromal hydration control: Fluid leak into the stroma through the paracellular space – determined by the barrier integrity – is driven by a hydraulic gradient equivalent to swelling pressure (SP) of ~ 50 mmHg at normal stromal hydration. Despite the leaky nature of the endothelium (TER < 25 Ω cm^2), stromal thickness is held constant by the fluid-pump mechanism, which counterbalances the fluid leak. When the barrier integrity breaks down, the pump mechanism cannot cope with the leak and hence stromal edema becomes inevitable. Inflammatory stress – which can reduce the barrier integrity – is not known to stimulate the pump function concomitantly. In fact, when the tight junctions are compromised, the fluid-pump mechanism cannot be sustained since the local osmotic gradients generated by ion transport are dissipated by futile solute back-flux.

Bicarbonate/Carbonic Anhydrase

Early studies have shown that the endothelial pump is significantly inhibited in the absence of bicarbonate suggesting that bicarbonate transporters and anion channels may be components of the endothelial pump. A role for bicarbonate was strengthened when it was found that carbonic anhydrase inhibitors (CAIs) – applied directly to the endothelium – also slowed the pump. With the advent of topical carbonic anhydrase inhibitors to lower intraocular pressure (IOP), there was some concern that this could cause corneal edema. However, numerous clinical studies have shown that in humans with normal endothelial cell counts, topical CAIs do not cause corneal edema. Only when cell counts are low and/or in the presence of significant endothelial guttata have topical CAIs been shown to cause corneal edema. This suggests that whatever role bicarbonate/CA activity has in pump activity, there must be a large functional reserve. Interestingly, endothelial pump activity can be maintained in the absence of bicarbonate, but only when bicarbonate is substituted with a high concentration of another buffer. These observations suggest that part of the role of bicarbonate/CA in the endothelial pump may be its buffering capacity, possibly for lactic acid.

Anion Transporters and Channels

Several anion transporters and channels that could participate in a bicarbonate secretory pump mechanism are expressed in corneal endothelium. At the basolateral (stromal side) membrane, the sodium bicarbonate cotransporter (NBCe1) is highly expressed (**Figure 3**). This protein transports one Na^+ with two HCO_3^- ions into the cells from the stroma. Application of the anion transport inhibitor 4,4′-diisothiocyanatostilbene-2,2′-disulphonic acid (DIDS) or genetic knockdown of NBCe1 expression using siRNA significantly reduces bicarbonate uptake and transendothelial bicarbonate flux. DIDS also results in corneal swelling *in vitro*, suggesting that this anion-transport process has an important role in the endothelial pump activity. NBCe1 is responsible for the large Na^+-dependent (Cl^- independent) bicarbonate permeability of the basolateral membrane. The bicarbonate permeability of the apical membrane of the corneal endothelium is about one-third of basolateral membrane and it is independent of Na^+ or Cl^-, suggesting that the smaller apical permeability is conferred by a channel. To date, only two apical anion channels have been described in the corneal endothelium – the cystic fibrosis transmembrane regulator (CFTR) and a calcium-activated chloride channel (CaCC). These channels are permeable to both Cl^- and HCO_3^- in about a 5:1 ratio. Physiological experiments with rabbit corneas have shown, however, that CFTR-channel inhibitors have no effect on the endothelial pump rate. Furthermore, siRNA knockdown of CFTR in cultured cells – while inhibiting cyclic adenosine monophosphate (cAMP)-activated anion flux, did not change the basal bicarbonate flux. This is consistent with clinical studies that indicate normal corneal thickness and function in cystic fibrosis patients. Similarly, siRNA knockdown of CaCC channels had no effect on basal bicarbonate permeability, but reduced calcium-activated flux. To date, the nature of the apical HCO_3^- transport remains unknown.

Recent studies have also shown that removal of Cl^- will also produce significant corneal swelling *in vitro*,

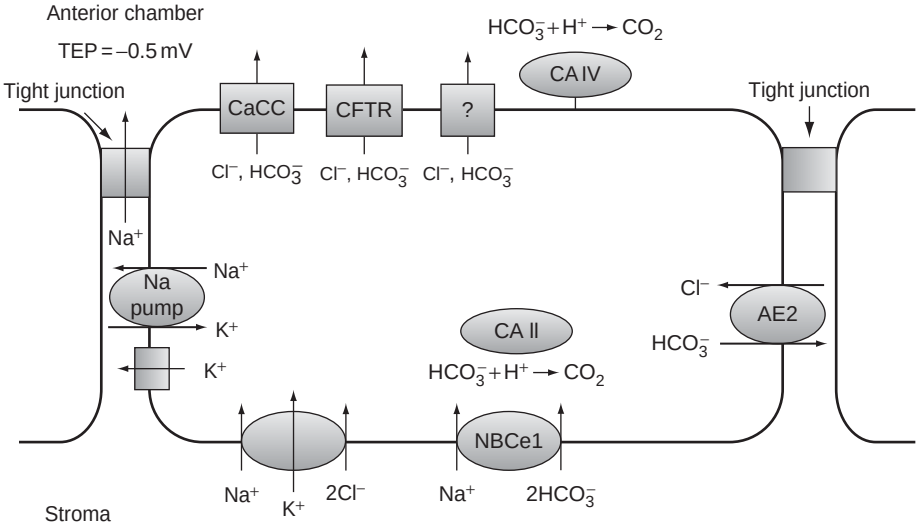

Figure 3 Model for transendothelial bicarbonate transport. NBCe1 uses the inward [Na^+] gradient to transport bicarbonate into the cell at the basolateral surface. This is facilitated by carbonic anhydrase II (CAII). Anion channels at the apical surface that are permeable to bicarbonate can provide an efflux pathway. CAIV is present on the apical surface and may facilitate net HCO_3^- flux. A chloride transport pathway is also in place, which may only be activated during endothelial stress.

suggesting the possibility that both anions – Cl^- and HCO_3^- – participate directly in the pump mechanism. In fact, the basolateral membrane expresses the Na^+:K^+:$2Cl^-$ cotransporter and the cytoplasmic [Cl^-] is 35 mM, which is above electrochemical equilibrium (**Figure 3**). Thus the potential for apical anion channel mediated Cl^- flux is in place. However, the highly specific inhibitor of the Na^+:K^+:$2Cl^-$ cotransporter – bumetanide – has no effect on corneal thickness *in vitro*. In addition, studies examining transendothelial Cl^- fluxes have been equivocal. This indicates that a basal Cl^- flux across the endothelium is unlikely to have a role in the pump mechanism. The presence of Cl^- may have two other roles that could support HCO_3^- fluxes. First, because NBCe1 is electrogenic ($1\ Na^+ : 2HCO_3^-$), membrane potential hyperpolarization (e.g., from −50 to −65 mV) will stop NBCe1 dependent HCO_3^- influx. Cl^- efflux through CFTR or other unidentified anion channels could dissipate the hyperpolarizing effects of NBCe1 activity. Second, the anion exchanger AE2 is expressed on the basolateral membrane as shown in the rabbit corneal endothelium. Thus, the transmembrane Cl^- gradient can help regulate intracellular [HCO_3^-]. Further studies are needed to elucidate the role of Cl^- or Cl^- transporters in the corneal endothelial pump mechanism. **Figure 3** illustrates a possible model for bicarbonate transport.

Aquaporin-1 (AQP1)

Aquaporin-1 (AQP1) water channels are highly expressed on both apical and basolateral membranes of corneal endothelium. No other AQP channel is expressed in the corneal endothelium. AQP1 confers a very high osmotic permeability and allows for rapid cell-volume regulation in response to anisosmotic solutions. In AQP1-knockout mice, corneal endothelial cell osmotic permeability is reduced, as expected. Corneal de-swelling rates are also significantly reduced. This indicates that a significant amount of water flux across the endothelium – at least under non-steady-state conditions – is transcellular. However, steady-state corneal thickness of these mice is slightly thinner than wild-type mice. This result may indicate that the pathway for water fluxes driven by the pump and the leak (GAGs-dependent stromal swelling pressure) is the same, which would result in no net effect. Thus AQP1 (and AQP5 in the corneal epithelium) may be present to increase the rate of water fluxes in response to osmotic changes that can occur, for example, following eye closure or exposure to hypotonicity that occurs during swimming.

Pump Mechanism

The conventional view of epithelial cell secretion and absorption of water is that these cells create local osmotic differences in the lateral spaces between the cells and/or on the apical surfaces of cells within an unstirred layer. These osmotic gradients are the driving forces for water movement across cellular membranes. This standing gradient osmotic theory, first developed by Diamond and Bossert, has come under fire as a general mechanism for fluid transport. For example, in many epithelial cells – including the corneal endothelium – there is no evidence that these gradients exist. This has led to the consideration of other mechanisms, such as electro-osmosis, which has been championed by Jorge Fischbarg for the corneal endothelium. In this theory, cells generate a transepithelial potential (0.5 mV apical-side negative in corneal endothelium) that draws counter-ions – for example, Na^+ – through a paracellular pathway that is ion specific. This produces electro-osmotic coupling across the TJ. Another mechanism for fluid transport across epithelial cells that has been recently developed is the cotransporter model. In this model, water is directly transported or coupled with the movement of the associated ions and metabolites within the cotransporter protein. Since the endothelium expresses several cotransporters – for example, $1Na^+$:$2HCO_3^-$ and Na^+:K^+:$2Cl^-$ cotransporters – and at least two monocarboxylic acid (lactic acid) cotransporters – MCT1 and MCT2 – there is potential for downhill fluid transport by this mechanism.

Barrier Integrity

Barrier integrity – which implies resistance to diffusion of solutes or fluid leak through the paracellular pathway – is dependent on the TJs. TJs are supramolecular assemblies localized at the apical domain of epithelial/endothelial monolayers. The transmembrane molecules (occludins, claudins, and junctional adhesion molecule (JAM)) – which are all expressed in corneal endothelium associated with the TJs – these transmembrane molecules of one cell interact with their homotypic counterparts in the neighboring cells. This interaction – facilitated by intercellular tethering forces through Ca^{2+}-dependent adherence junctions (AJs) – brings about occlusion of the paracellular space. The cytoplasmic domains of the transmembrane molecules of the TJs are structurally linked to a thick band of cortical actin cytoskeleton (called peri-junctional actomyosin ring (PAMR)) via adapter molecules such as zona occludens-1 (ZO-1). For AJs, the association with PAMR is mediated through catenins. The adapter molecules of both AJs and TJs also form a scaffold for a number of signaling molecules which are now implicated in the control of the stability of AJs and TJs and hence in the regulation of barrier integrity. Recent studies have demonstrated that increased contractility of the PAMR induces a breakdown of the barrier integrity through a reduction of the intercellular tethering forces at the TJs and AJs and also possibly through redistribution

of the AJ and TJ molecules at the apical junctional complex. An increase in contractility of the actin cytoskeleton is induced by an increase in the phosphorylation of the regulatory light chain of myosin II (also called myosin light chain or MLC; 20 kDa). Recent studies have shed light on the importance of actomyosin contraction in the regulation of corneal endothelial barrier integrity.

MLC Phosphorylation and Actomyosin Contraction

Phosphorylation of myosin light chain (MLC) – which is bound to the motor protein myosin II – induces actomyosin interaction resulting in increased contractility of the actin cytoskeleton (**Figure 4**). The extent of MLC phosphorylation is regulated by two opposing pathways: myosin light-chain kinase (MLCK)-driven phosphorylation, and myosin light-chain phosphatase (MLCP)-driven dephosphorylation. MLCK is activated after binding to the Ca^{2+}-calmodulin complex and its activity is dedicated to MLC phosphorylation. MLCK activity is also modulated by other protein kinases by direct phosphorylation, especially the large-size isoform of MLCK called vascular endothelial cell MLCK (EC-MLCK; 220 kDa). MLCP is a hetero-trimeric complex consisting of PP1Cδ (the catalytic subunit), the myosin-binding subunit (MYPT1; 130 kDa), and a small subunit of unknown function (M20). Phosphorylation of MYPT1 by Rho kinase (at Thr-696 and Thr-850) – a downstream effector of the small GTPase RhoA – inhibits the phosphatase activity of PP1Cδ. Protein kinase C (PKC) isoforms also inhibit the activity of MLCP through phosphorylation of CPI-17 (PKC-activated 17-kDa inhibitor protein of type 1 phosphatase) and consequent inactivation of PP1Cδ. Thus, activation of Rho kinase and/or PKC results in contraction of the actin cytoskeleton and a breakdown in barrier integrity.

Effect of MLC Phosphorylation on Corneal Endothelium Barrier Integrity

The mechanisms associated with MLC phosphorylation – which are well characterized in smooth muscle cells – are also present in corneal endothelial cells as demonstrated in several recent studies. Thus, it is now known that corneal endothelial cells – similar to vascular endothelial

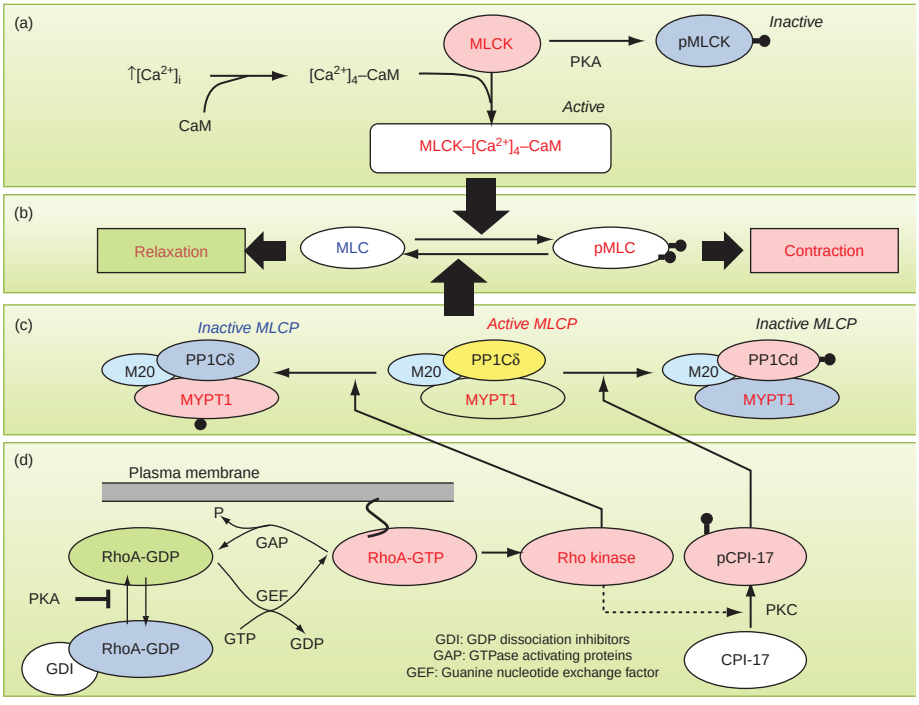

Figure 4 Regulation of myosin light-chain (MLC) phosphorylation in the corneal endothelium. (a) MLC phosphorylation is catalyzed by Ca^{2+}-Calmodulin-dependent myosin light-chain kinase (MLCK). Expression of both endothelial and smooth muscle isoforms is known in corneal endothelium. (b) MLC phosphorylation promotes actomyosin contraction. (c) MLCK activity is opposed by myosin light-chain phosphatase (MLCP), which catalyzes dephosphorylation of pMLC. MLCP is a heterotrimeric complex consisting of MYPT1 (a regulatory subunit), PP1Cδ (the catalytic subunit), and M20 (function unknown). (d) Rho kinase – effector of RhoA – phosphorylates MYPT1. This inhibits PP1Cδ. When RhoA is phosphorylated by protein kinase A (PKA) at its Ser-188, dissociation of RhoA-GDI from RhoA-GDP is opposed. Guanine exchange factors (GEFs) promote the release of GDP and subsequent binding to GTP; G-protein accelerating proteins (GAPs) stimulate the GTPase activity of RhoA; guanine nucleotide-dissociation inhibitor (GDIs) stabilize the inactive state of RhoA. Yet unidentified isoforms of PKC phosphorylate CPI-17 leading to inhibition of PP1Cδ.

cells – possess both EC-MLCK and a smaller smooth muscle isoform of MLCK (SM-MLCK; 120 kDa). In addition, myosin II isoforms (myosin IIA and IIB) are also expressed in the endothelium. To show the importance of MLC phosphorylation and its effects on the corneal endothelial barrier integrity, several G-protein-coupled receptor (GPCR) agonists have been employed. Thus, thrombin – which activates the RhoA–Rho-kinase axis through Gα12/13-coupled PAR-1 receptors in corneal endothelial cells – led to an increase in MLC phosphorylation. This was found to disrupt PAMR with a concomitant breakdown of the barrier integrity. Pretreatment with ML-7 – a selective inhibitor of MLCK – could not significantly block the thrombin-induced MLC phosphorylation. However, the Rho-kinase inhibitor Y-27632 was effective in blocking the thrombin effect. These findings indicate the dominance of the RhoA-mediated Ca^{2+}-independent pathway downstream of PAR-1 activation. The importance of the Ca^{2+}- and PKC-dependent mechanisms in MLC phosphorylation, however, have also been demonstrated independently through activation of histamine H1 receptors, which are coupled to Gαq/11 G-protein and are not known to activate RhoA. Thus, histamine-induced MLC phosphorylation and the resultant loss of endothelial barrier integrity could be suppressed by ML-7 and chelerythrine (a nonspecific PKC inhibitor). Taken together, these data have emphasized a strong role for actin cytoskeleton in the regulation of the endothelial barrier integrity and also suggest that bioactive factors and proinflammatory mediators found in the aqueous humor may influence the barrier function through their respective cell surface receptors.

Transplantation Failure and Tumor Necrosis Factor

Tumor necrosis factor (TNF-α) is a 17-KDa proinflammatory cytokine implicated in corneal endothelial failure during graft rejection (**Figure 2**). TNF-α mRNA has been detected in corneal allografts undergoing rejection, and TNF-α protein levels are significantly elevated in the aqueous humor and the serum of hosts that reject corneal allografts. A study with rabbit corneas has demonstrated that TNF-α breaks down the barrier integrity of the endothelial cells concomitant with disruption of actin cytoskeleton. The cytokine is well known to breakdown barrier integrity in vascular endothelial cells. Some of the important molecular mechanisms involved include activation of RhoA, MLC phosphorylation, significant loss of PAMR, microtubule disassembly secondary to activation of p38 MAP kinase, mobilization of oxidative stress, and formation of stress fibers. In recent studies with bovine corneal endothelium, it is becoming evident that TNF-α also induces disassembly of microtubules concomitant with a gradual loss of barrier integrity and disappearance of PAMR. These effects could be blocked by pretreatment with paclitaxel, SB-203580 (a selective inhibitor of p38 MAP kinase), and inhibitors of matrix metalloproteinases. These results suggest that a number of mechanisms are involved in the breakdown of the barrier integrity in response to TNF-α which converges directly and indirectly on actin and microtubule cytoskeleton.

Regulation of Transport Activity and Barrier Integrity

Adenosine, Soluble Adenylate Cyclase, and cAMP

The corneal endothelial fluid pump is thought to proceed at one rate and when this rate matches the leak rate driven by the stromal GAGs, corneal hydration and thickness reaches a steady state. There are other forces that can influence the leak rate including evaporative loss across the epithelial surface and contact lens-induced hypoxic stimulation of epithelial lactate production, which can produce substantial additions to stromal osmotic pressure. There is no evidence that the pump speeds up when the cornea is edematous or slows down if the cornea thins.

Shortly after it was clear that the endothelium was actively transporting water, it was discovered that the rate of fluid transport could be increased by the addition of adenosine. Later, it was shown that adenosine increases intracellular [cAMP] in endothelial cells through activation of adenosine $A2_b$ receptors. Other approaches that increase cAMP within the cells – for example, stimulating adenylate cyclase (AC) directly or inhibiting phosphodiesterase – also increased corneal endothelial fluid-transport rates. More recently, the expression of a new type of AC, called soluble AC (sAC), was shown in corneal endothelium. Unlike the transmembrane-linked adenylate cyclases, sAC is distributed throughout the cytoplasm and it is activated by HCO_3^- and Ca^{2+}. Because of the robust $1Na^+$:$2HCO_3^-$ cotransporter in endothelial cells, the sAC is active and raises the basal [cAMP] by ~50%, suggesting that it may have a small role in maintaining basal fluid transport rates. Raising cAMP activates protein kinase A (PKA) and this demonstrably phosphorylates the apical CFTR channel, increases apical Cl^- and HCO_3^- permeability, and increases transendothelial HCO_3^- flux. Together, this could contribute to the increased fluid transport observed by increasing cAMP. Corneal endothelial cells can produce adenosine from ATP at the apical surface. When stressed, corneal endothelial cells release more ATP – which, when converted to adenosine, will enhance fluid transport and could help counter the negative effects of the stress.

Role of cAMP–PKA axis in the Regulation of Barrier Integrity

An *in vitro* study with rabbit cornea first showed that adenosine could also promote corneal deturgescence through enhanced barrier integrity. Consistent with this finding, several recent studies have shown that adenosine induces MLC dephosphorylation through mobilization of cAMP–PKA axis via $A2_b$ receptors as noted above. More importantly, consistent with MLC dephosphorylation, exposure to adenosine led to an increase in the barrier integrity as measured by the trans-endothelial electrical resistance. Similar findings were noted with extracellular ATP – which was found to undergo extracellular hydrolysis resulting in formation of adenosine and subsequent activation of $A2_b$ receptors. In addition to these findings, forskolin (direct activator of adenylate cyclase), adenosine, and ATP have been found to overcome thrombin- and histamine-induced MLC phosphorylation as well as loss of barrier integrity. At the molecular level, the locus of action of elevated cAMP is also becoming evident. PKA is known to induce MLC dephosphorylation through modulation of the RhoA–Rho-kinase axis. One potential mechanism involves direct phosphorylation of RhoA by PKA and consequent increase in the affinity of the small guanosine triphosphatase (GTPase) to its guanosine diphosphate (GDP) dissociation inhibitor (GDI). An alternative mechanism involves direct phosphorylation of MYPT1 by PKA. The latter is known to prevent Rho kinase from phosphorylating MYPT1 leading to inactivation of MLCP. cAMP may also influence cell–cell adhesion through activation of a small GTPase, namely Rap1. This involves activation of Epac – a guanine nucleotide-exchange factor (GEF) for Rap1. Activated Rap1 promotes formation of AJs, presumably through enhanced cadherin ligation.

Summary and Perspective

The corneal endothelium is responsible for maintaining corneal hydration and transparency. Active transport processes – through mechanisms that are not fully elucidated – provide a Pump that exactly counterbalances the stromal glycosaminoglycan induced Leak. The Pump is regulated through cAMP-dependent signaling that acts on components of ion transport and the barrier integrity of the endothelial monolayer. Further understanding of the Pump and Leak mechanisms are needed to provide medical therapies that could maintain stromal deturgescence in diseased or traumatized corneal endothelium.

Regulation of Extracellular Matrix Turnover in the Aqueous Humor Outflow Pathways*

R Fuchshofer and E R Tamm, University of Regensburg, Regensburg, Germany

Glossary

Bone morphogenetic proteins (BMPs) – A group of growth factors originally named for its ability to induce the formation of bone and cartilage. BMP2 to BMP7 belong to the transforming growth factor-β superfamily and have important roles during development.

Cytokine – A protein or polypeptide that is used in cellular communication.

Growth factor – A protein capable of stimulating growth, proliferation, and differentiation of cells. The term growth factor is often used interchangeably with the term cytokine.

Pseudoexfoliation glaucoma – A form of open-angle glaucoma characterized by granular material at the pupillary margin of the iris and throughout the inner surface of the anterior chamber.

Smads – A class of proteins that modulate the activity of the TGF-β superfamily of ligands. Smad proteins are homologs to the protein mothers against decapentaplegic (MAD) in *Drosophila melanogaster* and the protein SMA in *Caenorhabditis elegans*. The name is a combination of the two.

Thrombospondin-1 – An adhesive glycoprotein that mediates cell-to-cell and cell-to-matrix interactions.

Transforming growth factor-β (TGF-β) – A secreted protein that exists in three isoforms called TGF-β1, TGF-β2, and TGF-β3. TGF-β's belong to a superfamily of proteins known as the transforming growth factor-β superfamily.

Introduction

In primary open-angle glaucoma (POAG), a major cause of blindness worldwide, the critical risk factor for axonal damage at the optic nerve head is an intraocular pressure (IOP), which is very high for the health of the optic nerve head. IOP is increased in POAG when aqueous humor (AH) outflow resistance in the juxtacanalicular tissue (JCT) region of the human trabecular meshwork (TM) is abnormally high. The mechanisms that are responsible for the increase in TM outflow resistance in POAG are unclear. There is some evidence, however, that changes in the amount and quality of the TM extracellular matrix (ECM) are involved, as eyes with POAG show a significant increase in fibrillar ECM in the JCT outflow pathways. Our knowledge on the molecular factors that govern ECM turnover in the TM has considerably increased in recent years. It has become quite clear that quality and quantity of ECM in the TM are regulated by several signaling molecules that interact with each other to promote synthesis, degradation, or extracellular modification of the ECM. This article reviews the growing list of molecules that act in a complex network to influence ECM homoeostasis in the TM.

Transforming Growth Factor-β

Transforming growth factor-β (TGF-β) is a member of a family of dimeric polypeptide growth factors. There are three isoforms of TGF-β: TGF-β1, TGF-β2, and TGF-β3, which are each encoded by a distinct gene. In the normal anterior eye, TGF-β2 appears to be the predominant isoform as it is found at relatively high concentrations in the AH of normal eyes. This isoform is very likely secreted into the AH from the epithelial cells of ciliary body and lens.

Immunohistochemical studies have shown immunoreactivity for TGF-β1 in the stroma of the ciliary processes, while TGF-β3 was not detected in structures of the anterior eye. The normal TM does not label with antibodies against the various TGF-β isoforms, but cultured TM cells are capable of secreting TGF-β2 and TGF-β1, and expressing receptors for both factors. The physiological role of TGF-β2 in the AH appears to be tightly linked with the immunosuppressive environment of the anterior chamber and the phenomenon of anterior-chamber-associated immune deviation (ACAID).

Among the factors that modulate ECM turnover in the TM, TGF-β2 is the one which is most likely involved in the pathological ECM increase in POAG. Multiple groups have reported significantly higher levels of TGF-β2 in the AH collected from human POAG eyes as compared with AH from patients who underwent cataract operation. The factors which cause or contribute to the increase in TGF-β2 in the AH of patients with POAG are unclear.

*An adaptation and extension of Fuchshofer, R. and Tamm, E. R. (2009). Modulation of extracellular matrix turnover in the trabecular meshwork. *Experimental Eye Research* 88: 683–688. http://www.sciencedirect.com/science/journal/00144835.

In addition, there is no information available on the nature of the ocular tissues which secrete higher-than-normal amounts of TGF-β2 in the AH, but because of the direction of AH flow, ciliary body and lens are more likely candidates than the TM. The increase in TGF-β2 appears to be typical for POAG and not to be directly caused by an increase in IOP, as patients with pseudoexfoliation glaucoma do not show elevated levels of TGF-β2 in their AH. In contrast, AH of patients with pseudoexfoliation syndrome or glaucoma contains elevated amounts of TGF-β1 and TGF-β3.

In multiple disorders throughout the body, TGF-β signaling mediates a pathological increase in ECM secretion and deposition, and is causatively involved in fibrosis. It is reasonable to assume that the passage of higher-than-normal amounts of TGF-β2 through the TM will induce changes in TM gene expression that may result in an increase in TM ECM deposition. Experimental support for this assumption comes from experiments involving anterior eye segment perfusion cultures, in which perfusion with TGF-β2 promoted a focal accumulation of fine fibrillar extracellular material in the TM and an increase in fibronectin synthesis, effects that were correlated with a reduction in outflow facility. Comparable results were obtained in experiments involving monkey anterior eye segment organ cultures, in which perfusion with TGF-β2 caused a decrease in outflow facility by ~40% compared to pretreatment baseline. The decrease in outflow facility correlated with an increase in cochlin, a secreted protein that comprises the major noncollagen component of the ECM of the inner ear, and is present in glaucomatous TM, but absent in the normal TM. In addition, numerous studies provided evidence that treatment of TM cells in monolayer cell culture leads to a substantial increase in the expression and synthesis of a broad variety of ECM proteins (collagens III, IV, and VI, elastin, fibronectin, versican, laminin, and myocilin), all of which contribute to the ECM of the TM *in situ*.

TGF-β2 treatment of cultured TM cells also stimulates the synthesis of proteins that modify turnover and deposition of ECM. Accordingly, TGF-β2 induces in TM cells the expression of tissue transglutaminase and its messenger RNA (mRNA), as well as its action on irreversible and covalent cross-linking of fibronectin. Moreover, TGF-β2 leads to an increased TM synthesis of plasminogen activator inhibitor (PAI-1), which is a potent inhibitor of matrix metalloproteinases (MMPs). In the TM, PAI-1 appears to primarily inhibit MMP2, an enzyme that degrades collagen type IV, the major structural component of basement membranes. The expression of matrix Gla protein (MGP), which is among the most highly expressed genes in fresh human TM, is significantly downregulated following treatment with TGF-β2. In certain soft tissues, MGP is important to prevent ectopic calcification, and mice that are deficient in Mgp ($Mgp^{-/-}$) develop severe vascular atherosclerosis and calcification. While the available data on the morphology and pathology of human TM in POAG very clearly indicate that a major calcification process comparable to that in atherosclerosis is absent in the TM, it is certainly tempting to speculate that a more subtle mineralization of the TM ECM or a comparable process is involved in the structural changes of the TM in POAG, and that TGF-β signaling is causatively involved.

It is of interest to note that TGF-β signaling does not only effect ECM turnover in the TM, but also acts on the TM actin cytoskeleton, as treatment with TGF-β1 induces the expression of α-smooth muscle actin in cultured TM cells. α-Smooth muscle actin is the isoform of actin that is expressed in smooth muscle cells and myofibroblasts, a cell type that predominates in connective tissues of healing wounds and scars. In myofibroblasts, the induction of α-smooth muscle actin by TGF-β1 substantially enhances cell traction force. In the normal TM *in situ*, some cells are immunoreactive for α-smooth muscle actin, while virtually all cells in the scleral spur region, close to the posterior attachment of the TM, express this actin isoform. There is the distinct possibility that an increase in the activity of TGF-β signaling in the eye increases the number of α-smooth muscle actin-positive cells in the TM, thereby increasing TM cell tone, an effect that has been shown to correlate with an increase in outflow resistance.

TGF-β Activation and Thrombospondin-1

TGF-β signaling is not only involved in ECM turnover, but also acts in other extremely important biological processes throughout the body and in the eye, including proliferation, apoptosis, and modulation of the immune system. Accordingly, defects in TGF-β function are associated not only with fibrosis, but also with other pathological states such as tumor cell growth and autoimmune diseases. Because of their multifunctional role, the activity of TGF-β *in vivo* needs to be subject to tight control mechanisms. TGF-β's are secreted as large latent complexes (LLCs), which are unable to interact with cellular receptors, a mechanism that prevents uncontrolled activation of the TGF-β signaling pathway. LLCs consist of the native TGF-β dimer which is noncovalently associated with its propeptide, the latency-associated protein (LAP), and of a second gene product, the latent TGF-β-binding protein (LTBP) which binds covalently to LAP. Mammalian cells express four different LTBP isoforms, of which only three (LTBP-1, -3, and -4) can associate with TGF-β. Following secretion, the LLC may be covalently linked to the ECM through the N-terminus of LTBP. Upon TGF-β activation, TGF-β is liberated from both LAP and LTBP.

Since TGF-β2 in the AH of normal and POAG eyes is mostly found in its latent, inactive form, it seems reasonable to assume that its effects on TM biology will considerably increase, if it is locally activated in the TM. *In vitro*, active

TGF-β is generated by extremes of pH, heat, or chaotropic agents, mechanisms that are not likely to be of physiological relevance for TGF-β activation *in vivo*. The physiological mechanisms of TGF-β activation *in vivo* may involve proteolytic processing as *in vitro* studies have identified a number of proteases, including plasmin, MMP-2, and MMP-9 as activators of latent TGF-β. TM cells would be capable to activate TGF-β by proteolysis, as they express active tissue plasminogen activator (t-PA), and MMP-2.

A very potent activator of latent TGF-β *in vivo* and *in vitro* is thrombospondin-1 (TSP-1), a matricellular protein which belongs to a small family of secreted glycoproteins. Matricellular proteins are secreted proteins that influence cell function by modulating cell–matrix interactions. TSP-1 might be critical for TGF-β activation in the TM, as there is a considerable constitutive TSP-1 expression in the JCT of the human TM (**Figure 1**). In the TM of patients with POAG, an increase of immunoreactivity

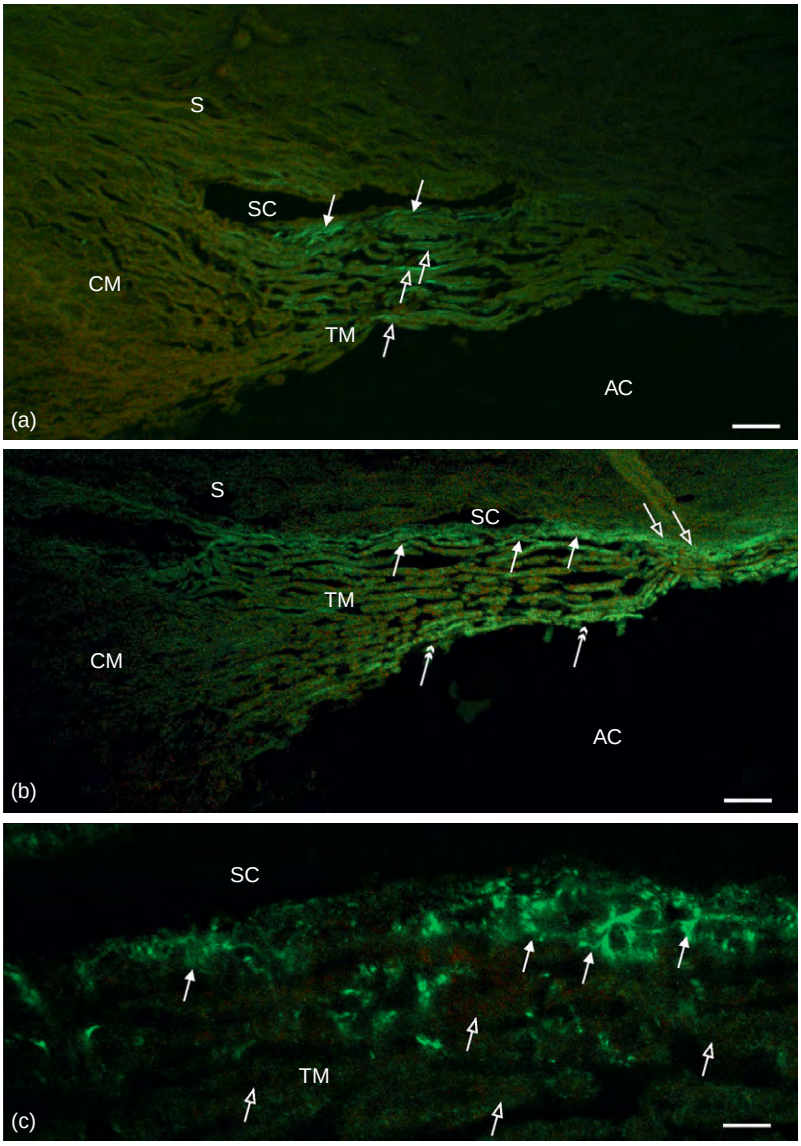

Figure 1 Immunohistochemistry for TSP-1 in the TM of normal human donors. (a) The TM of a 52-year-old donor shows immunoreactivity for TSP-1 in focal areas of the juxtacanalicular region (solid arrows). In addition, focal staining of uveal and corneoscleral TM cells is observed (open arrows). (b) In the TM of a 70-year-old donor, there is continuous labeling for TSP-1 in the juxtacanalicular region (solid arrows), which extends to the area of Schwalbe's line (open arrows). In addition, there is intense labeling of the anterior uveal TM (double arrows). (c) Upon higher magnification, juxtacanalicular immunoreactivity for TSP-1 is predominately localized to extracellular areas surrounding juxtacanalicular TM cells (solid arrows). In contrast, the connective tissue core of the corneoscleral TM lamellae is largely negative for TSP-1 (open arrows). Magnification bar = 47 μm (a, b); 6.6 μm (c). AC, anterior chamber; SC, Schlemm's canal; CM, ciliary muscle; S, sclera. From Flügel-Koch, C., Ohlmann, A., Fuchshofer, R., Welge-Lüssen, U., and Tamm, E. R. (2004). Thrombospondin-1 in the trabecular meshwork: Localization in normal and glaucomatous eyes, and induction by TGF-beta1 and dexamethasone *in vitro*. *Experimental Eye Research* 79: 649–663.

for TSP-1 has been observed in about one-third of patient eyes that were investigated (Figure 2). The expression of TSP-1 in TM cells is induced upon treatment with TGF-β1 and TGF-β2, indicating the presence of self-amplifying mechanisms for TGF-β signaling in the TM outflow pathways.

Another mechanism of activation depends on the direct interaction between integrin αvβ6 and LAP. Integrin-mediated TGF-β activation in the TM would only be relevant for TGF-β1, but not for TGF-β2, as it requires an integrin-binding arginine–glycine–aspartic acid (RGD) sequence in LAP, which is missing in the LAP of TGF-β2. Integrins are dimeric cell surface receptors that connect the cytoskeleton with the ECM. Since latent TGF-β1 binds simultaneously to the ECM through LTBP and to integrin αvβ6 through LAP, it has been hypothesized that mechanical traction is the relevant *in vivo* stimulus for integrin-mediated TGF-β1 activation.

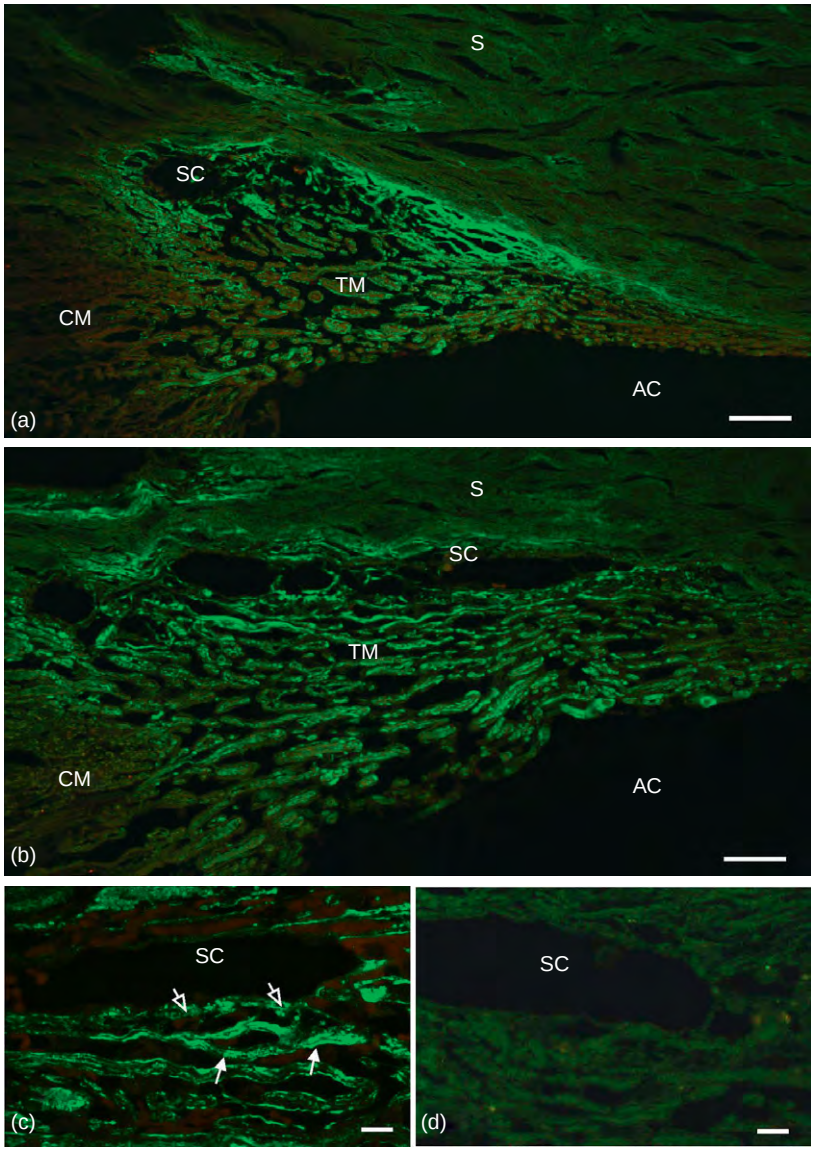

Figure 2 Immunohistochemistry for TSP-1 in the TM of a 67-year-old patient with POAG (a), and a 71-year-old patient with POAG after long-term treatment with topical steroids (b). (a, b) In the TM of both patients, intense immunoreactivity for TSP-1 is observed throughout all regions of the TM. TSP-1 labeling is also observed in the scleral tissue that lines the outer wall of Schlemm's canal and the collector channels, which originate from it. (c) Upon higher magnification, the cells lining the corneoscleral and uveal trabecular lamellae are labeled (solid arrows). In addition, positive staining is observed in the connective tissue core of the lamellae (open arrows). (d) In a control section, no positive immunoreactivity for TSP-1 is observed. Magnification bar = 47 μm (a, b); 6.6 μm (c, d). AC, anterior chamber; SC, Schlemm's canal; CM, ciliary muscle; S, sclera. From Flügel-Koch, C., Ohlmann, A., Fuchshofer, R., Welge-Lüssen, U., and Tamm, E. R. (2004). Thrombospondin-1 in the trabecular meshwork: Localization in normal and glaucomatous eyes, and induction by TGF-beta1 and dexamethasone *in vitro*. *Experimental Eye Research* 79: 649–663.

Clearly, in the living eye, mechanical traction between TM cells and their surrounding ECM would be augmented by an increase in stretch or strain in the TM, for instance, due to an increase in IOP. It is of interest to note that cyclic mechanical stretch of cultured TM cells activates the promoter of TGF-β1 and induces its expression in TM cells. Taken together, the action of TGF-β signaling on TM cells may depend not only on the presence and the amounts TGF-β2 in the AH, but also on that of TGF-β1, which is locally secreted and activated in the TM. Treatment with both TGF-β1 and TGF-β2 induces the expression of TGF-β1 in TM cells, indicating that self-amplifying mechanisms are capable to substantially augment the biological actions of TGF-β signaling on the TM outflow pathways. Upon activation, the biological effects of TGF-β1 and TGF-β2 on TM cells should be rather similar, as they bind to the same cellular receptors, albeit with different affinity, and initiate similar intracellular signaling cascades.

Connective Tissue Growth Factor

Connective tissue growth factor (CTGF) is a member of the CCN (CTGF, cysteine-rich angiogenic protein 61, and nephroblastoma overexpression gene) family of regulatory proteins. In the eye, the expression of CTGF has been found in TM, iris sphincter and ciliary muscle cells, retinal vascular endothelial cells, epi- and subretinal membranes, plaques of human anterior subcapsular cataracts, corneal scars, tear fluid, and pterygia. CTGF has also been detected in the AH and recent studies reported that the concentration of CTGF is increased in the AH of patients with pseudoexfoliation syndrome. CTGF has been identified as a critical downstream mediator of the fibrogenic action of TGF-βs. Similar to TGF-β's, the expression of CTGF is upregulated in a substantial number of disorders that are associated with a pathological increase in ECM, including scleroderma, renal and pulmonary fibrosis, inflammatory bowel disease, and atherosclerosis. The expression of CTGF in the fresh TM is considerably high. As in other tissues, treatment of cultured TM cells with TGF-β2 causes an increase in CTGF expression. CTGF is also found in higher amounts in the TM following mechanical stretch, an effect that is probably induced by the action of TGF-β1, which is also upregulated in TM cells by stretch.

In a recent study, it was shown that recombinant CTGF is as potent as TGF-β2 to induce ECM expression in TM cells. Following treatment with CTGF, an increase was observed in the expression of fibronectin, and of the collagen types I, III, IV, and VI (**Figure 3**). Moreover, transfection with CTGF-specific small interfering (si) RNA inhibited the TGF-β2-induced upregulation of CTGF and fibronectin, providing evidence that CTGF acts also in the TM as downstream mediator of TGF-β2 signaling. CTGF did not affect the expression of MMP-2, MMP 9, or PAI-1, indicating that CTGF mediates the TGF-β2-induced expression of TM ECM components, but is apparently not a downstream mediator of the effects of TGF-β2 on the extracellular proteolytic system in the TM. The effects of CTGF on TM cells were not restricted to the expression of ECM molecules, as TM cells synthesized also higher amounts of the integrin subunits, αv and β1, following treatment with CTGF.

CTGF is among the most highly expressed genes in the human TM, and it is tempting to speculate that the function of CTGF signaling in the TM involves the remodeling of cell–matrix adhesions in response to an increase in stress or strain in the TM, especially as CTGF induces the integrin subunit β1, an important component of fibronectin and collagen type IV binding integrins. While remodeling of JCT, cell–matrix adhesions might be the primary role of CTGF in the normal TM, a pathological increase in CTGF expression, for example, caused by activation of the abnormally high TGF-β2 levels in the AH of patients with POAG, could result in an increase in JCT ECM.

Bone Morphogenic Proteins

The action of TGF-β2 and CTGF on ECM turnover in the TM is strongly antagonized by bone morphogenetic protein-7 (BMP-7), a growth factor of the BMP family. BMP-7 is a 35-kDa homodimeric protein and member of the TGF-β superfamily of cysteine knot cytokines. In embryonic life, BMP-7 plays a critical role during renal and eye development. In the adult organism, the expression of BMP-7 is retained in the eye, in which its expression and that of its receptors have been shown in cornea, TM, and optic nerve. BMP-7 strongly antagonizes *in vitro* the TGF-β2-induced expression of a broad panel of molecules, which would result in an accumulation of ECM in the TM *in situ*. While treatment of human TM cells with TGF-β2 induces the expression of CTGF, TSP-1, fibronectin, collagen types IV and VI, and PAI-1, these effects are inhibited when TGF-β2 is added in combination with BMP-7 (**Figure 4**). BMP-7 by itself has no effects on the expression of all of these molecules. As BMP-7 is expressed in the adult TM *in situ*, it seems more than reasonable to assume that it similarly modulates and antagonizes the effects of TGF-β2 signaling on the TM *in vivo*. This protein has been shown to suppress TGF-β-induced effects on ECM synthesis also in other systems. In the cornea, BMP-7 antagonizes TGF-β-induced effects on corneal scarring. In the kidney, it counteracts an epithelial-to-mesenchymal transition that is induced by TGF-β1 and reverses chronic renal injury. In addition, BMP-7 antagonizes the TGF-β-dependent fibrogenesis in mesangial cells of the kidney-glomerulus. BMP-4 has very similar activities on the

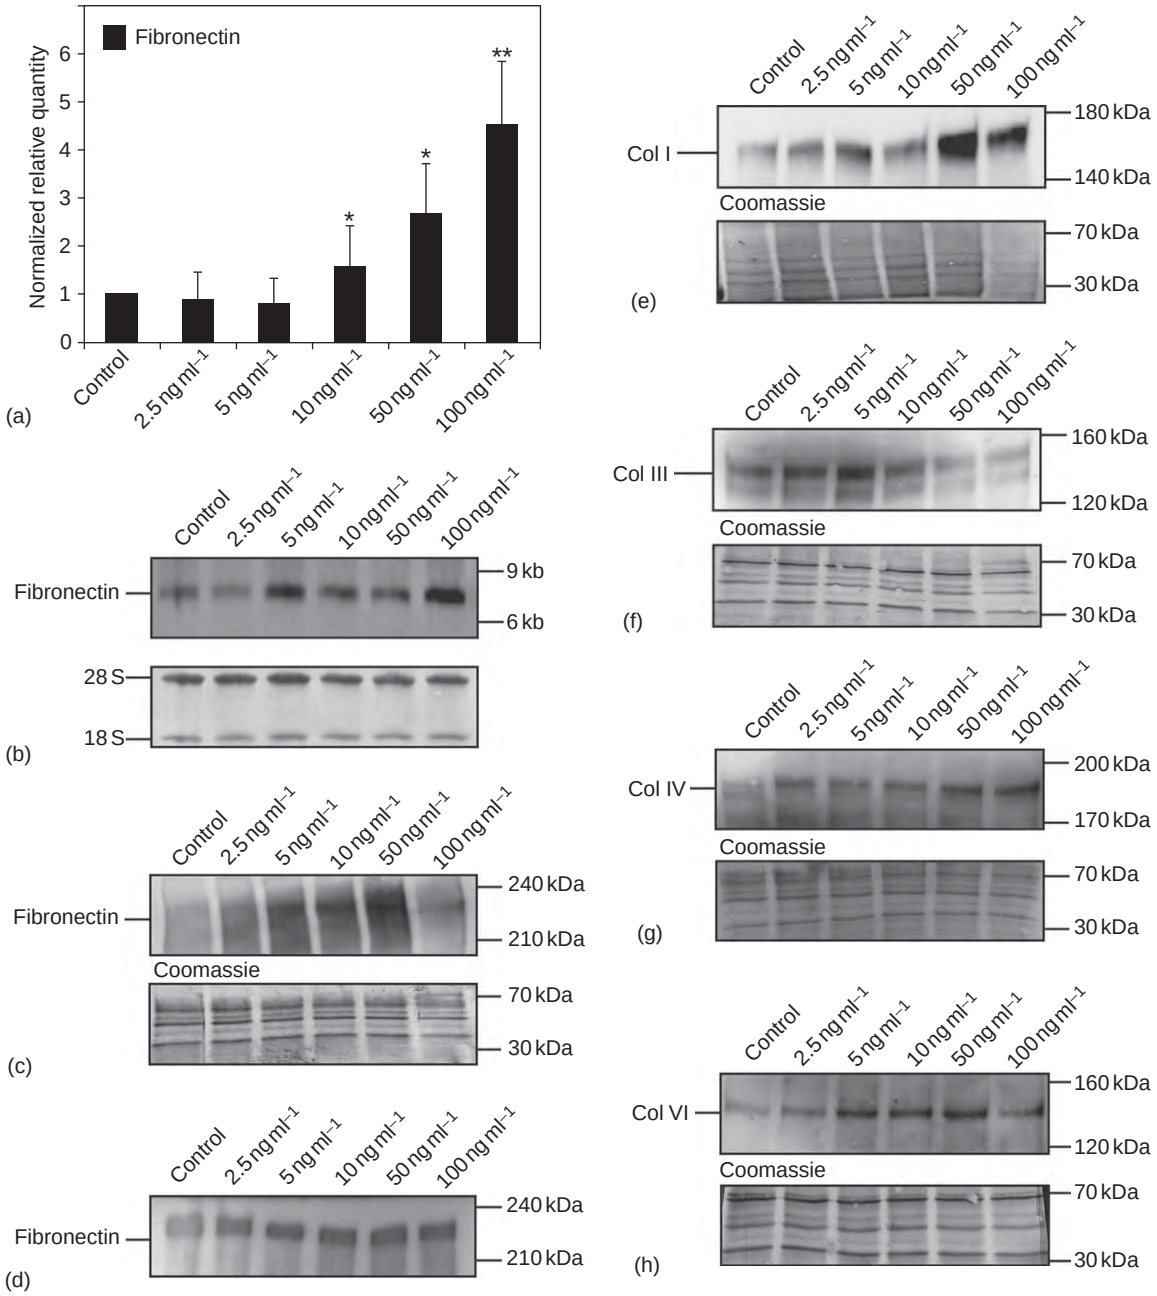

Figure 3 CTGF and its influence on the expression of ECM molecules in HTM cells. biology of TM cells as BMP-7 and also counteracts the action of TGF-β. Cultured TM cells treated with TGF-β 2 significantly increase fibronectin synthesis, while BMP-4 blocks the induction of fibronectin.

There are a number of molecules that regulate the signaling action of BMP family members, including that of BMP-7 and BMP-4, by binding to BMPs and preventing the ligand from interacting with the cellular receptor

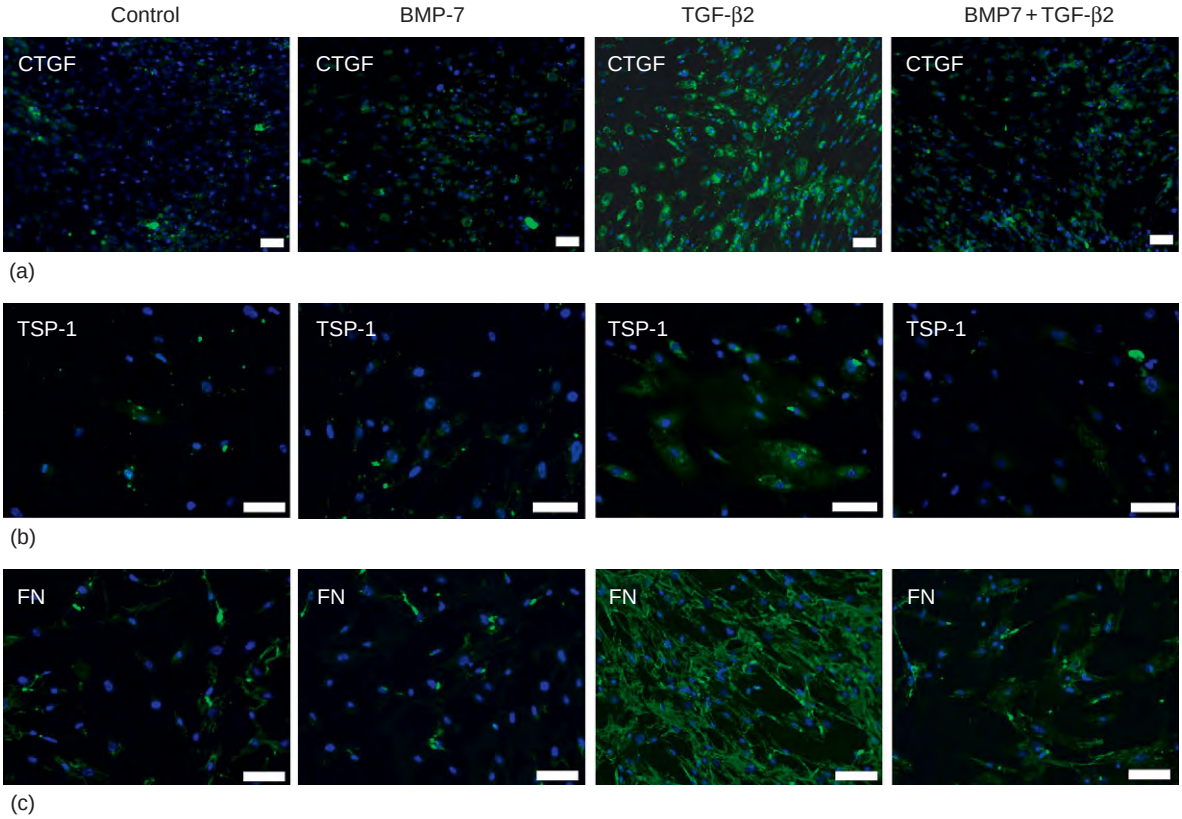

Figure 4 Immunoreactivity for connective tissue growth factor (CTGF, (a)), thrombospondin-1 (TSP-1, (b)), and fibronectin (FN, (c)) in cultured human trabecular meshwork cells following treatment with 300-pM bone morphogenetic protein-7 (BMP-7), 300-pM transforming growth factor-β2 (TGF-β2), or a combination of both. Treatment with 300-pM BMP-7 caused no changes in immunoreactivity. In contrast, after treatment with 300-pM TGF-β2, the intensity of staining for CTGF, TSP-1, and FN was considerably enhanced, an effect that was markedly reduced following treatment with a combination of BMP-7 and TGF-β2. Inset in (a) shows immunoreactivity for CTGF in cellular vesicles (arrowhead). Magnification bar = 100 μm. From Fuchshofer, R., Yu, A. H., Welge-Lüssen, U., and Tamm, E. R. (2007). Bone morphogenetic protein-7 is an antagonist of transforming growth factor-beta2 in human trabecular meshwork cells. *Investigative Ophthalmology and Visual Science* 48: 715–726, with permission from Association for Research in Vision and Ophthalmology.

complex. The expression of some of these BMP-associated molecules that act as BMP antagonists, such as follistatin, gremlin, and chordin, has been observed in TM cells. Applying gene chip analyses, the expression of molecules involved in BMP signaling was profiled and compared between normal TM cells and those from donors with POAG. As a result of this study, an upregulation of gremlin and its mRNA was found in POAG samples. In subsequent experiments, it was shown that gremlin blocks the negative effect of BMP-4 on the TGF-β2 induced upregulation of fibronectin. In anterior segment perfused organ cultures, gremlin added to the medium causes an elevation of outflow resistance strongly indicating that the BMP signaling pathway is involved in the modulation of TM outflow resistance.

Smad7

In order to learn more about the signaling network that is induced in TM cells treated with BMP-7, TGF-β2, or the combination of both factors, a microarray study was performed to identify genes that are differentially regulated following these treatment protocols. While multiple antagonistic and synergistic effects on the expression of a considerable number of genes with different functional properties were observed, it was also noted that both growth factors caused a substantial induction of Smad7. In contrast to receptor-associated Smads, such as Smad2 and Smad3, which mediate TGF-β signaling, Smad7 is an inhibitory Smad that functions as intracellular antagonist that inhibits TGF-β signaling. Since TGF-β1 and BMP-7 induce the expression of Smad7 in several cell types, the concept has been proposed that Smad7 plays an essential role in an autoinhibitory negative-feedback regulation of TGF-β signaling. Several mechanisms have been suggested on how Smad7 exerts its negative effects on TGF-β signaling. Smad7 inhibits signaling through stable binding to activated type I receptors and competition with receptor-associated Smads for receptor activation. In addition, Smad7 can

recruit the E3 ubiquitin ligases, Smurf1 and Smurf2, to the type I receptors, resulting in receptor ubiquitination, degradation, and termination of signaling. Finally, it appears also to act in the nucleus to disrupt the formation of the TGF-β-induced functional Smad–DNA complex. Indeed, by performing experiments with siRNA specific for Smad7, it could be confirmed that the knockdown of Smad7 mRNA expression in TM cells completely inhibits the antagonizing effects of BMP7 on TGF-β2 signaling (**Figure 5**).

The results strongly indicate that Smad7 is a key molecule to prevent TGF-β2-induced gene expression in the TM. The model would imply that TGF-β2 induces Smad7 in TM cells, an effect that shortens the time interval during

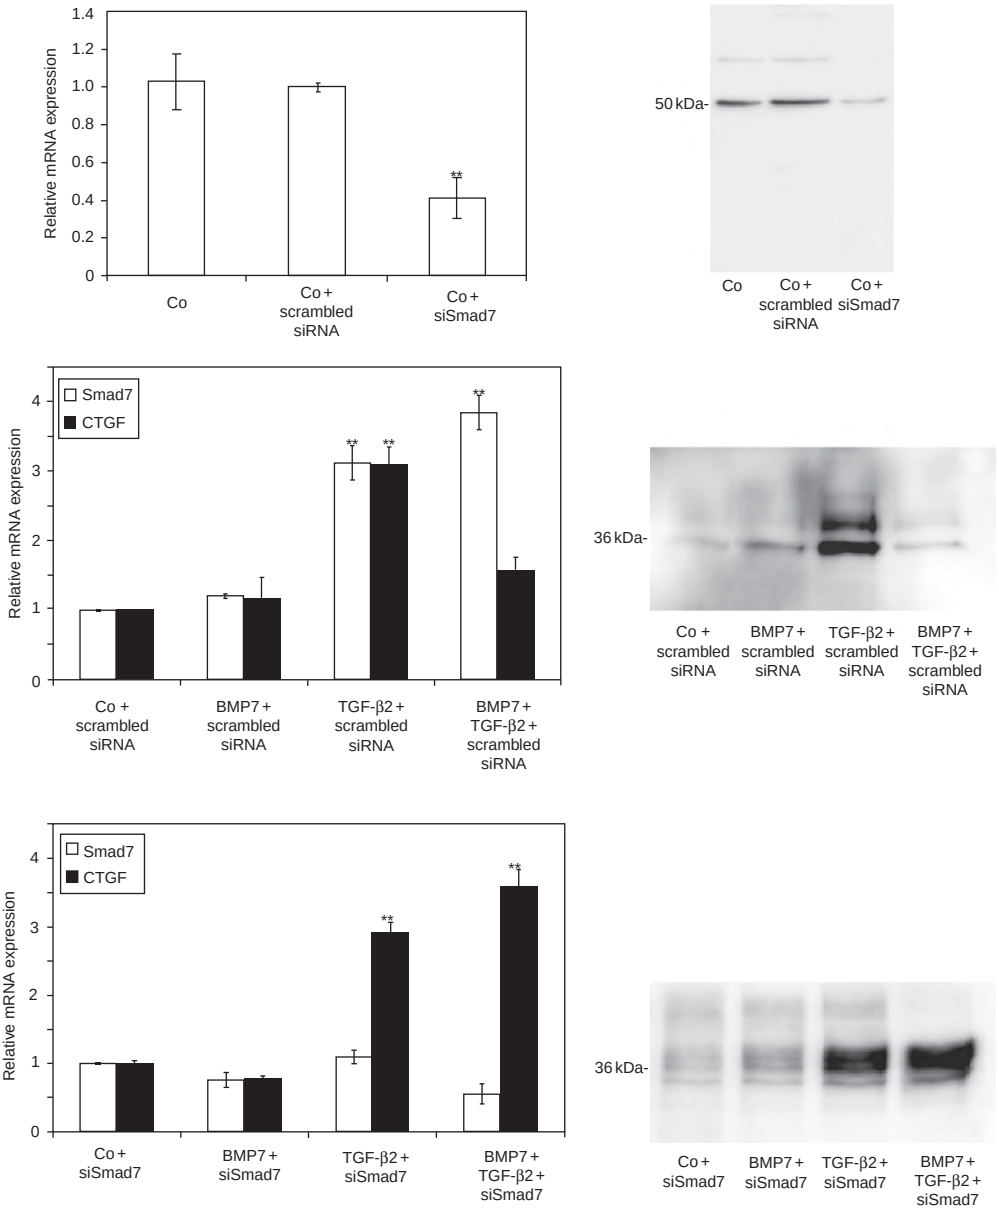

Figure 5 Silencing of Smad7 mRNA following transfection with specific siRNA (siSmad7) or scrambled siRNA, and its effects on Smad7 and CTGF expression in untreated HTM cells (Co), or cells treated with BMP-7, TGF-β2, or combined BMP-7/TGF-β2. (a) Real-time RT-PCR for Smad7 mRNA and Western blot analysis for Smad7. (b) Real-time RT-PCR for Smad7 and CTGF mRNA, and Western blot analysis for CTGF in culture medium of HTM cells transfected with scrambled siRNA. (c) Real-time RT-PCR for Smad7 and CTGF mRNA, and Western blot analysis for CTGF in culture medium of HTM cells transfected with siRNA against Smad7. Figure 6 Molecules that modulate extracellular matrix homeostasis in the trabecular meshwork (TM). Transforming growth factor-β's (TGF-β's), thrombospondin-1 (TSP-1), and connective tissue growth factor (CTGF) contribute to induce ECM deposition in the TM. Bone morphogenetic proteins (BMP)-7 and -4 antagonize the effects of TGF-β-signaling on matrix deposition, an effect that requires Smad7. From Fuchshofer, R. and Tamm, E. R. (2009). Modulation of extracellular matrix turnover in the trabecular meshwork. *Experimental Eye Research* 88: 683–688.

which TGF-β2-signaling is promoting the expression of its specific target genes. If BMP7 is added to TGF-β2, the expression of target genes is blunted or completely prevented, as the available amounts of Smad7 are induced to much higher levels than when TGF-β2 would act alone.

Conclusions

In recent years, important parts of the signaling network have been identified, which regulate homeostasis of ECM turnover in the TM (**Figure 6**). TGF-β, which derives from the AH or may be locally expressed, induces the expression of a variety of TM ECM molecules. The action of TGF-β very likely requires activation by TSP-1 and is partly mediated by its downstream mediator CTGF, both of which are constitutively expressed in the TM. BMP-7 and BMP-4 effectively antagonize the effects of TGF-β2 on matrix deposition. The antagonizing effects of BMP-7 are mediated in TM cells through Smad7.

Regulation of Intraocular Oxygen by the Vitreous Gel

N M Holekamp, Barnes Retina Institute, St. Louis, MO, USA
Y-B Shui and D C Beebe, Washington University, St. Louis, MO, USA

Glossary

Ascorbate – An ion of ascorbic acid; it is an antioxidant and a cofactor in vital enzymatic reactions. Almost all organisms manufacture ascorbate internally, with humans a notable exception. L-ascorbate is the biologically active form of vitamin C.
Intraocular oxygen tension – Oxygen as measured in mmHg by an optical oxygen-sensing probe when the probe is placed inside the eye, usually at various locations within the vitreous or aqueous humor of the eye.
Liquefaction – The process by which the gelatinous nature of the vitreous gel degenerates into liquid, and it usually accompanies aging.
Nuclear sclerotic cataract – A type of cataract characterized by increasing hardness or density at the center of the crystalline lens. Believed to be due to oxidation of nuclear proteins within the lens, and it usually occurs with aging.
Open-angle glaucoma – The most common type of glaucoma caused by gradual increase in resistance to normal outflow of aqueous from eye despite an apparently open anterior chamber angle. If untreated, results in gradual painless irreversible loss of vision.
Oxygen consumption – The process by which oxygen is a substrate in a biochemical reaction leading to the formation of a new product and a reduction in molecular oxygen.
Vitreous gel – The transparent, colorless, gelatinous mass comprised of water, fine collagen fibrils, and hyaluronic acid that fills rear the two-thirds of the eye between the lens and the retina. The water content of the vitreous is 98% yet the vitreous has a viscosity 2–4 times that of pure water, giving it a gelatinous consistency.

Introduction

The anatomy of the eye brings highly vascularized, oxygenated structures such as the retina, the ciliary body, and the iris within close proximity of avascular, relatively low oxygen structures such as the crystalline lens, aqueous, and vitreous. It is critical to the health of the eye that the low oxygen structures remain in a hypoxic environment. Thus, intraocular oxygen must be tightly regulated. There is new evidence that the human vitreous gel has the important biophysical function of oxygen consumption and therefore intraocular oxygen regulation. This function is markedly reduced as the gel undergoes age-related vitreous liquefaction or removal by vitrectomy surgery. Thus, a new understanding of vitreous gel function suggests that vitreous liquefaction may be central to the pathologic process in which excessive intraocular oxygen leads to oxidation-induced conditions such as nuclear sclerotic cataract and open-angle glaucoma.

Mapping of Intraocular Oxygen: Oxygen Gradients

Recent work by researchers at the Washington University School of Medicine in St. Louis has provided a partial map of intraocular oxygen tension in the human eye. Inhaled room air consists of 21% oxygen. Figure 1 shows that the avascular and translucent spaces of the eye are characterized by an oxygen tension below 4%. The definition of hypoxia is 5% oxygen or less. Thus, a large proportion of the human eye, specifically the avascular structures, exists under hypoxic conditions.

Figure 2 shows the actual oxygen measurements as measured by an optical oxygen probe that measures oxygen tension through fluorescence decay. In the anterior chamber there is a concentration gradient of oxygen from 25 mmHg right behind the central cornea to 3 mmHg just in front of the crystalline lens. Oxygen diffuses across the cornea into the anterior chamber. Both the aqueous and the crystalline lens have the ability to act as an oxygen sink to consume or metabolize the oxygen. In the posterior chamber, there is a concentration gradient from 9 mmHg adjacent to the ciliary body to 7 mmHg in the center of the vitreous cavity. Although not shown in Figure 2, oxygen tension at the retina has been measured by other investigators and was found to be quite high as expected, exceeding 30 mmHg. Thus, in the posterior segment most of the molecular oxygen comes from the retina. The vitreous gel acts as the sink to consume or metabolize the oxygen.

Figure 3 compares the oxygen mapping of the human to the oxygen mapping of the rabbit. The most notable difference is that in the posterior segment of the eye, the oxygen concentration gradient in the human is lowest in

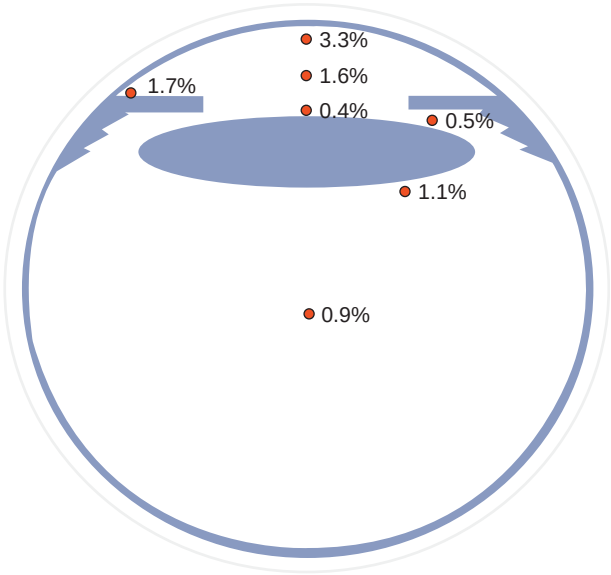

Figure 1 Oxygen distribution in the human eye (%). Reproduced from Holekamp, N. M., Shui, Y. B., and Beebe, D. C. (2005). the center of the vitreous gel, while the oxygen concentration gradient for the rabbit is lowest at the posterior surface of the lens. This elucidates an important difference in intraocular oxygen regulation between the species. In humans, the vitreous has the largest capacity to consume oxygen, while in the rabbit this important biochemical property resides mostly in the lens. Corroborating evidence is provided by the work of colleagues at the Washington University School of Medicine who found that the human eye differs from most other laboratory animals studied: the human vitreous has a much larger capacity to consume oxygen than the human lens. In animals, this relationship appears to be reversed. The animal lens has a much greater capacity to consume oxygen than the animal vitreous. Thus, in most animals, the lens protects itself from oxidative damage. In humans, it is primarily the vitreous gel that protects the lens from oxidative damage. This difference between humans and experimental animals may help explain why there is currently no animal model of nuclear sclerotic cataract.

The Vitreous Gel Consumes Oxygen: Experiments with Cadaver Vitreous

The vitreous gel is the largest component structure in the human eye and is located centrally between the highly oxygenated retina and the hypoxic crystalline lens. Within the vitreous gel is a steep oxygen concentration gradient. In order to maintain this gradient the vitreous gel must consume oxygen. **Figure 4** shows the results of an experiment in which a small sample of cadaver vitreous was placed in an oxygen-impermeable glass tube sealed with an optical oxygen probe. Oxygen tension starts out quite high at 120 mmHg and slowly falls to zero within 2 h. Thus, cadaver vitreous consumes oxygen. This metabolism is unaffected by boiling of the vitreous gel, suggesting an acellular, heat-resistant process.

The postulated biochemical reaction in which vitreous consumes oxygen is shown in **Figure 5**. In the presence of heat-stable, metal ion catalysts and the enzyme catalase, two molecules of oxygen react with one molecule of ascorbate to produce one molecule of oxygen and two molecules of water, with dihydroascorbate and hydrogen peroxide serving as intermediate products. It is important to note that water and ascorbate alone will not consume oxygen. Thus, factors important to this proposed chemical reaction are intrinsic to the vitreous gel.

The heat-stable catalyst in vitreous that promotes the ascorbate–oxygen reaction is not known. The oxidation of ascorbate can be catalyzed by metal ions, like copper or iron, and trace concentrations of metals have been detected in human vitreous. Although ethylenediaminetetraacetic acid (EDTA) completely prevents copper from catalyzing the oxidation of ascorbate by oxygen in a model reaction, treatment of vitreous with 10 mM EDTA slightly enhances the consumption of oxygen by vitreous humor. Compounds that bind iron and inhibit its ability to catalyze oxidation reactions only partially inhibit the ascorbate-dependent consumption of oxygen. This suggests that free iron contributes to this reaction,

but at least one other catalyst is also involved. These additional factors have not yet been fully elucidated.

Additional experiments with cadaver vitreous indicate that the rate at which the vitreous consumes oxygen varies proportionally to concentration of ascorbate in the vitreous gel, as shown in **Figure 6**.

Ascorbate in the Vitreous Gel

Ascorbate is essentially ascorbic acid or vitamin C. The concentration of ascorbate in human vitreous is remarkably high compared to other animal species. In a recent study, the mean concentration of ascorbate in the human vitreous gel was found to be approximately 2 mM. Blood levels are only 50–60 μM, suggesting a 33- to 40-fold difference. The high concentration of ascorbate in the vitreous is maintained by a sodium-dependent ascorbate transporter (SLC23A2) in the pigmented layer of the ciliary epithelium. The function of such high levels of ascorbate in the vitreous gel was once speculative, but now appears to be critical to the role of the vitreous gel in maintaining a low oxygen environment for the crystalline lens. It is important to note that as the vitreous gel consumes oxygen both the oxygen and the ascorbate are consumed in the reaction. Active transport of ascorbate into the vitreous gel is the only known mechanism by which to maintain a physiologic level. Little is known about the human transport molecule. However, the rat ortholog of this transporter shows half-maximal saturation at ~10 μM ascorbic acid, well below the concentration in human blood. Unless ascorbate transport by human ciliary epithelial cells is markedly different compared to rats, dietary supplementation with vitamin C is unlikely to significantly increase the concentration of ascorbate in the vitreous gel. This observation is consistent with large epidemiologic studies showing that oral vitamin C supplementation has minimal effect on the incidence or progression of nuclear cataract.

Oxygen Consumption in the Human Vitreous Gel

Laboratory experiments on the consumption of oxygen by human cadaver vitreous have been duplicated with samples of fresh human vitreous obtained at the time of vitrectomy surgery. Figure 7 shows a normal rate of oxygen consumption in vitreous gel obtained from a 55-year-old patient undergoing vitrectomy surgery for the first time. In contrast, Figure 8 shows a markedly slower rate of oxygen consumption in vitreous fluid obtained from a 79-year-old patient undergoing vitrectomy surgery for the third time. The fluid obtained from the 79-year-old patient was not gel but rather liquid, most likely the aqueous humor that fills the posterior segment after vitrectomy surgery. A comparison of Figures 7 and 8 suggest that the gel nature of the vitreous is important to its ability to consume oxygen. In fact, this proves to be true when large numbers of eyes are compared. Gel vitreous consumes oxygen at a significantly higher rate that liquid vitreous. Furthermore, gel vitreous has a significantly higher concentration of ascorbic acid than liquid vitreous.

The Importance of the Gel Structure of the Vitreous

Oxygen moving from the retina toward the crystalline lens will diffuse through gel as easily as water. The difference, however, between gel and liquid is flow or currents moving across the retinal surface. When the vitreous is mostly in the gel state, oxygen diffusing into the gel from retinal vessels is taken up and metabolized by nearby retinal tissue, as shown by oxygen microelectrode studies in experimental animals. However, when the vitreous liquefies, oxygen diffusing from the retinal vessels is readily carried away and distributed throughout the eye by fluid currents generated by convection and movement of the eyes or head. Therefore, as suggested above, the critical difference between gel and liquid vitreous may be the extent of mixing that occurs. The more that oxygen is mixed with the vitreous fluid, the more opportunity it will have to react with ascorbate. If the rate of transport of ascorbate into the eye is constant, the net result of increased mixing would be a lower concentration of ascorbate in the vitreous fluid, slowing down the consumption of oxygen. This hypothesis is consistent with previous studies in

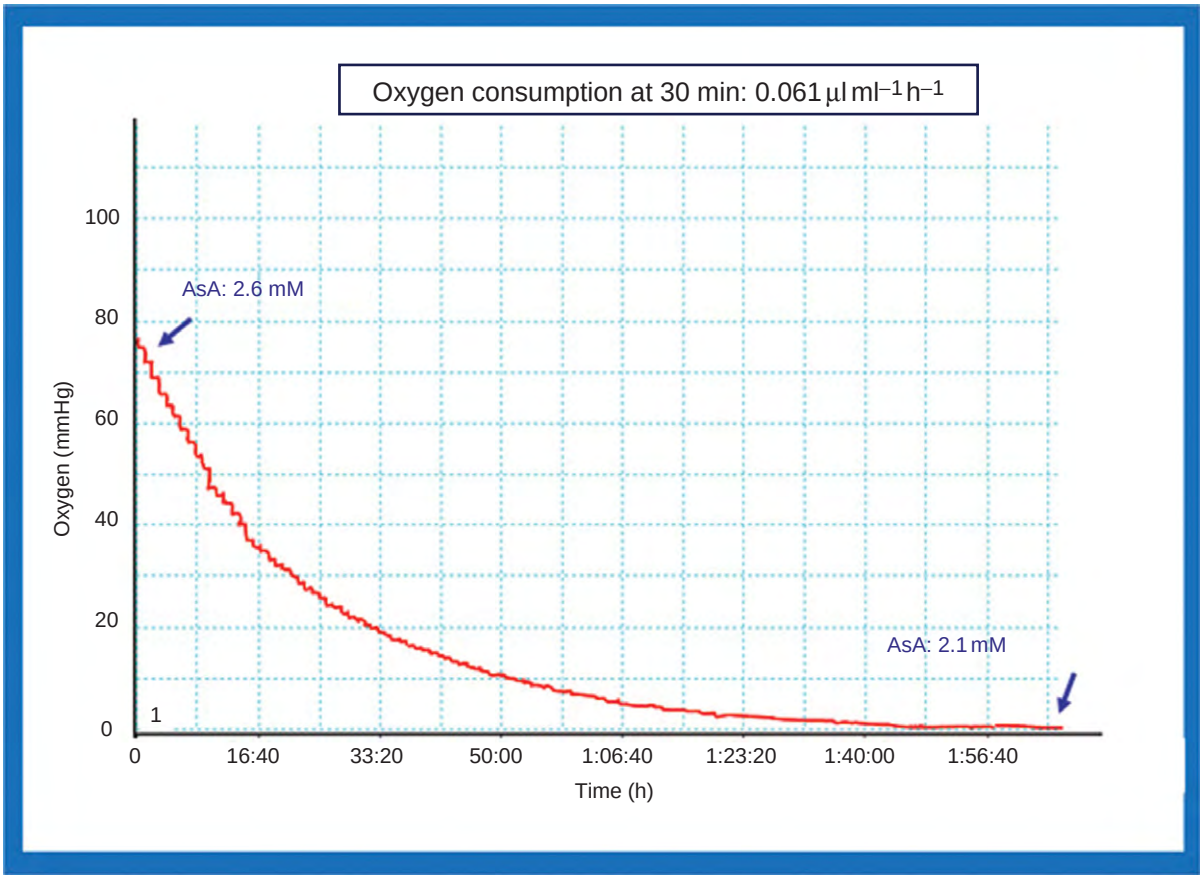

Figure 7 A 55-year-old-patient WF; first vitrectomy.

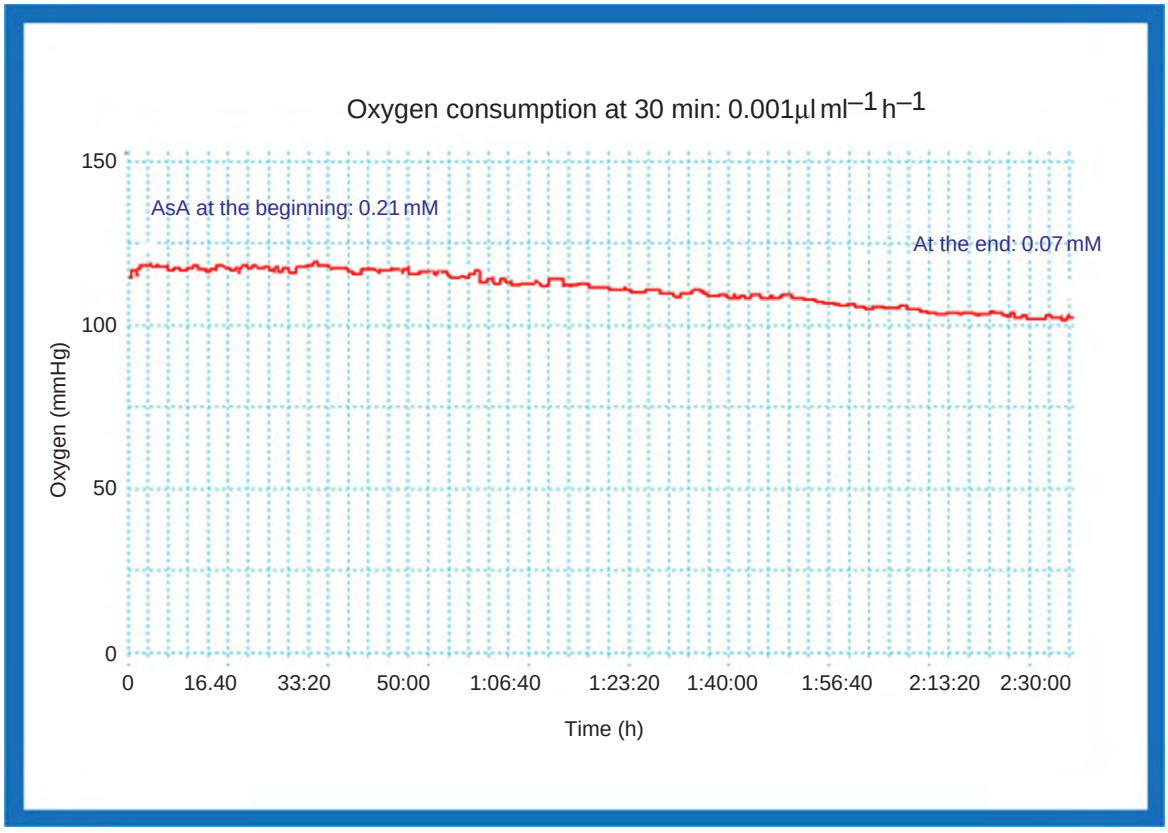

Figure 8 A 78-year-old patient WF; third vitrectomy.

which oxygen tension in the posterior segment of the eye was found to be higher in eyes that had the vitreous gel removed by vitrectomy surgery and physiologically replaced with aqueous.

Vitreous Liquefaction/Surgery Leads to Loss of Vitreous Gel Function

One newly identified function of the vitreous gel is to consume oxygen and protect the crystalline lens from oxidation of the nuclear proteins that ultimately leads to nuclear cataract. As the vitreous gel liquefies, this function diminishes. Harocopos and co-workers have documented the importance of vitreous liquefaction in nuclear cataract formation. **Figure 9** shows the results of a study of almost 100 cadaver eyes in which the degree of vitreous liquefaction correlates with degree of nuclear sclerotic cataract, independent of age.

Vitrectomy surgery is tantamount to instantaneous vitreous liquefaction. Vitrectomy surgery in phakic patients over the age of 50 years leads to significant nuclear cataract progression within 2 years. With few exceptions (as discussed below), such patients will invariably require cataract surgery within 2 years. Patients under the age of 50 likely have a cushion of formed vitreous gel immediately behind

Correlates	Adjusted for:	Partial Spearman coefficient	*P*-value
NS and liq.	Age	0.37	<0.0001
NS and age	Liquefaction	0.57	<0.0001

Figure 9 Liquefaction independent of age contributes to nuclear cataract. Reproduced from Harocopos, G. J., Shui, Y., McKinnon, M., Holekamp, N. M., Gordon, M. O., and Beebe, D. C. (2004). Importance of vitreous liquefaction in age-related cataract. *Investigative Ophthalmology and Visual Science* 45(1): 77–85. Copyright Association for Research in Vision and Ophthalmology.

the lens that is not removed at the time of vitrectomy. This may prove sufficient to consume oxygen and protect the lens from oxidative damage. Alternatively, a younger lens may retain some ability of its own to consume oxygen and protect itself. If these patients who undergo vitrectomy surgery prior to the age of 50 are followed for a period of 10 or more years, a milky-white discoloration of the nucleus of the crystalline lens with a myopic shift can be

noted. Another exception is that diabetic patients develop less-frequent and less-dense post-vitrectomy nuclear cataract than nondiabetic individuals. This may be explained by the fact that diabetic individuals have lower intraocular oxygen tension following vitrectomy. As noted above, the molecular oxygen is coming from the vascularized tissues of the eye. These patients are likely to have relative ischemia due to the microvascular complications of diabetes mellitus.

Corroborating evidence that surgical removal of the vitreous gel leads to loss of vitreous gel function and progressive nuclear sclerotic cataract can be found in a study of nonvitrectomizing vitreous surgery. In 2005, Sawa and co-workers published a series of 30 patients, median age of 70 years, who underwent nonvitrectomizing vitreous surgery in which an epiretinal membrane was delaminated without removal of vitreous gel or infusion of balanced salt solution. Scheimpflug lens photographs were taken at baseline and at a median of 5 years of follow-up. In contrast to what would be expected in this group of older patients, there was no significant progression of nuclear cataract.

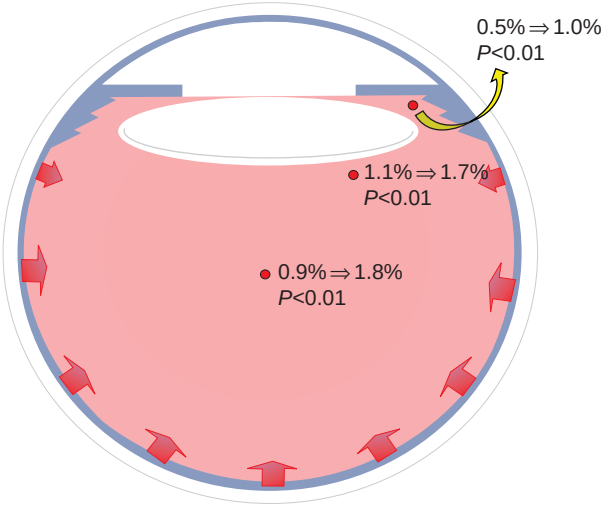

Figure 10 Oxygen levels increase long term after vitrectomy surgery. Reproduced from Holekamp, N. M., Shui, Y. B., and Beebe, D. C. (2005). Vitrectomy surgery increases oxygen exposure to the lens: A possible mechanism for nuclear cataract formation. *American Journal of Ophthalmology* 139(2): 302–310, with permission from American Journal of Ophthalmology.

Intraocular Oxygen Tension after Vitrectomy Surgery

Referring back to **Figures 1** and **2**, intraocular oxygen mapping of the human eye indicates that there are standing intraocular oxygen gradients. The vitreous gel maintains those gradients. Similar measurements taken immediately after removal of the vitreous gel through vitrectomy surgery shows that those gradients are lost. Similar measurements taken many months to years after vitrectomy surgery indicate that the intraocular oxygen tension is chronically higher. This reduction in oxygen consumption by the vitreous and the resultant loss of oxygen gradients and the elevation in intraocular oxygen tension transmit throughout the posterior pole up to the iris plane. **Figure 10** shows that the intraocular oxygen tension is statistically significantly higher long term after vitrectomy surgery. The human crystalline lens also has the ability to consume oxygen, although to a lesser extent than the vitreous gel. The lens may act as a physical and functional barrier to the increased oxygen tension in the posterior segment being transmitted to the anterior chamber. **Figure 11** indicates the changes in anterior chamber oxygen tension that occur when the crystalline lens is removed by cataract surgery. The anterior chamber oxygen tension increases, and this change has statistical significance centrally.

The vitreous gel and, to a lesser extent, the crystalline lens have the ability to consume oxygen and regulate intraocular oxygen tension. The loss of the vitreous gel after vitrectomy surgery raises intraocular oxygen tension and leads to nuclear sclerotic cataract. Once the opacified

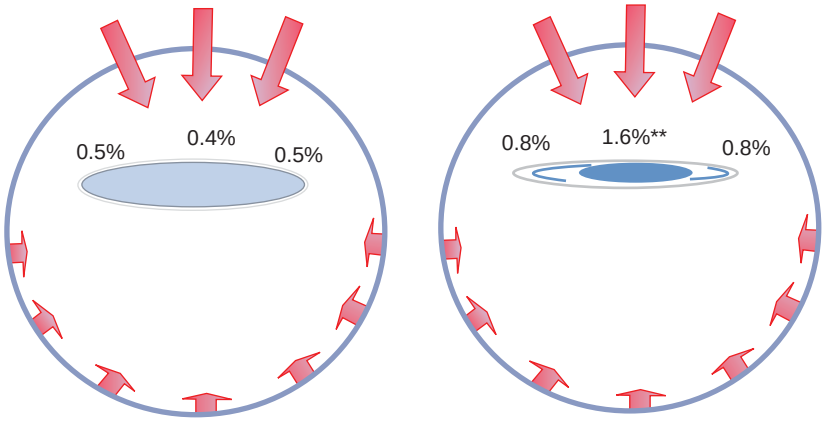

Figure 11 Cataract surgery increases anterior chamber oxygen levels.

lens is removed with cataract surgery the anterior chamber also experiences increased intraocular oxygen tension. In 2006, Stanley Chang hypothesized and supported with a large retrospective clinical study that 15–20% of eyes undergoing vitrectomy surgery followed by cataract surgery will develop open-angle glaucoma if followed long term. This work was duplicated recently by Luk and coworkers. There is growing evidence that oxidative stress may damage the cells of the trabecular meshwork as well as induce apoptotic neuronal cell death, two important mechanisms of open-angle glaucoma. Thus, removing the vitreous gel with vitrectomy surgery and removing the crystalline lens with cataract surgery render the eye devoid of two important tissues with the ability to consume oxygen and regulate intraocular oxygen.

Conclusion

Intraocular oxygen tension is highly regulated. In the human eye, the vitreous gel is the predominant intraocular tissue with the important biophysical property to consume molecular oxygen. It does so in an acellular, ascorbate-dependent chemical reaction. In addition, the gel nature of the vitreous is essential to this function. As the gel vitreous undergoes age-related liquefaction or surgical removal, the ability to consume oxygen is markedly reduced. The result is a significant long-term loss of normal intraocular oxygen concentration gradients and chronic elevation of intraocular oxygen tension. Thus, vitreous liquefaction or surgical removal may be an abnormal or pathologic state contributing to oxidation-mediated disease processes such as nuclear sclerotic cataract or open-angle glaucoma.

In summary, an intact vitreous gel is central to a healthy human eye. Currently, vitreous liquefaction is unavoidable in the human eye. The mechanism underlying this process is poorly understood. Very few mammals experience vitreous liquefaction, making the use of an animal model difficult. Currently, there are no major research efforts to prevent age-related vitreous liquefaction or to identify its causes. Future research on the vitreous gel should focus on the following areas: understanding and ultimately preventing vitreous liquefaction, methods to supplement liquefied vitreous with sufficient ascorbate to reestablish normal oxygen consumption capacity, vitreous substitutes that re-create the gel structure, and finding artificial means to regulate intraocular oxygen tension as the vitreous gel liquefies or is surgically removed.

Retinal Cannabinoids

S Yazulla, Stony Brook University, Stony Brook, NY, USA

Glossary

Age-related macula degeneration (AMD) – It comprises a variety of diseases, mainly of the elderly, that involves loss of vision in the central region of the retina.
Endocannabinoids – Natural chemicals in the body that are mimicked by the active component of marijuana.
Monoamine oxidase (MAO) – An enzyme that degrades dopamine.
Snellen acuity – A test of visual acuity that uses a standard sized "E" in four orientations.
Transient receptor potential type vanilloid 1 receptor (TRPV1) – An ionotropic receptor that increases intracellular calcium either by entry through the plasma membrane or from intracellular stores. It is activated by noxious heat, capsaicin, and the endocannabinoid, anandamide.
Vernier acuity – A test of visual acuity that tests the ability to detect displacement of two lines end-to-end.

Marijuana and the Endocannabinoids

The active component of the marijuana plant *Cannabis sativa*, Δ^9-tetrahydrocannabinol (THC), mimics endogenous chemicals, endocannabinoids (eCBs) that activate membrane receptors. eCBs include a variety of amide, ester, and ether derivatives of arachidonic acid. The most widely studied of these are arachidonoyl ethanolamide (anandamide, AEA) and *sn*-2 arachidonoyl glycerol (2-AG) (Figure 1). Other eCBs have been identified with varying degrees, or no affinity for cannabinoid receptors, and also compete with AEA and 2-AG for metabolizing enzymes. In this way, they modulate activity by competition at the receptors or by affecting substrate availability for metabolism.

Synthesis and Release

Unlike water-soluble transmitters, AEA and 2-AG are lipophilic and not stored in synaptic vesicles. Rather, membrane phospholipids are metabolized on demand to liberate AEA and 2-AG by calcium-dependent phospholipases. The precursor of AEA is *N*-arachidonyolphosphatidyl ethanolamine (NAPE), formed by calcium-dependent transfer of arachidonic acid (AA) from arachidonoylphosphatidylcholine to phosphatidylethanolamine (PE). There are multiple pathways for AEA liberation from the membrane. First, NAPE is hydrolyzed by phospholipase D (PLD) to release AEA and phosphatidic acid. Second, NAPE is hydrolyzed to *N*-acyl-lyso-PE by phospholipase A_1/A_2; then, AEA is released by lysophospholipase D. Third, phospholipase C (PLC) cleaves NAPE to generate phosphoanandamide, which is dephosphorylated to liberate AEA. The PLC pathway may be involved in the on-demand synthesis of AEA rather than in maintaining basal tissue levels of AEA. The primary pathway for 2-AG synthesis involves hydrolysis of diacylglycerols (DAG) by DAG lipase isozymes, DAGLα and DAGLβ. DAGs may be produced by the PLC β-catalyzed hydrolysis of phophotidylinositol or hydrolysis of phosphatidic acid by a phosphohydrolase. AEA and 2-AG freely diffuse within the membrane where they interact with the active sites of degradative enzymes and receptors. AEA binds reversibly to serum albumin, and it is likely that such binding is critical for the movement of AEA and 2-AG in blood, the extracellular matrix, and the cytoplasm. The presence and localization of AEA and 2-AG are inferred from the distribution of receptors, synthesizing and inactivating enzymes as well as physiological effects on identified cells.

Inactivation

AEA and 2-AG are inactivated following intracellular accumulation by fatty acid amide hydrolase (FAAH), monoacylglycerol lipase (MGL), cyclooxygenase-2 (COX-2), and lipoxygenase (LOX). AEA and 2-AG are hydrolyzed by FAAH into AA and ethanolamine or glycerol, respectively. 2-AG, but not AEA, is hydrolyzed by MGL. Following hydrolysis of AEA or 2-AG, AA is incorporated into membrane phospholipids. COX-2 oxidizes arachidonic acid, AEA, and 2-AG to prostamides or prostaglandin glyceryl esters, leading to prostaglandins. In addition, oxidation of AA by LOX produces 12-(S)-hydroperoxyeicosatetraenoic acid (15-(S)-HPETE), 5-(S)-HETE, and leukotriene B_4, all of which are agonists of TRPV1 receptors (Figure 2).The effects of AEA and 2-AG are modulated by the balance of metabolic enzymes that is specific to each cell type.

Receptors

Effects of cannabinoids are mediated by metabotropic (G-protein-coupled receptors (GPCRs)) and ionotropic

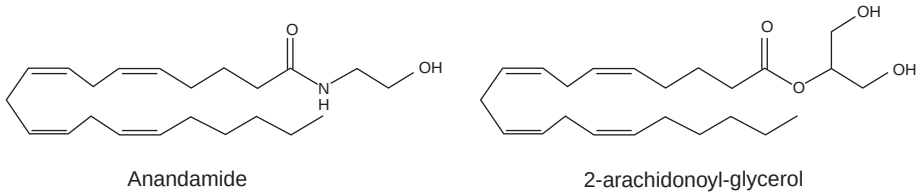

Figure 1 Chemical structures of endocannabinoids: arachidonoyl-ethanolamide (anandamide, AEA) and 2-arachidonoyl-glycerol (2-AG).

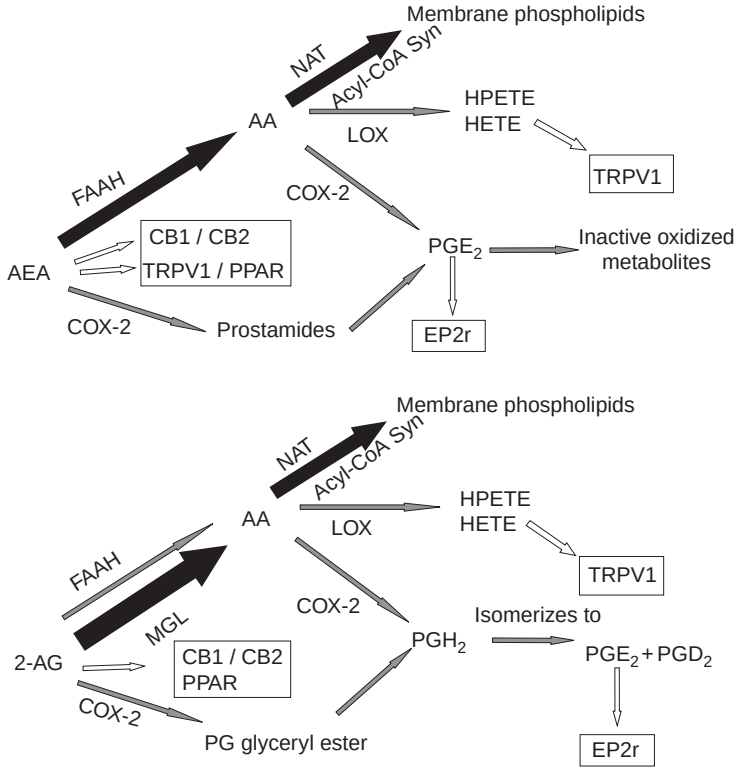

Figure 2 This schematic illustrates some of the metabolic pathways for the degradation of AEA and 2-AG. In the dominant pathways (bold arrows), AEA and 2-AG are hydrolyzed to arachidonic acid (AA), and then rapidly incorporated into membrane phospholipids via *N*-acyltransferase (NAT) and acyl-Coenzyme A synthetase. Lesser pathways (shaded arrows) involve oxidation by cyclooxygenase-2 (COX-2) of AEA, 2-AG, and AA to prostaglandins (PGE_2 and PGD_2). Additionally, AA may be oxidized by lipoxygenase (LOX) to 12-(S)- and 15-(S)-HPETE and 5-(S)-HETE. Hollow arrows show that AEA and 2-AG are endoligands for CB1, CB2, and PPAR receptors, while AEA also activates TRPV1 receptors. Metabolites of COX-2 oxidation activate EP2 receptors, and metabolites of LOX oxidation activate TRPV1 receptors.

(ion channel) receptors (Figure 2). In general, activation of cannabinoid 1 receptors (CB1Rs), via heterotrimeric guanosine-5'-triphosphate (GTP)-binding proteins Gi/o (Gi/o), modulates voltage-gated K^+ and Ca^{2+} conductances, resulting in a reduction of neurotransmitter release, particularly γ-aminobutyric acid (GABA) and glutamate. CB2 receptors, which also signal through Gi/o, are expressed in cells of the immune system and the central nervous system (CNS), particularly in astrocytes. There is evidence for additional cannabinoid receptors, perhaps GPCR 55. AEA, but not 2-AG, activates the ionotropic transient receptor potential type vanilloid 1 receptor (TRPV1) that increases intracellular calcium either by entry through the plasma membrane or from intracellular stores. Prostamides and prostaglandin glycerol esters, produced by eCB oxidation by COX-2, bind to a variety of prostaglandin receptors. eCBs are ligands for peroxisome proliferator-activated receptors (PPARs), members of the nuclear receptor superfamily that are involved in lipid metabolism, insulin sensitivity, regulation of inflammation, and cell proliferation.

Distribution and Function

CB1Rs are the most numerous GPCRs in the brain. eCBs, their receptors, and metabolizing enzymes are enriched in

brain regions associated with the physiological and psychomotor effects of cannabis. AEA and 2-AG have short- and long-term effects on synaptic plasticity and neuroprotection. The effects depend largely on retrograde transmission in which postsynaptic dendrites release an eCB that binds to presynaptic CB1Rs to reduce transmitter release. Retrograde release of eCBs is evoked by two mechanisms. In a voltage-dependent mechanism, depolarization of postsynaptic dendrites by L-glutamate opens voltage-gated calcium channels. The increase in intracellular Ca^{2+} activates Ca-dependent PLD to release an eCB. A second mechanism involves activation of heterotrimeric GTP-binding protein $G_{q/11}$ ($G_{q/11}$) coupled metabotropic receptors, usually group I metabotropic glutamate receptors (mGluRs), mGluR1 and mGluR5, and muscarinic receptors (M1 and M3). By enzymatic cascades that may or may not release calcium from intracellular stores, eCBs are released from the plasma membrane. The eCB-induced reduction of presynaptic glutamate and GABA release contributes to synaptic plasticity, while the reduction of glutamate release inhibits excitotoxicity following ischemia. Evidence implicates 2-AG more so than AEA in plasticity, while both AEA and 2-AG are involved in neuroprotection.

Cannabinoids and Ocular Tissues

Marijuana induces conjunctival vasodilation and reduces intraocular pressure (IOP), but is not a mydriatic. These effects are mediated locally by eCBs as demonstrated in the ciliary body, iris, choroid, and trabecular meshwork in mammalian tissues. THC, as low as 10^{-12} M, increases monoamine oxidase (MAO) activity in the bovine trabecular meshwork, choroid, and ciliary processes but not in the iris. Hydrolysis of anandamide has been measured in the porcine iris, choroid, lacrimal gland, and optic nerve. CB1 mRNA and CB1R-immunoreactivity (IR) have been detected in the ciliary body, trabecular meshwork, and conjunctival epithelium of rat, mouse, bovine, and human. AEA and 2-AG have been measured by gas chromatography in human ocular tissues. The content of eCBs varies in certain disease states, suggesting the importance of eCBs in maintaining ocular homeostasis. For example, 2-AG levels are lower in the ciliary body of patients with glaucoma. However, in diabetic retinopathy there are higher levels of 2-AG only in the iris, and increased levels of AEA in the retina, ciliary body, and cornea. Eyes of patients with age-related macula degeneration (AMD) also show increases of AEA in the retina, choroid, ciliary body, and cornea. Topically applied AEA reduces IOP by activation of CB1R and activation of the prostaglandin E 2 receptor (EP2R) after conversion of AEA to prostamides (see **Figure 2**). Administration of either AEA or THC to human nonpigmented epithelium (NPE) cells induces COX-2 expression, indicating a relationship among prostaglandins, COX-2, and eCBs in lowering IOP. In addition, EP2 receptors have been localized in the NPE of mouse, porcine, and human ciliary body.

Cannabinoids – Retinal Anatomy

Early studies of the effects of cannabis on vision were performed in concert with the effects of alcohol in order to examine the influence on visual motor behaviors as they related to driving. Anecdotal reports also came from studies citing side effects of cannabis when used as an analgesic. Effects on vision are subtle and include blurred and double vision, a reduction in vernier and Snellen acuity, alterations in color discrimination, an increase in photosensitivity and an increase in recovery from foveal glare. It is unlikely that all of these effects of marijuana are due to cortical or preretinal sites because processes of light–dark adaptation take place in the retina. Knockout mice that lack CB1Rs or FAAH are not blind, but the effects on vision have not been studied.

Biochemical Assay

The first evidence for cannabinoids in the retina was the demonstration that THC induced an increase in MAO activity, indicating a role in dopaminergic transmission. Later, FAAH-mediated hydrolysis of ^{3}H-AEA was shown in homogenates of porcine, bovine, and goldfish retinas. AEA and 2-AG were detected in mammalian retina by gas chromatography. Release of AEA from bovine retinal extracts in a physiological buffer demonstrated that the extracts contained the metabolic machinery necessary for eCB release, the precursor NAPE, and PLD.

Localization – Cannabinoid Receptors

CB1Rs have been localized by immunohistochemistry in the retinas of numerous species, including human, monkey, mouse, rat, chick, salamander, and goldfish. Despite differences in detail, there is a common theme. In general, the most prominent label is in cells of the through pathway: photoreceptors, bipolar cells, and ganglion cells. Cone pedicles in all species contain CB1Rs. Rod spherules appear to be labeled in all species except goldfish. Ultrastructural analysis has been performed exclusively on goldfish cones. CB1R-IR is on plasma membrane at the perimeter of the pedicle as well as within the invagination. CB1R-IR is not immediately apposed to the synaptic ribbon, but is at some distance from it. Regarding bipolar cells in mammals, CB1R-IR is restricted to rod bipolar cells as confirmed by double labeling with antisera against PKC. In goldfish, there is a higher proportion (~3:1) of CB1R-IR in ON bipolar cells compared to OFF bipolar

cells. This difference holds for mixed rod–cone bipolar cells as well as for cone bipolar cells. CB1R-IR, on the bipolar cell synaptic terminal membrane, is not adjacent to the synaptic ribbons. Rather, the CB1R-IR is always some distance removed from the ribbon, the same as observed for the cone pedicles.

Regarding rat horizontal cells, CB1R-IR is confined to the cell bodies and is not present on the dendrites, unlike bipolar cells. CB1R-IR is also found on a population of large amacrine cells, identified in rat as a rare type that is immunoreactive for PKC and GABA. In goldfish, CB1R-IR is on presynaptic membrane of amacrine cell boutons. These boutons appear throughout the depth of the inner plexiform layer and are presynaptic to bipolar cell terminals and small processes derived from ganglion cells. It is likely that these CB1R-immunoreactive processes are from a single type of diffuse amacrine cell.

CB1R-IR is on Müller's cells in goldfish but not in any other preparation. There are inconsistent reports of CB1R-IR in mammalian astrocytes, microglia, and oligodendrocytes. Activation of CB1Rs inhibits excitatory amino acid transport and induces glutamate release from astrocytes in the mammalian brain. CB1R and CB2R are involved in gliotic responses to injury. The interaction of eCBs and glia has not been investigated in the retina. CB2 mRNA was described in all cellular layers of the rat retina; this could include glial labeling, particularly Müller's cells.

Localization – Metabolizing Enzymes

There is relatively little information regarding the distribution of eCB metabolizing enzymes in the retina. The distribution of FAAH-IR in the rat and mouse is quite different from that in the fish. FAAH-IR, in rat and mouse, is most prominent in medium size and large ganglion cells, while weaker FAAH-IR is observed in the soma of horizontal cells, large dopaminergic amacrine cells, dendrites of starburst amacrine cells, and Müller's cells. FAAH-immunoreactive bipolar cells in rat and mouse are exclusively cone bipolar cells, in contrast to CB1R-IR that is exclusively in rod bipolar cells. In goldfish, FAAH-IR is present over cone photoreceptors, Müller's cells, and some amacrine cells, not ganglion cells as in mouse and rat. The distribution of FAAH-IR as it relates to FAAH activity was studied in goldfish retina. ^{3}H-AEA is hydrolyzed by FAAH with ^{3}H-AA rapidly incorporated into membrane phospholipids. Silver-grain deposition represents the trapping of ^{3}H-arachidonic acid in the plasma membrane. FAAH-IR and specific ^{3}H-AEA uptake showed the same pattern over cone photoreceptors, Müller's cells, and some amacrine cells. The co-distribution of FAAH-IR and ^{3}H-AEA uptake indicates that the bulk clearance of AEA from the extracellular space in the retina occurs as a consequence of a concentration gradient across the plasma membrane created by FAAH activity.

AEA is a ligand for the TRPV1 receptor whose binding site is on an intracellular domain. As FAAH and TRPV1 are integral membrane proteins of the endoplasmic reticulum and plasma membrane, respectively, FAAH activity may regulate the levels of AEA for TRPV1 activation. Also, following the hydrolysis of AEA by FAAH, LOX metabolites of AA could activate TRPV1. AEA then could act as an intracellular mediator by being produced from and/or degraded by the same neurons that express TRPV1 receptors. Supporting anatomical evidence for this scheme was provided first in goldfish in which co-localization of TRPV1-IR with FAAH-IR occurs in three types of amacrine cells, two of which are GABAergic. These cells ramify in interplexiform layer sublaminae *a* and *b*, indicating a general function in the OFF, ON, and ON/OFF pathways. The role would depend on the downstream cascade following the increase in calcium concentration.

MGL-IR co-localizes with FAAH-IR over medium size and large ganglion cells and with CB1R-IR in all rod bipolar cells in rat and mouse. In rat retina, COX-2-IR is constitutive in horizontal, amacrine, and ganglion cells. Following transient ischemia, COX-2 is upregulated in these cell types and induced in Müller's cells. This pattern in rat differs from mouse in which COX-2 is restricted to bipolar cell bodies and their axons. COX-2 bipolar cells are a mixed group, with 65% rod bipolar cells and 35% cone bipolar cells. Also rod bipolar cells are of two types: 68% contain COX-2-IR and 32% do not.

The cannabinergic system in vertebrate retinas, as indicated by CB1R-IR, FAAH-IR, COX-2-IR, and MGL-IR, is concentrated in the through pathway of photoreceptors, bipolar cells, and ganglion cells (**Table 1**).These cells for the most part use L-glutamate as their neurotransmitter. Cells of the inhibitory lateral pathways, horizontal cells and amacrine cells, do not feature as prominently. Exceptions are some horizontal cells, dopaminergic amacrine cells, and cholinergic starburst amacrine cells that label weakly for FAAH-IR. Bipolar cells tend to be of the on type and differentiated by rod and cone input. CB1R-IR and MGL-IR are restricted to rod bipolar cells, FAAH-IR to cone bipolar cells, and COX-2-IR to subtypes of rod and cone bipolar cells.

Cannabinoids – Retinal Physiology

Effects on Transmitter Release

Stimulation of CB1Rs via $G_{i/o}$ reduces voltage- and Ca^{2+}-evoked release of [^{3}H]-noradrenaline and [^{3}H]-dopamine in guinea pig retina. Agonists of CB1Rs, but not CB2Rs, inhibit K^{+}- and ischemia-evoked [^{3}H]

Table 1 The general distribution of CB1 receptors, FAAH, MGL, and COX-2 immunoreactivities in the retina of a variety of species as determined by immunohistochemistry

Species	*CB1*	*FAAH*	*MGL*	*COX-2*
Fish	Cones	Cones		
	25% OFF BC / 100% ON BC			
	Diffuse AC	TRPV1 AC		
	Müller's cells	Müller's cells		
Rat/Mouse	Rods/cones			
		HC (weak)		
	Rod BC	Cone BC	Rod BC	Rod/cone BC
	PKC AC	DA AC/ACh AC (weak)		
	Ganglion cells	Ganglion cells	Ganglion cells	
Salamander	Rods/cones/ganglion cells			
Chick	Rods/cones/ganglion cells			
Monkey	Rods/cones/ganglion cells			

BC – bipolar cells, AC – amacrine cells, DA – dopamine. Specific details may be found in the citations indicated for each species.

D-aspartate release from isolated bovine retina. Uptake of [^{3}H] D-aspartate identifies high-affinity uptake sites for L-glutamate and L-aspartate in photoreceptors, a small percentage of ganglion cells and Müller's cells. The rank order of potency for the CB1 agonists differs for K^+- and ischemia-evoked release. As photoreceptors are more resistant to ischemia than ganglion cells, the difference in the rank order could reflect the relative potencies of the agonists on CB1Rs on these cell types.

Effects on Ganglion cells

CB1R-mediated activity was demonstrated in rat retinal ganglion cells by [^{35}S]GTPγS autoradiography and reverse transcription polymerase chain reaction (RT-PCR). Voltage-activated Ca^{2+} currents in cultured rat ganglion cells are suppressed by cannabinoid agonist, WIN 55,212-2, an effect that is blocked by CB1 antagonists, SR141716A and AM281. The presence of CB1R function on rat retinal ganglion cells appears unusual in that CB1Rs tend to be at presynaptic boutons. One possibility is that CB1Rs are present on associational ganglion cells, whose axons and axon collaterals do not leave the retina. Rat and mouse ganglion cells also contain FAAH and MGL, putting them in position to regulate AEA and 2-AG as potential retrograde transmitters for suppression of bipolar cell and amacrine cell activity.

Effects on Bipolar Cells

CB1-mediated inhibition of L-type calcium (I_{ca}) and delayed rectifier ($I_{K(V)}$) currents has been reported for ON-bipolar cells of salamander and goldfish. As yet there are no data on OFF-bipolar cells. The voltage-activation range of the currents is not altered, but simply scaled down over the entire activation range. Goldfish mixed rod–cone (Mb) bipolar cells also have D1 dopamine receptors that enhance I_{Ca} and $I_{K(V)}$ via G protein G_s. CB1R agonists and dopamine oppose each other to modulate $I_{K(V)}$ of Mb bipolar cells. Co-application of WIN 55,212-2 (0.1–0.25 μM) reversibly blocks the enhancement induced by 10 μM dopamine even though low concentrations of WIN 55,212-2 have no effect when applied alone. The effects of dopamine and cannabinoid agonists on $I_{K(V)}$ occur within the physiological range of Mb bipolar cell function (∼–25 to 0 mV). $I_{K(V)}$ would be activated during the on portion of the response and, as a counter current, would modulate the peak:plateau ratio of the response. CB1R activation should make the Mb bipolar cell on response more tonic by suppressing the hyperpolarizing effect of $I_{K(V)}$, whereas D1 receptor activation should make the on response more phasic by enhancing $I_{K(V)}$. The effect on ganglion cells should be relatively tonic responses in scotopic (dark-adapted) conditions and relatively phasic responses in photopic (light-adapted) conditions. CB1-induced suppression of calcium currents should reduce transmitter release and reset sensitivity to further increments.

Cannabinoids and Photoreceptors

Voltage-Gated Currents

CB1-mediated modulation of photoreceptor membrane currents has only been reported for tiger salamander and goldfish. The voltage-activation ranges of these currents are not affected. Salamander rods and cones responded differently to WIN 55,212-2. I_K is suppressed in single cones and rods, whereas I_{Ca} is suppressed in cones but enhanced in rods. The differential effect on I_{Ca} and I_K in rods would increase transmitter release, resulting in the reduction of sensitivity, which is an apparent counter-adaptive effect. Goldfish cones show a biphasic response

to WIN 55,212-2: an enhancement of I_K, I_{Cl}, and I_{Ca} via G_s at concentrations $<1\,\mu M$, and suppression via $G_{i/o}$ at concentrations $>1\,\mu M$. The data obtained with retrograde suppression, to be described below, suggest that the enhancement produced by WIN 55,212-2 may be due to agonist-specific trafficking in which binding of agonists to CB1Rs favors coupling to different G proteins. For example, WIN 55,212-2 increases intracellular calcium by $G_{q/11}$ coupling in human trabecular meshwork cells, while other CB1 agonists, including THC, 2-AG, CP55940, and methanandamide couple to $G_{i/o}$ but not to $G_{q/11}$. The caution is that the data obtained with WIN 55,212-2 may or may not apply to other agonists or the eCBs.

An effect of evoked released of eCBs in the retina was demonstrated in goldfish. Retrograde suppression of membrane currents in goldfish cones in a retinal slice was achieved by applying a puff of saline with 70 mM KCl or an mGluR1 agonist, RS-3,5-dihydrophyenylglycine (DHPG), through a pipette at an Mb bipolar cell body while recording $I_{K(V)}$ from cone inner segments under whole-cell voltage clamp (**Figure 3(a)**). Retrograde inhibition of $I_{K(V)}$ was reversible and stable over several hours

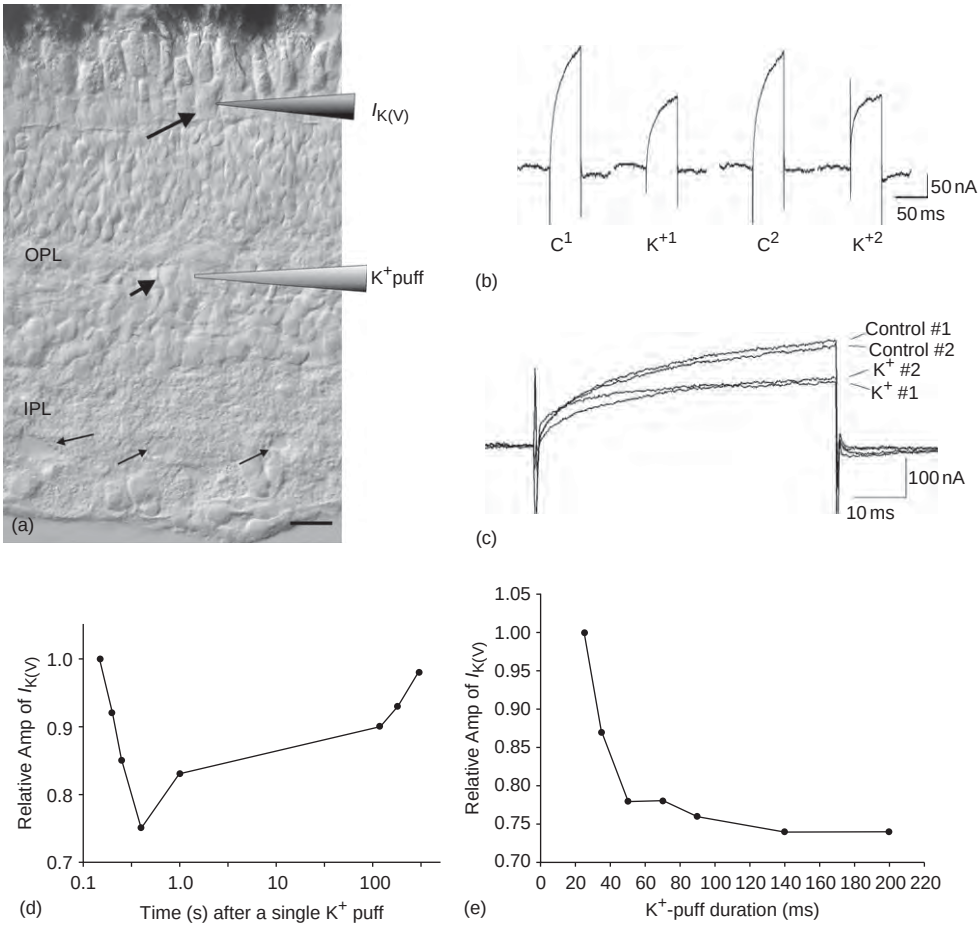

Figure 3 Properties of the retrograde responses of cones. (a) An illustration of the method used to detect retrograde responses in goldfish cones in a retinal slice. Whole cell recordings of $I_{K(V)}$ were obtained from long-single cones (long arrow). A puff pipette, containing 70 mM KCl, was positioned slightly upstream and at the cell body of an Mb bipolar cell (short arrow). Thin arrows indicate the synaptic terminals of Mb bipolar cells. OPL – outer plexiform layer, IPL – inner plexiform layer. Calibration bar = 20 μm. (b), (c) Sequential and overlay of raw records of $I_{K(V)}$ from a single cone evoked by a 50-ms depolarizing pulse to +54 mV from a holding potential of –70 mV. The records have not been normalized. A 50-ms K^+ puff was delivered twice. $I_{K(V)}$ in response to K^+ puff #1 was reduced compared to that evoked for the prepuff control #1. The cone was allowed to recover for 30 min after K^+ puff #1. $I_{K(V)}$ returned to control amplitude (C2, control #2). The K^+ puff #2 produced an equivalent reduction in $I_{K(V)}$. (d) Time course (log scale) of the reduction of $I_{K(V)}$ in response to a single 50-ms puff of K^+ shows a latency of about 200 ms following the puff, a peak response at about 500 ms, and a gradual return to control level by 5 min. (e) Effect of K^+ puff duration on $I_{K(V)}$. These data were obtained from a single cone over 4 h. After a prepuff control value of $I_{K(V)}$ was obtained, a 25-ms K^+ puff was administered and the effect on $I_{K(V)}$ was determined. The cell was allowed to recover for 30 min and another prepuff control and a K^+ puff of a longer duration was administered. This sequence was followed for all puff durations. Thus, the value plotted for each puff duration is relative to its own prepuff control. There was no effect with a puff of ≤25 ms duration. Near maximal suppression of $I_{K(V)}$ at about 25% was achieved with a puff of 50 ms and there was little additional effect with puffs as long as 200 ms. Reproduced from Fan, S. F. and Yazulla, S. (2007). Retrograde endocannabinoid inhibition of goldfish retinal cones in mediated by 2-arachidonoyl glycerol. *Visual Neuroscience* 24: 257–267.

(Figures 3(b) and 3(c)). It had a latency of about 200 ms after a K^+ puff, was reduced on average by 25%, and had a halftime of 3.4 min to recover (Figure 3(d)). Retrograde suppression of $I_{K(V)}$ was unaffected by a combination of the GABA receptor antagonist, picrotoxin, and α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA) glutamate receptor antagonist, 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX), but blocked completely by the CB1 antagonist, SR141716A, indicating mediation by CB1 receptors. Experiments with the FAAH inhibitor (URB597), a COX-2 inhibitor (nimesulide), and a blocker of 2-AG synthesis (Orlistat) indicated that 2-AG, rather than AEA, is the retrograde eCB.

Two conditions evoke 2-AG release from Mb bipolar cells, strong depolarization and activation of mGluR1, corresponding to voltage-dependent and voltage-independent mechanisms. Rods and cones release glutamate at a steady rate under any ambient illumination; this rate is increased by decrements of light intensity and decreased by increments in light intensity. Voltage-dependent release of 2-AG would occur following depolarization of the Mb bipolar cell in response to a light flash. The retrograde suppression of glutamate release from cones would be a positive feedback that would amplify the reduction in cone transmitter release initially caused by increasing light intensity. This may not be physiologically relevant because the halftime to recover from a 50-ms stimulus is several minutes. The long half-life of the suppressive effect should make this mechanism insensitive to rapid changes in intensity.

The voltage-independent mechanism that provides negative feedback on glutamate release may be more functional. Hypothetically, glutamate, released during ambient illumination, stimulates mGluR1α on Mb bipolar cells tonically to maintain a steady release of 2-AG via a $G_{q/11}$ mechanism. The degree of feedback inhibition of glutamate release from cones varies inversely with ambient illumination; the

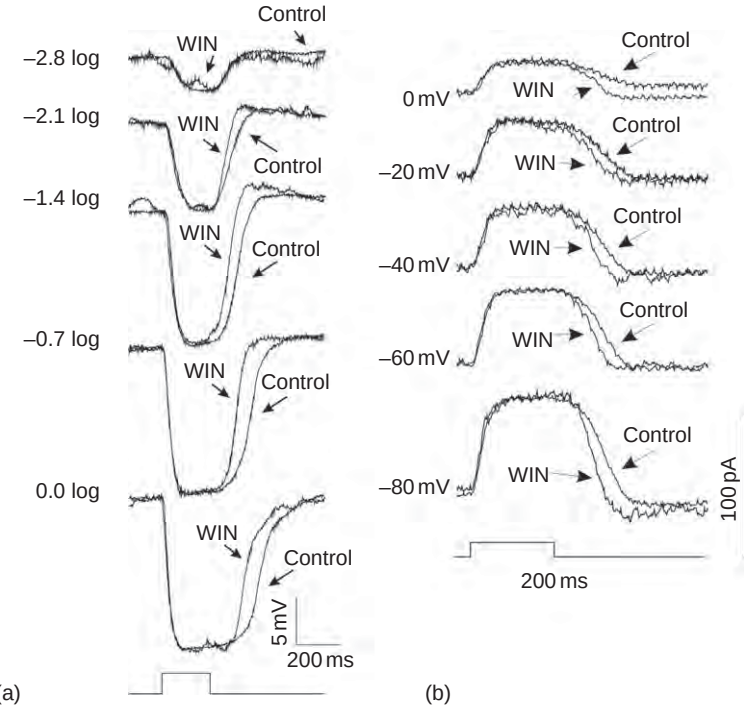

Figure 4 Effect of WIN 55,212-2 on the responses of goldfish cones in an isolated retinal preparation to flashes of light. (a) Voltage-light responses of an L-cone under current clamp to a 200-ms light stimulus of increasing intensities (log unit changes, top to bottom) for Control conditions and after 8 min in 10 μM WIN 55,212-2. Indicated at the left are relative stimulus intensities. The response amplitudes in the control and WIN conditions differed from each other by about 10%. To facilitate comparison, the traces were normalized and superimposed. Except for the dimmest intensity (-2.8 log), there was a speeding up of the response to light offset and an enhancement of the overshoot at two intermediate intensities. There was no effect on the response to light onset or on the plateau phase of the response. The 5 mV calibration refers to the control response. (b) Current-light responses of an L-cone at different holding potentials to a 200-ms light stimulus of approximately half-maximal intensity in control and 10 μM WIN 55,212-2. The timing of the light stimulus is indicated at the bottom of the figure. The amplitude of the light response decreased with decreasing holding potential because the holding potential approached the reversal potential of the photocurrent. The response amplitudes in the control and WIN conditions differed from each other by 5–20%. To facilitate comparison, the traces were normalized and superimposed. Speeding up of the response to light offset in response to WIN 55,212-2 is apparent at all holding potentials. There was no effect of WIN 55,212-2 on the response to light onset or plateau phases of the light response. The holding potential did not change the kinetics of the light responses. The 100 pA calibration refers to the control response. Modified from Struik, M., Yazulla, S., and Kamermans, M. (2006). Cannabinoid agonist WIN 55212-2 speeds up the cone light offset response in goldfish. *Visual Neuroscience* 23: 285–293.

dimmer the background, the stronger the negative feedback. As background is increased, feedback is reduced. Thus, ambient illumination produces an eCB tone that maintains transmitter release from cones within narrow limits. In this way, the ability of the cone to respond to increases and decreases of light intensity is maintained regardless of background. Retrograde transmission occurs even though Mb bipolar cells were hyperpolarized by glutamate acting on either the excitatory amino acid transporter (EAAT) or mGluR6 receptor. The retrograde effect was suppression of currents and not biphasic as expected from data obtained with low concentrations of WIN 55,212-2. It was this finding that led to the idea that the enhancing effect of WIN 55,212-2 on goldfish cones and salamander rods was due to agonist specific trafficking.

WIN 55,212-2 Affects the Cone Light Response

WIN 55,212-2 affects not only cone membrane currents, indicative of presynaptic modulation, but also the response of cones to light. Goldfish cones in an isolated retina preparation were stimulated by light in combination with voltage- and current-clamp protocols (**Figure 4**). WIN 55,212-2 (10 μM) has no effect on the absolute sensitivity of the cones or the kinetics of the onset response. However, the light offset response is faster and the depolarizing overshoot is enhanced. This effect is seen at all but dim intensities (**Figure 4(a)**) and is independent of holding potential (**Figure 4(b)**). This is found under current-clamp as well as under voltage-clamp conditions, indicating modulation of the cyclic guanosine monophosphate (cGMP)-gated channels in the cone outer segment rather than by voltage-dependent currents. The effects of WIN 55,212-2 are not blocked by SR141716A, indicating that CB1Rs are not involved. Given a train of flashes, the photocurrent recovers more quickly with WIN 55,212-2, such that the peak-to-peak response to succeeding flashes is increased. This effect, combined with the shortened recovery time to the offset of bright flashes, could increase contrast detection or critical flicker frequency. A concern is whether the effect of WIN 55,212-2 on the photoresponse would be observed with other CB1 agonists or eCBs because the effect of WIN 55,212-2 is not mediated by CB1 receptors.

In summary, cannabinoids presynaptically suppress the synaptic output of photoreceptors and on-bipolar cells. The effect is subtle as might be expected since smoking marijuana does not produce blindness. Evidence for effects of cannabinoids on amacrine cells is strongest for their suppression of dopamine release. Dopamine, a signal for light adaptation in the retina, antagonizes the action of cannabinoids in on-bipolar cells. eCBs are critically involved in neuronal plasticity. This also appears to include light and dark adaptation, processes of neuronal plasticity that occur in the retina.

Cannabinoids – Development and Neuroprotection

Studies regarding the effects of prenatal-marijuana use on children show deficits on visual habituation, tremors, and startle responses in neonates of 4–30 days old, but no effects on children of 1–6 years old. Problems with behavior, visual perceptual tasks, language comprehension, attention, and memory in 9-year-olds are attributed to effects on the prefrontal cortex, an area enriched in CB1Rs. Although CB1R localization and effects on GABA release have been studied in embryonic rat and chick retinas, no studies have investigated or commented on the effects of manipulating eCBs on retinal development.

The end point of glaucoma is ganglion cell death by apoptosis that may be caused by optic nerve injury following compression or ischemia. CB1 agonists (THC and cannabidiol) as well as inhibition of FAAH protect ganglion cells from glutamate excitotoxicity and ischemia caused by increased IOP. In contrast, COX-2 contributes to neuronal cell death following ischemia or NMDA-toxicity in glial cells, retinal pigment epithelium (RPE), and ganglion cells, while COX-2 blockers prevent ganglion cell apoptosis. Despite progress on the interaction of eCBs, COX-2 metabolites, and EP2 receptors in neuroprotection in the brain, such information is lacking in the retina.

Conclusion

The cannabinergic system is concentrated in the through pathway of the retina. Cannabinoids suppress dopamine release from amacrine cells and presynaptically inhibit potassium currents and glutamate release from cones and on-bipolar cells. How this relates to light and dark adaptation, receptive field formation, temporal properties of ganglion cell responses, and ultimately visual behavior needs to be addressed. eCBs are the most recently described neuromodulators to be studied extensively in neural and non-neural tissues. The existence of multiple eCBs, degradative enzymes, and receptors paints a picture of great complexity. They are important for their role in neuroplasticity and neuroprotection. Further study will verify the importance of eCBs in the retina as well.

Retinal Degeneration through the Eye of the Fly

N J Colley, University of Wisconsin, Madison, WI, USA

Glossary

ABC-type multidrug transporter – A family of adenosine-triphosphate-binding cassette (ABC) transmembrane proteins that transports various molecules, including proteins, ions, sugars, and lipids, across extracellular and intracellular membranes using energy derived from adenosine triphosphate (ATP).
Allele – One member of a pair of genes occupying a specific location on a chromosome (locus) that controls the same trait, for example, eye color.
cGMP phosphodiesterase (PDE) – This enzyme is found in several tissues, including the rod and cone photoreceptor cells, and it belongs to a large family of cyclic nucleotide PDEs that catalyze the hydrolysis of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) into AMP and GMP, respectively.
Class B scavenger receptors – A family of proteins, which includes the scavenger receptor class B type I (SR-BI), and CD36, which are cell surface receptors that mediate lipid uptake. They are also thought to play an important role in vitamin A metabolism by mediating the uptake of carotenoids into cells.
Cyclophilin – A protein that binds the immunosuppressant drug, cyclosporin, which is often used to suppress tissue rejection following an organ transplantation. The protein displays peptidyl prolyl *cis–trans* isomerase activity, which catalyzes the *cis/trans* isomerization of peptide bonds on proline residues and is thought to play a role in protein folding.
Flippases – The enzymes located in the membrane that aid in the movement of phospholipid molecules between the two leaflets that comprise a cell's membrane. The process requires energy derived from ATP.
Homeodomain-containing transcription factors – A homeobox is a DNA sequence found within genes that regulates developmental processes in animals, fungi, and plants. A homeobox is about 183-DNA-bp long and it encodes a 61-amino-acid protein domain, called the homeodomain, which binds DNA and plays a key role in the regulation of gene expression.
Paired domain – A conserved domain found in a set of transcription factor proteins which are important in regulating gene expression during development. Paired box (PAX) genes belong to the PAX family of transcription factors.
Rab-GTPase – These are small guanine-nucleotide-binding proteins (G proteins) conserved from yeast to humans and are members of the Ras superfamily of small GTPases. They function in distinct steps in membrane trafficking pathways, including vesicle formation, actin- and tubulin-dependent vesicle movement, and membrane fusion events.
Retinitis pigmentosa (RP) – A heterogeneous group of genetically inherited retinal degeneration disorders leading to progressive loss in vision. Many people with RP retain some sight all their life, others become legally blind in childhood, and some become legally blind in their 40s or 50s. The progression of RP is different in each case.
Rhabdomere – The light-sensing organelle of the *Drosophila* photoreceptor cell. It is the functional equivalent of the outer segment of vertebrate rod and cone cells. A rhabdomere is made up of 60 000 tightly packed microvilli, and each microvillus is 50 nm in diameter and about 1–2 μm in length.
Second-site modifier screens – The genetic screens that are designed to detect a mutation in a second locus (gene) that enhances or suppresses the effect of an existing mutation.

'Prized pest'
You hover over the soft, brown
bananas like a floater, in and out
of my vision, you whose eyes
are so much like my own.

Who am I, dear one,
to swat at you, send you
swirling toward the ceiling
when, really, we share
the same humble beginnings.
And you in your simplicity
hold the key to my complexity.

Let me set out a plate of the sweetest
peaches, invite you to rest
on the arm of my chair,
however late it is.

Marilyn Annucci

Each model organism used to study retinal degenerative diseases has the advantage that others lack. Frogs, fish, rats, and mice have all provided great insights, but it is the tiny fruit fly, *Drosophila melanogaster*, that has played a central role in elucidating the molecular genetics of eye development and the early identification of mutations that cause retinal degeneration. The first mutations in *Drosophila* known to cause retinal degeneration were identified in the 1960s by the pioneering studies of Bill Pak and co-workers. At that time, these findings were only of interest to a few investigators. It was thought that animals as different as flies and humans could not share a similar genetic makeup and, therefore, the amount of transferable knowledge would be limited.

The revolutionary finding that put flies into the spotlight was the one showing that genes controlling pattern formation and development in flies could also do so in humans. In the 1980s, homeodomain-containing transcription factors were found to be essential during development in *Drosophila* for directing the production of appendages, such as the legs and the antennae. Almost identical homeodomain-containing genes were found in the genomes of a wide range of organisms, including humans and mice. This knowledge led to the conclusion that organisms as different as flies and humans contain nearly identical genes. A few years later, working on eye development, Walter Gehring's lab cloned the *eyeless* gene in *Drosophila*. They discovered that *eyeless* is a transcription factor, containing a paired domain and a homeodomain, that directs eye formation. The *eyeless* gene is related to the mouse and human *Pax6* genes (paired box), and the *eyeless*/*Pax6* genes regulate a cascade of genetic processes involved in eye development. Mutations in these genes result in aniridia in humans, a Small eye (*Sey*) phenotype in mice and an *eyeless* phenotype in *Drosophila*. Aniridia is a congenital condition that is characterized by incomplete iris formation. Further, when expressed in flies, both the *Drosophila eyeless* gene and the mouse *Pax6* gene (*Small eye*, or *Sey*) were able to direct the production of ectopic compound eyes. That *Sey* induced the formation of compound eyes and not mouse structures revealed that mice and flies share signaling components that are interchangeable. The proteins encoded by these genes share 94% identity in the paired domain and 90% identity in the homeodomain. It is remarkable that *eyeless* is not only essential for eye formation, but also its ectopic expression can override other developmental processes in a variety of tissues. For example, *eyeless* is capable of directing leg, wing, and antennal tissues to form eyes. As a result of these findings, *eyeless*/*Pax6* was dubbed a master regulatory gene for eye formation during development. These landmark discoveries led to an explosion of exciting work in the 1990s that prompted a reassessment of the evolution of eyes. A complex network of eye determination genes direct eye formation, including another Pax6, *twin of eyeless* (*toy*), *sine oculis (so)*, *eyes absent (eya)*, and *dacshund (dac)*. Counterparts of these genes play a role in mammalian eye development and have been implicated in a variety of human diseases. These studies reveal that even though the compound eye of the fly looks very different from mammalian eyes, both share similar signaling pathways that are able to substitute for each other to form an eye.

Due to these elegant findings, it is now widely accepted that many genes are functionally equivalent between flies and humans. In addition, the same (or similar) mutations cause disease in both species. In fact, nearly three-fourths of all human disease genes have related sequences in *Drosophila*. Examples include gene mutations involved in retinal degeneration, deafness, skeletal malformations, cognitive impairment, cancer, immunity, alcoholism, cocaine and nicotine addiction, heart disease, metabolic and storage diseases, Alzheimer's disease, Parkinson's disease, and Huntington's disease.

At the turn of the twentieth century in the hands of Thomas Hunt Morgan, the founding father of *Drosophila* research, *Drosophila* emerged as a powerful genetic workhorse. In 1910, Morgan identified the first mutation in *Drosophila*, which was a spontaneous *white* eye-pigment mutation that caused a normally red-eyed fly to be white eyed (**Figure 1(a)**). This first allele transformed our understanding of genetics and heredity. The *white* gene encodes a membrane-associated, adenosine triphosphate (ATP)-binding, ATP-binding cassette (ABC)-type multidrug transporter required for the transport of pigment precursors involved in eye pigment biosynthesis. In humans, mutations in the *ABCA4* gene (also *ABCR*) account for approximately 3% of autosomal recessive retinitis pigmentosa (RP) and are linked to both recessive cone–rod dystrophy and recessive Stargardt macular dystrophy. Similar to the *Drosophila white* gene, the *ABCA4* gene encodes a membrane-bound, ATP-binding transporter that in humans localizes to the rims of rod and cone outer segment disks. The ABCA4 transporter serves as a flippase in the retinoid cycle. When the *ABC4* gene is mutated, toxic detergent-like by-products accumulate in the retinal pigment epithelium (RPE) leading to severe pathology. Therefore, the *white* gene, discovered at the turn of the century, was subsequently found to encode an ABC-type transporter required for eye pigment biosynthesis in *Drosophila*, and is related to another ABC-type transporter in the human eye that is involved in the retinoid cycle and several types of retinal diseases.

Not only do we share many genes in common with flies, but we also share a great deal of the same metabolic and signaling pathways. Flies are now being used as genetic models for the National Aeronautics and Space Administration (NASA) astronauts and are providing vital information on how space travel and gravitational changes alter gene expression. Work on flies continues to reveal

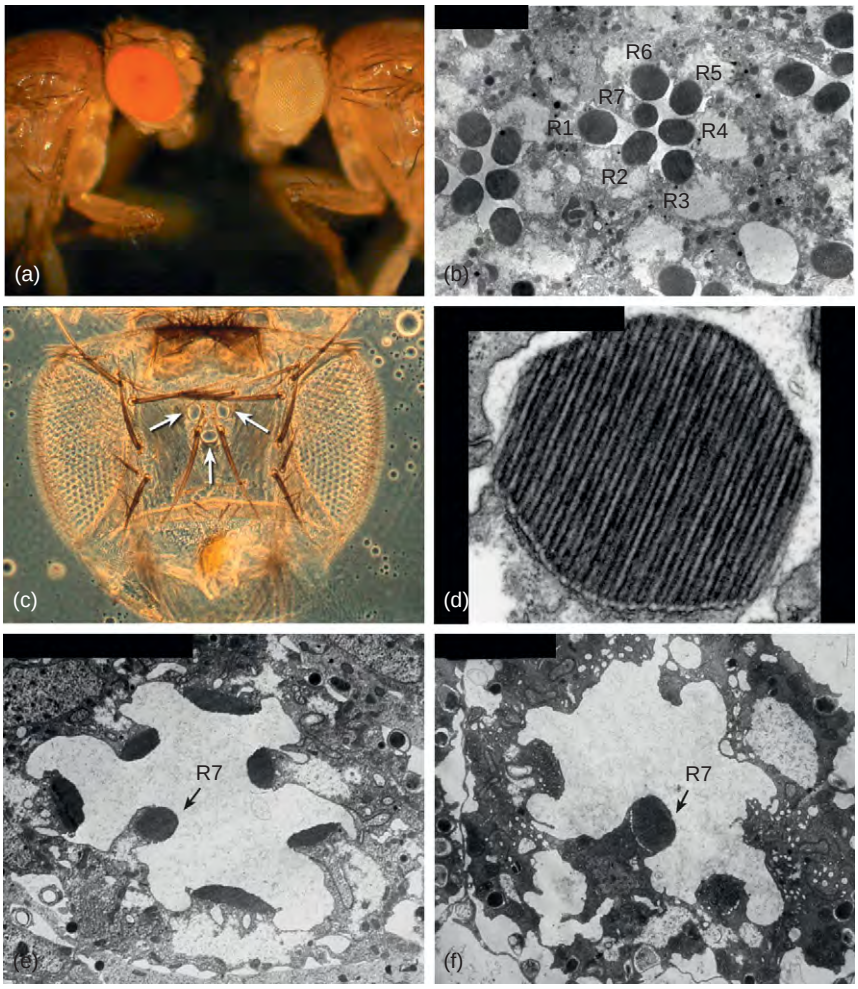

Figure 1 (a) Wild-type red-eyed fly, Canton S compared to a white-eyed mutant fly, w^{1118}. (b) Cross section through the compound eye showing the R1-7 photoreceptor cells and their photosensitive rhabdomeres (R). The R8 photoreceptor cell is located below the plane of the section. (c) The adult *Drosophila* visual system showing the two compound eyes and the three simple eyes (ocelli) located on the top of the head (arrows). (d) A higher magnification of a rhabdomere showing the microvilli. The rhabdomeres are made up of about 60 000 microvilli and are 50 nm in diameter and 1–2 μm in length. (e) A newly eclosed $ninaE^{I17}$ mutant fly, showing the reduced size of the rhabdomeres. $ninaE^{I17}$ is a null allele, so the flies completely lack Rh1 rhodopsin expressed in the R1-6 photoreceptor cells. (f) Six-day-old $ninaE^{I17}$ fly, showing that the rhabdomeres of the R1-6 photoreceptor cells are almost completely gone, but the R7 cell rhabdomere remains.

general principles that are fundamental to a wide spectrum of biological processes. Studies in *Drosophila* have led to conceptual and technical breakthroughs in the areas of development, gene expression, learning and memory, sleep, alcoholism, cocaine and nicotine addiction, ecology and evolution, olfaction, taste, mechanotransduction, vision, hearing, aging, pigmentation, biological clocks and circadian rhythms, courtship and mating behaviors, and human disease and the development of new pharmaceuticals.

In addition to sharing genes and signaling pathways with humans, flies are a powerful model for providing insights into human health and disease for other reasons. In spite of their small size, flies display complex rituals such as courtship behavior, so questions related to the genetic basis of complex behavior are tractable in the fly. The fruit fly uses the same or similar genes to develop from a fertilized egg to an adult, but they do it in the short time of about 11 days. A female will lay hundreds of eggs, allowing large numbers of genetically identical offspring to be obtained. Flies have a short life span of about 2 months, so the onset and progression of age-related retinal degeneration disorders or any other age-related degenerative process can be studied quite rapidly.

The eye is not essential for viability or fertility of the flies, therefore genes encoding proteins that are uniquely required for visual function may be easily manipulated and studied. Large-scale mutagenesis screens have been carried out, producing hundreds of thousands of mutant flies whose phenotypes can be analyzed to identify genes required for vision. In addition, second-site modifier screens have been used to identify novel genes in

signaling pathways. Fly models can be used to dissect the cell biological basis and physiological basis of retinal degeneration, and therefore can be used to obtain insights into mechanisms of degenerative disorders. Just like in humans, electroretinogram (ERG) recordings can be carried out, and they have proved to be an indispensable means for uncovering visual system defective phenotypes that would otherwise have remained unnoticed.

Transgenic flies can be easily produced and, as a result, mutant genes may be introduced and mutant phenotypes may be complemented with wild-type transgenes. Using specialized promoters, genes may be targeted to specific tissues and may also be overexpressed. The fly has a relatively small genome, made up of about 13 600 genes in four pairs of chromosomes. However, despite the dramatic differences in size and apparent complexity between humans and flies – we have less than twice as many genes as a fly – our genome is estimated to be made up of only 20 000–25 000 genes contained in 23 pairs of chromosomes. Therefore, despite the fly's perceived simplicity, or our perceived complexity, our genetic makeup may not be all that different. Its versatility for genetic manipulation and convenience for unraveling fundamental biological processes continue to guarantee the fly a place in the spotlight for unraveling the basis of and therapeutic treatments for human disease.

The Compound Eye and Phototransduction

The *Drosophila* compound eye is composed of approximately 800 individual eye units called ommatidia, each containing the outer, R1-6 photoreceptor cells that extend the full length of the retina and express the major rhodopsin in the eye, the blue-sensitive rhodopsin, Rh1 (**Figure 2**). Rh1 is encoded by the *ninaE* gene, and it displays 22% amino acid identity with human rhodopsin. The inner photoreceptor cells, R7 and R8, are arranged such that a subset of the R7 cells expresses the ultraviolet (UV)-opsin, Rh3. They pair with the R8 cells expressing the blue-sensitive opsin Rh5 (p-ommatidia), while the R7 cells expressing the UV-opsin Rh4 pair with the R8 cells expressing the green-sensitive opsin Rh6 (y-ommatidia). The R7 cells are located above their partner R8 cells (**Figures 1(b)** and **2**). Above the photoreceptor cells are four cone cells and two lens components; the pseudocone (also called the crystalline cone) and the corneal lens. Two primary pigment cells surround the cones and each ommatidium is optically isolated by a sheath of secondary and tertiary pigment cells (**Figure 2**). The adult visual system also contains three simple eyes, ocelli, located on the top of the head (**Figure 1(c)**). The ocelli express the violet-sensitive, Rh2 opsin. *Drosophila* photoreceptor cells contain specialized portions of the plasma membrane,

Figure 2 Schematic of an ommatidium. Adapted from Tomlinson, A. and Ready, D. F. (1987). Cell fate in the *Drosophila ommatidium*. *Developmental Biology* 123: 264–275.

called rhabdomeres, which comprises approximately 60 000 tightly packed microvilli containing rhodopsin photopigments and other components of the phototransduction cascade (**Figure 1(b)** and **1(d)**). The microvillar processes of the rhabdomeres are functionally similar to the phototransducing disk membranes present in the vertebrate photoreceptor outer segments (**Figure 3**).

Phototransduction in *Drosophila* utilizes a signaling cascade in which light stimulation of rhodopsin leads to the activation of the heterotrimeric guanine-nucleotide-binding G protein (Gq) and the stimulation of phospholipase C beta (PLC-β), leading to the opening of the cation-selective transient receptor potential (TRP) and TRP-like (TRPL) channels. The photoreceptors depolarize as intracellular calcium dramatically rises from about 100 nm to about 10 μM. In the rhabdomeres, calcium rises even higher, to about 1 mM, and it is required for amplification, rapid response kinetics, and light adaptation in *Drosophila*. Calcium is subsequently removed from the rhabdomeres by a combination of sodium/calcium exchange and diffusion into the cell body where calcium increases to about 10 μM. Calcium in the cell body is buffered by calcium-binding proteins and is removed by uptake into intracellular stores by the sarco/endoplasmic reticulum (ER) calcium ATPase. The *Drosophila* phototransduction cascade shares some similarities with the phototransduction cascade in mammalian rod and cone photoreceptor cells. Both cascades are initiated by light-activation of rhodopsin that in turn leads to the stimulation of heterotrimeric G proteins. Phototransduction in *Drosophila* as well as in humans is terminated when the protein arrestin binds to light-stimulated rhodopsin and blocks the binding of rhodopsin

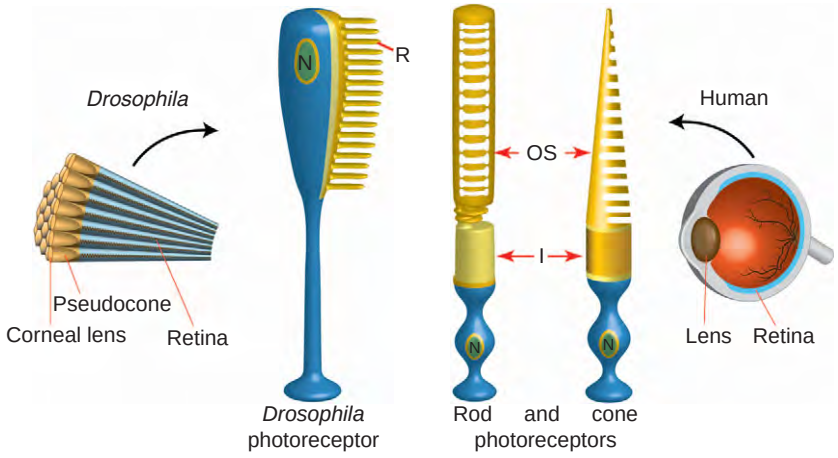

Figure 3 The *Drosophila* photoreceptor cell compared with human rod and cone photoreceptor cells. In *Drosophila*, the pseudocone cone (also called the crystalline cone) and the corneal lens are the lens elements, and they are secreted by the underlying cone cells. The *Drosophila* lens is comprised of droscrystallin, which is similar to insect cuticular proteins. R, rhabdomere; OS, outer segments; I, inner segments; N, nucleus. to Gq. However, notable differences are that rod and cone channels are gated by cyclic nucleotides and they close in response to light, leading to a hyperpolarizing response.

Although certain features of phototransduction in *Drosophila* differ from rod and cone phototransduction, *Drosophila* phototransduction shares many common features with the cascade in intrinsically photosensitive retinal ganglion cells (ipRGCs). These cells function in circadian rhythm entrainment and pupil constriction. The light response in ipRGCs is initiated with absorption of light by melanopsin, which is more similar to *Drosophila* rhodopsins than to the photopigments in rods and cones. Light-stimulated melanopsin is thought to activate a phophoinositide cascade leading to the opening of channels that display similar properties to TRP channels. Therefore, *Drosophila* photoreceptor cells and ipRGCs share similar phototransduction cascades, and studies in flies will continue to provide insights into ipRGC function.

Genetic Screens Identify Retinal Degeneration Loci

Several forward genetic screens in *Drosophila* led to an explosion in the identification of many genes involved in retinal degeneration, and their counterparts in human disease. The approach has been to chemically mutagenize flies to disrupt photoreceptor cell function. The mutagenized flies are tested for function by ERG analysis, morphology by a deep pseudopupil (DPP), or Western blotting for the loss of candidate gene expression (such as arrestin). The ERG approach was pioneered by Bill Pak and co-workers in the 1960s and led to the isolation of over 200 ERG-defective mutants. In the 1980s, the development of gene-cloning techniques for *Drosophila* made it possible to isolate the corresponding genes. For example, *neither inactivation nor after potential E* (*ninaE*), a mutant isolated in the original ERG screen was later found to harbor a mutation in the structural gene for the major rhodopsin in *Drosophila*, Rh1. In 1985, almost a decade prior to the cloning of eyeless, *Drosophila* rhodopsin, Rh1, was cloned and sequenced by two groups and found to display 22% amino acid identity with bovine rhodopsin. In addition, the first evidence that mutations in a rhodopsin gene led to retinal degeneration came from elegant studies in the 1980s in *Drosophila*. The use of the ERG in *Drosophila* was an effective strategy to identify mutants in phototransduction and also in retinal degeneration.

The DPP is a sensitive phenotype in the eye that can be easily assessed in live flies. It is based on the precise packing of the photoreceptor cells. Any mutation leading to, even subtle, structural alterations in photoreceptor cells will cause attenuation in the DPP. For example, a reduction in rhodopsin levels in the R1-6 photoreceptor cells in *ninaE* mutants, leads to structural alterations in the photoreceptor cells (**Figures 1(e)** and **1(f)**) and attenuation in the DPP. A variety of mutants were isolated by this method, including dominant alleles of *ninaE* (rhodopsin), and alleles of two chaperone proteins, *ninaA* (cyclophilin) and *calnexin*. Both the ERG and the DPP screens accelerated the pace of identifying mutations that cause retinal degeneration in *Drosophila*.

Retinal Degenerations in Flies and Humans

Mutations in rhodopsin are the leading cause of blinding disease in RP. RP is a heterogeneous group of inherited disorders that is characterized by progressive retinal

degeneration and eventual blindness. RP may be inherited as an X-linked (about 5–15% of cases), autosomal recessive (50–60%), and autosomal dominant trait (30–40%). It affects one person in 4000 worldwide and is often restricted to the eye, but not always. In about 20–30% of the cases of RP, the genetic defects are not eye specific. There are approximately 30 syndromes that involve RP. One of the most common syndromes is Usher's syndrome. This syndrome is characterized by vision and hearing impairment, and mutations in myosin VIIA are responsible for one form, Usher 1B syndrome. Interestingly, loss of myosin VIIA function leads to deafness in *Drosophila*. In flies, like in humans, there are many examples of mutations in which the phenotype caused by the mutation is restricted to the eye, whereas there are others that are not. For example, mutations in the gene encoding rhodopsin (*ninaE*) and the *arrestin* gene cause defects that are restricted to the eye. Mutations in genes such as *retinal degeneration B* (*rdgB*, encoding a phosphatidylinositol transport protein), involve olfactory as well as visual defects.

Since the initial findings, in 1983, that mutations in *Drosophila* rhodopsin lead to retinal degeneration, over 100 mutations in human rhodopsin have been found to cause autosomal dominant RP (adRP). The first mutation identified in adRP patients, published by Dryja and coworkers in 1990, was a mutation that caused a proline residue located near the N-terminus of rhodopsin to be replaced by a histidine residue (Pro23His). A great majority of these mutants, including Pro23His, produce misfolded rhodopsin that is improperly transported through the secretory pathway. However, the mechanism by which the mutant rhodopsins cause dominant retinal degeneration was not known. In 1995, studies in *Drosophila* on rhodopsin mutations that act dominantly to cause retinal degeneration revealed that the retinal degeneration results from the interference in the maturation of normal rhodopsin by the mutant protein. These studies in *Drosophila* provided a mechanistic explanation for the cause of certain forms of adRP.

Mechanisms of Retinal Degenerations

Light-Dependent Retinal Degenerations

It is now widely appreciated that retinal defects and retinal degeneration can be triggered by mutations in almost every component of the photoreceptor cells. These mutations can be divided into two distinct classes. One class pertains to the unregulated activities of phototransduction and/or calcium toxicity. Mutations in this class lead to retinal degenerations that are dependent on or influenced by light stimulation of the cascade and the opening of the TRP and TRPL channels, and these are termed light dependent.

For example, some mutations in rhodopsin itself or mutations in the *arrestin* gene lead to light-dependent retinal degeneration. Arrestin is required for deactivating rhodopsin, and loss of arrestin causes unregulated rhodopsin and hence excessive activation of phototransduction. It is also thought that the loss of arrestin causes decreased endocytosis of Rh1 and all of these defects lead to retinal degeneration.

The precise spatial and temporal regulation of calcium is also essential for photoreceptor survival in flies and people. Prolonged elevation of cytosolic calcium or low levels of calcium can be toxic, leading to cell death and retinal degeneration. In *Drosophila*, mutations in *arrestin*, the $Na^{+}/Ca2^{+}$ exchanger (*calx*), the diacylglycerol kinase (*retinal degeneration A*, *rdgA*), and constitutively active TRP channels are all thought to trigger cell death by causing abnormally high levels of calcium. In humans, a lack of cyclic guanosine monophosphate (cGMP) phosphodiesterase (PDE), caused by mutations in *PDE6A* and *PDE6B*, leads to an elevation in the cGMP concentration in the outer segments, which in turn causes cGMP channels to be open, resulting in excessive levels of calcium. Defects in PDE6A and PDE6B cause recessive RP.

Light-Independent Retinal Degenerations

A second class of retinal degenerations involves defects in rhodopsin maturation and does not require activation of phototransduction by light. These are termed light independent. In *Drosophila*, as in humans, Rh1 is synthesized and glycosylated in the ER, binds its vitamin-A-derived chromophore (11-*cis* 3-hydroxyretinal), at a lysine residue in the seventh transmembrane domain, is transported through the various compartments of the Golgi, and is delivered to its final destination for phototransduction. The mechanisms that regulate rhodopsin maturation, such as its folding, glycosylation, chaperone interaction, chromophore attachment, and transport, are key to photoreceptor survival in flies and humans.

In flies, the transport of Rh1 from the ER to the rhabdomere requires the cyclophilin, NinaA. Cyclophilins are known to display peptidyl-prolyl *cis–trans* isomerase and are thought to play a role in protein folding during biosynthesis. Consistent with a role in protein folding, NinaA resides in the ER. In addition, NinaA is detected in secretory transport vesicles together with Rh1, and forms a specific and stable complex with Rh1, consistent with a broader role as a chaperone in the secretory pathway. Similarly, in mammals a cyclophilin-like protein (RanBP2/Nup358) modulates protein biogenesis. The *Drosophila* cyclophilin, NinaA, is a chaperone that is specifically required for Rh1 biosynthesis and maturation. Another chaperone required for Rh1 biosynthesis in *Drosophila* is calnexin and mutations in *ninaA* (cyclophilin), *ninaE* (Rh1), and *calnexin*

all lead to severe retinal pathology in flies. In mammalian photoreceptors, calnexin is also expressed in the ER. Although calnexin is not required for the expression of rod rhodopsin, cone M-opsin, or melanopsin (in the ipRGCs) in the mouse, it is required for proper retinal morphology.

Rhodopsin in both mammals and flies undergoes N-linked glycosylation during biosynthesis, and in flies, elimination of the glycosylation site, asparagine 20 (N20I), results in the retention of rhodopsin in the secretory pathway. Moreover, in both mammals and flies, genes involved in rhodopsin chromophore biosynthesis and transport are critical to rhodopsin maturation and expression as well as photoreceptor function. Defects in chromophore production in the *Drosophila* mutants *ninaB*, *ninaD*, *ninaG*, and *santa maria*, cause a failure in Rh1 transport from the ER to the rhabdomere, resulting in a severe reduction in Rh1 and retinal pathology. The *ninaB* gene encodes an enzyme that catalyzes the conversion of carotenoids to retinal (β, β′ – carotene-15, 15′-monoxygenase) and *ninaG* encodes an enzyme that acts to convert retinal to 3-hydroxyretinal (oxidoreductase). Two additional *Drosophila* loci, *ninaD* and *santa maria*, are both similar to the mammalian class B scavenger receptors and play a role in transporting β-carotene to cells. In flies, β-carotene is required in the diet for the production of all-*trans* retinol, which is in turn converted to 11-*cis* 3-hydroxyretinal. Upon light stimulation 11-*cis* 3-hydroxyretinal is photoconverted to all-*trans* 3-hydroxyretinal. Mutations in chromophore biosythesis result in defective Rh1 maturation, low levels of Rh1, and retinal pathology, establishing the importance of vitamin A in the fly.

Once rhodopsin exits the ER, it requires several Rab-guanosine triphosphate (GTP)ases for vesicular transport through the secretory pathway in flies and in mammals. Rab-GTPases are conserved from yeast to humans and are members of the Ras superfamily of small GTPases. They function in distinct steps in membrane trafficking pathways including vesicle formation, actin- and tubulin-dependent vesicle movement, and membrane fusion events. In *Drosophila*, Rab1, Rab6, and Rab11 mediate vesicular fusion between the ER and the Golgi (Rab1), intra-Golgi (Rab6), and post-Golgi (Rab11) transport of rhodopsin in *Drosophila.* Defects in Rab function cause inadequate Rh1 transport and retinal pathology. Therefore, the mechanisms that regulate Rh1 maturation, such as its folding, chaperone interaction, and chromophore binding and transport are essential for photoreceptor health in flies and humans.

Retinal Degenerations Caused by Mutations in Dual-Role Proteins

Although most retinal degenerations are classified as either light dependent or light independent, there is a growing list of retinal degenerations that fall into both classes. In these cases, the corresponding mutant proteins play dual roles. For example, as was described above, calnexin is a chaperone required for rhodopsin maturation. In addition, it is a calcium-binding protein for regulating calcium in photoreceptor cells. Mutations in *calnexin* lead to defects in Rh1 maturation and retinal degeneration. The degeneration due to defects in rhodopsin maturation is light independent, but *calnexin* mutants also display prolonged and elevated levels of calcium, following light stimulation. In the *calnexin* mutants, the retinal degeneration is enhanced by the stimulation of phototransduction by light. Therefore, calnexin plays a dual role: one in rhodopsin maturation and another in calcium modulation.

Summary

In the 1980s, *Drosophila* took on a surprising new role, as an animal model for retinal disease, when the genetic similarities and fundamental processes between flies and humans became apparent. It became clear that information obtained in flies was transferable to human blinding diseases. As a result, and since then, there has been an explosion in the use of *Drosophila* as an animal model for unraveling the molecular genetic basis of retinal degeneration disorders. Despite its perceived simplicity, the fruit fly is, indeed, a remarkably complex creature with a genetic makeup that is surprisingly similar to our own. Investigators continue to capitalize on a whole host of versatile genetic techniques together with the accessibility of the fly to dissect fundamental photoreceptor cell mechanisms *in vivo.* The short life span of the fly, only 2 months, allows for monitoring the onset and progression of retinal degeneration in a short time. These advantageous features place *Drosophila* at the forefront of current research efforts, aimed at unraveling the basis of and therapeutic treatments for retinal degenerative disorders.

Acknowledgments

Our research, on retinal degeneration in *Drosophila*, is supported by funding from the National Eye Institute, the Retina Research Foundation, and the Retina Research Foundation/Walter H. Helmerich Research Chair. I gratefully acknowledge C. Vang, E. Rosenbaum and B. Larson for assistance with preparing the figures. For the poem, I thank M. Annucci, author of Luck (Parallel Press) and member of the Department of Languages and Literatures at the University of Wisconsin-Whitewater.

Retinal Ganglion Cell Apoptosis and Neuroprotection

K M Coxon, J Duggan, L Guo, and M F Cordeiro, UCL Institute of Ophthalmology, London, UK

Glossary

Apoptosis – The process of programmed cell death, whereby the cell proceeds through a highly regulated series of morphological changes resulting in the controlled disassembly of the affected cell.
Bax, Bak, Bad, and Bid – Proapoptotic proteins.
Bcl-2 – B-cell CLL/lymphoma 2, an antiapoptotic protein.
Excitotoxicity – The process by which raised levels of neurotransmitters trigger cell death.
Glaucoma – A major cause of blindness worldwide, resulting from the loss of retinal ganglion cells, with raised intraocular pressure as a major modifiable factor.
Neuroprotection – The use of therapeutic agents to prevent or reverse neuronal damage thereby retaining physiological function.
Neurotrophic factors – The growth factors that promote the growth, differentiation, and survival of neurons.
Retinal ganglion cells – The neurons that relay visual information from their cell soma located in the retina, through their axons which project along the optic nerve to the brain.

Introduction

Retinal ganglion cells (RGCs) relay visual information from their cell soma located in the retina, through their axons which project along the optic nerve to the brain. Their loss is associated with various optic neuropathies such as Leber hereditary optic neuropathy, optic neuritis, anterior ischemic optic neuropathy, and glaucoma. The most prominent of these is glaucoma, which is a major cause of irreversible blindness worldwide. In this article, glaucoma is used to highlight the challenges involved in unraveling the complexities of RGC apoptosis and neuronal cell death in order to facilitate more effective treatment strategies.

Apoptosis

Unlike necrosis, apoptosis is a regulated process of cell death leading to chromatin condensation, DNA fragmentation, oxidative damage, and autophagic degeneration, commonly proceeding through either extrinsic or intrinsic caspase-dependent pathways outlined in Figure 1. Identifying which aspect of apoptosis regulation is susceptible in glaucoma has important implications for the elucidation of pharmacological targets.

Apoptosis in Glaucoma

The exact mechanism triggering RGC apoptosis in glaucoma is still unidentified, although the major modifiable risk factor identified is that of raised intraocular pressure (IOP) and is commonly used to investigate apoptotic mechanisms. Mitochondria play a fundamental role in RGC apoptosis, with raised hydrostatic pressure inducing apoptosis that is at least partially dependent on mitochondria. More specifically, Bax, a regulator of membrane permeability, has been suggested to be essential in triggering apoptosis, with RGCs-expressing mutant Bax showing complete resistance to raised hydrostatic pressure, even after axonal loss.

While the primary site of damage in RGCs appears to be the axon, leading to axonal degeneration, and a positive correlation between raised IOP and axon loss has been established, it does not inevitably lead to cell soma death. The contribution of axonal degeneration and secondary challenges to the cell soma are evaluated below.

Diagnosis and Measuring Glaucoma Progression

Traditionally, glaucoma is screened by monitoring changes in IOP using tonometry, a technique lacking sensitivity in glaucoma detection, as damage to the RGCs can occur in the absence of raised IOP. This lack of sensitivity sparked the development and introduction of alternative screening methods. Examples of these are standard automated perimetry to measure visual-field loss, optical coherence tomography, allowing the quantification of the retinal nerve fiber layer (RNFL) thickness, and disk tomography to assess any structural damage to the optic nerve head (ONH). The major drawback common to these methods is the inability to detect the disease before considerable damage to the retina has occurred. It is estimated that death of 50% of the RGCs occurs before there is a significant-enough visual loss to diagnose glaucoma. The development of detection of apoptosing retinal cell (DARC), a method of detecting RGC apoptosis in glaucoma before the onset of visual loss, may be instrumental in early diagnosis and successful treatment

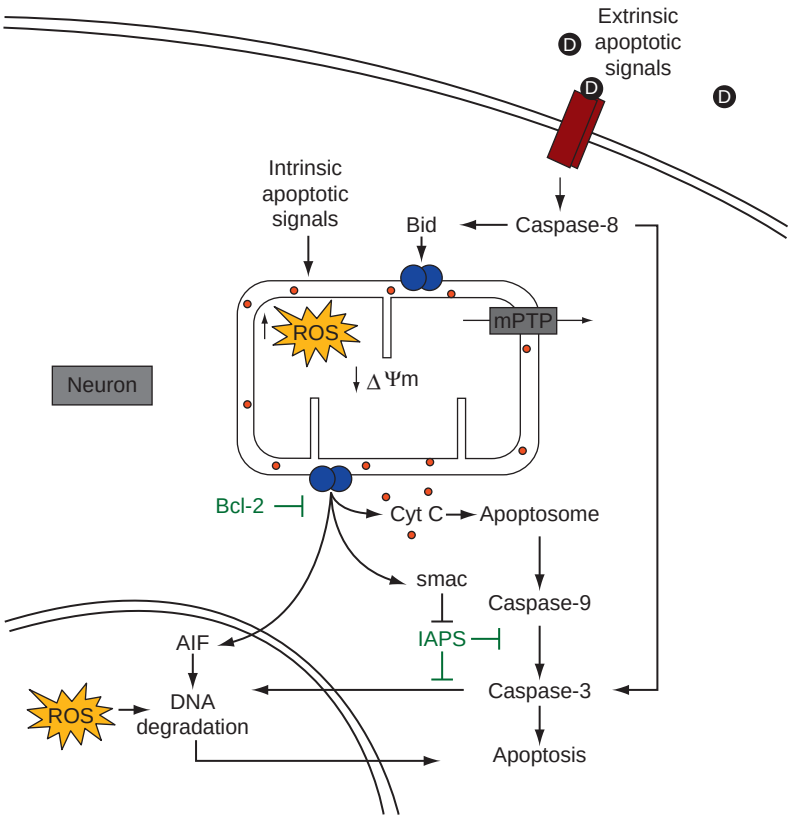

Figure 1 The intrinsic and extrinsic pathways of apoptotic cell death. Apoptosis can be triggered extrinsically through the binding of a death ligand to death receptors at the cell surface. The recruitment of procaspase-8 to the death receptors by adaptor proteins such as FADD follows allowing the conversion of procaspase-8 to its active form, caspase-8. Caspase-8 can cleave procaspase-3 triggering caspase cascade and the activation of the various effecter caspases which degrade DNA and various proteins. It can also act through a mitochondria-dependent manner, cleaving Bid, facilitating its translocation to the mitochondrial membrane and thereby initiating release of death mediators. Various intrinsic signals are also able to mediate apoptosis, through disruption of mitochondrial activity causing a subsequent decrease in the mitochondrial membrane potential ($\Delta\psi m$) and the activation of the mitochondrial permeability transition pore (mPTP), or through the actions of proapoptotic proteins such as Bax, Bak, Bad, and Bid. Following loss of mitochondrial stability various death mediators are released including cytochrome C (Cyt C), which in conjunction with APAF-1 and procaspase-9 forms the apoptosome which activates caspase-9 and triggers a caspase cascade. The release of Smac facilitates this process by inhibiting the actions of IAPS, an inhibitor of the caspase cascade. Various compounds, such as apoptosis-inducing factor (AIF), are also released from the mitochondria and are able to translocate to the nucleus where they trigger chromatin condensation and apoptosis. Mitochondrial dysfunction also leads to the increased generation of reactive oxygen species (ROS), which can trigger cell death through the modification of various molecules, including lipids, proteins, and DNA.

of the disease as well as a high-throughput screening method for new neuroprotectants.

Current Treatments for Glaucoma

Once diagnosed, the current treatments for glaucoma concentrate on lowering the raised IOP. First-line pharmacological therapies include prostaglandin analogs which increase aqueous humor outflow and beta-blockers to reduce aqueous humor formation. Alpha-agonists to increase the uveoscleral outflow of aqueous humor and carbonic anhydrase inhibitors suppressing enzymes involved in aqueous humor production are used as second-line treatments, while third- or fourth-line treatments rely on increasing trabecular outflow using cholinergenic agonists and miotic agents. The disadvantages all the drugs share are the potential side effects and the requirement for topical administration up to four times daily. Furthermore, the incidence of poor compliance and persistence with the topical application is high and so the success of glaucoma management is limited. In addition, glaucoma appears to progress in many sufferers despite the continued use of pharmacological treatments. In these cases, surgery such as trabeculoplasty to reduce resistance to the outflow of aqueous humor by modifying the trabecular meshwork or trabeculotomy to remove part of the trabecular meshwork, allowing enhanced drainage of the aqueous humor, may prove successful in reducing IOP. As the degeneration of visual field in glaucoma is known to progress through RGC apoptosis, research is currently underway to develop neuroprotective treatments for glaucoma.

Neuroprotection

Neuroprotection is defined as the use of therapeutic agents to prevent or reverse neuronal damage, thereby retaining physiological function. For example, neuroprotective treatments are being researched for diseases which progress through the death of neurons of the central nervous system such as Alzheimer's, Parkinson's, and Huntington's. The efficacy of these therapeutic agents in clinical trials has been somewhat controversial. A number of clinical trials performed on stroke patients testing different neuroprotective agents showed either little success or adverse side effects, while treating patients of spinal cord trauma with the neuroprotective agent methylprednisolone resulted in improved motor function. The variation in success of these agents is thought to be due to the mechanism of neuronal death in the different diseases. In strokes, neuronal injury occurs at the cell body, so irreversible cell death occurs instantly; therefore, treatment with a neuroprotective agent would be given too late. However, in spinal cord trauma, neuroprotective treatment may have the desired effect as injury occurs at the axon and death of the cell body results hours later. For this reason, the use of neuroprotection as a treatment for glaucoma, thought to be brought about by death of RGC axons, seems a promising option.

Research Models

Research into the eye disease uses models which are important tools allowing researchers to monitor the progression of the disease and test new therapies. In order for these models to provide informative and transferable data, similarity to the human disease and reproducibility is required. A number of different models are used in the study of the disease, all of which have their strengths and limitations.

In Vitro Glaucoma Models

Initial experiments for neuroprotection in glaucoma are likely to be carried out *in vitro*. A number of ocular cells have successfully been cultured and present a cost-effective alternative to animal models for studying the effects of apoptosis and neuroprotection. Cell cultures have the advantage of allowing rapid screening of potential therapies and observation of direct effects on the cultured cells, under strict environmental control. Cell culture also provides a greater understanding of how compounds function at a cellular level; however, the response of the isolated cells, maintained in an artificial environment, may differ from that *in situ*. For this reason and the contentious use of immortalized cells to study apoptosis, a number of *in vivo* glaucoma models have been developed.

In Vivo Glaucoma Models

Pioneered in rat and more recently developed in monkey, the optic nerve crush is a well-calibrated and reproducible model of glaucoma. Damage to the optic nerve results in cell-body death and subsequent secondary injury to adjacent neurons, as seen in glaucoma. Alternatively, RGC apoptosis can be induced by raising the IOP and causing retinal ischemia, typically achieved through blockage of the aqueous humor outflow, including injection of hypertonic saline into the episcleral veins, cauterization of the episcleral veins, and laser photocoagulation of translimbus. As an alternative, excessive exposure to excitotoxins, such as glutamate or *N*-methyl-D-aspartic acid (NMDA) by intravitreal injections can be used to induce RGC apoptosis. A further model can be generated by laser coagulation at the retina where RGC apoptosis is induced adjacent to the site of laser contact. The DBA/J2 mouse is a genetically determined glaucoma model showing increased IOP, RGC apoptosis, optic nerve atrophy, and ONH cupping.

Mechanisms of Apoptosis and Development of Neuroprotective Agents

Neurotrophic Factor Withdrawal

Deprivation of neurotrophic factors (NFs) induces apoptosis, and has been suggested to play a role in glaucoma as outlined in **Figure 2**. Raised IOP is proposed to lead to a blockade of anterograde and retrograde transports, preventing transport of NFs. The neuroprotective effects of neurotrophins (NTs), a family of NTFs, are thought to be mediated through the activation of phosphoinositide (PI)-(3)-kinase, the inhibition of which is sufficient to block the survival effects of NT. PI(3)K phosphorylates and activates Akt which is known to target several key apoptosis regulators, including Bcl-2 antagonist of cell death (Bad) and cyclic adenosine monophosphate (cAMP) response element binding protein (CREB). The phosphorylation of Bad promotes its sequestration by the chaperone protein 14-3-3, while CREB is activated by Akt (also known as protein kinase B), leading to the upregulation of B-cell CLL/lymphoma 2 (Bcl-2). The actions of Akt have downstream consequences for mitochondrial function and both caspase activation and increased ROS production have been attributed to loss of NT-stimulated pathways.

NFs as Neuroprotective Agents

Brain-derived neurotrophic factor (BDNF) has been showed in a number of studies to have neuroprotective effects. Intravitreal injections of the NT administered to rats, following optic nerve transection and IOP-induced ischemia, increased the survival of RGCs. In addition to BDNF, ciliary neurotrophic factor (CNTF), glial-cell-line-derived neurotrophic factor (GDNF), and pigment-epithelium-derived

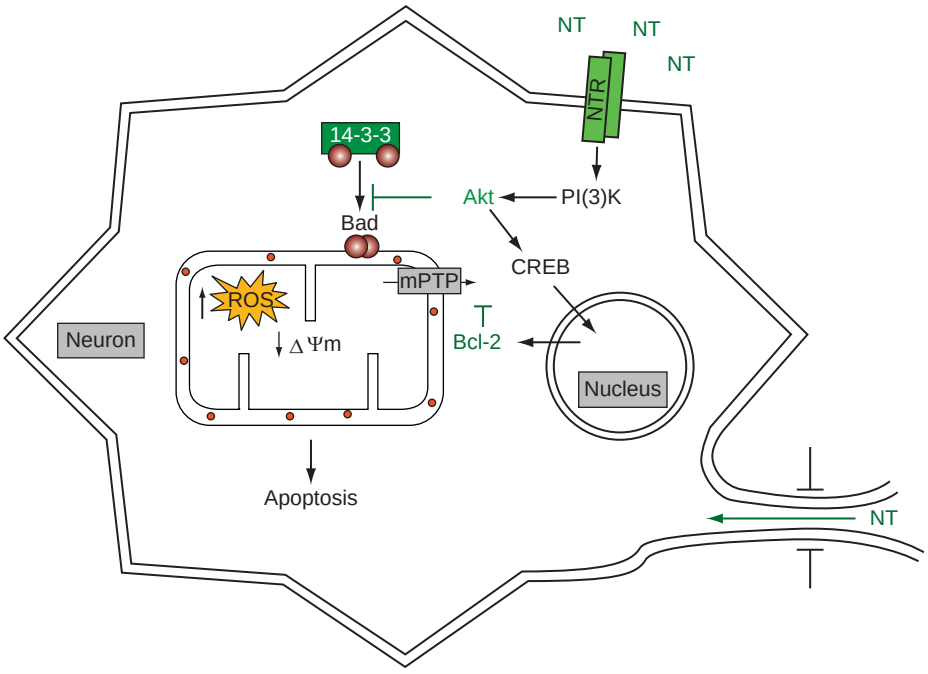

Figure 2 Apoptosis induced by neurotrophic factor withdrawal. Axotomy prevents the retrograde transport of both neurotrophins (NTs) and neurotrophic receptors (NTRs). NTs are able to suppress apoptotic signaling through the binding of NTR, the activation of phosphotidylinositol-3-kinase (PI(3)K), and subsequent activation of Akt. Akt promotes cell survival through multiple pathways, including the phosphorylation of Bad, which promotes its sequestration by the scaffold protein 14-3-3 and the activation of CREB, which promotes increased expression of Bcl-2. Bcl-2 is an essential antiapoptotic protein, which inhibits the release of death mediators, thereby preventing initiation of the caspase cascade.

growth factor (PEDF) have also demonstrated protection of RGCs in rat glaucoma models. The neuroprotective effects of the NFs are short-lived, with reduced survival of RGCs only weeks after a single injection. The longevity of the treatment has been addressed using a number of techniques. Injection of PEDF-peptide-loaded nanospheres into an ischemic rat model reduced RGC apoptosis over a longer period. The same technique was used to administer GDNF to the DBA/2J mouse glaucoma model and an ischemic rat model; again, increased survival of RGCs was observed over a longer period. An alternative method, meant to prolong the effects of the treatment, used an osmotic pump to administer NFs to an axotomized rat model. The technique was successful in reducing RGC apoptosis but most cells were dead within 1 month.

As an alternative to prolonged administration of NTs, researchers in this field have also looked toward gene transfer as a way of maintaining the required level of the NFs for long-term RGC survival. Transformation of a rat glaucoma model with the BDNF gene extended the life of the axotomized RGCs for a similar period. This work was furthered in the same model by injecting BDNF while simultaneously expressing the gene encoding the BDNF receptor, TrkB, known to show reduced expression in glaucoma models. The results showed increased survival of 76% of RGCs over a prolonged period.

Excitotoxicity

Glutamate is a neurotransmitter reported in raised concentrations in the vitreous of glaucoma patients and in animal models. RGCs are known to be highly susceptible to cell death through not only glutamate excitotoxicity and but also treatment with the glutamate analog, NMDA. This has lead to glutamate excitotoxicity being proposed as both a mechanism of primary insult upon RGCs and as a secondary insult following the death of RGCs and the release of further excitory amino acids and glutamate. At elevated levels, glutamate triggers the excessive activation of ionotrophic receptors, such as NMDA receptors, resulting in a subsequent influx of Ca^{2+} ions and an increase in oxidative stress leading to cell death as depicted in **Figure 3**.

Ca^{2+} is shown to increase mitochondrial permeability to ions and solutes and thought to regulate the mitochondrial permeability transition pore (mPTP), which is associated with the release of proapoptotic factors such as cytochrome C (Cyt C). Ca^{2+} has also been proposed to activate nitrous oxide synthase (NOS), leading to the generation of pathological quantities of nitric oxide (NO) and the subsequent production of reactive NO free radicals capable of triggering cell death, the full implications of which are discussed later.

Calpains are a family of cytoplasmic-calcium-activated cysteine proteases. Axotomy, ocular hypertension, and

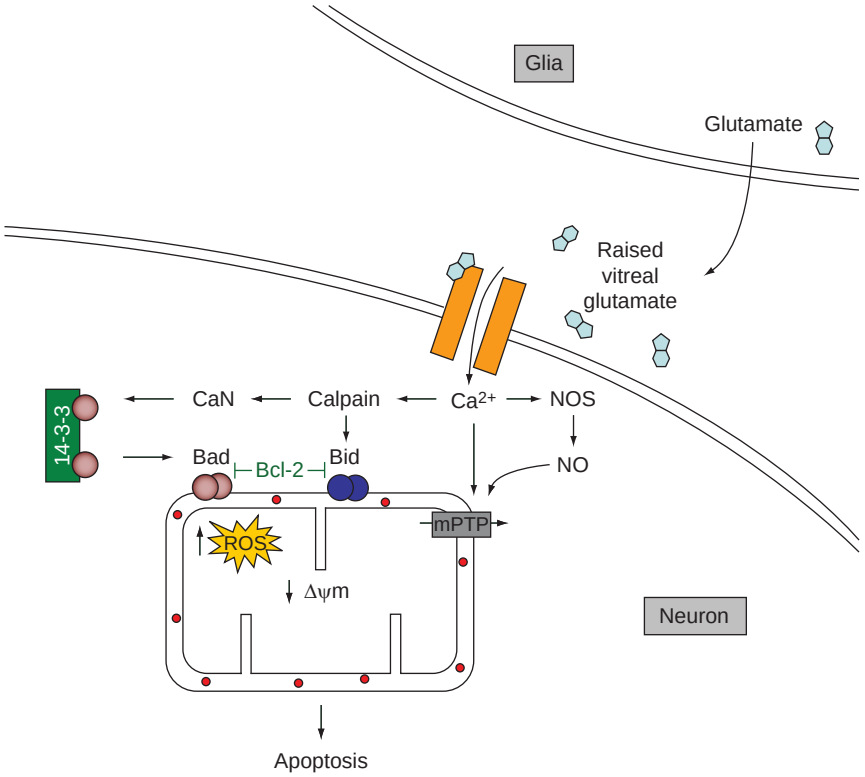

Figure 3 Excitotoxicity-induced apoptosis. Raised vitreal glutamate triggers the activation of ionotrophic calcium channels such as NMDA receptors. The resultant increase in intracellular calcium activates calpain and, in turn, calcineurin (CaN), which promote the translocation of Bad and Bid to the mitochondrial membrane, and the subsequent release of death mediators. Ca^{2+} also activates nitric acid synthase (NOS) which promotes mitochondrial dysfunction, ROS production, and activation of the mitochondrial permeability transition pore (mPTP). Increased cellular ROS and the release of death mediators, such as Cyt C and AIF, leads to apoptosis.

NMDA excitotoxicity all demonstrated calpain activity with inhibition showing reduced RGC loss. Increased Ca^{2+} in the retina correlates with increased calpain activity, which can activate the caspase cascade as well as lead to the phosphorylation of spectrin, Tau, and p35, and cleavage of known calpain substrates, including the autoinhibition domain of calcineurin (CaN).

In addition to activation by calpains, CaN has also been shown to undergo activating cleavage by caspases and interestingly raised IOP, although the mechanism of the latter is unknown. Sustained Ca^{2+} has also been shown to lead to increased levels of CaN, which induces apoptosis through the dephosphorylation of Bad, releasing the pro-apoptotic protein from sequestration by the chaperon protein 14-3-3. Bad is then able to translocate from the cytosol to the mitochondria, allowing it to heterodimerize with Bcl-2 and B-cell leukemia X_L (Bcl-X_L), leading to the release of Cyt C and the triggering of apoptosis. A role for CaN is further supported by the observation that dosing of cells with glutamate led to the translocation of a green fluorescent protein (GFP) fusion protein of Bad from the cytosol to the mitochondria, and the prevention of this in cells containing an inactive mutant form of CaN.

As mentioned previously, Bad phosphorylation is regulated by NT and treatment with NT is sufficient to confer resistance to excitotoxic insult. This suggests that excitotoxicity rather than working alone could act in conjunction with withdrawal of NFs to facilitate RGC apoptosis. Recent findings, however, have thrown doubt upon the hypothesis of glutamate excitotoxicity. Crucially, the raised glutamate levels observed in humans and animals have failed to be reproduced in follow-up studies. In addition, NMDA was able to induce apoptosis in the absence of Bax, a proapoptotic factor, suggested to be essential in apoptosis of RGCs in glaucoma. An alternative explanation for increased intracellular calcium and the subsequent triggering of apoptotic pathways is the activation of stress-activated channels by raised hydrostatic pressure.

NMDA-Antagonists and Neuroprotective Agents

This breakthrough of excess glutamate resulting in RGC apoptosis has led to considerable interest in the use of NMDA-receptor antagonists as neuroprotective therapies, many of which have been identified and characterized. MK801, a noncompetitive NMDA-receptor blocker, has been shown to protect RGCs from apoptosis in a number of experimental models including increased IOP and following intravitreal injections of NMDA in

rats. Despite showing promise as a successful neuroprotectant in the animal models, MK801 was never used in clinical trials due to its adverse side effects of inducing vacuole formation in neurons and neuronal necrosis.

Other NMDA-receptor antagonists were also studied for use as potential neuroprotectants. For example, detromethorphan was shown to aid the recovery of retinal activity in rabbits suffering from IOP-induced ischemia and flupirtine had a similar effect on the same model. Riluzole, an agent used for treatment of amyotrophic lateral sclerosis, reduced neuronal death following retinal ischemia brought about by raised IOP in rats. The most promising neuroprotective agent to date, memantine, is similar to MK801 but lacks the neurotoxic effects. Successfully used in the treatment of Alzheimer's disease (AD) and Parkinson's disease, memantine has also been shown to protect neurons from apoptosis in many different glaucoma models. Disappointingly, a recent second phase III clinical trial of memantine has revealed the compound to have no positive effect on visual-field deterioration in glaucoma patients.

Reactive Oxygen Species

Oxidative stress leading to neuronal apoptosis is an early event, occurring within hours of raised IOP, both *in vitro* and *in vivo*. Following atoxomy of RGCs, there is both an increase in reactive oxygen species (ROS) and cell death. Inhibition of ROS demonstrated a 50% reduction in RGC loss as did increasing expression of superoxide dismutase (SOD), known to be reduced in rat models with raised IOP.

The principal mechanism for ROS production is disruption of mitochondrial function, shown in **Figure 4**, leading to loss of mitochondrial membrane potential and subsequent release of death factors. In addition to raised IOP, light exposure has been suggested as a risk factor in glaucoma, through the increased generation of ROS. In addition, ROS can mediate apoptosis by reacting directly with various molecules including DNA, proteins, and lipids.

Mitochondrial Dysfunction and ROS Generation

ROS generation, particularly through the inhibition of complexes I and IV of the electron transport chain, has been implicated in various mechanisms of apoptosis, with treatment of antioxidants preventing apoptosis by inhibiting ROS generation and Cyt C release. A wide variety of antioxidants have been suggested as neuroprotectants in glaucoma, including vitamin E, 3-methyl-1,2-cyclopentanedione (MCP), and melatonin. Derivatives of catechin have been suggested to be potent antioxidants, and intravitreal co-addition of epigallocatechin was shown to attenuate the

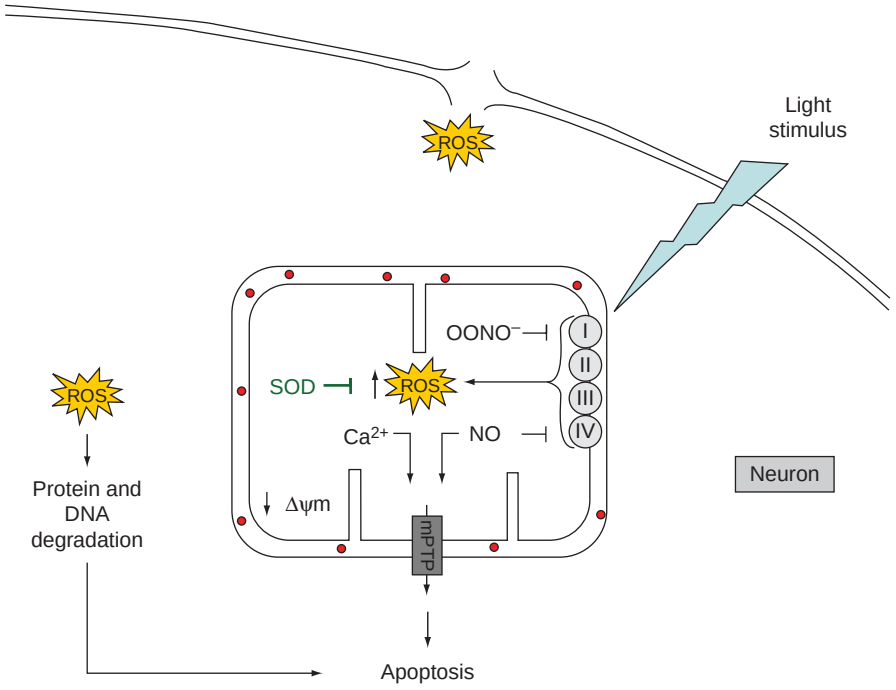

Figure 4 Reactive oxygen species (ROS) and mitochondrial dysfunction in apoptosis. Increased concentrations of ROS can lead to apoptosis through the modification of lipids, proteins, and DNA. Superoxide dismutase (SOD), a key enzyme involved in the removal of ROS, is reduced in glaucoma, potentiating the cells to increased damage by ROS. Inhibition of the electron transport chain by compounds, such as nitric oxide (NO) and peroxynitrite ($OONO^-$), leads to reduced mitochondrial membrane potential ($\Delta\psi m$) and increased generation of ROS, as has exposure to light. NO and Ca^{2+} can also promote mitochondrial dysfunction through activation of the mitochondrial membrane permeability transition pore (mPTP), and the release of death mediators.

retinal damage caused by treatment with the NO donor, sodium nitroprusside.

Ubiquinone (CoQ_{10}), a member of the electron transport chain, has been demonstrated to prevent lipid peroxidation and DNA damage. Furthermore, in recent tests in rats, the intraocular administration of CoQ_{10} afforded neuroprotective effects.

Antioxidants as Neuroprotective Agents

The most promising antioxidant treatment to date is that of orally administered *Gingko biloba* extract, which contains a number of substances shown to be effective in preventing mitochondrial damage through oxidative stress. Visual improvement has also been demonstrated in a double-masked long-term placebo-controlled study, with efficacy and safety reports suggesting a daily dose of 120 mg to be sufficient.

Protein Misfolding

The observation that AD patients demonstrated RGC loss typically associated with glaucomatous changes, including optic neuropathy and visual impairment, suggested possible mechanistic similarities. Supportive of mechanistic similarities between Alzheimer's and glaucoma is the observations of abnormal and phosphorylated Tau, a major plaque component, in the retina of glaucoma patients. β-Amyloid (Aβ), generated by the abnormal processing of amyloid precursor protein (APP), is another major component in Alzheimer's plaques. APP and Aβ are present in RGCs following elevation of IOP in rat models and in the DBA/2J mouse model. It has been shown *in vivo* that Aβ is neurodegenerative and that disruption of these APP processing pathways is sufficient to reduce RGC apoptosis in glaucoma models in rats.

In AD, mutations altering the function of APP processing proteins lead to increased Aβ production and, subsequently, increased apoptosis. A complementary mechanism, shown in **Figure 5**, has been implicated for glaucoma whereby normally rapid anterograde transport is blocked resulting in increased somal concentrations of APP. This has been proposed to trigger the abnormal processing of APP by caspase-3 in RGCs in glaucoma models generating increased Aβ in the retina and is supported by observations of decreased vitreal Aβ (suggesting increased deposition) in glaucoma patients.

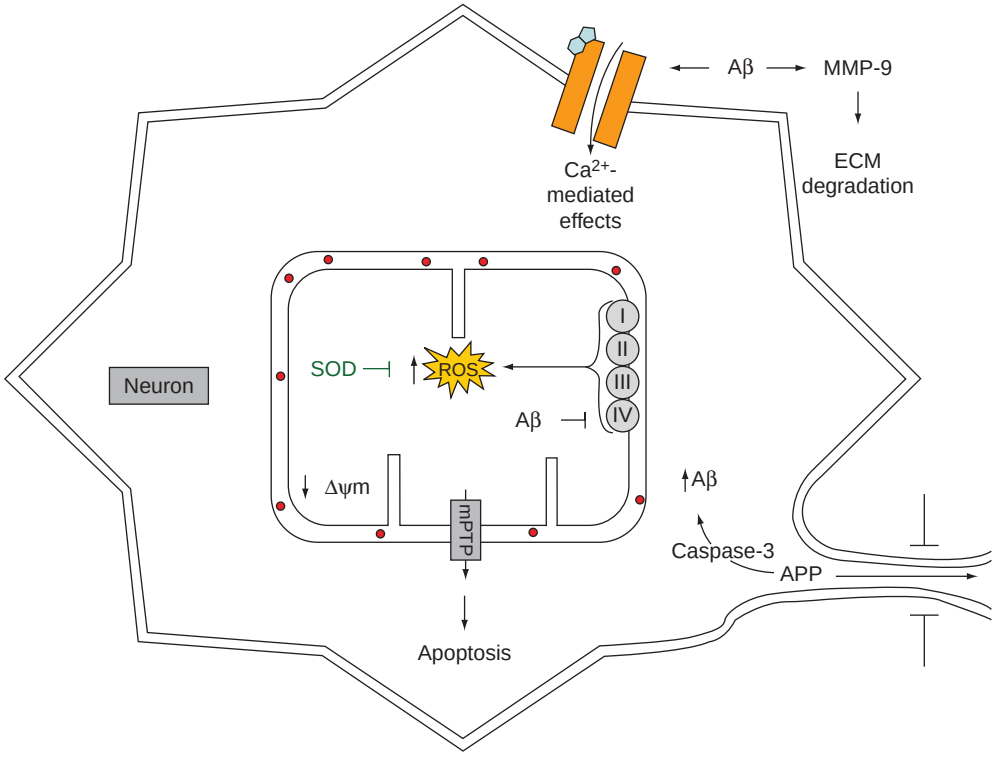

Figure 5 Aβ-induced apoptosis. The anterograde transport of amyloid precursor protein (APP) is blocked by axotomy, leading to increased somal concentrations of APP. At elevated concentrations, APP triggers the abnormal activation of caspase-3 which cleaves APP to yield Aβ, which has both intracellular and extracellular actions in promoting apoptosis. Aβ is shown to target the electron transport chain promoting increased reactive oxygen species (ROS) production and mitochondrial dysfunction. Additionally, Aβ upregulates the activity of ionotrophic calcium channels, increasing intracellular calcium and therefore promoting calcium-mediated apoptosis. Metalloproteinase-9 (MMP-9) also shows increased activity in the presence of Aβ, promoting increased extracellular matrix (ECM) degradation and apoptosis through anoikis.

Aβ is believed to induce apoptosis through elevated intracellular calcium and increased oxidative stress, as seen in AD, where oxidative damage is observed before significant plaque formation. Increased oxidative damage is indicative of mitochondrial dysfunction and both APP and Aβ have been shown to target mitochondria. At raised levels associated with glaucoma, APP has been shown to interact with mitochondria clogging them and preventing normal function. Aβ has been implicated in the inhibition of ketoglutarate dehydrogenase and complex IV of the electron transport chain, inhibition of both of which leads to increased ROS generation. This process could constitute a positive-feedback loop accelerating cell death, as the presence of ROS has been shown to facilitate Aβ production. Following mitochondrial dysfunction, apoptosis has ultimately been suggested to be mediated through the initiation of a caspase cascade.

Reduction of Misfolded Proteins in Neuroprotection

Recent *in vivo* studies have shown that a reduction in RGC apoptosis can be achieved by targeting the Aβ pathway. Inhibition of β-secretase, responsible for Aβ production, reduced plaque formation and RGC apoptosis. Increased plaque removal and inhibition of plaque formation had a similar effect. All of these mechanisms were shown to be effective in reducing RGC apoptosis, with the greatest benefit seen through the use of combination therapy, which resulted in a maximal reduction in RGC apoptosis of greater than 80%.

Glial–Neuronal Interactions

Glial cells, comprised of astrocytes, microglia, and Müller cells, act as support cells for neurons, maintaining their regular function by providing both neurotrophins and sustenance while removing toxic neurotransmitters and ions. Glaucoma induces dramatic changes in the glia gene expression patterns, potentially converting them from supportive to neurotoxic, as summarized in Figure 6. In the scope of this article, the impact of distinct types of glial cells are not differentiated, but evaluated as a whole.

Glial cell activation has been demonstrated in the glaucomatous optic nerve, in the retina of glaucoma

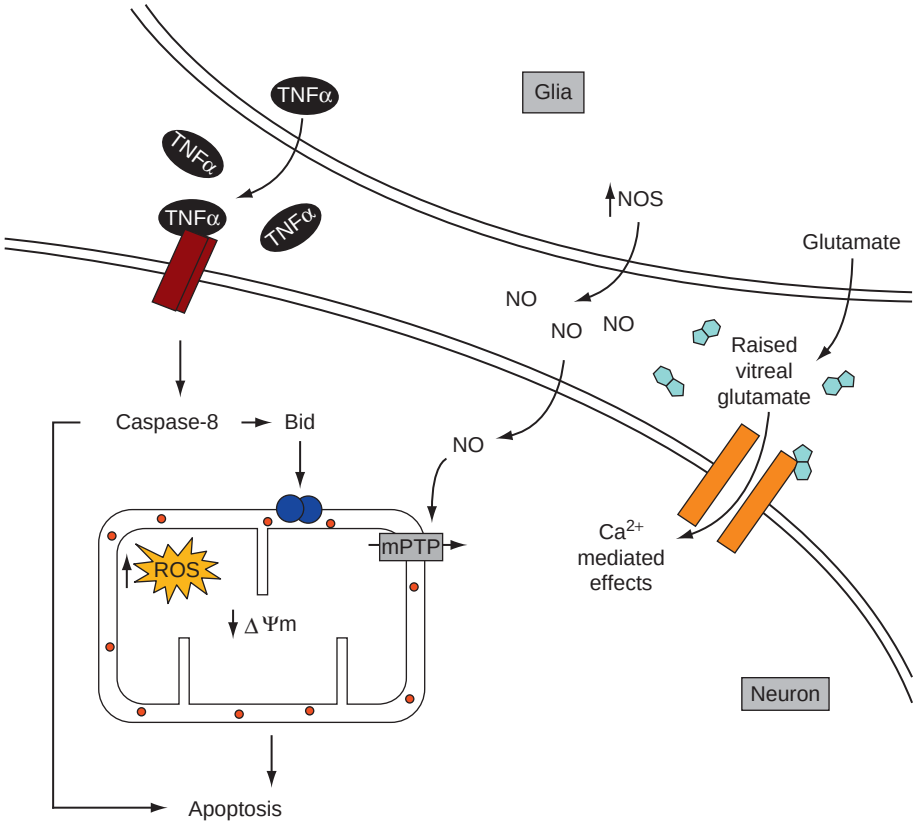

Figure 6 Apoptosis induced by glial–neuronal interaction. Glial cells release neurotoxic molecules such as TNF-α, glutamate, and nitric oxide (NO), which are known to induce apoptosis in RGCs. TNF-α is a death ligand and triggers caspase-8-mediated extrinsic apoptosis. Elevated intravitreal glutamate, due to increased secretion and decreased uptake by glia, leads to apoptosis through calcium-mediated mechanisms, while increased NO causes mitochondrial dysfunction and the subsequent release of death mediators as well as increased reactive oxygen species (ROS) and cytotoxic modifications to key cellular components.

patients and in glaucoma models showing altered levels of secretion. Increased secretion of NT appears to represent an attempted neuroprotective function, supporting damaged neuronal cells, while other changes, such as decreased secretion of interleukin (IL)-6 and increased secretion of NO and tumor necrosis factor (TNF)-α, which have been implicated in RGC apoptosis.

TNF-α, a trigger for extrinsic apoptosis, activates caspase-8 leading to activation of the caspase cascade, Bid activation, the loss of mitochondrial membrane potential, and the subsequent release of cell-death mediators such as apoptosis-inducing factor (AIF) and Cyt C. Increased secretion of TNF-α by glia has been shown to correlate with increased disease severity in glaucoma patients and is further accompanied by the upregulation of TNF receptor 1 (TNF-R1) in glial cells and in RGCs and their axons in glaucoma patients. TNF-α also represents a possible genetic component for glaucoma with the TNF-α-308 gene polymorphism identified in glaucoma patients suggesting a role for TNF-α signaling.

Glial cell secretion of NO, potentially stimulated by TNF-α, is raised in glaucoma with elevated NO concentrations shown to trigger axonal degradation and cell death in RGCs. There are three isoforms of NOS: neuronal (nNOS), inducible (iNOS), and endothelial (eNOS). Initially, iNOS received the most attention as it is induced under various stress conditions. It was suggested to be raised in the ONH of glaucoma patients and also shown to be raised in glaucoma rat model utilizing cauterization, where treatment with inhibitors was sufficient to abate apoptosis.

However, validation of this work in alternative models failed to produce correlating results, with both a murine model and a rat glaucoma model of IOP raised through intravitreal injections, failing to show the involvement of NOS or a reduction in RGC apoptosis by NOS inhibitors. It appears that iNOS upregulation could be due to secondary factors caused by the cauterization process and not raised IOP. While the role of iNOS in glaucoma has been called into doubt, it does not undermine the potential importance of NO signaling. nNOS and eNOS have been showed to be expressed at low levels in normal eyes in glial cells in the ONH, but shows dramatically raised levels in the ONH of glaucoma sufferers.

The main mechanism, through which NO triggers cell death, appears to be disruption of mitochondrial function. An interaction between NO and the mPTP directly facilitates the release of Cyt C and AIF, with mPTP inhibitors abating NO-induced neuronal apoptosis. Caspase-3 activation, however, has been shown without initial loss of mitochondrial membrane potential, suggesting activation may result from blockade of the electron transport chain and subsequent increased levels of ROS. Loss of mitochondrial membrane potential can be triggered as a downstream event, following prolonged inactivation of the electron transport chain.

NO binds complex IV of the electron transport chain, also known as cytochrome oxidase, reducing the enzyme's affinity for oxygen. Prolonged exposure to NO or peroxynitrite ($OONO^-$), a highly destructive molecule formed from ROS and NO, can lead to blockade of complex I of the electron transport chain. This facilitates further ROS production and $OONO^-$ synthesis, which are capable of extensively modifying cellular components leading to apoptosis, while antioxidant treatment in NO-induced apoptosis was shown to abate caspase activation.

Disruption of mitochondrial respiration has also been suggested to facilitate the disruption of Ca^{2+}, associating NO with excitotoxicity-induced apoptosis. This link was strengthened by observations that nNOS-deficient mice were resistant to NMDA-induced RGC death. NO induced modest increases in the amplitude of Ca^{2+} channels and the induction of the Ca^{2+}-mediated death effectors, the calpains.

Extracellular Matrix Degradation

Glaucomatous changes include extensive remodeling of the extracellular matrix (ECM), altering the levels of the various ECM components, including collagen I and IV, matrix metalloproteinases (MMPs), tissue inhibitors of metalloproteinases (TIMPs), transforming growth factor beta 2 (TGF-β2), and laminin.

MMP expression in particular has received attention, with expression in glaucoma patients being raised in comparison to normal patients. The condition of the ECM both regulates and is regulated by the expression and release of MMPs, with the subsequent reduced levels of laminin contributing to cell death, and significant RGC loss in the retina. Supportive evidence from the ability of TIMP-1 to abate neuronal apoptosis, as well as observations that MMP-9-deficient mice demonstrate reduced laminin degradation and increased resistance to neural trauma, further highlights the potential importance of MMPs in glaucoma.

It was recently demonstrated *in vivo* that raised IOP induced remodeling of the ECM within the retina. Raised IOP was shown to correlate to decreases in laminin and TGF-β2 and increased MMP-9, TIMP-1, and RGC apoptosis. Loss of survival signals from the ECM is thought to induce a specific form of apoptosis called anoikis.

Whether glaucomatous changes are initiated at the retina or ONH is still a matter of contention. Astrocytes in the ONH have been shown to be activated by raised IOP and produce MMPs that are able to remodel the ECM, possibly resulting in axonal compression and thereby facilitating apoptotic mechanisms associated with the blockade of anterograde and retrograde transport.

In addition to raised IOP, potential apoptotic mechanisms such as Aβ, NO, ROS, excitotoxicity, and TNF-α have all been implicated in triggering an increase in

MMP-9, suggesting that MMP-9 may represent an important downstream executor of apoptosis rather than a primary affecter.

Neuroprotective Vaccine

Studies using rat and mouse models of glaucoma have suggested a potential role for autoimmunity in the protection of neurons from secondary damage. Following the initial insult, nonspecific T-lymphocytes have been shown to accumulate at the primary lesion site. While nonspecific T-lymphocytes did not exhibit neuroprotection, effects were observed upon injection with myelin basic protein (MBP)-specific T-lymphocytes or immunization with MBP. Unfortunately, injections of anti-MBP-specific T-lymphocytes and MBP immunization induced the paralytic condition – experimental autoimmune encephalomyelitis (EAE).

Copolymer 1 (Cop 1), a synthetic peptide based on MBP, was discovered to suppress EAE and shown in clinical trials to be beneficial to patients with multiple sclerosis. Further studies have revealed that immunization with Cop 1 increases RGC survival following optic nerve crush, glutamate injections, and increased IOP in rats. This research shows that there is potential for the development of a glaucoma vaccine.

Summary

The primary mechanism of RGC loss in glaucoma is through apoptosis, which can be triggered through a variety of mechanisms both intrinsic and extrinsic. Apoptotic signaling shows a large level of redundancy with extensive cross talk. This redundancy poses a major problem in terms of neuroprotection with inhibition of one apoptotic pathway merely delaying apoptosis before mediation through an alternative pathway or the triggering of necrosis. It is still unclear as to the primary mechanism of apoptosis induction in glaucoma, although an increased understanding would aid a more effective development of neuroprotective strategies. Fundamental to the successful development of neuroprotective strategies is targeting the apoptotic pathway upstream and at multiple points to maximize effectiveness.

The studies of neuroprotective agents on glaucoma models carried out to date have shown great promise with many different agents demonstrating efficacy in a large number of models, summarized in Table 1. Unfortunately, translation of this research from animals through to clinical trials has exposed complications with side effects and inefficacy, hindering progression. However, due to the complicated nature and a number of different overlapping pathways inducing apoptosis, the identification of a multitude of potential neuroprotectants has been possible. One major problem still faced in the analysis of these compounds is the difficulties monitoring efficacy *in vivo*.

Table 1 Comparison of the models used to test the different neuroprotective agents

Neuroprotectant	*Animal*	*Model*
MK801	Rat	Increased IOP
		NMDA injection
Detromethorphan	Rabbit	Increased IOP
Flupirtine	Rabbit	Increased IOP
	Rat	Increased IOP
		NMDA injection
Riluzole	Rat	Increased IOP
Memantine	Monkey	Increased IOP
	Mouse	DBA/2J
	Rat	Glutamate injection
		Increased IOP
		Optic nerve crush
Brain-derived neurotrophic factor (BDNF)	Rat	Increased IOP
		Optic nerve transection
Ciliary neurotrophic factor (CNTF)	Rat	Increased IOP
		Optic nerve transection
Glial-cell-line-derived neurotrophic factor (GDNF)	Mouse	DBA/2J
	Rat	Increased IOP
Pigment-epithelium-derived growth factor (PEDF)	Rat	Increased IOP
		Optic nerve transection
Myelin basic protein (MBP) T-lymphocytes	Rat	Optic nerve transection
		Spinal cord contusion
Myelin basic protein (MBP)	Rat	Spinal cord contusion
Copolymer 1 (Cop 1)	Rat	Glutamate injection
		Increased IOP
		Optic nerve crush
Monoclonal anti-Aβ IgG	Rat	Increased IOP
Congo Red	Rat	Increased IOP
β-Secretase inhibitor	Rat	Increased IOP
Epigallocatechin (EGC)	Rat	NO donor
Ubiquinone (CoQ_{10})	Rat	Increased IOP
Vitamin E	–	Primary cultures
	Human	Glaucoma patients
Gingko biloba	Rat	Increased IOP
	Human	Glaucoma patients

It is hoped that the development of the novel DARC technique for early diagnosis of glaucoma may also be a valuable tool in the analysis of potential neuroprotectants.

Retinal Histogenesis

J A Brzezinski, IV and T A Reh, University of Washington, Seattle, WA, USA

Glossary

Birthdate or born – The time when a progenitor permanently exits the cell cycle. Marking cells in their final division is referred to as birthdating.
Cell fate determination – The process by which a progenitor is programmed to become a specific cell type and its functional maturation. In the retina, a progenitor needs to acquire competence, exit the cell cycle, become specified, and differentiate.
Competence – The potential to adopt a certain cell fate(s).
Differentiation – The functional maturation of a specified cell.
Histogenesis – The development of a mature tissue from a naive progenitor population.
Lineage – A cohort of cells derived from division(s) of a common progenitor. This is also referred to as a clone.
Lineage tracing – The use of an indelible marker to label cells and all their descendants. Analysis at a later time point allows the inference of lineal relationships. This is also referred to as fate mapping.
Multipotent progenitor/progenitor – A cell that has competence to adopt several different fates. These cells may or may not be proliferative.
Progressive restriction model – A model of cell fate determination where multipotent progenitors lose the competence to adopt multiple cell fates over time. By this model, early progenitors have the competence to form all fates in a tissue.
Serial competence model – A variation on the progressive restriction model whereby multipotent progenitors transiently gain and subsequently lose competence for a subset of fates in a tissue over time. By this model, progenitors do not have the competence to form late fates at the earliest time points.
Specification or commitment – The point when a progenitor cell has irreversibly decided on a cell fate.

Birthdating

An interesting property of retinal cells is that they do not continue to divide after they differentiate. This means that at some point in development, a progenitor permanently exits the cell cycle, referred to as its birthdate. Investigators took advantage of this property and designed a clever pulse-chase experiment to investigate whether different cell types exited the cell cycle at characteristic times. Animals at various stages of development were given a pulse of ^{3}[H]-thymidine (3HdT). The 3HdT is incorporated into replicating DNA during synthesis (S)-phase and any excess is cleared from the body quickly. The incorporated 3HdT is maintained in the newly synthesized DNA permanently. If the cell continues to divide, it will dilute the 3HdT signal by one-half each division. Next, autoradiography was conducted after the retina was fully formed (the chase). Cells that retained maximum labeling are those that exited the cell cycle (born) on the day of 3HdT administration. More recently, birthdating studies have been conducted with synthetic nucleotides, such as 5-bromo-2-deoxyuridine (BrdU), which can be detected by antibodies instead of autoradiography.

About 50 years ago, Sidman used birthdating studies to test what order, if any, retinal cells were formed in the rodent retina. The observations of Sidman and future investigators revealed a stereotypical birth order that was broadly broken down into early and late groups (**Figure 1**). Retinal ganglion cells (RGCs) were born first, followed closely by horizontal cells, cones, and amacrines. The late cohort comprised rods, bipolar cells, and Müller glia. Birthdating has been conducted in several vertebrate species. While there are some small differences in the order, the first cells born in all species examined are RGCs. Although there is clearly an overall birth order, which is evident from the production onset of each cell type, there is also considerable overlap in the genesis of the cell types, such that multiple cell types are born on the same day of development (**Figure 1**). This overlap is also observed in species where retinal histogenesis is long, such as in monkey. These data implied that cell fate determination is not strictly regulated by measuring time (or cell cycles) during development. Nonetheless, the observance of a birth order indicated that there is a temporal input into cell fate determination.

These studies raised several questions about retinal progenitors. Are all retinal cell types derived from the progenitors in the optic cup? Are there different progenitors for each retinal cell type? Is fate choice predetermined or stochastic? These questions were addressed by tracing the fate of individual progenitors.

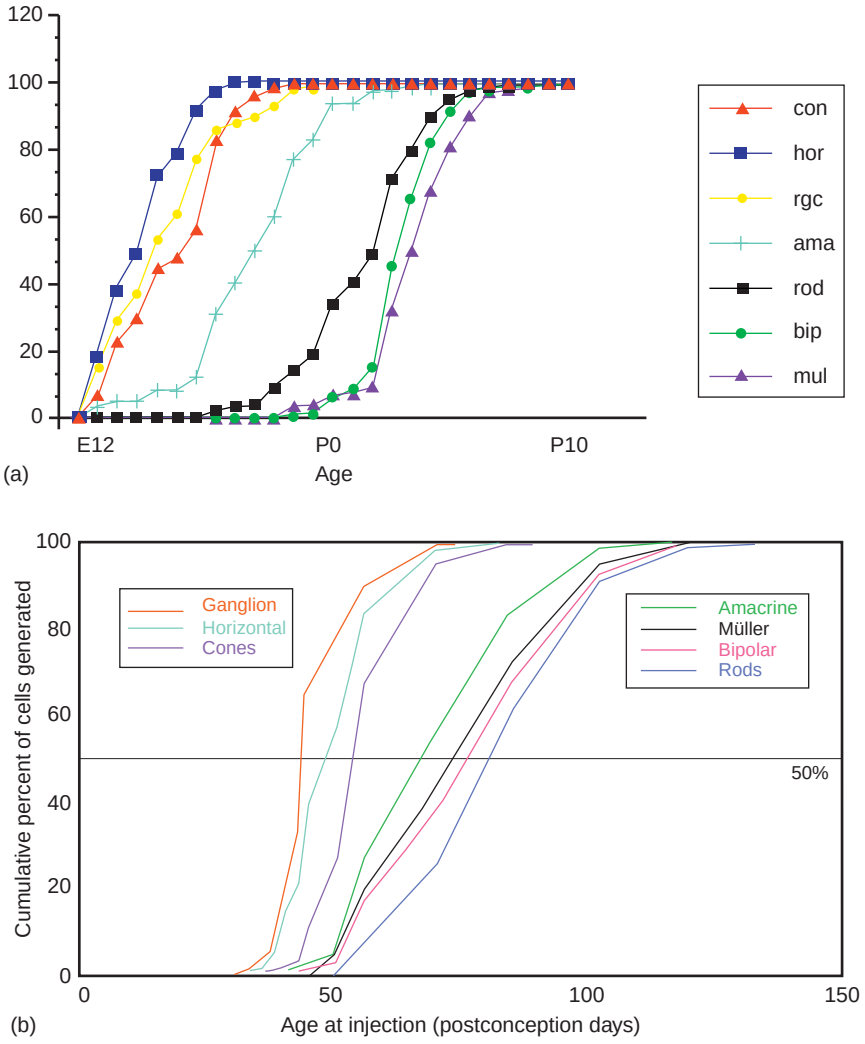

Figure 1 Birthdating. (a) Data from the rat retina showing the birthdates for each cell type as a percentage of its total. The progression from early to late cell-type generation that was first observed by Sidman can be clearly identified. CON, cone; HOR, horizontal cell; RGC, retinal ganglion cell; AMA, amacrine cell; BIP, bipolar cell; and MUL, Müller glia. (b) Similar thymidine labeling study in monkey shows a similar, though not identical, pattern of birthdates for the various types of retinal cells. Despite the fact that the patterns of generation are not identical, the early and late fates are largely segregated. (a) Data from Rapaport, D. H., Wong, L. L., Wood, E. D., Yasumura, D., and LaVail, M. M. (2004). Timing and topography of cell genesis in the rat retina. *Journal of Comparative Neurology* 474(2): 304–324. (b) Modified from La Vail, M. M., Rapaport, D. H., and Rakic, P. (1991). Cytogenesis in the monkey retina. *Journal of Comparative Neurology* 309(1): 86–114.

Lineage Tracing

To understand the behavior of progenitor cells, a way to trace the fate of individual progenitors was needed. Starting in the late 1980s, investigators designed elegant lineage-tracing (fate-mapping) experiments to study the retina. In rodents, Turner, Snyder, and Cepko used replication-incompetent retroviruses encoding a marker gene (e.g., *LacZ*) to infect retinal progenitors at various time points. These retroviruses can only infect dividing progenitors. Since the virus integrates into the genome, the progenitor and its descendents become permanently labeled. By adjusting the titer of the virus, individual progenitor lineages (clones) can be mapped from mature retinas (**Figure 2**).

The first set of retroviral lineage-tracing studies examined postnatal infections of rat retinas. In postnatal day 0 (P0) infections, majority of clones contained rods and were predominantly small (one to four cells). A large number of clones contained only rods, whereas others contained rods, amacrines, bipolars, and/or Müller glia (**Figure 2** and **Table 1**). There were few clones that did not contain any rods. Cell types born before P0 (e.g., cones, horizontals, and RGCs) were not observed in these clones, consistent with previous birthdating analyses. Clones generated from P2, P4, and P7 infections become progressively smaller. This reflects the progressive decrease in progenitor division that occurs in the first postnatal week. Clones were heterogeneous; some

contained multiple cell types and others one cell type or just a single cell. From all these time points, there was no obvious lineage hierarchy that could be constructed from the clone composition data. This showed that mammalian retinal cell fate determination is stochastic, or nondeterministic. Importantly, they observed two-cell clones that had different fates. This implied that fate choice is decided during or after the last cell division.

To see if the progenitors in the optic cup can give rise to all the retinal cell types, the investigators generated clones from embryonic (E) time points when few cells have exited the cell cycle. For this reason, they injected their retroviruses into the subretinal space of E13 and E14 mice *in utero*, a difficult procedure. The mice were allowed to mature and clone composition was examined. The clone size and composition were highly heterogeneous (Table 1). All seven cell fates were represented in these clones. Moreover, these clones never contained any other cell types (i.e., astrocytes, vascular endothelial cells, pigment epithelium, etc.). These early lineage traces showed that all seven retinal cell types derive solely from a retina-restricted progenitor pool. The heterogeneity in clone composition (there were few multicell clones alike) reinforced that fate choice is apparently stochastic. Consistent with retinal cell frequency (~78% are rods in mice), nearly all clones contained one or more rods. Clone size varied from 1 to

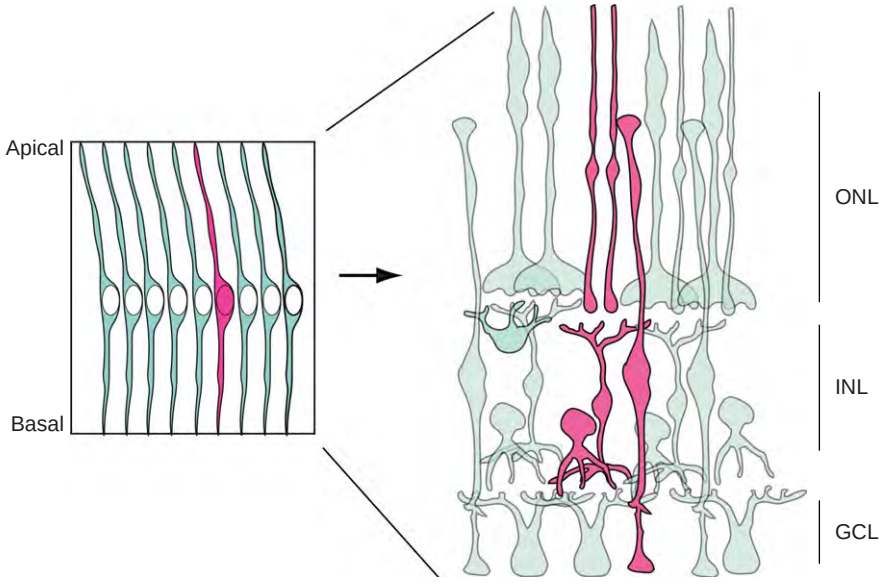

Figure 2 Lineage analysis. Diagram showing the basic strategy to track the lineages of the retinal progenitor cells. A progenitor cell is labeled (red) at an early stage of development, by using either a retroviral vector with a reporter gene, or a direct injection of a tracer. The cell undergoes multiple rounds of division in this case, and when the retina is examined in the adult animal, the different types of retinal cells can be identified by their laminar position and their morphology. In this case, two rods, a bipolar cell, an amacrine cell, and a Muller glial cell were derived from the progenitor. See Table 1 for more examples of the types of clones found in these experiments.

Table 1 Retroviral lineage tracing in rodents

Age of infection	*E13*	*E14*	*P0*	*P2*	*P4*	*P7*
Ave. clone size	46.4	26.3	2.5	1.6	1.4	1.1

[a]Cell fates represented in clones (r, rod; b, bipolar; a, amacrine; c, cone; m, Müller; g, ganglion; h, horizontal) listed in decreasing frequency observed. In mice, the cell frequency in decreasing order is r, a, b, m, c, g, and h.
Data from Turner, D. L. and Cepko, C. L. (1987). A common progenitor for neurons and glia persists in rat retina late in development. *Nature* 328: 131–136; and Turner, D. L., Snyder, E. Y., and Cepko, C. L. (1990). Lineage-independent determination of cell type in the embryonic mouse retina. *Neuron* 4: 833–845.

234 cells and had a bimodal distribution. There were abundant small clones (<5 cells) and abundant large clones (>20 cells). The largest clones are simply too big to have been generated by simple asymmetric (one progenitor, one neuron) divisions in the time allotted for development. Based on the distribution of clone sizes, it is possible that progenitors preferentially utilize symmetric divisions during retinal histogenesis. Lineage-tracing studies have been conducted in other vertebrates, yielding similar results.

These lineage-tracing studies answered several questions. First, retinal progenitors in the optic cup are multipotent and give rise to all seven cell types. Second, there are no separate progenitors for each cell type. Nonetheless, rod-only clones were observed, raising the possibility of a rod-only progenitor. Since rods make up 78% of the mouse retina, small- to medium-sized rod-only clones are expected from multipotent progenitors. Fourth, cell fate choice is stochastic. Fifth, cell fate specification occurs during the last cell cycle or later. These data raised several more questions about the mechanisms of retinal histogenesis. Is fate determination a cell autonomous process, a cell nonautonomous process, or a combination of both? Do retinal progenitors have broad competence that is gradually lost, or are progenitors more limited in their cell fate choices during development? These questions have been addressed by manipulating the local cellular environment.

Environmental Challenge

Several approaches have been undertaken to discriminate between cell autonomous and cell nonautonomous control of retinal cell fate determination. Most of these experiments involve challenging retinal progenitors with different environments. Unlike the previous birthdating and lineage-tracing studies, these environmental challenge experiments are harder to interpret and, at times, yield conflicting results.

One type of experiment was designed to answer the question: What is the default state of retinal progenitors? For these experiments, retinal progenitors were labeled with 3HdT and dissociated to single cell density to examine their potential for differentiation in isolation. Reh and Kljavin saw that when rat progenitors were isolated from early stages of development, the majority of the progenitors differentiated into RGCs, while progenitors isolated from late stages of development differentiated into cell types normally generated late in development, like rods. A somewhat different result was obtained from similar studies in the chick embryo by Adler and colleagues, suggesting that cones were the default cell fate. However, subsequent studies in chick revealed a ganglion cell bias for the progenitors isolated from the earliest stages of retinal development. Together, these results led to the concept of a rolling default, or shifting competence in the progenitors; in other words, there is an intrinsic bias to the types of neurons generated by the progenitors that shifts progressively over developmental time. This idea has been recently supported by Notch-signaling studies. The Notch receptor is active in progenitor cells throughout development, and inhibition of signaling leads to premature progenitor differentiation. Inhibition of Notch in early progenitors leads to the overproduction of RGCs and cones, whereas inhibition of Notch function later in development results in overproduction of rods, but not of RGCs or cones. These results show that retinal progenitors change their competence intrinsically over time.

In the next type of experiment, investigators asked whether inductive interactions among the retinal cells played a role in their cell fate determination. Studies from *Drosophila* eye imaginal disk had shown an important role for cell–cell interactions in directing the ommatidial progenitors to their individual identities. In that tissue, the data were best fit by a sequential cell induction model in which the first cells, the R8 photoreceptors, induce the recruitment of the next type of photoreceptor, and so on. To test whether similar sequential inductions occurred in vertebrate retinas, investigators used heterochronic co-cultures, surrounding early embryonic progenitors with late-generated retinal cells. The groups of Raff and Reh co-cultured early embryonic rodent retinal cells with an excess of postnatal retinal cells. In both sets of experiments, the early progenitors were more likely to develop into rhodopsin expressing (rod photoreceptors) cells when compared to early progenitors cultured alone (which developed primarily early retinal fates). This increase was not seen when the challenging (older) cells were derived from the brain instead of the retina. Watanabe and Raff also found that the increase in rods was observed when the two cell populations were separated by a cell-impermeable membrane. Together, these data showed that a soluble factor(s) from late retina can promote rod fate in younger cells. In addition, very early mouse retinal progenitors (E11–E12) could form rods when cultured with an excess of older rat retinal cells; birthdating analyses indicate that rods are not normally generated by progenitors from this very early retina, which suggests that rod competence precedes rod genesis by at least 1 day. These experiments led to the idea that although progenitors may have an intrinsic bias in the types of cells they generate at any time in development, their fate can be influenced by factors in the microenvironment. Many subsequent studies have identified signaling factors in the developing retina that can influence the fate of the progenitors and, particularly, factors that can increase the percentage of these cells that differentiate into rods; however, since low-density cultures do not support robust rod differentiation (i.e., expression of

rhodopsin and other markers), it is possible that most of the factors identified to date have more of an effect on the expression of these identifiers, rather than the choice of the rod fate *per se*.

Another concept that emerged from the early studies of retinal development was the idea that specific cell types use feedback regulation to control their density. Elimination of dopaminergic amacrine cells in the developing frog leads to an overproduction of these cells by progenitors at the ciliary marginal zone. This suggested that there is a nonautonomous feedback regulation to negatively control amacrine cell number. *In vitro* experiments found a similar effect in developing rat retina. When E16 retinal cells were co-cultured with an excess of P0 cells, fewer amacrines were generated. However, when the P0 cells were depleted of amacrine cells, there was an increase in the number of amacrine cells generated by the E16 cells. When the converse experiment was done, P0 cells co-cultured with an excess of E16 cells, an increase in amacrines and bipolars was seen along with a decrease in rods. This confirmed the presence of negative feedback on amacrine cells and implied feedback regulation of bipolar cell genesis. The concept of feedback regulation of retinal cell production was extended to ganglion cells by Waid and McLoon. They examined the influence of a late retinal environment on RGC fate determination using heterochronic co-cultures in chick. Early cells were inhibited from RGC fate when co-cultured with late retinal cells. This inhibition was not observed when RGCs were depleted from the challenging (late) cell population, which showed that RGCs can nonautonomously feed back to inhibit further RGC production. In a subsequent study from the McLoon lab, they blocked Notch signaling (an RGC inhibitor) at different times. Interestingly, when later time points were examined, they saw newborn RGCs in areas where RGC genesis had ceased in controls. This suggested that RGC competence extends beyond RGC genesis.

Although the studies described above have supported a role for cell–cell interactions in the regulation of cell fate in the vertebrate retina, some types of studies have failed to find nonautonomous effects. Rapaport and colleagues conducted heterochronic transplants in frogs. When younger retinal tissue was transplanted into older hosts, the donor tissue did not adopt later fates or differentiate early. This result was also seen in co-cultured cells *in vitro*. Importantly, the donor cells directly adjacent to the older host cells were not fate shifted. This suggested that cell fate determination is not regulated by changing environmental stimuli, rather, that cell competence is limiting in frogs. Cayouette and colleagues combined lineage tracing and single cell culturing of rodent progenitor cells. In this experiment, E16–E17 rat progenitors were plated at single cell density and the resulting clones were examined 7–10 days later. In parallel, they conducted a retroviral lineage trace (similar to above) in E16–E17 retinal explants (intact tissue) cultured the same amount of time. The clones in both cases were screened for rod, bipolar, amacrine, and Müller glial cell fates. The clone composition and size in both experimental systems were similar in isolation and in explants. This suggested that fate choice is largely cell autonomous and that any given cell type is not required to induce (specify) another. In sum, while many studies have shown a role for cell–cell interactions in the control of retinal cell fate, the relative importance of intrinsic and extrinsic regulation is still not resolved.

These data have been used to assemble cell fate determination models (**Figure 3**). One model, progressive restriction, argues that early progenitors have competence to adopt all retinal cell fates and that this competence is gradually lost (restricted) over time. By this model, nonautonomous contributions are expected to specify cell fate in these multipotent progenitors over time. Early progenitors should be able to adopt late fates (if stimulated properly) and competence should extend beyond the normal genesis window to allow for feedback inhibition. Another model, serial competence, contends that progenitors have competence for only a few cell fates at any given time and that progenitors serially cycle through numerous restricted competence states. By this model, cell nonautonomous inputs are not required for fate specification. Presumably, the mechanism that controls competence dynamics would be reflected by the complement of transcription factors expressed in progenitors. In the next section, we discuss evidence that transcription factors regulate competence.

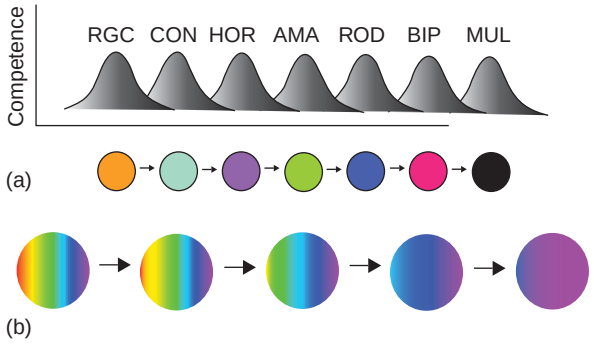

Figure 3 Cell fate determination models. (a) Serial competence model. The progenitor changes over time in their potential to generate different types of retinal cells. These changes in competence would be mediated by changes in the complement of transcription factors present in the cells. (b) Progressive restriction model. The progenitor can initially generate all types of retinal neurons, but over time loses one or another of the transcription factors needed for a specific fate. This is shown in the figure as what is initially a rainbow-colored cell, progressing into a cell that is only red. In principle, the progressive restriction could be due to a loss in key transcription factors, or alternatively by the addition of new repressors.

Transcription Factors and Competence

How transcription factors regulate retinal progenitor competence is beginning to be characterized (**Figure 4**). Although most of these transcription factors are expressed in the postmitotic cells, and therefore are unlikely to regulate the competence of the progenitor cells *per se,* there are members of several different transcription factor families that are expressed in the mitotically active cells. One transcription factor expressed by progenitors that appears to convey competence is *Pax6*. This eye-field transcription factor is expressed in all progenitors and directly promotes the expression of other transcription factors (*Ascl1*, *Ngn2*, *Atoh7*, etc.). Specific deletion of *Pax6* from progenitors leads to the apparent loss of competence to generate all retinal cell types except amacrine cells. A complementary result is obtained when *FoxN4*, a transcription factor expressed in a subpopulation of progenitors, is deleted in mice. In *FoxN4* null mice, amacrine cells fail to develop. This suggests that the combination of FoxN4 and Pax6 can convey progenitors with competence for all retinal cell fates. Ikaros is a transcription factor that is expressed primarily by early-staged progenitors, and mice deficient in this gene have fewer early-born neurons.

While these examples show that changes in transcription factors can affect the types of neurons produced by progenitors, and hence their competence to generate specific neuronal types in the retina, it has also become clear that a more general level of competence, to generate neurons versus glia, is also conveyed by these factors. Another transcription factor expressed in a subset of progenitors is *Ascl1* (*Mash1*), a member of the bHLH class. Prior to E15 in the rat retina, there is little *Ascl1* expression in the retina, though progenitors by this age are producing RGCs, cones, rods, and horizontal and amacrine cells. Even after E15, *Ascl1* is expressed in most, but not all, progenitors. Deletion of this gene in mice leads to an overproduction of Müller glia, apparently at the expense of rods and bipolar cells. It appears that *Ascl1* imparts retinal progenitors with the competence for late-generated retinal neurons, while also inhibiting Müller glial fate specification (**Figure 5**) in part by maintaining the expression of *Hes6*, but also by driving expression of key components of the Notch pathway, including *Hes5* and *Hes1*, to maintain the progenitors in an undifferentiated state while they generate additional neurons. When Notch signaling is reduced, even for times as short as 6 hours, the retinal progenitors are irreversibly committed to exit the cell cycle and differentiate. Since the Notch effector genes, *Hes1* and *Hes5* are normally regulated during the cell cycle, such they are lowest during the G2 and M-phases, one model for the mechanism by which progenitors initiate differentiation is through a progressive slowing of the cell cycle as development proceeds (**Figure 5**). Immunolabeling for the active Notch intracellular domain in mouse retina has confirmed that Notch signaling is lowest in cells whose nuclei are at the apical surface. However, this is apparently not the case in the fish retina. Live imaging studies in cortex by Kageyama's group confirm that Notch signaling oscillates through the cell cycle, with the lowest levels in the progenitors with nuclei located at the apical surface, those cells that are in G2- or M-phases of the cell cycle. Given the highly transient nature of Notch signaling and the very fast cell cycles in fish, further studies using highly destabilized reporters will be needed in the fish to determine whether this difference is real.

Another member of the bHLH class of transcription factors, *Atoh7* (*Math5*), is transiently expressed by a small subset of postmitotic progenitors. Lineage-tracing and genetic-deletion studies have shown that it is necessary for RGC competence. In addition to these transcription factors expressed in progenitors, there are many that are expressed in subpopulations of nascent neurons. For example, *Ptf1a*, *NeuroD1*, and *Math3* are expressed in amacrine cells, and loss of one or more of these genes leads to defects in amacrine cell fate determination or survival. Moreover, overexpression of transcription factors such as *NeuroD1* can drive progenitor differentiation into specific cell types, though the types appear to vary depending on the species and the method of

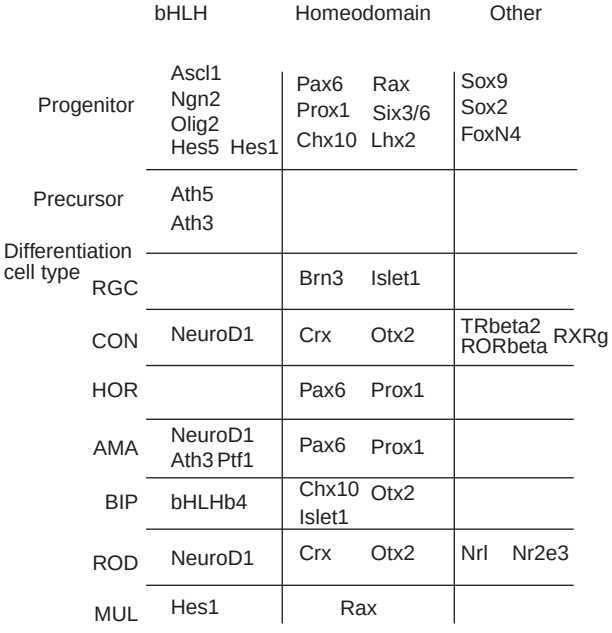

Figure 4 Transcription factor code. Kageyama and others have proposed that a combination of bHLH and homeodomain transcription factors specify each retinal cell type. Although most of these factors are expressed primarily in postmitotic cells, and therefore might not be candidates for the changing competence models described above, several lines of evidence indicate that these factors are necessary for the full differentiation of these cell types.

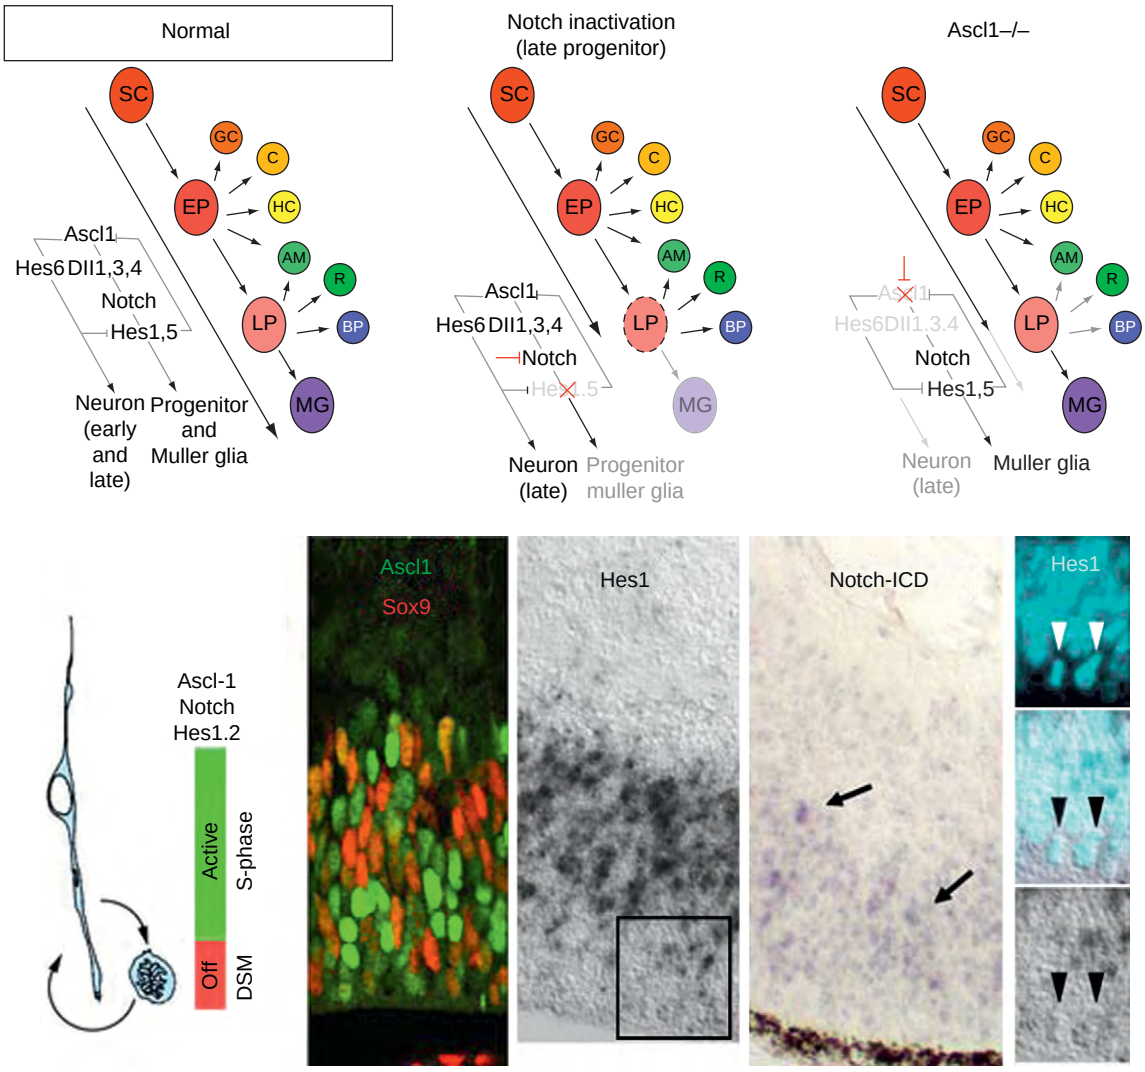

Figure 5 (Top row) *Ascl1/Mash1* functions to maintain neuronal competence in the progenitors. Deletion of this gene in mice leads to an overproduction of Müller glia, apparently at the expense of rods and bipolar cells. It appears that *Ascl1* imparts retinal progenitors with the competence for late-generated retinal neurons, while also inhibiting Müller glial fate specification by maintaining the expression of Hes6, and by driving expression of key components of the Notch pathway to maintain the progenitors in an undifferentiated state while they generate additional neurons. SC, stem cell; EP, early progenitor; LP, late progenitor; GC, ganglion cell; C, cone; HC, horizontal cell; AM, amacrine cell; R, rod; BP, bipolar cell; and MG, Müller glia. (Bottom row, left) Model of how Notch signaling changes with the cell cycle in mouse and chick retina. Notch signaling is high during the S-phase of the cell cycle and low to absent at the apical (ventricular) surface when cells are in G2 and M-phases of the cell cycle. This can be seen in the lower middle and right panels by the Notch ICD immunoreactivity (arrows) and the expression of Hes1, a downstream effector of Notch. By contrast, progenitor markers like Sox9 (red) and Ascl1-GFP (green), are expressed throughout the cell cycle in progenitor cells. Modified from Nelson, B. R., Hartman, B. H., Ray, C. A., et al. (2009). Acheate-scute like 1 (Ascl1) is required for normal delta-like (Dll) gene expression and notch signaling during retinal development. *Development Dynamics* 238: 2163–2178; and from Nelson, et al. (2007) Transient inactivation of notch signaling synchronizes differentiation of neural progenitor cells. *Developmental Biology* 304: 479–498.

overexpression. These studies show that few transcription factors fit cleanly in the simple models of progressive restriction or serial competence. Moreover, since few targets of these transcription factors have been identified, the nature of competence regulation remains unclear. Nevertheless, the transcription factor networks for two cell types, RGCs and rod photoreceptors, are beginning to be worked out.

Conclusions

A great deal has been done over the past 50 years to understand the developmental mechanisms of vertebrate retinal histogenesis. Birthdating studies have revealed a characteristic genesis order of the retinal cell types. Lineage-tracing experiments have shown that retinal progenitors are multipotent and that fate choice is stochastic.

Experiments that challenge the environment of retinal progenitors have revealed that both cell autonomous and cell nonautonomous factors contribute to fate determination. More recent techniques, such as expression fate mapping (lineage by gene expression) and live imaging of cell lineages, will further our understanding of retinal fate determination. In addition, the recent increase in early cell-type-specific markers will allow us to more precisely examine the effects of environmental challenges. While several factors have been identified, many more experiments are needed to elucidate the molecular mechanisms of retinal fate determination.

Retinal Pigment Epithelial–Choroid Interactions

K Ford and P A D'Amore, Schepens Eye Research Institute, Boston, MA, USA

Glossary

Angiogenesis – The formation of new blood vessels from preexisting ones.
Atrophy – To wither or deteriorate.
Blood–retinal barrier – Specialized, nonfenestrated, tightly joined endothelial cells that form a transport barrier for certain substances between the retinal capillaries and the retinal tissue.
Choroidal neovascularization – A condition whereby new blood vessels that originate from the choroid grow and break through Bruch's membrane into the subretinal pigment epithelium (sub-RPE) or subretinal space.
Dominant negative – A genetic mutation where the gene product adversely affects the normal, wild-type gene product within the same cell.
Fenestration – A small pore (60–80 nm in diameter) within the endothelium wall that allows the passage of small molecules and a limited amount of proteins.
Microphthalmia – An abnormal smallness of the eyes, occurring as the result of disease or of imperfect development.
Phagocytosis – The process in which phagocytes engulf and digest microorganisms and cellular debris.
Quiescence – The absence of proliferation.
Trophic factor – A molecule that promotes cellular growth and/or survival.

Introduction

Located at the back of the eye, the retinal pigment epithelium (RPE)–choroid complex is comprised of the RPE, a polarized, epithelial monolayer and the choroid, a highly fenestrated vascular bed. Separated by Bruch's membrane (BrM), an elastic lamina, the RPE and choroid each play a vital role in normal eye physiology. Considerable evidence indicates that there is not only a great deal of interaction between the RPE and choroid, but that the integrity of this interaction is critical to normal eye function. Examination of the morphology of the choroidal microvasculature reveals that the vessels are "polarized," with fenestrations preferentially localized to the capillary surface proximal to the RPE and BrM. Whereas the cytoplasm of the endothelial cell is thinnest in this region, endothelial cell bodies and nuclei are more prominent distal to the RPE. These observations led to the speculation that the RPE exerts an inductive effect on the choriocapillaris by releasing a factor that diffuses across BrM to provide a trophic effect and to mediate the anatomic specializations in the capillary endothelial cells. Preservation of a normal interaction between the RPE and choroid is required for proper eye physiology. This review explores the intricacies of the RPE and choroid, and their interactions during development, in the adult and with aging.

RPE–Choroid Complex Development

RPE Development

The development of the RPE is dependent upon the coordination of transcription factor expression and inductive signals received from the tissues surrounding the developing eye. Eye development proceeds from two principal tissue components: the neural ectoderm, which buds from the wall of the forebrain to form the optic vesicle, and the surface ectoderm, which forms the lens (**Figure 1**). When the optic vesicle comes in contact with the surface ectoderm, it invaginates, forming the optic cup. The optic cup consists of an inner layer, which gives rise to the neural retina, and an outer layer, which forms the RPE. At the optic cup stage, the presumptive RPE and retina are separated by a thin remnant of lumen, which becomes filled by a material known as the interphotoreceptor matrix (IPM). Coincident with this is the onset of the expression of RPE65, which encodes a protein involved in the conversion of all-*trans*-retinal to 11-*cis*-retinal. Prior to this stage, the RPE is a ciliated and pseudo-stratified epithelium; however, following IPM formation, RPE maturation commences. The onset of RPE maturation is marked by melanogenesis, which requires the activation of the tyrosinase promoter.

As the RPE continues to differentiate, it displays a complete apical to basolateral polarity, with short apical microvilli and small basolateral membrane infoldings, and the formation of tight junctions between the RPE cells, which can be divided into three stages. The early stage of tight junction formation is characterized by the expression of key tight junction proteins, such as zona occludens 1 (ZO-1), occludin, and claudins. However, these tight junctional complexes are rudimentary so the RPE lacks complete barrier properties and is therefore leaky. As the

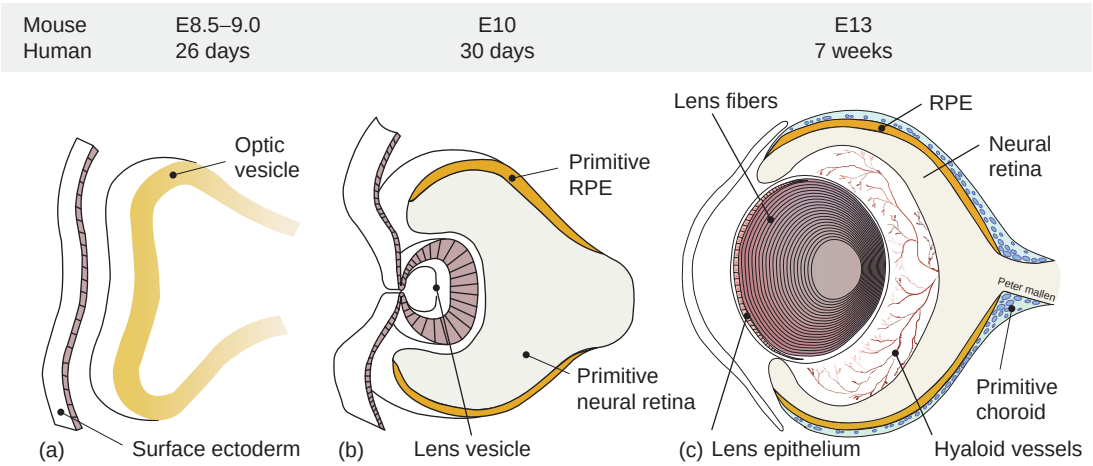

Figure 1 Development of the RPE and choroid. (a) Eye development begins with the budding of the neural ectoderm from the wall of the forebrain to form the optic vesicle. (b) When the optic vesicle comes in contact with the overlying surface ectoderm, it invaginates, forming the optic cup, which consists of an inner layer and an outer layer. The inner layer gives rise to the neural retina, and the outer layer eventually forms the RPE. Choroidal development proceeds from two embryonic tissues: the mesoderm and cranial neural crest cells. The endothelial cells of the choroidal blood vessels are derived from the mesoderm, whereas neural crest cells give rise to the stromal cells, melanocytes, and pericytes. (c) Choroid development begins early in eye development, as the oxygenation of the retina is supplied solely by the choroid and the transient hyaloid vascular system. Initially, tubes and spaces form in the surrounding periocular region of the optic vesicle, and eventually expand to form a plexus. Primitive capillaries develop from this plexus adjacent to the RPE as the optic vesicle invaginates. In humans, the choroidal plexus fuses to form a singular vessel known as the annular vessel at the anterior region of the optic cup during the second and third months of gestation. This primitive plexus is then organized into a complex network, and a well-defined choriocapillaris layer also appears at this stage.

early phase ends, Na^+ K^+ ATPase (ATPase, adenosine triphosphatase) becomes concentrated at the apical surface, and the apical microvilli begin to elongate. In the second stage, the tight junctions become increasingly less permeable, presumably due to the alterations in the distribution of various tight-junction proteins. At this stage, the RPE now prevents the free diffusion of membrane proteins, and the basolateral membrane is remodeled. In the last stage of tight-junction formation, the composition of tight-junction protein isoforms stabilizes and the RPE begins to display barrier properties characteristic of a tight epithelium. Following completion of tight-junction formation, the RPE begins to express specialized proteins, such as the glucose transporter, that aid in the transport of essential nutrients from the RPE to the photoreceptors. As RPE maturation concludes, the RPE becomes fully functional and is able to interact with the photoreceptors.

Choroid Development

Blood vessels develop by vasculogenesis and angiogenesis. In vasculogenesis, primitive vascular cells assemble into a primitive capillary plexus, which is remodeled to define the pattern of the vascular architecture, whereas in angiogenesis, new vessels develop as sprouts from preexisting vessels. It is thought that the superficial vessels of the retina form by vasculogenesis at the optic nerve and expand along a gradient from the posterior to the anterior retina. However, new vessels then sprout via angiogenesis and invade the retina to form intermediate and deep capillary beds. Nonetheless, the primitive vessels derived via vasculogenesis or angiogenesis must still be remodeled before they are considered mature. Remodeling involves the growth of new vessels and regression of others. In addition, alterations in lumen diameter and vessel wall thickness, which are dictated by the local needs of the tissue, must also occur.

The choroid develops from two principle embryonic tissues: the mesoderm and cranial neural crest cells. The mesoderm gives rise to the endothelial cells of the choroidal blood vessels, whereas the stromal cells, melanocytes, and pericytes are all derived from the neural crest cells. Choroid development begins early in eye development, which is not surprising considering that the differentiation of the ocular tissues relies upon the oxygen and nutrients supplied by the primitive vascular system. In early eye development, the oxygenation of the retina is supplied solely by the choroid and the transient hyaloid vascular system. The vascularization of the retina itself is actually a late event. Initially, tubes and spaces form in the surrounding periocular region of the optic vesicle. These tubes, which are lined by the mesodermal endothelium, expand to form a plexus as eye development proceeds. Concomitant with optic vesicle invagination, the primitive capillaries develop from this plexus adjacent to the RPE. In humans, choroidal capillaries completely encircle the optic cup by the 13-mm stage of development and remain separated from the retina by the basement

membrane of the RPE. At the anterior region of the optic cup, the choroidal plexus fuses to form a singular vessel known as the annular vessel, and during the second and third months of gestation, this primitive plexus is organized into a complex network. A well-defined choriocapillaris layer also appears at this stage. Pigmentation does not appear in choroidal melanocytes until late gestation – between 6 and 7 months; however, it is complete at birth.

BrM Development

In mice, the formation of the choroidal vessels precedes the deposition of BrM, and maturation of the BrM layers is not complete until 6 weeks following birth. However, in humans and monkeys, BrM layers are completely formed *in utero*. BrM formation commences near the RPE, and is initially comprised of a single basement membrane derived from the RPE. The RPE is able to synthesize many of the extracellular matrix (ECM) components that comprise BrM; therefore, it is not surprising that BrM development begins near the RPE. On the 17th to 18th day of gestation in rats, collagenous fibrils gradually accumulate in the space between the RPE and choriocapillaris endothelium and begin to form a three-dimensional meshwork within BrM. The meshwork consists of three sublayers: the basement membranes of the RPE and choriocapillaris endothelium, and a collagenous layer. The final component of BrM, the central elastic layer, appears on the fifth postnatal day. Initially, dense elastic deposits appear within the collagenous layer, and subsequently accumulate to form a single continuous layer, which separates the collagenous layer into an inner and outer layer. Finally, an immature, but five-layered BrM is formed by the ninth day after birth.

RPE–Choroid Complex: Structure and Function

RPE Structure and Function

It is apparent that the RPE performs a variety of complex functions that are essential for proper visual function. If any aspect of one of the many roles that the RPE serves is disrupted or fails, retinal degeneration, loss of visual function, and ultimately blindness may result. Therefore, the RPE is an indispensable component of the RPE–choroid complex. Anatomically, the RPE is juxtaposed to the outer segments of the photoreceptors at its apical surface, extending long apical microvilli that surround the outer segments. These microvilli provide a means for a complex structural interaction between the RPE and photoreceptors. BrM, which is at the basolateral side of the RPE, separates the RPE from the fenestrated endothelium of the choriocapillaris.

The RPE serves many functions that are vital to normal eye function and physiology. These functions have been categorized based on the characteristics of three classes of cells: epithelium, macrophage, and glia. The major function of an epithelium is to control the passage of substances from one extracellular space to another; therefore, the epithelial aspect of the RPE is its role in actively transporting ions, water, and metabolic end products from the subretinal space to the blood. The RPE is also involved in the uptake of nutrients, such as glucose, retinol, and fatty acids from the blood to nourish the photoreceptors. One of its most critical functions is the exchange of retinal with the photoreceptors. The photoreceptors are unable to reisomerize all-*trans*-retinal; therefore, it is transported to the RPE where it is reisomerized to 11-*cis*-retinal, and then transported back to the photoreceptors, a process known as the visual cycle of retinal.

The RPE also functions as a macrophage in that it phagocytoses the photoreceptor outer segments, which are constantly being renewed. As new membrane is added to the base of the outer segment, the older membrane is advanced toward the tip, and subsequently shed. The phagocytosis of the shed outer segments by the RPE is critical to normal photoreceptor function because it maintains the excitability of the photoreceptors. The vital nutrients, such as retinal, which are recycled and returned to the photoreceptors following outer segment digestion help rebuild the light-sensitive outer segments from the base of the photoreceptors.

The final role that the RPE plays is that of a glial cell. RPE resembles glial cells in the manner in which they respond electrically to changes in the concentration of extracellular K^+, which is determined by the photoreceptors. The RPE possesses tight junctions at both its basolateral and apical membranes, which generate transepithelial resistance (TER); furthermore, the tight junctions at the basolateral surface form the RPE portion of the blood–retinal barrier.

Choroid Structure and Function

The choroid is a vascular bed that supplies nutrients and oxygen to the RPE and outer nuclear layer of the retina. It consists of larger vessels and a highly fenestrated choriocapillaris (**Figure 2**), whose endothelial basement membrane comprises one layer of BrM. Fenestrated endothelium is a characteristic of tissues that are involved in secretion and/or filtration. The photoreceptors are metabolically very active and the fenestrated choriocapillaris facilitates the transport of oxygen and nutrients to fulfill their metabolic needs. RPE tight junctions, in combination with sophisticated transport systems, determine which components of the choriocapillary secretions are transported to the photoreceptors.

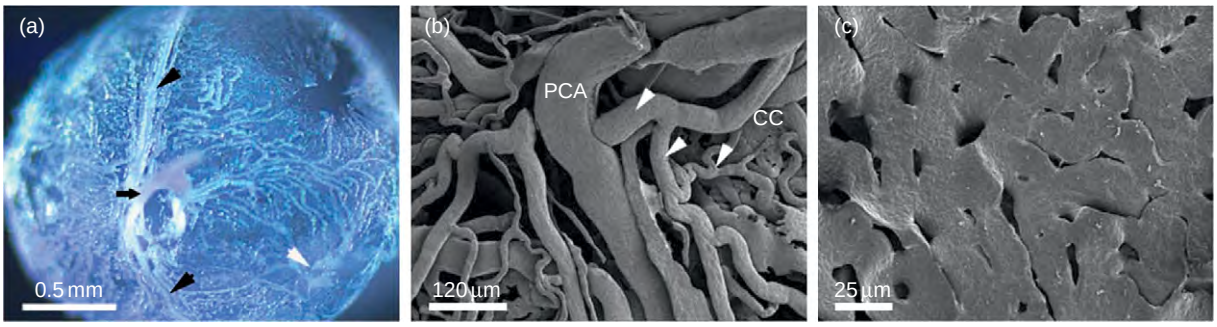

Figure 2 Corrosion cast of adult mouse choroidal vasculature. The choroid is a vascular bed that supplies nutrients and oxygen to the RPE and outer nuclear layer of the retina. It consists of larger vessels and a highly fenestrated capillary bed known as the choriocapillaris. (a) Scleral view of the entire adult choroid. Major vessels can be easily identified: posterior ciliary artery (black arrow), long posterior arteries (black arrowhead), and vortex vein (white arrowhead). (b, c) Scanning electron micrographs of vascular cast of the choroidal vasculature. (b) Posterior view showing one posterior ciliary artery (PCA) around the optic nerve. On each side, the artery divides regularly into smaller branches (arrows) and choriocapillaris (CC). (c) Anterior view showing the extremely dense choriocapillaris plexus.

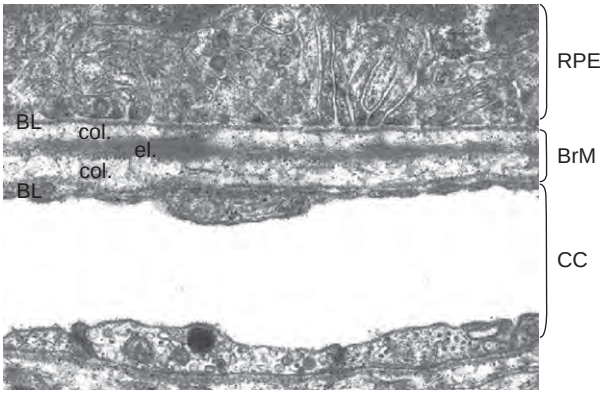

Figure 3 Ultrastructure of the RPE–BrM–choriocapillaris. The RPE and choriocapillaris are separated by a thick (1–4 μm) elastic lamina, BrM, which consists of five layers: the RPE basement membrane (BL), an inner collagenous layer (col), a central elastic layer (el), an outer collagenous layer (col), and the choriocapillaris (cc) endothelium basement membrane (BL), respectively, from top to bottom. BrM acts as a barrier for macromolecules and regulates the diffusion of small molecules between the RPE and the choriocapillaris.

BrM Structure and Function

Located between the RPE and the choriocapillaris, BrM is a thick (1–4 μm) pentalaminar ECM, which consists of the RPE basement membrane, an inner collagenous layer, a central elastic layer, an outer collagenous layer, and the choriocapillaris endothelium basement membrane (Figure 3). BrM is comprised of several types of extracellular components, including many types of collagen, laminin, fibronectin, and proteoglycans. The collagenous layers of BrM are primarily composed of type I collagen and collagenous-associated proteins. It is believed that these components fortify the framework of BrM and aid in the resistance to the force that intraocular pressure exerts on the back of the eye. The basement membranes of the RPE and choriocapillaris endothelium are composed of type IV collagen, which can indirectly interact with cells via laminin, and also binds to heparin and heparan sulfate proteoglycans. The central elastic layer consists of cross-linked elastin fibers that are associated with fibulin 5, an ECM protein that is thought to aid in elastin fiber assembly and serve as a link between the elastin fibers and cell surface receptors. BrM acts as a support and a barrier between the retina and the choroid, and is thought to support the many functions of the RPE. BrM is semi-permeable, and therefore controls the transfer of molecules and cellular components between the RPE and the choroidal vasculature.

RPE–Choroid Interactions

Interactions During Development

The presence of the RPE is required for proper choroid development. Studies have shown that an intact, fully differentiated RPE is required for normal choroidal development; when the RPE is transdifferentiated into a neural retina by expressing fibroblast growth factor (FGF)-9 under the control of the tyrosine-related protein 2 (TRP-2) promoter, the choroid fails to develop. This is further illustrated in humans with colombas where RPE differentiation has failed and there are abnormalities in development of both the choroid and sclera. Basic fibroblast growth factor (bFGF) has also been implicated in choroidal development. Transgenic mice in which a dominant-negative bFGF receptor (FGFR1) was overexpressed in the RPE displayed choroidal abnormalities, such as incomplete and immature choroidal vessels.

The RPE also secretes a variety of growth factors and an increasing body of evidence indicates that RPE-derived vascular endothelial growth factor (VEGF) is essential to choroidal development. Studies in humans and rodents have illustrated that both VEGF and its

receptor, VEGFR2, are highly expressed by the RPE and the underlying mesenchyme, respectively, at the time of choriocapillaris formation. Furthermore, mice with an RPE-specific deletion of VEGF presented a variety of defects, including microphthalmia, loss of visual function, and the complete absence of the choriocapillaris. In addition, the RPE itself was discontinuous, suggesting that RPE-derived VEGF is not only important for choroidal development, but also for RPE survival. Whether the RPE abnormality is secondary to the defects in choroidal development or due to a direct effect of VEGF on RPE has not been elucidated.

Interactions in the Adult

Normal RPE–choroid interactions are not only important during development, but also in the adult. Several studies have revealed the impact of RPE loss on choroidal structure and function. The presence of an intact RPE is critical to proper choroidal function, as surgical RPE removal causes several changes throughout the choroid. Both large choroidal vessels and the choriocapillaris display a reduction in circulation, and depending upon the extent of RPE removal, choroidal nonperfusion can be permanent due to fibroblast infiltration. A landmark study in which the RPE was selectively destroyed by sodium iodate treatment illustrated that within 1 week following iodate injection, the choriocapillaris had reduced fenestrations and displayed signs of atrophy, such as degenerating endothelial cells, and pericapillary basal laminae that had begun to separate from the apparently shrunken endothelium. Together, these data illustrate the critical role the RPE plays in both survival and in the maintenance of the choriocapillaris.

Growth factor secretion

RPE secretes a variety of growth factors, including VEGF, FGFs, transforming growth factor-β (TGF-β), and ciliary neutrophic factor (CNTF). The RPE also secretes pigment-epithelium-derived factor (PEDF), which functions not only to maintain the retina by acting as a neuroprotective factor, but also to provide antiangiogenic activity to inhibit endothelial cell proliferation, thereby stabilizing the choriocapillaris endothelium. VEGF, a well-characterized angiogenic factor, also plays a role modulating blood vessel permeability. Differential splicing of VEGF premessenger RNA (mRNA) gives rise to multiple isoforms, with the most notable being VEGF120, VEGF164, and VEGF188 in mice, and VEGF121, VEGF165, and VEGF189 in humans. VEGF120 does not bind heparin sulfate proteoglycans (HSPGs) and is readily diffusible, whereas VEGF164 is partially sequestered on the cell surface and in the ECM. VEGF188, with high affinity for heparan sulfate, is therefore primarily cell-surface- and matrix-associated. The RPE primarily expresses the diffusible isoforms, VEGF164 and VEGF120, while VEGF188 is virtually undetectable. RPE-derived VEGF is essential for both survival and maintenance of the underlying choriocapillaris endothelium. Interestingly, PEDF and VEGF are secreted by the RPE in a polarized fashion in opposing directions. PEDF is secreted to the apical surface of the RPE to support the neurons and photoreceptors of the retina, whereas VEGF is primarily secreted to the basolateral surface where it acts on the choroidal endothelium (**Figure 4**). Despite the fact that a small fraction of total VEGF, a potent angiogenic factor, is secreted to the apical surface by the RPE, the outer nuclear layer of retina remains completely avascular, presumably due to the balance between antiangiogenic (PEDF) and angiogenic (VEGF) factors.

Receptor expression

In parallel with the many factors secreted by the RPE, the choroid expresses a number of corresponding receptors, including FGF receptors, type I and II TGF-β receptors, and VEGFR2. Of particular interest is the fact that VEGFR2 is observed primarily in the choriocapillaris adjacent to the RPE, with substantially less VEGFR2 expression observed in the major vessels of the choroid. Furthermore, VEGFR2 is localized to the apical surface of the choriocapillaris endothelium and to the photoreceptors where it is constitutively activated, which is surprising given that adult choroidal vasculature is mature and quiescent.

Isoform-specific VEGF mouse model

In support of a critical role for RPE-derived VEGF in the maintenance of the adult choriocapillaris, we have shown that the absence of soluble VEGF isoforms in the RPE leads to changes that recapitulate the classical features of dry age-related macular degeneration (AMD). Mice expressing only VEGF188 (i.e., lacking the diffusible isoforms that they normally express) display signs of RPE dysfunction, such as increased autofluorescence, loss of barrier proprieties, and accumulation of basal deposits that are similar to drusen, extracellular deposits that build up beneath the basement membrane of the RPE within BrM. These changes occur prior to the formation of both focal choroidal atrophy and RPE attenuation, which progress to large areas of RPE loss. The abnormalities are age dependent and increase in severity over time.

Choroidal change impact on RPE

The RPE–choroid interactions do not merely function to serve the choroid; changes in the choroid have also been shown to impact the RPE. Choroidal ischemia has been reported to lead to opaque RPE lesions and subsequent serous retinal detachment. Furthermore, very early studies on the effects of choroidal congestion on RPE–retina function revealed that increased choroidal pressure may

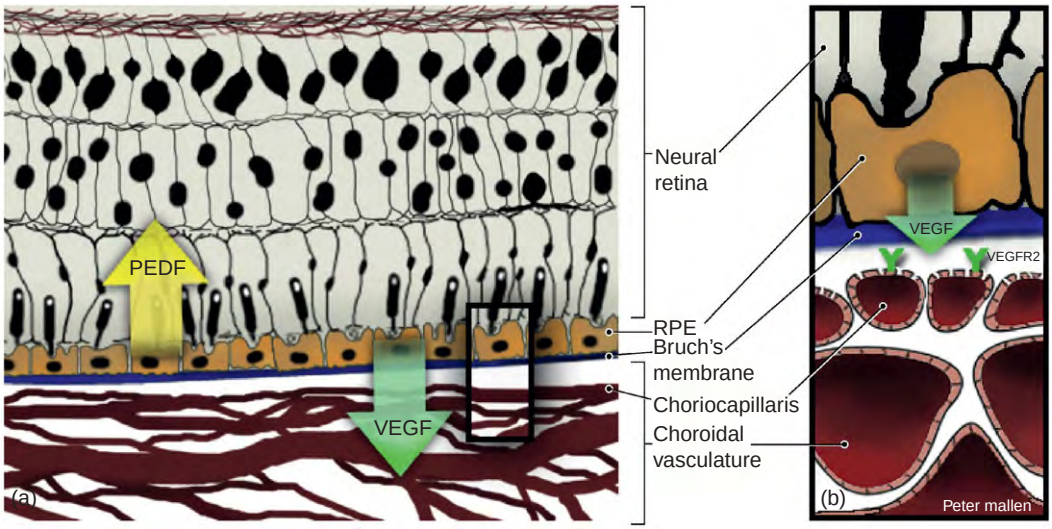

Figure 4 Polarized secretion by the RPE and localization of VEGFR2. (a) The RPE secretes both VEGF and PEDF in polarized fashion in opposing directions. PEDF is secreted to the apical surface of the RPE to support the neurons and photoreceptors of the retina, whereas VEGF is primarily secreted to the basolateral surface where it acts on the choroidal endothelium. RPE-derived VEGF is essential for both survival and maintenance of the underlying choriocapillaris endothelium, and PEDF functions not only as a neuroprotective factor, but also as an antiangiogenic factor to maintain the avascularity of the outer nuclear layer of the retina. (b) Higher magnification of selected area in (a) showing fenestrations in choriocapillaris and localization of the VEGFR2 receptor. In parallel with the VEGF secreted by the RPE, the choroid expresses the corresponding VEGF receptor, VEGFR2. VEGFR2 is observed primarily in the choriocapillaris adjacent to the RPE, with substantially less VEGFR2 expression observed in the major vessels of the choroid.

cause RPE–retina dysfunction by altering normal fluid movement across the RPE, modifying the integrity of the subretinal space.

RPE–Choroid Changes with Age

Various changes occur in the RPE–choroid complex with aging. In light of the close association among the RPE, BrM, and choroid, it is not surprising that an alteration in a single component of this complex compromises the normal RPE–choroid interaction and ultimately leads to disease. Studies have shown that the density and diameter of the choriocapillaris and medium-sized choroidal vessels substantially decline with age, resulting in decreased choroidal blood volume and blood flow. The aging RPE exhibit changes such as a reduction in cell density and a loss of RPE melanin. Melanin pigmentation is believed to play a protective role, acting to protect cells against oxidative stress. Oxidative changes in RPE melanin may be attributed to complexing of melanin with lipofuscin, pigment granules composed of lipid-containing residues of lysosomal digestion, which generate reactive oxygen species upon excitation with blue light, thereby making the aged RPE more susceptible to oxidative damage.

BrM Changes

Changes in BrM include increased thickness, accumulation of lipids, and subsequent alterations of the BrM permeability. Collectively, these changes can limit the diffusion of water-soluble proteins, leading to a range of problems. Furthermore, drusen are known to accumulate in the aging eye (**Figure 5**). There is a strong correlation between the presence of drusen and ocular pathology, such as AMD. It has been speculated that drusen lead to a gradual reduction in the diffusion of RPE-derived factors, such as VEGF, which may be causal in the atrophy of segments of the RPE and underlying choriocapillaris, known as geographic AMD. Drusen accumulation and coalescence may also lead to breaks in BrM that are believed to be the initiating event in the formation of choroidal neovascularization (CNV), in which new blood vessels sprout from preexisting choroidal vessels and invade the overlying RPE and retina. The development of CNV associated with wet AMD leads to visual loss due to the fact that the neovessels are leaky and cause damage to the surrounding tissues.

Gene Expression

Gene expression of the RPE–choroid also changes with age. There is considerable upregulation of the expression of genes and proteins involved in leukocyte extravasation, and the accumulation of leukocytes at the RPE–BrM interface suggests that leukocytes are possibly recruited to aid in the removal of cellular waste. Furthermore, there have been reports of increased macrophages in the aged RPE–choroid; mice harboring mutations that render them deficient in macrophage recruitment display hallmarks of

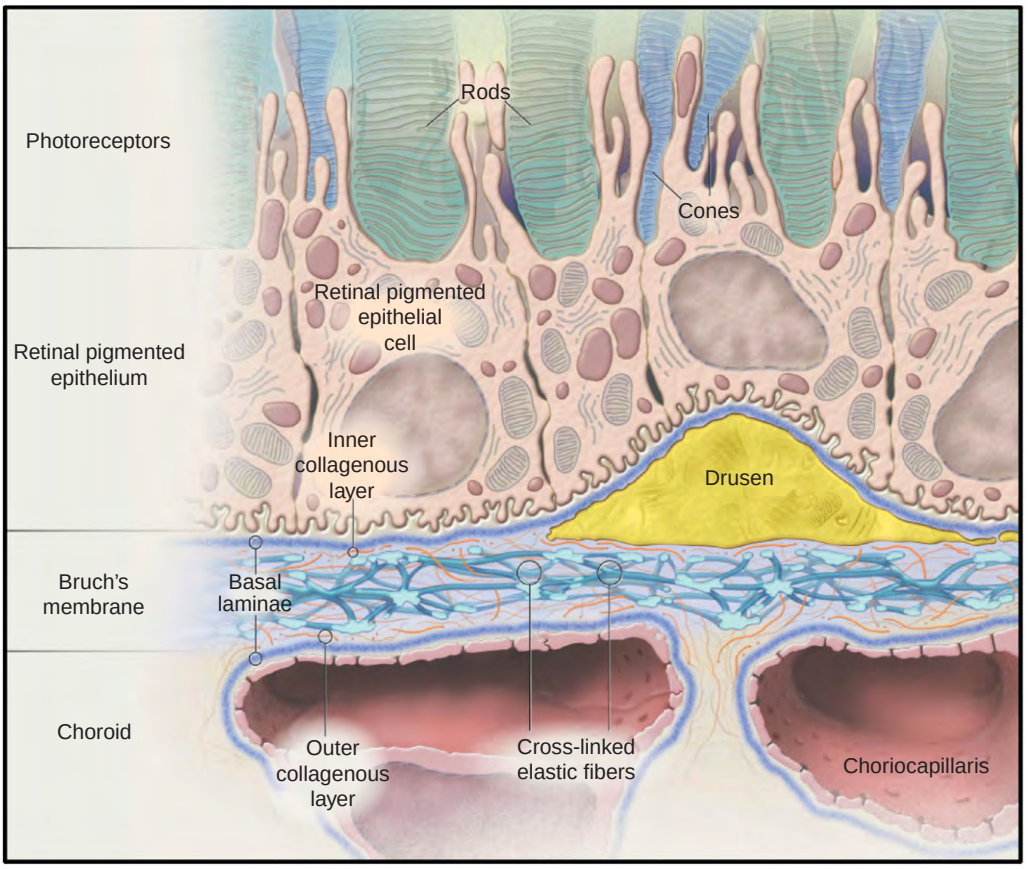

Figure 5 The accumulation of drusen beneath the RPE within BrM. In the aging eye, it is common for drusen to accumulate at the interface between the inner collagenous layer of BrM and the basal lamina of the RPE. Drusen are extracellular deposits that are strongly correlated with ocular pathology, such as age-related macular degeneration (AMD). It is proposed that drusen deposits between the RPE and the BrM as well as within BrM, and causes a gradual reduction in the diffusion of RPE-derived factors, such as VEGF, which may lead to the atrophy of segments of the RPE and underlying choriocapillaris, also known as geographic AMD. Drusen accumulation and coalescence may also cause breaks in BrM that are believed to be the initiating event in the formation of choroidal neovascularization (CNV), in which new blood vessels sprout from preexisting choroidal vessels and invade the overlying RPE and retina. Adapted from Johnson, L. V. and Anderson, D. H. Age-related macular degeneration and the extracellular matrix. *New England Journal of Medicine* 351(4): 320–322.

AMD. It is also thought that the aged RPE–choroid synthesizes proteins that not only attract leukocytes, but that also activate the complement pathway, which is a part of the immune response and can lead to inflammation. Recent associations between polymorphisms in a member of the complement pathway reinforce the role of inflammation in the development of AMD.

Conclusions

Despite the fact that the RPE and choroid are separated by BrM, there is a great deal of interaction between the tissues. The presence of an intact, fully differentiated RPE is not only required for proper choroidal development, but is also essential for survival and maintenance of adult choriocapillaris endothelium specializations (fenestrations) and integrity. The RPE secretes a variety of factors, one of the most notable being VEGF. The secretion of VEGF by the RPE is somewhat of a double-edged sword. Although VEGF is vital to choroidal homeostasis during both development and in adult, breakdown of the RPE barrier upon direct contact with choroidal endothelial cells is thought to involve a VEGF-mediated mechanism, for VEGF has been shown to mediate the vessel growth and permeability associated with wet AMD. Thus, maintenance of proper RPE–choroid interaction is vital to normal function, and any perturbation to this system can ultimately lead to disease.

Retinal Pigment Epithelium: Cytokine Modulation of Epithelial Physiology

S S Miller, A Maminishkis, R Li, and J Adijanto, National Eye Institute, Bethesda, MD, USA

Published by Elsevier Ltd.

Glossary

Cytokines – A large and diverse family of polypeptide regulators that are used in cell regulation.
ELISA – The enzyme-linked immunosorbent assay is a biochemical technique that uses an enzyme-linked antibody to detect its corresponding ligand within a sample. It can be used to assay for chemokines and cytokines.
Subretinal space (SRS) – The extracellular space between the retinal photoreceptors and the apical surface of the retinal pigment epithelium.
Tight junctions – A structure of specialized proteins that form a seal between neighboring cells and regulate ion and small molecule selectivity and resistance in the paracellular pathway between epithelial cells. Tight junction proteins include occluding, claudins, and junction adhesion molecules (JAMs).

Introduction

In the back of the vertebrate eye, the apical membrane of the retinal pigment epithelium (RPE) and the photoreceptor outer segments form a very tight anatomical relationship (Figure 1). This structural feature supports a whole host of mechanical, electrical, and metabolic interactions that maintain the health and integrity of the neural retina throughout the life of the organism. Like all epithelia, the RPE plasma membrane contains a wide variety of proteins, enzymes, and small molecules that are specifically segregated to the apical or basolateral sides of the epithelium, which face the neural retina and choroidal blood supply, respectively (Figure 2).

The asymmetrical distribution of these functionally distinct molecules is maintained by junctional complexes that surround each cell and by the continuous synthesis and regulated traffic of these molecules to each membrane. Epithelial polarity is defined by the steady-state maintenance of this asymmetric distribution and is critical for the ongoing vectorial transport of ions, metabolites, fluid, and waste products across the RPE. Epithelial polarity is also fundamentally important for controlling changes in the volume and chemical compositions of the extracellular spaces on either side of the RPE, following transitions between light and dark. In the distal retina, the extracellular or subretinal space (SRS) separates the photoreceptor outer segments and the RPE apical processes. The chemical composition of this space is tightly buffered by the cells which surround it (Müller cells, photoreceptors, and RPE). On the opposite side of the RPE, an extracellular space is formed between its basolateral membrane and Bruch's membrane, which is adjacent to the choriocapillaris. The physiological and pathophysiological states of the RPE/distal retina complex are significantly affected by changes in the chemical composition of these extracellular spaces as evidenced in disease processes such as age-related macular degeneration (AMD) or uveitis. AMD develops within the RPE/distal retina complex and eventually leads to RPE impairment and loss of photoreceptor function. The RPE's ability to control and respond to varying levels of oxidative insult from light quanta, outer segment phagocytosis, vitamin A uptake and delivery, and oxygen consumption diminishes with age. These changes significantly affect the chemical composition of the surrounding extracellular spaces, SRS and choroid, and are a major factor in disease pathogenesis. In recent years, significant advances have been made in identifying the role of the immune system in neurodegenerative disease in general and in AMD, in particular (summarized by Hageman and colleagues and by Nussenblatt and Ferris). This article summarizes recent experiments from our lab and others, which show that inflammation induced changes in the environment surrounding human RPE can significantly alter intracellular signaling and physiology. This study provides a basis for understanding disease progression and regression.

This article is divided into three main parts. We begin with a description of our development of a robust and well-defined primary cell culture model of human fetal retinal pigment epithelium (hfRPE). We use this model to analyze how metabolic waste products, produced in the retina following light/dark transitions, can be disposed of by CO_2/HCO_3 and lactate transporters located in the apical and basolateral cell membranes. In the second part, we use this cell culture model to analyze RPE antioxidant mechanisms that are protective against disease processes, such as AMD or uveitis. In the third part, we describe a series of experiments that use this model to define the impact of cytokines on human RPE function. Finally, we briefly focus on the role of interferon gamma (INFγ) in controlling RPE physiology.

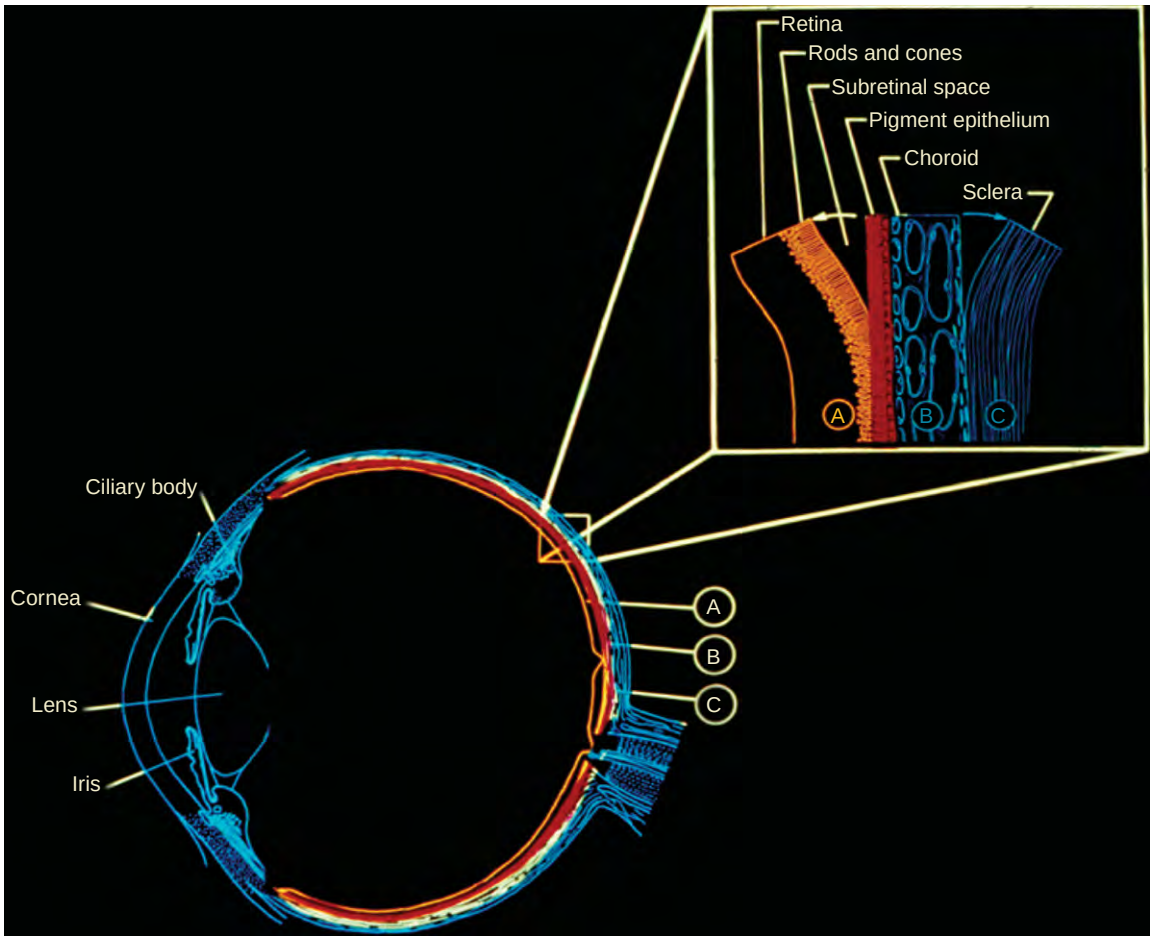

Figure 1 Schematic diagram of the eye. The retinal pigment epithelium is located in the back of the eye between neural retina and choroid.

Human RPE: Morphology, Polarity, and Function

The availability of native human tissue, fetal or adult, is limited and extant models of cultured human RPE have been, in varying degrees, less than adequately characterized or understood, not reproducible or available in large quantities, and lacking expression of melanin pigment and key functional proteins such as bestrophin (Best1), and RPE-specific protein 65 (RPE65). Therefore, we developed a set of standard procedures for producing confluent monolayers of hfRPE cells and demonstrated that they have the morphology, polarity, and function of the native tissue from which they were derived (Figure 3). Light and electron microscopy (EM) studies confirmed the presence of apical processes (microvilli) and basal infoldings that increased the elaboration of the apical and basolateral membranes, respective, in cultured hfRPE cells. We carried out immunoblot and immunofluorescence experiments for a variety of proteins to help define the polarity of this model. In the course of these experiments, we discovered that human RPE tight junctions contain a variety of membrane proteins (claudins) that are important for regulating the selectivity and conductance of the paracellular pathway, and we also confirmed the presence of several visual cycle and cytoskeleton proteins. Intracellular recordings confirmed many membrane physiological properties and demonstrated the polarity of purinergic and adrenergic receptors at the apical membrane, which serve to regulate cell calcium and transepithelial fluid absorption (Figure 2). By enzyme-linked immunosorbent assay (ELISA), we showed that these monolayers constitutively secrete pigment epithelium-derived factor (PEDF) to the apical bath and vascular endothelial growth factor (VEGF) to the basal bath; the former provides neuroprotection for the retina and the latter would allow active regulation of endothelial cell fenestration, a structural feature critical for choroidal circulation.

pH_i – Induced Changes in Fluid Absorption

In previous experiments we showed that acetazolamide, a carbonic anhydrase (CA) inhibitor, reduced net ^{36}Cl flux across frog RPE. Subsequent animal models and clinical

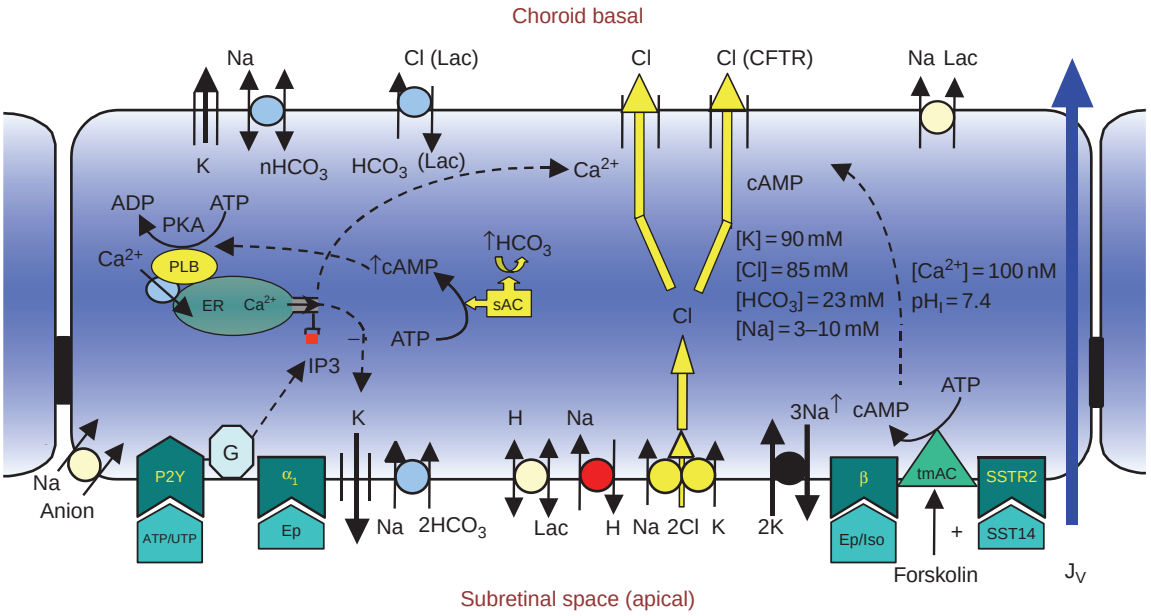

Figure 2 Schematic diagram of retinal pigment epithelium (RPE) summarizing some membrane proteins, channels, and receptors that are responsible for a variety of RPE functions such as fluid transport, pH maintenance, or cell-volume regulation. The arrows highlighted in yellow indicate a main pathway for solute-driven fluid transport across the RPE, consisting of a sodium, potassium, 2 chloride co-transporter (Na/K/2Cl co-transporter) at the apical membrane, and a cyclic AMP-activated chloride channel, CFTR (cystic fibrosis transmembrane conductance regulator), and Ca^{2+}-activated Cl-channels at the basolateral membrane. The apical membrane contains a variety of receptors, for example, purinergic (P2Y), adrenergic (α-1 and β), and somatostatin (SSTR2), which when bound to their specific ligands, activate Ca^{2+} and cAMP second-messenger signaling systems. The plasma membrane localization of previously described ion transporters such as the Na/2HCO_3 co-transporter, Na/H exchanger, 3Na/2K ATPase, H/Lac co-transporter, Cl/HCO_3 exchanger, and potassium channels are also shown. trials have utilized CA inhibitors to reduce disease-induced abnormal accumulation of retinal fluid. CAs catalyze the reversible hydration of CO_2 to HCO_3 and protons, which are transported across the plasma membrane (e.g., Na/HCO_3 or H/lactate co-transporters) to regulate cell pH. As a first step, we have identified and localized several highly expressed CAs in human RPE and begun study of their physiology. A total of 16 CAs have been identified in human tissues. In human fetal RPE cell cultures, 14 of the 16 known isozymes have been confirmed by quantitative real-time polymerase chain reaction (qRT-PCR). Immunocytochemical studies indicate that CA II is localized intracellularly, as in many other cell types. CA IV, XII, and XIV are localized to the apical surface, while CA IX, the most abundantly expressed isozyme in hfRPE cultures, is expressed apically and laterally (**Figure 4**). However, it should be noted that CA IX messenger RNA (mRNA) and proteins are not expressed in native adult or fetal human RPE. CA inhibitors have had limited success in alleviating the effects of retinal disease, partly because of systemic side effects, but mainly because of their lack of specificity. The positive clinical outcomes for some patients with retinal edema suggest that nonspecific CA inhibitors, such as acetazolamide, may be affecting multiple CAs or other transport-related mechanisms that can either increase or decrease net fluid absorption across the RPE in varying degrees in different patients. This is supported by *in vivo* animal studies, in which intravenous administration of acetazolamide to rabbits increased fluid clearance from the SRS. The regulatory role of CAs is potentially important in human RPE, which critically depends on HCO_3 transport to maintain fluid absorption (J_V) out of the SRS (**Figure 5**).

Modulation of SRS Metabolic Load and Chemical Composition

In the intact eye (cat/monkey), the transition from light to dark causes significant alterations in SRS pH, Ca^{2+}, and K. In addition, the transition from light to dark increases photoreceptor O_2 consumption by ≈2-fold as measured *in situ* in cat and nonhuman primate retina. The rates of retinal O_2 consumption in light and in dark were used by Linsenmeier and Winkler and their colleagues to estimate the associated changes in glucose metabolism that leads to the concomitant release of carbon dioxide, lactic acid, and water from the photoreceptor inner segments into the SRS. This metabolic acid load is potentially damaging to all of the cells that surround the SRS (i.e., photoreceptors, Müller cells, and RPE). It raises the

question of how the RPE could help prevent this accumulation of metabolic acid and water in the SRS.

In *in vivo* studies of rabbit eye, it was estimated that ≈70% of fluid absorption across the RPE is linked to metabolite transport to the choroidal blood supply. In addition, *in vitro* studies of frog RPE showed that steady-state fluid absorption decreased by ≈70%, following the removal of HCO_3 from both bathing solutions, implicating HCO_3 transport in a regulatory role on fluid transport. The RPE functionally expresses several different HCO_3 transport proteins at the apical and basolateral membranes as illustrated in **Figure 5**. In an earlier study, a 4,4′-diisothiocyano-2,2′-stillbene-disulfonic acid (DIDS)-sensitive electrogenic $Na/2HCO_3$ co-transporter was localized to the apical membrane of frog and bovine RPE; DIDS is a bicarbonate transport inhibitor. At the basolateral membrane, HCO_3 is transported out of the RPE through a pH-sensitive Cl/HCO_3 exchanger with a possible contribution from a Na/HCO_3 co-transporter. These HCO_3 transporters in the RPE are linked to Na and Cl transport, which are major driving forces for fluid transport. Recently, the identities of some of these HCO_3 transporters have been characterized in our laboratory and by other groups. NBC1 ($Na/2HCO_3$ co-transporter) and NBC3 (NBCn1; electroneutral Na/HCO_3 co-transporter) were localized to the apical membrane. AE2 (Cl/HCO_3 exchanger) mRNA transcripts were detected, but protein expression in the RPE remains to be determined. The identity of the basolateral membrane $Na/nHCO_3$ co-transporter (NBC) is still unknown.

In vitro, we mimic the increased retinal CO_2 production, following the transition from light to dark by increasing apical bath CO_2 level from 5% to 13%. This maneuver increased NaCl uptake at the apical membrane and can enhance CA-mediated Na/HCO_3 co-transport across the RPE, thus increasing net $NaHCO_3$ absorption. This increase in solute transport would drive additional fluid across the RPE as observed in *in vitro* experiments. The transport of metabolic waste products from the SRS to the choroidal blood supply by the RPE helps maintain ionic and pH homeostasis of the SRS. The RPE handles the increased metabolic load by transporting

Figure 4 Carbonic anhydrase (CA)-mediated CO_2/HCO_3 transport in retinal pigment epithelium (RPE). Membrane-bound CA IV, XII, and XIV are expressed exclusively at the apical membrane (immunostaining of CA XIV shown in insert on lower left). CA IX is expressed at both the apical and basolateral membranes of cultured human fetal RPE. CA II is expressed in the cytosol and can be recruited to the inner leaflet of the membrane. Experimental data (immunostaining, Western blots, and RT-PCR) that support the localization of the various CAs are listed in the table (lower right). Membrane-bound CAs hydrate CO_2 into HCO_3 and H^+, which are substrates for NBC1 (sodium bicarbonate co-transporter) and MCT1 (proton lactate co-transporter) at the apical membrane. Cytosolic CA II regulates CO_2 and HCO_3 equilibrium in the RPE. The anion exchanger isoform 2 (AE2) mediates Cl/HCO_3 exchange at the basolateral membrane, while a sodium proton exchanger (NHE) at the apical membrane helps regulate intracellular pH.

CO_2 across the RPE in the form of HCO_3 through HCO_3-transporters, and this process is mediated by the catalytic activity of CAs. This increase in Na and HCO_3 absorption provides the driving force for increased net fluid absorption across the RPE, which dehydrates the SRS and creates retinal adhesion, thus allowing the RPE to maintain proper anatomical relationship with the photoreceptors.

In the retina, ≈95% of glucose consumption is metabolized through glycolysis into lactic acid, which is subsequently deposited into the SRS. In addition to the high glycolytic activity of the retina, several other mechanisms cause additional lactic acid to be released by the retina following light–dark transition: (1) increased glucose metabolism at the outer retina; (2) reduced retinal oxygen level in the dark-adapted eye, leading to an increased anaerobic lactate production; and (3) glutamate-induced lactate release from Müller cells. The RPE disposes of this metabolic load by transporting lactic acid to the choroid through monocarboxylate transporters (MCTs) of the MCT family. We previously demonstrated that the RPE is extremely resistant to pH change compared to other epithelia and that part of this regulation comes from H/Lac co-transporters at the apical and basolateral membranes.

In human RPE, Philp and colleagues showed that monocarboxylate transporter 1 (MCT1), a H/Lac co-transporter, is immunolabeled at the apical membrane (**Figure 5**). They also showed that MCT3, a H/Lac co-transporter expressed exclusively in the RPE and choroid plexus basolateral membranes, meditates lactate efflux from the RPE into the choroidal blood supply (**Figure 5**). In addition, a Cl/Lac exchanger, possibly anion exchanger 2 (AE2), has been shown to transport lactate at the basolateral membrane. The importance of lactate transport in the mammalian eye has also been demonstrated in mice lacking MCT1, MCT3, and MCT4 expression – the mutant mice gradually lose photoreceptor function and

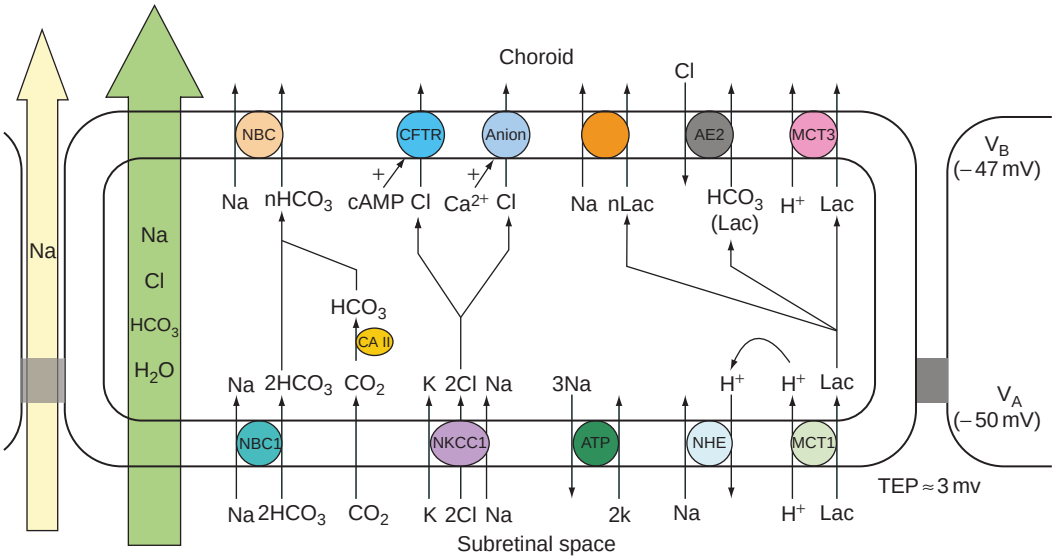

Figure 5 Na, Cl, HCO_3, and lactate transport mechanisms in retinal pigment epithelium (RPE). CO_2 enters the apical membrane via diffusion and HCO_3 is transported into the cell by NBC1 (sodium bicarbonate co-transporter). As CO_2 enters the cell, it can be hydrated into HCO_3 in a reversible reaction catalyzed by carbonic anhydrase II. Cl enters the apical membrane via NKCC1 (sodium potassium chloride co-transporter – Na/K/2Cl) and exits the basolateral membrane via CFTR or Ca^{2+}-activated Cl channels. Lactic acid is transported across the apical membrane by MCT1, and out of the basolateral membrane through MCT3 (H/Lac co-transporter) and AE2 (Cl/Lac exchanger). These ion-transport mechanisms at the apical and basolateral membranes mediate net solute transport across the RPE, which drives fluid absorption. The apical and basolateral membrane potentials are given by V_A and V_B, respectively, and their difference is the transepithelial potential (TEP).

were completely blind after 41 weeks. Further, altered visual function in MCT3-null mice demonstrates the importance of lactate transport specifically in the RPE.

Oxidative Stress

The RPE encounters significant levels of oxidative stress on a daily basis and this onslaught promotes mitochondrial (mt) damage and decreases in mt potential and respiration, which may contribute to inflammation and the onset of age-related diseases such as AMD (summarized by Jarrett and colleagues). In opposition to these oxidative stresses, there exist mt protective mechanisms that provide direct antioxidant protection and those that enhance glutathione (GSH) production; furthermore, there is evidence that all of these protective mechanisms weaken with age. Different cell types can exert different levels of protection; for example, it has been shown that hfRPE monolayers are significantly more resistant to oxidative stress than ARPE-19 cells. Volobouева and colleagues used the hfRPE primary cultures to examine mt and other pathways that are putative targets for therapeutic intervention against oxidative stress. In one set of experiments they studied the protective effects of α-lipoic acid (R-form), a potent intracellular antioxidant that has been shown in other systems, to induce all three cellular protective mechanisms. The R form of lipoic acid is a coenzyme in mt that has been shown to reverse the age-related decrease in mt function. Measurements of cell viability, mt potential, cell death, oxidative stress, apoptosis, and GSH/GSSH show that lipoic acid can protect hfRPE cells in three ways: (1) directly scavenge reactive oxidative species; (2) repair and protect mt enzymes; and (3) activate antioxidant defenses through phase 2 enzymes. Our results suggest that (R)-α-lipoic acid can be used as an all-purpose therapeutic intervention against the slow accumulation of oxidative damage that can occur in AMD.

Cigarette smoke is an important risk factor for AMD and causes significant oxidative damage in RPE that also can be mitigated by (R)-α-lipoic acid. RPE mitochondria are themselves a main generation site of oxidants and a critical and sensitive target of specific cigarette-smoke components. Acrolein is present in the gas phase of cigarettes (25–140 μg per cigarette), and it is estimated that the gas phase of one cigarette reaches a concentration of 80 μM in the airway surface fluid. Acrolein has a high hazard risk in cigarette smoke and causes oxidative stress in cells by reacting with sulfhydryl groups. In the physiological range (0.1–100 μM), it causes significant mt damage in hfRPE that can be ameliorated by (R)-α-lipoic acid, for example, by inducing GSH and other phase-2 antioxidant protective enzymes. Pretreatment by (R)-alpha-lipoid acid has a protective effect against peroxide induced mt oxidative stress in several ways: (1) by lowering cell calcium; (2) by increasing mt electron chain complexes I, II, and III

activity levels; (3) by increasing mt membrane potential; and (4) by increasing total antioxidant power as well as GSH peroxidase/GSH/superoxide dismutase levels. Collectively, these data indicate that lipoic acid may be an effective therapeutic strategy against age-related, oxidant-induced RPE degeneration.

As summarized recently by Dunaief, AMD patients have elevated levels of iron within the RPE that also can lead to oxidative damage to mitochondria. Based on that observation, Volobouéva and colleagues showed that ferric ammonium citrate increased intracellular iron and oxidant production and decreased GSH and mt complex IV activity in human fetal cultured RPE. They also showed that N-*tert*-butyl hydroxylamine (Nt-BHA), a known mt antioxidant, reduced oxidative stress, mt damage, and age-related iron accumulation. These data show that the application of Nt-BHA may be an effective therapeutic strategy against AMD.

RPE–Immune System Interactions in and around the SRS

The integrated effect of proinflammatory molecules on RPE function depends on the polarized location of the cognate receptors and the access of their ligands (cytokines and chemokines) to the apical and basolateral membranes, and the interactions of downstream signaling pathways. For the experiments summarized in **Table 1**, we used a mixture of three proinflammatory cytokines, interleukin 1 beta (IL-1β), interferon gamma (IFNγ), and tumor necrosis factor-alpha (TNF-α) to stimulate confluent monolayers of hfRPE. These proinflammatory cytokines are elevated in patients with uveitis and are detected in the vitreous and blood of patients with proliferative diabetic retinopathy (PDR) and AMD with choroidal neovascularization (CNV).

As a first step in understanding how the RPE *in vivo* can actively control the inflammatory environment in the SRS and choroid, Shi and colleagues used confluent monolayers of human fetal RPE primary cultures to (1) measure the constitutive and polarized secretion of angiogenic/angiostatic cytokines by the RPE; (2) determine how this pattern of polarized secretion changes in the inflammatory state; and (3) demonstrate that the inflammatory state alters RPE physiology. Constitutively, the human RPE secretes massive amounts of monocyte chemoattractant protein 1 (MCP-1) to the SRS and lesser amounts of IL-6 and IL-8 (**Table 1**), all of which contribute to the ongoing downregulation of the immune environment of the retina. RPE activation was achieved using a cocktail of IL-1β, TNF-α, and INFγ with similar concentrations as that detected in the diseased eye. We showed that IL-1β receptors are mainly localized to the apical membrane and TNF-α and INFγ (subunit 1) receptors are mainly localized at the basolateral membrane. This cocktail significantly increased the secretion of various cytokines/chemokines to both baths, but significantly more to the apical bath. The increase in angiogenic cytokine secretion exceeds the increase in angiostatic cytokine secretion. However, two chemokines generally thought to be angiostatic, interferon-inducible T-cell α-chemoattractant (I-Tac) and monokine induced by γ interferon (MIG), were secreted to the apical bath in significant quantities. The mechanisms by which these chemokines exert their effects and their role in eye physiology are not yet known. Similarly intriguing and not understood are the secretions into the apical bath of interferon-inducible protein 10 (IP-10), monocyte chemoattractant protein 3 (MCP-3), and the Rantes chemokine. In animal model experiments from Charlotte Reme's group, blue-light-induced oxidative damage induces the invasion of blood-borne monocytes and activation of retinal microglia, thus stimulating the secretion of cytokines to induce an inflammatory response. Our experiments strongly suggest that the RPE is a significant source of cytokines and chemokines. Thus both retinal microglia and RPE can contribute to the inflammatory response in a diseased eye. Our further demonstration that basolateral addition of the cocktail acutely increases fluid absorption across the RPE (**Figure 6**), from the apical to basal baths (retina to choroidal side of tissue), and significantly decreases transepithelial resistance after a 24-h treatment is important because of the possibility that with age or accumulated oxidative stress these changes can alter chemokine/cytokine gradients across the RPE. These gradients regulate the attraction of monocytes to the RPE basement membrane and, thus, play a role in the accumulation of drusen with age. We believe that this concept is important for understanding early events that underlie chronic disease processes, such as AMD, a notion revisited below.

Modulation of RPE Proliferation and Migration by Cytokines and Growth Factors

Breakdown of the inner or outer blood–retinal barrier can lead to significant alterations in the chemical composition of the SRS, including cytokines and growth factors, which trigger the activation of normally quiescent RPE cells. In proliferative vitreoretinopathy (PVR), RPE cells proliferate and migrate to the vitreous cavity along with other types of cells (e.g., glial cells, fibroblasts, and macrophages) and form fibrocellular membranes on the retinal surface or in the vitreous. These newly formed membranes, if left untreated, eventually contract, resulting in retinal detachment and eventual vision loss.

Several isoforms of platelet-derived growth factor (PDGF) are present in retinal membrane from patients

The table summarizes the polarized secretions of simultaneously measured chemokines (12) and cytokines (3) using multiplex sandwich ELISAs. The left-hand column of this table defines the stimuli and the site of addition of pro-inflammatory mediators. These data are reported as actual concentrations and therefore corrected for transwell volume differences. Each Table entry is the mean ± SD for three experiments and the levels of significance are color coded for ease of comparison.

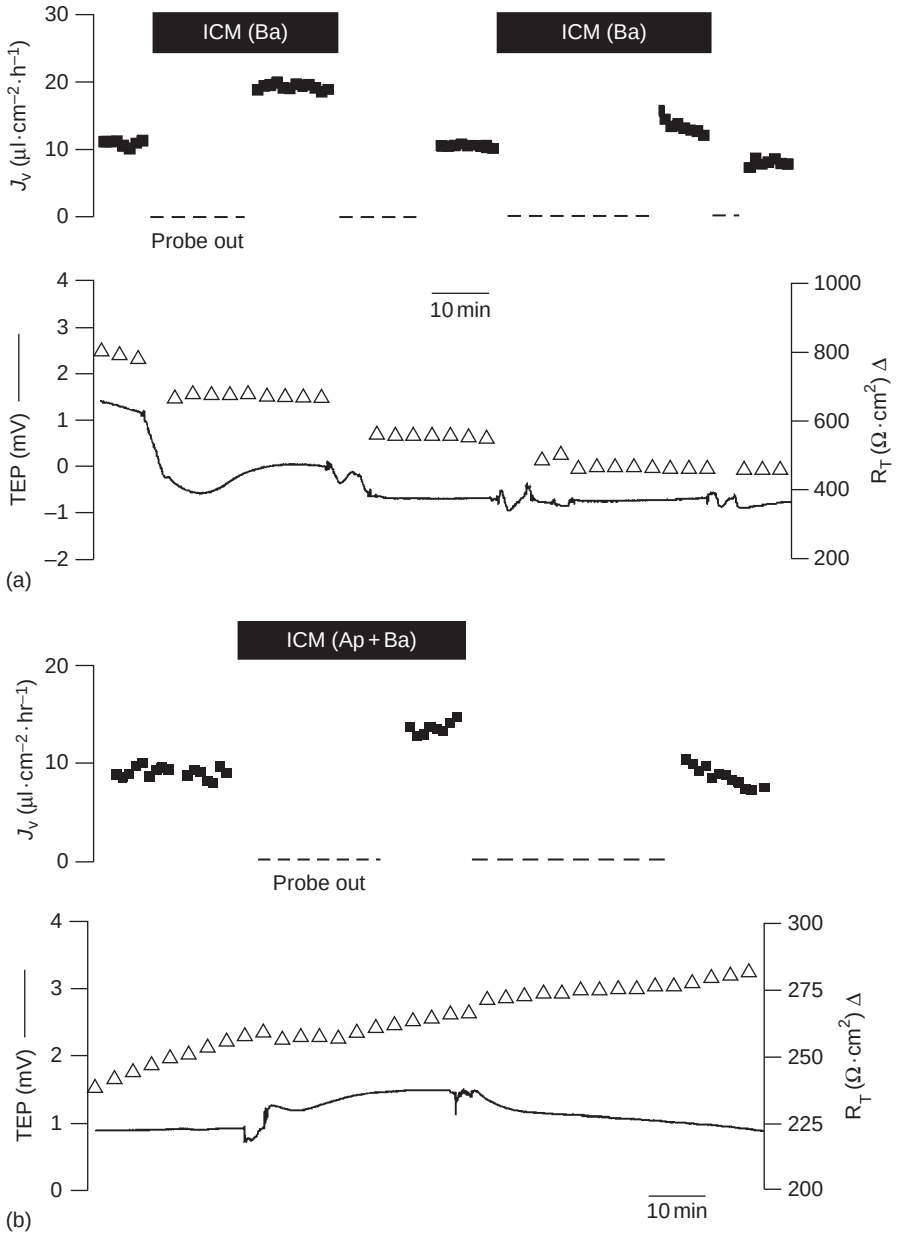

Figure 6 Inflammatory cytokine mixture (ICM) induced changes in hfRPE fluid transport (J_V). In all panels, the top trace is J_V, which is plotted as a function of time; net fluid absorption is indicated by positive values and TEP and total tissue resistance (R_T) are plotted in the lower traces. (a) Addition of ICM to the basal bath increased J_V by ≈13 μl ·cm^{-2}· hr^{-1} with no significant changes in TEP and R_T. (b) Concomitant addition of ICM to apical and basal baths increased J_V by ≈10 μl ·cm^{-2}· hr^{-1} with no change in TEP and a slight increase in resistance that is not statistically significant. From Shi, G., et al. (2008). *Investigative Ophthalmology and Visual Science* 49(10): 4620–4630. © Association for Research in Vision and Ophthalmology.

with PVR and PDR and are elevated in the vitreous of PVR eyes. Recently we showed that PDGF-C, -D are highly expressed in human fetal and adult RPE and that the mRNA levels of these two isoforms are up to 100-fold higher than PDGF-A and -B. PDGF-C and -D have been implicated in PVR and lens epithelial cell proliferation, but relatively little is yet known about their function in RPE. In other systems, they play an important role in angiogenesis and wound healing.

PDGFR-α and PDGFR-β, the receptors for PDGF-C and -D, respectively, are mainly localized to the apical membrane of human fetal RPE as shown in **Figure 7**. PDGF-CC, -DD, and -BB significantly stimulated hfRPE cell proliferation, while PDGF-DD, -BB, and -AB significantly stimulated cell migration. Furthermore, the stimulatory effects of PDGF were abrogated by a proinflammatory cytokine cocktail composed of TNF-α, IL-1β, and IFNγ. Comparison of the component effects

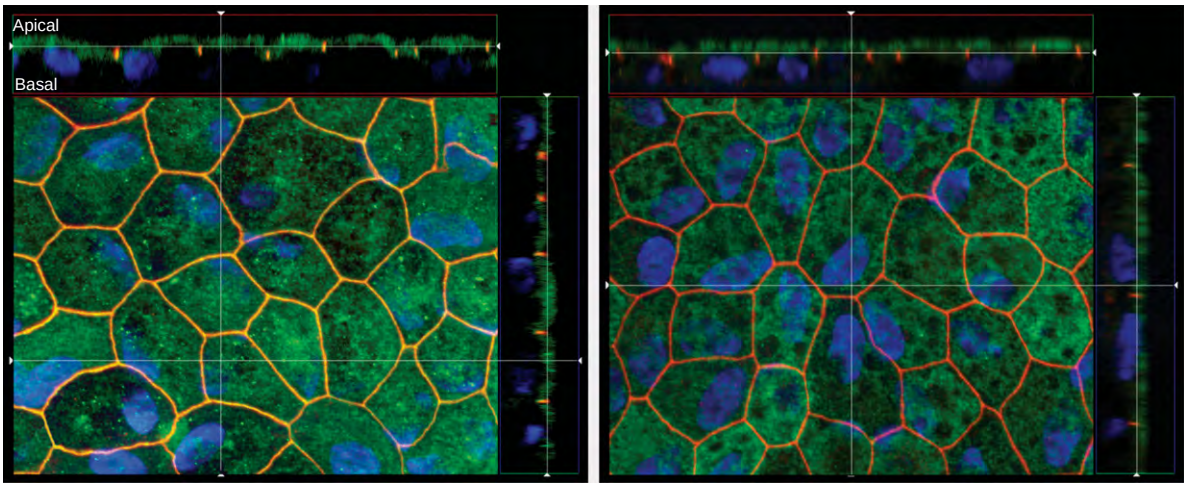

Figure 7 Immunofluorescence localization of PDGF receptors on hfRPE. The main part of each panel is an *en face* view of a cell culture monolayer shown as a maximum intensity projection through the *z*-axis. The top and right side of each panel is a cross section through the Z-plane of multiple optical slices obtained using the Apotome. In all experiments shown, the nucleus was stained with DAPI (blue), and the tight junction protein (ZO-1) was immunolabeled in red. The platelet-derived growth factor receptor PDGFR-α (green) is shown in (a), and while the beta subunit, PDGFR-β (green) is shown in (b). Both were detected on the apical membrane of hfRPE. From Li, R., et al. (2007). *Investigative Ophthalmology and Visual Science* 48(12): 5722–5732. © Association for Research in Vision and Ophthalmology.

showed that IFNγ was more effective in suppression than the entire cocktail or any subset of the cocktail, indicating that the downstream cytokine signaling pathways are interactive. Identifying the elements of this putative network and the specific nature of these interactions could provide targets for therapeutic intervention. For example, the proinflammatory cocktail may activate PDGF secretion by the RPE. In preliminary experiments, we showed that IFNγ increased the polarized secretion of PDGF-AA to the apical bath, providing a possible autocrine signal mediating RPE proliferation/migration. We have shown that the cytokine cocktail induces cell apoptosis, alters cytoskeleton distribution, and significantly decreases transepithelial resistance, which can help mediate leukocyte traffic to the SRS. The cytokine cocktail-induced in hibition of RPE proliferation/migration indicates a potential therapeutic role against proliferative responses at the retina/RPE/choroid interfaces.

Since IFNγ has a strong inhibitory effect on RPE proliferation and migration, it is natural to ask how this signaling pathway might provide the basis for inhibition. Native human adult RPE and hfRPE cells constitutively express two transcription factors, interferon regulatory factors 1 and 2 (IRF-1 and IRF-2), which are well-characterized members of the IFN regulatory family and key factors in the regulation of cell growth through their effects on cell cycle. In hfRPE, we showed that stimulation by IFNγ significantly increased IRF-1 protein levels with no effect on IRF-2. If these two transcription factors are mutually antagonistic, as shown in other systems, this may explain the strong inhibitory effect of IFNγ on RPE proliferation and migration, which we hypothesize is caused by an increase in the ratio of IRF-1/IRF-2.

IFNγ Regulation of RPE Fluid Transport

Immunoblots, immunofluorescence, intracellular recordings, pharmacology, and fluid transport data indicate a basolateral location of cystic fibrosis transmembrane conductance regulator (CFTR), a chloride channel, in native adult and fetal human RPE. As a first step in unraveling the network of cytokine interactions, we focused on INFγ since it is a main determinant of several key effects produced by the inflammatory cocktail. IFNγ has been implicated in the pathogenesis of a number of inflammatory diseases of infectious or presumed autoimmune origin and it has been detected in vitreous aspirates of patients with uveitis, PVR, and other inflammatory ocular diseases. In human RPE, IFNγ activates several intracellular signaling pathways, including the canonical janus-activated kinase and signal transducers and activators of transcription protein (JAK/STAT) pathway and P38 mitogen-activated protein kinase (MAPK), leading to the elevation of cyclic adenosine monophosphate (cAMP) and the subsequent activation of protein kinase A-dependent chloride channels – CFTRs. This results in a significant increase in net fluid absorption across the epithelium (**Figure 8**). These data and the data summarized below provide a possible basis for the etiology of chronic inflammatory diseases, such as posterior uveitis and AMD. In the diseased eye, the IFNγ-induced dehydration of the SRS

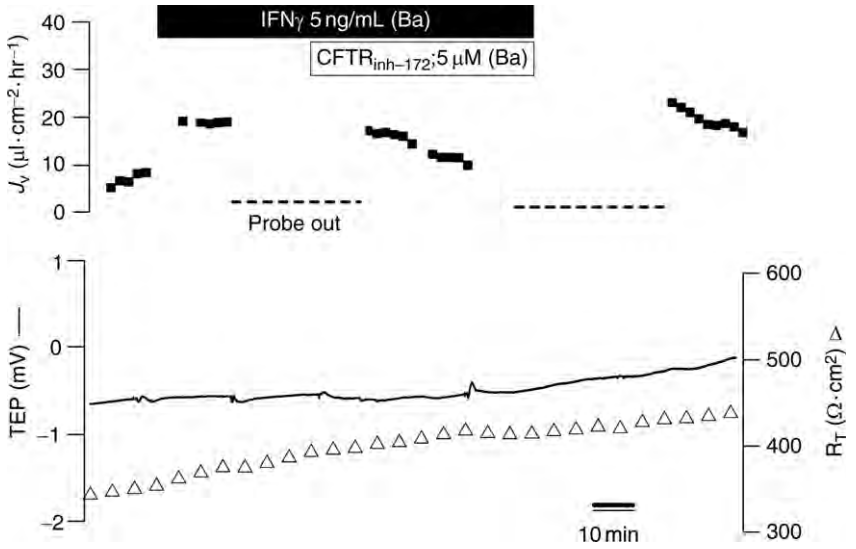

Figure 8 IFNγ-stimulated fluid transport (J_V) increase is inhibited by 5 μM $CFTR_{inh}$-172, an inhibitor of the cystic fibrosis transmembrane conductance regulator (CFTR), added to basal bath. J_V is plotted as a function of time in the top trace and net fluid absorption (apical to basal bath) is indicated by positive values; TEP (−) and R_T (△) are plotted as function of time in the two lower traces.

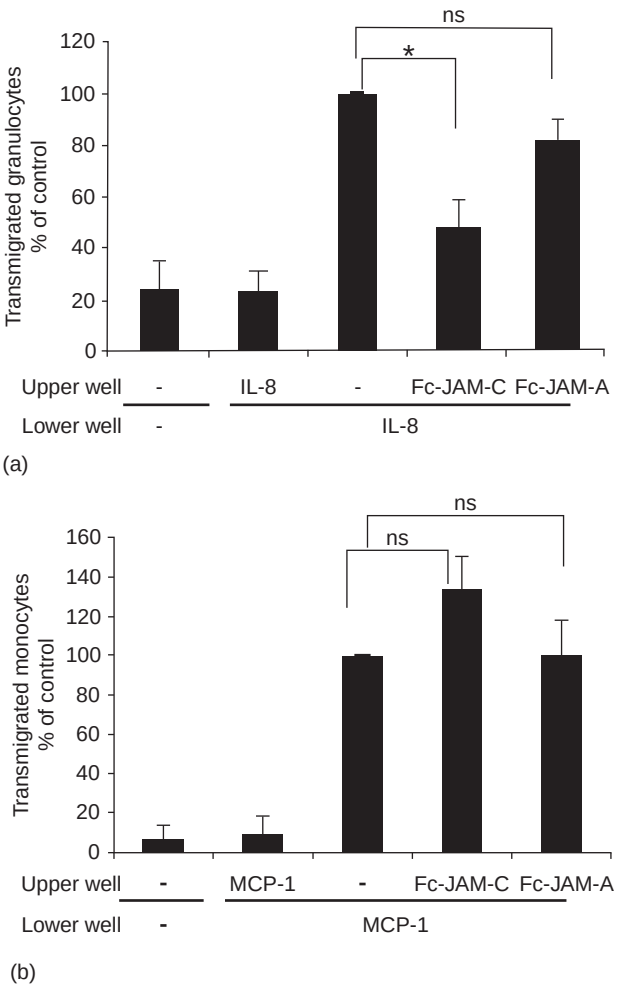

Figure 9 IL-8 and MCP-1 regulated transmigration of leukocytes. (a) Basolateral to apical transepithelial migration of granulocytes. The number of transmigrating granulocytes is shown as % of control. Exogenous addition of modified junctional adhesion molecule Fc-JAM-C competes with JAM-C/JAM-C interactions between adjacent cells, significantly reducing IL-8 induced transmigration of granulocytes. (b) In contrast, Fc-JAM-C had no significant effect on the basolateral to apical transepithelial migration of monocytes toward MCP-1. Addition of another RPE JAM isoform Fc-JAM-A, did not alter transmigration of granulocytes or monocytes. From Economopoulou, M., et al. (2009). *Investigative Ophthalmology and Visual Science* 50(3): 1454–1463. © Association for Research in Vision and Ophthalmology.

could increase the concentration of the already-accumulating chemokines and thereby help draw monocytes and neutrophils to the RPE basement membrane or across the RPE to the SRS. This helps control the continuing accumulation of debris from incompletely digested photoreceptors, oxidative stress, and accumulation of drusen that normally occur in and around the RPE over the first five decades of life. Based on a variety of risk factors that activate the immune system (e.g., monocytes), these protective gradients may dissipate with age, aided perhaps by the loss of RPE barrier function and the steady buildup of an immunologically hostile environment.

Leukocyte Migration across the RPE: A Model of Disease Progression

The integrity of the RPE monolayer depends on the inter-epithelial junctions that include tight and adherens junctions and desmosomes. The main constituents of tight junctions are three families of transmembrane proteins: occludins, claudins, and junctional adhesion molecules

(JAMs). The third member of the JAM family, JAM-C, has been identified in various cell types and implicated in inflammatory processes and shown to participate in the transmigration of leukocytes through endothelial and gut epithelial cells. Economopoulou and colleagues found that JAM-C is localized at the tight junctions of intact monolayers of adult and fetal human RPE, it is found at the initial cell–cell contacts of newly forming junctions, and that it helps initiate hfRPE junction formation and polarization. JAM-C also promotes the transepithelial migration of granulocytes through intact monolayers of cultured hfRPE driven by physiological gradients of interleukin 8 (IL-8). Thus, in the intact eye, JAM-C may be an important determinant of RPE initial junction formation, cell polarization, and immune-system-mediated pathophysiology at the retina–RPE interface (**Figure 9**). Recent animal model studies have implicated monocyte chemoattractant protein 1 (MCP-1) and fractalkine receptor in retinal microglia as critical regulators of drusen accumulation, local inflammation, and the development of AMD. As demonstrated by Shi and colleagues, the RPE secretes significant amounts of MCP-1 and IL-8 to the apical side in a polarized manner (**Table 1**). Both chemokines could form gradients across the RPE that coordinate monocyte and neutrophil movement to the RPE basement membrane. This could provide local surveillance/protection against the accumulation of immunologically active debris (drusen). The transformation over time of monocytes into macrophages would slowly degrade the RPE's ability to maintain protective chemokine gradients for the removal of immunologically active debris and eventually lead to degeneration/disease.

Retinal Pigmented Epithelium Barrier

L J Rizzolo, Yale University School of Medicine, New Haven, CT, USA

Glossary

Adherens junctions – A component of the apical junctional complex that provides mechanical strength to cell–cell adhesions and, together with the tight junction, regulates cell size, shape, and proliferation.
Apical junctional complex – An assembly of tight, adherens, and gap junctions that join neighboring cells of an epithelial monolayer together. The junctions form a belt that completely encircles each cell at the apical end of the lateral membranes.
Apical membrane – The region of the plasma membrane that interdigitates with the photoreceptors of the neural retina. It is separated from the basolateral membranes by the apical junctional complex.
Basolateral membrane – The region of the plasma membrane that rests on Bruch's membrane and faces the choroid. It is separated from the apical membrane by the apical junctional complex.
Claudins – A family of proteins that forms tight junctional strands and determines the selectivity and permeability of the tight junctions.
Paracellular space – The space between the neighboring cells of an epithelial monolayer.
Subretinal space – The thin space that lies between the apical membrane of the retinal pigment epithelium and the photoreceptors. It becomes a wide space with retinal edema and detachment.
Tight junctions – A component of the apical junctional complex that regulates transepithelial diffusion through the paracellular space, retards diffusion of lipids and membrane proteins between the apical and basolateral membranes, and, together with the adherens junction, regulates cell size, shape, and proliferation.
Transepithelial electrical resistance (TER) – An amalgam of the electrical resistances of the apical membrane, basolateral membrane, and paracellular space. It is commonly used as a reflection of the electrical resistance of tight junctions. When the sum of the membrane resistances greatly exceeds the paracellular (shunt) resistance, the TER approximates the electrical resistance of the tight junctions.

Introduction

Blood–tissue barriers were first revealed by the inability of injected proteins, or protein-bound dyes, to move from the blood into certain tissues. Only the brain, testes, and placenta shared this property. The cells that formed the barrier exhibited reduced transcytosis and were bound together by seemingly impermeable tight junctions. Transcytosis is one mechanism to move serum solutes across the cells of the barrier, whereas tight junctions partially occlude the paracellular spaces to reduce transepithelial diffusion between the cells. This initial conception has since been expanded to include all mechanisms of transcellular transport and the metabolic and catabolic pathways that alter solutes during transport.

The blood–retinal barrier has two divisions. The inner layers of the retina are supplied by a vascular bed, whose endothelia form the inner blood–retinal barrier. This endothelial barrier typifies most of the blood–brain barrier. This article focuses on the outer blood–retinal barrier, which is more similar to the choroid plexus and testes blood–tissue barriers. These barriers are a collaboration of a fenestrated capillary bed with an epithelium. In the outer retina, the collaboration is between the choriocapillaris and the retina pigment epithelium (RPE). As fenestrae make the capillaries porous, the RPE forms the barrier to serum components (**Figure 1**). Certainly, the Bruch's membrane that separates the capillaries and RPE serves as a filter; however, this aspect of the outer blood–retinal barrier is discussed elsewhere in the encyclopedia. A good example of a metabolic pathway that participates in barrier function is the visual cycle. Vitamin A, transported by the serum, is endocytosed and transformed into *cis*-retinal as it is transported across the cell and exported to the photoreceptors. Ultimately, the paracellular and transcellular transport of ions and small organic solutes should be considered as a unit. Because explorations of how these pathways interact remain in their infancy, the two topics are discussed separately in this encyclopedia. This article focuses on the paracellular pathway, but includes the transcellular pathway whenever a connection between the two can be made. We discuss the assembly of RPE tight junctions, their retina-specific properties, and how the RPE and its tight junctions are regulated by the surrounding tissues.

Structure and Function

Tissue Level

The distinctive structure of the outer blood–retinal barrier leads to unique functions. Unlike other epithelia and endothelia, the RPE separates two solid tissues – the choroid and the neural retina. Early in embryogenesis, the apical surface of the RPE borders a fluid-filled lumen, the lumen of the optic vesicle. As development proceeds, this lumen is reduced to a potential space known as the subretinal space (Figure 2). In this space, the microvilli of the RPE's apical pole interdigitate with the outer segments of the photoreceptor cells. The intimate contact of the RPE and photoreceptors allows retinoids of the visual cycle to readily shuttle back and forth across the subretinal space, and allows disk membranes shed by the photoreceptors to be phagocytosed by the RPE. The ionic composition of the subretinal space is carefully regulated to support the functions of the photoreceptors and the RPE. To this end, the RPE absorbs water. Water continuously enters the retina from the inner vascular bed and vitreous and is transported by the RPE into the choroid for removal by the choroidal circulation. Failure of this process results in retinal edema and even retinal detachment. Contrast this with another region of the blood–brain barrier, the epithelium of the choroid plexus. The epithelium of the choroid plexus is also derived from the neuroepithelium, but in this case, the lumen of the neural tube expands to form the ventricular system. Rather than absorb fluid, the choroid plexus secretes copious volumes of cerebral spinal fluid. To understand the functional differences between the RPE and the epithelium of the choroid plexus, we need to look more closely at the structure of the barrier.

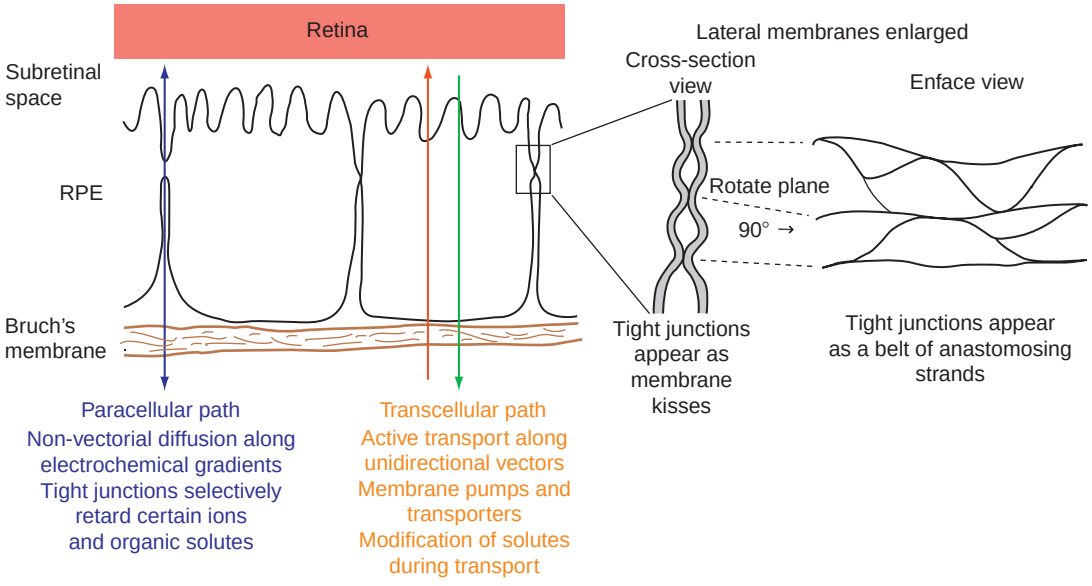

Figure 1 Mechanisms that regulate transport across the outer blood–retinal barrier.

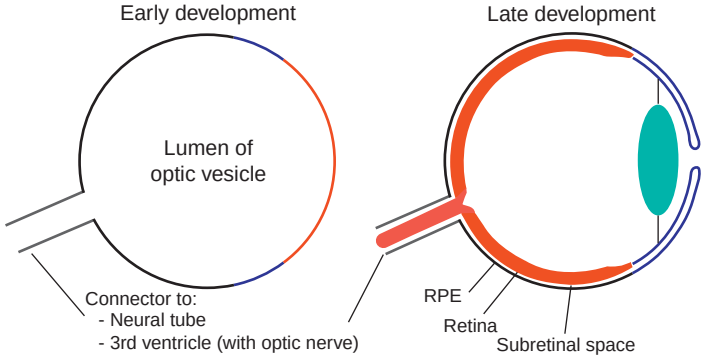

Figure 2 The lumen of the embryonic optic vesicle becomes the subretinal space.

Cellular Level

The RPE is a monolayer of cells that are joined by a complex of junctions known as the apical junctional complex. The apical junctional complex encircles each cell to bind the monolayer together much like the plastic rings that hold together a six-pack of canned beverages. The complex consists of three junctions (tight, adherens, and gap) whose functions are intertwined. Adherens junctions bind neighboring cells together. Tight junctions form a partially occluding seal that semiselectively retards diffusion through the paracellular spaces of the monolayer (**Figure 1**). Both junctions regulate proliferation, cell size, and the polarized distribution of plasma membrane proteins. The junctions of the complex work in concert, but we focus on how tight junctions contribute to barrier function.

Tight junctions form a barrier between the apical and basolateral poles of the cell. They work in conjunction with intracellular trafficking pathways to create and maintain an apicobasal polarity that is essential for the blood–retinal barrier to function. Unlike most epithelia, the Na,K-ATPase (ATP, adenosine triphosphate) is enriched in the apical membrane rather than localized to the basolateral membrane. Although this initial discovery suggested that the RPE is an upside-down epithelium, it is now known that only a few RPE proteins have an atypical distribution. What is crucial for RPE function is the distribution of membrane channels and transporters. The RPE and the epithelium of the choroid plexus both have an apical Na,K-ATPase that provides the energy for vectorial transport. It is the distribution of the various ion channels and transporters that determines whether the RPE absorbs water or the epithelium of the choroid plexus secretes it. Briefly, the polarized distribution of transporters in the RPE results in the active transport of chloride from the apical to basal side of the cell. As a result, the apical side of the monolayer has a positive charge relative to the basal side. Sodium and potassium are transported down this electrical gradient to balance the chloride transport. The osmotic gradient that results pulls water in the apical to basal direction. The polarized distribution of the various channels and transporters differs in the epithelium of the choroid plexus to support the opposite, basal to apical, transport of water. There are general housekeeping mechanisms that recognize the targeting signals encoded in a protein's structure to deliver it to the correct membrane. In some cases, different tissue-specific isoforms encode different targeting signals; in others, tissue-specific variations in the targeting machinery give each epithelium its unique character.

The vectorial transport mechanism outlined above would have little effect, if transepithelial ion gradients were dissipated by the paracellular pathway. Early microscopists believed that a zonular band of junctions occluded the paracellular space by completely encircling each cell. Their name for this junction, zonula occuldens or tight junction, is misleading because the junction is selectively leaky. The degree of leakiness, and selectivity for certain ions, not only varies among epithelia, but is essential for epithelial function as well. The permeability and semiselectivity of the junctions are matched to transcellular transport mechanism. For example, RPE tight junctions need to be leakier to sodium than to chloride, because RPE pumps chloride across the cell and needs a leak for cations to passively follow the chloride flux. The inadequate capacity for sodium and potassium to cross the cell is ameliorated by the sodium-selective leak through the tight junction.

A compelling example of how transcellular transport is matched to tight junction selectivity is provided by the kidney. The diuretic hormone, aldosterone, changes the flux of water by acting simultaneously on a membrane sodium channel and a tight junction protein that regulates sodium selectivity. In the retina, the volume and composition of the subretinal space vary with the day/night cycle. It remains to be investigated how the properties of tight junctions and membrane transporters are coordinated to manage the subretinal space during this cycle.

Molecular Level

Proteins of the apical junctional complex fall into transmembrane, adaptor, and signaling/regulatory categories. Adaptors link the transmembrane proteins to signaling proteins and a cortical band of actin filaments. Besides known members of the tight junction (**Figure 3**), proteomics suggest that over 912 proteins are associated with the tight junction. The adaptor proteins express multiple copies of PDZ domains. This protein-binding domain of approximately 100 amino acids takes its name from the three proteins that defined this class of protein-binding domain: postsynaptic density protein 95 (PSD-95), disks large, and zonula occludins 1 (ZO-1). PDZs are the largest family of protein-binding domains and form the basis of many protein complexes. Each adaptor protein expresses

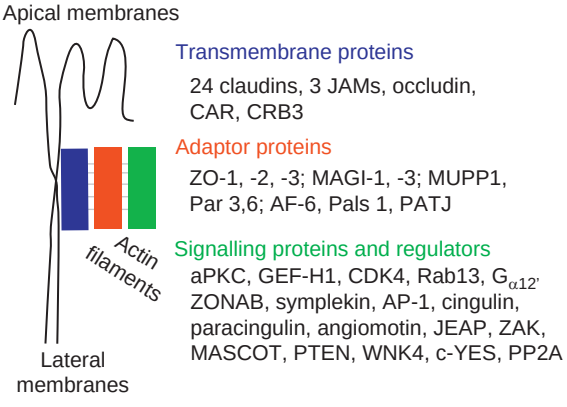

Figure 3 Composition of the tight junctions.

multiple homologs of PDZ domains that have distinct, but sometimes overlapping binding specificities. Together with other protein-binding motifs, for example, SRC homology 3 domain, guanylate kinase, bi-tryptophan domain that binds proline-rich peptides, Dilute domain, and Phox and Bem1P domain, the known adaptor proteins have the capacity to bind the large number of regulatory proteins that proteomics suggests. A junction of such complexity would be inconsistent with the original view of the tight junction as a static barrier.

The tight junction is a highly dynamic structure with the potential to rapidly respond to environmental stimuli. Photobleaching studies demonstrate that ZO-1 and occludin, a regulator of permeability, rapidly associate and dissociate from the junction. Occludin has a very short half-life and its degradation is regulated by endocytic and ubiquitin pathways. Therefore, the cell exerts a fine control over the properties of the tight junction that can rapidly respond to changes in the environment. This flexibility extends to the claudin family of transmembrane proteins. Membrane proteins typically have a half-life on the order of days, but the claudins that have been studied have a half-life of 4–12 h. Claudins form the anastomosing network of strands that are observed by freeze-fracture electron microscopy (**Figure 4**) and schematized in **Figure 1**. There are 24 or more claudins. Each epithelium expresses a subset of claudins. The subset of claudins, expressed and localized to the tight junction, determines the selectivity and permeability of the junction. In the kidney example given above, aldosterone decreases the expression of claudin 4 to increase the sodium leak through the tight junctions.

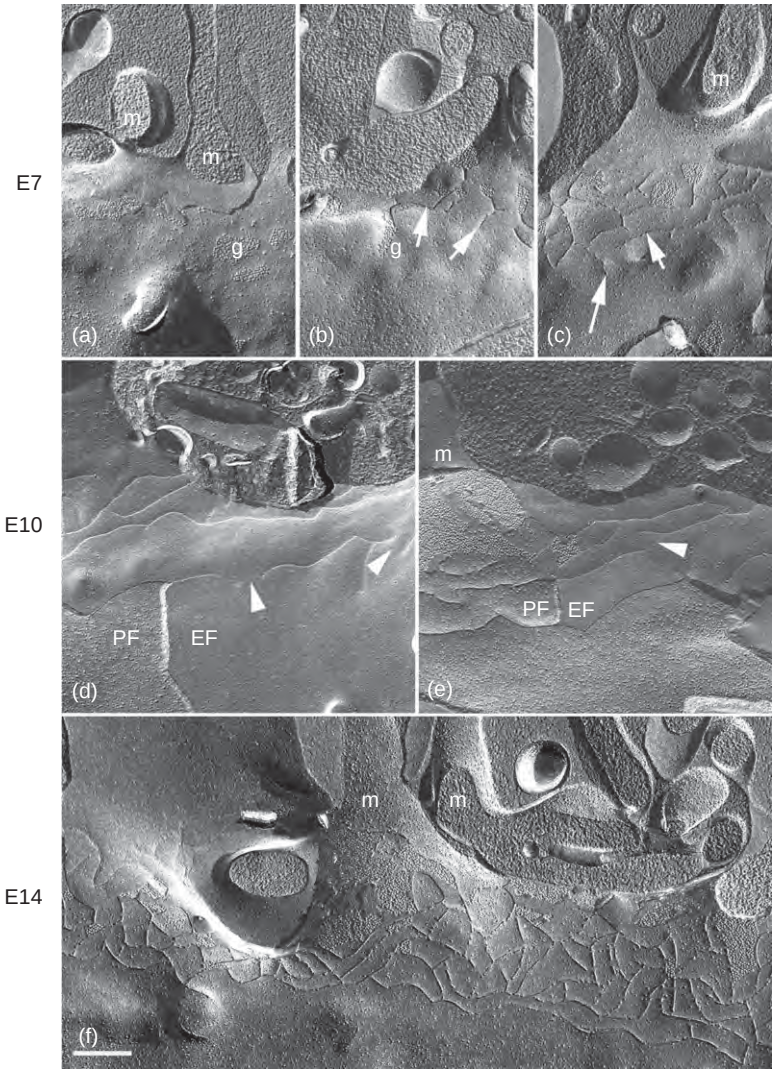

Figure 4 Strands of the tight junction gradually coalesce during development. Freeze-fracture replicas show how sparse, disconnected strands on E7 become a necklace of strands with discontinuities by E10 and a continuous, uninterrupted network by E14. Microvilli (m) at the top of each panel indicate the apical end of the lateral membrane. Arrows, tight junctional strands; Arrowheads, discontinuities. EF, E-face; PF, P-face; Bar = 0.25 μm.

Although the basic structure of the outer blood–retinal barrier is conserved among species, there are species-specific variations in the composition of the subretinal space, the properties of transmembrane transport, and the composition of the tight junctions. In human RPE, the principal claudins appear to be claudins 3, 10, and 19. Claudin 19 has been linked to kidney disease and visual impairment. By contrast, chick RPE expresses primarily claudins 1 and 20 with lesser amounts of claudins 2, 4L2, 5, and 12. Claudins 1 and 3 are fairly ubiquitous with most epithelia expressing one or the other. Claudin 2 increases sodium permeability in some contexts. However, the study of how claudins affect permeability is in its infancy particularly in regard to the effects of cellular context on function.

Regulation of RPE Tight Junctions

Clues from Embryonic Maturation

What is a mature, differentiated RPE monolayer? Which markers and how many should we use to render this judgment? Might enhancing the expression of some markers in a culture experiment lessen the expression of others? If cellular pathways form an integrated web, would over- or underexpression of a protein have deleterious effects? A default path for human embryonic stem cells appears to be an RPE-like cell, but those cells lack some RPE proteins and express non-RPE proteins. The RPE is the first retinal cell to form during development, but despite its undeniable RPE character, the early RPE cell is only partially differentiated. It will undergo many transformations, as the neural retina and choroid differentiate on either side of it. The RPE is very plastic. Depending upon pathology or culture conditions, one can observe many partially differentiated states, or even transform RPE to other phenotypes. This may be the reason why RPE transplants fail when retinal degeneration is advanced. Dedifferentiation would be a normal response of healthy RPE to this abnormal environment. In support of this hypothesis, RPE transplants were most successful when the RPE and neural retina were co-transplanted. In some ways, culture is like a disease state where a degenerate neural retina and choroid no longer send RPE the signals that maintain key functions. In the chick culture model described, we found that retinal secretions promote RPE differentiation over the course of days rather than the months required without the retina. More work will be needed to determine whether these findings apply to mammalian eyes.

A study of chick embryonic development illustrates the maturation process. We can describe early, intermediate, and late phases of development. The early phase extends from the time that the RPE forms on embryonic day 3 (E3) until the inner segments of photoreceptors protrude the outer limiting membrane on E9. The intermediate phase extends from E9 to E15, when photoreceptors begin to elaborate outer segments. The late phase extends from E15 until hatching on E21. During the intermediate phase, the layers of Bruch's membrane gradually form. Fenestrations in the walls of the choroidal capillaries begin to form in the intermediate phase, but are not fully elaborated until the middle of the late phase. In parallel with the formation of fenestrations in the capillaries, infoldings of the basolateral membrane begin to form in the intermediate phase, but are not completely elaborated until the middle of the late phase. As the basolateral membranes elaborate infoldings, apical membrane microvilli elongate in coordination with the elongation of photoreceptor inner and outer segments. Some plasma membrane proteins have a distribution that is polarized between the apical and basolateral membranes as early as E7. Nevertheless, some proteins become polarized later in development in parallel with the morphological changes of the apical and basolateral membranes. Examples include basigin, monocarboxylate transporters, and the Na,K-ATPase. This coordination of the development of photoreceptors, RPE plasma membranes, Bruch's membrane, and the choriocapillaris is conserved between chickens and mammals. It is in the context of this maturing environment that the RPE completes its differentiation.

The RPE is the first retinal layer to overtly differentiate. Despite an epithelial morphology and the expression of RPE markers, early embryonic RPE is still immature. Between E7 and E18 of chick development, 40% of the transcriptome changes with substantial effects on the extracellular matrix, junctional complexes, cell surface receptors, signal transduction pathways, cytoskeleton, regulators of gene expression, and transmembrane transport proteins. Some genes turned on and others off, but most changed their level of expression relative to one another. These data suggest why RPE cultures that express the same tissue-specific markers can function so differently. Without direction from the neural retina or choroid to establish balanced gene expression, cultured RPE can adopt the range of behaviors it displays during development *in vivo*.

Assembly of Tight Junctions during Differentiation

Most studies of the assembly of the apical junctional complex were performed in mouse blastocysts or in culture using kidney or intestinal cell lines. The rapid kinetics of assembly in these models makes it difficult to parse the role of the putative assembly proteins. The consensus is that a primordial adherens junction forms first, followed by the segregation of tight junction components into a nascent tight junction. Nectin, E-cadherin, and junctional

adhesion molecule-A (JAM-A) trigger the formation of the primordial adherens junction. These transmembrane proteins form homodimers with their counterparts on the neighboring cell. Their cytoplasmic domains crystallize a complex of proteins by binding an adaptor protein. For example, JAM-A binds the adaptors, AF-6 (Afadin), PAR3 (Partitioning defective-3 homologue), and ZO-1. Their multiple protein-binding domains enable these adaptors to assemble a complex. For example, PAR-3 binds PAR-6 (Partitioning defective-6 homologue) and the atypical protein kinase C, which contributes to cell polarity. JAM-A also localizes ZO-1 to the apical side of the complex to initiate the formation of a tight junction. The tight junction transmembrane proteins, occludin and claudin, bind this nascent complex. Anti-JAM-A antibodies block the formation of tight junctions, as evidenced by the mislocalization of occludin and a low transepithelial electrical resistance (TER). Nevertheless, the adherens junction did form, as evidenced by the localization of E-cadherin and ZO-1. Taken together, these data suggest that JAM-A may play a role in assembling adherens junctions, but plays a more critical role in assembling tight junctions.

As the apical junctional complex assembles slowly during normal RPE development, the process may be studied in greater detail. In chick, primordial adherens junctions are already present in the neuroepithelium that forms the RPE on E3, days before rudimentary tight junctions begin to form on E7. Many of the proteins described above in the assembly of the apical junctional complex are present at this time, but the adherens junction will remodel throughout development both morphologically and molecularly. In each phase of development, different cadherins will appear and disappear. The early phase includes many tight-junctional proteins: ZO-1, occludin, and the assembly proteins AF-6, JAM-A, PAR3, and PAR6. Nonetheless, tight junctions are absent until claudins expression begins on E7 and short, sparse tight-junctional strands begin to appear (**Figure 4**). During the intermediate phase, tight-junctional strands grow in number and length to gradually coalesce into a complete network that encircles each cell. The tight junction first becomes functional between E10 and E12 (defined by the ability to block the transepithelial diffusion of horseradish peroxidase). During the late phase, structural modifications of the tight junctions continue. Like the adherens junctions, these morphological changes are accompanied by molecular changes. Some claudin messenger RNAs (mRNAs) appeared early, but others appeared during the intermediate or late phases. The expression of some of the early-appearing claudins decreased during the late phase. During the intermediate phase, there was a switch in the expression of ZO-1 isoforms, an event also observed during tight-junction formation in pre-implantation embryos. ZO-3 did not appear until the late phase of development. Although changes in protein expression parallel gene expression to some extent, it appears that the claudins and ZO proteins are also regulated by effects on protein stability and subcellular localization.

The molecular and morphological changes in the apical junctional complex imply the function of the outer blood–retinal barrier changes during this long maturation process. The changes in claudin expression imply changes in the selectivity and permeability of the tight junctions. It would be reasonable to expect that this would be coupled with changes in transepithelial transport. Among the changes in the transcriptome, many involve membrane transporters. Several should be mentioned, because there is also physiological and cell biological data to corroborate the changes in gene expression. Changes in the expression and polarized distribution of the monocarboxylate transporters and Na,K-ATPase have already been mentioned. Early in development, several facilitated glucose transporters are expressed, but more are expressed later in development, including a sodium-coupled glucose transporter. The appearance of the latter transporters corresponds to the time that the tight junctions become relatively impermeable to glucose. These changes are essential because the retina has a high demand for glucose. It appears that housekeeping transporters that are sufficient for the RPE's individual needs are replaced by a transcellular, active transport mechanism at the time the blood–retinal barrier forms. These conclusions are based on studies of a primary cell culture model of RPE maturation.

Culture Models to Study Regulation of the Outer Blood–Retinal Barrier

RPE can be cultured on matrix-coated filters that are suspended in a culture dish (**Figure 5**). This architecture separates the media compartment into apical and basal chambers. The cultures spontaneously polarize with the basal membrane against the filter substrate and the apical microvilli projecting into the upper chamber. The culture architecture allows the cells to feed from the basolateral membranes, as *in vivo*. By contrast, plastic-grown cells need to feed from the apical membranes. Another advantage is that it is easy to measure barrier function by placing tracers in one medium chamber and measuring their flux

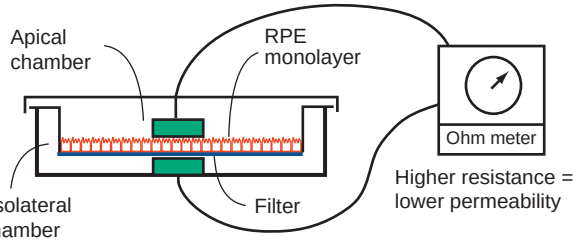

Figure 5 RPE cell culture.

across the monolayer into the opposite chamber. Further, electrodes may be placed to measure a TER. This flexibility is important because selectivity and permeability of tight junctions are regulated semi-independently. The TER is commonly used to assess tight junctions, but TER is an amalgam of transcellular and paracellular resistances to a current that is carried by all the ions of the extracellular space. The TER often approximates the resistance of the tight junctions, because the transjunctional current is often much greater than the transcellular current. Junctions of epithelia with a similar TER can differ in their ion selectivity. Therefore, it is valuable to measure ion fluxes directly. Further, the permeation of mannitol (a small organic tracer) can be modulated independently of TER, and vice versa. Accordingly, multiple assays of barrier function are required for a full assessment.

Although it is relatively easy to culture RPE from many species, including human adults, it is difficult to establish cultures that form an effective barrier. A good example of the problems encountered is the human-derived ARPE19 cell line. This spontaneously transformed cell line has many RPE-specific properties, but its tight junctions are immature. Many claudins were expressed that are undetected in native tissue, and some of the claudins expressed *in vivo* were undetected in ARPE19. By modifying culture conditions, barrier function, morphology, and melanin expression could be improved. Although claudin expression was affected somewhat, large differences between native RPE and ARPE19 remained. Like the chick studies described above, genomic analyses of native and cultured human RPE have become or are becoming available, which will allow a molecular definition that can compare native to cultured RPE.

Several culture systems have been devised that allow RPE to form a barrier that resembles native RPE. The most highly differentiated are primary or secondary cultures that were isolated from the intermediate phase of RPE development. This stage corresponds to E14 in the chick, postnatal day 5 in rat, and 18–22 weeks gestation in the human. Notably, human fetal RPE appears to have a broader window, as cultures isolated from 13-week fetuses also have excellent properties. Each culture relies on highly specialized medium that includes low amounts, or no, serum. In some cases, the medium appears to remove the need for choroidal or retinal stimulation, but these cultures require 1–2 months in culture to fully mature. Rat and chick cultures that were maintained in serum-free medium were very sensitive to the addition of serum to the apical medium chamber, as might be seen in pathology. For each species, apical serum decreased barrier function, as measured by the TER.

In contrast to the other models, the chick model was designed to study tissue interactions. It used primary cultures that formed incomplete tight junctions with a low TER in a serum-free medium. However, the cultures were very sensitive to retinal secretions. A medium conditioned by the organ culture of neural retinas induced the formation of complete tight junctions with a TER that was similar to native RPE. Reconstitution experiments showed that contact with the neural retina was required for the proper polarized distribution of the Na,K-ATPase and certain integrins. A central finding was that retinal interactions promoted differentiation on a timescale of days rather than months. Besides cellular junctions, the retinal conditioned medium affected the expression of genes related to the visual cycle, phagocytosis, cytoskeleton, and transmembrane transport. Besides gene expression, retinal conditioned medium affects the half-life and subcellular localization of claudins and ZO proteins. By regulating membrane transporters and tight junctions, the retina and RPE appear to collaborate in regulating the subretinal space. This is an area of research that needs to be explored in greater detail.

RPE in the Larger Context of Ocular Biology and Disease

Many diseases are coming to be viewed as a low-grade inflammatory process, including age-related macular degeneration. Investigations of inflammatory diseases of the intestine (Crohn's) and central nervous system (multiple sclerosis) demonstrate that disease can affect the tight junctions in part through the action of inflammatory cytokines. Certainly, disease also affects the membrane transporters of epithelia and endothelia. In the renal field, there has been progress in understanding the interrelationships of tight junctions and membrane transporters and how they are coordinately regulated. The retina field lags behind, but the availability of good culture models and the advances in genomics and systems biology hold great promise for the future.

Retinal Vasculopathies: Diabetic Retinopathy

N C Steinle and J Ambati, University of Kentucky, Lexington, KY, USA

Glossary

Cotton-wool spots (CWSs) – Also known as soft exudates, these may be found in nonproliferative diabetic retinopathy (NPDR). They are composed of accumulations of neuronal debris within the retinal nerve fiber layer, and result from disruption and stasis of axoplasmic flow.
Diabetes control and complications trial (DCCT) – A study that contributed to our understanding that intensive glycemic control is associated with a reduced risk of newly diagnosed retinopathy and a reduced progression of existing retinopathy in people with diabetes.
Diabetes mellitus (DM) – A metabolic disorder characterized by sustained hyperglycemia secondary to lack or diminished efficacy of endogenous insulin.
Diabetic retinopathy (DR) – A retinal disease consequent to development of DM.
Insulin-dependent diabetes mellitus (IDDM) – A term sometimes used to refer to type I diabetes.
Intraretinal microvascular abnormalities (IRMAs) – The tortuous, hypercellular micro vessels that develop in NPDR.
New vessels elsewhere (NVE) – The neovascularization of the retina found greater than one disk diameter from the optic nerve head.
New vessels on disk (NVD) – The neovascularization on or within one disk diameter of the optic nerve head.
Non-insulin-dependent diabetes mellitus (NIDDM) – An older term for type II diabetes or adult-onset diabetes.
Nonproliferative diabetic retinopathy (NPDR) – DR characterized by intraretinal microvascular changes which precede the proliferative phase.
Optical coherence tomography (OCT) – A noninvasive imaging technique that permits analysis of retinal structure in the living eye.
Proliferative diabetic retinopathy (PDR) – DR characterized by the presence of retinal neovascularization.
The early treatment diabetic retinopathy study (ETDRS) – A large study of progression and treatment of DR.
United Kingdom Prospective Diabetes Study (UKPDS) – A study that contributed to our understanding that intensive glycemic control is associated with a reduced risk of newly diagnosed retinopathy and a reduced progression of existing retinopathy in people with diabetes.
Vascular endothelial growth factor (VEGF) – A growth factor that promotes development of endothelial cells.

Background

Diabetes mellitus (DM) is a metabolic disorder characterized by sustained hyperglycemia secondary to lack or diminished efficacy of endogenous insulin. The terminology used for classification of different types of diabetes is evolving and can be a source of confusion. Traditionally, there have been two types of DM: type I diabetes and type II diabetes (these terminologies are used throughout the remainder of this article). Immune-mediated diabetes is the latest, and perhaps most descriptive, terminology applied to type I diabetes. Autoimmune destruction of insulin-producing pancreatic islet cells is postulated as instrumental in the pathogenesis of type I diabetes. Previous terminology used for type I diabetes included insulin-dependent diabetes mellitus (IDDM), and juvenile-onset diabetes. Type II diabetes is characterized by relative deficiencies of insulin and/or peripheral insulin resistance. It was previously known as non-insulin-dependent diabetes mellitus (NIDDM) or adult-onset diabetes.

DM is a common medical problem and is a major global source of morbidity and mortality. The incidence of DM is thought to be increasing throughout the world in part due to an increasing incidence of obesity and sedentary lifestyles. In the United States, it is estimated that 7.8% of the total population has DM, and it causes a vast array of long-term systemic complications which have a significant impact on both quality and quantity of life. Patients with DM have heart disease, death rates, and stroke rates that are 2–4 times higher than adults without diabetes, and DM is the leading cause of end-stage renal disease in the United States. Further, people with diabetes are more susceptible to many other illnesses and, once acquired, often have worse prognoses (e.g., pneumonia).

From an ophthalmic standpoint, DM causes numerous complications. Chief among these complications are diabetic retinopathy (DR), unstable refractions, accelerated

cataracts, rubeosis iridis, which can lead to neovascular glaucoma, cranial nerve palsies, reduced corneal sensitivity, papillopathy, and poor wound healing. The incidence of blindness is 25 times higher in patients with diabetes than in the general population. Furthermore, DR is the most common cause of blindness in patients aged 20–74 years, accounting for 12 000–24 000 new cases of blindness in the United States each year.

Risk Factors for DR

The prevalence of DR in the diabetic population increases with the duration of diabetes and patient age. Studies have shown that after 20 years of diabetes, nearly 99% of patients with type I DM and approximately 60% of patients with type II DM have some degree of DR (**Figure 1**). DR rarely develops in children younger than 10 years of age, regardless of the duration of diabetes. The risk of DR increases after puberty. Approximately 5% of type II diabetics have DR at presentation; this observation is a reflection of the typically insidious onset of hyperglycemia in type II diabetes many years before the diagnosis is firmly established.

In addition to duration of DM, other risk factors for the development of DR include poor glycemic control, the type of diabetes (type 1 more than type 2), and the presence or absence of associated conditions such as hypertension, smoking, dyslipidemia, nephropathy, and pregnancy. The Diabetes Control and Complications Trial (DCCT) and the United Kingdom Prospective Diabetes Study (UKPDS) demonstrated that intensive glycemic control is associated with a reduced risk of newly diagnosed retinopathy and a reduced progression of existing retinopathy in people with DM (type I in DCCT (**Figure 2**) and type II in UKPDS). According to the DCCT, intensive insulin therapy reduced the incidence of new cases of DR by as much as 76% compared with conventional therapy. The UKPDS found similar results in type II diabetics; each 1% point reduction in glycosylated hemoglobin was associated with a 37% reduction in development of retinopathy. Further, the UKPDS showed that control of hypertension was also beneficial in reducing progression of DR. Pregnancy is occasionally associated with rapid progression of DR; thus, women with diabetes who become pregnant require more frequent evaluation of the retina. Pregnant women without any DR are at a 10% risk of developing nonproliferative diabetic retinopathy (NPDR) during their pregnancy. Of those with preexisting NPDR, 4% progress to proliferative retinopathy (**Figure 3**).

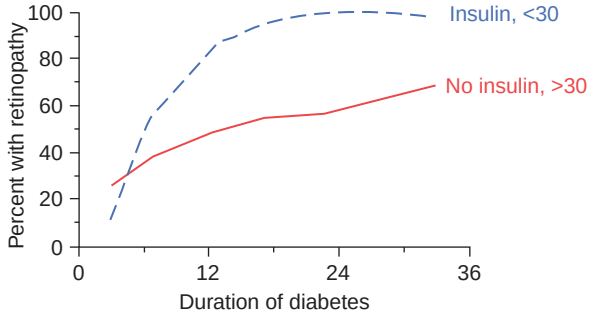

Figure 1 Incidence of diabetic retinopathy (DR) increases over time. Duration of DM is directly associated with an increased prevalence of DR in people with both type I and type II DM. The figure represents the percent of diabetic patients with retinopathy according to duration of disease in patients under the age of 30 years who were treated with insulin (primarily type I diabetics) and patients over the age of 30 years who were not treated with insulin (primarily type II diabetics). Retinopathy increased over time in both groups, affecting virtually all patients with type I diabetes by 20 years. The increased incidence in type II diabetes at 3 years is likely secondary to the difficulty in determining the exact time of onset of type II DM. Data from Klein, R., Klein, B. E., Moss, S. E., Davis, M. D. and DeMets, D. L. (1984). The Wisconsin Epidemiologic Study of Diabetic Retinopathy: III. Prevalence and risk of diabetic retinopathy when age at diagnosis is 30 or more years. *Archives of Ophthalmology* 102: 527.

Pathogenesis

The pathogenesis of DR is the current subject of intense research. It is theorized that exposure to chronic hyperglycemia results in a number of biochemical and physiologic alterations that ultimately produce retinal vascular changes and subsequent retinal injury and ischemia. The list of hematologic and biochemical abnormalities theorized to play a role in the development of DR

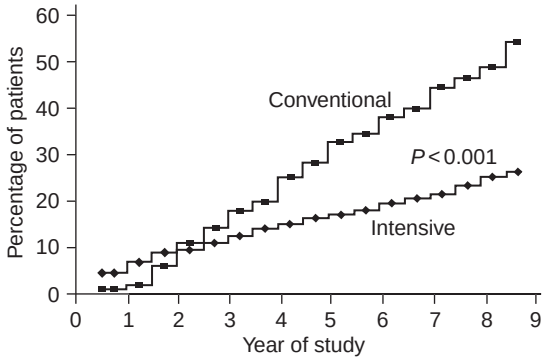

Figure 2 Intensive glycemic control slows progression of retinopathy. Cumulative incidence of progressive retinopathy in patients with type 1 diabetes and early nonproliferative retinopathy who were treated with either conventional or intensive insulin therapy for 9 years. Intensive glycemic control reduced the risk of DR progression over time by 54%, although intensive therapy was associated with transient worsening in the first year ($p < 0.001$). Data from Diabetes Control and Complications Trial Research Group (1993). The effect of intensive treatment of diabetes on the development and progression of long-term complications in insulin-dependent diabetes mellitus. *The New England Journal of Medicine* 329: 977.

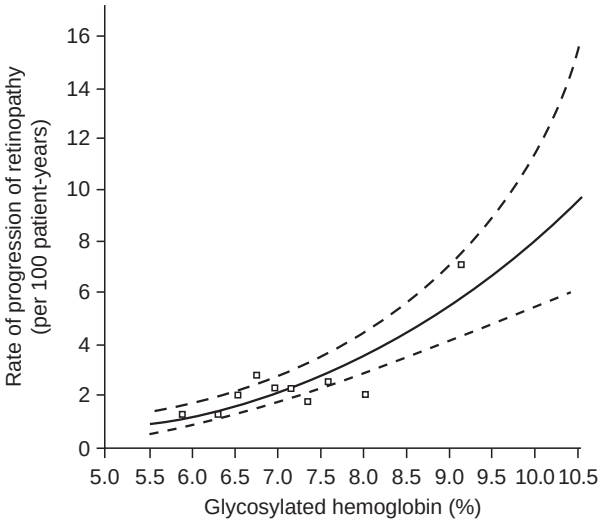

Figure 3 Progression of DR in relation to glycemic control. The figure shows the rate of progression of retinopathy in patients with type 1 diabetes according to mean glycosylated hemoglobin values (solid line). Better glycemic control was associated with slower rates of DR progression. The dashed lines represent the 95% confidence intervals. Data from Diabetes Control and Complications Trial Research Group (1993). The effect of intensive treatment of diabetes on the development and progression of long-term complications in insulin-dependent diabetes mellitus. *The New England Journal of Medicine* 329: 977.

includes the following: impairment of retinal blood vessel autoregulation, the occurrence of retinal microthrombosis and subsequent ischemia, accumulation of advanced glycosylation end products, and damage caused by reactive oxygen species. The role that growth factors (e.g., vascular endothelial growth factor (VEGF)) play in the formation of DR is discussed later. There have also been recent considerations of categorizing DR as an inflammatory disease. Trials investigating anti-inflammatory agents for prevention or treatment of DR in humans are ongoing.

Specific retinal vascular changes theorized to be instrumental in DR include the loss of pericytes, basement membrane thickening, and impaired endothelial cell function. The walls of retinal capillaries consist of endothelial cells and pericytes and are devoid of smooth muscle and elastic tissue. Endothelial cells form a single layer on a basement membrane and are linked by tight junctions that form the inner blood–retinal barrier. Pericytes are found external to the endothelial cells and have pseudopodial processes that envelop the capillary. It is believed that pericytes have contractile properties and are thought to participate in autoregulation of the microvascular capillary circulation (analogous in function to the smooth muscle found in larger arteries). The classic histologic finding of early DR in the human retina is the loss of microvascular pericytes; however, the exact mechanism by which pericytes are preferentially lost early in DR is unknown. Thickening of the retinal capillary basement membrane is another well-known lesion found in DR. In addition to basement membrane thickening, patients with DR are also found to have vacuolization and deposition of fibrillar collagen in their basement membranes. Similar to the loss of pericytes, the exact biochemical events that lead to basement membrane alterations in DR are not fully evident. Several studies implicate the sorbitol pathway in this process. The sorbitol pathway is the name given to the sequence of reactions that convert glucose to fructose involving the enzymes aldose reductase and sorbitol dehydrogenase. In this pathway, glucose is reduced first to sorbitol, which is then oxidized to fructose. However, since the latter reaction occurs slowly in many cells, sorbitol may build to high, and possibly, toxic concentrations. The toxicity of sorbitol is theorized to perhaps lead to basement membrane alterations. The final vascular change that appears to be instrumental in DR is the loss of endothelial cell function and the subsequent breakdown of the blood–retinal barrier. One possible cause of the blood–retinal barrier breakdown is opening of the tight junctions (zonulae occludentes) between adjacent microvascular endothelial cell processes. Several proteins are known to be involved with tight junction function, namely ZO-1, occluding and claudin. Studies have shown that high glucose levels appear to inhibit ZO-1 expression. Further experiments have shown reduced expression and anatomical distribution of occludin in experimental diabetes. Finally, studies have shown that intravitreal injections of the growth factor VEGF in rats increased production of nitric oxide (NO) and increased phosphorylation of ZO-1 and occludin, changes that result in increased breakdown of the blood–retinal barrier.

Advanced stages of DR are marked by the proliferation of new blood vessels. Retinal neovascularization is a devastating process that can lead to blindness in DR. Neovascularization develops through angiogenesis, in which capillaries develop from preexisting blood vessels. In DR, the regulatory mechanisms of angiogenesis can become compromised, which leads to uncontrolled endothelial cell division. On a molecular level, angiogenesis is a complicated pathway involving interplay between a number of angiogenic messengers, proteolytic enzymes, and the preexisting vessels themselves. The common final product in angiogenesis is activation of vascular endothelial cells. Several endothelial cell mitogens have been isolated and studied, including VEGF, platelet-derived growth factor (PDGF), insulin-like growth factor (IGF), basic fibroblast growth factor (bFGF), protein kinase C (PKC), antiopoietins, integrins, and ephrins. VEGF is commonly considered the most potent angiogenic factor, and some of the other molecules may act indirectly through VEGF. As the activated endothelial cells proliferate, they secrete proteolytic enzymes that degrade the parent vessel's basement

membrane as well as the extracellular matrix. Once the endothelial cells gain access to the extravascular space, they migrate and form new capillary sprouts. Mesenchymal cells are then recruited to form smooth muscle cells in arterioles and a new basement membrane is deposited to complete the process of angiogenesis. The resulting abnormal vessels lack structural integrity and are prone to leak fluid, leading to retinal edema. Further, the abnormal vessels often are associated with a fibrovascular membrane. This membrane can become adherent to both the retina and the posterior hyaloid face. As the vitreous contracts, the fibrovascular membrane can cause tractional forces on the retina, leading to retina edema, vitreous hemorrhages, retinal heterotropia, retinal tears, and tractional retinal detachments. Fortunately, the majority of DR follows a fairly predictable course; thus, screening examinations and prophylactic interventions can be implemented to reduce the devastating and potentially blinding consequences of advanced DR.

Classifications

The classification of DR is classically based on the severity of intraretinal microvascular changes and the presence or absence of retinal neovascularization. Thus, DR is divided into two main forms: nonproliferative and proliferative. NPDR is characterized by intraretinal microvascular changes which precede the proliferative phase. Proliferative diabetic retinopathy (PDR) is characterized by the presence of retinal neovascularization. These two classifications of DR (NPDR and PDR) have been useful for the analysis of treatment efficacy in the literature and serve as general indicators for treatment strategies. However, it should be noted that an individualized approach to the treatment of DR is prudent, as every patient with DR has a unique combination of findings, symptoms, and rate of progression.

Nonproliferative Diabetic Retinopathy

The retinal microvascular changes found in NPDR are, by definition, limited to the confines of the retina and do not extend beyond the innermost retinal layer – the internal limiting membrane. Characteristic findings in NPDR include microaneurysms, retinal hemorrhages, retinal edema, hard exudates, cotton-wool spots (CWSs), areas of capillary nonperfusion, intraretinal microvascular abnormalities (IRMAs), and venous beading. NPDR primarily causes visual decline through either capillary nonperfusion leading to macular ischemia, or through increased vascular permeability, resulting in macular edema.

The first visible sign of NPDR is the retinal capillary microaneurysm. Clinically, microaneurysms are identified as red dots from 15 to 60 μm in diameter (**Figure 4**).

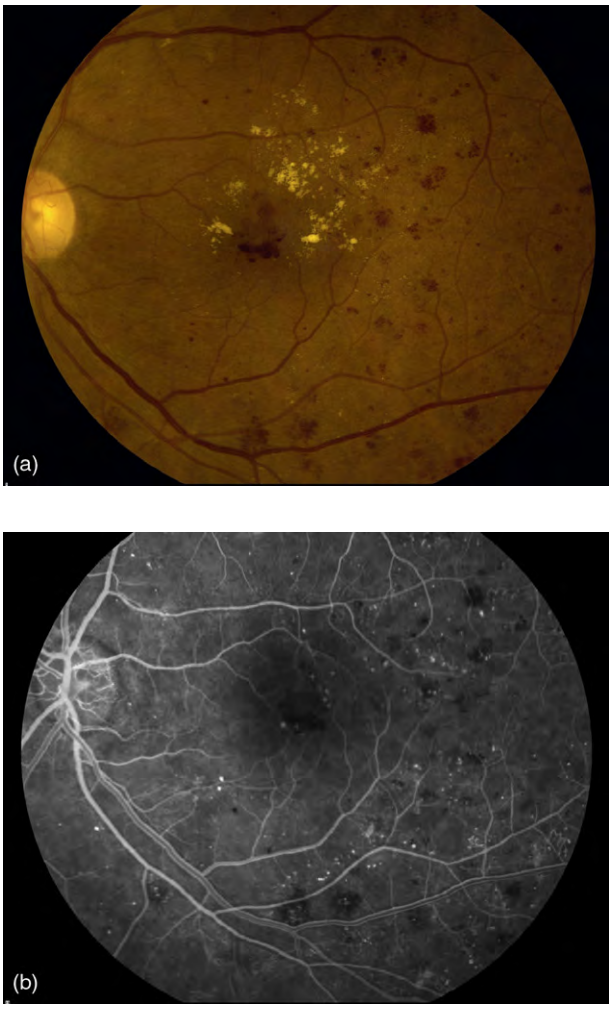

Figure 4 (a) Severe non-proliferative diabetic retinopathy. Color fundus photograph and a red-free fundus photograph of the left eye of a patient with severe NPDR. The photographs demonstrate numerous diffusely scattered microaneurysms, dot-blot hemorrhages, and hard exudates. (b) Microaneurysms and retinal hemorrhages. Arteriovenous phase fluorescein angiogram image of the same left eye (a). The microaneurysms demonstrate marked early hyperfluorescence, whereas the retinal hemorrhages block fluorescein and thus appear hypofluorescent.

On histologic examination, microaneurysms are hypercellular saccular outpouchings of the capillary wall. They are often found in relation to areas of capillary nonperfusion. Postulated mechanisms behind microaneurysm formation include the release of vasoproliferative factors (e.g., VEGF) with endothelial cell proliferation, weakness of the capillary wall secondary to the loss of pericytes, abnormalities of the adjacent retina, and increased intracapillary pressure. Microaneurysms can be differentiated from punctate retinal hemorrhages, which are also seen in DR, through fluorescein angiography. Microaneurysms will demonstrate marked early hyperfluorescence against the darker choroidal background; whereas, retinal hemorrhages

will block fluorescein and thus appear hypofluorescent (Figure 4(b)). Late fluorescein angiography frames often demonstrate leakage emanating from microaneurysms as a result of the breakdown in the blood–retinal barrier. Individual microaneurysms typically appear and disappear over time. Microaneurysms often foreshadow progression of DR as an increase in microaneurysms often is associated with progression of DR.

The retinal hemorrhages most commonly seen in NPDR include both dot-blot hemorrhages and retinal nerve fiber layer hemorrhages. Dot-blot hemorrhages are punctate, intraretinal hemorrhages that arise from the venous end of retinal capillaries and are located within the compact middle layers of the retina. These compact, vertically aligned, middle retinal layers confer upon the retinal hemorrhages their characteristic red, dot-blot appearance (Figure 4). Retinal nerve fiber layer hemorrhages arise from the more superficially located precapillary arterioles. The horizontal alignment of the retinal nerve fiber layer gives these hemorrhages their classic flame shape.

As discussed previously, another consequence of DR is excessive vascular permeability, which can result in retinal edema, usually in the macular region. Retinal edema is often accompanied by macular hard exudates, which are lipid deposits that accumulate in association with lipoprotein leakage from decompensated endothelial tight junctions. On clinical examination, hard exudates are yellowish intraretinal deposits often found at the border of edematous and nonedematous retinal tissue (Figure 4). Macular edema initially accumulates between the outer plexiform and inner nuclear layers. With chronic edema, the entire thickness of the retina becomes edematous and can assume a cystoid appearance. Retinal thickening secondary to macular edema is best detected by indirect slit-lamp biomicroscopy; in addition, optical coherence tomography (OCT), can be used to detect thickening and may be used to assess response to therapy (Figure 5).

CWSs, also known as soft exudates, may often be found in NPDR. CWSs are composed of accumulations of neuronal debris within the retinal nerve fiber layer. These result from disruption and stasis of axoplasmic flow. As CWSs heal, debris is removed from the nerve fiber layer by autolysis and phagocytosis. Clinically, CWSs are seen as yellowish, fluffy superficial lesions which obscure the underlying blood vessels. Interestingly, CWSs are only found in the postequatorial retina where the nerve fiber layer is of sufficient thickness to allow visualization of the CWSs.

As NPDR progresses, it can lead to the obliteration of retinal capillaries. These areas of capillary nonprofusion are seen on fluorescein angiography as patches of hypofluorescence. Adjacent to areas of nonperfusion, tortuous, hypercellular vessels often develop. It is difficult to determine whether these vessels are actually dilated preexisting capillaries or whether they represent new vessels forming within the retina. These vessels have been

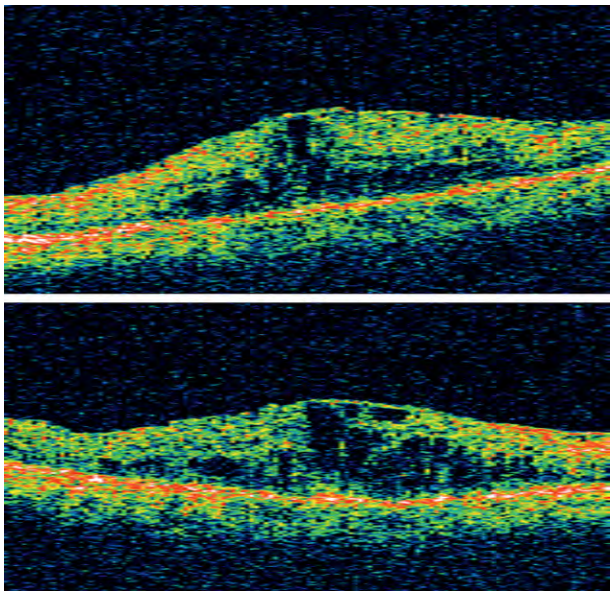

Figure 5 Macular edema secondary to diabetic retinopathy. OCT (two images) demonstrating retinal thickening and cystoid intraretinal spaces created by extensive capillary leakage and secondary macular edema in a patient with severe NPDR.

referred to as IRMAs, a term which encompasses both possibilities. The main distinguishing features of IRMAs are their intraretinal location, failure to cross major retinal blood vessels, and absence of leakage on flouroscein angiography. As areas of capillary nonperfusion become extensive, it is common to see an increase in intraretinal hemorrhages or dilated segments of retinal veins (referred to as venous beading). The degree of retinal capillary nonperfusion is directly associated with the severity of IRMAs, intraretinal hemorrhages, and venous beading.

NPDR is further categorized into four levels of severity: mild, moderate, severe, and very severe (Table 1). The clinical extent of microaneurysms, retinal hemorrhages, venous beading, and IRMA determine the level of severity of nonproliferative disease. Mild and moderate NPDR are characterized by relatively few microaneurysms and intraretinal hemorrhages and only minimal venous changes or IRMA. Severe NPDR is characterized by diffuse intraretinal hemorrhages, two quadrants of venous beading, or moderate IRMA in at least one quadrant. If any two of these features are present, the retinopathy is considered to be very severe NPDR. The Early Treatment Diabetic Retinopathy Study (ETDRS) found that severe NPDR had a 15% chance of progression to high-risk PDR within 1 year. Very severe NPDR had a 45% chance of progression to high-risk PDR within 1 year.

Macular Edema

Macular edema is the most common cause of visual impairment in patients with NPDR. Due to the

Table 1 Classification of diabetic retinopathy

Nonproliferative diabetic retinopathy (NPDR)
Mild NPDR: At least one microaneurysm Criteria not met for other levels of DR
Moderate NPDR: Hemorrhage/microaneurysm ≥standard photograph #2A or Soft exudates (cotton-wool spots), venous beading, and intraretinal microvascular abnormalities definitely present Criteria not met for severe NPDR, very severe NPDR, or PDR
Severe NPDR: Hemorrhage/microaneurysm ≥standard photograph #2A in all four quadrants or Venous beading in at least two quadrants or Intraretinal microvascular abnormalities ≥standard photograph #8A in at least one quadrant
Very servere NPDR: Any two or more of criteria for severe NPDR Criteria not met for PDR
Proliferative diabetic retinopathy (PDR)
Early PDR: New vessels Criteria not met for high-risk PDR
High-risk PDR: Neovascularization of the disk ≥1/4 to 1/3 disk area or Neovascularization of the disk and vitreous or preretinal hemorrhage or Neovascularization elsewhere ≥1/2 disk area and vitreous or preretinal hemorrhage
Advanced PDR: Posterior fundus obscured by preretinal or vitreous hemorrhage or Center of macula detached

breakdown of the blood–retinal barrier, leakage of fluid and plasma constituents leads to retinal edema (**Figure 6**). If the retinal edema threatens the center of the fovea, there is a higher risk of visual loss. In the ETDRS, the 3-year risk of moderate visual loss was 32% (moderate visual loss was defined as a doubling of the initial visual angle or a decrease of three lines or more on a logarithmic visual acuity chart). The ETDRS investigators classified macular edema by its severity. More specifically, macular edema was defined as clinically significant macular edema (CSME) if any of the following features were present: (1) thickening of the retina at or within 500 µm of the center of the macula; (2) hard exudates at or within 500 µm of the center of the macula, if associated with thickening of the adjacent retina; or (3) a zone of thickening larger than one disk area if located within one disk diameter of the center of the macula (**Table 2**). Many of the current treatment paradigms for the management of diabetic macular edema are derived from the ETDRS. The ETDRS demonstrated that eyes with CSME benefited from focal argon laser photocoagulation treatment when compared to untreated eyes in a control group. Furthermore, focal argon laser photocoagulation treatment for CSME reduced the risk of moderate visual loss, increased the chance of visual improvement, and was associated with only minor losses of visual field. Specifically, in patients with CSME involving the center of the macula, focal treatment reduced moderate visual loss by 60% after 3 years of follow-up. In patients with less than CSME, little difference was noted between the untreated and treated groups during the first 2 years of follow-up, after which there was a trend toward less frequent visual loss in the treated group.

Treatment patterns regarding CSME continue to evolve. In patients with refractory CSME, intravitreal administrations of corticosteroids have been shown to be beneficial. Intravitreal anti-VEGF agents have also been shown to improve CSME. Currently, several trials investigating corticosteroid use as well as anti-VEGF agents in the treatment of CSME are underway. Pars plana vitrectomy and detachment of the posterior hyaloid may also be useful for treating CSME. Surgical intervention may prove particularly beneficial when there is evidence of posterior hyaloidal traction and diffuse macular edema.

Proliferative Diabetic Retinopathy

As the degree of retinal ischemia increases, extensive hypofluorescent areas representing retinal nonperfusion are seen on fluorescein angiography. Eventually neovascularization may develop in an attempt to revascularize hypoxic retinal tissue. This neovascularization is the hallmark of PDR. It has been estimated that over one-quarter of the retina has to be nonperfused before PDR develops. PDR affects 5–10% of the diabetic population (**Figure 7**). Type I diabetics are at particular risk for PDR with an incidence of about 60% after 30 years. Although new vessels may arise from anywhere in the retina, neovascularization is particularly common on the optic disk itself (this location is termed new vessels on disk, or NVD). NVD is defined as neovascularization on or within one disk diameter of the optic nerve head. It can be differentiated from normal vessels by utilizing fluorescein angiography, which demonstrates profuse leakage in NVD but not in normal vasculature (**Figure 8**). Neovascularization of the retina found greater than one disk diameter from the optic nerve head is termed new vessels elsewhere, or NVE. NVE typically is found along the course of the major retinal vessels. The rate of growth of NVD or NVE is extremely variable. In some patients, neovascularization may show little change over many months, while in others definite changes in neovascularization may be seen in as little as 1–2 weeks. As neovascularization

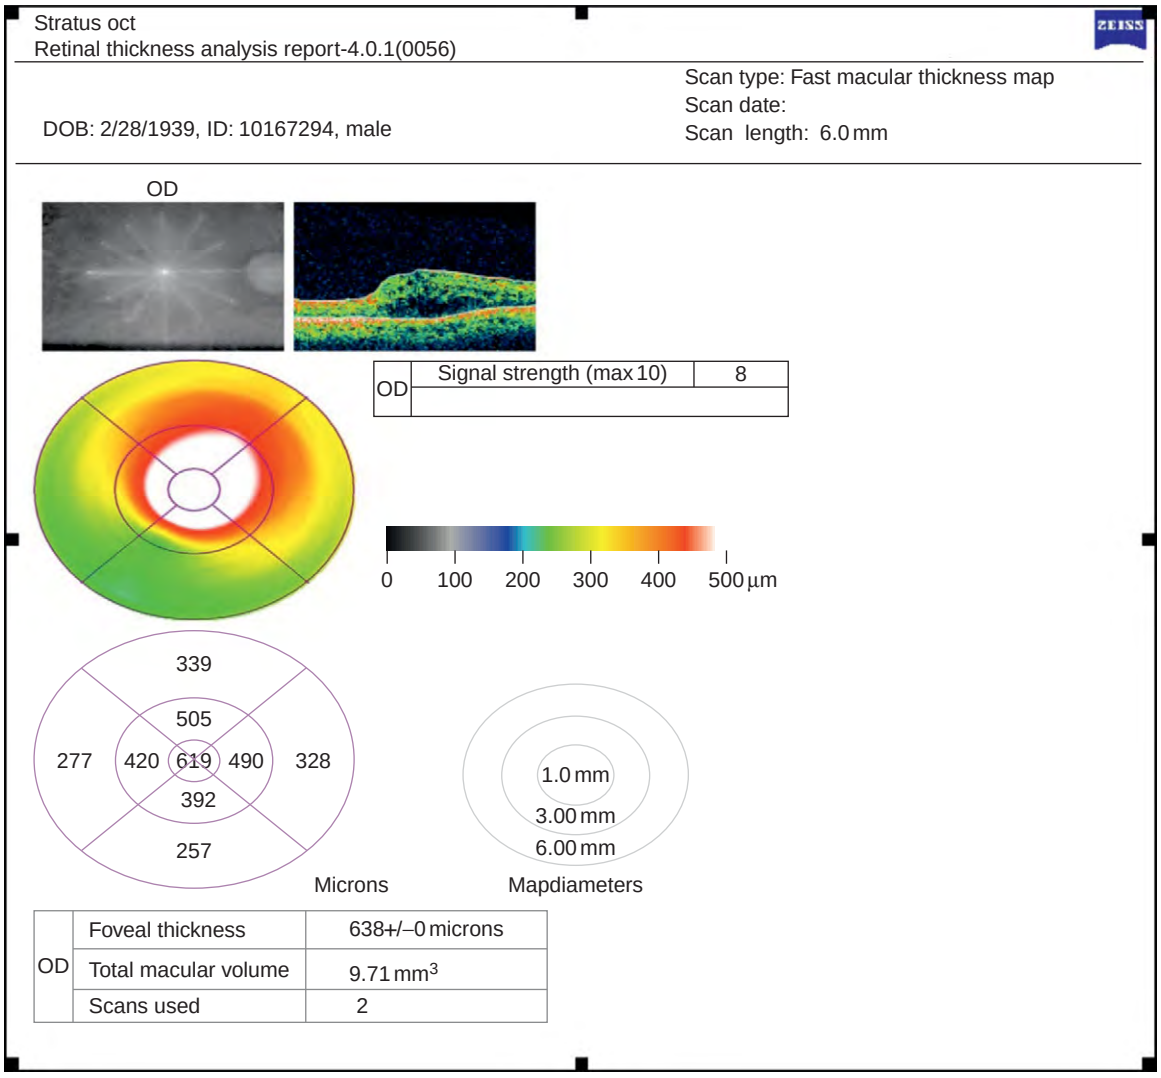

Figure 6 OCT demonstrating CSME. OCT of a diabetic patient with CSME. The patient has marked thickening of the central macula secondary to CSME. The OCT retinal cross section reveals cystic intraretinal and subretinal changes.

Table 2 Clinically significant macular edema as defined by ETDRS

Thickening of the retina ≤500µm from the center of the macula
or
Hard exudates and adjacent retinal thickening ≤500 µm from macular center
or
Zone of retinal thickening at least 1 disk area in size located <1 disk diameter from the center of the macula

progresses, a white fibrous membrane composed of fibrocytes and glial cells accompanies the growth of the new vessels. As mentioned previously, this membrane can become adherent to both the retina and the posterior hyaloid face. As the vitreous contracts, the fibrovascular membrane can cause tractional forces on the retina, leading to retina edema, vitreous hemorrhages, retinal heterotropia, retinal tears, and tractional retinal detachments. The main therapy used to prevent the devastating complications of PDR is the application of thermal laser photocoagulation in a panretinal pattern in order to induce neovascular regression. Numerous panretinal photocoagulation (PRP) application protocols exist.

The classification of PDR is determined by the location and size of the neovascularization, along with the presence or absence of vitreous hemorrhage (Table 1). The Diabetic Retinopathy Study (DRS) defined high-risk PDR as any one of the following: (1) mild NVD with vitreous or preretinal hemorrhage, (2) NVD $\geq$ 1/4 to 1/3 disk area with or without vitreous hemorrhage, (3) NVE $\geq$ 1/2 disk area with vitreous or preretinal hemorrhage. The DRS was designed to evaluate the effectiveness of photocoagulation for treating diabetic retinopathy. As complications from PDR can result in severe vision loss (SVL), the primary outcome measured in the DRS was SVL, defined as visual acuity of less than 5/200. The DRS found that PRP

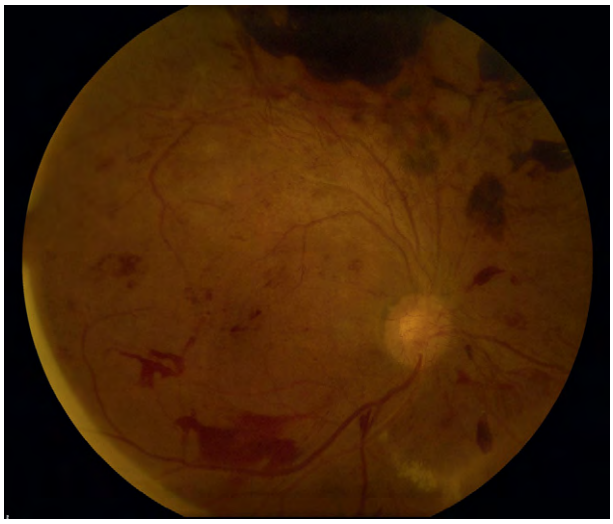

Figure 7 High-risk PDR. Color fundus photo of the right eye of a patient with high-risk PDR. Patient has significant NVD and NVE. This patient also has several areas of preretinal hemorrhages. CWSs can be seen inferior to the optic disk.

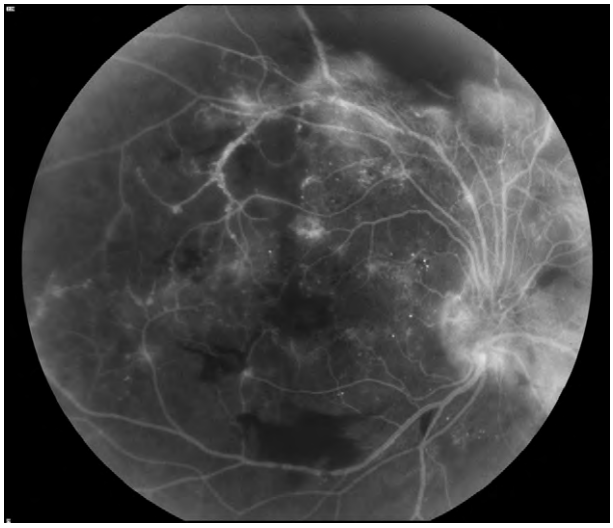

Figure 8 Leakage of NVD and NVE on fluorescein angiography. Fluorescein angiogram of the same patient seen in **Figure 7**. This patient has developed severe NVD and NVE causing significant hyperfluorescences secondary to profuse vascular leakage.

produced a 50% reduction in the rates of SVL in eyes treated with PRP compared to untreated control eyes during a follow-up of over 5 years. Treated eyes with high-risk PDR achieved the greatest benefit; thus, the DRS recommended prompt PRP treatment of eyes with high-risk PDR because this group had the highest risk of SVL.

Surgical management of PDR can be employed in patients with severe, persistent vitreous hemorrhages, progressive tractional retinal detachments, combined tractional and rhegmatogenous retinal detachments, and dense macular preretinal hemorrhages. Investigation into the use of anti-VEGF agents in the treatment of PDR is ongoing.

Screening for Diabetic Retinopathy

Proper screening for DR is critical as diabetic patients often do not experience visual disturbances until late in the disease course. Screening examinations allow for the prompt diagnosis and treatment of DR before the development of potentially blinding complications. In patients with type I diabetes, initiating screening examinations 3–5 years after diagnosis is recommended. In patients with type II diabetes, an initial examination upon diagnosis is recommended. Pregnant women with preexisting diabetes should undergo screening early in the first trimester. More frequent retinal evaluations are subsequently required during pregnancy and in the early postpartum period.

Retinopathy of Prematurity

M E Hartnett, University of North Carolina, Chapel Hill, NC, USA

Glossary

Aggressive posterior retinopathy of prematurity (APROP) – Severe ROP manifesting at young ages in zone 1 with flat neovascularization. Outcomes may be poor with conventional management.
Avascular retina – Retina that lacks blood vessel growth in the inner capillary plexus.
Intravitreous neovascularization – Endothelial budding or blood vessels that grow above the inner limiting membrane of the neurosensory retina into the vitreous.
Oxygen-induced retinopathy – Includes a number of models of recently born animals of species that complete retinal vascular development after birth. Exposure to oxygen stresses varies depending on the model but shares the features of first avascular retina followed by intravitreous neovascularization.
Peripheral severe ROP (PSROP) – It refers to zone II, stage 2–3 ROP, plus disease, in this article.
Plus disease – A feature of severe ROP, it refers to the dilation and tortuosity of retinal arterioles and veins.
Postgestational age – The age measured in weeks that is the sum of the gestational age (age of preterm infant from conception or last menstrual period) and the chronologic age (age since the birth of the infant). For example, a 24-week gestational age infant who was born 16 weeks ago would have a postgestational age of 40 weeks. Similar terms used include postmenstrual age, postconceptual age, or corrected age.
Retinal detachment – A fluid develops between the photoreceptor outer segments and the retinal pigment epithelium. A traction retinal detachment occurs by vitreous tractional forces, a rhegmatogenous retinal detachment because of a break in the retina, and a serous retinal detachment from exudation often as a result of inflammation or leaky vessels, and is sometimes seen after treatment for severe ROP.

Clinical Background

Epidemiology

The Institute of Medicine reported that preterm births were up 30% from 1981 and now account for 12.5% of all births in the US. Furthermore, developing countries are witnessing an increase in retinopathy of prematurity (ROP); therefore, ROP has now become a leading cause of childhood blindness worldwide. A report from a national registry of children in the US (Babies Count) found that ROP was the earliest cause of visual impairment and one of the three most prevalent conditions to cause visual impairment along with cortical visual impairment and optic nerve hypoplasia. ROP of any stage affects approximately 16 000 infants yearly in the US. Most early stages of ROP resolve, but about 1100 infants require treatment. Even with treatment, blindness occurs in 550 infants per year. In the US, ROP is seen more commonly in Caucasians than African-Americans, but once severe ROP occurs, the outcomes appear similar. Asians also have an increased risk of ROP. ROP has been reported in preterm infants of larger birth weight and older gestational ages in developing nations compared to those in the US, possibly because of variations in ethnic groups, regulation and monitoring of oxygen delivery, and the availability of prenatal care.

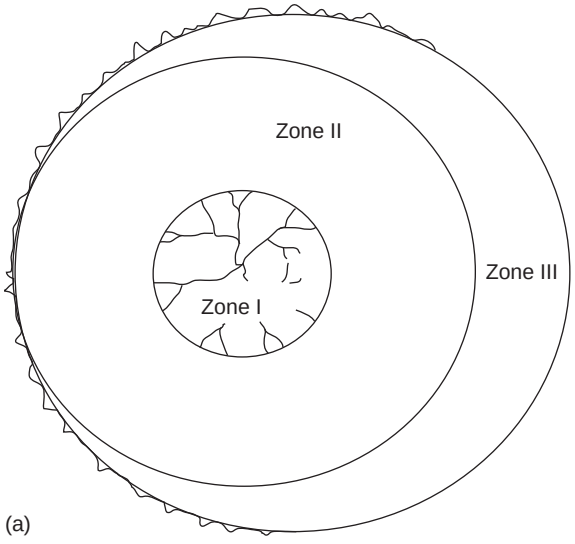
Clinical Classification of ROP

Based on the International Classification of ROP (ICROP), it is characterized by several parameters: zone, stage, extent of stage, and the presence of plus disease.

The zone of ROP is the retinal area supplied by the retinal vasculature and is an indicator of the extent of retinal vascular development (**Figure 1(a)**). Zone I is the smallest, having the largest area of avascular retina. Zone II has a greater area of retinal vascularization than zone I, and less than zone III. When vascularization completely extends to the ora serrata, it is termed complete vascularization. The risk of a poor visual outcome is greatest when severe ROP occurs in zone I (**Figure 1(b)**) and is still substantial in zone II. The risks of severe ROP and poor vision are rare when retinal vascularization extends into zone III. There are five stages of ROP. Stages 1 through 3 are the acute forms of ROP and are named for the appearance of the retina at the junction of vascular and avascular retina. A line (stage 1) or ridge (stage 2, **Figure 2(a)**) can often regress and vascularization of the previously avascular retina can occur. Stage 3 ROP has intravitreous neovascularization, a feature of severe ROP (**Figure 2(b)**). Stages 4 (**Figure 2(c)**; also see **Figures 6(a)** and **5** (**Figures 2(d)** and **2(e)**) define partial or complete retinal detachment, respectively, and are associated with vitreous and fibrovascular changes. The extent of ROP indicates the number of clock hours of a stage. Plus disease

is the presence of dilated and tortuous retinal vessels in two or more quadrants around the optic nerve and is a feature of severe ROP (Figure 3).

There is a useful distinction to note between retinal drawings and images of dissected retinal flat mounts. The retina covers the inner sphere of the eyeball and, when dissected, must be cut with relaxing incisions in order to flatten it onto a microscope slide. The result is a clover-leaf appearance (Figure 4(a)). However, clinicians and surgeons represent the retina as a round clock face and use clock hours to describe the location of pathologic features on the retina determined in clinical examinations (Figure 4(b)).



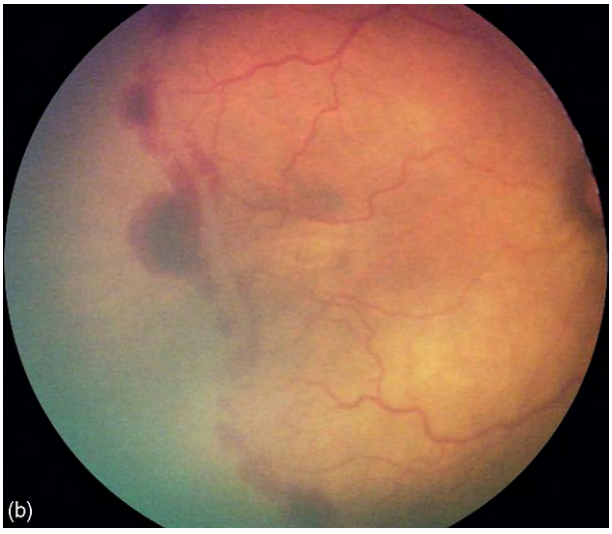


Figure 1 (a) Retinal drawing of left eye showing vascularization into zone I and the areas of the retina that would encompass zone II or zone III. (b) Image taken with wide-angle viewing system (Retcam, Clarity) of the right eye of an infant with zone I ROP (optic nerve barely visible at right of image); Courtesy Sarah Moyer, CRA, OCT-C.

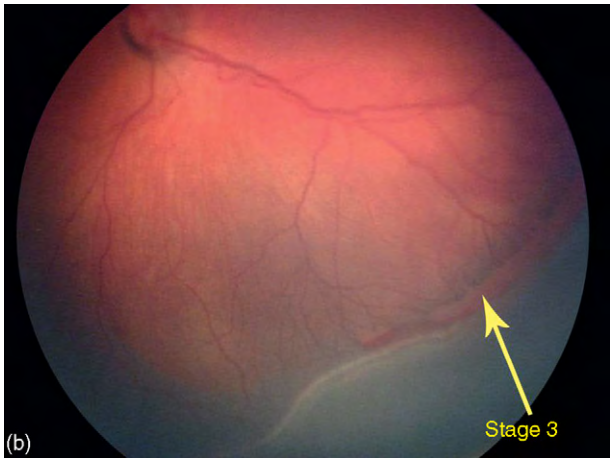
Management of ROP

Based on the American Academy of Pediatrics and American Academy of Ophthalmology, infants born at or younger than 30 weeks gestational age or less than 1500 g birth weight are screened for retinal vascular development



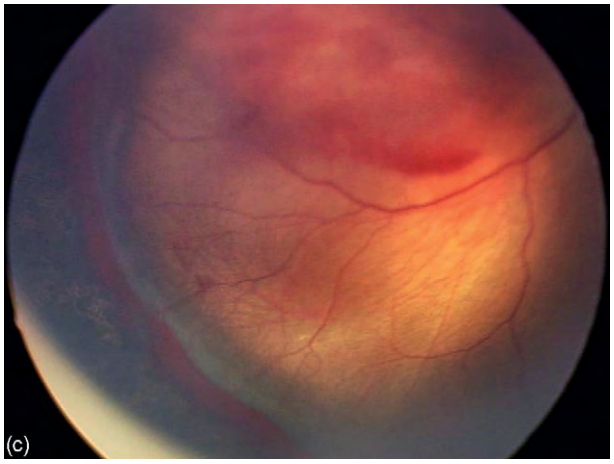


Figure 2 (Continued)

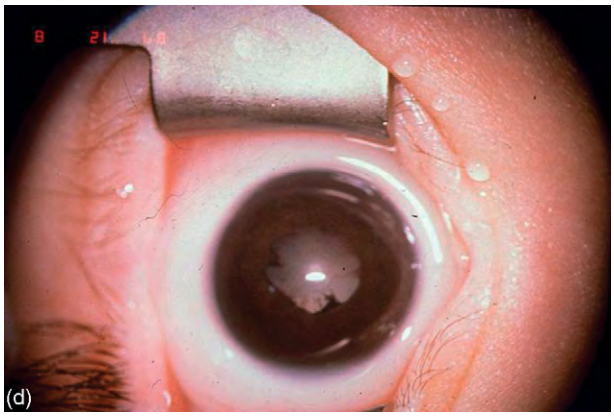

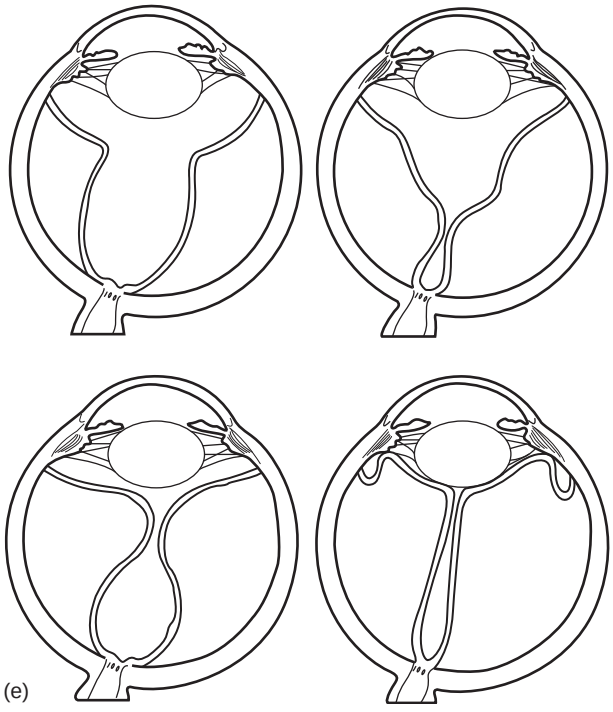

Figure 2 Images taken with wide-angle viewing system (Retcam, Clarity) of infant left eyes with (a) stage 2 ROP with early ridge and (b) stage 3 ROP with areas of intravitreous neovascularization (arrow) and hemorrhage adjacent to avascular retina (3–5 o'clock in image). Images of infant right eye with (c) early stage 4A ROP and (d) stage 5 ROP showing total retinal detachment with white pupil. (e) Diagram showing cross section of possible retinal appearances in stage 5 ROP; Figures 2(a), 2(b), and 2(c) courtesy Sarah Moyer, CRA, OCT-C. **Figure 2(e)** from Schepens' Retinal Detachment and Allied Diseases, 2nd edn (eds. Schepens, Hartnett, and Hirose) copyright 2000. Butterworth-Heinemann, Boston, MA: Figure 26-19, p. 534.

and the presence of ROP. The screening examination is performed 4–6 weeks after birth (chronologic age) or at 31 weeks postgestational age, whichever is older. (The postgestational age is the gestational age + chronologic age from birth in weeks and is similar in meaning to postmenstrual, postconceptual, or corrected ages). At any

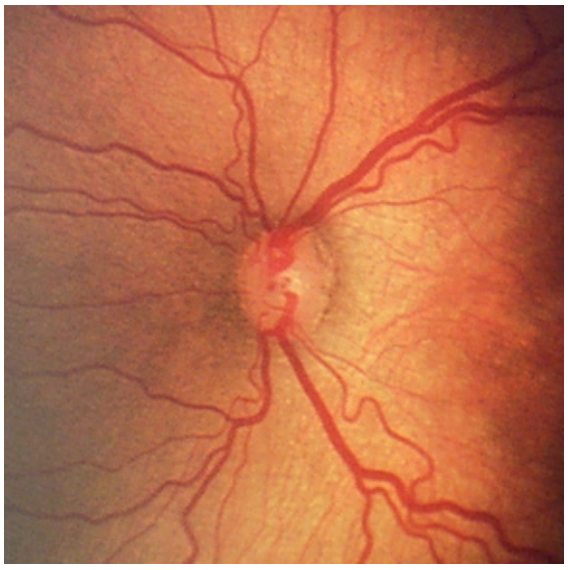

Figure 3 Plus disease (dilated and tortuous vessels in all four quadrants around optic nerve) of right eye in infant with severe ROP; Courtesy Sarah Moyer, CRA, OCT-C.

examination, the risk of a bad outcome depends on the presence of plus disease or stage 3 ROP (both features of severe ROP). Severe ROP develops at about 35–37 weeks postgestational age, regardless of the gestational age or birth weight of the infant.

At the screening examination, the extent of retinal vascular development is determined (i.e., the zone of ROP), along with the presence and stage of ROP and presence of pre-plus or plus disease. (Pre-plus is less severe than plus disease and alerts the clinician to follow the infant closely.) If ROP is not severe, follow-up examinations are performed until full vascularization of the retina occurs or until severe ROP develops, at which time the treatment for acute neovascular ROP is performed.

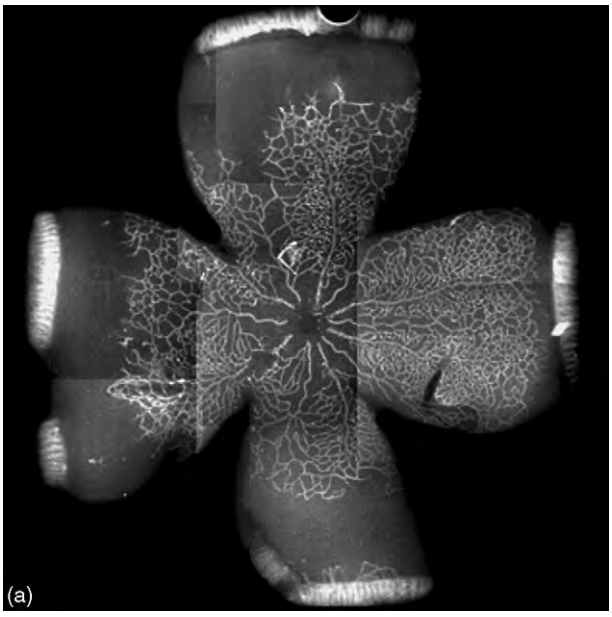
Treatment of ROP

Acute neovascular stages

Based on the Cryotherapy for Retinopathy of Prematurity (CRYO-ROP) and Early Treatment for Retinopathy of Prematurity (ETROP) studies, the treatment for ROP is strongly considered for infants with type 1 prethreshold ROP and almost always performed for infants with threshold ROP (**Table 1**). Laser is preferred to cryotherapy because it causes less inflammation, is less destructive, and is less often associated with myopia. The laser is applied to the peripheral avascular retina (**Figure 5**). Infants are then followed up weekly for regression of severe ROP or for the development of progressive stage 4 ROP.

Fibrovascular stages/retinal detachment

Stage 4 ROP refers to partial retinal detachment and develops as a result of fibrovascular changes and



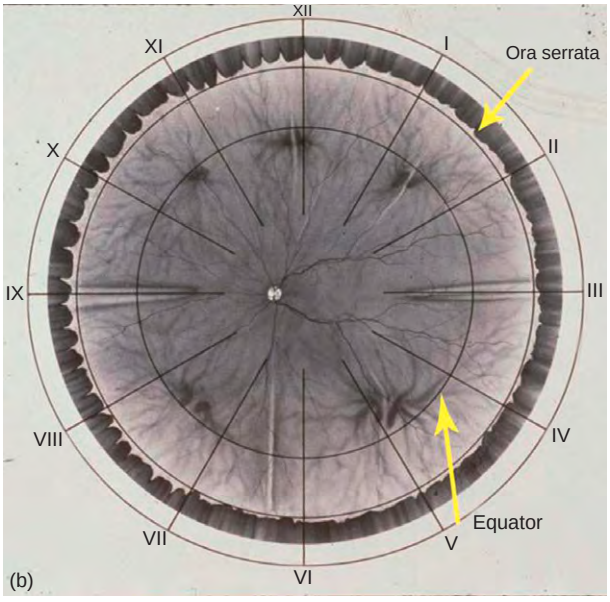


Figure 4 (a) Retinal flat mount stained with Alexa Fluor 568 conjugated isolectin B4 lectin (lectin-B4) to demonstrate vasculature from postnatal day 14 rat pup from the rat 50/10 oxygen-induced retinopathy model. (b) Artist's drawing of retina with clock hour delineations, often used clinically to localize regions of pathology on the retina. Innermost circle at vortex vein ampullae indicates equator of the globe; middle circle indicates ora serrata; and outermost circle indicates pars plana region in adult.

vitreoretinal traction that particularly occur at the junction of vascular and avascular retina and optic nerve to lead to retinal detachment (Figure 6(a)). The timing of the development of stage 4 ROP is often between 37 and 44 weeks postgestational age and represents a change

Table 1 Definitions of threshold and type 1 prethreshold retinopathy of prematurity

Threshold ROP (CRYO-ROP) (risk of unfavorable outcome approaches 50%)	Type 1 prethreshold (risk of unfavorable outcome is ≥15% – ETROP)
Zone I or II, stage 3 (5 contiguous or 8 total clock hours with plus disease*)	Zone I, any stage with plus disease*
	Zone I, stage 3 without plus disease*
	Zone II, stage 2 or 3 with plus disease*

CRYO-ROP – Cryotherapy for Retinopathy of Prematurity Study.
ETROP – Early Treatment for Retinopathy of Prematurity.
*The ETROP recognized plus disease as two quadrants of dilated and tortuous vessels whereas CRYO-ROP defined it as four quadrants.

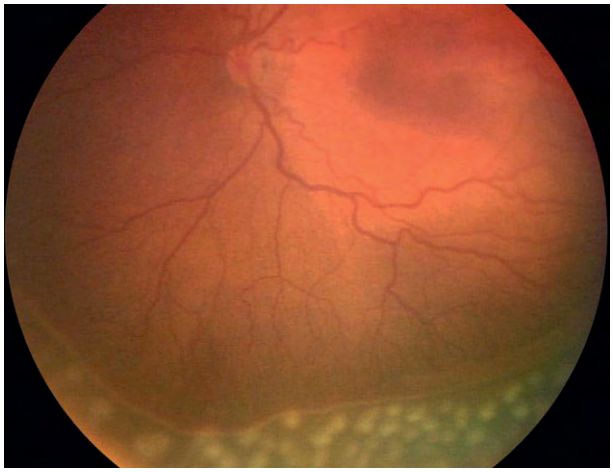

Figure 5 Type 1 prethreshold ROP (zone II, stage 2 severe ROP) after laser; it shows white spots from recently delivered laser to avascular retina and skipped areas between laser spots that will need to be filled in with laser in the left eye.

from neovascular to fibrovascular changes. Once progressive stage 4 ROP is diagnosed, surgery, preferably with a lens-sparing vitrectomy (Figure 6(b)), is performed to release vitreous tractional forces that detach the retina. The main forces addressed are those around the optic nerve, between the ridge and anterior aspect of the eye and lens, between the ridge and optic nerve, between the ridge and ora serrata, and from ridge to ridge (Figure 6(b)). The retina then reattaches in the postoperative period (Figure 6(c)), although the ridge and pulled-up retina often persist. Occasionally, a scleral buckle is performed, often when a break, that is, rhegmatogenous component, is present.

The decision to operate must be carefully considered in the preterm infant eye because there are surgical difficulties that make operating on an infant eye different from operating on an adult one. The infant eye is about two-thirds the diameter of the adult eye and the region of safe

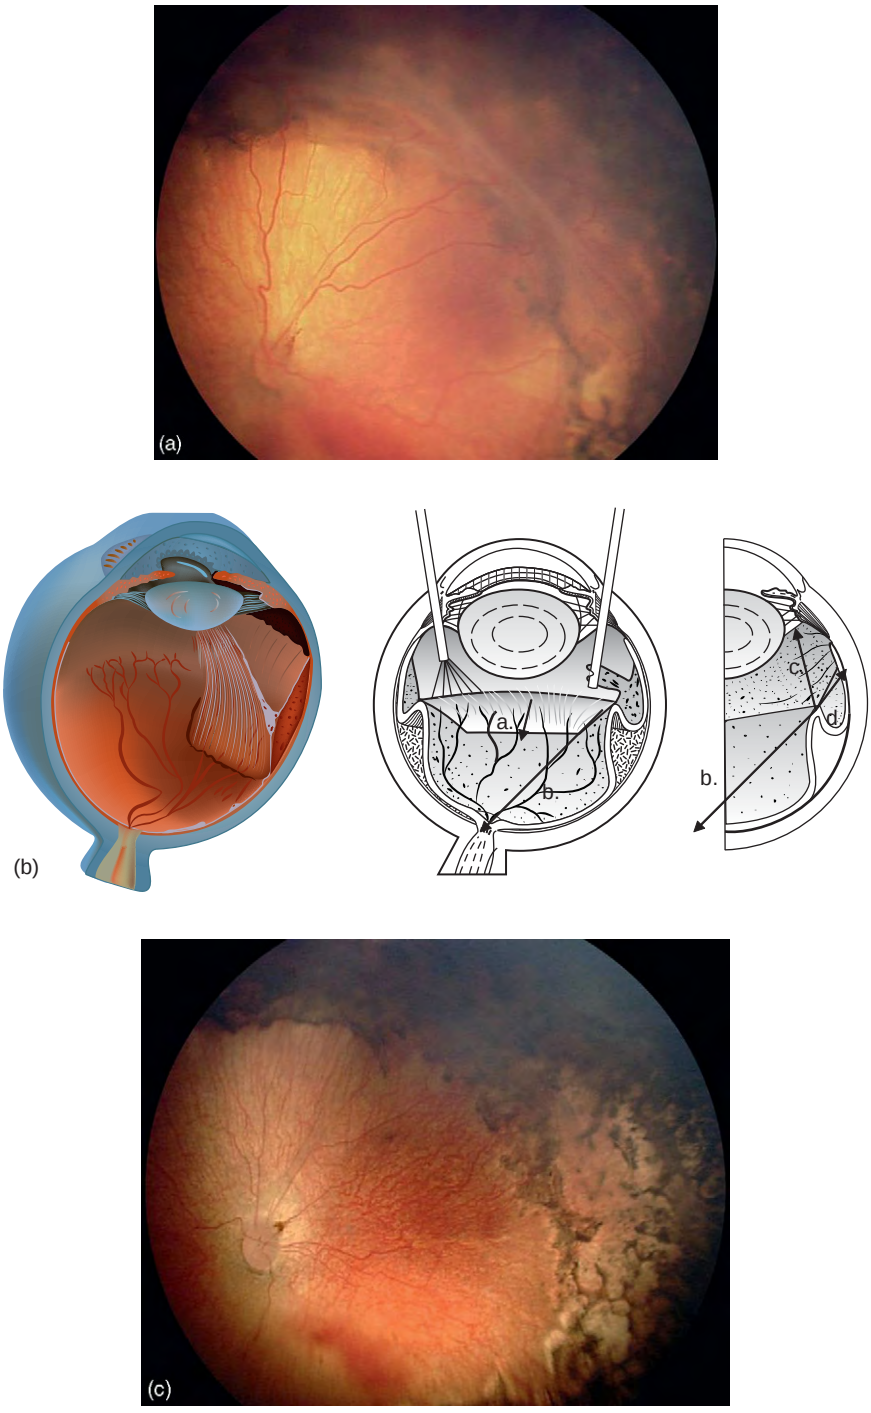

Figure 6 Image taken with wide-angle viewing system (Retcam, Clarity) of infant left eyes with (A) stage 4B ROP showing superior and temporal region of ridge with incorporated retinal detachment and retinal detachment extending posteriorly toward the optic nerve. Pigmented laser spots are in the peripheral region of avascular retina. Focus is on the retinal detachment posterior to the ridge; therefore ridge, which is more anterior in the eye, and optic nerve, which is posterior in the eye, are out of focus. Detachment extends from about 11 o'clock until 4 o'clock and involves the macular region; Courtesy of Sarah Moyer, CRA, OCT-C. (B) An artist's representation of traction retinal detachment and of lens-sparing vitrectomy on left. On the right, the vitrectomy is done to address the vitreous between the (a) ridge and the optic nerve, (b) around the optic nerve, (c) ridge to the anterior portion of the eye, and (d) ridge to the ora serrata. Care is taken not to cut the elevated ridge, which can have retina drawn into it, and risk causing a retinal break. At the end of the case, an air bubble is placed into the vitreous cavity to maintain the globe form while the sclerotomies are sewn closed. (C) 2-week postoperative image taken with wide-angle camera (Retcam, Clarity), showing the resolution of retinal detachment posterior to the ridge and elevated ridge/retinal detachment in the region of the pigmented avascular retina. In addition, note the reduction in plus disease. Residual vitreous hemorrhage is present along the inferior retinal arcade. Lens remains clear; Courtesy Sarah Moyer, CRA, OCT-C.

entry without damage to the retina is less than 1 mm in width compared to about 6 mm in the adult eye. Unlike in the adult, a retinal break can lead to an inoperable retinal detachment and blindness in an infant. The ridge/junction region often has retinal detachment incorporated into it. Therefore, in order to reduce the risk of causing an iatrogenic retinal break, the surgical strategy is to release vitreous traction rather than to remove the ridge or dissect preretinal tissue from it. In addition, injury to the lens can lead to cataract, amblyopia, and poor vision. Therefore, the timing of surgery is prior to that when the retina and ridge are pulled anteriorly to contact the posterior lens capsule.

Visual rehabilitation in preterm infants

Infants with ROP are more likely to be myopic and develop strabismus in childhood than full-term infants. The more severe the ROP, the greater the risk of developing high myopia. Infants who develop stage 5 ROP or total retinal detachment have very poor vision, and are usually legally blind (bilateral visual acuity $<20/200$) even after successful surgery to reattach the retina. Therefore, the goal in managing ROP is to prevent stage 5 ROP. Surgery at early stage 4 ROP often permit the retention of the lens which is important in visual development. Infants who have their lenses removed have compromised visual development and reduced visual acuity from aphakic amblyopia, even with optical means to correct aphakia.

Genetics Related to ROP

Based on retrospective analysis of monozygotic and dizygotic twins, a 70% variance in the susceptibility of ROP was found to be from genetic factors, suggesting that genetics plays a strong role in ROP. However, studies of candidate genes are not in agreement and suggest that a more complex situation exists, involving genetics and environmental factors such as nutrition, oxygen, and the health of the infant.

The Norrie disease gene produces the gene product, norrin, which is also a downstream ligand for receptors in the Wnt signaling pathway. Norrie disease is usually x-linked and causes visual and hearing loss. The Wnt pathway and norrin are important in retinal and vascular development. Genetic mutations in the Norrie disease gene [Xp11.2-11.3] were reported to account for 3% of the cases of advanced ROP, but were not found in a study in infants with severe ROP compared to control preterm infants with no or minimal ROP within a racially diverse population. Another study reported that mutations within the cysteine knot configuration of the Norrie disease gene were associated with severe retinal dysplasia, whereas other polymorphisms within the gene had less severe vitreoretinopathies.

Severe ROP has been reported in infants with certain polymorphisms in the gene of vascular endothelial growth factor (VEGF), but the same polymorphisms have not been confirmed in other studies. Despite the finding that low serum insulin-like growth factor-1 (IGF-1) was associated with more severe ROP, one study failed to show a relationship between a prevalent polymorphism in the IGF-1 receptor and the presence of ROP. The role of genetics requires greater study and will continue to be elucidated along with the effect of environmental factors on gene function.

Pathophysiology of ROP

To understand ROP, it is helpful to understand the known processes in human retinal vascular development. It is believed that vasculogenesis or *de novo* development of the central vasculature around the optic nerve occurs from angioblasts, or endothelial cell (EC) precursors. Angioblasts lack markers commonly thought to be present on ECs such as CD31, CD34, and von Willebrand's factor, but do express CD39 and CXCR4. Retinal vascular development is believed to be completed mainly through a process of angiogenesis, but the role of circulating endothelial precursors is being appreciated more. During angiogenesis, a front of migrating cells, astrocytes in cat or angioblasts in dog, sense physiologic hypoxia and express VEGF. The ensuing ECs are attracted to VEGF and migrate to create blood vessels. The VEGF signaling pathway has been found to regulate and integrate several cell processes important during sprouting angiogenesis. Whereas VEGF concentration is thought to regulate EC division rate, the presentation of VEGF, as in a gradient, may regulate filopodia formation of endothelial tip cells at the migrating front and direct the growth of ECs. The delta-like ligand 4/Notch1 (Dll4/Notch1) signaling pathway regulates VEGF-induced endothelial tip/stalk cells at the junction of vascular and avascular retina and permits ordered angiogenesis.

Role of Oxygen in Retinal Development

The oxygen level has been long recognized as important in the development of ROP. High unregulated oxygen at birth likely accounted for many of the early cases of ROP first described in the 1940s and 1950s. With improved oxygen monitoring and avoidance of hyperoxia, ROP virtually disappeared. However, as infants of younger gestational ages and lower birth weights survived, ROP re-emerged. Currently, it is recognized that fluctuations in oxygen, as well as high oxygen at birth, are important

risks for severe ROP. Although a multicenter clinical study (Supplemental Therapeutic Oxygen for Prethreshold Retinopathy of Prematurity) to test the effects of supplemental oxygen to prevent severe ROP found no adverse effect from supplemental oxygen and, perhaps, a benefit in a subgroup, some reports indicate that severe ROP is associated more commonly with infants who have had high oxygen saturations during their courses.

High oxygen early in development causes loss of perfused central capillaries and is the basis for the development of several animal models of oxygen-induced retinopathy (OIR) in cats, mice, beagles, and rats. One mechanism proposed is that hyperoxia inhibits basic fibroblast growth factor (bFGF)-induced angioblast differentiation into ECs *in vitro*. Although most models of OIR recapitulate this high constant hyperoxia, it is not relevant to what preterm infants experience in neonatal intensive care units (NICUs) in which oxygen is well regulated, in whom minute to minute fluctuations in oxygen have been measured rather than constant oxygen. Furthermore, almost all studies of the mechanisms of oxygen stress on retinal vessels have been performed using models that subject animals to high constant oxygen.

Table 2 Mouse and 50/10 rat models of OIR

Constant high hyperoxia: Mouse OIR model of human APROP	
	p12 Low retinal VEGF Central avascular retina p17 Intravitreous neovascular budding
Fluctuations in oxygen: Rat 50/10 OIR model of more common PSROP	
	p14 Rat 50/10 OIR; ~32 weeks premature infant High retinal VEGF
	p18 Rat 50/10 OIR; ~35-37weeks premature infant High VEGF164 and VEGFR2 signaling Intravitreous neovascularization
	~p30 Rat 50/10 OIR; 40 weeks preterm infant Intraretinal vascularization and regression of IVNV

Animal Models of Severe ROP

Models of severe ROP take advantage of the fact that several species undergo retinal vascular development after birth. Furthermore, the newly developed capillaries are susceptible to oxygen stresses such that high oxygen will cause loss of capillaries. No model uses premature animals. In addition, no model develops stage 4 or 5 ROP (retinal detachment). The beagle OIR model comes closest to stage 4 ROP with the development of tractional retinal folds, but does not develop stage 5 ROP.

Mouse OIR (model of aggressive posterior ROP)

The mouse OIR model also uses high constant oxygen and is probably the most useful to study mechanisms of extreme oxygen insult by using genetically modified animals (**Table 2** and **Figure 7**). This model may mimic aggressive posterior ROP (APROP, **Figure 8**), a less-common form of severe ROP, in which there are broad areas of central avascular retina. APROP may share the retinal oxygenation pattern as does the avascular hypoxic retina during relative hypoxia in the mouse OIR model. Fluorescein angiograms of infants with APROP demonstrated extensive capillary loss centrally that appeared similar to that seen in perfused retinas from the mouse OIR, and several studies have shown avascular retina in OIR models to be hypoxic.

Rat 50/10 OIR (model of peripheral severe ROP)

The rat 50/10 OIR model mimics the more common form of severe ROP, peripheral severe ROP (PSROP). Here, newborn rat pups are placed into an oxygen environment that cycles concentrations between 50% and 10% oxygen every 24 h for 14 days. The oxygen extremes in the rat 50/10 OIR model cause rat arterial oxygen levels to be similar to the transcutaneous oxygen levels measured in preterm infants who developed severe ROP. In addition, rather than constant oxygen used in other models, the 50/10 OIR model exposes pups to repeated fluctuations in oxygen, a risk factor for severe ROP. As in PSROP, in which there is reduced peripheral retinal vascularization and perfusion with minimal central nonperfusion, the rat 50/10 OIR model has mainly peripheral avascular retina and minimal central capillary loss (**Figure 4(a)**). The 50/10 OIR model reproducibly and consistently first develops avascular retina (analogous to human zone II ROP) and, subsequently, vessel tortuosity (analogous to human plus disease) and intravitreous neovascularization (analogous to human stage 3 ROP). All OIR models have regression of tortuosity and intravitreous neovascularization with later intraretinal vascularization; however, the beagle model takes the longest to regress.

Role of Avascular Retina

Although the size of the avascular retina does not always correlate with the presence of intravitreous neovascularization in animal models, multicenter clinical trials have shown that eyes with the largest peripheral retinal avascular zones have the worst outcomes from ROP. Furthermore, the avascular, hypoxic retina is believed to be a source of angiogenic

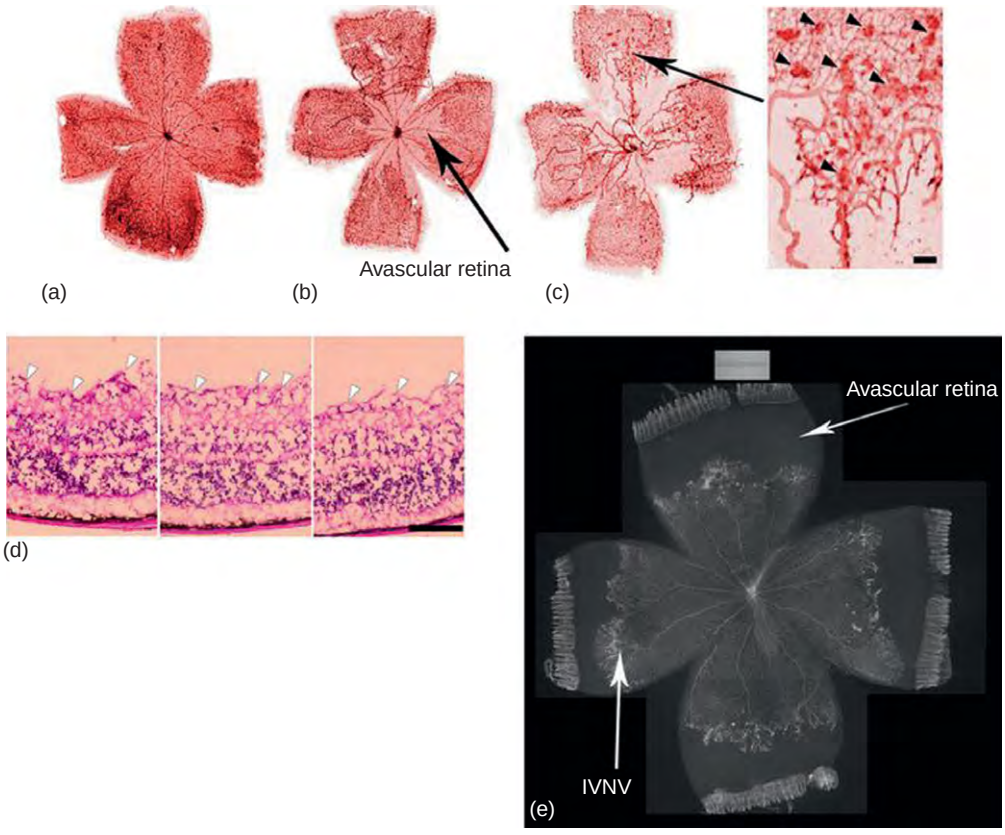

Figure 7 Retinal flat mounts from (a) room air raised mouse at postnatal day (p)12; (b) mouse raised in oxygen-induced retinopathy (75% constant oxygen for 5 days) with central capillary loss (arrow) at p12. ((c), left) After 5 days in room air (relative hypoxia) with capillary budding into the vitreous at p17, possibly mimicking aggressive posterior ROP (see **Table 2**). ((c), right) Enlargement of area centered at arrow; arrowheads indicate capillary budding; and (d) cross section of (c) showing endothelial budding into the vitreous (white arrowheads). (e) Lectin B4-stained retinal flat mount from rat 50/10 OIR model following oxygen fluctuations between 50% and 10% oxygen until p14, followed by 4 days of room air. At p18, intravitreous neovascularization (IVNV) appears at the junction of vascularized and peripheral avascular retina similar in appearance to peripheral severe ROP (see also **Table 2**).

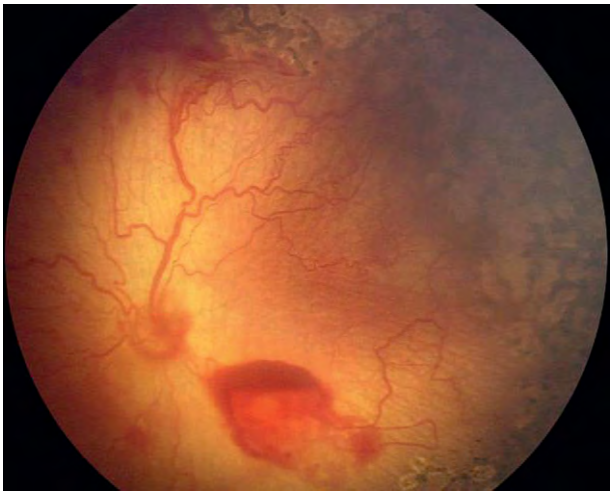

Figure 8 Preterm infant left eye with APROP after laser treatment showing pigmentation of laser to the right of image, plus disease, and vitreous hemorrhage inferior to optic nerve; Courtesy Sarah Moyer, CRA, OCT-C.

factors that cause pathologic intravitreous neovascularization in some models of ROP. What causes avascular retina remains largely unknown. Delayed retinal vascular development in B-cell lymphoma protein 2 ($bcl2^{-/-}$)-deficient mice that have a defect in protection against apoptosis supports the thinking that increased apoptosis of ECs or their precursors may contribute to avascular retina. Protection of newly formed capillaries from hyperoxia-induced endothelial death occurs by giving growth factors or nutritional supplements prior to the hyperoxic insult, and these protective agents largely prevent intravitreous neovascularization that would occur in the hypoxic phase of the mouse OIR model. The activation of nicotinamide adenine dinucleotide phosphate [NADPH] oxidase from repeated oxygen fluctuations in the rat 50/10 OIR model contributed to the avascular retina through apoptosis. Thus, the area of avascular retina appears to be one factor involved in the severity of human ROP, and apoptosis of ECs or their precursors may contribute to its size.

Role of Growth Factors

Molecular mechanisms of OIR have been identified mainly from the mouse OIR model, which mimics APROP, but does not mimic most cases of severe ROP.

Vascular Endothelial Growth Factor

VEGF is an important factor in retinal vascular development and is also neuroprotective. However, it is also one of the most important angiogenic factors involved in pathologic retinal and choroidal vascular diseases. Mice in OIR had reduced VEGF expression in association with capillary loss centrally when exposed to high constant hyperoxia. Subsequently, when placed into relative hypoxia that occurred in room air, VEGF messenger ribonucleic acid (mRNA) was overexpressed in association with the development of endothelial budding above the internal limiting membrane. If VEGF was given during hyperoxia, capillary loss could be reduced and, if agents to inhibit VEGF were given during relative hypoxia, endothelial budding into the vitreous was also reduced.

In the rat 50/10 OIR model, a relevant model of most cases of severe ROP in the US currently, neutralizing VEGF with an antibody made against $VEGF_{164}$ reduced tortuosity (analogous to plus disease) and intravitreous neovascularization (analogous to stage 3 ROP). Too low a dose appeared to lead to a rebound in intravitreous neovascularization and persistence of the avascular retina.

Clinical trials are underway, testing intravitreous injections of antibodies to VEGF in severe ROP. There are concerns regarding the effect of dose based on animal studies described above, and the possible adverse effect of inhibiting VEGF in the developing preterm infant. VEGF is neuroprotective and besides the possible local effect on the retina, there is the potential adverse effect systemically from the absorption of the antibody into the bloodstream. Compared to the adult, an intravitreous drug in the newborn can achieve a higher concentration in the bloodstream and affect measurable outcomes, such as body weight gain in animal models. However, in some forms of severe ROP, such as APROP, there are few other options to prevent retinal detachment and permit the development of vision in these infants. Therefore, clinical trials are necessary and the data obtained will be important in developing improved treatments for severe ROP.

IGF-1 – IGF 1BP3

IGF-1 is important in the physical growth of the infant. However, IGF-1 levels that occur *in utero* are not maintained upon birth in preterm infants. Low serum IGF-1 was found to correlate with greater avascular retinal area in human preterm infants. Furthermore, transgenic mice expressing a growth hormone antagonist gene, or wild-type mice treated with an inhibitor to growth hormone, had reduced intravitreous neovascularization in the mouse OIR model. IGF-1 was also found to be important for signaling through the mitogen-activated protein (MAP) kinase pathway, which is important in cell proliferation. In addition, VEGF and IGF-1 synergistically triggered the serine-threonine kinase, Akt, which is important in cell survival. Based on these findings, it is theorized that IGF-1, which is low in the preterm infant, is necessary for early retinal vascular survival and growth, but can result in later intravitreous neovascularization in ROP. However, the timing and dose of IGF-1 appear to be critical.

A hypoxia-regulated binding protein of IGF-1, IGF-1BP3, was shown to be important in reducing hyperoxia-induced capillary loss and in promoting vascular regrowth into the retina in the mouse OIR model. IGF-BP3 was shown to promote differentiation of endothelial precursor cells into ECs and in promoting angiogenic processes, such as cell migration and tube formation.

Erythropoietin

Erythropoietin is angiogenic, erythropoietic, and neuroprotective. It is upregulated after the stabilization of hypoxia-inducible factor (HIF)-1α in response to hypoxia. In the mouse OIR model, hyperoxia reduces the expression of erythropoietin. The administration of exogenous erythropoietin prior to hyperoxia reduced capillary loss, whereas giving erythropoietin during relative hypoxia in room air enhanced pathologic neovascularization. Clinical studies have reported an association between the number of administrations of erythropoietin for anemia of prematurity and the prevalence of severe ROP and have found that recombinant erythropoietin is an independent risk factor for severe ROP.

HIF 1α

The stabilization of HIF1α occurs under hypoxic conditions or secondary to reactive oxygen species (ROS) generated from NADPH oxidase, nitric oxide, mitochondria, and other enzymes. HIF1α binds to the hypoxia response elements to cause transcription of several genes including angiogenic factors, VEGF, and erythropoietin. A knock-out to HIF 1α is lethal, but a knock-out to the HIF-1α-like factor (HLF)/HIF-2α provided evidence that erythropoietin was a major gene involved in intravitreous neovascularization after relative hypoxia from hyperoxia-induced capillary loss in the mouse OIR model.

Role of Oxidative Stress

Oxidative stress has been proposed to be important in the development of ROP because the retina is susceptible to oxidative damage given its high metabolic rate and rapid rate of oxygen consumption. In addition, the premature infant has a reduced ability to scavenge ROS, increasing

its vulnerability to oxidative stress. End products of ROS, lipid hydroperoxides, were increased in the 50/10 OIR model at time points corresponding to intravitreous neovascularization. When injected into the vitreous, these compounds caused intravitreous neovascularization in the rabbit. In addition, ROS can trigger signaling pathways relevant to apoptosis or angiogenesis, both important in the pathogenesis of ROP.

The treatment of pups in the 50/10 OIR model or humans with ROP using a broad antioxidant, *N*-acetylcysteine, failed to show a reduction in clock hours of intravitreous neovascularization, or the avascular retinal area. In a clinical trial in preterm infants, there was no difference in the incidence in ROP between those receiving *N*-acetylcysteine or control. However, reduction in ROS with preparations of vitamin E or liposomes containing the antioxidant enzyme, manganese superoxide dismutase, reduced OIR severity. Also, a meta-analysis of human preterm infants treated with vitamin E showed a significant reduction in severity of ROP. Reducing the activation of NADPH oxidase, an enzyme that produces ROS, can also reduce the size of the avascular areas and subsequent intravitreous neovascularization in certain OIR models.

Light was proposed to be important in ROP development through photooxidation of polyunsaturated fatty acids within photoreceptor outer segments. On the other hand, during the dark, photoreceptors are more metabolically active. A clinical trial testing the effect of light or shade on the development of ROP showed no significant difference.

Future Treatment Considerations

There are difficulties in studying treatments for ROP in developing infants. Preterm infants with severe ROP often have other developmental and health problems, making it difficult to assess long-term complications of a drug in clinical trials. Inhibiting the bioactivity of VEGF has been reported to be beneficial in adult diseases, such as proliferative diabetic retinopathy, but this strategy has been reported to interfere with neuronal and endothelial survival in some animal models, and these are issues of concern in the developing preterm infant. Inhibition of ROS may be detrimental to the preterm infant, whose abilities to combat infection are limited. A reduction in inspired oxygen concentration may also be detrimental to the developing preterm infant brain and long-term effects of such reductions are unknown. The timing and dose of neuroprotective agents such as erythropoietin and growth factors are critical but vary among individual infants, so that an agent may worsen rather than lessen ROP severity. Currently, the optimal time or dose of an agent cannot be safely determined for an individual infant. However, the current standard of care laser treatment for severe ROP does not address vascular development that is ongoing in the developing human preterm infant. Better treatments for severe ROP are needed.

Rhegmatogenous Retinal Detachment

S C Wong, Moorfields Eye Hospital, London, UK
Y D Ramkissoon, Royal Hallamshire Hospital, Sheffield, UK
D G Charteris, Moorfields Eye Hospital, London, UK

Glossary

Retinopexy – A Laser- or cryotherapy-induced chorioretinal adhesion surrounding a retinal break as prophylaxis for or during surgical treatment of rhegmatogenous retinal detachment.
***Rhegma* (Greek)** – A rupture, rent, or fracture.
Rhegmatogenous retinal detachment – A separation of the neurosensory retina from the retinal pigment epithelium associated with a full-thickness hole, break, or tear in the retina. The detachment occurs secondary to the passage of vitreous fluid through the break.
Tamponade – The plugging on a retinal break so that fluid can no longer pass through it (e.g., with a gas bubble).
Vitreous – Pertaining to the vitreous body of the eye located in the posterior chamber of the eye.

Rhegmatogenous retinal detachment (RRD) is defined as a separation of the neurosensory retina from the underlying retinal pigment epithelium (RPE) due to accumulation of subretinal fluid (SRF) via one or more full-thickness retinal breaks. With an incidence of 1 in 10 000 among the general population, RRD is relatively uncommon but remains an important cause of vision loss. In 1918, Jules Gonin recognized the importance of retinal breaks in the etiology of RRD and transformed the prognosis of this previously untreatable, blinding condition. Using thermocautery to seal retinal breaks, he demonstrated successful retinal reattachment in 30–40% of his cases. Modern vitreoretinal surgery can now achieve a final retinal reattachment rate of >95%.

Pathophysiology

Under physiological conditions, retinal attachment is principally maintained by the following mechanical and metabolic factors: (1) fluid or intraocular pressure (IOP) differentials (hydrostatic and osmotic forces); (2) glue-like interphotoreceptor matrix at the photoreceptor outer segment and RPE interface; and (3) RPE pump (NA^+–K^+ adenosine triphosphate (ATP)ase metabolic pump transporting ions and fluid across the subretinal space).

For RRD to occur, the following factors need to be present to overcome the attaching forces: (1) full-thickness retinal break in the neurosensory retina and (2) vitreous liquefaction and vitreoretinal traction. Vitreoretinal traction may coexist at the site of the retinal break, and varies depending on the type of break.

Full-thickness retinal breaks are classified as tractional tears, round holes, or dialyses.

Retinal tractional tears (also known as U, horseshoe, or flap tears) develop following posterior vitreous detachment (PVD) and are the most common causes of RRD. They occur at sites of enhanced vitreoretinal adhesion, such as in peripheral retinal lattice degeneration, chorioretinal scars, or at the posterior edge of the vitreous base. Persistent vitreous traction exerted on the flap of a tear promotes rapid, continuous recruitment of liquefied vitreous into the subretinal space and progression to retinal detachment, which usually occurs more rapidly than with a round hole or dialysis (where there is no posterior vitreous separation).

Retinal hole formation is not usually associated with overt vitreous traction. This is caused by localized retinal atrophy and occurs more commonly in myopic patients. The pathophysiology of progression from retinal hole to RRD is not entirely clear, as 5–10% of postmortem eyes have full-thickness retinal holes without RRD.

Retinal dialyses are circumferential retinal breaks occurring along the ora serrata with concurrent avulsion of the overlying vitreous base. There is often a history of ocular trauma, although spontaneous cases are not uncommon.

Clinical Features

Symptoms

Many patients present acutely with classic symptoms of flashing lights (photopsia) and visual floaters in the affected eye, usually resulting from PVD. Photopsia lasts for seconds, is more noticeable in dim light conditions, may be precipitated by ocular movements, and commonly occurs in the temporal field but is not localizing. Floaters in the visual field vary from a solitary floater (e.g., Weiss ring formation) to innumerable minute dark spots (pigment or hemorrhage in vitreous). As an RRD develops and progresses, patients may notice peripheral visual-field loss, which is often described as a black curtain,

shadow, or half-moon. Central vision is lost if SRF spreads to involve the macula and detaches the fovea.

In a minority of patients, RRD may be asymptomatic. Typically, this occurs in young myopic patients with atrophic round holes who often present late only when the detachment encroaches the macula.

Signs

Nonspecific signs of RRD may include reduced visual acuity, relative afferent pupillary defect, mild anterior uveitis, and low IOP compared to the fellow eye. Up to 2% of patients may present with raised IOP or Schwartz–Matsuo syndrome. This typically occurs in young patients with chronic RRD, and is due to rod photoreceptor outer segments passing into the anterior chamber and blocking trabecular outflow. A positive Shaffer's sign, defined as the presence of tobacco dust or pigment granules in the anterior vitreous, is highly predictive of a retinal break particularly when associated with any of the above symptoms.

Stereoscopic fundal examination reveals an elevated neurosensory retina in the area of the detachment, with reduced visibility of underlying choroidal markings. The detached retina has a convex configuration and may have a corrugated surface due to intraretinal edema. This is in contrast to tractional non-RRD, which has a concave configuration.

In addition, one or more full-thickness retinal breaks may be visible as evidenced by discontinuity of the retinal surface. These typically occur anterior to the equator. Visualization of the type, number, and distribution of all retinal breaks is important for surgical planning. This is best achieved with the aid of indirect ophthalmoscopy and scleral indentation. However, this may be difficult in the presence of media opacities. Identification of break type in RRD is crucial, as it determines the choice of appropriate surgical technique for repair.

Break type – identification

Retinal tears

1. Horseshoe or U-shaped tear (may be irregular; Figure 1).
2. Persistent point of vitreous traction present at anterior edge of flap.
3. Giant retinal tear (GRT) is a circumferential retinal tear of 3 or more clock hours.
4. Avulsion of the anterior flap of a retinal tear may result in a round break with overlying retinal operculum. A tear with an operculum that is fully separated from the retina is known as a fully operculated round hole (FORH).
5. Retina is visible anterior to break.

Retinal round holes

1. Round atrophic hole without overlying retinal operculum (Figure 2).
2. May be associated with retinal degeneration (e.g., peripheral lattice degeneration).
3. Retina is visible anterior to break.

Figure 1 Right eye. Retinal tear in the superotemporal retinal periphery causing an acute macular-sparing retinal detachment. HST, horseshoe tear; RRD, rhegmatogenous retinal detachment.

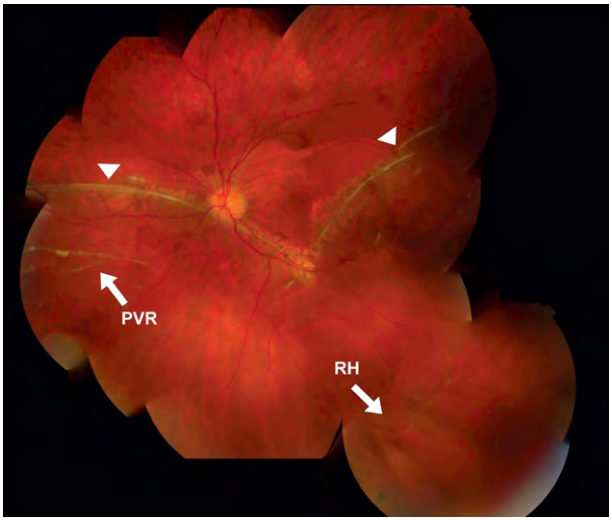

Figure 2 Left eye. Retinal round hole in the inferotemporal retinal periphery causing a chronic macular-sparing retinal detachment. A demarcation line (arrowhead) indicates several months of stasis and nonprogression of the retinal detachment. Proliferative vitreoretinopathy in the form of subretinal band formation is consistent with the chronicity of the detachment. RH, round hole; PVR, proliferative vitreoretinopathy.

Retinal dialyses

1. Circumferential retinal break at the ora serrata without a PVD (Figure 3).
2. No visible retina anterior to retinal break.

Lincoff first described the principles of predicting retinal break location, taking into account the effect of gravity on the spread of SRF from the primary break and the resultant topography of an RRD. This is influenced by anatomical limits such as the disc, the ora serrata, and any chorioretinal adhesions that might be present.

Break localization – principles based on topography of RRD

Superotemporal and superonasal

1. SRF descends on the same side of break toward the disc, then revolves around the inferior pole of the disc and rises on the opposite side.
2. SRF may rise as high on the opposite side of the disc as the level of the primary retinal break, but never as high as the fluid level on the primary side.
3. The primary break will be found within 1.5 clock hours of the highest border of the detachment in 98% cases.

Midline (12 o'clock meridian) and total detachments

1. Detachments that cross the 12 o'clock meridian originate from breaks at or near 12 o'clock.
2. These detachments can become total.
3. In subtotal detachments, if the break is slightly to one side of 12 o'clock, the fluid front will be more extensive on the side coincidental with the break.
4. The more posterior the break, the more it can deviate from 12 o'clock position and still cause a detachment that will cross the vertical meridian. Therefore, contour edges of the detachment are of less localizing value.

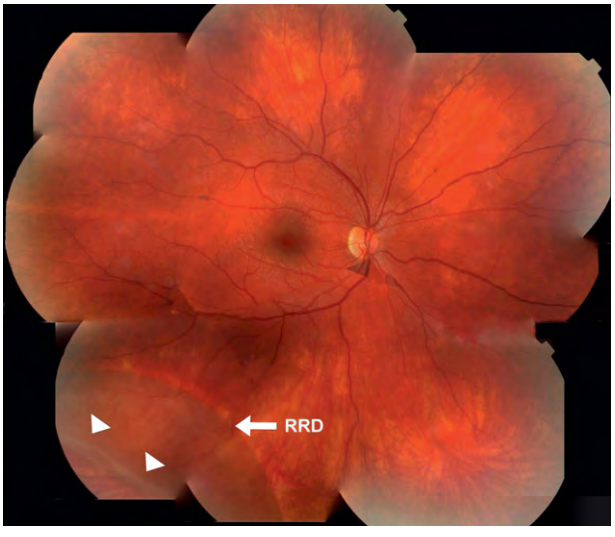

Figure 3 Right eye. Retinal dialysis (arrowhead) in the inferotemporal retinal periphery causing a macular-sparing retinal detachment.

Inferior

1. The SRF that arises from breaks below the level of the optic disc develops first around the break and then advances toward the disc and macula, rising higher on that side of the disc where the break lies.
2. The break need only be 1 or 2 mm from the 6 o'clock position for it to cause a difference in fluid levels.
3. When the levels are equal, the hole is at the 6 o'clock meridian.
4. Such detachments are never bullous.

Chronic RRD

The distinction between an acute and chronic RRD is important, as it may determine both the urgency of treatment and prognosis. Signs of chronicity are:

1. Retinal atrophy – retina may be thinned and atrophic.
2. Intraretinal cysts – these can develop in long-standing RRD, typically those over 12 months duration. At the time of surgery, they can be left undisturbed as they do not usually interfere with retinal reattachment and can subsequently collapse.
3. Subretinal demarcation lines – also known as high watermarks or tidemarks, these develop at the advancing front of the RRD as a result of proliferation of RPE cells. Their presence simply indicates a period of stasis of the RRD at the point of the demarcation line. However, it does not confer the strength of a chorioretinal scar that is generated by retinopexy; thus, RRD progression may still occur.
4. Proliferative vitreoretinopathy (PVR) (Figure 4) – This is a process of cellular proliferation and fibrocellular membrane contraction that complicates between 5% and 12% of all RRD, and is the most common reason for final failure of RRD surgery. PVR has a higher incidence in RRD secondary to GRTs (16–41%) and in eyes sustaining penetrating trauma (10–45%). Once PVR has developed, visual recovery is usually limited despite improving anatomical surgical success rates. The location and extent of epiretinal or subretinal proliferation have been classified by the Retina Society Terminology Committee in 1991 (Table 1).

Differential Diagnoses

RRD must be distinguished from other causes of retinal or choroidal elevation. Differential diagnoses include PVD, exudative RD, tractional RD, retinoschisis, choroidal lesions, and artifacts (Table 2).

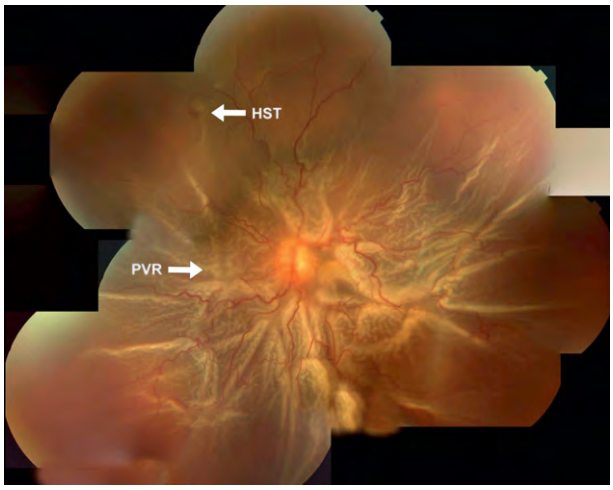

Figure 4 Right eye. Total rhegmatogenous retinal detachment secondary to a small superior retinal tear. Proliferative vitreoretinopathy is evidenced by posterior starfolds involving approximately 11 clock hours (PVR CP11). HST, horseshoe tear; PVR, proliferative vitreoretinopathy. Reproduced with kind permission from Paul M. Sullivan.

Table 1 Proliferative vitreoretinopathy classification by the Retina Society Terminology Committee

Grade (stage)	*Characteristics*
A	Vitreous haze; vitreous pigment clumps; and pigment clusters on inferior retina
B	Wrinkling of the inner retinal surface; rolled and irregular edge of retinal break; retinal stiffness; vessel tortuosity; and decreased vitreous mobility
C P 1 – 12 (clock hours)	Posterior to equator: focal, diffuse, or circumferential full-thickness retinal folds; and subretinal strands
C A 1 – 12 (clock hours)	Anterior to the equator: focal, diffuse, or circumferential full-thickness retinal folds; subretinal strands; anterior displacement; and condensed vitreous with strands

Management

The primary aim in the management of RRD is to prevent complete loss of central and peripheral vision, that is, progression to no perception of light. In patients with symptomatic RRD, the secondary aim of management is restoration/improvement of peripheral visual field and central vision. Depending on the type of retinal break, size, and rate of progression of the RRD and PVD status, treatment may be either conservative or active. Conservative management involves observation for progression of RRD without intervention. Active management includes either barrier laser demarcation to wall off the detachment and prevent further progression, or surgery to reattach the retina. The various treatment options are discussed in turn, categorized by type of causative retinal break.

Conservative

Conservative management consists of either self-monitoring by the patient for development or progression of RRD symptoms, and/or observation by regular clinical examinations charting any signs of an enlarging RRD. This option is usually reserved for patients with chronic RRD without clinical signs of recent progression who are often asymptomatic and discovered to have RRD as an incidental finding. Another group of patients, where conservative management may be appropriate, comprises those with such significant systemic comorbidity that active treatment cannot be safely administered. When considering conservative management regardless of the specific indication, the ophthalmologist should discuss in detail its risks and benefits versus active therapies with the patients, allowing them to make informed decisions regarding their care. In addition, it is important to ensure that the patient understands the symptoms of RRD progression, and are able to reliably monitor their vision monocularly to detect changes before macula detachment occurs.

RRD due to retinal tear

RRD due to retinal tears occurs following PVD and tends to be rapidly progressive in nature due to persistent vitreoretinal traction on the anterior edge of the tear. It is therefore unusual for this to be asymptomatic or present as chronic RRD, and so much less likely to be managed conservatively.

RRD due to retinal hole or dialysis

Both retinal holes and retinal dialyses are usually associated with an attached vitreous, that is, without a PVD. This is thought to account for the relatively slower progression of RRD compared to those caused by retinal tears. As such, these patients often present with signs of chronicity and nonprogression, and many are asymptomatic until the macula becomes involved. Conservative management may be considered with appropriate patient selection.

Laser Demarcation

Laser photocoagulation results in the formation of a chorioretinal scar, conferring enhanced adhesion between the neurosensory retina and RPE. Laser demarcation for RRD is applied to the area of attached retina immediately adjacent to the most posterior edge of the RRD, walling off the area of detachment and preventing further

Table 2 Differential diagnosis of rhegmatogenous retinal detachment

Differential diagnosis	*Features*
Posterior vitreous detachment	– Weiss ring, vitreous syneresis – Attached retina
Exudative RD	– RD configuration convex, but smooth without corrugated surface – Shifting SRF – configuration of RD responds to changes in posture and its gravitational effects – No full-thickness retinal breaks present – May be associated with uveitis, scleritis, tumor, vascular, and other disorders
Tractional RD	– Associated with proliferative diabetic retinopathy or penetrating ocular trauma – RD has concave configuration – No full-thickness retinal breaks present, unless combined tractional and rhegmatogenous – Limited retinal mobility; no shifting fluid – Retina less elevated, and associated with sites of vitreoretinal traction
Retinoschisis	– Age-related or congenital X-linked – Occurs secondary to intraretinal splitting (age-related: splitting at outer plexiform or less commonly inner nuclear layer. X-linked: splitting at nerve fiber layer) – Often bilateral, and more common in hypermetropes – Retinal elevation has concave configuration – No full-thickness retinal breaks present – Partial thickness retinal breaks may be visible involving the inner and/or outer leaf – Does not produce demarcation line – Produces absolute scotoma, unlike RD which produces relative scotoma – Laser reaction test – this can help differentiate retinoschisis from a retinal detachment. Low-energy argon green laser is applied to the area of retinoschisis. Intensity of gray burn reaction should be equal to a control shot in peripheral flat retina. No reaction is seen in RRD.
Choroidal lesions	– Choroidal detachments or choroidal masses (tumors or inflammatory lesions) – No full-thickness retinal breaks present – May be associated with exudative RD
Artifacts	
– Vitreous hemorrhage	– Hemorrhage in vitreous cavity – Absence of true retinal vessel configuration
– Lens opacity – cataract or pseudophakic capsule opacification	– No relative afferent pupillary defect – Visible lens opacity – No vitreous haze or pigment granules – No mobility of opacity – Attached retina on ultrasound B scan

progression. Two to three contiguous rows of laser are required, extending anteriorly up to the ora serrata on either side of the RRD. This is usually achieved using indirect laser ophthalmoscopy with scleral indentation. Increased adhesion at the site of laser photocoagulation is evident within 24 h in histological studies of animal and human eyes, and is twice normal by 2–3 weeks. Therefore, laser demarcation is only appropriate for RRD with signs of slow progression or recent stasis. Cryotherapy is not appropriate for RRD demarcation as a large area of retinopexy is required, causing more extensive tissue destruction and is less precise than laser.

RRD due to retinal tear

As discussed previously, acute RRD due to retinal tears tends to progress rapidly and is therefore not usually suitable for laser demarcation. Possible exceptions are localized RRD from a single small tear, particularly if within inferior retina.

RRD due to retinal hole or dialysis

Patients with limited or no symptoms from RRD secondary to retinal hole or dialysis, with associated signs of chronicity, may be suitable candidates for laser demarcation. Exceptions are patients with significant symptoms, especially visual field loss, signs of recent rapid progression, or when the SRF has progressed to the major vascular arcades. Laser demarcation limits rather than alleviates RRD symptoms. Laser-induced chorioretinal scars in the posterior pole can expand up to 13% per year, potentially causing a symptomatic central scotoma, if this is close to the macula.

Pneumatic Retinopexy

Pneumatic retinopexy for RRD was introduced by Hilton and Grizzard in 1986 as a two-step outpatient procedure without conjunctival incision. This involves an intravitreal

gas injection to temporarily close the retinal break preventing further recruitment of SRF from liquefied vitreous, followed by retinopexy (laser or cryotherapy) to permanently seal the break. Postoperative posturing for a minimum of 5 days is required in all patients. Careful case selection is required as not all patients are suitable for pneumatic retinopexy.

This procedure is not suitable in the following cases:

1. multiple breaks spanning over 3 clock hours;
2. giant retinal breaks;
3. inferior breaks involving inferior 4 clock hours;
4. presence of PVR grade C; and
5. inability to maintain postoperative posturing.

RRD due to retinal tear

Pneumatic retinopexy is most suitable for RRD with a single superior tear situated in the superior 8 clock hours. Patients must be able to posture, and attend clinic regularly in the early postoperative period to monitor the outcome of treatment. Additional gas injection or further surgery with scleral buckling or vitrectomy may be required in the event of treatment failure.

RRD due to retinal hole or dialysis

Pneumatic retinopexy is not suited to either of the following pathologies: RRD due to retinal hole or dialysis. The presence of an attached vitreous in both retinal holes and dialyses increases the risk of complications of the procedure, including new retinal break and formation of multiple small gas bubbles (see the section titled 'Complications').

Scleral Buckling

The concept of scleral buckling was introduced by Custodis in 1949. Prior to the advent of noncontact wide-angle viewing systems for vitrectomy, scleral buckling was the most commonly performed operation for RRD, and remains so in certain countries due to high primary success rates of over 90%. It is typically performed under general anesthesia, although local anesthesia may be used.

The basic principle of scleral bucking (**Figure 5**) is to close retinal breaks by indentation of the sclera, preventing further recruitment of fluid into the subretinal space. Scleral indentation is achieved by using a variety of explant materials sutured externally to the scleral surface. Encircling explants afford a permanent 360° indent, while segmental explants provide a localized indent, which supports the break for a period of several months until the indent fades. Segmental explants are preferred due to lower associated ocular comorbidity. Permanent break closure must be ensured by application of retinopexy, typically cryotherapy. Intraoperative drainage of SRF may be performed either to aid more rapid resolution of the RRD, or to create space within the vitreous cavity for the scleral indent by substituting SRF volume for the volume of indent, thus preventing excessive IOP elevation. Drainage of SRF involves surgical penetration of the sclera and choroid to the subretinal space. Indications for drainage remain controversial as this converts scleral buckling surgery from an external to an internal procedure, with associated increased risk of intraoperative complications (see the section titled 'Complications').

RRD due to retinal tear

RRDs due to a single tear, or a cluster of tears spanning 2–3 clock hours at the same anteroposterior position, are suitable for scleral buckling. Scleral buckling should be considered in patients with inferior tears, particularly as these are more difficult to effectively tamponade with a vitrectomy and gas procedure. Relatively young phakic patients are ideal candidates for scleral buckling as accommodation is preserved and the risk of developing cataract is small. Scleral buckling is not suitable for patients with significant media opacity, large tears, GRTs, or posterior breaks.

RRD due to retinal hole or dialysis

Patients with retinal holes or dialyses respond well to scleral buckling, typically with segmental explants. Primary reattachment rates of up to 100% have been reported.

Vitrectomy

Machemer performed the first pars plana vitrectomy in 1971. Since then, significant progress has been made in our understanding of vitreoretinal pathology alongside improvements in microsurgical instrumentation and techniques. In the United Kingdom, vitrectomy is now the most commonly performed procedure for both simple and complex RRD.

Vitrectomy (**Figure 6**) is performed via three pars plana sclerostomy ports. Standard 20-gauge (0.9 mm) instruments are most widely used. The technique involves removal of vitreous with relief of vitreous traction at the site of retinal breaks, followed by intraocular drainage of SRF, application of retinopexy (cryotherapy or laser), and intravitreal injection of gas or silicone oil tamponade. Noncontact wide-angle viewing systems allow for superior depth of field, visualization, and break localization compared to scleral buckling. This is particularly useful in pseudophakic patients and those with media opacities.

RRD due to retinal tear

In both the UK and USA, vitrectomy has become the treatment of choice for RRD due to retinal tears as there is usually a preexisting PVD. This simplifies

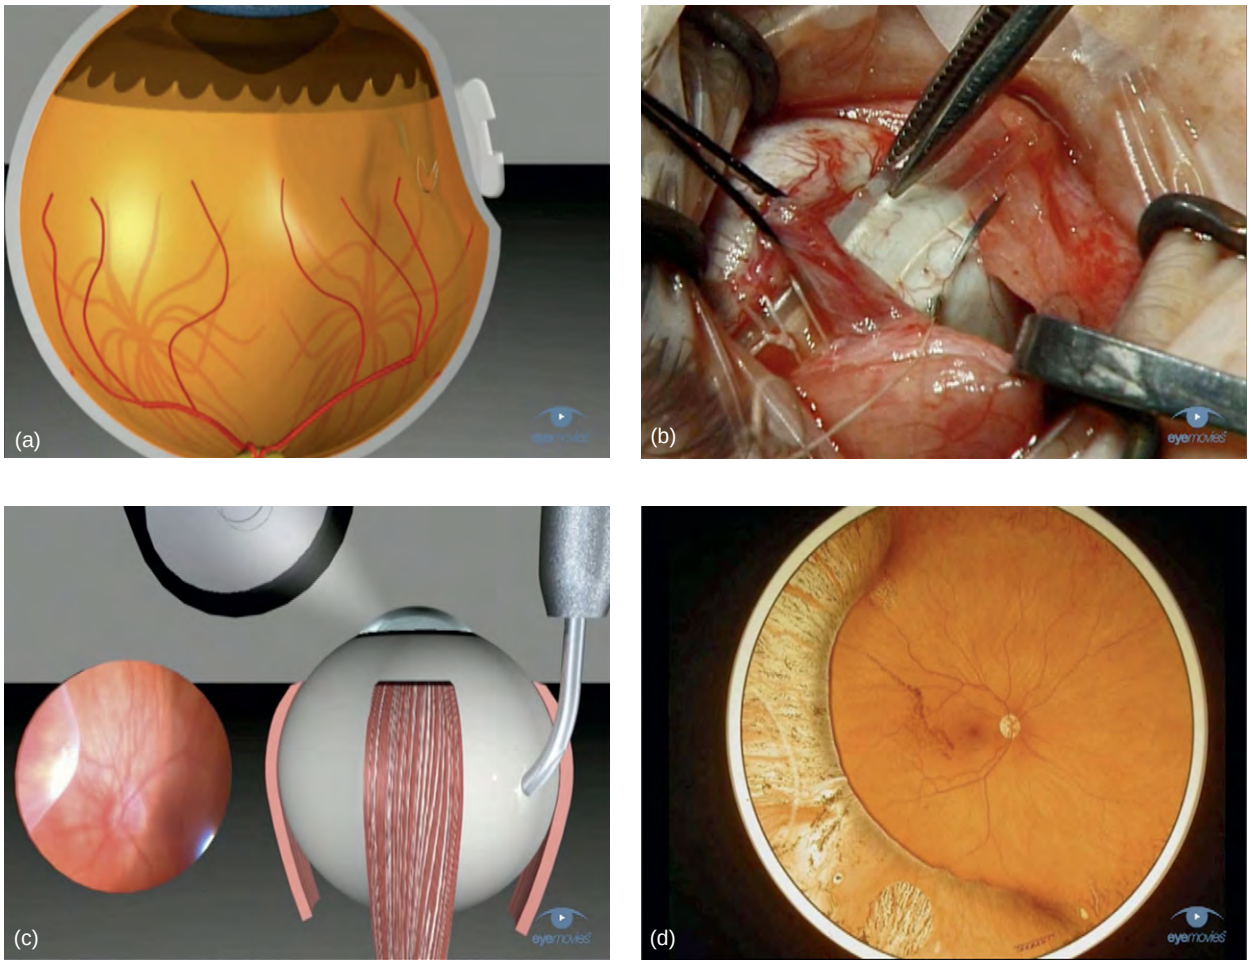

Figure 5 Scleral buckling surgery. (a) Schematic of explant placement on scleral surface. An underlying retinal tear is visible. (b) Silicone explant being secured to scleral surface using a 5/0 Ethibond suture. Part of the explant is positioned under a rectus muscle as shown. (c) Schematic of cryotherapy application to a retinal break viewing through an indirect ophthalmoscope. Inset photo demonstrates corresponding retinal whitening during cryotherapy application. (d) Schematic of postoperative scleral indent. Chorioretinal scars from previous cryotherapy are visible over the indent with successful retinal reattachment. Reproduced from Aylward, G. W., Sullivan, P. M., and Vote, B. (2007). *Vitreoretinal. Volume 1: Basic Techniques* (*DVD*). Surrey: Eye Movies, with kind permission from Eye Movies.

vitrectomy surgery as induction of a PVD is not required and direct relief of vitreoretinal traction at the tear can be achieved. A PVD is present in approximately 75% of people aged over 65. Therefore, the majority of patients with retinal tears is already presbyopic, minimizing the consequences of postoperative cataract formation.

RRD due to retinal hole or dialysis

Vitrectomy is rarely indicated in RRD secondary to retinal holes or dialyses, which usually have an attached vitreous. Surgically inducing a PVD in these typically young patients is often difficult, adding an unnecessary layer of complexity with increased risk of complications, for example, iatrogenic break formation. In addition, in the case of a dialysis, PVD induction would convert the break into a GRT.

Outcomes

Pneumatic Retinopexy

Pneumatic retinopexy is less invasive than scleral buckling or vitrectomy, with less local tissue damage and inflammation. Primary success rate in a selected patient group has been shown to be noninferior to scleral buckling in a multicenter, randomized, controlled trial by Tornambe and co-workers. A recent comprehensive review of 4128 eyes reported in the literature over a 21-year period (1986–2007) showed that pneumatic retinopexy has an overall primary retinal attachment rate of 74.4%, lower than scleral buckling or vitrectomy, with a final reattachment rate of up to 96.1%. Aphakic or pseudophakic patients appear to do less well, with primary retinal reattachment rates of 41–67%.

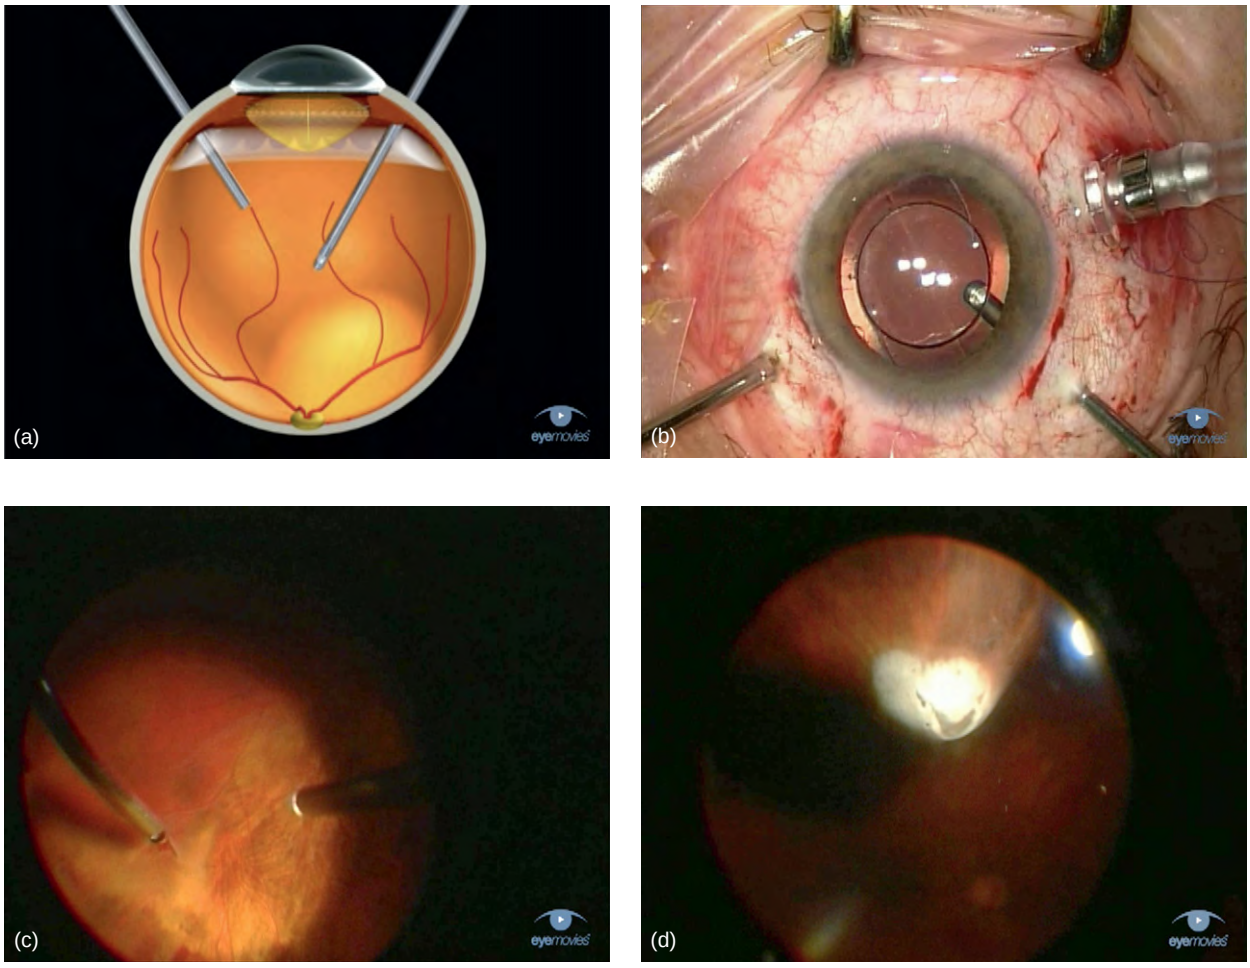

Figure 6 Pars plana vitrectomy. (a) Schematic of vitrectomy. Instruments are inserted 3.5–4mm posterior to the corneal limbus, entering the posterior segment through the pars plana. (b) Microscope view of standard instrumentation. Three scleral ports are usually required for vitrectomy. Instrumentation consists of a fluid infusion line, endoillumination, and vitrector (cutter). (c) Intraoperative view of vitrectomy for rhegmatogenous retinal detachment due to a retinal tear. Vitrectomy is being performed close to a retinal tear. (d) Intraoperative view of cryotherapy application to a retinal tear. Reproduced from Aylward, G. W., Sullivan, P. M., and Vote, B. (2007). *Vitreoretinal. Volume 1: Basic Techniques* (*DVD*). Surrey: Eye Movies, with kind permission from Eye Movies.

Scleral Buckling

Primary retinal reattachment occurs in over 90% of cases with scleral buckling alone, although up to 100% has been reported in small series. In patients with RRD and an attached macula, 90% achieve visual acuity of 20/30 or better at 6 months, although reduction in two Snellen lines of visual acuity occur in 10% despite anatomical success. Causes include macular epiretinal membrane and cystoid macular edema. Patients, who have their macular detached preoperatively, achieve a visual acuity of 20/50 or better in 38–71% of cases. A recent study involving foveal optical coherence tomography (OCT) imaging, by one of the authors (DGC), showed that postoperative resolution of foveal SRF can be delayed by over 6 weeks in 55% of patients, and complete resolution can take over 12 months. These patients have worse visual outcomes.

Pars Plana Vitrectomy

Primary retinal reattachment rates with vitrectomy are similar to scleral buckling, ranging from 65% to 100% with a mean of 85%. Final reattachment rate is 96–99%. Median visual acuity is 20/30 in macula-attached RRD, and 20/40 in macula-detached RRD. In an OCT imaging study by the same author (DGC), delayed resorption of foveal SRF was less common following vitrectomy, occurring in 15% of patients.

Complications

Intraoperative and postoperative complications for each procedure are discussed below.

Pneumatic Retinopexy

The main intraoperative complication of pneumatic retinopexy is formation of multiple small intravitreal gas bubbles or fish eggs during injection of gas, rather than a single large bubble as desired. This can result in subretinal gas migration, inadequate break tamponade, and treatment failure. This is principally managed by postoperative posturing to allow the gas bubbles to coalesce.

Postoperatively, new retinal break formation occurs in up to 20% of patients, and is a significant cause of surgical failure. PVR occurs in approximately 5% of patients.

Scleral Buckling

Intraoperative complications include inadvertent scleral perforation during suture placement, or SRF-drainage-related problems. Consequences include hypotony, choroidal or subretinal hemorrhage (with or without subfoveal tracking of blood), and retinal incarceration.

Postoperative complications include glaucoma, anterior segment ischemia (following encirclement), diplopia secondary to ocular dysmotility, change in refractive error and astigmatism, explant extrusion/intrusion or infection, and PVR. Contact lens users should be forewarned about possible lens-wear intolerance due to an irregular tear film and ocular surface following surgery, particularly as many patients who undergo scleral buckling are young myopes.

Pars Plana Vitrectomy

Intraoperative complications include iatrogenic retinal breaks, vitreous and retinal incarceration into the sclerostomy ports, lens trauma, and suprachoroidal hemorrhage.

Postoperatively, cataract formation is common and occurs in 81% of patients by 6 months. Raised IOP in the early postoperative period is common, and there appears to be an associated risk of late secondary glaucoma. PVR complicates between 5% and 12% of RRDs. Endophthalmitis following 20-gauge vitrectomy is rare.

Treatment Failure

In approximately 1 in 100 patients, it is not possible to reattach the retina despite multiple surgical attempts resulting in loss of vision. Consequences include chronic uveitis, rubeosis iridis, glaucoma, hypotony, band keratopathy, leukocoria, phthisis bulbi, and chronic ocular discomfort which may be severe enough to necessitate evisceration or enucleation of the eye.

New Developments

Smaller 25-gauge vitrectomy instruments were first introduced in 1990. Since then, techniques have evolved to enable sutureless transconjunctival surgery, with the benefits of reduced surgical time, less postoperative inflammation, more rapid wound healing, and improved patient comfort. As yet, small-gauge sutureless vitrectomy has not replaced 20-gauge systems, principally due to concerns regarding higher rates of endophthalmitis. A large retrospective series of 8601 patients from the Wills Eye Hospital demonstrated a 12-fold higher incidence of endophthalmitis with 25-gauge compared to 20-gauge vitrectomy. A smaller difference has been supported by other studies. Until this concern is adequately addressed, 20-gauge systems with conjunctival peritomy and suturing of ports will remain the gold standard.

The need for gas tamponade and postoperative posturing following vitrectomy for RRD has recently been challenged. A small prospective study of 60 patients by Martínez-Castillo and co-workers demonstrated a 98.3% primary reattachment rate without tamponade following complete drainage of SRF and laser retinopexy. This has not yet been supported by larger studies.

PVR remains to be the most important cause of failure of RRD treatment. Novel prophylactic treatment with adjunctive intraoperative 5-fluorouracil and low-molecular-weight heparin showed promise with decreased incidence of PVR in high-risk cases. However, this has not been reflected in unselected RRD undergoing primary vitrectomy, and may in fact be detrimental to visual acuity outcomes in patients with macula-attached RRD. Reducing the risk of PVR formation remains an important area of research.

Rod and Cone Photoreceptor Cells: Inner and Outer Segments

D H Anderson, University of California, Santa Barbara, CA, USA
D S Williams, UCLA School of Medicine, Los Angeles, CA, USA

Glossary

Cilium – An organelle that projects from a cell and contains a defined array of microtubules.
Electron microscope – A microscope that uses a particle beam of electrons to illuminate a specimen and create a highly magnified image. An electron microscope has much greater resolving power than a light microscope because the wavelength of an electron is much smaller than that of visible light.
Glycoconjugate – A class of carbohydrates covalently linked to proteins, lipids, and other types of molecules.
Mitochondrion – A cellular organelle that provides most of the chemical energy, in the form of adenosine triphosphate, for metabolism in eukaryotic cells.
Plasma membrane – A bilayer of lipid molecules that physically separates the interior of cells (i.e., cytoplasm) from the extracellular environment.

In this article, we focus on the organization of the photoreceptor inner and outer segments, with an emphasis on the structural similarities and differences between rods and cones. The process by which the photoreceptor outer segments replace their disk membranes; soma and synapse; and cilim, phototransduction, soluble protein dynamics, and the visual cycle are described elsewhere in this encyclopedia.

In the late nineteenth century, Schultze proposed an organizational framework for vertebrate photoreceptors that, today, has become a cornerstone of visual science. According to this duplicity theory, photoreceptors may be anatomically and functionally divided into two main groups: rods and cones. These terms emerged from early anatomical observations showing that the distal portions of photoreceptors, the so-called outer segments, are either cylindrical or conical in shape. However, it soon became clear that there were exceptions to the outer segment shape criterion, most notably in the foveas of some species where cone outer segments possess a distinct rod-like configuration. Therefore, with the passage of time, the definitions of rods and cones were relaxed somewhat to include the combined shapes of the outer and inner segments (**Figure 1**). More recently, light-sensitive ganglion cells without obvious outer segments have been identified.

Duplicity theory also stipulated that rods and cones may be distinguished functionally by the light levels to which they are tuned. Rods were regarded primarily as a sensitivity mechanism; whereas cones were considered to be an acuity mechanism, and a prerequisite for color vision. The predominance of rods in nocturnal species and of cones in diurnal species provided compelling evidence in support of this generalization.

With the advent of electron microscopy in the latter half of the twentieth century, it became apparent that there were also ultrastructural differences between rods and cones. In longitudinal sections, rod outer segments are visualized as a stack of hundreds of free-floating disks that resemble a stack of coins. The disk stack in rods is enclosed by, and separated from, the cell's plasma membrane, except at the base where new disks are formed (**Figure 2**, left). In cones, however, many and perhaps all of the disk membranes appear to be in continuity with the plasma membrane (**Figure 2**, right; **Figure 4**). This ultrastructural difference between rod and cone outer segments has been confirmed in a wide variety of vertebrates, and still remains a distinction with no known exceptions. In cross section, single-rod disks have a scalloped margin all of which are in alignment; in contrast, cone disks possess a single incisure that extends from the margin to the center of the disk.

The photoreceptor cell is the epitome of a specialized neuronal cell. It is dedicated to the absorption of light energy (photons) and transduction of that energy into an electrochemical signal that is transmitted throughout the retina and, ultimately, to the brain. The packing density of the inner and outer segments defines the spatial resolution of the retina. Where visual acuity is at a premium, the segments form a fine array, the density of which is limited only by the wave nature of light. Hence, in many retinas, the inner and outer segments are long, narrow structures that may be as small as 1 μm in diameter.

The photoreceptors form the outermost layer of the neural retina (**Figure 3**). Rod and cone outer segments are enveloped by microvilli (mv) that emanate from the apical surface of the retinal pigment epithelium (RPE). In rods, the outer segments abut the apical surface; but in many species, including humans, cone outer segments are slightly recessed from the apical surface (see **Figure 1**). A highly organized array of mv known as the cone sheath extends down from the apical RPE surface and ensheaths the cone outer segments. Cone outer and inner segments are also ensheathed by an extracellular matrix rich in glycoconjugates known as the cone matrix sheath (**Figure 4**). The inner segments lie between the outer segments and the photoreceptor cell nuclei. Broadly speaking, the inner segment provides the metabolic support for the outer segment.

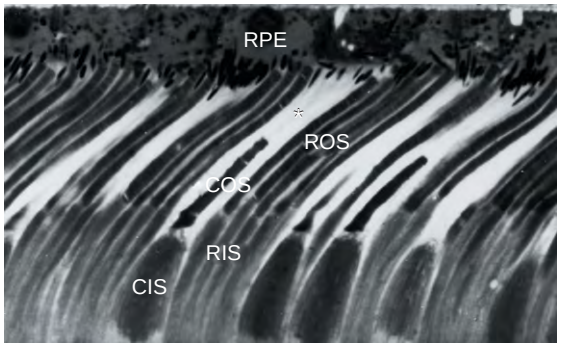

Figure 1 Light micrograph showing the photoreceptor cell layer in a monkey retina. RPE, retinal pigment epithelium; ROS, rod outer segment; RIS, rod inner segment; COS, cone outer segment; CIS, cone inner segment; *, cone sheath.

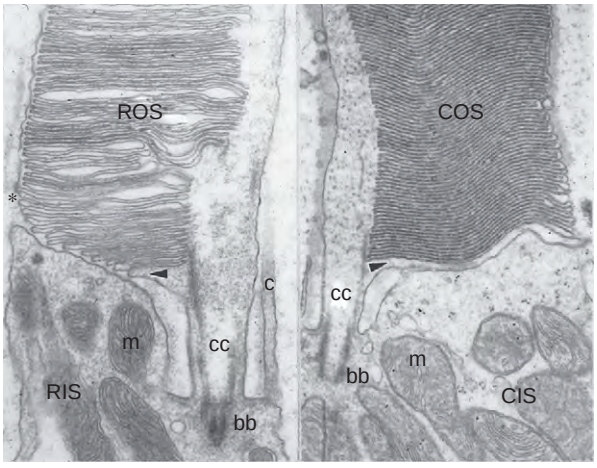

Figure 2 Electron micrographs illustrating the organization of disk membranes at the base of mammalian rod and cone outer segments. The only cytoplasmic link between inner and outer segments is through a connecting cilium. Arrowheads indicate growth points for the evagination of new disk membranes from the plasma membrane adjacent to the centric face of the connecting cilium. In cones, most disks retain a connection to the enclosing plasma membrane; whereas, in rods, only the most basal disks (below the asterisk) retain a plasma membrane connection. bb, basal body; c, ciliary process; cc, connecting cilium; CIS, cone inner segment; m, mitochondrion; RIS, rod inner segment.

The distal region of the inner segment, known as the ellipsoid, contains a high concentration of mitochondria that are excluded from the outer segment. The only cytoplasmic link between inner and outer segments is a connecting cilium (**Figure 2**). The proximal region of the inner segment, the myoid, is the primary site for the synthesis of proteins destined for the outer segment (**Figure 3**). Projecting from the lateral margin of the ellipsoid is an array of calycal processes containing longitudinally oriented, filamentous actin and myosin. In monkey cones, each ellipsoid contains an array of actin-containing cables that originate in the myoid region, converge as they course through the

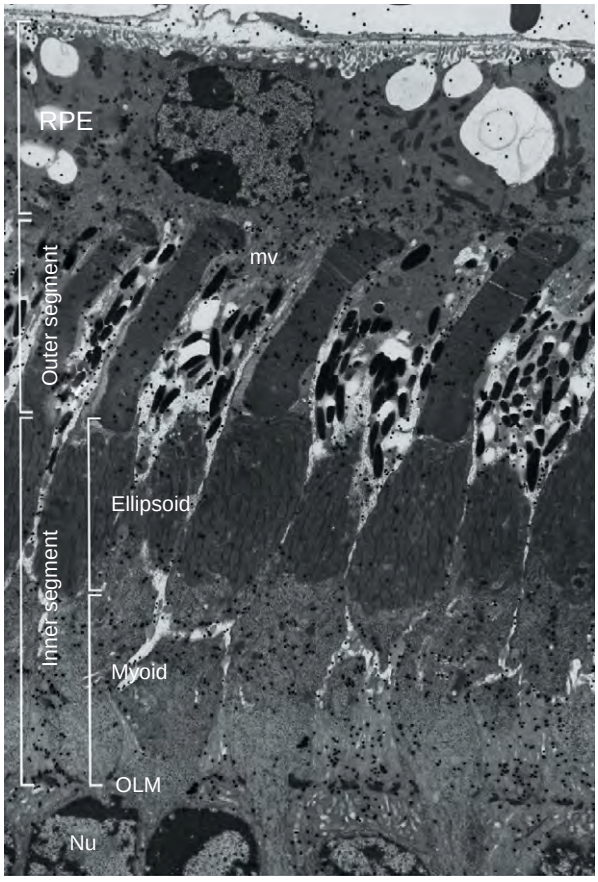

Figure 3 Low power electron microscopic autoradiogram of squirrel photoreceptors, illustrating the ellipsoid and myoid regions, the outer segments, and their relationship to the RPE. The black dots over the tissue are developed silver grains that signify sites of incorporation of a sugar residue (fucose) that had been labeled with a radioactive isotope (tritium). mv, microvilli; Nu, nucleus; OLM, outer limiting membrane; RPE, retinal pigment epithelium.

ellipsoid, and terminate within the calycal processes that form a circumferential ring at the base of the outer segments (**Figure 5**).

Just proximal to the myoid is the outer limiting membrane (OLM) (**Figure 3**). In longitudinal sections, the OLM appears as a demarcation line between the inner and outer retina. In reality, it is not a membrane but a series of aligned adherens junctions between photoreceptor cells, and between photoreceptor cells and adjacent radial glial cells (i.e., Mueller cells), that are linked to the cells' actin cytoskeleton. In lower vertebrates, the myoid region of the inner segment is quite labile, and is capable of expansion and contraction in response to changes in ambient lighting. These so-called retinomotor movements are considered to be a light-adaptive mechanism in many species of lower vertebrates.

Approximately 90% of the membrane protein in the rod disk and plasma membranes consists of the visual pigment opsin, a light-sensitive guanine nucleotide-binding protein

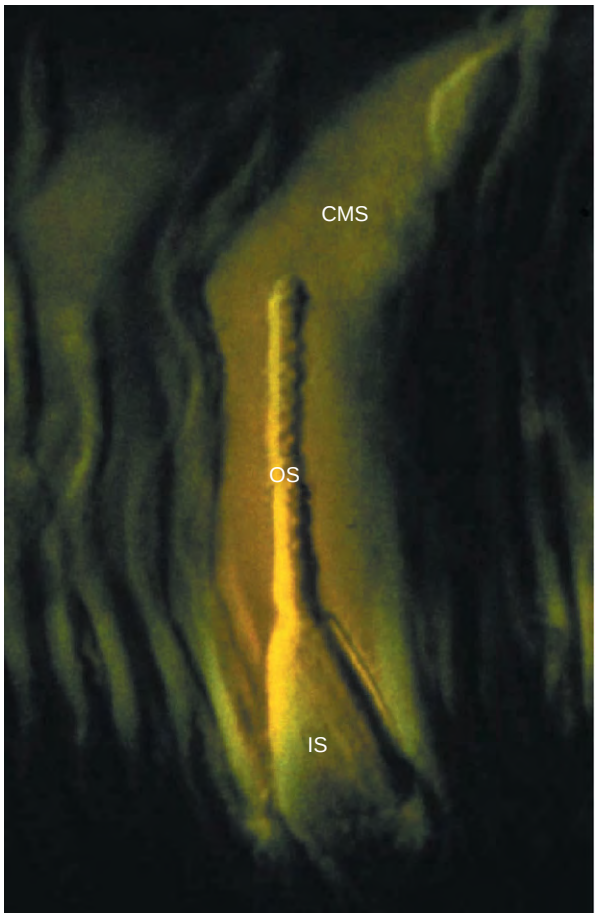

Figure 4 Longitudinal section of a human cone photoreceptor inner segment (IS) and outer segment (OS) labeled with a plant lectin (peanut agglutinin) conjugated to a fluorescent probe. The cone matrix sheath (CMS) (shown in yellow) is a distinct domain of the retinal interphotoreceptor matrix that is rich in glycoconjugates and envelops cone outer and inner segments. Modified from Hageman, G. S. and Johnson, L. V. (1991). Progress in Retina Research. In: Osborne, N. and Chader, J. (eds.) *Structure, Composition, and Function of the Retinal Interphotoreceptor Matrix*, Vol 10, Ch.9, p. 226.

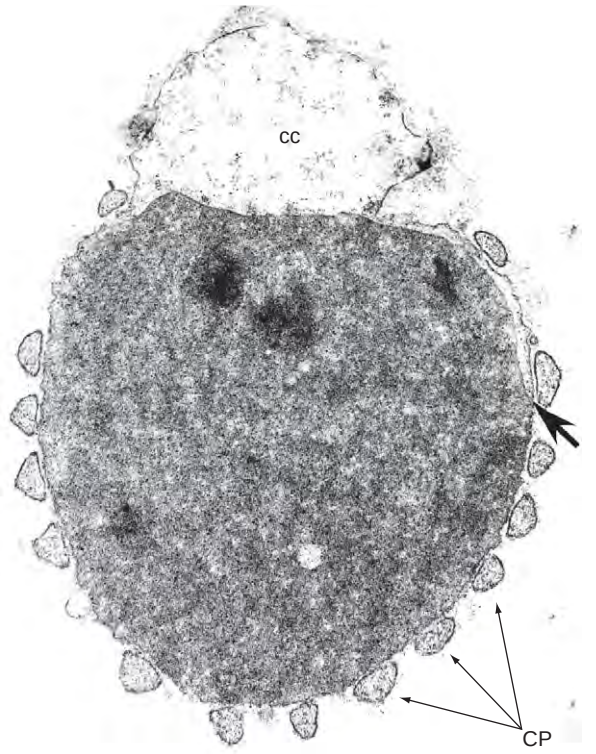

Figure 5 Electron micrograph of a tangential section through a monkey cone outer segment. The calycal processes (small arrows) that project from the ellipsoid form a basket at the base of the cone outer segment. At one point, the rim of the cone disk and the outer plasma membrane appear to be in continuity (large arrow), signaling a potential growth point. cc, connecting cilium; CP, calycal processes.

(G-protein)-coupled receptor. Cone outer segments contain homologous visual pigment proteins, also known as photopsins or iodopsins. Numerous other proteins that participate in the phototransduction cascade are also present in the outer segments. Rod outer segments, especially from bovine and rodent retinas, have been used widely in biochemical studies of structure and function. The ciliary connection between the inner and outer segments is quite fragile, such that outer segments are readily broken off in solution by shaking retinas that have been detached from the adjacent RPE. Following purification over a density gradient, relatively pure biochemical preparations of outer segments can be obtained. With additional steps, the disk and plasma membranes of rod outer segments can be separated from each other, and have thus been shown to contain some notable differences in protein composition. For example, the light-dependent cyclic nucleotide-gated channel and Na^+, K^+, Ca^{2+} exchanger proteins are restricted to the plasma membrane, while the retinal degeneration slow (peripherin/rds), rod outer segment membrane protein 1 (rom-1), and the ATP-binding cassette family A 4 (ABCA4) transporter proteins are present only in disk membranes. Opsin is present in both membrane domains. The disk membranes also contain two distinctive domains. Opsin is a ubiquitous component of rod disk membranes, except at their rims where a complex of peripherin/rds and rom-1 enables the formation of a loop that gives the disk its characteristic bilamellar structure.

In development, the outer segments form by repeated outgrowths or evaginations of the distal plasma membrane of the connecting cilium. In a mature photoreceptor cell, new rod and cone disks are also formed from evaginations originating from the centric face of the connecting cilium (**Figures 2** and **6**). The mature outer segment remains connected to the inner segment by what corresponds to the transition zone of the cilium, and what has been referred to historically as the ciliary stalk or connecting cilium. In recent years, it has been recognized that, while the photoreceptor cilium is highly unusual with its attached

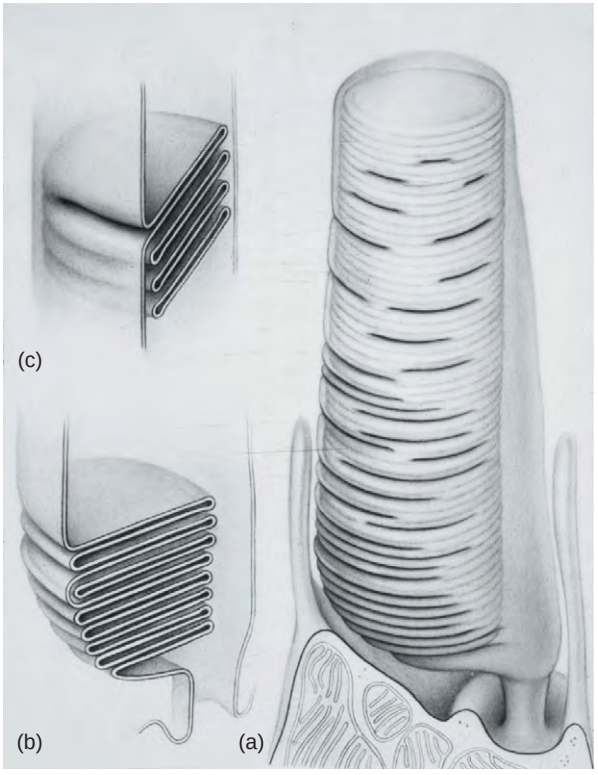

Figure 6 Schematic of the cone photoreceptor outer segment, inner segment, and connecting cilium (a). (b) Base of the cone outer segment and its relationship to the plasma membrane of the connecting cilium. (c) Illustration of the continuity between cone disks and the outer segment plasma membrane. network of outer segment disks, it is homologous to other primary cilia located elsewhere in the body. For example, like other primary cilia, it possesses microtubule motor proteins that may function in the transport of outer segment components. There are numerous other proteins shared by primary cilia and photoreceptor cilia. Thus, despite the extraordinary specializations of the inner and outer segments, the connecting link between them is an organelle that is highly conserved. This point has been made most poignantly by demonstrations in a variety of syndromic disorders, such as Senior Loken and Bardet Biedel syndromes. These disorders are characterized, in part, by retinal degeneration, as well as kidney and other disorders, caused by mutations in genes which encode ciliary proteins that subserve shared functions.

Rod and Cone Photoreceptor Cells: Outer-Segment Membrane Renewal

Glossary

Autoradiography – A technique used to localize radioactivity emitted by cells, tissues, or organisms that have been treated or injected with a radioactive isotope.
Electron microscope – A microscope that uses a particle beam of electrons to illuminate a specimen and create a highly magnified image. An electron microscope has much greater resolving power than a light microscope because the wavelength of an electron is much smaller than that of visible light.
Lysosome – An organelle in a cell that contains digestive enzymes.
Phagocytosis – The engulfing and internalization of particles by a cell.
Retinal pigment epithelium – A single layer of pigmented epithelial cells that borders the back of the sensory retina. The outer segments of the photoreceptor cells interdigitate with the apical processes of the retinal pigment epithelium cells.

Based upon their observations of photoreceptor disk membrane-like inclusions in the cytoplasm of rodent retinal pigmented epithelial (RPE) cells, A. Bairati and N. Orzalesi proposed in 1963 that the disk membranes of photoreceptor outer segments were in a dynamic state of turnover. A few years later, in a classic series of autoradiographic studies, Richard Young and his colleagues provided the first direct evidence that vertebrate rod photoreceptors continually replace their disk membranes. Following injection of radiolabeled amino acids into a series of frogs, a transverse band of radioactive protein became apparent at the base of rod outer segments within 24 h following injection (**Figure 1**). We now know that the main proteinaceous component of the phototransductive disk membranes is the visual receptor, opsin. Over the ensuing days, the band became progressively displaced toward the tip of the outer segment, and eventually became evident in inclusions within the cytoplasm of the RPE cells. Electron microscopic observations later revealed that packets of disks derived from the tips of rod outer segments were engulfed by microvillous processes on the apical surface of the RPE cells and internalized into the RPE cytoplasm. These membrane-bound inclusions, called phagosomes, were then degraded by the RPE. Young proposed the term outer-segment renewal to refer to the overall turnover process. It encompasses a number of stages, including protein synthesis, transport to the outer segment, disk formation, disk displacement, shedding, phagocytosis and degradation, all of which result in the vectorial flow of membrane from the photoreceptor inner segment to the RPE (**Figure 2**).

Many cell types have short lives and are replaced on a regular basis. However in a terminally differentiated cell, such as a photoreceptor cell, the components must be turned over to prevent the formation and build up of macromolecular byproducts that can interfere with cellular function. Accordingly, it is widely believed that the turnover of phototransductive membrane is part of a normal preemptive process to replace macromolecules before they become dysfunctional. Because phototransductive membrane is typically an extremely amplified membrane system, its turnover involves an extraordinarily high rate of synthesis and degradation of membrane proteins. Some nocturnal arthropods provide the most extreme examples, with the turnover of nearly all of their phototransductive membrane each day. Even at the more pedestrian rate of 10% per day, as found in rodent and primate rods, the turnover of disk membranes represents a major metabolic challenge for the photoreceptor and RPE cells. In each human retina, which contains approximately 100 million photoreceptor cells, an average of 9 billion opsin molecules turn over every second. Not surprisingly, therefore, the processes involved in disk membrane turnover are critical for photoreceptor cell viability, as shown with some of the first-studied rodent models of retinal degeneration. For example, in the RCS rat, phagocytosis by the RPE is defective, and in the retinal degeneration slow (rds) mouse disk membrane morphogenesis is blocked; photoreceptor cell death and blindness ensues in both these models.

Whereas the experiments using radiolabeled amino acids convincingly demonstrated the renewal of the rod outer-segment membranes, and the involvement of the RPE in the degradation phase, the case for cone outer-segment renewal was less compelling. In contrast to rods, no discrete band of radioactivity was detected at the base of frog cone outer segments; instead, it appeared to be distributed diffusely throughout the cone outer segment. However, in the cones of diurnal rodents, quantitative electron microscopic autoradiographic studies showed that a

concentration of radioactive glycoconjugates could be detected in the proximal portion of cone outer segments within a few hours after injection of radiolabled fucose (Figure 3). In retrospect, it is now appreciated that the banding pattern in rods is due to the confinement of newly synthesized membrane proteins to rod disks, which mature into discrete units. In contrast, cone outer-segment disks remain interconnected, so that radiolabeled protein is free to diffuse longitudinally throughout the disk stack. Studies demonstrating the presence of disk shedding in cones, and the presence of phagosomes in RPE cells overlying regions of high cone density, such as in the human fovea and in all-cone retinas, also helped to demonstrate that the unidirectional flow of disk membrane proteins, from inner segment to outer segment, and then to the RPE, occurred in cones as well as rods.

The *de novo* synthesis of opsin-containing membranes occurs mainly in the proximal region of the inner segment (i.e., the myoid). Membranes containing newly synthesized protein are then transported from the *trans*-Golgi network, through the ellipsoid, to the base of the connecting cilium (Figure 2). Opsin contains motifs that appear to be important for its targeting to the outer segment. The best characterized are its C-terminal amino acids. Missense mutations that affect this region result in mistargeting of opsin and underlie forms of inherited retinal degeneration in humans. It seems likely that a molecular motor, like a dynein, which travels toward the minus ends of microtubules, is involved in this vectorial transport. In support of this notion is the finding that opsin binds to tctex-1, a light chain of dynein, *in vitro*. Further studies have reported roles for a number of other proteins that appear to be important for the targeting and fusion of membrane near the base of the cilium. These proteins include small GTPases, such as ADP ribosylation factor 4 (ARF4) and the RAS oncogene-related protein RAB8. It is likely that RAB8 promotes membrane fusion near the base of the cilium, and may be recruited to the post-Golgi membranes by a complex of Bardet–Biedl syndrome (BBS) proteins; mutations in BBS proteins are responsible for BBS, which includes photoreceptor degeneration

along with defects in cilia throughout the body. In photoreceptors that have a high rate of delivery of disk precursor membrane to the outer segment, the site of membrane fusion appears as a periciliary ridge complex, where the surface area of the plasma membrane has been greatly amplified by forming a series of ridges and grooves around the base of the cilium.

Transport along the cilium to the site of disk membrane morphogenesis involves molecular motors and associated proteins. Myosin VIIa, an actin-based motor, participates in this transport, although there is a clearer requirement for the kinesin-2 family of microtubule motors. In the absence of functional heterotrimeric kinesin-2, opsin delivery to the outer segment fails, and the ectopic build up of opsin causes rapid photoreceptor cell death. A homodimeric kinesin-2, KIF17, may also function in ciliary transport of outer-segment proteins. A group of intraflagellar transport proteins appear to function in concert with kinesin-2 motors. These proteins, which function in anterograde transport in primary cilia in other cells, are present in the photoreceptor axoneme, and IFT88 is required for the assembly and turnover of the outer-segment disk membranes. The specific cargoes of the different motor systems along the photoreceptor cilium are not known, but it is likely that there are a variety of different routes along the cilium. For example, evidence indicates that opsin and the rim-specific protein, peripherin-rds, are transported by different mechanisms.

Historically, the process of disk formation in rods was thought to result from an invagination of the outer plasma membrane toward the centric face of the connecting cilium. However, in 1980, an alternative evagination model of disk membrane morphogenesis was proposed that could account for disk morphogenesis in both rods and cones. Over the years, experimental evidence has been generated in support of this model. According to this model, as successive evaginations of new disk membrane occur, a second membrane growth phase forms the nascent rims around the newly formed evaginations. In rod cells, rim formation occurs relatively quickly, so that only a small number of disks at the base of the stack remain continuous with the outer plasma membrane. The vast majority of rod disks are discrete units that form a stack, completely surrounded by the plasma membrane. In cone cells, however, the process of rim formation remains incomplete and a connection(s) between the disk and the outer plasma membrane is retained in many, if not all cone disks.

Although there have been some challenges to the evagination model of disk membrane morphogenesis, some key observations provide strong support. First, in contrast to mature rod disks, the evaginating membranes can be labeled with tracer molecules, showing that they are open to the extracellular milieu. Second, the nascent disks contain specific membrane proteins that are not found in mature disks, and they lack the proteins added at the stage of rim formation. This latter observation indicates that there must be a mechanism(s) to sort different groups of outer-segment proteins prior to disk membrane morphogenesis.

Most cells are responsible for the complete turnover of their lipids and proteins. However, vertebrate photoreceptor cells are unusual in that they have recruited another cell type, the RPE cell, for the catabolic phase of disk membrane turnover. The disposal of the distal outer-segment disks requires an interaction between the photoreceptor and RPE cells. When the photoreceptors are detached from the RPE, the distal disks are not shed, indicating that disk membrane shedding and phagocytosis by the RPE are not independent events (**Figure 4**). In 1976, Matthew LaVail reported that rod disk shedding in rodents followed a daily rhythm, and that a peak of shedding was apparent near the

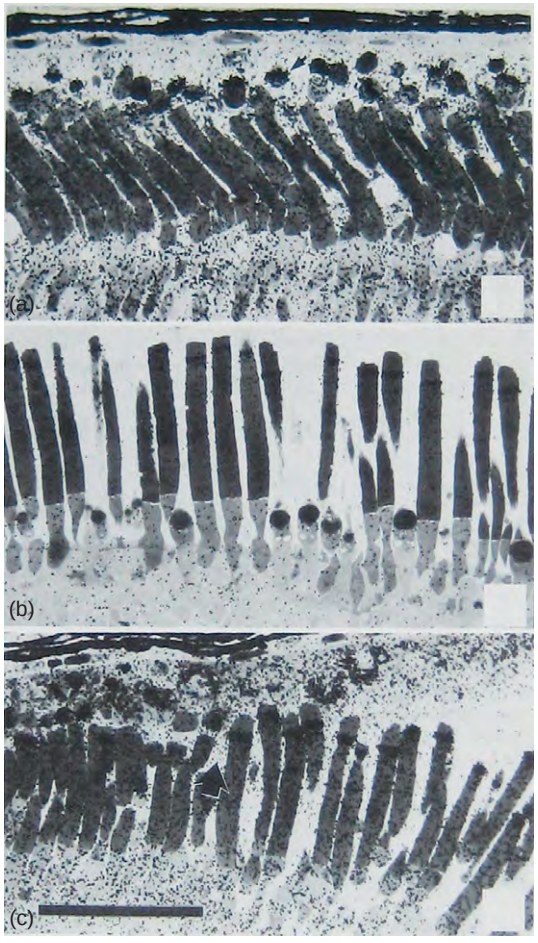

Figure 4 Light micrograph autoradiographs of retinas from frogs injected with radiolabeled amino acids. The band of radiolabel had migrated to the distal disks, and the eyecups were removed and placed in culture for the next shedding phase. Where the retina has remained attached to the RPE (a, and to the left of arrow in (c)), radiolabeled phagosomes are evident in the RPE. Where the retina was detached from the RPE (b, and to the right of arrow in (c)), the band of radiolabel is still evident at the distal end of each outer segment, indicating that the distal disks have not been shed. Scale bar = 50 μm. From Williams DS and Fisher SK (1987) Prevention of rod disk shedding by detachment from the retinal pigment epithelium. *Investigative Ophthalmology and Visual Science* 28: 184–187.

time of light onset. Subsequent studies have shown that the shedding of phototransductive membrane occurs at dawn in other vertebrates, as well as invertebrates. However, cone photoreceptors of most vertebrate species provide an exception to this rule; the peak of cone disk shedding typically occurs shortly after dusk (or light-offset). In crepuscular and nocturnal arthropods, the morphogenesis and shedding phases occur at dusk and dawn, respectively, resulting in different-sized light-absorbing structures (known as rhabdoms) between day and night. In this manner, the turnover of phototransductive membrane is coordinated to increase the efficiency of photon absorbance by individual photoreceptors at night.

The signaling mechanisms involved in the phagocytosis of disk membranes are not well understood; however, the requirement for a number of molecules has been determined. The c-mer proto-oncogene (*Mertk)* gene encodes a receptor tyrosine kinase, which is localized to the apical membrane of the RPE. In the absence of a functional form of this receptor, the ingestion of disk membranes does not occur, as is found in the retina of the RCS rat which carries a mutation in the *Mertk* gene. A role for the $\alpha v\beta 5$ integrin receptor and its ligand, milk fat globule EGF factor 8 (MFG-E8), has also been detected. This receptor appears to be required for the diurnal rhythm of shedding and phagocytosis since, in $\beta 5$ integrin knockout mice, disk membranes are still phagocytosed, but there is no peak of disk shedding at light onset.

Following internalization, the phagosomes are transported out of the apical region of the RPE where they subsequently fuse with lysosomes, and are degraded enzymatically. In mice lacking myosin VIIa, phagosome transport in the cytoplasm is impaired, thus indicating a role for this actin-based motor in the transport process. Microtubule motors also appear to be required in facilitating phagosome–lysosome fusion. A major enzyme in the degradation of opsin is cathepsin D, which is highly concentrated in the RPE lysosomes. Lysosomal enzymes have also been detected in RPE melanosomes, which may have a minor degradative role. The degradation of disk membrane proteins and lipids represents the end of the catabolic phase of the turnover process.

Rod Photoreceptor Cells: Soma and Synapse

R G Smith, University of Pennsylvania, Philadelphia, PA, USA

Glossary

Endocytosis – Active incorporation of external membrane into the cell, used to recover vesicular membrane that has fused with the external membrane at a chemical synapse.
Invagination – A permanent infolding of a cell's external membrane, associated in photoreceptors with their synaptic ribbons, and containing fine dendritic processes of bipolar and horizontal cells.
Mesopic – The 3-log unit range of background illuminance in which rod and cone signals temporally sum in cones and the cone bipolar pathway.
Poikilotherm – A species such as fish, turtles, and frogs whose body temperature varies with the environment.
Refractory period – A period immediately after an event, for example, the release of a vesicle of neurotransmitter, during which the next event cannot occur.
Rhodopsin – The rod pigment molecule that absorbs photons and starts the visual transduction cascade.
Ribbon – A presynaptic structure that collects vesicles of neurotransmitter for release.
Scotopic – The range of background illuminance from starlight to moonlight in which rods absorb one photon or less per integration time (~200 ms).
Spherule – The rod terminal, normally in the shape of a sphere, that contains synaptic ribbons.
Telodendria – Fine axonal processes extending laterally from the base of the cone terminal, which contact neighboring rod and cone terminals.

Introduction

Photoreceptors are the vertebrate retina's primary site for transduction of light into a neural signal. The rod photoreceptor is responsible for vision at night. Rods are essential for vision over the scotopic range (starlight through moonlight) into the mesopic range (twilight) where their signals mix with cone signals. In starlight they must transduce single-photon signals, but in twilight they function more like sensitive cones to temporally integrate photon signals and to adapt before finally saturating in bright daylight. The rod's exquisite combination of signal-processing mechanisms makes it a marvel of signal processing for a dedicated purpose.

Structure

Morphology and Topology

The rod is a specialized neuron consisting of an outer segment, inner segment, soma, axon, and axon terminal (Figure 1(a)). The biochemical pathways responsible for transducing light into an electrical signal are contained in the outer segment. The electrical signal passes to the inner segment where it is transformed by voltage-gated channels. The inner segment of the vertebrate rod lies just above the external limiting membrane. The rod soma lies in a variable location in the outer nuclear layer, connected to the inner segment above and the terminal below by the axon. For rods of most species, the soma is larger in diameter (~3–5 μm) than the outer segment. It contains the nucleus which holds the cell's DNA, necessary for development and to maintain the cell's biochemical machinery. Many mammalian species have ~20-fold more rods than cones, so the outer nuclear layer consists mainly of several layers of rod somas. Rods of most species fill the space between the cones, and are closely spaced (~100 000–200 000 mm^{-2}) to capture as many photons as possible.

Axon and Terminal

The rod axon, which carries the electrical signal from the soma to the axon terminal, varies in length depending on the species and the eccentricity (distance from central retina) of the rod. In para-foveal rods near the center of the primate eye, rod axons extend along with cone axons up to 200–400 μm laterally to allow the cone outer segments to be packed tightly together in the fovea and the axon terminals to be given adequate space outside the fovea to make their synaptic connections. In other mammals, the rod axon is shorter; in a cat it is vertical and typically extends ~50 μm through 6–10 layers of rod somas in the outer nuclear layer, and in guinea pig the axon is shorter, typically 10–25 μm, depending on the number of layers of rod somas. Typically, rod axons are ~0.5 μm in diameter, interspersed between rod somas and cone axons of 1–2 μm diameter (Figure 1(a)). The mammalian rod axon terminal is typically 2–3 μm in diameter, and is spherical; hence, it is

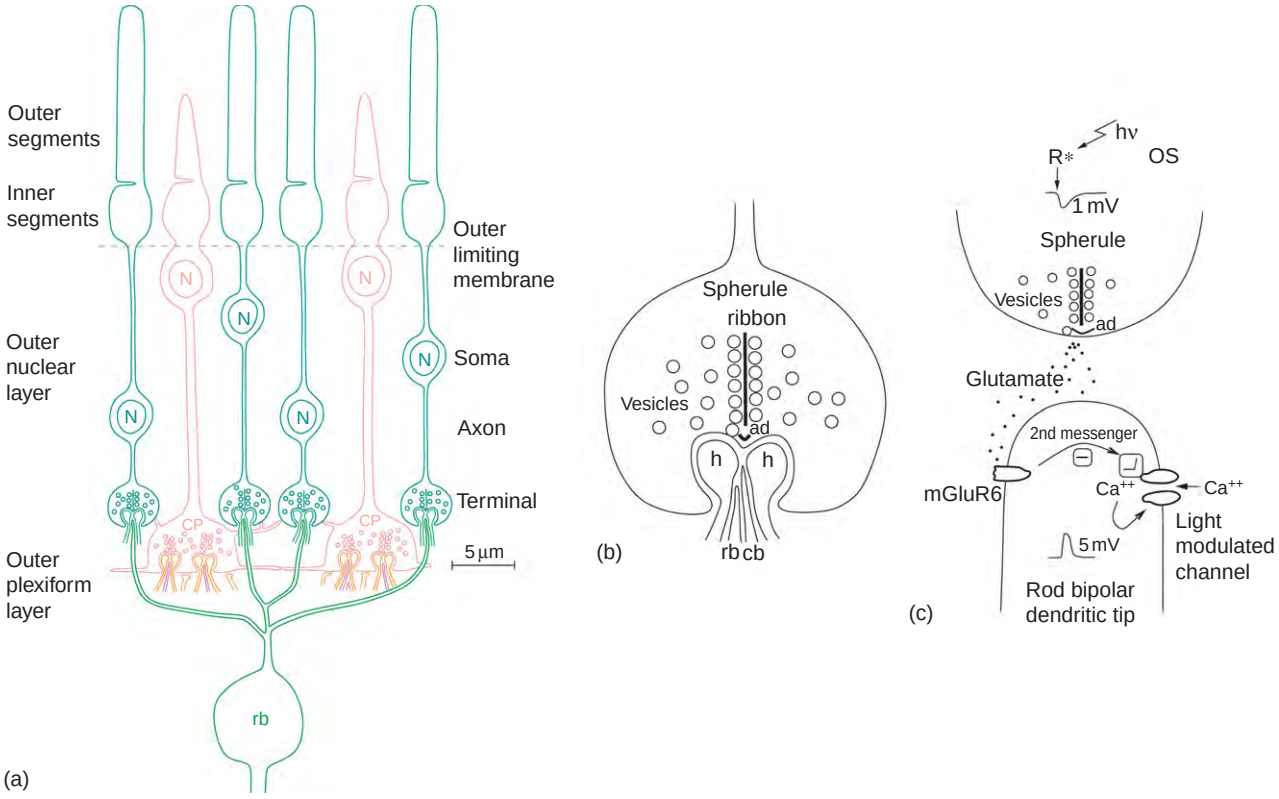

Figure 1 The rod is specialized to capture single photons in starlight but also functions in twilight. (a) Rods (blue-green) in most mammals and in distal primate retina extend vertically interspersed between cones (light red). The rod spherules are electrically coupled to cones at gap junctions on basal processes that emanate from cone terminals. At the bottom, a rod bipolar (green) collects signals from 20 to 100 rods, depending on the species. (b) The rod ribbon synapse sits at the apex of an invagination into the basal surface of the rod spherule. Attached to the ribbon are two rows of vesicles that contain glutamate. The vesicles are released at the active zone near the arciform density (ad). For each ribbon, two horizontal cell processes (h) and one invaginating rod bipolar cell dendrite (rb) extend into the spherule to receive glutamate from vesicles released at the ribbon. One type of OFF-cone bipolar (cb) also invaginates the spherule. (c) A photon absorption ($h\nu \rightarrow$ R*) in the rod outer segment (OS) generates a 1 mV hyperpolarizing signal, which travels down the axon to the rod spherule, where it slows glutamate release by the ribbon synapse. The glutamate level falls via transporters in the rod spherule's membrane and by diffusion out of the invagination. Glutamate unbinds from the mGluR6 receptors on the rod bipolar dendrite, which through an inverting second-messenger cascade opens the ion channel. The single-photon R* signal passes through two nonlinearities: the high-gain release of glutamate and the threshold nonlinearity in the second-messenger cascade. Calcium entering the rod bipolar's ion channel closes the channel after a delay, generating a ~5 mV response more transient than the rod's signal.

commonly called a spherule. The spherules of adjacent rods are located at different heights, allowing them to fit just above the cone terminals where they can be reached by cone telodendria and fine dendritic processes of bipolar cells.

Synapse

The rod makes chemical synaptic contacts onto one type of rod bipolar cell, one or more types of OFF-cone bipolar cell, and one type of horizontal cell at its axon terminal (**Figure 1(b)**). The synapse releases glutamate via small packets of membrane called synaptic vesicles, which are small (~30 nm) organelles, created by endocytosis from the cell's external membrane and filled with glutamate by transporter proteins. The vesicles diffuse freely around the cytoplasm while they are being filled. The presynaptic machinery in the terminal contains one or two dense structures called ribbons, because in cross section they are thin and extend vertically away from the cell's membrane, easily seen in electron micrographs or by confocal visualization of specific presynaptic proteins (ribeye, kinesin). The ribbon is thought to be a specialization to allow high release rates, for it collects several rows of vesicles and tethers them for release. The mechanism for vesicle release is complex and contains several dozen proteins, and its details are not yet understood, but it is known to be initiated by calcium ions binding to a receptor protein which causes the vesicle to fuse with the external membrane and thus release its contents into the extracellular space. The ribbon is thought to gather vesicles ready to be docked to provide a larger readily

releasable pool. As the rod is depolarized for long periods at night, its ribbon mechanism is specialized to release vesicles at a high rate continuously.

Invagination

The rod's ribbon synapse is located in a way similar to the cone's ribbon, in an extension of extracellular space into the bottom surface of the spherule called an invagination, where very fine processes of horizontal and bipolar cells extend to form postsynaptic specializations. Each invagination contains two ribbons, each of which is presynaptic to two horizontal cell dendrites from different horizontal cells. In addition, each ribbon is presynaptic to one rod bipolar cell, for a divergence from a rod to two rod bipolars. In addition, the rod terminal in some species contacts one or more types of OFF bipolar cells. The function of the invagination is unknown, but it has been suggested to limit diffusion of the neurotransmitter released by the cone or by horizontal cells for negative feedback.

Biophysical Properties

The inner segment and axon terminal of rods are similar to those of cones in that they contain several membrane-bound ion channels, including K_v, K_{Cn}, BK, and L-type Ca^{2+}. The K^+ channels (K_v, K_{Cn}, and BK) of the inner segment and soma are activated by depolarization, providing an outward current to balance the inward dark current through the light-modulated cyclic guanosine monophosphate (cGMP)-gated channels of the outer segment. These channels provide an adaptational influence, opposing the dark signal, and indirectly opposing the light signal by deactivating with hyperpolarization. The K_{Cn} channels in the soma, axon, and terminal underlying the hyperpolarization-activated current (I_h) provide a delayed depolarization when activated by hyperpolarization. The rod terminal's L-type Ca^{2+} channels ($Ca_v1.4$) uniquely include α 1F subunits and may have special gating properties in conjunction with CaBP4, a calmodulin-like binding protein that shifts the $Ca_v1.4$ gating activation curve to provide higher gain. In addition, the terminal contains a calcium-sensitive chloride current ($I_{Cl(Ca)}$) which provides signal enhancement because the chloride gradient is depolarizing in rods. However, the resulting chloride efflux is thought to downmodulate the calcium current. Further, the rod terminal contains a calcium-sensitive potassium current (BK) which limits depolarization and calcium entry, and calcium-induced calcium release (CICR) from internal stores which amplifies the internal calcium signal. The rod terminal contains a high-affinity calcium system which includes buffers, plasma membrane calcium ATPase pumps (PMCAs), ryanodine receptors, and inositol triphosphate (IP_3) receptors to modulate calcium release from internal stores. One possible reason for these specializations is that the calcium channels that trigger vesicle release must be modulated by a tiny single-photon signal and thus the system must have high gain. The rod terminal contains several transporters with special functions. Some of them transport glutamate, including at least two isoforms in the membrane of vesicles to load them with glutamate. A glutamate transporter sitting in the external membrane of the rod terminal is important for uptake of glutamate from the extracellular space.

Gap Junctions

The rod spherules in most vertebrates are electrically coupled by gap junctions to the neighboring cones. The gap junctions are made between the rod spherule and cone telodendria which are basal processes emanating from the cone terminals. This coupling allows rod signals to enter cones at twilight and to be carried through cone pathways to ganglion cells. In addition, rods in some, possibly all, mammals are directly coupled by small gap junctions which may reduce voltage noise in the rod terminal that originates in transduction and membrane ion channels.

Function

The Single-Photon Signal and Noise

The rod is faced with a difficult task. Vertebrate species active in night, such as most mammals, can see in starlight backgrounds when photons are rare and a rod receives a photon only every 20 min. Over the ~3-log unit range of scotopic backgrounds, a rod receives one photon or less per integration time (200 ms) so that its signal is binary. To generate a continuous visual image at such low backgrounds requires that signals from many rods be summed. A typical mammalian ganglion cell sums signals from several thousand rods, and can detect the signal from just one photon in that huge field. This extraordinary feat is a challenge because the single-photon signal is tiny, about 1 mV in amplitude. To detect such a tiny signal in a huge field of rods would be straightforward if all the rods were silent in the dark; but the mechanisms of transduction and synaptic transmission are noisy. The noise from the rods converging to a ganglion cell, if linearly summed with the single-photon signal, would completely mask it, preventing its transmission through the visual pathway. Therefore, the rod pathway has evolved mechanisms to remove the dark continuous noise before it is summed with photon signals.

Sources of Noise

The mammalian rod generates dark continuous noise of thermal origin in its transduction cascade with an amplitude of 10–30% of the peak single-photon signal.

In addition, the rod generates thermal isomerizations of its pigment molecule rhodopsin, called dark thermal events, at a rate equivalent to starlight on a cloudy night. The signals generated by dark thermal events are identical to the single-photon signal, so they appear as real photons from the visual environment and are sometimes referred to as dark light. Another source of noise is variability in the single-photon signal's amplitude. Further, the rod synapse generates robust noise from fluctuation in vesicle release, which masks single-photon events in a way similar to the dark continuous noise. These sources of noise would not be a problem for detecting a single-photon signal from one rod, but if the signals of more than 10 rods were linearly summed, the noise would mask the single-photon signal. To mitigate the problem, synaptic convergence in the rod pathway is accomplished in several stages. The first stage of convergence, from rods to the rod bipolar, is limited to between 20:1 and 100:1 depending on the species, but even this limited amount of convergence would mask the rod signal without special synaptic mechanisms.

Synaptic Transfer Function: High Gain and Temporal Filtering

The rod ribbon synapse is specialized to transmit the rod signal at scotopic backgrounds. It is thought to transmit a binary single-photon signal because, over the range of starlight to moonlight, single-photon events predominate, and when measured with brighter flashes, the variance of the rod bipolar response saturates at the single-photon level. The rod's presynaptic release function (vesicle release as a function of voltage) has very high gain, possibly as high as $\sim$1 mV e^{-1}-fold change, allowing the tiny single-photon signal to modulate a large fraction of the dark release rate. Indeed, the rod's calcium channels, high-affinity buffering, internal calcium stores, and PMCA are thought to participate in the high-gain release, to maximize modulation of vesicle release by the 1 mV hyperpolarization of the single-photon signal. In addition, the postsynaptic half of the rod synapse in the rod bipolar dendrite includes several mechanisms specialized for its unique single-photon function (**Figure 1(c)**). It contains a second-messenger cascade that inverts the signal. A photon signal causes a drop in the rod's glutamate release, which reduces glutamate binding to the postsynaptic mGluR6 receptor to deactivate the second-messenger cascade, opening the postsynaptic ion channels and depolarizing the rod bipolar. The second-messenger cascade includes several steps of temporal filtering, which remove the high-frequency components of the dark continuous noise. In some species (e.g., salamander), the synaptic filter in the rod synapse is $\sim$10-fold slower than the corresponding cone synapse. This matches the slower rod transduction response and allows more complete removal of the noise. In mammals, the light-modulated ion channel in the rod bipolar dendrite is blocked after a short delay by calcium entering the channel. The effect is to generate a transient that limits the duration of the light response in the rod bipolar.

Rate of Vesicle Release

The random release of vesicles by the rod ribbon is a major source of noise for the rod pathway. Although the details of the ribbon's release mechanism are not known, it is stochastic (noisy), similar to a modulated Poisson distribution, for which the standard deviation is equal to the square root of the mean. The rod's ribbon synapse is similar to other ribbon synapses in the cone and bipolar cell, but its challenge is simpler and yet more extreme. The rod's binary signal simplifies the requirements for the synapse; it must only transmit two discriminable levels, signifying the presence or absence of a photon. However, to transmit a discriminable level, the rod must drop its calcium level, in response to a 1 mV hyperpolarization, by a fraction adequate to modulate its random release by more than one standard deviation over the single-photon signal's rise time (100 ms). The rod's rate of vesicle release is thought to be $\sim$100 s^{-1}, equivalent to 10 vesicles in 100 ms, with a standard deviation of $\sim$3 vesicles, which would be adequate if the release were modulated by more than 30%, but the 1 mV single-photon signal is thought to modulate the rod's calcium channels by only 20%. This implies either (1) a higher release rate, for example, 250 ves/s, (2) a higher voltage gain for calcium-channel gating, (3) an unknown mechanism to remove vesicle fluctuation noise, or (4) an unknown mechanism for amplifying the single-photon signal so that it can modulate a greater fraction of release. There is some evidence of a refractory period that could generate more regular release. Protons released along with a cone photoreceptor's vesicles bind to the local calcium channels which may generate a short refractory period, allowing release to be more regular. If release in this case could be more regular than a Poisson distribution, it raises the question of why synaptic release is typically found to be Poisson-like.

Synaptic Transfer Function: Nonlinear Threshold

The second-messenger cascade in the rod bipolar dendritic tip contains a nonlinear threshold to process the single-photon signal embodied in the binding of glutamate to the mGluR6 receptor. The rod bipolar's dendritic ion channels do not open unless the rod signal rises above the nonlinear threshold. This mechanism removes much of the dark continuous noise remaining after the cascade's temporal filter. When the peak amplitude of the single-photon signal falls below the nonlinear threshold,

the photon signal is lost, resulting in a false-negative, reducing the quantum efficiency of vision. When the peak amplitude of the continuous dark noise rises above the nonlinear threshold, a false-positive event is generated, which may mask individual real photon events, confounding their detection. A high nonlinear threshold will reduce the false-positive rate, but cannot reduce the rate of dark thermal events because they are identical to real photon events. Therefore, the dark thermal rate will mask a low false-positive rate, obviating the need to reduce the false-positive rate to zero. The optimal level for the nonlinear threshold thus is a compromise between false-negative and false-positive rates, and depends on the level of continuous noise, the variability of the single-photon signal, and the thermal event rate. The optimal level for the threshold is suggested by some studies to be in the range of 0.4–0.8 times the peak amplitude of the single-photon signal, which will cause a false-negative rate of ~30–50%. In some studies, the optimal level was suggested to be 1.3 times the peak amplitude of the single-photon signal, thus losing most of the photon signals. The discrepancy between these studies emphasizes that not all the details of the rod synapse are understood. However, it is clear that when signals from 20 rods are summed in a rod bipolar cell, the nonlinear threshold reduces the noise level enough to allow a single-photon signal to be detected downstream in the visual pathway.

Electrical Coupling in Starlight

The electrical coupling between rods not only reduces their voltage noise by averaging their signals, but also reduces the amplitude of the single-photon signal. The amplitude of the single-photon signal is reduced proportionate to the equivalent number of rods, but the noise amplitude is reduced only by the square root of the equivalent number of rods coupled, which produces a net reduction in signal-to-noise ratio at each rod synapse. This type of lateral electrical coupling would not affect performance if the rod bipolar were to sum rod signals linearly, for example, without the nonlinear threshold, but in that case the noise would swamp single-photon signals as described above. The nonlinear synaptic threshold of the rod synapse depends, for its noise-reduction effect, on the amplitude of the single-photon signal, implying that electrical coupling between rods reduces the signal-to-noise ratio of the single-photon signal transmitted to the rod bipolar cell. This paradoxical result suggests that the gap junctions may be modulated by light or by the circadian clock. Alternately, the distribution of each single-photon signal to several nearby rod terminals by electrical coupling may allow vesicle fluctuation noise from rod ribbons to be averaged downstream. The amount of improvement in this case would depend on the gain and degree of nonlinearity and the amount of noise in rod vesicle release.

Electrical Coupling in Twilight

At mesopic backgrounds, rods receive ~1–1000 photons per integration time, so they temporally integrate photon signals and function more like cones except that their response gain is 30-to100-fold higher than the cone signal. As the rod synapse is specialized for single-photon signals and the rod bipolar pathway is specialized for high-gain spatial summation, the robust signals in rods at twilight need an alternate pathway. The electrical coupling between rods and cones allows twilight signals to pass from rods into neighboring cones and thence into cone pathways, where, as the background level increases, the rod component drops as rods saturate or adapt and the rod-cone coupling is downmodulated. In most mammals, the rod–cone coupling is not selective for cone type, so different cone spectral types have a similar rod contribution. This is convenient because opponent color signals computed by subtraction in retinal circuits can then remove the rod contribution. The mixing of the cone's signal with the higher-gain rod signal represents a form of adaptation because it extends by 2–3 log units the background range over which the cone ribbon synapse can transmit a signal. Rods of some species (frog, turtle, and fish) are much larger in diameter than mammalian rods and therefore, when warm, generate more dark thermal events and are more likely to receive multiple photon events at scotopic backgrounds; so in this case rod–rod coupling imitates mesopic cone–cone coupling and is advantageous. However, at low temperatures these poikilotherms (cold-blooded species) have a low dark thermal event rate and can respond to stimuli that evoke single-photon signals.

Negative Feedback

The rod ribbon synapse is similar to the cone ribbon synapse in that two horizontal cell dendritic processes are postsynaptic to each ribbon. The horizontal cell is the type B axon terminal (HBat; H1 in primate) which contacts only rods and is known to carry exclusively rod signals. The HBat is therefore considered to be electrically isolated from its cone-driven soma and dendritic tree. The function of this horizontal cell appendage is thought to be feedback to rods, but little evidence exists for negative feedback at the rod terminal. In salamander, the buffer 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) when applied in the perfusion bath *in vitro* blocks the shift in the calcium current originating in horizontal cells, suggesting that rod horizontal cell feedback functions in a way similar to cone horizontal cell feedback. The HBat collects from several hundred to several thousand rods, making it a good candidate to collect an average rod signal in starlight to control, through negative feedback, the rods' release of neurotransmitter. One likely possibility is that feedback to

rods helps to closely regulate the synaptic threshold for neurotransmitter release, to provide maximal gain for transmitting the tiny single-photon signal. Corroborating evidence for this role exists in recordings from ganglion cells at scotopic backgrounds where the antagonistic receptive field surround has been reported as hidden (summing nonlinearly with the receptive field center) and is only evident when a light stimulus is also applied to the center. This would be expected in the case where negative feedback from the HBat to the rod must pass through the rod synapse's nonlinear threshold to be sensed by the rod bipolar pathway.

Conclusion

The rod functions both at night and in twilight, but is specialized to transduce signals over the scotopic range of illuminance from starlight to moonlight where photons are rare. The single-photon signal is tiny and would be swamped by the dark continuous noise present in a large array of rods, but the rod ribbon synapse contains several mechanisms to reduce the noise and amplify the single-photon signal. Horizontal cells are thought to provide negative feedback at the rod synapse, and may provide a means to regulate the presynaptic release of neurotransmitter to optimize the single-photon signal. The balance between signal and noise in the rod's signal processing mechanisms is delicate. However, the rod's striking ability to capture and transmit single-photon signals suggests that each of its components has a specific function, and that biology has found for each a nearly optimal solution.

Role of Complement in Ocular Immune Response

P Jha, P S Bora, and N S Bora, University of Arkansas for Medical Sciences, Little Rock, AR, USA

Glossary

Complement factor H (CFH) – It regulates the alternative pathway of complement activation.
Complement regulatory proteins (CRegs) – These regulate complement system.
Experimental autoimmune anterior uveitis (EAAU) – An animal model of human idiopathic autoimmune anterior uveitis.
Membrane attack complex (MAC) – The end product of complement activation that forms pore and cause lysis of cells.

Introduction

The complement system consists of a large group of plasma and membrane-bound proteins and is an important part of the innate immune system. It is critical for the defense against infection and in the modulation of immune and inflammatory responses. The components of the complement system can be divided into two categories: the first category is comprised of the proteins that initiate and participate in the activation of complement pathways, and the second category comprises the proteins that regulate complement activation (Figure 1). The proteins in the first category are present in an inactive form and are activated either by cleavage by other components or by conformational change in their structure leading to the activation of the complement cascade. The activation of the complement system leads to the release of biologically active peptides like anaphylotoxins (e.g., C3a, C4a, and C5a) and formation of membrane attack complex (MAC).

Activation of Complement System

The complement system can be activated via three distinct pathways, namely the classical, the alternative, and the lectin pathways. The classical pathway can be activated when complement component C1 (which is a complex of C1q, C1r, and C1s) binds to antigen-bound IgM or IgG or when it binds to substances such as C reactive protein. This binding induces changes in conformation of C1q, which results in sequential activation of C1r and C1s (both are serine proteases). The activated C1 complex then cleaves C4 and C2 to form the C4bC2a complex, which is called C3 convertase, because it cleaves C3. The alternative pathway provides a rapid, antibody-independent route of complement activation and amplification. In the alternative pathway, C3 is activated (cleaved) either directly by enzymes or spontaneously when it interacts with certain activating surfaces (e.g., zymosan and lipopolysaccharides). The membrane-bound C3b (cleaved fragment of C3) binds to complement factor B that is cleaved by complement factor D into Ba and Bb. The C3bBb complex then can cleave more C3 and thus activating and amplifying the whole complement cascade. The lectin pathway is activated by interaction of certain serum lectins, such as mannose-binding lectin (MBL), with mannose and *N*-acetyl glucosamine residues present surfaces of pathogens. The binding of lectins to mannose activates the MBL-associated serine proteases (MASP-1 and MASP-2) that are functionally similar to C1r and C1s of classical pathway. MASP-1 and MASP-2 then cleave C4 and C2 to generate C4bC2a complex (C3 convertase).

Although the complement system can be activated by three pathways, all the pathways converge to a common step that results in the formation of C3 convertase. After the C3 convertase is formed, the downstream process (also known as terminal pathway) is activated. Cleavage of C3 results in the release of the fragments C3a and C3b. C3b binds to the C3 convertase to form C5 convertase (C4b2a3b for classical as well as lectin pathway and C3bBb3b for alternative pathway). C5 convertase cleaves C5 into C5a and C5b. C5b binds to C6 to form C5b6 complex that subsequently binds to C7 and then C8. Once C8 is bound to the complex, then the C5b678 complex inserts into lipid membrane where several C9 molecules bind to the complex to form a pore-forming polymer on the membrane. The deposition of MAC on a cell surface such as those of bacteria causes the formation of pores in the membrane that leads to lysis of the cells.

Regulation of the Complement System

The second category of proteins of complement system comprises the family of proteins called complement regulatory proteins (CRegs). The activated complement system is not equipped to distinguish between self and non-self cells. Therefore, the complement system has a potential to also destroy self components if left unregulated. The body protects itself from complement-mediated damage by expressing various CRegs that regulate the complement system at different stages of the complement activation cascade. CRegs can be classified into two

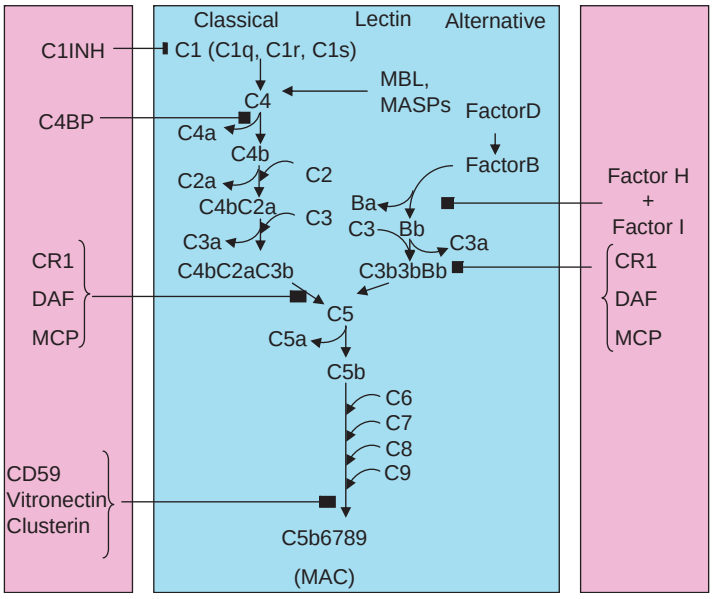

Figure 1 The complement system. Complement components and complement activation pathways are shown in the middle box. Complement regulatory proteins (CRegs) shown in the side boxes regulate the complement system at various check points.

categories: membrane bound and soluble proteins. Decay accelerating factor (DAF, CD55), membrane cofactor protein (MCP, CD46), complement receptor 1 (CR1, CD35), and membrane inhibitor of reactive lysis (MIRL, CD59) are important membrane bound CRegs. As mentioned before, these CRegs regulate the complement system by blocking/degrading the different components at various stages of the cascade. DAF regulates the activation of C3 and C5 and MCP acts as cofactor for factor I, which cleaves and inactivates C3b. CR1 has both DAF and MCP functions. CD59 regulates the assembly and function of MAC. Crry (512 antigen) is a membrane-bound CReg that is present only in rodents and has both decay accelerating and cofactor activities. C1 inhibitor (C1INH), C4-binding protein (C4bp), complement factor H (CFH), and complement factor I (CFI) are some of the important soluble CRegs. C1INH inhibits C1, whereas C4bp increases the cleavage of C4b by CFI. CFH is a cofactor for factor I-mediated cleavage of C3b and also has decay accelerating activity against the alternative pathway C3 convertase, C3bBb.

Complement System and Protection of Eye

The complement system is critical in protecting ocular tissues and is also involved in constant immune surveillance of the eye. A functionally active complement system that is activated at low levels is present in the normal eye even in the absence of any inflammation. Along with the functionally active complement system, several CRegs, such as DAF, MCP, CD59, factor I and factor H are also differentially expressed in eye. These CRegs are also functionally active and provide a perfect balance between the activation and regulation of the complement system. Any disturbance in this balance causes inflammation in the eye. For instance, if the CRegs present in the eye are inhibited, the activation of complement system is left unregulated and hence is amplified. This results in the inflammation of the eye. Similarly, if the complement system is activated by external factors such as zymosan, inflammation is initiated in the eye. This inflammation can be controlled by inhibiting the complement system. Therefore, the continuous presence of a functionally active complement system (i.e., finely regulated) ensures that a rapid immune response can be generated in case of a biological or chemical insult to the eye.

Complement System and Ocular Immune Responses

Ocular Tolerance

The eye is an immune-privileged site. If an antigen is introduced into the AC, there is a deviation of immune response to that antigen and systemic tolerance is developed against that particular antigen. This phenomenon is known as AC-associated immune deviation. Within the eye, iC3b, the activation product of C3, plays an important role in the generation and maintenance of tolerogenic/suppressive antigen-presenting cells (APCs). iC3b binds to complement receptor 3 (CR3) on the APCs (e.g., dendritic cells) and this interaction results in increased

expression of anti-inflammatory cytokines, such as TGF-β2 and IL-10, instead of inflammatory cytokines, such as IL-12. Thus, within the eye binding of iC3b to CR3 leads to the development of tolerance and ocular immune privilege.

Autoimmune Uveitis

Activation of complement system has been implicated in the pathogenesis of autoimmune anterior uveitis (AU) in humans and experimental autoimmune anterior uveitis (EAAU) in rats. EAAU is an animal model of human idiopathic AU and is induced in Lewis rats using antigens purified from the iris and ciliary body. There is a direct correlation between intraocular complement activation and disease activity in EAAU. In the EAAU model, the complement system is required to mount the antigen-specific CD4+ T-cell-mediated immune responses that cause inflammation in the anterior segment of the eye. The complement system contributes to the immune response in EAAU by regulating the production/expression of immune mediators, such as IFN-γ, IP-10, ICAM-1, and LECAM-1. The potential role of the complement in EAAU is summarized in **Figure 2**. In EAAU, the expression of various CRegs on ocular tissues is upregulated. If the function and/or expression of these CRegs is inhibited, then the inflammation is more severe and the duration of the disease is prolonged. This exacerbation of the disease is the result of excessive complement activation due to loss of regulation by CRegs. In the absence of CReg-mediated control of complement activation, more C3 convertases are formed, leading to more MAC formation and deposition. Apart from EAAU, the complement system also plays an important role in other animal models of uveitis such as experimental autoimmune uveoretinitis, which is an animal model for posterior uveitis. Although the complement system appears to be a potential target for therapeutic purposes, more research is required for designing anticomplement therapy to treat uveitis. Future studies identifying the contribution of each complement activation pathway will help in the development of more efficient and effective therapies for uveitis.

Complement and Age-Related Macular Degeneration

Age-related macular degeneration (AMD) is one of the leading causes of vision loss among the elderly population. As the name suggests, AMD is caused by the damage of macula that leads to the loss of central vision. There are

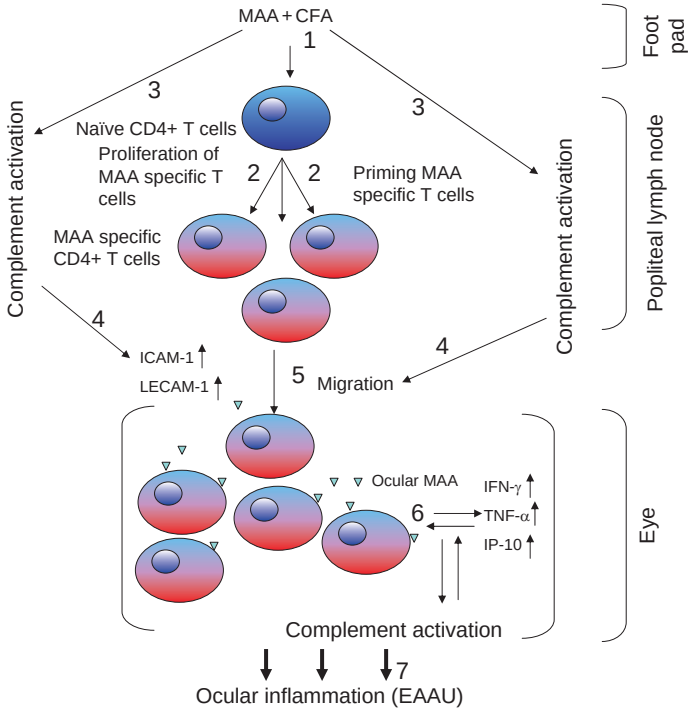

Figure 2 Role of the complement in EAAU. In EAAU animal model, ocular inflammation is induced by subcutaneous injection of melanin-associated antigen (MAA) emulsified in CFA (1) in the foot pad of male Lewis rats. This is followed by complement activation accompanied by priming and proliferation of MAA-specific $CD4^+$ T cells in popliteal lymph nodes (2). This step requires activation of the complement system because, in the absence of complement system, this step is inhibited. Complement activation (3) upregulates the expression of docking molecules like ICAM-1 and LECAM-1 (4), which results in migration of MAA-specific T cells to the eye (5). T cells recognize the MAA present within the eye and are further activated to express pro-inflammatory cytokines as well as chemokine (6). The complement system is also activated in the eye and results in ocular inflammation (7).

two types of AMD: dry (nonneovascular) and wet (neovascular). Studies conducted during the past 5 years have established that AMD is also an immunologic disease, as the complement system plays an important role in its development and its pathogenesis. In humans, unregulated complement activation is central to the pathogenesis of both types of AMD. In dry AMD, complement activation products are elevated in patient's serum. Drusen are the abnormal extracellular deposits underneath the basal surface of retinal-pigmented epithelium. The complement system has been implicated in the formation of drusen and various complement activation products (C3a, C5a, and MAC), and complement regulatory proteins (factor H, CR1, CD46, and Vitronectin) are present in drusen of patients with AMD.

One of the most convincing pieces of evidence that the complement system plays a central role in the immunopathogenesis of AMD is the association between polymorphisms of the complement factor H gene (HF1) and significantly increased risk of AMD in humans. This polymorphism occurs at position 402 of the codon-encoding factor H. If at this position a tyrosine residue is present, then the risk of AMD is reduced. However, if at this position a histidine residue is present, then there is a significantly higher risk to develop AMD. The variant of factor H with a tyrosine residue at position 402 (CFH_{YY402}) is called a protective variant and the variant with a histidine at position 402 (CFH_{HH402} or CFH_{YH402}) is called the risk variant for AMD. Due to the variation, the risk variant is less efficient in regulating the complement system compared to the protective variant. The replacement of a tyrosine residue results in a decreased ability of factor H to degrade C3. A similar polymorphism in complement component C2 and factor B is also associated with AMD. As mentioned before, both of these components belong to the first category of the complement system that participates in its activation. However, the effect of risk variation in these two complement components on their activity is different from that of factor H. In the case of factor H, the mutation that leads to the risk variant reduces the activity of factor H. In contrast, the mutation in the risk variant of factor B and C2 results in increased activity of these components. A reduction in complement activity of factor H and an increase in activity of factor B and C2 result in an overall increase in complement activation that initiates the inflammatory cascade and drusen formation in AMD.

The second form of AMD is wet AMD. Choroidal neovascularization (CNV) is the hallmark of wet AMD. The immunopathology and therapeutic strategies to treat wet AMD have been explored using various animal models of this disease. CNV can be induced in animals by rupturing Bruch's membrane with laser photocoagulation. In this animal model, the complement system plays an important role in CNV. The final product of complement activation, the formation of the MAC, is critical for the immune process leading to the development of CNV. Mice that are deficient in complement components C3 (C3−/−) do not develop CNV after laser photocoagulation. C3 is a key component of the complement system and is indispensable for the formation of MAC. In C3−/− mice the MAC formation is inefficient because of the unavailability of C3. If C3 is depleted in wild-type mice by administering cobra venom factor or if the MAC formation is inhibited directly by blocking complement component C6, the development of laser-induced CNV is inhibited. MAC formation is critical for the upregulation of various mediators of angiogenesis, such as VEGF, TGF-β2, and β-FGF. As mentioned earlier, MAC can be formed by classical, alternative, or the lectin pathways of complement activation. However, only alternative pathway activation is responsible for MAC formation and development of laser-induced CNV in mice (**Figure 3**). Similar to dry AMD in humans, factor B and factor H play an important role in the pathogenesis of laser-induced CNV in mice. Factor H levels decrease and factor B levels increase during CNV, which again demonstrates the importance of the critical balance between the complement activation and regulation in ocular immune responses. The importance of regulation of the complement system in the development of CNV is further evident by the decrease in the levels of CD59 (regulator of MAC) in eyes with CNV. Furthermore, laser-treated animals fail to develop CNV if CD59 is replenished by administration of exogenous recombinant CD59.

Keratitis

The cornea is the first barrier that protects the ocular tissue from the various insults including biological and

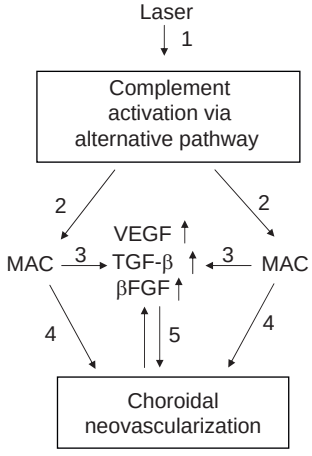

Figure 3 Role of the complement in CNV. The injury caused by laser treatment activates the complement system via the alternative pathway in the posterior segment of the eye (1). The activation of complement system leads to formation of MAC (2). MAC deposition on the cell surface leads to increased expression of growth factor (3). Increased production of growth factors and MAC deposition leads to the development of CNV (4).

environmental. Chronic activation of the complement system in the cornea ensures that this tissue is protected from various insults. It is due to the robust nature of the complement system, rapid activation and amplification of this defense system is possible in the case of any pathological condition, such as bacterial infection. The complement system is required to mount an immune response and protect the cornea from *Pseudomonas aeruginosa* infection. *P. aeruginosa* is the most common causative agent of microbial keratitis. However, unlike autoimmune uveitis and AMD, MAC does not play a critical role in protection against *P. aeruginosa* in microbial keratitis. The complement component C3 and functions associated with it, such as opsonization and regulation of phagocytosis, are important in protecting the cornea during microbial keratitis.

Glaucoma

Glaucoma is a leading cause of vision loss world-wide. Glaucoma is characterized by the slow, progressive loss of retinal ganglion cells and their axons, and by progressive excavation of the optic nerve head resulting in the loss of vision. Elevated intraocular pressure (IOP) is an important risk factor for glaucoma. Recent studies implicate autoimmune mechanisms in the development of glaucoma with the complement system as a key player. These studies provide an autoimmune basis for the development and progression of glaucoma. In animal models of glaucoma, inhibition of complement activation protects the optic nerve from damage induced by increased IOP. Furthermore, the complement component C1qs appear to play a major role in the immunopathogenesis of glaucoma, both in humans and rodents.

Retinal Disorders

The complement system has been implicated in the pathogenesis of several other retinal disorders, such as diabetic retinopathy, light-induced photoreceptor damage, and proliferative vitreoretinopathy (PVR). Unregulated complement activation, due to the loss of complement regulator, results in increased MAC formation. This leads to increased permeability and apoptosis of choriocapillaries in diabetic retinopathy.

Unregulated activation of the alternative pathway plays a critical role in the light-induced damage of photoreceptor cells in the retina. The regulation as well as the activation of alternative pathway is very important in the protection as well as maintenance of normal function of the retina.

PVR is another ocular disorder that affects the retina and complement activation has been associated with its pathogenesis in humans. Future studies investigating the exact role of the complement in the pathogenesis of PVR using animal models would help us understand and design better strategies to manage and treat PVR.

Role of Proteoglycans in the Trabecular Meshwork

T S Acott, K E Keller, and M J Kelley, Oregon Health and Science University, Portland, OR, USA

Glossary

Aqueous humor outflow resistance – A poorly understood physical resistance to aqueous humor outflow as it exits through the trabecular meshwork. This resistance is responsible for regulating intraocular pressure.
Extracellular matrix – The structural environment supporting and surrounding most cells that is comprised of a complex and highly organized group of many specialized proteins, glycoproteins, proteoglycans, and glycosaminoglycans.
Glycosaminoglycan – A highly charged carbohydrate chain composed of distinctive disaccharide repeats.
Juxtacanalicular or cribriform region – The deepest 10–20-μm-thick portion of the trabecular meshwork, which is adjacent to Schlemm's canal, is comprised of several layers of trabecular meshwork cells embedded in extracellular matrix, and is thought to be the site of the aqueous humor outflow resistance.
Proteoglycan – A protein with one or more glycosaminoglycan side chains. A glycoprotein is similar, except that the carbohydrate side chains are various monosaccharide patterns rather than disaccharide repeats.
Trabecular meshwork – A small fenestrated tissue surrounding the cornea on the inside of the eye that is responsible for providing and regulating resistance to aqueous humor outflow and maintaining intraocular pressure homeostasis.

Aqueous Humor Outflow Resistance

Trabecular Meshwork

The trabecular meshwork (TM) is thought to provide most of the flow resistance to aqueous humor outflow. Modulation of the trabecular outflow resistance is responsible for the regulation of intraocular pressure (IOP). In open-angle glaucoma, sustained increases in trabecular outflow resistance commonly result in elevated IOP, which is the primary risk factor for glaucomatous optic neuropathy and subsequent vision loss.

Site of Outflow Resistance

The outer uveal and corneoscleral portions of the TM are highly fenestrated and composed of several irregular layers of extracellular matrix (ECM) covered by TM beam cells. These beams become more flattened and sheet-like in the deeper portions of the TM. They are normally covered and maintained by continuous monolayers of TM cells, which reside on a basal lamina with a lamina rara and lamina densa. The center or stroma of the beams exhibits typical collagen fibrils, elastic fibers, and microfibril sheath-derived (SD) material. Between the beams and sheets, irregular intertrabecular spaces form tortuous flow channels leading to the cribriform or juxtacanalicular tissue (JCT) region, which lies adjacent to Schlemm's canal (SC). The size of the intertrabecular spaces is sufficiently large that it is unlikely that they contribute directly to the outflow resistance. The cells on the outer layers of the TM are actively phagocytic and are thought to act primarily as prefilters, removing debris from the aqueous humor prior to its passage through the less-porous inner JCT and SC regions.

Sequential serial dissection and microcapillary studies with perfused eyes suggest that the outflow resistance resides somewhere within the deepest one-quarter to one-third of the TM, approximately 7–14 μm from the inner wall of SC. This is approximately the thickness of the JCT region. This region is composed of an amorphous ECM with a discontinuous scattering of several layers of cribriform or JCT cells on the trabecular surface and embedded within the ECM. These JCT cells form occasional contacts with each other and with SC inner wall endothelial cells, often through extended processes using gap and adherens junctions. No continuous occludens junctions are apparent between JCT cells or between JCT and SC cells. Conversely, SC inner wall cells form a continuous monolayer and exhibit occasional gap junctions and extensive continuous tight occludens junctions. SC inner wall cells reside on a discontinuous basal lamina that may be affected by the movement of aqueous humor through these cells. Whether JCT cells have basal lamina is controversial. These cells have been considered to be fibroblast-like and thus without a basal lamina. However, basement membrane proteins, such as type IV collagen, laminin, and basement membrane proteoglycans (PGs), have been identified closely associated with the JCT cells. One study found basement membrane components adjacent to all JCT cells. This varied in amount and location with individual cells and was associated with at least half of the surface of most JCT cells.

It was generally not observed on the face of JCT cells, where they abut the apparent open spaces found scattered throughout the JCT region.

Extracellular Matrix

ECM, particularly the highly charged glycosaminoglycans (GAGs), has long been believed to contribute significantly to the outflow resistance, although some controversy about the exact nature of this contribution remains. Perfusion of the outflow pathway with several enzymes that degrade specific GAGs has been shown to increase outflow facility in several species, but the effects in primates and humans are ambiguous. Perfusion of both porcine and human anterior segments with enzyme inhibitors, which interfere with GAG biosynthesis or GAG sulfation, increased outflow facility. In addition, perfusion of human or porcine anterior segments with matrix metalloproteinases (MMPs) or with agents that stimulate MMP synthesis increased outflow facility, while perfusion with agents that specifically inhibit endogenous MMPs reversibly reduced outflow facility. Thus, ongoing ECM turnover, mediated by the MMPs, appears to be absolutely essential for maintaining the outflow resistance.

There is evidence for a direct involvement of JCT or SC cells or both in the resistance. Manipulations of the cellular cytoskeleton have strong and fairly immediate effects on outflow facility. Cells and ECM are highly interactive, thus separating their individual contributions is difficult.

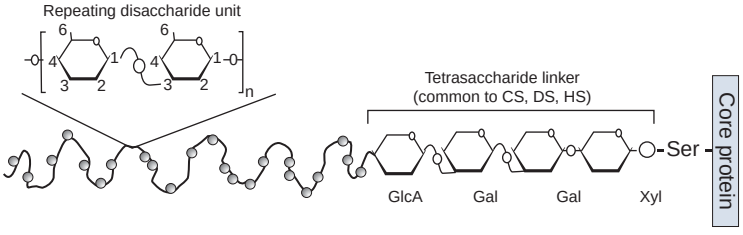
Glycosaminoglycans

Structure and Properties

With the exception of hyaluronan, GAGs are synthesized directly as covalent side chains on serine/threonine or asparagine groups of specific PG core proteins (Figure 1). These are long carbohydrate chains composed of several distinctive disaccharide repeat units. They include hyaluronan or hyaluronic acid (HA), chondroitin sulfate (CS), dermatan sulfate (DS), keratan sulfate (KS), and heparan sulfate (HS). The defining disaccharide units are various alternating glucuronic acid (GlcA) and *N*-acetyl glucosamine (GlcNAc) or galactosamine (GalNAc), where some GlcAs are epimerized to iduronic acid (IdoA). They all have an abundance of carboxyl groups and many are O- or N-sulfated in complex patterns. Both carboxyl and sulfate groups are negatively charged at physiologic pH levels, giving a very high charge density along these chains.

GAG Biosynthesis

Hyaluronan is synthesized at the cell surface by an integral plasma membrane synthase and the growing GAG chain is extruded directly out of the cell and into the extracellular milieu. By contrast, HS, CS, DS, and KS are synthesized in the Golgi prior to secretion of the PG. HS, CS, and DS are *O*-linked to a consensus Ser-Gly/Ala-X-Gly motif of a core protein, while KS can be *N*-linked or *O*-linked. The resultant polysaccharide–protein conjugate is called a proteoglycan (Figure 2). Since KS is less abundant in the TM and utilizes a complex biosynthetic scheme, the nuances will not be presented herein. CS, DS, and HS GAG biosynthesis is initiated by transfer of a xylose (Xyl) onto the hydroxyl group of a Ser or Thr residue of a core protein (Figure 1). To the Xyl, two consecutive galactose (Gal) residues are added, followed by a GlcA. Synthesis of this initial chain is achieved by xylosyltransferase (XylT), galactosyltransferase I (GalT-I), galactosyltransferase II (GalT-II), and glucuronyltransferase I (GlcAT-I). XylT is highly regulated and this step is rate limiting. Distinctive GAG disaccharide repeats are



GAG class	Disaccharide	Modifications
Heparin/heparan sulfate (HS)	$GlcA/IdoA_{2x(\alpha/\beta1,4)}$-$GlcNAc_{NY,\ 3x,\ 6x\ (\alpha1,4)}$	X = sulfated; Y = acetylated/sulfated
Chondroitin sulfate (CS)/ dermatan sulfate (DS)	$GlcA/IdoA_{2x(\alpha/\beta1,3)}$-$GalNAc_{NAc,\ 4x,\ 6x\ (\beta1,4)}$	X = sulfated
Keratan sulfate (KS)	$Gal_{6x(\beta1,4)}$-$GlcNAc_{NAc,\ 6x(\beta1,3)}$	X = sulfated
Hyaluronic acid (HA)	$GlcA_{(\beta1,3)}$-$GlcNAc_{NAc(\beta1,4)}$	None

Figure 1 Glycosaminoglycan structures and sulfation. The identities of the disaccharide units are shown with the position and type of bonding between monosaccharides indicated by α or β. The position of acetylation or sulfation is indicated by the number associated with X or Y, for example, 2X represents 2-*O*-sulfation.

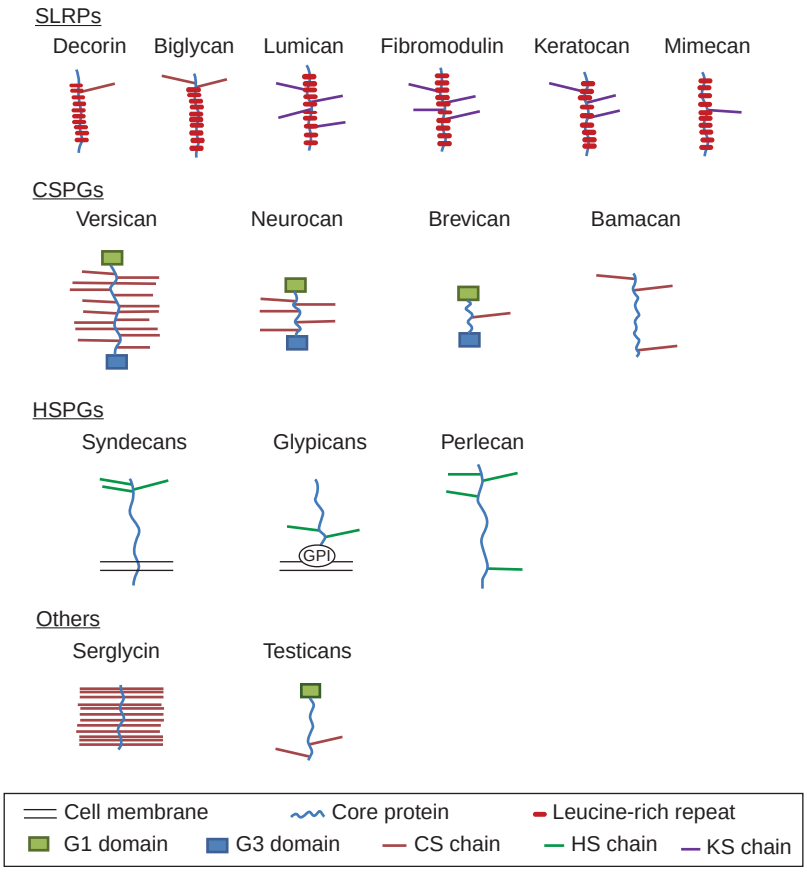


Figure 2 Typical proteoglycan structures are as shown with GAG side chains and approximate domain structures of the core proteins as indicated.

then added to this core tetrasaccharide linker by addition of either a GlcNAc or a GalNAc residue by the respective GlcNAc transferase-1 or GalNAc transferase-1. This step determines the identity of the final mature GAG chain as HS or CS/DS, respectively. Enzymes involved in the GAG-defining step must recognize other features of the core protein and more than just the common tetrasaccharide linker in order to extend the correct type of GAG chain. GAG chain extension steps are achieved by several exostosin (EXT) enzymes for HS or chondroitin synthases for CS or DS. Epimerization of GlcA in some CS chains to IdoA produces a DS chain. Some GlcA in HS chains are also epimerized.

All GAG chains, except HA, are sulfated in various positions and to varying degrees. For HS chains, GlcNAc residues can be N-acetylated or N-sulfated and sulfation then occurs at the 2-*O*, 3-*O*, and 6-*O* positions. Heparin (Hep) is more highly sulfated than HS. For CS/DS chains, the three main sulfation events are 4-*O* and 6-*O* sulfation of GalNAc and 2-*O* sulfation of GlcA/IdoA. The density of sulfation within regions of a GAG chain and length of chains is variable and carefully controlled. Thus, there is a potential for considerable diversity in GAG chain structure and properties.

GAGs of the TM

The GAG composition in TM extracts has been determined by sequential enzymatic degradation with various GAG-degrading enzymes. Sources included extracts of TMs from human eyes a few hours post mortem, stationary or perfused human anterior segment organ cultures, and densely confluent early-passage human TM cell cultures. Relatively good agreement was found in the amount of each type of GAG in the TM using these models and all of the normal GAGs were identified. Of the total human trabecular GAGs, approximately 20–25% is HA, 40–60% is CS and DS, 5–10% is KS, and 15–20% is HS. These percentages are based on GAG staining or ^{3}H- or ^{35}S-radiolabel incorporation and are not strictly calibrated molar amounts. When normalized to a relative ng amount based on GAG standards, HA was 15%, CS/DS was 38%, KS was 6.5%, and HS was 40% of the total. GAG distributions of other species are similar.

Localization of GAGs within the TM was determined by similar enzymatic degradation methods using various GAG stains and light or transmission electron microscopy (TEM). Hyaluronan-binding protein and GAG-specific antibodies have also been used to localize GAGs within

the TM. Most studies found HA primarily in the JCT region with less in the remainder of the TM. Since the other GAGs are sulfated, alternative staining methods are possible. When GAGs were stratified within the JCT of normal human eyes, fg μm^{-2} values obtained were 7.78 for HA, 8.18 for CS, 0.29 for DS, and 2.48 for HS (where HS included a small contribution from undegraded material). Using four-layer stratification, HA and HS were found to be higher near SC and declined somewhat toward the trabecular side of the JCT, while CS and DS were found to increase modestly toward the trabecular side of the JCT. Eyes from persons with glaucoma showed decreased HA and increased CS in all layers of the JCT.

Using antibodies specific to the various sulfated GAG chains, it was found that for all cell layers in the TM and JCT, CS, DS, and HS were present at higher levels just beneath the cells. CS/DS GAGs were also found as small clumps in the center of TM beams, apparently associated with collagen fibrils and elastin microfibrils. The JCT showed relatively dense staining throughout for CS, DS, and HS sulfated GAGs. Using Cuprolinic or Cupromeronic blue to stain sulfated GAG chains in conjunction with GAGase treatments, sulfated PGs have been localized at the ultrastructural level within the TM. With Cuprolinic blue staining, small, thin structures were found to be closely associated with collagen fibrils. A large, thick structure was located more peripherally, both with and between collagen fibril bundles, and was found associated with fine filaments. Both of these structures contained predominantly DS/CS GAGs. Basement-membrane-associated structures contained HS GAGs. Using Cupromeronic blue and a slightly different analysis, fairly similar distributions were obtained. In one study, sulfated GAGs were also found associated with JCT cell basement-membrane-like material.

GAG Turnover

GAG synthesis and degradation are tightly regulated in order to maintain a constant concentration within tissue. Several mammalian genes have been identified that degrade specific GAGs or remove sulfates. Targeted degradation of GAGs to smaller fragments, or removal of specific sulfates, modifies the function and/or biological activity of the GAG chain. Hence, some of these events may serve as functional processing steps rather than actual degradation. Superimposed on these specific GAG-chain-directed degradation events are targeted mechanisms for PG and other ECM component degradation, which involve MMPs and other proteinases. In these cases, the GAGs are likely captive bystanders and their subsequent degradation in lysosomes may not be as specific and may use more generic enzymes.

Hep/HS chains in mammals are degraded by heparanase-1 (HPSE-1), which is an endo-β-D-glucuronidase. This enzyme cleaves HS chains at only a few sites, resulting in HS fragments of appreciable size (5–10 kDa, 10–20 disaccharides). HPSE-1 is a pro-enzyme that is activated by removal of an N-terminal 6-kDa fragment. It is localized in endosomes/lysosomes in the cell and shows maximal endoglycosidase activity in acidic (pH 5.5–6.0) environments. However, active HPSE-1 can be secreted from intracellular compartments in response to certain stimuli, for example, tumor necrosis factor (TNF)-α and interleukin (IL)-1α, and it degrades syndecan-1 and perlecan at the cell surface. In addition, HPSE-1 enhances synthesis and shedding of the ectodomain of syndecan-1. Although heparinase-2 has been recently identified, no HS-degrading activity has been reported for this enzyme.

Hyaluronan synthesis and degradation are also tightly regulated to maintain a constant HA concentration within tissues. HA is catabolized rapidly in blood (half-life = 2–5 min), modestly in skin (~1 day), and relatively slowly in cartilage (1–3 weeks). HA catabolism is regulated by six hyaluronidase-like genes, HYALs 1–4, PH-20/SPAM1, and HYALP1. HYAL1 is a lysosomal enzyme, while HYAL2 is a glycosylphosphatidylinositol (GPI) lipid-anchored cell-surface protein. HYAL2 cleaves HA into ~20-kDa (~50 disaccharide units) fragments at the cell surface, which are then endocytosed by CD44, a cell surface receptor for HA. The rate-limiting step of HA catabolism is internalization. If HA is large or is bound by other PGs, then internalization is sterically inhibited. After uptake, HA fragments are delivered to lysosomes where HYAL1 degrades them into smaller tetrasaccharide units. HA fragments are inflammatory, immunostimulatory, and angiogenic. They can compete with larger HA polymers for cell-surface receptors such as CD44.

Sulfatases are also involved in GAG degradation. Human lysosomal sulfatases act on the GAG in an exoenzymatic fashion, only as specific residues are exposed at the nonreducing terminus by a glycosidase. A class of extracellular sulfatases, known as the Sulfs, is involved in cell signaling. Wnt, bound to HSPG, was released following 6-*O*-sulfate cleavage by Qsulf1, while desulfation of HS PGs by HSulf1 influences fibroblast growth factor (FGF) and epidermal growth factor (EGF) signaling pathways. Other known sulfatases are membrane-bound ER and Golgi network enzymes with a neutral pH optimum.

Proteoglycans

Structure and Properties

PG families

Proteoglycans (PGs) are a heterogeneous group of proteins with between 1 and over 100 GAG side chains of different lengths and a wide range of core protein sizes (**Figure 2**). The small leucine-rich PG (SLRP) family is comprised of 17 gene products, some of which are not true

PGs. Among these are biglycan, decorin, lumican, fibromodulin, keratocan, proline/arginine-rich end leucine-rich repeat protein (PRELP), and mimecan or osteoglycin. Different members have CS, DS, or KS GAG chains. A number of ocular disorders have been linked to these genes. Members of the SLRP family also affect cytokine and growth factor signaling pathways involving TNFα and insulin-like growth factor (IGF) and bind to and modulate bone morphogenic protein (BMP) and transforming growth factor (TGF)β receptors. They also serve in an array of ECM organizational functions, such as modulating collagen fibril formation.

Another family of PGs, the chondroitin sulfate proteoglycans (CSPGs) is the large aggregating and hyaluronan-binding family, including aggregan (CSPG 1), versican (CSPG 2), neurocan (CSPG 3), melanoma-associated proteoglycan (CSPG 4), and brevican. Versican (**Figure 3**) is comprised of four domains with numerous CS GAGs attached to two central GAG domains and a number of binding sites for other ECM proteins, cell surface receptors, cellular components, and HA. The other members of this family are similar, although each shows distinct characteristics and domains.

The cell surface HS PGs break down into three groups based on their mode of interaction with cells. Syndecans 1–4 are transmembrane proteins with small cytoplasmic tails and larger extracellular regions containing several HS chains and in some cases, a CS chain. The cytoplasmic tail has two conserved regions, C1 and C2, which are, respectively, proximal and distal to the inner surface of the plasma membrane and which sandwich a variable (V) domain. C1 and C2 bind, respectively, to actin-binding ezrin, radixin, and moesin (ERM) proteins and to post-synaptic density, disk large, and zo-1 protein domains (PDZ)-containing proteins such as syntenin. Binding to the V domain has not been defined, but appears to involve cell spreading, actin and fascin bundling, and ECM assembly. The ectodomains of syndecans bind a variety of ECM proteins, several cell surface receptors such as integrins, and numerous growth factors, for which they act as both sequestration and activation sites. They bind to the Hep II domain of fibronectin, which has been shown to modulate aqueous outflow facility. Under some conditions, the ectodomain is shed following a proteolytic event near the extracellular membrane surface. The soluble fragments then compete for binding sites. Signal transduction, both outside-in and inside-out, has been shown for the syndecans. There are phosphorylation sites on their cytoplasmic tails that are involved in their regulation.

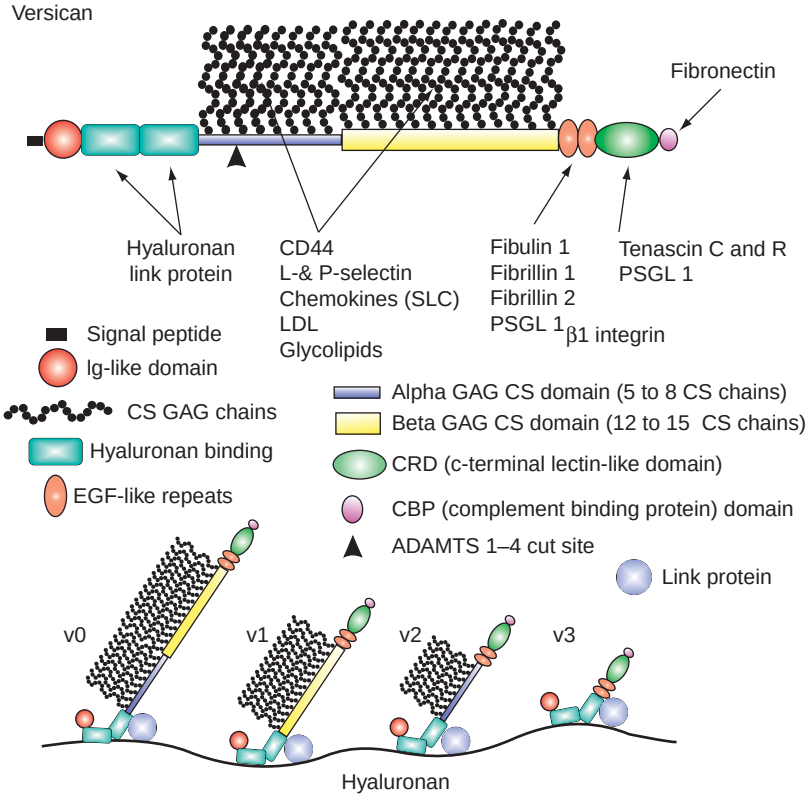

Figure 3 Versican domain structure, GAG attachment sites, binding sites of various binding partners, alternative splicing isoforms, a disintegrin and metalloproteinase with thrombospondin motifs (ADAMTS) cleavage sites, and hyaluronan binding with stabilization by link protein. Modified from Acott, T. S. and Kelley, M. J. (2008). Extracellular matrix in the trabecular meshwork (Review). *Experimental Eye Research* 86: 543–561.

A second group of HSPGs, glypicans 1–6, are cell surface PGs that attach to the cell through GPI lipid anchors. They typically have two HS chains attached near the plasma membrane and a conserved extracellular domain with 14 Cys residues. Glypicans are implicated in FGF, IGF, Wnt, BMP-2, and TGFβ signaling, development, axonal guidance, and have been associated with several genetic diseases and cancers. Evidence for glypican recycling between the cell surface and Golgi has been presented, although the functional significance of this process is not clear. They bind various ECM and cell surface proteins, including the Hep II domain of fibronectin, much as observed for the syndecans.

The third type of HSPGs cell surface attachment is through receptor binding or similar types of interactions and this includes the large basement-membrane HS PG, perlecan. Perlecan has a very large core protein with several HS chains and is an integral component of cellular basement membranes. Bamacan (CSPG 6), a similar large basement-membrane CS PG, is also important in basement membrane structure. Perlecan is thought to serve as a scaffold in basement membrane organization with various complex interactions between collagen type IV, laminins, nidogen, and a variety of other ECM and cell surface proteins. Perlecan normally has one HS chain near the C-terminus and three near the N-terminus. It has numerous laminin domains, laminin EGF-like domains, immunoglobin-like domains, EGF-like domains, and a nidogen-like domain that interacts with nidogen-1. The other perlecan domains interact with fibulin-2, fibrillin, fibronectin, integrin β1, α-dystroglycan, acetylcholinesterase, Hep, and others. The HS side chains bind heparin-binding growth factors such as FGF, vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and connective tissue growth factor (CTGF). Fragments of perlecan, such as endorepellin, have other independent functions such as inhibiting angiogenesis. Perlecan can also modulate focal adhesion or focal contact function and impacts the C-terminal domain of focal adhesion kinase (FAK) (FRNK) and FAK cytoplasmic distributions and signaling.

Several ECM PGs only have GAG chains attached to some isoforms, often due to insertion of different domains by alternative mRNA splicing, as discussed later. Several collagens, such as types XII, XIV, and XV, are PGs in some instances. Another such molecule is CD44, a transmembrane glycoprotein with a large extracellular domain that functions in cell signaling, migration, adhesion, and cell–cell interactions. CD44 is a primary cellular hyaluronan receptor (**Figure 4**). Its large N-terminus also binds numerous other ECM components including, collagen, fibronectin, and osteopontin. Its cytoplasmic tail interacts with the cytoskeleton through actin-binding ERM proteins. Thus, CD44 is an important mediator of

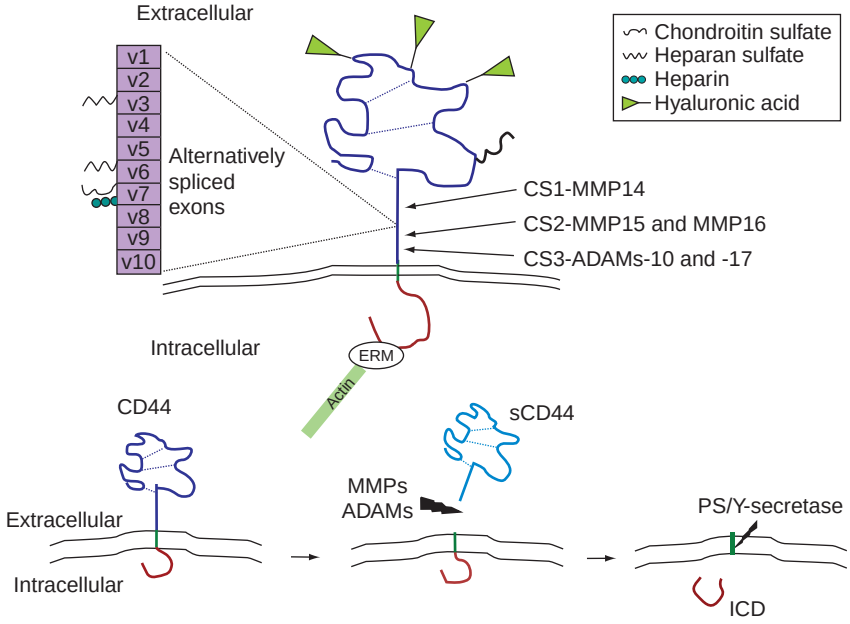

Figure 4 Schematic of CD44. CD44 is a transmembrane glycoprotein that binds hyaluronan and other proteins in the extracellular matrix and interacts with the intracellular cytoskeleton through ERM proteins. Up to 10 additional exons (v) can be included by alternative mRNA splicing and these may introduce additional GAG-binding sites. Proteolytic cleavage sheds the extracellular domain and the positions of three cleavage sites (CS) are shown. The lower diagram shows the sequential proteolytic cleavage events. Following proteolytic release of sCD44, presenilin (PS) or γ-secretase cleavage releases the intracellular domain (ICD), which is translocated to the nucleus where it affects transcription of itself and various other genes. MMP, matrix metalloproteinases; ADAM, a disintegrin and metalloproteinase; ERM, Ezrin/Radixin/Moesin.

extracellular signals. The N-terminal soluble ectodomain of CD44 (sCD44) can be shed from the parent molecule by proteinase cleavage. Shedding, or cleavage of membrane-anchored proteins, is one mechanism by which cell surfaces are modified and biologically active molecules are released. Regulated proteolysis also allows rapid down-regulation of adhesion molecules and ectodomain shedding may contribute to regulation of cell adhesion and migration. There are three cleavage sites implicated in shedding of CD44, involving MMPs and ADAMs (a disintegrin and metalloproteinases). These release sCD44 of different sizes and since the cleavage sites span the variant region, alternative splicing may affect cleavage activity or site selection. This also infers that sCD44 may also contain variant domains. Shedding can happen constitutively or in response to cytokine stimulation, and correlates with enhanced proteolytic degradation and matrix remodeling.

PGs of the TM

A number of PGs have been identified in the TM of anterior segments or in TM cells in culture. This includes a number of SLRPs, CSPGs, HSPGs, and other types of PGs, including CD44 and collagen types XII, XIV, and XV (**Table 1**).

Some specific core proteins have been localized to regions of the TM by immunohistochemistry using light or TEM. Perlecan was localized to the basement membranes of TM beams and SC inner wall cells. By immunofluorescence, syndecan 1 immunostaining in the TM/SC was light or absent. Syndecan 2, 3, and 4 immunostaining was observed through the TM/SC region with syndecan 3 immunostaining being somewhat stronger in the JCT/SC region. As would be expected for a transmembrane protein, syndecan immunostaining was strongest at the cell edges. At the ultrastructural level, decorin and versican immunostaining were found within electron-dense elastic fiber cores and the surrounding microfibril sheath material, both within TM beams and the JCT region. Both PGs were also localized to long-spaced collagen (100–120-nm periodicity) and normal collagen fibrils. With confocal immunofluorescence, we see similar versican and fibromodulin distributions with a significant amount also associated with the TM beam, JCT, and SC cells.

Many of these PGs have complex structures with multiple binding domains and exhibit alternative splicing. For example, versican (**Figure 3**) is a large lectican, which can bind to hyaluronan chains and interact with various other ECM proteins or cellular receptors. It has four alternative mRNA splicing variants, which appear to be important in TM function, as discussed later. Versican is also cleaved by specific proteinases at various sites, which results in fragments with very different activities such as stimulation of cell division, disruption of chemokine function,

Table 1 Trabecular meshwork proteoglycans

Proteoglycan	*GAG(s)*	*Type or family*	*Known alternative splicing*
CSPG 2, versican	CS	Large aggregating, HA binding	Yes, TM
CSPG 3, neurocan	CS	Large aggregating, HA binding	
CSPG 4, melanoma-associated	CS	Large aggregating, HA binding	
CSPG 6, bamacan	CS	Basement membrane CSPG	
HSPG 1, perlecan	HS	Basement membrane HSPG	Yes
HSPG 2, LDL receptor	HS	Cell surface HSPG	Yes
Biglycan	CS/DS	SLRP	Yes
Decorin	CS/DS	SLRP	Yes
Lumican	KS	SLRP	
Fibromodulin	KS	SLRP	
Mimecan, osteoglycin	KS	SLRP	Yes
Syndecan 1	HS	Cell surface transmembrane	
Syndecan 2	HS	Cell surface transmembrane	
Syndecan 3	HS	Cell surface transmembrane	
Syndecan 4	HS	Cell surface transmembrane	Yes
Glypican 3	HS	Cell surface GPI anchored	
Glypican 4	HS	Cell surface GPI anchored	
Glypican 5	HS	Cell surface GPI anchored	
CD44	HS/CS	Cell surface hyaluronan receptor	Yes, TM
Testican 1	CS	SPARC, osteonectin	Yes
Testican 3	CS	SPARC, osteonectin	Yes
Secretory granule PG 1	CS/HS	Serglycin	
Collagen XII	CS	Nonfibrillar collagen	Yes, TM
Collagen XIV	CS	Nonfibrillar collagen	Yes
Collagen XV	CS	Nonfibrillar collagen	Yes

These proteoglycans have been identified in the TM by Western immunoblots, immunohistochemistry, RT-PCR, cDNA libraries, microarray, or general proteomics approaches. For alternative splicing, yes indicates that it has been reported in other tissues and TM indicates that it has also been studied in the TM.

and apoptosis. In the TM, the versican fragment produced by ADAMTS (a disintegrin and metalloproteinase with thrombospondin motifs) 1- or 4-cleavage between Glu441 and Ala442 in the αGAG domain, is found in moderate abundance and may be higher in areas of high segmental outflow. Versican has also been shown to distribute with TM cell podosome- or invadopodia-like structures (PILS), functional units recently identified in the outflow pathway that appear to serve in targeted ECM turnover. Versican formed a novel ring around the center of the PILS in TM cells. The ADAMTS-4 cleaved form of versican also co-localized with these distinctive rings beneath TM cell PILS.

Recent studies have found that sCD44 is significantly increased in primary open-angle glaucoma (POAG) aqueous humor. Although shedding likely occurs elsewhere in the anterior chamber, aqueous sCD44 may affect TM cell function. When it flows through the TM, it may disrupt interactions of membrane-bound CD44 with its typical binding partners. This in turn may interfere with the normal function of CD44 in the TM. A previous study showed that sCD44 was cytotoxic to TM cells.

Alternative splicing

Many ECM genes, including numerous PGs, undergo alternative splicing, a process by which various exon sequences of the primary transcript are differentially included in the mature mRNA. This allows cells to produce multiple proteins with different domains included or excluded using variations of a single gene-coding sequence. The most common form of alternative splicing is exon skipping, which results in exclusion of certain regions from the protein. Since many PGs are comprised of protein domains encoded by single exons, exon skipping is a relatively common phenomenon. Other alternative splicing mechanisms include alternative 5′ and/or 3′ splice sites, intron retention, and mutually exclusive splicing, where one exon is selected from an array of two or more possible exon variants. Alternative splicing generates protein diversity, although in most cases the specific function of the alternatively spliced exon is not yet known.

The gene for versican contains two large central exons (7 and 8) that are alternatively spliced. These encode the αGAG and βGAG domains that are substituted with CS GAG chains (**Figure 3**). Four alternate transcripts are therefore expressed: V0, V1, V2, and V3, which contain both, either the βGAG or αGAG domain, or neither domain, respectively. Consequently, the number of GAG chains varies between alternate splice forms. The V1 isoform is the most abundant splice variant expressed by TM cells, and the proportion of V1 transcripts increased when TM cells were subjected to mechanical stretch. Concomitantly, total versican mRNA levels decreased. This results in a net reduction of CS GAG attachment sites in the TM and may affect structural organization and/or disrupt signaling systems in the TM. TGFβ treatment of TM cells produced the opposite effect, that is, it shifted toward more V0 splice variants with more potential GAG attachment sites per PG molecule. Both TNFα and IL-1α also modulate versican splicing.

CD44 is also well known for its complex alternative splicing (**Figure 4**). CD44 is composed of 20 exons, 10 of which can be regulated by alternative splicing. In human TM cells, three isoforms of CD44 were observed. These include CD44 that does not contain any variant exons, CD44v-I, which contains exons v3 and v7-v10, and CD44v-III, which contains exons v8 and v9. Mechanical stretching and TNFα or IL-1α treatment of porcine TM cells increased the amount of v7 exon included in CD44 transcripts. However, the function of these variant domains in TM cells is unknown.

A novel splice variant of syndecan-4 has been reported. It incorporates exon V-b as a terminal exon instead of the transmembrane-encoding exon V-a. This generates a soluble ectodomain of syndecan-4, which mimics that generated by proteolytic cleavage. Thus, the alternative splice form of exon V-b would have functional consequences that were similar to proteolytic shedding. Syndecan splicing has not yet been analyzed in TM cells.

Several other PGs also undergo alternative splicing. For instance, biglycan has several isoforms that have a truncated core protein with shorter CS/DS GAG chains. Decorin has two alternatively spliced leader exons in the 5′ untranslated region, while mimecan has three different-sized mRNA transcripts that suggest it also is alternatively spliced. A truncated form of testican-3, N-tes, is generated by alternative splicing. It lacks C-terminal GAG chain sites and inhibits MMP-14 and-17 activities, which in turn compromises pro-MMP2 activation. None of these splicing alternatives has been assessed in the TM at this time. The NC3 domain of collagen XII has two splice forms, a short and a long form. The long NC3 isoform is increased in TM cells subjected to mechanical stretch, which provides additional CS and heparin-binding sites not found in the short NC3 form.

Secondary Photoreceptor Degenerations*

M B Gorin, Jules Stein Eye Institute, Los Angeles, CA, USA

Glossary

Epigenetic – The heritable modifications of gene expression that are not the result of changes in the DNA sequence. This can include methylation of DNA that results in inactivation of gene transcription or factors that modify how RNA transcripts are spliced to form the final transcripts that are translated into peptide sequences.

Extrinsic factor – An agent external to the organism that contributes to or is causative of a disease state. This can include drugs, foods, normal nutrients (excess or deficiency), toxins, inhaled chemicals, infectious agents, and exposures to radiation such as light, sound, and high-energy particles.

Intrinsic factor – An agent that is inherent to the organism that contributes to or is causative of a disease state. While commonly these factors are genetic variants in the organism's DNA that may predispose (or be protective) of specific conditions, other intrinsic factors include epigenetic changes, aging changes, and the effects of the biology of symbiotic bacteria in the skin or gut. Another intrinsic agent is an organism's immunologic response behavior and memory (though obviously the immunologic memory is heavily affected by the exposure to extrinsic agents, such as viral infections).

Microbiomics – The genetic information expressed by the microbes that are indigenous to a host organism (e.g., bacteria colonized to the skin or intestinal tract).

Introduction

Secondary retinal degeneration occurs when cells in the retina die by a process triggered by factors not inherent to retina. Secondary retinal degeneration can be caused by trauma, infection, inflammation, toxins, anti-retinal antibodies, or as an adverse effect of medications.

In the past, clinicians have tended to view genetic and nongenetic etiologies of retinal degeneration as easily separated categories. The molecular studies of hereditary retinal degenerations have shown that, while some retinal conditions are caused by mutations in genes with photoreceptor-specific expression, many retinal conditions are the results of mutations in genes that are widely expressed in the body as well as from the secondary effects of metabolic changes caused by the expression of mutated genes in ocular cell types other than photoreceptors as well as from other organs and tissues distant from the eye. Based on our understanding of complex genetic disorders, we now realize that there can be interplay of genetic and nongenetic factors that run the entire spectrum of possibilities. For example, rhegmatogenous retinal detachments, which can lead to secondary photoreceptor degeneration, may be influenced or caused by genetic variants (e.g., COL11A1, VCAN, COL9A1, and COL2A1) that are expressed in nonretinal cells, and whose expression may be limited to a particular period in ocular development. Thus, we have to consider this continuum of causality as we attempt to make useful classifications that can guide diagnostics and therapy. In light of these complexities, we offer the following operational distinctions among primary and secondary photoreceptor and retinal degenerations that may be relevant to therapeutic approaches.

- If the genetic defect is such that it would require actual alteration of the gene expression in the photoreceptors to correct the abnormality and arrest the degeneration, then this can be considered a primary photoreceptor degeneration. The genetic alteration is necessary and sufficient to cause photoreceptor degeneration. The gene that is mutated may (e.g., opsin, peripherin/rds, cone transducin, AIPL1, and GUCY2D) or may not (e.g., splicing factors PRPF8, PRPF3, and PRPF31, IMPDH1, and CA4) be photoreceptor specific. For a primary photoreceptor degeneration, one would expect that the correction of the genetic alteration outside of the photoreceptors would not be sufficient to prevent photoreceptor degeneration. However, a secondary photoreceptor degeneration that results from loss of expression or expression of a mutated protein in either other retinal cells or the retinal pigment epithelium (RPE) (e.g., RPE-65, RGR, and LRAT) might be corrected by gene therapy to the key nonphotoreceptor cells in the retina or RPE.
- If one reviews the genes attributed to primary photoreceptor degenerations, it is clear that many of these causative genes are not limited to photoreceptor-specific

* All of the genes that are mentioned in this article are described in Table 2 of Chapter 210 (for the retinal degenerations), RetNet (www.sph.uth.tmc.edu/retnet/), and/or Online Mendelian Inheritance of Man (OMIM) (www.ncbi.nlm.nih.gov/Omim/).

expression. Mutations in these genes have been attributed to nonsyndromic primary photoreceptor degenerations (such as retinitis pigmentosa (RP), Leber congenital amaurosis (LCA), cone dystrophy, and cone–rod dystrophy) as well as syndromic forms (e.g., Usher syndrome, Bardet–Biedl syndrome, Alstrom disease, and Cohen syndrome). Most of these conditions are further described and discussed elsewhere in the encyclopedia. In some instances, the mechanisms of action of these genes may not be solely mediated through their direct effects on the photoreceptors, thus raising the possibility that, in some cases, the photoreceptor degeneration is mediated through a mixed primary and secondary photoreceptor degeneration model (see below). Two unique examples of this potential ambiguity are the ABCA4 (Stargardt disease, cone–rod dystrophy) and RS1 (X-linked retinoschisis) genes. Both genes are specifically expressed in the photoreceptors, but their mechanism of action appears to be mediated through other retinal/RPE cells that lead to a secondary photoreceptor degeneration (see below).

- If the photoreceptors degenerate as the result of an alteration in a gene whose expression is primarily in other retinal or RPE cells, then this would be a primary retinal degeneration with secondary photoreceptor degeneration. Correction of the genetic defect would require modification of the effects of those retinal/RPE cells. A primary retinal degeneration without photoreceptor degeneration can occur such as with optic neuropathies that lead to retinal ganglion cell loss without significant loss of photoreceptors (Table 1).
- A mixed model of primary and secondary photoreceptor degeneration can be considered in two different modes. One is when a genetic alteration within the photoreceptors themselves would not be sufficient to cause photoreceptor degeneration by itself but would predispose to degeneration in the presence of an extrinsic or intrinsic agent. The genetic alteration within the photoreceptors could be necessary, conditional, or probabilistic but not sufficient. An intrinsic agent could be a genetic alteration in nonphotoreceptor retinal cells or due to expression elsewhere in the body. As noted above, a number of genes that are expressed in photoreceptors and for whom there are mutations that are known to be responsible for photoreceptor degeneration also have expression in other retinal cells as well as in other tissues. In some of these cases, it is not always clear if the expression in the photoreceptors alone is sufficient to cause cell death or whether or not there is a component of photoreceptor degeneration that is secondary to the effects on other cells and tissues. The only way to distinguish a secondary effect from a primary one would be to create animal models in which the genetic alteration is limited to specific cell populations and to determine if the photoreceptors are spared when their gene expression is normal. This is especially true for the forms of RP that are associated with mutations in genes that affect metabolic processes throughout the body. Examples of these conditions include gyrate atrophy, Bietti crystalline retinopathy, abetalipoproteinemia, and Refsum disease. At this time, we simply cannot establish if the effects of these genetic mutations are mediated by a primary effect on the photoreceptors or by secondary mechanisms. In the case of gyrate atrophy and Refsum disease, there is evidence that nutritional therapy can ameliorate the progression of the condition, which suggests an interplay of a person's intrinsic genetic makeup and diet (an extrinsic agent), but we still do not know if the effect is due to the systemic reduction of toxic metabolites or a photoreceptor-specific mechanism is also involved. Similarly, with Bietti crystalline retinopathy, the defect in CYP4V2 has multitissue consequences but it is not known if a systemic correction of the metabolic defect would be sufficient to overcome the enzyme deficiency in photoreceptor cells. Only future studies will be sufficient to distinguish if these conditions are representative of a mixed model of photoreceptor degeneration or secondary photoreceptor degenerations of an intrinsic type (see below).

Table 1 Secondary photoreceptor degenerations associated with primary retinal/RPE degeneration/dystrophy

Gene involved, site of cell/tissue expression related to retinal degeneration (RPE-retinal pigment epithelium, RVE-retinal vascular endothelium, RVP-retinal vascular pericytes, MGC-Muller glial cells), and phenotype (LCA-Leber congenital amaurosis, RP-retinitis pigmentosa) (from RetNet)		
RPE65	RPE	LCA and RP
MERTK	RPE	RP
CRALBP	RPE, MGC	Bothnian dystrophy
LRAT	RPE, liver	RP
RGR	RPE	RP and dominant choroidal sclerosis
TIMP3	RPE, RVP	Macular dystrophy
C1QTNF5	RPE	Macular dystrophy
ABCC6	REV	Macular dystrophy
AMD-related genes	RPE, liver	Macular dystrophy
BEST1	RPE	Macular dystrophy

An extrinsic agent can be a drug or environmental exposure (including something in the diet). There are relatively few established human examples of this model for retinal degenerations, though retinal degeneration-B (rdgB) mutants in *Drosophila* show light-dependent photoreceptor degeneration. This mixed model could possibly account for some of the cases of photoreceptor degenerations with incomplete penetrance (individuals who have the disease-causing mutation but show no clinical evidence of retinal degeneration).

- If one could prevent the photoreceptor degeneration by preventing an individual's exposure to an extrinsic agent or condition (e.g., toxin, drug, infectious agent, light, and trauma), then this is secondary photoreceptor degeneration of the extrinsic type (even if the body converts that agent to a toxic form as part of a normal metabolic pathway – such as methanol to formaldehyde). Clearly, the primary method of management is to avoid exposure to the extrinsic conditions that would induce the degeneration. This form of degeneration can be due to exposure to an external agent as well as deprivation of a mandatory nutrient (such as vitamin A). The deficiency can be the result of a lack of intake or synthesis of the key nutrient (vitamin-A- or zinc-deficient diet) or due to the inability to process or use such a metabolite/nutrient. Examples would be malabsorption of vitamin A and zinc due to intestinal disorders or drugs which block utilization, such as fenretinide or accutane (Table 2).
- A second mode of a combined primary and secondary photoreceptor degeneration is when one group of photoreceptors, such as the rod photoreceptors, undergoes a primary degenerative process due to a mutation in a gene that is expressed in those photoreceptors that precipitates apoptosis. At the same time, there is a second group of photoreceptors, the cone photoreceptors, which undergoes a secondary degenerative process due to alterations in the cellular environment induced by the death of neighboring cells. This situation is actually very common among patients with retinal dystrophies such as rod–cone (e.g., RP) or cone–rod forms. Recent studies of several mouse models of RP due to rod-photoreceptor specific genes have showed that the nonautonomous death of the cone photoreceptors is influenced by activation of the rapamycin pathway that can be modified by exogenous insulin, suggesting a possible intrinsic mechanism that could be influenced by a systemic therapeutic approach. The importance of this mechanism cannot be overemphasized since preservation of cone photoreceptor cells and function in a patient with RP would have a dramatic impact on maintaining useful visual function and it does not necessarily require the correction of the primary photoreceptor degeneration mechanism in the rod photoreceptors.
- If one can prevent photoreceptor degeneration by correcting or reversing a systemic or ocular metabolic or immune process, then it is a secondary photoreceptor degeneration of the intrinsic type. A number of these conditions are driven or influenced by genetic etiologies (necessary and sufficient in the case of metabolic syndromes, but often conditional or probabilistic in immune-related conditions), but the retinal degeneration is still secondary. Intrinsic causes are not exclusively genetic, one may have to consider epigenetic factors as well as immunologic memory and the microbiomics of the natural flora. Clearly, one would primarily direct therapy to correcting the primary metabolic or immune disturbance rather than focusing on modifying the behavior of the photoreceptors. Therapy might be directed specifically to the affected eye(s), (such as periocular or intraocular steroid therapy) rather than systemically, but it would be intended to primarily modify effector cells in the tissue, rather than the photoreceptors themselves (Table 3).

Table 2 Retinotoxic drugs and agents, nutrient deficiencies, infectious agents, light injury, and trauma

Drugs
Ethambutol, aminoglycosides, epinephrine, desferroximine, antimalarials (hydroxychloroquine, chloroquine, quinine), vigabatrin, phenothiazines (e.g., fluphenazine, mellaril, and stellazine).
Nutrient deficiencies
Zinc, vitamin A, omega-3 fatty acids.
Infectious
Toxoplasmosis, cytomegalovirus, herpes simplex, varicella zoster, HIV, DUSN (nematode), rubella, syphilis, prion, corona virus, others.
Toxins
Cadmium, iron (siderosis), lead, mercury (suspected), copper (intraocular chalcosis), cobalt, iodoacetic acid (IAA), methanol.
Light
Solar, laser chronic exposure.
Trauma
Commotio, retinal detachment.
Vascular
Occlusive disease, embolic, inflammatory, retinopathy of prematurity (ROP), Coats disease.

Table 3 Intrinsic factors: genes, phenotypes (e.g., RP nonsyndromic, RP syndromic, and macular degeneration), mechanism (e.g. metabolic, immune, inflammatory (inflamm))

OAT	Gyrate atrophy	Metabolic
CYP4V2	Bietti crystalline retinopathy	Metabolic
PEX1, PEX2	Zellweger Syndrome	Metabolic
PEX7, PHYH	Refsum disease (adult)	Metabolic
MTP	Abetalipoproteinemia	Metabolic
PANK2	Hypoprebetalipoproteinemia	Metabolic
	Niemann–Pick	Metabolic
	neuronal ceroid lipofuscinosis	Metabolic
CTNS	Cystinosis	Metabolic
CA4 (carbonic anyhydrase 4)	RP	Metabolic
LRP5	FEVR	Metabolic
HLA-B27, A29, B7	Ankylosing spondylitis	Immune
	Birdshot choroidopathy	Immune
	Bechet's disease	Immune
Unknown, retinal antigens, cancer	Cancer-assoc. retinopathy	Immune
	Autoimmune retinopathy	Immune
CFH	Hemolytic uremia – mac deg	Inflamm

- A mixed intrinsic and extrinsic etiology for a secondary photoreceptor degeneration would be when a person has a genetic variant that creates a toxic metabolite in the presence of an extrinsic molecule that would normally not be encountered. A normal person would not experience a retinal degeneration under the same exposure conditions. This set of conditions has overlap with the purely extrinsic and intrinsic etiologies if the genetic variation simply shifts the dose–response characteristics of the host. For example, a person is genetically predisposed to react to an extrinsic molecule at levels in the normal environment, while another person would experience similar photoreceptor degeneration only when the exposure is at levels that would exceed normal exposures. Reduction of the extrinsic exposure below the normal levels could be beneficial for these individuals (such as Refsum disease or gyrate atrophy). Alternatively, correction of the genetic variant would allow the person to cope with normal exposure levels. An animal model of the mixed intrinsic and extrinsic secondary photoreceptor degeneration would be the RPE65-MET450 mutants (intrinsic) that have varying reduced sensitivity to light-induced (extrinsic) photoreceptor degeneration as compared to animals that have the LEU450 variant in the RP65 gene.
- We are only beginning to understand these types of situations, although it is likely that many of the idiosyncratic reactions that some patients experience to certain situations or medications are the result of genetic variations that affect drug bioavailability, mechanism of action, and elimination. One such example would be the patient who develops cystoid macular edema (CME) after uncomplicated surgery. The surgical intervention would be considered an extrinsic agent. While CME is common in cases of complicated surgery and postsurgical inflammation, it is relatively uncommon (but not rare) in individuals whose surgery and postoperative care are uneventful and have no predisposing clinical conditions. Yet, this is most likely due to intrinsic (nonphotoreceptor-specific) genetic factors that govern inflammation. Persistent CME can lead to secondary photoreceptor degeneration.

If the extrinsic exposure cannot be manipulated, then essentially, one is forced to treat the mixed etiology as a purely intrinsic issue. For example, if a person had a genetic condition from an intrinsic metabolic defect that is light sensitizing such that normal ambient light would trigger photoreceptor degeneration, the distinction between an intrinsic etiology and a mixed intrinsic/extrinsic etiology becomes almost meaningless, since having a person avoid all light exposure to prevent photoreceptor degeneration is neither feasible nor desirable. However, reduction of the light exposure might alter the rate of disease progression, but therapy directed toward the intrinsic factor(s) would be essential to preserve vision under normal exposure circumstances. This situation is comparable to the mixed primary and secondary photoreceptor degeneration category (such as a mutation in an photoreceptor-specific gene that is responsible for light-dependent degeneration) except that, instead of the intrinsic etiology being disconnected from the photoreceptors themselves, the photoreceptors are directly affected by a genetic variant that renders the photoreceptors vulnerable to the extrinsic factor (e.g., light). While the reduction of the extrinsic exposure would be desirable, it may not be realistic and thus therapy would also have to be directed to the photoreceptors themselves.

The combination of extrinsic and intrinsic factors that affect photoreceptor degeneration is comparable to the genetic and environmental interactions that are often discussed in the context of complex genetic diseases such as age-related macular degeneration. At this time, our understanding of these interactions is very limited, but there are some examples for simpler retinal conditions. Mice that are heterozygous for a deletion in the PDE6B subunit (the rd mouse), a dose of sildenafil citrate (Viagra) that would normally have no effect in the normal mouse, will show a major change in the electroretinogram. It is likely that some of the individuals who experience visual side effects from this medication may have a genetic variant that reduces the overall level of phosphodiesterase activity in their retinas, thus conferring sensitivity. Another mixed etiology of secondary photoreceptor dysfunction (which can ultimately lead to degeneration) can be seen in an individual with a normally adequate intake of vitamin A, who becomes vitamin A deficient due to an acquired or hereditary malabsorption syndrome (including postsurgical bowel resection or remodeling). The etiology may be intrinsic or iatrogenic, but the treatment is directed toward the extrinsic agent by increasing the dose or mode of absorption of the vitamin A.

Mechanisms of Secondary Photoreceptor Death

Photoreceptors can die from several mechanisms, including physical lysis, destruction by thermal denaturation (such as by laser), or by triggering the apoptotic pathways. Apoptosis can be triggered by a number of disruptions, including loss of key trophic factors such as vascular endothelial growth factor (VEGF), energy depletion through mitochondrial failure, oxidative damage of proteins and lipids, release of calcium by shifts in membrane permeability, which can be caused by deregulation of ionic channels, or from the fixation of complement to the membrane

surface. Light levels below those that cause thermal denaturation can lead to direct activation of caspases, calpain 2, and cathepsin D. In addition, mitochondrial-dependent apoptotic pathways also appear to be activated.

In a number of cases, signaling of the apoptotic pathway appears to be governed by at least two pathways: the Wnt pathway and the Jak–STAT pathway. A number of research groups are attempting to identify nonspecific therapies that can block or inhibit the pathways that result in photoreceptor death. The use of ciliary neurotrophic factor (CNTF) as a trophic factor to inhibit activation of the apoptosis pathway is currently in clinical trials to treat primary and secondary photoreceptor degenerations.

As one considers these multiple mechanisms of photoreceptor death, it becomes clear that a major value of experimental animal models for these conditions is to specifically determine the extent to which photoreceptor death is a primary event and if genetic defects within the photoreceptors themselves are necessary and sufficient to initiate apoptosis. At the same time, this does not negate the importance of understanding the intrinsic (both genetic and nongenetic) factors and extrinsic factors that either trigger or modify cell death that may be amenable to therapeutic intervention at a systemic level. Finally, even in the presence of a combination of factors that lead to photoreceptor death, there is the possibility of interrupting or inhibiting the common apoptosis signaling pathways within the photoreceptor cells and other retinal neurons in order to preserve function and vision.

Secondary Photoreceptor Degenerations: Age-Related Macular Degeneration

L V Johnson, University of California, Santa Barbara, CA, USA

Glossary

Drusen – The abnormal deposits containing cellular debris and inflammatory molecules that form beneath the retinal pigmented epithelium (RPE) and are associated with the development of age-related macular degeneration.

Macula – The portion of the retina that is responsible for fine acuity vision in the central visual field. It is a small (~6 mm diameter) area located at the posterior pole of the eye near the optic nerve that is structurally unique and contains the highest concentration of cone photoreceptor cells in the retina.

Photoreceptor – The cells of the retina responsible for the absorption of light and its conversion to electrical signals that are transmitted to the brain. In humans, there are two types of photoreceptor cells: rods and cones. Rod photoreceptor cells are very sensitive in dim light situations but do not provide high resolution or color vision. Cone photoreceptor cells are less sensitive than rods but in bright light distinguish colors and provide for high-acuity vision owing to their concentration in the macula.

Retina – The light-sensitive part of the eye that lines its inner surface. It is a multilayered tissue that collects light, processes electronic signals produced by the light, and transmits those signals to the brain.

Retinal pigmented epithelium(RPE) – A pigmented monolayer of cells lying directly adjacent to the retina that provides support for the photoreceptor cells. Its functions include absorption of excess light; processing of molecules required for transduction of light into electrical signals; removal of cellular debris shed by photoreceptor cells; and transport of nutrients, waste products, and ions.

Introduction

Age-related macular degeneration (AMD) is a disease of the eye that causes loss of vision in the center of the visual field. Central vision is mediated by a region of the retina, known as the macula that is specialized for fine acuity vision such as that used for reading and other tasks that require fine focus and high resolution. While the macula comprises only 4% of the retina (it is only 6 mm in diameter), it is responsible for essentially all scotopic (bright light) vision and almost 10% of our visual field. In AMD, the light-sensitive photoreceptor cells in this critical region of the retina become dysfunctional and die resulting in symptoms ranging from slight visual distortions to complete loss of central vision.

Incidence

As the name implies, AMD is most common in the elderly, its incidence being highest in those over 50 years of age. It is the most common cause of irreversible blindness in elderly individuals worldwide and its clinical symptoms are recognized in more than one-third of persons over the age of 75 in industrialized societies. In 2004, it was estimated that over 9 million persons were affected by some form of AMD in the United States alone. It is expected that this number will reach almost 15 million by the year 2020. There are other diseases that affect the macula in younger individuals, but the frequencies of these are significantly less than for AMD and many of these are known to be monogenic diseases, that is, caused by single gene mutations (e.g., vitelliform macular dystrophy, Sorsby's fundus dystrophy, and malattia leventinese).

The Macula

It is not yet clear why the macula is preferentially affected in AMD. The term macula is derived from the Latin *macula lutea* (yellow spot) that describes the appearance of the macula in life due to the accumulation of two carotenoid pigments, lutein and zeaxanthin, in the macular retina. Lutein and zeaxanthin are thought to function as antioxidants and filters of high-energy blue light, and thus protect the macula from light-induced oxidative damage. The fovea is the centermost 2 mm of the macula and is the region of the retina where cone photoreceptor density is highest (up to 200 000 cells mm^2) and visual acuity is maximal. One factor that may contribute to macular sensitivity is its relative lack of vasculature compared to the rest of the retina. Despite the fact that photoreceptor cell density is highest in this region of the retina and photoreceptor cells consume oxygen at a higher rate than any other cells in the body, the inner retina here is thinned and avascular. As a consequence, macular photoreceptors appear to rely on the choroidal capillary bed, the choriocapillaris, as their primary source for oxygen and nutrients. Age-related decreases in choroidal vascular volume and flow could thus compromise macular photoreceptor cells. Age-related changes in Bruch's membrane that are more pronounced in the macular region than elsewhere in the eye may also contribute to the macula's particular susceptibility to pathogenic changes leading to AMD.

Clinical Symptoms

AMD is typically classified into early and late forms. Early AMD (dry or atrophic AMD) is characterized by the appearance of abnormal extracellular deposits known as drusen that form below the retinal pigmented epithelium (RPE) and by focal areas of increased or decreased pigmentation in the RPE and choroid. Drusen are classified as hard (small, distinct, and hemispherical) or soft (large, diffuse, and amorphous) based on their fundoscopic and histologic appearance. Late AMD has two forms: neovascular AMD (wet or exudative AMD) and geographic atrophy, the end stage of dry AMD when neovascularization does not occur (**Figure 1**).

Neovascular AMD is typified by the growth of blood vessels from the choroid into the RPE and the subretinal space (choroidal neovascularization or CNV) and subretinal hemorrhage that cause severe damage to the retina, leading to precipitous vision loss. Physicians

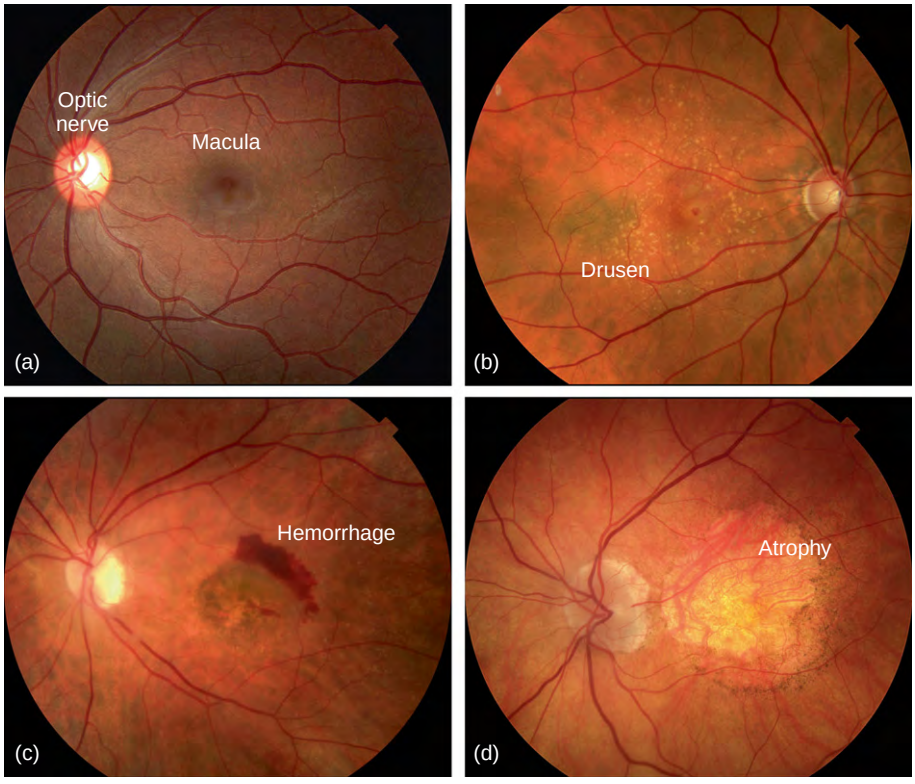

Figure 1 Fundus photographs. Characteristic examples of fundus photographs from a normal, nondiseased eye (a) and eyes with dry AMD (b), wet AMD (c), and geographic atrophy (d). In (b) the hard drusen (numerous small spots) that are characteristic of dry AMD can be seen surrounding the macula. In (c) an area of bleeding (hemorrhage) is present near the macula of an eye with wet AMD. In (d) a large area of atrophy encompassing the entire macular region can be seen in an eye with geographic atrophy. Photographs: courtesy of Dr. Robert Avery.

often use a procedure known as fluorescein angiography to assess the extent of CNV in patients suspected of having neovascular AMD. If untreated, neovascular AMD can lead to the development of a disk-shaped fibrovascular scar underlying the macula and severe loss of central vision (central scotoma). Individuals who develop neovascular AMD in one eye are likely to have it develop in the other (contralateral) eye and thus the risk of bilateral vision loss is high in neovascular AMD. Geographic atrophy is characterized by widespread areas of depigmentation that represent areas of degeneration of the RPE and adjacent photoreceptor cells of the retina. Atrophy of the capillary bed (choriocapillaris) of the choroid is also commonly associated with geographic atrophy. Ultimately, these areas coalesce to form a large distinct area of degeneration that encompasses the macula and causes loss of central vision.

In early, dry AMD, vision loss is gradual and progresses over many years. As such, individuals with early AMD are often unaware of their visual dysfunction. More rapid and severe vision loss is seen in individuals where early AMD progresses to geographic atrophy or neovascular AMD; this occurs in 10–15% of individuals in each case.

Histopathology

Numerous studies show that the earliest pathologic changes associated with AMD occur in the RPE and the adjacent extracellular matrix complex known as Bruch's membrane, which undergoes a substantial number of changes in association with aging and AMD. These include thickening, accumulation of lipids and cholesterol, decreased permeability, and development of deposits of extracellular debris between Bruch's membrane and the RPE. The most prominent of these deposits are known as drusen (German for geodes, because of their glittering appearance when first described) (Figure 2).

Large numbers and extensive areas of drusen deposits in the macula (especially soft drusen) are potent risk factors for the development of AMD. It is thought that drusen diminish access to vital nutrients and oxygen diffusing from the choroidal vessels, leading to the compromise of overlying RPE cells and secondarily to the dysfunction and death of the photoreceptor cells in the adjacent neural retina.

The process of drusen formation is poorly characterized. Drusen are comprised of protein and lipid molecules, many of which are known to be involved in inflammatory processes. These include activators of the complement system, activated complement components, and complement regulatory molecules. As such, it has been proposed that drusen formation is the byproduct of chronic local inflammatory processes. Many drusen components are normal constituents of circulating plasma and it has been suggested that reduced choroidal blood flow associated with AMD leads to increased hydrostatic pressure in the choroidal capillaries forcing plasma proteins extravascularly into the sub-RPE space. However, some drusen-associated molecules are known to be biosynthetic products of RPE cells and cellular debris, likely of RPE origin, is frequently observed in drusen. It is thus likely that RPE-derived molecules also contribute to drusen biogenesis; however, causative conditions and precise mechanisms remain to be identified. It has also been noted that some molecular constituents of drusen have been oxidatively modified, consistent with the idea that oxidative damage may be an important component of drusen formation and AMD pathogenesis.

Risk Factors

The two most significant risk factors for AMD are age and heredity. As noted above, the disease is most commonly diagnosed in individuals over 50 years of age. There is a

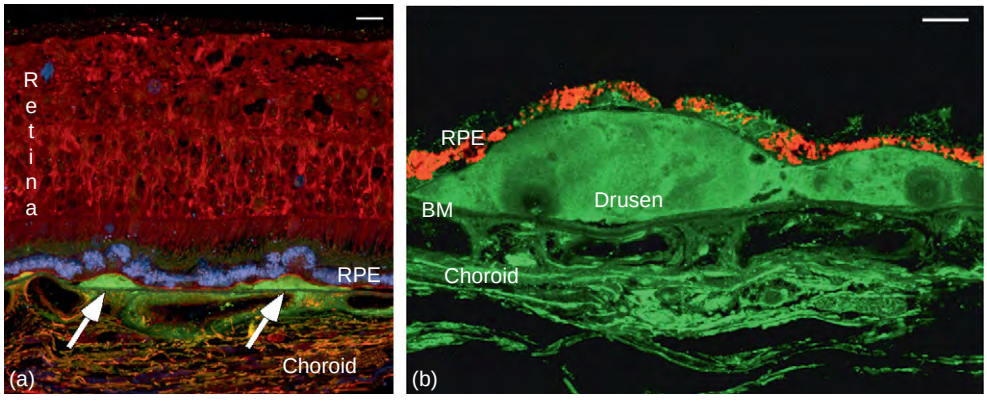

Figure 2 Drusen histology. (a) Two large drusen (green, arrows) are seen lying between the retinal pigmented epithelium (RPE, blue) and the choroid. The adjacent retina is stained red. Scale = 10 μm. (b) At higher magnification, two adjacent drusen (green) are seen displacing the RPE (red) from Bruch's membrane (BM). Scale = 5 μm.

significant increase in AMD risk if close family members are afflicted with the disease. Individuals who have a first-degree relative (parent or sibling) with the disease are more than twice as likely to be afflicted as those without afflicted relatives. They also tend to be affected at an earlier age. These results indicate that specific genetic attributes are likely to be involved in influencing an individual's susceptibility to AMD (see the section titled 'Genetics').

Of environmental risk factors, smoking is the most significant modifiable risk factor for AMD. One study indicates that approximately 25% of AMD cases in individuals over 70 may be attributable to risk conferred by smoking. The preponderance of epidemiological data shows that smokers have a two- to threefold increased risk of having late AMD, neovascular AMD, or geographic atrophy, compared to individuals who have never smoked. There is a dose–response effect in that the risk of developing AMD increases in relation to the duration and intensity of smoking history. It also appears that the average age of onset of AMD symptoms is earlier in smokers compared to nonsmokers, as is the likelihood of disease in both eyes. Stopping smoking, however, can have beneficial effects. While ex-smokers still have an increased AMD risk compared to never-smokers, it is significantly lower than for current smokers. It has been suggested that the increased AMD risk conferred by smoking is related to oxidative damage in the retina, induction of proinflammatory mediators, reduced choroidal blood flow, and decreased levels of protective carotenoid pigments (lutein, zeaxanthin) in the macular retina.

Obesity (or elevated body mass index) has also been linked to an increased risk of progression to late-stage AMD. It has been proposed that this relationship is due to increased oxidative stress, reduced antioxidant defense mechanisms, and/or increased incidence of chronic low-grade inflammation in obese individuals. Low-grade systemic inflammation may contribute to AMD pathogenesis directly through inflammatory damage at the level of the RPE and Bruch's membrane, or secondarily by reducing systemic availability of the macular pigments, lutein and zeaxanthin (increased body fat is associated with decreased serum and macular levels of carotenoids).

Reduced progression of early AMD and reduced risk for neovascular AMD is associated with dietary supplementation with antioxidant vitamins and minerals (the Age-Related Eye Disease Study (AREDS) supplement: 500 mg vitamin C, 50 mg vitamin E, 15 mg beta carotene, 80 mg zinc, and 2 mg copper daily). Diets high in foods that are good sources of the macular carotenoid pigments (e.g., certain green leafy vegetables) and omega-3 fatty acids (e.g., fatty fish and flaxseed) are also associated with decreased incidence of AMD. Interestingly, some epidemiological studies have noted a decreased risk of AMD in individuals who regularly use antacids or anti-inflammatory medications.

Genetics

Genes in two chromosomal regions, one on chromosome 1 (1q32) and one on chromosome 10 (10q26), have now been linked to a significant proportion of AMD cases. In both cases, certain single-base differences in DNA sequence (single-nucleotide polymorphisms or SNPs) in specific genes have been shown to be present at higher frequency in individuals with AMD than in those not afflicted with the disease. Together, genetic variants in these two chromosomal loci confer significant risk for AMD and can account for over half of AMD cases. The implicated gene on chromosome 1 is that for complement factor H (*CFH*), which lies within an area of the chromosome known as the regulator of complement activation (RCA) locus that is known to be involved in modulating activity of the complement system. The involvement of the complement system in AMD that is implied by these observations is consistent with pathological evidence suggesting that chronic inflammation has a primary role in the AMD disease process (see the section titled 'Histopathology'). The AMD-associated genes on chromosome 10 are tightly linked and include *PLEKHA1, ARMS2 (LOC387715)*, and *HTRA1*. The functions of the proteins encoded by these genes and their potential relationship to AMD pathogenesis are less well defined than for *CFH*. *HTRA1* encodes a serine protease and *PLEKHA1* a plekstrin-homology-domain-containing protein; the product of the *ARMS2* gene has not been completely characterized but may be a mitochondrial protein. Polymorphisms in the genes in these two chromosomal loci, especially *CFH* and *ARMS2/HTRA1* (see below), can account for a substantial number of AMD cases. Several additional genes, including those encoding complement component C3, complement factor B, the adenosine triphosphate (ATP)-binding cassette transporter (ABCA4), fibulin-5, apolipoprotein E, human leukocyte antigens, and others have been associated with smaller percentages of AMD cases.

CFH

A SNP (rs1061170) in the gene for *CFH* has been shown in numerous studies to be associated with increased risk for both forms of late AMD. The *CFH* gene is located on human chromosome 1 (1q32) in an area often linked to AMD in familial and population-based studies. The risk-conferring polymorphism in *CFH* results in a thymidine (T) to cytosine (C) substitution at nucleotide position 1277 in exon 9 of the gene. Individuals carrying one copy of the C allele (heterozygotes) are 2–5 times more likely to be afflicted with AMD and carriers of two copies (homozygotes) are 3–7 times more likely to be afflicted. The T → C nucleotide change leads to a tyrosine to histidine shift at amino acid position 402 (Y402H) of the

CFH protein. At the time of writing, the functional implications of this amino acid change have not been fully characterized but the affected site in the protein is one that is known to contribute to a number of CFH functions, including the binding of heparin and C-reactive protein. *CFH* is an important negative regulator of the alternative pathway of complement activation and it is hypothesized that the 402H variant of the molecule may have reduced inhibitory activity. Compromised regulation of the complement system could lead to inflammation and complement-mediated damage to the RPE, and secondary damage to the retina. Combined analyses of polymorphisms in *CFH* and genes encoding some other members of the complement system (complement factor B, complement component 2) indicate that their AMD risk-conferring variants can together account for nearly 75% of AMD cases. There is additional evidence that environmental risk factors, such as smoking and obesity, can combine with genetic risk to increase AMD susceptibility even further. For example, the risk of AMD is 8–10 times higher in individuals who are both homozygous for the risk-conferring C allele in the *CFH* gene and smoke. Additional variants in the *CFH* and related genes have also been linked to AMD risk. For example, deletion of two *CFH*-related genes (*CFHR1* and *CFHR3*) has been shown to have protective effects and decrease the likelihood of AMD.

ARMS2/HTRA1

Both the *ARMS2* and *HTRA1* genes contain polymorphisms that have been associated with increased risk for AMD and they exhibit a high degree of linkage disequilibrium (i.e., they are essentially always transmitted together). Because of this latter property it has been difficult to determine which of the polymorphisms is responsible for the associated AMD risk. In addition, biological evidence supporting a role for both has been presented. One *ARMS2* polymorphism (rs10490924) leads to a change in a region of the gene that is predicted to result in an amino acid change from alanine to serine at position 69 (A69S) of the ARMS2 protein. Some data suggest that the ARMS2 protein is located in mitochondria and that it is involved in modulating oxidative stress and associated apoptosis, but there is no direct evidence yet linking ARMS2 protein dysfunction and the AMD disease process. An additional *ARMS2* polymorphism that involves both deletion and insertion of genetic material has been shown to lead to messenger RNA (mRNA) instability and marked reduction in the levels of *ARMS2* transcripts, and is significantly associated with AMD risk. ARMS2 protein is highly expressed in the retina and it has been proposed that dysfunctional ARMS2 and/or reduced levels of ARMS2 in mitochondria-rich retinal photoreceptor cells may enhance susceptibility to age-associated mitochondrial dysfunction that leads to photoreceptor compromise and visual loss.

The AMD-linked polymorphism in the *HTRA1* gene (rs11200638) lies in the gene's promoter region and some data have suggested that the risk-conferring allele leads to altered binding of transcription factors, increased transcription of the gene, and elevated HTRA1 protein levels, but other studies have not confirmed this observation.

Treatments

Most therapeutic approaches for AMD have historically focused on the neovascular form of the disease, as it is the one which is responsible for the most severe and precipitous vision loss. Therapies for neovascular AMD have included thermal laser photocoagulation of leaky neovessels and photodynamic therapy that utilizes laser activation of an intravenously administered compound that damages the endothelial cells of neovessels, leading to thrombosis. These approaches were applicable to less than half the patients with neovascular AMD and thus, to less than 5% of all AMD patients. More recently, molecular inhibitors of vascular growth factors (primarily vascular endothelial growth factor, VEGF) have been exploited to limit neovascularization in a variety of ocular neovascular processes. Such VEGF inhibitors are generally administered in multiple intravitreal injections and act by inhibiting the interaction of VEGF with its receptor on the surfaces of vascular endothelial cells. The binding of VEGF to its receptor promotes endothelial cell proliferation, vessel growth, and increased vascular permeability, leading to the development of CNV in affected eyes. The most striking results to date have been provided by antibody-based compounds (Lucentis and Avastin) that are directed against VEGF and inhibit its function. These compounds have provided unprecedented benefits in terms of visual stabilization in most patients with CNV and visual improvement in many. It is anticipated that advances in the specificity, efficacy, durability, and deliverability of anti-VEGF compounds, as well as compounds directed against additional vascular growth factors, will continue to advance the physician's ability to combat neovascular AMD. However, similar therapeutic advances have not been made for the dry or atrophic forms of AMD that represent 85–90% of disease cases.

Stability and Functional Integrity of New Blood Vessels

A Uemura, Kobe University Graduate School of Medicine, Kobe, Japan

Glossary

Adherens junction – The protein complex at cell–cell junction in epithelial tissue, which appears as a band encircling the cell.
Extracellular matrix – The matrix surrounding cells that includes the interstitial matrix and the basement membrane. It provides structural support to the cells, serves as a reservoir of cytokines and growth factors, and mediates various biological functions.
Inflammation – The complex biological response of blood vessels to extrinsic stimuli, such as pathogens, involving the increased movement of plasma and leukocytes from the blood into the injured tissues.
Tight junction – The close association between two cells whose membranes join together to form a firm, impermeable barrier to fluid.
Weibel–Palade body – The endothelial organelle storing presynthesized molecules that are rapidly released in response to thrombin, histamine, serotonin, and other secretagogs. The stored molecules include von-Willebrand factor, P-selectin, angiopoietin-2, and others involved in the control of hemostasis, inflammation, or permeability.

Formation of New Blood Vessels During Development and Under Pathological Conditions

During development, an imbalance between oxygen supply and demand within growing organs or tissues results in physiological hypoxia, which triggers a series of cellular and molecular events leading to the formation of new blood vessels. This process is called angiogenesis. Among the increasing list of pro-angiogenic growth factors, the best characterized is vascular endothelial growth factor (VEGF, also referred to as VEGF-A), which binds to the receptor tyrosine kinases, VEGF receptor-1 (VEGFR-1; Flt-1) and VEGFR-2 (Flk-1; KDR). VEGF binding to VEGFR-2 on endothelial cells evokes multiple cascades of intracellular signaling events, which stimulate the proliferation and migration of endothelial cells, and increase vascular permeability. New blood vessels are initially leaky and unstable, but homotypic endothelial–endothelial contacts limit paracellular leakage and provide structural continuity, connecting the cytoskeletal structure of adjacent cells. In addition to these homotypic contacts, nascent endothelial cells also recruit pericytes, which become embedded in the vascular basement membrane and extend long cytoplasmic processes that make focal contacts with several different endothelial cells. Pericytes have long been assumed to simply support the mechanical integrity of the vascular structure, but recent studies have revealed that they also contribute to the stability of the vascular structure through the release, presentation, and activation of signals that act on endothelial cells and strengthen cell–cell and cell–matrix associations. The combination of homotypic and heterotypic cell–cell contacts produces an infrastructure that not only renders blood vessels quiescent, with endothelial cell turnover rates of months to years, but also renders them highly resistant to leakage and inflammation. However, this functional integrity of blood vessels is disrupted in some pathological conditions, such as certain ocular diseases, by pro-angiogenic insults. In diabetic retinopathy and age-related macular degeneration, angiogenesis occurs in response to ischemia or inflammation, but the newly formed blood vessels are unstable, resulting in prolonged retinal edema and hemorrhage. It is therefore clinically important to understand the complex mechanisms underlying the stability and functional integrity of new blood vessels. Recent studies have revealed the cellular and molecular bases responsible for the control of both the homotypic and heterotypic cellular interactions that take place in blood vessels. Surprisingly, the extracellular and intracellular signals involved in these events are closely associated, and provide potentially valuable information for the development of novel therapeutic modalities for restoring vascular integrity in retinal vascular disorders.

Cell–Cell Adhesive Junctions in Blood Vessel Walls

Cell–cell contacts in blood vessel walls are remarkably complex, comprising membrane-associated adhesion proteins, including vascular endothelial (VE)-cadherin and neural (N)-cadherin at adherens junctions, and occludin, claudins, and junctional adhesion molecules at tight junctions. Among these junctional proteins, VE-cadherin and claudin-5 are endothelial-specific molecules, present in most blood vessels. These adhesive junctions contribute to the lack of paracellular permeability, especially in the blood–retina barrier, where endothelial–endothelial interfaces are enriched in tight junctions. In addition, cell–cell contacts modulate various endothelial functions

through a network of intracellular signals. At adherens junctions, VE-cadherin is directly or indirectly bound inside the cells to multiple intracellular partners, including β-catenin, p120-catenin, plakoglobin, vascular endothelial protein tyrosine phosphatase (VE-PTP), density-enhanced phosphatase (DEP)-1, and others. The intracellular components at tight junctions are members of the zonula occludens protein (ZO) family (ZO-1, -2, and -3), AF6/Afadin, PAR-3/ASIP, MUPP-1, and others. Upon contact with neighboring endothelial cells, the formation of adherens junctions precedes that of tight junctions. Interestingly, in the course of junction formation, ZO-1, which is initially localized at adherens junctions, moves to the tight junctions. The nature of these junctions changes depending on the angiogenic status, allowing vessels to grow, or return to a quiescent state.

While tight-junction components interact with several signal transduction molecules, such as G proteins and protein kinases, intensive studies on adherens junctions have demonstrated the importance of VE-cadherin in mediating intracellular signals to control endothelial behavior (**Figure 1**). During the quiescent state, VE-cadherin clustering transmits intracellular signals that promote survival and inhibit the motility of endothelial cells, by regulating the activities of phosphoinositide 3-kinase (PI3-K) and the serine–threonine kinase Akt, as well as the small guanosine triphosphatases (GTPases), Ras-related C3 botulinum toxin substrate (Rac1) and Ras homolog gene family, member A (RhoA). PI3-K/Akt activation by VE-cadherin inactivates the forkhead transcription repressor FKHR (FOXO1), leading to upregulation of the claudin-5 gene, suggesting that molecular communication between adherens and tight junctions strengthens inter-endothelial cell contacts. Furthermore, VE-cadherin associates with VEGFR-2 and negatively regulates its intracellular signaling properties. For example, density-enhanced phosphatase-1 (DEP-1) and other phosphatases associated with the VE-cadherin/catenin complex dephosphorylate VEGFR-2 and inhibit its internalization, leading to reduced activation of mitogen-activated protein kinase (MAPK). These functions of VE-cadherin may partly explain the poor proliferative responses of quiescent vessels to stimulation by VEGF. However, during the angiogenic state, VEGF binding to VEGFR-2 activates nonreceptor Src family kinases that mediate VE-cadherin phosphorylation, leading to dissociation from p120- and β-catenin, internalization into clathrin-coated vesicles, and β-arrestin-dependent endocytosis of VE-cadherin. Thus, the increased vascular permeability mediated by VEGF signaling can be explained, at least in part, by the disassembly of adherens junctions, and subsequent disruption of the endothelial barrier function. Moreover, redistribution of VE-cadherin further enhances VEGF signaling through reduction of the activities of the c-Src tyrosine kinase (Csk), which can bind to phosphorylated VE-cadherin and inactivate Src family kinases. In addition to VEGF, fibroblast growth factor signaling also mediates decoupling of p120-catenin from VE-cadherin, leading to a loss of vessel integrity.

Recruitment of Pericytes in New Blood Vessels

While pericytes are assumed to belong to the same cell lineage as vascular smooth muscle cells (vSMCs), they are distinguished by their location: pericytes occur in intermediate- to small-sized vessels, while vSMCs occur in large arteries or veins. However, depending on the vascular beds, pericytes display remarkable heterogeneity in their morphology, as well as in their frequency relative to endothelial cells, which may reflect their diverse functions. Likewise, depending on the organs or tissues, pericytes have multiple origins, including mesoderm or neural crests. While pericyte differentiation from mesenchymal precursor cells can be induced by transforming growth factor (TGF)-β signaling in *in vitro* culture systems, variable effects of this signaling, both on endothelial cells and pericytes, have hindered a clear understanding of their *in vivo* functions in blood vessel formation. It should be noted that endothelial dysfunction accounts for many of the vascular abnormalities seen in mice with genetic mutations of the ligand TGF-β1, its receptors (activin-receptor-like kinase (Alk)-1 and -5, TGF-β receptor II, and endoglin), or its downstream effector (Smad5), as well as in human hereditary hemorrhagic telangiectasia (HHT) where the endothelial receptors endoglin (type 1 HHT) or Alk1 (type 2 HHT) are mutated. TGF-β modulates the differentiation, proliferation, or migration of endothelial cells, depending on distinct subsets of receptors and downstream effectors, whereas its antiproliferative and antimigratory effects are enhanced in the presence of clustered VE-cadherin.

During the maturation of blood vessels, the pericyte population is expanded by signals mediated by platelet-derived growth factor (PDGF)-B and its receptor β (PDGFRβ). In newly formed blood vessels, PDGF-B derived from endothelial cells, especially those residing at the sprouting vascular tips, promotes the proliferation and migration of PDGFRβ-expressing pericytes. In addition to its localized gene expression in the actively angiogenic endothelium, the spatial distribution of PDGF-B protein is strictly controlled by the binding of its retention motif to heparan sulfate proteoglycans. Disruption of either the PDGF-B or PDGFRβ gene in mice perturbs pericyte recruitment, leading to defective endothelial integrity. Interestingly, vascular dysfunction due to a lack of pericytes is most remarkable in the central nervous system, where pericyte recruitment depends exclusively on their migration from preexisting vessels to new vessel walls, rather than on their *de novo* induction from the

surrounding mesenchyme. This indicates less potential for PDGF-B/PDGFRβ involvement in the initial steps of pericyte differentiation.

Upon recruitment to new blood vessels, endothelial–pericyte contacts are promoted by N-cadherin, which is expressed in both endothelial cells and pericytes. The trafficking of N-cadherin to polarized plasma membrane

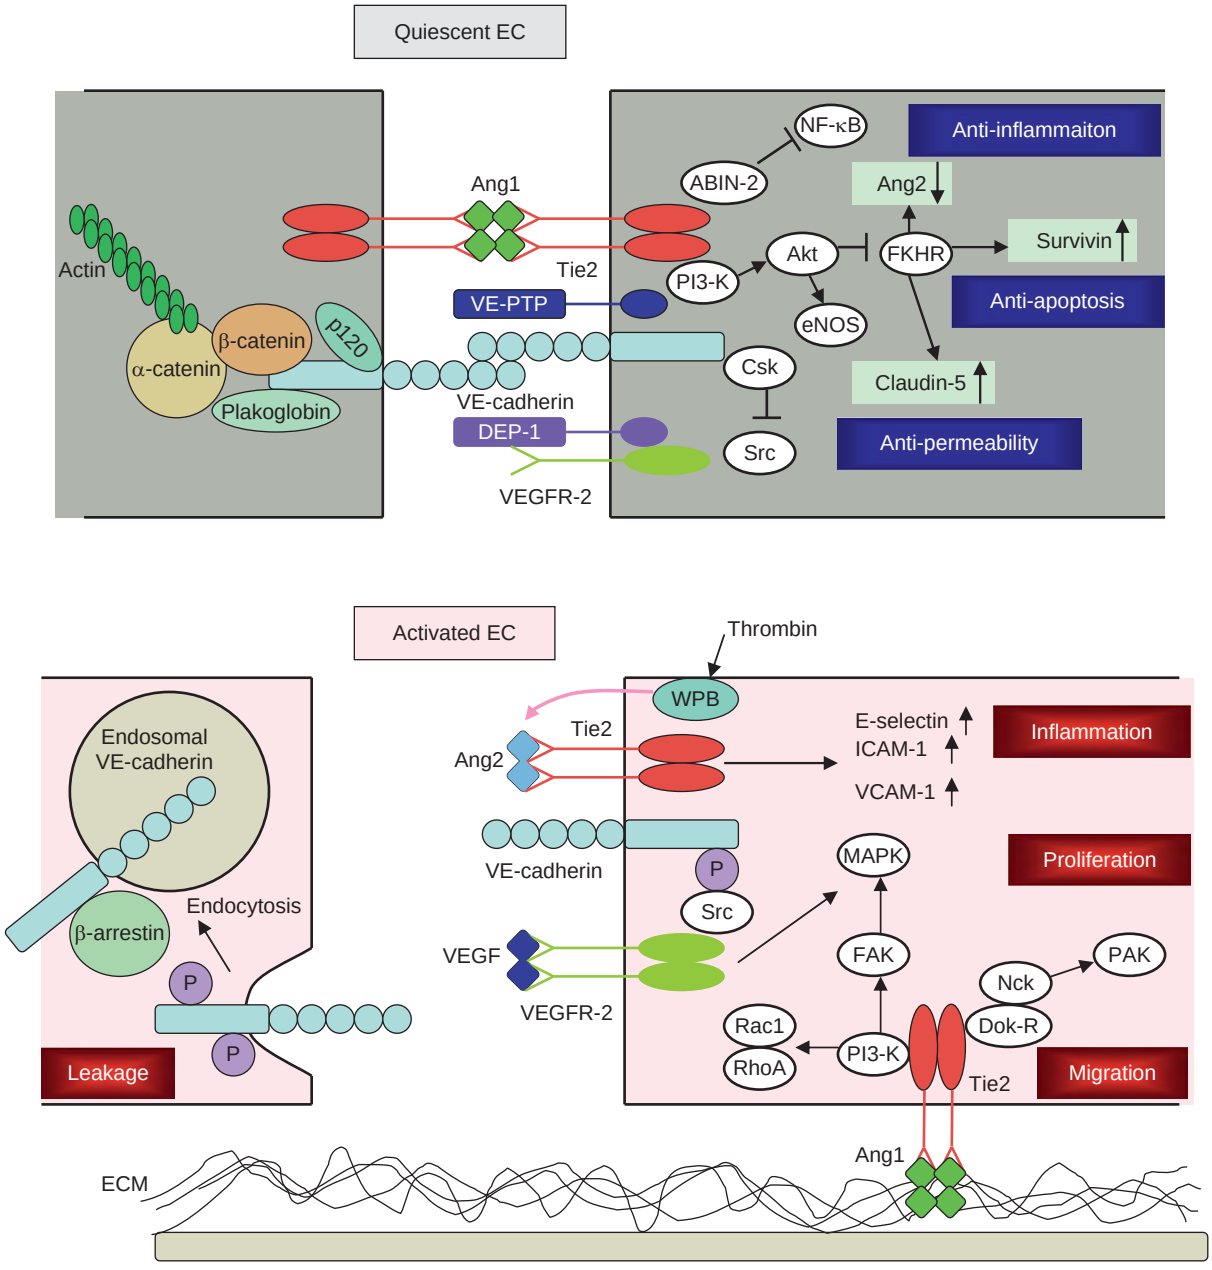

Figure 1 Extracellular and intracellular signals in quiescent and activated endothelial cells. In quiescent endothelial cells (EC), clustering of VE-cadherin at adherens junctions promotes the formation of multimolecular complexes in which plakoglobin and β-catenin directly associate with actin-binding proteins such as α-catenin. DEP-1 dephosphorylates VEGFR-2, whereas Csk negatively regulates Src-mediated VE-cadherin phosphorylation, leading to the maintenance of endothelial barrier function and vascular quiescence. At cell–cell contacts, *trans*-associated Tie2 complexes bridged by multimerized Ang1 comprise Tie1 and VE-PTP, and activate the PI3-K/Akt pathway, leading to enhancement of endothelial survival. Activated Tie2 also recruits ABIN-2 and suppresses inflammatory responses by inactivating NF-κB. On the other hand, Ang2 protein stored in Weibel–Palade bodies (WPB) is rapidly released upon stimulation by thrombin or other secretagogs, rendering EC highly responsive to pro-angiogenic and proinflammatory cytokines, such as VEGF and TNF-α, respectively. VEGF binding to VEGFR-2 activates Src, and subsequent phosphorylation and endocytosis of VE-cadherin impair junctional integrity, leading to increased vascular permeability. In the absence of cell–cell contacts, Ang1–Tie2 complexes anchor basal plasma membranes to the extracellular matrix (ECM) and preferentially activate signaling pathways involved in the control of cell migration, including Dok-R and FAK.

domains is facilitated by sphingosine-1-phosphate (S1P)-mediated activation of the G protein-coupled endothelial differentiation gene (EDG)-1 receptor, which is crucial for pericyte adhesion to endothelial surfaces.

Angiopoietin/Tie Signals as Regulators of Stability and Integrity of Blood Vessels

Angiopoietin-1 (Ang1) secreted from pericytes activates the Tie2 receptor tyrosine kinase expressed on endothelial cells. Whereas the Ang1/Tie2 signal regulates the dynamic, morphogenetic processes of growing vascular networks, constitutive Tie2 activation is further required for promoting endothelial survival and preventing vascular leakage and inflammation in quiescent blood vessels. By contrast, Ang2 counteracts the Ang1/Tie2 signaling axis, thereby rendering endothelial cells responsive to pro-angiogenic and proinflammatory stimuli. Thus, the Tie2 activation status determined by the balance between Ang1 and Ang2 is critical in the organization and stabilization of vascular structure.

Molecular Properties of Angiopoietins and Tie Receptors

Ang1, Ang2, Ang3, and Ang4 have been identified as endogenous ligands for Tie2, among which Ang1 and Ang2 have been characterized as the predominant regulators of Tie2 activities. The angiopoietins share a similar overall structure, with a short amino-terminal motif followed by a coiled-coil domain and carboxy-terminal fibrinogen-like domain. The fibrinogen-like domain is responsible for receptor binding, the coiled-coil domain is required for dimerization of angiopoietin monomers, and the short amino-terminal motif forms ring-like structures that cluster dimers into variable sized multimers, which is a necessary step in Tie2 activation. Ang1 and Ang2 have indistinguishable binding sites on Tie2 and similar binding affinities. Although Ang2 counteracts Ang1/Tie2 signaling in endothelial cells, direct evidence for an inhibitory effect of Ang2 on Tie2 phosphorylation is lacking. In *in vitro* culture systems, Ang2 can activate Tie2 transfected into nonendothelial cells, or even native Tie2 expressed on endothelial cells under certain experimental conditions. Indeed, Ang2 has been demonstrated to act as an autocrine factor that activates Tie2 *in vivo*, inhibiting apoptosis and vascular leakage in stressed endothelial cells. Ang2 might therefore be better considered as a partial agonist, rather than a full antagonist. In addition to Tie2, its close relative, Tie1, is also phosphorylated in endothelial cells by Ang1, but not by Ang2. It is likely that Ang1 activates Tie1 either directly, or indirectly through binding to Tie2, which forms a complex with Tie1. Moreover, Ang1 can bind to integrin $\alpha 5\beta 1$, an endothelial receptor for fibronectin, through the receptor-binding fibrinogen-like domain. Ang1-mediated bridging of Tie2, integrin, and fibronectin anchor endothelial membranes to the underlying extracellular matrix and enhance Ang1-activated endothelial adhesion and motility. By contrast, at endothelial–endothelial contacts, Ang1 induces the formation of homotypic Tie2–Tie2 *trans*-associated complexes that include VE-PTP and Tie1, leading to inhibition of paracellular permeability and promotion of endothelial quiescence. Intriguingly, distinct downstream signals are activated depending on the Tie2 localization, either at cell–matrix or cell–cell contacts, which may explain the differential effects of Ang1 in the formation and stabilization of blood vessels (**Figure 1**).

Regulation of Angiogenesis and Vascular Homeostasis by Ang/Tie Signals

Significant insights into the functional roles of Ang/Tie signals have been obtained from studies of genetically mutated mice. Defects in the remodeling of primary capillary networks, which show reduced morphological complexity with dilated vessels, diminished branching and sprouting, and vessel rupture, are common features of mouse models lacking the Tie2 or Ang1 gene. In these mutant mice, dysfunctional endothelial cells fail to properly associate with the underlying matrix and the pericytes. These findings suggest a critical role for the Ang1/Tie2 signal in the stabilization and maturation of vascular structure. This notion is further supported by the presence of leakage-resistant vessels in the skin of transgenic mice overexpressing Ang1 under the control of a keratinocyte-specific promoter. On the other hand, mice lacking Tie1 demonstrate a phenotype characterized by defective vascular integrity and quiescence, which is partially similar to, but distinct from, that seen in mice lacking Tie2 or Ang1.

In contrast to the relatively stable expression of Ang1 in pericytes, Ang2 expression occurs predominantly in areas where either vascular sprouting or regression is taking place. Transgenic mice overexpressing Ang2 under the control of an endothelium-specific promoter display a vascular phenotype similar to that observed in Ang1- or Tie2-deficient mice. These findings suggest that binding of Ang2 to Tie2 interferes with Ang1-induced vascular stabilization, making vessels more sensitive to the actions of other cytokines, such as VEGF. In this model, Ang2 acts as a pro-angiogenic cytokine in the presence of VEGF, whereas it induces vascular regression in the absence of VEGF. The latter scenario is consistent with the delayed regression of the hyaloid vessels seen in the eyes of Ang2-deficient mice. Interestingly, defective vascular phenotypes selectively seen in postnatal retinas, but not in other organs, of Ang2-deficient mice suggest that Ang2 is required for specific angiogenic processes, presumably those involved in sprouting angiogenesis.

In the adult vasculature, Ang1 derived from pericytes constitutively phosphorylates Tie2 at a low level to

maintain the mature phenotype of the endothelium. The importance of the degree of Tie2 activation is demonstrated by the observation that an activating mutation of the Tie2 gene causes venous malformations in humans. This Ang1/Tie2 signal can counteract leakage-inducing stimuli such as VEGF. Ang2 expression is almost absent in the quiescent vasculature, but Ang2 gene expression is dramatically upregulated, mainly in endothelial cells, in response to hypoxia or VEGF. Ang2 destabilizes the endothelial–pericyte association, thereby priming endothelial cells to respond to pro-angiogenic stimuli. In addition, upon stimulation by thrombin or other secretagogs, presynthesized Ang2 protein stored in Weibel–Palade bodies is rapidly released, rendering quiescent endothelium highly responsive to proinflammatory cytokines such as tumor necrosis factor (TNF)-α, leading to the upregulation of a number of endothelial–leukocyte adhesion molecules, including E-selectin, intercellular adhesion molecule-1 (ICAM-1), and vascular cell adhesion molecule-1 (VCAM-1). Thus, vascular homeostasis, maintained by the Ang1/Tie2 default pathway, can be disrupted by Ang2 activation.

Intracellular Signaling Cascades Mediated by Tie2 Activation

Ang1 binding to the Tie2 extracellular domain rapidly mediates receptor dimerization, activation of its kinase domain, and autophosphorylation of specific tyrosine residues in its intracellular domain. Among the intracellular events triggered by Tie2 activation, signaling through PI3-K appears to be essential for Tie2-mediated survival and motility of endothelial cells. Binding of PI3-K to the phosphorylated tyrosine residue in the Tie2 intracellular domain activates Akt, which in turn inactivates FKHR, leading to upregulation of the survivin gene and downregulation of the Ang2 gene. The PI3-K/Akt pathway further activates endothelial nitric oxide synthase (eNOS) that modulates various endothelial functions, including cell survival. These signals together exert anti-apoptotic effects and promote vascular quiescence. PI3-K also regulates the activities of intracellular signals involved in the control of cell adhesion and migration, including the focal adhesion kinase (FAK), RhoA, and Rac1, which may lead to Ang1-induced vascular sprouting and remodeling. Besides PI3-K, Tie2-mediated stimulation of endothelial migration involves recruitment of the adaptor protein, Dok-R, to activated Tie2, leading to the creation of binding sites for Nck and the serine kinase p21-activating kinase (PAK). Interestingly, distinct subsets of Tie2-mediated intracellular signals are preferentially enhanced depending on the endothelial cell microenvironment; Dok-R and FAK are activated at cell–matrix contacts in migrating endothelial cells, whereas Akt and eNOS are activated at homotypic endothelial cell–cell contacts to maintain vascular quiescence. Tie1, like Tie2, can activate PI3K/Akt, but it does not activate Dok-R/Nck/PAK, which may explain the differential effects of Tie1 and Tie2, especially in endothelial migration.

Although the mechanism whereby Tie2 mediates anti-leakage and antiinflammatory effects is poorly understood, several signaling events involved in these vasoprotective functions have recently been identified. Ang1 binding to Tie2 inhibits VEGF-mediated Src activation, thereby preventing the phosphorylation-dependent redistribution of VE-cadherin. On the other hand, Tie2 activation recruits the A20-binding inhibitor of nuclear factor κB-2 (ABIN-2), leading to the suppression of nuclear factor κB (NF-κB), a transcription factor critical for the regulation of inflammatory gene expression (**Figure 1**).

Stability and Functional Integrity of Retinal Blood Vessels

The retinas in both human and mouse embryos initially have no vascular systems, and the resulting hypoxia in the retinal neurons stimulates an influx of astrocytes from the optic nerves. Retinal astrocytes subsequently form fine networks within the superficial retinal areas and secrete VEGF and fibronectin, which cooperatively promote sprouting angiogenesis in the retinas of human embryos or mouse neonates. The extracellular fibronectin matrices serve as depositories of matrix-bound VEGF isoforms and contribute to the establishment of concentration gradients of VEGF proteins, which regulate the direction of endothelial sprouting. These extracellular fibronectin matrices also provide physical scaffolds to which α5β1 integrin-expressing endothelial cells adhere. Thus, retinal vascular networks migrate over the preexisting astrocyte networks, using them as templates. Upon contact with blood vessels, the astrocytes rapidly lose their pro-angiogenic properties by downregulating their expression of VEGF and fibronectin genes. They cover the blood vessel walls to contribute to establishment of the blood–retina barrier, in cooperation with tight junctions formed at endothelial–endothelial contacts.

Throughout the processes of retinal vascular development, pericytes are found over the entire vascular network, except at the sprouting vascular tips, although not all endothelial cells surfaces are covered by pericytes. Recruitment of pericytes in retinal blood vessels is largely dependent on PDGF-B/PDGFRβ signaling, as revealed by the complete inhibition of pericyte recruitment by pharmacological blockade of PDGFRβ. In the absence of pericytes, retinal vessels are enlarged, with multiple clefts formed in endothelial–endothelial junctions, leading to progressive edema and hemorrhage. Intriguingly, intraocular administration of Ang1 protein can suppress the vascular leakage and ameliorate the morphogenetic remodeling of vascular architecture, without restoration of pericyte recruitment. These direct actions of Ang1 on endothelial integrity

indicate that Ang1 plays central roles in pericyte-mediated vascular stabilization (Figure 2).

In the capillaries of adult retinas, pericytes are flattened and elongated with long cytoplasmic processes along the capillary axis, with a pericyte:endothelial cell ratio of 1:1, the highest in the body, implying their significant contribution to the maintenance of vascular integrity. Indeed, the loss of pericytes is regarded as a critical event triggering a series of vascular abnormalities seen in diabetic retinopathy, including microaneurysm formation, retinal hemorrhage and edema, and vascular obstruction. In contrast to the developmental period, pharmacological blockade of PDGFRβ in adult mice has no obvious effects on the retinal vascular structure. Together with the absence of endothelial PDGF-B expression in quiescent retinal vessels, it is less likely that the maintenance

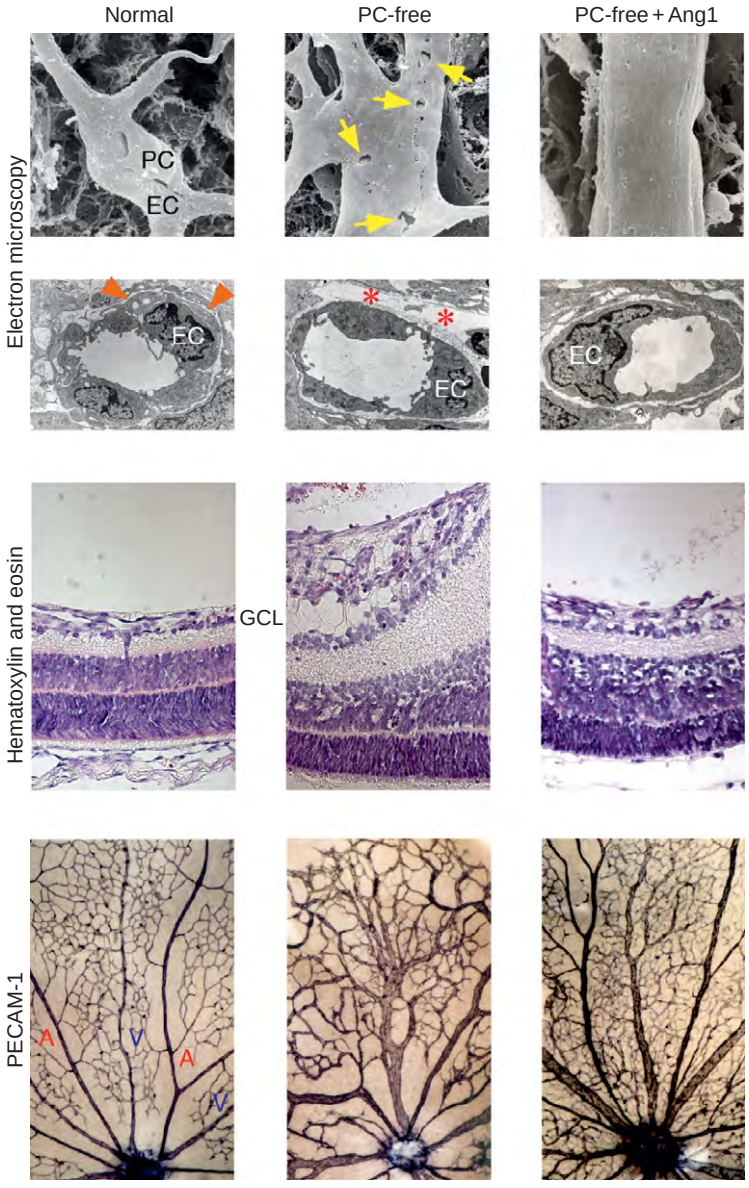

Figure 2 Ang1-mediated restoration of retinal vascular integrity in the absence of pericytes. In developing blood vessels of normal mouse retinas (left columns), pericytes (PC, arrowheads) extending long cytoplasmic processes associate with nascent endothelial cells (EC). The superficial vascular networks formed above the ganglion cell layer (GCL) undergo morphogenetic remodeling into arteries (A), veins (V), and capillaries, as demonstrated by whole-mount immunostaining with PECAM-1. Systemic injections of anti-PDGFRβ blocking antibody completely inhibit PC recruitment to retinal vessels (middle columns), resulting in multiple cleft formation at denuded endothelial cell–cell junctions (arrows), extraluminal fluid accumulation (asterisks), progressive exacerbation of edema and hemorrhage in the superficial retinal areas, and disorganized architecture of vascular networks. These defects in functional integrity, as well as morphogenetic remodeling of retinal blood vessels, can be substantially ameliorated by intraocular injection of Ang1 protein, even without restoration of pericyte recruitment (right columns). Adapted from Uemura, A. et al. (2002). *Journal of Clinical Investigation*.

of an endothelial–pericyte association constitutively requires PDGF-B/PDGFRβ signaling. By contrast, Ang2 is upregulated in the retinas of diabetic animal models, and direct administration of Ang2 protein into the eye induces pericyte loss from retinal microvessels. Furthermore, high glucose levels increase Ang2 transcription in cultured endothelial cells. These findings collectively suggest that upregulation of Ang2 in response to hyperglycemia could be partly responsible for the destabilization of vessel integrity in diabetic retinopathy.

Clinical Therapies to Restore Vascular Integrity in Retinal Vascular Disorders

Improvement of vision in diabetic retinopathy and age-related macular degeneration might be expected to be achieved either by inhibiting new vessel formation, or by stabilizing leaky blood vessels. Currently available anti-VEGF drugs are administered based on the theory that new blood vessels fail to recruit pericytes, thereby rendering naked endothelial cells, but not healthy blood vessels, selectively sensitive to VEGF deprivation. Indeed, inhibition of pericyte recruitment by pharmacological blockade of the PDGFRβ signal enhances the anti-angiogenic effects of VEGF neutralization in experimental models of choroidal neovascularization. However, the assumed lack of pericyte coverage of new blood vessels needs to be confirmed. This uncertainty could be due to difficulties in identifying all of the heterogeneous pericyte populations using a single marker, such as smooth muscle α-actin. Indeed, by combining multiple markers (desmin, PDGFRβ, NG2, or RGS5) and ultrastructural observations, new blood vessels in developing retinas, which were often previously reported to lack pericytes, have recently been shown to have abundant pericytes. It is notable that developing retinal vessels undergo regression, under hyperoxia or by VEGF neutralization, or even in the normal developmental course, despite their association with pericytes. This suggests that the presence of pericytes *per se* does not stabilize new blood vessels. The degree to which pericyte–endothelial contacts ensure vascular stability requires further elucidation.

In addition to the neutralization of VEGF signals, alternative therapeutic approaches aimed at achieving selective regression of abnormal vessels, while leaving normal vessels intact, should be evaluated. Interestingly, during tumor angiogenesis, a monoclonal antibody against a VE-cadherin epitope that is only accessible on endothelial cells forming new adherens junctions, has been demonstrated to specifically inhibit the formation of new blood vessels without affecting the permeability of resting blood vessels.

In addition to their anti-angiogenic ability, anti-VEGF drugs have also been proven to be effective in reducing vascular permeability. However, constitutive expression of cell-autonomous VEGF is reportedly required for endothelial homeostasis in healthy, quiescent, blood vessels. Furthermore, in adult retinas, both VEGF and VEGFR-2 are expressed by various types of neurons and Müller glia, indicating a constitutive requirement for this signal in retinal homeostasis. Indeed, sustained inhibition of VEGF signaling results in neuronal or glial cell death, leading to a decline in retinal function. These findings indicate the potential for adverse effects of anti-VEGF drugs used for retinal diseases. Alternatively, restricted manipulation of signaling molecules specifically responsible for vascular permeability may be a more desirable method of effectively restoring vascular integrity without affecting retinal function. VEGF-induced vascular permeability in retinas is inhibited by blockade of Src kinase, suggesting that this signaling molecule is a potential therapeutic target. Furthermore, the therapeutic potential of Ang1 is indicated by its ability to inhibit retinal vascular leakage induced by VEGF, inflammation, or the loss of pericytes. Ang2-neutralizing reagents may also be effective in restoring the quiescence of retinal blood vessels.

Conclusion

In blood vessel walls, multiple ligand–receptor systems and junctional protein complexes at homotypic and heterotypic cell–cell contacts act in concert to modulate intracellular signaling events to switch endothelial cells between quiescent and activated states, depending on their microenvironmental conditions. Accumulating evidence has determined that angiogenesis-regulating signals are also crucially involved in governing the stability of blood vessels. While a list of the extracellular and intracellular signals responsible for vascular stabilization is emerging, further investigations are needed to identify specific molecules relevant to the development of pinpoint therapies targeting the functional integrity of blood vessels in retinal vascular disorders.

Stem Cells of the Ocular Surface

Y Du and J L Funderburgh, University of Pittsburgh, Pittsburgh, PA, USA

Glossary

Basement membrane – Every epithelial sheet elaborates a noncellular dual-layered membrane of collagen and proteoglycans to which the cells are anchored. In addition to anchoring the cells, basement membranes (also called basal laminae) serve to maintain epithelial differentiation and to provide a biological barrier preventing contact between the epithelial cells and the underlying mesenchymal tissue.
Cell therapy – Stem cells are injected directly into pathological tissues to restore tissue function.
Conjunctiva – The squamous epithelium overlaying the sclera and inner eyelid.
Corneal stroma – This tough connective tissue provides 90% of the corneal thickness and consists mostly of collagen, proteoglycans, and water. Cells make up 4% of the stromal tissue.
Crypts – These structures, originally named in the intestine, represent small dead-end tubes that protrude from the surface of an epithelial layer into the surrounding mesenchymal tissue.
Cytokeratin – Hair and the epidermis consist primarily of the fibrous proteins, keratins. Moist epithelia such as intestine and cornea were originally thought not to be 'keratinized' but the outer layers cells in these tissues express intracellular keratin proteins as they differentiate. Due to the large number of keratin genes, keratin expression is highly tissue specific.
Endothelium – Corneal endothelium is a single epithelial layer of cells on the posterior (inner) side of the cornea which provides a hydrodynamic pumping function to maintain corneal hydration. It is unrelated to vascular endothelium.
Keratocyte – These are dendritic, quiescent cells of the corneal stroma. They produce the complex extracellular matrix of the corneal stroma but, during wound healing, also produce an opaque scar tissue.
Limbus – In the eye, the border between the transparent cornea and the opaque sclera is known as the limbus. The limbal region of the overlying epithelia is continuous with no obvious boundary, but the conjunctival and corneal cells can be distinguished by the types of cytokeratins that are expressed.
Neural crest – In early embryonic development a small population of cells between the ectoderm and the neural tube migrates out into the embryo, differentiating into a wide variety of tissues including autonomic nerves, cartilage, smooth muscles, and melanocytes. A number of ocular tissues (corneal stroma and iris) are derived from neural crest.
Niche – A stem cell niche is a phrase loosely used to describe the microenvironment in which stem cells are found, which interacts with stem cells to regulate stem cell fate.
Squamous epithelium – Multilayered epithelia show differences between the basal cells attached to the basal lamina and the more superficial cells of the layer. The apical cells flatten and express tissue-specific keratins. These outer cells die by apoptosis and leave the layer (known as desquamation) to be replaced by underlying cells. Single-layer epithelia such as the corneal endothelium do not undergo the process of desquamation and renewal.

The Ocular Surface

Anatomy

Beneath the protective tear film, the human ocular surface is covered with a contiguous layer of moist squamous epithelium, consisting of the bulbar conjunctival epithelium over the sclera and the transparent corneal epithelium of the cornea (**Figure 1**). The bulbar conjunctival epithelium rests on a loose, vascularized connective tissue which allows the movement of the eyelid over the sclera and maintains the limbal vascular supply. This epithelium is contiguous with the corneal epithelium and with the conjunctiva of the fornix located in the folded region between the sclera and the eyelid. The conjunctival epithelium contains goblet cells – the source of soluble mucins in the tear film. These cells are an essential element in maintenance of the integrity of the ocular surface. The cornea is covered with a phenotypically unique epithelial sheet 5–11-cell layers deep which is transparent to light and devoid of goblet cells. The flattened cells of the corneal surface overlie wing-shaped cells – which, in turn, rest on a cuboidal basal epithelium. Unlike the conjunctival epithelium, the corneal epithelium is firmly connected to rigid tissue of the stroma via an anchoring complex involving keratin and collagen fibrils extending into the acellular anterior collagenous layer of the stroma. The interface between the corneal and conjunctival epithelium is known as the

corneoscleral limbus (Figure 1(a)). This region features a network of physical folds in the surface of stromal tissue known as the palisades of Vogt (Figure 1). As described below, the palisades harbor a small population of cells identified as limbal stem cells (LSC). The limbal region also contains pigmented cells and a population of immune cells related to the Langerhans' cells of the dermis.

Underlying the corneal epithelium is the corneal stroma, a tough, transparent connective tissue making up 90% of the thickness of the cornea (Figure 1(c)). The stroma contains layers (lamellae) of aligned collagen fibrils sandwiching quiescent keratocytes, flattened mesenchymal cells. The specialized arrangement of the collagenous ultrastructure in the stroma is responsible for the remarkable tensile strength of this tissue as well as its unique light transparency. On the posterior side of the stroma a single cell layer – the corneal endothelium – is separated from the stromal tissue by Descemet's membrane. The three tissue layers of the cornea each make an important physiological contribution to maintenance of corneal transparency. In addition, the cornea provides 75% of the refractive power required to focus the light on the retina and acts as an effective biological barrier.

Development

Formation of the human cornea begins at approximately 5–6 weeks of gestation. After the lens vesicle pinches off from the surface ectoderm of the head, the overlying ectoderm transforms into a layer of cuboidal epithelial cells, which continue to develop into the corneal epithelium. At 6–7 weeks, neural crest cells migrate between this epithelium and the lens, forming the corneal endothelium. Shortly afterward, a second wave of cell migration from neural crest forms the stroma – which then begins to generate collagenous matrix in the 8th week.

Homeostasis and Repair

The cellular layers of the cornea and conjunctiva differ markedly in several important characteristics of homeostasis and repair. In the corneal epithelium, the superficial cells are lost by exfoliation and replaced by the underlying wing cells. These, in turn, are continually replaced by mitotically active basal cells. In addition to the basal to superficial migration of corneal epithelial cells, there is a well-documented migration of epithelial cells from the periphery to the center of the cornea, measured at 2–3 μm per day. The dynamics of the corneal epithelium have been characterized as the X,Y,Z equation, in which the exfoliation rate (X) equals the rate of production of new cells from the basal cells (Z) plus cells added by the centripetal migration of cells (Y). When injured, the corneal epithelium closes wounds first by migration of the intact sheet over the denuded area, followed by a delay before increased cell division is observed. Bulbar conjunctival epithelium is contiguous with the corneal epithelium without any obvious physical barrier; however,

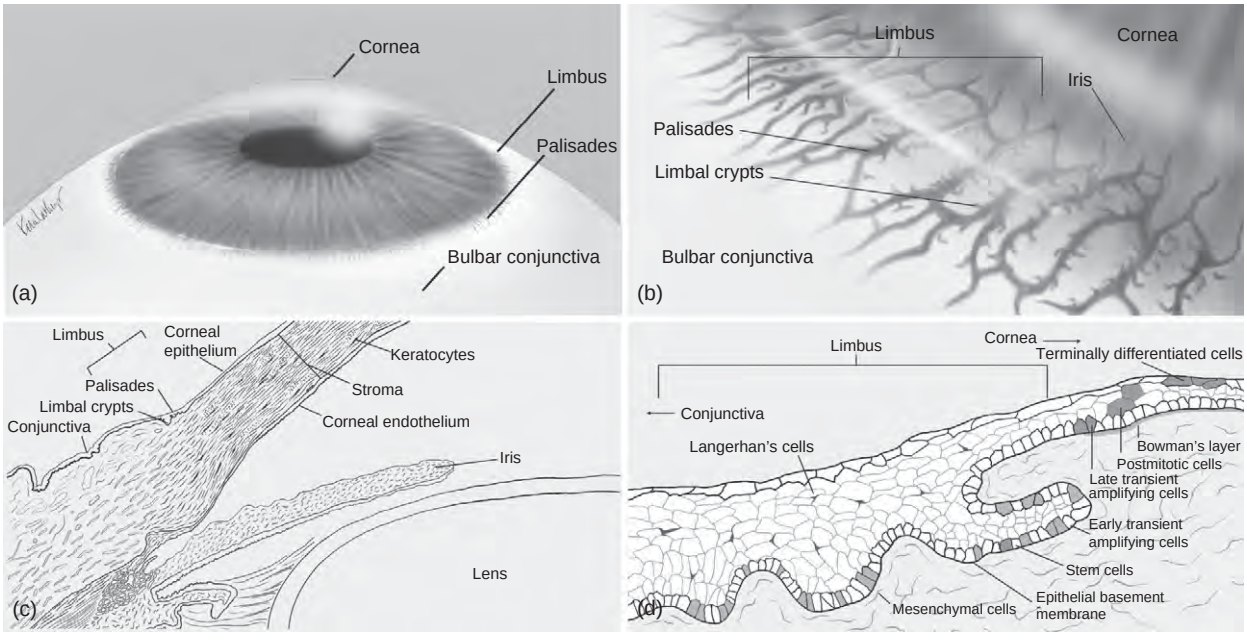

Figure 1 The ocular surface. (a) The location of the corneal, conjunctival, and limbal surfaces are displayed along with the location of the palisades of Vogt. (b) Artists rendering illustrating a close-up view of the anatomy of the palisades of Vogt and the dead-end crypts that branch off from these folds in the tissue. these cells express different cytokeratin markers and are found not to migrate in the unwounded eye. Cell division by basal cells and exfoliation is observed throughout the conjunctiva.

The cells of the corneal stroma – the stromal keratocytes – show little cell division in normal adults. The keratocytes undergo rapid cell division after localization in the cornea in late embryogenesis, but, following birth, the keratocyte cell number stabilizes and little or no mitosis can be detected throughout life. In the case of inflammation or wounding, however, the stromal keratocytes become activated and mitotic. The activated keratocytes adopt a fibroblastic phenotype and, later, display characteristics of myofibroblasts. Connective tissue secreted by these cells during wound healing is not transparent but becomes opaque scar tissue. Following healing, the cells become quiescent, but human corneal scars are very slow to resolve; it is not clear if the resident cells ever return to a fully keratocytic phenotype. These properties suggest a limited process of tissue renewal in the corneal stroma.

Renewal of corneal endothelial cells is even more limited than that of the keratocytes. Following childhood, human corneal endothelial cells do not divide. Compensation for endothelial damage is accomplished by flattening of the remaining cells to cover the posterior surface of the cornea. *In vitro* as well, human corneal endothelial cells show only limited ability to divide following infancy.

These characteristics have led to a conventional view that, while the corneal epithelium is maintained by a stem cell population, the stroma and the endothelium – with limited ability for self-renewal – are not maintained by mitotically active, tissue-resident stem cells.

Properties of Stem Cells

Stem cells, by definition, undergo asymmetric cell division; that is, they undergo self-renewal while giving rise to differentiated daughter cells. Embryonic stem cells derived from the inner cell mass of the blastocyst are pluripotent, giving rise to most cells of the body. In culture, embryonic stem cells can be propagated indefinitely in an undifferentiated state. Although they can be isolated from umbilical cord blood, fully pluripotent stem cells are thought to be scarce or absent in adult tissues. Stem cells in adult organisms have long been associated with self-renewing tissues, such as the hematopoietic system, dermis, and intestine. The resident stem cells in these tissues are generally capable of generating only one type of cell, making them unipotent. In recent years, understanding of a new class of stem cells has emerged: known as mesenchymal stem cells (MSC), these cells appear to be present in small numbers in many somatic tissues and can also be isolated from bone marrow. Studies show these MSC to participate in injury repair, and – when expanded in culture – the MSC exhibit potential to differentiate into a number of lineages, and thus can be considered as being multipotent. Considerable effort has gone into identifying common characteristics of adult stem cells, but in spite of such efforts there appears to a dearth of global phenotypic markers for such cells. *In vitro*, clonal growth, extended life span, and the ability to express phenotypic markers of multiple differentiated cell types have been useful in stem cell identification, but cell surface markers for stem cells – as well as properties enabling isolation of these populations – often need to be defined for individual tissues.

In self-renewing tissues, stem cells appear to be localized in an anatomical niche, a restricted microenvironment which interacts with stem cells to regulate stem cell fate. The niche provides physical and chemical factors that both control the replication and maintain the differentiation potential of the stem cells. Typically, the niche is near a vascular bed, usually containing a population of unrelated cells that serve as feeder cells.

Stem Cells in the Corneal Epithelium

Characteristics of Limbal Stem Cells

Abundant research supports the idea that a stem cell population is localized in the corneoscleral limbal region. These cells – termed limbal stem cells (LSC) – share a number of features with the stem cells of other self-renewing tissues. They have small cell size and high nuclear-to-cytoplasmic ratio. They lack expression of differentiation markers expressed by corneal epithelial cells, specifically cytokeratins (CK) 3 and 12. Like stem cells in other self-renewing tissues, the LSC divide very infrequently (slow cycling), and, therefore, DNA-labeling agents – such as bromodeoxyuridine – are retained in these cells for months. Label retention has often been used in identifying stem cell candidates in intact tissues. Cells from the limbal region also grow clonally in large colonies known as holoclones, whereas clones from the central cornea are less abundant and grow through fewer population doublings. Furthermore, unlike central corneal cells, LSC proliferation is resistant to inhibition by phorbol esters. LSC express several genes linked to stem cell self-renewal, including CEBPD, Bmi1, and Notch1. Cornea-specific ablation of Notch1 resulted in differentiation of LSC into hyperplastic, keratinized, epidermal-like cells, indicating the probability that Notch1 expression is essential in maintenance of the LSC stem potential. LSC also express a transporter protein, ABCG2, responsible for efflux of fluorescent dye Hoechst 33342. Expression of ABCG2 enables isolation of cells using fluorescence-activated cell sorting (FACS). Cells isolated using this dye-efflux assay are known as a side population,

based on the distribution pattern of the fluorescent cells following FACS. Side-population cells from the corneal epithelium are present exclusively in the limbus; following sorting, they exhibit slow cycling and clonal growth properties consistent with their identification as stem cells. Ability to isolate LSC has allowed a detailed comparison of the differences between this population and the other cells of the corneal epithelium. A summary of these differences is given in **Table 1**.

Limbal Stem Cell Niche

Centripetal migration of pigmented cells in healing epithelial wounds was first observed in the 1940s, and, in 1971, Davanger and Evenson proposed that the source of the migrating cells was the palisades of Vogt. These are a series of radially oriented fibrovascular ridges concentrated along the upper and lower corneoscleral limbus (**Figure 1(a)** and **(b)**) described originally in the early twentieth century. The morphology of these features has been elucidated by Daniels and by Dua, showing that they are present throughout the limbus but more concentrated in the superior and inferior regions. The ridges and valleys of the palisades are maintained by a specialized vascular system and form an interwoven network, often terminating in tunnels or 'crypts' under the surface of the stroma (**Figure 1(b)**). The bases of these crypts contain cells strongly expressing the several marker genes used in identifying LSC (**Table 1**), providing further evidence that these crypts represent the LSC niche. Recently, it was observed that pigmented melanocytes in the limbal crypts express N-cadherin, as do the LSC. During expansion in culture the LSC lose N-cadherin expression as they differentiate. N-cadherin-dependent cell–cell interactions with melanocytes may consequently represent a feature of the niche environment involved in maintaining the slow cycling and stem cell potential of the LSC.

Table 1 Expression markers for determining epithelial stem cell differentiation

Gene	*Limbal stem*	*Cornea: Basal*	*Cornea: Apical*
Positive (stem cell) markers			
ΔN-p63α	++	−	−
ABCG2	+++	−	−
Vimentin	+++	−	−

Cx 43	−	+++	+++
E-Cadherin	+/−	+++	+++

Modified from Secker and Daniels (2008).

The presence of label-retaining cells in the limbus and the centripetal migration of the more rapidly dividing cells in the corneal epithelium prompted Schermer and colleagues to suggest that the slow-cycling LSC are precursors to the mitotic basal cells throughout the epithelium. These mitotic daughter cells are termed transient amplifying (TA) cells. The TA cells are hypothesized to migrate from the limbus throughout the central cornea before ceasing cell division and differentiating to the superficial cells of the corneal surface. Labeling with both tritiated thymidine and bromodeoxyuridine followed by various chase periods provided kinetics showing that migrating basal cells are indeed mitotic, but are not label retaining – that is, cycle faster than the LSC. The LSC appear small and round compared to the TA cells, thus may be more primitive than the TA cells. Cloning studies also show the mitotic cells in the central stroma to be less able than LSC to generate the large holoclones indicative of high replicative potential.

TA cells are not fully committed to corneal epithelial differentiation. TA cells in adult central corneal epithelium – when transplanted to embryonic dermis – have demonstrated potential to differentiate into hair follicles and other dermal tissue types. Thus, these basal cells of the central epithelium maintain a clear stem cell potential. Are these central corneal stem cells progeny of the LSC? DNA-labeling kinetics are consistent with an interpretation that slow-cycling cells in the limbus are the origin of mitotic cells of the central cornea. Lamellar keratoplasty in male rabbits with corneal tissue from females led to the gradual replacement of the sex chromatin in the central corneal graft, suggesting that LSC from the host were the source of the cells that mature and exfoliate from the superficial central cornea. In spite of these and a number of related studies, however, there is still only indirect evidence that LSC are the progenitors of the mitotic basal TA cells in undisturbed corneal epithelium. In fact (as discussed below), recent studies suggest the possibility that the LSC may contribute to the central corneal epithelial cell populations only in healing wounds.

Limbal Stem Cell Deficiency

It is well documented that, following wounding, the LSC become more mitotically active and participate in centripetal migration. Cells from the limbus can, in fact, rapidly repair wounds involving the entire central corneal epithelium. However, injuries or conditions resulting in loss or inactivation of the LSC present a markedly

different outcome. After loss of the limbal cells, cells from the conjunctiva – including goblet cells – migrate across the corneal surface. This conjunctivalization results in inflammation, neovascularization, and growth of a fibrovascular pannus which severely reduces visual acuity. This phenomenon, known as limbal stem cell deficiency, can result from either hereditary or acquired causes. Transplantation of central corneal tissue without the accompanying LSC provides only temporary amelioration of this condition. Successful treatment, however, can be affected by autologous transplantation of limbal tissue from a contralateral, unaffected eye to the conjunctivalized eye. Reestablishing the LSC population can restore a stable and transparent corneal epithelium both in experimental animal studies and in human patients. Allografts can serve the same purpose but require immune suppression to prevent rejections. Expansion of LSC in culture has also been used to prepare epithelial sheets that restore long-term human epithelial function as well. It is worth noting that autologous, cultured epithelial sheets from buccal epithelial cells – as well as from conjunctival cells cultured under conditions in which goblet cells do not form – can also restore epithelial function. The biological implications of this use of nonlimbal cells to restore corneal epithelial function have not been fully explored. It is not clear, for example, if stem cells in these cultured layers colonize the limbal crypts and become a kind of ectopic, but functional, LSC population. The conclusions of the studies on limbal stem cell deficiency and its therapy are that the LSC are effective in replacing the corneal epithelial layer in a wound healing situation, and that the LSC create a biological barrier preventing conjunctival migration onto the corneal surface.

Understanding the Role for LSC in Corneal Homeostasis

Several studies have suggested the possibility that during normal corneal homeostasis the LSC may not contribute cells to the corneal epithelium. Studies of the destrin-knockout mouse showed that these mice lack the centripetal migration of corneal epithelium. Destrin is an actin-binding protein involved in cytoskeletal dynamics and thus may be involved directly in such motility. The corneal epithelium forms correctly in these mice, but, later in life, the tissue becomes vascularized and hyperplastic. The presence of mitotic basal cells in the absence of migration suggests that the basal cells are not TA progeny of the LSC but arise from a distributed stem cell population in these mice. Thus, the LSC may not be necessary for establishing a fully differentiated corneal epithelium. In a later study using mice, limbal tissue expressing a β-galactosidase marker gene was transplanted to the limbus of non-β-Gal-expressing nude mice. Over a period of months, β-Gal was not found in the central cornea of unwounded mice, but β-Gal cells rapidly migrated into the central cornea after wounding. β-Gal-expressing cells from central cornea were able to reconstitute a full epithelial sheet following transplantation, and furthermore, the reconstitution after transplantation could be carried out serially. These results indicate the existence of a nonlimbal population of corneal epithelial stem cells in mice that can give rise to a functional corneal epithelium. Such studies indicate LSC may not be necessary for formation or normal homeostasis of mouse cornea but support the principle that the LSC does participate in restoration of the tissue after wounding. There are no experimental data extending these results to humans, but until such data are presented, the role of the LSC in normal tissue homeostasis of the central corneal epithelium should be considered as unresolved.

Conjunctival Stem Cells

The bulbar conjunctiva contains basal mitotic cells that migrate to the surface and become quiescent as they differentiate; however, the cell layer does not undergo a lateral migration similar to that of the cornea. Differentiated conjunctival epithelium also differs from corneal epithelium in the expression of cytokeratins. Whereas cornea is positive for CK3 and CK12, conjunctiva lacks these keratins while expressing CK19, an antigen absent in cornea. Label-retaining cells can be observed in the fornix region, and clonal culture of these gives rise to both epithelial cells and goblet cells. Thus, the fornix appears to contain bipotent stem cells. Similarly, cells in the fornix are more strongly stimulated to proliferate by phorbol ester than those in the bulbar epithelium. These studies support the idea of a stem cell population in a fornicial niche. Clonogenicity studies, however, support the idea that cells with extended replicative potential (e.g., stem cells) are present both in the fornix and the bulbar surface. The lack of lateral migration of the cells of the bulbar conjunctiva, however, strongly supports the idea that during normal tissue homeostasis the tissue is maintained by a distributed population of resident stem cells.

Careful examination of stem-like cells in the bulbar conjunctiva has identified rare clusters of cells expressing the CK3/12 keratins characteristic of the cornea. Furthermore, transplantation of limbal β-galactosidase-expressing tissue into the limbal region of nude mice showed that, following wounding, some of these cells migrate into the conjunctiva and differentiate to both conjunctival epithelial and goblet cell phenotypes. These studies suggest that some of the stem cells distributed in the bulbar conjunctiva may derive from the LSC. Conversely, cells cultured from the bulbar region can be used to reconstitute the corneal epithelium in transplantation studies. Following transplantation to the cornea, these conjunctival-derived cells express the cornea-specific keratins CK3/12. The idea of

conjunctival/corneal transdifferentiation, once popular, is currently out of favor; however, these experiments support the possibility that stem cells in both the conjunctiva and cornea can – and do, in fact – produce differentiated cells in the neighboring tissue. The extent and the conditions under which this phenomenon occurs require further elucidation.

Corneal Stromal Stem Cells

The corneal stroma is a mesenchymal connective tissue making up 90% of the corneal thickness, with physical properties that provide the cornea its essential character. The stroma is formed during late embryogenesis by a population of neural crest cells migrating from the periocular mesenchyme. Chicken keratocytes from late embryogenesis retain neural crest progenitor properties even after transplantation into a new environment along cranial neural crest migratory passageways. In adult mammals, however, numerous *in vitro* experiments show that keratocytes rapidly lose their characteristic phenotype following several population doublings. Such a loss of phenotype occurs in healing wounds *in vivo* as well as *in vitro*. Recently, the authors found that the stroma of bovine corneas contain a small population of cells exhibiting self-renewal ability for an extended number of population doublings in culture. These corneal stromal stem-like cells were clonogenic and proliferated *in vitro* for over 100 doublings. A similar population of stem cells was isolated from human corneas as a side population using FACS. These stromal stem cells demonstrated potential for differentiation into several noncorneal cell types – a characteristic similar to that found in adult stem cells from other mesenchymal tissues. These cells also expressed several genes clearly designating them as tissue-specific mesenchymal stem cells, including ABCG2, Notch1, BMI1, SIX2, and KIT. ABCG2-expressing cells were localized in the limbal stroma subjacent to the epithelial basement membrane in the regions near the LSC niche.

Human corneal stromal cells remained viable for months after injection into mouse corneal stroma and were able to increase the transparency of lumican-knockout mouse corneas. In serum-free monolayer culture, keratocytes express stroma-specific gene products, but do not accumulate or organize extracellular matrix resembling that of the corneal stroma. However, when human stromal stem cells were cultured in attachment-free conditions they produced a stromal-like tissue including the stroma-specific keratan sulfate proteoglycan keratocan and generated parallel layers of collagen fibers resembling those in the stroma. These results suggest the potential use of stromal stem cells in bioengineering of corneal stroma or in direct stem cell-based therapy for corneal scars or corneal dystrophies.

Corneal Endothelial Stem Cells

The corneal endothelium is a single layer of flat hexagonal cells forming a boundary between the corneal stroma and the anterior chamber. This layer of cells functions as a pump to regulate stromal hydration. Although – like the keratocytes – the corneal endothelium is derived from neural crest, the endothelial cell characteristics are different from those of keratocytes. The human corneal endothelial cells are arrested in G1 phase *in vivo* and do not normally replicate to replace dead or injured cells. This lack of cell division results in a physiological reduction of cell density of about 0.3–0.5% per year. Scattered evidence, however, suggests the potential for some mitotic events in human corneal endothelium. Mitotic figures were observed *in vivo* by specular microscopy study following a rejection reaction on a corneal graft. Clusters of cells smaller than surrounding cells suggested that, at least under some circumstances, mitosis occurs in the endothelium of the adult human cornea. Recently, Yokoo and coworkers identified cells in the human corneal endothelium able to form cell-spheres in attachment-independent culture. Cells in these spheres, formed under conditions similar to those used for isolation of neural stem cells, can be expanded and generate daughter cells expressing neuronal and mesenchymal molecular markers. These properties suggest a stem cell origin for the cells forming the spheres. The sphere-forming cells also adapted the polygonal morphology characteristic of endothelial cells, suggesting the presence of endothelial progenitors. These precursors were effective *in vivo* in restoring endothelial function in an animal model of corneal endothelial deficiency. Both peripheral and central rabbit corneal endothelia contain a significant number of precursors, but the peripheral endothelium contains more precursors and has a stronger self-renewal capacity than the central region by sphere-forming assay. As the long-term culture of human endothelial cells has not been carried out and because of a lack of both stem cell and endothelial markers, positive identification of the proposed endothelial stem cells *in situ* has yet to be accomplished.

Conclusions

The ocular surface contains multiple populations of cells with stem cell-like properties. Some of these are localized to a distinctive niche in the corneoscleral limbus but other populations are more dispersed. Stem cells also are present in corneal stroma and endothelium. Stem cells support self-renewal of the corneal and conjunctival epithelia and the limbal stem cells prevent conjunctivalization of the corneal surface; however, relationships among the different stem cell populations in normal tissue homeostasis – and in

response to wounding – are not yet fully characterized. Ocular-surface stem cells have a high potential for use in cell-based therapy for a variety of ocular pathologies, and in tissue engineering. Continuation of the characterization of ocular stem cells is, therefore, a high priority both for understanding the biology of the ocular surface and for development of sight-saving therapies.

Steroid-Induced Ocular Hypertension and Effects of Glucocorticoids on the Trabecular Meshwork

A F Clark, North Texas Eye Research Institute, University of North Texas Health Science Center, Ft. Worth, TX, USA

Glossary

Arachidonic acid metabolism – The degradation of a membrane lipid that leads to the generation of inflammatory signaling molecules.
Cortisol – The endogenous glucocorticoid (GC) in man.
Cytoskeleton – The internal scaffolding inside cells that regulates a variety of cell functions as well as cell shape.
Extracellular matrix (ECM) – An organization of specific proteins outside cells and tissues.
Glucocorticoid (GC) – A steroid molecule that regulates carbohydrate, lipid, and protein metabolism, which is often used therapeutically as an anti-inflammatory agent.
Intraocular pressure (IOP) – The pressure inside the globe of the eye.
Ocular hypertension – The pressure inside the globe of the eye that is higher than normal.
Osteoporosis – A condition of thinning and weakening bone structure.
Posterior subcapsular cataract – The clouding that occurs at the back of the ocular lens.
Primary open-angle glaucoma (POAG) – The most common form of glaucoma in most populations.
Steroid glaucoma – The glaucoma that occurs in some individuals due to the therapeutic use of GCs.
Steroid responsiveness – The ability of an individual to develop ocular hypertension upon steroid therapy.
Trabecular meshwork (TM) – A tiny tissue located at the junction of the iris and cornea, which is responsible for drainage of aqueous humor from the eye.
Transcription factor – A special protein that binds to DNA and regulates gene expression.

Introduction

Glucocorticoids (GCs) physiologically regulate carbohydrate, lipid, and protein metabolism and are absolutely essential for life. GC receptors (GRs) are ubiquitously expressed and, therefore, almost all tissues are targets for GC action.

GCs have been used therapeutically for over 60 years and are unsurpassed in their broad-based anti-inflammatory and immunosuppressive activity. However, prolonged GC therapy can also cause undesired side effects, including osteoporosis, muscle wasting, thinning of the skin, altered distribution of body fat, immunosuppression, and psychological disturbances. In addition, GC therapy has been linked, as a causative factor, to ocular side effects such as posterior subcapsular cataracts as well as to the development of ocular hypertension and iatrogenic open-angle glaucoma.

The intraocular pressure (IOP) elevation induced by GCs is associated with GC-mediated changes in the trabecular meshwork (TM), a small, reticulated tissue at the junction of the iris and cornea. The TM regulates aqueous humor outflow resistance in the eye. This article briefly summarizes steroid-induced ocular hypertension and highlights the effects of GCs on the TM. Full citations for many of the topics discussed can be found in the recently published *Experimental Eye Research* review (see the section titled 'Further reading').

Steroid-Induced Ocular Hypertension

Therapeutic administration of GCs can cause ocular hypertension and steroid glaucoma in certain individuals. The propensity to develop GC-induced ocular hypertension depends on the route of administration, the duration of therapy, the potency of the therapeutic GC, and individual susceptibility. GC-induced ocular hypertension has been reported with topical ocular, intraocular, periocular, oral, inhalation, intranasal, and topical dermal administration. Although GC-induced ocular hypertension can occur within a week of administration in some individuals, it often takes one or more months for this condition to develop. The more potent and longer-acting GCs, such as dexamethasone (DEX), betamethasone, triamcinolone acetonide, and fluocinolone acetonide, are more likely to raise IOP compared to less potent and shorter-acting GCs. However, ocular hypertension has been reported even with weaker and shorter-acting GCs, such as fluoromethalone or medrysone, in some individuals.

GC-induced ocular hypertension is generally reversible upon discontinuation of GC therapy. There are some reported cases where IOP remains elevated after cessation of GCs. These cases may be due to extensive and irreversible GC-mediated damage to the outflow facility or could be due to the actual development of primary open-angle glaucoma (POAG), since most POAG patients are steroid responders (see below).

Not all individuals treated with GCs develop ocular hypertension, and there is considerable heterogeneity in individual responsiveness to this GC-mediated side effect. Early studies categorized three classes of steroid responsiveness in the normal population after frequent (q.i.d.) topical ocular dosing with potent GCs for 4–6 weeks. Approximately 5% of the individuals developed substantially increased IOPs and were termed high responders, while 33% had moderately elevated IOPs and were termed moderate responders. The remaining population were considered nonresponders with no or only slightly elevated IOPs. Therefore, approximately 40% of the population developed ocular hypertension after topical ocular GC treatment, and individual steroid responsiveness was reproducible. Identified steroid responders remained steroid responsive and nonresponders remained nonresponsive when rechallanged with GCs. It is interesting to note that this 40% responder rate also occurs in individuals who receive intravitreally injected triamcinolone acetonide as well as in individuals receiving oral GC therapy.

In contrast to the normal population, almost all POAG patients are steroid responders. Interestingly, descendents of POAG patients have a higher rate of steroid responsiveness, suggesting that steroid responsiveness may be heritable.

The clinical presentation and features of GC-induced ocular hypertension and GC-iatrogenic glaucoma are very similar to POAG in many aspects. In fact, GC treatment is one of the exclusionary factors for the diagnosis of POAG. IOP elevation in both conditions is due to compromised aqueous outflow and is associated with similar morphological and biochemical changes in the TM. Moreover, in both diseases, there are not only similar optic disk cupping and visual-field changes, but also increased deposition of extracellular material, including fibronectin, in the TM; however, in steroid glaucoma, there is also the deposition of fingerprint-like deposits in the TM.

GC-induced ocular hypertension is not unique to humans. Topical ocular administration of DEX also elevated IOP in monkeys, rabbits, cats, cows, sheep, rats, and mice and can cause similar ECM deposition and biochemical changes in the TM. In addition, DEX-induced ocular hypertension can occur in isolated perfusion-cultured human donor eyes, indicating that GCs act directly on the anterior segment outflow pathway.

A summary of the key features of GC-induced ocular hypertension and steroid glaucoma is given in **Table 1**.

Possible Role of GCs in POAG

There are several lines of evidence suggesting that GCs may play a role in the development of POAG. The endogenous GC in humans is cortisol, which is less potent than most therapeutic GCs. Several investigators have reported that POAG patients have elevated levels of plasma cortisol, although other studies have not found this association. One research group also reported abnormal cortisol metabolism in the TM and peripheral blood leukocytes of POAG patients. Others have suggested that changes in the activities of the 11β-hydroxysteroid dehydrogenases, which interconvert cortisol and cortisone, may regulate IOP in glaucoma patients, although there is no evidence yet that these steroid metabolic enzymes play any role in GC-induced ocular hypertension. Furthermore, there have been reports that POAG patients have increased sensitivity to GC-induced vasoconstriction in the skin, to plasma cortisol suppression after oral DEX, and to GC-induced suppression of a mitogen response in peripheral blood leukocytes, although others have not been able to reproduce the latter study.

Another line of evidence further suggests a link between GCs and POAG. Individuals who were classified as high responders to topical ocular GC administration were at significantly higher risk of developing POAG compared to nonresponders.

GC Effects on the TM

GCs have multiple effects on the TM. The TM contains GC receptors and is a GC-responsive tissue and cell type. GCs directly regulate a number of TM cell functions, including inhibition of phagocytosis, cell proliferation,

Table 1 Key features of glucocorticoid-induced ocular hypertension and glaucoma

- Therapeutic administration of GCs can cause elevated IOP (steroid responsiveness) and iatrogenic glaucoma in susceptible individuals
- Steroid responsiveness is higher in primary open-angle glaucoma patients and their descendents
- Steroid responsiveness is a risk factor for the development of primary open-angle glaucoma
- Clinical features mimic primary open-angle glaucoma
- Elevated IOP is due to increased aqueous humor outflow resistance in the conventional outflow pathway
- Associated with biochemical and morphological changes in the trabecular meshwork

and migration, as well as decreased cellular acidification (related to decreased metabolic activation). They also alter TM cell morphology with an overall increase in cell and nucleus size. GCs cause an activated intracellular morphology that includes increased levels of rough endoplasmic reticulum, Golgi apparatus, and secretory vesicles.

GCs and their receptors act as a ligand-dependent transcription factor; hence, it is not surprising that GCs alter TM cell gene expression. Myocilin (MYOC) was one of the first GC-induced genes discovered in the TM, and it also turned out to be the first glaucoma gene identified. MYOC is a secreted glycoprotein, currently of unknown function. Although several studies have shown that glaucomatous mutations in MYOC cause a gain-of-function phenotype that may account for the elevated IOP associated with MYOC glaucoma, currently there is no evidence that MYOC plays a role in GC-induced ocular hypertension. Overexpression of wild-type MYOC in mouse eyes does not elevate IOP or alter anterior segment morphology.

Five independent studies have evaluated the effect of DEX on global gene expression in cultured human TM cells. As expected, there is some overlap in the sets of GC-responsive genes between the studies, and many of the differences reported could be due to variability between the TM cell lines and the duration of DEX exposure. All the studies reported altered expression of MYOC, IGFBP2, SERPNA3, and GAS1. GCs induced the expression of alkaline phosphatase, which is suggested to be a marker for TM cell calcification. DEX treatment of perfusion-cultured anterior segments increased the expression of pigment-epithelium-derived factor (PEDF) in the TM. GCs also decreased the sensitivity of TM cells to four different growth factors, most likely mediated by decreased expression of their respective growth factor receptors.

GC treatment alters TM cell junctions. Exposure of cultured TM cells to DEX changes the morphology and distribution of gap junctions and increases the expression and distribution of several proteins associated with tight junctions. In addition, GCs change the expression of integrin $\alpha 2$, $\alpha 5$, and αV subunits, which may alter TM cell adhesion.

One of the most striking features of GC treatment is the increased deposition of ECM in TM cells and tissues. Expression of fibronectin, laminin, collagen, and elastin was increased in DEX-treated TM cells. Glycosaminoglycan (GAG) metabolism was also altered by GCs, with decreased hyaluronan and increased levels of chondroitin sulfate and GAGase-resistant material. GCs decrease TM ECM turnover by decreasing matrix metalloproteinases, urokinase plasminogen activator, and increasing levels of plasminogen activator inhibitor-1. They also increased the expression of the fibrogenic growth factor connective tissue growth factor (CTGF) and thrombospondin-1 (TSP-1), which helps bioactivate transforming growth factor (TGF)-β, further reinforcing ECM deposition.

A novel effect of GCs on TM cells is the reorganization of the actin cytoskeleton. Microfilaments bundled into stress fibers and actin networks in the cell periphery are the major actin structures in cultured TM cells as well as in TM cells *in situ*. Treatment of confluent human and bovine TM cells with GCs causes a major reorganization of the microfilaments to form geodesic-dome-like structures called cross-linked actin networks (CLANs) (**Figure 1**). GC-induced CLAN formation takes several days to develop and progresses over time, reaching a maximum after several weeks of GC exposure. These CLAN structures are reversible after withdrawal of the GC from the culture medium. GC-induced CLAN formation appears to be unique to the TM because it does not occur in many other ocular and nonocular cell types tested. In addition to cultured primary TM cells, GC treatment also induces CLANs in the TM of perfusion-cultured anterior segments. Intriguingly, alterations in the actin cytoskeleton, including very similar CLAN structures, are found in glaucomatous TM (GTM) cells and in the TM of glaucomatous donor eyes, even in the absence of exogenous GCs. GTM cells are more sensitive to GC-mediated CLAN formation. The actin cytoskeleton regulates a number of cellular functions, and a GC or glaucomatous reorganization of actin structures may compromise TM cell homeostasis. In addition to effects on the actin cytoskeleton, GCs also cause microtubule tangles in cultured TM cells. However, this effect on microtubules could be associated with TM cell size and shape changes and could be secondary to GC-mediated CLAN formation. Moreover, these findings may help explain the finding that DEX-treated cells are more resistant to microtubule-disrupting agents.

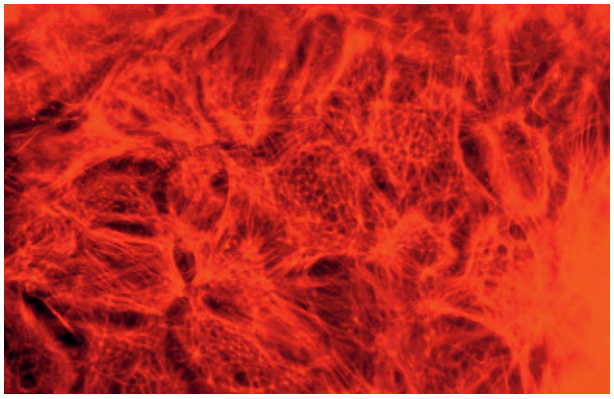

Figure 1 Steroid (DEX)-induced cytoskeletal reorganization to form cross-linked actin networks (CLANs) in trabecular meshwork cells.

Similar to their effects in other tissues, GCs also inhibit arachidonic acid metabolism in TM cells. Currently, there is evidence that IOP-lowering prostaglandin analogs (PGF2α agonists) increase conventional outflow through the TM, in addition to their effects on the uveoscleral outflow pathway. PGF2α is endogenously made by the TM and may play a role in maintaining normal outflow. Inhibition of PGF2α production by GCs may therefore compromise normal outflow.

As mentioned previously, there is considerable individual heterogeneity in the propensity to develop GC-induced ocular hypertension. What is the molecular mechanism(s) responsible for determining steroid responsiveness in normals and why are POAG patients steroid responders? The biological activities of GCs are mediated by the GR. However, there are two alternative forms of the human GR that are both encoded by exons 1–8, but are formed by alternative splicing of exons 9α and 9β. GRα (containing amino acids from exon 9α) is the biological, physiological, and pharmacological receptor for GCs that regulates gene expression in *cis* (through GC response elements (GREs) in the promoter of responsive genes) or in *trans* (through binding to and inhibiting other transcription factors, such as activator protein 1 (AP-1)). GRβ (containing amino acids encoded by exon 9β) lacks the carboxy terminal GC-binding domain and acts as a dominant negative regulator of GC action. Increased expression of GRβ has been implicated in GC resistance in a number of diseases such as rheumatoid arthritis, inflammatory bowel disease, and asthma, among others.

It is possible that altered expression of GRβ in the TM could be responsible for differences in GC sensitivity. In fact, differences in GRβ levels have been demonstrated between normal and GTM cells. GRβ expression is higher in normal TM cells compared to GTM cells, and therefore the GTM cells are more sensitive to GC induction of a GRE-luciferase reporter gene compared to normal TM cells. Transduction of TM cells with a GRβ expression vector makes TM cells more resistant to DEX induction of a GRE-luciferase reporter gene, DEX induction of fibronectin and MYOC, and DEX inhibition of TM cell phagocytosis.

In addition to differences in GRβ levels, there is another potential mechanism for GRβ regulation of GC responsiveness. Both GRα and GRβ are made in the cytoplasm and have to be translocated to the nucleus for their biological effects. GRα nuclear translocation is initiated by GC binding and is mediated by heat-shock protein 90 (hsp90), the immunophilin FK506-binding protein 52 (FKBP52), and the dynein microtubule motor protein complex. GRβ also utilizes hsp90 and dynein for nuclear translocation. However, in contrast to GRα, GRβ translocation to the nucleus is ligand independent and is mediated by the immunophilin FKBP51. In fact, overexpression of FKBP51 in the TM cells enhanced endogenous GRβ nuclear translocation, making these TM cells more GC resistant.

There are still many unanswered questions about the potential involvement of GRβ in GC responsiveness. What is the cause of altered GRβ expression between normal TM and GTM cells? A splicesome protein (SRp30c) responsible for this alternative splicing has been identified; can altered activity of this protein be responsible for different levels of expression in the TM? Could polymorphisms in GR, SRp30c, or FKBP51 lead to altered GRβ expression or activity? Is altered GRβ expression specific for the TM or is this a more generalized systemic phenomenon? Finally, does GRβ directly regulate GC-induced and/or glaucomatous ocular hypertension?

Summary

GC-induced ocular hypertension and iatrogenic glaucoma have been recognized for more than a half a century as serious side effects of GC therapy. This still is an important clinical condition, especially with the increased use of intraocular GCs for the treatment of several retinal conditions. In addition, GC-induced ocular hypertension is an important tool that provides a better understanding of POAG because there are many clinical, morphological, and biochemical similarities. GCs have a plethora of effects on the TM (**Table 2**; **Figure 2**). However, we still are unaware of not only which effect or combination of effects are responsible for the GC-mediated increased outflow resistance and elevated IOP, but also whether the endogenous GC cortisol plays any role in the pathogenesis of glaucoma. In the future, it may be possible to determine whether a person is a steroid responder prior to GC therapy, so that patients can be more closely

Table 2 Summary of effects of glucocorticoids on the trabecular meshwork

- TM cells and tissues express glucocorticoid receptors (GRs) and are targets for GC action
- Glucocorticoids alter TM cell gene and protein expression
  - Induction of the glaucoma gene myocilin
  - Suppression of growth factor receptor expression
- Glucocorticoids inhibit TM cell proliferation, migration, and phagocytosis
- Glucocorticoids promote extracellular matrix deposition in the TM through increased synthesis and decreased degradation
- Glucocorticoids reorganize the TM actin cytoskeleton (forming cross-linked actin networks)
- Levels of GRβ, an alternatively spliced form of the glucocorticoid receptor, regulate glucocorticoid sensitivity in TM cells

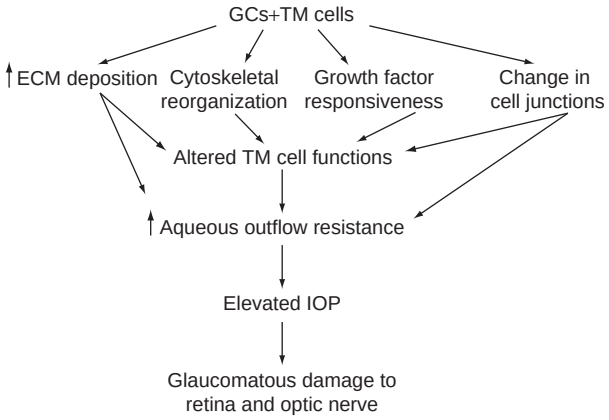

Figure 2 Effects of glucocorticoids on the trabecular meshwork and development of steroid glaucoma.

monitored, and to determine the potential enhanced risk for developing POAG.

Structural Changes in the Trabecular Meshwork with Primary Open Angle Glaucoma*

E Lütjen-Drecoll and O-Y Tektas, University of Erlangen-Nürnberg, Erlangen, Germany

Glossary

Cribriform elastic network – A network of elastic-like fibers which is continuous with that part which forms the core of the trabecular lamellae, and which is connected to the inner wall of Schlemm's canal.
Elastic-like fibers – The elastic fibers in the trabecular meshwork which are different from ordinary elastic fibers as they contain little elastin, and are surrounded by a sheath of cross-linked fibrils (previously termed curly collagen).
Glaucomatous (POAG) SD plaques – The SD plaques to which fine fibrils (which are immunoreactive to type VI collagen) adhere, thereby forming irregular thickenings that are responsible for the increase in SD plaques' area in glaucoma eyes as compared to age-matched controls.
Sheath-derived (SD) plaques – Those parts of the elastic-like fibers and their cross-linked fibrillar sheath that are seen in ultrathin sections viewed by transmission electron microscopy.

Introduction

It is generally accepted that increased resistance to aqueous humor outflow is a predominant risk factor for the increase in intraocular pressure (IOP) in glaucomatous eyes. Neither the pathophysiology nor the structures responsible for the increase in outflow resistance are presently known. The main problem in this respect is the lack of an animal model that shows structural changes in the outflow pathways comparable to those seen in glaucomatous eyes.

It is known, however, that under physiological conditions ciliary muscle (CM) contraction can influence outflow resistance. With increasing age and development of presbyopia, the effect of CM contraction on outflow resistance is diminished and outflow resistance increases. Aging is a main risk factor for the development of primary open-angle glaucoma (POAG). We, therefore, assume that understanding the connection of the CM system with the trabecular meshwork (TM) and its age-related changes is a prerequisite for understanding why POAG develops mainly in elderly human eyes.

Effect of Accommodation on Outflow Resistance

Using serial tangential sections in parallel to the inner wall of Schlemm's canal (SC), Rohen and colleagues in 1967 found that the anterior tendons of the CM insert into the trabecular lamellae. Later on, these findings were confirmed by electron microscopical studies of tangential sections. The studies showed that the curled cribriform fibers in the juxtacanalicular region of the TM consist of bent fibrillar bundles connecting the cribriform elastic fiber network and the elastic fiber network of the TM to the inner wall endothelium of SC (the so-called connecting fibrils (CFs)). The elastic tendons of the outermost longitudinal CM fibers obliquely bend into the TM and insert either into the scleral spur or into the cribriform elastic fiber system (**Figures 1**, and **2(a)** and **(b)**).

The elastic tendons and the elastic fibers in the TM show a specific morphology and were therefore previously termed elastic-like fibers. The elastic fiber core contains only little elastin and is surrounded by elastic microfibrils and a sheath of cross-banded fibrils. The nature of these cross-banded fibrils is not yet known. Histologically, the sheath stains for type VI collagen. At the ultrastructural level, antibodies against various proteins seem not to penetrate into the banded fiber sheath. Here, only the fibrils entering the banded sheath stain for type VI collagen. In the ciliary body, type VI collagen connects basement membranes of smooth muscle cells and vascular endothelial cells with the surrounding connective tissue. In the TM, the elastic fiber network is connected to patches of basement membrane material of the cribriform cells and to the basement membrane or cell membrane of the endothelial lining of SC. The CFs are derived from the sheath of the elastic fibers and also contain type VI collagen.

The posterior elastic tendons of the CM insert into the choroidal elastic fiber system and Bruch's membrane. The ultrastructural details of the fibers differ from those seen at the anterior muscle tips and the TM. They contain large amounts of elastin and appear morphologically

(b)

Figure 2 (a) Cribriform elastic network (black), outer elastic tendons of the ciliary muscle (red), and bend connecting fibrils (blue) in a relaxed ciliary muscle; (b) following ciliary muscle contraction. The spaces of the cribriform network are enlarged, the connecting fibrils straightened, and the subendothelial region widened through an inward movement of the ciliary muscle and its tendons.

nearly homogeneous. During accommodation and CM contraction, the posterior muscle tendons become elongated or stretched, and the muscle shortens posteriorly. The anterior muscle tips stay in place. The CM moves anterior inwardly, thereby expanding the TM. Expansion of the cribriform elastic network allows the bent CFs to straighten. This straightening of the fibers leads to an enlargement of the spaces in the cribriform elastic network, and to a widening of the subendothelial region of SC and its lumen (**Figures 2 (a) and 2(b)**). Physiologically, the morphological changes are accompanied by an increase in outflow facility. When Barany measured resting facility following CM contraction induced by pilocarpine treatment in Thailand stump-tailed macaques, there was a significant correlation between optically empty spaces in the subendothelial region of SC and resting outflow facility. It is possible that wash-out of extracellular matrix (ECM) from the subendothelial region contributes to the increase in outflow facility following CM contraction, at least in monkey eyes, and presumably also in younger human eyes.

Age-Related Changes of the CM–TM-System

With increasing age and the development of presbyopia not only the CM but especially the elastic tendons undergo age-related changes. The changes profoundly differ between anterior and posterior tendons. With age, the CM remains shortened, even in a relaxed position, following atropine treatment, indicating that the muscle cannot be pulled backwards in the same way as in young eyes. It is tempting to speculate that loss of elasticity of the posterior tendons might be involved in this diminished backward movement of the muscle.

The anterior elastic tendons of the muscle do not seem to lose elasticity as the tips of the muscle do not move backward, but stay in place at the scleral spur even in very old human eyes. This finding indicates that the special structural elements of the TM elastic fibers undergo different age-related changes than the posterior elastic tendons. The sheath of the anterior tendons and the TM elastic fibers significantly thicken with increasing age, whereas the diameter of the elastin-containing central core of the fibers remains constant throughout life. This thickening and presumably even stiffening of the fiber sheath prevents collapse of the TM and SC with age. On the other hand, thickening of the elastic fiber sheath leads to a decrease in size of the pores of the cribriform network. In addition, concomitant with the sheath, the CFs thicken. The resulting increase in the amounts of ECM in the outer TM might contribute to the increase in outflow resistance seen in normal elderly eyes. This hypothesis is supported by findings in elderly rhesus monkeys. Here, increase in cross-sectional area of the

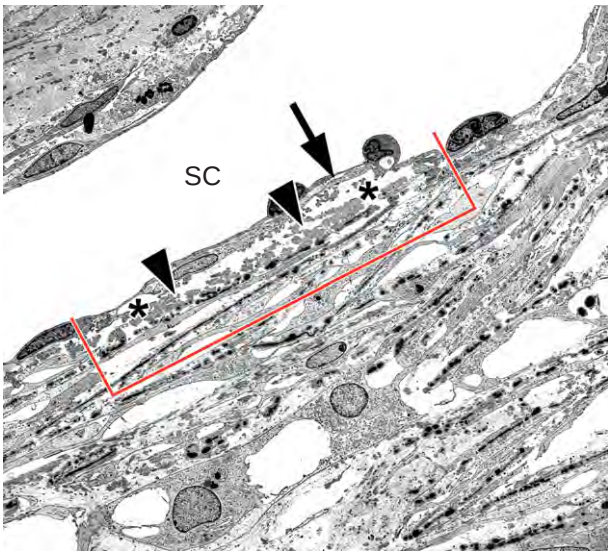
elastic fibers with their sheaths in the outer TM is significantly correlated with increase in outflow resistance. This correlation exists, even if the absolute changes in the TM of old rhesus monkeys were found to be much less prominent than in human eyes of comparable relative ages. The morphology of the TM and CM in a (very old) 30-year-old rhesus monkey resembled that of a 30-year-old human eye. Age-related changes similar to that observed in the eyes of more than 60-year-old humans have not been observed in any animal model investigated so far.

In old human eyes, there is a steady decline in cells throughout life. Alvarado and colleagues found a decrease of 0.56% of cells per year. Grierson and colleagues recorded a decrease from 763 000 cells in 20-year-old humans to 403 000 in 80-year-olds, with a loss rate of 6000 cells/year. The loss of cells was least in the cribriform region of the TM. Only if increased cell loss occurs, fusion of denuded beams might contribute to collapse of the TM, and to an increase in outflow resistance.

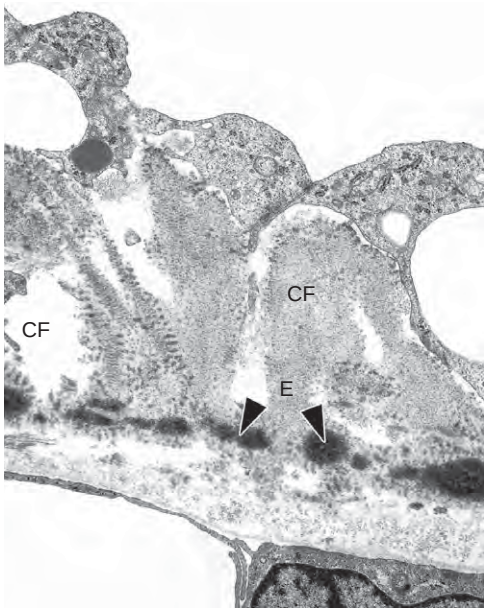
Morphological Changes in the Outer TM of Eyes with POAG

In collaboration with Doug Johnson, we studied the morphological changes in the TM not only in trabeculectomy specimens from advanced-glaucoma patients undergoing surgery, but also from donor eyes with different stages of the disease. The morphology of the outer TM in eyes with POAG does not differ very much from that of age-matched controls; however, there are quantitative differences. The amount of SD plaques is significantly higher in glaucomatous than in normal eyes (**Figures 3(a)** and **3(b)**, and **4(a)** and **4(b)**). In a few eyes with advanced stages of POAG, it was possible to perform enzyme digestion studies on serial tangential sections and to study these sections electron microscopically. In these sections, fine fibrils adhered to the cribriform elastic network and to the CF. Most of the fibrils stained for type VI collagen (**Figure 5**). In nondigested specimens, they are surrounded and masked by glycoprotein and proteoglycan-rich ground substances also masking the banded sheath of the elastic fibers. In 2002, Ueda and colleagues found fibronectin, vitronectin, laminin, and tenascin as glycoproteins, decorin and versican as proteoglycans, as well as hyaluronan, collagen I, III–VI, MAGP-1, and fibrillin in the sheath material. In contrast to our previous findings, myocillin was also found, probably because of differences in the antibodies that were used for immunocytochemical staining.

Adherence of additional fibrillar material to the network of the TM, which is masked by the various ECM components, can explain why in eyes with POAG the thickness of the sheath is irregular and that plaque material can even be found separated from the elastic fibers (**Figure 4(b)**). In eyes with POAG, the CF are also surrounded by increased amounts of type VI collagen and various other components of the ECM. In more advanced cases of POAG, they form fibrous plates which could participate in blocking of outflow pathways.



(a)



(b)

Figure 3 Inner wall regions of eyes with POAG. (a) The red lines indicate the area quantitatively evaluated by Gottanka and colleagues in 1997. The area of SD plaques (arrow heads), basement membrane-like material (arrow), optically empty spaces (asterisks), etc. were measured. There was a significant increase in SD plaques in glaucomatous eyes compared to age-matched controls. (b) Higher magnification of SD plaques. The cribriform elastic fiber network (E) and its CF are surrounded by a homogeneous sheath. Sections through the elastic fibers and sheaths, as well as through the CF and their surrounding extracellular material, were measured as SD plaques.

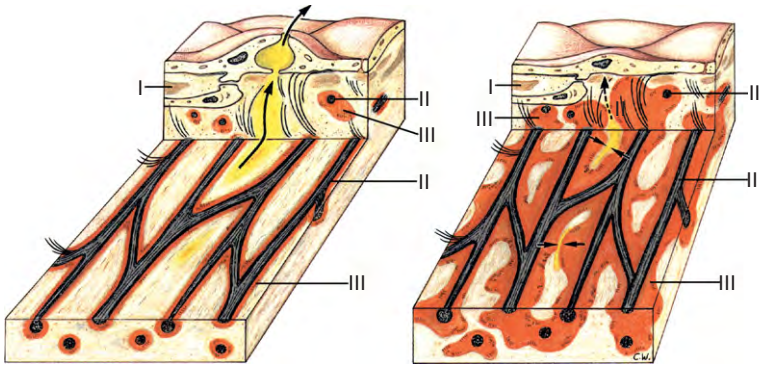


Figure 4 (a) The subendothelial elastic fiber network and its CF (II) in normal; (b) in glaucomatous eyes. The sheaths of the elastic fibers (red, III) thicken and become irregularly arranged in glaucomatous eyes thus narrowing the intertrabecular outflow channels (yellow, arrows). In cross sections, the elastic fibers and their sheaths form SD plaques. The basement membrane-like deposits adjacent to the inner wall endothelium (I) are not changed in glaucomatous eyes.

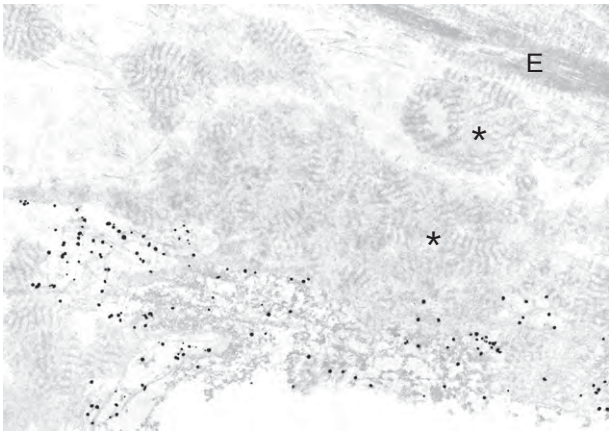

Figure 5 Immunogold labeling of type VI collagen fibrils. Oblique ultrathin section through the cribriform region. Note that the fine fibrils adhering to the sheaths (asterisks) of the elastic fibers (E) are type VI collagen immunoreactive.

Studies by Rohen and colleagues in 1993 enabled a comparison between POAG TM specimens that had been treated with antiglaucomatous drugs with specimens from patients who had not received any treatment. There was no difference in the amount of plaques between the two groups. Therefore, increased and irregular thickening of elastic fiber sheaths seems to be a sign for POAG disease, and is not caused by long-term treatment with antiglaucomatous drugs. This is supported by the fact that such thickening of elastic fiber sheaths is not seen in age-matched eyes suffering from pseudoexfoliation or steroid-induced glaucoma, but also having undergone long-term treatment.

Regional Differences

Sections from different parts in the circumference of the eye showed that there are marked regional differences in the individual eye with POAG. Pigmentation of trabecular cells appeared to be a marker for aqueous flow regions. In areas with thin trabecular lamellae covered by trabecular cells and with wide open spaces in the subendothelial region of SC, many cells contained pigment granules (**Figure 6(a)**). In other parts of the circumference nearly no pigment granules were present in the TM. In these regions the trabecular lamellae appeared thickened and fused (**Figure 6(b)**). Often, the SC filtration region appeared to be smaller and the cribriform region densified, presumably indicating a diminished perfusion.

Correlation between TM Changes and Axon Loss in the Optic Nerve

Interestingly, the area of SD plaques in POAG TM significantly correlates with axon loss in the optic nerve. As plaques in the TM cannot cause axon loss in the optic nerve, it is possible that common factors are responsible for both changes. The search for such factors has been undertaken mainly *in vitro*.

Many factors known to increase expression in other tissues or factors induced by oxidative damage are increased in the aqueous humor of a number of eyes with POAG.

One of the factors increased in the aqueous humor of nearly 50% of eyes with POAG is TGFβ_2. In fact, *in vitro* TGFβ_2 can stimulate trabecular cells to synthesize increased amounts of various ECM components, of the enzyme transglutaminase which cross-links proteins to complexes nondegradable by metalloproteinases and of plasminogen activator inhibitor that inhibits activation of metalloproteinases. Further studies will clarify which other factors could be responsible for induction of the TM changes seen in eyes with POAG.

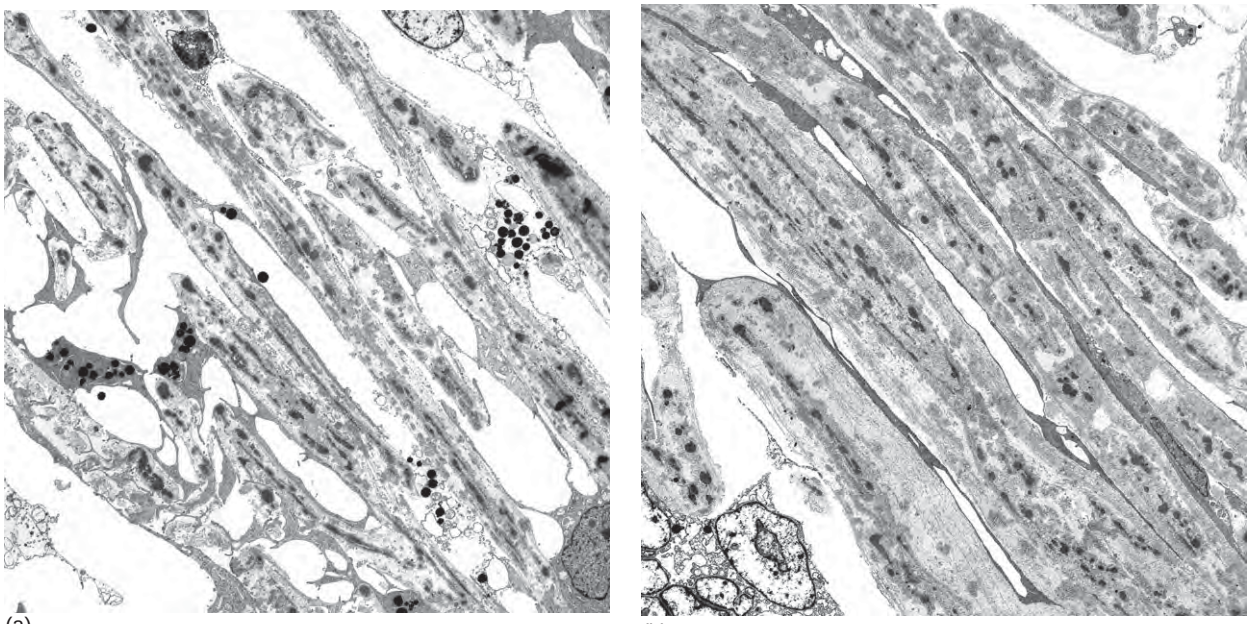

Figure 6 Electron micrographs of sagittal sections of the TM. (a) In areas with open intertrabecular spaces and thin lamellae, most of the trabecular cells contain pigment granules. (b) In areas with small or occluded intertrabecular spaces and thick lamellae, few cells contain pigment granules.

Acknowledgments

We are grateful to Doug Johnson for his collaboration in the study of morphological changes in the TM.

Structure and Evolution of Crystallins

G Wistow, National Eye Institute, Bethesda, MD, USA
C Slingsby, Birkbeck, University of London, London, UK

Published by Elsevier Ltd.

Glossary

Crystallins – The proteins that accumulate to very high levels in the cytoplasm of lens fiber cells, usually comprising more than 10% of the total protein. They may either belong to the group of classical crystallins, present in all vertebrate lenses, or be taxon specific. Taxon-specific crystallins, as the name suggests, are expressed in the lenses of species in a limited number of taxonomic groups.

Heat-shock proteins – The proteins that accumulate in cells in response to stress or that protect cells from stress. These proteins were originally named by their selective expression in cells exposed to elevated temperatures and for their ability to increase the temperature resistance of the cells in which they are expressed. Many proteins that, based on structural criteria, are heat-shock proteins are expressed constitutively and may protect cells from a variety of harmful insults.

Refractive index – In practical terms, this is the property that alters the speed of light passing through a substance. Lenses must have a refractive index that is different from the medium that surrounds them. The high protein concentration in biological lenses gives them a refractive index that is higher than the fluids around them.

What Are Crystallins?

To fulfill its function in light refraction and image formation in the vertebrate camera eye, the lens needs to have a high refractive index. This is largely conferred by high concentrations of soluble cytoplasmic proteins which as a group are known as the crystallins. The lenses of vertebrates contain three classes of crystallins, the α-, β-, and γ-crystallins, which must have been present in an early common ancestor. α-Crystallins belong to the small heat-shock protein (sHSP) superfamily, while the β- and γ-crystallins are related to each other and belong to another widespread superfamily. Other crystallins are taxon specific, restricted to specific evolutionary lineages. These crystallins are mostly enzymes and became crystallins through modification to their genes conferring greatly increased expression specifically in the lens, a process called gene recruitment.

Indeed, this is probably the mechanism by which all crystallins arose. This is illustrated most tellingly by the discovery of a protein related to β- and γ-crystallins that is expressed in cells of the primitive light-sensitive organ of the urochordate *Ciona intestinalis*, an organism which diverged from the vertebrate lineage before the development of the lens. When the promoter of the gene for the *Ciona* protein is transferred to amphibians, it directs expression in the lens and other parts of the visual system. This suggests that the most ancient crystallins arose from proteins with a functional role in the ancestral eye whose expression could be enhanced in the newly evolving lens and that the lens made use of elements of the transcriptional repertoire of light-sensitive cells (such as Pax6) that are still used in vertebrate eyes.

While different proteins serve as crystallins, not just any protein will do. Crystallins must be able to accumulate to high concentrations without aggregating, precipitating, or undergoing phase separations into protein-rich and protein-poor regions, any of which would give rise to light scattering that would render the lens opaque. Since the lens grows as layers of terminally differentiated fiber cells that lose their nuclei (probably to enhance transparency), crystallins have low (or no) turnover in the lens. They must be stable for the lifetime of the organism while subject to light exposure and the threats of oxidation and other insults. These requirements put constraints on the shape, thermodynamic stability, and surface properties of crystallins.

The selection of an existing protein as a crystallin would be more likely if the protein was already expressed at moderately high levels in the lens (or precursor cells) and if it had other useful features that might confer a selectable benefit on the lens, such as stabilization of unfolded proteins or protection from oxidative damage.

α-Crystallins

The lenses of all vertebrates contain α-crystallins, 18–20-kDa polypeptides which form large, polydisperse assemblies in the 600-kDa size range. In terrestrial species, two genes (Cryaa and Cryab), the result of an ancient duplication, provide all this protein. The two gene products (αA and αB-crystallin) belong to the widespread sHSP superfamily, part of a network of molecular chaperones. sHSPs have roles in binding, stabilizing, and solubilizing

unfolded or partially folded polypeptide chains. Unlike the HSP70 and HSP90 families, the sHSPs do not have adenosine triphosphate (ATP)-dependent active protein folding processes. Their role seems to be rescue or protection of unfolded proteins from aggregation before they can be refolded (or degraded) by other systems. They also associate with cytoskeleton and have activity in protecting or shepherding multimolecular assemblies in the cytoplasm and the cell nucleus. Since one of the most significant features of the cellular lens in vertebrates is the enormous elongation of fiber cells and the elaboration of very extensive cytoskeletal structures, high levels of proteins with sHSP activity is probably beneficial. Selection of a sHSP as a crystallin could have contributed both increased refractive index and improved stability of cytoarchitecture in the evolving lens.

Of the two α-crystallins, αB is most similar to the ancestral state since, although it is highly expressed in lens, it is also widely expressed in other tissues and is stress inducible. In contrast, αA-crystallin has become much more specialized for lens (although it does exhibit some nonlens expression, particularly in retina). This history of duplication and specialization has gone one step further in some fish. In zebrafish (*Danio rerio*), there has been a duplication of the gene for αB-crystallin. Recapitulating the original duplication in this family, one copy (αB1) is highly specialized for lens and has compromised some of its chaperone-like properties, while the other (αB2) is widely expressed and has normal chaperone properties. (Since specialization for lens is accompanied by a reduction in chaperone activity, this may not be of central importance to the role of α-crystallins in lens.)

Structure and Implications for Function

sHSPs contain a core domain of about 90 residues (known as the α-crystallin domain; ACD) in addition to highly variable N-terminal domain extensions (**Figure 1(a)**). X-ray structures have been solved for some nonlens sHSPs, although none from vertebrates and all contain a conserved β-sandwich in the ACD. The solved structures are for proteins that form well-defined multimers built up from dimers, unlike the polydisperse α-crystallins, but reveal significant variations in the way N- and C-terminal regions influence subunit interactions (**Figure 1**). In particular, the structure of the metazoan sHSP Tsp36 from the flatworm *Taenia saginata* shows differences in dimerization mechanism from the other solved sHSP structures. However, in all cases, the β-sandwiches have hydrophobic grooves that are filled by residues from N- or C-terminal extensions in self assembly. Acting as chaperones, these grooves could be used to stabilize various secondary structural elements of client proteins. Other metazoan sHSPs, including α-crystallins, are likely to show further variability in multimerization, but following this general mechanism.

The β- and γ-Crystallins

The β- and γ-crystallins belong to the same protein superfamily, the βγ-crystallins. They consist of polypeptides of 20–30 kDa and share many structural features. They also have major differences, the most obvious of which is that β-crystallins are multimeric, while γ-crystallins are monomers. β-Crystallins also have long N-terminal, and sometimes C-terminal, extensions that are subject to post-translational cleavage in the lens.

The βγ-Crystallin Fold and Tertiary Structure

The β- and γ-crystallins are the result of duplications of a distinctive structural motif of about 40 amino acid residues that conforms to a modified Greek key pattern of four β-strands (**Figure 2**). One motif cannot exist as a stable structure alone, but a pair of motifs can associate around a pseudo-twofold axis to create a highly stable, wedge-shaped domain, with two β-sheets sandwiching a tightly packed hydrophobic core capped with connecting loops that link the sheets.

If the strands of each motif are designated *a, b, c,* and *d,* the fold begins with an *ab* hairpin, which bends back on itself, and is defined by highly conserved residues giving a YxxxxF/YxG signature (**Figure 2(a)**). The glycine, lacking a side chain, is essential for the geometry of the fold. Strand *c* extends away so that strands *b* and *c* define the wedge shape of the domain. A long loop, often containing a helical stretch, connects across the top of the wedge to strand *d*, which contains a conserved serine that contributes to the structure of the folded *ab* hairpin. Thus, each β-sheet in a βγ-crystallin domain has four strands in the order *b, a, d,* and *c′* (with *c′* coming from the paired motif).

Two other secondary structural features are common (but not universal) in the βγ domain. One is a tyrosine corner in one motif (the second in β- and γ-crystallin domains) in which a tyrosine from the *c* strand hydrogen bonds to a main-chain carbonyl group of the *b* strand. The same motif also often possesses a tryptophan (Trp) corner, in which a Trp near the start of the *a* strand similarly hydrogen bonds to main chain at the end of the *d* strand of the other motif. Both these features stabilize the base of the domain wedge and contribute to correct folding (**Figure 2(b)**).

The β- and γ-crystallins have two domains that are linked by a connecting peptide (**Figure 3**). In γ-crystallins, the connecting peptide is bent and the two domains interact around another pseudo-twofold axis. In βB2-crystallin, a different arrangement occurs. The connecting peptide does not bend, so the two domains of one subunit cannot interact; instead, two subunits pair up head to tail and form interdomain contacts similar to those seen in γ-crystallins but with domains from the other subunit. This is an example of domain swapping in which

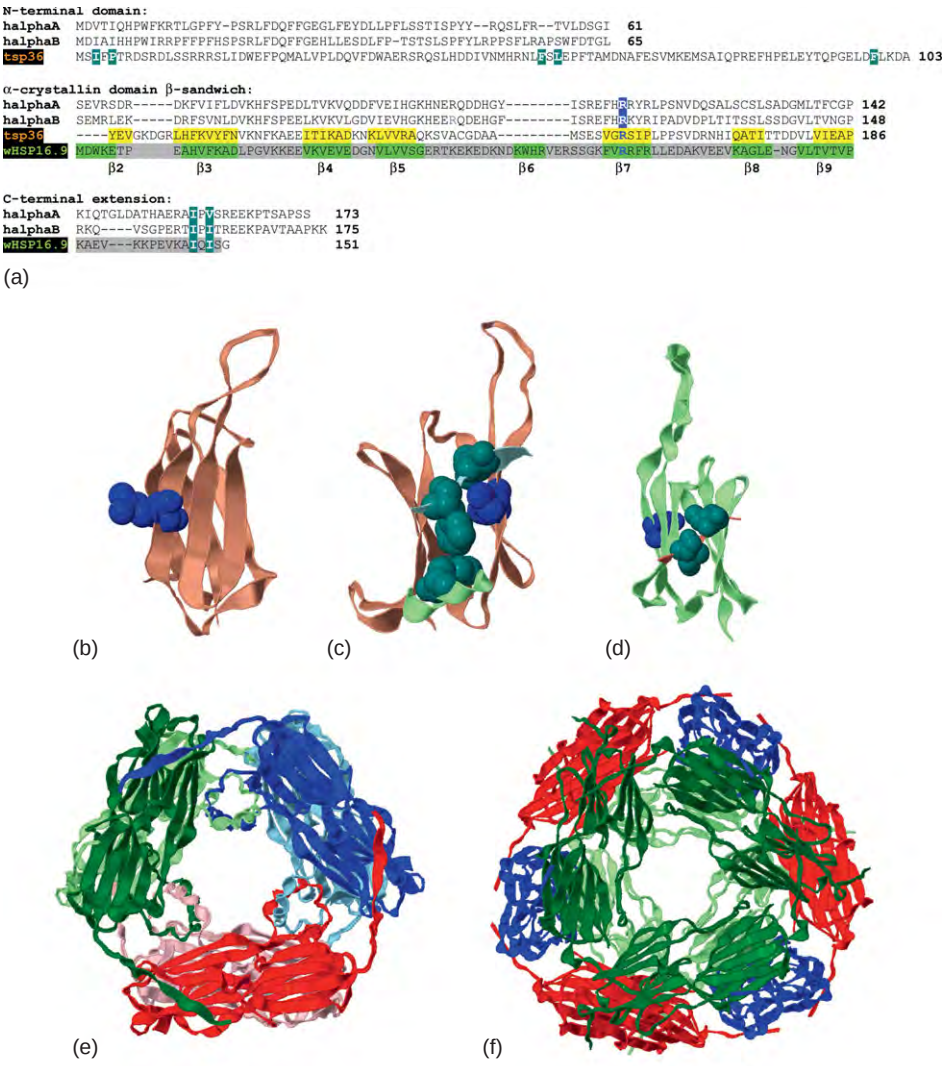

Figure 1 The conserved α-crystallin domain (ACD). (a) sHSPs have a variable N-terminal domain and a conserved ACD that includes a β-sandwich and an ordered extension (highlighted here in gray in the wheat HSP16.9 sequence). The sandwich β-strands, highlighted in bright green and yellow, are labeled. (b) The ACD β-sandwich, represented here by the one from the first ACD (it has two) from the flatworm protein tsp36, shown in salmon pink, taken from Protein Data Bank (PDB) 2bol. These sHSP beta-sandwiches have open, hydrophobic N-terminal (left) and C-terminal (right) sides that attract other hydrophobic sequences. The residue shown in blue space-fill in the model and in the alignment is a conserved arginine that when mutated in human αA- and αB-crystallins causes, respectively, cataract or myopathy. (c) This view of the tsp36 domain rotated 90° relative to (b) shows how hydrophobic residues from the variable N-terminal region, shown in dark green in the 3D structure and in the alignment, patch the open face of the sandwich, close to the conserved arginine. (d) The same region of wheat HSP16.9 (PDB 1gme) is shown in ribbon representation in pale green, with the ordered C-terminal extension of another subunit in salmon pink, to indicate that the interaction is between different chains in the 12-chain assembly structure. In this view, with the C-terminal side in the foreground, the open face is patched with hydrophobics from the ordered extension, shown in dark green in the 3D structure and the alignment, with the conserved arginine in the background. Different arrangements of subunits in two sHSP multimers from (e) wheat HSP16.9 and (f) archaebacterium (*M. jannaschii*), PDB 1shs. Dimers, colored in uniform color, show extensions interacting with beta-sandwiches from other dimers.

dimerization can occur in proteins by substituting interfor intramolecular contacts. However, there are alternative ways in which β-crystallins can dimerize. In a truncated version of βB1-crystallin (missing most of its N-terminal extension), the domains of one subunit associate in the γ-crystallin manner with a bent connecting peptide. Dimerization now occurs by side-to-side interactions of γ-like subunits similar to the way βB2 dimers associate with symmetry-related dimers in the crystal lattice. Mixed multimers of β-crystallin subunits may explore many modes of assembly.

Surface and sulfur

A striking feature of γ-crystallins is the high percentage of intramolecular surface ion pairs. This may reduce the amount of bound water, suitable for the dehydrated core

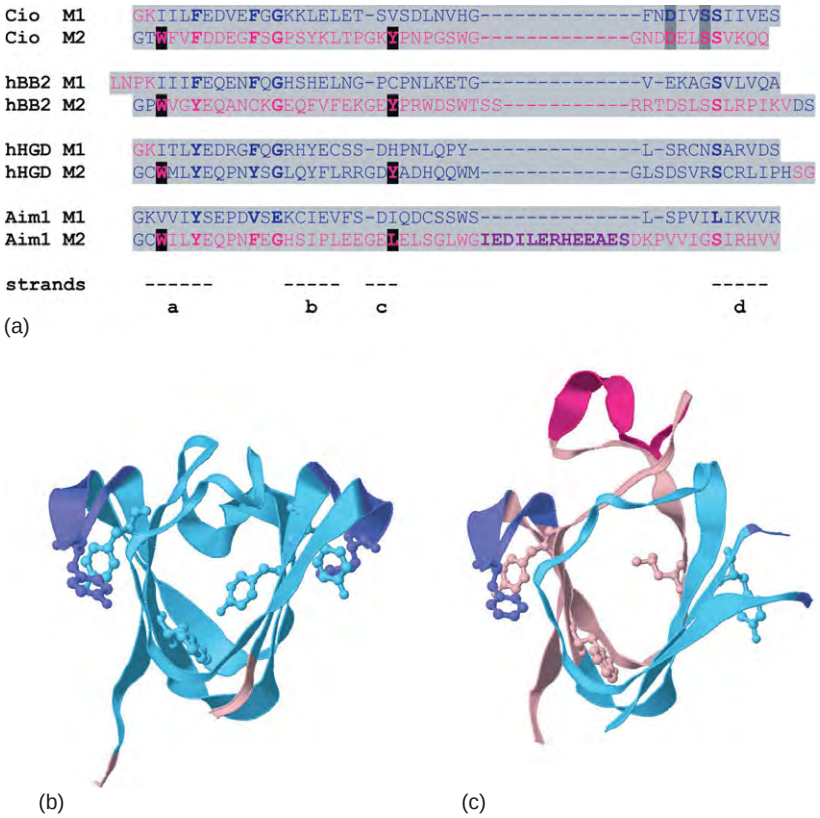

Figure 2 The βγ-crystallin motif and domain structure. (a) Sequence alignment of representative domains from the ancestral *Ciona* βγ-crystallin (cio); human βB2-crystallin (N-terminal domain) (hbb2); human gD-crystallin (N-terminal)(hGD) and Aim1 (domain 1); arranged so that the two Greek key motifs of each domain (M1, M2) are shown in pairs, aligned vertically, and color-coded to show the exons. For Cio, side chains that bind calcium are highlighted in dark gray. Residues corresponding to the βγ-crystallin fingerprint are in bold. The positions of *a, b, c,* and *d* strands are indicated. (b) The N-terminal domain of human γD-crystallin (PDB 1hk0), showing that most of the domain is encoded in a single exon, colored blue. The *ab* hairpins are colored purple and the fingerprint and corner aromatic residues have been appended as ball-and-stick models. The tyrosine corner residue is prominent in the center of the view. (c) The first βγ-domain of human AIM1 (PDB 3cw3). Sequences corresponding to separate exons are colored pink and blue and in general correspond to motifs. The same pattern is seen in β-crystallins. The absence of critical conserved residues in the second motif has resulted in a disordered conformation of the *ab* hairpin. The extra acidic insertion in the *cd* loop region is shown in crimson.

region of some hard lenses. Various cataract-causing mutations also show that small changes in surface residues can have major effects on solubility in γ-crystallins. It seems that polar groups on each γ-crystallin create characteristic molecular dipoles that may define the relative orientation of the molecules in solution. Disruption of the dipole by even a single side-chain alteration may disrupt the ordering of the proteins so that in dense solutions they undergo phase change or precipitation.

The γ-crystallins, particularly in fish, also have high contents of cysteines and methionines. These sulfur-containing side chains may contribute to stability or packing of crystallins at high density. Even in mammals the sulfur content of γ-crystallins is significant and may be a risk factor for oxidation in cataract.

Mapping of Protein and Gene Structure

The regular, repeated structure of β- and γ-crystallins is reflected in their gene structure, but with a characteristic difference (**Figures 2** and **3**). In the former, each motif is encoded in a separate exon, consistent with a history of duplication from an ancestral motif gene. One or more additional exons encode the N-terminal extension. γ-Crystallins (with the interesting exception of γN) lack the intron dividing the exons for each pair of motifs in one domain. Instead of one exon per motif they have one exon per domain.

Nonlens Relatives

The characteristic sequence signature of β- and γ-crystallins has allowed the identification of a βγ-crystallin superfamily that includes one, two, and six domain proteins in species ranging from prokaryotes to vertebrates (**Table 1**) Unlike the sHSP superfamily to which α-crystallins belong, the nonlens relatives of the βγ-crystallins do not reveal a clear common function. Two well-characterized members, the two-domain Protein S of the prokaryote *Myxococcus xanthus* and the one-domain spherulin 3a of the eukaryotic slime

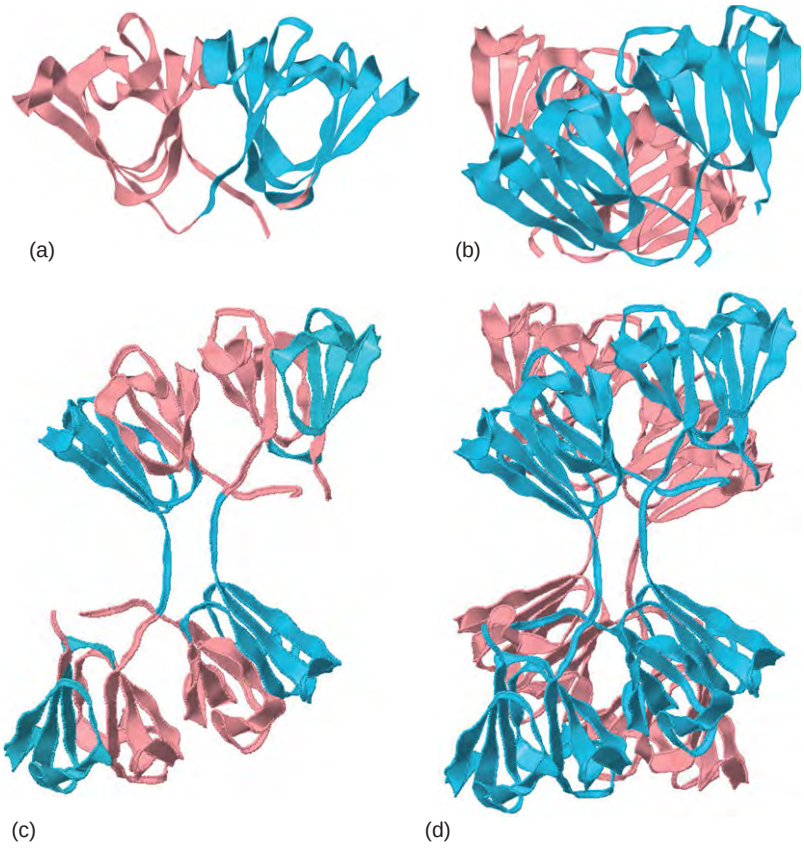

Figure 3 Modular domain interactions in βγ-crystallins. (a) Intramolecular domain pairing in a γ-crystallin (PDB 1hk0) with the N-terminal domain shown as a blue ribbon and the C-terminal domain in pink. The junction between exons 2 and 3 is in the middle of the connecting peptide. (b) A dimer of N-terminally truncated βB1-crystallin (PDB 1oki) with each chain in uniform color showing that each monomer has a similar domain organization as a γ-crystallin. (c) A dimer of βB2-crystallin (PDB 1ytq) with each polypeptide chain colored by exon showing that intrachain domains do not interact with each other, but that the interchain domain–domain interface is very similar in overall geometry to the intramolecular interface in monomeric γ-crystallin. (d) A tetramer of βB2-crystallin as observed in the crystal lattice showing a domain-swapped dimer in the foreground that is colored in blue, and a domain-swapped dimer in the background that is colored in pink. Note that the set of four upper domains (or four lower domains), all from different chains, has a similar organization to the βB1-crystallin dimer.

mold *Physarum polycephalum*, have well-defined calcium-binding sites and are induced in spore or cyst formation, suggesting possible roles in long-lived, dehydrated structures. The calcium-binding sites in these two proteins, distantly related in evolution, are very similar to those found in the one-domain *Ciona*-crystallin, but they are absent from the lens βγ-crystallins (**Figure 2**). (While low levels of calcium binding have been observed in β- and γ-crystallins, it is not clear whether this has physiological significance.)

The structure of Protein S also has remarkable similarities and differences with its lens relatives. Protein S too has tyrosine corners, but in the first motif of each domain rather than the second. Thus, while the motifs in the crystallins follow an ABAB pattern, in Protein S the pattern is BABA. Ancestral prototypes of A and B motifs may have existed as products of separate genes that folded together as a dimer of motifs. The genes may have fused in the order AB in the line leading to vertebrates and BA in the ancestors of *M. xanthus*.

Two other members of the superfamily may give clues to the functional role of βγ-crystallins in vertebrates. Epidermis differentiation specific protein 1 (EDSP or Ep37) of the newt *Cynops pyrrhogaster*, which has calcium-binding sites, is associated with plasma membrane in the developing epidermis. Absent in melanoma 1 (AIM1), which lacks calcium-binding sites, is encoded by a gene in a region of human chromosome 6 known to contain a suppressor of malignancy in melanoma. AIM1 expression is associated with changes in cell morphology that may reflect the formation of a more organized cytoskeleton. Thus, EDSP and AIM1 may have roles in control of cellular architecture.

AIM1 is also striking because it contains 12 βγ-crystallin motifs arranged as six domains with the

Table 1 Nonlens members of the βγ-crystallin superfamily

	Protein	*Distribution*	*Domains*
Eukaryote			
	AIM1 (and AIM1-like)	Vertebrates	6
	EDSP/ Ep37/ GEP	*Cynops pyrrhogaster* (newt)	2
	βγ-CAT	*Bombina maxima* (frog)	2
	Ciona crystallin	*Ciona intestinalis* (tunicate)	1
	Spherulin 3a	*Physarum polycephalum* (slime mold)	1
Prokaryote			
	Protein S	*Myxococcus xanthus*	2
	Yersina crystallin	*Yersinia pestis*	2 or 3
	Hahellin	*Hahella chejuensis*	1
	Caulollin	*Caulobacter crescentus*	1
	M-crystallin	*Methanosarcina acetivorans*	1

Other proteins have similar β-sheet topology to the βγ-crystallins but lack the characteristic folded hairpin and sequence signatures and are unlikely to be evolutionarily related.

crystallin-like ABAB pattern, perhaps forming a structure similar to a β-crystallin trimer. Indeed, AIM1 gene structure is like a β-crystallin with each motif encoded by a separate exon. Among the six AIM1 domains, numbers 1 and 6 show the greatest divergence from the canonical signatures of any superfamily member so far identified. In domain 1, residues of the characteristic folded hairpin of the first motif are not conserved, while the second motif lacks the tyrosine corner and contains a large insertion in the *c–d* loop (**Figure 2(a)**). X-ray analysis (**Figure 2(c)**) shows that the variant hairpin has no defined rigid structured but, while stability may be impaired, the domain folds compactly and follows βγ-crystallin domain topology.

In addition to the βγ-crystallin domains, AIM1 contains an alternatively spliced N-terminal extension that may be rod-like and a C-terminal ricin-like trefoil domain (a protein interaction domain found in many classes of proteins). Multidomain proteins may have arisen by fusion of genes encoding interacting partners. This raises the possibility that some other βγ-crystallins may have interactions with trefoil domains. Indeed, a multifunctional toxin secreted by the skin of a frog (*Bombina maxima*) is a heterodimer of an EDSP-like protein and a trefoil protein.

Gene Families

The β-crystallins are subdivided into two classes (A, acidic; B, basic) with three genes for each class giving rise to βA1/3, βA2, βA4, βB1, βB2, and βB3-crystallins (βA1 and βA3 are the products of the same gene through alternative translation start sites). This repertoire is present in vertebrates from fish (in which some members are duplicated) to mammals and birds (**Figure 4**). The diversification of these six genes must have occurred in a very early vertebrate ancestor and has been conserved through 300 million years of evolution. This may mean each β-crystallin has a very specific role in the organization or development of the lens. Conversely, since β-crystallins form a wide range of homo- and hetero-multimers, this may restrict the options for divergence in individual proteins.

Genes for β- and γ-crystallins are not randomly distributed in the genome. Those for βB1 and βA4 are arranged head to head on human chromosome 22, while 1.4 Mbp away on the same chromosome, the genes for βB2 and βB3 are also close together. The gene for βA2-crystallin is on human chromosome 2 about 1 Mbp away from a cluster of six γ-crystallin genes. Whether this degree of linkage for such ancient genes is related to coordination in regulation is not known.

While β-crystallins have orthologs in all vertebrate species examined, γ-crystallins are much more variable. Typical placental mammals, such as mice, have six closely related γ-crystallins, γA–F (85–98% identical in amino acid sequence), encoded by genes closely linked in a single chromosomal locus. They are highly expressed in the embryonic lens and contribute to the dense lens core region (the lens nucleus). They have no orthologs in nonmammals; in fish there are many γM-crystallins but these are highly divergent from the mammalian proteins (**Figure 4**).

The γ-crystallins are often associated with regions in the lens of higher refractive index. They are very abundant in fish and in the hard, spherical, myopic lenses of rodents. However, they are (essentially) absent from the softer, highly accommodating lenses of birds. In humans, the genes for γE and γF are nonfunctional, while expression of human γA and γB is low. γ-Crystallins may have evolved to provide the high refractive index needed to diffract and focus light under water in the aquatic ancestors of all vertebrates. In water, the cornea makes little contribution to focusing and therefore all the work must be done by the lens. The multiple, sulfur-rich γ-crystallins of fish provide the hard lens with a protein content that can reach 60% or more wet weight. In contrast, many terrestrial species need a softer lens for fine focusing and accommodation, adapting vision for near and far objects and in terrestrial vertebrates the lens has undergone major changes in γ-crystallin content (**Figure 5**).

The loss of γ-crystallins is most pronounced in birds and reptiles (although data on reptiles are still rather limited) where they have been replaced by taxon-specific crystallins. It seems likely that the reptile-like ancestors of mammals would similarly have lost or downregulated

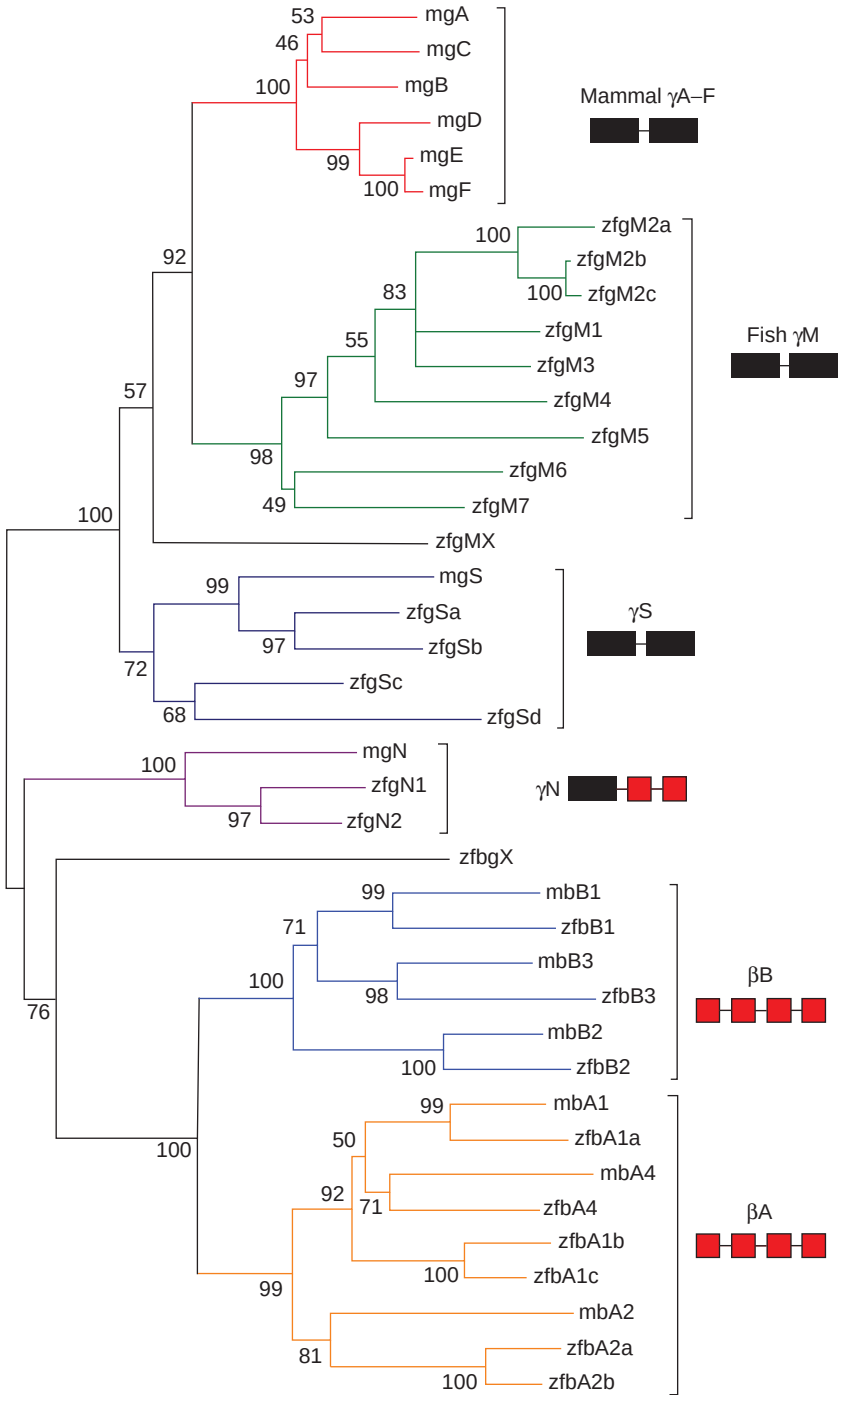

Figure 4 Family tree of β- and γ-crystallins. The complete repertoire of mouse (m) and zebrafish (zf) β- and γ-crystallins were aligned and a family tree constructed using the neighbor-joining procedure using the program MEGA. Mouse βA, βB, γS, and γN crystallins lie on the same branch as orthologs (sometimes duplicated) in zebrafish, showing strong conservation from ancestral sequences. However, γM and γA–F form separate branches, suggesting separate histories of divergence and duplication. For each branch, the exon structure encoding the βγ motifs and domains in each gene class is shown with small red boxes representing individual exons encoding individual motifs (typical of β-crystallins) and lager black boxes representing fused exons encoding both motifs of a single domain (typical of γ-crystallins). γN has hybrid gene structure suggesting it represents an evolutionary intermediate.

ancestral γ-crystallin genes and, yet in many modern mammals (such as mice), high contents of γ-crystallins are found in the lens. It is possible that the mammalian γA–F-crystallin gene cluster was reinvented through a series of duplications from a remaining γ-crystallin gene during a time when the ancestors of placental mammals were nocturnal, burrowing animals for whom a close-vision lens may have been advantageous. However, as

mammals diversified into other ecological niches in more recent evolutionary periods and the need arose once more for lenses capable of accommodation and distance vision, γ-crystallins again began to disappear in some lineages, often replaced with taxon-specific crystallins.

There are two other types of γ-crystallin that are not so tightly associated with the dense core of the lens and which are better conserved through evolution (**Figure 4**). One is γS-crystallin (~50% identical to γA–F), while the other is the recently discovered γN-crystallin. Both have orthologous genes in birds, although their level of expression is not yet known. They also have orthologs in reptiles (*Iguana*) and in fish. γS-crystallin is expressed at its highest levels in the adult lens, making major contributions to the softer lens cortical regions than to the harder nucleus, and is the most abundant γ-crystallin in the human lens. In mouse, γN is detectable at low levels in lens, while complementary DNA (cDNA) analysis suggests γN is moderately abundant in lenses of other species; however, in humans its gene may be nonfunctional, producing only rare aberrant transcripts. Similar to γE and F, it seems to have been deleted from the repertoire of the primate lens. In zebrafish, both γS and γN have undergone gene duplications to form families of two and four genes respectively (**Figure 4**).

γN has a particular significance in the evolution of β- and γ-crystallins. Cladistically, it is close to the division between the two classes. Furthermore, its gene structure is clearly intermediate between β and γ with the first domain encoded in one exon, like a γ gene, and the other encoded as separate motifs, like a β gene (**Figure 4**). The γ gene structure may have arisen by intron loss in a β-like gene (giving rise to γN), followed by loss of a second intron, perhaps by gene conversion.

Taxon-Specific Crystallins

The ancestral vertebrate lens evolved to suit the needs of aquatic species. During evolution, the composition of the

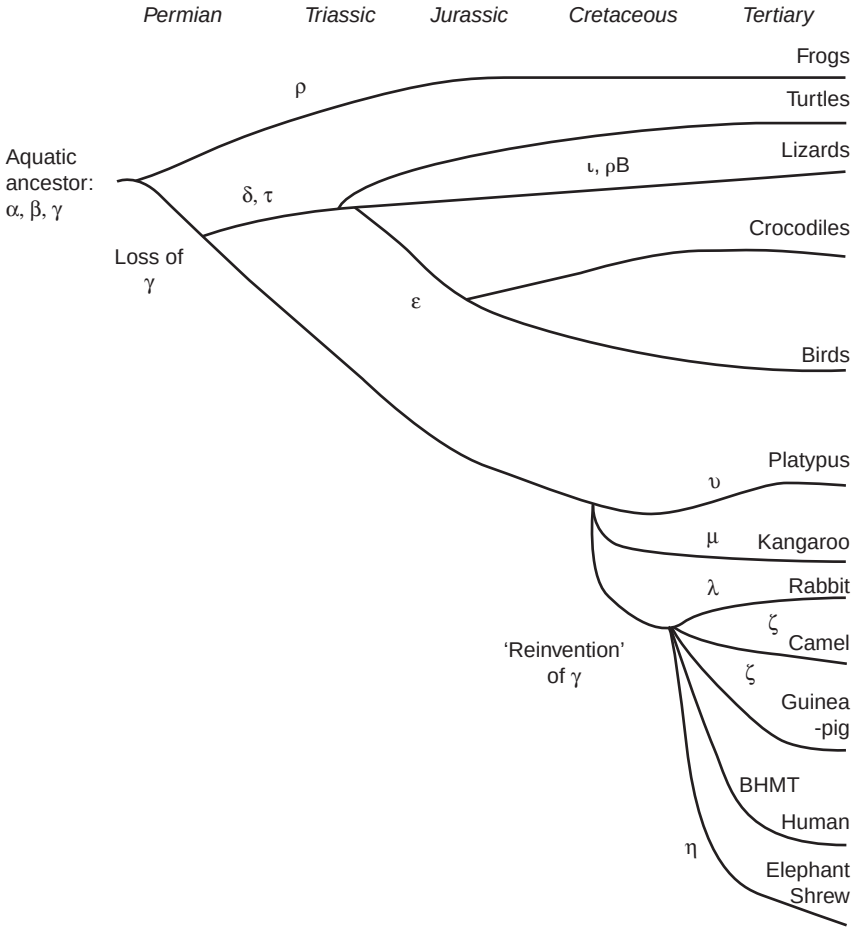

Figure 5 The evolutionary history of vertebrate crystallins. Some major lines of terrestrial vertebrates are shown along with the approximate appearance or disappearance dates for different crystallins by geological epoch. Ancestors of mammals may have lost, then reacquired abundant γ-crystallins during evolution. Different taxon-specific crystallins were recruited at different times, often replacing γ-crystallins in soft, accommodating lenses.

Table 2 Taxon-specific enzyme crystallins

Crystallin	*Distribution*	*Identity (or ~similar)*
δ	Most birds, reptiles	Argininosuccinate lyase
ε	Some birds, crocodiles	Lactate dehydrogenase B
ζ	Guinea pig, camel, llama	NADPH quinone oxidoreductase
η	Elephant shrew	Aldehyde dehydrogenase A1A
λ	Rabbit, hare	~Hydroxyacyl CoA dehydrogenase
?	Primates	Betaine-homocysteine methyltransferase
μ	Australian marsupial (kangaroo, etc.)	~Ornithine cyclodeaminase
ν	Monotreme (platypus)	Lactate dehydrogenase A
τ	Turtles, other reptiles	Enolase 1
ι	Gecko (*Lygodactylus*)	Retinol-binding protein 1
π	Gecko (*Pheksuma*)	Glyceraldehyde 3-phosphate dehydrogenase
ρ	Gecko (*Lepidodactylus*); frogs	~Aldose reductase

Several of these proteins, notably enolase and glyceraldehyde 3-phosphate dehydrogenase, are moderately abundant in lenses of many species where they do not count as crystallins. However, in the species listed, these enzyme crystallins may account for 5–50% of total lens protein and are unambiguously crystallins.

lens has been modified many times, to reengineer its optical properties for different needs (**Figure 5**). Often, this has involved loss and divergence of γ-crystallins. Another evolutionary strategy has been to acquire new crystallins, to replace or perhaps dilute the γ-crystallins. Remarkably, this usually involves the gene recruitment of different metabolic enzymes (**Table 2**). Examination of expressed genes in lenses of different species shows many moderately abundant housekeeping enzymes that occur at much higher levels as crystallins in other species. Thus, taxon-specific enzyme/crystallins have been selected from a pool of enzymes that were already moderately abundant in the lens. (In parallel, enzymes such as glutathione S-transferase have also been recruited as crystallins in the cellular lenses of some invertebrates, a remarkable instance of convergent evolution.)

In birds, the γ-crystallins of the lens core region have gone, replaced by high levels of δ-crystallin. δ-Crystallin is derived from the enzyme argininosuccinate lyase (ASL). Early in the bird and reptile lineage, this enzyme must have acquired high expression in lens as a crystallin. It underwent gene duplication and, as in the case of α-crystallins, one copy (δ2-crystallin) maintained the ancestral functional role, while the other (δ1-crystallin) specialized for lens and, in so doing, lost the enzyme activity that was not needed for the new role. In some birds, both proteins are expressed at high levels in lens, while in others the level of δ2-crystallin is decreased.

Birds and crocodiles also have another major taxon-specific crystallin: ε-crystallin, which is identical to the enzyme lactate dehydrogenase B (LDHB). Unlike δ-crystallin, this has not (yet) undergone duplication and separation of functions. As such, it carries the burdens of two functions: enzyme and crystallin. Indeed, these and other crystallins illustrate an important mechanism in protein evolution in which a single protein may acquire two roles, creating an adaptive conflict. This can be resolved by duplication allowing the duplicate genes to diverge and specialize. While α- and δ-crystallins may have relieved adaptive conflict by this mechanism, ε-crystallin has not, but perhaps this will occur in some lineage of birds in the future.

If enzyme/crystallins are at least partially involved in replacing the lens-hardening γ-crystallins, the same might be expected to have occurred in primate lenses in which γ-crystallins also seem to be on the way out. Indeed the embryonic lens in humans and other primates contains very high levels of the enzyme betaine–homocysteine methyltransferase (BHMT). Although this has not received the accolade of a Greek letter, BHMT certainly seems to fit the criteria for a taxon-specific crystallin, partially replacing γ-crystallins in the human lens core.

Several different enzymes serve as crystallins in different species. In all cases, the enzymes are so abundant in the lens that they exceed any conceivable metabolic requirement. Some (but not all) of them bind nicotinamide adenine dinucleotide phosphate (NAD(P)H) cofactors that could act as ultraviolet (UV) filters or as reservoirs of reducing potential, potentially useful additional effects of their recruitment in the lens. Since many enzymes associate with cytoskeleton, it is also possible that, like other crystallins, enzyme/crystallins help to maintain the architecture of the lens fiber cells. Indeed, there is one recruited enzyme that, although it does not reach the levels of abundance usually associated with crystallins, has a specialized role in lens associated with cytoskeleton. Lengsin is a member of the glutamine synthetase superfamily but has lost enzyme activity. It is conserved in all vertebrate lenses where it plays a role in interacting with the lens-specific beaded filaments in terminally differentiating fiber cells.

In terms of three-dimensional (3D) structural adaptations to the lens role, the enzymatically inactive duck δ1-crystallin shows specific changes in substrate-binding regions that presumably enhance its role as a crystallin. η-Crystallin, a type 1 aldehyde dehydrogenase that is a major component of the lens in the elephant shrew (*Elephantulus* sp.), shows reduced flexibility in regions related to the active site tunnel; the protein may have acquired increased stabilization of its tertiary structure in response to the requirements of the lens perhaps at the expense of the enzyme role.

Conclusions

Vertebrate crystallins are a diverse group of proteins that, fitting certain criteria of stability and solubility, form the bulk refractive structure of a cellular lens. The proteins need to be stable and to interact with each other and other lens components in an orderly way (including short-range order) that maintains the supramolecular structure of the lens cytoplasm, forming no centers for light scattering and thereby maintaining transparency. In addition to their roles in lens, crystallins and their relatives have functional roles in other tissues.

T

Tear Drainage

F P Paulsen and L Bräuer, Martin Luther University Halle-Wittenberg, Halle, Germany

Glossary

Dacryocystitis – An infection of the efferent tear ducts.
Dacryolithiasis – The formation and presence of dacryoliths.
Dacryostenosis – The obstruction or narrowing of one or both canaliculi or the nasolacrimal duct. It may be present at birth.
Epiphora – An abnormal overflow of tears down the face.
Horner's muscle – A branch of the orbicularis oculi muscle passing behind the lacrimal sac; it contributes to the lacrimal pump.
Natural killer (NK) cells – A type of cytotoxic lymphocytes that constitute a major component of the innate immune system.
Pseudostratified epithelium – A type of epithelium that, though comprising only a single layer of cells, has its cell nuclei positioned in a manner suggestive of stratified epithelia.
Rheology – The study of the flow of matter: mainly liquids but also soft solids or solids under conditions in which they flow rather than deform elastically. It applies to substances which have a complex structure, including muds, sludges, suspensions, polymers, many foods, bodily fluids, and other biological materials. The flows of these substances cannot be characterized by a single value of viscosity (at a fixed temperature) – instead the viscosity changes due to other factors.

The upper and lower canaliculi, lacrimal sac, and nasolacrimal duct are subsumed under the terms nasolacrimal ducts, efferent tear ducts, or lacrimal passages. After birth, the function of the nasolacrimal ducts is to drain tear fluid into the inferior meatus of the nose.

The physiology of lacrimal drainage has been under study for over a century. Various mechanisms have been proposed to explain tear drainage, reflecting the unique anatomic configuration of the efferent tear ducts (Table 1). These include an active lacrimal pump mechanism that functions by contraction of the orbicularis eye muscle; a wringing-out mechanism governed by a system of helically arranged fibrillar structures; the bulging and subsiding of a cavernous body that surrounds the lacrimal sac and nasolacrimal duct; the action of epithelial secretion products; and physical factors such as capillarity, gravity, respiration, evaporation, and absorption of tear fluid through the lining epithelium of the efferent tear ducts. Nevertheless, the complex mechanism by which the tear fluid is brought from the ocular surface to the inferior meatus of the nose is yet not completely understood.

The median transit time of a single applied teardrop containing fluorescein dye has been shown to be 4.5 min or 8 min, depending on whether the fluorescein is applied without or with anaesthetizing the ocular surface, respectively. Without anaesthetizing, some reflex tearing of the lacrimal gland is initiated that increases lacrimal fluid volume, which in turn shortens the dye transit time. However, the passage time is subject to distinctive intraindividual variability with a standard deviation of 3.23 min and minimum and maximum values between 15 s and more than 18 min, respectively. There may be several factors that determine the high level of intraindividual variability in dye transit time: fluctuations within a single individual over time, family predisposition, emotional status, the fluid balance, basal tear film production, atmospheric conditions of testing, tear pump efficiency, hormonal status, and blink rate.

History

The first exact description of the efferent tear duct system dates back to Giovanni Battista Carcano Leone (1574). Together with the work of Niels Stensen (1662) on tear secretions, Leone's explanations led to a plausible concept for the entire lacrimal system.

Table 1 Mechanisms of tear drainage

Active lacrimal pump mechanism aided by contraction of the lacrimal portion of the orbicularis muscle
Distension of the lacrimal sac by the action of the lacrimal portion of the orbicularis muscle
Epithelial secretion products (mucins, TFF peptides, and surfactant proteins) of the epithelia of the lacrimal sac and nasolacrimal duct
Wringing-out mechanism governed by a system of helically arranged fibrillar structures
Opening and closing of the lumen of the lacrimal passage effected by the bulging and subsiding of the cavernous body
Capillarity
Respiration
Evaporation
Absorption of tear fluid through the lining epithelia of the lacrimal sac and nasolacrimal duct

Development

During the third month of embryological development, the eyelid folds contact each other and fuse. The specialized structures of the eyelids develop during the period of fusion. Some epithelial cores from both margins of the lid folds get buried in them, at the inner sixth of the eyelids, to form the precursors of the puncta and canaliculi. The epithelial buds, which have grown inside the tarsus, become canalized, as do the epithelial cores that will form the puncta and canaliculi. In the sixth month, the nasolacrimal system becomes patent as a result of lysis in the central cells of both epithelial rods (one starting from the inner canthus and extending toward the nose and the other starting from the nasal mucosa and extending toward the inner canthus) at their site of junction. At birth, the nasolacrimal canal is patent from the puncta to the nasal mucosa, under the lower concha (also known as turbinate). The lower end of the lacrimal duct is separated from the inferior meatus of the nasal cavity by a membrane (Hasner's membrane) consisting of the apposed mucosa lining the nasal fossa and the lower end of the duct. Many newborns suffer from congenital obstruction of the lacrimal pathways. The rate of congenital membranous stenosis of the lacrimal excretory systems in newborns has been reported to be as high as 50%. Fortunately, there is a high rate of spontaneous relief of the epiphora within the first 9 months of life. The repair of a lacrimal duct obstruction should therefore only rarely be performed prior to this age.

Anatomy and Dimensions

The lacrimal passages consist of a bony passage and a membranous lacrimal passage. The bony passage is formed anteriorly by the frontal process of the maxilla and posteriorly by the lacrimal bone. The membranous part includes the lacrimal canaliculi, the lacrimal sac, and the nasolacrimal duct (**Figure 1**).

Each canaliculus starts with a 0.25 mm (upper) to 0.3 mm (lower) large, round, oval, or slit-like lacrimal punctum with a nearly 2-mm-long vertical part. Consequently, the lacrimal canaliculus nearly runs at a right angle into the horizontal part, which measures approximately 8 mm. In most cases (*c.* 65–70%), the two canaliculi join to form a common canal that penetrates the wall of the lacrimal sac regularly 2–3 mm below the apex of the sac, termed fornix or fundus sacci lacrimalis. The vertical diameter of the sac is close to 12 mm, the saggital 5–6 mm, and the transversal 4–5 mm. The nasolacrimal duct normally measures 12.4 mm in adults. The bony coat is nearly 10 mm long and has a diameter of 4.6 mm.

The upper and lower canaliculi are lined by pseudostratified/stratified columnar epithelium and surrounded by a dense ring of connective tissue as well as muscle fibers of the lacrimal portion of Horner's muscle (orbicularis oculi muscle and tensor tarsi muscle). The lacrimal sac and the nasolacrimal duct are lined with a double-layered epithelium, revealing a superficial columnar layer with microvilli and a deep flattened layer of basal cells. Both layers sometimes appear pseudostratified. Some cells of the nasolacrimal duct are lined by kinocilia (sincular kinocilium; a motile cilium on the apex of distinct cells, for example, cells covering the nasal cavity and nasal sinus). Besides epithelial cells, goblet cells are also integrated in the epithelium, sometimes forming intraepithelial mucous glands. Moreover, small seromucous glands are present in the lamina propria, especially in the fundus of the lacrimal sac.

Comparative Anatomy

Unlike the human and ape nasolacrimal systems composed of upper and lower canaliculi, the lacrimal sac, and the nasolacrimal duct, the lacrimal systems in dogs, rabbits, cats, deer, pigs, and rats consist solely of the upper and lower canaliculi, leading directly into the nasolacrimal duct. Human, ape, dog, rabbit, cat, deer, and pig tissues reveal a pseudostratified, columnar epithelium with double layering in most areas, a basal cell layer and a superficial columnar layer. The rat shows a multilayered epithelium. The upper cell layers consist of larger squamous elements over several layers of essentially cuboidal cells. Goblet cells are integrated in the epithelia of humans, rats, and cats as solitary cells and in human and rat epithelia as intraepithelial mucous glands. By contrast, the epithelia of apes, dogs, rabbits, deer, and pigs contain no goblet cells. However, ape, dog, rabbit, and pig epithelia do contain many epithelial cells that show mildly positive staining with alcian blue (pH 1.0) in the upper cytoplasm; from investigations in dogs, it is known that

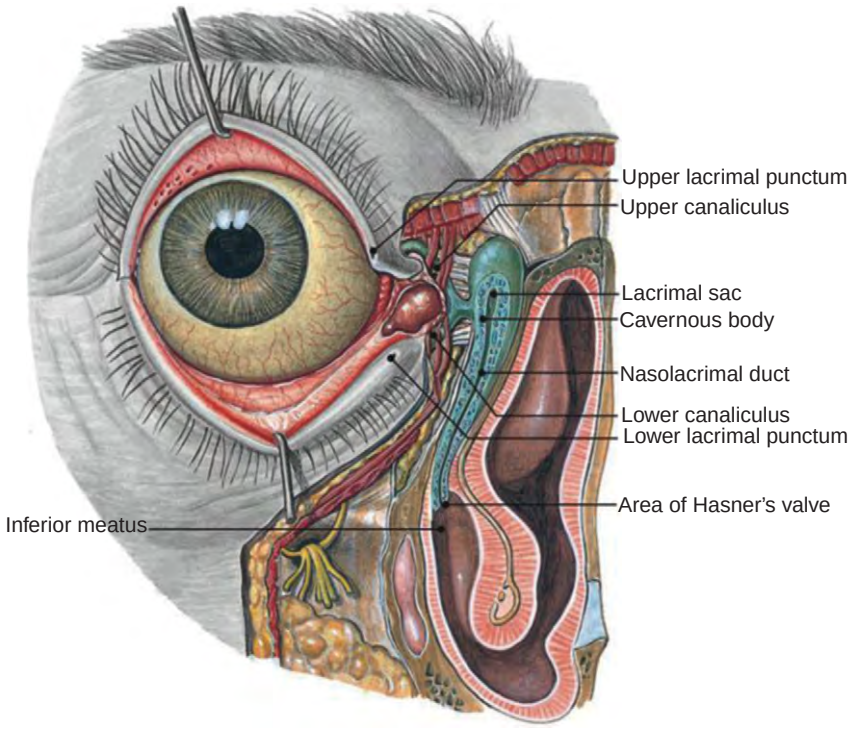

Figure 1 Nasolacrimal ducts. At the medial rim of the upper and lower lids, the lacrimal puncta open, leading into the lacrimal sac through the upper and lower canaliculi. The lacrimal sac is situated in the orbital lacrimal fossa and proceeds into the nasolacrimal duct. The nasolacrimal duct is surrounded by a bony canal created by the maxillary and lacrimal bones and opens into the inferior meatus of the nose. Both the lacrimal sac and nasolacrimal duct are surrounded by a vascular plexus comparable to a cavernous body that is connected to the cavernous system of the nose. From Putz / Pabst: Sobotta, Atlas der Anatomie des Menschen, 22. Auflage © 2006 Elsevier GmbH, Urban & Fischer Verlag München.

this positive staining corresponds to mucins (authors' observations). The cells with the mild staining are mostly arranged in cell groups. There are also epithelial areas without such cells or cell groups. Subepithelially, the lamina propria of the human lacrimal passage is composed of loose connective tissue containing elastic fibers and lymphatic cells and a rich venous plexus comparable to a cavernous body. A surrounding cavernous system of blood vessels is also found in apes, dogs, rabbits, deer, and pigs, but is absent in rats and cats. Small seromucous glands with excretory ducts opening into the lacrimal passage are integrated in the lamina propria of humans and pigs. None of the other animals possesses seromucous glands. Compared to humans, the efferent tear duct system of dogs and pigs is long. Therefore, the similarities between rabbit and human nasolacrimal ducts support the use of the rabbit for experimental studies of the efferent tear duct system.

Tear Transport through Canaliculi

The drainage of tears involves a number of different mechanisms that are not completely understood. It has been suggested that physical factors such as gravity, respiration, and evaporation might play a role in the drainage of tears through the lacrimal passage. Brienen and Snell postulated that the main, and presumably the sole, force that impels lacrimal flow from the conjunctival sac is the pressure brought about by closing of the eyes; in all probability, their expansions and contractions are secondary consequences of pressure fluctuations in the conjunctival sac. Jones introduced the concept of the lacrimal pump system which functions with blinking and might be responsible for lacrimal drainage by analyzing the structure of the medial palpebral ligament and the palpebral part of the orbicularis oculi muscle. It has also been shown that, during blinking movements, the canaliculi and medial canthal tendon are compressed and a uniform volume of lacrimal fluid is squirted into the lacrimal sac. The expansion of the lacrimal sac then causes suction during the opening phase of the blink, and, after the opening phase of the punctual areas, the canaliculi and lacrimal sac vacuum breaks to reload with tear fluid. The small canaliculi may also act as capillary tubes. Lacrimal fluid is attracted by capillarity into the lacrimal puncta, and, upon closing of the eyelids, the contraction of the preseptal muscle creates a negative pressure and sucks the tear fluid into the sac. The existence of negative pressure and the active transport of tears into the sac are, however,

questioned by many. Nevertheless, the importance of Horner's muscle becomes clear in cases of facial palsy. Tears are not pumped through the lacrimal system. Even with a Jones tube (a small tube allowing tears to drain into the nose) in place, there will be a decrease in tear flow if the orbicularis muscle function is insufficient. Support for the existence of a canalicular pump system on lid closure also came from experimental work carried out by others. Amrith et al. demonstrated that the puncta elevate and meet forcefully when the lids are half shut, and, on complete lid closure, the canaliculi and sac are compressed, forcing tears into the sac and nasolacrimal duct. The elastic expansion of the channels during lid opening and the drawing apart of the puncta break the vacuum, and the tear from the marginal strip is drawn into the puncta. Doane concluded that the force generated in the canaliculi during lid closure alone is sufficient to transport the non-reflex secretion, as it is less than 1 $\mu l\,min^{-1}$. If excess fluid is available, as in reflex tearing, it is possible that the sac may contribute to drawing the fluid. However, high-speed photographic and cinematographic techniques have not been useful in demonstrating what happens in the lacrimal sac during a blink. Even the role of gravity is not clear since Hurwitz concluded that gravity does play a significant role in the transport of tears.

Tear Transport through Lacrimal Sac and Nasolacrimal Duct

It is a popular misinterpretation that the tear fluid is drained into the inferior meatus of the nose by the contraction of musculature surrounding the lacrimal sac and/or nasolacrimal duct. Underneath the epithelium, the lamina propriae of the lacrimal sac and nasolacrimal duct consist of loose connective tissue containing a thin layer of elastic fibers and a rich venous plexus situated under this tissue that is connected caudally to the cavernous body of the nasal inferior turbinate. Collagen bundles as well as elastic and reticular fibers between the blood vessels of a rich venous plexus are arranged in a helical pattern and run spirally from the fornix of the lacrimal sac to the outlet of the nasolacrimal duct, where they contribute biomechanically to tear outflow during blinking. Specialized types of blood vessels are distinguishable inside the vascular tissue and are comparable to a cavernous body.

The blood vessels are specialized arteries (barrier arteries), venous lacunae (capacitance veins), veins (throttle veins), and arteriovenous anastomoses. They facilitate the opening and closure of the lumen of the lacrimal passage by swelling and shrinkage of the cavernous body. Swelling occurs when the barrier arteries (arteries with an additional muscular layer) are opened and the throttle veins (veins whose tunica media contains a muscle layer of helically arranged smooth muscle cells) are closed. Filling of the capacitance veins (widely convoluted venous lacunae) occurs at the same time as closure of the lumen of the lacrimal passage. By contrast, closure of the barrier arteries and opening of the throttle veins reduce the blood flow to the capacitance veins, simultaneously allowing blood outflow from these veins with resultant shrinkage of the cavernous body and dilatation of the lumen of the lacrimal passage. Arteriovenous anastomoses enable direct blood flow between arteries and venous lacunae; thus, the subepithelially located capillary network can be avoided and rapid filling of capacitance veins is possible when the shunts of the arteriovenous anastomoses are open. While regulating the blood flow, the specialized blood vessels permit opening and closing of the lumen of the lacrimal passage, effected by the bulging and subsiding of the cavernous body, and simultaneously regulate tear outflow.

The presence of the cavernous body is lacking in nearly all textbooks of anatomy and is therefore unknown to most nasolacrimal surgeons and radiologists. It is, however, densely innervated. Epiphora related to emotions such as sorrow or happiness occurs not only by increased tear secretion from the lacrimal gland and accessory lacrimal glands, but also by closure of the lacrimal passage. This mechanism acts, for example, to provide protection against foreign bodies that have entered the conjunctival sac: Not only is tear fluid production increased, but tear outflow is also interrupted by the swelling of the cavernous body to flush out the foreign body and protect the efferent tear ducts themselves. Moreover, it can be assumed that the valves in the lacrimal sac and nasolacrimal duct described in the past by Rosenmüller, Hanske, Aubaret, Béraud, Krause, and Taillefer could be caused by different swelling states of the cavernous body and must therefore be considered speculative.

In fact, the cavernous body of the efferent tear ducts plays an important role in the physiology of tear outflow regulation and can be influenced pharmacologically. Interestingly, administration of a decongestant drug or insertion of a foreign body at the ocular surface prolong the tear transit time significantly, but by different mechanisms (**Figure 2**). The application of a decongestant drug simultaneously with insertion of a foreign body shortens the tear transit time significantly compared to the effect of the decongestant drug alone, but there is no significant difference compared with application of a foreign body alone. The tear transit time is independent of side (right or left), gender, whether eyeglasses are worn, and whether the person is suffering from a common cold.

Tear outflow is further supported by the regional distribution of epithelial secretion products in the lacrimal sac and nasolacrimal duct (see the section titled 'Innate immune mechanisms'). These include membrane-bound and secretory mucins and trefoil factor family

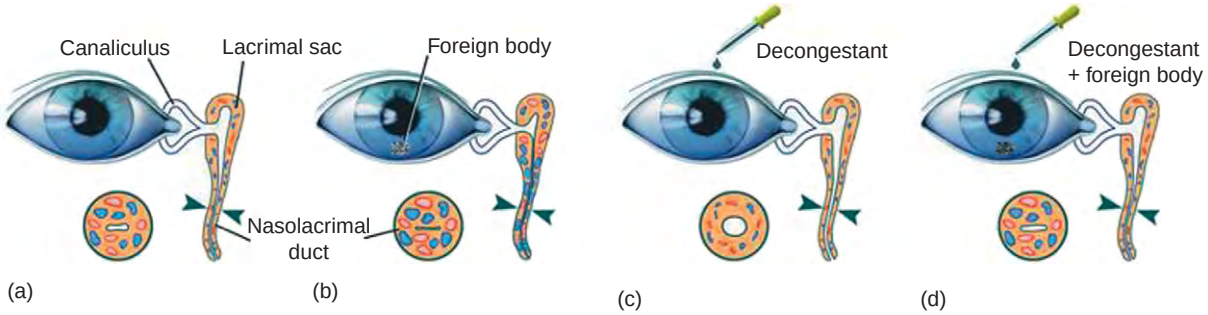

Figure 2 A Schematic/anatomical model of the state of the cavernous body and lacrimal passage in the (a) resting state and (b–d) under different experimental conditions, indicating the specific swelling and compression of the cavernous body and how it permits or restricts tear drainage. Reproduced from Paulsen, F. P., Schaudig, U., and Thale, A. B. (2003). Drainage of tears: Impact on the ocular surface and lacrimal system. *Ocular Surface* 1: 180–191.

(TFF) peptides and, as recently shown, surfactant proteins. The epithelial secretion products might influence the rheology and flow of tears through the efferent tear passages. There is speculation that at the ocular surface, mucin composition, distribution, and function are influenced by shear forces generated during blinking. Such forces are absent in the nasolacrimal ducts, and other mechanisms are necessary to ease the flow of tears. From the data available so far, it can only be said that mucins, TFF peptides, and surfactant proteins are likely to interact and may thus affect tear outflow. However, concrete data addressing this feature are lacking.

Table 2 Functions of the epithelia of the lacrimal sac and nasolacrimal duct

Secretion of antimicrobial substances (lysozyme, lactoferrin, secretory phospholipase A_2, bactericidal-permeability-increasing protein, heparin-binding protein, human β-defensins, and surfactant proteins A and D)
Secretion of mucins (MUC2, MUC5AC, MUC5B, MUC7, MUC8) and production of membrane-bound mucins (MUC1, MUC4, and MUC16)
Secretion of trefoil factor (TF) peptides (TFF1 and TFF3)
Secretion of surface active components (surfactant proteins B and C)
Production of lipids
Absorption of tear fluid components

Innate Immune Mechanisms

As is the case with all mucosae, the surfaces of the lacrimal sac and the nasolacrimal duct are in constant interaction with environmental microorganisms and are therefore vulnerable to infection. Similar to conjunctiva and cornea, the mucosa of the nasolacrimal ducts has developed a number of different nonspecific defense systems that can protect against dacryocystitis (**Table 2**); the epithelial cells thus produce a spectrum of different antimicrobial substances, such as lysozyme, lactoferrin, and secretory phospholipase A_2, as well as defensins, which protect against the physiological germ flora inside the lacrimal passage. When infectious and/or inflammatory dacryocystitis pose a threat, changes in the expression pattern occur, inducing the production of some of the antimicrobial substances, for example, antimicrobial peptides such as human inducible beta defensins 2 and 3, which are not produced under healthy conditions in the efferent tear ducts.

Besides supporting tear outflow, the product of the mucus component formed by goblet cells and epithelial cells has been attributed largely to immunological response. It contains mucins MUC1, MUC2, MUC4, MUC5AC, MUC5B, MUC7, MUC8, and MUC16 and probably additional mucins. Moreover, the epithelium of the nasolacrimal ducts expresses and produces – as already mentioned – the TFF peptides TFF1 and TFF3. Disturbances in the balance of single mucins or TFF peptides are important in the development of dacryostenosis, daryolithiasis, and daryocystitis. Mucins have several functions. In addition to lubricating the mucosa and waterproofing to regulate epithelial cell hydration, mucins protect mucosal surfaces against potentially harmful substances; however, a variety of oral and intestinal bacteria have been shown to produce sialidase, an enzyme that can degrade mucins by removing sialic acid. Additionally, oral and intestinal bacteria synthesize an array of other glycosidases that can attack the oligosaccharide residues of mucins. Early results of current investigations reveal that such glycosidases are also present at the ocular surface.

Finally, secretory immunoglobulin A (sIgA; the class of antibodies produced predominantly against ingested antigens, found in body secretions such as saliva, sweat, and tears, and functioning to prevent the attachment of viruses and bacteria to epithelial surfaces) is incorporated into the mucus layer of mucosal surfaces, supplementing the protective activity. It can interact with functionally diverse cells, including epithelial cells, B- and T-lymphocytes, natural killer (NK) cells, cells

of the monocyte/macrophage lineage, and neutrophils. All of these latter cell types, as well as sIgA, are present on and in the nasolacrimal ducts and belong to the lacrimal mucosal immune system (see below). This defense is supported by the collectins (surfactant-associated proteins) SP-A and SP-D in the service of nonspecific natural immune defense and in the activation of the adaptive immune system. As a substance intrinsic to drained tear fluid, they protect the ocular surface in conjunction with IgA, defensins, and mucins against infection by *Pseudomona aeruginosa*, *Staphylococcus aureus*, and other pathogenic microbes in preventing the formation of dacryocystitis.

Adaptive Immune Mechanisms

Subepithelially, lymphocytes and other defense cells are amply present inside the efferent tear ducts, sometimes aggregated into follicles. Aggregated follicles are present in nearly a third of nasolacrimal ducts from unselected cadavers with no known history of disease involving the eye, efferent tear ducts, or the nose. These aggregations and the surrounding tissue fulfill the criteria for designation as mucosa-associated lymphoid tissue (MALT). They consist of organized mucosal lymphoid tissue characterized by the presence of reactive germinal centers and mantle zones. Around the mantle zone, there is an additional zone of somewhat larger cells corresponding to marginal zone cells. These larger cells extend into the overlying epithelium, forming a lymphoepithelium.

In accordance with the terminology of MALT in other body regions, MALT of the human nasolacrimal ducts was termed TALT and, in conjunction with CALT of the conjunctiva, EALT for eye-associated lymphoid tissue. Current analysis of EALT, as well as different epithelial cells of the lacrimal passage, is interesting with regard to the induction of tolerance in the nasolacrimal system and at the ocular surface.

Specific secretory immunity depends on a sophisticated cooperation between the mucosal B-cell system and an epithelial glycoprotein called the secretory component. The initial stimulation of Ig-producing B-cells is believed to occur mainly in organized MALT. It has become evident that considerable regionalization or compartmentalization exists in MALT, perhaps determined by different cellular expression profiles of adhesion molecules and/or the local antigenic repertoire. The antigenic stimulation of B-cells results in the generation of predominantly IgA-synthesizing blasts (an immature stage in cellular development before the appearance of the definitive characteristics of plasma cells) that leave the mucosae through efferent lymphatics, pass through the associated lymph nodes into the thoracic duct, and enter the circulation. The cells then return selectively to the lamina propria (nasolacrimal ducts) as plasma cells or memory B-cells by means of homing mechanisms and contribute to mucosal sIgA.

Absorption of Tear Fluid Components

Recent animal experiments in rabbits have indicated that the components of tear fluid are absorbed in the nasolacrimal passage and transported into the surrounding cavernous body that is subject to autonomic control and regulates tear outflow. Under normal conditions, tear fluid components are constantly absorbed into the blood vessels of the surrounding cavernous body. These vessels are connected to the blood vessels of the outer eye and could act as a feedback signal for tear fluid production (**Figure 3**), which ceases if these tear components are not absorbed.

Conclusions

The human efferent tear ducts are part of the lacrimal system. They consist of the upper and the lower lacrimal canaliculi, the lacrimal sac, and the nasolacrimal duct. As a draining and secretory system, the nasolacrimal ducts play a decisive role in tear transport and nonspecific immune defense. In this context, an active lacrimal pump mechanism that functions by contraction of the orbicularis eye muscle has the major impact on tear transport from the ocular surface into the lacrimal sac. From here, tears are transported by a wringing-out mechanism governed by the helical arrangement of fibrillar structures within the vascular system surrounding the lacrimal sac and nasolacrimal duct, the action of epithelial secretion products such as mucins, TFF peptides, surfactant proteins as well as probably others, and physical factors such as capillarity, gravity, respiration, and evaporation.

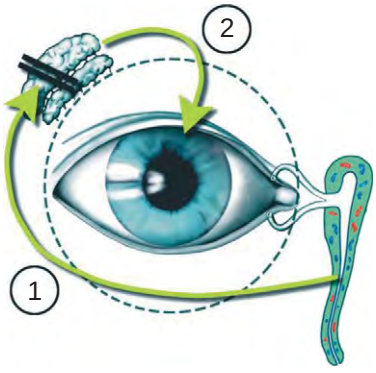

Figure 3 The normally constant absorption of tear fluid components into the blood vessels of the surrounding cavernous body of the nasolacrimal ducts and their transport to the lacrimal gland by blood vessel connections (1) could be a feedback signal for tear fluid production (2). Reproduced from Paulsen, F. P., Schaudig, U., and Thale, A. B. (2003). Drainage of tears: Impact on the ocular surface and lacrimal system. *Ocular Surface* 1: 180–191.

Moreover, components of the tear fluid are absorbed by the epithelium of the nasolacrimal passage and transported into the surrounding vascular system of the lacrimal sac and nasolacrimal duct. This system is comparable to a cavernous body that is subject to autonomic control and also regulates tear outflow from the sac into the inferior meatus of the nose. TALT is present in the efferent tear ducts, displaying the cytomorphological and immunophenotypic features of mucosa-associated tissue MALT.

Tear Film

J P Craig, University of Auckland, Auckland, New Zealand
A Tomlinson and L McCann, Glasgow Caledonian University, Glasgow, UK

Glossary

Fluorescein sodium – A topical agent used extensively as a diagnostic tool in ophthalmology to enhance tear film visibility or to highlight epithelial cell loss. The molecule is highly fluorescent, with excitation and emission occurring at 494 and 521 nm, respectively. Interference bandpass filters are commonly combined with the observation systems used in ophthalmology to optimize visualization of the fluorescence alone.
Lacrimal gland – The lacrimal gland is a compound tubuloalveolar gland, similar to the salivary gland, situated superotemporally in the orbit, which secretes aqueous tear fluid.
Lacrimal sac – The lacrimal sac forms part of the tear drainage system, collecting tear fluid from the ocular surface via the puncta and canaliculi. Blinking controls the pumping action of the lacrimal sac into the nasolacrimal duct for drainage into the nasal cavity.
Meibomian gland – Vertically oriented tubulo-acinar glands, embedded in the upper and lower tarsal plates, which release meibum (lipid).
Videokeratoscopy – A computerized, dynamic technique, based on the principle of keratoscopy, used traditionally to assess the shape of the anterior surface of the cornea (corneal topography) from the reflection of a series of projected concentric rings.

The tear film is a thin film of fluid, which covers the exposed ocular surface. Essential for the health and normal function of the eye and visual system, any abnormality in quantity or quality of the tear film can lead to signs and symptoms of dry eye disease and ultimately to a loss of vision.

The Role of the Tear Film

The tear film has a number of important functions, the first of which, as the most anterior element of the visual system, is maintenance of high-quality vision. Alterations in the stability of the tear film due to abnormal tear evaporation, production, and/or drainage can cause optical aberrations and adversely affect retinal image quality.

Secondly, the tear film plays an important role in ocular surface defence. Environmental challenges such as extremes of temperature or humidity, and exposure to irritants such as pollutants and allergens, can have a detrimental effect on the tear film. The tear film must be sufficiently robust to be able to withstand these challenges and be capable of responding rapidly with reflex tearing to help flush out irritants when required. External and adnexal infectious agents pose an additional risk to the exposed ocular surface. Antimicrobial components of the tear film, which include lysozyme, lactoferrin, and immunoglobulin A, help to protect the ocular surface from microbial infection.

Lubrication is another important tear film function. The non-Newtonian rheological properties of the tear film mucins enable the tear film to lubricate the corneal and mucosal surfaces. The normal blinking mechanism draws the tear film across the ocular surface, enhancing comfort and cushioning the ocular surfaces from the shearing forces present during the blink, while the mucins that trap and coat foreign particles in the tear film for removal at the caruncle, confer further epithelial surface protection.

Finally, the tear film plays a vital nutritive role in the transport of substances necessary for corneal metabolism and regeneration. Uniquely avascular for transparency, the cornea requires a nonvascular route for the supply of oxygen, electrolytes, growth factors, and nutrients to, and for the removal of metabolic by-products such as carbon dioxide from the ocular surface. While glucose diffuses primarily from, the aqueous humor, oxygen must be transported to the tissue through the tear film, either from the air in the open eye state or via the palpebral conjunctival vessels in the closed eye state.

Structure and Thickness of the Tear Film

Initial reports described the tear film as trilaminar in structure, consisting of a thin superficial lipid layer, an intermediate aqueous layer, and an underlying mucous layer. Each of these layers has the potential to be affected by different conditions resulting in qualitative and quantitative changes. Almost half a century later, it was proposed that interfaces existed between the layers, giving rise to a six-layer model, with an oily layer, a polar lipid monolayer, an absorbed mucoid layer, an aqueous layer, and a mucoid layer on a glycocalyx base. The carbohydrate-rich

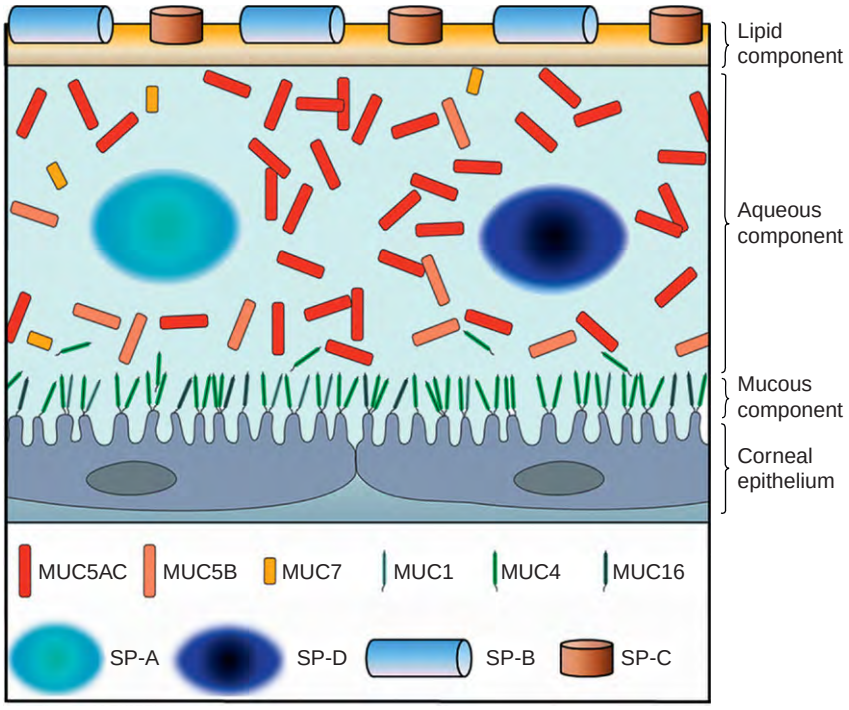

Figure 1 Diagrammatic representation of our current understanding of tear film structure. The tear film comprises a thin superficial lipid layer, and an aqueous-mucin continuum increasing in mucin concentration toward the glycocalyx, adjacent to the ocular surface epithelium. Adapted from Bräuer, L. and Paulsen, F. P. (2008). Tear film and ocular surface surfactants. *Journal of Epithelial Biology and Pharmacology* 1: 62–67, with permission.

glycocalyx, produced by the surface cells of the corneal epithelium and subsurface vesicles of the conjunctival epithelium, is believed to attach the tear film to the surface of the epithelial cells. The most recent studies do not differentiate this number of distinct layers, but instead suggest the existence of an aqueous-mucin continuum that contains a decreasing concentration of dissolved mucus toward the superficial lipid layer, and is anchored to the epithelium by glycocalyx (Figure 1).

The thickness of the precorneal tear film has proven to be a subject of great debate. Early estimates placed the thickness of the tear film in the region of between 4 and 8 μm. Later, on the basis of noninvasive techniques such as interferometry, it was proposed that due to a previously underestimated contribution from the mucous layer, the tear film thickness was closer to 40 μm in thickness. However, the most recent findings using techniques such as tomography and reflectance spectra propose values closer to the original measurements, suggesting that the tear film thickness is approximately 3 μm.

The Lipid Layer

The superficial lipid layer of the tear film forms the initial barrier between the ocular surface and the environment. This thin, oily layer approximates 100 nm in thickness, although values ranging between 10 and 600 nm have been reported. It is derived primarily from the meibomian glands, with additional lipid secreted by the eyelid glands of Moll and Zeiss. The lipids are excreted as meibum onto the ocular surface through the gland orifices located at the mucocutaneous junction of the lid margins.

Between blinks, the lipid layer forms in two distinct phases. An inner, thin, polar layer spreads as a monolayer across the aqueous in the initial phase after the blink, then a thicker, outer, nonpolar layer follows, creating a final lipid structure with multiple layers. The lipid layer must be spread evenly by the blink to form a continuous layer without excessively thin or thick patches in order to inhibit evaporation and to prevent accelerated tear breakup from mucin contamination, respectively.

Table 1 describes the proportions of the major lipid components of meibum. The polar layer consists of phospholipids, free fatty acids, and cerebrosides, while the less surface-active, nonpolar layer comprises mainly wax esters and sterol esters. The lipid layer confers a number of important protective functions including the formation of a hydrophobic barrier to prevent tear overflow onto the lids and to provide a water-tight seal during overnight lid closure, and the prevention of tear film contamination by skin lipids. However, arguably one of the most critical roles of the superficial lipid layer is to retard evaporation from the ocular surface. The polar lipids of the ocular tear film in the normal eye are capable of reducing its rate of evaporation by about 80–90%.

Tear Evaporation

Numerous investigators have measured evaporation of fluid from the tear film, since it was established that the lipid layer retarded evaporation in a rabbit model, in 1961. Later work, also in a rabbit model, passed dry air over a cornea enclosed within a chamber. From the weight of water collected, the evaporative rate was measured as 10.1×10^{-7} g cm^{-2} s^{-1}, and a fourfold increase in evaporation was found to occur with the removal of the rabbit tear film lipid layer. A similar increase in human tear film evaporation has since been confirmed in patients with incomplete or absent lipid layers (**Figure 2**).

The use of different techniques for measurement of tear film evaporation makes comparison of evaporation rates in different studies difficult because the absolute values recorded are technique-dependent. However, a pattern to the observations reported in the literature does exist, making evaporation rate a useful measurement in the differential diagnosis of dry eye. In most cases, significant increases from normal tear film evaporation are seen in patients with aqueous deficient dry eye (ADDE), evaporative dry eye (EDE), and meibomian gland dysfunction (MGD). The evaporation in normal eyes averages $13.57 \pm 6.52 \times 10^{-7}$ g cm^{-2} s^{-1}, while in ADDE the values average $17.91 \pm 10.49 \times 10^{-7}$ g cm^{-2} s^{-1}, and in EDE, $25.34 \pm 13.8 \times 10^{-7}$ g cm^{-2} s^{-1}.

Table 1 Major lipid components of meibum

Component	*Percentage (%)*
Synthesised lipids	
Wax esters	44
Sterol esters	33
Triglycerides	5
Diglycerides	2
Monoglycerides	Trace
Fatty alchohol	Trace
Hydrocarbons	2
Membrane-derived lipids

The Aqueous Layer

The aqueous component of the tear film is a watery phase, bordering the lipid layer and comprising most of the tear film thickness. It is produced principally by the main lacrimal gland and accessory lacrimal glands of Krause and Wolfring although additional water and electrolytes are secreted by the epithelial cells of the ocular surface. The typical or basal level of tear flow present is believed to originate mainly from the accessory glands while the reflex tears, produced in response to mechanical, noxious, or emotional stimuli, arise from the main lacrimal gland.

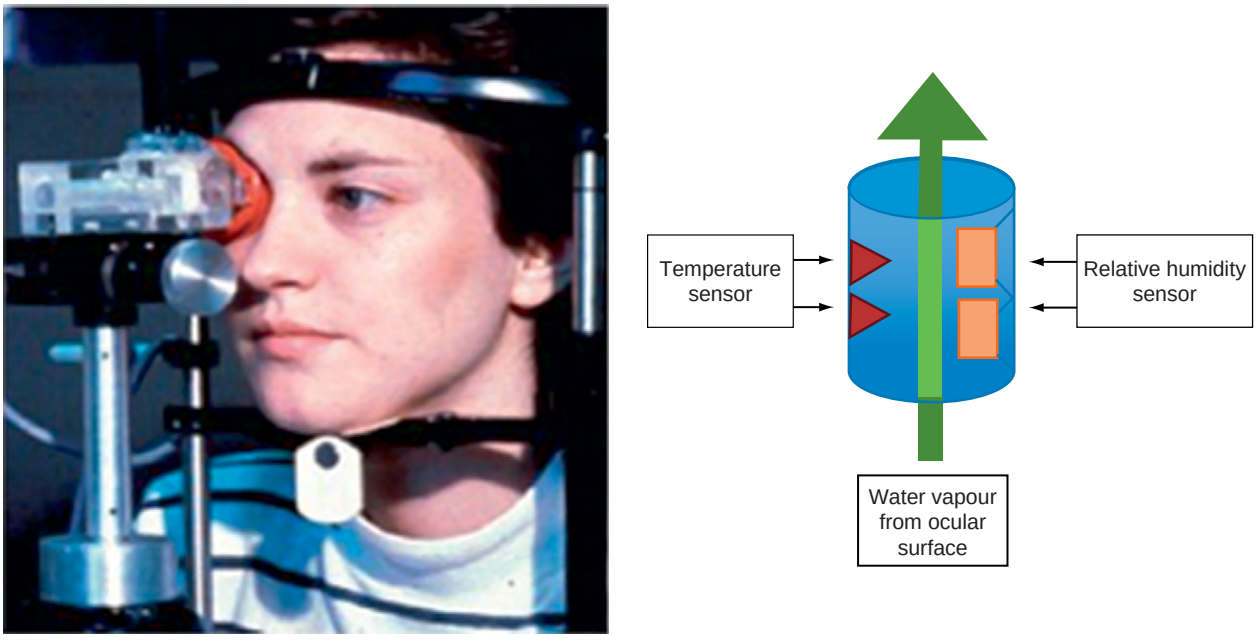

Figure 2 Tear film evaporation rate measured by a modified ServoMed EP-3 Evaporimeter (Kinna, Sweden). This technique involves the measurement of the vapor pressure gradient from recordings of relative humidity and temperature at two points a known distance above the ocular surface. Reprinted from *The Ocular Surface* (www.theocularsurface.com), with permission.

During sleep, tear production is minimal but in the normal eye, in the open eye state, sensory stimulation of the exposed ocular surface induces tear production at a rate that varies according to the demands of the external environment. The secretion of electrolytes, protein, and water onto the ocular surface serves to nourish and protect the epithelia and convey messages between the structures bathed in aqueous.

Corneal innervation is denser than that of any other part of the body, resulting in extreme pain if the corneal epithelium is damaged. Sensory nerve supply to the ocular surface arises from the trigeminal nerve. Stimulation of these nerve endings causes the release of neuropeptides such as substance P and calcitronin gene-related peptide (CGRP), which, through initiation of the inflammatory cascade, is believed to be an important step in the pathogenesis of many cases of dry eye.

The lacrimal and meibomian glands are innervated by parasympathetic efferent nerve fibers (muscarinic and vaso-intestinal peptide (VIP)-ergic fibers) and to some extent they, and the blood vessels supplying them, are sympathetically innervated through tyrosine hydroxylase (TH) and neuropeptide Y fibers. Parasympathetic efferent nerve terminals surrounding the goblet cells suggest that conjunctival secretions are also under neurogenic control.

The aqueous phase has a number of important responsibilities. These include creating a nurturing environment for the epithelial cells of the ocular surface, carrying essential nutrients and oxygen to the cornea, allowing cell movement over the ocular surface, and washing away epithelial debris, toxic elements, and foreign bodies. The major electrolytes present in the tear film are sodium, potassium, bicarbonate, and chloride, with magnesium, calcium, nitrate phosphate, and sulfate present in smaller quantities. The electrolytes dictate the osmolarity of tears, besides acting as a buffer to maintain pH and playing a role in maintaining epithelial integrity. An increase in the electrolyte concentration, described as hyperosmolarity, can cause damage to the ocular surface.

The tear film protein concentration is approximately 10% that of plasma. The proportion of lacrimal gland versus serum-derived proteins and enzymes varies with tear flow rate, epithelial surface stimulation, blinking, and ocular surface disease. The tear proteins are involved in defense of the ocular surface and the maintenance of tear film stability. Electrophoresis has confirmed the presence of approximately 80 different components of human tear proteins. Around 30 proteins have been identified, half of which are enzymes. The principal tear proteins are lysozyme, lactoferrin, albumin, tear-specific pre-albumin, and globulins. **Table 2** shows typical concentrations of the most significant tear proteins. The tear film also contains antioxidants such as vitamin C and tyrosine, which scavenge free radicals from within the tear film, while the abundance of growth factors facilitates constant epithelial regeneration and promotes wound healing.

Table 2 Average concentration of the principal tear proteins

Protein component	*Average concentration* ($mg\,ml^{-1}$)
Total protein	7.51
Lysozyme	2.36
Albumin	1.30
Tear specific prealbumin	1.23
Lactoferrin	1.84
Immunoglobulins (IgA, IgG, IgM, and IgE)	0.43

Alterations in tear composition or inflammatory changes within the conjunctival vascular endothelia can act as the stimulus to ocular surface inflammation in which both cellular and soluble mediators play a significant role. The numbers of T lymphocytes and the relative proportions of activated T cells are increased in dry eye. The ocular surface epithelial cells are directly involved in such ocular surface inflammation with the release of a number of pro-inflammatory cytokines such as interleukin (IL)-1α, IL-1β, IL6, IL8, transforming growth factor beta 1 (TGF-β1) and tumor necrosis factor alpha (TNFα), and increased expression of immune activation molecules such as CD54 and HLA-DR. Increased proteolytic enzyme levels and activity have been observed in dry eye with, in particular, high levels of matrix metalloproteinase 9 (MMP9), which are not present on the normal ocular surface. The inflammatory markers described as precipitating dry eye are also recognized to perpetuate ocular surface inflammation, triggering an escalating cycle of ocular irritation, inflammation, apoptosis, and tear film dysfunction and instability, epithelial cell disease, and disruption of corneal epithelial barrier function.

Tear Production

Traditional methods of measuring tear production rates are based on absorption of tears by Schirmer strips or cotton threads; however, both tests have been found to be poor quantifiers of tear production; the Schirmer test is marred by low specificity and sensitivity and the exact parameter measured with the cotton thread test has been questioned. As a result, a number of tests have been devised to measure the rate of disappearance of a dye marker placed in the tear film, as new tears are produced and the waste eliminated. In most studies in recent years, the rate of disappearance of instilled sodium fluorescein dye has been used to determine tear turnover (TTR) by the technique of fluorophotometry (**Figure 3**).

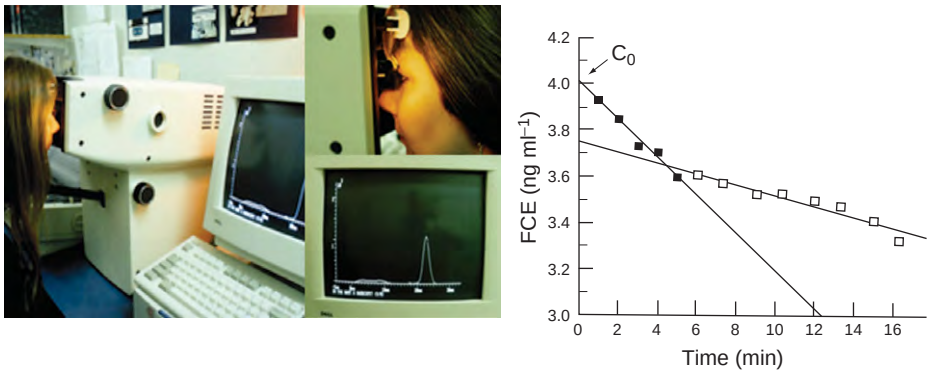

Figure 3 Commercial fluorophotometer (Fluorotron Master, Coherent Radiation Inc, CA, USA) shown with a typical trace of ocular surface fluorescence decay following instillation of fluorescein sodium into the eye. A biphasic curve of fluorescence is observed with initial rapid decay (due to reflex tearing) followed by a more gradual decay (due to basal tear turnover). Adapted from *The Ocular Surface* (www.theocularsurface.com), with permission.

The values reported for tear turnover (%min^{-1}) and tear flow (μl min^{-1}) in the major studies in the literature for normal and dry eye subjects of studies using the commercial fluorophotometer have recently been collated. The data reported for normals in the majority of studies ranges from 10% to 20% min^{-1}, which equates to an average basal tear flow rate of 1.03 ± 0.39 μl min^{-1} (16.19 ± 5.10% min^{-1}). For dry eye, in all its forms, it averages 0.58 ± 0.28 μl min^{-1} (9.36 ± 5.68% min^{-1}) and, within the dry eye subtypes, averages 0.40 ± 0.10 μl min^{-1} (7.71 ± 1.02% min^{-1}) and 0.71 ± 0.25 μl min^{-1} (11.95 ± 4.25% min^{-1}) for ADDE and for EDE, respectively. These are the rates of tear production under nonstimulated conditions in normal and dry eyes. However, the eye is capable of producing copious reflex tears under provocative conditions, providing the lacrimal gland has the ability to function at the required capacity. Reflex rates have been quoted as approximately 100-fold those under basal conditions.

The Mucin Layer

The innermost, mucin layer of the tear film lies adjacent to the hydrophobic epithelial cells of the ocular surface. The layer consists of soluble, gel-forming mucins, which are capable of retaining large quantities of water, and corneal and conjunctival epithelial mucins (principally MUC1, 2, 4, and 16), which form the glycocalyx. The glycocalyx functions, through the membrane-spanning domain of MUC1, to anchor the soluble mucin layer to the plasma membrane of the corneal and conjunctival epithelial cells, while the soluble mucins interact with these transmembrane mucins and with the overlying aqueous layer, to form a water-retaining gel. The most significant soluble mucin for the ocular surface is MUC5AC, secreted by the goblet cells of the conjunctiva.

The high-molecular-weight glycoproteins, with additional proteins, electrolytes, and cellular material that contribute to the mucous layer, enable fulfilment of several important functions in the maintenance of a healthy ocular surface. In addition to providing a hydrophilic surface upon which to support a stable aqueous layer, the mucous layer offers protection against the shear force of blinking and environmental insult, and facilitates maintenance of a smooth ocular surface for optical clarity. The constituents are also believed to protect the ocular surface by inhibiting inflammatory cell adhesion.

Tear Distribution and Stability

The distribution of tear fluid on the ocular surface is highly dependent on the blink. Lid closure during a blink progresses from the temporal to the nasal side of the eye spreading tears across the ocular surface and facilitating tear drainage through the lacrimal puncta. The inter-blink period in normal individuals averages 4.0 ± 2.0 s and is significantly decreased in patients with dry eye (to 1.5 ± 0.9 s); a high blink rate in dry eye patients maximizes the tear supply to the ocular surface. In detailed reading tasks, requiring concentration, the blink rate drops to about a half (from 22.4 ± 8.9 to 10.5 ± 6.5 min^{-1}).

In the clinical setting, tear film stability has traditionally been measured following the instillation of fluorescein sodium solution into the tear film, to improve visualization of the film. Tear breakup time has been defined as the time taken for the tear film to form a dark spot or streak, following a blink. However, subsequent awareness of the disruptive effect of fluorescein instillation on the tear film has encouraged use of noninvasive techniques where tear film stability is determined by observing mires reflected from the tear film surface, for signs of disruption or distortion following a blink. A tear breakup time of greater than 10 s is considered normal while values less than 5 s are suggestive of dry eye. Values between 5 and 10 s are

generally considered to correspond to borderline dry eye, although it should be noted that this reported range was originally established for Caucasian eyes, and Asian eyes may exhibit significantly shorter tear film stabilities. In noninvasive techniques, without instillation of fluorescein, the reported cut-off values are longer with mean values around double those of the traditional fluorescein breakup test.

The distribution of the tear film can further be observed *in vivo* using thin film interferometry. Interference fringes are produced by light reflected at the air-lipid and at the lipid-aqueous boundaries of the tear film due to the changes in refractive index. Specular reflection from the lipid layer precludes a clear view of the aqueous layer of the precorneal tear film although where the lipid layer is very thin or absent, aqueous fringes may be observed.

Based on this optical principle, a number of clinical instruments, together with qualitative grading systems have been developed. These are useful for observing the structure of the tear film and offer some insight into its stability. Significant differences in appearance (and grade) have been observed in dry eye conditions, with the partial or complete absence of the lipid layer being a feature. Recent work in this field has concentrated on developing quantitative analyses of interferometric images from the tear film of normal and dry eye patients (**Figures 4** and **5**, respectively). With the use of kinetic analysis of sequential interference images, it has been possible to quantify the lipid-spread time of tears in normal and dry eye patients. This spread time, defined as the time taken for the lipid film to reach a stable interference image, is significantly slower in ADDE, at 2.17 $\pm$ 1.09 s, than it is in normal eyes (0.36 $\pm$ 0.22 s). Because of this slower spread time, the resultant lipid film has been found to be thicker on the inferior cornea than the superior cornea, with the thickness being measured from a color reference chart created from the reflectance images of thin film interference generated by a white light source. Almost 90% of the patients with aqueous tear deficiency exhibit an interferometric pattern with vertical streaking, rather than the horizontal propagation typically observed in the superior corneal region.

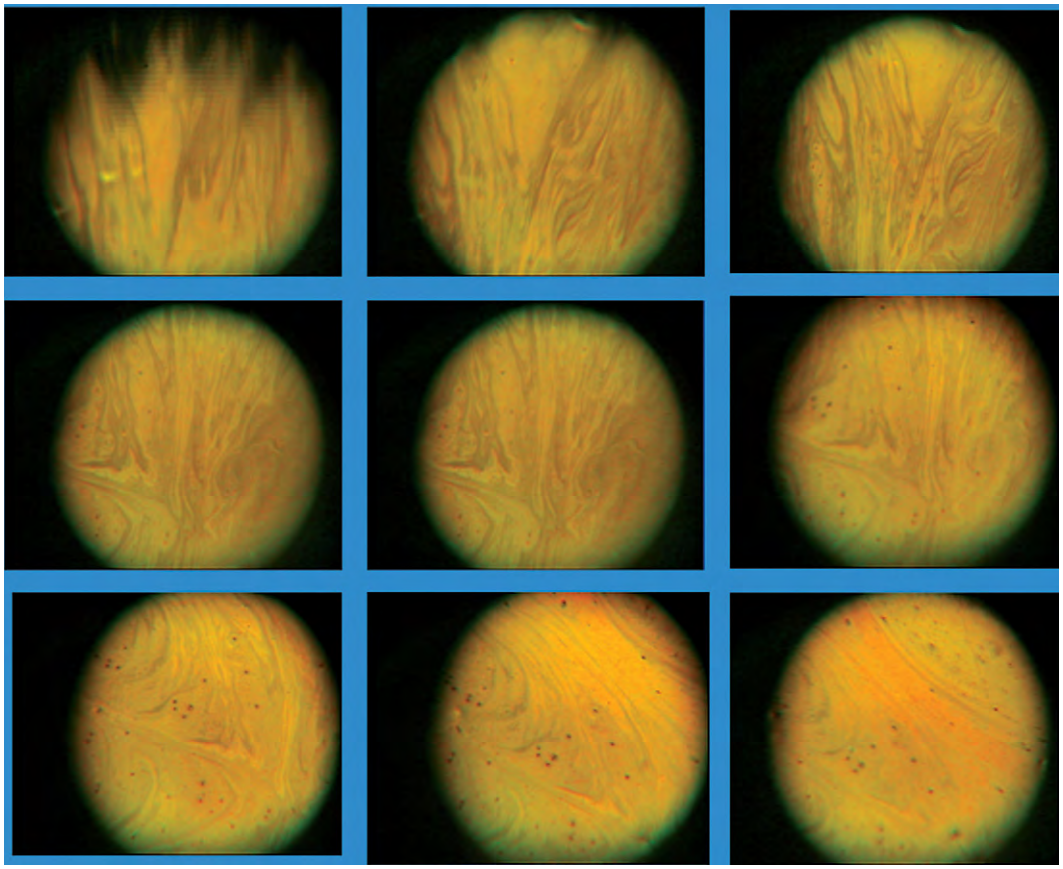

Figure 4 Series of images obtained by dynamic thin film interferometry in a normal, asymptomatic subject. The images are obtained at 1 s intervals, following a blink. The lipid layer of the normal tear film reaches a relatively stable pattern within the first second after the blink. This pattern is then stable for about 6 s. Reprinted from *The Ocular Surface* (www.theocularsurface.com), with permission.

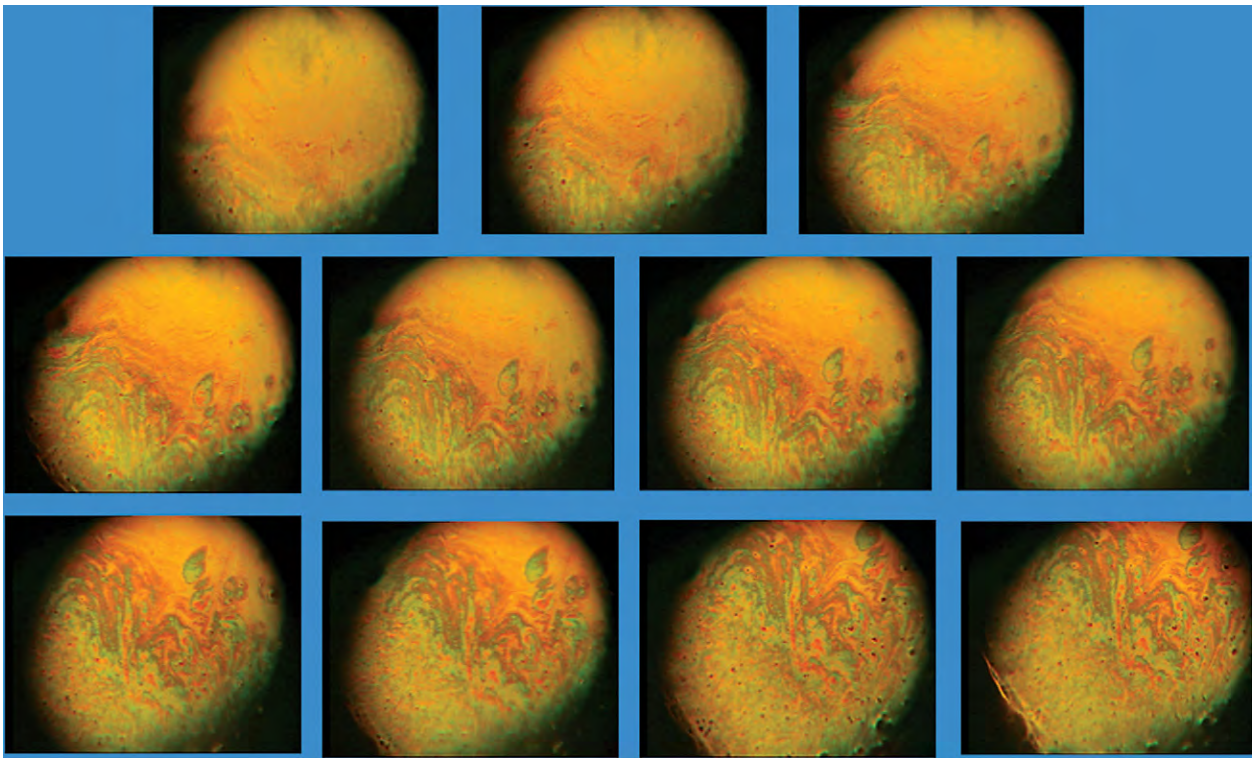

Figure 5 Series of thin film interferometry images obtained from a patient with severe dry eye. The patient had primary Sjögren's syndrome with a tear turnover rate of 4% min^{-1}, evaporation of 25.5 g cm^{-2} s^{-1}, volume of 3.9 μl and osmolarity of 337.6 mOsm ml^{-1}. The images are obtained at 1 s intervals following a blink. The lipid layer of the tear film is incomplete and variable in thickness, exhibiting color fringe patterns. A stable pattern is reached in 2–3 s after the blink, but this pattern begins to be disrupted within the next 3 s. Reprinted from *The Ocular Surface* (www.theocularsurface.com), with permission.

Evaluation of tear film particle movement can also provide an indication of the time necessary to obtain stability of the tear film after the blink. The observed particles are thought to be accumulations of newly secreted lipid from the meibomian glands. Measuring the displacement of these tear film particles immediately after a blink has shown that the time necessary to reach zero velocity (tear stabilization time) is 1.05 ± 0.3 s.

A commercial thin film interferometer has been developed, which enables the specular reflection from the tear surface to be monitored digitally and the tear film interference patterns classified. Research with this apparatus has shown that thicker lipid layers are associated with greater tear film stability. A number of grading systems have been developed mostly assessing the uniformity of the interference fringe pattern. A change in color and loss of uniformity in distribution indicates tear film instability. Such patterns are found more commonly in dry eyes in association with thin lipid layers and reduced stability.

Assessment of the reflected images from the cornea and tear film has been used to evaluate tear film quality and stabilization following the blink. High-speed videokeratoscopy assesses the regularity indices, such as surface regularity index (SRI) and surface asymmetry index (SAI), in the time interval following a blink. These indices have been found to correlate significantly with the results of standard diagnostic tests for dry eye, such as symptoms, tear breakup time, Schirmer test, fluorescein staining score, and best corrected visual acuity.

Tear Film Osmolarity

Adequate production, retention, distribution, and balanced elimination of tears are necessary for ocular surface health and normal function. Any imbalance of these components can lead to the condition of dry eye. A single biophysical measurement that captures the balance of inputs and outputs from the tear film dynamics is tear osmolarity, the end-product of variations in tear dynamics. Normal homeostasis requires regulated tear flow, the primary driver of which is osmolarity. Hyperosmolarity is thus an important biomarker for dry eye disease.

Tear hyperosmolarity has been found to be the primary cause of discomfort, ocular surface damage, and inflammation in dry eye. In studies of rabbit eyes, tear osmolarity has been found to be a function of tear flow rate and evaporation. In rabbit conjunctival cell cultures, hyperosmolarity has been demonstrated to decrease the density of goblet cells and, in humans, a 17% decrease in

goblet cells density for subjects with dry eye has been reported. Granulocyte survival is significantly decreased with increases in solute concentration. Rabbit cells cultured in hyperosmolar states, above 330 mOs ml^{-1}, show significant morphological changes, similar to those seen in subjects with dry eye. Hyperosmolarity-induced changes in surface cells in dry eye can be correlated with the degree and distribution of rose bengal staining.

Measuring tear osmolarity is of benefit in the diagnosis of conditions such as dry eye. In a meta-analysis of human tear osmolarity values recorded in studies between 1978 and 2004 with freezing point depression (FPD) and vapor pressure (VP) osmolarity tests, normal values averaged 302.0 $\pm$ 9.7 compared with 326.9 $\pm$ 22.1 mOs ml^{-1} for patients with dry eye disease.

Drainage of Tears

A principal means of elimination of tears from the eye is by drainage through the puncta of the eye. Tears then pass through the canaliculi, the lacrimal sac, and finally the nasolacrimal duct before reaching the nose. A technique for measuring tear turnover, which allows direct observation of tear drainage, involves instilling a radioactive dye into the tear film. In the technique of lacrimal scintigraphy a small quantity (0.013 mls) radioactive tracer such as technetium 99 (99M Tc), is introduced into the lower marginal tear strip. The distribution of the tracer is imaged serially by a gamma camera as it passes down the lacrimal drainage system (**Figure 6 a–c**). Images are typically taken at 10-s intervals for 1 min and then at less frequent intervals until all of the tracer has drained into the nasal cavity. The technique has been used to quantify tear turnover from the eye and drainage through the lacrimal system. The drainage through this system is not linear, as a significant number of naso-lacrimal folds and ducts offer physiological obstruction to normal tear flow, and variable tear flow has been shown to be a typical feature of the drainage facility in asymptomatic individuals (**Figure 6(d)** and **(e)**). Therefore, most models of lacrimal drainage favor compartmental analysis to evaluate tear flow through the system, with separate components for the conjunctival sac, lacrimal sac, the nasolacrimal duct, and the nasal cavity. Although most quantitative lacrimal scintigraphy measurements describe the transit time of the radioactive tracer through the system, the compartmental model has be used to estimate tear flow rates. Depending on the number of compartments considered, basal flow rates have been estimated to fall between 0.45 and 8 µl min^{-1}. Using a single compartment model for decay of the radioactive tracer on the conjunctival surface, mean values of reflex and basal turnover of 3.33 $\pm$ 1.95 µl min^{-1} and 0.56 $\pm$ 0.32 µl min^{-1}, respectively, have been recorded by gamma scintigraphy.

The mechanism of lacrimal drainage and the influence of blinking on the mechanics of the system have been observed by high-speed photography and by intracanalicular pressure measurements. Taking an anatomical approach and observing the lacrimal systems of human cadavers has shown that the surrounding vascular plexus of the lacrimal sac and the nasolacrimal duct is comparable to a cavernous body. While regulating the blood flow, the specialized blood vessels of this body permit opening and closing of the lumen of the lacrimal passage, which is effected by the bulging and subsiding of the cavernous body, thereby regulating tear outflow from the eye. Attempts have been made to quantify the regulation of tear outflow by measurement of the transit time of a fluorescein drop from the conjunctival sac into the inferior meatus

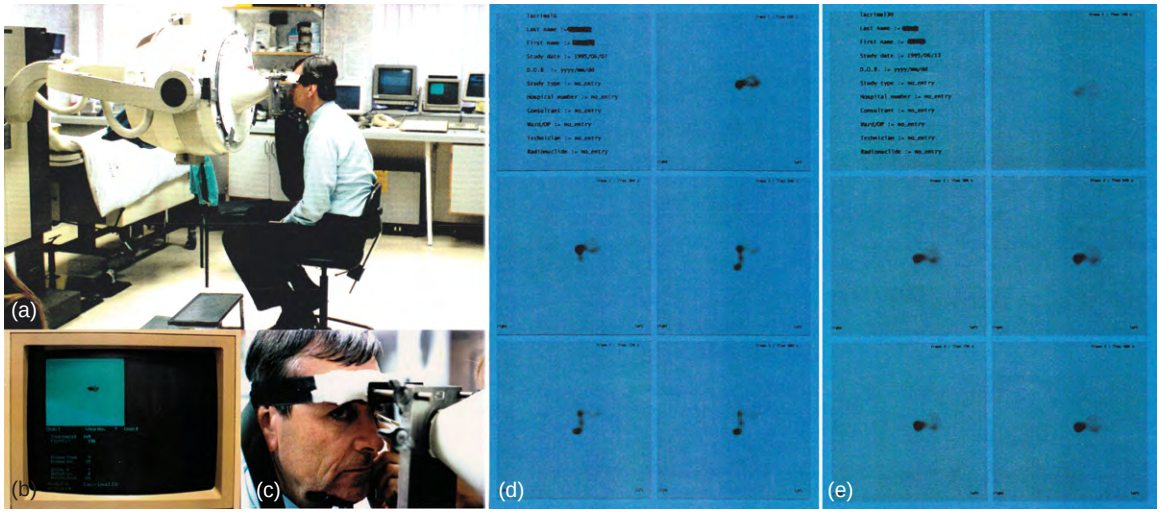

Figure 6 Gamma camera (a–c) used in the recording of intensity of a radioactive dye at various stages as it passes through the lacrimal system (d). In many cases of normal systems, the tracer does not proceed beyond the lacrimal sac (e). Reprinted from *The Ocular Surface* (www.theocularsurface.com), with permission.

of the nose. Application of a decongestant drug or placement of a foreign body on the ocular surface have both been found to significantly prolong the dye transit time, indicated restricted drainage through the lacrimal system in these conditions. It has therefore been concluded that the cavernous body of the lacrimal sac and naso-lacrimal duct plays an important role in the physiology of tear outflow regulation; it is subject to autonomic control and is integrated into a complex neural reflex feedback mechanism between the blood vessels, the cavernous body, and the ocular surface.

Absorption of Tears by the Ocular Surface

Another method by which tears can be eliminated from the eye is by absorption into the tissues of the ocular surface and the drainage system. The possibility has been suggested that the epithelial lining of the drainage system absorbs tear fluid before it reaches the nose. It has been shown in an animal model that lipophilic substances are absorbed from the tear fluid by the epithelium of the naso-lacrimal duct and that the cavernous body surrounding this duct may play a role in drainage of absorbed fluid. No quantification of fluid volume eliminated by this route has been reported. However, tears absorbed in the blood vessels of the cavernous body may, because these vessels connect to the blood vessels of the outer eye, have a role in a biofeedback mechanism for tear production.

Observations of the absorption of tear film onto the anterior ocular surface have been made in studies of corneal permeability. The proportion absorbed, in the absence of compromised corneal function, appears to be small at $0.24 \pm 0.13\%$ of the dye instilled in the eye.

The lacrimal system of the human eye is, in the vast majority of individuals, a robust system, which allows the ocular surface to maintain its health and normal function throughout life, and under modest provocation. It is only in a relatively small proportion ($\sim$15%) that the imbalance between evaporative loss and tear production results in dry eye. Recent research has confirmed that an increase in this ratio of approximately 2–3 times, as most often occurs in older individuals, appears to lead the condition of dry eye.

The tears covering the anterior ocular surface, form a dynamic structure with a complex nature and a number of important functions. The tear film components are interdependent and have a close relationship with those of the adjacent ocular tissues such that failure of any one of aspect of the tear film or lacrimal system can cause imbalance and result in dry eye.

Tear Film Overview

M Uchino and K Tsubota, Keio University School of Medicine, Tokyo, Japan

Glossary

Aqueous layer of the tear film – The middle watery phase of the tear film, approximately 6.5–7.5-μm thick.
Functional visual acuity – Sharpness of vision.
Higher order aberration (HOAs) – A distortion acquired by a wave front of light when it passes through an eye with irregularities of its refractive components.
Tear film – Fluid covering the ocular surface. The tear film is composed of mucin/aqueous gel next to the ocular surface that decreases in density toward the lipid layer, the outermost layer.
Tear-film break-up time (TFBUT) – A test to determine tear-film stability. In this test, the time taken for the first black spot to appear in the fluorescently labeled tear film is measured.
Tear lipids – Lipids secreted by the meibomian glands which comprise the outermost layer of the tear film.
Tear mucins – Proteins of a high molecular weight due to the presence of a large number of carbohydrate moieties covalently attached to the protein core. Mucins in the tear film provide lubrication to the ocular surface, allowing the eyelid margins and palpebral conjunctiva to slide smoothly.
Tear proteins – Proteins present in the tear film, mainly in the aqueous layer. Over 60 different proteins have been identified in human tears.
Tear-stability analysis – A test that measures the tear stability of the tear film as a function of serial surface regularity and asymmetry.
Visual maintenance ratio (VMR) – The percentage of time that a patient is able to maintain the best visual acuity over the entire time of the test.

The Structure and Function of the Tear Film

The tear film has been traditionally suggested to have a unique three-layer structure that enables it to perform many functions. These layers include an outer lipid layer, a middle aqueous layer, and an inner mucous layer. There is also a mucin-containing glycocalyx interface that extends from the apical membranes of the corneal and conjunctival epithelia which acts as an integral part of the tear film. However, several types of measurements question the existence of a free-fluid layer beneath the lipid layer. The currently proposed tear-film structure is that of a mucin/aqueous gel decreasing in density toward the lipid layer (**Figure 1**).

The major functions of the tear film are:

1. to maintain a smooth surface for light refraction as the tears form the first refractive surface encountered by light on its path to the retina. For clear vision, it is critical to maintain the transparency of the second refractive surface that rays of light encounter, that is, the cornea.
2. to lubricate of the eyelids, conjunctiva, and the cornea by providing a smooth surface, thus avoiding ocular surface mechanical damage from the surprisingly high pressures generated by each blink.
3. to supply the cornea with nutrients by transporting oxygen and a limited number of other nutrients to the avascular cornea, and regulation of the electrolyte composition and pH.
4. to provide white blood cells with access to the cornea and conjunctiva.
5. to remove foreign materials from the cornea and conjunctiva. The tear film protects the ocular surface from the external environment by responding dynamically to a wide range of external conditions and potentially damaging situations. These external stresses include desiccation, bright light, cold, mechanical stimulation, physical injury, noxious chemicals, and bacterial, viral, and parasitic infections.
6. to defend the ocular surface from the pathogens via specific and nonspecific antibacterial substances.
7. to protect the ocular surface from free-radical insults with antioxidants such as ascorbic acid, lactoferrin, uric acid, and cysteine. An increase in oxidative stress markers and changes in antioxidant-related gene expression can chronically distort the regenerative capacity of the corneal epithelial cells in dry eye conditions. This suggests a strong relationship between the accumulations of oxidative stress and the etiology of corneal epithelia alterations in the blink-suppressed dry eye.

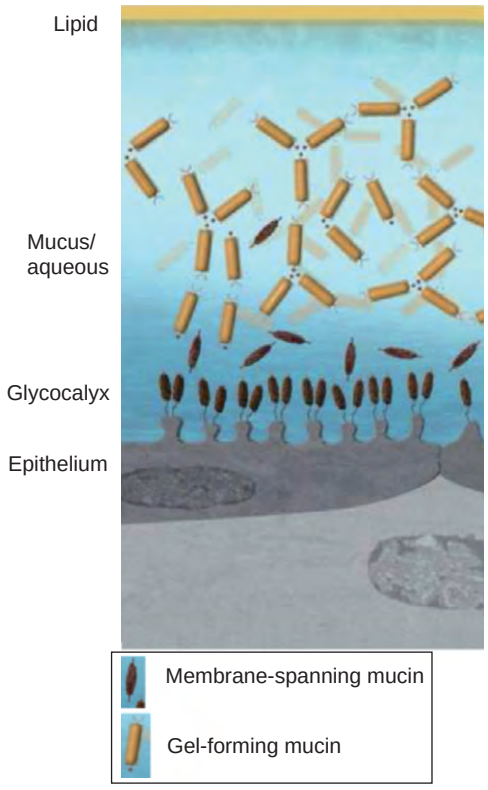

Figure 1 The structure of tear film.

The Function and Structure of the Lipid Layer of Tear Film

Lipids secreted from the meibomian glands are an essential component of the tear film, providing a smooth optical surface for the cornea and retarding evaporation from the eye. The meibomian lipids stabilize the tear film by lowering its free energy, carrying water into the tear film during its formation and interacting with lipid-binding proteins.

Meibomian glands secrete a complex fluid containing hydrocarbons, wax esters, triglycerides, diesters, free sterols, sterol esters, free fatty acids, and polar lipids. The polar lipids interact with the aqueous phase of the tear film and spread in advance of the nonpolar lipids.

The complexity of meibomian gland fluid reflects the products from the disintegrating cells as well as from the synthesized lipids. Meibomian gland lipids differ from cellular lipids in the acyl-chain and sterol types. The major classes of lipids are the wax monoesters and sterol esters that make up about 77% of the meibomian gland fluid. Other synthesized lipids are di- and triglycerides. A third type of lipid is the diesters that form ester linkages with fatty acids, fatty alcohols, or sterols. These diester compounds make up about 8% of the fluid. A new model of the structure of the lipid layer is described elsewhere in this encyclopedia.

The Relationship Between Tear-Film Lipids and Refraction

A stable tear film over the corneal surface is essential for achieving an optically smooth surface. The unstable and irregular tear film is disrupted over the irregular ocular surface in dry eye and is associated with poor quality of vision. Even a small change in tear-film stability and volume will significantly change the quality of vision (primarily contrast sensitivity). Functional visual acuity (FVA) measurements have shown impaired FVA in patients with dry eye during gazing. Moreover, investigators in several studies who measured continuous corneal topographic data or corneal and ocular wave front aberrations in the normal and dry eyes have reported that the dynamic changes in tear film affect the optical quality after blinking, with decreased optical quality in eyes of patients with dry eye. Recent studies have shown that corneal higher order aberrations (HOAs; a distortion acquired by a wave front of light when it passes through an eye with irregularities of its refractive components) after blinking tend to increase with dry eye, and both ocular and corneal HOAs are significantly greater than those in normal eyes.

The Structure and Function of Aqueous Layer of the Tear Film

The major, intermediate watery phase of the tear film is approximately 6.5–7.5-μm thick and contains dissolved ions and proteins. The aqueous phase originates from the main lacrimal gland and the accessory glands of Wolfring and Krause.

The electrolytes present in the tear film are responsible for the osmolality of the tears. These essential ions play an important role in maintaining epithelial integrity. Proteins present in the tears also serve many functions. These include a generalized wetting action by lowering the surface tension, and allowing the tear film to spread over and wet the corneal and conjunctival surfaces more effectively. Other important functions include metal transport, control of infectious agents, osmotic regulation, and buffering against pH changes that would affect ionic equilibrium and enzymatic activity.

More than 60 different protein components of the human tear have been identified. The major tear proteins from the lacrimal gland are lysozyme, lactoferrin, tear lipocalin, lacritin, secretory immunoglobulin A (IgA), and serum proteins such as albumin, transferrin, IgG, and IgM.

The relative proportions of the proteins present in an individual tear sample depend on the method of tear collection. Invasive methods, including filter paper

and cellulose sponges, stimulate the conjunctiva, induce serum leakage, and result in a higher proportion of plasma proteins. Samples collected by less invasive means, such as fine capillary tubes dipped into the tear meniscus, demonstrate a higher proportion of lacrimal gland proteins. Around 20–40% of total tear protein is made up of lysozyme, the most alkaline protein in tears. It has the ability to dissolve bacterial walls by enzymatic digestion of tissue mucopolysaccharides. Patients with Sjögren's syndrome have been reported to have decreased lysozyme production. Tear lipocalin is an acidic protein abundant in tears. The lipocalins, complexed with other tear components, may also contribute to the high, non-Newtonian viscosity of the tear film and its low surface tension – features which are essential for tear-film stability. IgA is the most abundant immunoglobulin of the tears and is normally attached to an antigenic fragment, secretory component. This has been proposed as the first line of the host defense mechanism by furnishing the conjunctiva with an immunologic coating.

The Structure and Function of Mucous Layer of the Tear Film

Ocular mucins provide lubrication to the ocular surface, allowing the eyelid margins and the palpebral conjunctiva to slide smoothly over one another with minimal friction during blinking and ocular rotational movements. Another important function is protection of the epithelial surfaces by covering foreign bodies with a slippery coating, thus protecting the cornea and conjunctiva.

The last 10 years have seen remarkable progress in understanding the structure and character of mucins which are heavily glycosylated glycoproteins with 50–80% of their mass comprised of carbohydrates. Molecular cloning and sequencing of genes encoding mucin apoproteins have extended the definition of glycoproteins from, "mucins are large molecules that have as their major mass carbohydrate" to include the fact that they have tandem repeats of amino acids rich in serine and threonine in their protein backbone that serve as sites for *O*-glycosylation.

Mucins have been given number designation in order of their molecular characterization. To date, although 20 numbers have been assigned, cloning has shown that several mucins are in fact the result of different gene products. For example, MUC3 and MUC5 have now been redesignated to include MUC3A, MUC3B and MUC5AC, and MUC5B.

Mucins can be either secreted or associated with the cell surface. The membrane-associated mucins form the scaffold for the mucous layer. The secreted mucins can either be small soluble mucins or large gel-forming mucins. They are stored in secretory granules in the condensed form and secreted with the appropriate stimulus. Soluble mucins are smaller in molecular weight than the gel-forming mucins, but are stored and secreted similarly to them.

Multiple mucins have been identified in tears and localized to corneal or conjunctival epithelial cells. The gel-forming mucin MUC5AC is secreted solely by the goblet cells. The membrane-bound mucins MUC1, MUC4, and MUC16 are produced in the stratified squamous cells of both the cornea and conjunctiva. In addition, the cornea and conjunctival epithelia also produce MUC2 and MUC7, and other membrane-bound mucins.

Methods to Evaluate the Ocular Surface Health and Tear Functions

Several methods have been developed to assess the health of the ocular surface epithelial cells. These include the use of vital stains and impression cytology.

Fluorescein Staining

Fluorescein staining indicates increased epithelial permeability of the cornea or conjunctiva by staining devitalized areas of the ocular surface. A minimal amount of dry fluorescein (1 μl of 1% fluorescein) is applied with a sterile disposable applicator using a micropipette, or by using a fluorescein-impregnated strip. The strip is wet with a drop of sterile preservative-free solution, the excess is shaken off, and the strip is touched to the lower fornix. The ocular surface is visualized using a yellow barrier-filter with the cobalt blue light of the slit lamp.

Rose Bengal/Lissamine Green Staining

Rose Bengal stains dead or degenerating conjunctival cells, corneal epithelial filaments, or areas not covered by mucins with a dark pink color. It is toxic to the epithelium and causes irritation on instillation even in small amounts. One microliter of 1% Rose Bengal is applied with a sterile disposable applicator. Lissamine green is similar to Rose Bengal in that it is seen best over the sclera and least over the dark iris, but it is less toxic and is better tolerated.

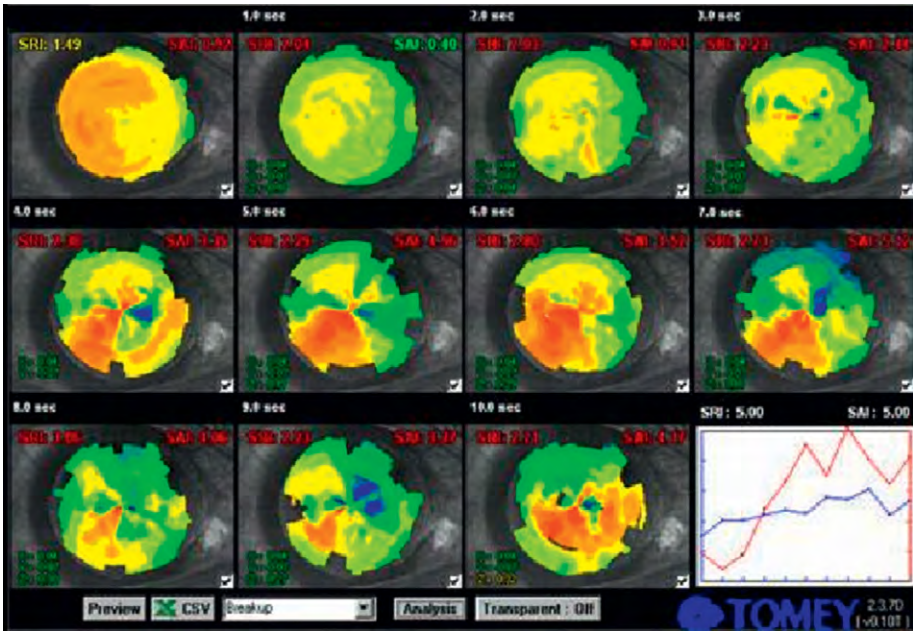
Impression Cytology

Impression cytology is a simple diagnostic method where a cellulose filter paper is placed onto the ocular surface epithelium following anesthesia and then removed. The superficial layer can be easily removed from the deeper epithelium layers by impression cytology, which allows

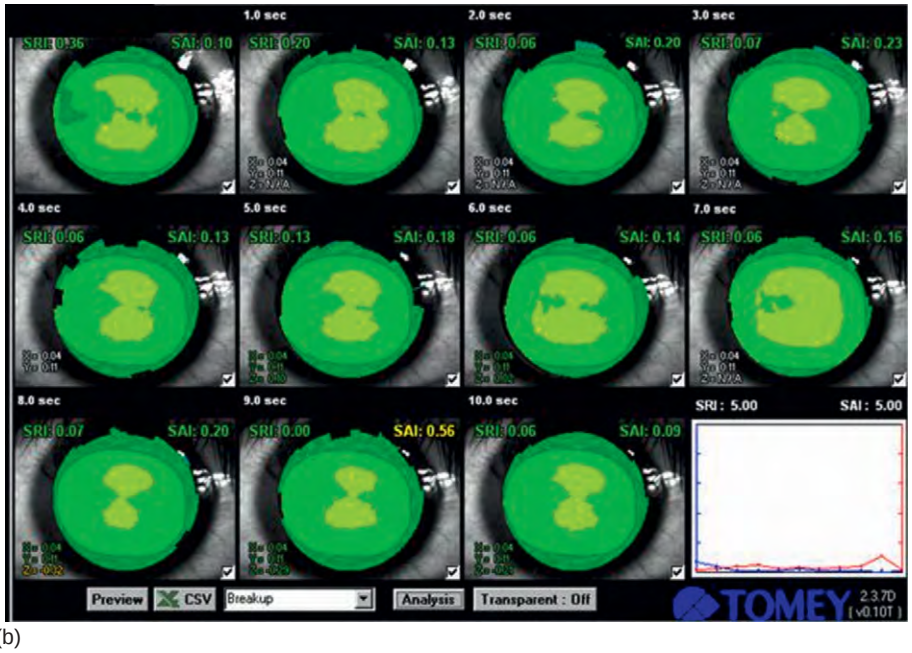
visualization of epithelial cells and quantization of goblet cells by staining the cells with stains such as alcian blue/Periodic Acid Schiff's reagent or by immunofluorescent techniques. This technique can also identify pathological alterations that develop in ocular surface disease and define the state of keratinization of the superficial epithelial layers. A nonkeratinized state of the ocular surface is crucial to its health.

Assessment of Tear Film Stability and Quantity

Assessment of the stability and quantity of the tear film are important parameters to diagnose dry eye. Tear-film stability is measured by determining the tear-film break-up time, while Schirmer's test measures the quantity of tears.



(a)



(b)

Figure 2 (a) Tear-stability analysis system (TSAS) in dry-eye patient. Tear-film break-up time is 3 s. Note the dramatic change in the TSAS pattern with time. The tears evaporate from the lower part of the cornea. (b) Tear-stability analysis system in normal subject. Tear-film break-up time is 12 s.

Tear-Film Break-Up Time (TFBUT)

This is carried out using a small amount of fluorescein, which is applied to the lower fornix using an applicator and the use of a yellow barrier-filter to enhance the visibility of the break-up of the fluorescent tear film. The patient is asked to blink and then keep the eyes open. The time taken for the first black spot in the stained tear film is recorded as the TFBUT. The test is ideally repeated 3 times and the mean is recorded as the TFBUT of that eye. Currently, a TFBUT value greater than 10 s is regarded as normal.

Schirmer's Test

Aqueous tear quantity is measured by Schirmer's test, which may be performed with or without the use of a topical anesthetic. For the Schirmer's test, a strip of filter is placed with its tip in the lower lateral conjunctival fornix, and the length of strip that becomes wet after 5 min is measured. The patient's eyes should be closed during the test. Aqueous deficiency is suspected if there is less than 5 mm of strip wetting after 5 min without anesthesia.

Assessment of Other Tear Functions

Tear Osmolarity

Although techniques to measure tear osmolarity are currently inaccessible to most practitioners, the development of commercial instruments may make such measurements feasible in the near future. As an objective measure of dry eye, hyperosmolarity is attractive as a signature feature, characterizing dryness. The diagnostic cut-off is in excess of 316 MOsm l^{-1}.

Lipid-Layer Interferometry

Interference cameras measure the tear-film lipid-layer interferometry. This can assist in analyzing the changes in thickness and the structure of the tear lipid layer. Reflective meniscometry measures the tear-meniscus curvature which has been shown to be decreased in patients with dry eye. This decrease correlates well with increased ocular surface staining. Lipid-layer interferometry, along with measurement of tear osmolarity is a potentially useful tool in the diagnosis of dry eye.

Tear-Stability Analyses

Tear-stability analysis measures tear stability as a function of serial surface regularity index and surface asymmetry index. These topographical indices assess the tear-film-related corneal surface changes. This analysis has shown a decrease in tear stability with increase in surface regularity index and surface asymmetry index in patients with dry eye. Tear-stability analysis has been found to be useful in evaluating the effects of punctum-plug treatment in patients with dry eye (Figure 2). Punctum-plug insertion is a treatment for patients with dry eye where the nasolacrimal punctum is plugged, thereby decreasing tear drainage.

Functional Visual Acuity

The FVA system continuously measures changes in visual acuity over time (Figure 3). The test begins with the best corrected Landolt visual acuity, which is the baseline of FVA. Landolt optotypes (consists of a ring that has a gap, thus looking similar to the letter C) are presented on the frame every second within a defined time (1–5 s), which increases in size when the answer is incorrect or when there is no response within the set display times, and decreases in size when the answer is correct. Each response is recorded on a table and as graphs, which are composed of points joining the correct answers only. FVA-test parameters include the mean FVA and visual maintenance ratio (VMR). VMR measures the percentage of the time a subject is able to maintain his or her best visual acuity over the present-time testing. The mean logMAR FVA and VMR scores have been reported to decrease in dry-eye patients compared to healthy control subjects. Both parameters improve with punctum-plug occlusion (Figure 4) but may deteriorate with epiphora (watery eyes).

Higher Order Aberration (HOA) Measurement

Wave front sensors can measure serial ocular HOAs continuously. During the measurement, each subject is instructed to blink every 10 s. The HOA data can analyze, in the central 4-mm cornea, up to the sixth-order aberrations by expanding the set of Zernike polymials (a sequence of

Figure 3 Functional visual acuity (FVA) system. This is a compact device developed to measure changes in continuous visual acuity over time.

polynomials that are orthogonal on the unit disk). Two quantitative indices are used to indicate the sequential changes in HOAs over time – the fluctuation index and the stability index of the total HOAs. The fluctuation index is defined as the fluctuations in the total HOAs obtained that showed the fluctuations in the total HOAs measured between blinks. Stability index is defined as the slope of the linear regression line of the total ocular HOAs between blinks. The total ocular HOAs are reported to be significantly greater in dry eye with central corneal staining than in dry eye without staining. The low tear volume in dry eye may not cause sequential increases in HOAs after blinking. Sequential assessment of HOAs may be useful for evaluating the sequential changes in corneal optical quality in patients with dry eye.

The Active Pulley Hypothesis

J L Demer, University of California, Los Angeles, CA, USA

Glossary

Active pulley hypothesis (APH) – A kinematic hypothesis that explains how actively generated translational shifts in the positions of connective tissue pulleys in the orbit can control the pulling directions of the extraocular muscles so as to regulate how muscle pulling direction changes with eye orientation. The APH states that the orbital layers of the extraocular muscles translate the pulleys to control the muscle pulling direction, while the global layers rotate the eye directly in directions determined by pulley locations. The APH explains Listing's law as a mechanical phenomenon not explicitly commanded by innervation to torsionally acting extraocular muscles.

A-pattern strabismus – Horizontal binocular misalignment in which the eyes are more convergent (or less divergent) in upward gaze, and more divergent (or less convergent) in downward gaze.

Commutativity – A property of sequential mathematical operations whose outcome is identical regardless of the sequence of operations. For example, addition is a commutative operation. Sequential rotations of a solid object, however, are not commutative.

Craniosynostosis – A pathological condition in which the suture junctions between the bony plates of the skull fuse prematurely during maturation, resulting in deformity of the skull and often of the ocular orbit.

Esotropia – Convergent horizontal strabismus, in which the eyes are crossed.

Exotropia – Divergent horizontal strabismus, opposite to the misalignment of esotropia.

Excycloduction – Rotation about the line of sight so that the superior part of the eye or orbit is rotated away from the midline.

Extorted (position) – Oriented in a position achieved by excycloduction. This term may be applied to the eye or to the orbit.

Hypertropia – Strabismus in which the eyes are misaligned vertically, so that the visual direction of one eye is higher than that of the other.

Incomitant strabismus – A binocular misalignment that varies in degree or direction with the direction of gaze.

Incycloduction – Rotation about the line of sight so that the superior part of the eye or orbit is rotated toward the midline.

Intorted (position) – Oriented in a position achieved by incycloduction. This term may be applied to the eye or to the orbit.

Kinematic – Relating to the rotational motion of the eye.

Lateral enthesis – The lateral anchor of the pulley connective tissue system onto the lateral orbit at the orbital tubercle of the zygomatic bone (Whitnall's tubercle).

Levator aponeurosis – The expansion of the tendon of the levator palpebrae superioris that ultimately inserts into the skin of the upper eyelid.

Listing's law – A constraint on ocular torsion about the line of sight first described by von Helmholtz: with the head upright and stationary, torsional eye position is always that value attained by a rotation from a primary starting position about a single axis. All such physiologic axes lie in a single plane termed Listing's plane. An equivalent formulation of Listing's law in the velocity domain is termed the half-angle rule, wherein the velocity axis of the eye changes by half of eye position.

Medial enthesis – The medial anchor of the pulley connective tissue system onto the medial orbit at the posterior lacrimal crest.

Orbit – The tissues surrounding the ocular globe, including the bony eye socket.

Orbital pulley – A connective tissue structure that constrains the path of an extraocular muscle. Except for the rigid, cartilaginous trochlea of the superior oblique muscle, orbital pulleys consist of soft, ring-shaped specializations in posterior Tenon's fascia into which are attached the fibers of the orbital layers of their corresponding extraocular muscles.

Saccade – Rapid refixational eye movement executed in ballistic fashion without ongoing sensory feedback.

Secondary gaze position – An eye position achieved by a purely horizontal or vertical rotation from primary position.

Tertiary gaze position – An eye position achieved by a combination of horizontal and vertical rotations.

Trochlea – A cartilaginous structure in the superiomedial part of the orbit through which the

superior oblique runs and results in a complete change in superior oblique muscle path.
V-pattern strabismus – Horizontal binocular misalignment in which the eyes are more divergent (or less convergent) in upward gaze, and more convergent (or less divergent) in downward gaze.

Gross Anatomy of Orbital Tissues

The six striated ocular rotary extraocular muscles (EOMs) are configured as antagonist pairs. The medial rectus (MR) and the lateral rectus (LR) muscles rotate the eye horizontally, with the MR adducting (rotating toward the midline) the eye and the LR abducting it (rotating away from the midline). The superior rectus (SR) and the inferior rectus (IR) muscles form a vertical antagonist pair, but some vertical action is contributed by the oblique EOMs. The superior oblique (SO) muscle, seemingly paradoxical in view of its name, has an infraducting (downward rotating) action, while the inferior oblique (IO) muscle has a supraducting (upward rotating) action. More importantly, the oblique EOMs act torsionally to rotate the eye around the line of sight. The SO incycloducts the eye by rotating its superior pole toward the nose, while the IO muscle excycloducts the eye by an oppositely directed rotation around the line of sight.

Pulleys and Muscle Paths

Rectus EOMs originate deep in the orbit, traveling anteriorly toward insertions on the ocular globe. The EOMs were traditionally described as following the shortest paths from origin to scleral insertion, which implies that the EOMs sideslip over the sclera. The shortest-path concept also implies that the rotational axis imposed upon the eye by a rectus EOM is fixed in the orbit. The X-ray tomographic observations of Simonsz and magnetic resonance imaging (MRI) observations of Miller first showed that EOMs do not follow shortest paths from origins to insertions. In eccentric gaze, rectus EOM paths are inflected sharply at discrete points in the anterior orbit by pulleys that constrain sideslip and cause EOM pulling direction to change with eye position.

The modern concept of orbital pulleys describes a change in the anterior paths of rectus EOMs, and thus their pulling directions, in an orderly way during duction. This is shown in the axial MR images in **Figure 1**, illustrating that the IR's anterior path changes by half the change in the duction angle. MRI shows similar behavior for all rectus EOMs: the anterior direction changes by half the duction angle.

Connective tissue pulleys surround the rectus and IO EOMs at their points of perforation of posterior Tenon's

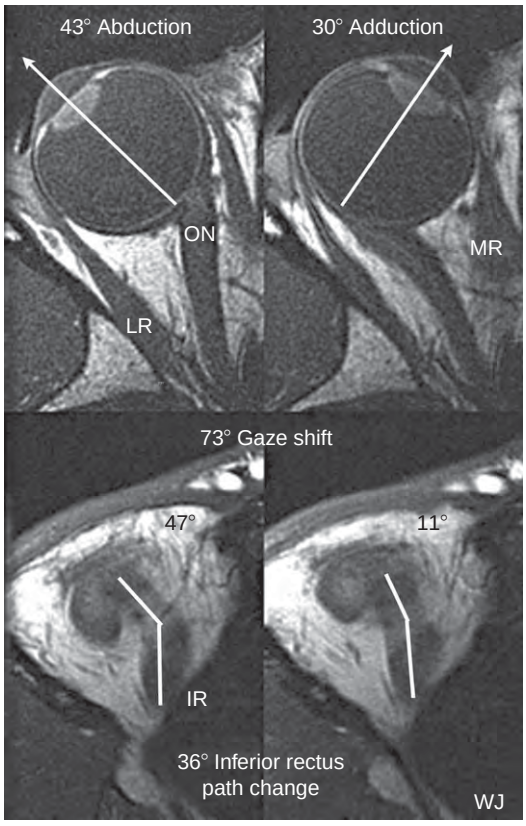

Figure 1 Axial magnetic resonance imaging views of human right orbit at the level of lens, fovea, and optic nerve (top row) and simultaneously in an inferior plane along the inferior rectus (IR) muscle path (bottom row), in abduction (left) and adduction (right). Note the two-part IR path, with an inflection corresponding to the IR pulley. For this 73° horizontal gaze shift, there was a corresponding 36° shift in IR muscle path anterior to its pulley. Reproduced from Demer, J. L. (2004). Pivotal role of orbital connective tissues in binocular alignment and strabismus. The Friedenwald lecture. *Investigative Ophthalmology and Vision Sciences* 45, 729–738, with permission from Association for Research in Vision Ophthalmology.

fascia. In secondary and tertiary gazes, EOM paths are inflected at these pulleys away from the shortest paths to EOMs' scleral insertions that have been shifted by ocular rotation. Since an EOM rotates the globe in a direction determined by the EOM's direction of pull as it departs the globe surface, path inflections influence an EOM's oculorotary direction. Systematic changes in EOM path direction produce a complex but systematic dependence of EOM pulling direction on instantaneous eye position, thus varying the amount of horizontal, vertical, and torsional rotation an EOM produces.

Structure of Pulleys

The overall structure of the orbital connective tissues is schematized in **Figure 2**. Points of rectus EOM inflection

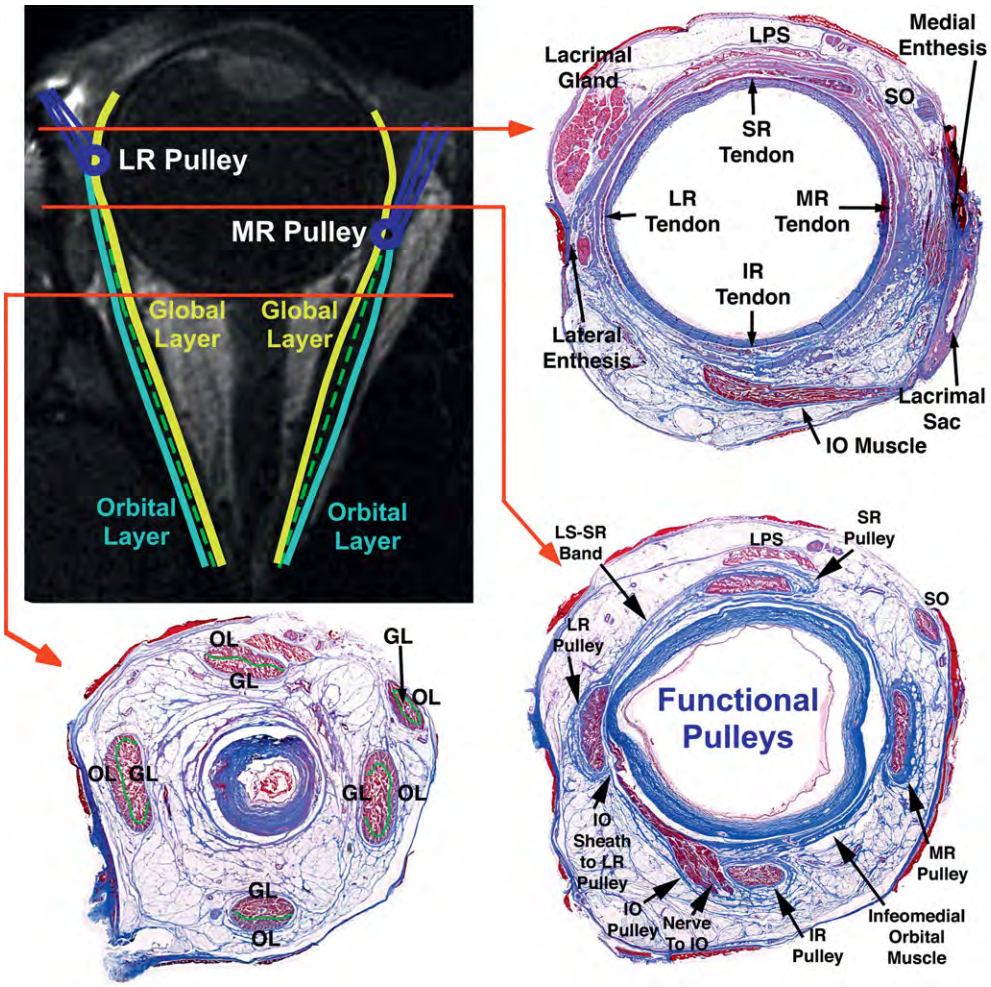

Figure 2 Anatomy of the human orbit. Axial magnetic resonance imaging (MRI) scan at upper left includes the medial (MR) and lateral rectus (LR) muscles whose orbital layers (OLs) and global layers (GLs) are demarcated by broken green lines. For each horizontal rectus EOM, the GL is illustrated as a yellow line that inserts upon the sclera, while the OL is illustrated as a light-blue line that terminates on the corresponding pulley (dark-blue ring). Pulleys are suspended from anteriorly located enthuses, attachments to the orbital wall. Superimposed on the MRI are three red lines denoting planes of coronal histological sections stained with Masson trichrome, which stains collagen blue and muscle in red. The upper right section is anterior to the globe equator, where the anterior pulley slings surrounding the thin rectus tendons are convex toward the orbital walls. The lower right section is posterior to the globe equator near the level of the functional pulleys, which appear as dense blue collagenous encirclements of the rectus and inferior oblique (IO) muscles. Note that the levator palpebrae superioris (LPS) muscle lacks a pulley. The lower left section is through the posterior pole of the globe, where the connective tissues have become attenuated to thin slings convex toward the globe. Each EOM exhibits an OL and GL, whose borders are demarcated by the broken green line. IR, inferior rectus muscle; LR, lateral rectus muscle; MR, medial rectus muscle; SO, superior oblique muscle; SR, superior rectus muscle.

constitute the functional orbital pulleys, and from the standpoint of ocular rotation, constitute functional EOM origins. Pulleys consist of discrete rings of dense collagen encircling the EOM, transitioning gradually into less substantial but broader collagenous sleeves (Figure 2). Anteriorly, these sleeves thin down to form slings convex to the orbital wall, and posteriorly the sleeves thin down to form slings convex toward the orbital center. The anterior pulley slings have also been called the intermuscular septum. Fibrils of collagen in the pulleys have an interlaced configuration suited to high internal rigidity. There are bands of smooth muscle in some pulley suspensions, and particularly in a distribution called the inframedial peribulbar smooth muscle between the MR and IR pulleys. The MR and LR pulleys are suspended by fibroelastic connective tissues from anteriorly located entheses, or anchors, on the orbital bones. The medial enthesis is at the posterior lacrimal crest, while the lateral enthesis is at the orbital tubercle.

IO and IR Pulleys

The IR pulley is coupled to the IO pulley in the central part of the inferior tarsal ligament (Lockwood's), the

connective tissue hammock spanning the inferior orbit. The IR and IO pulleys share a common collagenous sheath stiffened by dense elastin. The IR's orbital layer inserts on its pulley and does not continue anteriorly. The IO's orbital layer inserts partly on the conjoined IO–IR pulleys, partly on the IO sheath temporally and partly on the LR pulley's inferior aspect. As the orbital layer of the IR contracts during infraduction, the IR pulley shifts posteriorly to maintain a constant distance from the scleral insertion. Being only partially coupled to the IR pulley, the IO pulley shifts by half of this distance.

Elastin and smooth muscle are present in the region of the inferior tarsal ligament which supports the IR–IO pulleys. The inframedial peribulbar smooth muscle is positioned upon contraction to displace the IR pulley nasally. The smooth muscle retractors of the lower eyelid, the inferior tarsal muscle (Müller's muscle), and the connective tissues extending to the inferior tarsal plate are also coupled to the conjoint IR–IO pulley, coordinating lower eyelid position with the eye during vertical duction. Pulley smooth muscle has autonomic innervation, including: sympathetic with a norepinephrine projection from the superior cervical ganglion; cholinergic parasympathetic, probably from the ciliary ganglion; and nitroxidergic, probably from the pterygopalatine ganglion.

Trochlea

With its rigid pulley – the trochlea – the SO is unique that its orbital layer inserts via the SO sheath on the SR pulley's medial aspect. SO pulling direction changes half the duction angle because the thin, broad SO tendon wraps over the globe.

Functional Anatomy of Pulleys

According to the APH, the insertion of each rectus EOM's orbital layer on its pulley is the principal driving force translating (linearly moving) that pulley posteriorly during EOM contraction. In humans and monkeys, orbital layer fibers form small tendons that insert into the dense encircling tissue of the pulley system in a distributed manner over an anteroposterior region several millimeters (mm) in anteroposterior extent. MRI suggests that the pulley-system tissues move in coordination with the insertion and underlying sclera, although histological examinations show no direct connections between these tissues. The connective-tissue sleeves themselves have a substantial anteroposterior extent along which connective-tissue thickness varies.

Active Pulley Shifts

Since the EOMs pass through their encircling pulleys, physiological pulley locations are inferred from EOM paths. Pulley locations and shifts during ocular duction have been determined quantitatively from coronal MRIs in secondary and tertiary gazes. Imaging in tertiary (combined horizontal and vertical) gaze positions shows changes in anteroposterior positions of EOM path inflections. These data have confirmed that all four rectus pulleys move anteroposteriorly in coordination with their scleral insertions by the same anteroposterior amounts. MRI studies in living subjects have been consistent with histological examinations of the same regions in cadavers.

Pulley Positions

Although MRI indicates that rectus and IO pulleys are mobile along the axes of their respective EOMs, pulleys are located stably and stereotypically in planes transverse to the EOM axes. The 95% confidence intervals for horizontal and vertical coordinates of normal rectus pulleys range over less than $\pm$ 0.6 mm. Pulley stability in the coronal plane implies that pulleys are suspended by stiff tissues. The APH proposes that anteroposterior mobility of pulleys is accomplished by application of substantial force by each EOM's orbital layer. Aging causes inferior sagging of the horizontal rectus pulley positions, which shift downward by 1–2 mm from young adulthood to the seventh decade in people with normal binocular alignment, and more in people with strabismus or high axial myopia. Vertical rectus pulley positions change little with aging.

Globe Translation

The globe itself makes small translations – linear shifts – during normal ocular duction. The globe translates 0.8 mm inferiorly from 22° downward gaze to 22° upward gaze, and it also translates slightly nasally in both abduction and adduction. Even these small translations affect EOM force directions since the globe center is only 8 mm anterior to the plane of the rectus pulleys.

Pulley Translation

While pulleys limit EOM sideslip during globe rotations, small physiologic transverse shifts of rectus pulleys do occur. Coronal MRI shows that the MR pulley translates 0.6 mm superiorly from 22° infraduction to 22° supraduction. The LR pulley translates 1.5 mm inferiorly from infraduction to supraduction, opposite to the direction predicted by the shortest-path concept. The IR pulley shifts 1.1 mm medially in supraduction, but moves 1.3 mm temporally in infraduction. The SR pulley is relatively stable in the mediolateral direction, but moves inferiorly in supraduction and superiorly in infraduction.

Gaze-related shifts in rectus pulley positions are uniform among normal people.

Pulley Kinematics

Orbitally fixed pulleys make the eye's rotational axis dependent on eye position in a way important to ocular kinematics. Sequential rotations are mathematically non-commutative, so that final eye orientation depends on the order of rotations. Each combination of horizontal and vertical orientations could also be associated with many torsional orientations representing rotations around the line of sight, but the eye is constrained when the head is upright and immobile by Listing's law (LL): torsion in any gaze direction is that which the eye would have reached by a single rotation from primary eye position about an axis lying in Listing's plane (LP). LL is formulated in the kinematic position domain. Equivalent in the three-dimensional velocity domain, the half-angle rule states that LL is satisfied if the ocular rotational velocity axis shifts by half of the ocular duction. For example, if the eye supraducts 30°, then the vertical velocity axis about which it rotates for subsequent horizontal movement should tip back by 15°. Conformity to the half-angle rule makes the sequence of ocular rotations appear commutative to the brain, a property crucial to the control of ocular motility. It means that the brain does not need to keep track of the history of prior eye rotations in order to program subsequent eye rotations.

Active Pulley Hypothesis

Muscle Path Geometry

The APH explains how rectus pulley position can implement the half-angle kinematics required by the half-angle rule. EOMs rotate the globe about axes perpendicular to the tendon paths near the insertion. In **Figures 3(a)** and **(b)** it is seen from simple small-angle trigonometry that a horizontal rectus EOM's pulling direction tilts posteriorly by half the angle of supraduction when the pulley is located as far posterior to globe center as the insertion is anterior to globe center. Since all rectus EOMs and their pulleys are arranged similarly, all rotational forces acting on the eye-change direction by half of eye orientation. This configuration thus mechanically implements the half-angle rule, and thus LL.

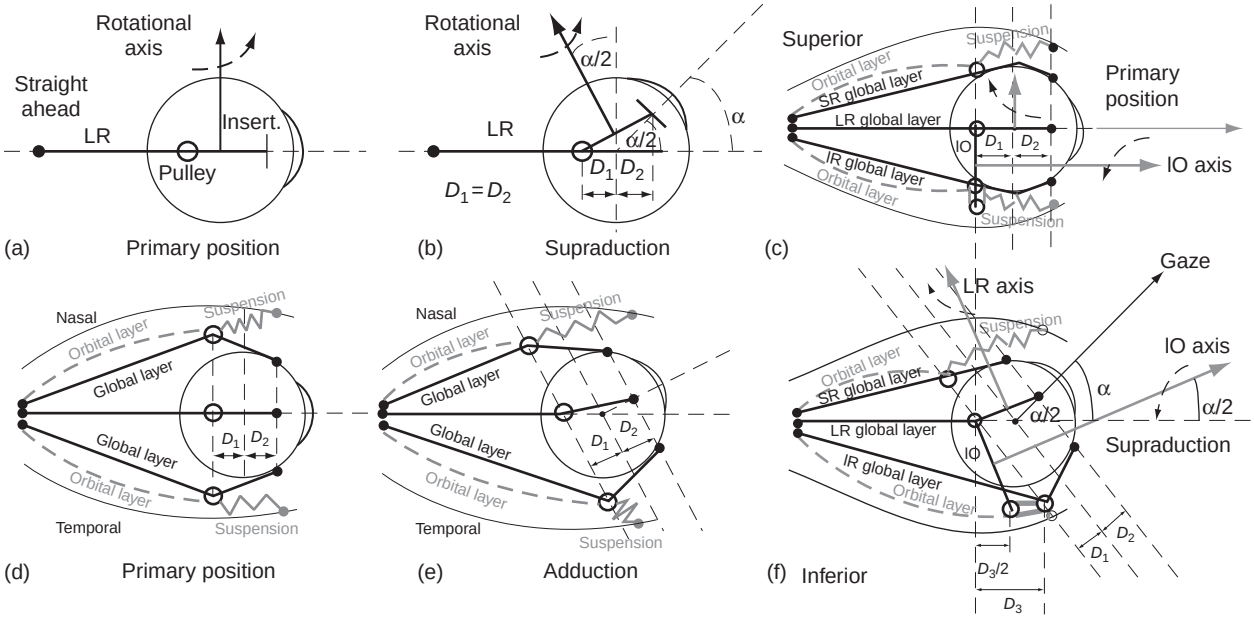

Figure 3 Diagram of extraocular muscle (EOM) and pulley behavior for half-angle kinematics conforming to Listing's Law. (a) Lateral view. EOM's rotational velocity axis is perpendicular to the segment from pulley to scleral insertion. The lateral rectus (LR) velocity axis is vertical in primary position. (b) Lateral view. In supraduction to angle alpha, the LR velocity axis tilts posteriorly by angle alpha/2 if distance D_1 from pulley to globe center is equal to distance D_2 from globe center to insertion. (c) Lateral view. In primary position, terminal segment of the inferior oblique (IO) muscle lies in the plane containing the LR and inferior rectus (IR) pulleys into which the IO's orbital layer inserts. The IO velocity axis parallels primary gaze. (d) Superior view of rectus EOMs and pulleys in primary position, corresponding to A. (e) Superior view. In order in adduction to maintain $D_1 = D_2$ in an oculocentric reference, the medial rectus (MR) pulley must shift posteriorly in the orbit, and the LR pulley anteriorly. This is proposed to be implemented by the orbital layers of these EOMs, working against elastic pulley suspensions. (f) Lateral view similar to (c). In supraduction to angle alpha, the IR pulley shifts anteriorly by distance D_3, as required by the relationship shown in E. The IO pulley shifts anteriorly by $D_3/2$, shifting the IO velocity axis superiorly by alpha/2. Reproduced from Demer, J. L. and Clark, R. A. (2005). Magnetic resonance imaging of human extraocular muscles during static ocular counter-rolling. *Journal of Neurophysiology* 94: 3292–3302, with permission from American Physiological Society.

Were primary and secondary gaze positions the only ones required, rectus pulleys could be rigidly fixed in the orbit. However, agonist–antagonist EOM alignment and conformity with LL are possible only if pulleys move in the orbit. Tertiary gazes, such as adducted supraduction, require the rectus pulleys to actively shift anteroposteriorly in the orbit, maintaining a fixed oculocentric relationship (**Figures 3(d)** and **(e)**). The APH explains that pulley shifts are generated by the contraction of the orbital layers acting against elasticity of the pulley suspensions, which are anchored from the bone of the anterior orbit at the entheses.

Muscle Commands

Despite coordinated movements, however, ocular rotation by the orbital layer and pulley translation by the global layer would require different EOM actions and neural commands. The global layer's mechanical load can be hypothesized to be predominantly the viscosity of the relaxing antagonist EOM. Viscosity is a resisting force proportional to rotational speed, and is a prominent mechanical feature of an EOM. The orbital layer's load, however, is postulated to be primarily due to the elasticity of the pulley suspension. Elasticity is a mechanical load independent of speed, but proportional to the duction angle. Electromyography (EMG) shows high, phasic global-layer activity during saccades, with a smaller-maintained tonic change in activity in eccentric gaze. The phasic activity of the global layer is thus appropriate to overcome viscosity of the relaxing antagonist EOM when the eye rotates quickly during a saccade, while the global layer's lesser tonic activity is appropriate to overcome the elastic forces of the opponent EOM and the connective tissues that oppose maintenance of an eccentric eye position. In the orbital layer, there is sustained, high EMG activity in eccentric gaze, but no phasic activity during saccades. The tonic activity of the orbital layer is appropriate to overcome mainly the elastic load of the connective tissues suspending an EOM's pulley. In cat, the most powerful and fatigue-resistant LR motor units, comprising 27% of all units, innervate both the orbital and global layers. Such bilayer motor units could command similar tonic contraction in the two layers, which may, in turn, maintain the pulley position relative to the EOM insertion. Other motor units project selectively to either the orbital or global layer, appropriate to differentiated muscle control.

Non-Listing's Kinematics in Convergence

Not all eye movements conform to LL. Violations of LL occur during the vestibulo-ocular reflex (VOR) and during convergence due to action of the oblique EOMs. Excycloduction refers to a rotation of the eye around the line of sight so that the superior pole of the eye shifts laterally. It occurs in convergence which violates LL. During asymmetrical convergence to a target aligned to one eye, this excycloduction is binocular, and interpretable as temporal tilting of LP for each eye. MRI during convergence to a target aligned to one eye has distinguished the effect of convergence from that of adduction. In the aligned orbit, there is extorsional shift of most rectus pulleys similar to globe extorsion. During convergence, the rectus pulley array rotates about the orbital axis in coordination with ocular torsion, changing the torsional pulling directions of all rectus EOMs but maintaining half-angle dependence on horizontal and vertical ductions. This would cause a parallel, torsional offset in LP.

An active mechanism probably implements torsional pulley shifts during convergence. The IO muscle's orbital layer inserts on the IR pulley and, at least in younger specimens, also on the LR pulley. Contraction of the IO orbital layer would excycloduct the LR and IR pulleys. Contractile IO thickening has been directly demonstrated by MRI during convergence. Inferior LR pulley shift would be coupled to produce lateral SR pulley shift because these pulleys are coupled by a ligament connecting the superior and lateral rectus pulleys, the LR–SR band. The SO muscle's orbital layer inserts on the SO sheath posterior to the trochlea, with both tendon and sheath passing anteriorly through the rigid pulley so that the SO sheath inserts on the SR pulley's nasal border. Relaxation of the SO orbital layer during convergence is consistent with single-unit recordings in the monkey trochlear nucleus and could contribute to pulley array excycloduction. The inframedial peribulbar smooth muscle may also contribute to rectus pulley excycloduction in convergence.

Non-Listing's Kinematics in Ocular Counterrolling

Ocular counterrolling (OCR) is a static torsional vestibulo-ocular reflex mediated by the otoliths of the inner ear. MRI during OCR shows coronal plane positions of the rectus EOMs being shifted torsionally in the same direction as the eye rotates about the line of sight. Pulley array torsion has been estimated to be roughly half the amount of OCR. Torsional shift of the rectus pulley array half of OCR would change rectus EOM pulling directions by one-quarter of OCR (**Figure 4**). During OCR, oblique EOMs exhibited changes in MRI cross section consistent with active roles in rotating the rectus pulley array. This finding suggests that the array of rectus pulleys constitutes a kind of inner gimbal conforming to Listing's half-angle kinematics for visually guided movements such as fixations and saccades, but that is rotated torsionally by

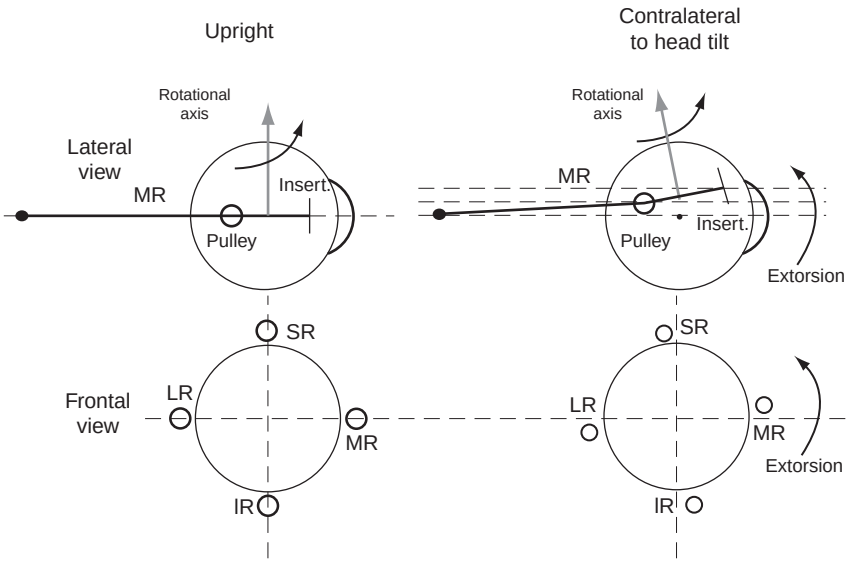

Figure 4 Diagram of effects of head tilt on rectus pulleys in lateral (top row) and frontal (bottom row) views. With head upright, the inferior (IR), lateral (LR), medial (MR), and superior rectus (SR) pulleys are arrayed in a cruciate pattern when viewed frontally. The MR passes through its pulley, represented as a ring, to its scleral insertion. The rotational velocity axis imparted by the MR is perpendicular to the segment from pulley to insertion. The pulley array extorts during contralateral head tilt. Since during head tilt the MR pulley shifts superiorly by the half the distance the insertion shifts, the MR's velocity axis changes by one-fourths of the ocular torsion. Reproduced from Demer, J. L. and Clark, R. A. (2005). Magnetic resonance imaging of human extraocular muscles during static ocular counter-rolling. *Journal of Neurophysiology* 94: 3292–3302, with permission from American Physiological Society.

the oblique EOMs to implement non-LL eye movements such as the slow and quick phases of the VOR.

Electrophysiologic Evidence for the APH

Electrophysiologic evidence supports the APH. Motor neurons innervating the vertical rectus and oblique EOMs in monkeys signal no neural commands for LL torsion during pursuit tracking, although pursuit conforms to LL. Direct electrical stimulation of the monkey abducens nerve evokes saccade-like movements that conform to the half-angle rule and thus to LL. These findings support the APH contention that the ocular torsion required by LL arises from mechanical properties of rectus EOMs and orbital connective tissues, rather than by explicit neural commands to the cyclovertical EOMs to generate ocular torsion.

Implications for Strabismus

As the EOM pulley array is anchored to the bony orbit, bony abnormalities may malposition pulleys to alter EOM pulling directions. Typically, the heterotopic array of rectus pulleys is extorted or intorted, not necessarily symmetrically. Computer simulations suggest rectus pulley malpositioning, as in craniosynostosis, can produce incomitant strabismus. Extorsion of the pulley array is associated with V patterns and intorsion associated with A patterns (**Figure 5**). Surgery for pulley disorders recently has emerged for treatment of three types of pathologies.

Pulley Heterotopy

Pulley heterotopy may involve stable malpositioning of one or several rectus pulleys. Initial efforts to treat heterotopy involved transpositions of the scleral insertions of EOMs whose pulleys were heterotopic, later augmented by fixations of EOM bellies to the underlying sclera ~8 mm posteriorly. MRI has demonstrated that this surgery shifts the involved rectus pulley somewhat toward the desired direction. However, because the pulley does not shift as far as the insertion, the operation introduces undesirable ocular torsion opposite to the direction of transposition. Since normal pulleys are not attached to sclera, posterior fixation compromises normal pulley kinematics and introduces abnormal globe translation during duction. Newer approaches to pulley heterotopy involve surgery on connective tissues suspending the pulleys without scleral suturing. A technically convenient approach to treatment of inferior displacement of the LR pulley is to shorten and stiffen the ligament coupling the LR and SR pulleys, the LR–SR band.

Extreme pulley heterotopy is associated with esotropia and hypotropia in axial high myopia. In this condition, historically called the heavy-eye syndrome, the LR pulley shifts inferiorly to approach the IR, and the globe

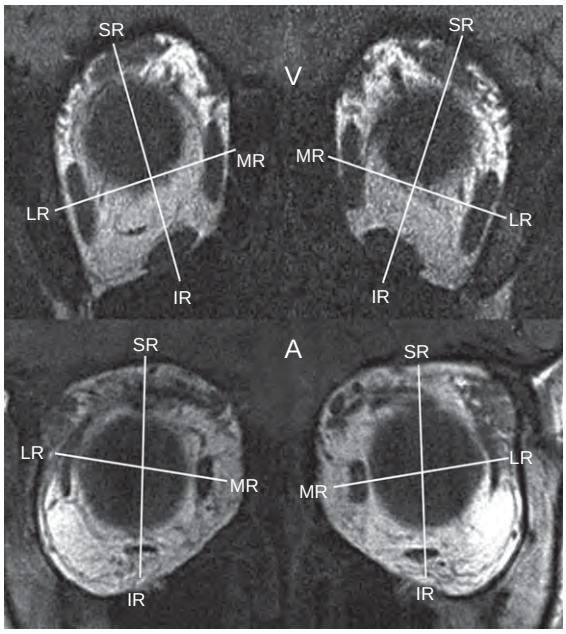

Figure 5 Magnetic resonance imaging scan showing typical pulley configurations for A and V patterns. A-pattern strabismus is a horizontal binocular misalignment in which the eyes are more convergent (or less divergent) in upward gaze, and more divergent (or less convergent) in downward gaze. V-pattern strabismus is a horizontal binocular misalignment in which the eyes are more divergent (or less convergent) in upward gaze, and more convergent (or less divergent) in downward gaze.

correspondingly shifts superotemporally in the orbit. A similar degenerative condition occurs in elderly, nonmyopic people, in whom it is termed the sagging-eye syndrome. Surgical anastamosis of the lateral margin of the SR belly with the superior margin of the LR belly may be effective in correcting esotropia associated with inferior displacement of the LR pulley, since the procedure normalizes EOM paths relative to the globe in a manner impossible for more conventional strabismus surgery.

Pulley Instability

Large gaze-related shifts or one or more pulleys are associated with incomitant strabismus. Pulley instability also has been termed gaze-related pulley shift. Inferior LR pulley shift in adduction produces restrictive hypotropia closely resembling Brown syndrome, caused by hindrance of SO travel in the trochlea, or X-pattern exotropia characterized by greater deviation in both up and down gaze compared to central gaze. Early efforts to treat pulley instability consisted of posterior fixation of the involved EOM to the underlying sclera. More recently, physiologically driven approaches involve tightening lax connective tissue bands in pulley suspensions.

Pulley Hindrance

In pulley hindrance, normal posterior shift with EOM contraction is mechanically impeded. This creates a mechanical restriction to ocular rotation in the field of action of the EOM. Intentionally created hindrance can be therapeutic, as done by the technique of posterior fixation (also known as retroequatorial myopexy and fadenoperation) of an EOM to the underlying sclera. Posterior fixation was postulated to work by reducing the EOM's arc of contact, diminishing its rotational lever arm. MRI demonstrates that posterior fixation works by hindering posterior shift of the contracting EOM's pulley, mechanically restricting EOM action. A technically simpler and safer modification of posterior fixation involves temporarily placing the MR-pulley suspension under tension, with the MR pulley sutured to the EOM belly. This operation is at least as effective as posterior fixation with scleral suturing in treatment of accommodative esotropia with excessive accommodative convergence.

Only relatively small shifts of pulleys are observed by MRI after simple transposition of the scleral insertions of rectus EOMs to treat paralytic strabismus. Posterior suture fixation of transposed EOMs shifts the pulley farther into the direction of the transposed insertion. This changes the pulling direction to mimic more closely that of the paralyzed EOM, increasing the effectiveness of transposition.

Conclusion

The ocular motor system consists of an intricate mechanical arrangement comprising a trampoline-like suspension supported by the rectus EOMs and their associated connective tissues, in turn circumferentially controlled by the oblique EOMs. Rectus EOMs and their connective tissue pulleys constitute the inner gimbal that is postulated to mechanically implement LL without explicit neural specification of ocular torsion. The inner gimbal has commutative properties that simplify neural commands for binocular coordination. The outer gimbal moves the inner by oblique EOM forces to generate ocular torsion not conforming to LL. Outer gimbal shift noncommutatively influences the inner gimbal in appropriate physiologic situations. While pathology of the orbital connective tissues may cause some forms of strabismus, the connective tissues are surgically accessible, so surgery on them may be therapeutic for specific types of disorders of ocular motility.

The Biology of Schlemm's Canal

W D Stamer, The University of Arizona, Tucson, AZ, USA

Glossary

Adherens junction – A type of cell–cell junction in which the cytoplasmic face of proteins in the junction complex is attached to actin filaments of the cytoskeleton.
Aqueous humor – A clear fluid that fills the anterior and posterior chambers of the eyeball and supplies the metabolic needs of the avascular lens, cornea, and trabecular meshwork.
Blood–aqueous barrier – Formed by the tight junctions (zonula occludens) of the nonpigmented ciliary epithelium, the endothelial cells of iris vessels, and the Schlemm's canal endothelium, to separate blood and aqueous humor compartments.
Collector channel – Openings in Schlemm's canal lumen that facilitates transport of aqueous humor to systemic venous system.
Endothelial cell – The flattened cell type that forms a sheet, the endothelium, lining blood vessels.
Gap junction – A communicating cell–cell junction that allows ions and small molecules to pass from the cytoplasm of one cell to the cytoplasm of a cell neighbor.
Giant vacuole – Cellular distention into Schlemm's canal lumen by endothelia that are formed by pressure gradient across the inner wall.
Integrins – The members of a large family of transmembrane proteins involved in the adhesion of cells to the extracellular matrix and to each other.
Juxtacanalicular tissue – The region of the conventional outflow pathway, including the cribiform (outermost) trabecular meshwork and inner wall of Schlemm's canal, where resistance to aqueous humor outflow is generated.
Syndecans – A family of glycoproteins at the plasma membrane of cells that act as receptors for extracellular matrix and are involved in intracellular communication.
Trabecular meshwork – The major component tissue of the conventional outflow pathway is located at the iridocorneal angle and consists of cells and extracellular matrix that functions to filter intraocular debris and regulate intraocular pressure.
Tight junction – A type of cell–cell junction that seals epithelial or endothelial cells together, forming a barrier such that even small molecules cannot pass between cells. An alternative term is zonula occludens.

Introduction

Intraocular pressure (IOP) is a function of the balance of aqueous humor secretion into and drainage out of the eye. Resistance generation that regulates the drainage of aqueous humor out of the eye is a dynamic process, maintaining IOP within a narrow range throughout a lifetime. Over a century ago, it was postulated that elevated IOP (ocular hypertension) in glaucoma is caused by increased resistance of aqueous humor drainage in the conventional outflow pathway. As it leaves the eye, the bulk of aqueous humor (70–90%) passes through the conventional outflow pathway, a complex pressure-sensitive tissue that is comprised of various cell types under constant mechanical strain (Figure 1). Multiple studies directed to identify the location of normal resistance generation in the conventional drainage tract implicate the juxtacanalicular tissue (JCT), a region populated by JCT–trabecular meshwork (TM) cells and the endothelium of Schlemm's canal (SC). The JCT region also appears to be the diseased tissue in glaucoma; implicated for generating the elevated outflow resistance associated with most forms of glaucoma. Still unknown today, however, are the mechanisms for aqueous humor outflow resistance generation, regulation, and why resistance becomes elevated in glaucoma, a group of diseases that affects ~70 million people worldwide. Significantly, even though the site of damage that leads to blindness in glaucoma is at the optic nerve head in the back of the eye, all current strategies to treat glaucoma (including normal-tension glaucoma) involve reducing IOP. In fact, results from multiple, large, clinical trials show that if IOP is lowered sufficiently and maintained over time, disease progression as indicated by visual performance is completely halted. Therefore, understanding the biology of SC endothelia in its contribution to the generation and regulation of outflow resistance is paramount to developing rational therapeutic strategies to intervene in those who suffer from glaucoma. This article reviews the biology of SC endothelia and the unique environment in which it functions.

Development

SC is vascular in origin, forming from the intrascleral venous plexus present in the developing human eye. Starting around week 17 of gestation, deep scleral vessels are observed in the SC region. By week E28, a complete SC can be seen in some regions of the eye. Soon afterward, around week 29 of gestation, some characteristic features (large, pressure-dependent distensions into the canal

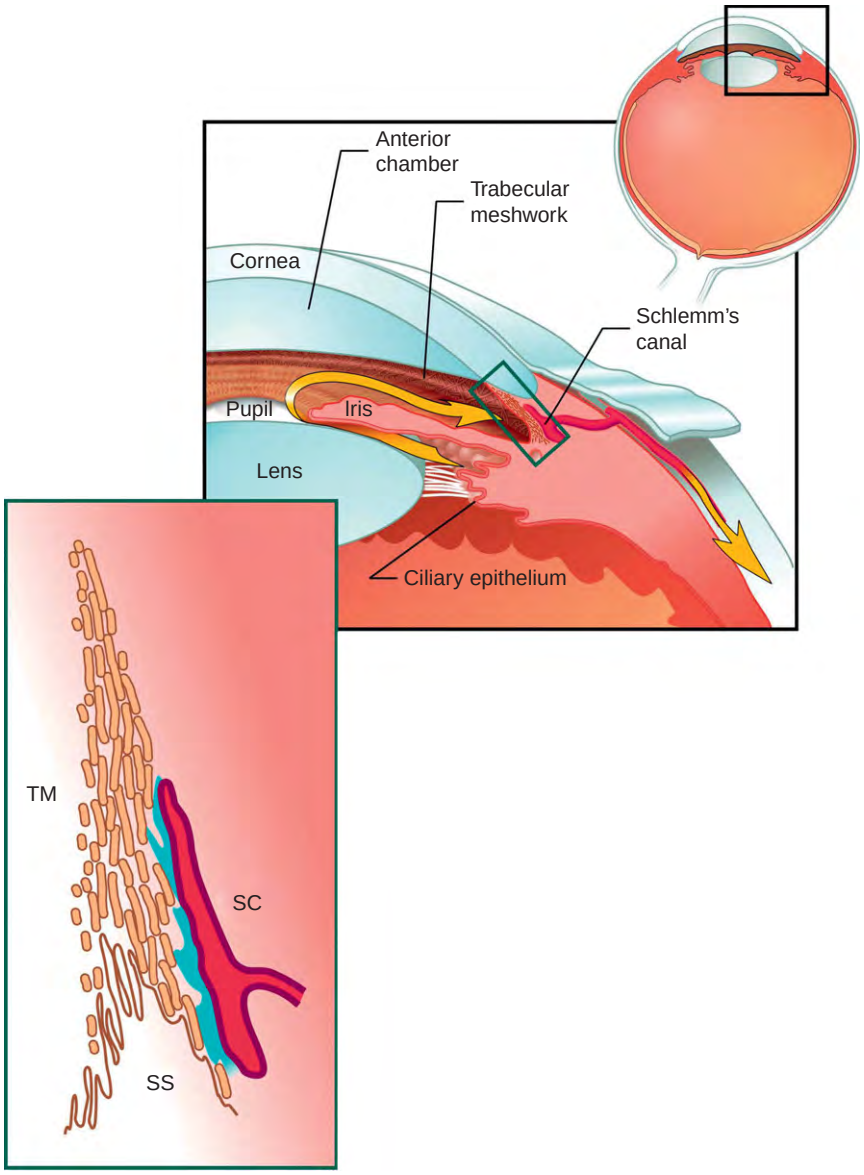

Figure 1 Flow pattern for aqueous humor and conventional outflow structures in the human eye. The black box indicates the region of the eye that is enlarged and structures labeled. Yellow ribbon arrows depict the origin of aqueous humor secretion by the ciliary epithelium and direction of flow into the posterior chamber, through the pupil, into the anterior chamber, and out through the conventional outflow pathway. The conventional outflow pathway is highlighted by a green rectangle and enlarged as an inset on the bottom left, showing the trabecular meshwork (TM), the scleral spur (SS), and Schlemm's canal (SC). The area shaded in blue is the juxtacanalicular region.

lumen called giant vacuoles; see below) are found in inner wall cells, indicating the presence of a pressure gradient and associated fluid flow. Preceding the formation of the SC, the TM tissues can be seen developing from the neural crest. TM cells start populating the regions contiguous with SC by week E16 and, by week E23, TM cells start interacting with the branching scleral vessels that will develop into the SC around week E28. Thus, it appears that the interactions between TM and SC cells begin early during development to guide the formation of a functional conventional outflow pathway, the primary route for aqueous humor to exit the eye.

The Conventional Outflow Pathway

Aqueous humor is drained from the human eye by two routes: the conventional pathway (also known as the trabecular pathway) and the unconventional pathway (also known as uveoscleral or uveovortex pathway). The unconventional pathway accounts for a small fraction (10–30%) of total aqueous humor drainage from the human eye and does not contribute significantly to normal outflow dynamics in older eyes, nor does it contribute to the generation of elevated outflow resistance in glaucoma, although the enhancement of uveoscleral outflow

underlies effectiveness of prostaglandin-$F_{2\alpha}$ analogs (current first-line therapy) in lowering IOP. The majority of aqueous humor leaves the eye through the conventional pathway, which is comprised of the TM, SC, and the collector channels/intrascleral venous plexus/aqueous veins (Figure 2). The TM is usually divided into three regions: the innermost uveal meshwork, the deeper corneoscleral meshwork, and the outermost JCT, which lies adjacent to SC, a ring-shaped venous vessel that encircles the eye at the corneoscleral junction. Collector channels and intrascleral aqueous plexus/aqueous veins connect SC lumen to the episcleral veins on the surface of the eye.

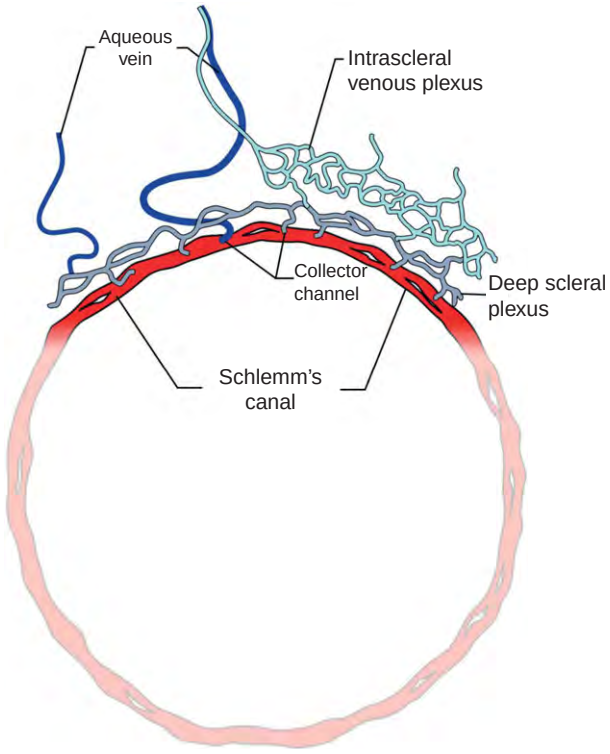

Figure 2 The morphology of Schlemm's canal and its relationship with distal venous system. The drawing shows complete vascular ring, which is Schlemm's canal. In the upper quadrant, detail is provided to reveal specific connections that collector channels make directly with aqueous veins or with deep scleral plexus and/or intrascleral venous plexus prior to joining aqueous veins.

Trabecular Meshwork

The majority of the TM, including the uveal and corneoscleral regions, is designed like a filter to intercept cell debris, including pigment, as it leaves the eye. Aqueous humor first encounters the uveal meshwork, which is made up of an irregular netlike structure of lamellae. Next, aqueous humor enters the corneoscleral meshwork, consisting of a number of porous sheets that are attached to the scleral spur posteriorly and the peripheral cornea at Schwalbe's line anteriorly. Both of these networks of extracellular matrix (ECM) are covered and maintained by resident TM cells. The openings in the uveal meshwork and in the sheets of the corneoscleral meshwork decrease progressively as they approach SC, creating turbulence, but neither generates any significant resistance to flow.

The final portion of the TM that aqueous humor encounters before reaching SC is known as the JCT, also called the endothelial meshwork or cribriform region. The JCT is bordered on one side by the innermost corneoscleral TM sheet and on the other by the basement membrane of the inner wall of Schlemm's canal – a separation distance of 10 μm on average. Cells that populate the JCT are not confluent monolayers similar to cells in the innermost TM regions, but suspended in ECM materials (mostly glycosaminoglycans), and make cell–cell attachments on corneoscleral TM, SC, and/or JCT–TM cells. At physiological IOPs (13–18 mm Hg) and episcleral venous pressures (7–8 mmHg in SC), a pressure gradient exists across the conventional outflow pathway, distending TM and inner wall tissues toward the outer wall of SC (Figure 3). Under the influence of a physiological pressure gradient, spaces between cells

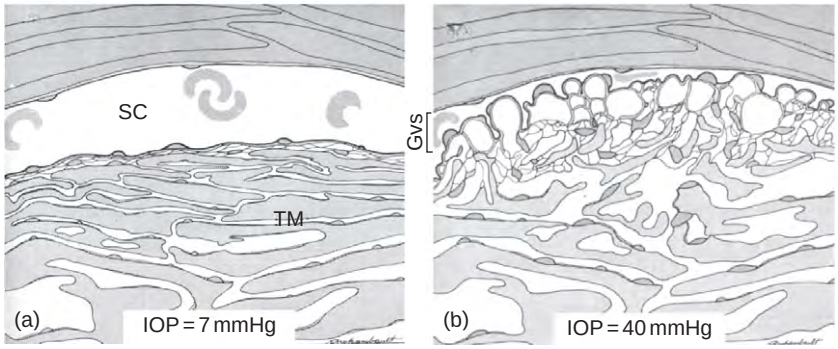

Figure 3 Changing configuration of trabecular meshwork (TM) tissue and Schlemm's canal (SC) inner wall endothelium at low (a) and high (b) perfusion pressure. Bracket indicates inner wall region where giant vacuoles (GVs) form in response to change in pressure gradient. Reproduced from Johnstone, M. A. and Grant, W. G. (1973). Pressure-dependent changes in structures of the aqueous outflow system of human and monkey eyes. *American Journal of Ophthalmology* 75: 365–383, with permission from Elsevier.

in the JCT emerge (1–3 μm in diameter). Together with associated ECM and the inner wall of SC, the JCT–TM likely generates a major portion of the resistance to outflow.

Schlemm's Canal

After passing by JCT–TM cells, aqueous humor encounters the inner wall of SC, the only continuous cell monolayer that aqueous humor must cross in the conventional outflow pathway. The inner wall of SC is characterized by predominantly elongated and flattened (thickness $\leq$ 1 μm) endothelial cells aligned parallel to the longitudinal axis of the canal (**Figure 4(a)**). While highly variable in appearance, these cells can be generally characterized as spindle shaped (100–150 μm in length and 8–10 μm in width). This confluent layer of cells is attached to one another by tight junctions and adhered to a discontinuous basement membrane. In contrast, the cells that populate the outer wall of SC are situated on a continuous basement membrane. Perhaps fluid flow across the inner, but not the outer wall of SC in the basal-to-apical direction, is responsible for such a difference.

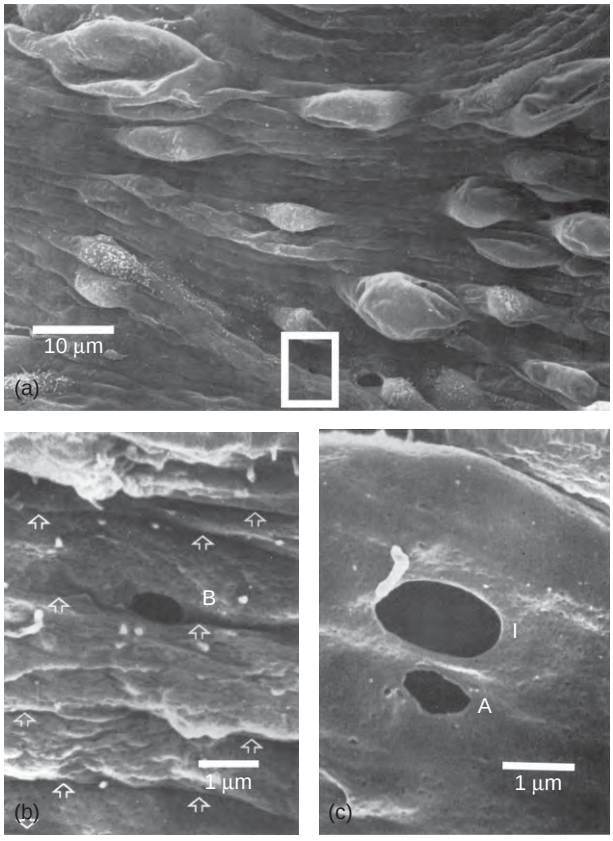

Figure 4 As viewed from the canal lumen, scanning electron micrographs showing morphology of inner wall of Schlemm's canal and two types of pore structures. (a) Overview of inner wall morphology. (b) A high-powered view of intercellular or border pore (*B*) from boxed area in (a). (c) A high-powered view of intracellular pore (*I*) and artifactual pore (*A*). Arrows in (b) point out cellular margins to demonstrate that ''B'' pore is intersected on each edge. From Ethier, C. R., Coloma, F. M., Sit, A. J., and Johnson, M. (1998). Two pore types in the inner wall endothelium of Schlemm's canal. *Investigative Ophthalmology and Visual Science* 39: 2041–2048. The Association for Research in Vision and Ophthalmology.

Driven by a pressure gradient, fluid flow across the inner wall of SC often creates structures that have been named giant vacuoles (**Figure 3**). Dimensions of giant vacuoles are 1–10 μm in width, 1–7 μm in height, and sometimes extending to 20 μm in length. Such significant morphological structures are not an intracellular compartment, but instead outpouchings of cells into its lumen caused by the pressure drop across the inner wall. In fact, the size and density of giant vacuoles positively correlate with IOP. Interestingly, vacuoles appear to be concentrated near collector channel ostia, suggesting that the pressure drop at these locations is greater; consistent with studies showing preferential flow patterns near collector channel ostia.

At the site of these outpouchings, the inner wall is very attenuated and thin; where the endothelial cells are most distended, unique pores appear to form. Inner wall pores usually range in size from 0.1 to 3 μm with an average diameter of about 1 μm. The majority (about 75%) of pores is transcellular and the minority is paracellular, located at the border of neighboring cells (**Figures 4(b)** and **4(c)**). For transcellular pores, the inner and outer plasma membranes of SC endothelial cells appear to have come together and fused, making membrane-limited openings (similar to fenestrae). While primarily found associated with giant vacuoles, pores are occasionally found on flat, thin portions of the inner wall; perhaps artifacts of fixation. Indeed, the original estimates of inner wall pores (2000 pores mm^{-2}) have been revised to less than 1000 pores mm^{-2} due to new methods that mark active pores and reveal that only a portion carries fluid into the canal lumen. These recent data are consistent with two previous studies showing that aqueous humor must pass through pores to access the SC lumen because: (1) tracer particles up to 1 μm in size pass freely through the conventional outflow pathway to enter SC and (2) the inner wall has an unusually high measured hydraulic conductivity compared to other endothelia. Potentially relevant to the pathology of glaucoma, fewer pores are observed in the inner wall in those with glaucoma compared to age-matched control eyes.

After passing through the inner wall endothelium, aqueous humor enters the SC lumen. In cross section, the canal's shape is that of a highly elongated ellipse with a diameter along its long axis that ranges between 190 and 350 μm. Often (about 40% of the time), SC divides into more than one lumen (**Figure 2**). Throughout the canal, but especially near collector channels, are septa that bridge between the inner and outer walls of the canal.

The proximity of these structures to collector channel ostia suggests that they prevent collapse of the canal lumen and subsequent occlusion of collector channel ostia that may occur at elevated IOP.

Once inside of the canal, aqueous humor travels circumferentially around the eye until reaching one of 20–30 collector channel ostia (tens of microns in diameter) that open from the outer wall of SC (**Figure 2**). Collector channels transport aqueous humor to the eye surface and the episcleral venous system through two parallel pathways: one pathway leads through an anastomotic system of intrascleral plexus and the other is a more direct pathway through a set of aqueous veins.

Mechanical Environment

The mechanical environment of SC is unique. In addition to the basal-to-apical pressure gradient, the inner wall endothelial cells are exposed to shear forces as aqueous humor travels circumferentially on its way to exit the canal lumen and enter a collector channel. The magnitude of shear force applied to SC endothelia is influenced by the separation of the inner wall from the outer wall. This separation, or canal height, is dependent upon IOP, which at higher levels progressively collapses the SC as conventional outflow tissues pressed exteriorly, toward the outer wall (**Figure 3**).

IOP varies with time and activity. Two recurring physiological factors that affect IOP, and thus the microenvironment of the inner wall endothelial cells, are ocular pulsations and circadian IOP cycles. Aqueous humor secretion is not constant throughout the day. Instead, it has a sinusoidal behavior where the maximum rate is found at night ($\sim$3.4 µl min^{-1}) and the minimum is in the morning ($\sim$1.5 µl min^{-1}). These circadian oscillations in secretion contribute to consequential changes in IOP that vary during the day (2–8 mmHg). Importantly, several studies observe that circadian fluctuations are often more severe in those with glaucoma or ocular hypertension. The second factor, pulsatile IOP associated with each heart beat (ocular pulse), has a magnitude of 1–4 mmHg (average is 2.7 mmHg) and a frequency of approximately 1 Hz. Such pulsations in pressure have been shown to modulate outflow resistance, presumably in the JCT–TM and/or SC.

In addition, other unavoidable everyday activities (i.e., ocular massage and squinting and/or postural variations) cause dramatic changes in IOP, often creating transient spikes in IOP that approach 100 mmHg. Interestingly, after such transient IOP elevations, IOP quickly returns to baseline levels, indicating that the conventional tissues including SC have the capacity to hold the displaced fluid without allowing it to enter the SC lumen and consequently decreasing IOP. The expansion of the JCT and inner wall into the SC lumen appears to act as a temporary reservoir.

Cell Attachments

Due to its unusual anatomy and physiology, the inner wall of SC must participate in the generation of outflow resistance (and thus IOP), provide a barrier for reflux of blood into the eye (part of the blood–aqueous barrier), accommodate the transendothelial passage of micron-sized cell debris, and stay in place in the face of a pressure gradient in the basal-to-apical direction (opposite of other vascular endothelia). To function in such a dynamic environment, SC relies on a variety of cell–cell and cell–matrix attachments.

Cell–Cell Interactions

Ultrastructural examination of the JCT under a pressure gradient shows that JCT cells have cytoplasmic processes that extend from the corneoscleral meshwork on one side to the subendothelial space/inner wall endothelium on the other, making contact on either its cell surface or basal lamina. These processes were proposed to provide an anchoring or tethering support to the inner wall to compensate for the discontinuous basement membrane underlying the inner wall endothelium and the unique direction of the pressure gradient across the endothelium. Thus, with increasing IOP, inner wall cell nuclei make a dramatical transition from a rounded into a fusiform shape tapering toward the processes, indicating the magnitude of force on the cells. The JCT cells connect the inner wall to the rest of the conventional outflow tissues, creating a mechanically continuous network for sensing, distributing, and transmitting forces. While the nature of the adhesions between JCT and SC cells is currently not known, SC–SC adhesions include gap, adherens, and occluding (tight) junctions.

Working together, tight, adherens, and gap junctions form a complex that contributes to stabilize cell–cell interactions. Electron microscopy studies demonstrate that tight junctions are continuous around the circumference of SC cells. However, inner wall tight junctions rarely branch or anastomose, forming a loose arrangement of parallel strands (<4 sealing strands). These structures appear to respond to elevated IOP by decreasing the number and/or complexity of strands. In the inner wall, tight-junction strands are transversed by maze-like pathways, which go from the basal to the apical side of the cells, and have been previously referred to as slit-pores or intrajunctional openings. Such openings are more frequent and apparent at elevated IOPs. The importance of intrajunctional openings in generating resistance to aqueous humor drainage is highlighted by effects of calcium chelators, which pull calcium from junctional complexes, resulting in junctional disassembly and associated decrease in outflow resistance. In contrast, the perfusion of human eyes with tracers such as cationic ferritin, which preferentially obstructs intrajunctional openings, increases outflow resistance.

The outer wall of SC rests on a more continuous basement membrane that is supported by sclera, is not involved in drainage of aqueous humor, and does not appear to have heterotypic cell–cell interactions (with subendothelial fibroblasts). Moreover, adhesions along the lateral borders between outer-wall cells reveal fewer junctional modifications compared to their inner wall counterparts. Hence, the mechanical and hydrodynamic environment of the inner wall compared to the outer wall is significantly different.

Cell–ECM Interactions

A complementary mechanism to secure inner wall cells to their substratum in the face of pressure differentials appears to involve tethering to the elastic fibers that originate in the ciliary muscle and extend out from the cribriform plexus through the JCT. Connecting elastic fibrils reach from the cribriform plexus into the JCT where they make contact with plaque material, basement membrane components, or inner wall cells. In fact, cell membranes of inner wall cells are densified where the elastic fibrils make contact, resembling adhesion plaques. Consistent with the idea that these fibrils support mechanical stress, the intracellular filaments of inner wall cells are often observed in the same orientation (mechanically continuous) as the connecting fibrils. The manner by which SC cells attach to elastic fibers is unknown, but is likely through integrin binding to components of elastic sheath material.

Also providing mechanical support for inner wall cells are adhesive interactions with their basement membrane; a discontinuous scaffold composed mostly of collagen I, IV, fibronectin, laminin 111, 211, and 511, and heparin sulfate proteoglycans (and to a lesser extent collagens III, V, and VI). Cell–ECM adhesions involving integrins and/or syndecans are likely involved in attaching the inner wall endothelium to the basement membrane.

The two major integrin pairs expressed by SC cells appear to be $\alpha_5\beta_1$ and $\alpha_6\beta_1$, binding fibronectin and laminin, respectively. SC also expresses $\alpha_v\beta_3$ integrin pairs, particularly in young eyes. Syndecans, particularly syndecan-3 and -4, bind collagen and fibronectin and likely participate in SC–ECM adhesion. As a potential mechanism to increase adhesion, SC cells extend finger-like processes that interdigitate into the basement membrane, anchoring the cell into the basement membrane and increasing the surface area for integrin or syndecan adhesion. Perfusion with a recombinant HepII domain of fibronectin, that includes both integrin- and syndecan-binding sites, decreases outflow resistance in human organ culture eyes. Emphasizing the importance of cell–ECM adhesion by SC, heparin-binding (HepII) domain treatment apparently separated inner wall cell linkages to elastic fibrils and their basement membrane.

Cell–Cell and Cell–ECM Adhesion Strength

To maintain the morphology and function of the outflow pathway, cell–cell and/or cell–ECM adhesions must be physically capable of supporting the loads arising from the pressure drop across these tissues. A clue as to the magnitude of the pressure gradient that the inner wall supports may be obtained by calculating the apparent strength of these various attachments.

For instance, the forces necessary to detach adherent cells from fibronectin-coated substrates typically range from 1 to 10 nN cell^{-1}, but can be as high as ~200 nN, depending upon the assay. Using the highest reported cellular adhesion strength of 200 nN and a cellular surface area for SC cells of approximately 450 μm^{-2}, the maximum pressure load that can be supported by SC is estimated to be approximately 3 mmHg. This calculation is consistent with recent data using modulus measurements of SC cells that estimates the inner wall would fail at pressure drops greater than 2.8 mmHg.

Mechanical force transmission between cells is typically mediated through cell–cell adhesions involving cadherins (as part of adherens junctions). While the strength of these adhesions is not as well characterized, it has been suggested that the strength of cadherin adhesions is similar to that of focal adhesions. If true for adhesions between inner wall cells and JCT cells, then cadherin adhesions would likely be mechanically challenged in their ability to support a significant pressure drop across the inner wall endothelium. It is unknown, however, how cell adhesion strength is affected by cell overlap and dynamic junctional remodeling, both of which are characteristic features of SC.

Since inner wall cell continuity is preserved despite IOPs of 30 mmHg or higher, it is possible that the combination of attachments that SC makes with cell neighbors and its substratum is synergistic and much stronger than those measured for other cell types *in vitro* or that only a small fraction of the total pressure drop in the aqueous outflow pathway occurs directly across the inner wall endothelium. This latter explanation is consistent with the funneling theory; predicting that, despite the inner wall pores acting to modulate resistance, the bulk of outflow resistance is generated within the JCT.

Funneling Theory

The best evidence indicates that aqueous humor crosses the endothelium of SC through micron-sized pores in an otherwise continuous and relatively impermeable endothelial monolayer. The wide pore separation distance of 20–30 μm (or greater) implies that flow must be nonuniform since the flow patterns must funnel or converge as flow approaches a pore. Since the JCT is immediately upstream of these pores, the flow patterns through the JCT must also be nonuniform (**Figure 5(a)**). The funneling theory predicts that such

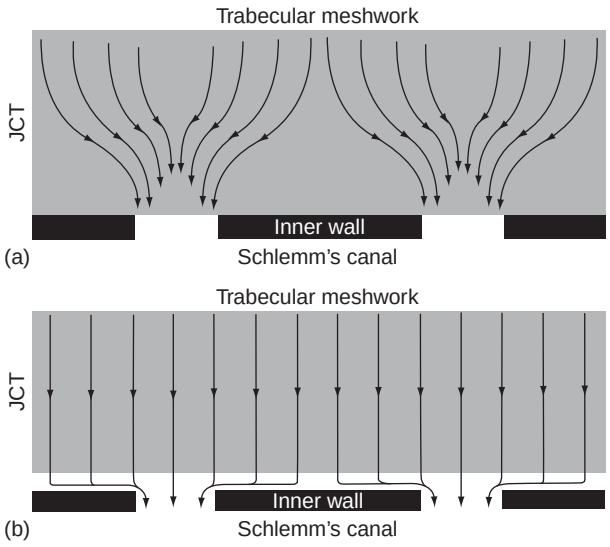

Figure 5 The streamlines of aqueous flow through the JCT across Schlemm's canal as predicted by the funneling hypothesis. (a) Shows that to enter Schlemm's canal, aqueous humor must converge onto discrete openings along the inner wall, which decreases the available area for flow and increases outflow resistance. (b) Demonstrates that treatments (such as H-7 or washout) that result in separation of the inner wall from the JCT eliminates the funneling pattern, increases the available area for flow, and increases outflow facility. Reproduced from Overby, D., Gong, H., Freddo, T., and Johnson, M. (2002). The mechanism of increasing outflow facility during washout in the bovine eye. *Investigative Ophthalmology and Visual Science* 43: 3455–3464. The Association for Research in Vision and Ophthalmology.

nonuniform flow patterns decrease the effective area available for flow through the JCT, which in turn increases the effective hydraulic resistance of this region. Modeling found that funneling increases the JCT flow resistance by a predicted 30-fold increase.

Physical evidence for funneling is found in tracer studies that observed nonuniform distribution of tracer along the inner wall. For example, a colloidal gold tracer occupied only 10–20% of the inner wall length and was found in sparse foci, consistent with funneling. Interestingly, when eyes were treated with 300 μM 1-(5-isoquinolinylsulfonyl)-2-methylpiperazine (H-7), a nonselective protein kinase inhibitor, gold particles redistributed to occupy >80% of the inner wall length in a more uniform pattern, suggesting that H-7 eliminates funneling (**Figure 5(b)**). New evidence suggests that H-7 works by separating the inner wall from underlying JCT, while connections between SC cells appear unaffected. Similar to previous studies, the change from a punctate to a uniform tracer decoration pattern and JCT expansion coincided with nearly a twofold decrease in outflow resistance, without a perceptible change in endothelial continuity. Importantly, the effects of H-7 upon outflow resistance were reversible 2.5 h after drug removal, coinciding with a return of inner wall/JCT morphology toward normal.

The importance of connectivity between JCT and inner wall cells in funneling is found with the phenomenon known as the washout effect. Washout is the progressive decrease in outflow resistance that occurs during prolonged perfusion of conventional outflow tissues of many species (e.g., bovine, porcine, canine, and monkey, but not human) with nutrient media. The name washout originated from the thought that perfusion of nutrient media was washing out ECM from the conventional outflow tissues. However, two studies that specifically examined ECM content following perfusion reveal no significant change over time. Recently, new evidence shows that washout is the result of a loss of mechanical tethering between the inner wall endothelium and the JCT. Similar to H-7 effects, perfusion of conventional outflow tissues physically separates the inner wall and JCT, apparently eliminating funneling (**Figure 5(b)**). By stopping perfusion and allowing SC and JCT to reestablish connections, washout can be reversed during a time frame too short to resynthesize and replace ECM materials. Taken with H-7 data, it appears that the relationship between the JCT–TM and SC is essential to facilitate funneling and create resistance.

Concluding Remarks

SC, and in particular its inner wall, has evolved unique features that enable it to function (1) to assist in the pressure-dependent regulation of IOP; (2) as a capacitor to accommodate transient spikes in IOP due to everyday activities; (3) in maintaining the blood–aqueous barrier; (4) to transport micron-sized cell debris/cells into canal lumen; and (5) as part of the venous system to return aqueous humor to the general circulation. Thus, to accommodate these diverse physiological responsibilities the inner wall endothelia have adapted features not found in other vascular endothelia. Therefore, while SC is continuous tight endothelia similar to other endothelia, its inner aspects sit on a discontinuous basal lamina and endure a pressure gradient and associated fluid flow in the basal-to-apical direction unlike its brethren. To fasten the inner wall in place, cells are anchored in spots by attachments to its discontinuous basement membrane and tethered by both elastic fibrils (that originate in the ciliary muscle) and cell processes from underlying JCT cells (anchored to cribiform plates). As cells lift off from their basement membrane and form giant vacuoles in response to transient or constant pressure gradient/waves, pressure relieving and regulating pores dynamically form and disappear to facilitate a relatively stable, pressurized ocular environment. Taken together, SC is defined by its unique name, morphology, physiology, and biological responsibilities.

The Circadian Clock in the Retina Regulates Rod and Cone Pathways

S C Mangel and C P Ribelayga, The Ohio State University College of Medicine, Columbus, OH, USA

Glossary

Circadian clock – A type of self-sustained molecular oscillator with a period of approximately 24 h.
Dopamine – The main retinal catecholamine produced by a type of amacrine or interplexiform cell. Dopamine activates D_1 and D_2 receptors and plays key roles in light-adaptive processes and in the effects of the retinal clock. Most of the effects of retinal dopamine are through volume transmission; thus, dopamine acts as a neurohormone in the retina.
Electrical conductance – A measure of how easily electrical current flows along a certain path that has a difference in voltage or potential.
Entrainment of a circadian clock – Altering the phase of a circadian oscillator due to the presence of environmental input (e.g., light/dark, temperature) generally in the early or late night.
Ganglion cell – The output neuron of the retina that sends its axon to other parts of the brain.
Gap junction – A type of electrical synapse that is comprised of intercellular channels that directly connect the cytoplasm of two cells and facilitate the cell-to-cell passage of ions and small molecules.
Horizontal cell – The second-order interneuron in the outer retina that regulates photoreceptor–bipolar cell synaptic activity.
Melatonin – The neurohormone produced by the retina in the photoreceptor cells and in the pineal gland and whose production is increased at night under the control of circadian clocks.
Mesopic – An adjective that describes the dim ambient light levels between the scotopic and photopic ranges, such as those observed at dawn and dusk, to which both rods and cones can respond.
Photopic – An adjective that describes the bright ambient light levels, such as those observed during a sunny day, to which cones, but not rods, can respond.
Rod (cone) pathway – The ensemble of retinal cells (circuit) that sequentially relay the electrical signals through the retina from the rods (cones) to the ganglion cells.
Scotopic – An adjective that describes the very dim ambient light levels, such as those observed during a moonless night, to which rods, but not cones, which have been separated from the retina, can respond.
Synapse – A zone of contact between two cells that allows the transmission of an electrical signal from one cell to the other. Although a synapse may be chemical or electrical (gap junction), when used alone, the term usually refers to a chemical synapse.

Introduction

Most vertebrate retinas contain both rods and cones, photoreceptor cells that detect and transduce visual images into neural signals. These neural signals are then transmitted to bipolar cells, second-order neurons that then signal ganglion cells, the output neurons of the retina (Figure 1). As we live on a planet that rotates, the ambient or background illumination during a bright sunlit day, compared to a moonless night, changes by approximately 20-billion-fold on a daily basis. The retina must be able to function effectively during this dramatic daily environmental change. At least three adaptive mechanisms are thought to have evolved in the vertebrate retina to facilitate its day/night operation. First, because isolated rods and cones, which have been dissociated from the retina, display high and low light sensitivity, respectively, it has been accepted that rods and cones function under different illumination conditions, that is, that rods mediate dim light (scotopic) vision at night and cones mediate bright light (photopic) vision during the day. Second, external environmental factors, such as the level of ambient illumination itself, can modulate the light responses of retinal neurons and alter the operating characteristics of neural networks within the retina. For example, although ganglion cells exhibit a center-surround receptive field under light-adapted conditions, such as occurs in a bright sunlit day, their receptive fields exhibit only center responses if the retina is subsequently maintained in the dark for 30–40 min, such as occurs if an animal moves from a brightly illuminated area to the shade for a prolonged period. Third, intrinsic retinal processes, such as the circadian (24-h) clock or oscillator in the retina, can also modulate the light responses of retinal neurons and alter the operating characteristics of neural networks within the retina. Although it was originally thought that the transition between day vision and night vision is a passive process driven by the intensity of ambient illumination, it is

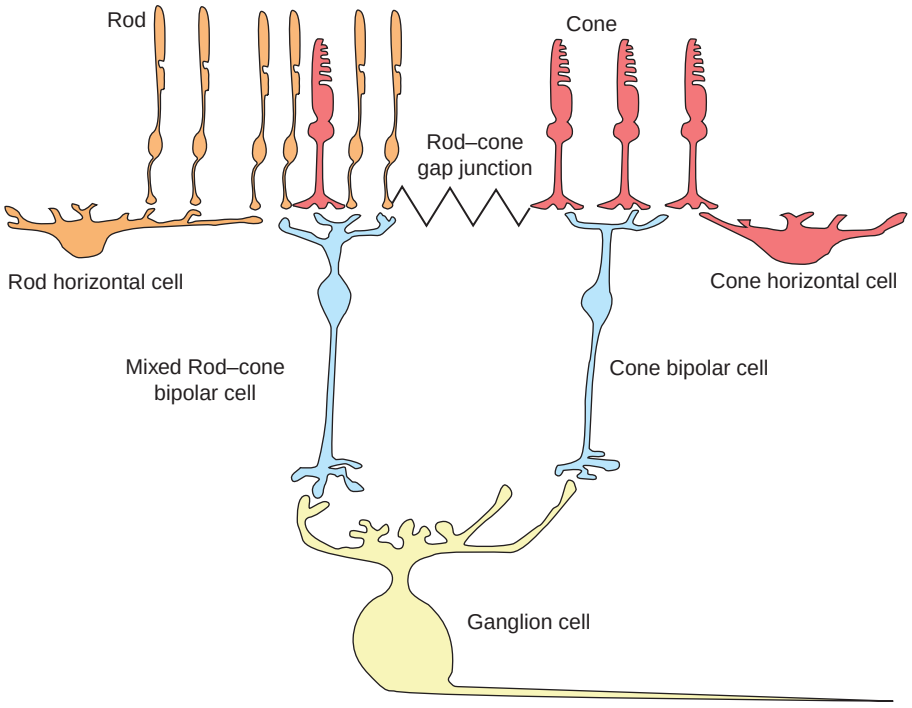

Figure 1 Rod and cone pathways in the goldfish retina. This schematic drawing shows retinal cell types and rod and cone pathways in the goldfish retina. In goldfish retina, as in all vertebrate retinas, rods and cones are anatomically connected or coupled by gap junctions, a type of electrical synapse. Both rods and cones synapse onto second-order neurons, the bipolar cells and horizontal cells, but with some degree of segregation. Mixed rod–cone bipolar cells in goldfish receive direct synaptic input from rods and cones. In the mammalian retina, a single class of rod bipolar cell makes synaptic contact exclusively with rods (not shown). In the goldfish, rod horizontal cells make synaptic contact only with rods and cone horizontal cells and cone bipolar cells make synaptic contact exclusively with cones. In goldfish, bipolar cells directly relay the photoreceptor light responses to ganglion cells, the output neurons of the retina. Individual ganglion cells in both fish and mammals can be driven by signals from both the rod and cone pathways. In mammals, however, rod bipolar cells do not directly synapse onto ganglion cells, but instead communicate rod signals to cone bipolar cells and then to ganglion cells through an interneuron, the AII amacrine cell (not shown).

now known that the retinal clock plays a key role in this mechanism.

A circadian clock is a biological oscillator that has persistent rhythmicity (i.e., a molecular process that rewinds itself) with a period of approximately 24 h under constant environmental conditions (e.g., constant darkness and temperature). Thus, day/night differences in biochemical, morphological, and physiological processes, which are observed under constant environmental conditions, can be attributed to the action of a circadian clock. In the vertebrate retina, many such day/night differences have been observed, including differences in neuronal light responses, dopamine and melatonin content and release, visual sensitivity, retinomotor movements, extracellular pH, photoreceptor disk shedding, and gene expression. A number of these day/night differences have been demonstrated to be under the control of the circadian clock in the retina, and not the circadian clocks located elsewhere in the brain (i.e., suprachiasmatic nucleus of the hypothalamus, pineal gland) or in peripheral organs (i.e., liver).

This article focuses on how the circadian clock in the retina regulates rod and cone pathways, especially concerning circadian regulation of rod–cone coupling. Our review focuses primarily on findings that have been obtained from the fish retina, because this aspect of circadian function has been most thoroughly studied in the fish. However, the available evidence suggests that the circadian mechanisms, discussed in this article, occur in the vast majority of vertebrate species, including both mammals and nonmammals. These similarities will be noted when evidence from mammalian and other nonfish species is available. Information on how the retinal clock regulates other retinal processes is dealt with elsewhere in this encyclopedia and in other recent reviews and papers, which are listed under the section, titled 'Further reading'.

Rod and Cone Pathways in the Fish Retina

As shown in Figure 1, rod signals can reach ganglion cells through at least two separate pathways in all vertebrate species that have both rods and cones. First, rod input can reach ganglion cells through cones. In both mammalian and nonmammalian retinas, rods and cones are anatomically connected or coupled by gap junctions, a type of electrical synapse at which rod input can enter the cone

circuit and thereby reach ganglion cells. Although it was thought that rod–cone electrical coupling is relatively weak, recent evidence has demonstrated that rod–cone coupling in both fish and mice is strong at night, but weak during the day due to the action of the retinal clock.

Second, rod input can reach ganglion cells through bipolar cell pathways that do not involve cones. Rods signal bipolar cells at chemical synapses in all vertebrates. In fish, these bipolar cells also receive synaptic contact from cones and, thus, are called mixed rod–cone bipolar cells (Figure 1). In contrast, in mammals, bipolar cells that receive rod input do not receive cone input. Individual ganglion cells in both fish and mammals can be driven by signals from both the rod and cone systems. In fish, mixed rod–cone bipolar cells synapse directly onto ganglion cells, whereas in mammals, rod bipolar cells do not directly synapse onto ganglion cells but instead provide indirect rod input to ganglion cells through AII amacrine cells, which then signal cone bipolar cells.

Day/Night Differences in the Light Responses of Neurons in the Fish Outer Retina

The first evidence that supported the idea that the retinal clock regulates rod and cone pathways by modulating the electrical synapses between rods and cones was obtained from electrical recordings of goldfish cone horizontal cells, second-order cells that receive synaptic contact from cones, but not from rods (Figure 1). Under dark-adapted conditions during the day, the hyperpolarizing light responses of these cells are cone driven (Figure 2). However, under dark-adapted conditions at night, the light responses of the cells are dominated by rod input. Specifically, the cells respond to light that is 100× dimmer at night, than in the day. In other words, the threshold stimulus that evokes a response is in the low scotopic range (i.e., intensities to which isolated rods, but not isolated cones, respond) at night, but in the low mesopic range (i.e., the threshold intensity of isolated cones) in the day. In addition, the light responses of dark-adapted cone horizontal cells at night, but not in the day, have a time course that is similar to that of rod horizontal cells; they are slower and of longer duration, especially to brighter light stimuli. Additional support that the cells receive rod input at night, but not in the day, was the demonstration that the L-type (or H1) cone horizontal cells, which make synaptic contact with red (long-wavelength)-sensitive cones, are most sensitive to long-wavelength stimuli during the day, but are most sensitive to middle-wavelength stimuli at night, which is typical of rods. Interestingly, the light responses of rod horizontal cells, which make synaptic contact with rods, but not with cones (Figure 1), are similar in the day and night under dark-adapted conditions (Figure 2).

The day/night differences in the light responses of cone horizontal cells described above are due to the action

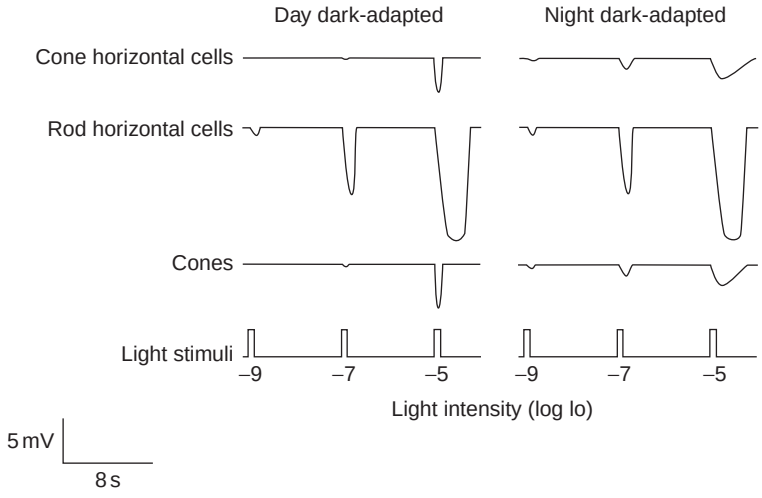

Figure 2 The light responses of goldfish cones and cone horizontal cells depend on the time of day. Schematic intensity-response series are shown for a cone horizontal cell (top trace), a rod horizontal cell (middle trace), and a cone (bottom trace) in the goldfish retina during the day under dark-adapted conditions (left column) and during the night under dark-adapted conditions (right column). At night, the rising and falling portions of the light responses of cones and cone horizontal cells are slower, response duration is longer than stimulus duration, and response threshold is approximately 2 log units lower, compared to daytime. These light-response characteristics are similar to those of rod horizontal cells (although the light responses of rod horizontal cells are larger at night), indicating the presence of significant rod input to cones and cone horizontal cells at night. In contrast, the low-threshold, slow rod-driven light responses of rod horizontal cells do not change between day and night. The light response traces were generated from the averaged response latency, time-to-peak, response duration and amplitude of the cells. Stimuli were full-field white light. Light intensity is relative to a standard (*Io*), with $Io = 2.0\,\text{mW cm}^{-2}$.

of a circadian clock, and not the result of acute dark-adaptive or other environmental effects, because similar day/night differences are observed when the fish and/or their *in vitro* retinas are maintained in constant darkness and temperature for 24–72 h. In addition, prior reversal of the 12-h light/12-h dark cycle in which the fish are maintained, reverses the day/night differences in the light responses of the cone horizontal cells. As circadian clocks can be entrained or phase-shifted by the light/dark cycle, this finding demonstrates that the observed day/night differences in the light responses of L-type cone horizontal cells are circadian in nature, and not due to day/night differences in environmental factors.

More recently, electrical recordings of the light responses of goldfish cones in the day and night, following 24–72 h of constant darkness, revealed that they are also under circadian control. Specifically, the cone light response threshold is 100× lower at night (i.e., low scotopic) than in the day (**Figure 2**). In addition, the light responses of dark-adapted cones at night, but not in the day, have a time course that is similar to that of rod horizontal cells; they are slower and of longer duration, especially to brighter light stimuli. Moreover, although recorded cones can be distinguished as either blue (short-wavelength)-sensitive, green (middle-wavelength)-sensitive, or red (long-wavelength)-sensitive during the day, all recorded cones at night are most sensitive to middle-wavelength light, and their sensitivity closely matches that of rods.

The circadian clock regulates the light responses of cones and cone horizontal cells in part through activation of the D_2 family of dopamine receptors. Dopamine receptors have been divided into the D_1 and D_2 receptor families based on their opposite effects on the level of intracellular cyclic adenosine monophosphate (cAMP) and the difference in their affinity for dopamine. D_1 receptors are approximately 500× less sensitive to dopamine than D_2 receptors, and D_1 receptor activation increases cAMP, whereas D_2 receptor activation decreases it. Substantial evidence indicates that both the D_1 and D_2 families of receptors are found in the retina and that rods and cones express D_2 receptors, whereas rod and cone horizontal cells express D_1 receptors. Moreover, the retinal clock produces a circadian rhythm in dopamine release through melatonin. Specifically, the clock increases melatonin synthesis and release at night, compared to the day. As melatonin inhibits dopamine release, a circadian rhythm in dopamine release is generated, but one in which extracellular dopamine levels are higher in the day, than at night (i.e., the dopamine and melatonin rhythms are in antiphase).

The retinal clock produces a variety of circadian rhythms in the retina, including daily rhythms in retinomotor movements and cyclic guanosine monophosphate (cGMP)-gated cationic channels in cones, by increasing dopamine levels in the day so that D_2 receptors are activated. The clock does not appear to utilize D_1 receptors, apparently because it does not increase dopamine levels sufficiently to activate the low-affinity D_1 receptors in the retina. Similarly, the retinal clock modulates the strength of rod input to cones and cone horizontal cells by increasing the activation of the D_2 receptors on rods and cones during the day. When D_2 receptor activation is minimal at night, as evidenced by the lack of effect of D_2 receptor antagonists at night, rod input dominates the light responses of cones and cone horizontal cells. In contrast, when the retinal clock activates D_2 receptors in the day, rod signals do not reach cones and cone horizontal cells, as evidenced by the finding that application of D_2 receptor antagonists during the day increases rod input to cones and cone horizontal cells. Indirect evidence based on data obtained from cone horizontal cells further suggests that the decrease in intracellular cAMP in rods and cones that is evoked by D_2 receptor activation in the day eliminates rod input to cones and cone horizontal cells. Although this idea requires further direct testing on cones, a circadian rhythm of cAMP content in retinal photoreceptors, with high levels at night, has been described in several vertebrate species.

The Circadian Clock in the Retina, and Not the Retinal Response to the Ambient Illumination, Controls Rod–Cone Coupling

The day/night differences in the strength of the rod input to cones and cone horizontal cells originate in part from changes in the conductance of rod–cone gap junctions. Following the injection of a membrane-impermeant, gap-junction-permeant, biotinylated tracer (biocytin) during the day, the tracer accumulates in the injected goldfish cone. However, when the experiment is conducted at night, the tracer diffuses to many cones and rods in the vicinity of the injected cell, consistent with an increase in the conductance of the rod–cone gap junctions. The tracer experiments demonstrate that the modulation of the rod–cone gap-junctional conductance is the primary means through which the retinal clock controls the strength of the rod signal that flows into cones and cone horizontal cells (**Figure 3**).

Consistent with the effects of the clock on the light responses of cones and cone horizontal cells described above, the clock uses dopamine to control the extent of rod–cone tracer coupling. Specifically, the clock-controlled daytime increase in dopamine decreases rod–cone tracer coupling, whereas the nighttime drop in dopamine levels is required to increase the coupling. The day/night difference in rod–cone coupling can be pharmacologically manipulated and the results are consistent with the involvement of D_2, and not D_1, dopamine receptors. Thus, by increasing dopamine release and D_2 receptor activation during the day, the retinal clock decreases rod–cone coupling and

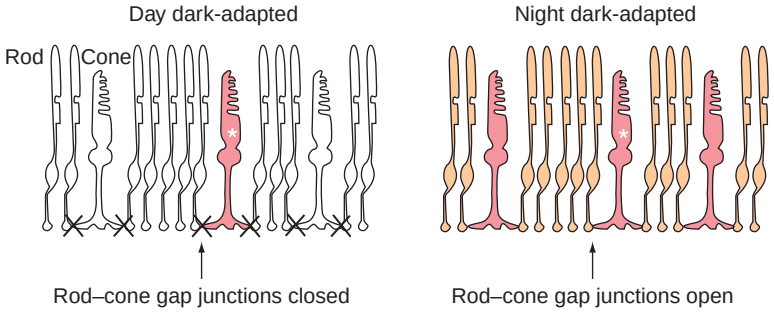

Figure 3 Day/night changes in rod–cone gap-junctional coupling. This drawing illustrates that following injection of the biotinylated tracer biocytin into a single goldfish cone (indicated by an asterisk) during the day (left panel), the tracer remains restricted to the injected cone (filled cone). In contrast, injection of biocytin into a single cone at night (right panel) leads to tracer staining of numerous rods and cones (filled cells) in the vicinity of the injected cell. Since biocytin is a membrane-impermeant molecule that can diffuse through gap junctions, these observations demonstrate that the rod–cone gap junctions are closed during the day and open at night. A similar day/night difference in rod–cone tracer coupling occurs in the mouse.

thereby decreases rod input to cones and cone horizontal cells. Conversely, the nighttime decrease in dopamine release enhances rod–cone coupling and increases rod input to cones and cone horizontal cells.

Interestingly, the effects of the clock on rod–cone tracer coupling and on cone light responses are not altered when dim background lights are present. More specifically, similar results are obtained in the day and night, with and without dopamine D_2 receptors blocked, when the intensity of the ambient illumination is very dim (i.e., low scotopic), as occurs on a moonless night, or is brighter, but still dim (i.e., mesopic), as occurs on a moonlit night. Most significantly, at night, the extent of rod–cone tracer coupling and the strength of rod input to cones and cone horizontal cells are not decreased even when the intensity of the ambient illumination is in the mesopic range. As the background light level at night normally varies between very dim starlight and dim moonlight conditions, these results indicate that the retinal clock, and not the retinal response to the normal visual environment at night, regulates rod–cone coupling. The clock decreases rod–cone coupling at dawn by increasing D_2 receptor activation and increases rod–cone coupling at dusk by reducing D_2 receptor activation.

The Circadian Clock in the Mammalian Retina Controls Rod–Cone Coupling

Although it may be thought that circadian regulation of retinal function occurs in nonmammals, and not in mammals, substantial evidence indicates that the circadian clock in the mammalian retina regulates a variety of cellular phenomena, including melatonin and dopamine production and release, neuronal activity, rod disk shedding, extracellular pH, and rod–cone coupling. Recent findings, using bath application of the gap-junction-permeant, tracer molecule neurobiotin onto mouse retinas that had been cut in pieces with a razor, indicated that neurobiotin diffused extensively through photoreceptor cell gap junctions under dark-adapted conditions at night and in the day when D_2 receptors were blocked, but diffused significantly less under dark-adapted conditions in the day. Thus, it seems likely that the retinal clock controls the strength of rod–cone coupling in most, if not all, mammalian and nonmammalian retinas that have both rods and cones. Moreover, in most vertebrate species, including mammals, the fact that (1) rods and cones are connected by gap junctions, (2) D_2 receptors are expressed by rods and cones, but not by horizontal cells, and (3) the retina contains a circadian clock supports this view. Although the clock increases the conductance of rod–cone gap junctions at night, evidence to date does not address whether at night the clock also increases the conductance of cone–cone and/or rod–rod gap junctions, which are also found in vertebrates.

A Circadian Clock Pathway in the Retina

The circadian clock in the fish retina regulates the light responses of cones and cone horizontal cells in part through a melatonin/dopamine pathway that controls rod–cone coupling (Figure 4). Specifically, the clock regulates melatonin synthesis, so that melatonin synthesis and release are kept low during the day and dramatically increased at night. Melatonin inhibits dopamine release from dopaminergic interplexiform cells, and consequently, the extracellular levels of dopamine are the lowest at night. The relief in the inhibition of dopamine release during the day generates an increase in the extracellular levels of dopamine in the day, so that the D_2 receptors on photoreceptor cells are activated, which then lowers intracellular cAMP and protein kinase A (PKA) levels in the photoreceptors, decreasing the conductance of rod–cone gap junctions. As a consequence, rod input to cones and cone horizontal cells is decreased. At night, because the clock decreases

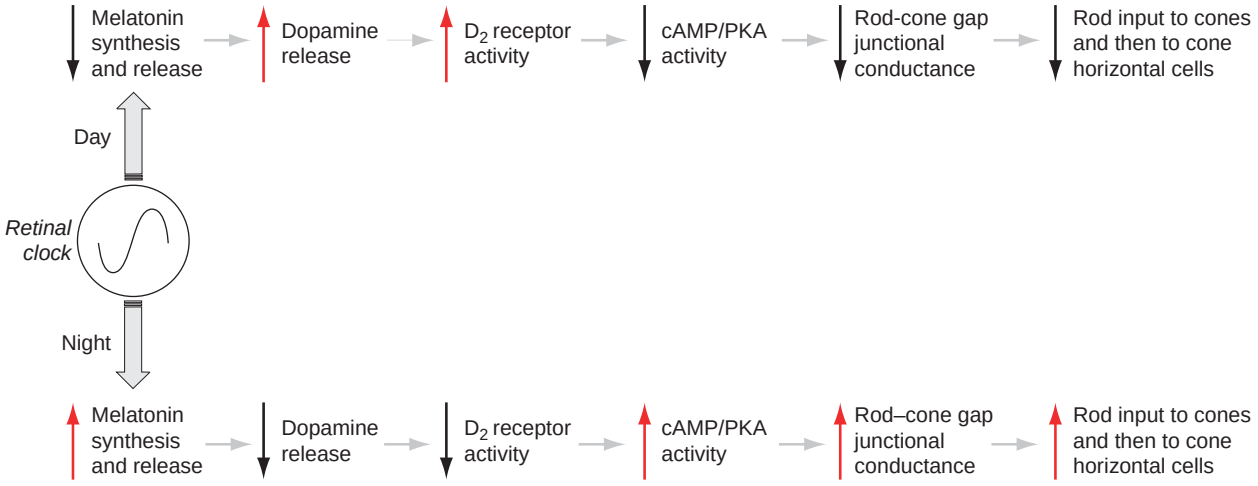

Figure 4 A retinal circadian clock pathway that controls rod–cone coupling. The circadian clock in the retina utilizes melatonin and dopamine to control rod–cone coupling. Specifically, the clock exerts transcriptional and post-translational control of melatonin synthesis, so that melatonin synthesis and release are kept low during the day and dramatically increased at night. Melatonin inhibits dopamine release and consequently extracellular levels of dopamine are the lowest at night. The relief in the inhibition of dopamine release during the day generates an increase in the extracellular levels of dopamine in the day so that the D_2 receptors on photoreceptor cells are activated, which then lowers intracellular cAMP and protein kinase A (PKA) levels in photoreceptors, decreasing the conductance of rod–cone gap junctions. As a consequence, rod input to cones and cone horizontal cells is decreased. At night, because the clock decreases dopamine levels below the threshold of D_2 receptor activation, the intracellular cAMP level in photoreceptor cells increases, raising the conductance of rod–cone gap junctions and increasing rod input to cones. As a result, rod signals are transmitted to cone horizontal cells, even though these cells do not make direct synaptic contact with rods. In the daytime and nighttime sequences of events that are illustrated, upward pointing red arrows and downward pointing black arrows indicate increases and decreases, respectively, in the events with which they are associated. Although the pathway illustrated here has been established from data collected in goldfish, accumulative evidence indicates that this pathway is likely conserved among vertebrates.

dopamine levels below the threshold of D_2 receptor activation, the intracellular cAMP level in photoreceptor cells increases, raising the conductance of rod–cone gap junctions and increasing rod input to cones. As a result, rod signals are transmitted to cone horizontal cells, even though these cells do not make direct synaptic contact with rods. Although the circadian pathway illustrated here has been established from data collected in goldfish, accumulative evidence indicates that this pathway is likely conserved among vertebrates, including mammals. However, it is still unresolved as to whether the clock in the mammalian retina increases dopamine release in the day by generating a melatonin rhythm, as occurs in nonmammals, or by direct control of dopamine metabolism in dopaminergic cells.

It is interesting to note that circadian clock pathways in the retina may be different from light-responsive and light/dark-adaptive pathways. As described above, the retinal clock, and not the retinal response to the level of ambient illumination, uses specific neurotransmitters (i.e., melatonin), neurotransmitter receptors (i.e., melatonin receptors, dopamine D_2 receptors), and synaptic processes (i.e., rod–cone gap junctions) to control the strength of rod–cone electrical coupling, These physiological processes, which participate primarily in circadian clock pathways within the retina, may be distinct from other processes that primarily respond to light stimuli, such as those that mediate bright light adaptation (i.e., D_1 receptors). In the case of dopamine receptors, this segregation of pathways may be explained by the difference in the affinity of D_1 and D_2 receptors for endogenous dopamine. Although the retinal clock increases extracellular dopamine levels sufficiently to activate the high-affinity D_2 receptors on rods and cones, the low-affinity D_1 receptors on horizontal cells are not activated, as evidenced by the absence of a day/night difference in horizontal-cell gap-junctional coupling under dark-adapted conditions. Instead, horizontal cell coupling, which is modulated by D_1 receptor activation, is decreased by bright light stimulation during the day, which increases extracellular dopamine levels sufficiently to activate the D_1 receptors on horizontal cells. Viewed from this perspective, the D_1 and D_2 receptor systems in the retina function in a complementary manner; the retinal clock activates D_2 receptors at dawn and reduces their activation at dusk, whereas bright lights activate D_1 receptors during the day. Retinal function (neurotransmitters, synapses, pathways, adaptation, etc.) may therefore arise from the interplay of both light-responsive and circadian clock pathways.

Functional Implications of Circadian Clock Control of Rod–Cone Coupling

As the retinal clock increases the strength of the electrical synapses between rods and cones at night, very dim light

signals from rods can reach cones and then cone horizontal cells at night. Thus, although individual cones that have been separated from the intact retina cannot respond to very dim light (i.e., low scotopic) stimuli, dark-adapted cones in the intact retina at night can do so because the clock opens the electrical synapse between rods and cones at night. Circadian control of rod–cone electrical coupling therefore serves as a synaptic switch for the direct introduction of rod signals to cones and cone pathways at night, but not in the day.

In addition to enabling rod signals to reach cones at night, the circadian increase in rod–cone electrical coupling may also enhance the detection of very dim, large light stimuli by the rod to bipolar cell to ganglion cell circuit. Many rods converge onto each bipolar cell, summing visual signals over a large spatial area at synapses that are highly nonlinear. Although noise in one photoreceptor cell is independent of the noise in nearby photoreceptor cells, dim, large visual objects will produce similar or correlated responses from nearby photoreceptor cells. As a result, an increase in electrical coupling between nearby photoreceptor cells will decrease photoreceptor noise more than it reduces their light responses to dim, large objects. Increased photoreceptor coupling at night will therefore augment the signal-to-noise ratio and the reliability of rod responses to dim, large stimuli before the nonlinear rod to bipolar cell synapse distorts the signal and the noise. Circadian control of rod–cone electrical coupling thus enhances the detection of very dim, large objects at night, and by decreasing rod–cone coupling at dawn, improves the detection of small objects in the day. The absence of rod signals in the cone pathways during the day facilitates the processing of high acuity and color information by the cone pathways during the day. In contrast, the increase in rod–cone coupling at night may maximize nighttime vision and tune the retina to detect large, dim objects. Moreover, circadian control of rod–cone coupling may also mediate in part the circadian rhythm in visual sensitivity that occurs in many vertebrates, including fish and human.

Finally, the nighttime increase in rod–cone coupling may influence photoreceptor survival. Specifically, the metabolic exchange of small signaling molecules and nutrients will likely occur between rods and cones each night because open gap-junctional channels are large enough to allow the diffusion of such small molecules between coupled cells. Healthy rods might improve cone survival by providing coupled cones with nutrients and protective factors at night and/or dying rods might facilitate the death of coupled cones through the diffusion of pro-apoptotic factors each night.

The Colorful Visual World of Butterflies

F D Frentiu, University of Queensland, St. Lucia, QLD, Australia

Glossary

Gene duplication – Duplication of a region of DNA containing a gene, thought to be one of the most powerful evolutionary mechanisms for diversification.
Filtering pigment – Molecules present in photoreceptor cells that act as spectral filters by absorbing particular wavelengths of light.
λ_{max} – Wavelength of peak spectral absorbance of a visual pigment, measured in nm.
Neofunctionalization – The origin of a new gene function by mutation.
Phylogeny – A description of the evolutionary relationships among species inferred to have descended from a common ancestor.
Positive selection – Process through which advantageous mutations increase in frequency in a population.
Visual pigment – An opsin protein bound to a light-sensitive molecule, the chromophore, which is derived from retinal.

Introduction

Butterflies are some of the most colorful animals on the planet. The diversity of their wing colors and patterns has not only inspired human artistic expression but it has also made these animals prominent study systems in biology. For example, butterflies have become leading model animals for the study of evolution and development, particularly of how wings are patterned. Equally, our understanding of defensive signaling is based largely on butterflies, for example, mimicry in *Heliconius* species where two butterflies unpalatable to predators resemble one another in color and pattern. Butterflies also play an important ecologic and economic role by pollinating flowers and orchard crops, where they utilize vision among other senses to find sources of nectar. Understanding vision in butterflies therefore gives us a fascinating insight into how these animals might see their surroundings, their own wing colors, and may also inform us on their patterns of habitat use and pollination.

So what do butterflies see? Can they see in color and if so, how do they use color vision? Here, what we currently know about color vision in the butterflies within an evolutionary context has been reviewed. First, this article provides an overview of the butterfly group and its evolutionary history. Subsequently, a mechanistic account of how the structure of the butterfly eye makes color vision possible is provided, paying particular attention to the molecular basis of the visual pigments that enable this type of vision to occur. Next, is discussed the evolutionary processes that have led to a diversification of the visual systems present in this group that is unparalleled in other insects. Finally, the ecological significance of color vision in the butterflies is explored.

The Butterflies and Their Evolutionary History

The butterflies (Rhopalocera) are a charismatic group of insects that includes an estimated 15 000 species. This is a recently evolved group within the order Lepidoptera, which includes the moths. The Rhopalocera comprises the true day-flying butterflies (Papilionoidea), the skippers (Hesperioidea), and a newly identified group of nocturnal butterflies (Hedyloidea) (**Figure 1**). Within the true butterflies (Papilionoidea), which are the subject of most studies, five families are recognized. The families are: the Papilionidae (including the swallowtails and birdwings), the Pieridae (including the whites and sulfurs), the Lycaenidae (the blues and coppers), the Nymphalidae (the brush-footed butterflies, including the famous monarch, the morphos, and frittilaries), and the Riodinidae (the metalmarks) (**Figure 1**).

The butterflies are thought to have originated on the ancient continent of Gondwana during the Cretaceous period, sometime prior to the extinction of dinosaurs at the Cretaceous–Tertiary (K/T) boundary and possibly concurrent with the radiation of the flowering plants. However, the paucity of fossil butterflies has led to scientific disagreement as to the exact date of when butterflies first appeared, with estimates of their age ranging from 150 to 70 Ma. New molecular approaches are helping resolve some of these controversies. Molecular phylogenies (i.e., reconstructions of the lineages of species using DNA sequence data) have indicated that the Nymphalidae and the Pieridae families were probably present at the K/T boundary, around 65 Ma, and in the case of the Pieriae, may date to 100 Ma. Definitive resolution of the age of the butterflies and timing of divergence of the major families, however, awaits the development of additional molecular markers.

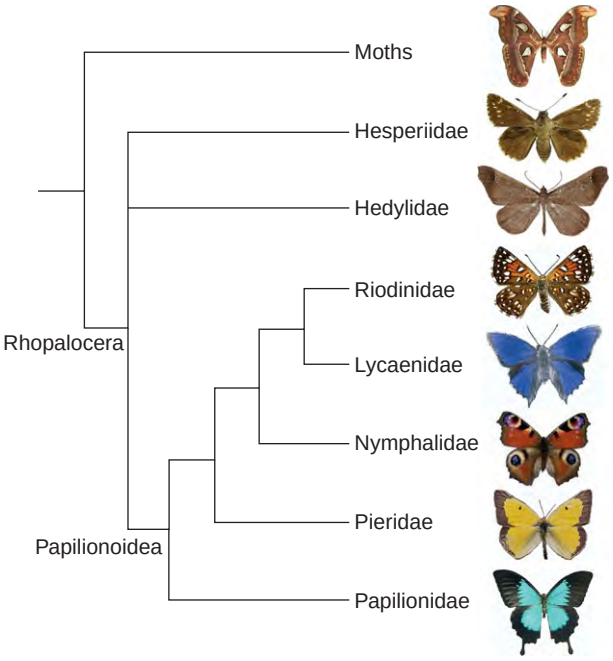

Figure 1 Evolutionary relationships of the major lineages in the Rhopalocera.

Color Vision and the Butterfly Eye

Most organisms detect light through the presence of photosensitive molecules located in specialized organs, such as eyes. However, only arthropods (the phylum that includes insects, spiders, and crustaceans) and vertebrates have developed eyes capable of true color vision. Color vision is the ability to discriminate between two visual stimuli based on their wavelength regardless of their relative intensities. Color vision also requires the presence of at least two photoreceptors with overlapping spectral ranges so that the same point in space can be compared.

Despite the observations that butterflies use colored flowers as food sources and that they employ color-based signaling via their wings, it was only relatively recently that color vision was demonstrated in butterflies using behavioral tests. *Papilio* butterflies were trained to associate rewards containing sucrose with particular colors. When butterflies were behaviorally tested, a majority of animals chose colors previously associated with food rewards among an array of colors regardless of their intensity.

Butterflies, like other insects, have compound eyes that contain thousands of units called ommatidia (**Figure 2(a)**). In butterflies, each ommatidium contains nine photoreceptor cells (cells R1 to R9) (**Figure 2(b)**), that is, cells that possess light-sensitive visual pigments that make color vision possible. The cell membranes of the photoreceptors are folded into microvilli (cell membrane projections) that form the rhabdomeres. The rhabdomeres

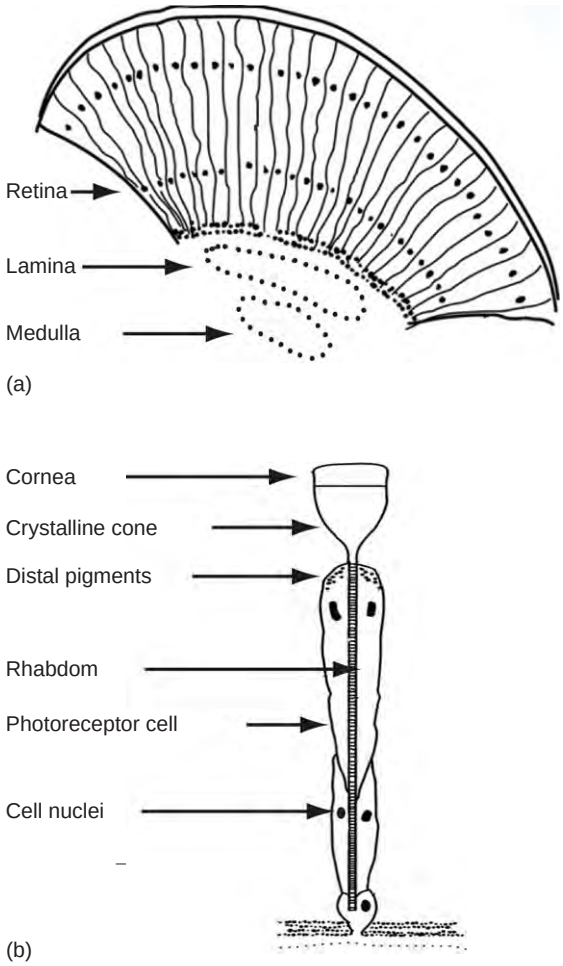

Figure 2 Schematic diagram of the butterfly compound eye. (a) Diagram of a longitudinal section through the eye showing the numerous repeated ommatidia comprising the butterfly retina as well as non photoreceptor regions (lamina and medulla). (b) Diagram of a longitudinal cross-section of an individual ommatidium. Reproduced from Frentiu, F. D., et al. (2007). © National Academy of Sciences USA.

of one ommatidium form a cylinder (the rhabdom) that acts as an optical waveguide for light passing through (**Figure 2(b)**). Light passes through the lens and is focused by the crystalline cone onto the rhabdom. When light propagates down the rhabdom, the majority of it is absorbed by the visual pigments in the photoreceptor cell membranes. Light that is not absorbed by the visual pigments is reflected back by the tapetum, a structure that sits at the base of the ommatidium and is found in most butterflies except papilionids and the pierid genus *Anthocharis*. In addition to visual pigments, butterflies also possess filtering pigments that surround the rhabdom and act as spectral filters by absorbing wavelengths of light and shifting the peak spectral sensitivity of their photoreceptors to longer wavelengths.

Key to color vision in both arthropods and vertebrates are the visual pigments and, most importantly, the presence of at least two spectrally distinct types of visual

pigments. Neural inputs from at least two types of photoreceptor cells that bear different visual pigments are required for color discrimination. A visual pigment comprises of an opsin protein bound to a light-sensitive molecule, the chromophore (**Figure 3**) that, in butterflies, is 11-*cis*-3-hydroxyretinal. Photons reaching the chromophore cause its photoisomerization and induce a conformational change in the opsin protein. In turn this activates a guanine nucleotide-binding protein (G-protein) that initiates the phototransduction cascade that converts light into signals to the brain through a series of biochemical reactions. The eyes of invertebrates employ fundamentally different phototransduction cascades than those of vertebrates.

The absorbance spectrum of a visual pigment depends on the interaction of the chromophore with critical amino acids in the opsin protein. By itself, the chromophore has a wavelength of maximum absorption (the λ_{max} value) in the ultraviolet (UV) part of the light spectrum at approximately 380 nm. However, through the chromophore interacting with key amino acids in the binding pocket of the opsin protein, a diversity of visual pigment λ_{max} values can be achieved, a phenomenon called spectral tuning. The sensitivities of different photoreceptors to light (**Figure 4**) are determined by the opsins that they express and any associated filtering pigments they may contain. The visual pigments of butterfly species sampled to date range in λ_{max} from 340 to 600 nm (**Table 1**), although the exact opsin amino acids involved in producing this diversity remain to be elucidated.

The opsins that form the basis of visual pigments are ancient molecules that belong to the large G-protein-coupled receptor family. They have a seven transmembrane domain structure, with a diagnostic lysine residue in the seventh helix that binds to the chromophore. The opsin family predates the emergence of the major groups of animals present today. Phylogenetic reconstructions suggest that the ancestral arthropod may have been able to see in color, including in the ultraviolet. Insect ultraviolet/blue (UV/B) and blue-green opsins originated early in arthropod evolution. Distinct insect UV and B opsins then evolved via duplication of the ancestral UV/B opsin and the long wavelength (LW) opsin evolved from a duplication of the ancestral blue-green opsin. The blue-green opsin was however lost in most insects, with the exception of some flies (e.g., *Drosophila*). Insects such as bees, butterflies, and moths now possess at least three classes of visual pigment in their photoreceptors that enable them to see in the UV (UV, 300–400 nm), blue (B, 400–500 nm), and long wavelength (LW, 500–600 nm) parts of the light spectrum. However, compared to moths and bees, butterflies display an unusual diversification of their visual systems. In the following, I explore the diversification of butterfly eyes and the evolutionary processes that have produced it.

Spectral Heterogeneity of Butterfly Eyes

Although ommatidia are anatomically identical in structure, they are spectrally very heterogeneous: that is, they hold different complements of photoreceptors that express different visual pigments; different photoreceptors within an ommatidium are designated as R1-R9 and may express different pigments. Using molecular genetic techniques such as *in situ* hybridization to visualize patterns of opsin mRNA has allowed us to map the types of ommatidia present in the butterfly eye. Three types of ommatidia exist in the main retinas of butterflies, with all types of ommatidia expressing LW visual pigments but differing in the expression of the UV and B visual pigments.

The extent of spectral heterogeneity of butterfly eyes differs among the major butterfly families. For example,

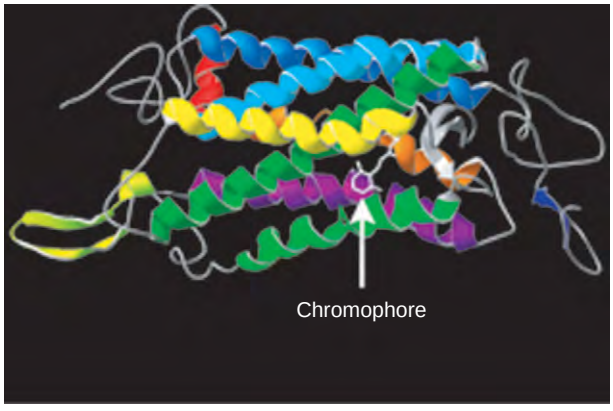

Figure 3 Three-dimensional model of a visual pigment comprising a seven-transmembrane opsin protein and a chromophore (indicated by the arrow). The seven transmembrane domains are shown in different colors. Reproduced from Frentiu, F. D., et al. (2007). © National Academy of Sciences USA.

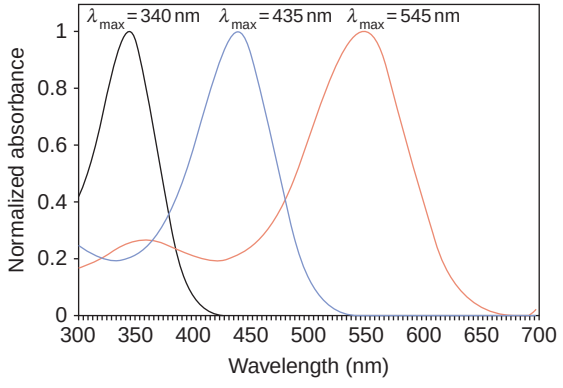

Figure 4 Normalized absorbance spectra of visual pigments in the eye of the monarch, *Danaus plexippus*. Wavelengths of peak absorbance (λ_{max}) for the three visual pigments are estimated to be 340, 435, and 545 nm. Peak absorbance values from Stalleicken et al. the eyes of Nymphalidae species are quite simple in terms of ommatidial heterogeneity. Studies of Nymphalidae species to date show that they have only three types of ommatidia in the main retina and one type in the dorsal rim area (DRA) of the eye, which is an eye region specialized for the detection of polarized skylight. All ommatidial types in the main retina express long wavelength visual pigments in their R3-R8 photoreceptor cells, but the expression of the UV and B opsins in the R1 and R2 cells is variable (the R9 cell expresses the LW opsin in the main retina and may express the UV opsin in the DRA). One ommatidial type contains one UV and one blue receptor, the second has two blue receptors, and the third has two UV receptors. In the DRA ommatidia, the R1-R8 cells express the UV opsin. This type of eye employs a straightforward, one-to-one relationship between the type of visual pigment expressed and spectral phenotype of the photoreceptor cell. It may also best represent the ancestral butterfly eye and it resembles the eyes of bees and moths.

By contrast, the eyes of other families of butterflies are much more diverse in their spectral complements. For example, the butterfly *Pieris rapae* (family Pieridae) expresses four opsins but photoreceptors with seven different peak sensitivities have been identified, due to the presence of filtering pigments. Perhaps the most spectrally diverse butterfly eye studied so far belongs to the papilionid butterfly, the Japanese swallowtail, *Papilio xuthus*. *Papilio xuthus* expresses five different opsins in the eye, has eight different types of photoreceptors, and employs tetrachromatic color vision. In these animals, both opsin gene duplications and pigments acting as spectral filters have led to spectral diversification of visual systems. Below, I consider the evolutionary mechanisms that have led to butterfly visual system diversity.

Diversification of Visual Pigments via Gene Duplication and Positive Selection

The eyes of some butterflies express a larger number of visual pigments than the three UV, B, and LW known to

be present in bees and moths. The diversity of visual pigments is primarily due to opsin gene duplications that have occurred independently in different butterfly families (**Figure 5**). Duplications of the B opsin gene have occurred independently in two of the five butterfly families: the Pieridae and the Lycanenidae, giving rise to four different visual pigments. In the Pieridae, as exemplified by the well-studied *Pieris rapae* (the cabbage white), duplicate B opsins have diversified into violet- ($\lambda_{max} = 425$ nm) and blue-absorbing ($\lambda_{max} = 453$ nm) visual pigments. In the Lycaenidae, duplication of the B opsin has also facilitated the emergence of two visual pigments. However, the peak wavelength sensitivities in species such as *Polyommatus icarus* are different from those found in the Pieridae, with one visual pigment absorbing in the blue ($\lambda_{max} = 437$ nm) and the other in the blue-green ($\lambda_{max} = 500$ nm).

Duplications of the LW opsin gene have occurred independently in three butterfly families, also leading to diversification of visual pigments. In the Papilionidae, three LW opsins are now expressed in the eye, each the result of a round of gene duplication. In *Papilio xuthus*, these duplicated opsins now encode three different visual pigments with λ_{max} values ranging from 515 to 575 nm. The LW opsin gene duplications have also occurred in two species of butterflies in the Nymphalidae and one in the Riodinidae families. In total, of more than 50 butterfly species studied to date, 7 LW opsin duplicates have been identified. The most red-shifted visual pigment known to date in the riodinid butterfly *Apodemia mormo*, with a λ_{max} of 600 nm, has resulted from a gene duplication specific to the family Riodinidae. Molecular evidence has also suggested that duplication was followed by elevated rates of amino acid evolution in one of the LW duplicates. However, not all opsin duplications have resulted in visual pigments expressed in the eye, with some expressed in the optic lobes and brain.

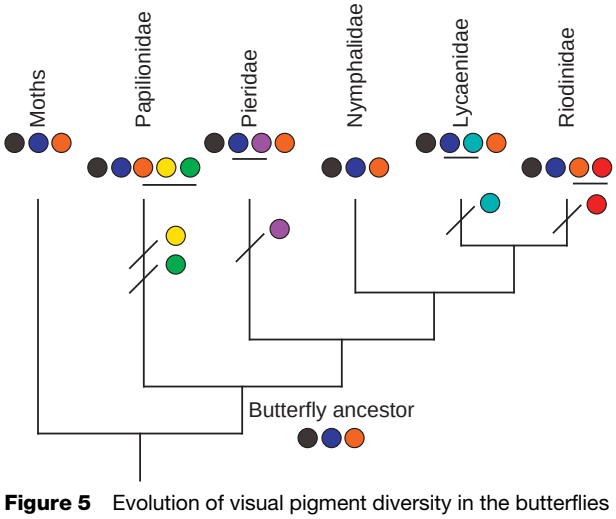

Figure 5 Evolution of visual pigment diversity in the butterflies and hypothesized complement of pigments in the ancestral butterfly eye. Circles indicate UV (gray), blue (blue), and long wavelength (orange) visual pigments. Diagonal lines along the branches of the phylogeny denote opsin duplications.

In addition to gene duplication, a mechanism that generates spectral diversity in butterflies is positive selection on single opsin genes, whereby novel mutations that enhance an organism's fitness spread through a population and may replace other genetic variants. The most striking example of this process to date comes from the North American butterfly genus *Limenitis*. Butterflies in this group have radiated across the North American continent from a European ancestor during the past 3–4 My. The genus is best known for species that display wing color pattern mimicry such as the viceroy *Limenitis archippus*, which mimics the monarch *Danaus plexippus*, and *L. arthemis astyanax*, which mimics the more toxic pipevine swallowtail *Battus philenor*. An unusual diversity in λ_{max} values of the LW visual pigment has been found in this group of butterflies, suggesting that their visual systems had diversified in tandem with wing color patterns (**Figure 6**). Reconstruction of phylogenetic relationships within the genus indicated that a shift in spectral sensitivity towards the blue part of the light spectrum had occurred (**Figure 6**). Wavelength sensitivities of LW visual pigments had diversified from an ancestral λ_{max} of 545 nm in *L. arthemis astyanax* to a λ_{max} of 515 nm in *L. archippus archippus*.

Using several molecular evolutionary analyses, the signature of positive selection was found at several amino acid sites in *Limenitis* LW opsins. The *Limenitis* opsin protein was modeled against the bovine rhodopsin crystal structure (homology modeling) in order to visualize where the amino acid sites were located. The results indicated that some of the amino acids found to be under positive selection were located in the chromophore-binding pocket, strongly suggesting that they interact with the chromophore to determine spectral sensitivities. The same amino acids were found to change in parallel in butterfly species that were distantly evolutionarily related to the *Limenitis* genus but that also showed a shift in λ_{max} in the same direction (**Figure 6**). Interestingly, one of the amino acid sites under positive selection in butterflies is evolutionarily homologous to an amino acid site in the cone opsin of humans that is responsible for a 5–7 nm shift to the blue part of the light spectrum and which is under balancing selection in New World monkeys. These findings suggest a common molecular basis for spectral shifts in insects and vertebrates, a feature that has been retained across more than 540 My of evolution. However, opsin amino acid sites suggested by molecular evolutionary analyses to be involved in the spectral tuning of butterfly visual pigments need to be tested and functionally characterized experimentally.

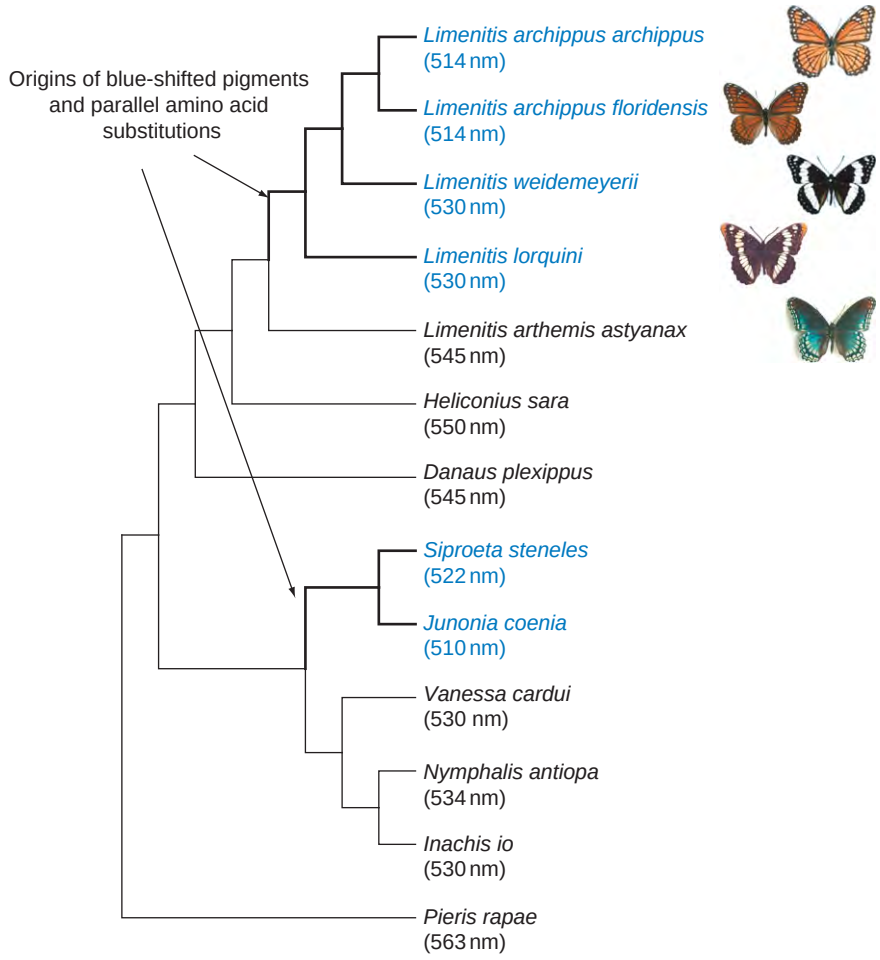

Figure 6 Diversification of wing colors and LW visual pigment spectral sensitivities in the genus *Limenitis* following colonization of North America. Blue-shifted visual pigments ($\lambda_{max} \leq 530$ nm) in evolutionarily independent lineages of butterflies in the family Nymphalidae display parallel substitutions in the opsin protein at key amino acid sites that interact with the chromophore. Diversification of Photoreceptor Types via Filtering Pigments

Some butterflies possess photoreceptor cells containing filtering pigments that coat the rhabdom (**Figure 1**), which are red, orange, and yellow in color. Filtering pigments act as spectral filters by absorbing particular wavelengths of light traveling down the rhabdom. Whilst the breadth of wavelength sensitivity of a photoreceptor is determined by the opsin it expresses, by absorbing shorter wavelengths of light, filtering pigments shift the λ_{max} of some photoreceptors towards longer wavelengths. The color discrimination abilities of butterflies in a particular wavelength range are thus enhanced by comparing neural inputs from two types of photoreceptors that express the same opsin but have differing peak spectral sensitivities (λ_{max}) due to the presence or absence of filtering pigments.

Filtering pigments play a role in the diversification of the peak spectral sensitivity of photoreceptors in the ommatidia of some butterflies. The same visual pigment, in conjunction with filtering pigments, is used to expand photoreceptor sensitivities in *Heliconius* butterflies. For example, in *Heliconius erato*, two types of LW photoreceptors express the same LW visual pigment but differ in peak spectral sensitivity as a result of the presence of a red-filtering pigment. This expanded wavelength discrimination in the LW range is used in foraging behavior. In *Pieris rapae*, filtering pigments expressed in conjunction with the same LW opsin are used to produce two additional photoreceptor types that enhance wavelength discrimination in the red part of the light spectrum, although the behavioral and ecological reasons for this pattern are unclear.

Currently very little is known about the genetic basis, molecular identity, evolution, and ecological significance of butterfly filtering pigments. Both *Pieris* and *Papilio* butterflies have lateral filtering pigments suggesting that filtering pigments are an evolutionarily old feature of the butterfly eye. Some of the pigments used in butterfly wing

colors are molecularly similar to eye pigments found in *Drosophila*, although butterflies may employ a much larger repertoire of pigments than flies. Tantalizing clues from a handful of studies suggest that, aside from diversifying photoreceptor sensitivities, filtering pigments may play a role in the co-evolution of photoreceptors and color-based mating signals. The same genes that mediate both spectral sensitivities in photoreceptors via filtering pigments may also influence the expression of wing pigments expressed in butterfly wings. However, this hypothesis remains to be tested empirically by identifying and molecularly characterizing the genes involved. Filtering pigments and their expression in the butterfly eye offer a fruitful avenue for research into the co-evolution of animal color-based signals and the ability to perceive them.

Evolution of Sexually Dimorphic Eyes: Opsin Duplications and Sex-Specific Filtering Pigment Expression

One of the most interesting aspects of butterfly vision is that some species display sexually dimorphic eyes: males and females detect different colors in the same areas of the eye. This feature appears to have evolved independently in two butterfly families, the Lycaenidae and the Pieridae, via two different mechanisms. In the North American butterfly *Lycaena rubidus* (Lycaenidae), duplication of the B opsin has facilitated the evolution of a sexually dimorphic eye. The eyes of this butterfly express four opsin genes, one UV, two B (B1 and B2), and one LW. In the dorsal part of the eye, *L. rubidus* males exclusively express the B1 opsin in the R3-R8 photoreceptors, whereas in the female both B1 and LW are expressed. The R1 and R2 cells primarily express UV opsins in this dorsal part of the eye. Therefore, duplication and neofunctionalization of the B1 domain of expression have potentially allowed the evolution of dichromatic and trichromatic color vision in this part of the eye in males and females respectively. The male *L. rubidus* may use dichromatic color vision in the dorsal part of the eye in behaviors associated with defense of its mating territory. If opsin duplication has facilitated the evolution of sexually dimorphic eyes, we may yet discover these eyes to be more prevalent in the butterflies than previously thought given how frequently such duplications have occurred in this group of insects.

In *Pieris rapae* subspecies *crucivora* (Pieridae), sexually dimorphic eyes have also been documented, however in this case mediated by the sexually differentiated expression of filtering pigments in some photoreceptors. The sexual dimorphism occurs in the violet photoreceptors of this species present in some ommatidia. In females, violet photoreceptors match their expected peak spectral sensitivity ($\lambda_{max} = 425$ nm). However, in males, the expression of a violet-absorbing filtering pigment modifies violet photoreceptors into double-peaked blue photoreceptors that have a much narrower spectral sensitivity, with a λ_{max} of 416 nm. This sexual dimorphism may aid males in discriminating the different wing colors of males and females that differ in the short wavelength part of the spectrum, but this hypothesis requires empirical testing through behavioral tests. Not all subspecies of *Pieris rapae* show sexually dimorphic filtering pigment expression, suggesting that pigment-mediated changes in spectral sensitivities may rapidly facilitate fine-tuning of visual systems according to the ecology of a particular species or subspecies.

Ecological Significance of Butterfly Visual System Diversity

Why are butterfly eyes so diverse? What are the ecological reasons for such a diversity of color vision systems? To date, however, the ecological and life history factors driving the diversity observed have been far less thoroughly investigated than the molecular basis of this pattern. No clear adaptive matching of the visual pigments to ambient light, as demonstrated in fish, has ever been found in butterflies. For example, the coelacanth lives at a depth of 200 m and only receives light at around 480 nm in wavelength. Its two visual pigment sensitivities peak at around 475 and 485 nm, suggesting adaptive matching to the light environment in this species. In cichlids, visual system spectral sensitivities also seem to match the ambient light environments of these species. In butterflies, the limited evidence available to date suggests that visual pigment diversity may be driven by the social signaling and foraging needs of the animals rather than their particular light environment.

Like many other insects, butterflies utilize vision for a whole range of tasks. They use vision to locate food sources, select suitable oviposition sites, and in intraspecific communication. *Papilio* butterflies use two of their duplicated LW opsins to see in the green part of the light spectrum when ovipositing and foraging. The lycaenid butterfly *Polyommatus icarus* uses one of the duplicate B opsins together with the LW opsin-based visual pigment to see green up to 560 nm when foraging. Importantly, opsin gene duplications resulting in the diversification of photoreceptor types have clearly impacted on the foraging behavior of butterflies.

Mate choice in many butterfly species also occurs via color-based signaling. For example, *Heliconius* butterflies appear to use both colored and polarized light for finding mates. The size of UV-reflecting eye spots on the wings seems to correlate with mating success in *Bicyclus anynana*. These observations suggest that there might be selective pressure for visual systems to evolve to detect the specific

spectral signals of wings. Correlative evidence suggests that photoreceptor sensitivities have evolved in tandem with wing coloration but empirical evidence is needed.

Conclusions

It is clear that the visual systems enabling butterflies to see in color are functionally very diverse compared to other insects, particularly their moth ancestors. Visual system diversity has been achieved primarily through opsin gene duplication, positive selection at single opsin loci, and heterogeneous expression of filtering pigments in photoreceptors. The evolutionary basis of this pattern of diversification has recently received significant attention, however the exact molecular basis of spectral tuning of butterfly visual pigments remains unknown. Butterfly visual systems offer an excellent opportunity to study the evolutionary and functional genetic links from genotype to phenotype through to behavioral and ecological consequences. To this end, further work is required to explicitly link the pattern of photoreceptor diversification in different butterflies to their ecology, behavior, and life history traits. Only then will we gain a complete understanding of the evolutionary significance of visual system diversification in these insects.

The Corneal Stroma

J L Funderburgh, University of Pittsburgh, Pittsburgh, PA, USA

Glossary

Adherens junctions – Protein complexes that occur at cell–cell junctions, involving calcium-dependent homophilic interactions of a family of transmembrane proteins called cadherins.
Connexin – Gap-junction proteins; family of structurally related transmembrane proteins that assemble to form vertebrate gap junctions. Each gap junction is composed of two hemichannels, or connexons, which are themselves each constructed out of six connexin molecules.
Corneal dystrophies – Group of disorders characterized by a noninflammatory, inherited, bilateral opacity of the cornea.
Crystallins – Water-soluble structural proteins found in the lens of the eye, accounting for the transparency of the structure.
Ectomesenchyme – It has similar properties to mesenchyme. The major difference is that ectomesenchyme arises from neural crest cells, which are a critical group of cells that form in the cranial region during early vertebrate development.
Glycan – It refers to a polysaccharide or oligosaccharide. Glycan may also be used to refer to the carbohydrate portion of a glycoconjugate, such as a glycoprotein, glycolipid, or a proteoglycan.
Glycosaminoglycans – Long, linear carbohydrate polymers that are negatively charged under physiological conditions, due to the occurrence of sulfate and uronic acid groups.
Hurler's syndrome – Known as mucopolysaccharidosis type I (MPS I), Hurler's disease, or gargoylism, this genetic disorder results in the buildup of mucopolysaccharides due to a deficiency of alpha-L iduronidase, an enzyme responsible for the degradation of mucopolysaccharides in lysosomes. Without this enzyme, a buildup of dermatan sulfate occurs in the body. Symptoms appear during childhood and early death can occur due to organ damage.
Keratan sulfate – Also called keratosulfate, it is any of several sulfated glycosaminoglycans (structural carbohydrates) found especially in the cornea, cartilage, and bone. Keratan sulfates are large, highly hydrated molecules which, in joints, can act as a cushion to absorb mechanical shock.
Keratocytes – The basic cell type found in the corneal stroma. The keratocytes are sparse in distribution, occupying less than 5–10% of the stromal volume.
Lamellae – A lamella is a thin plate-like structure, often one among many lamellae very close to one another, with open space between.
Lumican – Also known as LUM, it is a human gene. This gene encodes a member of the small, leucine-rich proteoglycan (SLRP) family that includes decorin, biglycan, fibromodulin, keratocan, epiphycan, and osteoglycin. In these molecules, the protein moiety binds collagen fibrils and the highly charged hydrophilic glycosaminoglycans regulate interfibrillar spacings. Not only is lumican the major keratan sulfate proteoglycan of the cornea, but it is also distributed in interstitial collagenous matrices throughout the body. Lumican may regulate collagen fibril organization and circumferential growth, corneal transparency, and epithelial cell migration and tissue repair.
Macular corneal dystrophy – An autosomal recessive condition, which is the least common but the most severe of the three major stromal corneal dystrophies. It is characterized by multiple, gray-white opacities that are present in the corneal stroma and that extend out into the peripheral cornea.
Mesenchyme – Loosely organized connective tissue present in the embryo regardless of origin. Viscous in consistency, mesenchyme contains collagen bundles and fibroblasts.
Myofibroblast – Cell with a phenotype between a fibroblast and a smooth muscle cell in differentiation. It can contract by using smooth muscle-type actin–myosin complex, rich in a form of actin called alpha-smooth muscle actin. These cells are then capable of speeding wound repair by contracting the edges of the wound.
Neural crest – Transient component of the ectoderm, located between the neural tube and the epidermis of an embryo during neural tube formation. Neural crest cells migrate during neurulation, an embryological event marked by neural tube closure.
Proteoglycan – Special class of glycoproteins that are heavily glycosylated. They consist of a core protein with one or more covalently attached glycosaminoglycan (GAG) chain(s).
Scheie's syndrome – Mildest form of mucopolysaccharidosis type I (MPS I) (see Hurler's syndrome).

Sutural fibers – The elasmobranch (sharks, skates, and rays) cornea resists swelling because of unique structural adaptations in the stroma called sutural fibers. These are collagen fibers running anterior-to-posterior, perpendicularly to the stromal lamellae, tying the anterior limiting lamella to Descemet's membrane.

Transforming growth factor-beta – Transforming growth factor-beta (TGF-β) is a small protein-growth factor with a broad array of functions. It controls proliferation, cellular differentiation, and other functions in most cells. It plays a role in immunity, cancer, and heart disease.

Stromal Anatomy

In humans, the cornea has a diameter of about 11.5 mm and a thickness of 0.5–0.6 mm in the center and 0.6–0.8 mm at the periphery. Almost 90% of the human cornea is composed of stroma (**Figure 1(a)**). By weight, water in the extracellular matrix makes up 65% of the stroma and cellular water 11%. This hydration is roughly similar to that of cartilage, but surprisingly, it is higher than that of bone, muscle, or adipose tissue. As discussed below, the proteoglycans of the stroma are hydrophilic and, given free access to water, the tissue will imbibe up to 10-fold its normal content of water. Thus the tissue composition, particularly its hydration, is a dynamic property.

The majority of the stroma consists of thin sheets (lamellae) of tightly packed collagen fibrils. In human corneas, there are up to 200–250 such lamellae, each about 2-μm thick. Within each lamella, the collagen fibrils run parallel to the corneal surface, parallel to one another, and regularly spaced. Ends of the fibrils are not abundant and thus fibrils extend essentially the entire width of the cornea. The lamellae are largely self-contained, but occasional bundles of fibrils extend from one lamella to another. Directional orientation of the fibril layers varies between neighboring lamellae. In the posterior stroma the fibril orientation is almost perpendicular from one layer to the next. Anteriorly, it is more oblique. This arrangement of layers of parallel rigid rods in a friable matrix is not unlike that of composite structural materials such as fiberglass or reinforced concrete. Such an arrangement gives the cornea its remarkable toughness and tensile strength.

Numerous electron micrographic studies have documented the striking regularity of the collagen in the stroma. The collagen fibrils in central stroma have a diameter of about 31 nm and the distribution of diameters is narrow, giving a remarkably homogeneous distribution of collagen within each fibril bundle. Within the fibril bundles electron-dense material, identified as proteoglycans, encase the individual fibrils and form bridges between neighboring fibrils (**Figure 1(b)**). In central stroma of normal human cornea, the proteoglycan bridges occur at highly regular intervals, and the bridging structures are of uniform lengths, about 1.8 nm. Such tight interaction between fibrils is considered to participate in generating the parallel alignment of the fibrils in each bundle and the highly regular spacing between neighboring fibrils. As discussed below, this lattice-like structure of the collagen fibrils in the central stroma is thought to be essential for corneal transparency.

The anterior portion of most corneal stromas is limited by an acellular layer of dense, irregularly organized collagen immediately subjacent to the epithelial basement membrane. This anterior limiting lamella (ALL) is also known as Bowman's layer or Bowman's membrane. In human corneas, the ALL is about 10-μm thick in the central cornea and absent in the periphery. ALL is also prominent in chickens and some other terrestrial mammals, but it is very thin or not detected in other species such as felines. Collagen fibrils in the ALL are randomly interwoven to form a dense, felt-like sheet composed primarily of collagen types I, III, and V. Collagen VII, associated with anchoring fibrils of the overlying epithelium, is also present within the ALL. The posterior of the ALL merges with the lamellar stroma via oblique fibril bundles, recently revealed using two-photon microscopy. These connecting fibers appear to serve as a stabilizing feature, anchoring the anterior lamellae to the more rigid ALL and indirectly to the epithelial basement membrane. These anterior anchoring fibers appear analogous to the well-known sutural fibers present in corneas of some species of sharks. The sutural fibers traverse the cornea perpendicular to the orientation of the lamellae and prevent the stroma from swelling when exposed to water. The oblique anterior anchoring fibrils recent identified in human corneas may provide a similar function in that studies show the swelling of human corneas in water occurs almost exclusively in central and posterior stroma. The extremely dense collagen in the ALL has prompted speculation that it may serve as a defense against bacterial or viral infection; however, little hard evidence supports such a role.

Stromal Development

The embryonic origins of the corneal stroma were detailed in a elegant study by Hay and Revel in 1969. In developing chicks, a wave of migrating neural crest cells, destined to become corneal endothelium, moves between the overlying ectoderm and the lens during early embryogenesis. Shortly thereafter, the epithelium secretes an acellular layer of matrix, termed the primary stroma, which becomes hydrated and swells before a second wave of neural crest cells move into the stroma and begins active

(B) Interaction between collagen fibrils and stromal proteoglycans. The core proteins bind fibrillar collagen at regular intervals and glycosaminoglycan chains protrude into the interfibrillar space. (C) Cultured primary bovine keratocyte with its extensive cellular processes (Green, actin; Red, vinculin).

secretion of the abundant extracellular matrix of the stroma. The orientation of collagen in the primary stroma is thought to direct formation of lamellae elaborated by the invading stromal cells. At day 14 (before hatching at day 21), the stroma undergoes dehydration in response to thyroxine, leading to thinning of the stroma and initiation of stromal transparency. Mammalian corneas show a somewhat different developmental pattern. No obvious primary stroma is present, and the endothelium and stromal cells are formed after a single influx of neural crest cells. After the endothelium is formed, neural crest cells in the stroma begin to elaborate new extracellular matrix. In mice and rabbits, cells in the stroma are mitotically active until after birth. In mice, approximately at the time of eye opening (12–14 days postnatal) a decrease in the number of stromal cells occurs along with thinning and dehydration of the stroma. Simultaneously, the cornea-specific glycosaminoglycan – keratan sulfate – appears in the stroma, the stromal cells become quiescent, stromal proteins known as corneal crystallins accumulate in keratocytes, and transparency of the cornea increases significantly. Human stroma, by contrast, matures earlier in development. Keratan sulfate and corneal transparency are observed in embryos at 10–12 weeks of gestation, and infants are born with fully transparent corneas. Despite these species-related differences, the pattern of neural

crest population of the stromal space, secretion of corneal-specific matrix components following formation of the endothelial barrier, and corneal thinning due to dehydration present a common pattern of stromal development.

Stromal Cells

Cells populating the adult stroma are known as keratocytes. Although the same term has been used for fish epidermal cells, corneal keratocytes are neural crest-derived mesenchymal cells (ectomesenchyme). In adult tissue, the keratocytes are located between collagenous lamellae, exhibiting a flattened cell body with numerous extended cellular processes (**Figure 1(c)**). Keratocytes are the population of cells responsible for deposition and maintenance of the extracellular matrix which provides strength and transparency to the cornea. This population of cells is highly interconnected via their processes with numerous junctions between neighboring cells. At sites of contact, gap junctions containing connexin 43 and adherens junctions with cadherin 11 are present. A localized stimulus, such as an epithelial scratch, activates keratocytes throughout the stroma, as indicated by uptake of the dye neutral red. Such a global response to a localized stimulus demonstrates presence of a network of active cell–cell communications maintained by interconnected keratocytes. Following maturity, keratocytes remain quiescent, almost never exhibiting mitotic nuclei or uptake of DNA precursors. Studies of keratocyte turnover in mammals find half-lives too long to estimate accurately. DNA of keratocytes in adult humans shows a high incidence of acquired chromosomal abnormalities, but that of infants and children does not. This fact suggests that keratocytes do not regularly enter the cell cycle in which DNA repair is initiated, but accumulate damage from environmental exposure to light and oxidative stresses over long periods of time. Thus, in the nonwounded cornea, keratocytes may exist for years or decades without turnover.

In spite of their quiescence, keratocytes maintain an active synthesis of the extracellular matrix. Proteoglycan secretion is maintained at a high rate throughout life. Because collagen becomes cross-linked in adult corneas, however, collagen turnover is reduced in adult keratocytes compared to that in embryonic tissue. Adult keratocytes also retain the ability to enter the cell cycle and divide. Nearly 100% of keratocytes isolated by collagenase digestion of bovine corneas enter the cell cycle when exposed to serum or mitogens. Collagenase-isolated primary keratocytes cultured in serum-free conditions maintain the keratocyte phenotype, as defined by quiescence – a dendritic morphology (**Figure 1(c)**) – and expression of high levels of cornea-specific products (**Table 1**); however, when exposed to serum or other mitogens, these cells dedifferentiate into a fibroblastic phenotype similar to that of other mesenchymal cells cultured in serum. Following short-term culture in serum, some keratocyte properties return under quiescent conditions, but after multiple passages in culture transition to the fibroblast phenotype appears to be irreversible. When cultured corneal fibroblasts are exposed to transforming growth factor-beta (TGF-β), the cells express mRNA and protein for alpha-smooth muscle actin and assume a contractile phenotype known as the myofibroblast. TGF-β also induces a range of new gene products, many associated with corneal scarring or fibrosis *in vivo*. Genes and gene products which have been identified in corneal fibrotic (scar) tissue and also as products of myofibroblasts are shown in the top rows of **Table 1**. These include cell-associated markers such as Thy-1, matrix proteins (fibronectin, SPARC, tenascin c, etc.), collagens, proteoglycan proteins (biglycan), and glycosaminoglycans. The last four entries of **Table 1** show components expressed at high levels in keratocytes which are reduced or disappear in corneal scars and are not expressed by myofibroblasts. These include corneal crystallins (such as ALDH3), the keratan sulfate proteoglycan keratocan, and the cell-surface marker CD34. As described below, the characteristic changes in collagens, crystallins, and proteoglycans occurring during keratocyte–myofibroblast transition directly impact stromal transparency. Thus, loss of transparency in extracellular matrix deposited in response to wound healing can be directly attributed to responses of the keratocytes to wounding. Smooth muscle actin-containing cells appear in healing corneas 1–2 weeks following wounding, and this appearance can be blocked with antibodies to TGF-β. This inhibition suggests that *in vivo*, as *in vitro*, TGF-β is an important inducer of fibrotic scar tissue. Several weeks following healing of corneal wounds, smooth muscle actin-containing cells are no longer seen in the wound area. It not clear, however, that the loss of smooth

Table 1 Markers of stromal fibrosis

muscle actin expression corresponds to a return to normal stromal extracellular matrix production. In fact, experimental animal studies show expression of fibrotic markers for months following wounding, and human scar tissue can persist for many decades.

In addition to keratocytes, other cell types have been observed in the stroma. Most prominent are bone marrow-derived cells. Mice in which bone marrow cells express green fluorescent proteins have about 10% of stromal cells demonstrating fluorescence. Most stromal leucocytes express the CD11b marker, but not other dendrite, granulocyte, T-cell, or NK markers, placing them in the monocyte/macrophage lineage. Following minor damage to the epithelium, the number of green inflammatory cells in the stroma increases dramatically within a few hours. These transient inflammatory cells are primarily neutrophils.

A population of stem or progenitor cells has also been identified in the corneal stroma. Transplantation of avian corneal keratocytes into the neural crest migratory pathways of early embryos showed that some of the transplanted cells changed phenotype, migrating and differentiating into a variety of neural crest-derived tissues, thus demonstrating that progenitor cell potential is maintained following stromal differentiation. In mammals, similarly, stromal cells with stem cell properties can be isolated using a variety of techniques including spheroid culture, cloning, and fluorescence-activated cell sorting. These cells exhibit multipotent differentiation, clonal growth, and expression of a number of stem-cell-associated genes. These stromal stem cells do not express characteristic keratocyte markers, but can do so under selected culture conditions or when injected into corneal stroma *in vivo*. These stromal stem cells can restore transparency to lumican null mice with stromal haze, suggesting they may be appropriate for cell-based therapy of corneal diseases. The stromal stem cells appear to reside in the anterior region of the stroma near the limbus, but it is currently unknown what specific roles they play in corneal maintenance or repair.

Transparency

The cornea is one of the few complex biological tissues with high transparency to light, and the biophysical properties which allow such transparency have been the subject of debate for decades. In most transparent tissues such as the lens, all structures have a similar index of refraction so that light is not scattered as is passes through the tissue. Birefringence studies of the cornea, however, demonstrate that the corneal collagen has an index of refraction different from the extrafibrillar matrix surrounding it, and thus should scatter light, producing an opalescent or white appearance. David Maurice proposed, in 1957, that the highly regular structure of the collagen fibrils in the stroma functioned like a crystal, producing destructive interference of scattered light, allowing nonscattered light to pass. Mathematical models by McCally, Farrell, and others supported this concept, suggesting that, as long as the collagen fibrils were small, tightly packed, and aligned, transparency was possible. The crystal-like regularity of the stromal collagen allows for analysis using classical techniques such as X-ray diffraction. In a large number of such studies, Keith Meek and collaborators have confirmed the high regularity of spacing of nearest neighbor collagen fibrils and loss of that regularity in virtually every instance in which the cornea loses transparency. These studies have confirmed stromal hydration as one of the most critical parameters in maintenance of transparency. Excess water is adsorbed by the proteoglycans between collagen fibrils, disrupting the critical spacing and eliminating the order essential for transparency. Stromal transparency is consequently a highly dynamic property, dependent both on the removal of water from the tissue by the pumping action of the endothelial layer and by the water-binding properties of the stromal proteoglycans.

Recently, a new aspect of corneal transparency has come to notice with the discovery of abundant soluble proteins in keratocytes and other cellular tissues of the cornea. These proteins, termed corneal crystallins, are typically enzymes with housekeeping functions present in corneal cells at concentrations vastly exceeding that in other tissues. This group of proteins includes isoforms of aldehyde dehydrogenase (ALDH), transketolase, and up to a dozen or more unrelated enzymes. The variety of proteins involved and their unusual abundance has led to the suggestion that – like lens crystallins – these proteins serve to alter the refractive index of cells, thus reducing light scatter by corneal cells. Studies by Jester and coworkers have shown light scatter by keratocytes correlates with abundance of corneal crystallins in these cells, supporting a role for crystallins in stromal transparency.

Stromal Extracellular Matrix

Collagens are the most abundant proteins in the cornea, and most of the collagen in the stroma is involved in the collagen fibrils of the lamellae. Studies by Birk and coworkers have shown that fibrils in the stroma are heterotypic, containing both types I and V collagens in the same fibril. The triple-helical domain of the type V collagen molecules is buried within the fibril with its NH2-terminal domains exposed at the fibril surface. These exposed domains alter lateral association of collagen molecules during fibrillogenesis and, therefore, limit fibril diameter. The abundance of collagen type V is a likely factor in the small diameter of the stromal fibrils compared to fibrils in dermis and sclera, which contain mostly collagen types I and III. In corneal scarring and

haze, collagen type III is elevated in the stroma suggesting a direct correlation between the abundance of the small type I and V fibrils and corneal transparency.

Type XII collagen is found associated at regular intervals with stromal fibrillar collagen. The long form of this fibril-associated (FACIT) collagen can be modified with chondroitin sulfate, making it also a fibril-associated proteoglycan. Mice expressing a truncated form of type XII show altered collagen fibril spacing in the stroma. In addition to fibrillar collagen, stroma is very rich in type VI – a nonfibrillar collagen. This protein interacts with cells and numerous components of the stroma forming a beaded network throughout the stroma. Type VI microfibrils can be visualized running perpendicularly to the fibrils in lamellae and may help stabilize the lamellar structure. Numerous other collagen types have also been identified in the stroma in small amounts. Type IV collagens, often associated with basement membrane, are seen in the stroma to be associated with keratocytes. One of these, alpha3(IV) is downregulated as keratocytes become activated by wound healing or mitogens, and thus serves as a marker of keratocyte phenotype.

Proteoglycans are the second most abundant component of the corneal stroma. The corneal proteoglycans all belong to the small leucine-rich proteoglycan (SLRP) family, consisting of proteins of about 40 kDa, decorated with several N-linked oligosaccharides and one to two glycosaminoglycan chains. Normal adult stroma has one proteoglycan protein, decorin, which is modified with dermatan sulfate and three more SLRP proteins– lumican, keratocan, and osteoglycin (mimecan) – which have keratan sulfate chains. During healing, a fifth SLRP protein, biglycan, is detected in the stroma. Biglycan joins decorin as a second dermatan sulfate-containing proteoglycan in scar tissue. These SLRP proteoglycans contain multiple leucine repeat regions (LRR) – motifs involved in protein–protein binding. Each of the stromal proteoglycans binds collagen in a repeating pattern along the length of the fibrils with the keratan sulfate-containing SLRP's binding sites different from that of decorin. X-ray studies and molecular modeling reveal that SLRP proteins fold into compact horseshoe-shapes with the glycosylation on the convex portion of the curve and the collagen-binding region on the inner face. Thus, proteoglycan association with collagen produces glycosaminoglycan chains protruding from the fibril with a 'bottle brush' like appearance, as documented by deep freeze etch electron microscopy (**Figure 1(b)**). The interactions between proteoglycan and collagen has an effect on the rate and size of the fibrils formed during fibrillogenesis, effecting the diameter and length of the collagen fibrils, and thus the physical properties of the tissue. Decorin-knockout mice thus have weakened skin, whereas lumican-knockout mice exhibit large and heterogeneous collagen fibrils in the posterior corneal stroma leading to corneal haze. These *in vivo* models confirm the importance of the SLRP proteins in maintenance of the stromal ultrastructure required for vision. In addition to structural roles, the SLRP proteins interact directly with cells and growth factors. Decorin activates the EGF receptor on cell surfaces and also binds to and inactivates TGF-β, leading to reduced fibrosis in experimental models. Lumican stimulates attachment of macrophages and also has been shown to stimulate the healing of corneal epithelial wounds. Lumican-knockout mice show reduced responsivness to lipopolysaccharide-induced septic shock, and poor induction of proinflammatory cytokines. Lumican core protein also binds the CXC-Chemokine KC (CXCL1) and thus regulates neutrophilic infiltration. The SLRP proteins, therefore, clearly play important roles in mediating the response of the stroma to injury and inflammation.

The glycosaminoglycan chains (glycans) – decorating SLRP proteins – constitute about half of the molecular weight of the proteoglycans. Because of their high level of sulfation, these glycans are hydrophilic, providing the impetus for influx of water into the stroma against which the endothelium provides an active pump. Dermatan sulfate is a widespread and abundant glycan which, in the cornea, is less highly sulfated than in skin or sclera. Keratan sulfate, while detectable in many tissues, is present in abundance only in cartilage and cornea. In addition, only in the cornea are lumican, keratocan, and mimecan glycanated with keratan sulfate, making the stromal keratan sulfate proteoglycans an abundant, structurally unique, tissue-specific class of matrix molecules. Keratan sulfate binds water differently than dermatan sulfate, and it is clear that the ratio of these glycosaminoglycans in the stroma is important for stromal transparency. In genetic diseases such as Scheie's and Hurler's syndromes, dermatan sulfate cannot be degraded and accumulates in the cornea. In such cases, intense corneal opacity occurs early in life. In macular corneal dystrophy, keratan sulfate is not properly sulfated. In this disease, the cornea loses transparency in the second decade of life. It is notable that, in scar tissue, keratan sulfate is absent or greatly reduced, whereas dermatan sulfate is more abundant and highly sulfated. It is thought that such long-term differences in the glycosaminoglycan content of scar tissue contributes to light scattering as a result of differential water binding by the two types of glycosaminoglycan.

Biosynthesis of glycosaminoglycans is controlled differently from that of the proteins to which they are attached. For example, TGF-β treatment of keratocytes *in vitro* causes little change in lumican or decorin secretion; however, keratan sulfate modifying the lumican becomes dramatically shorter and virtually unsulfated during this treatment and dermatan sulfate modifying the decorin becomes longer and much more highly sulfated. These changes in glycanation can have dramatic effects on the properties of the proteoglycan. Lumican with short, unsulfated glycan chains serves as an

attachment substratum for macrophages and stimulates cell migration. Lumican modified with highly sulfated keratan sulfate, on the other hand, is antiadhesive and serves as a barrier for migrating cells. Thus the state of the glycan chains of the SLRP proteins serves not only to regulate water binding, but also other biological properties of the molecules. Modification of synthesis of the glycosaminoglycan is complex and not yet fully understood. Initiation, elongation, and sulfation of dermatan sulfate requires the participation of up to 16 different glycosyltransferase and sulfotransferase enzymes. For keratan sulfate, not all of participating enzymes are known as yet. One important gene has been clearly identified, however. CHST6 codes for a cornea-specific keratan sulfotransferase. This enzyme is mutated or nonfunctional in macular corneal dystrophy, leading to undersulfation of keratan sulfate.

In healing wounds and fibrotic corneas, not only are keratan sulfate and dermatan sulfate altered but another glycosaminoglycan, hyaluronan (HA), is present. This glycan, not present in normal corneal tissue, appears rapidly in the stroma in most pathological conditions and remains for many months following healing. The hyaluronan biosynthetic enzyme HAS2 is upregulated in keratocytes in response to mitogens and TGF-β. Mice lacking HAS2 in the stroma do not express HA in response to induced inflammation, demonstrating that upregulation of HAS2 mRNA in the keratocytes is the source of HA during stromal pathology. Hyaluronan is a simple, unsulfated, acidic polysaccharide but is known to exhibit a large number of biological activities. It is associated with cell motility, inflammation, and with metastatic potential of cancer cells. In culture, knockdown of HAS2 mRNA reduces keratocyte ability to respond to TGF-β with fibrotic matrix components. These results suggest that HA might represent an extracellular signal that mediates scarring in the stroma.

A final class of matrix components important to stromal function are the noncollagenous matrix proteins. Some of these are listed in **Table 1**. Another member of this group is protein BIGH3 (TGF-β-inducible gene H3). This secreted protein interacts with collagen and contains an RGD amino-acid sequence. It promotes cell attachment and in a number of systems the BIGH3 protein inhibits cell growth and motility. In the cornea, it has been shown that mutations in the gene coding for this protein (TGFBI) lead to a variety of corneal dystrophies presenting as opaque deposits in the stroma, usually in adults. Some of the specific syndromes caused by BIGH3 are granular dystrophy, Groenouw type I, Reis–Bucklers, lattice dystrophy type I, and Avellino dystrophy. The discovery that a minor component of the stromal extracellular matrix leads to marked disruption of vision attests to the complex biophysical equation involved in maintenance of stromal transparency. There are likely to be more important components of this system yet to be discovered.

Conclusion

The corneal stroma is a physically tough tissue with the remarkable property of transparency to light. Stromal transparency is essential for vision, and corneal scarring obscures vision for millions of individuals worldwide. Although we have gained an understanding of how stromal fibrosis disrupts vision, we do not yet understand how this process might be reversed biologically. An important challenge for the future is to employ our understanding of stromal biology to design pharmaceutical or cell-based treatments to reverse the scarring process and restore the complex balance of cells, molecules, and water in order to provide vision for those affected by corneal blindness.

Glossary

Actomyosin – The contractile cytoskeletal system, consisting of actin and myosin that, together with additional regulatory components, constitutes a force-generating system in muscle and nonmuscle cells.
Adherens junctions – The cell–cell adhesion sites (commonly referred to as: junctions) that are associated with the actin cytoskeleton, via cadherin receptors.
ATP – Adenosine 5′-triphosphate (ATP) is a multifunctional nucleotide that is most important as a molecular currency of intracellular energy transfer. In the context of this article, ATP plays a major role in cytoskeletal contraction.
Cytoskeleton – The internal network of fibers present within the cell's cytoplasm, composed largely of actin filaments, intermediate filaments, and microtubules.
Focal adhesions – Also known as focal contacts, these are specific types of large, membrane-bound macromolecular assemblies through which cells attach to the extracellular matrix (ECM). They are associated with the actin cytoskeleton, and their adhesion to the ECM is mediated by integrin receptors.
Glaucoma – A group of eye diseases characterized by a specific loss of the retinal nerve fiber layer, excavation of the optic disk, and visual-field deficits, typically caused by an intolerance to elevated or even normal intraocular pressure, and potentially leading to blindness.
Phosphorylation – The addition of a phosphate group to an organic molecule, thereby affecting the biological properties of the phosphorylated molecule. For example, phosphorylation of protein molecules (by enzymes, known as protein kinases) can affect their overall structure, interactions with other molecules, and biological activity.
Polymerization – A chemical process whereby individual components (defined as monomers) interact with each other, forming a stable molecular chain.
Schlemm's canal – A circular endothelium-lined channel that is located in the front of the eye internal to the limbus. It collects aqueous humor from the anterior chamber and drains it into the general circulation.
Trabecular meshwork – An area of tissue composed of arrays of collagen beams covered by endothelial-like cells with ECM occupying the spaces. It is located in the angle of the anterior chamber internal to Schlemm's canal and allows aqueous humor to drain into Schlemm's canal from the anterior chamber.

Actomyosin System in the Trabecular Outflow Route

Aqueous humor enters the posterior chamber of the eye from the ciliary processes, flows around the lens and through the pupil into the anterior chamber, and leaves the eye primarily through the trabecular route and the uveoscleral route at the anterior chamber angle. The trabecular route is the predominant outflow pathway in human eyes and consists of the trabecular meshwork (TM) and Schlemm's canal. The TM is composed of arrays of collagen beams covered by endothelial-like cells, with loose extracellular matrix (ECM) occupying the spaces between the cells of the adjacent beams. The outermost, juxtacanalicular (JCT) or cribriform region has no collagenous beams, but rather several cell layers immersed in a loose web of ECM fibrils. The adjacent Schlemm's canal is a continuous endothelium-lined channel that drains aqueous humor to the general venous circulation. TM structure and experimental flow studies suggest that flow resistance is maximal in the JCT region and/or the inner wall of Schlemm's canal, although the exact location of the major resistance barrier is not clear. Glaucoma is an ophthalmologic disorder responsible for visual impairment. Generally, glaucoma is characterized by progressive optic neuropathy usually associated with elevated or intolerable intraocular pressure (IOP), consequent to abnormally high flow resistance in the TM. Since glaucomatous eyes exhibit fewer TM cells and abnormally appearing JCT ECM compared to the eyes of age-matched normal individuals, cells and ECM in the JCT region may be critical in resistance regulation. In the last two decades, dynamics of the actin cytoskeleton in TM/Schlemm's canal cells have been confirmed to play important roles in the regulation of aqueous humor outflow.

*An adaptation and extension of Tian, B., Gabelt, B. T., Geiger, B., and Kaufman, P. L. (2009). The role of the actomyosin system in regulating trabecular fluid outflow. *Experimental Eye Research* 88: 713–717. Copyright Elsevier (2008).

The actomyosin system, composed of actin microfilaments and associated proteins, is one of the three major systems (the actomyosin system, the microtubule system, and the intermediate filament system) of the cytoskeleton. Microfilaments assemble within cells into complex bundles or three-dimensional meshworks located subjacent to the plasma membrane, and attach to the plasma membrane at a variety of sites, including adherens cell–cell junctions and focal adhesions, through specific receptors, namely cadherins and integrins, respectively. This link is mediated through a network of anchor proteins and additional structural and signaling molecules. The actomyosin system is present in essentially all cells, including TM and Schlemm's canal cells. Microfilament-based structures, such as adherens cell–cell junctions, focal contacts, and microfilament bundles, are highly organized in the cells along the trabecular outflow pathway (**Figure 1**). Intact microfilament bundles in TM/Schlemm's canal cells are essential to maintain physiological contractility of the JCT–Schlemm's canal region. Conversely, a physiologically contracted state of the JCT–Schlemm's canal region is required to maintain the microfilament-related structures in the outflow pathway. Microfilaments are involved in a variety of cellular processes from cell adhesion and motility to organelle trafficking to adhesion-mediated signal transduction. Therefore, microfilament dynamics play important roles in cellular morphogenesis, such as changes in cell shape, volume, contractility, and adhesion to neighboring cells and to the ECM. These changes in TM and/or Schlemm's canal cells, which could affect trabecular outflow resistance by altering the dimensions or direction of flow pathways, the amount and composition of the ECM, and the structures of adherens cell–cell junctions and focal adhesions, can be modulated directly by actin-disrupting agents or indirectly by inhibition of specific protein kinase(s) or cellular contractility through administration of protein kinase inhibitors or gene therapies. In addition, since the three cytoskeleton systems function in concert, changes in the microtubule system or intermediate filament system can also induce radical changes in the actomyosin system itself.

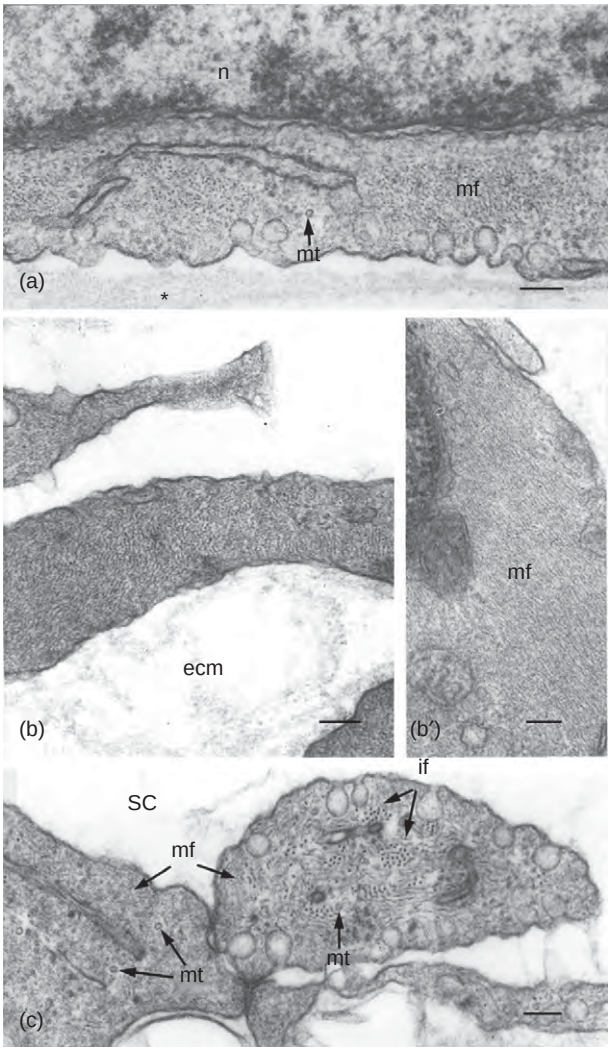

Figure 1 Transmission electron microscopy showing abundance of cytoskeletal filaments in different cellular compartments of the trabecular outflow pathway in a monkey eye. (a) Ventral aspect of a TM cell, which interacts with underlying collagen beam (*) through many focal-adhesion-like structures, is highly enriched with cytoskeletal filaments, including actin-rich microfilaments (mf) and microtubules (mt); n, nucleus. (b, b′) Juxtacanalicular cells displaying numerous microfilaments (mf), seen in cross section (b) or longitudinal (b′) section; ECM, extracellular matrix. (C) Inner-wall endothelial cells of Schlemm's canal (SC), displaying numerous intermediate filaments, organized in discrete bundles (if). Microtubules (mt) are also present. Microfilaments (mf) are usually seen in the cortical cytoplasm and near cell–cell junctions. Magnification = 0.1 μm. from Tian, B., Geiger, B., Epstein, D. L., and Kaufman, P. L. (2000). Cytoskeletal involvement in the regulation of aqueous humor outflow. *Investigative Ophthalmology and Visual Science* 41: 619–623. Reprinted with permission of ARVO.

Trabecular Outflow Enhancement Following Actomyosin Inhibition

Disruption of Microfilaments

The actin microfilament (filamentous actin; F-actin), which is the major component of the actomyosin system, is composed of many G-actin (globular actin) monomers. Pharmacological disruption of microfilaments in TM and Schlemm's canal cells alters the cell shape, inhibits cellular contractility, affects adhesions of cell–cell and cell-ECM, and in turn decreases outflow resistance in the trabecular outflow pathway.

Cytochalasins

Cytochalasins are fungal metabolites that interfere with the polymerization process by which G-actin aggregates into F-actin. Anterior chamber infusion of microgram to milligram doses of cytochalasins B or D, in live monkey

eyes and/or organ cultures of enucleated postmortem human eyes, cause distension of the cribriform meshwork, separation of its cells, and ruptures of the inner-wall endothelium of Schlemm's canal, leading to washout of ECM and significant increases in trabecular outflow facility. This is completely independent of ciliary muscle contraction, because the effect persists in the ciliary muscle-disinserted live monkey eye and in the cultured human anterior segment in which the ciliary muscle is not functionally interacting with the TM. Subthreshold doses of cytochalasin B and the trabecular outflow enhancer H-7 (see below) significantly increased outflow facility in living monkeys, indicating that the pathways by which the two drugs reduce aqueous humor outflow resistance converge at some point presumably involving deterioration of actin microfilaments in TM/Schlemm's canal cells. *In vitro* studies with cultured human and monkey trabecular cells confirm the alteration of cell shape and, with human cells grown on filters, the increased hydraulic conductivity.

Latrunculins

Latrunculins, which are macrolides produced by the marine sponge *Negombata magnifica*, are specific and potent actin-disrupting agents. They sequester monomeric G-actin, leading to massive disassembly of the polymeric form, namely F-actin. The addition of latrunculin A or B causes destruction of microfilament bundles and associated proteins in a wide variety of cultured cells, including human TM cells. This effect is manifested by cell rounding and retraction of the lamellipodium, and is accompanied by an apparent arborization of the cells. In living monkey eyes or organ cultures of enucleated porcine or postmortem human eyes, latrunculin A or B induces major increases in outflow facility and/or decreases IOP. Morphological studies indicate that the latrunculin-B-induced decrease in outflow resistance is associated with microfilament-disruption-related structural changes in the TM. Electron microscopy of the live monkey eye has revealed substantial ballooning of the JCT region following latrunculin B treatment, leading to a substantial expansion of the space between the inner wall of Schlemm's canal and the trabecular collagen beams without observable separations between inner-wall cells (**Figure 2**). In postmortem human eyes, the facility increase is accompanied by increased openings between inner-wall cells (more border or paracellular pores) with only very modest rarefaction of the JCT tissue and separation of the inner wall of Schlemm's canal from JCT tissue.

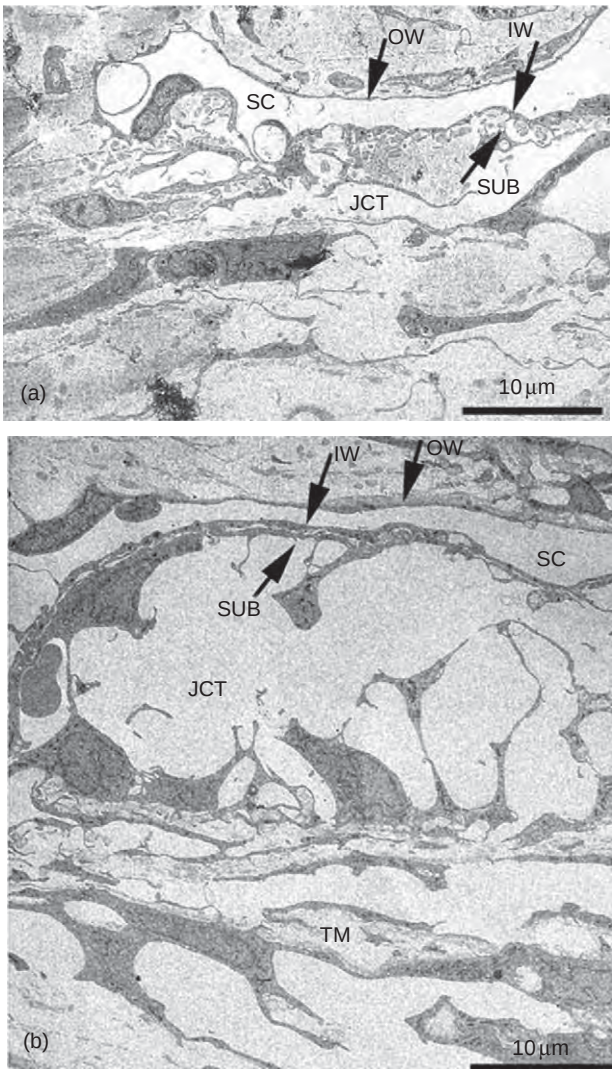

Figure 2 Transmission electron microscopy of the trabecular meshwork (TM) of a monkey eye following vehicle or LAT-B treatment: (a) shows normal JCT region and its circumjacent structures (vehicle-treated eye); (b) indicates the massive ballooning of the JCT region and the retention of close contact between IW and SUB (LAT-B-treated eye). IW, inner wall; JCT, juxtacanalicular region; OW, outer wall; SC, Schlemm's canal; SUB, subcanalicular cells. Modified from Sabanay, I., Tian, B., Gabelt, B. T., Geiger, B., and Kaufman, P. L. (2006). Latrunculin B effects on trabecular meshwork and corneal endothelial morphology in monkeys. *Experimental Eye Research* 82: 236–246. Copyright Elsevier.

Swinholide A

Unlike latrunculins, swinholide A, another marine macrolide, severs microfilaments but stabilizes the dimeric form. However, swinholide A significantly increases outflow facility in living monkeys similar to latrunculins. Since swinholide A decreases the level of F-actin without significantly increasing the concentration of G-actin, its positive effect on outflow facility further indicates that microfilament depolymerization or consequent disorganization of the actomyosin system in the TM/Schlemm's canal, and not the increase in G-actin concentration, is the major mechanism responsible for the latrunculin-induced increase in outflow facility.

TM Contractility Inhibition

Muscle and nonmuscle cellular contraction is associated with Ca^{2+}-dependent activation of myosin light-chain kinase (MLCK) and consequently phosphorylation of the regulatory myosin light chain. This phosphorylation, and consequent contraction, can be greatly enhanced by G-protein-mediated activation, in which the small G protein known as Rho activates a protein kinase, namely Rho kinase (ROCK). Rho, as well as other G proteins, including Rac and Cdc42 (signaling proteins that are activated by guanosine triphosphate (GTP), thereby regulating the activity of different partner proteins which, in turn, regulate the organization of the actin cytoskeleton) play key roles in the regulation of cellular contraction. Rho-activated Rho kinase triggers myosin II activity by inhibiting myosin light-chain phosphatase as well as by phosphorylating the myosin II regulatory light chain. Myosin II is the major cytoskeletal protein that drives the assembly of contractile bundles of actin and myosin, known as stress fibers in nonmuscle cells and is responsible for the generation of cellular tension. The TM possesses smooth-muscle-like properties and the actomyosin system in TM cells plays a key role in its contraction. Expression of nonmuscle myosin IIA and IIB has been confirmed in human TM cells, suggesting that myosin II activity is also involved in the actomyosin-driven TM contractility. Pharmacological inhibition of TM contractility enhances trabecular outflow facility in living animals and cultured anterior segments of enucleated animal or human eyes.

Broad specificity protein kinase inhibitors (H-7)

H-7, a broad spectrum serine–threonine kinase inhibitor, dramatically inhibits actomyosin-driven contractility. This leads to cellular relaxation, deterioration of the microfilaments and perturbation of their membrane anchorage, and loss of stress fibers and focal contacts in many types of cultured cells. H-7 increases outflow facility and decreases IOP in living monkeys and/or organ cultures of enucleated porcine, monkey, or postmortem human eyes, similar to actin disruptors. Morphological studies in the live monkey eye indicate that the H-7-induced increase in outflow facility is associated with cellular relaxation and drainage-surface expansion of the TM and Schlemm's canal, accompanied by loss of ECM. The inner-wall cells of Schlemm's canal become highly extended, yet cell–cell junctions are maintained (**Figure 3**). The morphological changes in the TM of live monkey eyes are consistent with functional changes in isolated bovine TM strips, where the TM precontracted by carbachol was relaxed by H-7. In postmortem cultured anterior segments of human eyes, H-7 causes a partial loss of the endothelial lining of Schlemm's canal.

The specific target kinases affected by H-7 are not well defined, because H-7 inhibits multiple protein kinases, including MLCK, Rho kinase, and protein kinase C (PKC). Studies have confirmed that the nonselective PKC inhibitor staurosporine, the specific PKC inhibitors chelerythrine and GF109203X, and the specific MLCK inhibitor ML-7 similarly increase outflow facility in living monkeys or cultured porcine anterior segments.

Rho-kinase inhibitors (Y-27632, Y39983, HA-1077, H-1152, and INS117548)

Inhibition of Rho kinase may play a key role in regulating trabecular outflow. A specific Rho kinase inhibitor, Y-27632, induces reversible changes in cell shape and decreases in actin stress fibers, focal adhesions, and protein phosphotyrosine staining in human TM cells and Schlemm's canal cells. In isolated bovine TM strips, Y-27632 completely blocks Ca^{2+}-independent phorbol myristate acetate or endothelin-1-induced contraction. As expected, Y-27632 and other Rho kinase inhibitors (such as Y-39983, HA-1077, H-1152, and INS117548) increase outflow facility and/or decrease IOP in living rabbits, rats, monkeys, and/or enucleated porcine eyes, similar to H-7. A recent morphological study in bovine eyes indicates that, with

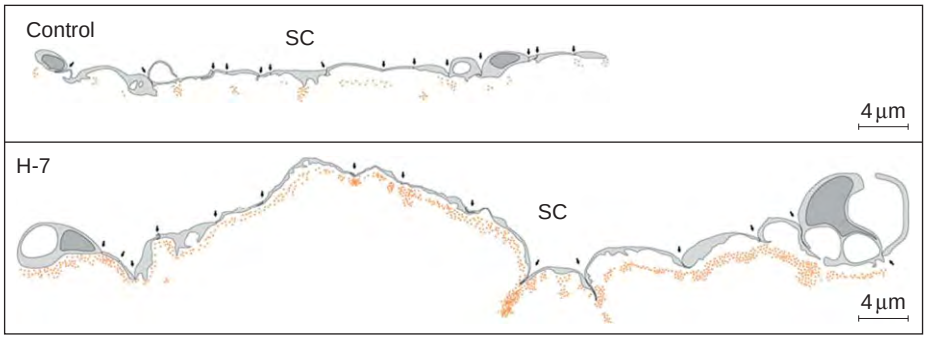

Figure 3 Schematic drawing depicting 15-cell stretches (cell–cell junctions marked by arrows) along Schlemm's canal (SC) and distributions of perfused gold particles that crossed the juxtacanalicular area of control and H-7-treated monkey eyes. Location of individual gold particles represented by red dots. Modified from Sabanay, I., Gabelt, B. T., Tian, B., Kaufman, P. L., and Geiger, B. (2000). H-7 effects on the structure and fluid conductance of monkey trabecular meshwork. *Archives of Ophthalmology* 118: 955–962, with permission from American Medical Association.

Y-27632, the inner wall of Schlemm's canal and the JCT connective tissue are significantly distended compared to control eyes, with discernible separation between the inner wall and JCT connective tissue (**Figure 4**). The average percent effective filtration length of the inner wall of Schlemm's canal (filtration length/total length × 100) is threefold larger in Y-27632-treated eyes than in controls. A significant positive correlation is found between the average percent effective filtration length of the inner wall and the average percent separation length (separation length/total length × 100, where separation length is the length exhibiting separations between the JCT connective tissue and inner wall), suggesting that the structural correlate to the increase in outflow facility after Y-27632 is physical separation between the JCT connective tissue and the inner wall of Schlemm's canal. The Y-27632-induced TM structural changes are consistent with those induced by latrunculin B or H-7, further indicating that cellular relaxation and drainage surface expansion in the TM are likely the key mechanisms by which cytoskeletal agents increase outflow facility. Recently, a ROKβ/ROCK-I and ROKα/ROCK-II inhibitor, INS117548, was confirmed to induce a dose-dependent decrease in the number of stress fibers, focal adhesion size, and numbers in HeLaJW cells. INS117548 also significantly lowered IOP in living monkeys. Since prolonged, acute exposure of formulated INS117548 produced no observable effects on the ocular surface at nearly threefold of a minimally effective IOP-lowering dose, INS117548 could be a potential efficacious and well-tolerated IOP-lowering agent for glaucoma therapy.

Myosin II inhibitors (blebbistatin)

Blebbistatin is a highly specific inhibitor of myosin II that inhibits both the adenosine triphosphatase (ATPase) and gliding motility activities of myosin II without inhibiting MLCK. It does not affect ATP binding or hydrolysis, but instead binds to the myosin–ADP–Pi complex, interfering with phosphate release, keeping myosin in an actin-detached state and preventing actomyosin interaction.

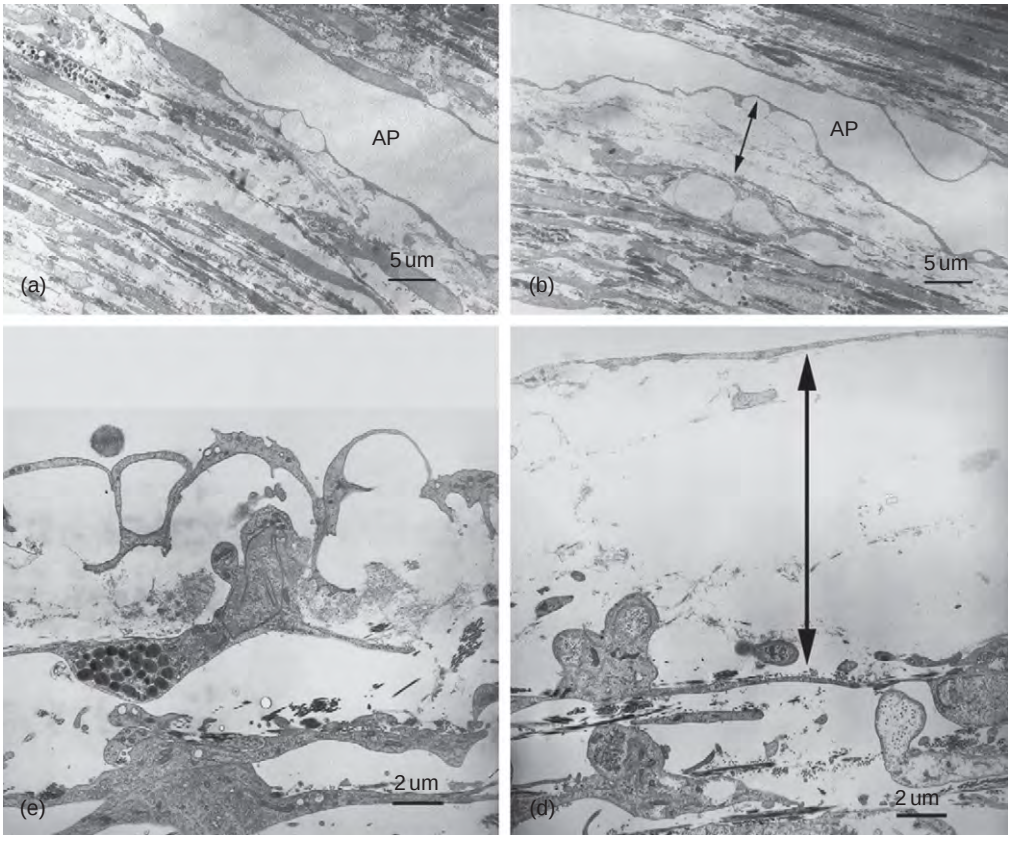

Figure 4 Electron microscopic analysis of the trabecular meshwork of bovine eyes. (a) In a control eye, the inner wall of Schlemm's canal and JCT tissue were more in contact with underlying structures, the JCT tissue appeared compact and without separation between the inner wall and JCT tissue. (b) In a Y-27632-treated-eye, the inner wall appeared distended, the JCT tissue was loose with significant separation between the inner wall and JCT tissue (double arrow). (c) In areas without separation, the connection between the inner wall and JCT cells and between the inner wall and JCT matrix were maintained. (d) In separated areas, the connection between the inner wall and JCT cells and between the inner wall and JCT matrix were lost (double arrow). Modified from Lu, Z., Overby, D. R., Scott, P. A., Freddo, T. F., and Gong, H. (2008). The mechanism of increasing outflow facility by rho-kinase inhibition with Y-27632 in bovine eyes. *Experimental Eye Research* 86: 271–281. Copyright Elsevier.

Confluent cultures of primary porcine TM cells treated with blebbistatin in the presence of serum have revealed dose-dependent changes in cell morphology, decreases in actin stress fibers, and in focal contacts and cell–cell adherens junctions. Perfusion of anterior segments of enucleated porcine eyes with blebbistatin significantly increases outflow facility. The effects of blebbistatin on TM cell morphology and actomyosin cytoskeletal organization are consistent with the effects of the inhibitors of Rho kinase, PKC, and MLCK on TM cells. However, unlike these inhibitors, which mediate their effects by inhibiting myosin II activity through decreased MLC phosphorylation, blebbistatin mediates its effects without affecting the phosphorylation status of MLC in TM cells, confirming its specificity to myosin II ATPase activity. Since the integrity of the inner wall of aqueous plexi in blebbistatin-perfused porcine eyes is intact, and the TM cell morphology after the drug appears to be similar to that noted in vehicle-treated eyes, observable structural deterioration in the TM may not be the main mechanism for the drug-induced increase in outflow facility, but rather the cellular relaxation of the trabecular outflow pathway following blebbistatin may be involved.

Actomyosin-Modulating Gene Therapy

Modulating proteins that negatively regulate actin–myosin interactions can also induce TM relaxation. Caldesmon is such a protein, whose function is the regulation of actomyosin contractility. When caldesmon is overexpressed, actin becomes uncoupled from myosin, which can affect both actomyosin-driven contractility and actin polymerization. In addition, exoenzyme C3 transferase may also affect actin–myosin interactions. Rho GTPases are the preferred intracellular targets of exoenzyme C3 transferase. The latter specifically inhibits Rho-GTP at the beginning of the Rho activation cascade, thereby blocking the whole Rho cascade. Adenovirus-delivered exoenzyme C3 transferase (C3-toxin) complementary DNA (cDNA) and nonmuscle caldesmon cDNA have been successfully expressed in cultured human TM cells. Perfusions in organ-cultured human or monkey eyes following overexpression of these genes have shown significant increases in outflow facility. Specific inhibition of Rho-kinase activity in the TM by dominant-negative Rho expression also increases outflow facility in organ-cultured anterior segments of postmortem human eyes. All these suggest that, similar to pharmacological approaches, gene therapies may also inhibit actomyosin system in the TM and in turn increase trabecular outflow facility through blocking the Rho activation pathway and overexpressing modulating proteins.

Microtubule Inhibition

The microtubule system consists of microtubules and associated proteins. Similar to microfilaments, microtubules are also highly organized in cells of the trabecular outflow route (**Figure 1**). They are not intrinsically contractile, but are important for directional cell motility and driven by specific microtubule motor proteins for cytoplasmic trafficking of vesicles and organelles. Associated proteins that bind to microtubules can affect the latter's stability and potentially attach the latter to other cytoskeletal filaments (e.g., microfilaments). Microtubule function could affect outflow pathway events through direct cellular mechanical effects (e.g., tensegrity), influences on ECM or cell membrane turnover (through vesicle movement), or through secondary signaling (e.g., leading to activation of the actin cytoskeleton).

Ethacrynic acid, known to be a potent microtubule inhibitor, reduces outflow resistance in enucleated calf and human eyes and in living monkey eyes, and concomitantly reduces IOP in live rabbit, monkey, and human eyes. Although ethacrynic acid primarily inhibits microtubule assembly, it also induces a rapid decrease in phosphotyrosine levels of focal adhesion kinase and a more subtle decrease in paxillin phosphorylation. Dephosphorylation of these proteins disrupts signaling pathways that normally maintain the stability of the actin microfilaments and cellular adhesions, and consequently induces the onset of retraction, stress fiber disruption, or complete disruption of focal adhesions. This indicates a close relationship between the microtubule system and the actomyosin system. Several new derivatives of ethacrynic acid significantly decrease IOP in cats and monkeys. These derivatives are more potent than ethacrynic acid in terms of inducing cell-shape alterations and decreasing actin stress fibers in human TM cells, suggesting that microtubule disruption may reduce outflow resistance at least partially through perturbation of the actomyosin system.

Significance of Actomyosin Inhibition in Glaucoma Therapy

Glaucoma is one of the most common causes of irreversible blindness in the world. At present, the only effective approach available to treat glaucoma is to reduce IOP. Pharmacologically reducing IOP is usually the first choice in glaucoma therapy. Medications used clinically to decrease IOP include aqueous humor secretory inhibitors (e.g., beta-adrenergic receptor antagonists, alpha2-adrenergic agonists, and carbonic anhydrase inhibitors), uveoscleral-outflow enhancers (e.g., prostaglandin analogs), cholinergic drugs that affect trabecular outflow indirectly by contracting the ciliary muscle and deforming the TM, and epinephrine drugs that work on both the TM (inducing changes in cell shape through a beta-adrenergic receptor-cyclic adenosine monophosphate (cAMP)/PKA-mediated cellular relaxation) and the uveoscleral (mediating endogenously synthesized prostaglandins) outflow routes. Secretory

suppression may affect supplies of oxygen and nutrients to the nonvascularized cornea, lens, and TM. Prostaglandin analogs do not substantially improve trabecular outflow. Cholinergic drug effects on the pupil and accommodation limit their clinical use. Epinephrine-like drugs are no longer used clinically because of their local and systemic side effects. Thus, there are no TM-selective outflow enhancers in current clinical use.

Since evidence has shown, as discussed in this article, that cytoskeletal agents or relevant gene therapies decrease outflow resistance by a mechanism directly related to the TM/Schlemm's canal, pharmacological or genetic perturbation of the actomyosin system in the TM may have potential to open a new avenue in glaucoma treatment. However, although cytoskeletal drugs effectively increase outflow facility and decrease IOP, they could, in principle, have detrimental effects on other anterior segment tissues, especially the cornea. Lower drug concentrations in larger volumes could minimize corneal toxicity without significantly sacrificing the drug's effect on the TM following topical administration. However, the potential cornea toxicity is still an obstacle to the use of higher concentrations of the drugs topically for a greater outflow facility increase. To overcome this problem, novel methods of drug delivery need to be developed. Receptors might be different in different cell types or ECM; therefore, a better understanding of the biomolecular differences between cornea and TM, the different molecular targets or mechanisms for different actin-disrupting agents, and a pro-drug, gene therapy or other site-activated approach, could facilitate the development of TM-selective drugs that reduce outflow resistance without affecting other ocular tissues.

Acknowledgments

This study was supported by grants from the US National Eye Institute (EY002698 and EY016665), Research to Prevent Blindness, the Wisconsin Alumni Research Foundation, and the Ocular Physiology Research and Education Foundation. BG is the incumbent of the E. Neter Chair in Cell and Tumor Biology.

The authors would also like to disclose here that the University of Wisconsin and the Weizmann Institute of Science hold a patent related to cytoskeletal compounds, (latrunculins and H-7), and that patent has been licensed by Inspire Pharmaceuticals; accordingly, Drs. Kaufman (UW) and Geiger (WIS) have a proprietary interest. Additionally, Inspire conducts research in Dr. Geiger's and Dr. Kaufman's laboratories, and both Dr. Kaufman and Dr. Geiger serve as advisors/consultants to Inspire. Inspire also provides unrestricted support for research in Dr. Kaufman's laboratory.

The Development of the Aqueous Humor Outflow Pathway

E R Tamm, University of Regensburg, Regensburg, Germany

Glossary

Corectopia – Distorted or displaced pupils.
Mesenchyme – An embryonic connective tissue that usually derives from the mesoderm. Only in the cranial region, mesenchyme derives from the neural crest.
Neural crest – Originates from the ectoderm and is located between the neural tube and the surface ectoderm. Neural crest cells migrate extensively during development and give rise to multiple cell types. Cranial neural crest cells largely contribute to the ocular mesenchyme.
Polycoria – Extra holes in the iris.
Transcription factor – A protein that binds to DNA, and controls the transcription of genetic information from DNA to RNA.

Anterior Eye Development

Eye development begins when the two optic vesicles appear as lateral outgrowths of the prosencephalon (forebrain). Both vesicles grow and get into contact with the cells of the adjacent surface ectoderm that respond by forming a local thickening which is called lens placode. Upon contact with the lens placode, the distal part of the optic vesicle is invaginated into its proximal part, and the optic vesicle converts into a double-layered optic cup. The neural retina derives from the inner layer of the optic cup, while the retinal pigmented epithelium differentiates from the outer layer. In a parallel process, the lens placode enlarges and deepens to form the lens pit. The lens pit subsequently forms the lens vesicle, which remains in contact with the surface epithelium with the help of the lens stalk. Finally, the lens stalk detaches from the surface epithelium, and the lens vesicle invaginates into the optic cup (**Figure 1(a)**).

Ocular Mesenchyme and Development of the Chamber Angle

In the human eye, ocular mesenchyme is first seen around the sixth week of development (**Figure 2(a)**). By then, the lens stalk has already separated from the surface epithelium, and the lens vesicle has invaginated into the optic cup. There is evidence from fate-mapping studies in the avian eye, from cell-grafting and labeling experiments in the mouse eye, and from transgenic mouse models that the ocular mesenchyme largely derives from the neural crest. In addition, there appears to be some contribution from cells that derive from the cranial paraxial mesoderm. The mesenchymal cells which migrate to the eye are first seen in the space between surface epithelium and lens epithelium, where they form several layers of loosely aggregated, star-shaped cells (**Figure 1(a)**). The cells condense into a dense layer that finally forms the corneal endothelium, while mesenchymal cells continue to migrate into the space between the surface epithelium and the developing corneal endothelium to form the future corneal stroma (**Figure 1(b)**).

The cells in this area differentiate into keratocytes or corneal stroma fibroblasts, the cell type that is critically required for synthesis of the extracellular matrix of the transparent cornea. The surface epithelium covering the anterior eye differentiates into the corneal epithelium. While the cells at the innermost layer of the corneal stroma differentiate into the corneal endothelium, the inner epithelial layer of the future cornea, the lens becomes separated from the cornea by a fluid-filled space (**Figure 3(a)**). Subsequently, the peripheral edge of the optic cup starts to elongate and grow toward the fluid-filled space to form the ciliary body and the iris, and finally divides the space into an anterior and a posterior chamber. At the same time, in a second migratory wave, mesenchymal cells arrive at the angle between the future cornea and the edge of the optic cup. They continue to grow along the optic-cup-derived epithelial layers of iris and ciliary body to form the stroma of both structures (**Figure 3(b)**).

Finally, trabecular meshwork and Schlemm's canal develop. Around the 15th to 17th week of human embryonic development, shortly after the optic cup has started to elongate to form iris and ciliary body, neural-crest-derived mesenchymal cells form a dense mass of cells in the chamber angle, which extends onto the anterior surface of the developing ciliary body/iris (**Figure 2(b)**). About a month later, the mesenchymal cells in the chamber angle are separated from each other by small fluid-filled spaces (**Figure 2(c)**). Consequently, extracellular matrix is deposited in the spaces, while vessels grow toward the chamber angle from the immediate adjacent sclera. During this period, the chamber angle cells that give rise to the trabecular meshwork are still localized at or behind the posterior border of the chamber angle, and are covered by uveal tissue that extends from the iris rot. In the next

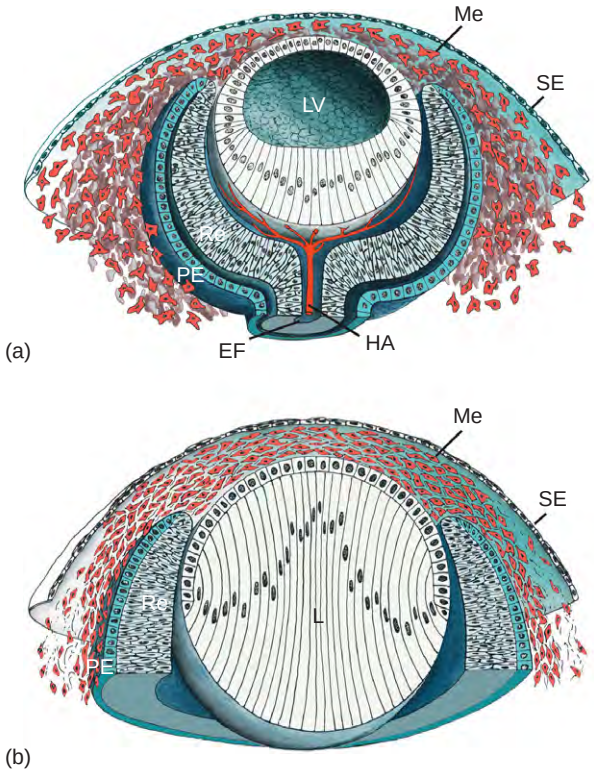

Figure 1 Schematic diagram of ocular mesenchyme development in the mouse eye between embryonic days (E) 12.5–14.5. (a) At E 12.5–13.5, the lens vesicle (LV) has detached from the surface epithelium (SE) and become invaginated into the optic cup. Mesenchymal cells (ME) start to migrate into the space between the anterior epithelium of the lens vesicle and the surface ectoderm. The inner layer of the optic cup forms the neural retina (Re), the outer layer, the retinal pigmented epithelium (PE). The optic cup is incompletely inferior at the so-called embryonic (choroidal) fissure (EF), which is used by the hyaloid artery (HA) to pass into the optic cup. (b) At E 13.5–14.5, the mesenchyme cells condense to form several flat layers that are separated from each other by a loose fibrillar extracellular matrix. In the lens (L), the primary lens fibers elongate to close the lumen of the lens vesicle. Adapted from Cvekl, A. and Tamm, E. R. (2004). Anterior eye development and ocular mesenchyme: New insights from mouse models and human diseases. *BioEssays* 26, 374–386, with permission from John Wiley & Sons, Inc.

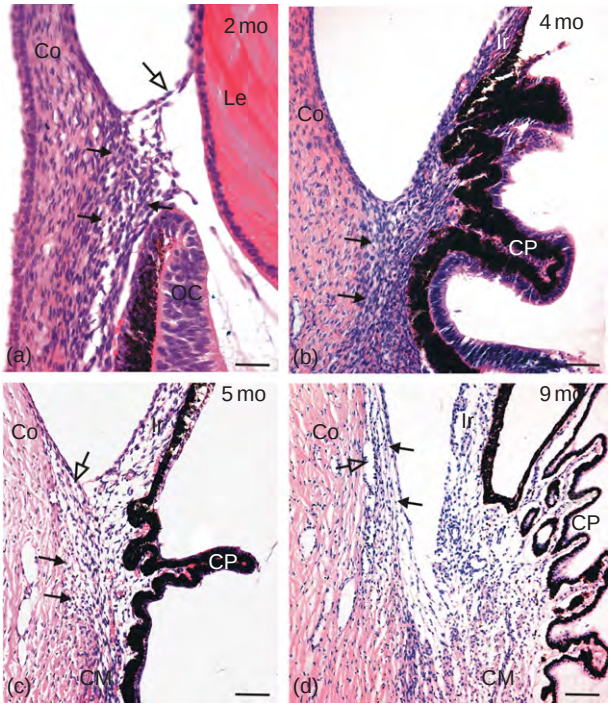

Figure 2 Development of the chamber angle and trabecular meshwork in human embryonic and fetal eyes at 2 (a), 4 (b), 5 (c), and 9 (9) months of development. (a) At 2 months, mesenchymal cells (arrows) are seen between the anterior edge of the optic cup (OC) and the future cornea (Co). Cells of the anterior pupillary membrane (white arrow) extend from the peripheral cornea to the anterior surface of the lens. (b) At 4 months, mesenchymal cells (arrows) form a dense mass at the chamber angle, which extends onto the anterior surface of the developing iris (Ir). (c) In 5-month-old fetal eyes, the cells of the future trabecular meshwork (solid arrows) are separated from each other by small open spaces. Uveal tissue (open arrow) covers the anterior surface of the trabecular meshwork. (d) At term, most of the trabecular meshwork (solid arrows) is exposed to the anterior chamber. Schlemm's canal (open arrow) is seen at the outer side of the trabecular meshwork. CP, ciliary process; CM, ciliary muscle. Sections kindly provided by Dr. Christian Vorwerck, Department of Ophthalmology, University of Magdeburg, Germany. Magnification bars: (a) = 20 μm; (b) = 30 μm; (c) = 40 μm; (d) = 60 μm. Adapted from Tamm, E. R. (2004). Genetic changes and their influence on structure and function of the eye in glaucoma. In: Grehn, F. J. and Stamper, R. (eds.) *Essentials in Ophthalmology. Glaucoma.* Berlin, Heidelberg, New York: Springer, with permission from Springer Science+Business Media.

months, the extracellular fibers in the chamber angle become organized into trabecular meshwork beams or lamellae, which are covered by flat trabecular meshwork cells. In parallel, the vessels in the adjacent scleral coalesce to form a circumferential Schlemm's canal. Maturation of the trabecular meshwork and optic cup occurs alongside a posterior move of the peripheral margin of the anterior chamber and the chamber angle. Thereby, the anterior surface of the trabecular meshwork becomes exposed to the anterior chamber and the aqueous humor within (Figure 2(d)).

The critical morphogenetic steps of trabecular meshwork development become complete around the time of birth. Still, some minor modeling of the trabecular meshwork continues throughout the first years of life. Between the trabecular meshwork lamellae and the endothelial lining of Schlemm's canal, there still remain some cells with a stellate phenotype that do not cover the trabecular lamellae. Instead, these cells develop cell-to-cell contacts with the endothelial cells of the Schlemm's canal on one side and the cells covering the trabecular beams on the other side, and form the juxtacanalicular or cribriform layer of the trabecular meshwork, where most of the resistance to aqueous humor outflow is located.

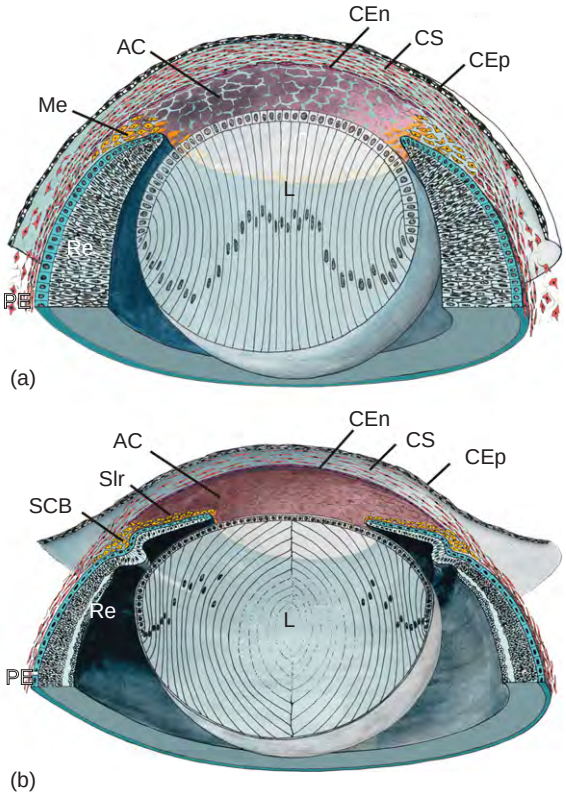

Figure 3 Schematic diagram of ocular mesenchyme development in the mouse eye between embryonic days (E) 14.5–19.5. (a) At E 14.5–15.5, the posterior mesenchyme cells closest to the lens flatten, become connected by apicolateral contacts, and form an endothelial monolayer. At the end of this process, all layers of the future cornea have been defined. The endothelial monolayer that has been formed from the posterior mesenchyme cells becomes the corneal endothelium (CEn), and the surface ectoderm that covers the anterior side of the mesenchyme becomes the corneal epithelium (CEp). Mesenchyme cells between the corneal epithelium and endothelium differentiate into keratocytes, the specific cell type of the corneal stroma. During differentiation of the corneal endothelium, the lens (L) detaches from the future cornea and a fluid-filled cavity, the anterior chamber (AC) is generated between both the structures. In parallel, a new group of mesenchyme cells (Me) arrives at the angle between the future cornea and the anterior edge of the optic cup. (b) Beginning at approximately E 15.5, the anterior edge of the optic cup enlarges to form the iris and ciliary body. Mesenchyme cells migrate along the epithelial layers of both structures and finally differentiate into the stroma of the iris (Slr) and ciliary body (SCB). Adapted from Cvekl, A. and Tamm, E. R. (2004). Anterior eye development and ocular mesenchyme: New insights from mouse models and human diseases. *BioEssays* 26, 374–386, with permission from John Wiley & Sons, Inc.

In the mouse eye, an animal model that is commonly used to study developmental aspects of chamber angle formation and its genetic control, the morphogenetic processes are very similar. A minor difference appears to be the formation of the corneal endothelium, which is not formed in the mouse before multiple layers of cells have filled the space between the lens and the surface epithelium (**Figure 1(a)**). The development of the trabecular meshwork and the Schlemm's canal starts at postnatal day 1, and is completed at around postnatal day 21. The principal morphogenetic processes of chamber angle development are essentially similar to that seen in humans (**Figure 4**).

Anterior Segment Dygenesis

Typical clinical disorders that occur from failure of correct mesenchyme differentiation during anterior eye development are part of the broad spectrum of Axenfeld–Rieger's syndrome which includes Rieger's anomaly or syndrome, Axenfeld's anomaly, and iridogoniodysgenesis. All of these conditions are commonly inherited in an autosomal-dominant fashion, and affected patients may develop juvenile glaucoma in about 50% of cases. Rieger's anomaly is characterized by midperipheral adhesions from the iris to the cornea (**Figure 5(b)**). In addition, there are structural defects, such as polycoria and corectopia, and a marked iris hypoplasia. When ocular changes are associated with systemic developmental defects, such as dental or facial abnormalities, the term Rieger's syndrome is used. In Axenfeld's anomaly, iris strands attach to a structure called posterior embryotoxon, which is a ring of collagenous fibers at the peripheral end of Descemet's membrane forming a prominent Schwalbe's line (**Figure 5(a)**). Posterior embryotoxon presents clinically as a ring-shaped opacity in the peripheral cornea. Patients with iridogoniodysgenesis have an iris with hypoplastic stroma, abnormal chamber angle tissue, and glaucoma.

The broad spectrum of different specific clinical phenotypes, which are all part of Axenfeld–Rieger's syndrome, results from mutations in two genes, the bicoid-like homeobox gene *PITX2*, or the forkhead/winged-helix transcription factor gene *FOXC1*. Both genes encode for transcription factors that obviously control the morphogenetic processes of anterior eye development and the role of the ocular mesenchyme therein.

Peters Anomaly

Another phenotype that is seen in anteriorsegment dysgenesis is Peters anomaly. Peters anomaly is characterized by central corneal opacities (leukoma) that are associated with abnormalities of the deepest corneal stromal layers and local absence of the corneal endothelium (**Figure 5(c)**). The lens may adhere to the back of the corneal opacity and show signs of an anterior polar cataract. Peters anomaly is often associated with iris hypoplasia and corectopia, and with iridocorneal adhesions that arise from the pupillary region. About 50–70% of the cases may develop abnormally high

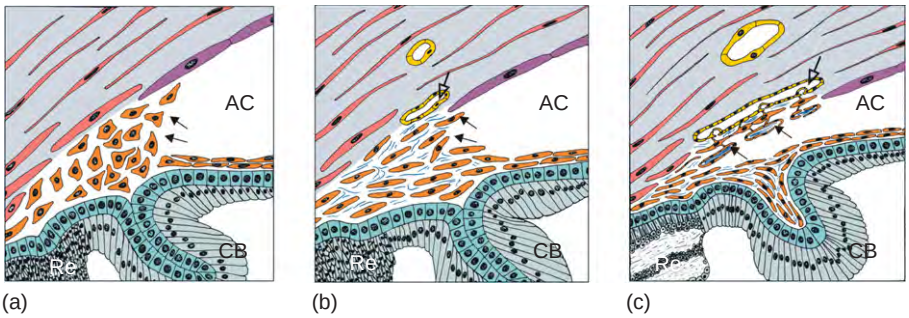

Figure 4 Schematic diagram of the development of chamber angle and trabecular meshwork in the mouse eye between postnatal days (P) 1–14. (a) From P1 to P4, the chamber angle is occupied by a dense mass of mesenchymal cells (arrows). (b) From P4 to P10, chamber angle cells (solid arrows) become separated from each other by small open spaces that are partially filled with extracellular fibers, while vessels appear in the immediate adjacent sclera (open arrows). During this period, the chamber angle is level with the anterior border of the future trabecular meshwork. (c) From P11 to P14, the extracellular fibers in the chamber angle organize themselves into trabecular beams that become covered by trabecular meshwork cells, while the scleral vessels next to the chamber angle coalesce to Schlemm's canal. In parallel, the peripheral margin of the anterior chamber moves posteriorly and the inner surface of the trabecular meshwork becomes exposed to the anterior chamber. Adapted from Cvekl, A. and Tamm, E. R. (2004). Figure 5 Schematic drawing of typical phenotypes seen in the spectrum of anterior segment dysgenesis. (a) In Axenfeld's anomaly, iris strands traverse the chamber angle and insert into a prominent Schwalbe's line (posterior embryotoxon). (b) In Rieger's anomaly, midperipheral adhesions from the iris to cornea are seen in addition to Axenfeld's anomaly. (c) The phenotype of Peters anomaly consists of a central corneal opacity (leukoma), with local absence of the corneal endothelium. The lens may adhere to the back of the corneal opacity. Peters anomaly is usually associated with iridocorneal adhesions that arise from the pupillary region. Adapted from Tamm, E. R. (2004). Genetic changes and their influence on structure and function of the eye in glaucoma. In: Grehn, F. J. and Stamper, R. (eds.) *Essentials in Ophthalmology. Glaucoma.* Berlin, Heidelberg, New York: Springer, with permission from Springer Science+Business Media.

intraocular pressure and glaucoma, very likely due to dysgenesis and/or malfunction of the aqueous humor outflow tissues in the iridocorneal angle. In humans and in mice, mutations in several transcription factors such as *PITX2, PITX3, FOXC1, FOXE3, MAF, SOX11*, and *PAX6* have been found in Peters anomaly associated with anterior segment dysgenesis.

Aniridia

Pax6, a transcription factor that is characterized by a paired domain and paired-like homeodomain, is also critically required for the morphogenesis of the anterior eye. It is a key regulator of eye development in both vertebrates and invertebrates. Patients with heterozygote mutations in *PAX6* develop the phenotype aniridia, which is commonly associated with iris hypoplasia, corneal opacification, cataract, and foveal dysplasia. In addition, mutations in *PAX6* may also cause Peters anomaly, and about 50–75% of patients with aniridia develop juvenile glaucoma.

Anterior Segment Dysgenesis and Glaucoma

Juvenile glaucoma develops in about 50% of patients with Axenfeld–Rieger's syndrome. The electron microscopy of affected patients reveals considerable amounts of amorphous extracellular material in the juxtacanalicular or cribriform region of the trabecular meshwork, for example, the part of the trabecular meshwork outflow pathways which is most critical for outflow resistance

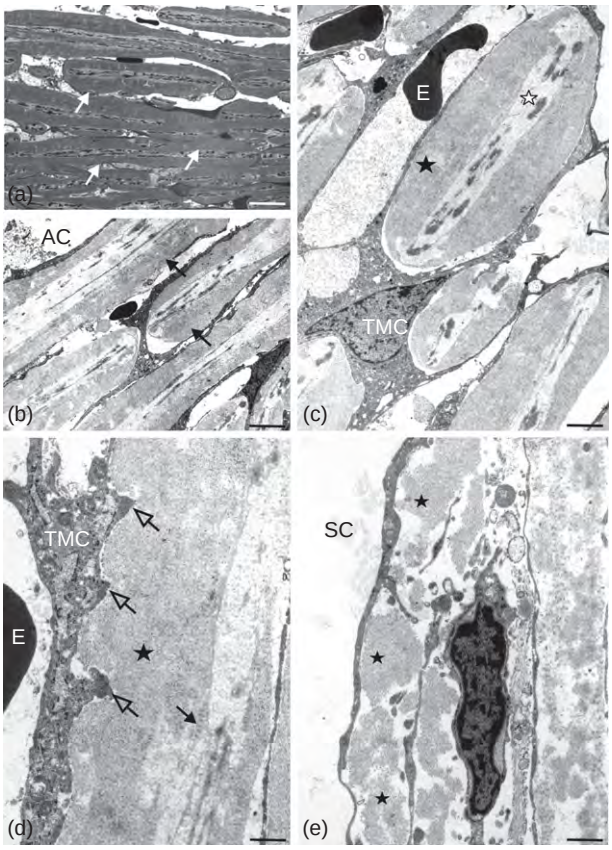

Figure 6 Light (a) and electron microscopy (d-e) of the trabecular meshwork (TM) in a 24-year-old patient with Axenfeld's syndrome and glaucoma. (a, b) The intertrabecular spaces are markedly narrowed because of an abnormally thickened basement membrane in the TM lamellae (arrows). (c) The basement membrane (black asterisk) surrounds the central core of TM lamellae (white asterisk), which is of normal thickness. (d). Processes of TM cells (open arrows) protrude into the thickened basement membrane (asterisk), which appears granular and contains aggregates of broad-banded material (solid arrow). (e) The extracellular spaces of the juxtacanalicular meshwork contain numerous aggregates of sheath-derived plaque material (asterisks). AC, anterior chamber; TMC, trabecular meshwork cell; SC, Schlemm's canal; E, erythrocyte. Magnification bars: (a) = 4 μm; (b) = 1.7 μm; (c) and (e) = 1 μm; (d) = 0.7 μm. Adapted from Tamm, E. R. (2004). Genetic changes and their influence on structure and function of the eye in glaucoma. In: Grehn, F. J. and Stamper, R. (eds.) *Essentials in Ophthalmology. Glaucoma.* Berlin, Heidelberg, New York: Springer, with permission from Springer Science+Business Media.

(Figure 6). In addition, the extracellular matrix of the trabecular lamellae was found to be markedly thickened due to an increase in electron-dense material in the basement membrane of trabecular meshwork cells (Figure 6).

Haploinsufficiency in *FOXC1* or *PITX2* may lead to an abnormal turnover of the extracellular matrix in the juxtacanalicular trabecular meshwork during development, which continues into childhood and adolescence. An abnormal quantity and/or quality of the extracellular matrix in the trabecular meshwork may finally lead to an increase in aqueous humor outflow resistance and cause glaucoma in Axenfeld–Rieger's syndrome.

Glaucoma in patients with aniridia appears to result from a different mechanism. Studies in mouse strains with mutations in *Pax6* indicate that the trabecular meshwork does not differentiate and Schlemm's canal is absent.

Primary Congenital Glaucoma

Primary congenital glaucoma is an inherited developmental defect in the trabecular meshwork and chamber angle that manifests in the neonatal or infantile period. Increased intraocular pressure, corneal enlargement, and optic nerve cupping are typical signs. Several histopathological studies describe that the iris insertion and anterior ciliary body overlap the posterior portion of the trabecular meshwork, but leave the angle open. Apparently, during chamber angle development, the iris and the ciliary body fail to recede posteriorly. In addition, an increase in extracellular matrix has been described in the trabecular meshwork. In familial cases of primary open angle, an autosomal recessive mode of inheritance is commonly observed, and mutations in the gene *CYP1B1* coding for the enzyme cytochrome P4501B1 were found to be causative for some forms.

The ocular substrate for cytochrome P4501B1 is not known, but it is reasonable to assume that it is a part of an important signaling pathway during development, and possible candidates are steroids, all-*trans*-retinol, fatty acids, or arachidonic acid.

The Epidemiology of Cataract

S K West, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Glossary

Etiology – A causal relationship underlying a condition or disease. In this sense, high sunlight exposure has been shown to be part of the etiology of cortical cataracts.
Incidence – The rate at which a condition appears in a population over time. Incidence studies measure the rate at which cataracts appear in a population from baseline values established using prevalence data.
Prevalence – The occurrence of a trait or disease, in this case cataract, in a population.

Introduction

As the leading cause of blindness worldwide, cataract is and should be a primary focus for public health in ophthalmology. The World Health Organization estimates 36.9 million persons are blind. Forty-eight percent of all blindness worldwide is due to cataract. A recent review suggests that there has been a decrease in global blindness, about 15 million fewer cases than had been projected, and not as many blind from cataract, despite the increase in the age group 50 years and older worldwide. The authors attribute this success to an increase in the quantity and quality of cataract surgery, helped by the advent of low-cost intraocular lenses. However, cataract is not yet preventable, and this success will continue only if there is vigilance in restoring sight lost from cataract through high-quality surgery and continued research efforts on prevention.

Considerable progress has been made in understanding the epidemiology of cataract. Leads from this research point to very promising directions for further work. The next sections review the progress made in the epidemiology of cataract and suggest future work.

Cataract Classification Systems: Characterization of Phenotype

Rigorous investigations into the etiology of cataract have been considerably enhanced by the development of valid and reliable classification systems to assess the presence and severity of different cataract types. Differentiation of nuclear, cortical, and posterior subcapsular (PSC) lens opacities is important, as it has permitted careful phenotypic description of the type of cataract and better characterization of the distribution of cataract types in populations, which provide clues into possible causal factors. Moreover, as the different cataract types have been associated with different etiologies, precision in characterization of cataract is critical in epidemiological studies.

The classification systems are based on images of the lens taken in standardized fashion, and largely rely on graders who compare features of the images to standard photographs and grade severity. At least four classification systems have been developed, which differ largely in the standards photographs used. Unfortunately, many of the major cataract epidemiological studies have used different grading schemes and, more importantly, different cutoff points to define opacification. This makes comparisons more difficult. Reliability between graders using any of these systems, based on photographs, is usually very good, but adapting these grading methods to assessment in the eye clinic has proved more difficult. To address this problem, the World Health Organization developed a clinical tool for simple assessment of cataract type at the slit lamp. This tool may prove to be useful for surveys of patients during treatment.

Attempts have been made to automate image analyses, with varying results. Most success has been achieved quantifying the density of nuclear opacification, but this still relies on specification of the nuclear region by a grader. A recent study, using anterior segment ocular coherence tomography (OCT) to determine the degree of nuclear opalescence, showed some promise, as it removes some of the variability in slit lamp and flash settings in subjective assessment of nuclear density. However, further work is needed to test the value of this approach in the assessment of cortical and posterior subcapsular opacities. This is especially true because, for these opacities, there need to be multiple scans in several meridians and OCT appears to be subject to the production of artifacts from the anterior surface. Analysis of the loss of retinal image clarity is associated with cataract severity. However, this approach cannot determine the type of cataract and does not detect the early stages of opacification.

Further investigations of automated grading systems and better, low-cost, digital-image capture systems for cortical cataracts and PSCs are warranted, as this would substantially reduce the cost of cataract assessment.

However, the systems that are already available permit careful characterization of cataract type. These have, and will continue to enable the precise identification of the risk factors for cataract.

Distribution of Different Lens Opacity Types in Different Racial Groups or Populations

Differences in the distribution of the cataract types within racial or ethnic populations point to potential differences in genetic, genetic/environment or environmental exposures that could be exploited to find the causes of cataract. For example, population studies in Barbados and Salisbury, Maryland, have shown that African Americans/Caribbeans have a higher prevalence of cortical cataract and lower occurrence of nuclear and posterior subcapsular opacities, when compared to Caucasians. Incidence rates of cortical opacities are high in African Americans/Caribbeans as well, confirming the difference seen in prevalence studies. In the Salisbury study, this difference was not explained by differences in sunlight exposure, diabetes, or gender, suggesting other exposures and/or a strong genetic component may be operative.

There is conflicting evidence about rates of occurrence of PSCs in Chinese as compared to Caucasians. Based on two Asian studies, which used clinical grading rather than image assessment, rates appear to be higher in Asian subjects. However, in the most recent lens opacity study in Beijing, there was no substantial difference in the rates of PSCs among Chinese, compared to similarly aged Caucasians in the Salisbury study. Comparisons between Latinos and Caucasians for rates of specific cataract types are somewhat hampered, as the two Latino studies relied on clinical grading and did not use image-based cataract assessment systems. With this caveat in mind, Latinos in Los Angeles appear to have higher rates of PSC, compared to the rates in Caucasians. However, this may also be due to differential access to cataract surgical services.

There are sex differences in the prevalence of lens opacities, with women having consistently higher rates of cortical opacities than men. This gender difference is not explained by any difference in diabetes, sunlight exposure, or age. The 10-year, age-adjusted incidence rates of nuclear and cortical opacities were higher in females than males in the Caucasian populations of Blue Mountain, Australia. Similarly, 10- and 15-year, age-adjusted incident nuclear opacities were higher in females in Beaver Dam, USA. There is less evidence for a gender difference in PSC. The reason(s) for a gender difference in cataract are not clear. However, a study of expression differences in the lens proteomes between male and females rats suggested potential differences in oxidative stress regulation that deserves further research. There is considerable evidence for higher rates of vision loss caused by cataract in females worldwide, which is discussed in more detail below.

These population differences provide clues about the etiology of cataracts. Future research is needed to discover why such differences exist.

Risk Factors for Cataract

An exhaustive review is beyond the scope of this article, so this section covers only highlights and recent literature. Readers are also directed to the reviews listed in the section titled 'Further reading'.

Diabetes

By the 1950s the development of cataract in a diabetic rat model was fairly well established. Despite differences in animal and human lens, researchers suspected that diabetes was a cause of cataract in human diabetic patients as well. There was good biological plausibility to expect diabetes was a risk factor for cataracts, based on the effects of elevated levels of glucose on the sorbitol pathway, and increased free radical production leading to oxidative damage. Recent work on calpains provides further insight into diabetes-induced cataracts.

Population-based studies have identified the excess risk of cortical and PSC lens opacities in persons with diabetes. The risk appears to increase with increasing duration of diabetes. The level of control of blood glucose, as measured by levels of glycated hemoglobin, is related to the prevalence, onset, and progression of opacity. Diabetes is not usually associated with increased risk of nuclear cataracts.

There are no data on the differential effect, if any, of diabetes on cataract formation in different racial or ethnic populations. The risk of cataracts attributable to diabetes in African/Caribbeans is estimated at 14%, but is likely to be different among other populations, depending upon the prevalence of diabetes and the level of control of blood sugar.

Chronic Ultraviolet Light Exposure

Early work in animal models identified exposure to optical radiation as a cataractogenic agent, with an action spectrum that implicated ultraviolet light B (UVB; 290–320 nm). Recent work in rabbit lenses suggest that cumulative effect of repeated UVB radiation is more harmful to the lens metabolic profile than the same dose as a single irradiation. Geographic differences in cataract risk were long associated with differences in ambient sunlight. Population-based

surveys over large geographical areas, using latitude as the marker of exposure, found elevated risk of cataract where ambient UVB exposure was highest.

However, such studies are subject to bias known as ecologic fallacy, wherein many other risk factors could vary along with ambient sunlight, producing a spurious association. A classic example was the fall in diarrheal disease with the rise in home televisions (TVs), where clearly TV was just another marker of improved socioeconomic status and not an etiological agent. The imprecision of the measure of ocular exposure to UV light was also a hindrance, with many studies using ambient UV or skin sunburns as indices. Methods to estimate ocular exposure in a more precise way were developed, using a Maryland Sun Year as a unit of measure. This metric was tied to the average amount of UVB that falls on a flat plane in Maryland in a year, as measured over several years. Ocular radiation was estimated by factoring in the use of a brimmed hat, sun or corrective eyeglasses, season, time of day, and geographic location, coupled with self-report of being outside during daylight hours. This detailed assessment of cumulative ocular exposure to UV light in a high-risk group, Maryland fishermen, showed a dose–response relationship between exposure and risk of cortical opacities. However, there were no African Americans or females in the study. A subsequent evaluation in a population-based study demonstrated that, for all groups including women and African-Americans, there was an increased risk of cortical opacity with increasing ocular exposure to UVB, even with the type of exposure found in a general population. For every 0.01-MSY increase in ocular exposure, there was a significant, 10% increase in the risk of cortical opacity.

The public health ramifications of this association between UV light exposure and lens opacity extend to global warming and increases in lens opacity have been predicted, based on various scenarios attributable to the ozone hole. However, exposure to UVB can be limited through very simple measures; wearing plastic glasses or sunglasses when outside or wearing a brimmed hat. These measures have become part of the sun awareness campaigns carried out in Australia, Canada, and, by the US Environmental Protection Agency's SunWise program, in the United States.

Other Radiation Exposure

Cataract formation has long been known to result from exposure to ionizing radiation. Fortunately, the atmosphere filters ionizing radiation and human populations are not exposed from solar sources. Human populations have been exposed as atomic bomb survivors, nuclear reactor survivors, or through exposure to therapeutic radiation. Earlier reports suggested that the minimum dose required to produce a detectable cataract was 1.5 Gy (single exposure). Such data supported the recommendations of the National Council on Radiation Protection, which state that single 2-Gy dose is the minimum required to produce a detectable cataract, with a 5-Gy limit for a fractioned dose.

Recent data from exposed populations challenge the threshold recommendations. A recent re-analyses of cataract prevalence among the atomic bomb survivors in Japan suggests no evidence for a threshold effect. Cataract among the 8607 cleanup workers at the nuclear site in Chernobyl was assessed at 12 and 14 years after exposure. PSC and cortical cataract rates were present in a dose-dependent fashion, suggesting a threshold under 1 Gy. Using cataract extraction as a surrogate for cataract, a study in 35 705 radiologic technologists followed up for 20 years found that those reporting three or more X-rays to the head and neck were 25% more likely to have a cataract extraction. In addition, the technologists who worked in the highest category of exposure (mean 60 mGy) were 18% more likely to have cataract extraction compared to those in the lowest category of exposure (5 mGy), although the latter difference was not statistically significant. These differences suggest that there may be no threshold, or at least that the threshold is considerably less than current recommendations of the National Council on Radiation Protection.

Other Oxidative Stress

Most ocular tissues are vascularized and supplied with ample levels of oxygen, except the lens whose cells are normally hypoxic. Animal models suggest that the lens may have difficulty controlling the consumption of oxygen. Increasing oxygen exposure to the posterior lens surface is associated with higher consumption of oxygen by the lens. Such a scenario may lead to increased production of reactive oxygen species, known to contribute to opacification.

One mechanism by which increasing levels of oxygen may reach the posterior lens is through breakdown in vitreous gel that lies between the lens and retina, or removal of vitreous altogether. Vitrectomies are associated with rapid development of nuclear opacities, and exposure of the posterior lens to higher-than-normal levels of oxygen is felt to be the mechanism. It may also explain age-related nuclear opacification; one study has already shown that there is an association between age-related vitreous liquefaction and nuclear opacification. The observational studies that have shown a relationship of early-onset myopia (not myopic shift due to nuclear cataract) to nuclear cataract may also be explained by the association of myopia with vitreous degeneration. However, not all studies have found an association of myopia with nuclear cataract; some report that another cataract type, PSC, is related to myopia.

If oxidative stress is cataractogenic, then prevention or amelioration of the stress should be protective. This has led to the postulate that antioxidant nutrients, vitamins, or supplements may be protective against cataractogenesis. However, numerous studies have attempted to demonstrate a protective effect of antioxidant nutrients, vitamins, and supplements against cataract with no clear, consistent findings. Notably, several clinical trials of antioxidant vitamins in diverse populations have failed to demonstrate any consistent, protective effect for cataract. The Age-Related Eye Disease Study (AREDS) clinical trial followed up 4629 patients randomized to four combinations of antioxidants with zinc and placebo. No protective effect was seen on incidence or progression of lens opacities. A more recent study of 1020 participants randomized to multivitamin versus placebo, using the same AREDS grading scheme, found a protective effect of supplementation for nuclear opacity, and a twofold increased risk for PSC. All these trials have been criticized for not including the correct supplement, or dosing for too short a period of time, or being conducted in study populations which are already taking supplements outside the trial. Considering the huge investment in research in this area, and the conflicting findings across many different populations and study designs, this field deserves a thorough and careful review with recommendations of promising approaches before any further research is warranted.

Medications

The promise of medication to prevent or retard cataract growth has proved elusive. Initial hope for aspirin or non-steroidal anti-inflammatory agents as anticataract agents was not supported by research. The seemingly protective effect of hormone replacement therapy in women was not borne out in the longitudinal follow-up in both Beaver Dam and Salisbury populations. It is likely that other endogenous hormonal effects are implicated in cataractogenesis in women. Two reports of protective effect of long-term statin use against nuclear cataract or any cataract are intriguing, due to the anti-inflammatory and antioxidant effects of these medications. However, the findings were in a small sample of the Beaver Dam and Blue Mountains populations (in the latter there was insufficient power to evaluate cataract subtypes). This observation deserves confirmation in other studies designed to specifically evaluate the possible protective effect of statins.

Other medications have been shown to be cataractogenic. Oral steroids, particularly in high doses or with prolonged use, have long been implicated in PSC. Early studies suggested an absence of increased risk for inhaled corticosteroids. However, these were criticized for being conducted in primarily young populations or for being confounded by oral steroid use as well. Several studies have now reported increased risk of cataract among users of inhaled steroids. A dose–response relationship was reported from the study by Mitchell and co-workers, lending more weight to the association. Steroids may appear to be a risk factor for PSC and, interestingly, for nuclear opacity as well.

Topical medications for lowering intraocular pressure were associated with incident nuclear opacity in a population-based study of African Caribbean persons in Barbados, an association that was confirmed in the Early Manifest Glaucoma (EMG) trial. The most frequently used medication in the Barbados study was topical beta-blockers. After careful adjustment to exclude high intraocular pressure itself as the risk factor, a consistent elevated risk was observed. Another large study of glaucoma treatment, the Ocular Hypertensive Treatment Study (OHTS) did not detect an increased risk of lens opacity after treatment with glaucoma medications. This might be attributed to the cross-sectional assessment of cataract after a large proportion of persons in the medication treatment arm had already had cataract surgery. The initial findings in a population-based study resulted in cataract components being added to the OHTS and EMG clinical trials to provide more information about this potentially damaging consequence of glaucoma medication. These findings could have considerable clinical relevance when treating older persons, who are at risk for both diseases.

Smoking

Since the first epidemiological reports of smoking associated with nuclear cataract, a large and consistent body of literature has supported this relationship. A dose–response relationship exists, and smoking increases the incidence and progression of nuclear opacification. Smoking cessation appears to reduce the risk of cataract, which may be due to either the lower cumulative doses smoked by those who stopped, or some reversible damage. The consistency of the association, the presence of a dose–response relationship, and findings of change after cessation provide strong evidence for causality, with smoking now a well-accepted risk for nuclear cataract. Cataract has now been added to the US Surgeon General's report on health effects of smoking, the first ocular condition to have this dubious distinction. An estimated 20% of cataract cases in the US may be attributable to smoking. In countries such as China, where smoking is common, cataract is and will continue to be epidemic.

Genetics and Cataract

The likelihood of a genetic predisposition to nuclear and cortical cataract has been evaluated in several population studies. In studies of monozygotic and dizygotic Caucasian twins in the UK, the heritability of nuclear cataract

was estimated at 48%, with unique environmental factors estimated to account for another 14% of the variability. The heritability in sibling pairs has been estimated at 36% in an older cohort in Salisbury after adjusting for smoking. In extensive analyses in the Beaver Dam cohort pedigrees that included smoking, the data suggest contributions to nuclear cataractogenesis from multiple genes, characteristic of a complex disorder. Promising work has been carried out investigating mutations in the crystalline genes, using congenital or autosomal dominant nuclear cataract cases, but further work linking these to age-related cataract is needed.

Similarly, there appears to be a strong genetic component to cortical cataract. In the UK Twin Study, additive and dominant genes accounted for 53–58% of the variability in cortical cataract, with unique environmental factors accounting for 26–37%. The heritability for cortical cataract in the Salisbury sibling pairs was 24%.

To date, much research has identified polymorphisms and mutations that are associated with autosomal dominant or recessive congenital cataracts, with some work in age-related cataract. This is a growing field that will continue to evolve. Fascinating work on the crystalline genes has provided not only leads into cataractogenesis, but also associations with other neurological, cardiac, and muscular disorders that will likely provide insights into the aging process.

Cataract as a Predictor of Mortality

A provocative link between lens opacity and increased risk of early mortality has now been reported from several, although not all, epidemiological studies. Nuclear opacity and mixed opacity in particular have been found to be independent risk factors for mortality, adjusted for health status, frailty, and other confounders. This association is clearly not causal, but suggests that the lens may well be a natural window into the aging process. This is being explored by cell biologists interested in aging tissues, especially in lens proteins. Further research may well involve development of lens biomarkers that serve as an index of early senescence

Cataract Surgery and Outcomes

In addition to playing a major role in understanding cataract etiology, epidemiological research has also helped to identify issues relating to access and barriers to cataract surgery, the outcomes of cataract surgery, methods to improve the cost effectiveness, and the impact of cataract and cataract surgery on quality of life. These important accomplishments could be the subject of another review, so only highlights are covered here.

The development of the simple tool, called Rapid Assessment of Cataract Surgical Services, has allowed countries to determine how well the cataract blind are accessing surgery. This reporting tool has been invaluable for the VISION 2020 community to chart the coverage of its mission to reduce cataract as an avoidable cause of blindness by the year 2020.

However, surgical coverage indices alone are not a complete indicator of success in reduction of cataract blindness. For example, when coverage improved in India under a World Bank program to increase cataract surgery, epidemiological assessments of outcomes showed that vision restoration was less than ideal, with the potential for higher rates of poor visual outcome occurring in the rush to increase coverage. These findings were instrumental to the institution of surgical audits of outcomes to be certain that quality was not sacrificed for quantity.

Surgical coverage may not be equitable. Women experience more barriers to cataract surgery, especially in countries were gender equality is less than ideal. The rates of blindness and visual loss due to cataract are significantly higher in women compared to men in many countries. Women have more difficulty accessing the resources necessary to obtain cataract surgery and cataract campaigns are not designed especially to encourage women. Further operational research designed to determine barriers specific for women, and especially cost-effective strategies to eliminate these barriers, should be undertaken.

Barriers are not confined to less-wealthy countries. In the US, African-Americans are less likely to have cataract surgery, compared to Caucasians, despite having similar or higher rates of disability due to an opacified lens. The reasons for this health disparity are unknown. Language and financial barriers have been identified as impediments among Latinos in the US who need cataract surgery. Recent efforts to document the inequities in eye care delivery should now be expanded to determine why such inequities exist and how these disparities in underserved minorities may be eliminated.

The use of large, simple trial methodology has demonstrated that medical testing before cataract surgery does not improve outcomes and could be eliminated with significant cost savings. The use of large existing databases is becoming a valuable resource to study small, increased risks with changes in methods for cataract surgery, or to investigate large population inequities in access to services where generalizability is important.

The development of self-reported quality-of-life tools for use in studying the impact of visual impairment began with research on cataract surgery patients, demonstrating how sensitive these tools were to improvement in vision following surgery. The original tool, Activities of Daily Vision, was followed by the development of shorter sets of

questions specifically for cataract surgery, such as the visual function 14 (VF-14) questionnaire. These have been used to document patient complaints due to cataract, complaints that are not necessarily captured by tests of acuity or contrast sensitivity. Recognition of the broad impact of cataract on patient function led to a change in surgery best practices. This guideline states that, in addition to deficits in visual acuity, cataract surgery may be indicated when patient function is compromised.

Summary

The epidemiologic study of cataract and lens opacity has made great strides in determining the magnitude of the problem and the burden that cataract places on human populations. Considerable progress has been made in characterizing different opacity phenotypes, ethnic and racial population differences, and identifying risk factors with public health importance. Future research must address the questions of why these population differences exist, using creative collaborations in diverse population laboratories.

While the risk of cataract can be reduced, it cannot be prevented. Therefore, continued emphasis on health services research is needed, using effective methodologies to identify disparities and inequities in access to surgical treatment for cataract. Links with systemic models of aging are at the forefront of research and deserve special attention for the broader implications that may be revealed by findings markers for early senescence.

The Evolution of Opsins

T H Oakley and D C Plachetzki, University of California, Santa Barbara, Santa Barbara, CA, USA

Glossary

Bilaterian – A major family of animals characterized by bilateral symmetry, including insects, nematode worms, mollusks, vertebrates, echinoderms, and other animals.

Chromophore – A light-reactive chemical that binds to a protein, such as opsin, and which allows biological sensitivity to light.

Ciliary – Relating to cilia, which are subdivided into motile and sensory types. Ciliary photoreceptors are those in which phototransduction occurs in a sensory cilium.

CNG (cyclic nucleotide-gated ion channel) – A family of proteins that acts (along with other functions) as the ion channel in ciliary photoreceptor cells. CNG proteins open in the presence of cyclic nucleotides to allow positively charged ions such as calcium to flow into the cell.

Cnidaria – A group of animals that includes jellyfish, anemones, hydras, and corals.

Co-duplication – The simultaneous duplication during evolution of interacting components (e.g., genes or proteins).

Co-option – The pattern or process whereby existing components (e.g., genes or proteins) are used in the evolution of a new structure or function.

Eumetazoa – A major group of animals characterized by the presence of numerous cell types, tissues, and organs and that includes bilaterians and cnidarians.

GPCRs – Guanine-nucleotide-binding protein (G-protein)-coupled receptors form a class of proteins that functions by embedding in cell membranes. These proteins function to detect a signal outside the cell and then signal to proteins inside through a G protein to the cell to change the cell's state in some way.

G protein (Gt, Gq, Go, Gs) – A family of multi-unit proteins that are activated by GPCR receptor proteins to transmit signals into cells. Gt, Gq, Go, and Gs are subfamilies of G-alpha proteins activated by opsins.

Photopic vision – The vision in high light levels, which may include color vision.

Phototransduction – The conversion of a light signal received by an animal opsin to an electrical signal that is transmitted to the nervous system.

Rhabdomeric – A type of photoreceptor cell with numerous microvilli. It is also called microvillar photoreceptors.

Rhodopsin – A name originally given to isolated visual pigments that contained both opsin protein and nonprotein chromophore. Today the term still applies to visual pigments, and is also used commonly to describe the opsin protein expressed in vertebrate rod (dim-light) photoreceptors, and the opsins of certain organismal groups, such as bacteria.

Scotopic vision – A monochromatic vision in low light levels.

Spectral tuning – The changes in specific amino acids of opsin proteins that mediate the maximum sensitivity to different wavelengths of light of different visual pigments.

Tetrachromatic – A visual system based on four classes of visual pigments with four different λ-*max* values.

Trichromatic – A visual system based on three classes of visual pigments with three different λ-*max* values.

TRP (transient receptor potential ion channel) – A family of proteins that acts (along with other functions) as the ion channel in rhabdomeric photoreceptor cells. TRP proteins open in the presence of products derived from the lipid diacylglycerol to allow positively charged ions to flow into the cell.

Type I opsin – The retinylidene proteins present in bacteria and algae, which are referred to by various names, including bacteriorhodopsin, bacterial sensory rhodopsins, channelrhodopsin, halorhodopsin, and proteorhodopsin. These proteins have varied functions, including bacterial photosynthesis (bacteriorhodopsin), which is mediated by pumping protons into the cell, and phototaxis (channelrhodopsin), which is mediated by depolarizing the cell membrane.

Type II opsin – The retinylidene proteins present for approximately 600 million years in eumetazoans (animals not including sponges), and unknown from sponges or any nonanimals. The proteins of this family have varied functions, including phototransduction and vision, circadian rhythm entrainment, mediating papillary light reflex

(pupil constriction), and photoisomerization (recycling the chromophore).
λ-max – The wavelength of light to which a visual pigment (opsin plus chromophore) is maximally sensitive.

Introduction

Opsins are a group of proteins that underlie the molecular basis of various light-sensing systems, including phototaxis, circadian (daily) rhythms, eye sight, and a type of photosynthesis. They are sometimes called retinylidene proteins because they bind to a light-activated, nonprotein chromophore called retinal (retinaldehyde). Opsins are also, in some cases, called rhodopsins, a name originally given to isolated visual pigments that contained both opsin protein and nonprotein chromophore in a time before the two separate components were known. Today, the term rhodopsin is used commonly to describe the opsin expressed in vertebrate rod (dim-light) photoreceptors, and the opsins of certain organismal groups, such as bacteria.

General Opsin Structure and Function

Opsins are light-sensitive proteins that snake in and out of a cell membrane 7 times. Crystal structures of opsins have been generated, which allows a detailed understanding of this protein structure. Opsin light sensitivity is mediated by light-sensitive chemicals called chromophores. Opsin proteins covalently bind a chromophore through a Schiff base linkage to a lysine amino acid in the seventh membrane-spanning region of the protein. The absorption of a photon of light results in a photoisomerization, or shape change, of the chromophore. Photoisomerization then causes a shape change in the liked opsin protein.

Type I and Type II Opsins

Two major classes of opsins are defined and differentiated based on primary protein sequence, chromophore chemistry, and signal transduction mechanisms. Several lines of evidence indicate that the two opsin classes evolved separately, illustrating an amazing case of convergent evolution.

Type I opsins are present in bacteria and algae and are referred to by various names, including bacteriorhodopsin, bacterial sensory rhodopsins, channelrhodopsin, halorhodopsin, and proteorhodopsin. These opsins have varied function, including bacterial photosynthesis (bacteriorhodopsin), which is mediated by pumping protons into the cell, and phototaxis (channelrhodopsin), which is mediated by depolarizing the cell membrane. Type II opsins are present in eumetazoans (animals not including sponges), but are unknown from sponges or any nonanimals. As opsins are known from cnidarians and bilaterian animals (animals with bilateral symmetry, including humans, flies, and earthworms), type II opsins are inferred to have been present in their common ancestor, which lived about 600 million years ago. These opsins have varied function, including phototransduction and vision, circadian rhythm entrainment, mediating pupillary light reflex (pupil constriction), and photoisomerization (recycling the chromophore).

Despite their functional similarity and despite both being seven-transmembrane proteins, multiple lines of evidence indicate that type I and type II opsins evolved independently. First, the primary amino acid sequences of type I and type II opsins are no more similar than expected by chance. Second, the orientation of the transmembrane domains differs between the major groups. Third, the major opsin groups differ in chromophore chemistry. Prior to light activation, the chromophore of type I opsins is an all-*trans* isomer. Light activation then involves isomerization of the chromophore to 13-*cis* retinal. In contrast, prior to light activation, the chromophore of type II opsins is 11-*cis* retinal. Light activation of type II opsins involves isomerization to all-*trans* retinal (**Figure 1**). Fourth, type II opsins belong to the larger protein family called G-protein-coupled receptors (GPCRs), which transmit varied signals from outside to inside cells by activating guanosine triphosphate (GTP)ase proteins, which in turn signal to second messengers that affect the state of the cell in various ways. Type I opsins do not activate G proteins. Furthermore, type II opsins are more closely related to nonopsin, light-insenstive GPCRs than they are to type I opsins.

Major Type II Opsin Classes

Based on phylogenetic analyses, there are four major classes of type II opsins in animals: cnidops, retinal G-protein receptor (RGR)/Go, rhabdomeric (Gq), and ciliary (Gt) (**Figure 2**).

Cnidops

In 2007, a new major class of opsins was described based on analyses of whole genome sequences of the phylum Cnidaria, which includes sea anemones and jellyfish. This cnidarian-specific class of opsins is called cnidops. The molecular details of cnidops-mediated phototransduction are not yet fully elucidated, but box jellyfish cnidops appears to activate Gs-class G proteins, which in turn activate adenylyl cyclase. For what might cnidarians be using opsins? Some jellyfish are known to use light cues to

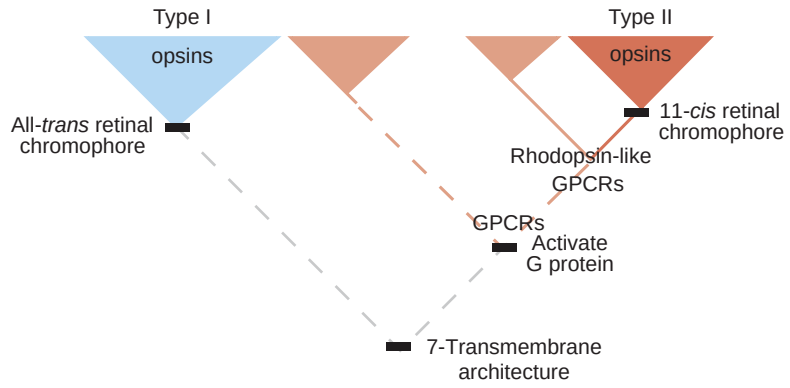

Figure 1 Evolutionary relationships of type I and type II opsins, and G-protein-coupled receptors (GPCRs). Triangles represent major groups with many genes from many species. Solid lines indicate good support for evolutionary relationship (common descent) based on sequence similarity and other evidence. Dashed lines indicate there is no evidence for common ancestry beyond random similarity of sequences and similar function. Type I opsins are well known from bacteria and function in a type of photosynthesis and, in some cases, to mediate movement toward or away from light. Type II opsins are found only in animals (see **Figure 2** and **Table 1**), and are likely related to nonopsin GPCRs, which include chemoreceptor and other proteins that detect a signal outside a cell, and mediate a response inside the cell. A chromophore is a light-sensitive chemical that is bound to opsin. Type I and type II opsins use different chromophores.

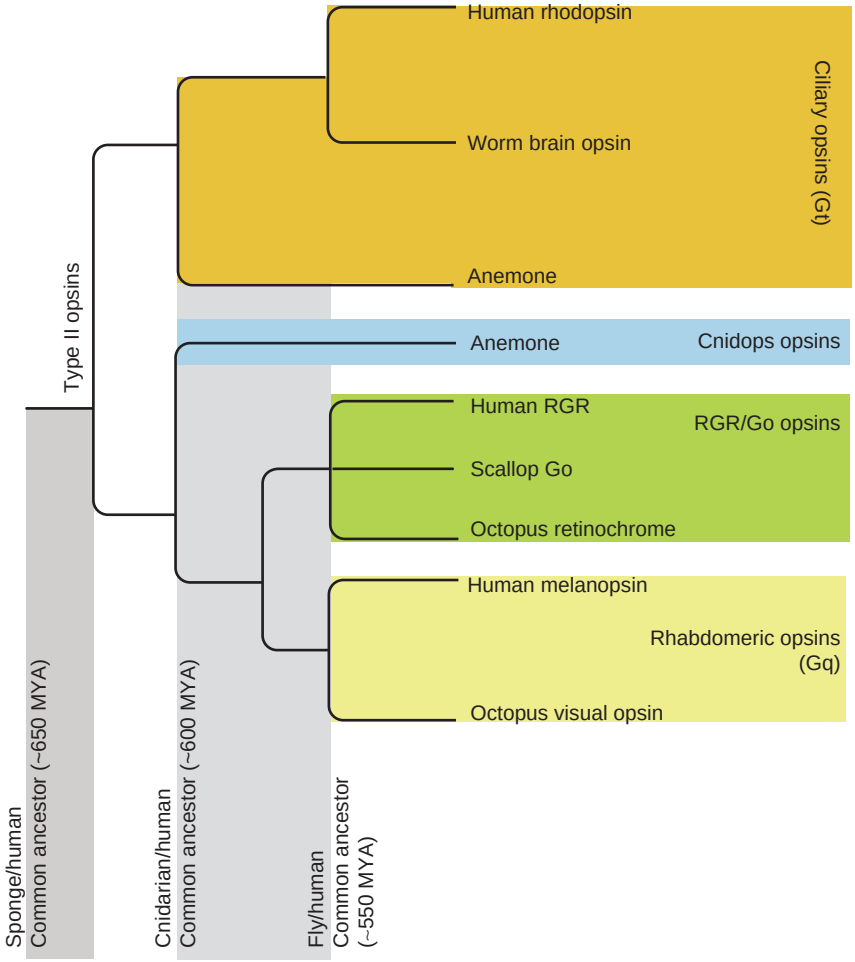

Figure 2 Illustrated are possible evolutionary relationships of the major groups of opsin genes (ciliary, cnidops, RGR/Go, and rhabdomeric). Here, each major group is represented by genes from one to three species, but each major opsin group is found in many other species as well. **Table 1** shows names of other opsins, some not on this figure, and the major opsin group to which they belong. Based on presence in anemone (a cnidarian) and bilaterian animals (humans and annelid worms), ciliary opsins and therefore all type II opsins originated before the common ancestor of cnidaria and bilateria, which lived some 600 million years ago.

regulate their depth in the water column and their swimming speed, while others (box jellyfish) possess sophisticated camera eyes analogous those of humans. These complex cnidarian eyes may be capable of image-forming vision, and are used for obstacle avoidance and perhaps for hunting prey. At present, there is no evidence for cnidops-mediated color vision.

Retinal G-Protein Receptor/Go

Retinal G-protein receptor (RGR) and Go opsins are functionally distinct from each other, but sometimes group together in phylogenetic analyses, indicating they may share more recent common ancestry with each other than with the other major opsin classes. Opsins grouping in this clade include those from vertebrates, cephalochordates (invertebrate chordates represented by the lancelet *Branchiostoma*), and mollusks.

In humans, three opsins often fall within the RGR/Go group: peropsin, neuropsin, and RGR. Cephalopod mollusks also possess a related opsin called retinochrome. Interestingly, members of this opsin class have not been noted from any arthropod or any other ecdysozoan (a group of molting invertebrates, including arthropods and nematode worms).

The RGR opsins are not well understood, but some important clues to their function exist. These opsins preferentially bind an all-*trans* isomer of retinal, contrasting with rod and cone opsin, which require 11-*cis* retinal for function. When tested in specific wavelengths of light that ranged from blue to ultraviolet (UV), RGR was able to convert all-*trans* retinal to the 11-*cis* isomer. Thus, it would seem that RGRs function to provide fresh retinal of the functional 11-*cis* conformation that is required for proper rod and cone opsin function. Retinochrome opsins from mollusks also have this photoisomerase function.

In addition, in mollusks and cephalochordates are opsins that may interact with a Go-class G protein, and as such are called Go opsins.

Rhabdomeric (Gq)

Opsins belonging to the rhabdomeric (Gq) class are present in bilaterian animals (animals with left and right sides), but unknown from Cnidaria. Where known, these opsins activate Gq-class G proteins, which drive phospholipase C second messengers. The opsins are sometimes called rhabdomeric opsins, because they tend to be expressed in specific cell types (rhabdomeric photoreceptor cells) that increase cell surface area using microvilli. Gq opsins are well known for mediating vision of many invertebrate animals, and are particularly well studied in the compound eyes of the fly *Drosophila melanogaster*. In chordates, including humans, Gq opsins are not expressed in the primary visual photoreceptors; instead, a Gq opsin, called melanopsin is known to be expressed in retinal ganglion cells, which are among the cells that relay signals from the primary photoreceptors to the optic nerve. Melanopsin is also involved in mediating the papillary reflex.

Ciliary (Gt)

Opsins belonging to the ciliary (Gt) class are present in eumetazoan animals, including vertebrates, annelid worms, and cnidarians (anemones and jellyfish). In vertebrates, these opsins activate Gt-class G proteins (transducins), which drive phosphodiesterase (PDE) enzymes. In invertebrates, the G protein that is activated by ciliary opsins is unknown. This class of opsins is often called ciliary opsins because they are known to be expressed in ciliary photoreceptor cells, which assemble a phototransduction organelle from a sensory cilium membrane. In annelids and bees, ciliary opsins are expressed in the brain. Although the organismal function of ciliary opsins is unknown in invertebrates, some have suggested a role in entraining circadian rhythms. In vertebrates, ciliary (Gt) opsins are expressed in the primary photoreceptors, the rods and cones, with different subclasses of opsin expressed in rods versus cones and further subclasses expressed in different cones to mediate color vision. Ciliary opsins with extraretinal expression are also known from vertebrates, and have been given various monikers, often named for their site of expression, such as pinopsin, parapinopsin, and tmt opsin. Details about the molecular and organismal functions of these extraretinal ciliary opsins are scarce (**Table 1**). One opsin in this class, parietopsin, is expressed in the parietal eye of a lizard and activates a Go-class G protein.

Opsin and Color Vision

Color vision, the ability to discriminate between light information of different wavelengths, is present in various groups of animals including insects and vertebrates, and involves opsin genes. Although color vision is a behavioral phenomenon that involves processes of both physical detection and neurobiological comparison, duplicated opsin proteins expressed in the retina directly mediate the physical detection of different wavelengths of light.

The specificity of a given opsin protein to a given wavelength of light is summarized by its λ-*max*, a measure of the peak absorbance across the light spectrum. The specific λ-*max* of a given opsin protein is largely a function of its amino acid sequence. Opsins representing the different spectral classes are specifically expressed in individual photoreceptor neurons called cone cells. When stimulated by light of the proper wavelength, opsins trigger a cellular response, leading to a change in the resting electric charge, or potential, of a photoreceptor cell. Color vision emerges from this system through the comparison

Table 1 Various names for type II opsins

Name	*Major clade*	*Taxon*	*Expression*	*Function*
Encephalopsin/ panopsin	Ciliary		Brain	Retinoid Receptor?
Exo-rhodopsin	Ciliary	Zebra fish	Pineal	Unknown
Parapinopsin	Ciliary	Vertebrates	Parapineal, pineal	
VA/VAL opsin	Ciliary	Vertebrates	Horizontal and amacrine cells, pineal, brain	Unknown
Cone L-opsin	Ciliary	Vertebrates	Cone cells	Photopic Vision
Cone M-opsin	Ciliary	Vertebrates	Cone cells	Photopic Vision
Cone S-opsin	Ciliary	Vertebrates	Cone cells	Photopic Vision
Cone V-opsin	Ciliary	Vertebrates	Cone cells	Photopic Vision
Pinopsin	Ciliary	Vertebrates	Brain, pineal organ	
Pteropsin	Ciliary	Bees, Mosquitoes	Brain	Unknown
Rhodopsin	Ciliary	Vertebrates	Rod cells	Scotopic Vision
TMT opsin	Ciliary	Teleost fishes	Many tissues	Unknown
Parietopsin	Ciliary	Zebra fish, fugu, Xenopus, lizard	Parietal eye	Photoreception
Cnidops	Cnidops	Cnidarians (hydra, anemone, and jellyfish)	Neurons	Light perception
Neuropsin	RGR/Go	Mammals	Testes, brain, spinal cord, eye	Photoisomerase?
Peropsin	RGR/Go	Mammals	RPE	Photoisomerase?
RGR	RGR/Go		RPE and Müller cells	Photoisomerase
Retinochrome	RGR/Go	Cephalopoda	Retina	Photoisomerase
Go	RGR/Go	Scallop, lancelet	Scallop eye	Photoreception
Arthopsin	Rhabdomeric	Daphnia	Unknown	Unknown
Melanopsin	Rhabdomeric	Vertebrates	Retinal ganglion cells	Circadian rhythms, papillary reflex
Rhabdomeric (Gq) opsin	Rhabdomeric	Invertebrates	Eye	Vision

of the resultant potentials of cone cells with those that express opsins of differing *λ-max* expressed in adjacent cone cells. For instance, humans possess three cone-opsins with *λ-max* values falling roughly into the categories of blue, blue–green, and yellow–green. Compared to other vertebrates, human opsins represent a single blue S opsin and two M opsins (blue–green and yellow–green) that resulted from a primate-specific gene duplication event. When red light falls upon a cone cell that is sensitive to yellow–green, it activates opsin signaling because light of this wavelength falls within the activity spectrum of this protein. However, red light does not fall within the sensitivity spectra of either the blue or blue–green opsins. Together, comparisons made between activated and non-activated cone cells lead to the human perception of red light. In most vertebrates, these comparisons are made by additional cells in the retina (i.e., the horizontal and ganglion cells) and also in a portion of the brain called the visual cortex.

In vertebrates, four distinct opsin classes, each with distinct sensitivities, accomplish the full spectral range. These include violet-(V) short-(S), middle-(M), and long-(L) wavelength varieties. Studies in the sea lamprey, a distant vertebrate relative of humans, have provided data that allow scientists to infer that the four major classes of vertebrate retinal opsins are the result of ancient gene duplication mutations that likely occurred before the origin of all living vertebrates. This implies that major opsin clades must have been lost in various vertebrate lineages. For instance, placental mammals likely originated from nocturnal ancestors that lost the V and M spectral classes of opsin. In addition, some marine mammals are known to have further lost the S class of opsin and are cone monochromats. Similar losses have been reported in a deep-dwelling, Lake Baikal fish. In general, each of these examples of opsin loss can be correlated to photoecology. When spectral sensitivity of a given wavelength is not required, selection against mutations at these loci is relaxed, allowing the loss of functional copies. However, on numerous occasions, photoecology has provided a generative context for the origination of new opsin genes and classes in vertebrate and invertebrate lineages alike. Often, these new visual repertoires converge both in spectral sensitivity (i.e., *λ-max*) and in the specific mutations that have lead to the functional shift.

Despite major differences between insect-faceted eyes and vertebrate camera-like eyes, both eye types utilize opsins in a similar way to achieve color vision. Similar to vertebrate color vision, insect color vision is based on a process of physical detection of light by opsins of differing *λ-max*, followed by neurobiological comparison of these light data. In insects and other arthropods, the neurobiological basis for color vision is less well understood but

likely involves a part of the insect brain called the medulla. While the neurobiological basis for insect color vision requires further clarification, it is clear that opsin gene duplication has been a driving force for the evolution of color vision in insects and other invertebrates. For example, the duplicated opsin genes of fruit flies are well studied. Two fly opsins are maximally sensitive to UV (345, 375 nm), one to blue (437 nm), two to blue–green (420, 480 nm), and one to green (508 nm) light.

Molecular Basis of Wavelength Sensitivity

Different *λ-max* values of different opsins are mediated by specific amino acid differences, which in some cases have been experimentally demonstrated. For example, in primates, three amino acid sites have a dominant role in differentiating red-sensitive and green-sensitive opsins. In birds, one opsin gene is blue sensitive in some species, and UV-sensitive in other species, a difference that is mediated by a single amino acid change. Changing the 84th amino acid of a zebra finch opsin allowed the protein's sensitivity to change from UV to blue when the protein was expressed in cultured cells. Conversely, pigeon and chicken blue-sensitive opsins became UV sensitive in cell culture after a change of the 84th amino acid. The combination of gene duplication and differential changes in amino acids of duplicated opsins has generated a diversity of proteins in different species.

Opsin and Modes of Phototransduction Evolution

As discussed above, opsin genes were very often duplicated and retained during animal evolution. Early opsin gene duplications led to the major opsin groups and more recent duplications mostly led to additional specializations, such as the ability for color vision. As members of highly coordinated protein networks, changes in opsin proteins are sometimes correlated with changes in partnering proteins. The interaction of two evolutionary processes has resulted in the diversity of opsin-based phototransduction pathways observed today that contains a combination of shared and distinct interactions. First, co-option refers to instances where an opsin recruited different intracellular signaling components than its ancestor during evolution. Second, co-duplication involved the simultaneous duplication of multiple genes of an ancestral network. Co-option and co-duplication are not discrete alternatives; instead, some genes of a network originated by co-duplication, whereas others joined the network by co-option. This becomes especially clear if we examine the evolution of particular networks at multiple timescales, or at increasing spatial scales by increasing the number of interactions considered.

An example of phototransduction pathways that evolved largely by co-duplication is the different pathways used in rod and cone cells of vertebrate retinas. Rods are specialized for dim light (scotopic) vision, and cones are specialized for bright light (photopic) vision. Rods and cones utilize different, duplicated opsins as well as different duplicated genes downstream of opsin. Multiple rod-specific and cone-specific genes originated through large-scale segmental duplication of an ancestral vertebrate genome before the origin of gnathostomes (jawed vertebrates) and after the split of vertebrates and their closest nonvertebrate relatives. As such, the duplication of multiple genes in these pathways maps to the same time interval and is consistent with co-duplication.

Examples of the origin of new opsin pathways involving co-option probably include the origin the major opsin groups, which signal to different G proteins. In particular, the rhabdomeric opsins are the only opsins to signal through Gq G proteins and transient receptor potential (TRP) ion channels. Since rhabdomeric opsins originated in the ancestor of living bilaterally symmetric animals, and are unknown from Cnidaria, they have a more recent evolutionary origin than ciliary opsins, which are present in Cnidaria. This pattern indicates co-option: at or near their origin, rhabdomeric opsins began signaling to Gq and TRP, proteins that predate bilaterian animals.

The Fibrillar Extracellular Matrix of the Trabecular Meshwork

M K Schwinn, J A Faralli, M S Filla, and D M Peters, University of Wisconsin, Madison, WI, USA

Glossary

Actomyosin network – A complex of myosin and actin filaments that regulates cell contractility.
Alternative splicing – The mechanism by which introns (noncoding regions) are removed from eukaryotic pre-messenger RNAs (mRNAs) to produce several different mature mRNAs and protein products from one gene.
Basement membrane – A thin layer of extracellular matrix proteins under a cell layer that supports cell attachment.
Cooperative signaling – Occurs when activation of one cell surface receptor activates or enhances activity of another cell surface receptor.
Exons – The coding sequences of genes.
Matrix metalloproteinases – A family of endopeptidases that cleave extracellular matrix proteins.
Mechanochemical – The conversion of mechanical stimuli into intracellular chemical signals.
RGD – The three-letter code for the amino acid sequence of arginine–glycine–asparagine. This amino acid sequence is found in many extracellular matrix proteins that bind integrins.
Rho GTPase – A member of the Ras family of guanine-nucleotide-binding proteins that control the polymerization of actin filaments and serves as a molecular switch to regulate cell proliferation, morphogenesis, migration, and gene expression.

Introduction

Intraocular pressure (IOP) is maintained through a delicate balance between aqueous humor (AH) production and its drainage through the trabecular meshwork (TM) and ciliary muscle. A major regulatory site of AH drainage in humans resides within the extracellular matrix (ECM) of the juxtacanalicular tissue (JCT) and the underlying inner wall of Schlemm's canal. The role the ECM plays in regulating AH outflow is unknown. One theory suggests that the ECM acts as a passive filter that restricts outflow across the TM by providing physical resistance to the movement of AH. Increases in fibronectin and collagen deposition could conceivably clog the filter and restrict AH movement. More recent studies, however, suggest that changes in the composition of the ECM would affect AH outflow by altering either the compliance of the TM or the contractile properties of the trabecular cells in the TM. In this article, we discuss the properties of collagen and fibronectin fibrils and how they might affect AH outflow.

Collagen: Structure and Localization

Collagens are composed of three α-chains that intertwine to form stable triple helical protomers. The protomers are either homo- or heterotrimers that assemble into unique supramolecular complexes. In vertebrates, there are at least 28 different types of collagens which are divided into several families based upon their structure. A number of collagens have been identified in the TM (**Table 1**); however, comparatively little is known about their molecular composition, relative abundance, or function within the TM. This article focuses on two of the major collagens found in the TM types I and IV collagen.

The collagens are highly conserved in terms of both their structure and function. Type I collagen is a heterotrimer of two identical chains called α1(I)-chains and one chain called α2(I)-chain. Each α-chain is synthesized from a single gene as a precursor molecule called procollagen that contains additional peptide extensions on both the N- and C-termini of the α-chains. These extensions referred to as propeptides maintain the solubility of type

Table 1 Collagens found in the trabecular meshwork

Family	*Type*	*Molecular form*	*Localization*
Fibril forming 	I III V XI	$[\alpha1(I)]_2\alpha2(I)$ $[\alpha1(III)]_3$ $[\alpha1(V)]_3$ $[\alpha1(V)]_2\alpha2(V)$ $\alpha1(V)\alpha2(V)\alpha3(V)$ $\alpha1(XI)\alpha2(XI)\alpha3(XI)$	Core of beams, JCT
Type IV 	IV	$[\alpha1(IV)]_2\alpha2(IV)$ $\alpha4(IV)$-$\alpha6(IV)$*	Basement membranes of inner wall, along beams and underneath trabecular cells in JCT
Hexagonal networks 	VIII	$[\alpha1(VIII)]_2\alpha2(VIII)$	Corneoscleral meshwork; within the JCT; both walls of Schlemms's canal
Beaded filaments 	VI	$\alpha(VI)\alpha2(VI)\alpha3(VI)$	Core and basement membrane of beams; JCT; outer wall of Schlemm's canal
FACITs 	XII XIV XXII	$[\alpha1(XII)]_3$ $[\alpha1(XIV)]_3$ $\alpha1(XXII)$*	Gene level only
Multiplexins	XV	$[\alpha1(XV)]_3$	Gene level only

*Molecular form unknown.

I collagen at physiological pH and play a regulatory role in modulating fibril formation. The propeptides are cleaved off by the specific proteases, procollagen N-proteinase and procollagen C-proteinase, which then triggers the spontaneous self-assembly of type I collagen molecules into fibrils. Within fibrils, type I collagen molecules are staggered relative to a neighboring molecule to create a striated collagen fibril exhibiting a 67-nm banding pattern. Type I collagen fibrils are found in the center of the trabecular beams, in the basement membrane along the beams and throughout the JCT. They are responsible for providing tensile strength to the TM, which is an essential physical requirement given the biomechanical demands on the TM. Type I collagen fibrils are often co-assembled into fibrils with types III and V collagen. Both these collagens are also found in the center of the beam and the JCT, but it is not known whether they are co-assembled with type I collagen into the same fibril and how this affects the function of the TM.

In addition to type I collagen, another major collagen in the TM is type IV collagen. In mammals, there are six homologous α-chains, α1(IV)–α6(IV), that are assembled into five distinct heterotrimeric protomers (**Table 1**). Each α-chain is characterized by three domains: a cysteine rich N-terminal 7S domain, a central triple helical domain, and a globular C-terminal noncollagenous domain (NC1). The central collagenous domain is interrupted by several noncollagenous sequences, which presumably contribute to the increased flexibility of type IV collagen relative to type I collagen. The assembly of the type IV chains is

different from that of type I chains in that the propeptides are not cleaved from the type IV molecule and the flexible type IV chains assemble into a network of filaments rather than linear fibrils.

Another interesting difference is that the NC1 domains of type IV collagen can exist as biologically active fragments in tissues or in the circulation. For instance, the isolated NC1 domains of the α1, α2, and α3 chains referred to as arrestin, canstatin, and tumstatin, respectively, are inhibitors of angiogenesis. *In vitro*, NC1 domains of type IV collagen regulate cell attachment, migration, proliferation, and gene expression. In particular, the NC1 domains control expression of matrix metalloproteinases (MMPs) that are important in the regulation of AH outflow. The activities of the NC1 domains are only expressed after type IV collagen has undergone proteolytic degradation. This implies that the activities of the NC1 domains are conformation dependent and would only be exposed in the TM as the ECM is remodeled. The release of these domains and additional upregulation of the MMP activity could be one way that matrix turnover and outflow are enhanced.

Type IV collagen is a major constituent in basement membranes and comprises approximately 50% of all basement membranes. In the TM, type IV collagen is found in the basement membranes covering the trabecular beams, along the inner and outer walls of Schlemm's canal and underneath the TM cells in the JCT. Together with laminin, type IV collagen is crucial for the stability and function of basement membranes. The functional specificity of the different basement membranes is derived in part from the different type IV collagens expressed in the tissue. For example, in kidney at least three distinct type IV collagens can be found. Bowman's capsule basement membrane contains the $[\alpha1(IV)]_2\alpha2$ (IV) protomer and perhaps the $[\alpha5(IV)]_2\alpha6$ (IV) protomer, while glomerular basement membrane contains the $\alpha3(IV)\alpha4(IV)\alpha5(IV)$ protomer. Whether there is any heterogeneity among the various basement membranes in the TM is not known, but clearly if there was, it could play a role in imparting different functional properties to the layers of the TM.

The synthesis of all collagens involves the coordination of several post-translational modifications that require specific enzymes and chaperones. These enzymes include the three collagen hydroxylases: prolyl 4-hydroxylase, lysyl hydroxylase, and prolyl 3-hydroxylase. The hydroxylation of proline and lysine residues is unique to collagens and is needed to stabilize the formation of the triple helix. These enzymes require ascorbate as a cofactor, which could explain one reason why ascorbate is found in high concentrations in the AH. It would also explain why ascorbate has been found to enhance collagen deposition into the ECM. Collagen synthesis also involves two collagen glycosyltransferases (galactose transferase and glucose transferase) that add galactose and glucose to hydroxylysyl and galactosylhydroxylysyl residues, respectively. This glycosylation is distinct from *O*- and N-glycosylation that occurs on most other proteins and is another unique post-translational modification of collagen precursors. Another post-translational modification includes the removal of the *N*- and C-propeptides by procollagen N-proteinase and procollagen C-proteinase. Procollagen C-proteinase belongs to the tolloid family and was originally called bone morphogenic protein-1 (BMP-1). Finally, collagen synthesis involves two isomerases (peptidyl-prolyl *cis–trans* isomerase and protein disulfide isomerase), an oxidase (lysyl oxidase), and a collagen-specific chaperone (HSP47). Together, these proteins mediate the assembly of collagen molecules into fibrils and create the covalent cross-links that are necessary for normal tensile strength and function of the fibril.

Fibronectin: Structure and Localization

Fibronectin is another major ECM fibrillar protein in the TM. Similarly to type I collagen, it is found in the core of the trabecular beams as well as along the basement membranes on the beams. In addition, fibronectin can be found in the sheath material surrounding the elastin tendons, in the amorphous fibrogranular material in the JCT and scattered along the basement membranes of the inner wall of Schlemm's canal. Fibronectin is also found as a soluble protein in AH.

An important feature of fibronectin's activity is its modular and flexible structure. As a soluble protein, fibronectin exists as a soluble, compact protein with many of its biological domains inaccessible. The active form of fibronectin is generally thought to be an extended protein assembled into an insoluble fibril. In contrast to the self-assembly of collagen fibrils, fibronectin fibrillogenesis is a highly controlled cell-mediated process involving integrins (especially α5β1) and cell contractility. Any changes in this process are likely to affect outflow facility because it would affect the incorporation of fibronectin into the ECM in much the same way as changes in the levels of fibronectin expression would.

Although single chain forms of fibronectin have been found in cartilage and zebra fish, human fibronectin primarily exists as a dimer composed of two nonidentical polypeptide chains that are disulfide bonded at their carboxyl termini (**Figure 1**). Each chain contains a series of homologous units called type I, II, and III repeats. The type III repeats comprise the majority of each chain and play a critical role in determining the activity of fibronectin in part because their conformation is sensitive to proteolysis or mechanical perturbations. Perturbations in the tertiary structure of the type III repeats expose novel cryptic sites with unique biological activities. For example, a 30–35% stretch applied to immobilized fibronectin revealed a cryptic site in the III1 repeat that promotes the assembly of fibronectin fibrils and stimulates cell growth and contractility.

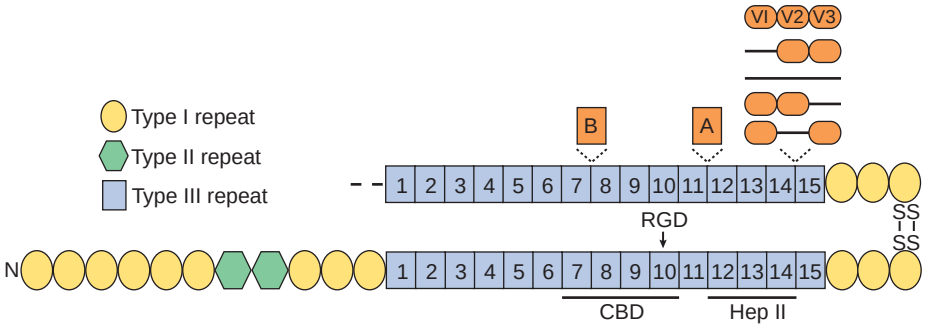

Figure 1 Fibronectin. Two nonidentical polypeptide chains consist of homologous type I (circles), II (hexagons), and III (squares) repeats that are disulfide bonded at the C-termini. Omitted portion of top strand (dashes) is identical to bottom strand. The RGD containing cell-binding domain (CBD) and the HepII domain are underlined. Alternatively spliced exons (EDA, EDB, and V) are offset from the fibronectin chain.

The flexibility of these repeats is retained even after fibronectin has been assembled into a fibril. Thus, a fibronectin fibril is elastic and can stretch about 4 times its original length. The force required to unfold these repeats and stretch a fibronectin fibril can be generated by the actomyosin network. This suggests that changes in contractility, or IOP, which stretch the TM, would alter the biological activity of fibronectin in the matrix. Interestingly, not all fibrils exhibit the same level of stretch, which implies that fibronectin fibrils could have different activities in different regions of the TM.

Fibronectin is a multidomain protein with each domain exhibiting a remarkable number of biological activities, including cell adhesion, migration, proliferation, differentiation, apoptosis, and gene expression. These domains also regulate growth factor signaling and the organization of the actin cytoskeleton. Since many of the domains are resistant to proteolysis and can be isolated without a loss in activity, it is possible that similar to the NC1 domain of type IV collagen, small bioactive domains of fibronectin could be available in the TM *in vivo* during ECM turnover.

The HeparinII (HepII) domain of fibronectin is an example of such a domain. This domain is especially relevant to the regulation of outflow resistance, because when it is perfused into either human- or monkey-cultured anterior segments, outflow facility is increased. This domain consists of the 12th–14th type III repeats (**Figure 1**) and can bind heparan sulfate proteoglycans (HSPGs) either on the cell surface or in the ECM. It also binds myocilin, a glucocorticoid response protein associated with glaucoma and vascular endothelial growth factor (VEGF), which is present in AH and upregulated in glaucomatous eyes.

The HepII domain regulates a number of biological activities, including cell survival and MMP expression. This domain, however, is probably best known for its ability to regulate the organization of the actin cytoskeleton and the contractile properties of the TM which play an important role in regulating outflow facility (see **Figure 2(a)**).

Fibronectin is a highly conserved protein. The sequence homology among mammals is greater than 90% and between chickens and mammals, the homology is greater than 80%. As many as 20 variants of fibronectin are derived from a single gene. These forms arise from alternative splicing of three exons called EDA (or EIIIA), EDB (or EIIIB), and IIICS (or V). The exons for EDA and EDB are spliced out entirely whereas the V exon undergoes exon subdivision to generate a V1, V2, or V3 region (**Figure 1**). In primary porcine TM cells, fibronectin messenger RNA (mRNA) contains all three regions of the V exon, but it lacks both the EDA and EDB exons. This is consistent with the observation that the EDA and EDB exons are mainly expressed in embryonic tissues or in some disease states.

In the TM, alternative splicing of these regions can be regulated by stretch or the growth factors, transforming growth factor beta 1 (TGF-β1) and TGF-β2. For example, in stretched porcine TM cells, the V1 and V3 regions are expressed, but the V2 region is spliced out. Stretch does not significantly affect expression of the EDA and EDB exons, since at least 90% of the transcripts from stretched porcine TM cells lack the EDB exon and none of the transcripts contains the EDA exon. In contrast, TGF-β1 and TGF-β 2 upregulate the expression of the EDA and EDB exons. Thus, patients with primary open-angle glaucoma, in which the levels of TGF-β2 are elevated, are more likely to express EDA- and EDB-containing fibronectin.

Expression of the splice variants is likely to alter the biological activity of fibronectin in the TM and consequently AH outflow. It still needs to be determined exactly how expression of the different variants of fibronectin affects outflow facility. Theoretically, inclusion of the EDA domain could increase outflow facility because it triggers the reorganization of actin stress fibers into cortical actin filaments and induces MMP-1, MMP-3, and MMP-9 expression. Inclusion of the EDA domain, on the other hand, could decrease outflow facility because it also promotes the assembly of fibronectin matrices. Alternative splicing of the V region is likely to affect the contractile properties of the TM because that would remove several binding sites that cells use to regulate adhesion and the contractile properties of cells. Alternative splicing of the V region could also modify the

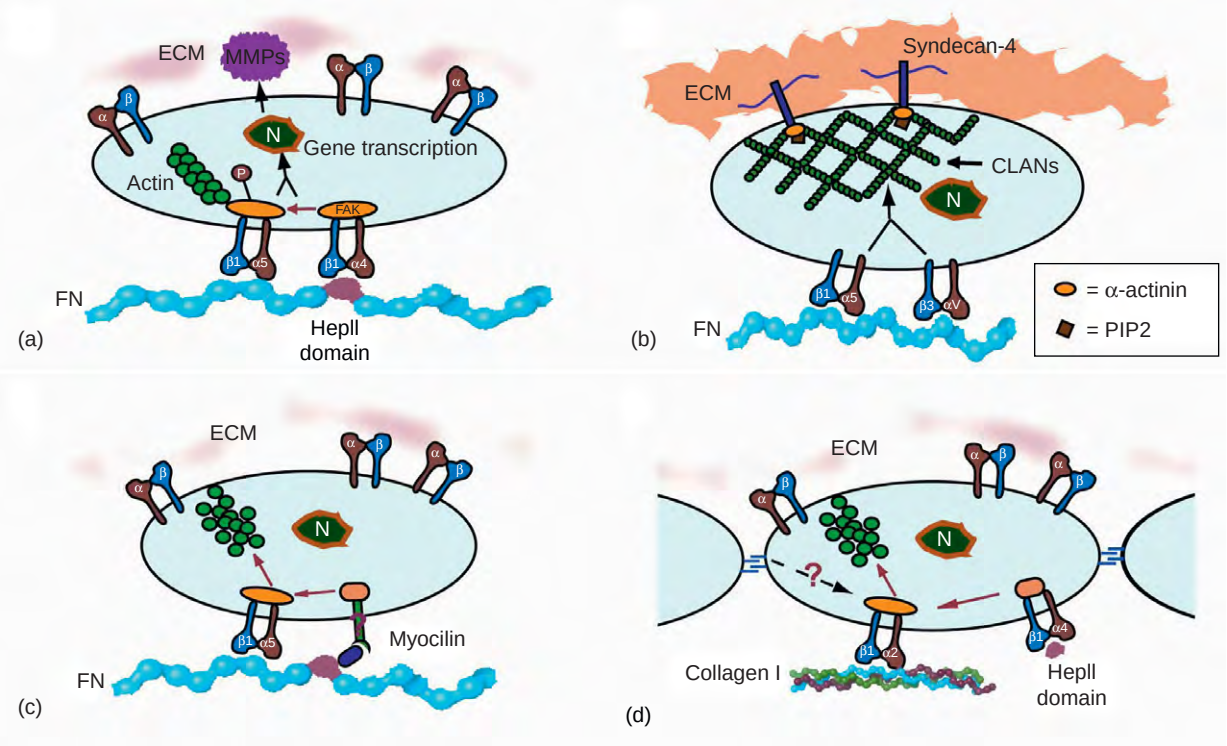

Figure 2 Model of fibronectin (FN) signaling in the TM. (a) In subconfluent cells, engagement of α4β1 integrin by the HepII domain initiates co-signaling with α5β1, which induces phosphorylation of FAK and enhances actin stress fiber and focal adhesion (FA) formation. This co-signaling could also trigger changes in gene transcription and levels of MMPs resulting in less ECM. (b) Cooperative signaling between β1 and β3 integrins enhances cross-linked actin network (CLAN) formation in TM cells. Molecules such as syndecan-4, α-actinin and PIP2 have been shown to localize to the vertices of CLANs. (c) Myocilin downregulates the assembly of actin stress fibers when TM cells or fibroblasts are plated on FN. It is not known how myocilin does this. It may be due to signaling through an unknown receptor or by binding to the HepII domain of FN and inhibiting signaling through α4β1 integrins. (d) In confluent TM cell monolayers, co-signaling from the HepII domain bound to α4β1 integrins and collagen engaged integrins (i.e., α2β1) results in the disassembly of cell–cell contacts and stress fiber disassembly.

adhesive properties of the heparin-binding activity of the HepII domain of fibronectin, switching it from a HSPG-dependent binding domain to a HSPG-independent-binding domain. This could affect the ability of the HepII domain to regulate AH outflow because it could alter how the HepII domain interacts with the ECM and cell surface receptors. Finally, alternative splicing of the V region has been shown to modulate the ability of the HepII domain to regulate MMP expression and cell survival that could also affect outflow facility. In summary, fibronectin has a modular and flexible structure which could provide a unique mechanochemical mechanism that the ECM can use to mediate AH outflow.

Factors that Affect Collagen and Fibronectin Expression and Assembly into the ECM

Although a number of studies have reported increases in ECM deposition in glaucoma and during aging, it is unknown whether this is due to an increase in the synthesis and deposition of collagen and fibronectin and/or a decrease in turnover of fibronectin and collagen fibrils. Factors that have been shown to increase the expression of types I and IV collagen and fibronectin in the TM as well as increase outflow resistance include: glucose, glucocorticoids, ascorbic acid, TGF-β1, and TGF-β2. Glucocorticoids, TGF-β1, and ascorbate could also alter the assembly of collagen fibrils. Glucocorticoids lead to a downregulation of type I C-propeptides and the α2(I) chain in the TM, while ascorbate and TGF-β1 lead to an increase in the hydroxylation of prolyl and lysyl residues used to stabilize the triple helix. TGF-β1 enhances the hydroxylation of prolyl residues because it increases the expression of the gene for protein disulfide isomerase which is essential for proline hydroxylation.

Elevated levels of TGF-β2, which have been reported in glaucoma patients, would also promote the accumulation of collagen and fibronectin into the ECM because it activates tissue transglutaminase. Tissue transglutaminase is a calcium-dependent enzyme that promotes the cross-linking of collagen and fibronectin via the formation of an isopeptide bond. This would modify the stability of the collagen and fibronectin fibrils in the ECM by rendering them more resistant to degradation. Tissue transglutaminase has also

been reported to form a cross-linked complex with fibronectin. Interestingly, this complex has been shown to amplify signaling to Rho guanosine triphosphate (GTP)ases which would increase the contractile properties of the TM and reduce outflow facility.

Age-related changes in collagen fibrils are also likely to occur, especially if there is a slower turnover of collagen. One critical change would be the formation of new cross-links derived from sugar through the Maillard reaction. In hyperglycemic conditions, excess sugar accelerates this reaction, leading to an accumulation of advanced glycation end products (AGEs) and a subsequent increase in collagen-collagen cross-links. Increased levels of AGEs have been correlated with diabetes mellitus, a condition that is considered a possible risk factor for glaucoma. The resulting cross-links are not readily broken down by the enzymes capable of degrading type I collagen. MMP-1 is only capable of digesting native type I collagen fibrils, while the other enzymes, called gelatinases, degrade collagen only after it has been cleaved by MMP-1 or if it is denatured. Thus, in the aging eye or in diabetic patients, turnover of the ECM could lead to the formation of a matrix that consists of highly cross-linked collagen fragments or partially cleaved fibrils. The presence of this fragmented and cross-linked matrix would impair the structural and mechanical properties of the ECM in the TM. This could lead to alterations in the compliancy of the ECM, a decrease in the contractile properties of the TM, changes in the expression of genes such as MMPs, and even cell death.

Finally, despite the fact that over 1100 mutations have been reported to occur in types I, II, III, IV, and VII collagens, nothing is known about how about these mutations may affect the function of the deposition and remodeling of collagen fibrils. Interestingly, mice that have a targeted mutation in type I collagen that impairs collagen remodeling exhibited ocular hypertension.

Collagen and Fibronectin Receptors

Extensive literature from other cell types suggests that fibronectin, collagen, and their receptors provide mechanical support for cell attachment and activate signaling pathways that regulate many of the biological processes involved in modulating outflow resistance, including matrix production, ECM turnover, gene expression, growth factor signaling, and cytoskeletal organization. Furthermore, fibronectin and collagen receptors modulate mechanochemical responses to physical forces such as stretch.

Many of the biological activities of collagen and fibronectin are mediated via interactions with integrins. Integrins are heterodimeric transmembrane receptors composed of α- and β-subunits. Those found in the TM include α2β1 and α1β1. α2β1 integrins preferentially bind type I collagen, while α1β1 integrins bind type IV collagen. The integrin α11β1 also binds type I collagen but, as of yet, this integrin has not been identified in the TM. The TM also contains the integrins α3β1, αvβ1, α5β1, αvβ6, α4β1, and α4β7 that bind fibronectin and the integrins αvβ3 and αvβ5 that bind both fibronectin and type IV collagen. These integrins are distributed throughout the TM with the heaviest localization observed along cells on the beams.

The major integrin-binding site in fibronectin for all integrins, except α4β1, is the arg–gly–asp (RGD) sequence in the III10 repeat. The α4β1 integrin binds RGD homologs found in five different regions of fibronectin. They are: the KLDAPT sequence in the III5 repeat, the EDGIHEL sequence in the EDA domain, the IDAPS sequence in the III14 repeat of the HepII domain, and the LDV and REDV sequences in the V1 and V3 regions of fibronectin, respectively (**Figure 1**).

The integrin-binding site in type IV collagen is in the NC1 domain and appears to be specific for the various α(IV)-chains. Hence, the α1(IV) NC1 domain binds α1β1 integrins, the α2(IV) NC1 domain binds α1β1, αvβ3, and αvβ5 integrins, and the α3(IV) NC1 domain binds αvβ3 and αvβ5 integrins. Additional binding sites for α1β1 and α2β1 can also be found in the collagenous regions α1(I)CB3 and α1α2(IV)CB3 in types I and IV collagen, respectively. Although the sequence GRGDTP was initially reported as the integrin-binding sequence for type I collagen, several reports now show that the GER motif, in particular, the hexapeptide GFOGER, may be the more crucial sequence for binding integrins particularly to type I collagen fibrils. GER-containing motifs are not the only sequence recognized by the collagen integrins, αvβ3 and αvβ5 integrins may use both RGD and non-RGD motifs in the NC1 domain of type IV collagen. The collagen integrins appear to have specific activities. α1β1 integrins downregulate collagen synthesis and upregulate cell proliferation, while α2β1 integrins upregulate collagenase and collagen synthesis. The α2β1 integrin may also preferentially interact with type I collagen fibrils, whereas the α1β1 integrin binds monomeric type I collagen.

Integrin signaling in the TM is likely to be complex and controlled in part by the presence of other receptors and matrix proteins that co-direct signaling events with integrins. This process, referred to as cross talk, can be either cooperative or antagonist. For example, cooperative signaling between β1 and β3 integrins enhances the formation of cross-linked actin networks in TM cells (**Figure 2(b)**), while the matrix protein myocilin downregulates the assembly of actin networks formed when TM cells or fibroblasts are plated on fibronectin (**Figure 2(c)**). In subconfluent proliferating TM cells plated on fibronectin, activation of α4β1 integrins by the HepII domain triggers cross talk with α5β1 integrins bound to a fibronectin substrate (**Figure 2(a)**). Activation of the α4β1/α5β1 integrin signaling pathway enhances cell attachment to fibronectin by increasing actin stress fiber formation and focal adhesion kinase (FAK) phosphorylation. In contrast, co-signaling between the collagen integrin, α2β1,

and α4β1 appears to trigger the disassembly of actin filaments in confluent TM cultures. Integrin signaling is also likely to be controlled by the specific molecules associated with the cytoplasmic tails of the integrins, such as paxillin and talin.

Another major family of receptors for fibronectin and collagen in the TM are the syndecans, which are transmembrane HSPGs that typically use their heparan sulfate chains to interact with a heparin-binding motif that is rich in highly basic amino acids. All four members of the syndecan family are found in the TM, but only syndecans-1, -2, and -4 bind to fibronectin and only syndecan-1 has been reported to interact with types I and IV collagen. The most prominent syndecan in the TM is syndecan-4. It is best known for its role in focal adhesion formation, and organization of the actin cytoskeleton.

Integrins and syndecans are ideal candidates to regulate outflow facility. They control cell adhesion, growth factor signaling, and assembly and turnover of extracellular matrices. They also activate members of the Rho GTPase family which control the contractility of the actomyosin network and play a critical role in regulating AH outflow. In addition, integrin and syndecan signaling is responsive to stretch, steroids, and TGF-β; all factors that affect IOP. In the TM, stretch upregulates the expression of αv, α5, and β1 integrins. Steroids, on the other hand, downregulate the expression of αv integrins in TM cells, but upregulate the expression of the α5 integrins. To date, it is not known if TGF-β affects integrin and syndecan expression in the TM. In other cell types, TGF-β increases the expression of α5, αv, β1, and β3 integrins and syndecan-1. In some instances, integrin expression may not be affected by these factors, but its activity is. For example, α4β1, α5β1, α2β1, and αvβ3 integrins can switch from an inactive (low-affinity) state to an active (high-affinity) state in response to stretch and external stimuli. ECM signaling through integrins and syndecans, therefore, could easily be adapted to meet changes in IOP and potentially play an important role in the maintenance of AH homeostasis.

Summary and Future Perspectives

In conclusion, very little is known about how the ECM contributes to the regulation of outflow facility. As discussed in this article, changes in both the relative amounts of collagen and fibronectin deposition as well as their level of cross-linking by tissue transglutaminase in the TM have been reported in glaucomatous tissues. However, it is not known how these changes could affect outflow facility. Will they only affect the compliance and permeability of the TM? Or will the changes also affect ECM-mediated signals responsible for cellular function and survival? Clearly, studies are needed in order to better understand how alterations in collagen and fibronectin deposition contribute to the pathophysiology of glaucoma.

The Genetics of Primary Open-Angle Glaucoma: A Review*

R R Allingham and Y Liu, Duke University, Durham, NC, USA

Glossary

Association – A statistical statement used to describe the co-occurrence of alleles or phenotypes.
Chromosome – A linear structure found in all nucleated cells consisting of both DNA and proteins. Genes are organized on strands of DNA. The normal human complement consists of 23 pairs of chromosomes.
Complex disease – A disorder that is inherited in a manner not consistent with conventional Mendelian genetics that are controlled by a single locus or gene. The phenotype of a complex disorder results from the contribution of multiple genes in combination with environmental factors.
Gene – The DNA or RNA that codes for a functional RNA or protein product.
Linkage analysis – A statistical and biomolecular approach to determine the location of a gene or genes in an organism.
Locus (plural: loci) – The physical or relative location of a gene within a chromosome.
Mutation – A heritable change in genetic material that can potentially be passed from parent to offspring. This change may occur in a gene or in a chromosome and can result from the loss, gain, or rearrangement of genetic material.
Polymorphism – A piece of DNA that has more than one form (allele), each of which occurs with at least 1% frequency is said to be polymorphic. Polymorphisms are a normal part of genetic variability, and they may or may not result in functional changes of the gene.
Single nucleotide polymorphism (SNP) – It consists of a single base change in a DNA sequence.

Introduction

Glaucoma is a heterogeneous group of disorders which constitute the leading cause of irreversible blindness worldwide. It is a pathologic condition in which there is a progressive loss of retinal ganglion cells, specific visual-field deficit, and a characteristic excavative atrophy of the optic nerve. Primary open-angle glaucoma (POAG) is the most common type of glaucoma and is characterized by the presence of glaucomatous optic neuropathy in the absence of an identifiable secondary cause (**Figure 1**). Abnormally elevated intraocular pressure (IOP) is frequently associated with glaucoma and is a major risk factor for this disease.

POAG as a Complex Inherited Disorder

The familial nature of POAG has been recognized for decades. In studies of patients with POAG, up to 50% have a positive family history. In a large population-based study conducted in the Netherlands, Wolfs and coworkers examined family members of individuals with and without POAG. These investigators found that first-degree relatives of an affected individual had a 22% risk of developing POAG compared with only a 2.3% risk in family members of controls. The overall risk of developing POAG among first-degree relatives of an affected individual is increased from three- to ninefold. These evidences strongly suggest that specific genetic defects contribute to the pathogenesis of POAG.

Our modern understanding of the genetic architecture of POAG has been steadily evolving since the first gene for POAG, myocilin (MYOC), was mapped and identified. The MYOC gene and other reported genes for POAG were mostly identified from large families with glaucoma inherited in a Mendelian pattern, where the altered function of a single gene is sufficient to cause the disease. However, it has become increasingly clear that POAG, in most cases, is inherited as a complex trait, where the disease results from the interaction of multiple genes and environmental factors. This should not come as a surprise since the glaucoma phenotype itself is quite complex, resulting from diverse pathological processes that involve, but are not limited to, the aqueous humor outflow pathway, the retina, and optic nerve.

Genetic Approaches to Gene Identification

Identifying genes that either cause or contribute to the development of disease is challenging, especially in complex disorders such as POAG. The most commonly used method to identify genes that are transmitted in a Mendelian pattern, such as an autosomal dominant or

*Adapted from Allingham, R. R., Liu, Y., and Rhee, D. J. (2009). The genetics of primary open-angle glaucoma: A review. *Experimental Eye Research* 88(4): 837–844.

recessive trait, is genetic linkage analysis. This method employs the use of families where multiple members are affected. The power to detect linkage is proportional to the number of individuals affected within families and the total number of families. Once linkage to a specific chromosomal locus is identified, analysis of the genes and their variants that are within the region of interest is conducted. To date, disease genes for the vast majority of inherited disorders have been identified using traditional linkage analysis. However, despite this success, more than 90% of the genetic contribution for POAG still remains to be determined.

In an effort to address the challenges associated with gene identification for common, complex disorders that do not exhibit classical Mendelian inheritance patterns, newer and more robust methods have been developed. The most promising of these is genome-wide association with high-density single-nucleotide-polymorphism (SNP) arrays and massive enlargement of cohort sizes. This approach utilizes data sets containing large numbers of unrelated cases and controls to determine statistical associations between common genetic variations within the human genome and disease. SNPs are the mainstay of this type of analysis and, numbering in the millions, they are dispersed throughout the human genome – making them ideal for genetic analysis. Although the theory underlying this approach has been known for decades, only recent advances in massive throughput genotyping have made this approach practical. It is now possible to genotype 1 million SNPs per individual on large data sets containing thousands of samples in just a few days. This approach has led to the identification of common disease-associated genetic variants in chronic disorders, including diabetes mellitus, heart disease, cancer, and others. Ophthalmology has greatly benefitted from this approach. Major, common genetic variants that predispose to age-related macular degeneration (CFH) and pseudoexfoliation syndrome (LOXL1) have recently been identified by genome-wide association studies.

In addition to whole-genome association, there are additional methods being developed to determine the cause of inherited disease. Admixture mapping is a method used to localize disease-associated genetic variants that differ in frequency across populations. This powerful method has been successfully used to locate the chromosomal location for a gene that causes prostatic cancer and is currently being used to locate disease-associated variants for POAG in the African-American population. Another area of intense interest is the role that DNA copy number variants and genetic imprinting may have in a variety of human disorders including POAG. As these approaches are increasingly used, additional susceptibility loci and genes for POAG will likely be discovered.

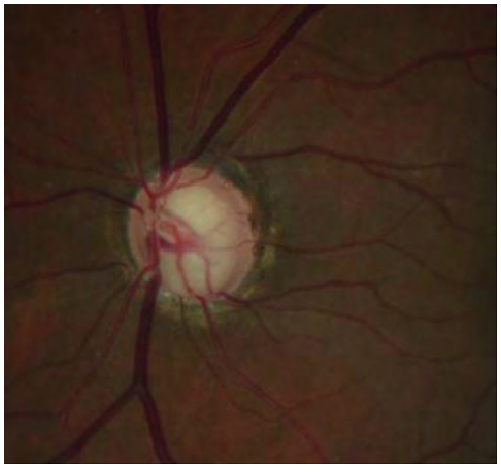

Figure 1 The optic disk photo demonstrates moderate to advanced optic disk cupping in a patient with POAG. There is complete loss of the inferior neuroretinal rim.

Chromosomal Loci for POAG

A genetic locus (singular; loci is plural) refers to a specific physical region of a chromosome that defines an area harboring a gene or genes that are associated with a specific phenotype or disease. Currently 14 chromosomal loci for POAG (GLC1A-N) are listed by the Human Genome Organization (HUGO; Geneva, Switzerland) and many more have been reported in the literature (Table 1). In most cases, these loci have been identified in family datasets using genetic linkage analysis. Three genes associated with glaucoma have been identified within these loci, including myocilin/TIGR (GLC1A), optineurin (GLC1E), and WDR36 (GLC1G).

Myocilin

MYOC was identified by Stone and coworkers in the GLC1A, which was the first locus for POAG located

Table 1 Currently reported POAG chromosomal loci

Chromosomal location	*POAG phenotype*	*Locus name*	*Candidate gene*
1q23-q24	JOAG, adult-onset	GLC1A	MYOC
2cen-q13	Adult-onset	GLC1B	
2p12	Elevated IOP		
2p16.3-p15	JOAG, Adult-onset	GLC1H	
3p22-p21	Adult-onset	GLC1L	
3q21-q24	Adult-onset	GLC1C	
5q22.1	Adult-onset	GLC1G	WDR36
5q22.1-q32	JOAG	GLC1M	
7q35-q36	Adult-onset	GLC1F	
8q23	Adult-onset	GLC1D	
9q22	JOAG	GLC1J	
10p13	Adult-onset, NTG	GLC1E	OPTN
15q11-q13	Adult-onset	GLC1I	
15q22-q24	JOAG	GLC1N	
19p13.2	Elevated IOP		
20p12	JOAG	GLC1K	

on chromosome 1. The MYOC protein was previously known as trabecular-meshwork-inducible glucocorticoid response protein or TIGR. Disease-associated mutations of MYOC are generally associated with a juvenile or early adult form of POAG. This genetic form of glaucoma is typically associated with high IOPs and frequently requires surgical intervention for disease control. In adult POAG populations, the prevalence of MYOC mutations in POAG cases varies between 3% and 5% making it the most common form of inherited glaucoma currently known.

The MYOC gene consists of three exons. MYOC protein has sequence similarities to the muscle protein myosin at the N-terminus, from which it gets its name, and olfactomedin at the C-terminus. Most glaucoma-associated mutations in the MYOC gene are located within the third exon which codes for the olfactomedin-like domain. MYOC is expressed by most tissues of the eye and multiple tissues throughout the body. Although MYOC is widely expressed, the only disorder that results from genetic variants of this gene is glaucoma.

MYOC-associated glaucoma is transmitted as an autosomal dominant Mendelian trait. Carriers of disease-associated mutations develop the glaucoma phenotype in an estimated 90% of cases. Interestingly, individuals who are homozygous, where both MYOC copies are abnormal, for certain MYOC mutations Gln368STOP and Lys423Glu do not appear to develop glaucoma. However, one patient with a congenital form of open-angle glaucoma was reportedly homozygous for the Gln48His MYOC mutation. Although MYOC mutations generally cause an earlier-onset form of glaucoma, some variants such as the Gln368Stop mutation often have a later adult onset.

When first discovered, MYOC was a novel gene and protein. Over the past decade, our knowledge about the physiological role of MYOC is improving. Although MYOC protein expression is greatly increased upon administration of glucocorticoids in trabecular meshwork (TM) cells, this property does not appear to be related to steroid-induced ocular hypertension. Fautsch and coworkers demonstrated that the introduction of MYOC protein increases outflow resistance in the perfused human anterior segment model system, while Caballero and coworkers showed that overexpression of the N-terminal domain of MYC results in an increase of outflow facility in perfused anterior segment model system.

A number of animal model studies of MYOC have been conducted in the genetic mouse model. Neither absence of MYOC nor increased expression of wild-type MYOC in the TM produces elevated IOP. In a transgenic mouse model, the effect of a mutated form of MYOC, Tyr423His, was studied. Similar to humans, the mutated form of MYOC was not secreted and accumulated in the TM but failed to elevate IOP. However, in other studies utilizing the same MYOC mutation, increased IOP did occur which was associated with loss of retinal ganglion cells, findings being consistent with glaucoma.

Interestingly, MYOC protein is normally found in the aqueous humor of many species including humans; however, this protein is absent in the aqueous humor of patients with glaucoma-associated MYOC mutations. Recent studies have shown that MYOC is associated with the shedding of small vesicles called exosomes into the aqueous humor. In other tissues, exosomes contain ligands that participate in autocrine and paracrine signaling, and thus serve as vehicles that may play a role in TM homeostasis. It is possible that interference in this pathway induced by mutations in MYOC may play a role in causing glaucoma.

These data suggest that mutant, disease-associated forms of MYOC interfere with protein trafficking and result in the intracellular accumulation of misfolded protein. How this process causes an increase in aqueous humor outflow resistance and why the onset of glaucoma in most cases takes decades to occur remains to be determined. However, it is clear that the discovery of MYOC is leading to a better understanding of the pathobiology of POAG.

Optineurin

The second gene discovered that is associated with POAG was optineurin (OPTN). OPTN is located in the GLC1E locus on chromosome 10. The phenotype for affected individuals with OPTN variants was remarkable for glaucoma associated with normal IOP, or normal-tension glaucoma (NTG), in a large percentage of affected family members.

The original report identified OPTN variants in over 16% of open-angle glaucoma families. Subsequently, disease-associated variants have been reported by other investigators. However, most investigators have found that OPTN variants are uncommon in POAG and NTG cases. Of those OPTN mutations studied to date, the E50K variant, although rare, appears to be most strongly associated with open-angle glaucoma, particularly of the normal-tension type. Furthermore, it is reported that NTG patients who have the E50K mutation have a more severe form of glaucoma compared to NTG patients that lack the mutation. These mutation carriers appear to have a younger age of onset, develop more advanced optic nerve cupping, and require surgical intervention more frequently than their NTG counterparts.

Other investigators have also reported association between OPTN variants and glaucoma. Forsman and coworkers found that three OPTN SNPs, Thr34Thr, Glu163Glu, and 553-5C, were associated with an increased risk of glaucoma. In addition, specific OPTN variants have been associated with a higher IOP in a glaucoma population in India. Although controversial, the more common Met98Lys polymorphism of OPTN has been reported to increase susceptibility to normal-tension forms of open-angle glaucoma, especially in Asian populations.

It has been reported by Funayama and coworkers that the synonymous variant Thr34Thr is associated with POAG in the Japanese population. It was also reported that certain tumor necrosis factor-alpha (TNFα) variants in combination with OPTN variants were higher in POAG patients compared with controls and that these patients had a worse prognosis. This interaction between TNFα and OPTN is consistent with the belief that frequently the glaucoma phenotype is polygenic in origin. Although interesting, most of these associations remain to be corroborated.

Similar to MYOC, the mechanistic role of OPTN in the pathogenesis of glaucoma is unclear. Studies of OPTN expression in the human anterior segment perfusion model have produced conflicting results. There is evidence that OPTN may play a neuroprotective role by reducing retinal ganglion cell susceptibility to apoptosis. It has been reported that in response to apoptotic stimuli, OPTN translocates from the Golgi to the nucleus in a manner dependent on the guanosine triphosphate (GTP) ase activity of Rab8. Overexpression of OPTN blocks cytochrome c release from mitochondria and protects cells from hydrogen-peroxide-induced cell death. The OPTN E50K mutation inhibits translocation to the nucleus. Overexpression of this variant compromises the mitochondrial membrane integrity by increasing the susceptibility to death from external stressors. The protection against apoptosis may not translate to other tissues as overexpression in the lens of transgenic mice failed to protect against transforming growth factor-beta 1 (TGFβ1)-induced apoptosis of lens epithelial cells.

In studies examining the cellular role of the OPTN, investigators have found that OPTN negatively regulates TNFα-induced nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) activation. TNFα-stimulated NFκB-dependent gene transcription is greatly enhanced if the level of expression of OPTN is reduced, lowering the apoptotic threshold. Other investigators have observed that the OPTN E50K mutation increases binding to TANK-binding kinase 1 (TBK1), which forms a complex that regulates TNFα and its proapoptotic effects. It is suggested that the OPTN E50K mutant may cause aberrant activation of TBK1, which may underlie increased susceptibility to ganglion cell loss in subjects with familial NTG. These and other studies are bringing us closer to the role of OPTN variants and the pathogenesis of glaucoma.

WDR36 (WD40-Repeat 36)

In 2005, it was reported that sequence variants in WDR36 gene cause POAG. WDR36 encodes a protein with 951 amino acids. It is located in the GLC1G locus on chromosome 5q22. Similar to both MYOC and OPTN, the messenger RNA (mRNA) transcript is ubiquitous, and is found in various tissues of the body and throughout the structures of the eye. The prevalence of WDR36 sequence variations has been estimated to be present between 1.6% and 17% of POAG patients. Subsequent studies in a sample of West Africans as well as in other POAG families with autosomal dominant POAG have mapped to this region on chromosome 5, but have failed to identify genetic variants in WDR36 as the causative agent. Most investigators find little or no evidence for an association between WDR36 variants in POAG compared with controls. In one report, POAG patients with WDR36 sequence variations were associated with a more severe disease phenotype than those without, suggesting that sequence variants in WDR36 may play a role in disease susceptibility rather than causation. WDR36 functions in ribosomal RNA processing and interacts with p53 stress response pathway, suggesting the possible involvement of p53 in glaucoma.

Gene Variants Associated with POAG

In addition to the genes described above, over 20 gene variants have been associated with POAG as summarized in Table 2. These include apolipoprotein E (APOE), optic atrophy 1 (OPA1), tumor protein p53 (TP53), TNF, interleukin-1 (IL-1), and cytochrome P450 1B1 (CYP1B1). CYP1B1 has been reported to be associated with early onset POAG in Spanish, French, and Indian populations. Variants of OPA1 have been associated with normal-tension glaucoma in Japanese and Caucasian populations. OPA1 variants are not associated with glaucoma in Caucasian, African-American, and West-African POAG cases with elevated IOP. Most candidate gene associations with POAG have not been corroborated by other investigators or in other populations.

POAG Genetics and the Future

Clearly, an explosion in the understanding of the underlying genetic architecture of complex inherited disorders is underway. This is being driven by powerful new methods for genetic discovery, logarithmic growth in genotyping technology, and the assemblage of increasing large, robust clinical datasets. This knowledge will ultimately lead to a vastly improved understanding of the molecular mechanisms of complex diseases such as glaucoma. As the underlying genetics of POAG improve so will the contribution of environmental factors, which to date, is poorly understood.

Ultimately, genetic screening will greatly improve our ability to predict the risk of developing disease as well as disease severity. Importantly, expanding comprehension of the molecular pathways that produce disease will guide the development of more effective treatment options for individuals as well as their families. For diseases such as POAG, where end-organ damage is untreatable, the

Table 2 Gene variants associated with POAG

Gene symbol	*Gene name*	*Genomic location*	*OMIM*	*KEGG pathway*	*POAG phenotype*	*Population*
AGTR2	Angiotensin II receptor, type 2	Xq22-q23	300034	Renin–angiotensin system	NTG	Japanese

The Immunological Aspects of Aqueous Humor Turnover

F Bock and C Cursiefen, Friedrich-Alexander University Erlangen-Nürnberg, Erlangen, Germany

Glossary

Antigen presenting cells (APCs) – Cells that display foreign antigens together with a major histocompatibility complex (MHC) receptor on its surface. T cells are activated by these antigens via their T-cell receptors.
Aqueous humor – A clear body fluid in the posterior and anterior chamber of the eye supporting the vessel-free parts of the eye like the cornea and the lens with nutrients and contributing to the transparency of the cornea.
Delayed type hypersensitivity (DTH) – It belongs to the four groups of hypersensitivity which describes damaging or rejection reactions produced by the normal immune system. A hypersensitivity reaction is elicited by a presensitization of the host. The DTH is a cell-dependent immune reaction which is mainly triggered by T cells.
Glycoproteins – Proteins that contain covalently attached oligosaccharide chains (glycans) to the side chains of the polypeptide.
Lymphangiogenesis – Formation of lymphatic vessels from preexisting lymphatic vessels.
Lymphatic vessels – A vessel type comparable to blood vessels, but instead of blood, lymphatic vessels drain fluid (lymph) out of the tissue together with proteins and cells of the immune system through the draining lymph nodes back into the bloodstream.
Neuroendocrine – A hormone which is released into the circulating blood by neuroendocrine cells in response to a neural stimulus.
Plasminogen – A circulating proenzyme that is converted by cleavage into the active enzyme plasmin, which, for example, degrades fibrin.
T lymphocyte – One of the white blood cells known as lymphocytes, responsible for the cell-mediated immunity. In contrast to B cells, T cells mature in the thymus.

Aqueous Humor and the Immune Privilege of the Eye

For the immune response after organ or tissue transplantation, an analogy to the neural reflex arc was introduced named immune reflex arc. Herein the afferent limb is defined as an antigenic signal captured in the periphery and transmitted to secondary lymphoid tissues through lymphatic vessels. At the central processing mechanism, the antigenic signal is transduced into effector modalities such as antibodies and effector T cells. At last, the efferent limb represents the delivery of the effectors through the blood to the site of antigen, leading to its elimination.

The presentation of antigens in the anterior chamber (AC) provokes a series of immunological responses, which are characterized by the generation of noncomplement antibodies (IgG1), the formation of cytotoxic T lymphocyte (CTL) precursors and an obvious absence of a normal delayed-type hypersensitivity (DTH) response. For example, DBA/2-mice-derived P815 mastocytoma cells with a naturally fast immunogenic effect after subcutaneous transplantation into allogenic BALB/c mice can escape the immunologic rejection when injected in the AC. The fact that P815 tumor allografts were consequently rejected outside the eye shows that the growth of these highly immunogenic tumors in the eye is facilitated by the downregulation of a cell-mediated immunity (CMI). So, CD8+ CTL precursors invading in the intraocular tumor are not able to differentiate completely to gain their cytolytic function.

The CMI is also inhibited systemically. BALB/c mice which were primed with P815 DBA/2 mastocyte cells in the AC were unable to reject orthotopic DBA/2 allografts nor were able to reject skin allografts of third-party donors. Therefore, the systemic CMI of the host is inhibited actively. The AC priming with several antigens leads to the generation of regulatory T cells which impair the DTH. One population of the generated T cells is CD4+ and affects the afferent arm, and a CD8+ population affects the efferent arm of the immune response arc. These regulatory T cells secrete the transforming growth factor-β_2 (TGF-β_2), which is not only anti-inflammatory but also prevents the activation of CD4+ T cells which induce DTH. According to these findings, it became clear that this immune deviation induced by AC priming is a characteristic of the AC and therefore it was termed anterior chamber-associated immune deviation (ACAID).

The immune privilege of the AC is achieved by several unique features of this site.

1. One is the absence of blood and lymphatic vessels in the surrounding tissues (cornea, lens, and aqueous humor (AqH)).
2. Further important features are soluble immunomodulatory factors in the AqH, which are secreted from the

ciliary body. AqH from healthy eyes has been shown to have an inhibitory effect on many cells and factors involved in inflammation and immune response: (a) CD4+ T cells, which are inhibited in proliferation and secretion of effector cytokines, polymorphonuclear neutrophilic leukocytes inhibited in release and destructive potential of the cellular content; (b) macrophages activated by bacterial lipolysaccharides and IFN-γ, which reduced the production of reactive oxygen intermediates and nitric oxide; (c) natural killer (NK) cells, which reduced the capacity to lyse appropriate target cells and complement components C1q and C3 NK cells. On the other hand, AqH does not impair the capacity of functional cytotoxic T cells to lyse their specific targets and neutralizing, noncomplement-fixing antibodies retain their properties when AqH is present.

Furthermore, cell-surface immunomodulatory factors constitutively expressed on the pigment epithelium and corneal endothelium do also contribute to the immune privilege. It was shown that T cells are altered in their immunological function when passing the ocular pigment epithelium.

3. The immunosuppressive factors such as the TGF-β, thrombospondin 1 and 2 (TSP-1/ TSP-2) and prostaglandin E2 have been shown to be secreted from the cornea, the iris pigment epithelium (IPE) and the retinal pigment epithelium (RPE).
4. In addition, corneal endothelial cells secrete several molecules suppressing lymphocyte activation and inflammation and express molecules on their apical surface, which inhibit complement activation like CD46, CD55, CD59 and promote apoptosis by the CD95 ligand at CD95+ cells getting in contact with them.
5. The ability of the corneal endothelium which expresses CD95 ligand constitutively, but low levels of major histocompatibility complex (MHC) class I molecules to prevent intraocular activation of innate immune effectors prevents destruction by NK cells and neutrophils, and protects the visual axis from distortion by macrophage and complement-mediated inflammation. In addition, in the normal uninflamed cornea MHC class II-negative Langerhans cell (LaC)-type dendritic cells (DCs) in an immature state are present.

The AqH Combines Immune Modulation and Angiogenic Privilege

The AqH is supplied with antiangiogenic and immune modulatory factors from the AC circumscribing tissues such as the ciliary body, the trabecular meshwork, and the corneal endothelium.

In addition to maintaining corneal transparency through a pump-leak mechanism, the corneal endothelium plays an active role in the transport of certain proteins to supply nutrients for the stroma and to remove metabolites. So the agile exchange between the AqH and the cornea supports the theory that the AqH might contribute to the antiangiogenic privilege of the cornea.

Lymphangiogenesis and inflammation are intimately connected. Long-term clear allografts displayed an antigen-specific downregulation of DTH. Another connection between inflammation and lymphangiogenesis is that during DTH, macrophages are recruited through activated T-effector cells (Th1); Maruyama and Cursiefen described in 2005 that inflammatation-induced lymphangiogenesis in the cornea arises from CD11b-positive macrophages.

Thrombospondin

Like the macrophages the well-known antiangiogenic factor TSP also displays effects on both the immune and the angiogenic privilege in the anterior segment. TSPs are generated from a family of five genes encoding glycoproteins that regulate multiple extracellular matrix functions. Within this family, TSP-1 and -2 constitute a subfamily with strong antiangiogenic effects. TSP-1 can bind to latent TGF-β and promote its activation. It might inhibit angiogenesis through direct effects on endothelial cell migration and survival, for example, by inducing vascular endothelial cell apoptosis through its binding to CD36 as well as through indirect effects on growth factor mobilization, for example, by binding heparan sulfate proteoglycans. TSP-2 lacks a TGF-β binding site. It is also a multifunctional protein with antiangiogenic properties that binds to multiple receptors and is capable of inhibiting cell-cycle progression in endothelial cells in the absence of apoptosis. The exact mechanisms by which TSP-1 and -2 achieve their antiangiogenic effects are not yet fully understood. However, both TSP-1 and -2 have been shown to inhibit basic fibroblast growth factor (bFGF)-induced corneal neovascularization. TSP-1 and -2 are expressed in the normal cornea and in the AqH of healthy rat and bovine eyes, whereas they are significantly decreased in diabetic rat AqH. Thus, TSP1 may play a role in ocular vascular homeostasis and its absence may contribute to vascular dysfunctions associated with diabetes. On the other hand, TSP can also upregulate the expression of macrophage-inflammatory protein-2 (MIP-2), TGF-β_2, and tumor necrosis factor alpha which are all required to mediate tolerance induced by TGF-β-treated antigen presenting cells (APCs).

The AqH also contains many factors contributing to the immune privilege of the AC. Taylor and colleagues mentioned that only a few have been studied for their role in suppressing induction of DTH. They defined the criteria for such a immunosuppressive factor as that such a factor has to be physically present in the normal AqH,

second that the AqH concentration of such a factor has to have an *in vitro* immunosuppressive activity similar to whole AqH, and finally that neutralization of such a factor also leads to a neutralization of some aspects of AqH immunosuppressive activity. According to these criteria, only TGF-β_2, calcitonin gene-related peptide (CGRP), α-melanocyte-stimulating hormone (α-MSH), and vasoactive intestinal peptide (VIP) are identified so far as ocular immunosuppressors of DTH.

α-Melanocyte Stimulating Hormone

On the one hand, α-MSH suppresses antigen-stimulated effector T cells and IL1/TNF-induced thymocyte proliferation (IL, interleukin; TNF, tumor necrosis factor); on the other hand, it activates through the melanocortin 1 receptor (MC-1R) the activating protein 1 (AP-1), a transcription factor which binds the TPA (12-*O*-tetradecanoylphorbol 13-acetate) response element (TRE; nucleotide sequence: TGAG/CTCA). Most matrix metalloproteinases (MMPs) contain the TRE and so the following antiangiogenic MMPs might be expressed subsequently: MMP2, cutting plasminogen resulting in the antiangiogenic factor angiostatin and cutting off the ectodomain of the fibroblast growth factor receptor 1 (FGFR1), so the angiogenic activity of FGF is inhibited; MMP7, cutting plasminogen resulting in the antiangiogenic factor angiostatin: MMP9, cutting collagen XVIII, resulting in endostatin and cutting collagen VI , resulting in tumstatin, and cutting plasminogen resulting in the antiangiogenic factor angiostatin; and MMP3, 12, 13 and 20, cutting collagen XVIII, resulting in endostatin. The α-MSH receptor MC-1R has been shown to be expressed on human dermal microvascular endothelial cells.

α-MSH also has a proangiogenic effect which can be provoked by this hormone: α-MSH leads also to the release of interleukin 8 (IL8; CXCL8). This chemokine was shown to have a para- and autocrine angiogenic effect via nuclear factor kappa B (NFκB). Therefore, the antiangiogenic effect on blood endothelial cells (BECs) through different MMPs might be outbalanced by the autocrine proliferative effect of IL8 on endothelial cells, whereas this balance might be shifted in favor of the antiangiogenic effect in lymphangiogenesis.

Vasoactive Intestinal Polypeptide

VIP is a neuroendocrine factor and a 28-amino acid residue that was first isolated from hog upper intestinal tissue. This peptide is also found to be widely distributed in both the central and peripheral nervous system as a neurotransmitter. VIP has several biological functions such as intestinal water and electrolyte secretion, vasodilation, smooth muscle relaxation, thyroid hormone secretion, modulation of leukocyte migration, immunoglobulin production, and growth stimulation of B cells. The peptide also inhibited *in vitro* invasion and migration of murine colon 26-L5 carcinoma cells without affecting their growth and establishment of their liver metastases in mice probably by suppressing their arrest in the liver. The process of angiogenesis by endothelial cells is considered to be functionally similar to that of invasion by tumor cells, so VIP may affect angiogenic responses of endothelial cells by regulating their invasive and motile activities. It was demonstrated that VIP inhibited the morphogenesis of hepatic sinusoidal epithelial (HSE) cells into capillary-like structures on Matrigel-coated wells.

As far as the vascular endothelial cell growth factor (VEGF) activation of endothelial cells can lead to upregulation of the antiapoptotic molecule, Bcl-2, that in turn promotes the expression of endothelial cell-derived IL8, VIP could also inhibit the expression of IL8 in endothelial cells in a similar manner as in monocytes.

Transforming Growth Factor β

The TGF-β family consists of TGF-β1, TGF-β2, and TGF-β3. These are polypeptides of approximately 25 kDa produced by a variety of tissues. TGF-β forms an active complex with a dimeric latency-associated peptide (LAP). This complex binds with high affinity to the extracellular matrix, thereby creating pools of the latent growth factor. The growth factor is activated by proteolytic dissociation. By binding to the TGF-β glycoprotein receptors I, II, and III, a wide range of signaling pathways is activated: for example, regulation of cell growth and differentiation, extracellular matrix production, or changes in cell morphology. Besides the inhibition of epithelial, endothelial, and leukocyte cell growth, TGF-β is thought to stimulate proliferation of fibroblasts. The AqH contains up to 700 pg ml^{-1} latent TGF-β which is produced by the ciliary body and trabecular meshwork. If activated, it has an inhibitory effect on proliferation and motility. It was shown that TGF-β has antiangiogenic properties in the anterior segment at the concentrations present in the aqueous humor. Its proangiogenic effect in the cornea, however, remains controversial. Most important is the leading role of TGF-β in the induction of the AC-associated immune deviation (ACAID), by what the anterior segment becomes an immunologically privileged site avoiding visual damage due to cell-mediated inflammation. Through activation and binding of TGF-β2 to APCs by TSP-1, TGF-β2 impairs these cells to generate T-cell activating CD40 and IL-12, but juxtaposed T cells are promoted to further secrete TGF-β2 and other immunosuppressive factors. APCs migrate from the eye to the marginal zone of the spleen and interact with NK cells. The antigen-specific regulatory T cells are then guided by cytokines back to the eye preventing a delayed hypersensitivity response to the antigen. But at the same time, NK cells still have the ability to lyse their appropriate targets in the eye.

Calcitonin Gene-Related peptide

Another neuropeptide found in the AqH, the sensory neurons of the iris and the ciliary body, is CGRP. CGRP is a 37-amino acid neuropeptide. It is known to inhibit the mechanisms of antigen presentation by macrophages and dermal dendritic cells (Langerhans' cells) to induce DTH and contact hypersensitivity. In addition, CGRP inhibits in macrophages the production of reactive oxygen intermediates induced by IFN-γ. Thus, CGRP seems to suppress immunogenic inflammation induced by antigen-presenting cells and is an opponent of inflammatory cytokines produced by inflammatory T cells. So CGRP plays an important role by the mediation of immunosuppression in the AC.

In contrast to these immunosuppressive abilities, it was shown that CGRP also can promote localized inflammatory activity. In tissues with acute and chronic phases of inflammation, the CGRP concentration is raised. This increase of CGRP is also associated with the induction of neurogenic and endotoxin-induced ocular inflammation.

AqH suppression of DTH has mostly been described by its immunosuppressive effects on effector T-cell activity (Figure 1). CGRP mediates the suppression of DTH by inhibiting IFN-γ-induced inflammatory activity of macrophages, independent of neuropeptides and growth factors mediating T-cell-directed immunosuppression.

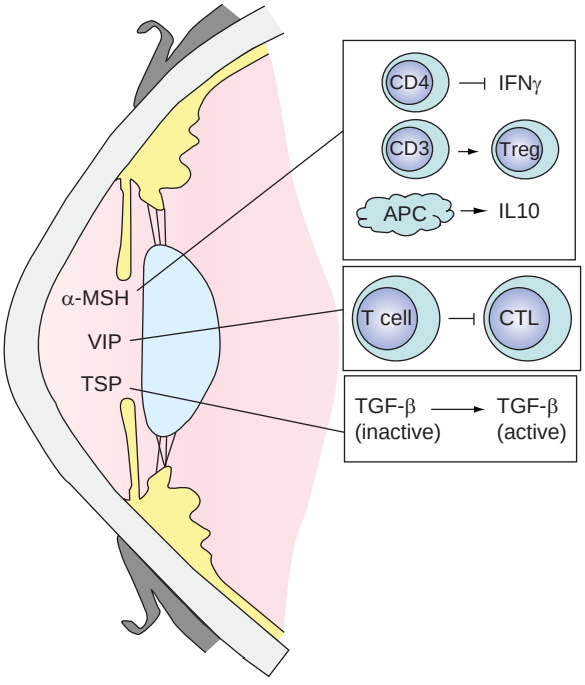

Figure 1 Aqueous humor factors that suppress delayed-type hypersensitivity (DTH). α-Melanocyte stimulating hormone (α-MSH), vasoactive intestinal peptide (VIP), and TSP are present in the aqueous humor and are known to suppress DTH. α-MSH inhibits the production of interferon (INF)-γ by CD4+ T cells, promotes the transformation of CD3+ T cells to T regulatory (Treg) cells, and promotes the release of interleukin (IL)10 from antigen presenting cells (APCs). VIP inhibits the transformation of T cells to cytotoxic T cell (CTL). TSP promotes activation of latent transforming growth factor (TGF)-β and promotes its activation.

By the help of CGRP AqH becomes anti-inflammatory, so the immune-privileged ocular microenvironment seems to suppress not only the T cells that trigger DTH, but also IFN-γ-dependent inflammation. CGRP regulates the inflammatory activities of T cells and macrophages in the ocular microenvironment, so the suppression of macrophage activity could prevent inflammation triggered by factors other than activated T cells.

Therefore, the AqH appears to carry multiple mechanisms to affect T-cell activation, IFN-γ production, macrophage activation, and lymphangiogenesis to suppress inflammation in the eye at multiple levels.

The Photoreceptor Outer Segment as a Sensory Cilium

J C Besharse and C Insinna, Medical College of Wisconsin, Milwaukee, WI, USA

Glossary

Axoneme – The cytoskeletal backbone of cilia and flagella composed of nine microtubule doublets aligned in a cylindrical array. Motile axonemes, generally referred to as 9 + 2 axonemes, contain a pair of central singlets and dynein arms.
Basal body – A centriole that becomes associated with the cell membrane for the nucleation of a cilium. Doublet microtubules of cilia in most animals are extensions of triplets of the basal body.
Centriole – A barrel-shaped or cylindrical organelle composed in most animals of nine triplet microtubules. A pair of centrioles, surrounded by an amorphous zone containing many proteins, constitutes the centrosome.
Cilia – The extensions of the cell surface that have a plasma membrane and contain a cytoskeletal core of microtubules, called an axoneme, which extends out from the basal body. They may be motile, as in the airway epithelium in humans, or nonmotile and sensory in function. Cilia and flagella have the same organization, but flagella are generally motile and are longer.
Intraflagellar transport – A microtubule-based trafficking pathway required for the formation and maintenance of cilia and flagella. Intraflagellar transport (IFT) involves the bidirectional transport of a protein adaptor complex composed of highly conserved IFT proteins. The pathway requires kinesin 2 family motors in the outward (anterograde) direction and a cytoplasmic dynein in the return (retrograde) direction. The pathway is equally important in cilia and flagella.
Kinesins – The plus-end-directed motor proteins powered by adenosine triphosphate hydrolysis to walk along microtubules. These are involved in multiple cellular functions, including transport of cargo, mitosis, and meiosis. Many different genes encode kinesins with different properties and functions.
Microtubules – The cytoskeleton tubules assembled from protofilaments composed of linear polymers of α- and β-tubulin heterodimers. These are asymmetric hollow cylinders with plus and minus ends that differ in polymerization rate and binding proteins. They form a dynamic network within the cell and organize themselves into complex structures, such centrioles, basal bodies, and cilia.
Microvilli – The membrane protrusion from the cell surface composed of cytoplasm and dense bundles of actin filaments serving to increase the surface area of the cell.
Sensory cilia – The cilia that contain membrane receptors and signaling components. These often have a nonmotile 9 + 0 axoneme, but actively motile cilia may also serve a sensory function.

Introduction

There are at least two fundamentally different designs for visual photoreceptors, generally referred to as the rhabdomeric type and the ciliary type. Rhabdomeric photoreceptors are widely represented among invertebrates and have been intensively studied in the horseshoe crab, fruit fly, and squid. Rhabdomeric photoreceptors concentrate the visual pigment for photon capture in a highly replicated array of microvilli, each containing an actin cytoskeletal core. The array of microvilli is called the rhabdomere. The visual pigment of ciliary photoreceptors is also concentrated in a photon capture organelle called the outer segment (OS). However, the OS is derived from the plasma membrane of a cilium and retains the microtubule-based cytoskeletal core, called an axoneme, which is common to all cilia. Often, rhabdomeric and ciliary photoreceptors are referred to as invertebrate and vertebrate types, respectively, but this distinction can be misleading. Both photoreceptor types appeared early in animal evolution and are present in multiple invertebrate phyla. Furthermore, some animals have both photoreceptor types, and the retina in the compound eye of the scallop contains a layered juxtaposition of both rhabdomeric and ciliary photoreceptors. Although vertebrate photoreceptors with true rhabdomeres have not been identified, the recent discovery of intrinsically light-sensitive ganglion cells (ipGCs) has led to the realization that their melanopsin photopigment and transduction pathway have features in common with rhabdomeric rather than ciliary photoreceptors. This suggests that ipGCs may have originated from an evolutionary ancient rhabdomeric precursor.

Turnover of the OS and Phototransduction Machinery

The light-sensitive OS of vertebrate photoreceptors is an elegantly complex organelle that serves as the starting

point for highly sensitive nighttime vision (rods) as well as high acuity, color vision (cones) in the daytime. The OS consists of a stack of membrane disks containing a photopigment (opsin) of the guanine-nucleotide-binding protein-coupled receptor (GPCR) family, and a large array of cytosplasmic, cytoskeletal, membrane, and membrane-associated proteins that are essential for phototransduction. The phototransduction cascade begins with photon absorption by the vitamin-A-derived chromophore of opsin and proceeds through activation of transducin, a guanine-nucleotide-binding protein (G-protein), which in turn activates a phosphodiesterase that reduces cytoplasmic cyclic guanosine monophosphate (cGMP) levels. The photoresponse is a hyperpolarization event that occurs when declining local cGMP levels result in closure of the cGMP-gated channel in the OS plasma membrane. The high sensitivity of the rod cells, which can respond to single-photon absorption events, and the rapid responses of cone cells in bright light, depend on the integrity of the disk stack and close juxtaposition of the protein components of the transduction cascade. Optimal function also depends on other OS proteins that support transduction such as membrane guanylyl cyclases (GC1 and GC2), which regenerate cGMP, a Na^+/Ca^{2+} exchanger which regulates Ca^{2+} levels, anaerobic glycolysis, which supplies a portion of the adenosine triphosphate (ATP), and the pentose phosphate shunt which supplies nicotinamide adenine dinucleotide phosphate (NADPH), essential for conversion of the all-*trans* retinaldehyde to retinol in the visual pigment cycle.

Two additional interdependent features of OS organization, essential for optimal visual function, are proper targeting of the phototransduction proteins to the OS and long-term maintenance through OS renewal. A striking feature of normal rods and cones is the high level to which phototransduction proteins are concentrated in the OS. Since those proteins are all synthesized at polyribosomes in the inner segment, a great deal of recent focus has been on those mechanisms that are essential for proper trafficking of OS proteins. This is a major problem throughout the life of the cell because OSs renew at a particularly high rate (see **Figure 1**). In the 1960s, Richard Young, then at the University of California at Los Angeles, thoroughly documented the fact that rod OSs are renewed through continuous new disk assembly adjacent to the inner segment. Furthermore, Young along with Dean Bok determined that OS length is maintained through a compensatory shedding of disks from the distal tip where they are phagocytized and degraded by the retinal pigment epithelium. In the 1970s, these same concepts were extended to include the cone OSs. The turnover of OSs is highly conserved, but occurs at very different rates in different species. In mice, rod OSs turnover once every 10 days.

The Photosensitive Organelle as a Sensory Cilium

With the advent of transmission electron microscopy in the 1950s, photoreceptors were an early subject of analysis, particularly by Eduardo de Robertis in Argentina and Kiyoteru Tokuyasu and Eichi Yamada in Japan. Those early studies showed that developing photoreceptors have the basic organization of cilia. During early differentiation, a centriole pair moves to the plasma membrane where one member serves as a template for assembly of a microtubule cytoskeletal structure called an axoneme (**Figure 2**); the other centriole is generally seen next to the basal body as an accessory centriole. Centrioles consist of an array of nine triplet microtubules and each triplet has an A-, B-, and C-tubule. The A-tubule is a complete microtubule comparable to cytoplasmic microtubules, but the B subtubule is a partial microtubule built on the wall of the A-tubule. Likewise, the C-tubule is built on the wall of B. The centriole that associates with the plasma membrane is called a basal body because it serves as a template for outgrowth of doublet microtubules that form the axoneme. As a consequence of basal body templating, the axoneme grows out as an array of nine doublet microtubules that are direct extensions of the A- and B-tubules of the basal body. The photoreceptor and other sensory cilia are generally said to have a 9 + 0 axoneme, in contrast to motile cilia, which have a 9 + 2 axoneme; the 2 in the latter designation refers to a central pair of single microtubules within the core of the axoneme. Although the 9 + 2 axoneme is found in a wide array of motile cilia, 9 + 0 cilia are sometimes motile. For example, the rotatory cilia of the embryonic Henson's node have a 9 + 0 axoneme.

As the axoneme elongates in rodents, the plasma membrane expands at the distal end of the cilium, and membrane vesicles and tubules accumulate (**Figure 2**). At this early stage, the photopigment apoprotein, opsin, is localized within the plasma membrane of the distal end of the cilium, and membrane vesicles and tubules accumulate. This region expands in the early stages of OS formation, quickly taking the form of an orderly stack of membrane disks (**Figure 2**). Frog OSs, as described by S. E. Nilsson in 1964, exhibit ordered disks from the very beginning of differentiation. At later stages, and, presumably during early development, new membrane disks are thought to form as evaginations of the ciliary membrane. The most proximal part of the cilium emanating from the basal body, called the connecting cilium by Eduardo de Robertis in 1956, connects the photosensitive OS with the cells synthetic machinery in the inner segment; components of the phototransduction machinery in the OS are synthesized in the inner segment and must be transported to the OS through the connecting cilium.

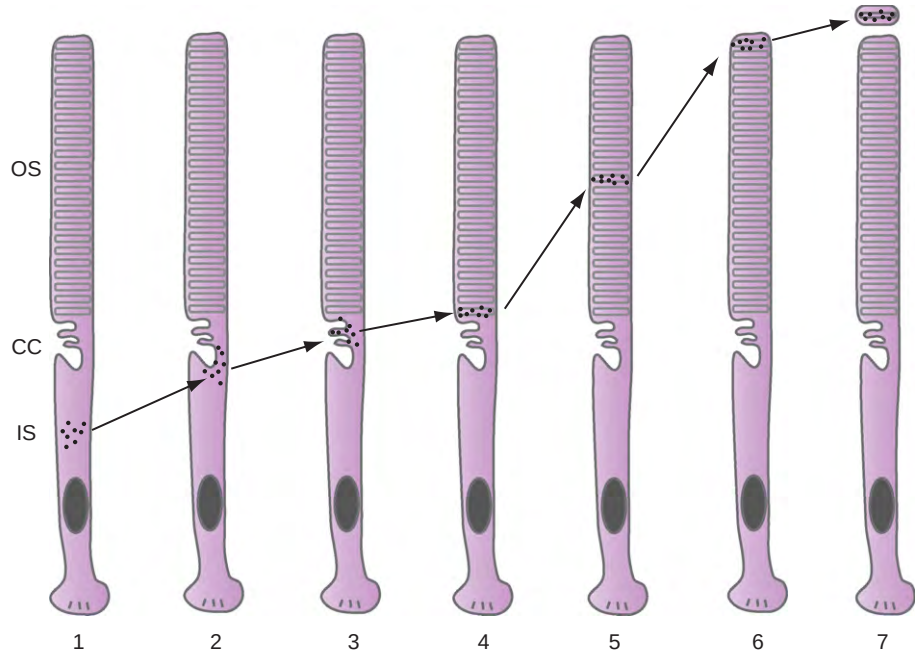

Figure 1 Conceptual diagram of a pulse chase autoradiography experiment revealing OS turnover in rod cells. Radioactive amino acids provided as a pulse at 1 (left) were incorporated into protein, mainly rhodopsin, in the inner segment (IS). Over the next few hours (2–3) radioactive protein was transported to the apical inner segment and disk-forming region at the connecting cilium (CC), and incorporated into newly formed disks creating a discrete radioactive band (4). Over the next ≈10 days (mammals), the band was gradually displaced toward the distal end of the OS (5–6) until discarded in a process called disk shedding (7). Discarded disks (7) are phagocytized by adjacent retinal pigment epithelium (not shown). From Young, R. W. (1967). The renewal of photoreceptor cell outer segments. *Journal of Cell Biology* 33: 61–72.

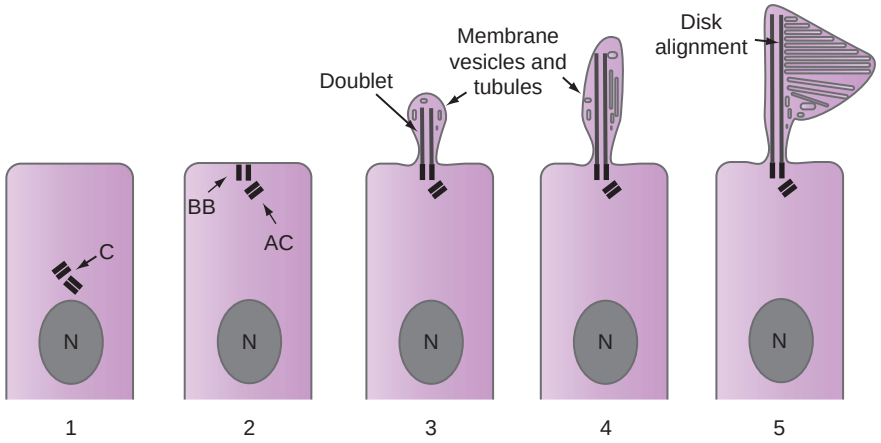

Figure 2 Early development of the outer segment. After the last mitotic division the centriole pair (1, left) moves to the cell surface (2). One member of the centriole pair associates with the plasma membrane where it is called a basal body (BB); the second centriole is often seen adjacent to the basal body in EM images where it is called the accessory centriole (AC). The basal body nucleates the extension of doublet microtubules at the cell surface to elongate the cilium (3). In the early stages of cilium elongation membrane vesicles and tubules are seen in the ciliary cytoplasm (3–4). Finally, disks align perpendicular to the axoneme composed of doublet microtubules (5). Figure 3 Structure of the ciliary axoneme of a mature photoreceptor. Longitudinal view is shown on the right and magnified cross sections at the position of the arrows on the left. The axoneme grows out of the basal body as an array of nine doublet microtubules. The microtubule plus ends extend distally and the minus ends are anchored in the basal body. The region adjacent to the basal body is a transition zone in which doublets are closely linked with the plasma membrane by Y-shaped cross-linkers (lower diagram on left); this region is often referred to as the connecting cilium. The region immediately distal to the transition zone is the site of new disc assembly. Within the OS the doublets loose their B-tubule to become singlets in the distal OS. This is shown as an abrupt transition on the right, but conversion to singlets appears to occur gradually leaving mixtures of singlets and doublets (middle diagram on left). The distal OS only has singlets.

The term connecting cilium refers to that portion of the cilium between the basal body and the disk-forming region of the OS. As originally demonstrated by Pal Röhlich in 1976, the connecting cilium is actually comparable to the transition zone, a structure common to all eukaryotic cilia and flagella (**Figure 3**). Here, the plasma membrane is closely linked to the doublet microtubules of the axoneme by cross-linkers that extend from the doublet microtubule to the plasma membrane. These cross-linkers are stable structures that remain bound to the axoneme after detergent extraction and link the axoneme to cell surface glycoconjugates through transmembrane connections. Although these microtubule-membrane cross-linkers exhibit a conserved Y-shaped structure across many cilium types, their molecular composition has not been determined. Recently, a number of cilium proteins relevant to human photoreceptor degenerative disease, such as retinitis pigmentosa guanosine triphosphate (GTP)ase regulator (RPGR) and RPGR-interacting protein 1 (RPGRIP), have been localized to the transition zone and some may be components of the cross-linking structures. Further high-resolution analysis of the composition of cross-linkers may lead to a better understanding of the function of connecting cilium proteins that are relevant to human disease.

Distally, beyond the transition zone, the axoneme extends deep into the OS (**Figure 3**). This point requires emphasis because the term connecting cilium refers to the link between inner and OS and the term is often used with the implication that this is the entire cilium. However, both early electron microscopic studies and numerous immunocytochemistry studies have shown that photoreceptor axonemes extend through much of the length of the OS (**Figure 4**); in some cases, they extend all the way to the distal tip. The recent finding of extremely long axonemes in mouse, frog, and zebrafish OSs, along with earlier studies showing much shorter axonemes, suggests that they may vary significantly in their length. The reason for variability in axoneme length observed in various studies is not known. A possible explanation, however, is that the distal axoneme is dynamic and unstable, resulting in some cases in poor preservation for morphological studies. The principles governing these length variations in either rods or cones remain unknown, but are likely to be relevant to the finding that OSs maintain a relatively constant length through many cycles of OS turnover.

Evidence for Intraflagellar Transport in Photoreceptors

Recently our work has demonstrated that the assembly of photoreceptor OSs depends on a highly conserved microtubule-based trafficking pathway called intraflagellar transport (IFT). IFT was originally discovered in the motile flagella of the green alga *Chlamydomonas rheinhartii* and quickly extended to the sensory cilia *Caenorhabditis elegans*. The essential components of IFT are the kinesin and dynein molecular motors that drive movement along axonemal microtubules and multiprotein IFT particles that are thought to link cargo such as cytoskeletal and phototransduction proteins to the IFT motors (see **Figure 5**). For example, at least 16 different proteins assemble to form two large protein complexes referred to as IFT particles (**Figure 5**), and all of these proteins are highly conserved between *C. rheinhartii* and man. IFT transport is bidirectional. In anterograde IFT plus-end-directed motors of the kinesin 2 family move IFT particles with attached cargo toward the plus end of the axoneme, while in retrograde IFT a minus-end-directed dynein motor returns the IFT machinery for exchange with a pool in the cell body. Again, the pathway is highly conserved in that the same molecular

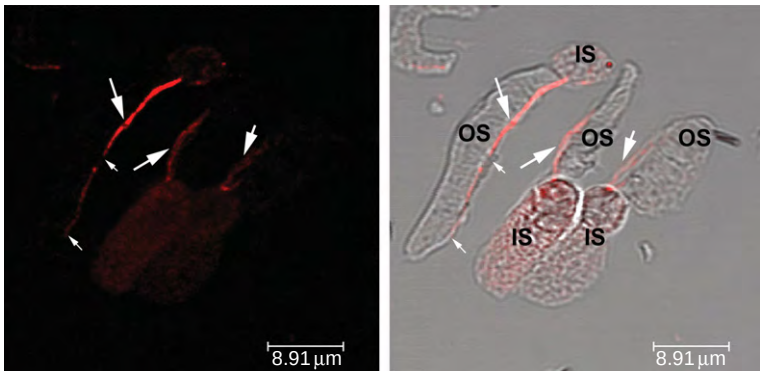

Figure 4 Immunocytochemical labeling of the axoneme of cone OSs from zebrafish. An antibody to α-tubulin was used to label (red) the microtubules of the axoneme (large arrows). An immunofluorescence image is on the left and for orientation this image is merged with a phase image of the same cells on the right. The image includes a long single cone (upper left) and a double cone (lower right). Note that the axoneme staining is attenuated distally (small arrows), particularly in the long single cone. Magnification bars in lower right equal 8.91 µm. IS, inner segment; OS, outer segment.

motors identified in *C. rheinhartii* and *C. elegans* perform similar functions in virtually all eukaryotic cilia including those in man. For example, heterotrimeric kinesin II, assembled from the kinesin family member 3A and 3B (KIF3A, KIF3B) along with kinesin-associated protein 3 (KAP3) proteins, is the canonical anterograde motor, while a dynein containing the cytoplasmic dynein 2 heavy chain (DNCH2) is the canonical retrograde motor.

A prominent role for IFT in photoreceptor OS formation is now well established. Four of the IFT proteins (IFT88, IFT57, IFT52, and IFT20) have been localized along photoreceptor axonemes and photoreceptor OS assembly defects have been fully characterized in rods of mice with a mutation in IFT88. This has been extended to cone cells with targeted, cone-specific deletion of IFT20, which results in disrupted OS assembly. A central feature of the IFT model is the multi-protein IFT particle (**Figure 5**). IFT particles containing IFT88, IFT57, IFT52, and IFT20 can be isolated from bovine photoreceptor outer segments. The photoreceptor IFT particle is large, fractionating in sucrose gradients at a peak size of ~500–750 kDa and has properties remarkably similar to those originally described in *C. rheinhartii*. This implies that the photoreceptor particle contains additional IFT proteins for which antibodies have not yet been generated. Evidence for photoreceptor IFT is also based on analysis of its canonical motors. All three subunits of kinesin II as well as DNCH2 have been localized to photoreceptor axonemes. Furthermore, conditional deletion of the KIF3A subunit of kinesin II disrupts OS assembly, causes rhodopsin mislocalization, and results in photoreceptor cell death.

A Special Role for KIF17 in Photoreceptors

The foregoing description of photoreceptor IFT describes conditions and expectation of a canonical IFT model that has applicability in virtually all ciliated cells. However, a novel feature of photoreceptor IFT is the critical involvement of an additional kinesin motor, the homodimeric kinesin family member 17 (KIF17). As illustrated in **Figure 5**, both kinesin II and KIF17 are associated with the IFT particle along doublet microtubules in the proximal OS, but KIF17 alone is associated with movement of the IFT particle along singlet microtubules in the distal OS. Our recent work has demonstrated that KIF17 is required to form outer segments, but does not simply replace kinesin II function; both kinesins are required. An interesting feature of this work is that while reduced kinesin II function disrupts both photoreceptor and kidney cilium elongation, knockdown of KIF17 results in failed OS assembly with no apparent effect in the kidney. The importance of KIF17 is likely related to the presence of singlet microtubule extensions in photoreceptors (see **Figure 3**). While singlet extensions are prominent in photoreceptor cilia, as originally illustrated in the older EM literature, singlet extensions in kidney sensory cilia are either very short or not present at all.

Work from the laboratory of Jonathan Scholey at the University of California at Davis has shown that the *C. elegans* KIF17 homolog, osmotic avoidance abnormal protein (OSM-3), is also required for sensory cilium elongation, specifically in cilia with singlet extensions. In *C. elegans* cilia OSM-3 serves as an accessory IFT motor along with kinesin II. Specifically, either kinesin motor can function and compensate for loss of the other motor in the proximal cilium, which contains doublet microtubules, but only OSM-3 can extend and move along the distal singlets. In fact, it was the existence of singlet extensions in photoreceptors that drew our attention to KIF17 and led to our finding of a prominent role of this accessory kinesin motor. However, the simple model for dual IFT kinesins in *C. elegans* does not fully explain findings in photoreceptors. The *C. elegans* model predicts that knockdown of KIF17 would result in short OSs that fail to elongate.

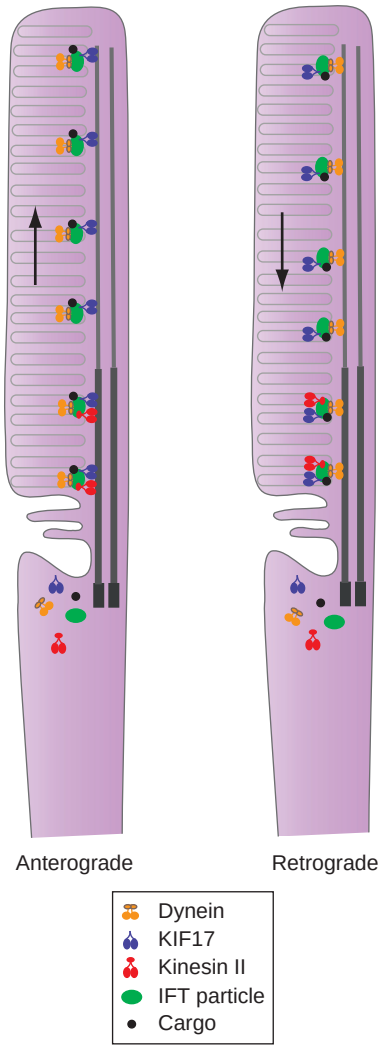

Figure 5 Conceptual diagram of intraflagellar transport (IFT) in photoreceptors. (Left) Anterograde IFT uses the plus end directed kinesin motors, kinesin II and KIF17, to move IFT particles with attached 'cargo' toward the distal, plus end of the axoneme (arrow). Note that the minus-end-directed motor, dynein, is illustrated as cargo for anterograde IFT. Based largely on work in *C. elegans*, it is hypothesized that kinesin II and KIF17, move cooperatively on doublets in the proximal outer segment and that KIF17 operates alone on singlets in the distal outer segment. (Right) Retrograde IFT uses a cytoplasmic dynein motor to return IFT particles and cargo to the inner segment. Note that kinesin II and KIF17 are illustrated as cargo for retrograde IFT. IFT complexes along with cargo and molecular motors are thought to assemble into large complexes in the inner segment in the region adjacent to the basal body.

Results from direct comparison of mutated forms of the KIF3B subunit of kinesin II and KIF17 suggest that the motors carry out nonredundant functions and suggest that, in addition to a role for KIF17 in distal cilium extension, the motor may also be involved in transport of proteins that are essential for disk assembly in the proximal outer segment. Although knockdown of KIF17 results in ablation of OS formation, a recent mutagenesis study of a consensus calcium, calmodulin kinase II (CaMKII) phosphorylation site in the KIF17 tail region, demonstrates that KIF17 plays a critical role in the distal OS in the control disk shedding (see **Figure 1**).

What Is the IFT Cargo?

The requirement for IFT in ciliogenesis has led to the general idea that the IFT particle serves as an adaptor to link IFT cargo to the requisite IFT motors. Some of the early evidence for cargo relates to the motors themselves. Since the axoneme plus end is at the distal end of the cilium, the minus-end-directed dynein motor required for retrograde IFT cannot move from the cell body to the distal tip on its own and available data suggest that it is cargo during anterograde IFT. Likewise, recycling of the plus-end-directed kinesins back to the inner segment appears to require retrograde IFT (see **Figure 5**). Another feature of axoneme organization is that its microtubules can assemble or disassemble only at the plus end, which is located distally. Since the axoneme can both elongate and shorten, its building blocks are likely cargo in both directions. It is important to point out that since the axoneme provides the principle cytoskeletal scaffold for the OS, IFT would be of great significance if its main purpose were to maintain axoneme structure. Recent evidence, however, suggests that IFT transports membrane components of the OS as well.

The photoreceptor OS provides a special challenge in that the components of phototransduction are present in high abundance and turn over rapidly. The question is: Which of these components is moved to the OS by IFT? One reasonably clear conclusion is that not all OS components require IFT. For example, some phototransduction proteins, such as arrestin and transducin, move between inner and OS in relationship to light and dark adaptation and a strong case can be made for free diffusion as the underlying mechanism for movement of abundant freely soluble proteins. Current evidence favors the idea that many membrane and membrane-associated proteins may require IFT. In *C. rheinhartii* and *C. elegans*, where real time imaging is feasible, movement of specific membrane proteins has been detected along the cilium. Rigorous proof that a particular protein is IFT cargo requires direct demonstration that it is linked to the IFT machinery and moves with IFT components, and there are no examples of this type of evidence outside of *C. rheinhartii* and *C. elegans*.

Nonetheless, mutation of the KIF3A subunit of the kinesin II motor, and mutation of the IFT88 subunit of the IFT particle both result in rhodopsin mislocalization, suggesting that rhodopsin is carried as IFT cargo. In support of the specificity of this effect, we recently demonstrated that expression of a dominant-negative

form of the KIF3B subunit of kinesin II in zebrafish cones results in cone opsin mislocalization, but dominant-negative KIF17 blocks OS elongation without causing opsin mislocalization. Since studies of protein mislocalization in cells carrying mutations is an inherently indirect measure, we have recently used a variety of pull-down assays to isolate IFT protein complexes containing the two kinesin motors as well as rhodopsin and another OS membrane protein, retinal guanylyl cyclase 1 (RetGC1 also called GUCY2E). The work with GC1 is particularly interesting because we have identified a small chaperone protein (DNAJB6) that binds specifically to IFT88 in the IFT particle and to the kinase homology domain in the cytoplasmic tail region of GC1. We have proposed that this is the key linkage required for association of membrane GC1 with the IFT machinery and that the binding can be regulated directly through the ATPase activity of heat-shock cognate protein 70 (HSC70). This represents the first specific model for the molecular linkage of a cargo protein with the IFT machinery.

Summary and Perspective

The fact that photoreceptor OSs are sensory cilia has been known for many years, but recent advances in understanding the mechanisms underlying ciliogenesis, including the IFT pathway, are likely to have a large impact on our understanding of the cell biology of photoreceptors. Although mutations in genes involved in ciliogenesis often cause embryonic lethal phenotypes and will not frequently appear among the causes of photoreceptor-specific degenerative disease, our understanding of disease mechanisms are likely to improve through understanding which photoreceptor proteins are IFT cargo. For example, human GC1 contains three human disease causing mutations in the domain that we have recently shown to bind a linker chaperone that couples GC1 to the IFT machinery. This has led us to propose that those human mutations lead to abnormal ciliary trafficking. The importance of photoreceptor cilia also provides a basis for understanding syndromic diseases such a Bardet–Biedl syndrome, which includes RP among a complement of other abnormalities. Such diseases are now referred to as ciliopathies because cilia provide a common basis for understanding pathology in the different tissues that are affected. Finally, placement of photoreceptor OSs in their appropriate niche as a special type of sensory cilium provides evolutionary perspective on pathways common to all cilia that emerged early in eukaryote evolution.

The Physiological Consequences of Vitreous Composition

T M Ranchod, D T Goldenberg, and M T Trese, Associated Retinal Consultants, Royal Oak, MI, USA

Glossary

Chromovitrectomy – The use of dyes during vitrectomy to identify and facilitate removal of the vitreous, epiretinal membranes, or internal limiting membrane.
Enzymatic posterior vitreous detachment – The posterior vitreous detachment induced by an enzyme injected into the vitreous cavity.
Posterior vitreous detachment (PVD) – The detachment of the vitreous cortex and posterior hyaloid face from the internal limiting membrane of the sensory retina.
Vitrectomy – The surgical removal of the vitreous body from the posterior segment of the eye.
Vitreoretinal interface – The site where vitreous collagen fibrils bind the internal limiting membrane of the sensory retina with the aid of glycoproteins.

Anatomy and Physiology of the Nonvitrectomized Eye

Vitreous is composed predominantly of water (99%) and the main extracellular matrix components are collagen and glycosaminoglycans. Vitreous collagen is predominantly type II; however, type IX, type V/XI, and small amounts of type VI are also present. Within the vitreous, collagen fibrils are interspersed with molecules of the glycosaminoglycan hyaluronan. Collagen fibrils are distributed unevenly throughout the vitreous body; they are most dense at the vitreous base, followed by the posterior vitreous cortex, then the anterior vitreous cortex, and they are least dense in the central vitreous body. The distribution of hyalocytes is similarly uneven, roughly corresponding to the distribution of collagen.

The vitreous body is bounded anteriorly by the lens–zonule–ciliary body–iris diaphragm and elsewhere by the neurosensory retina, of which the internal limiting membrane (ILM) is the innermost layer. Attachments of the vitreous body to adjacent structures are strongest at the vitreous base, which spans across the ora serrata, from the pars plana to the anterior retina. The next strongest adhesion exists at the borders of the optic disk. When a spontaneous posterior vitreous detachment (PVD) occurs, glial cells from the disk margin can remain on the posterior hyaloid face, seen clinically as a Weiss ring. The vitreous also adheres to the major retinal vessels, accounting for occasional avulsion of retinal vasculature during the process of PVD. A firm attachment is also present in the macula. Weaker adhesions are present anteriorly where the vitreous meets the posterior lens capsule, known as Wieger's ligament.

The structure of the vitreous body changes with age, as the gel matures into fluid pockets alternating with patches of condensed collagen (syneresis). A large fluid pocket, or lacune, often forms in the central vitreous body where collagen is least dense, and this pocket is frequently visible on anterior slit lamp examination as well as during vitrectomy surgery. Detachment of the posterior hyaloid from the retina (PVD) occurs spontaneously with age as well, and a Weiss ring may or may not be visible. The incidence of PVD increases with age, but the overall prevalence of partial or complete PVD may be lower than previously thought. The vitreous in children warrants special consideration. Vitreous adhesions are much stronger in children than in adults, making complete surgical removal of the vitreous difficult without the aid of enzymes (discussed below). Furthermore, the vitreous architecture is distinctly abnormal in children with retinopathy of prematurity (ROP), familial exudative vitreoretinopathy (FEVR), and some retinal dystrophies. In these patients, the vitreous cortex is composed of alternating layers of liquid and solid gel. The precise orientation of these sheets has not been clearly delineated, but removal of vitreous cortex layers can be confused for removal of the posterior hyaloid during surgery, resulting in unwanted residual vitreous following vitrectomy. Splitting of the posterior hyaloid, vitreoschisis, has also been noted in adult patients with proliferative diabetic retinopathy.

Mechanical Vitrectomy

Standard vitrectomy involves the creation of two or three full-thickness scleral incisions (sclerotomies) through the pars plana. Instruments and infusions are delivered through these ports during surgery, and the sclerotomies are traditionally sutured at the end of surgery with 20-gauge instruments. More recently, sutureless vitrectomy has become possible with 23- or 25-gauge and even with 20-gauge instruments. During vitrectomy surgery, the bulk of the vitreous is generally removed initially (core vitrectomy). If a PVD is not already present, the posterior hyaloid face is usually detached deliberately in

order to facilitate removal of the posterior vitreous cortex. It is often assumed that this is done leaving a collagen-clean anterior retinal surface but vitreoschisis can result. Vitreous cortex in the periphery may be trimmed to varying degrees depending on the goals of surgery, and some degree of peripheral cortex at the vitreous base invariably remains at the end of surgery. In some cases, such as rhegmatogenous retinal detachment, residual peripheral vitreous may act as a scaffold for cellular proliferation (proliferative vitreoretinopathy, or PVR); hence, meticulous removal of peripheral vitreous is warranted.

Pharmacologic Vitreous Manipulation

Several enzymatic agents have been used to alter vitreous structure in preparation for or in lieu or surgery. Hyaluronidase injected into the vitreous cavity results in vitreous liquefaction but does not cause a PVD. More recently, autologous plasmin enzyme and recombinant microplasmin (ThromboGenics Ltd., Dublin, Ireland) were shown to successfully cause vitreous liquefaction as well as complete PVD, and animal models have confirmed increased vitreous diffusion coefficients after microplasmin, consistent with reduced vitreous viscosity.

The presence or absence of attached posterior hyaloid may influence the flux of molecules across the vitreoretinal junction, either as a physical barrier or through molecular binding. In hyaluronidase-injected cat eyes (vitreous liquefaction without PVD) and in control eyes (no liquefaction and no PVD), the cortical vitreous appeared more densely compressed at the retinal surface than in microplasmin-injected eyes which demonstrated a smooth retinal surface free of cortical vitreous. Glycoproteins at the vitreoretinal interface may also bind free proteins, thereby preventing retinal penetration (**Figures 1–3**). Laminin and fibronectin are the main glycoproteins that bind vitreous collagen fibers of the posterior vitreous cortex to the ILM. The failure of tissue plasminogen activator (tPA) to penetrate the retina has been attributed to its specific binding to fibronectin, in addition to other proteins at the vitreoretinal juncture. Plasmin enzyme and microplasmin are able to hydrolyze laminin and fibronectin at the vitreoretinal junction, and studies are currently underway to determine if a microplasmin-induced PVD increases retinal penetration of tPA. A rabbit model has demonstrated that bevacizumab injected into the vitreous cavity achieves higher retinal penetration in the presence of microplasmin-induced PVD, supporting the hypothesis that attached posterior hyaloid plays a barrier role to molecular flux across the vitreoretinal border. Rapid transport of oxygen in and out of the vitreous cavity after enzymatic PVD is also consistent with this vitreoretinal barrier theory.

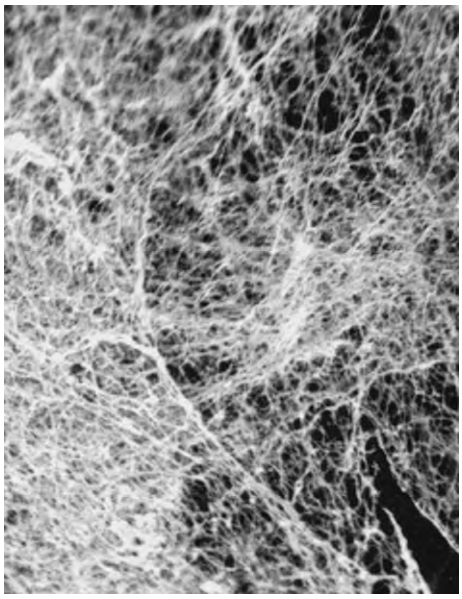

Figure 1 A scanning electron microscopy (SEM) image of the cat vitreoretinal interface demonstrates a network of cortical vitreous fibers adherent to the internal limiting membrane, consistent with the absence of a posterior vitreous detachment (PVD).

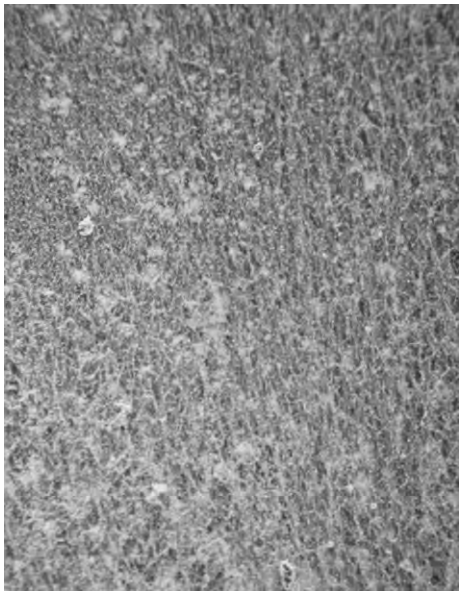

Figure 2 A scanning electron microscopy (SEM) image of the vitreoretinal interface after intravitreal injection of hyaluronidase demonstrates cortical fibers adherent to the internal limiting membrane. Hyaluronidase causes vitreous liquefaction without posterior vitreous detachment.

In adults, the utility of autologous plasmin has been demonstrated in several small series. Preoperative intravitreal injections of autologous plasmin were shown to induce PVD and increase resolution of macular edema in diabetic patients with advanced retinopathy. When used as an adjunct for macular hole repair surgery,

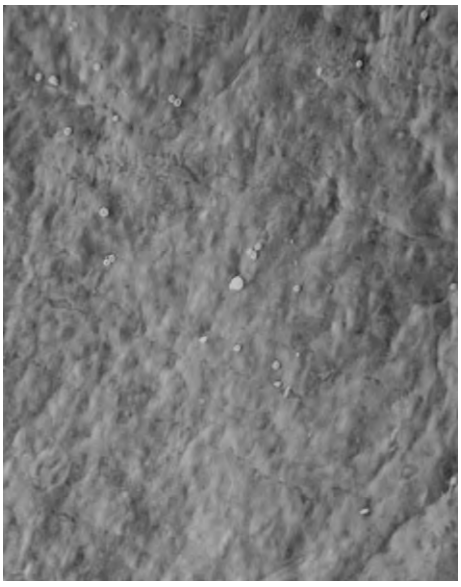

Figure 3 A scanning electron microscopy (SEM) image of the vitreoretinal interface after intravitreal injection of microplasmin demonstrates a smooth internal limiting membrane surface free of cortical vitreous, consistent with vitreous detachment. Microplasmin causes both vitreous liquefaction and posterior vitreous detachment.

autologous plasmin resulted in spontaneous PVD and reduced surgical time. In primary vitrectomy in the pediatric population, autologous plasmin allows for PVD creation and more complete vitreous removal. Microplasmin, a recombinant plasmin enzyme, is undergoing human clinical trials in both the United States and Europe.

Tractional Release During Vitrectomy

Vitrectomy may relieve traction on the neurosensory retina and consequently allow partial or complete restoration of normal retinal architecture in tractional disorders. Vitreous traction on the neurosensory retina is directly implicated in certain disease states such vitreomacular traction (VMT), a subset of diabetic macular edema, and macular hole formation.

During vitrectomy for conditions involving vitreoretinal traction, the ILM is often mechanically removed. The ILM is the innermost layer of the neurosensory retina, and adhesions between the ILM and vitreous cortex exist in normal eyes. Of importance during surgery, ILM adherence to underlying retinal structures is heterogeneous. Adhesions between the ILM and nerve fiber layer (NFL) are firm outside of the macula but much weaker within the macula due to attachment plaque distribution. Visually significant vitreoretinal traction occurs within the macula, where the ILM can be safely peeled due to weaker NFL adhesions. Peeling of the ILM becomes risky outside of the macula because strong NFL adhesions increase the risk of a retinal tear.

Cataract Formation after Vitrectomy

The incidence of visually significant cataract increases following vitrectomy, likely due to altered physiology of the rentrolenticular environment both during and after surgery. The human lens exists in a relatively hypoxic environment, and normal oxygen gradients within the vitreous cavity are lost when the vitreous is removed and replaced with fluid.

The infusate during vitrectomy surgery (most commonly a balanced salt solution, or BSS) contains oxygen at ten times the tension of oxygen in normal vitreous. Oxygen tension within the vitreous cavity remains elevated months after surgery compared to normal values, and the lens is therefore exposed to elevated oxygen tensions both during and after vitrectomy.

Other Molecular Changes after Vitrectomy

The flow of molecules within the vitreous cavity changes significantly after vitrectomy. The viscosity of aqueous humor or BSS is several 100-fold lower than that of vitreous gel. Consequently, the diffusion of oxygen, cytokines, and other molecules increases greatly when the vitreous gel is replaced by fluid. After vitrectomy, oxygen may circulate more freely from well-oxygenated retina to hypoxic retina, thereby decreasing the stimulus for vascular endothelial growth factor (VEGF) production. Furthermore, vitrectomy allows the diffusion of growth and permeability factors away from the retinal surface, likely reducing their stimulus on the sensory retina.

In certain pathologic states, such as retinal neovascularization in diabetes, vitreous oxygen tension is elevated in the immediate vicinity of the neovascularization. Immediately following vitrectomy, this local oxygen gradient dissipates, presumably due to high rates of diffusion in liquid compared to vitreous.

While increased diffusion within the vitreous cavity may alter oxygen circulation, the specific presence of a PVD appears to increase baseline oxygen tension within the vitreous cavity. When vitreous liquefaction was induced using hyaluronidase in an animal model, no PVD occurred and vitreous oxygen tension remained unchanged. When microplasmin was injected, causing both vitreolysis and spontaneous PVD, oxygen tension increased. This result might be explained by posterior vitreous cortex and the hyaloid face acting to reduce oxygen diffusion from the retinal circulation into the vitreous cavity, but the precise mechanism is not known.

Several vitreoretinal diseases are characterized by the presence of proinflammatory and angiogenic cytokines. Both VEGF and angiopoietin 2 are elevated in the vitreous in patients with proliferative diabetic retinopathy, and this elevation seems to be independent of PVD status. VEGF levels remain elevated immediately after vitrectomy, suggesting that changes in intravitreal VEGF following vitrectomy may occur due to flow and circulation of various factors rather than absence of vitreous alone.

Reactive oxygen species are elevated in the vitreous of patients with diabetic retinopathy. Oxidative stress, resulting from reactive oxygen species, may play a role in pathogenesis and correlate with severity of retinal microangiopathies such as diabetes, and it is not known if levels of reactive species change following vitrectomy.

When vitrectomy is combined with lensectomy, the eye effectively becomes unicameral, with oxygen tensions equalizing between the anterior and posterior segments. The anterior-chamber oxygen tension decreases from approximately 30 to 20 mmHg, while the posterior-segment oxygen tension remains near 20 mmHg. This equilibration may explain the increased rate of iris neovascularization seen following vitrectomy and lensectomy.

Chromovitrectomy

A variety of dyes may be used during vitrectomy in order to facilitate identification and removal of the vitreous, epiretinal membranes, or ILM. The most commonly used chromovitrectomy agents include indocyanine green (ICG), trypan blue, and triamcinolone acetonide.

ICG demonstrates a high affinity for the ILM and is therefore used during vitrectomy to identify and peel the ILM. ICG stains epiretinal membranes relatively poorly compared to other agents. At high doses, intraocular injections of ICG may cause retinal ganglion cell apoptosis, and subretinal injections in rats result in toxicity to the retinal pigment epithelium (RPE). During vitrectomy, however, small amounts of ICG are delivered in proximity to the macula for a brief period of time before removal, thereby limiting retinal exposure and potential toxicity. ICG may be delivered as a thin solution or as thicker solution when mixed with glucose. Experimental evidence for retinal toxicity at doses used during surgery is variable and inconclusive.

Trypan blue stains dead tissues and cells and is used during vitrectomy to selectively stain epiretinal membranes. As with ICG, experimental studies of retinal toxicity have yielded variable results.

Triamcinolone acetonide, a synthetic steroid used clinically for its anti-inflammatory effects, may be used during vitrectomy to help visualize vitreous. Triamcinolone is available in a preserved form as well as in a preservative-free form. The preserved form contains particles which may settle during surgery and help delineate epiretinal membranes, but the benzyl alcohol vehicle may have toxic effects. Toxicity concerns are relatively minor, as intraocular injections are tolerated well at high doses and subretinal injections have not shown significant toxicity to the retina or RPE.

Vitreous Replacements

During vitrectomy, the vitreous cavity may be filled with a variety of substances other than the default infusate, BSS. Some substances, such as perfluorinated liquids, are used temporarily, while others such as air, gas, and silicone oil may be left in the eye at the end of surgery.

Air is nonexpansile and absorbs within 1 week after surgery. Patients may be positioned postoperatively so that the air bubble tamponades a particular region such as the macula or an area of retinal detachment. Air is nontoxic to the retina but may prevent retinal reattachment if migration into the subretinal space occurs through a retinal break.

The most common gases used as vitreous replacements are sulfur hexafluoride (SF_6) and perfluoropropane (C_3F_8). SF_6 expands to double its original volume over a period of 24–78 h and absorbs over a period of roughly 2 weeks. C_3F_8 expands to 4 times its original volume over a period of 72–96 h and absorbs over a period of roughly 6 weeks when used at a nondiluted concentration. Nonexpansile concentrations may be used if volume expansion is not desired in the immediate postoperative period. As with air, patients may be positioned postoperatively in order to tamponade retinal breaks.

Silicone oil is generally used as a vitreous replacement in more complex surgeries such as repair of diabetic tractional retinal detachments or retinal detachments with PVR. Silicone oil does not change in volume and is not absorbed over time. The oil may be removed at the surgeon's discretion or left in place indefinitely in the absence of complications such as band keratopathy, elevated intraocular pressure (IOP), or cataract. Available *in vitro* evidence suggests that silicone oil has intrinsic antimicrobial effects with respect to causative agents of endophthalmitis. Silicone oil has a refractive index of 1.40, resulting in a hyperopic shift in the phakic patient, but this can be corrected with appropriate refraction. By comparison, useful refraction is not easily achievable in gas-filled eyes.

Silicone oil has a higher viscosity and lower specific gravity than saline. The lower specific gravity causes the oil to float within saline or aqueous. As oil is immiscible in water, surface tension is created at the interface, although less so than between gas and saline. The surface tension allows silicone oil to exert a tamponade effect on the

retina. Viscosity varies and the two main viscosities used are 1000 and 5000 centistoke. Lower viscosity is used more widely in the United States due to availability but is thought to have a higher rate of emulsification. Emulsification occurs when small droplets break off from the main oil bubble. The smaller droplets may travel into the anterior chamber, particularly in aphakic or pseudophakic patients. Silicone oil in the anterior chamber may be visible at the slit lamp as an inverted clear hypopion but is not necessarily clinically detectable. IOP may rise if oil enters the angle and prevents normal function of the trabecular meshwork. The degree of IOP elevation is proportional to the amount of emulsified oil in the anterior chamber. Elevated IOP in oil-filled eyes may also occur due to pupillary block or lens–iris diaphragm shift related to choroidal effusion.

There is some evidence that silicone oil in the vitreous cavity blocks diffusion of oxygen out of the anterior chamber into the posterior segment, thereby increasing anterior segment oxygen tension. This may help to explain why rates of iris neovascularization are reduced in eyes filled with silicone oil. Within the posterior segment, proteins and cytokine concentrations appear to be concentrated within the remaining fluid that bathes the oil bubble.

Perfluorocarbon (PFO) heavy liquids are sometimes used as a temporary vitreous substitute during vitreoretinal surgery. There is some evidence in animal models that because of greater oxygen solubility in PFO compared to BSS, eyes filled with PFO are less susceptible to ischemic retinal damage than eyes filled with BSS. PFO liquid has been safely used as a short-term postoperative tamponade after vitrectomy for retinal detachment, but animal data suggest retinal toxicity with long-term intravitreal use.

Sclerotomy Sites after Vitrectomy

During vitrectomy, instruments are inserted into the vitreous cavity through sclerotomy incisions. Incisions for traditional 20-gauge surgery are created using a sharp blade, after which instruments are inserted and removed through the wounds. Sclerotomies for small-gauge surgery are frequently created using trocars. The trocar is removed, leaving a cannula through which surgical instruments are inserted and removed for the duration of surgery, thereby minimizing trauma to the wound edges. At the end of surgery, sclerotomies are traditionally sutured after 20-gauge procedures and left sutureless after small-gauge surgery unless leakage is detected. Scleral wounds do not regain normal architecture postoperatively. In 20-gauge surgery, when sutures support wound closure integrity, wound gape may still occur. In sutureless surgery, a 5% rate of hypotony on the first postoperative day emphasizes the variable integrity of wound closure. Fibrovascular proliferation occurs at 10–15% of sclerotomy sites, and postoperative vitreous hemorrhage is more difficult to treat when associated with fibrovascular proliferation. In addition, trauma and traction on retinal tissue around sclerotomy sites may result in retinal breaks in both the early and late postoperative periods.

The Role of Acetylcholine and its Receptors in Retinal Processing

K T Keyser, V E Wotring and C E Strang, The University of Alabama at Birmingham, Birmingham, AL, USA

Glossary

Acetylcholine – A neurotransmitter ($C_7H_{17}NO_3$) released at autonomic and central nervous system synapses and neuromuscular junctions; it is synthesized from choline.
Agonist – A ligand or a drug that binds to and activates a specific receptor.
Antagonist – A ligand or a drug that opposes the action of an agonist by interacting with the receptor.
Ligand-gated ion channel – A membrane-spanning ion channel that is opened by the binding of a specific ligand, typically a neurotransmitter at a chemical synapse.
Nicotinic acetylcholine receptor – A neurotransmitter receptor comprising five subunits that contain a cation channel. The channel can be opened by the binding of acetylcholine, nicotine, and other substances to the receptor. These receptors are found at neuromuscular junctions, and at autonomic and central nervous system synapses.

Introduction

Studies in the 1970s revealed that acetylcholine (ACh) in the retina is synthesized in and released from two populations of amacrine cells. A population in the ganglion cell layer (GCL) releases ACh in response to light onset, and another population in the inner nuclear layer (INL) releases ACh in response to light offset. These amacrine cells are frequently referred to as starburst amacrine cells because of their distinctive morphology. The enzyme responsible for ACh synthesis is choline acetyltransferase (ChAT) and ChAT immunoreactivity is apparent in the starburst cells and their dendrites that narrowly ramify in the ON and OFF sublamina of the inner plexiform layer (IPL) in mammalian and nonmammalian retinas (Figure 1).

Under voltage clamp, starburst cells respond to light with slow graded currents, and release both ACh and γ-aminobutyric acid (GABA) in response to K^+ depolarization. While the tonic and light-evoked release of ACh by the starburst cells is commonly accepted as the only source of ACh in the retina, ChAT immunoreactivity has been reported in the A6 amacrine cell of the ground squirrel, a cell type that stratifies in the OFF sublamina of the IPL, and an alternative ChAT splice variant (pChAT), detected in the rat peripheral nervous system, has been reported to be expressed by retinal ganglion cells (GCs). The pChAT enzyme appears to be involved in the synthesis of ACh for release at retinorecipient sites, as it can only be detected in GCs when retinofugal axonal transport is blocked.

Physiological studies have shown that the activation of nicotinic acetylcholine receptors (nAChRs) by nicotine, choline, or ACh can have profound effects on the response properties of many GCs (including those that display directional selectivity) and on subpopulations of transient and sustained GCs. This article provides an overview of our current understanding of the expression of nAChRs in the retina and the functional consequences of nAChR activation.

nAChRs Receptors

Neuronal nicotinic acetylcholine receptors are ligand-gated, mixed cation channels that belong to the ligand-gated ion channel (LGIC) superfamily, which includes $GABA_A$, glycine, and 5-hydroxytryptophan-3 (5-HT3) receptors. Complementary DNAs (cDNAs) encoding nine α subunits (α2–α10) and three β subunits (β2–β4) of neuronal nAChRs have been cloned. In the vertebrate nervous system, nAChRs composed of α7, α8, α9, or α10 subunits exist either as homomers, in combination with each other (for α7 and α8), or with other as yet-unidentified subunits. The α subunits for these receptors contain both principal and complementary binding components. They form receptors that bind, and are blocked by, alpha bungarotoxin (αBgt), a high-affinity competitive antagonist from the venom of the banded krait.

Heteromeric nAChRs are composed of combinations of subunits α2–α6 assembled with subunits β2–β4 and are αBgt-insensitive. The α subunits carry the principal component for agonist binding, while the non-α-subunits have the complementary component. Agonist binding occurs at the interfaces of the α and β subunits. The known subunits in different combinations can theoretically yield a vast number of different receptor complexes. Studies in expression systems show that nAChRs with different subunit compositions differ in their ligand-binding affinities and in their physiological characteristics. Subunit composition also confers channel properties such as open times and desensitization rate.

nAChR Subunits in the Vertebrate Retina

Neuronal nAChR subunits are expressed in the retinas of many vertebrate species, although there are species differences. For example, nAChR subunits α2–α7 and β2–β4, but not α8,are present in mammalian retina. There are indications that α9 and α10 subunits, first discovered in the auditory system, may be expressed in retina; however, this is yet to be definitively demonstrated.

While α7 subunits are almost certainly assembled into the homomeric α7 nAChR subtype in the mammalian retina, or the α7α8 subtype in avian retinas, the determination of the subunit composition of heteromeric nAChRs has proven to be more difficult. Biochemical studies and labeling experiments using rodent, rabbit, and chick retinas have demonstrated the expression of simple heteromeric subtypes, including α2β2, α3β2, α3β4, α4β2, and α6β2 nAChRs. There are also indications that more complex heteromeric nAChRs are expressed, including α2α4β2, α6α3β4, or α6β2β3 subtypes. In addition, the expression levels of some nAChR subtypes are developmentally regulated, suggesting that the functional requirements for nAChRs change throughout development.

In order to understand the functional consequences of nAChR expression in the retina, considerable effort has been directed toward understanding the distribution of nAChRs in specific retinal circuits. The following two sections describe nAChR localization as revealed by methods, including radiolabeling, ligand-binding, immunohistochemistry, and *in situ* hybridization. While these studies were able reveal the expression patterns of one or more nAChR subunits, they do not provide information about the subunit composition of the assembled receptors.

Distribution of αBgt-Sensitive nAChRs

Radiolabeled or fluorescently labeled αBgt has been used to determine the localization of homomeric nAChRs. In live cells, αBgt binds only to receptors inserted on the cell surface. Thus, while αBgt binding is indicative of functional receptor expression, it has less utility in the determination of expression by specific cell types since binding is predominantly limited to the synaptic layers of the retina.

αBgt-sensitive nAChRs have been detected in the outer plexiform layer (OPL) of amphibian and avian species, while αBgt binding is broadly distributed throughout the IPL in both mammalian and nonmammalian tissue. The distribution in the IPL is more extensive than the narrow bands of ChAT immunoreactivity, suggesting the expression of nAChRs at a distance from the sites of ACh release.

As αBgt binding does not discriminate among the homomeric nAChR subtypes, specific antibodies have been used by themselves or in concert with αBgt binding to determine the expression patterns of αBgt-sensitive subunit expression.

In chick retina, α7, α8, and α7α8 nAChRs are widely expressed in subpopulations of amacrine and GCs, while a subpopulation of bipolar cells expresses α8-containing nAChRs. Immunohistochemical studies in rabbit retina have identified amacrine, ganglion, and three separate populations of ON bipolar cells that express α7 nAChRs (**Figure 2**). These include calbindin- and glycine-positive bipolar cells. The third bipolar cell type is neither calbindin nor glycine immunoreactive. Subpopulations of GABAergic and glycinergic amacrine cells and subpopulations of GCs also exhibit immunoreactivity to antibodies against the α7 subunit. The α7 immunoreactivity within the IPL closely correlates with concurrent fluorescent αBgt binding, supporting the specificity of the immunoreactivity.

The identification of expression patterns of α7 nAChRs by immunohistochemistry has been more problematic in

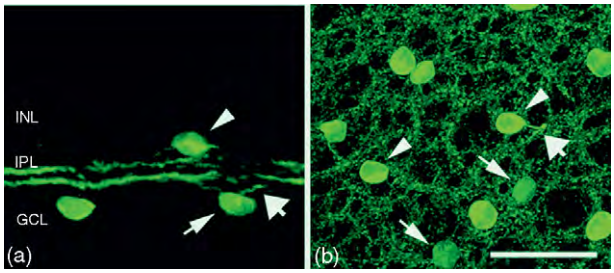

Figure 1 Choline acetyltransferase (ChAT) immunoreactivity in rabbit retina. (a) Vertical section through rabbit retina and (b) horizontal view of whole-mount rabbit retina demonstrate that two populations of amacrine cells are immunoreactive to antibodies against ChAT. The somas of the first population are located in the INL (arrowheads) with processes (arrowheads) descending to the OFF sublamina of the IPL. The second population consists of immunoreactive cells with somas in the GCL (arrows) and processes (broad arrows) ascending to the ON sublamina of the IPL.

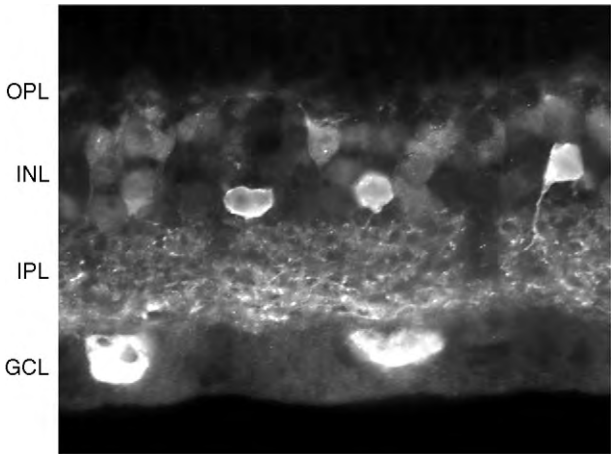

Figure 2 Expression of α7 nAChRs in rabbit retina. Immunoreactivity to an antibody generated against the α7 subunit demonstrates that α7 nAChRs are expressed by bipolar cells, amacrine cells, and ganglion cells. Labeling is distributed throughout the IPL, but is more intense in the ON sublamina (below, near ganglion cells). This may be accounted for by the populations of ON bipolar cells that express the α7 receptor.

the mouse retina. Studies using α7 knock-out mice have called into question the specificity of commonly used antibodies made against the α7 nAChR subunit. In some studies using homozygous α7 knock-out mouse tissue, there is residual anti-α7 antibody labeling in selected nonretinal parts of the brain. The residual immunoreactivity may be due to a lack of specificity, in that the antibodies also recognize an epitope on the α9 or α10 subunit or some other tissue constituent. Alternatively, in the case of a knock-out that has been generated by exon deletion, truncated nonfunctional proteins that contain the antibody-binding epitope may continue to be transcribed.

αBgt-Insensitive nAChR Expression in the Retina

Multiple αBgt-insensitive nAChR subtypes are widely expressed in the vertebrate retina. For example, in the chick, nAChRs that include β2, α3, or α5 subunits are expressed by amacrine and GCs, with the highest density of nAChR-expressing GCs in central retina. The α3β2 nAChR subtype is thought to be a major subtype, although binding and immunoprecipitation experiments have confirmed the presence of α4β4 and α6β4 nAChRs.

Heteromeric αBgt-insensitive nAChRs are also expressed in the mammalian retina and are distributed across much of the IPL, with bands of denser labeling overlapping the dendrites of the starburst cells (Figure 3). In rabbit retina, at least 60% of GCs in the visual streak display immunoreactivity to antibodies against the α3 subunit, as do many amacrine cells.

Most of the α3 subunit protein extracted from the rabbit retina can be co-precipitated with a specific β2 antibody, demonstrating co-assembly. However, a small but significant fraction of the α3 protein is not co-assembled with the β2 subunit, suggesting that there are nAChRs containing α3 and an alternative β subunit, perhaps the β4 subunit. The β4 subunit has been localized in the ground squirrel retina by immunohistochemistry and *in situ* hybridization in medium- to large-bodied GCs in the GCL, as well as in the INL and IPL. The β4 subunit gene is clustered with the α3 subunit gene, and both genes are expressed by amacrine and GCs in the developing rat retina. Co-localization with antibodies against glycine and GABA demonstrate that nAChRs are expressed by most glycinergic amacrine cells and by subsets of GABAergic amacrine cells in the rabbit retina. Interestingly, a small but variable fraction of starburst amacrine cells have been reported to express nAChRs.

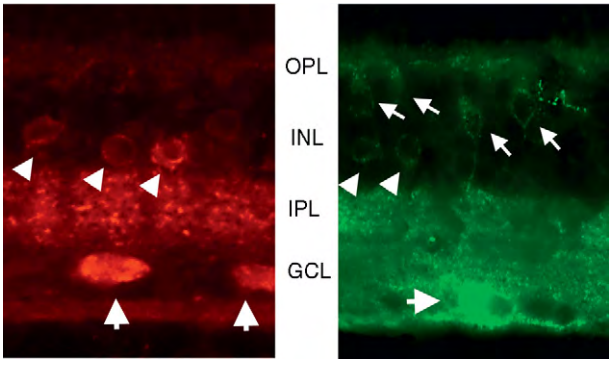

Figure 3 Distribution of heteromeric non-α7 nAChRs in rabbit (left) and mouse (right) retina. Amacrine (arrowheads) and ganglion cells (large arrows) of both species are immunoreactive to mAb210, and immunoreactivity is distributed throughout the IPL. However, bipolar cells (small arrows) are immunoreactive in mouse, but not rabbit retina. OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer.

In the rat retina, *in situ* hybridization studies detected transcripts for the α2–α6 and β2–β3 nAChR subunits in the INL and GCL. The distribution of α4 and β3 subunit transcripts is relatively the same between the INL and GCL, transcripts for the α5 subunit are more abundant in the INL than in the GCL, and the α2 subunit appears restricted to the INL. Transcripts for α3, α6, and β3 are distributed more strongly in the GCL relative to the INL.

In summary, nAChRs are localized predominantly in the inner retina of mammalian and nonmammalian species, although nAChRs have also been identified in the outer retina of nonmammalian species. In all species studied to date, nAChRs are expressed by subsets of bipolar, amacrine, and GCs; the distribution in the IPL is not restricted to the sublaminae containing starburst cell processes. Thus, while the identity of the particular receptor subtypes may vary, the commonalities in overall expression indicate that ACh exerts its effects via the activation of nAChRs expressed by many cells in diverse inner retinal circuits. That ACh may be able to act at a distance in the retina is supported by electrophysiological data. For example, subsets of rabbit αGCs respond to the application of nicotine and/or choline but do not co-stratify with cholinergic dendrites. Additionally, subsets of cholinoceptive amacrine and GCs express more than one nAChR subtype. Expression by inhibitory amacrine cells suggests that ACh may influence the overall excitability of the retina as well as modulate GC responses. Thus, the nAChR distribution suggests that ACh has the potential to exert complex effects on retinal responses.

nAChR Pharmacology

Pharmacological agents are widely used for identification of the receptor subtypes involved in nicotinic responses. While the crystal structure and mechanistic details of the interactions of ligands with nAChRs are increasingly being well understood, many of the agents available fail to exhibit ideally discriminative properties. However,

important information can be gained from pharmacology experiments, providing that caution is exercised in experimental design and interpretation of results.

Agonists

The endogenous agonist of all known nAChRs is ACh, although there is evidence that choline may act as an agonist at α7 and α9 subtypes. While many exogenous compounds are effective agonists, none of them exhibits strong selectivity, so the rank order of agonist potency has long been used as a tool for the determination of receptor subtype. Several of the commonly used nicotinic agonists are structurally similar which may, at least partially, explain their lack of specificity. All of those discussed below appear to interact with elements of the acetylcholine-binding site.

Nicotine

Nicotine is the agonist for which the entire class of nicotinic acetylcholine receptors is named and was originally isolated from tobacco leaves. It is not broken down by the enzyme acetylcholinesterase, which makes it a useful drug in preparations with active enzymes. It is a potent agonist of the heteromeric (α3-, α4-, α6-containing) αBgt-insensitive nAChR subtypes and of α8-containing receptors, while it is somewhat less effective at α7 homomeric nAChRs.

Carbamylcholine

Carbamylcholine or carbachol is an esterified form of choline that activates both nicotinic and muscarinic acetylcholine receptors. It is not metabolized by acetylcholinesterase, which makes it a useful drug *in vivo* or *ex vivo*. In the retina, α4-containing nAChRs would be most affected, while there would be somewhat less activity at α7-containing receptors. It also activates muscarinic AChRs, which greatly limits its experimental utility.

Cytisine

Cytisine is a plant alkaloid that is most active at α8 nAChRs, followed by α3-, α6-, and some α4-containing receptors. It may be less effective at α7.

Epibatidine

Epibatidine was originally isolated from the poison dart frog *Epipedobates* sp. and was first investigated as a potential analgesic. It is now used as an exquisitely sensitive (effective in the pM range) nAChR ligand in binding assays. Epibatidine is the most potent agonist at α3-, α4-, and some α6-containing receptors, but is not very effective at αBgt-sensitive receptors. However, it has been recently reported to bind 5-HT3 receptors, which could confound results in preparations where serotonin receptors may be expressed.

Choline

Choline is transported into cells through a high-affinity transporter and subsequently made into acetylcholine. It is not an effective agonist of any heteromeric retinal nAChR subtypes, but it is nearly as effective as ACh at α7 nAChRs. Choline sensitivity is frequently used as one indication of α7 receptors; however, choline is also an effective agonist at muscarinic AChRs, and a subtype-specific antagonist must be used to confirm α7 expression.

Antagonists

d-Tubocurarine (Curare)

This was the first antagonist used in experiments at the neuromuscular junction, and has been used in neuronal preparations as well. It acts through a competitive mechanism and blocks all nAChR subtypes with little specificity. It has also been shown to block $GABA_A$, glycine, and 5-HT3 receptors and some potassium channels. With such a wide range of activities, d-tubocurarine is of limited utility.

Dihydro-β-erythroidine

Dihydro-β-erythroidine (DHβE) is another plant-derived competitive antagonist of heteromeric nicotinic receptors. It is somewhat more effective at α4- and β2-containing receptors than at those containing α3 and is much less effective at α7 nAChRs. Its reversibility and specificity make DHβE an experimentally useful drug.

Hexamethonium and mecamylamine

These are classical blockers of autonomic ganglia nAChRs. They are used to block central nAChRs and also act through noncompetitive mechanisms, probably by occluding the channel pore. Blockade may be voltage dependent, which is an important caveat in electrophysiology experiments. They are considered nonselective among nAChR subtypes, although hexamethonium is somewhat more effective at receptors containing α3 or α6. Both require ~10-fold higher concentrations to block α7 nAChRs and are reversible as well; there is no evidence that either interacts with other LGICs. These facts, coupled with relatively low cost, make these drugs experimentally attractive blockers of nAChRs.

α-Bungarotoxin (α-Bgt)

The bungarotoxins are components of venom from the banded krait (*Bungarus multicinctus* and other species). αBgt binds homomeric α7–α9 receptors with high affinity and slow kinetics and is the ideal ligand for these receptor subtypes. The binding is of such high affinity, however, that it is essentially irreversible. There is a report that αBgt also binds β3-containing heteromeric $GABA_A$ receptors. This GABA receptor subtype is relatively of low abundance in the rest of the brain, but care should be exercised in retinal preparations.

α-Conotoxins

Among the many components of cone snail (family: Conidae) venom are the α-conotoxins. α-Conotoxin IMI is a

competitive antagonist of α7 at ~100 nM, and of α9 at 10-fold higher concentrations. α-Conotoxin AuIB is fairly specific for α3-containing nAChRs, and also acts through a competitive mechanism. α-Conotoxin MII competitively blocks α6-containing nAchRs.

Methyllycaconitine (MLA)

Methyllycaconitine is an antagonist of α6-, α7-, α8-, and possibly α9-, and α10-containing nAChRs at nM concentrations, but is nonspecific at μM concentrations.

While the pharmacology of nAChRs is clearly complex, the situation is made even more difficult by the nonselective effects of agonists and antagonists used in the study of other LGICs. The classical $GABA_A$ antagonist, picrotoxin, has been shown to block α3β4 and α7 nAChR subtypes with IC_{50} values of 96.1 ± 5.5 and 194.9 ± 19.2 μM, respectively. It also blocks glycine receptors and 5-HT3 receptors at ~30 μM. The cross-reactivity among LGICs has yielded interesting information about picrotoxin's mechanism and highlights the similarity among members of the picrotoxin family, but renders picrotoxin of limited use. Another commonly used $GABA_A$ antagonist, bicuculline, also inhibits nAChRs while gabazine seems to be a more specific antagonist, and should probably be used in lieu of picrotoxin or bicuculline.

Another example of a nonspecific LGIC antagonist is strychnine, which has been employed by physiologists to study the contribution of glycine receptors to retinal information processing. Unfortunately, strychnine is also a competitive antagonist of α7–α10 at ~1 μM. It also blocks heteromeric nAChRs at about 10-fold higher concentrations.

Atropine is often used at a concentration of 0.5–1 μM to block activity mediated by muscarinic acetylcholine receptors. It has also been found to block α3- and α7-containing nAChRs while potentiating those containing α4 subunits.

nAChR Function in the Retina

Physiological studies in the retina demonstrate that effects of cholinergic agents applied to the retina are complex. In rhesus monkey, the pattern electroretinogram (ERG) is enhanced by the ACh precursor L-α-glycerylphosphorylcholine. In cat, the application of ACh first enhances and then inhibits the ERG b-wave, an indicator of bipolar cell activation. These effects are attenuated by both nicotinic and muscarinic antagonists. The effects of ACh are more pronounced on the cone-driven ERG than on the rod-driven ERG, which is consistent with a report of α7 nAChR expression by cone, but not by rod bipolar cells in the rabbit retina. The subsequent inhibition of the b-wave may be due to either the desensitization of α7 nAChRs, or the expression of multiple types of AChRs, including muscarinic AChRs. In contrast to the cat, the frog ERG b-wave is inhibited by ACh, possibly through a cholinergic–glycinergic feedback loop onto the bipolar cells, or through activation of nAChRs on horizontal cells.

While *in vivo* ERG measurements provide important information about global or population responses to cholinergic agents, *in vitro* techniques have been used to explore the effects of nAChR activation on the responses of specific retinal cell types. For example, the application of ACh to isolated cat retina increases the responses of certain transient GCs, decreases the spontaneous firing of sustained ON cells with high background rates, and increases the spontaneous rate of sustained OFF cells with low background rates. It has been reported that, in some preparations, every GC tested responded to cholinergic agents. In the rabbit retina, ACh increases the activity of brisk GCs and ON-sluggish GCs. Brisk ON and OFF wide-field GCs are also affected by nicotinic agonists but are less sensitive.

In carp and rabbit, the effects of exogenously applied cholinergic ligands on many GCs persist after blockade of synaptic transmission, demonstrating the activation of nAChRs on the cells' surfaces. ACh application decreases a tonic inward current in dissociated rat GCs, and gates inwardly, rectifying cation channels in GCs dissociated from cat retina and in retinal slice preparations. Nicotine application also increases intracellular free calcium in many different GC classes, an effect that may be due in part to the activation of α7 nAChRs. These receptors are not very specific cation channels and sufficient Ca^{2+} can enter through them to regulate calcium-dependent events such as the activation of signal transduction pathways, including those mediating neuroprotection from glutamate excitoxicity. nAChR-mediated depolarization can also activate voltage-gated calcium channels providing an additional avenue for the initiation of calcium-dependent events.

There is evidence that the effects of cholinergic agonists on GCs are mediated by multiple nAChR subtypes. Evidence for α7 nAChRs includes blockade by MLA of responses to semiselective α7 nAChR agonists, including choline or anatoxin-a. Functional α3β4 (choline-sensitive; MLA-insensitive), and α4β4 and/or α3β2 (DHβE, nicotine-sensitive, MLA-insensitive) subtypes have also been identified.

The effects of cholinergic agents on retinal light responses appear to be mediated through multiple cell types. While there are limited data concerning the function of nAChR subtypes expressed by cells in the INL, nAChR-mediated depolarization of bipolar or amacrine cells can enhance or reduce the effects of activation of nAChRs expressed by GCs. These interactions have the potential to modulate complex operations in the retina, including GC center-surround receptive field organization, as well as directional selectivity.

Directional Selectivity

Directionally selective GCs (DS GCs) are perhaps the best-known cholinoceptive cells in the retina. The receptive fields of DS GCs are organized such that the cells respond preferentially to stimuli moving in one direction, for instance, the preferred direction, while responses to movement in the opposite, for example, the null direction, are reduced or absent. The dendrites of ON–OFF DS GCs co-stratify with those of the two populations of starburst amacrine cells. Although the details of the circuitry that underlie the DS mechanism remain uncertain, there is strong evidence that there is asymmetric inhibition of the responses to stimulus motion in the null direction. Current data suggest that, at least for simple stimuli, the asymmetry is generated by the starburst amacrine cell. Movement in the null direction results in GABA release that is thought to suppress the glutamate-mediated excitatory input from cone bipolar cells.

The role of ACh in directional selectivity is less clear. ACh contributes to, but is not required for, the preferred direction response to a moving bar or spot of light in turtle, chick, and rabbit. The cholinergic agonist dimethylphenylpiperazinium (DMPP) eliminates DS by increasing spontaneous firing to a level that masks the preferred response. Cholinergic blockade by mecamylamine decreases spontaneous firing and attenuates, but does not eliminate, preferred direction responses. Simultaneous blockade of ACh and *N*-methyl-D-aspartic acid (NMDA) receptors further attenuates the preferred response without completely abolishing DS. Interestingly, the preferred response is also attenuated by α7 nAChR-specific concentrations of MLA or α-conotoxin MII, suggesting that both αBgt-sensitive and αBgt-insensitive nAChRs are involved. In contrast to the responses to moving bars or spots, ACh is required for the DS response to a moving low spatial frequency grating in the rabbit. Curare blocks DS responses to moving gratings by decreasing the preferred response and enhancing the null response, indicating that in this case, DS is dependent on the activation of nAChRs. Application of physostygmine, an acetylcholinesterase inhibitor, also eliminates DS, presumably through saturating nAChRs. The activation of α7 nAChRs is also involved in DS responses to other complex stimuli such as moving sheets of spots and transparent motion.

nAChRs in Retinal Development

αBgt-sensitive and αBgt-insensitive nAChR expression in the retina is developmentally regulated and driven by intrinsic genetic programs as well as by visual experience. In chick retina, transcripts for structural nAChR subunits are detectable at embryonic day 6 (E6), increasing through and stabilizing after E10. In rat retina, multiple nAChR subtypes including αBgt-sensitive, α6-containing, α4-containing, and non-α6/non-α4 nAChR subtypes increase through postnatal day 21. Visual deprivation decreases the amount of α2, α6, and β3 subunits, and increases the amount of α4 and β2 subunits. Interestingly, while visual experience has effects on the expression patterns of some nAChR subtypes, the development of directional selectivity is independent of visual experience and cholinergic waves.

Spontaneous waves of activity are detectable in the GCL early in retinal development. The waves that occur during ganglion and amacrine cell synaptogenesis depend upon the activation of nAChRs, and may be involved in axon pathfinding. Retinal waves are altered in α3 or β2 nAChR knock-out mice, and projections to the LGN in β2 knock-out mice are altered. However, appropriate retinal organization and retinal projections recover after blockade of cholinergic retinal waves in non-knock-out animals. In fact, spontaneous activity in the retina recovers after conditional knock-out of ChAT eliminates retinal cholinergic activity. This evidence suggests that there are compensatory mechanisms for maintaining the integrity of the structure of the retina and the adult visual system.

Conclusions/Summary

ACh and choline exert their effects in the retina through the activation of nicotinic and muscarinic AChRs. The expression of several nAChR subtypes by neurons in diverse retinal circuits suggests that ACh and choline can affect many aspects of retinal information processing. Molecular, protein, and physiological experiments have aided in the understanding of these effects and the nAChR subtypes involved. However, our understanding of the role of nAChRs in retinal processing is based on studies that often involve pharmacological agents. Data from such studies must be interpreted with care, due to the limited specificity of currently available pharmacological agents.

The Role of Oxidative Stress in the Trabecular Meshwork

P Gonzalez, Duke University, Durham, NC, USA

Glossary

8-oxo-2,7-dihydro-2′-deoxyguanosine (oxo8dG) – One of the more than 20 DNA adducts, or pieces of DNA covalently bonded to a chemical, generated by oxidation of DNA. oxo8dG can be removed from damaged DNA through cellular processes of DNA repair involving nuclease activity. As it is relatively easy to quantify, the content of oxo8dG is the more frequently used method to evaluate oxidative damage to nucleic acids.

Free radicals – The atoms, molecules, or ions with one or more unpaired electrons on an open-shell configuration. The presence of unpaired valence-shell electrons makes them highly reactive and usually short lived.

Lipid peroxidation – The oxidative modification of lipids by a process in which reactive oxygen species steal electrons from the lipids in cell membranes. This process affects preferentially polyunsaturated fatty acids, because they contain multiple double bonds containing methylene (CH_2) groups that are particularly susceptible to interactions with reactive oxygen species.

Protein carbonylation – A terminal oxidative modification of amino acid side chains of proline, arginine, lysine, and threonine that results in the formation of glutamic semialdehyde and aminoadipic semialdehyde. Unlike oxidative modifications of proteins, such as the formation of methionine sulfoxide and cystein disulfoxide bonds, protein carbonylation is irreversible.

Reactive oxygen species (ROS) – The molecules or ions formed by the incomplete reduction of oxygen that results in the presence of unpaired valence-shell electrons. These reactive oxygen intermediates include singlet oxygen; superoxides; peroxides; hydroxyl radical; and hypochlorous acid.

Introduction

Denham Harman proposed in 1956 the free-radical theory of aging based on the similarities between the effects of ionizing radiation and aging, and the discovery that radiolysis of water generates free radicals. Harman hypothesized that endogenous oxygen-radical generation occurs *in vivo* as a by-product of enzymatic redox chemistry, and that this process contributes to cellular damage and aging. Initially, Harman's ideas did not gain much attention because the traditional thought was that free radicals were too reactive to exist in biological systems. However, the discovery of the enzyme superoxide dismutase (SOD) by McCord and Fridovich in 1969 provided compelling evidence of the generation of free radicals *in vivo*, and gave credibility to Harman's hypothesis. There is currently extensive evidence supporting the generation of free radicals in aerobic organisms. The major source of free radicals in living cells is believed to be the mitochondria. Electron transport in the respiratory chain appears to be imperfect and generates several reactive oxygen species (ROS). One-electron reduction of oxygen that takes place in the mitochondria leads to the generation of superoxide (O_2^-). Since spontaneous and enzymatic dismutation of O_2^- yields hydrogen peroxide (H_2O_2), both O_2^- and H_2O_2 are constantly generated as by-products of mitochondrial metabolism. In the presence of free transition metals, such as iron and copper, O_2^- and H_2O_2 generate the extremely reactive hydroxyl radical (^-OH), which is believed to be the species responsible for initiating most of the oxidative tissue damage. In addition to O_2^-, H_2O_2, and ^-OH, two energetically excited species of oxygen termed singlet oxygens can result from the absorption of energy (e.g., from ultraviolet light). Additional sources of free radicals *in vivo* include the beta-oxidation of fatty acids in peroxisomes, which generates H_2O_2 as a by-product, the microsomal cytochrome P-450 enzymes that metabolize xenobiotic compounds by catalyzing their univalent oxidation or reduction, and the respiratory burst of phagocytic cells that respond to pathogens with the production of a mixture of free radicals and other oxidants. The massive generation of oxidants by immune cells has led to the speculation that chronic inflammation, frequently associated with aging, may constitute a major contributing factor for oxidative damage. A variety of other enzymes are capable of generating free radicals and other oxidants, frequently in a tissue-specific manner. For instance, monoamine oxidase generates H_2O_2 in some neurons and has been implicated in the etiology of Parkinson's disease. Finally, the catalytic generation of nitric oxide by the isozymes of nitric oxide synthase, involved in some biological processes, can lead to the formation of several reactive species including the powerful oxidant peroxynitrite ($ONOO^-$).

The realization that other oxidants such as peroxides and aldehydes (that are not strictly free radicals) are also generated *in vivo* and contribute to oxidative damage in cells has led to a generalization of the free radical theory, now frequently referred to as the oxidative stress theory of aging. The current view of this theory is that cells of aerobic organisms are subjected to a chronic state of oxidative stress even under normal physiological conditions because of an imbalance between oxidant production and antioxidant defense mechanisms. This imbalance leads to a steady-state accumulation of oxidative damage in a variety of macromolecules and cellular structures, resulting in the functional alterations characteristic of the aging process and some age-related pathologies.

The concept that oxidative stress is one of the most significant determinants of the life span is currently supported by a large body of evidence from comparative studies of antioxidant defenses, ROS generation, and accumulation of oxidative damage in species with different maximum life-span potentials. It is, therefore, well accepted that oxidants are generated *in vivo* and can contribute to aging and numerous pathologies. However, until recently, the role of oxidative stress in the outflow pathway has not received much attention. Therefore, there is still relatively little evidence about how the cells of the aqueous humor (AH) outflow pathways cope with oxidative stress, the extent of oxidative damage that may occur with aging and glaucoma, and the consequences of oxidative stress in the physiology of the outflow pathways.

Antioxidant Mechanisms in the Outflow Pathways

Similar to other tissues, the conventional outflow pathway, formed by the trabecular meshwork (TM) and the Schlemm's canal (SC), has a variety of mechanisms to prevent oxidative damage by scavenging ROS as well as mechanisms to repair or replace oxidized molecules and cellular structures. Studies on enucleated calf eyes have shown the ability of the outflow pathway tissues to completely remove H_2O_2 at physiological concentrations present in the AH (25 μM). Some of the mechanisms to remove ROS studied in the TM include high concentration of reduced glutathione (GSH), as well as SOD and catalase activities. In addition, the outflow pathway may be protected against oxidative damage by the activity of other tissues that contribute to eliminate ROS in the AH that is drained out of the eye through the TM. In particular, the ciliary epithelium appears to provide a significant contribution to the elimination of ROS in the AH by releasing detoxifying enzymes such as glutathione peroxidase.

The ability of the TM and other tissues to eliminate ROS in the AH may be important in the maintenance of normal levels of outflow resistance. While exposure to H_2O_2 is known to have no direct effect on outflow facility in the normal eyes, the same treatment in eyes with the GSH-depleted TM results in a significant decrease in outflow facility. This observation suggests that, although GSH may not contribute directly to AH outflow regulation, a decrease in the ability to prevent TM H_2O_2-induced oxidative damage may result in an increase in outflow resistance.

The effectiveness of antioxidant defenses in many tissues declines during the process of normal aging as well as in certain pathologic conditions. The resultant increase in oxidative stress is believed to contribute to the functional alterations of these tissues in aging and contribute to the progression of some age-related pathologies.

Although a similar age-related decline in antioxidant protection seems likely to take place in the TM, experimental evidence is still limited to observations including the decrease of SOD activity in the TM of normal cadaver eyes.

There is, however, more information supporting a decrease of antioxidant defenses in the TM associated with glaucoma. Several studies have been conducted analyzing AH samples from glaucoma patients and nonglaucoma cataract age-matched controls. The AH of glaucoma donors has been shown to contain significantly lower levels of ascorbic acid. Perhaps more importantly, the total antioxidant redox potential (TRAP) of the AH was found to be noticeably lower than that of the nonglaucoma controls. Additional studies have been conducted in trabeculectomy specimens from patients with various stages of POAG and showed a decrease in GSH content that correlates with the stage of the disease.

Evidence of Oxidative Stress in the Outflow Pathway

Several attempts to quantify the levels of H_2O_2 and other ROS in the AH that suggest the presence of relatively high levels of H_2O_2 in the anterior chamber of the eye have been reported in the literature. However, since the direct quantification of ROS in living tissues is technically challenging because of the high instability of these molecules, the results from these studies remain controversial. Nevertheless, there is currently substantial evidence supporting the presence of oxidative stress in the TM. Most of this evidence has been provided by studying the presence of oxidation products of lipids, proteins, and nucleic acids, which constitute the main targets of ROS in living tissues. The first line of evidence is the observation that extracts from AH, TM, and SC show a significant increase in the accumulation of the primary, secondary, and end products of lipid peroxidation (diene and triene conjugates, Schiff's bases) in patients with primary open-angle glaucoma (POAG) as compared to nonglaucoma age-matched controls. This observation is potentially relevant, not only

because it supports the pathological relevance of oxidative stress in the TM, but also because such end products of lipid peroxidation are known to react with proteins to form adducts that induce protein dysfunctions and alter cellular responses. Therefore, a significant elevation of lipid peroxidation products could contribute to the functional alterations of the TM in glaucoma.

Further support for the presence of oxidative stress in the TM comes from the observation of protein oxidation in the TM: the presence and accumulation of oxidized proteins in the TM have been demonstrated by several laboratories. Reactive oxygen and nitrogen species can generate several oxidative modifications of proteins, including methionine sulfoxide, formation of free carbonyl groups, polypeptide backbone fragmentation, and cross-linking through disulfoxide bonds. An increase in methionine sulfoxide content that results from oxidation of methionine residues has been observed in the aging TM. Similarly, a significant increase in carbonyl groups, which results from terminal oxidation of amino acid residues, has been reported in primary cultures of TM cells from old donors when compared to those from young donors. Such increase in protein carbonylation appears to be associated with a decline in the ability of the proteasome to degrade proteins. This observation suggests that oxidative stress may be accompanied by a progressive loss of proteasomal function, which may contribute to the observed increase in the accumulation of oxidized proteins.

Finally, in addition to protein oxidation, there is also evidence for nucleic acid oxidation in the TM: oxidative damage of DNA results in the formation of several adducts of base and sugar groups, single- and double-strand breaks, and cross-links to other molecules. More than 20 different products are known to result from DNA oxidation. One of them, 8-oxo-2,7-dihydro-2′-deoxyguanosine (oxo8dG), is relatively easy to quantify and has been used extensively as a method to assess oxidative damage to DNA. Measurements of 8-OH-dG levels in TM specimens demonstrated a higher level of oxidative damage to the DNA in glaucoma patients compared to age- and sex-matched controls. Furthermore, this increase in 8-OH-dG correlated significantly with the severity of the disease evaluated by the degree of visual-field loss and intraocular pressure (IOP) elevation.

Additional indirect evidence of the role of oxidative stress in glaucoma is suggested by the observation that TM cells from glaucoma donors appear to exhibit a constitutive activation of a stress response. This sustained stress response has been observed in both cultured cells and tissue specimens and includes the activation of the transcription factor nuclear factor kappa B (NF-κB), the upregulation of inflammatory markers such as endothelium leukocyte adhesion molecule 1 (ELAM-1), as well a marked increase in the production of ROS by the mitochondria that is associated with decreased mitochondrial membrane potential. Upregulation of ELAM-1 has also been detected in the TM of glaucoma donors by gene-array analysis as well as in the aqueous outflow pathway of porcine eyes with induced glaucoma. The presence of inflammatory markers in the TM of glaucoma patients might be relevant to the pathogenesis of glaucoma. There is increasing evidence supporting a role for chronic inflammation as an underlying mechanism for the molecular alterations that link aging and major age-related diseases such as atherosclerosis, arthritis, osteoporosis, and cardiovascular diseases. Such chronic inflammatory response in aging tissues appears to be mediated by oxidative stress and the concomitant generation of intracellular ROS. An increase in ROS generation has been shown to activate an intracellular signaling cascade that can stimulate a chronic state of inflammation. Some of the key players involved in this process are believed to include the transcription factor NF-κB, cytokines interleukin 1 beta (IL-1b), and IL-6, and adhesion molecules such as ELAM-1. The reported upregulation of some of these markers in glaucoma supports the concept that oxidative stress may lead to chronic inflammation in the TM, which could contribute to both the aging process of the tissue and the pathologic manifestations associated with glaucoma. Experimental data in other systems suggest that the suppression of this age-related chronic inflammation helps to delay the progression of several age-related pathologies. Therefore, the observed activation of a chronic stress response in the TM deserves special attention in regard to new approaches for glaucoma therapy based on the suppression of proinflammatory mediators.

One general note of caution that has to be taken into consideration in these studies is that most glaucoma donors are treated with IOP-lowering agents that could potentially have effects on the redox status of TM. Topical AH suppressants inhibit active transport and might lead to a decrease in ascorbic acid and other protective agents in the anterior chamber of the eye. Carbonic anhydrase inhibitors could lead to acidosis and subsequent oxidative stress. Finally, although prostaglandins are likely to exert protective effects against oxidative damage, some preservatives such as benzalkonium chloride may increase oxidative stress.

Effects of Oxidative Stress on the Outflow Pathway

Despite the potential role of oxidative stress on the pathological changes of the TM during aging and glaucoma, very little experimental work has been conducted to investigate the effects of ROS on TM cells. Cultured bovine TM cells subjected to oxidative stress *in vitro* show a marked increase in the aggregation of damaged and cross-linked proteins. Short-term sublethal oxidative stress has also been demonstrated to have important effects

on the cytoskeleton and adhesive properties of TM cells. Treatment with 1 mM of H_2O_2 for 10 or 30 min significantly reduces the adhesion of TM cells to fibronectin, laminin, and collagen types I and IV. This short-term loss of cell–matrix adhesiveness is associated with increased levels of transcription factor NF-κB and NF-κB-binding activity, as well as with rearrangement of cytoskeletal structures. Although such changes are reversible, it is likely that repeated oxidative stress *in vivo* may result in a prolonged decrease in TM cell adhesion, leading to cell loss, and compromising TM integrity. Indeed, studies conducted using models of chronic oxidative stress provide evidence of a variety of permanent changes in TM cells. Incubation of TM cells at hyperoxic conditions (40% oxygen) leads to the accumulation of nondegradable material within the lysosomal compartment, which results in diminished lysosomal activity. Since the lysosomal system is responsible for the continuous turnover of cellular organelles, these results suggest that impaired lysosomal activity subsequent to chronic oxidative stress may lead to progressive failure of cellular TM function. In addition, chronic oxidative stress induced by repeated treatment with sublethal doses of H_2O_2 has been shown to increase the endogenous production of ROS by the mitochondria in TM cells, which in turn induces a sustained stress response characterized by activation of NF-κB and expression of inflammatory markers. Such endogenous production of ROS by TM cells resulting from chronic oxidative stress could potentially contribute to the pathogenesis of the TM by inducing the expression of inflammatory mediators previously observed in the TM of glaucoma donors and by increasing the levels of oxidative damage in the tissue. Interestingly, such increase in the endogenous generation of ROS and the subsequent upregulation of inflammatory mediators induced by chronic oxidative stress can be prevented *in vitro* by the naturally occurring polyphenol resveratrol, suggesting that it may be possible to develop effective therapeutic strategies aimed at delaying some of the alterations induced by oxidative stress in the cells of the outflow pathway (**Figure 1**).

Conclusions and Future Perspectives

A growing body of experimental evidence supports the concept that oxidative damage accumulates in the cells of the TM with aging and in glaucoma. However, the extent of the contribution of oxidative damage to the pathogenesis of the TM in glaucoma and the specific mechanisms by which it may contribute to an increase in AH outflow

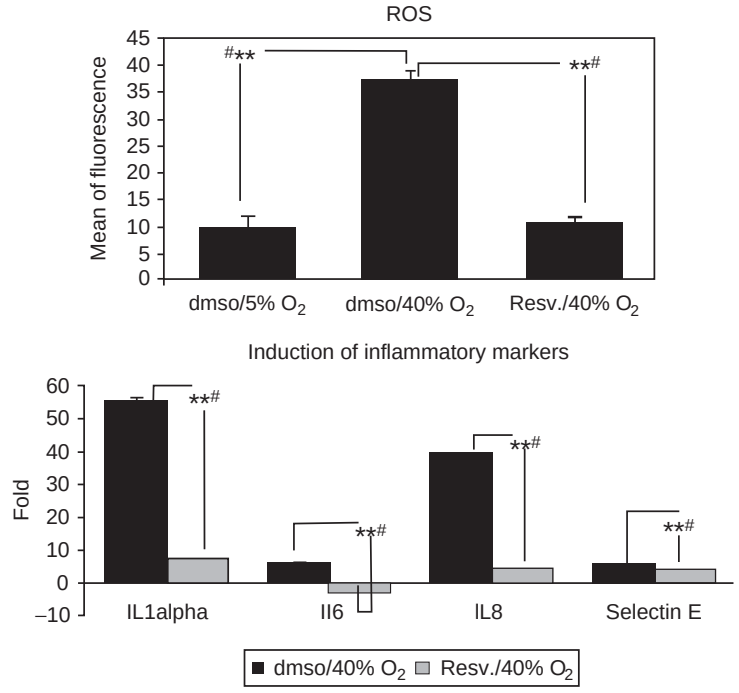

Figure 1 Effect of resveratrol treatment on the induction of endogenous generation of ROS (left) and the expression of inflammatory markers (right) mediated by chronic oxidative stress in porcine TM cells. Levels of ROS were measured by H2DCFDA and the expression of inflammatory markers was monitored by rt-Q-PCR in cells incubated at 40% oxygen and treated with resveratrol or vehicle and compared to cells incubated at physiological oxygen conditions (5%) ($N = 3$, t-test ,$^{**}P \leq 0.001$, # Kruskal–Wallis test $P \leq 0.049$). Adapted from figures 2 and 3 in Luna, C., Li, G.,Liton, P. B., et al. (2008) Resveratrol prevents the expression of glaucoma markers induced by chronic oxidative stress in trabecular meshwork cells. *Food and Chemical Toxicology* 47(1), 198–204, with permission from Elsevier Ltd.

resistance remain to be elucidated. Future research should help to clarify the extent of the role that oxidative damage may play in the aging of the TM and the pathological alterations of this tissue in glaucoma. An ongoing trend in the field of oxidative stress is the increasing recognition that ROS can play important roles as signaling molecules and may mediate some of the cellular responses relevant to understanding the process of cell aging. Similarly, there is increasing attention to the close relationship between oxidative stress and the activation of a chronic inflammatory response that may contribute to the pathologic alterations associated with aging in many tissues. Finally, a topic that deserves special attention is the study of the signaling networks that coordinately regulate the levels of ROS within the cell and the mechanisms protecting against oxidative damage. The identification of the pathways that regulate the longevity in yeast, *Caenorhabditis elegans*, and *Drosophila* suggest the existence of key regulators of the level of resources used by the cells to prevent and repair oxidative damage such as the sirtuin and FOXO families. Other examples may include p66SHC, Nrf2-ARE, and p53. Increasing our understanding on how these regulatory networks modulate the intracellular levels of ROS and the cellular defenses is currently a critical step to evaluate the importance of oxidative stress in glaucoma and could eventually lead to the development of new therapeutic strategies for this disease.

The Role of the Ciliary Body in Aqueous Humor Dynamics Structural Aspects

E R Tamm, University of Regensburg, Regensburg, Germany

Glossary

Ciliary body – It consists of ciliary processes and ciliary muscle and is the anterior continuation of retina and choroid.
Ciliary epithelium – It consists of two epithelial layers, the nonpigmented epithelium (NPE) that covers the surface of the ciliary body, and the pigmented epithelium that lies underneath the NPE. Both epithelial layers are required for active secretion of aqueous humor.
Ciliary muscle – A smooth muscle in the ciliary body that is required for accommodation. The anterior tendons of the ciliary muscle attach to the scleral spur and the trabecular meshwork. Contraction of the ciliary muscle causes an increase in trabecular outflow facility.
Desmosome – A spot-like junctional complex arranged on the lateral sides of cell membranes. This helps to resist shearing forces. An alternative term is macula adherens.
Gap junctions – These connect the cytoplasm of two neighboring cells by forming hemichannels (connexons) that connect across the intercellular space. These junctions allow molecules smaller than 1000 Da to pass through. An alternative term is nexus.
Tight junctions – A type of a junctional complex in which the membranes of two cells join together, thereby forming a barrier that is largely impermeable to fluid. An alternative term is zonula occludens.
Zonular fibers – The structural elements of the ciliary zonula that connects the ciliary body with the lens equator to form the suspensory ligaments of the lens. Zonular fibers are 10–12-nm microfibrils, and their major structural component is fibrillin-1, a secreted 350-kDa glycoprotein.

Introduction

The ciliary body in the anterior eye is the anterior continuation of retina and choroid. It consists of two parts: the posterior pars plana and the anterior pars plicata (Figure 1). The pars plana forms a smooth surface that is in contact with the anterior vitreous. The pars plicata gives rise to 70–80 radiating ridges, the ciliary processes. The stroma of the ciliary body contains the ciliary muscle, a smooth muscle that is required for accommodation. In a meridional section through a human eye, the ciliary muscle has the form of a right-angled triangle in which the angle is localized anterior-inward underneath the ciliary processes (Figure 1). The anterior muscle bundles of the ciliary muscle attach to scleral spur and trabecular meshwork, forming the main attachment site of the uvea to the outer coats of the eye. In the valleys between the ciliary processes, the zonular fibers originate that connect the lens with the ciliary body. The ciliary body is involved in two critical functional processes in the eye, namely accommodation and aqueous humor turnover. This article focuses on the roles of the ciliary body in aqueous humor dynamics.

Ciliary Processes

Each of the ciliary processes is filled with numerous capillaries (Figure 2). The capillaries are supplied by arterioles that originate from the major arterial circle of the iris.

The arterioles emerge from the major arterial circle and enter the anterior part of the ciliary processes to form a network of capillaries that frequently anastomose with each other. A larger capillary bends to the margin of each process to become the marginal venule that drains the blood into the veins of the posterior pars plana. Endothelial cells of ciliary process capillaries and marginal venule are of the fenestrated type and form numerous small openings that are covered by a diaphragm (Figure 3).

The diaphragmed fenestrae of the ciliary process capillaries are the reason for the high permeability of the capillaries that facilitates ultrafiltration of water and ions into the adjacent stroma. In addition, the fenestrated capillaries allow larger plasma-derived proteins, such as myoglobulin or gammaglubulin, to enter the stroma, an effect that leads to a high oncotic pressure in the ciliary process stroma. In younger eyes, the extracellular space between the basal laminae of capillaries and pigmented ciliary epithelium (PE) is relatively small, but increases with age. In the eyes of older humans, the stroma of the ciliary processes may contain large amounts of extracellular matrix that appear hyalinized in light microscopical sections (Figure 4).

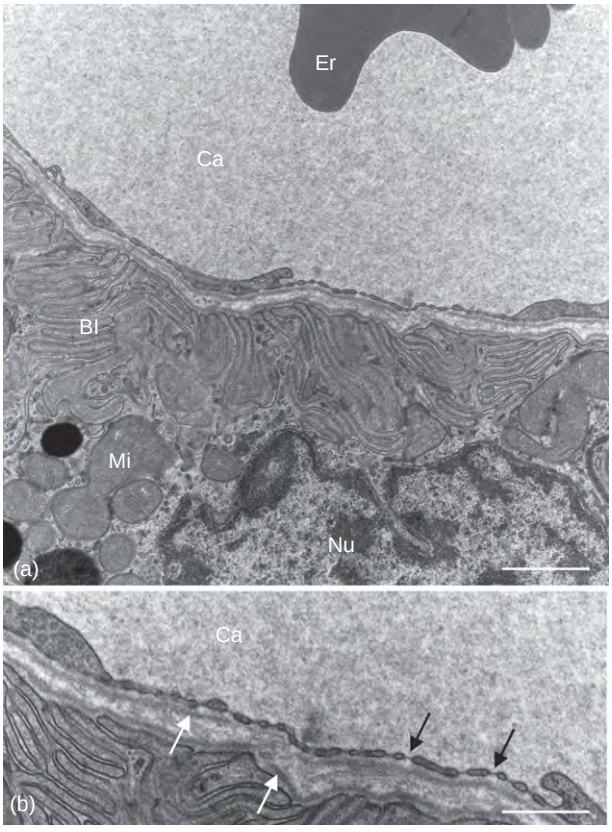

Figure 3 Electron microscopy of ciliary process capillaries ((b) is a higher magnification of (a)). (a) Electron micrograph of a ciliary process capillary (Ca) next to a cell of the pigmented ciliary epithelium (PE) with nucleus (Nu), numerous mitochondria (Mi), and basal infoldings (BI). An erythrocyte (Er) is present in the lumen of the capillary. (b) The endothelial cells of the capillary wall next to the basal laminae of capillary endothelium and PE (white arrows) form numerous fenestrae that are covered with a diaphragm (black arrows). Magnification: (a) 1 µm; (b) 500 nm.

In addition, there is a substantial thickening of the pigmented epithelium (PE) basal lamina (**Figure 5(a)**), which becomes increasingly multilamellated (**Figure 5(b)**). The age-related increase in extracellular matrix in the ciliary process stroma likely causes or contributes to the age-related decline in aqueous humor production.

The ciliary processes are covered by two epithelial layers of secretory cells (**Figure 6**). The pigmented outer epithelial layer (PE, pigmented epithelium) lies adjacent to the ciliary body stroma, contains pigment granules, and is a direct continuation of the retinal pigmented epithelium. The nonpigmented inner epithelial layer (NPE, nonpigmented epithelium) is a direct continuation of the retina. The two-layered ciliary epithelium originates in embryonic eye development when the optic vesicle invaginates to form the optic cup. As a result, the basal side of the NPE, which faces the posterior chamber and the vitreous, is covered by a basal lamina that is a direct continuation of the internal limiting membrane of the retina (**Figure 6**).

The cells of the ciliary epithelium form all the ultrastructural characteristics that are typically found in cells that are actively involved in energy-dependent transport processes. Accordingly, the basolateral surfaces of both NPE and PE form an elaborate system of cytoplasmic infoldings (**Figures 3, 6, and 7(a)**). The cell membrane of the infoldings shows intense histochemical and immunohistochemical staining for the enzymes Na-K-adenosine triphosphate (ATP)ase and carbonic anhydrase. To direct fluid transport across an epithelium, polarity between its luminal and basolateral membranes must be maintained. The tight junctions or zonulae occludentes that are required for this purpose are localized between the apical–lateral cell membranes of NPE cells, close to their contact with the cells of the PE. The tight junctions between the cells of the NPE form the

blood–aqueous barrier that is impermeable to plasma proteins or tracers such as horseradish peroxidase. While plasma proteins that leak from the capillaries of the ciliary body cannot pass the blood–aqueous barrier, they may move to the iris stroma and diffuse into the anterior chamber through the anterior surface of the iris, which is not covered by an epithelial layer. On the basal side of the tight junctions, adherens-type junctions are frequently observed.

Another type of junction that appears to be critically required for secretion of aqueous humor across the epithelial layers of the ciliary processes is gap junctions. Gap junctions, which allow ions and other molecules smaller than 1000 Da to pass through, are abundant in both layers of the ciliary epithelium. They are particularly numerous between NPE and PE (**Figure 7(d)**). The intense electrical coupling between both epithelial layers generates a functional syncytium that allows ions taken up from the stroma by cells of the PE to pass from PE to NPE. Ion transport between the epithelial layers appears to be critically required for secretion of aqueous humor as mice with a conditional inactivation of connexin 43 do not form gap junctions between both epithelial layers and show a substantial reduction in aqueous humor production.

To maintain the mechanical integrity of the NPE, the lateral sides of adjacent NPE cells are connected by well-differentiated desmosomes (**Figures 7(a),** and **7(b)**). At the adjacent cytoplasmic sides of the desmosomes, which are separated by a cleft 17 nm wide, electron-dense plaques are present, which are associated with 9–10-nm tonofilaments. Desmosomes of the NPE frequently form desmosomal–mitochondrial complexes in which the tonofilaments

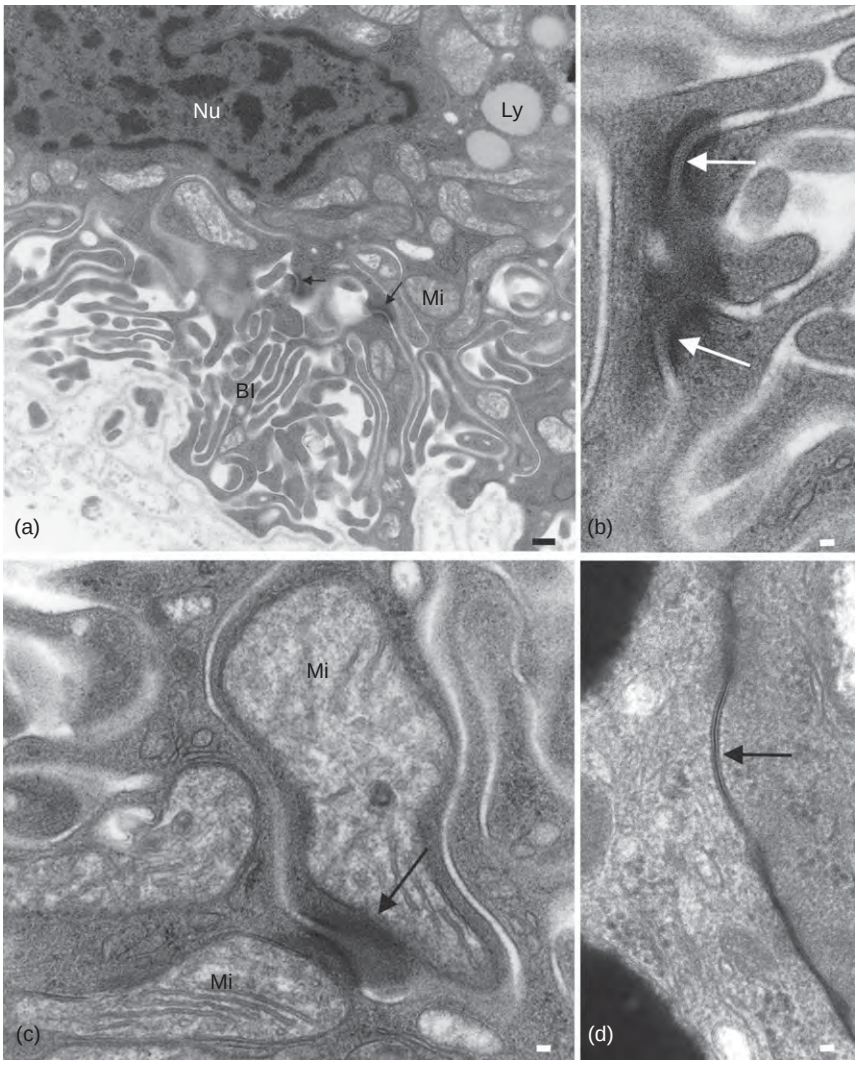

Figure 7 Electron microscopy of the nonpigmented ciliary epithelium. (a) The basal and lateral sides of nonpigmented ciliary epithelial cells form numerous infoldings (BI). contact the outer mitochondrial membranes. The functional significance of the desmosomal–mitochondrial complexes has not been finally clarified. Since calcium has been demonstrated in the associated mitochondria, the hypothesis has been put forward that the mitochondria may serve as buffers for intracellular calcium by controlling the local calcium concentration. This scenario might be advantageous for stability and functional integrity of desmosomal junctions in secretory or actively transporting epithelia with high endogenous calcium levels.

Mechanical stability is required for the epithelial layers of the ciliary body, as the zonular fibers which suspend the lens attach to the basal lamina of the NPE (Figure 8). While most of the zonular fibers originate in the posterior region of the pars plana, secondary tension fibers attach in the valleys between the ciliary processes to act as a fulcrum (pivot point). Accordingly, adherens-type junctions between NPE and PE have reported to be more numerous in the valleys between the ciliary processes than at their tips. In addition, the cytoplasm of the NPE contains less mitochondria in the valleys between the processes than at their tips, while the NPE cell membranes in the valley do not stain for Na-K-ATPase or carbonic anhydrase. Taken together, aqueous humor secretion appears to occur mainly at the tips of the ciliary processes, while the valleys between the processes primarily serve a mechanical function.

Cells of the ciliary epithelium typically show Golgi complexes and single cisternae of rough endoplasmic

reticulum (rER) that are both localized close to the nucleus. In the posterior part of the ciliary processes, cisternae of rER are more numerous and may form large aggregates with a fingerprint-like arrangement (**Figure 9(b)**). Proteins or peptides that are secreted into the aqueous humor may be produced in the fingerprint-like structures. Candidates are growth factors such as transforming growth factor-β2 or signaling molecules such as endothelin-1, which are both found in the aqueous humor and are synthesized by cells of the ciliary epithelium *in vitro*. In the eyes of older humans, lysosomes and lipofuscin particles may accumulate in the apical parts of NPE cells (**Figure 9(a)**).

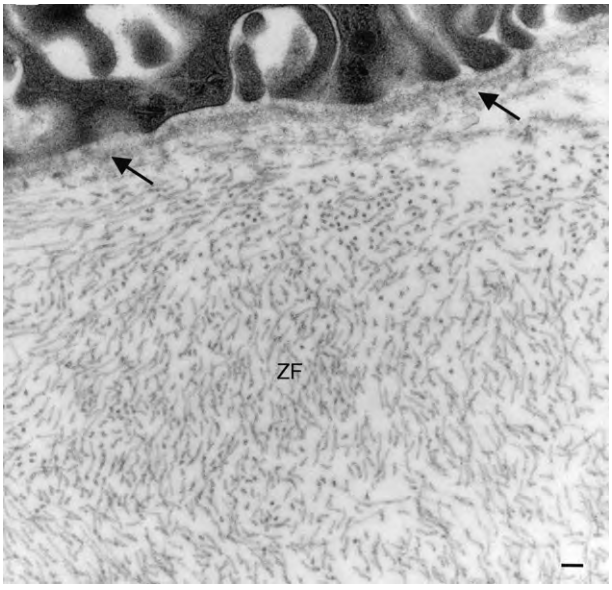

Figure 8 Attachment of zonular fibers (ZF) to the basal lamina (arrows) of the NPE. Electron micrograph. Magnification: 100 nm.

Ciliary Muscle

The stroma of the ciliary body is largely occupied by the ciliary muscle. While the main function of the ciliary muscle is related to accommodation, it is also critically involved in both conventional trabecular and unconventional uveoscleral aqueous humor outflow. Ciliary muscle contraction influences trabecular outflow due to the site of the anterior attachment of the muscle. The muscle bundles of the radial portion of the ciliary muscle and the inner bundles of its longitudinal portion form tendons in region of their anterior insertion that are continuous with the extracellular matrix of the trabecular meshwork beams (**Figure 10(a)**).

The tendons of the inner muscle bundles of the longitudinal portion pass the scleral spur at its inner aspect to continue to the trabecular meshwork (**Figure 10(b)**). The same banded material that forms the sheaths of the elastic fibers in the core region of the trabecular beams is the main structural element of the tendons. The banded material comes in direct contact with the cell membrane of the muscle cell, which forms dense bands at the cytoplasmic site (**Figure 10(c)**). In region of contact with the tendons, the muscle bundles taper and form deep furrows, which are filled with banded material. The outer muscle

bundles of the longitudinal portion of the ciliary muscle also form tendons, but connect with the extracellular matrix fibers of the scleral spur. The scleral spur contains collagen and elastic fibers that are circumferentially arranged (**Figure 11(a)**).

The elastic fibers are continuous with those of the core of the corneoscleral meshwork beams, or the cribriform plexus in the juxtacanalicular tissue. The outermost muscle bundles of the longitudinal portion of the ciliary muscle bend clockwise or counterclockwise before they attach to the scleral spur (**Figure 11(b)**). More inwardly, they do not bend, but insert to elastic fibers that are continuous with the circumferentially arranged elastic fibers of the scleral spur (**Figure 11(c)**). Because of the

structural connections between ciliary muscle and scleral spur, contraction of the ciliary muscle pulls the spur posteriorly and widens the trabecular spaces, thereby inducing changes in the geometry of the trabecular meshwork that lead to a reduction in outflow resistance. The intraocular pressure (IOP)-lowering effects of cholinergic parasympathomimetic agents, such as pilocarpine, are mediated through ciliary muscle contraction through its anterior insertion to scleral spur and trabecular meshwork. In monkeys, surgical disinsertion of the muscle from its anterior attachment abolishes the IOP-lowering effect of pilocarpine.

The ciliary muscle is not only involved in conventional trabecular outflow, but does also play a critical role in unconventional or uveoscleral outflow. The uveoscleral outflow route is open to the aqueous humor at the chamber angle in region of the anterior insertion of the ciliary muscle, as there is no complete endothelial or epithelial layer that covers the anterior surface of the ciliary body. When passing through the uveoscleral outflow pathways, aqueous humor exits the anterior chamber through the extracellular spaces between the ciliary muscle bundles, into the supraciliary and suprachoroidal space and out through the sclera into the extraocular tissues. Fluid in the uveoscleral pathways ultimately drains into the lymphatic system. Depending on the method that is used to measure it, unconventional or uveoscleral outflow is found to account for 10% or 25–57% of the total outflow in the human eye. In contrast to the conventional trabecular outflow, which is increased upon ciliary muscle contraction, uveoscleral outflow decreases, most likely because the available extracellular space is largely diminished in the contracted ciliary muscle. This pathway is important to understanding the mechanism of action of prostaglandin analogs in the treatment of glaucoma. In monkey eyes, treatment with prostaglandin analogs causes a widening of the extracellular spaces between the ciliary muscle bundles, resulting in an increase of available uveoscleral outflow pathways (**Figure 12**). This effect appears to be mediated through degradation of extracellular matrix compounds in the intramuscular connective tissue of the ciliary muscle.

The Role of the Vitreous in Macular Hole Formation

W E Smiddy, Bascom Palmer Eye Institute, Miami, FL, USA

Glossary

Henle's nerve fiber layer – The inner layer of cones at the fovea lacking overlying nerve fiber or inner nuclear layer cells that have the most attenuated internal limiting membrane covering; could be the most susceptible location for a breach in that layer that might initiate macular hole formation.
Internal limiting membrane – The confluence of inner footplates of Müller cells of retina that forms a membrane-like structure delimiting inner retinal surface where it contacts the posterior hyaloidal elements.
Macula – The retina that subserves central vision, populated by the most dense distribution of cone photoreceptors to offer the best visual resolution; this term is somewhat imprecisely used among clinicians (broader, perhaps 2 disk diameter zone) and histologists (more narrowly used to central point).
Posterior hyaloid – The most posterior elements of the vitreous body; this structure is more complex than previously thought, frequently exists as a multilaminated structure, and composed primarily of type IV collagen, but may be impregnated with cellular components.
Vitreoschisis – A phenomenon that is usually not visible, but could be important pathogenically whereby the vitreous body develops a splitting of some of its layers, most notably just anterior to the posterior hyaloidal attachment to the macula.

The pathogenesis of macular holes has undergone at least one full cycle of thought. Since macular holes were first identified following trauma, it was natural for early clinicians to deduce that a coup–countrecoup force transmitted through the vitreous caused macular hole formation. However, as it became apparent that trauma was only infrequently associated with the finding of a macular hole, other mechanisms were proposed as first summarized by Aaberg. Three principal, possibly coexisting, enhanced mechanisms have been proposed including unroofing or dissolution of the attenuated inner retinal layer of cystoid edema due to a range of etiologies, atrophy or degeneration of the retina, and vitreomacular traction. Advances in imaging have allowed unprecedented resolution which has ratified vitreomacular traction as the most prominent component, if not the basic underlying mechanism, of macular hole formation.

Undeniably, the vitreoretinal interface is the battlefront of macular hole formation and therapeutics. Some observations do not fully conform to the model of vitreomacular traction as the sole and universal cause of macular hole formation, but these may be consequences of vitreomacular traction or factors contributing to or potentiating vitreous traction. Thus, it is possible that the vitreous may play a prime-mover role, an innocent bystander role, or a collaborative role in the formation of macular holes. This article reviews the evidence and perspective of the role of the vitreous in macular hole formation.

Vitreous Anatomy and Biochemistry

The vitreous body has a much more complex structure and physiology than might initially be apparent from its transparent, paucicellar, predominantly aqueous appearance. It is a nonhomogeneous biochemical complex of collagen and hyaluronan. The physical structure of the vitreous is an extensive cisternal system of cavitated, more liquefied portions lined by extenuated and thickened walls. This seems to be accentuated with age (syneresis) or in certain disease states. Most specifically, the concept of a posterior precortical vitreous pocket and, consequently, a cortical vitreous layer has been defined and to a large degree imaged which, by its proximity to the fovea, mostly likely plays some role in the genesis of vitreous forces at the fovea. Improved optical visualization of the fine structure of the vitreous has allowed clinical detection of this pocket, and its size has been hypothesized to be proportional to the amount of tangential traction generated at the fovea.

The vitreous dual senescent processes of synchesis and syneresis render a posterior vitreous detachment (PVD) to be a much more complex process than the casual observer might suspect.

Vitreous Traction

Peripheral retinal breaks form at the time of a PVD. Thus, it was a natural step to conceive of the PVD as playing a formative role in causing macular holes. Gass' seminal grading scheme standardized observations of the stages involved in macular hole formation and it remains generally accepted. Its clinical relevance was immediately

seized upon and preventative surgery aimed at inducing the posterior vitreous separation before a macular break could occur led to several surgical investigations that seemed to offer promising results initially, but a randomized trial failed to establish the efficacy of this preemptive strategy. The surgical strategy employed at the time was to remove the cortical vitreous, which itself may reflect an incomplete or overly simplified understanding of the pre-hole dynamics.

Various clinical studies identified a lack of PVD to be associated with a higher risk of macular hole formation in the fellow eyes of patients with macular holes compared to fellow eyes with incident posterior vitreous separations. Histopathologic series not only established that posterior vitreous separation was more common among patients with full-thickness macular holes, but also made the observation that persistent attachments of the vitreous and associated cystic changes may imply a more complex mechanism than simple posterior vitreous separation.

The earliest imaging studies included ultrasound tests which also seem to establish the strong association of vitreous separation with macular hole formation. Subsequently, imaging with optical coherence tomography (OCT) depicted a compelling role for vitreous traction.

However, other observations have suggested that while traction at the time of posterior vitreous separation may well be important, it may be part of a more complex scenario. The fellow eyes of patients develop macular holes much more frequently than in the general populations, suggesting a constitutional susceptibility to macular hole formation, presumably at the time of posterior vitreous separation.

Vitreoretinal Interface

The second iteration of the vitreous separation at the fovea has focused on the nature and actions that occur at the vitreofoveal interface. Formerly, a vitreous separation was simplistically thought of as a clean, total separation of the hyaloid from the internal limiting membrane (ILM). However, the concept of an anomalous posterior vitreous separation at the fovea is what is probably most consistent with both the clinical behavior and the imaging appearances. Vitreous cortex remnants have been identified at the fovea and perifoveal area after apparent spontaneous posterior vitreous separation. In this way, the vitreous may be a necessary substrate for action at the fovea. Histopathologic studies have also suggested or have identified numerous other possible substrates that might mediate traction, but more of a delayed or tangential nature than the expected anterior-to-posterior traction of the simplified posterior vitreous separation. Anatomic features at the fovea are unique and may also account for what are incidental vitreoretinal forces elsewhere. For example, the fovea is thin centrally and the ILM as well as the basal lamina of the vitreous are extremely thin at the fovea. At the fovea, the outer plexiform layer and the photoreceptor layer (Henle's nerve fiber layer) are more exposed and the ILM is even more attenuated in this area. The tangential orientation of the fibers, their delicate nature, and the thin overlying ILM may make this layer more susceptible to incidental trauma at the time of vitreous separation at the fovea.

These anatomic and theoretic features seem to be consistent with other clinical observations, including the apparent predecessor lesion as a cyst. Thus, the question of the pathogenic role of the vitreous becomes open to its possible chronic role in inducing an inner cystic change, or its subsequent action on the weakened inner cystic layers to precipitate the full-thickness hole. Careful biomicroscopic study of the vitreous at the fovea can demonstrate vitreous separation or, more importantly, a partial vitreous separation at the fovea. Other imaging modalities besides OCT, including laser biomicroscopy kinetic ultrasound and retinal thickness analysis, also demonstrate these findings. The most convincing evidence for this role comes from the more newly advanced and available optical coherence tomography images which have corroborated the apparent impact of the vitreous at the fovea (**Figure 1**). This concept is demonstrated by cases with spontaneous closure of a macular hole after release of the persistent vitreofoveal attachment, whether in traumatically induced or in idiopathic cases. Applying this observation therapeutically, others have performed vitrectomy relieving the traction with peeling of the posterior hyaloid, vitrectomy with removal of the ILM, or even vitreolysis of its persistent attachment without a larger vitrectomy with resolution of a macular hole as well. However, the indication for intervention is not well established, and occasionally, the apparent vitreofoveal traction will spontaneously release (**Figure 2**).

Numerous case reports of macular hole formation associated with seemingly unrelated diseases share themes of vitreous traction in the setting of intravitreal injection, fungal endophthalmitis, and laser-assisted *in situ* keratomileusis (LASIK) associated with formation of full-thickness macular holes. A corollary of the role of the vitreous attachment at the fovea is that other case reports have suggested a sort of accomplice role that the vitreous may play in transmitting tractional effects from seemingly unassociated conditions as they burst as hemorrhage from a retinal microaneurysm, LASIK, transpupillary thermal therapy, yttrium aluminum garnet (YAG) laser injury, and subhyaloid hemorrhage. The possible contractile-potent quality of tissue in the vitreous is demonstrated by the ultrastructural analyses of removed tissue specimen from patients with impending macular holes which

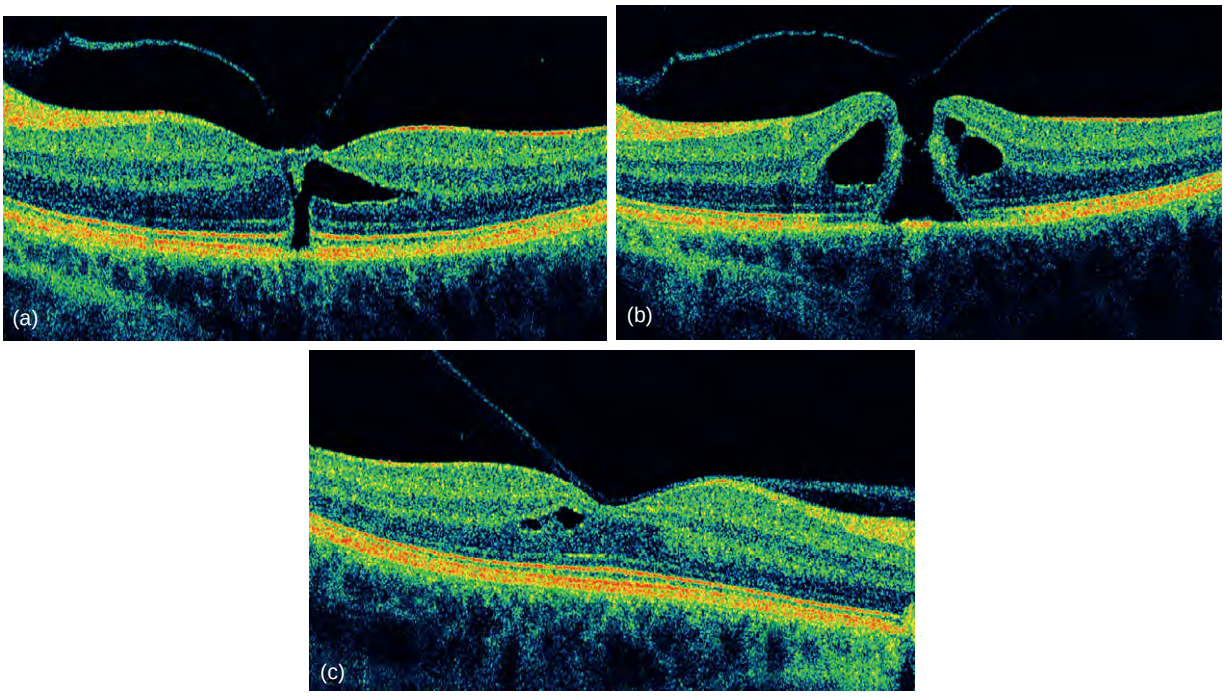

Figure 1 (a) Spectral domain OCT of right eye of a 60-year-old female with a visual acuity of 20/40 and a 2-week history of central visual disturbance. There is vitreous adherence at the fovea with associated cystic changes. (b) Spectral domain OCT 2 weeks later; the visual acuity has decreased to 20/70 with completion of a macular hole. (c) Fellow eye showing normal foveal contour with mild cystic change and with vitreous adherence at the fovea.

demonstrate glial-type tissue that might cause such a secondary tractional effect.

Confounding Observations

However, some macular holes have been observed under circumstances that do not seem to follow the mold of a direct or secondary, tractionally induced macular hole formation via active vitreous traction. These include macular hole cases that seemed to have been observed distantly after a documented short-term or long-term PVD, following the repair of retinal detachment repair or even after a vitrectomy for seemingly unrelated disorders. In addition, macular holes have been found to reopen clearly in the absence of any vitreous which would have been systematically removed at the time of previous surgery.

These observations have caused some to consider other possible mechanisms that may cause macular hole formation or may influence the vitreous role in macular hole formation. A leading mechanism besides vitreous traction as a primary element is the possible role of cystoid foveal changes. The finding of cystoid changes may represent a confounding of previously, undetected vitreous traction that might have been released, but may play a prominent role in the circumstances apparently leading to the macular hole by compromising the integrity of the already-delicate foveal elements. Unroofing of cystoid changes has been implicated in a variety of again, seemingly unrelated associations of macular hole formation with conditions including idiopathic juxtafoveal telangiectasis following uncomplicated phacoemulsification surgery and the presumed pseudophakic cystoid edema, macular edema for a branch vein occlusion, eyes with retinitis pigmentosa, and eyes as part of the Alport syndrome. The reopening of macular holes has been demonstrated to be preempted by some cystoid changes that seem to have no relationship to the vitreous since the vitreous was previously removed. Another case report of a formation of a macular hole after an OCT documented release of the posterior cortical remnant had been demonstrated a year and a half previously further brings into question the tractional induced role. The cystic changes observed might possibly be secondary to small breaks in the ILM or Henle's nerve fiber layer, which subsequently lead to hydration with secondary stiffening of the retina and extension of a separation into the deeper layers of the retina.

There are numerous elements that have been delineated above that may persist in the foveal area that could have contractile potential and lead to the separation of the foveal layers.

Figure 2 (a) Fundus appearance of left eye of a 70-year-old female with a visual acuity of 20/50 and a few months' history of an apparently nonprogressive central visual disturbance. (b) Time domain OCT shows vitreofoveal traction and mild cystic changes. (c) The clinical appearance and symptoms are unchanged 6 months later, but the OCT shows a more elongated vitreous attachment at the fovea. (d) There was a mild clinical improvement 3 months later, with visual acuity at 20/40, and the OCT appearance depicts spontaneous release of the vitreofoveal attachment.

Summary

The pathogenesis of macular holes has been widely reviewed. Undoubtedly, the vitreous plays a pivotal role in the formation of most, if not all, macular holes. Its actual role could vary from being the prime initiator and executor of traction at the fovea to being a sort of accomplice by transmitting traction generated elsewhere to being an innocent bystander to some other anatomic circumstances.

Cystoid changes seem to occur at least after a macular hole has occurred and very possibly before a macular hole is actually apparent. This could be because of hydration from a discontinuity in the Henle's nerve fiber layer or ILM break, or it could be a reflection of some other biochemical process that is occurring, possibly as a response to persistent vitreous traction. The formation of a macular hole in at least many cases is probably not simply from the vitreous separating, but rather from some abnormal features that are consummated by otherwise inconsequential persistent vitreous traction.

The Surgical Treatment for Corneal Epithelial Stem Cell Deficiency, Corneal Epithelial Defect, and Peripheral Corneal Ulcer

N Koizumi and S Kinoshita, Kyoto Prefectural University of Medicine, Kyoto, Japan

Glossary

Allogeneic – Taken from different individuals of the same species.
Aniridic keratopathy – The corneal opacification in congenital absence of the iris.
Atopic or vernal keratoconjunctivitis – The ocular conditions resulting from allergies. Type I and IV hypersensitivities have been demonstrated to play a role in the allergic response. Both disease processes manifest with classical symptoms of ocular allergy.
Cicatrization – The formation of scar tissue.
Corneal lenticules – Corneal disks, usually obtained from a donor.
Keratoepithelioplasty (KEP) – The transplantation of peripheral corneal lenticules harvested from donor tissue for the treatment of severe ocular surface diseases.
Keratolimbal allograft (KLAL) – A surgical procedure in which limbal tissue with peripheral cornea is obtained from donor eyes and transplanted to the recipient eyes. KLAL is performed to treat severe bilateral ocular surface disorders combined with limbal stem cell deficiencies.
Lamellar keratoplasty – An operation in which diseased corneal tissue is removed and replaced by lamellar corneal tissue from a donor. The procedure is performed either to improve vision (optical keratoplasty) or to provide structural support for the cornea (tectonic keratoplasty).
Limbal transplantation – The transplantation of limbal tissue including stem cells. Autografts and allografts of limbal transplantations were developed to improve the outcome of ocular surface reconstruction.
Mooren's ulcer – A rapidly progressive, painful, ulcerative keratitis, which initially affects the peripheral cornea and may spread circumferentially and then centrally.
Ocular cicatricial pemphigoid (OPC) – A chronic disease that produces adhesions and progressive cicatrization and shrinkage of the conjunctival, oral, and vaginal mucous membranes.
Penetrating keratoplasty – The corneal transplant involving the replacement of all layers of the cornea, yet retaining the peripheral cornea.
Stevens–Johnson syndrome – A condition affecting the skin in which cell death causes the epidermis to separate from the dermis. The syndrome is thought to be a hypersensitivity complex affecting the skin and the mucous membranes.
Superficial keratectomy – The removal of corneal epithelium and anterior stroma.
Symblepharon – Adhesion of the eyeball to one or both eyelids.
The *ex vivo* expansion of corneal epithelial cells/oral mucosal epithelial cells – A form of ocular surface reconstruction using cultivated corneal epithelial/oral mucosal epithelial cell sheets that are developed using tissue engineering techniques. Several types of cultivated epithelial sheets, with or without carrier materials, are used for the treatment of severe ocular surface diseases, such as Stevens–Johnson syndrome, ocular cicatricial pemphigoid, and severe chemical burns.

Introduction

The concept of an ocular surface has been widely accepted in the field of ophthalmology and investigations in this area have greatly improved our understanding of the important role that the ocular surface plays in the maintenance of vision and ocular health. The healthy ocular surface is composed of corneal and conjunctival epithelia, each of which has a distinct cellular phenotype. These two types of epithelia, with the presence of an intact tear film, maintain the ocular surface integrity. The corneal epithelium, especially, plays a critical role in maintaining corneal transparency and avascularity. On the basis of numerous investigations, it is now believed that corneal epithelial stem cells exist in the basal layer of the limbal regions where palisades of Vogt are seen in normal human subjects. Severe damage to the limbal

region, for example, damage caused by limbal stem cell deficiencies, results in serious corneal surface problems such as persistent epithelial defects, conjunctivalization with superficial vascularization, keratinization, scarring, etc., with an associated severe loss of vision.

In order to rescue such damaged ocular surfaces, surgical modalities have been developed over the past 20 years that are aimed at reconstructing the diseased ocular surface epithelium. In this article, we explain the surgical treatment for total stem cell deficiency.

Corneal Epithelial Transplantation for Total Stem Cell Deficiency

In Vivo Expansion of Corneal Epithelial Cells (Keratolimbal Allografts)

History and concept of ocular surface reconstruction

The concept of ocular surface reconstruction was first introduced via an autologous conjunctival transplantation for unilateral chemical injury reported in 1977 by Thoft. Thereafter, Thoft described a new technique known as keratoepithelioplasty (KEP), which involves the transplantation of peripheral corneal lenticules harvested from donor tissue for the treatment of severe ocular surface diseases. Following this development, autografts or allografts of limbal transplantations were developed to improve the outcome of ocular surface reconstruction. These surgical procedures, which involve the utilization of donor limbal stem cells in conjunction with the peripheral corneal lenticules, are now classified as keratolimbal allografts (KLALs), a kind of *in vivo* expansion of limbal stem cells.

Indications

KLAL is a procedure in which limbal tissue with peripheral cornea is obtained from donor eyes and transplanted to the recipient eyes. KLAL is performed to treat severe bilateral ocular surface disorders combined with limbal stem cell deficiencies. This procedure is also applicable to patients with unilateral disease who do not wish to use limbal tissue obtained from their healthy eye. KLAL is a surgery most suitable for diseases with total stem cell deficiency with less inflammation and less conjunctival cicatrization, such as ocular surface tumors (conjunctival intraepithelial neoplasia or squamous cell carcinoma) or aniridic keratopathy. For cases involving stem cell deficiency with severe inflammation, such as those resulting from chemical injury, Stevens–Johnson syndrome (SJS), or ocular cicatricial pemphigoid (OCP), a KLAL is applicable if the inflammation can be well controlled prior to surgery by steroid and immunosuppressive treatment and if conjunctival involvement is not severe. When the conjunctival scarring is severe, amniotic membrane (AM) transplantation combined with a KLAL is performed to reconstruct the conjunctival fornix (**Figure 1**).

Surgical procedure

For KLAL, fresh donor corneoscleral tissue preserved at 4 °C is used. Ideally, the donor tissue should be as fresh as possible when used, with surgery being performed within 6 days after preparation. After the central cornea of the donor tissue is excised with a 7.0–7.5-mm trephine, the peripheral cornea with scleral rim is sectioned into four to five pieces of lamellar grafts (lenticules). The residual corneoscleral rim after conventional penetrating keratoplasty is also useful. Under a surgical microscope, the excess peripheral scleral tissue of each lenticule is removed by scissors. Then, the posterior two-thirds of the corneal stroma that is attached by Descemet's membrane and the corneal endothelium are removed by lamellar dissection using spring scissors. After trimming the edge of each lenticule by spring scissors, the lenticules are placed onto the limbal area of the patient's eye and secured with two to three interrupted sutures per lenticule using 10-0 nylon. Immediately after surgery, a therapeutic soft contact lens is placed on the ocular surface to prevent donor epithelial damage and promote smooth corneal epithelial healing.

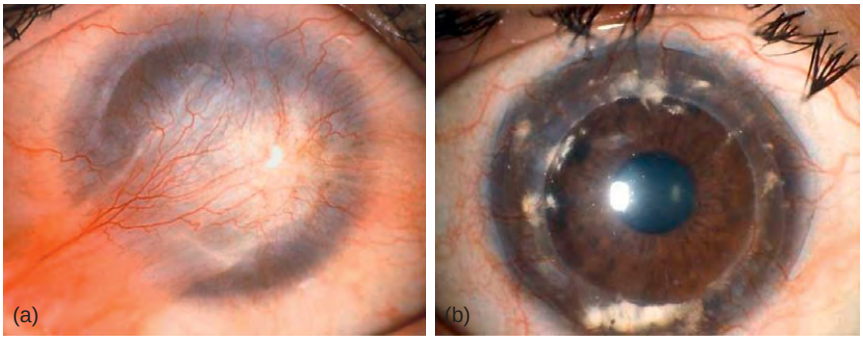

Figure 1 Keratoepithelioplasty combined with lamellar keratoplasty and amniotic membrane transplantation for chemical injury. (a) Before surgery, the patient's cornea was covered with conjunctival tissue. (b) One year after surgery, the corneal surface is covered with clear corneal epithelium and the patient recovered good vision.

Postoperative management

Compared to conventional penetrating keratoplasty, limbal allografts are at significantly higher risk for immunological rejection. Postoperatively, 0.1% dexamethasone and 0.05% cyclosporine A should be instilled topically, and dry-eye patients should receive preservative-free artificial tears. Systemic corticosteroids (betamethasone, 1 mg per day), cyclosporine A (3 mg per kg of body weight per day), and cyclophosphamide (1 mg per day), as well as mycophenolate mofetil (1 g per day), in some cases, should be used to prevent postoperative inflammation and immunological rejection. Systemic immunosuppression as described above should be used for at least 6 months postoperatively, after which it can be gradually reduced depending on clinical characteristics (Table 1). In many cases, it is necessary to administer a low dose of cyclosporine A (1 mg per kg of body weight per day) for up to 2–3 years.

A therapeutic soft contact lens should be used for several years after surgery, changing the lens once every 2–4 weeks, as it has been shown that continuous coverage of the corneal surface including the limbal area by use of a soft contact lens is effective for preventing immunological rejection as well as mechanical damage of the corneal epithelium. Although the working mechanism is unknown, it is speculated that the continuous soft contact lens wear may prevent the exposure of the donor limbal tissue to host immunocompetent lymphocytes in tears.

Other surgical procedures

Conjunctival limbal autograft (CLAU) is a procedure used for a unilateral stem cell deficiency, in which limbal tissue attached to a conjunctival carrier is transplanted from the healthy eye of the patient. The biggest advantage of this procedure is that no immunosuppression is required for an autograft. Living-related conjunctival limbal allograft (LR-CLAL) is a similar surgery to CLAU, yet in this procedure, a living relative of the patient is the source of the limbal tissue used for transplantation. LR-CLAL is applicable for bilateral stem cell deficiency. A major concern associated with both CLAU and LR-CLAL is the risk of stem cell deficiency of the donor eye. Prior to the surgery, it is vital to exclude any possibility of limbal stem cell damage in the donor eye, and it is important to continue observing the condition of the donor eye through postsurgical follow-up. Compared to the KLAL, the amount of limbal tissue that can be taken from the donor eye is limited in CLAU and LR-CLAL. Thus, partial stem cell deficiency is the appropriate condition for the use of those two procedures.

Table 1 Immunosuppressive treatment after all-corneal epithelial transplantation

Agent	*Dose and duration*
Topical	
corticosteroids	4 times per day, several years
Cyclosporine A	4 times per day, several years
Systemic	
corticosteroids	2–4 mg per day, 2–4 weeks
Cyclosporine A	100–200 mg per day, 6 months
Mycophenolate	1 g per day, 6 months
Cyclophosphamide (for Stevens–Johnson syndrome)	50–100 mg per day, 3 months

Ex Vivo Expansion of Corneal Epithelial Cells

History and concepts

There is no doubt that corneal epithelial transplantations, including limbal autografts and KLALs, have helped to improve the outcome of ocular surface reconstruction in a number of situations. However, in severe ocular surface diseases, such as SJS or OCP, severe inflammation interferes with *in vivo* epithelial healing and results in a persistent epithelial defect. An alternative concept to the *in vivo* expansion of corneal epithelial cells is the *ex vivo* expansion of corneal epithelium using a tissue engineering technique.

For this purpose, many investigators endeavored to reconstruct corneal epithelial sheets on carrier materials, such as collagen sheets, and corneal stromal carriers to create stratified corneal epithelial cell layers. Some groups tried to reconstruct not only the epithelial sheet, but also three layers of corneal tissue – a corneal equivalent – using cell-line cells supported by natural and synthetic polymers. This kind of corneal equivalent is now ready to be used for testing toxicity and drug efficacy, but it is not ready for clinical application.

Despite the potential drawbacks of cultivated corneal epithelial transplantation, its first clinical application was demonstrated in 1997. A method was developed to reconstruct stratified corneal epithelial cell sheets on petrolatum gauze or a soft contact lens as a carrier. Two patients, who had unilateral chemical burns, were treated by transplanting cultivated corneal epithelial cells taken from the limbus of the healthy contralateral eye. The well-established keratinocyte-culturing method, which involves the use of 3T3 feeder layers to help maintain epithelial stem cells, was used.

AM as a suitable carrier for corneal epithelial cell culture

Researchers soon realized the potential of AM as a carrier for corneal epithelial stem cell culture. AM is the innermost layer of the fetal membrane, and it is composed of a monolayer of amniotic epithelial cells, a thick basement membrane, and an avascular stroma. AM has been used for several years in a range of ocular surgeries, with or

without limbal transplantation, and has proven to be useful for the treatment of thermal and chemical injuries, severe pterygium, persistent or deep corneal ulcers, OCP, SJS, and other limbal stem cell deficiencies.

AM is known to have many unique characteristics that are beneficial to ocular surface reconstruction. Notably, AM inhibits conjunctival fibroblasts by suppressing the transforming-growth-factor-beta signaling system, and it also prevents myofibroblastic differentiation of normal fibroblasts. Furthermore, the normal differentiation of conjunctival epithelial cells is encouraged after AM transplantation. The basement membrane of AM is reported to resemble that of the conjunctival epithelium as well as that of corneal epithelium. In addition, growth factors, such as epidermal growth factor (EGF), keratinocyte growth factor (KGF), and hepatocyte growth factor (HGF), detected in AM may also play a role in accelerated epithelialization after AM transplantation. A high and therapeutic level of nerve growth factor (NGF) is also reported to be present in AM. It has been reported that AM has anti-inflammatory effects by inducing the suppression of interleukin 1α and interleukin 1β in limbal epithelial cells, as well as by trapping and preventing polymorphonuclear cells from infiltrating into corneal stroma.

Based on these interesting clinical and laboratory findings, preserved AM is considered to be one of the most appropriate carrier materials for transplantation of cultivated corneal epithelial cells. Although there is still debate surrounding its use, including the merits and demerits of the denuding process for amniotic epithelial cells and controversy regarding methods, the clinical results of cultivated corneal epithelial transplantation using an AM carrier are encouraging.

Cell culture procedure

Denuded AM is useful to promote the prompt migration of corneal epithelial cells *in vitro*, and AM has the potential to make well-stratified and differentiated corneal epithelial cell layers that express corneal-epithelium-specific keratins K3 and K12. In our clinical experiences, we have found that the ocular surface condition of candidates for cultivated corneal epithelial transplantation is very severe, often accompanied by complications such as severe aqueous-deficient dry eye and eyelid abnormality. For these patients, we consider it essential to transplant well-stratified epithelial cell layers that have developed barrier functions with well-controlled proliferative activity in basal cells and differentiated superficial cells. For this purpose, a culture system using an air-lifting method to promote epithelial cells via tight-junction formation was developed. By air-lifting, we have obtained cultivated epithelial cell sheets with smaller intercellular spaces in the superficial cells and with an epithelial barrier function. We have also attempted to transplant cultivated corneal epithelial cells, including limbal stem cells, and have developed a cell-suspension culture system capable of supplying cultivated corneal epithelial sheets that are well developed, potentially allowing the transplantation of more corneal epithelial stem cells.

Indications

In 1999, the Institutional Review Board of Kyoto Prefectural University of Medicine, Kyoto, Japan, approved the transplantation of cultivated corneal epithelial cell sheets. The use of cultivated corneal epithelial sheet transplantation was restricted to those patients who had poor visual prognosis with conventional corneal epithelial transplantation, such as a KLAL. Thus, cultivated corneal epithelial transplantation was performed on 39 eyes of 36 patients with total stem cell deficiencies such as severe chemical injury, SJS, and OCP (**Figure 2**). While the acute-phase eyes with persistent epithelial defects received cultivated corneal epithelial transplantation for the purpose of covering the corneal surface, alleviating intensive inflammation, and avoiding complications that accompany persistent epithelial defects, the chronic-phase eyes

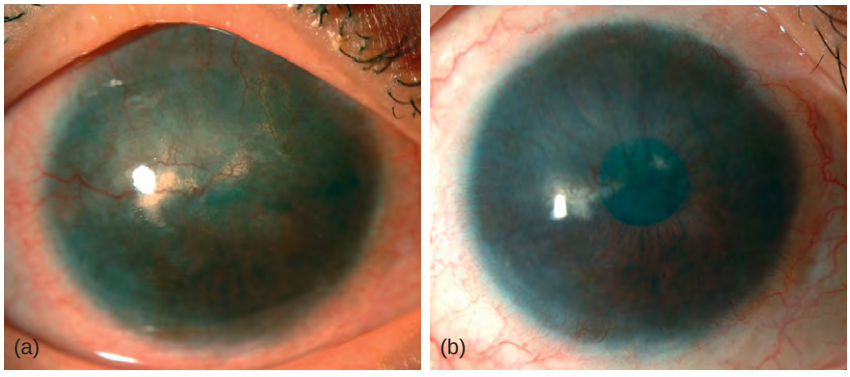

Figure 2 Ocular surface reconstruction using *ex vivo* expanded corneal epithelial cells for the chronic phase of Stevens–Johnson syndrome. (a) Before surgery, the patient suffered from total stem cell deficiency. (b) One year after surgery, the corneal surface is covered with clear corneal epithelium.

received cultivated corneal epithelial transplantation to obtain better visual function.

Surgical procedure

In our surgical procedure, scarred conjunctival tissue overlying the ocular surface from the cornea is removed up to approximately 3 mm outside of the limbus. After removing the subconjunctival tissue, the small tips of several microsponges containing 0.04% mitomycin C are placed in the subconjunctival space adjacent to the cornea for 5 min and vigorous saline washing is then performed to prevent the development of subconjunctival fibrosis after surgery. A cultivated corneal epithelial sheet on AM is then transplanted onto the corneal surface and sutured using 10-0 nylon. A therapeutic soft contact lens is then applied. For the chronic-phase eyes with corneal stromal scarring, lamellar keratoplasty is first performed with the use of preserved donor grafts to replace the scarred corneal stroma, followed by cultivated corneal epithelial transplantation.

Postoperative management

Postoperatively, 0.1% dexamethasone and 0.05% cyclosporine A are instilled topically, and dry-eye patients receive preservative-free artificial tears. Systemic corticosteroids (betamethasone, 1 mg per day), cyclosporine A (3 mg per kg of body weight per day), and cyclophosphamide (1 mg per day), as well as mycophenolate mofetil (1 g per day), in some cases, should be used to prevent postoperative inflammation and immunological rejections. Systemic immunosuppression as described above should be used for at least 6 months postoperatively, after which it can be gradually reduced depending on clinical characteristics (Table 1). In many cases, it is necessary to administer a low dose of cyclosporine A (1 mg per kg of body weight per day) for up to 2–3 years.

Clinical outcome of allogeneic cultivated corneal epithelial transplantation

The epithelial integrity was satisfactory in all cases, as evidenced by the fact that the transplanted corneal epithelium did not stain with sodium fluorescein just after being transferred onto the ocular surface during surgery. In addition, in every case there was no epithelial damage to the transplanted corneal epithelium 48 h after transplantation. The transplanted AM did not disturb the visual acuity, and clarity increased day by day. Surprisingly, the preoperative ocular surface inflammation, which had not been controlled by conventional treatment, decreased rapidly after surgery in all of the acute-phase patients.

In the chronic-phase eyes, the long-term visual prognosis and epithelial stability were varied in the three kinds of diseases discussed below. In the case of severe chemical injury, the transplanted corneal epithelium was clear and stable up to 8 years after transplantation, and very little conjunctival inflammation was present during the entire postoperative period. On the other hand, in patients with Stevens–Johnson syndrome, mild to moderate ocular surface inflammation occurred several months after surgery, and then decreased during the following 18 months. Whereas subconjunctival fibrosis had not progressed in the eyes with SJS, conjunctival scarring such as symblepharon and shortening of the fornix had progressed in the eyes with OCP. In most of the chronic-phase patients with SJS and OCP, the phenotypes of ocular surface cells on AM gradually changed from donor to host epithelial cells over a couple of years; however, subepithelial scarring and neovascularization did not progress. In other words, host conjunctival epithelium replacement on AM occurred without scarring. This phenomenon is considered to be partly due to a mild rejection of the transplanted corneal epithelial cells. Although graft survival was not very long in some eyes in these chronic cases, the ocular surface maintained its transparency and the patients obtained a better visual function than before surgery. It is possible to perform regrafting of cultivated corneal epithelium in which the severity of epithelial opacity progressed after an episode of rejection or persistent conjunctival inflammation.

In unilateral cases, autologous cultivated corneal epithelial transplantation is applicable. There is less damage to the contralateral eye than has been the case with limbal autografts, and the cultivated corneal epithelial sheets formed well-stratified epithelial layers from the very small amount of limbal tissue. After a substantial follow-up period, the transplanted epithelium remained transparent and stable, and the patient achieved good visual acuity with no complications in the healthy contralateral eye.

Ex Vivo Expansion of Oral Mucosal Epithelial Cells

Concept

Due to the fact that severe ocular surface diseases are usually bilateral, allogeneic corneal epithelial transplantation (either KLAL or cultivated corneal epithelial transplantation) is normally performed. However, these procedures not only require sufficient donor tissue, but they also are accompanied by the risk of rejection; therefore, prolonged immunosuppression is required that severely affects the clinical results. With these drawbacks in mind, we have established cultivated oral mucosal epithelial transplantation using autologous tissue.

Cell culture procedure

Small oral biopsies (approximately 2–3 mm in size) are obtained from the oral cavity under local anesthesia. The biopsy specimens are then incubated with enzymatic reagents, such as dispase and trypsin – ethylenediaminetetraacetic acid (EDTA), to separate the cells from the underlying connective tissue. The resultant single-cell suspension

of oral mucosal epithelial cells is then co-cultured for 2–3 weeks on a denuded AM carrier with inactivated 3T3 fibroblasts. Toward the end of the culture period, an air-lifting technique is used to facilitate epithelial differentiation and stratification. The oral mucosal epithelial cells cultivated on AM will show five to six layers of stratification and appear very similar to *in vivo* normal corneal epithelium. The cultivated oral mucosal epithelial sheet will show non-keratinized, mucosal-specific keratins 4 and 13, and cornea-specific keratin 3; however, keratinization-related keratin 1 or keratin 10 will not be detectable. Under appropriate culture conditions, oral mucosal epithelial cells cultivated on AM have the potential ability to differentiate into cornea-like epithelial cells.

Indications

In our clinical trials, we applied cultivated oral mucosal epithelial transplantation in two different forms of surgery with a total of 50 eyes. One form of surgery was reconstruction of the corneal surface of a severe bilateral corneal stem cell deficiency, using a cultivated oral mucosal epithelial sheet instead of allogeneic corneal epithelium. The other was reconstruction of the conjunctival fornix in patients with OCP, SJS, and chemical and thermal burns (**Figure 3**).

Surgical procedure and postoperative medications

The surgical procedure is almost the same as that of cultivated corneal epithelial sheet transplantation. After complete removal of damaged tissue on the corneal surface and subconjunctival fibroblastic tissue, residual subconjunctival tissue is treated for 5 min with 0.04% mitomycin C, followed by vigorous repeated washing with saline in order to suppress the excessive preoperative inflammation and subconjunctival fibrosis. Then, the cultivated oral mucosal epithelial sheet on AM is transplanted onto the corneal surface and secured with 10-0 nylon sutures at the limbus. The integrity of the cultivated oral mucosal epithelium is then confirmed via intraoperative fluorescein staining, and a therapeutic soft contact lens is applied. Postoperatively, topical antibiotics and corticosteroids are usually applied. Due to the fact that it is an autograft, immunosuppressives are not necessary, except for corticosteroids and cyclosporine to control the inflammation of the original disease.

Clinical outcome of cultivated autologous oral mucosal epithelial transplantation

Using slit-lamp examination with fluorescein staining, the survival of the transplanted epithelium can be confirmed 48 h after surgery. An epithelial phenotype of transplanted cultivated oral mucosal epithelium will be somewhat distinguishable from the conjunctival epithelium by fluorescein staining. Our preliminary data show the successful survival of autologous cultivated oral mucosal epithelium on the ocular surface without returning to an *in vivo* oral tissue phenotype, as was previously the case with oral mucosal transplantation. This major difference can be explained by the elimination of the subconjunctival fibrous tissue and vascular component in oral mucosa during the tissue culture system. It is possible that AM has some effect on this phenomenon as well. One adverse effect of this procedure is that the transplanted cultivated oral mucosal epithelium can sometimes show some neovascularization in the peripheral cornea with epithelial thickening. For cases with poor visual recovery due to the optical corneal opacity, the two-step surgical combination of cultivated autologous oral mucosal epithelial transplantation followed by penetrating keratoplasty is advised.

Cultivated oral mucosal epithelial transplantation is also useful for reconstruction of the conjunctival fornix; this form of surgery is successful in cases of cicatricial pemphigoid, chemical injury, etc. However, it is important to be aware of abnormal postoperative fibrovascular proliferation caused by primary diseases, which is still critical to the long-term prognosis.

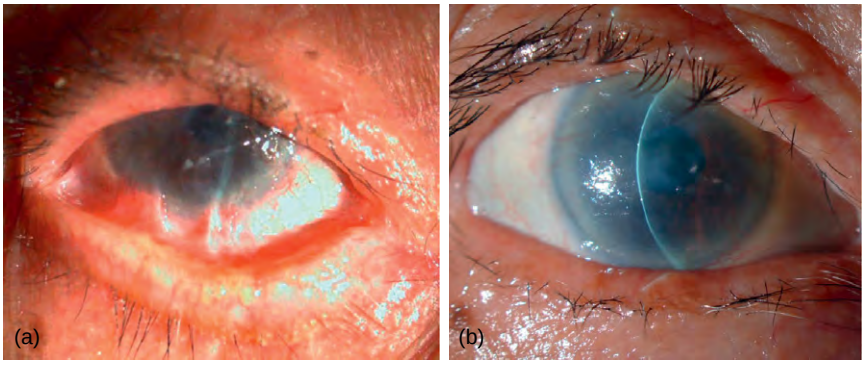

Figure 3 Ocular surface reconstruction using cultivated autologous oral mucosal epithelium for severe total stem cell deficiency in ocular cicatricial pemphigoid. (a) Before surgery. (b) Two months after surgery, the corneal surface is covered with cultivated oral mucosal epithelium and the fornix is well reconstructed by the surgery.

Phototherapeutic Keratectomy for Corneal Epithelial Disorders

Phototherapeutic keratectomy (PTK) using an excimer laser is a good therapeutic tool for a variety of corneal surface disorders, including corneal degenerations and dystrophies, epithelial adherence problems, persistent epithelial defects, corneal irregularities, and superficial stromal scars. PTK, with or without manual superficial keratectomy, can make the patient's corneal surface smooth and can effectively improve visual acuity or relieve symptoms such as pain, glare, and tearing.

PTK for Corneal Epithelial Defect

Indications

Recurrent epithelial erosions associated with posttraumatic or epithelial basement dystrophy resistant to the conventional therapy, including lubricative medications, bandage soft contact lens, or epithelial debridement, are good indications for PTK. PTK is also very effective for Schield ulcer seen in patients with either vernal or atopic keratoconjunctivitis.

Surgical procedure

Prior to an excimer laser abrasion to the surface, any disadherent epithelium adjacent to the epithelial defect, but not degenerated epithelium, should be removed by gentle manual debridement. Then, a 10–20-0m abrasion should be performed either focally or diffusely depending on the area for treatment. The area to be abraded should encompass the area of epithelial defect and include 1 mm of adjacent cornea. Application of artificial-tear eye drops just prior to laser abrasion will enhance the smoothness of the cornea surface.

Postoperative management

After the laser abrasion, a disposable bandage contact lens is applied to enhance reepithelialization and reduce the pain. For the best results, the patient should wear the contact leans for up to 3 months to establish permanent epithelial-basement-membrane adhesions. Topical antibiotics and corticosteroids are essential to prevent infection and decrease postoperative inflammation. We suggest the instillation of 0.1% betamethasone and 0.3% levofloxacin 4 times per day for 2 weeks, followed by a tapering-off of the dosage.

Tectonic Lamellar Keratoplasty for Peripheral Corneal Ulcers

Concept

Lamellar keratoplasty is an operation in which diseased corneal tissue is removed and replaced by lamellar corneal tissue from a donor. The procedure is performed either to improve vision (optical keratoplasty) or to provide structural support for the cornea (tectonic keratoplasty). Lamellar keratoplasty can be performed to replace just a portion of the corneal thickness when the endothelium is healthy. Depending on the location of the corneal abnormality, it may be sufficient to replace just the anterior layers with lamellar keratoplasty, or the full thickness of the corneal stroma without endothelium, with deep lamellar keratoplasty. Postoperative care involving the use of appropriate immunosuppressive therapy often influences the results of optic keratoplasty as well as tectonic keratoplasty.

Rheumatoid Arthritis

Peripheral corneal ulceration is associated with scleral or episcleral inflammation in rheumatoid arthritis (RA) patients. When corneal thinning progresses or perforation occurs in reaction to conventional steroid therapy, KEP combined with peripheral lamellar keratoplasty is effective. In RA patients, paracentral corneal perforation is also often observed. Small-size lamellar keratoplasty is a good surgical treatment for paracentral corneal perforation. However, it is important to bear in mind that the prognosis for penetrating keratoplasty is not good for RA patients.

Pre- and postoperative antirheumatic therapies improve surgical results. We recommend the application of therapeutic soft contact lenses at the conclusion of surgery; these should then be continuously used for several years to avoid the infiltration of immunoreactive cells from tears and prevent the recurrence of ulceration. Topical corticosteroids and antibiotic drops should be applied 4 times per day. The frequency should then be decreased as inflammatory signs subside to a level of two to three drops per day for several months. Careful removal of the sutures is performed during the first and second postoperative months to avoid epithelial damage. To avoid the recurrence of the original disease, corticosteroid drops should be continued once or twice per day for a number of years.

Mooren's Ulcer

For the treatment of severe Mooren's ulcer, which does not respond to steroids or immunosuppressive therapy using cyclosporine A, one surgical option which is available is KEP, with or without lamellar keratoplasty. By transplanting the Bowman's layer with a thin corneal stroma onto the sclera adjacent to the ulcerated area, inflamed conjunctival tissue is unable to invade the corneal surface and cellular infiltration of the ulcerated peripheral cornea is prevented (**Figure 4**). Pre- and postoperative anti-inflammatory therapy, including systemic cyclosporine A, is important for the achievement of good surgical results. In our cornea service, we administer oral

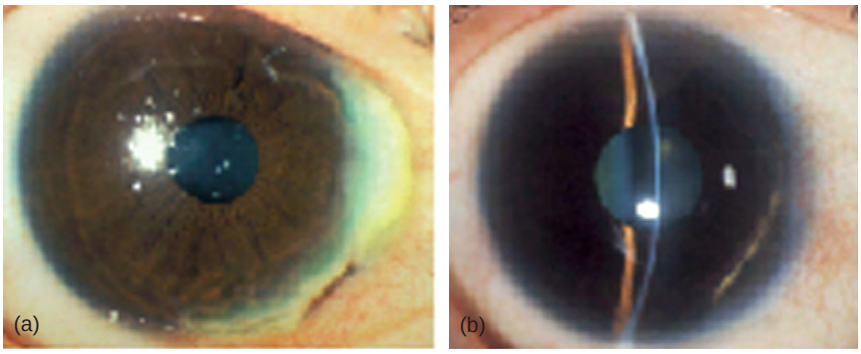

Figure 4 Keratoepithelioplasty for Mooren's ulcer. (a) Before surgery (visible from the 1 o'clock to 6 o'clock position). (b) Ten years after keratoepithelioplasty. There was no recurrence of Mooren's ulcer.

cyclosporine A (100–200 mg per day) and oral betamethasone (2–4 mg), as well as topical 0.1% dexamethasone (4 times per day) and antibiotics (0.3% ofloxacin).

As mentioned earlier, careful removal of the sutures is performed during the first and second postoperative months to avoid epithelial damage. To avoid the recurrence of the original disease, the extended use of therapeutic soft contact lenses and corticosteroid eye drops (1–2 times per day) should be continued for as many years as possible.

L C Shaw, S Li Calzi, J V Kielczewski, S Caballero, M E Boulton, and M B Grant, University of Florida, Gainesville, FL, USA

Glossary

Angioblast – One of two products derived from a hemangioblast; an undifferentiated endothelial progenitor cell that has yet to integrate into a blood vessel.
Angiogenesis – The formation of new blood vessels from preexisting ones; it involves sprouting of endothelial cells that contribute to the growing blood vessel.
CD34$^+$ cells – It is derived from HSCs, referred to as an endothelial progenitor cell, which can give rise to mature endothelial cells, that make up blood vessels. It expresses the CD34 early developmental cell marker.
Chimeric mice – The hybrid mice that are reconstituted with murine donor green fluorescent protein (GFP$^+$) hematopoietic stem cells (HSCs) via a bone marrow transplant, as well as a small subset of their own resident HSCs, which were not depleted after lethal body irradiation.
Choroid – A thin, vessel enriched membrane lying between the retina and the sclera that provides oxygen and nourishment to the outer layers of the retina.
CFU – Colony-forming unit, a measure of viable cells in which a colony represents an aggregate of cells derived from a single progenitor cell.
Differentiation – The process by which an unspecialized primitive cell acquires the features of a specialized cell, such as a heart, liver, or muscle cell. As cells differentiate they become more committed toward a final fate, losing the expression of early developmental markers.
Endothelial progenitor cell (EPC) – A bone-marrow-derived cell that circulates in the blood and has the ability to differentiate into an endothelial cell, the cells that make up the lining of blood vessels.
Hematopoietic stem cell (HSC) – The stem cell that originates from the bone marrow, which gives rise to all the blood cell types.
Homing – The process by which EPCs or HSCs, once in the bloodstream, extravasate and head to the area of injury where they are needed for tissue repair.
Ischemia – The deficient supply of blood to a body part that is due to obstruction of the inflow of arterial blood, resulting in tissue damage.
Neovascularization – The process involving abnormal formation of new blood vessels, usually in or under the retina. The new blood vessels are usually fragile, which tend to hemorrhage causing blood to leak into the eye and impairing vision. It can lead to vision loss or even blindness in diabetic retinopathy, macular degeneration, and other vascular occlusive diseases.
Stromal cell-derived factor-1 (SDF-1) – A chemokine with unique functions, including a role in the trafficking of EPCs. It is a potent migratory stimulus and upon injury recruits EPCs to sites of damage. SDF-1 exerts its action through binding to and activation of its cell surface receptor, CXCR4, expressed on EPCs and HSCs.
Vascular endothelial growth factor (VEGF) – One of the most important endothelial growth factors; it is often secreted by oxygen-deprived cells. VEGF stimulates new blood vessel formation by binding to specific receptors on nearby blood vessels, stimulating new blood vessels to form.
Vasculogenesis – The formation of new blood vessels from vascular stem cells; it involves incorporation of stem cells into the growing blood vessel and their differentiation into endothelial cells.

The Discovery of the Endothelial Precursor Cell and Circulating Endothelial Cells

By the early 1960s, patients with cardiovascular disease were undergoing artificial vascular grafts which, upon later excision, were covered by a layer of endothelial cells (ECs). While it was believed that the endothelium found on these vascular grafts grew from the original vessel ends at the site of anastomosis, Stump and co-workers determined that circulating cells could colonize this artificial substrate. This was cleverly tested by suspending a piece of Dacron material within a pig aortic graft and isolating the surface of the Dacron material from any microvasculature. Two weeks later they observed patches of endothelium on the graft, and by 20 days, the graft segment was completely lined by endothelium, concluding that circulating endothelial cells (CECs) must have attached and proliferated to coat the suspended material. Ten years later, Gaynor and co-workers measured the number of CECs in the blood of rabbits and demonstrated an increase in CEC concentration after endotoxin administration. He was the first to suggest that CECs might be a biomarker to measure vascular injury. Now it is well established that CEC levels reflect vascular injury and disease following coronary angioplasty, acute coronary syndromes, unstable angina, and in patients with diabetic retinopathy. Increased CECs are associated with peripheral vascular disease, inflammatory vasculitis, and during organ transplant rejection. The concentration of CECs in the blood of healthy individuals is quite low (about 3 cells ml^{-1}), but, as described above, this number is dramatically increased in disease.

In 1997, Asahara and co-workers purified a population of circulating cells that displayed properties of both ECs and progenitor cells, which he termed endothelial progenitor cells (EPCs); they were purported to give rise to differentiated ECs in a process termed postnatal vasculogenesis. Before this exciting finding, vasculogenesis was thought to occur only in the developing fetus when progenitors of endothelium (angioblasts) differentiate to form growing vessels in developing tissues. Vascular remodeling in the adult, however, involves the recruitment of not only endothelial progenitors, but also numerous different cells in an intricate collaboration. As elegantly described by Schatteman and co-workers, sprouted endothelium may line the vessel lumen, while other cells support vessel formation through secretion of cytokines.

Whereas the existence of EPC is no longer in question and the significance of CECs as biomarkers of vascular health is well accepted, the field now suffers from the lack of clarity in the identification of EPC populations and their precise function. Different cell types are involved in postnatal vasculogenesis, but they are all lumped together as EPCs. The origin of EPC is also in question and debate continues about lineages and their derivation.

Bone Marrow Microenvironment for the Hematopoietic Stem Cells

Hematopoietic stem cells (HSCs) are believed to be the source of EPCs by many investigators, whereas others believe that the vessel wall can also be a source of these precursors. The bone marrow (BM) stem cell niche consists of a specialized microenvironment that nurtures and regulates the stem cell pool (**Figure 1**). Parmar and co-workers showed that a relatively low level of oxygenation is a hallmark of the BM stem cell niche and that primitive hematopoietic cells in the BM are sequestered in a hypoxic microenvironment. This implies that low oxygen levels play a fundamental role in the maintenance of normal function of BM stem cells that are typically non-cycling with less metabolic need for oxidative respiration. Furthermore, quantitative proteomic analysis of isolated BM populations indicates that these cells express high levels of glycolytic and oxidative repair proteins, supporting that these cells are adapted to anaerobic metabolism. Moreover, hematopoiesis is improved *ex vivo* by maintaining cell cultures at levels of between 1% and 3% O_2. When mice were infused with Hoechst dye, which stains cells based on their proximity to blood vessels, the lowest Hoechst perfused BM fraction contained 90- to 200-fold more HSCs compared to the highest perfused fraction, supporting that HSCs are located in regions of the lowest oxygen concentration. These low Hoechst cells were also found to be hypoxic by co-staining with antibody to pimonidazole (PIM), a chemical marker for hypoxia. PIM binding and low Hoechst staining identified the long-term retaining (LTR)-HSC population. The oxygen gradient within the BM seems to provide a positional effect that not only defines the spatial organization of the hematopoietic system and confers a primary physiological role in maintaining stem cell homeostasis, but also provides a microenvironment protected from the toxic and mutagenic effects of oxygen-generated free radicals.

Clonal Relationship of EPCs to HSCs

In the original description of colony-forming unit (CFU)-ECs by Asahara and co-workers, 27.2% of the cultured cells retained cluster of differentiation 45 (CD45) expression and 6% expressed the hematopoietic antigen CD68. Hematopoietic antigen expression in the primary culture was taken as an indication for a relationship between CFU-ECs and HSCs. We proposed that any common precursor for both hematopoietic and endothelial lineages might be evaluated in long-term repopulating HSC transplant studies. Transplanting single HSCs into animals that subsequently underwent retinal injury, we observed that some of the vessels newly formed after injury to the retinal vasculature were derived from the donor stem cells. These results led us to

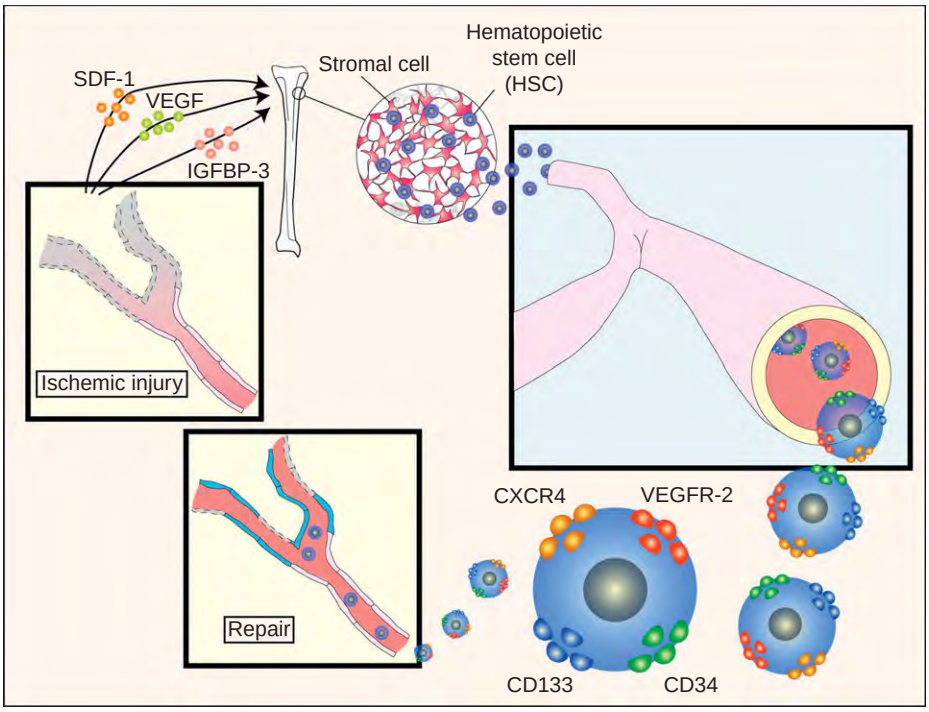

Figure 1 Schematic representation showing pro-angiogenic growth factors such as IGFBP-3, SDF-1, and VEGF, being released from ischemic blood vessel injury sites. The three ischemia-induced growth factors have a profound effect on $CD34^+$ EPCs, which reside in the bone marrow niche. IGFBP-3, SDF-1, and VEGF stimulate $CD34^+$ cells to migrate out of the bone marrow niche into the circulation where they home to sites of injury and actively participate in vascular repair and re-endothelialization.

conclude that HSC can generate all the blood elements and blood vessels and that a hemangioblast-like cell can persist into adulthood, and that these cells are derived from the same HSCs that have a long-term hematopoietic repopulating ability. Cogle and co-workers utilized the same murine retina injury model, but the injury was preceded with transplants of human umbilical cord blood (CB)-derived $CD34^+$ cells, which again repopulated the murine hematopoietic system; they also noted that human donor cells contributed to the murine host neovasculature, and speculated that only hematopoietic cell progenitors participated in blood reconstitution and blood vessel repair.

Nomenclature of the EPC

A complex relationship exists among EPC types and mononuclear cell (MNC) subtypes. The use of different isolation procedures from peripheral blood (PB) further complicates the comparisons. Recently, Yoder and colleagues have attempted to simplify the nomenclature in the field of EPC-related research and have integrated information on the phenotype of the cultured cells and their properties *in vivo*, thus taking on the task of classifying the different *in vitro* features and extrapolating to their *in vivo* origins (hematopoietic or nonhematopoietic) in these cells involved in repair of the vasculature. They conclude, as does Dimmler's group, that the vast majority (>99.99%) of $CD45^+$ MNCs are hematopoietic elements.

There are several common methods of EPC culture from the MNCs of the blood. To isolate CFU-EC includes a 5-day process wherein nonadherent MNCs give rise to an EPC colony. This is the approach used by Asahara to identify EPC for the first time. These represent a small fraction of blood MNCs, roughly in the range of 50–500 cells ml^{-1} of adult PB. Circulating angiogenic cells (CACs) are the adherent MNCs of a 4- to 7-day culture procedure. CAC cultures typically do not display colony formation. A major portion of circulating mononuclear phagocytes (roughly 5% of PB MNCs) has been termed CAC, a critically important cell to the healing process. The Yoder group hypothesized that CACs constitute a heterogeneous population of mostly differentiated myeloid cells. The detailed profile of cells within CAC cultures has not yet been established, but CACs have been reported to constitute 2% of all blood MNCs.

Endothelial colony-forming cells (ECFCs) are derived from adherent MNCs cultured for 7–21 days in conditions favoring endothelial differentiation, and colonies display cobblestone morphology. CFU-ECs are hematopoietic by clonal lineage tracking, a feature likely to be shared by CACs.

Based on *in vivo* studies using the retinal vasculature as the model system, single cell transplantation, and serial

transplantation, we concluded that HSCs give rise to all EPC populations. Yoder and colleagues disagree and expand on this by stating that the hematopoietic progenitor cells (HPC or HSC) overlap with CFU-ECs to a degree that has yet to be determined, and that the CAC population does not overlap with the HPC population. They propose that CD45 expression distinguishes hematopoietic from non-hematopoietic EPC populations and further propose that the nonhematopoietic CEC population constitutes a much smaller fraction of MNCs than do hematopoietic CAC and CFU-EC populations. They propose that ECFCs reside within the CEC population and that ECFCs display all the properties of a circulating endothelial progenitor. They also reported that ECFCs reside throughout the vascular endothelium and hypothesized that these ECFCs may get mobilized to become a propose that ECFCs reside within the CEC population. ECFCs are found at a concentration of about 0.05–0.2 cells ml^{-1} in adult PB, whereas CECs occur at a frequency of 3 cells ml^{-1} in adult PB. Thus, in human subjects, ECFCs appear to arise independently of hematopoietic precursors.

The complexity is increased by the common belief that the majority of work conducted in the field of EPC replacement therapy has been focused on cells that do not give rise to vessels, but which recruit or facilitate the cells that do. Recruitment has emerged as a critically relevant step in the healing process, which can be illustrated by the vast number of inflammatory cells at sites of ischemic injury, including the involvement of myeloid cells at those sites. Further research is required to link the processes involved in the recruitment of hematopoietic elements necessary for vascular repair to the endothelial progenitor recruitment from either the vessel wall or the circulation.

Making New Blood Vessels with BM Cells

Angiogenesis occurs in both the adult and embryo and is a process wherein differentiated ECs proliferate and migrate as the extracellular matrix is degraded at sites along existing blood vessels, allowing sprouts to form new tubes. Initially, capillaries are formed, some of which go on to recruit smooth muscle cells and mature into arterioles. Adult EPCs appear to contribute to this process (**Figures 2** and **3**). Schatteman and co-workers found that capillary-like structures are formed in $CD14^+$ BM-derived cell cultures through vacuolization and coalescence of multiple cells, a process normally associated with angiogenesis. Numerous papers have reported the sporadic integration of BM-derived cells into EC tubes *in vitro* and blood vessels *in vivo*, again consistent with a role for BM-derived cells in angiogenesis (**Figure 4**).

Studies of BM-derived cells indicate that this process can occur in the adult as well. Asahara showed the formation of blood-island-like structures by $CD34^+$-enriched BM-derived cells *in vitro*; however, more importantly, the formation of blood vessels *in situ* from BM-derived cells was subsequently reported *in vivo*, both of which are suggestive of adult vasculogenesis.

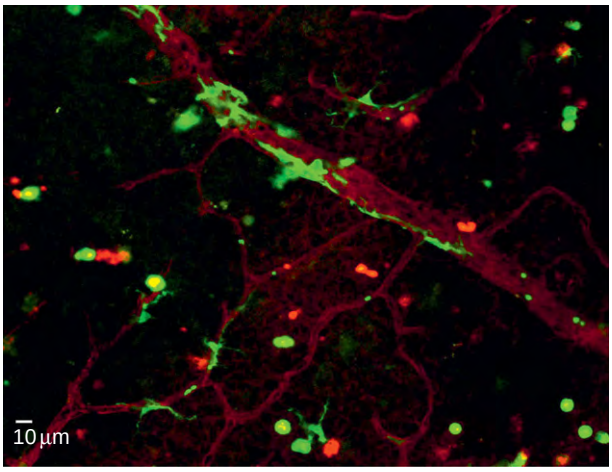

Figure 2 Laser injury promotes recruitment of bone-marrow-derived GFP^+ HSCs to the retinal vasculature. Confocal microscopy image of a retinal flat mount, from a chimeric mouse that underwent laser retinal vessel occlusion injury, double stained with rhodamine-agglutinin (red), to reveal blood vessels, and anti-GFP (green), to reveal GFP^+ $c\text{-}kit^+$, $Sca\text{-}1^+$ HSC. Scale bar = 10 μm.

Blood vessels can be formed by intussusception, which occurs in both the embryo and adult. This is the formation of a vascular network by division of larger vessels into smaller through focal insertion of a tissue pillar or by longitudinal fold-like splitting of a vessel. This process is difficult to study and, to our knowledge, no one has looked at intussusception in vessels of BM origin. A new process, the drilling of tunnels by monocytes, was described only recently. In this process, $F4/80^+$ monocyte/macrophages pattern the tissue space by degrading the extracellular matrix, thereby facilitating the penetration of EC precursors and other cells. In addition, the $F4/80^+$ cells can themselves form lumens and line the resulting tubes, apparently rapidly establishing a local microcirculation. The $F4/80^+$ cells may also stimulate differentiation of progenitors in the tube. The origin of the ECs that ultimately come to line these drilled tunnels is not yet known.

With the onset of neovascularization due to hypoxia, injury, or other stimuli, one might anticipate that the contribution of BM-derived cells to the endothelium would increase, and this has been observed repeatedly. For example, 8.3–11.2% of total ECs in the neovessels of an implanted angiogenic sponge and ischemic limb were found to be of BM origin. Similarly, the contribution of BM-derived cells to skin graft neovascularization was ~15–20% of new ECs. In addition, when a gradient of hypoxia was created in skin wounds in mice, recruitment

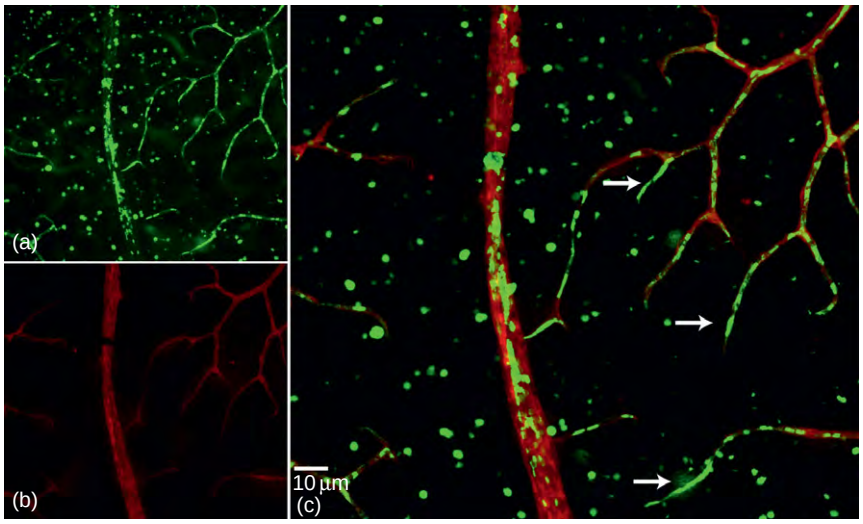

Figure 3 Insulin-like growth factor binding protein-3 (IGFBP-3) promotes recruitment of bone-marrow-derived GFP$^+$ HSCs to the retinal vasculature in the absence of injury. Confocal microscopy images of a retinal flat mount, from a chimeric mouse that underwent intravitreal injection of an IGFBP-3-expressing plasmid, double stained with rhodamine-agglutinin (red), to reveal blood vessels, and anti-GFP (green), to reveal GFP$^+$ c-kit$^+$, Sca-1$^+$ HSC. Green channel (a), red channel (b), and merged image (c) are shown. Arrows in (c) show areas where the GFP$^+$ HSCs appear to form new vessels and sprouts from existing vessels. Scale bar = 10 μm.

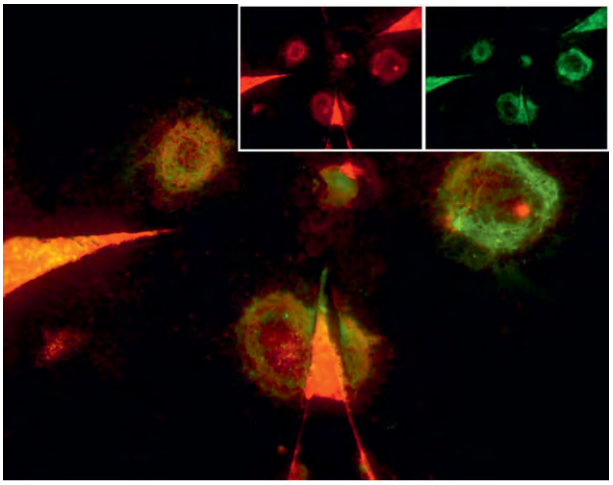

Figure 4 Normal mice whose bone marrow was ablated by lethal irradiation and reconstituted with bone-marrow-derived Lin$^-$/c-kit$^+$/Sca-1$^+$ HSC from homozygous GFP transgenic donors were subjected to Bruch's membrane rupture by laser injury. Two weeks after injury, the eyes were enucleated, preserved, reacted with rhodamine-conjugated *Ricinus communis* agglutinin I to visualize vasculature, and finally mounted flat for fluorescence microscopy. Representative image captures show the vascular lesions (red inset) and GFP-expressing cells (green inset) localizing to the CNV. These GFP$^+$ cells could only have come from the reconstituted bone marrow, thus indicating the participation of HSC in adult angiogenesis in the eye.

of BM-derived cells followed the gradient, and the greatest number of cells homed to and integrated into vessels of the most ischemic tissue. In addition, the proportion of EPC in the pancreas of mice after streptozotocin treatment (which is toxic to the pancreas) was 17.8%.

In contrast, engraftment of BM-derived ECs was only 1.6% in the peritubular endothelium of the kidney. When supraphysiological levels of growth factors are introduced, even greater BM-derived cell recruitment can be seen. In mice implanted subcutaneously with fibroblast growth factor-2-impregnated Matrigel plugs, 26.5% of ECs in the neovasculature were BM-derived.

EPCs as a Source of Paracrine Growth Factors for Vessel Growth

Whereas not everyone agrees on the source of EPCs, the general contention is that the cells contribute to the repair of endothelium, yet just how they do this is under debate. The recruitment of endogenous EPCs and treatment with exogenous EPCs (such as autologous cells injected systemically or locally) stimulate vascular growth in animal models and in patients subjected to clinical trials. One of the most striking features of EPC-mediated vascular growth is the rapidity with which it occurs. In some murine models, improvements are apparent within 2 days after treatment.

The functional integrity of the endothelium correlates with the number and activities of EPC, whereas EPC senescence is also associated with endothelial dysfunction. The argument continues whether EPCs can express hematopoietic markers or not; however, EPCs do express both endothelial and progenitor cell markers, some of which are species specific. A key EPC marker in humans is CD34. In contrast, EPCs in mice are lin$^-$ BM cells and

spinocerebellar ataxia type 1 (Sca-1$^+$) lin$^-$ circulating cells. Some EPC markers are expressed by both rodent and human EPCs such as vascular endothelial growth factor receptor 2 (VEGFR2) and CD133 (AC133).

However, with the exception of the retina, in most cases, the increase in neovascularization is not directly related to the differentiation of EPCs into ECs. Despite profound improvements in vascular growth, often few EPC are found in the neovascular endothelium. This has led to a revised hypothesis that the primary function of EPC is to secrete factors that stimulate vascular growth. Thus, the actual long-term physical participation of these cells in the growth of neovessels is probably highly dependent on the vascular bed, the nature of growth stimulus, and the characteristics of the individual (diabetic or nondiabetic).

What Are EPCs Doing in the Eye? When Are They Good? When Are They Bad?

EPC in the Cornea

Implantation of VEGF- or other growth-factor-impregnated pellets in the cornea results in corneal neovascularization. It has been found, using lethally irradiated mice transplanted with β-galactosidase-expressing BM cells, that in case of VEGF, corneal neovasculature had about 17.7% of BM-derived ECs. In another study using the same model, only 7.3% was reported in the absence of simvastatin, whereas drug treatment increased the percentage to 25.7%. In mice injected intraperitoneally with granulocyte-macrophage colony-stimulating factor (GM-CSF), corneal neovascularization in the micropocket assay was enhanced. EPCs that contributed to this enhanced neovascularization were also mobilized from BM as identified by the expression of β-galactosidase regulated by EC-specific Tie-2 promoter. Contrary to the data obtained with VEGF, implantation of fibroblast growth factor 2 (FGF-2) pellets did not lead to any contribution of the BM-derived cells to EC present in the corneal neovasculature as observed with green fluorescent protein (GFP) as BM cell marker. Instead, a large number of pericytes (53% total) originated from BM-derived cells. Another example of BM-derived cells differentiating into other cell types than EC came from the study of Nakamura and co-workers, who used intravenous transplantation of (lin$^-$, Sca-1$^+$) HSCs from GFP$^+$ transgenic mice. The progeny of these cells expressing GFP was found in the corneal stroma, where they apparently migrated from the limbal vessels at the corneal periphery. As calculated on corneal sections, GFP$^+$ cells comprised 27.3% (BM) and 24.0% (HSC) of total cells in the peripheral corneal stroma. In the central stroma, GFP$^+$ cells were 7.58% (BM) and 8.06% (HSC) of total cells. These data raise the possibility that the actual fate of EPC coming from the BM as a response to a stimulus may strongly depend on the nature of pertinent growth factor. In diseased conditions of the cornea, CD34$^+$ BM-derived cells were found in the stromal neovascularization associated with Mooren's ulcer.

EPC in Age-Related Macular Degeneration

Age-related macular degeneration (AMD) is the primary cause of blindness in people aged 50 years or more. The wet form leads to severe loss of central vision and is due to choroidal neovascularization (CNV). Moreover, the most common cause of blindness in the elderly in advanced countries is AMD with CNV. CNV is characterized by the subretinal invasion of a pathologic new vessel complex from the choriocapillaris. Although CNV is traditionally considered to consist of ECs, its cellular population is likely more complex in nature, comprising several different cell types. Knowledge of the cellular composition and origin might help understand the pathogenic mechanisms controlling CNV severity, as well as indicate potential targets for therapeutic intervention. We have examined whether the CNV cell population has a dual origin, circulating versus resident populations, and whether BM-derived cells participate in CNV. These studies were performed using GFP chimeric mice that were generated from highly enriched Sca-1$^+$, c-Kit$^+$, lin$^-$ cells, and following stable reconstitution underwent laser rupture of Bruch's membrane. Eyes were enucleated at 1, 2, 3, and 4 weeks after laser injury and CNV was examined by confocal microscopy of retinal flatmounts. We found that laser injury alone was sufficient to induce stem cell recruitment and subsequent CNV. GFP$^+$ cells formed part of the functional vasculature in the choroid as early as 1 week after injury and were present for the duration of the study (**Figure 4**). Interestingly, we found that the relative EPC contribution to CNV remained fairly constant throughout the study and constituted almost 50% of the total vasculature. We concluded that adult stem cells are recruited from the BM to the choroid in a model of CNV, where they contribute to forming aberrant new vessels, and targeting stem cell recruitment to the eye may offer a novel therapeutic strategy for AMD.

These studies were corroborated and extended by two other groups. Tomita and co-workers used a similar approach, however, with unfractionated (whole) BM from GFP$^+$ mice. Upon immunohistochemical analysis of the lesions, they observed that the vascular wall cells of the CNV expressed both GFP and CD31, indicating that the newly developed blood vessels in the CNV were derived from the BM cells. Espinosa-Heidmann and co-workers used the whole BM transplantation from GFP$^+$ mice and showed that GFP-labeled cells represented 17% of the total cell population in the lesion. Many of the GFP-labeled cells were immunoreactive for α-smooth muscle actin (39%), desmin, NG2, CD31 (41%), BS-1

lectin, or F4/80. GFP-labeled cells in CNV were morphologically indistinguishable from cells normally present in CNV lesions. They concluded that BM-derived progenitor cells not only are a source of endothelial, but also of smooth muscle-like cells.

Caicedo and co-workers used similar strategy to determine the relative role of recruited blood-derived macrophages versus resident microglia in the retina associated with CNV. They found that the cell adhesion molecules such as vascular cell adhesion molecule 1 (VCAM-1), intercellular adhesion molecule 1 (ICAM-1), and platelet endothelial cell adhesion molecule 1 (PECAM-1, CD31) were strongly upregulated in retinal blood vessels of the CNV lesion, that the GFP-labeled cells were immunoreactive for the macrophage marker F4/80, and that the density of resident microglia did not increase. Most GFP-labeled cells were found in close proximity to activated Müller cells. They then depleted circulating macrophages with clodronic acid and showed that the density of F4/80 immunoreactive cells, as well as the density of pERK-immunoreactive Müller cells in the retina, under CNV, decreased. They concluded that recruitment of blood-derived macrophages, more than resident microglia, seems to be associated with CNV. In addition, using GFP chimeric mice generated from whole BM transplantation, Espinosa-Heidmann quantitated the participating cell types in more detail. He found that macrophages represented 20%, ECs 25%, vascular smooth muscle cells 11%, retinal pigment epithelial (RPE) cells 12%, and nonlabeled cells 32% of the cells in the lesion. The macrophage population was mostly derived from circulating monocytes at all time points studied (70% were GFP-labeled), whereas endothelial and vascular smooth muscle cells were partly BM-derived (50–60% were GFP-labeled), and RPE cells appeared to be entirely derived from preexisting tissue-resident cells. They concluded that BM-derived progenitor cells contribute significantly to the vascular and inflammatory components of CNV.

Csaky and co-workers, utilizing GFP chimeras in which the BM was derived from mice expressing LacZ driven by the endothelial-specific Tie-2 promoter and injecting adenoviral vector expressing $VEGF_{165}$ subretinally to induce CNV, found that EPCs contribute to the formation of neovascularization in this VEGF-driven system. It is apparent from these studies that BM-derived ECs contribute to the pathological CNV in both laser-induced or VEGF-induced CNV.

EPC in the Retinal Disease

We have developed a novel model of retinal neovascularization in adult GFP chimeric mice to examine the role of EPC in revascularizing ischemic retinas. We showed that the recruitment of endothelial precursors to sites of ischemic injury had a significant role in neovascularization in the retina (Figure 2). Otani and co-workers showed that intravitreally injected lin^- BM cells selectively target retinal astrocytes, cells that serve as a template for both developmental and injury-associated retinal angiogenesis. When lin^- BM cells were injected into neonatal mouse eyes, they extensively and stably incorporated into forming retinal vasculature. When EPC-enriched HSCs were injected into the eyes of neonatal rd/rd mice, whose vasculature ordinarily degenerates with age along with photoreceptors, they rescued and maintained a normal vasculature. In contrast, normal retinal angiogenesis was inhibited when EPCs expressing a potent angiostatic protein were injected. They also showed that BM cells and astrocytes specifically interact with one another during normal angiogenesis and pathological vascular degeneration in the retina. The authors concluded that selective targeting with HSC may be a useful therapeutic approach for the treatment of many ocular diseases.

Hypoxia-Regulated Factors Recruit EPC to the Ischemic Retina

It remains unknown whether stem cells with tissue-specific antigenic repertoires reside in and move out of the BM when signaled to or whether generic stem cells modulate their phenotype before or after leaving the BM in response to a particular type of stimulus. In any case, the retrieved total peripheral blood mononuclear cells (PBMCs) produce more ECs in culture after these stimuli. This has been attributed to mobilization; however, this also may simply indicate that circulating cells have modulated their phenotype in response to the stimulus.

One of the most potent stimuli recruiting BM-derived cells to any tissue is ischemia. Ischemia leads to an influx of inflammatory cells that release cytokines, pro-angiogenic factors, matrix-degrading proteinases, and other effector molecules. Along with the influx of inflammatory cells, BM-derived cells expressing surface markers of EC precursors, including Sca-1, Tie-2, Fms-related tyrosine kinase 1 (Flt-1), vWF, VEGFR2, and CD133, are recruited in response to ischemia. Hypoxia-induced factors released at sites of tissue ischemia promote the recruitment of cells from the circulation into ischemic tissues. VEGF, stromal-derived factor-1 (SDF-1), erythropoietin (EPO), and, more recently, insulin-like growth factor binding protein-3 (IGFBP-3) have been shown to increase EPC recruitment to the retina (Figure 3). IGFBP-3 mediates EPC migration, differentiation, and capillary formation *in vitro*. Targeted expression of IGFBP-3 by genetically modified HSC resulted in the protection of the vasculature from hyperoxia-induced damage in the mouse oxygen-induced retinopathy (OIR) model.

Considering the pleiotropic effects of VEGF on ECs, it is not surprising that it can stimulate differentiation and proliferation of EC precursors. VEGF can mobilize and

recruit EC precursors from the BM into tissues. VEGF mobilization appears to be isoform-specific, because $VEGF_{165}$, but not $VEGF_{189}$, induced a rapid mobilization of $VEGFR2^+$ cells into the circulation. Like VEGF, the VEGF family member placental growth factor (PlGF) may also modulate recruitment or function of BM-derived EC precursors. Embryonic vessel growth is unaffected, but arteriogenesis is delayed in mice lacking PlGF. However, if the BM of $PlGF^{-/-}$ mice is replaced by wild-type BM, normal arteriogenesis is restored, suggesting that BM-derived cells stimulate vascular growth or stabilization through PlGF and its receptor VEGFR1. By increasing signaling through VEGFR1, PlGF amplifies the responsiveness of ECs to VEGF. Together, these data suggest that PlGF probably does not play a role in the differentiation of BM-derived cells to ECs, but may induce proliferation in the partially differentiated cells. It could also stabilize larger vessels.

Serum SDF-1 mobilizes hematopoietic stem and progenitor cells from the BM, as does the CXCR4 (the SDF-1 receptor) antagonist AMD3100, which disrupts the interactions of EC precursors with BM stromal cells. SDF-1 is chemotactic for EC precursors, and *in vitro* data suggest that it is required for recruitment of EC precursors to sites of injury. Studies with human into mouse BM transplants support this conclusion, because blockade of CXCR4 abrogated human $CD34^+$ BM-derived cell homing to the liver, whereas local injection of SDF-1 increased their homing.

In humans, vitreal SDF-1 concentration increases as diabetic retinopathy progresses to the proliferative stage. Treatment of patients with triamcinolone decreases SDF-1 levels in the vitreous, with marked disease improvement. SDF-1 induces human retinal EC to increase the expression of VCAM-1, a ligand of very late antigen-4 (VLA-4) found on many hematopoietic progenitors, and to reduce cellular tight junctions by suppressing occludin expression. Both changes would serve to recruit HSC and EPC along an SDF-1 gradient. We showed, using a murine model of branch retinal vein occlusion, that the majority of new vessels formed in response to oxygen starvation originates from HSC-derived EPCs. We also showed that the levels of SDF-1 found in patients with proliferative diabetic retinopathy induce neovascularization in our murine model. Intravitreal injection of blocking antibodies to SDF-1 prevented retinal neovascularization in this model, even in the presence of exogenous VEGF. Together, these data demonstrate that SDF-1 plays a major role in proliferative diabetic retinopathy and may be an ideal target for the prevention of its development.

However, studies in vascular beds outside the eye showed that overexpression of SDF-1 in the absence of VEGF failed to recruit BM-derived cells to the liver, whereas blocking CXCR4 decreased BM-derived cells in the liver even in the presence of high levels of VEGF. Together, these data suggest that SDF-1 is not sufficient to recruit the BM-derived cells to the tissue in the absence of another signal, such as VEGF or one of its targets. Instead, SDF-1 may play a crucial role in sequestering BM-derived cells at the site of injury once they have arrived. Furthermore, three studies have shown that the molecule is required for adhesion of BM-derived cells at sites of injury. Hypoxia is a potent mobilizer of BM-derived cells, and hypoxia-inducible factor-1α (HIF-1α) activity is induced by hypoxia. VEGF, in turn, is induced by HIF-1α, which then upregulates SDF-1 and CXCR4. A positive-feedback loop occurs because HIF-1α also induces SDF-1, which is a weak inducer of VEGF. This evidence supports the idea that VEGF and SDF-1 work in concert, such that VEGF and SDF-1 induce each other, SDF-1 mobilizes BM-derived cells, VEGF (or a VEGF-induced factor) recruits the cells, SDF-1 sequesters the arriving BM-derived cells, and VEGF promotes the differentiation and proliferation of the sequestered cells.

SDF-1 and its cognate receptor CXCR4 clearly play important roles in BM-derived cell differentiation and ability to induce vascular growth. Recently, a new receptor for SDF-1 has been found: the orphan receptor RDC1 (CXCR7). This finding will undoubtedly make sorting out their precise functions even more difficult. Another factor that may be critical in the HIF-1α/SDF-1 pathway is monocyte chemoattractant protein-1 (MCP-1). Monocytes are attracted to sites of injury, and once there, they secrete MCP-1, which, in turn, stimulates HIF-1α activity. Responsiveness of monocytes to VEGF is reduced in people with diabetes, resulting in fewer monocytes being recruited to sites of injury, the failure of which may lead to lower HIF-1α activity and reduced engagement of the VEGF/SDF-1 system. Attracted monocytes may also have an important role in laying out the scaffold on which neovessels will form.

EPO is a potent stimulator of vascular growth, and, like SDF-1, it is strongly induced by hypoxia. EPO increases the number of circulating $CD34^+VEGFR2^+$ BM-derived cells, whereas in another study of 28 patients with congestive heart failure, long-term EPO treatment failed to increase the number of $CD34^+$, $CD34^+CD45^+$, $CD34^+CD133^+$, $CD34^+VEGFR2^+$, or $CD34^+CD133^+$ $VEGFR2^+$ cells in the circulation. EPO has direct effects on EC precursors, stimulating proliferation of $CD14^+$ BM-derived cells and their differentiation into ECs as well as their adhesion to vascular ECs. Recently, Chen and co-workers showed that EPO increases the number of pro-angiogenic stem cells in the retina. They found that EPO treatment (5000 U kg^{-1}, i.p. P6 and P7) increases the number of $CD34^+$ EPCs per vessel length by approximately 80% in the retinas of postnatal day 8 mice exposed to oxygen. These results suggest that in addition to acting locally through EPO receptors in the retina, EPO can also

promote retinal vascular repair by recruiting BM-derived pro-angiogenic cells to the retina.

The angiopoietins have a role in mobilization and function of EC precursors. Angiopoietin-1 appears to regulate initial commitment to the EC lineage, whereas angiopoietin-2 induces BM-derived EC expansion *in vitro* and stimulates formation of neovessels by BM-derived cells *in vivo*. It was found that complete blockade of Tie-2 (angiopoietin-1 receptor) leads to rapid EC precursor death in culture (G. C. Schatteman and C. Jiao, unpublished observations). *In vivo*, $CD34^+$ BM-derived cells tend to localize near the sites of angiopoietin-1 and -2 immunoreactivity. Like VEGF, angiopoietin-1 can mobilize $VEGFR2^+$ cells, but the mobilization is delayed relative to response to VEGF. Tie-2^+ but not Tie-2^- BM-derived cells can differentiate into ECs in culture.

Do Cell Therapies Have a Role in the Eye? If so, Who Will Benefit?

Many ocular diseases, such as AMD, are diseases of the elderly, a population that should best benefit from cellular therapy. Interestingly, the number of HSCs in the circulation does not decrease with age, nor is the ability of HSCs to reconstitute the BM lost with age. Old cells cycle more frequently and home less efficiently than do young cells, indicating more subtle functional problems. Treatment of skin wounds with old lin^- BM-derived cells profoundly inhibited vascular growth, whereas young cells stimulated it. These experiments were performed in young mice, so the dysfunction was intrinsic to the BM-derived cells. A reduction in the repair capacity of mesenchymal stem cells with age has also been observed.

Type 1 Diabetes Induces BM-Derived Cell Dysfunction

Individuals with type 1 diabetes and vascular complications would potentially benefit from cellular therapy, but their EPCs are dysfunctional. HSCs and EPCs from adult type 1 diabetic patients produce fewer ECs, and their EC show reduced proliferative potential and migratory function. Diabetes disrupts normal signaling through pathways such as nuclear factor-kappa B (NF-κB), mitogen-activated protein kinases (MAPK), protein kinase C (PKC), and insulin receptor substrate (IRS); chronic activation of these pathways blunts acute responses. The increased nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and NF-κB expression in diabetes contribute to enhanced EPC oxidative stress. Recently, we showed that activation of SR1B (the high-density lipoprotein (HDL) receptor) is protective to diabetic EPC, whereas activation of oxidized low-density lipoprotein (ox-LDL) receptor downregulates endothelial nitric oxide synthase (eNOS) leading to reduced vascular reactivity and vasoconstriction. Accumulation of reactive oxygen species (ROS) increases cellular/replicative senescence, which is defined as the loss of division potential and the simultaneous change in morphology. Diabetes accelerates the onset of EPC senescence, which is accompanied by impairment of migration and proliferation capacities. Several atherosclerotic factors, such as angiotensin II, ox-LDL, and homocysteine, directly accelerate the onset of EPCs senescence and lead to cellular dysfunction.

Revascularization is impaired when dysfunctional EPCs from type 1 diabetic mice are injected into diabetic mice. Hemoglobin A1c levels inversely correlate with the number of EPCs that can be derived from PB of type 1 diabetic patients. Moreover, these cells show a reduced ability to integrate into EC tubes *in vitro*. We showed that when $CD34^+$ cells from healthy donors were tested for their potential to re-endothelialize ischemia-injured retinas, they induced repair of capillary endothelium, whereas diabetic $CD34^+$ cells did not.

Can Diabetes Alter Cytokine Secretion by EPCs?

It is now recognized that EPCs promote vascular growth by secreting pro-angiogenic factors. Thus, changes in the secretory profile of these cells as a function of diabetes is a relevant parameter to investigate. It is interesting to explore the possibility that diabetic EPCs secrete distinct and detrimental cytokines compared to nondiabetic cells. The release of such cytokines after injury would not potentiate healing and repair, but rather hinder this process and adversely affect vessel function.

Cytokines that may be dysregulated in diabetic EPCs include tumor necrosis factor-alpha (TNFα), interleukin-1 beta (IL-1β), and MCP-1. TNFα is an inflammatory cytokine that is rapidly upregulated after injury, and that directly and indirectly regulates many additional pro-angiogenic factors. It induces expression of molecules on ECs that mediate adhesion of inflammatory cells, intensifying the response. IL-1β, another important early mediator of inflammation, is both induced by and induces TNFα, so that these factors act synergistically to support inflammation. MCP-1 is essential for arteriogenesis, and recent work has shown it to be a key factor in FGF-2 mediated arteriolar growth as well, although its direct effects on capillary growth are modest. MCP-1 can be induced by TNFα. Monocytes secrete TNFα and MCP-1 when activated by IL-1β and other factors, so their arrival and activation in injured tissue initiate a positive-feedback loop that recruits more monocytes. Preliminary data from

our laboratory indicate that the cytokines released by EPC populations are specific to a particular subpopulation.

Type 1 Diabetes Induces Nitric Oxide Dysfunction in EPCs

Nitric oxide (NO) has an essential role in the mobilization and migration of $CD34^+$ cells into the sites of engraftment. NO also regulates survival by activating telomerase and delaying cell senescence. We and others have shown that diabetic EPCs have reduced bioavailable NO and decreased eNOS activity. More importantly, exogenous NO can correct the migratory defect in these cells. Diabetes is associated with increased oxidative stress due to upregulation of NADPH oxidase and eNOS uncoupling. As we have observed, pharmacological and molecular inhibition of NADPH oxidase restores bioavailable NO and improves the engraftment potential of EPCs. The impaired *in vivo* re-endothelialization capacity of human diabetic EPCs was restored by small interfering RNA silencing of NADPH oxidase subunit p47(phox). Propofol, a peroxynitrite scavenger, inhibits NF-κB activation, increases NO production, and protects cells from apoptosis. The Ox-LDL increase in diabetes directly inhibits EPCs survival, induces senescence, and inhibits eNOS. High glucose also enhances EPC senescence, and impairs migration and tube formation. Moreover, the deleterious effects of high glucose can be ameliorated by co-incubation with the NO donor sodium nitroprusside and worsened by eNOS inhibitors. Diabetic EPC dysfunction improves with peroxisome proliferator-activated receptor-gamma (PPAR-γ) activation. PPAR-γ agonists improve NO bioavailability and reduce arterial inflammation and oxidative stress. Rosiglitazone, a PPAR-γ agonist, was documented to promote the differentiation of angiogenic progenitor cells toward the endothelial lineage. Similarly, mice treated with pioglitazone exhibited increased EPC number and migratory activity, and reduced rate of EPC apoptosis.

Of note, the negative effects of C-reactive protein on EPC survival, differentiation, and angiogenic function were abrogated by pretreatment of EPCs with rosiglitazone, providing direct evidence of the salutary impact of anti-inflammatory eNOS-enhancing agents on EPC biology. The precise mechanisms involved in EPC stimulation by PPAR-γ agonists have yet to be investigated, while no data are still available on humans. PPAR-γ agonists should decrease EPC oxidative stress, induce mobilization, and improve functionality of EPCs, at least in theory.

As described above, reduced levels of bioavailable NO can be due to increased oxidative degradation of NO, and also reduced NO synthesis. Elevated blood levels of asymmetric dimethylarginine (ADMA), an analog of the amino acid L-arginine that inhibits the formation of NO, seem to augment vascular oxidative stress, partly through eNOS uncoupling, which results in the generation of higher superoxide radicals that are increased in diabetes. The latter finding was also confirmed by recent *in vitro* observations, showing that ADMA represses EPC proliferation, differentiation, and function in a concentration-dependent manner. The dimethylarginine dimethylaminohydrolase (DDAH) enzymes inactivate ADMA, co-segregate with NOS, and regulate NO production. Over-expression of DDAH *in vitro* results in increased endothelial NO production and overexpression of human DDAH in mice leads to increases in NO production and improvements in vascular resistance.

Drug Modulation of EPC Function

As discussed above, EPC functional activity may be impaired in disease conditions, such as diabetes. At the same time, proliferative diabetic retinopathy needs treatments inhibiting new retinal blood vessel formation, including EPC recruitment and engraftment therein. Conversely, other sites and disease conditions may actually need an increase of EPC activity toward tissue repair, for example, in myocardial infarction or stroke. The previous sections have emphasized the role of NO in maintaining normal function of BM-derived EPC. Certain agents increasing NO and NOS activity could be potentially used to boost EPC activity in patients who suffer from decreased EPC function, such as the elderly and diabetics. Not much is known about the ways of inhibiting EPC function and engraftment to sites of unwanted neovascularization as observed in tumors and retinopathies. The few emerging data, however, show that tumor cell-mediated recruitment and engraftment of BM-derived EPC can be specifically inhibited. This concerns inhibiting CXCR4, the receptor for SDF-1 that is important for tumor vasculogenesis, or infusion of endostatin into tumor-bearing animals. In our recent work, BM-derived GFP^+ EPC incorporation into hypoxia-induced retinal neovasculature in the mouse oxygen-induced retinopathy (OIR) model was examined. It was shown that EPC engraftment was substantially inhibited by systemically administered inhibitors of protein kinase CK2, a key enzyme in cell cycle, proliferation, and migration. One can hypothesize that blocking of EPC incorporation into neovasculature may be one of the mechanisms of action of a variety of anti-angiogenic drugs that have shown promise in animal studies. The use of antagonists of specific growth factors and their receptors (antibodies, soluble receptors, chemicals, and RNA interference) may emerge as another powerful approach to inhibiting EPC engraftment during pathological vasculogenesis.

Thyroid Eye Disease

M N Stan and R S Bahn, Mayo Clinic, Rochester, MN, USA

Glossary

Chemosis – Swelling of the conjunctiva.
Erythema – Redness of the skin resulting from inflammation, often due to capillary congestion.
Graves' disease – An autoimmune disease causing overproduction of thyroid hormones and associated with eye and skin manifestations.
IGF-1 receptor – A transmembrane tyrosine kinase receptor that mediates the action of insulin-like growth factor.
Proptosis – The forward protrusion of the globes from the orbit; often found in patients with GO.
RANTES (Regulated on Activation, Normal T cell Expressed and Secreted) – A member of the IL-8 superfamily of cytokines, selective for monocytes and memory T cells.
TRAb – Autoantibodies directed against the thyrotropin receptor.
TSH receptor – A G-protein-coupled receptor found on the surface of thyroid and other cells that binds TSH and autoantibodies.

Introduction

Thyroid eye disease (TED) is an inflammatory disorder that develops in the orbit in association with autoimmune thyroid disease (AITD). In the majority of cases, TED is associated with autoimmune hyperthyroidism, or Graves' disease (GD), and has therefore also has been termed Graves' ophthalmopathy or Graves' orbitopathy (GO). It is additionally referred to in the clinical literature as thyroid associated orbitopathy (TAO). For consistency, we will employ the abbreviation GO since it is the abbreviation used by EUGOGO (the EUropean Group On Graves' Orbitopathy), the only organization that has so far put forth a set of clinical guidelines for this entity.

The clinical presentation of GO is quite variable (Figure 1). Most patients have minimal symptoms of corneal irritation associated with some periocular swelling, eyelid retraction, and conjunctival injection. Only in a minority of cases (5%) is the disease severe and potentially sight-threatening, with severe inflammation, corneal ulceration, or optic neuropathy. The natural history of the disease is one of rapid deterioration that generally occurs over several months' time, followed by a plateau phase of variable length, and then gradual improvement toward the baseline. While the inflammatory signs and symptoms generally abate, resolution of proptosis and extraocular dysfunction may be incomplete.

Epidemiology

The incidence of GO varies depending on the criteria used to define its presence. On conservative clinical grounds, with lid signs not included, the incidence is 10–25%, whereas with orbit imaging, computerized tomography (CT), magnetic resonance imaging (MRI), or ultrasound, up to 90% of cases have evidence of ocular involvement. Fortunately, the vast majority of cases are mild, and only 5% of patients have severe disease. The incidence based on data from Olmsted County, Minnesota is, respectively, 16 cases for women and 2.9 cases for men per 100 000 per year. The clinical association between the onset of Graves' hyperthyroidism and the onset of GO is strong; 80% of patients afflicted with one of these conditions develop the other within 18 months.

Etiology

No single factor has been identified that universally induces GO. Rather, a number of factors of varying degree of importance appear to work together to cause or worsen the disease. We discuss here the most commonly accepted contributors to disease etiology.

Genetic Contributions

Familial aggregation of autoimmune thyroid disease (AITD; GD and Hashimoto's disease, also known as lymphocytic thyroiditis) has been known for some time. The prevalence of AITD in siblings of patients with GD is 33%, and is similar to the 36% incidence of AITD in the families of patients with GD or GO. Polymorphic forms of several genes involved in the regulation of the immune system, including HLA-DR3, CTLA-4, CD40, PTPN22, as well as several thyroid-associated genes, including thyroid-stimulating hormone (TSH) receptor and thyroglobulin, are associated with GD. However, studies have not identified any stronger links between these polymorphisms and susceptibility to GO in GD patients.

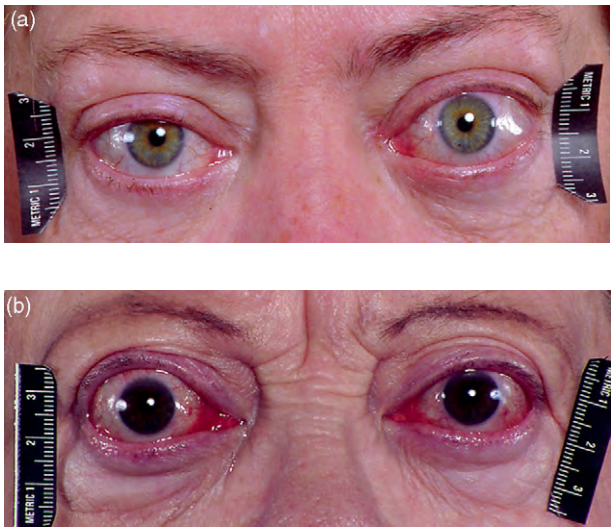

Figure 1 Photographs of two patients with GO: (a) asymmetric eyelid retraction with periocular edema and mild conjunctival congestion; (b) significant eyelid erythema and swelling with caruncular inflammation and conjunctival injection.

Similarly, other genes that have been found to confer susceptibility to GD with low relative risk, including T-cell receptor (TCR)-β-chain, tumor necrosis factor-β (TNF-β), and some immunoglobulin heavy chain-associated genes, confer no additional susceptibility to GO than to GD itself. This suggests that environmental factors may play a more significant role than genetic factors in the development of the ocular manifestations of GD.

Mechanical Factors

The bony confines of the orbit restrict the posterior expansion of the inflamed tissues within the GO orbit. Therefore, the increased volume of the orbital fat and extraocular muscle may lead to anterior displacement of the globe, or proptosis. This serves as a natural orbital decompression to relieve the intraorbital pressure. In addition to proptosis, other signs and symptoms of GO are attributable to mechanical pressures within the noncompliant bony orbit which may impair venous and lymphatic outflow and result in chemosis, periorbital edema, and increased inflammation. The latter is likely secondary to impaired drainage of inflammatory mediators. Individual anatomic variations in the orbital contour or the venous or lymphatic vessels may make some patients with GD more prone to the development of clinically significant GO or might explain the asymmetric eye disease seen in some patients. The trauma delivered by orbital tissue expansion within a noncompliant bony orbit may aggravate the underlying inflammatory process. This could further stimulate release of proinflammatory cytokines and chemokines and lead to augmentation of the orbital autoimmune process.

Uncontrolled Thyroid Dysfunction

Both hyper- and hypothyroidism have been shown in several case series and retrospective cohorts to be associated with increased risk for development of GO. DeGroot in a cohort of 264 patients found an odds ratio (OR) of 2.8 for development or worsening of preexistent GO in patients requiring more than a single treatment with radioactive iodine to control hyperthyroidism, compared with patients receiving only a single treatment. Prummel found, in a case series of 90 GO patients, that either hypothyroidism or hyperthyroidism increases the risk for severe GO almost twofold. In a smaller case series, Karlsson reported occurrence of GO after a period of hypothyroidism in 50% of patients, and Tallstedt in a retrospective cohort analysis found that patients who experienced hypothyroidism following radioactive iodine therapy for GD have an increased risk and an OR of 1.63 for development/worsening of GO compared to patients in whom hypothyroidism was prevented with early thyroid hormone replacement.

Tobacco Smoking

Smoking is the primary risk factor known for the development of GO in patients with GD; the relative risk, compared with nonsmokers with GD, is between 1.3 and 3.1. The risk is proportional to the number of cigarettes smoked per day, and former smokers have significantly lower risk than current smokers, even after adjusting for lifetime cigarette consumption. This suggests a direct and immediate effect of smoking on the development of GO. Smoking is additionally highly associated with more severe GO, with failure of immunosuppressive therapy and with worsening of GO after radioiodine treatment.

Mechanisms underlying the association between smoking and GO are unclear. Smoking has been associated with other autoimmune diseases, such as rheumatoid arthritis and Crohn's disease, suggesting that it increases the risk for immune self-attack with subsequent development of autoimmune conditions. Circulating levels of systemic cytokines do not appear to differ between smokers and nonsmokers, except for the presence of higher levels of interleukin (IL)-6 receptor in the former. However, these systemic levels might not be an appropriate surrogate for levels of these compounds within the GO orbit. Although patients with GO have higher levels of circulating IL-6 receptor than do GD patients without clinical GO, smoking and nonsmoking GO patients do not differ in this regard. Orbital fibroblasts cultured under hypoxic conditions produce increased levels of hyaluronic acid, and exposure of these cells to cigarette smoke extract appears to stimulate both adipogenesis and hyaluronic acid secretion.

Radioiodine Therapy for Graves' Disease

Studies have suggested that treatment with radioiodine may exacerbate eye disease in patients with GD who have preexisting, active GO. In one large study, patients were prospectively treated with radioiodine, methimazole, or a combination of radioiodine and prednisone. Within 6 months of treatment, mild progression of ocular disease was seen in 15% of patients treated with radioiodine alone, in approximately 3% of patients treated with methimazole, and in none of the patients treated with the combination of radioiodine and prednisone. By 1 year, the differences between the groups had almost disappeared, with only 5% of the radioiodine group having persistent symptoms that required additional treatment. Patients who experienced progression after receiving radioiodine were most commonly smokers and individuals with preexisting active GO. In addition, the higher incidence of hypothyroidism in the radioiodine group might have played a role in the outcome. Thus, it appears that progression of preexisting GO due to radioiodine therapy does occur in some patients. However, it is generally mild, temporary, and can be prevented by concurrent administration of corticosteroids. Patients with preexisting eye disease, smokers, those with high titers of autoantibodies directed against the thyroidal TSH receptor (TRAb), or those with severe thyrotoxicosis, high triiodothyronine (T3) levels, appear to be more likely to experience this complication. Ocular disease progression was not seen in another study in which postradioiodine hypothyroidism was carefully prevented by early thyroid hormone replacement, suggesting that hypothyroidism itself might play a role and should be avoided. Mechanisms responsible for ocular disease progression following radioiodine are unclear, but might include increased TRAb production, release of autoantigen from the thyroid, or destruction of radiosensitive suppressor T cells within the thyroid.

Pathophysiology

A number of factors appear to contribute to the pathogenesis of GO. Although we will describe each separately, their interplay determines the clinical outcome in a given patient (Figure 2).

Histology

The volume of the orbital adipose/connective tissue compartment and extraocular muscles is increased in GO. The muscle fibers are largely intact, but widely separated by edematous material composed largely of glycosaminoglycans (GAGs). Enlargement of these tissues can be ascribed in part to enhanced proliferation and secretion of hydrophilic GAG by orbital fibroblasts. In addition, new fat cell development, or adipogenesis, is active within the orbit and results in the observed expansion of the orbital adipose tissues. Within these tissues is found an infiltration of macrophages, T lymphocytes and to a lesser extent B lymphocytes, and natural killer cells. Further characterization of the activated T lymphocytes reveals increases in both CD4- and CD8-expressing populations and restriction in the T cell receptor repertoire. T-cell

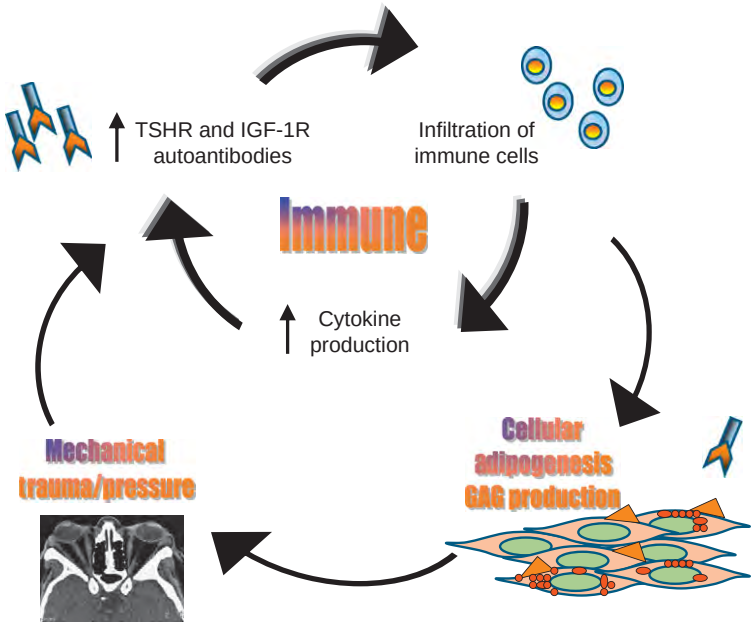

Figure 2 Immunological, cellular, and mechanical factors interact in a positive feedback loop to contribute to the development and progression of GO. TSHR – thyroid-stimulating hormone receptor. IGF-1R – insulin-like growth factor-1 receptor.

phenotyping has shown the presence of both Th1 and Th2 cytokine profiles of helper T cells (Th). Evidence suggests that the predominant profile found might depend on the stage of disease, with Th1 cells, which participate in cell-based immunity, appearing in early disease and the Th2 cells, which participate in antibody-mediated immunity, appearing in later stages.

Orbital fibroblasts are phenotypically heterogeneous multipotent cells. Subpopulations of these cells, distinguishable on the basis of the cell surface marker thymocyte differentiation antigen-1 (Thy-1), can be identified even within a single tissue. Approximately 20% of fibroblasts found within the normal orbital adipose/connective tissue compartment do not express this antigen and are preadipocyte fibroblasts capable of differentiating into adipocytes. The remainder are Thy-1 positive and do not possess adipogenic potential. In contrast, essentially all perimysial fibroblasts, those that form the individual fascicles within the muscles, are Thy-1 positive and therefore cannot differentiate into mature fat cells. A recent study showed an increase in Thy-1 positive cells within the adipose/connective tissues of the GO orbit, perhaps representing an adaptive response that limits disease progression. Individual differences in the distribution of cells expressing this antigen within the GO orbit may help to explain why some patients have predominant eye muscle disease while others have increased orbital adipose tissue volume as the predominant feature.

Cytokines

Orbital fibroblasts are capable of initiating lymphocyte recruitment via their secretion of proinflammatory cytokines which, in turn, stimulate the production of chemoattractant molecules by T cells. Two such molecules, IL-16 and RANTES, appear to account for the majority of T-lymphocyte migration initiated by orbital fibroblasts. Other cytokine-induced responses with potential relevance to GO include the inhibition of adipogenesis in orbital fibroblasts by transforming growth factor-β (TGF-β), interferon-γ (IFN-γ), and TNF-α, and its promotion by IL-6. Orbital fibroblasts also produce IL-1, IL-6 and IL-8, as well as prostaglandins, in response to ligation of their CD40 receptors by CD154 on T cells.

Orbital Autoantibodies

It is well accepted that autoantibodies against the TRAb are responsible for the hyperthyroidism of GD. The close clinical and temporal associations between Graves' hyperthyroidism and GO have led to the hypothesis that TRAb may also underlie the pathogenesis of GO. Indeed, the occurrence of GO is greatest in GD patients with the highest levels of circulating TRAbs, and the clinical activity of the disease correlates with serum levels of these autoantibodies.

A qualifying requirement to link TRAbs to the pathogenesis of GO is that the TSH receptor be expressed in orbital tissues. Recent studies have shown this to be the case as both TSH receptor mRNA and protein have been demonstrated in GO orbital adipose tissue specimens. Further, expression levels are higher in GO tissues than in orbital tissues obtained from normal individuals and a positive correlation has been shown between clinical activity scores and TSH receptor mRNA levels in patients' orbital tissues.

Studies *in vitro* show that orbital preadipocyte fibroblasts can be induced to differentiate into mature adipocytes and in doing so increase their expression of TSH receptor. When cultured in the presence in adipogenic agonists, levels of TSH receptor mRNA, as well as mRNA encoding various adipocyte-associated genes, increase roughly 10-fold in these cells. Studies of uncultured orbital fat specimens obtained from GO patients also show high levels of these genes compared with normal orbital fat specimens, suggesting that adipogenesis is increased within the orbit in GO. Whether this is directly caused by TRAb targeting TSH receptor on these cells is an area of active investigation.

Recent studies have implicated insulin-like growth factor-1 (IGF-1) receptor as another important autoantigen in GO. Human orbital fibroblasts have high-affinity IGF-1 binding sites, and immunoglobulin G (IgG) from the sera of GD patients interacts with these sites, while normal IgG does not. This IgG stimulates orbital fibroblasts to produce IL-16 and RANTES and to enhance their synthesis of hyaluronic acid. Evidence points toward these effects being mediated through the IGF-1 receptor, suggesting a possible role for IGF-1 receptor autoantibodies in the pathogenesis of GO.

Future Management

Current medical management of GO is inadequate, generally benefitting patients only modestly while they await spontaneous improvement in the disease. While orbital decompression surgery has proven beneficial to patients with severe disease, the prevention of this surgery is a primary goal of medical management. Recent progress in the understanding of GO pathogenesis has led to the identification of several potential targets for novel therapeutic agents. Both the production of autoantibodies by B cells and the release of proinflammatory cytokines by activated T cells can be impacted by targeting the initial stages of lymphocyte activation. As such, costimulation inhibitors (CTLA4-Ig or alefacept) could be of therapeutic benefit in early GO, and similar agents might ultimately hold promise in prevention.

Growing evidence for the involvement of autoantibodies directed against the TSH and IGF-1 receptors in GO has excited interest in the potential clinical utility of rituximab. This anti-B-cell monoclonal antibody targets the CD20 antigen and impacts antigen presentation and early steps in B-cell maturation. Trials of rituximab in the treatment of rheumatoid arthritis have shown significant improvement in active disease with decreases in serum activity markers. Results of uncontrolled trials of this agent in GO are promising and have paved the way for randomized controlled trials now underway.

The participation of proinflammatory cytokines and chemokines in the development of GO suggests that monoclonal antibodies targeting these molecules might be useful in treatment. In particular, biological agents that block TNF-α (infliximab, adalimumab, etanercept) or IL-1 receptor (anakinra) are attractive candidates for therapeutic trials in patients with active GO.

U

Unique Specializations – Functional: Dynamic Range of Vision Systems

A C Arman and A P Sampath, University of Southern California, Los Angeles, CA, USA

Glossary

Dynamic range – The full range of light levels over which retinal cells or pathways can dynamically modify their function to encode.
Mesopic vision – Intermediate light level vision mediated by both rod and cone photoreceptors under conditions where both are responsive, allowing a seamless transition from rod to cone vision.
Photopic vision – High light level vision mediated by cone photoreceptors.
Ribbon synapse – Synapses where a ribbon-like structure is present that optimizes the continuous release of neurotransmitter.
Rod spherule – The specialized synaptic terminal of the rod photoreceptor.
Scotopic vision – Low light vision mediated by rod photoreceptors.

Introduction

Nearly all sensory systems must find a way to represent a wide range of input signals and translate them into meaningful neural responses. The human visual system is able to operate effectively from starlight to bright sunlight, a range that spans about 12 orders of magnitude of light intensity. The pupil serves as the first stage of sensitivity control by changing the amount of the light reaching the photoreceptors. The diameter of the pupil can change by a factor of 4, allowing light intensity to change by a factor of 16. However, this alone cannot account for the complete range of light to which the mammalian retina is sensitive. To reliably transmit changes in light stimuli over this range, the mammalian retina has evolved several specializations to report changes in the light environment that include: (1) the evolution of two photoreceptor types, the rods and cones, that operate at different light levels; (2) several neural pathways with which to encode the output of these photoreceptors; and (3) adaptive mechanisms at all levels of retinal processing to modulate light sensitivity based on light history.

Rods versus Cones

The evolution of the duplex retina in vertebrates with two classes of photoreceptors, the rods and cones, marks a departure from the single type of photoreceptor present in many invertebrates. The use of two photoreceptor subtypes with different sensitivities to light allows the vertebrate retina to respond over a greater range of light intensities. By switching between rods and cones, the vertebrate retina is thus able to maximize visual sensitivity depending on the ambient light level. It is now believed that such an arrangement allows the vertebrate retina to reduce energy consumption in daylight, when the rods are not responsive.

Rods mediate vision when photons are scarce; their design and cytoarchitecture are optimized for maximal sensitivity to incoming photons and are capable of generating a reproducible response to a single absorbed photon, which is critical for setting the sensitivity of scotopic vision when the retinal circuitry pools thousands of rods (see the section titled 'The pathways concept' below). As the mean background light level increases, rods themselves are able to adapt, which allows them to signal light intensities up to ~1000 R^* or more per second.

Cone photoreceptors are ~100-fold less sensitive than rods, and are critical for our daytime vision under conditions when the exquisitely sensitive rod photoreceptors are saturated. The reduced sensitivity of cones arises from reduced amplification within cone phototransduction, and mechanisms designed to shut off phototransduction more quickly than rods. Furthermore, even in

the brightest light the cone photocurrent does not remain saturated, which leaves open the ability to adapt and signal changes in light intensity even under conditions where a majority of the photopigment is bleached. The optimizations of cones to function in bright light with virtually little overlap with rod light levels allows for a smooth transition from rod to cone vision, in what is referred to as the mesopic range.

The Pathways Concept

The adaptive features of the rod and cone light response allow these photoreceptors to remain responsive over a larger range of light intensities by preventing response saturation. However, the dynamic range of the rods and cones themselves cannot account for the ~12 orders of magnitude in light intensity we experience. Another strategy used by the mammalian retina to extend further the dynamic range of vision is to utilize multiple neural pathways to carry light-evoked signals. The functional properties of these pathways (e.g., convergence, gain, and adaptation) can then be adjusted to maximize the visual system's ability to remain responsive over the largest range of light intensities. To date, the most-studied retinal pathways in mammals are those that carry signals from rod photoreceptors to ganglion cells. These include the circuits that carry light information near scotopic threshold (rod bipolar pathway or classical rod pathway), and those that operate at higher rod light levels that may provide a seamless mesopic transition (rod–cone and rod–OFF pathways) to photopic vision. Rather less is known about the functional properties of the cone pathways that maximize dynamic range.

Rod Bipolar Pathway

Psychophysical studies have demonstrated at the limits of scotopic vision that the human visual system is capable of detecting the absorption of a few photons of light. This remarkable sensitivity arises from the fact that individual rods can reliably signal the absorption of a single photon, and that a specialized retinal circuitry referred to as the rod bipolar pathway can combine these signals such that a ganglion cell projecting centrally can pool thousands of rod signals. The discovery of a dedicated depolarizing bipolar cell and an amacrine cell that carries rod signals in the rabbit retina leads to the finding that this circuit appears conserved across all mammalian species. A hallmark of this pathway is the convergence of rod signals at many stages of processing that is critical for our scotopic sensitivity. For instance, as many as 20–100 rods converge on a rod (ON) bipolar cell, and 20–30 rod bipolar cells converge on an AII amacrine cell. Thus, a ganglion cell that sums the output of many AII amacine cells can pool upward of 10 000 rods. Ultimately, by pooling rod signals and eliminating rod noise to preserve best the single-photon response from individual rods, the rod bipolar pathway can extend the dynamic range of vision down to light levels where a small fraction of the rods absorb a photon.

Signal transfer from rods to rod bipolar cells

At scotopic threshold, vision relies on a sparse number of photons at the retina that produce few photon absorptions per thousands of rods within the 0.2-s integration time of the rod photoresponse. Under these conditions, the transmission of a small, graded hyperpolarization upon photon absorption requires that rod synapse is appropriately optimized. The transmission of small, graded single-photon responses at the rod synaptic terminal is aided by two specializations. First, the resting dark membrane potential, or voltage, sits at approximately –40 mV, near the steepest point in the relationship between voltage and L-type Ca^{2+} channel opening (**Figure 2**). Thus, small changes in membrane potential produce substantial changes in the number of open channels, thereby altering glutamate release. Second, if the rod bipolar cell is sensing reductions in glutamate release due to photon absorption, then statistical lapses of glutamate release in darkness would mimic light absorption. Thus, the high rate of glutamate release generated in darkness by the specialized synaptic ribbon in the rod spherule reduces the probability of these lapses. Together, these synaptic properties allow the small, light-evoked signals from rods to be reproducibly transferred to downstream neurons.

Despite the rod synaptic specializations for the transmission of single-photon absorptions, the depolarization in darkness due to open cyclic guanosine monophosphate (cGMP)-gated channels is also a complicating factor in the detection of these sparse signals. Open cGMP-gated channels in turn will report internal fluctuations in cGMP, produced by the phototransduction mechanism, which are commonly referred to as dark noise. Since rods generate a small, graded hyperpolarization upon photon absorption, the downstream convergence of thousands of rod signals would cause the light-evoked response from a single rod to be overwhelmed by the dark noise of the majority. Given the magnitude of dark noise in individual rods, it has been proposed that some type of nonlinear combination of rod signals would be required to increase the detection of the single-photon responses in downstream cells. Since rod photoreceptors are relatively depolarized in darkness, the steady release of glutamate from the synapse provides some insights into potential mechanisms. Postsynaptic saturation at the rod-to-rod bipolar synapse would allow noise generated by open cGMP-gated channels in the rod outer segment to be eliminated. It was proposed that the saturation of postsynaptic glutamate receptors would provide a nonlinear way to eliminate the rod noise, since the synapse would not be

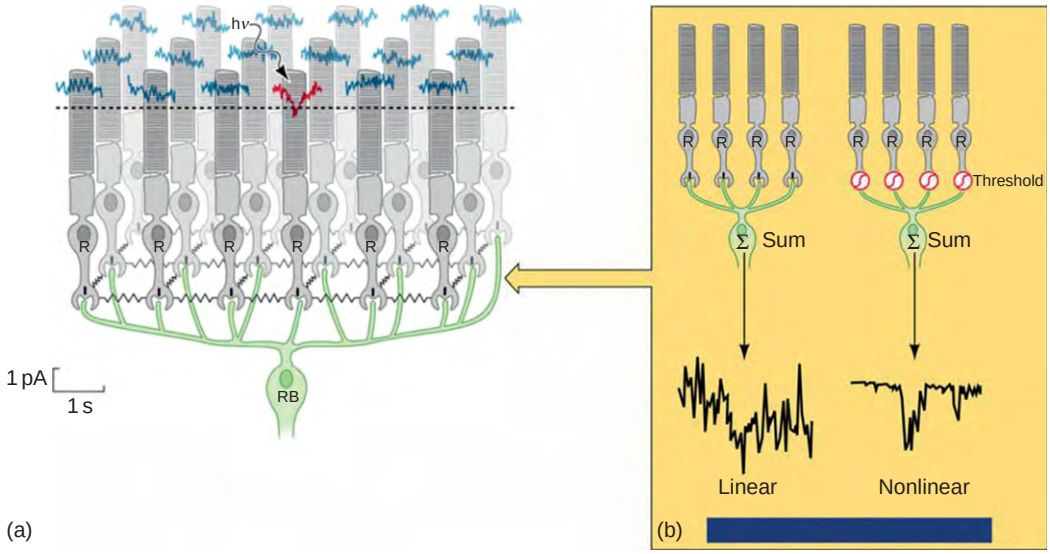

Figure 1 Convergence at the rod-to-rod bipolar synapse. (a) A rod bipolar cell pools inputs from many rods, but near absolute visual threshold only one rod may absorb a photon (red), while the remaining rods are generating electrical noise (blue). A nonlinear threshold (dashed) may improve photon detection at this synapse by retaining responses in rods absorbing a photon and discarding responses of the remaining rods. (b) Nonlinear signal processing can improve the fidelity of rod signals. If rod outputs from (a) are simply summed, the resulting trace is noisy, but when summed after applying a threshold for each rod in (a), the response is more detectable. From Okawa, H. and Sampath, A. P. (2007). Optimization of single-photon response transmission at the rod-to-rod bipolar synapse. *Physiology* 22: 279–286. With kind permission from The American Physiological Society.

able to relay small changes in membrane potential that reflect rod noise. Later work suggested that such thresholding is critical for maximizing the detection of the single-photon response in retinal neurons downstream of the rods (**Figure 1**). In particular, the extent of nonlinear signaling appears to be set to separate optimally the rod single-photon response from rod noise, allowing scotopic vision to reach the highest possible sensitivity.

The mechanism that underlies the nonlinear threshold at the rod synapse has been studied to some extent, but is hindered by a lack of identification of the components of the signaling pathway. Light-evoked signaling between rod photoreceptors and rod (ON) bipolar cells results in a membrane depolarization, effectively inverting the sign of the rod's hyperpolarizing light response. The postsynaptic mechanism underlying this sign inversion is a G-protein signaling pathway initiated by the metabotropic glutamate receptor, mGluR6. mGluR6, in turn, activates a guanine nucleotide-binding protein, $G_o\alpha$, which leads to a series of unidentified events that close a cationic transduction channel of unknown identity. Thus, upon light-absorption, glutamate release from rods is reduced, thereby reducing the activity of the mGluR6 signaling pathway and allowing transduction channels to open and depolarize the cell (**Figure 2**).

In the context of the mGluR6 signaling cascade, it now appears that the nonlinear threshold that eliminates rod noise is due to saturation within the signaling cascade, and not at the level of the glutamate receptors. Furthermore, evidence from axotomized rod bipolar cells indicates that nonlinear signal transfer does not arise due to feedback in the inner plexiform layer. Saturation of the mGluR6 signaling cascade allows the elimination of noise by making the rod bipolar cell insensitive to small fluctuations in glutamate, driven by noise in the rod photoreceptor. Only when the rod's membrane potential is hyperpolarized sufficiently does the glutamate concentration in the synaptic cleft reduce enough to relieve the synapse from saturation. Such an operation thus allows larger hyperpolarizations due to light absorption to cross the rod synapse, while masking smaller fluctuations that are more likely due to noise in the rod photocurrent or synaptic transmission. Near absolute visual threshold, such synaptic processing is necessary to maximize the detectability of rod signals.

Signal transfer from rod bipolar cells to AII amacrine cells

The convergence of the rod bipolar pathway moving from rods to rod bipolar cells and, finally, AII amacrine cells, requires the further accentuation of the single-photon response. Two main specializations between these cells appear well tuned to further improve the detection of the single-photon response, and thus push the dynamic range of vision to lower light intensities. First, a specialized ribbon synapse between the rod bipolar cell and the AII amacrine cells allows the coordinated release of multiple vesicles upon stimulation. Such multivesicular release increases the amplitude of the AII amacrine cell response, allowing it to be distinguished from vesicular release due to noise in the rod bipolar cell. Second, the electrical coupling

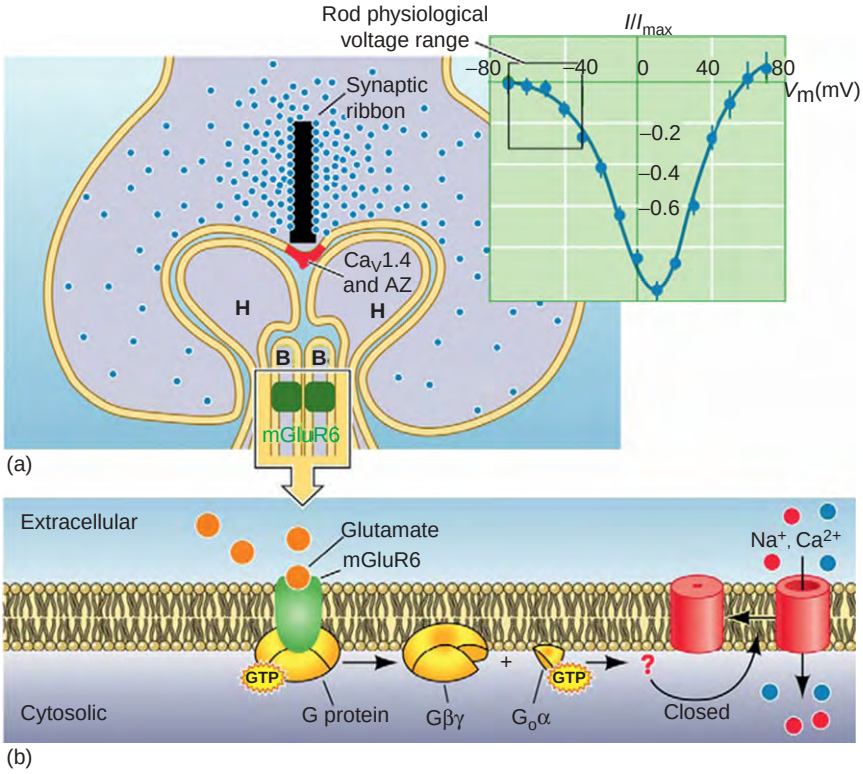

Figure 2 Structure and signal transfer at the rod-to-rod bipolar synapse. (a) The rod spherule is a specialized invaginating structure where the dendrites of horizontal (H) and rod bipolar cells (RB) are apposed to a glutamate release site controlled by a ribbon. Ca^{2+} channels ($Ca_V1.4$) are located near the active zone (AZ) and allow the continuous release of glutamatergic vesicles in darkness. In ON rod bipolar cells, glutamate is sensed by mGluR6 receptors located near the mouth of the invagination. (Inset) Release of glutamate is dependent on Ca^{2+} influx through Ca^{2+} channels, which is graded by voltage over the physiological range. (b) The signaling cascade in rod bipolar cell dendrites is poorly understood. mGluR6 activation leads to the activation of $G_o\alpha$, which through unknown mechanisms leads to the closure of a nonselective cation channel whose identity is also unknown. The light-evoked reduction in glutamate release relieves activity in this cascade and opens cation channels leading to depolarization. From Okawa, H. and Sampath, A. P. (2007). Optimization of single-photon response transmission at the rod-to-rod bipolar synapse. *Physiology* 22: 279–286. With kind permission from The American Physiological Society.

of AII amacrine cells by connexin 36 appears to reduce noise in the network, allowing an improved signal-to-noise ratio.

Ganglion cell sensitivity

Retinal ganglion cells can also relay single-photon responses to higher visual centers, a requirement for the high sensitivity of rod vision. Through the process of neural convergence, as well as the mechanisms described above, ganglion cells and AII amacrine cells have about the same flash sensitivity. Recordings of many groups from dark-adapted cat retinal ganglion cells indicate bursts of ~2–3 action potentials occurred with a frequency consistent with an upstream origin that may be the rods. The frequency of these bursts increased with background light, suggesting that the bursts were related to photon absorption. Similar conclusions have been drawn using a cross-correlation analysis from paired ganglion cell recordings in the presence and absence of background lights.

Rod–Cone Pathway

A consequence of the high sensitivity of the rod bipolar pathway is that it saturates at modest light levels where the rods themselves are not saturated. To capture light-evoked signals from rods until they themselves saturate additional pathways are required. Studies of the ultrastructure of the outer plexifom layer reveal that gap junctions exist between rods and rods, and rods and cones. The nature of the rod-to-rod gap junction is unclear, but has been proposed to dissipate small rod signals into the network allowing signal averaging at the cost of a twofold elevation in visual threshold. The rod-to-cone gap junctions have been studied in more detail and are found in a majority of rods. Evidence points to the expression of the gap junction subunit connexin 36 in cones, but not in rods. Thus, the electrical gap junctions between rods and cones must be heterologous. Given the lower input impedance of cones, signal transfer will preferably travel from rods to cones, which would allow these signals to be relayed to ganglion cells through the cone circuitry.

Physiological recordings have indicated robust rod signals in the cone photoreceptors of several species. In particular, measurements from dark-adapted retina indicate that rod-to-cone coupling must exist, going against the idea that, to maximize visual sensitivity, the rods and cones should be uncoupled in darkness. Recordings from mouse retinal whole mounts suggest that the signals through this pathway are 10-fold less sensitive than for the rod bipolar pathway. These physiological data correspond well with psychophysical experiments indicating a secondary rod pathway with a 10-fold lower sensitivity than the primary pathway.

Rod–OFF Pathway

A third rod pathway has been identified in some species of mammals. Under conditions where the rod–bipolar and rod–cone pathways are blocked or eliminated, OFF signals with rod sensitivity have been shown to persist in the mouse retina. Direct synaptic contacts have been identified anatomically in mice, rats, and rabbits. However, direct contacts between rods and OFF bipolar cells have not yet been reported in higher mammals. It is possible that an OFF rod pathway evolved as a specialization in nocturnal rodents to sense dark objects against a light sky.

The rod–OFF pathway is believed to be active at 5–10-fold higher light intensities than the rod bipolar pathway. Its prominence as a signaling circuit in rodents appears to vary based on the percentage of the OFF cone bipolar cell population that sees direct signals from rods. It is now believed that between 5% and >25% of cone OFF bipolar cells may see direct contacts from rods, the upper end suggesting that this pathway may play an integral role in visual processing.

Despite attempts by various groups to characterize the physiological response properties of the rod pathways, the exact sensitivities and operating ranges of each pathway remain unclear. The lack of physiological evidence elucidating the role of these pathways in rod vision arises from common signaling mechanisms used by each. Thus, genetic or pharmacological manipulation of each rod-signaling pathway will also influence other pathways, making it impossible to unambiguously identify the properties of each. Nevertheless, the evidence now points to the rod bipolar pathway as the primary carrier of single-photon responses near absolute visual threshold, with an ~5–10-fold reduction in the sensitivity of the rod–cone and rod–OFF pathways that may carry signals at higher light levels where cone function is merged.

Cone Pathways

Our understanding of the cone pathways is far less complete than our understanding of rod pathways in the mammalian retina. The physiological properties of the cones and cone pathways remain as one of the frontiers in retinal neurobiology, especially as cone function dominates our visual experience. To date, as many as nine types of cone bipolar cells have been identified in mammalian retinas, which may connect to as many as 10–15 types of retinal ganglion cells. Other than the specific pathway for S-cones, there is presently little understanding of specific circuits that carry cone responses to ganglion cells.

Adaptation to Mean Background Light

A common feature of all sensory systems is the ability to adapt to increases in the mean level of a stimulus by reducing the gain of the system. Such sensitivity adjustments allow the sensory system to remain maximally responsive as the stimulus intensity changes. Both rods and cones in the retina, as well as their circuitry, exhibit adaptive mechanisms that are designed to increase the dynamic range of the receptor. However, in the context of the dynamic range of the visual system, the influences of adaptation on the lower limit of scotopic and upper limit of photopic vision are opposite. To retain maximal sensitivity near absolute visual threshold, the retina must maximize its gain for the single-photon response and any adaptive mechanism would allow the rod circuitry to aid in the transition from scotopic to mesopic vision. Conversely, the upper light limits of our visual experience are ultimately defined by adaptation in the cone photoreceptors, which continue to operate even when a majority of the photopigment is bleached.

Adaptation: Rod Pathways

Adaptation within a neural circuit with considerable convergence will begin centrally and move peripherally. Under these circumstances, downstream cells will be the first to detect sufficient signal to adapt for the weakest stimuli, and the rod pathways are no exception. In the rod bipolar pathway, weak background light begins to reduce the gain of ganglion cells and AII amacrine cells before adaptation is detectable in rod bipolar cells or rod photoreceptors. Some mechanisms that provide this gain reduction have been identified, particularly at the rod-to-rod bipolar, and the rod bipolar-to-AII amacrine synapses. For instance, at the rod-to-rod bipolar synapse, the influx of Ca^{2+} through mGluR6 transduction channels reduces the bipolar cell gain for subsequent stimulation. In addition, at the rod bipolar-to-AII amacrine synapse depression mediated by depletion of the available pool of vesicles can be evoked at individual synapses by single-photon responses. These adaptive mechanisms allow the rod bipolar pathway to extend its range to higher light levels

where they merge with the other rod pathways. However, the extension of the dynamic range of vision to lower light levels requires that the retina remains maximally responsive to single photons, and thus these adaptive mechanisms would impair absolute threshold.

Adaptation: Cone Pathways

It has been well documented that adaptation of ganglion cell responses in the cone pathways occurs at lower light levels than where adaptive features of cone pathways have been documented. Cone and horizontal cell recordings have demonstrated that cone adaptation is observed at light levels that exceed those required for the adaptation of cone-driven signals in ganglion cells. This adaptation of the postsynaptic cone circuitry, in turn, prevents these pathways from saturating, thereby allowing the extension of the cone operating range through mesopic to photopic vision. Adaptation, both in the cones and in the postreceptoral circuitry, have been found to be mutually exclusive. Ultimately, the upper limits of cone vision are directly imposed by receptoral adaptation of the cones themselves and not by the postsynaptic circuitry.

Conclusions

The vertebrate retina has developed many strategies to maximize the dynamic range of vision. At the initial stages of light detection the evolution of two photoreceptor types, the rods and cones, allows the visual system to signal a wide range of light intensities. By dividing the output of these receptors across many retinal pathways, each of which is subject to its own optimization and adaptation, the human eye is capable of providing the brain with information that extends the range of vision to encompass approximately 12 orders of magnitude of light intensity.

Uveoscleral Outflow*

A Alm, University of Uppsala, Uppsala, Sweden

Glossary

Aqueous humor – The clear fluid found between the cornea and the iris.
Bulk flow – The proteins following fluid transport in proportion to its concentration in the fluid.
Ciliary muscle – The muscle that controls the eye's accommodation for viewing objects allowing the lens to focus on near, distant, and intermediate objects.
Glaucoma – An eye disease associated with increased intraocular pressure which can damage the optic nerve and may lead to vision loss.
Goldmann equation – The equation that describes the relationship between intraocular pressure, aqueous flow, outflow through the trabecular meshwork, and episcleral venous pressure.
LYVE-1 – A marker for lymphatic vessels, which is also expressed on some blood vessels and macrophages.
Prostaglandins – A group of lipid compounds, which act as a hormone-like substance that mediate many bodily functions.
Pseudoexfoliation – The abnormal deposits of white substance seen on the lens and usually associated with glaucoma.
Uveitis – The inflammation of the middle layer of the eye.

The circulation of aqueous humor through the anterior segment of the eye serves several purposes. It nourishes the avascular lens and cornea, rids the anterior chamber from inevitable debris accumulated during the years, and it maintains sufficient pressure within the eye to keep the eye globe rigid during eye movements. It has long been known that the fluid filling the anterior and posterior chamber, aqueous, is not a stagnant pool, but that there is a continuous secretion of aqueous from the ciliary processes, and that aqueous leaves the eyes through the tissues of the anterior chamber. The structures of the trabecular or conventional outflow route are well known. As this anatomical arrangement seems to fulfill the purpose of circulating aqueous it was long accepted that this was a complete description of the aqueous humor circulation, with the possible exception of some leakage to the vitreous and diffusion into nearby tissues. A second outflow route was, however, discovered when Anders Bill noted that in young monkeys about half of the aqueous leaves the eye by bulk flow through what became termed the unconventional or uveoscleral outflow.

Morphology

Thus the trabecular outflow route seems to provide all that is necessary in order for aqueous to circulate and pass out of the eye through bulk flow. It even permits very large particles, such as red blood cells (**Figure 1**), to leave the anterior chamber, a necessity for saving sight after trauma. Still, in retrospect, it may seem obvious that some aqueous can leave the eye through other tissues in the chamber angle than the trabecular meshwork. As seen in **Figure 2** there is no epithelial barrier between the anterior chamber and the iris/ciliary muscle and at least water and small molecules should be able to pass this way. The intermuscular connective tissue between the ciliary muscle bundles is sparse in young human eyes (**Figure 3(a)**). In monkeys even 1-μm large latex spheres can pass between the muscle bundles. From the supraciliary or suprachoroidal space, 0.1-μm spheres can enter the perivascular spaces in the sclera and 10-nM Thorotrast particles enter the sclera. In human donor eyes, stained gelatine or methyl methacrylate injected into the suprachoroidal space can be found in the perivascular spaces between the adventitia of the vessels and scleral fibrils (**Figure 4**), and even in direct channels from the suprachoroidal space communicating with the scleral venous plexus (**Figure 5**). Thus, proteins accumulating in the extravascular space of the highly permeable choroidal vessels can leave the eye through these routes, a task normally handled by lymphatic vessels. It has long been accepted that there are no lymph vessels in the eye. However, recent development of new markers for lymphatic endothelium has renewed interest on this subject. A network of channels stained with a specific marker for lymphatic endothelium has been seen in the ciliary muscle and processes of human eyes (**Figure 6**) and LYVE-1 positive macrophages, but no classical lymphatic vessels, are found in the choroid. However, the role of these new findings in the removal of proteins from the suprachoroidal and supraciliary spaces remains to be determined.

Techniques to Determine the Rate of Uveoscleral Flow

Experimental Animals

Aqueous flow can be determined in experimental animals where the anterior chamber is perfused with a large-molecular-weight tracer. Small tracers, such as sodium fluorescein that pass through the cornea, are used for clinical studies but about 10% is lost by diffusion into the surrounding tissues. Very little albumin is lost by diffusion and it leaves the anterior chamber mainly by bulk flow. In his search for a suitable tracer to determine aqueous flow in monkeys, Anders Bill noted that about

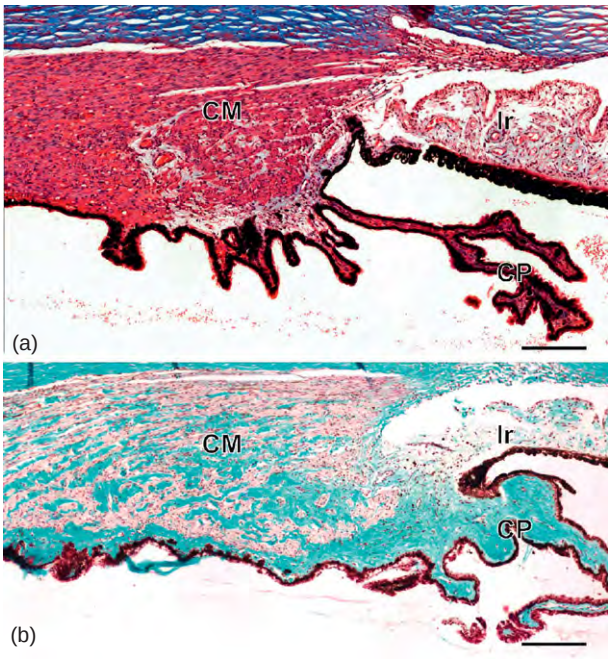

Figure 3 Ciliary body (pars plicata) of a 34-year-old (a) and an 80-year-old human donor stained after Masson (a) or Masson–Goldner (b), respectively. Smooth muscle cells of the ciliary muscle (CM) are labeled in red while extracellular fibrillar material is labeled in blue (a) or green (b). In the older eye, there is considerably more fibrillar extracellular material between the ciliary muscle cells and in the stroma of the ciliary processes (CP) as compared to the younger eye. half of the tracer injected into the anterior chamber did not appear in blood until much later. The lost albumin could be found in the ciliary muscle and the suprachoroidal space. Large-molecular-weight tracers have since been used for determination of aqueous flow in experimental animals. In order to determine uveoscleral flow, the concentration of labeled albumin in the anterior chamber is followed continuously and the animals are sacrificed after a fixed time. Albumin drained by the conventional outflow route is determined by following the appearance of radioactivity in blood samples. Albumin drained by the uveoscleral outflow route can then be calculated as the concentration in the ocular tissues, after removal of all aqueous, divided by the mean concentration in aqueous during the experiment. A second technique is based on near-continuous calculation of aqueous humor flow, and conventional outflow is determined by following the appearance of the labeled albumin in plasma. The rate of uveoscleral is then the difference between aqueous flow and conventional outflow during the experiment.

Human Eyes

There is no technique for direct, noninvasive measurements of uveoscleral flow in human eyes. The Goldmann equation, adjusted for uveoscleral flow, establishes the relationship between the IOP, aqueous flow (F_{IN}), uveoscleral flow (F_{US}), outflow facility through the trabecular meshwork (C), and episcleral venous pressure (P_{EV}).

$$\text{IOP} = P_{EV} + \frac{(F_{IN} - F_{US})}{C}$$

Thus

$$F_{US} = F_{IN} - C^{*}(\text{IOP} - P_{EV})$$

Unfortunately, determining the other components of aqueous humor dynamics will not provide sufficiently precise measurements to make calculations of F_{US} from the Goldmann equation meaningful. IOP and F_{IN} can both be determined with reasonable precision, but they are measured under markedly different conditions. IOP is an instant measurement and F_{IN} is averaged over several hours. Techniques to determine P_{EV} are difficult and it is usually assumed to be 8 or 9 mmHg. Clinical tonography is the weak link for clinical determination of F_{US}. It requires a marked increase in IOP and the measurement error is large. As aqueous flow, determined with a fluorophotometric technique, and IOP can be measured with reasonable precision, a clinical technique that is

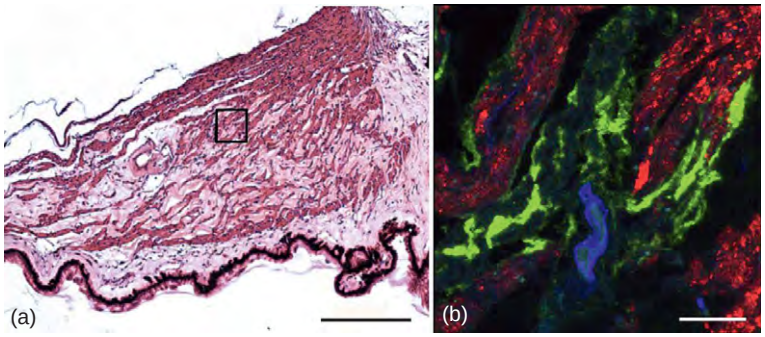

Figure 6 D2-40-immunoreactive lymphatic channels seen in human ciliary body. (a) H- and E-stained human ciliary body (calibration bar indicates 250 μm). (b) Confocal projection image (1 5 μm thick, 0.5 μm step, 60× oil immersion) taken from an area in the ciliary muscle (the square in (a)). D2-40-positive lymphatic channels (green) are seen along SMA-positive smooth muscle fiber bundles (red) and are distinct from CD34-blood vessel endothelium (blue) in the ciliary body (calibration bar indicates 40 μm). Courtesy of N. Gupta.

independent of C is now the technique that is usually applied for clinical determination of uveoscleral flow. IOP and F_{IN} are determined at two different levels, before and after administration of a combination of oral acetazolamide and a topical adrenergic β-receptor antagonist, timolol. Neither drug is expected to change F_{US}, C, or P_{EV}. A reasonable value for P_{EV} is usually assumed, and C can then be calculated as $\Delta F_{IN}/\Delta$IOP. The technique has obvious advantages over calculations based on standard tonography but it is sensitive to the difference between IOP and P_{EV} and even a small change in estimated P_{EV} would have a marked effect on the calculated uveoscleral flow, particularly in eyes with normal levels of IOP.

Normal Values

Values Obtained with Tracers in Different Species

Direct measurements of uveoscleral flow with tracers have been done in several species, including a few human eyes scheduled for enucleation (Table 1). In nonhuman primates 38–55% of aqueous flow left the eye through the uveoscleral route, while much lower values were found in rabbits (3–8%), cats (3%), and dogs (15%). The values for human eyes were much lower than in nonhuman primates, 4–14% respectively in two eyes. This may, however, reflect the fact that these values were determined in elderly eyes and there are good reasons to believe that uveoscleral flow is reduced with age (see below). When values obtained in nonhuman eyes are compared, there is a marked species difference that seems to reflect the degree of development of the ciliary muscle.

Table 1 Uveoscleral flow in different species determined with labeled tracers

Species	*F_{US} (μL min^{-1})*	*% of F_{IN}*	*Reference*
Human	nd/0.28	4/14	Bill and Phillips (1971)
Monkey			
Cynomolgus	0.96	55	Bill (1971)

Calculated Values from Human Eyes

Values calculated from measurements of aqueous humor dynamics in human eyes have, as a rule, provided considerably higher values for uveoscleral flow than that determined with labeled albumin in human eyes. Although, as pointed out above, clinical techniques are likely to be less precise than experiments with labeled tracers, the results are reasonably consistent suggesting that between 30% and 50% of aqueous leaves the anterior chamber of the human eye by the uveoscleral outflow route in young individuals (Table 2).

Effect of Age

Comparing uveoscleral flow in different species determined with tracers (Table 1), it is striking that the values reported for two human eyes are much lower than in nonhuman primates. Obviously, a true species difference may be involved; however, it is also possible that the main reason is that uveoscleral flow is reduced with age. The two human eyes were from patients aged 54 and 63 years, respectively. Both aqueous flow and outflow facility is reduced with age with little overall effect on IOP in Western populations. A similar, modest reduction seems to take place with uveoscleral flow. Clinical studies (Table 2) found a significant reduction in uveoscleral flow with age from 1.52 µl min^{-1} in eyes aged 20–30 years to 1.10 µl min^{-1} in eyes older than 60 years. The morphology of the ciliary muscles supports the concept that uveoscleral flow is age dependent. The spaces between the ciliary muscle bundles are markedly reduced with age. Connective tissue is increased from about 20% of the total area in human eyes between the age of 30 and 40 to more than 50% in eyes at an age of 60 or more in the reticular portion of the ciliary muscle, facing the anterior chamber (Figure 3(b)). This is likely to reduce the amount of aqueous passing through the uveoscleral route.

Table 2 Values for F_{US} determined in human eyes from indirect calculations

Physiology

Effect of IOP

Flow through the uveoscleral outflow occurs by bulk flow, which is always pressure dependent, but the unconventional outflow route is often referred to as pressure independent. This is because uveoscleral flow does not depend on the IOP to the same extent as trabecular outflow does. Within the normal range of IOP flow through the trabecular meshwork increases almost linearly, while uveoscleral flow is relatively stable (**Figure 7**). The main resistance to trabecular outflow is located in the trabecular meshwork. Measurements of pressure in the anterior chamber and in Schlemm's canal in monkeys have shown that the pressure in Schlemm's canal is only slightly higher in eyes with a marked artificial increase in IOP. Thus, as IOP is raised there is a concomitant and almost equal increase in pressure across the main resistance of the trabecular outflow route.

The pressure gradients for the uveoscleral flow are quite different. The fact that the sclera offers little resistance to flow, and that the choroidal vessels probably easily can absorb the small amount of aqueous delivered, makes it likely that the main resistance is within the ciliary muscle. Removing this resistance by cyclodialysis (surgery to create a hole between anterior chamber and suprachoroidal space) causes a very marked increase in uveoscleral flow in rabbits and monkeys. In addition, the previously mentioned parallel between age-related changes within the ciliary muscle and reduction in uveoscleral flow rate with age supports this assumption. Then the pressure gradient that determines uveoscleral flow is the one between the anterior chamber and the supraciliary and suprachoroidal spaces. This pressure gradient is only a few mmHg and as pressure in the supraciliary and suprachoroidal spaces increases if IOP is increased, there will be no or only a small effect on the pressure gradient for flow through the ciliary muscle when IOP is increased. This will cause an impression of a pressure-independent flow if only IOP is considered. Moreover, compression of the spaces between the ciliary muscle bundles at high IOP will increase resistance to flow and tend to compensate for the small increase in the pressure gradient. At a very low IOP, below 4 mmHg, the pressure gradient over the ciliary muscle becomes very low and uveoscleral flow is much reduced.

Effect of Ciliary Muscle Tone

The tone of the ciliary muscle has an effect on uveoscleral flow, contraction reduces it and relaxation increases it, most likely by its influence on the volume of the extracellular space between the muscle bundles. Thus, atropine increases and pilocarpine reduces uveoscleral flow (see below). The effect has mainly been studied in short-term experiments, but studies on monkeys with or without pretreatment with pilocarpine provided the first support that prostaglandins decreased IOP by increasing flow through the ciliary muscle (see below). In addition, the age-related changes in ciliary muscle morphology and uveoscleral flow mentioned above support the general assumption that the permeability of the ciliary muscle is an important determinant for the rate of uveoscleral flow.

Pharmacology

Cholinergic Agents

The first drugs tested for a possible effect on uveoscleral flow were drugs active on the cholinergic receptors. Pilocarpine markedly reduced uveoscleral flow in human and nonhuman primate eyes, and this was prevented by atropine, which when given alone, has a moderately increasing effect on uveoscleral flow in anesthetized monkeys. Pilocarpine also has a marked effect on the conventional outflow route mediated by the ciliary muscle which, when contracted, separates the lamellae of the trabecular meshwork and reduces outflow resistance. As pilocarpine is a potent ocular hypotensive drug, it is clear that the

IOP-lowering effect on the trabecular meshwork outweighs the reduction in uveoscleral flow and pilocarpine, thus both redirect and increase aqueous outflow.

Adrenergic Agents

Sympathetic tone has no effect on the uveoscleral flow but topical application of epinephrine increases uveoscleral outflow. In monkey eyes, it is almost doubled. Epinephrine is a nonselective adrenergic receptor agonist and the mechanism of action is not clear; part of it may be due to relaxation of the ciliary muscle induced by stimulating the β-adrenergic receptor. Considering the marked effect on uveoscleral flow in anesthetized monkeys, much larger than the effect seen with atropine, one must assume that other adrenergic mechanisms are involved. It seems likely that at least part of the effect is mediated by β-adrenergic receptors since studies both on nonselective (isoproterenol) as well as β_2-adrenergic receptor agonists (terbutaline and salbutamol) have shown that these tend to increase uveoscleral flow in monkey and human eyes. Still, the effect of β-adrenergic receptors on the normal uveoscleral flow rate is probably small and there is no known effect of topically applied β-adrenergic receptor blockers, such as timolol, on uveoscleral flow. It has also been suggested that stimulating the α_2-adrenergic receptor increases uveoscleral flow but results obtained with apraclonidine and brimonidine have been inconclusive.

Prostaglandins

Prostaglandins are a family of local hormones that are involved in many physiological processes and in inflammation. Inhibitors of prostaglandin synthesis have long been used clinically as nonsteroidal anti-inflammatory agents. The development of prostaglandin analogs to reduce IOP has had a marked impact on the treatment of open-angle glaucoma. Prostaglandin, mainly prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), is a powerful ocular hypotensive agent in many species, including rabbits, cats, dogs, and monkeys. In monkey eyes, it is clear that its mechanism of action is mediated through an increase in uveoscleral flow. Among the first observations supporting that prostaglandins affect flow through the ciliary muscle were studies that demonstrated that contraction of the ciliary muscle by pretreatment with pilocarpine reduced or eliminated the effect of prostaglandin $PGF_{2\alpha}$ on IOP. Morphological studies on monkey eyes treated for several days with $PGF_{2\alpha}$ showed enlarged spaces between the ciliary muscle bundles. Thus, it seems clear that prostaglandins remodel the extracellular matrix of the ciliary muscle and reduce flow resistance between the muscle bundles. Since prostaglandins relax the ciliary muscle, part of the early effect may be due to this; however, the long-term effect is due to remodeling of the extracellular matrix. As a consequence, $PGF_{2\alpha}$ and $PGF_{2\alpha}$ analogs do not reach their maximal effect on IOP until after 8–12 h, and after withdrawal of latanoprost, a $PGF_{2\alpha}$ analog, IOP is only slowly returning to pretreatment values over several weeks (**Figure 8**). Studies in human eyes have shown that prostaglandins and prostaglandin analogs have little or no effect on aqueous flow, and it is clear that the effect on IOP observed for the various $PGF_{2\alpha}$ analogs now in clinical use is on outflow. As pointed out above, clinical tonography cannot adequately separate between outflow through the trabecular meshwork and the uveoscleral outflow route, but the effects seen on outflow facility, determined with clinical tonography, have usually been too small to explain the effect on IOP. It seems reasonable that $PGF_{2\alpha}$ analog exerts its main effect also in the human eye by increasing uveoscleral flow.

The mechanism of action behind the remodeling of the ciliary muscle has been studied *in vitro* on cells and muscles from human and nonhuman primate eyes. Thus, topical application of $PGF_{2\alpha}$ as well as latanoprost reduce several collagens in the ciliary muscle of monkeys (**Figure 9**). Increased metalloproteinases (MMPs) have also been recorded in human ciliary muscle cells exposed to $PGF_{2\alpha}$ or latanoprost. The increased expression of MMPs seems to be a consequence of an increased expression of c-Fos in ciliary muscle cells. Factors other than reduction of collagen may well be involved. The shape of ciliary muscle cells exposed to latanoprost changes with alterations in the localization of the cytoskeleton proteins, actin and vinculin.

These changes in the ciliary muscle are likely to be mediated by prostaglandin FP receptors that have been identified in the ciliary muscle. The importance of the FP receptor for the effect on IOP is supported by observations that neither latanoprost nor bimatoprost has any effect on IOP in homozygous knock-out mice. Still, receptors other than the FP-receptor may well have been involved in the effect of $PGF_{2\alpha}$ and the prostanoid

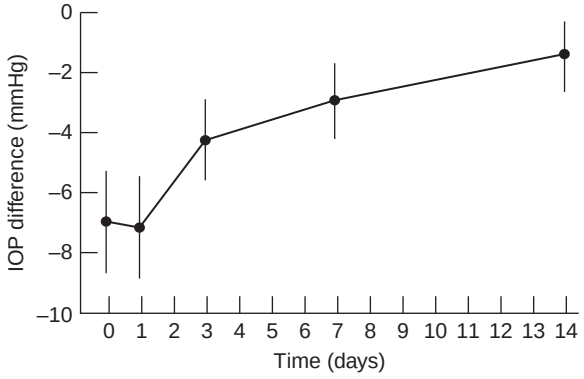

Figure 8 Mean difference (pretreatment IOP – IOP during follow up) versus time after cessation of latanoprost treatment. Error bars denote 95% confidence interval ($n = 26$). Effects on IOP restoration and blood-aqueous barrier after long term treatment with latanoprost in open angle glaucoma and ocular hypertension. *British Journal of Ophthalmology* 81: 370–372.

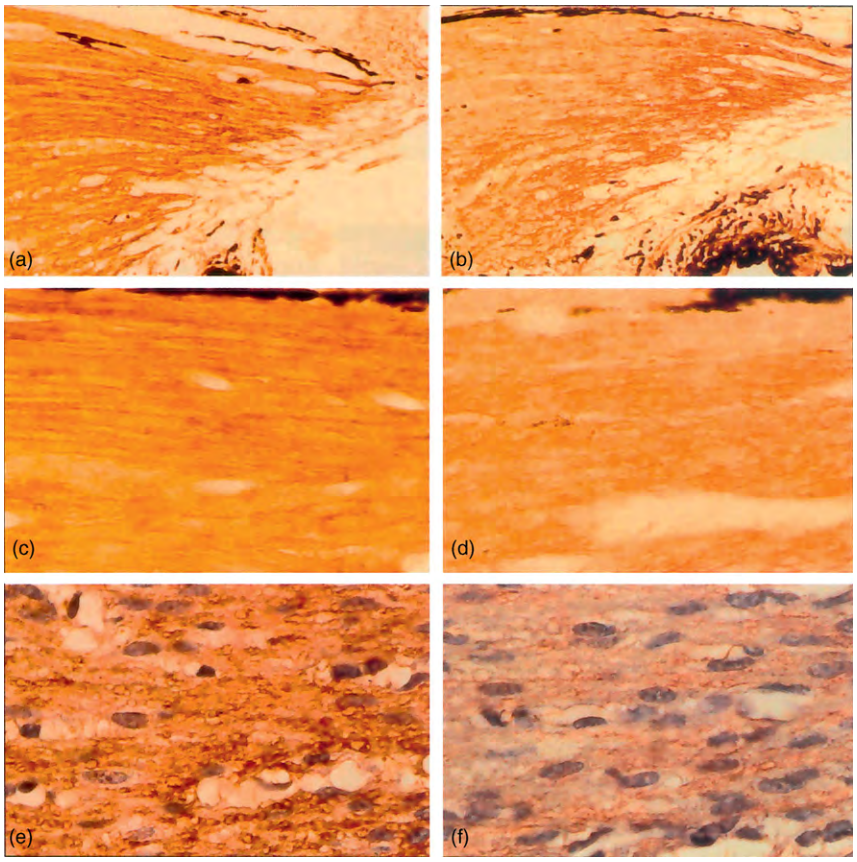

Figure 9 Immunoperoxidase stainings of the ciliary muscle from two cynomolgus monkeys 10 days after unilateral topical treatment with placebo (left panels) or 3 μg day^{-1} latanoprost (right panels). (a)–(d) collagen IV and (e, f) collagen VI. (a, b) ×100; (c)–(f) ×400. Apparent decreases in collagen types IV and VI immunoreactivity are seen in these latanoprost-treated eyes. Adapted from Ocklind, A. (1998). Effect of latanoprost on the extracellular matrix of the ciliary muscle. A study on cultured cells and tissue sections. *Experimental Eye Research* 67: 179–191.

EP_2 receptor agonist butaprost has also been shown to increase uveoscleral outflow in monkeys. Thus, receptors other than the FP receptor may contribute to a reduction of IOP, which may well be the case with $PGF_{2\alpha}$, which is not highly selective for the FP receptor.

Role of Uveoscleral Flow in Normal and Diseased Eyes

The physiological role of the uveoscleral outflow route is not clear. It removes a sizable fraction of aqueous in younger individuals, but seems to be markedly reduced with age, as a consequence of age-related changes in the ciliary muscle. This has no obvious effect on IOP, perhaps due to concomitant, modest, age-related reductions in both aqueous flow and outflow facility. There are also large species differences in the development of uveoscleral flow without any evidence of malfunction. One can then conclude that the lack of an epithelial barrier to prevent flow through the iris and ciliary muscle has no obvious negative consequences.

Thus, the uveoscleral route permits the passage of large molecules between the anterior chamber and the extravascular spaces of the uvea. The small amount of proteins present in aqueous is likely to be a result of some leakage of proteins from the supraciliary space and obviously large molecules in the anterior chamber can go in the other direction as demonstrated by the tracer methods for studies of uveoscleral flow. Albumin injected into the anterior chamber can be found in the suprachoroidal space as far back as the optic nerve (**Figure 10**). This is a consequence of the slow removal of proteins from the suprachoroidal space, mostly by passage through the sclera. For smaller molecules, however, such as drugs that can pass through the cornea the turnover in the suprachoroidal space is much faster and most of them will remain there for less than a minute. Other factors, such as polarity and lipofilicity, will affect the fate of a small molecule in the suprachoroidal space, but as a rule only a very modest improvement in drug concentration in the posterior suprachoroidal space can be expected for molecules small enough to penetrate the cornea.

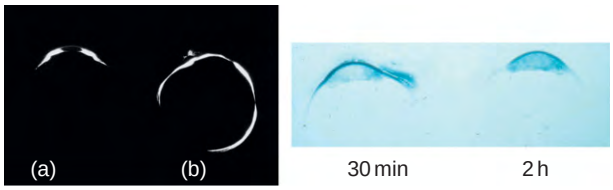

Figure 10 Autoradiograms from monkey eyes. (Right) Labeled albumin had been injected into the anterior chamber in the two eyes, one untreated (a) and one that had received $PGF_{2\alpha}$-1-isopropylester topically (b). (Left) Latanoprost had been applied to the eye 30 min of 2 h earlier. Note that unlike albumin latanoprost cannot be seen in the suprachoroidal space. Courtesy of J. Stjernschantz.

Glaucoma

As uveoscleral flow seems to decrease markedly with age in the human eye, a further reduction would probably have only a modest effect on IOP. It is not known if uveoscleral flow in human eyes with primary open-angle glaucoma (POAG) is reduced and studies in eyes with ocular hypertension (OH) have been inconclusive. In eyes with pseudoexfoliations, however, there is a markedly reduced uveoscleral flow, but the effect on IOP is small, only 2–3 mmHg compared to eyes without pseudoexfoliations. The main role for uveoscleral outflow in glaucoma may then well be the possibility to increase it and thereby reduce IOP.

For clinicians it is obvious that the effect of cholinergic agonists on the ciliary muscle, and its marked effect on uveoscleral flow, makes a combination of prostaglandins and miotics questionable. Still, clinical studies have demonstrated that combined 2% pilocarpine added to latanoprost is additive, and in normal eyes the effect of combining a strong miotic (physostigmin) and latanoprost on IOP was mainly additive. A likely explanation is that an intense contraction of the ciliary muscle is only seen for about 30 min after application of physostigmin permitting the much longer-acting drug, latanoprost, to exert its action on the ciliary muscle.

Uveitis

It is clear that, whether by design or not, the uveoscleral outflow route becomes important in eyes with uveitis. Cells and debris can be expected to congest the conventional outflow route, while prostaglandins released by the inflammation will increase outflow through the uveoscleral outflow route. In experimental uveitis in monkeys, there is a fourfold increase in uveoscleral flow, which in combination with a reduction of aqueous flow to less than half the normal values resulted in ocular hypotony, a condition not unusual in clinical practice.

Vessel Regression

H-P Hammes, University of Heidelberg, Mannheim, Germany

Glossary

Advanced glycation end products (AGE) – Highly reactive metabolic intermediates with the potential to modify structural and functional proteins such as matrix proteins, growth factors, and transcription factors.
Intercellular adhesion molecule 1 (ICAM-1) – It mediates adhesion of leukocytes to endothelial cells and is activated by inflammatory cytokines.
Platelet-derived growth factor B (PDGF-B) – Factor involved in promoting endothelial surival and pericyte recruitment.
Protein kinase C (PKC) – Enzyme transfering phosphates to serin and threonine residues; central role in regulation of important cellular functions such cell growth, survival, permeability, and motility.
Reactive oxygen species (ROS) – Short-lived highly reactive molecules involved in cell signaling under physiological conditions, but also in promotion of tissue damage under disease conditions.
Vascular endothelial growth factor (VEGF) – It describes a group of factors involved in angiogenesis; works also as survival factor and strong permeation factor.

Introduction

Vasoregression or the development of capillary obliteration in the retina of a diabetic patient represents the first and crucial step in the evolution of diabetic retinopathy. Its causal link to chronic hyperglycemia has been firmly established by both, experimental and clinical studies. All subsequent steps of progressive affection, detectable by the retinal expert through direct ophthaloscopy, are responses to this incipient injury. The underlying mechanisms of incipient vasoregression are highly complex, and to date not fully elucidated in their temporal and spatial relevance. However, novel concepts and innovative techniques have given some deeper insight into fundamental processes involved in capillary vasoregression.

Vasoregression in Diabetic Retinopathy

The term vasoregression in the diabetic retina relates to the vasoobliteration of previously unaffected capillaries. The first demonstration of vascular nonperfusion in diabetic retinopathy came from India ink-injection of autoptic (after autopsy) eyes from diabetic patients. The retinal vascular system was visualized by injecting India ink postmortem into the central retinal artery. Areas of exclusive capillary nonperfusion were identified in whole mounts of retinal tissue. Of note, retinal capillary microaneurysms were concentrated in these areas.

Using retinal digest preparations, capillary areas were identified in human diabetic retinae and in diabetic animal models which were devoid of the regular cellular composition of endothelial cells and intramural pericytes. These acellular capillaries were subsequently identified as regions of capillary nonperfusions by several techniques. An example of the widely used diabetic rat model of experimental retinopathy is shown in **Figure 1**.

The mere presence of acellular capillaries is not sufficient to claim the existence of diabetic retinopathy. The occurence of obliterations in isolated capillaries during incipient periods of diabetes is clinically irrelevant due to the density of the capillary network compensating for these minor lesions and the occasional presence of acellular capillaries in retinas of nondiabetic individuals. Importantly, the transition into stages where more capillaries become occluded marks the moment when diabetic retinopathy ensues, and represents the most important event that can elicit hypoxic tissue responses.

The Role of Pericytes in Vasoregression

The first structural capillary lesion observed in animals that is representative for the incipient stages of diabetic retinopathy is pericyte dropout. Pericytes are enigmatic cells. Their diverse ancestry reflected by a lack of a pancellular marker, and their complex functions in the various vascular beds are foiled by the fact that they are uniformely lost prior to the development of acellular capillaries in all experimental diabetic models studied in a diabetic time course. Pericyte loss precedes the formation of acellular capillaries by several months in rodent models and in dogs. In diabetic rodent models, pericyte loss commences 8 weeks after diabetes induction, while increasing numbers of acellular capillaries are not observed before 4–6 months of hyperglycemia.

Under normal conditions – and during developmental angiogenesis – pericyte coverage is thought to stabilize vessels. The concept was developed that pericytes inhibit endothelial cell proliferation requiring direct cell–cell

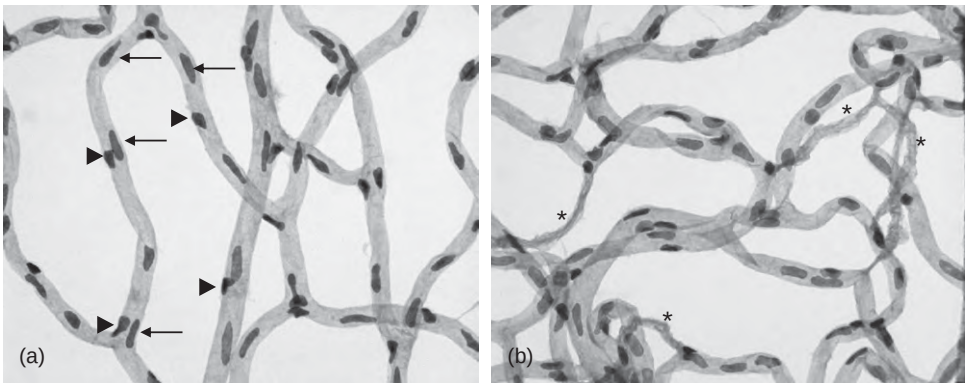

Figure 1 Retinal digest preparation of a nondiabetic (a) and a diabetic (b) rat retina. In the nondiabetic retina, an equal distribution of endothelial cells (arrow) and pericytes (arrowhead) in a uniform basement membrane tube system is depicted. In the diabetic retina (diabetes duration: 26 weeks), acellular occluded capillary segments (asterisks) are visible. Retinal digests were stained with period-acid Schiff base and hematoxyllin. Original magnification 400×.

contacts with activation of latent transforming growth factor (TGF). This general concept was supported by data from mice with a homozygous deletion of platelet-derived growth factor (PDGF)-B. As these mice die around birth when retinal vessels have not yet formed, vessels from the brain were studied. The absence of pericytes correlated with endothelial hyperplasia, increased capillary diameter, abnormal shape and ultrastructure of endothelial cells, and changes in the cellular distribution of junctional proteins such as VE-cadherin, occludin, and ZO-1. As the prenatal lethality of these mice precluded effects of pericyte deficiencies on the retinal vasculature, which in mice develops only postnatally, mice with an endothelium-restricted ablation of PDGF-B were analyzed. In these mice, an inverse correlation of pericyte density with microvascular abnormalities was observed. In particular, when pericyte deficiency was less than 50%, numerous capillary regression profiles were noted. When pericyte deficiency exceeded 50%, retinal neovascularizations occurred. Moreover, retinas of mice heterozygous for PDGF-B yielded a 30% reduction of pericyte coverage coinciding with an approximately 50% increased in the number of acellular capillaries. Thus, the concept prevails that pericytes control endothelial survival and proliferation in a coverage-dependent manner.

However, it must be noted that pericytes are absent from extended areas of diabetic capillaries without vasoproliferative activities. On the other hand, microaneurysms – which are considered as abortive attempts of neovascularizations can harbor pericytes – suggest that the link between pericyte loss and endothelial cell response may be more complex in the human diabetic retina.

The Mechanisms Leading to Pericyte Dropout

Pericyte apoptosis

For many years, the toxicity of metabolic intermediates accumulated in pericytes was considered primary in the sequence of events leading to pericyte dropout. For example, advanced glycation end products (AGEs) were found to accumulate in pericytes either upon injection in normal animals, or as the result of endogenous excess formation in diabetic animals. However, inconsistency between the time course of AGE accumulation (delayed) and pericyte loss (early) in animal models precluded a causal link. Differential susceptibility toward modified or irregular plasma proteins and the selective activation of proapoptotic pathways were documented as further mechanisms inducing diabetic pericyte loss. Thus, the loss of pericytes by apoptosis is considered one important mechanism.

Pericyte migration

Alternatively, migration of pericytes away from their allocated position in the capillary has been proposed as a mechanism of early pericyte loss preparing for diabetic vasoregression. In this context, the angiopoietin/Tie receptor system which is involved in pericyte recruitment during retinal vessel development and stabilization is important. The interaction of angiopoietin 1 (Ang-1) with Tie-2 is crucial for the timely and coordinated recruitment of pericytes to the developing vascular system. The notion that angiopoietin-2 acts as natural antagonist of Ang-1 led to the hypothesis that diabetic pericyte loss could be the result of a change of the Ang-1/Ang-2 ratio. Thus, the expression of Ang-1 and-2 was studied in a diabetic rat model, in which the onset of pericyte dropout was known. It was found that Ang-2 which is almost absent in the mature retinal vasculature, was excessively upregulated in a diabetic rat retina prior to the onset of pericyte dropout. Injection of recombinant Ang-2 into the vitreous of nondiabetic rats reproduced pericyte dropout within days. Studies in mice which lacked 50% of Ang-2 gene dose demonstrated the prevention of diabetic pericyte loss, suggesting that hyperglycemic Ang-2 overexpression was crucially involved in pericyte loss. Furthermore, constitutive overexpression of

Ang-2 in photoreceptor cells reduced pericyte coverage in the deep capillary layers of the retina during retinal development.

The next question is how hyperglycemia-induced upregulation of Ang-2 contributes to retinal pericyte loss. Quantitation of pericyte subpopulations in diabetic retinae demonstrated that only one subset of pericytes was lost upon hyperglycemic exposure over time, that is, pericytes positioned on straight parts of capillaries. Notably, pericytes which loosened the contact to intact capillaries were found more frequently, both – in diabetic mice and in mice with retinal overexpression of Ang-2 – while Ang-2-deficient mice completely lacked the hyperglycemia-induced increase in pericyte migration. These data support the hypothesis that pericyte loss pertains to one specific pericyte subpopulation, and may involve active migration.

Rather than opposing other concepts such as pericyte apoptosis, it complements them. Ang-2 expression is induced by hypoxia, cytokines, and, as noted recently, by hyperglycemia. A brief appraisal of the biochemistry of diabetic vasculopathy should be prepended.

The Biochemistry of Microvascular Damage and Vasoregression

The four biochemical pathways that have been discussed over years to be involved in the damage of blood vessels by chronic hyperglycemia are an increased activity of the polyol-pathway, the activation of PKC-isoforms by *de novo* synthesis of diacylglycerol, an increased flux through the hexosamine-pathway, and the excess flow of glycolytic intermediates to form AGEs. By increasing sorbitol and fructose levels, and reducing the cofactor nicotinamide adenine dinucleotide phosphate (NADPH) necessary to replenish an important intracellular antioxidant, glutathion, the activation of the polyol pathway was thought to reduce vascular resistance to increased oxidative stress. The effects of PKC activation were summarized as follows: blood-flow alterations through changes in the balance of vasoconstrictors and vasodilators; increased vessel permeability through activation of vascular endothelial growth factor (VEGF); vascular occlusion through increased matrix production and decreased fibrinolytic activity; and perpetuation of oxidative stress through activation of prooxidative pathways. The intracellular overproduction of AGE precursors appears to damage vascular cells by three mechanisms: (1) modification of intracellular proteins including those implicated in gene transcription; (2) modification of extracellular matrix molecules after diffusion out of the cells; and (3) activation of AGE receptors, causing production of inflammatory cytokines and growth factors affecting vessels. Finally, the increased hexosamine pathway activity was found to result in pathological changes in gene transcription by modifications of transcription factors through the hexosamine pathway product *N*-acetyl-glucosamine.

A novel concept was recently proposed, linking metabolic changes associated with increased intracellular AGE (most prominently methylglyoxal) with altered transcription of genes relevant in vascular remodeling such as Ang-2. Increased glycolytic flux – as observed in cells exposed to high glucose and unable to downregulate glucose transport – caused methylglyoxal modifications of the transcriptional corepressor mSin3A. These modifications caused the recruitment of the O-GlcNAc (O-glycosidic linkage) transferase to mSin3A, complexed with the transcriptional suppressor Sp3, which then modified Sp3 by O-linked *N*-acetylglucosamine. Modified Sp3 was less bound to a glucose-responsive GC box in the Ang-2 promoter resulting in the upregulation of Ang-2. The mechanism was found in renal microvascular endothelial cells as well as in retinal Müller cells.

Endothelial Damage and Loss Leading to Vasoregression

As mentioned, chronic hyperglycemia has been identified as the major underlying cause of diabetic microvessel damage. The explanation that endothelial cells are the primary target of hyperglycemia-induced injury was based on *in vitro* studies showing that endothelial cells in contrast to smooth muscle cells were unable to downregulate inward glucose transport in the presence of high ambient glucose. The resulting increased flux through glycolysis and the impact on mitochondrial reactive oxygen species (ROS) production has been identified as the unifying mechanism linking the four seemingly independent pathways with chronic hyperglycemia as the primary event. In cells exposed to normal ambient glucose, glucose is metabolized through glycolysis and the tricarbon cycle to generate electron donors for the mitochondrial respiratory chain that finally generated adenosine triphosphate (ATP). In hyperglycemic cells, increased flux through glycolysis and the tricarboxylic acid (TCA) cycle generates a voltage gradient of electrons surpassing a threshold which is blocked at the transition to complex III of the mitochondrial electron-transport chain. From complex III, the surplus of electrons is purported to coenzyme Q together with molecular oxygen-producing superoxide. The mitochondrial isoform of superoxide dismutase detoxifies this radical via hydrogen peroxide to water in the presence of oxygen. The link between the four biochemical pathways and the mitochondrial overproduction of ROS was made when it became evident that an important change in hyperglycemic cells and in experimental animals was the reduced activity of the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH).

When examining for biochemical modifications of the enzyme, it was observed that hyperglycemia-induced superoxides caused polymers of adenosine diphosphate (ADP)-ribose to attach to the enzyme and reduce its activity. These changes were prevented with the inhibition of superoxide generation, and with the inhibition of the nuclear enzyme poly-ADP-ribose polymerase (PARP) using a specific PARP inhibitor. The latter is activated upon DNA strand brakes known to form in hyperglycemic cells. Reduced GAPDH activity induced by PARP activates the biochemical pathways by increasing intermediates such as diacyl-glycerol (protein kinase C (PKC) pathway), glyceraldehyde-3-phosphate (AGE pathway), fructose-6-phosphate (hexosamine pathway), and intracellular glucose (sorbitol pathway). Experimental proof-of-concept was provided by studies demonstrating that endothelial cells which lack a functional mitochondrial electron transport chain did not produce ROS when exposed to high ambient glucose, and that ROS overproduction was prevented upon overexpression of uncoupling protein (UCP)-1 or Mn-superoxide dismutase (SOD). Together, these data indicate that hyperglycemia leads to increased oxidative stress from mitochondrial sources which activate biochemical abnormalities known to induce endothelial damage and, ultimately, vasoregression.

The Mediators of Vasoregression

The ultimate process leading to capillary obliteration has yet to be determined. Since the primary histological step is pericyte dropout, the definitive damage converting a perfused into a nonperfused capillary must affect the endothelial cell. As outlined above, oxidative stress and the progressive exhaustion of antioxidative defense systems which are upregulated during the early course of diabetic retinopathy may account for the stepwise, exponential increase in capillary obliteration. Mechanisms thought to contribute to capillary dropout include increasing lumen narrowing by basement membrane thickening, cumulative deposition of cellular debris from platelets and leukocytes, endothelial detachment from the increasingly modified matrix, and endothelial death by apoptosis.

Basement membrane (BM) thickening as a cause of vaso-obliteration is no longer discussed since the overproduction of matrix material by endothelial cells and pericytes is now considered an epiphenomenon rather than a cause. It has been demonstrated that the relative degree of luminal narrowing, and the time course of BM-thickening versus the formation of acellular capillaries precluded a significant causal contribution.

Direct evidence for a causal role of platelet aggregation or deposits of coagulation proteins has been scarce. Platelet aggregation and fibrin deposits have been observed in postmortem eyes of diabetic individuals and were twice as frequent as in nondiabetic individuals. In experimental diabetes, microthromboses were only reported in conjunction with severe hypertension. In diabetic animals and in humans, administration of platelet inhibitors or aspirin at low doses were unable to prevent capillary obstruction, suggesting that platelet aggregation/microthrombosis was not a primary mechanism of progressive capillary dropout.

Schmidt–Schönbein's group first reported that activated leukocytes adhere and possibly obliterate diabetic retinal capillaries. Further studies showed that leukocytes both adhere to and transmigrate through the capillary wall – a process that was associated with increased vascular leakage and that could be blocked by an antibody against intracellular adhesion molecule-1 (ICAM-1). Thus, leukostasis seemed to coincide and correlate with the onset of diabetic vascular damage. Studies in diabetic monkeys which develop retinopathy similar to humans revealed a higher number of neutrophils in the retina. Of note, neutrophils were preferentially located in areas of capillary dropout and microaneurysms, supporting the role of leukostasis in capillary nonperfusion. Subsequently, several studies indicated the preponderance of the 2-integrin-ICAM-1 system in the interaction between neutrophils and endothelial cells. In particular, the formation of acellular capillaries was reduced in diabetic ICAM 1/and CD 18/mice which led to the conclusion that chronic leukostasis in the retina, and the resulting leukocyte-mediated endothelial injury was causal for vasoregression. However, it has to be considered that despite the strong correlation between the apparent leukocyte–endothelial interaction and the occurrence of vasoregression, it is still unclear whether there is a causal relationship – or an epiphenomenon – since several questions remain to be clarified. Usually, leukocyte–endothelial interactions do not cause damage to the endothelial monolayer even under inflammatory conditions. Leukocytes transmigrate through endothelial cells without affecting junctional integrity. As the leukocyte–endothelial interactions in the retina reportedly result in endothelial injury and death, in direct injury of supportive cells like pericytes, and in the opening of tight junctions, this interaction must be unique to the retina, as opposed to other tissues where the same interactions do not cause any vascular damage. The glucose dependence of the interaction is questioned by the fact that nonhyperglycemic, insulin-resistant models exhibit increased leukostasis, and that increased interactions can occur at glucose levels as low as 5.5 mmol. Thus, leukostasis and the consequences of the interactions with endothelial cells is possibly less evident as suggested by recent studies.

A less well-studied, but possible mechanism leading to acellularity of capillaries in the retina, is endothelial cell detachment. Proper cell adhesion is dependent on a variety of mechanisms for each of which profound

diabetes-induced changes were reported. These include changes in the composition of extracellular matrix molecules, posttranslational modification by AGE, and modifications of binding sites for adhesion molecules. The levels, compositions, and binding capacities of heparan sulfate proteoglycans are affected by hyperglycemia leading to changes in the availability of survival promoting angiogenic factors. Intracellularly stored growth factors such as basic fibroblast growth factor (bFGF) are modified by intracellular glycation, and AGE formation, while the activation of the hexosamine pathway cooperates in the upregulation of Ang-2 which reduces the growth promoting action of Ang-1. In endothelial cells, junctional proteins and integrins may become altered due to hyperglycemia resulting in impaired attachment to the underlying matrix. Together, the mutual interaction of endothelial cells and the underlying matrix in the diabetic capillaries can result in a traceless loss of endothelial cells compensated by neighboring endothelial cells or by anchoring of bone marrow-derived precursor cells. A very low proliferation index of capillary endothelial cells, and the fact that only endothelial precursor cells of nondiabetic, but not from diabetic, origin can replace detached endothelial cells may explain the progressive failure to compensate for endothelial damage and loss. An increased number of circulating endothelial cells (also termed endothelemia) has been reported in diabetic patients and animal models. However, the retina as origin has not been specified.

Finally, endothelial cell apoptosis as the result of increasing damage and reduced survival promotion has been found in retinas of both, diabetic humans, and in diabetic rodent models. In experimental models, apoptosis of vascular cells becomes only apparent at the time when acellular capillaries increase in numbers, that is, they do not precede their formation. Despite the low numbers of apoptotic endothelial cells in a given retina, and the technical limitation to detect the cumulative damage exerted by apoptosis to retinal capillaries over time, the process, in general, may be sufficient to account for capillary degeneration.

Prevention of Vasoregression

The numerous mechanisms outlined above that participate in capillary obliteration in the diabetic retina were addressed in studies with equally numerous readouts. Therefore, the final part of this article focuses on those experimental therapies that affected vasoregression in animal (preferably rat and mouse) models.

Biochemial Pathway Inhibitors

Aldose reductase inhibitors have been extensively studied, using many different chemically unrelated compounds. Recently, a significant effect of sorbinil on capillary obstruction was recently reported in diabetic rats, while a study in dogs using the same drug did not inhibit vasoregression. The crucial question to explain the existing controversies about the relative importance of this pathway is to what extent the respective compound inhibited flux through the pathway (as compared with absolute, but static levels of aldoses).

PKC inhibitors have been used in rat models to demonstrate corrections on functional readouts such as vascular permeability and leukostasis. However, no data have been provided as to whether PKC inhibition is capable to prevent capillary regression.

Inhibitors of AGE formation had a substantial effect on vascular regression in several model systems. Aminoguanidine – which traps highly reactive dicarbonyls such as methylglyoxal – was the first to be tested in various animal models. Aminoguanidine reduced tissue levels of AGEs, inhibited extracellular crosslinks, and intracellular sequelae of AGE formation. It consistently prevented the formation of acellular capillaries by approximately 80% and the loss of pericytes to a lesser degree. It was also found that aminoguanidine inhibits oxidative stress, the activation of PKC and the upregulation of VEGF. Thus, the protection from diabetic vascular regression by aminoguanidine may be the result of the disruption of several pathogenetically important abnormalities.

Pyridoxamine was originally described as a post-Amadori inhibitor of the formation of AGEs, but also inhibits the formation of advanced lipoxidation end products (ALEs) on protein during lipid-peroxidation reactions. Treatment over 28 weeks of 1 g l^{-1} in the drinking water reduced diabetic capillary regression in diabetic rats by 71%. Whether this treatment also inhibits pericyte loss is unclear to date.

LR-90 (methylene bis [4,4prime-(2 chlorophenylureido) phenoxyisobutyric] acid) was developed as a member of a new class of multistage glycation inhibitors. *In vitro*, LR-90 exhibited general antioxidant properties by inhibiting metal-catalyzed reactions and ROS and reactive carbonyl species (methlyglyoxal and glyoxal) generations. The compound also prevents AGE-protein cross-linking reactions. It was recently shown to reduce both – acellular capillaries and the diabetic loss of pericytes.

No hexosamine pathway inhibitor has been developed to be tested in diabetic retinopathy models to date.

Metabolic Signal Blockers

Novel therapeutic approaches for the prevention and treatment of diabetic retinopathy were based on the unifying hypothesis, in particular metabolic signal blockers, and catalytic antioxidants.

The first class of new compounds emerged from an obvious feature of the unifying hypothesis, that is, the substrate accumulation upstream of the inhibited enzyme

GAPDH and shunted into the four biochemical pathways mentioned before. As two of the accumulating glycolytic metabolites – fructose-6-phosphate and glyceraldehyde-3-phosphate – are also products of the transketolase reaction, it was reasoned that the activation of transketolase should reduce the pathway overload f.e. on AGE formation, if the substrate flux could be directed toward the pentose phosphate pathway. Benfotiamine was selected because of its high activating efficiency *in vivo*, and was given to diabetic rats for 9 months. The treatment completely inhibited the formation of acellular capillaries. The effect of benfotiamine was also tested in a secondary interventional approach. The failure of many therapeutic concepts to translate into human diabetic retinopathy is often attributed to the secondary intervention character of human compared with animal studies. Benfotiamine (80 mg kg^{-1}) was given for 26 weeks to diabetic animals following a 26-week period of no treatment. Compared with untreated diabetic animals, secondary intervention with benfotiamine halted further progression of capillary obliteration almost completely, suggesting that the mode of action interfered with mechanisms that cause hyperglycemic memory.

A second concept in the group of metabolic signal blockers is PARP inhibition. PARP activation, as described above, is the result of mitochondrial overproduction of ROS and the cause for the inhibition of the glycolytic enzyme GAPDH. PARP inhibitors have been tested for microvascular damage, including diabetic retinopathy. PJ-34 – a potent PARP inhibitor – was given for 9 months to diabetic rats, and inhibited the development of acellular capillaries and pericyte ghosts. *In vitro* data suggested that PARP inhibition blocked the endothelial activation of nuclear factor kappa B (NFκB) and downstream increases of proinflammatory cytokine production while unpublished *in vivo* data suggest that PARP inhibition affects AGE formation and downstream activation of Ang-2.

Tenilsetam [(+)-3-(2-thienyl)-2-piperazinone] is a dicarbonyl scavenger (i.e., an AGE inhibitor) in the millimolar range and a transition metal ion chelator in the micromolar range. It was administered to diabetic rats at a dose of 50 mg kg^{-1} body weight, and reduced the formation of acellular capillaries by 70%. However, it did not affect pericyte loss. This study is the first of its kind to suggest that the primary target of treatment is the endothelial cell. In further *in vitro* studies, it was found that tenilsetam, given in a dose too low to exert an anti-AGE action, stimulated VEGF production in endothelial cells. Although VEGF is upregulated in the diabetic rat retina suggesting an increased need for survival factors rather than a stimulus for neovascularization, beneficial effects on vasoregression were observed when compounds were given that either reduced (aminoguanidine) or increased

(tenilsetam) retinal VEGF. Thus, more studies are needed to dissect the role of VEGF in the preservation of diabetic vascular obstruction.

Catalytic Antioxidants

Increased mitochondrial ROS due to chronic hyperglycemia favors a second class of compounds to be tested for its efficacy against diabetic capillary dropout, that is, antioxidants. Classical antioxidants are less favorable as they work stochiometrically and do not penetrate into the compartments of primary ROS overproduction. Only when given in combination, did antioxidants such as a-tocopherol, Trolox, or *N*-acetylcysteine prevent acellular capillary formation. Interestingly, two antioxidant compounds – nicanartine and probucol – failed to prevent the formation of acellular capillaries over 6 months, but significantly reduced pericyte loss, indicating that some of the ROS-dependent mechanisms leading to pericyte loss are amenable to antioxidant therapy, while many others linked to endothelial damage are resistant to classical antioxidant treatment.

One antioxidant, R-alpha-lipoic acid (ALA) is an exception because of three important aspects: it distributes to the mitochondria, it is regenerated by hyperglycemia-dependent mechanisms, and it has a very low redox potential. In fact, apart from a beneficial effect on parameters of oxidative stress, NFκB activation, and Ang-2 overexpression, long-term ALA treatment substantially reduced acellular capillaries, and pericyte loss in diabetic rats.

An obvious additional candidate to be used for the prevention of vasoregression is the mitochondrial form of superoxide dismutase. SOD mimetics have not yet entered the feasibility phase of long-term experiments in models. Therefore, animals with genetic gain- and loss-of-function modifications were studied for retinal pathology in diabetes. Unfortunately, meaningful results in particular with regard to the prevention of vasoregression were not to be achieved since both, SOD-overexpressing as well as SOD-deficient mice were prone to retinal degeneration.

A variety of chemically defined compounds have been tested in animal models. Furthermore, growth factors, antibodies against growth factors and inflammatory cytokines, and antisense oligos have been tested with varying results – in particular, on vasoregression.

Table 1 summarizes the effects of pharmacological intervention with a focus on acellular capillaries and pericyte dropout.

Vitreous Anatomy, Aging, and Anomalous Posterior Vitreous Detachment

J Sebag, University of Southern California, Los Angeles, CA, USA

Glossary

Anomalous posterior vitreous detachment – The result of vitreous gel liquefaction without concurrent dehiscence at the vitreo-retinal interface.
Hyalocytes – Mononuclear phagocytes embedded within the posterior vitreous cortex.
Pharmacologic vitreolysis – The use of drugs (enzymes and nonenzymatic agents) to induce gel liquefaction (liquefactants) and dehiscence at the vitreo-retinal interface (interfactants) resulting in prophylactic posterior vitreous detachment (PVD).
Posterior vitreous cortex – The outer shell of the vitreous with a higher density of collagen fibrils and hyaluronan than elsewhere in the vitreous body.
Synchisis – Liquefaction of the gel vitreous.
Syneresis – Collapse of the gel vitreous that results from profound synchisis.
Vitreoschisis – Splitting of the posterior vitreous cortex that results from anomalous PVD that leaves the outermost layer of vitreous attached to the retina, usually in the macula.

Invisible by design (**Figure 1**), vitreous was long unseen as an important part of the eye. In recent years, however, the roles of vitreous in ocular physiology and the pathobiology of various retinal diseases have been increasingly appreciated. As a result, the contribution of vitreous to blindness is being treated with ever-evolving therapeutic modalities, for the most part surgical. The future, however, will see the use of pharmacologic agents for therapy and prevention. To do so successfully requires an understanding of vitreous anatomy and biochemistry as well as an appreciation of how these change with aging and disease. In particular, many retinal diseases can now be conceived as anomalies in the process of posterior vitreous detachment (PVD). This unifying concept of vitreo-retinal diseases is known as anomalous PVD.

Vitreous Anatomy

Vitreous Body

In an emmetropic adult human eye (**Figure 2**), vitreous is approximately 16.5 mm in axial length, with a depression just posterior to the lens (patellar fossa). The hyaloideocapsular ligament (of Weiger) is the annular region 1–2 mm in width and 8–9 mm in diameter where vitreous is attached to the posterior lens. Erggelet's or Berger's space is at the center of the hyaloideocapsular ligament. Arising from this space and coursing posteriorly through the central vitreous is Cloquet's canal – the former site of the hyaloid artery in the primary vitreous. The former lumen of the artery is an area devoid of vitreous collagen fibrils, surrounded by multi-fenestrated sheaths that were previously the basal laminae of the hyaloid artery wall. Posteriorly, Cloquet's canal opens into a funnel-shaped region anterior to the optic disk known as the area Martegiani.

Dissection of the outer layers of the eye (sclera, choroid, and retina) can be performed and the naked vitreous body can be maintained intact and attached to the anterior segment of the eye (**Figure 1**). Studies have identified that within the adult human vitreous there are fine, parallel fibers coursing in an anteroposterior direction (**Figure 3**). These fibers, which probably represent bundles of vitreous collagen fibrils, attach into the vitreous base where they splay out anterior and posterior to the ora serrata. As the peripheral fibers course posteriorly, they are circumferential with the vitreous cortex, while central fibers undulate in a configuration parallel with Cloquet's canal. The fibers are continuous and do not branch. Posteriorly, these fibers attach into the posterior vitreous cortex, but not the retina.

Ultrastructural studies have demonstrated that vitreous collagen tends to be organized into bundles of parallel fibrils (**Figure 4**). It has been hypothesized that, initially, the collagen fibrils within these bundles are spaced apart by the chondroitin sulfate chain of type IX collagen, but with aging the chondroitin sulfate is lost and there is progressive aggregation of the fibrils leading to the formation of thick fibers. Eventually, the fibers attain sufficiently large proportions that they can be visualized *in vitro* (**Figures 3** and **4**) and clinically. The areas adjacent to these large fibers have a low density of collagen fibrils in association with hyaluronan (HA) molecules and, therefore, do not scatter light as intensely as the larger bundles of aggregated collagen fibrils. Furthermore, these adjacent areas offer relatively little resistance to bulk flow through vitreous, since they are largely occupied by hydrated HA.

Vitreous Base

The vitreous base is a three-dimensional zone that extends 1.5–2 mm anterior to the ora serrata, 1–3 mm posterior to the ora serrata, and several millimeters into the vitreous

body itself. The vitreous base posterior to the ora serrata varies in width depending on age. More than half of the population over 70 years of age have a posterior vitreous base wider than 1.0 mm. The width increases with increasing age to nearly 3.0 mm, bringing the posterior border of the vitreous base closer to the equator. This widening of the vitreous base is most prominent temporally. It has been proposed that the intra-retinal synthesis of collagen fibrils that penetrate the internal limiting lamina of the retina and splice with vitreous collagen fibrils, which may explain the increased vitreo-retinal adhesion at the vitreous base, traction, and retinal tears/detachment.

Vitreous Cortex

The vitreous cortex is defined as the peripheral shell of the vitreous body that courses forward and inward from the anterior vitreous base to form the anterior vitreous cortex, and posterior from the posterior border of the vitreous base to form the posterior vitreous cortex (**Figure 5**).

The anterior vitreous cortex, also called the anterior hyaloid face, begins about 1.5 mm anterior to the ora serrata. Here, the vitreous collagen fibrils are parallel to the surface of the cortex and are densely packed with looser collagen-fibril packing in the subjacent vitreous, giving the appearance of lamellae. The anterior vitreous cortex varies in thickness from 800 to 2000 nm with connections to the loose fibrils in the anterior vitreous and multiple interconnections with a branching fibrillar network in the posterior chamber.

The posterior vitreous cortex is 100–110 μm thick and consists of densely packed collagen fibrils. The organization of these collagen fibrils is lamellar, presenting a sheet-like appearance on immunohistochemistry (**Figure 6**). These potential tissue planes are important as sites of tissue separation during PVD (see Section Vitreoschisis) as well as during surgery while peeling membranes off the macula.

Hyalocytes (**Figure 7**) are bone marrow-derived cells widely spread apart in a single layer situated 20–50 μm from the retina in the posterior vitreous cortex and basal vitreous. The highest density of hyalocytes is in the region of the vitreous base, followed next by the posterior pole, with the lowest density at the equator.

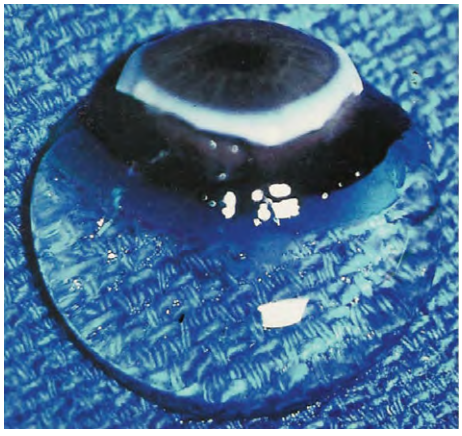

Figure 1 Human vitreous structure in a 9-month-old child.

Vitreoretinal Interface

There is a basal lamina on the inner surface of the retina to which the cortical and basal vitreous are attached. The basal lamina posterior to the ora serrata, known as the internal limiting lamina (ILL) of the retina, is actually the basement membrane of retinal Müller cells. Immediately

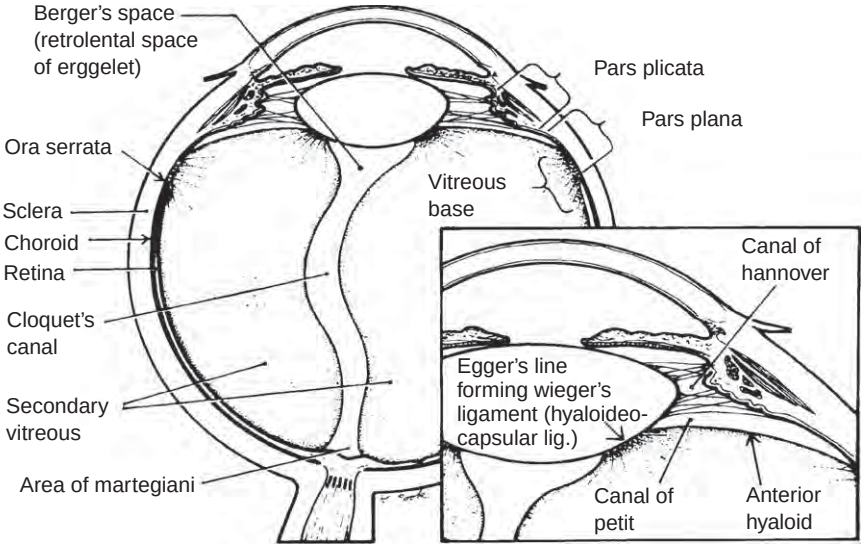

Figure 2 Schematic diagram of vitreous anatomy.

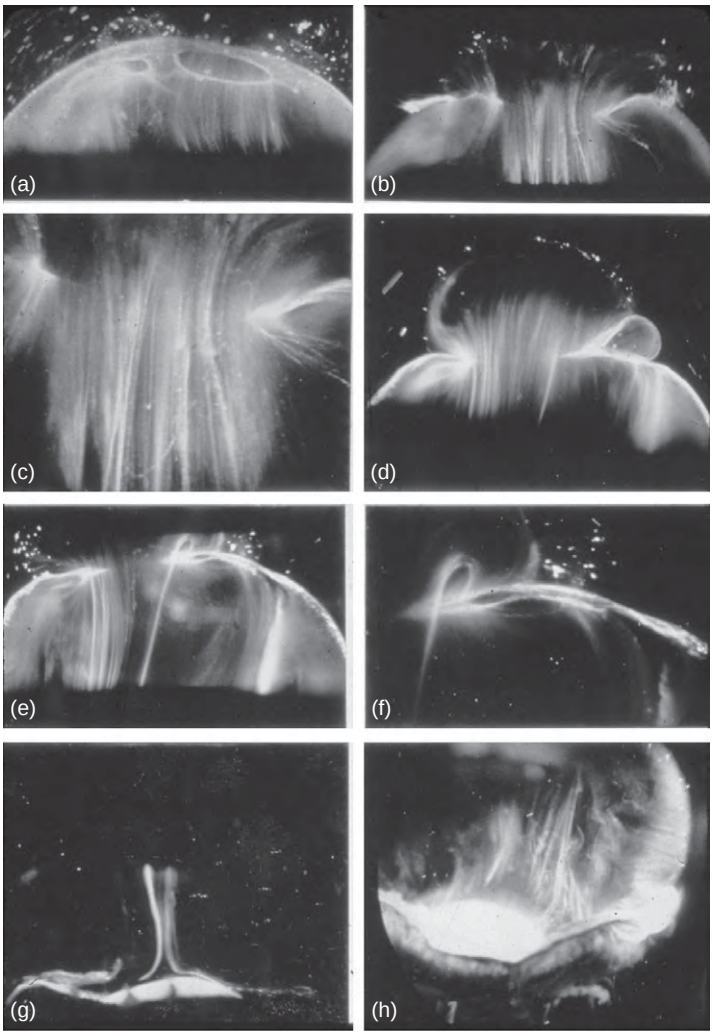

Figure 3 Dark-field slit-lamp microscopy of human vitreous. (a) Left eye of a 52-year-old man. The prepapillary hole in the vitreous cortex is to the left. (b) A 57-year-old man in whom a large bundle of prominent fibers is seen coursing anteroposteriorly and entering the preretinal space through the premacular vitreous cortex. (c) Same view as upper right at higher magnification. (d) A 53-year-old woman in whom there is posterior extrusion of vitreous out the prepapillary hole (to the right) and premacular (large extrusion to the left) vitreous cortex. Fibers course anteroposteriorly in the central vitreous and out into the preretinal, space. (e) Same specimen as second row right. A large fiber courses posteriorly from the central vitreous and inserts into the premacular vitreous cortex. (f) Same view as (e) at higher magnification. The curvilinear appearance is due to traction by vitreous extruding into the retro-cortical space. Because of its attachment to the posterior vitreous cortex, the fiber arcs back to its point of insertion. (g) Cloquet's canal is seen in this 33-year-old woman, forming the retro-lental space of Berger. (h) A 57-year-old man in whom the lens are surrounded by fibers coursing anteroposteriorly that insert into the vitreous base. These fibers splay out to insert anterior and posterior to the ora serrata.

adjacent to the Müller cell is a lamina rara (0.03–0.06 μm thick) that demonstrates no species variations, nor changes with topography or age. The lamina densa (i.e., the basement membrane itself) is thinnest at the fovea (0.01–0.02 μm) and disk (0.07–0.1 μm). It is thicker elsewhere in the posterior pole (0.5–3.2 μm) than at the equator or vitreous base. The existence of lamellae within the ILL has relevance to the pathophysiology and surgical repair of macular holes.

The vitreous is known to be most firmly attached at the vitreous base, at the disk and macula, and over retinal blood vessels. The posterior aspect (retinal side) of the ILL demonstrates irregular thickening the farther posteriorly one goes from the ora serrata. So-called attachment plaques between the Müller cells and the ILL have been described in the basal and equatorial regions of the fundus but not in the posterior pole, except for the fovea. It has been hypothesized that these plaques develop in response to vitreous traction on the retina. The thick ILL in the posterior pole dampens the effects of this traction except at the fovea where the ILL is thin. The thinness of the ILL and the purported presence of attachment plaques at the central macula could explain the predisposition of this region to changes induced by traction.

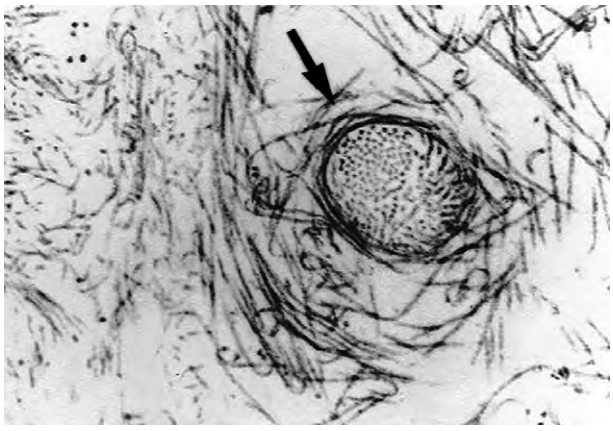

Figure 4 Transmission electron microscopy of human vitreous. Transmission electron microscopy of human vitreous demonstrates collagen fibrils organized in a bundle of parallel fibrils as seen here in cross-section.

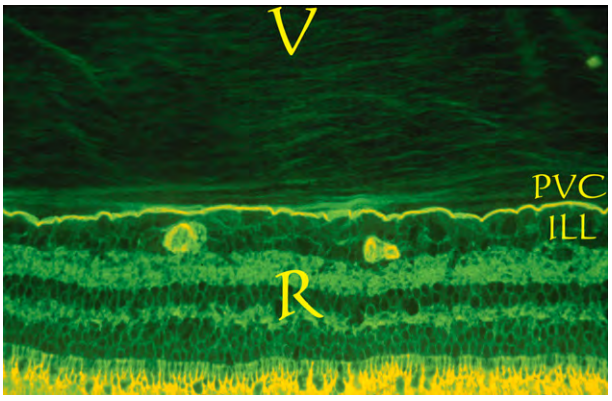

Figure 6 Immunohistochemistry of the human vitreoretinal interface demonstrates intense staining of the internal limiting lamina (ILL) with anti-ABA antibodies. This lectin binding is also evident, although less intense, in the lamellae of the posterior vitreous cortex (PVC, above the bright line in the middle – which is the ILL). Figure 7 Ultrastructure of the human hyalocyte. A mononuclear cell is seen embedded within the dense collagen fibril (black C) network of the vitreous cortex. There is a lobulated nucleus (N) with dense marginal chromatin (white C). In the cytoplasm there are mitochondria (M), dense granules (arrows), vacuoles (V), and microvilli (Mi) (×1670). Courtesy of JL Craft and DM Albert, Harvard Medical School, Boston.

Aging Changes

Throughout life, there are changes in vitreous structure (Figure 8). During late prenatal and early postnatal stages, there are no structures within the vitreous body other than the remnants of the hyaloid artery oriented

toward the prepapillary region (**Figure 8**, top row). The vitreous body is relatively small and has an overall dense appearance with marked density at the outermost shell corresponding to the vitreous cortex. The generalized density of the vitreous likely relates to the fact that, at this stage of development, collagen and proteoglycan(s) other than HA are the principal structural components. HA synthesis begins following birth, increasing transparency by the aforementioned mechanisms. During childhood, only the vitreous cortex scatters incident light and thus appears dense upon dark-field slit microscopy. There are no visible fibers within the vitreous until middle age (**Figures 3** and **8** – middle row). During old age, these fibers become thickened and tortuous, associated with many pockets of liquid vitreous and a collapsed (syneretic) appearance (**Figure 8**, bottom row). These changes are the result of age-related biochemical alterations in the composition and organization of the molecular components that simultaneously result in vitreous liquefaction and fiber formation. Pockets of liquid vitreous have classically been called lacunae. In addition to having a low density of collagen during youth, the central vitreous is the first region to undergo liquefaction during middle age. A large autopsy study of human eyes found that more than one-half of the vitreous was liquefied in 25% of persons in the age range of 40–49 and that this increased to 62% of individuals in the age range of 80–89. In another study, ultrasonography was used *in vivo* to detect echoes from gel–liquid interfaces in 444 normal human eyes and observed echoes in 5% of young persons, in more than half of those in the age range of 51–60, and in more than 80% of persons over 60 years. However, there is evidence of liquid vitreous following the age of 4 years and, by the time the human eye reaches its adult size (age range: 14–18 years), approximately 20% of the total vitreous volume consists of liquid vitreous.

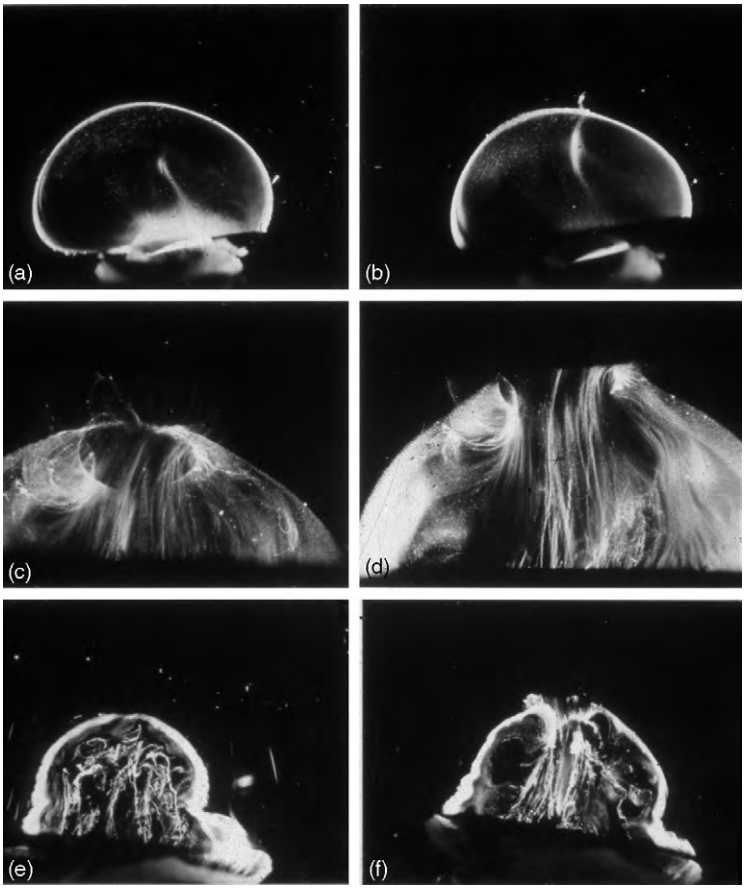

Figure 8 Changes caused by aging in human vitreous structure. (a, b) Dark-field slit microscopy of the posterior and central vitreous in a 33-week-old human embryo shows considerable light scattering arising from the vitreous cortex, due to densely packed collagen fibrils. In the central vitreous is the remnant of the hyaloid artery oriented toward the prepapillary posterior vitreous cortex. This structure is destined to become Cloquet's canal. (c, d) Vitreous structure in adults is characterized by macroscopic fibers with an antero-posterior orientation, inserting into the vitreous base. (e, f) In old age, there is aggregation of the fibers into tortuous structures with adjacent pockets of liquid vitreous that ultimately form lacunae (left side of photograph on right, bottom panel).

Posterior Vitreous Detachment (PVD)

True PVD (Figure 9) is a separation between the posterior vitreous cortex and the ILL of the retina. PVD can be localized, partial, or total (throughout the entire posterior pole up to the posterior border of the vitreous base). Although there are various methods for examining the vitreous, it is difficult to accurately determine the presence or absence of true PVD both in research and clinical settings. The future, however, may see improvements in this diagnostic acumen through the use of new diagnostic technologies, such as dynamic light scattering.

Epidemiology of PVD

In clinical studies, the incidence of PVD has been purported to be 53% in persons older than 50 and 65% in those older than 65. Autopsy studies revealed an incidence of 27–51% in the seventh decade and 63% in the eighth decade. It is not certain, however, that these are not overestimates owing to the suspension-in-air methods employed in these postmortem studies. PVD is more common in myopic patients, occurring 10 years earlier than in emmetropia and hyperopia. This is likely the result of myopic vitreopathy Cataract extraction in myopic patients introduces additional effects. In one study, PVD was present in 102 of 103 myopic eyes with myopia greater than −6 D that had undergone cataract extraction (presumably intracapsular).

There is a higher incidence of PVD in women than men, a finding that may be due to hormonal changes following menopause. This hypothesis is supported by findings that glycosaminoglycan synthesis can be influenced by a variety of hormones. There is also evidence that sex hormones can affect glycosaminoglycans metabolism, for example, there are variations in the concentration of HA following hormonal treatment. The vitreous HA concentrations in men ($120.89 \pm 75.44\,\mu g\ ml^{-1}$) is significantly greater than in women ($79.53 \pm 48.17\,\mu g\ ml^{-1}$; $p < 0.01$). This may be related to low estrogen levels in postmenopausal women and may explain why PVD is more common in women than men. Furthermore, all these lines of evidence support the concept that insufficient or abnormal HA destabilizes the gel state of vitreous contributing to liquefaction and PVD.

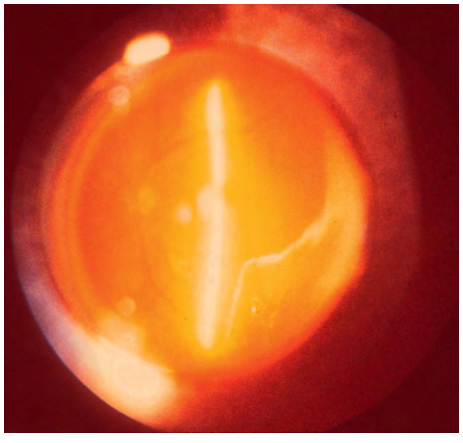

Figure 9 Posterior vitreous detachment. Preset lens biomicroscopy of the left eye in a patient with a complete PVD. The optic disk and retinal vessels can be seen to the left and the detached posterior vitreous cortex, which is brightly illuminated by the slit beam, is located to the right. Courtesy of C. L. Trempe, MD, Boston.

Pathogenesis of PVD

Several studies have shown that PVD begins at the posterior pole. PVD results from concurrent changes within the vitreous body and at the vitreoretinal interface. Whether due to age-related changes in collagen structure, HA conformation and/or concentration, light-induced or metabolically derived free radicals, hormonal effects, or combinations of all these factors, there is a disruption of the normal collagen–HA association transforming the gel vitreous to liquid. Dissolution of the ILL–vitreous cortex adhesion at the posterior pole allows this liquid vitreous to dissect a retro-cortical plane, resulting in collapse of the vitreous body. Further studies on the nature of HA–collagen interactions and the forces underlying posterior vitreous cortex–ILL adhesion should help to further identify the changes that result in PVD. Elucidating these mechanisms may enable the development of techniques by which liquefaction and PVD could be induced or prevented, depending on the clinical circumstances.

Sequela of PVD

In youth, the vitreous body is normally clear and has little or no effect on glare sensitivity. In old age, the aggregation of vitreous collagen fibrils into thick, irregular, visible fibers (Figures 3 and 8) can induce glare sensitivity, which may be subjectively bothersome. Furthermore, the high incidence of PVD in old age may also induce glare owing to scattering of light by the dense collagen fibril network in the posterior vitreous cortex (Figure 5). A group of individuals in whom glare diskomfort is a common complaint comprises patients who have undergone scleral buckling surgery for rhegmatogenous retinal detachment. The complaint of glare appears to be due to postoperative vitreous turbidity and not due to a change in the threshold sensitivity of retinal receptors. Scleral buckle surgery adds to the preexisting vitreous inhomogeneity by inducing temporary dysfunction of the blood ocular barriers – causing an influx of serum proteins and other macromolecules, as well as creating an inflammatory response and influx of cellular elements.

Floaters are the most common complaint of patients with PVD. These usually result from entopic phenomena caused by condensed vitreous fibers, glial tissue of epi-papillary origin, and/or intravitreal blood. Floaters move with vitreous displacement during eye movement and scatter incident light, casting a shadow on the retina that is perceived as a gray, hair-like or fly-like structure. In an autopsy series of cases with complete PVD, 57% had glial tissue on the posterior vitreous cortex and, in a study of cases of floaters, glial tissue was detected on the posterior vitreous cortex in 83% of patients.

Anomalous PVD

PVD is innocuous when gel liquefaction, which causes vitreous body destabilization – develops in tandem with dehiscence at the vitreo-retinal interface. If the degree of vitreo-retinal dehiscence is sufficient to allow syneresis (collapse), the vitreous body pulls away from the retina without untoward sequela (**Figure 9**). When there is insufficient vitreo-retinal dehiscence, the destabilized, liquefied vitreous cannot pull away cleanly, resulting in the development of anomalous PVD. There are various sequela to anomalous PVD (**Figure 10**).

When the entire (full-thickness) posterior vitreous cortex separates from the macula, but induces peripheral vitreo-retinal traction, retinal tears and detachments are induced. Posterior full-thickness traction can pull on the macula and induce vitreo-macular traction syndrome or place traction upon the optic disk, exacerbating neovascularization in proliferative diabetic retinopathy or other ischemic retinopathies, inducing vitreous hemorrhage, or resulting in vitreo-papillary traction syndromes. Partial PVD with splitting of the posterior vitreous cortex (vitreoschisis) may be the first event in macular pucker and macular hole pathogenesis.

Retinal Tears

Autopsy studies found that PVD is associated with retinal breaks in 14.3% of all cases. A degree of vitreous hemorrhage occurs in 13–19% of cases with PVD and, when patients suffer a severe vitreous hemorrhage that obscures the view of the fundus on ophthalmoscopy, there is a high-incidence of retinal tears (67%) and retinal detachments (39%).

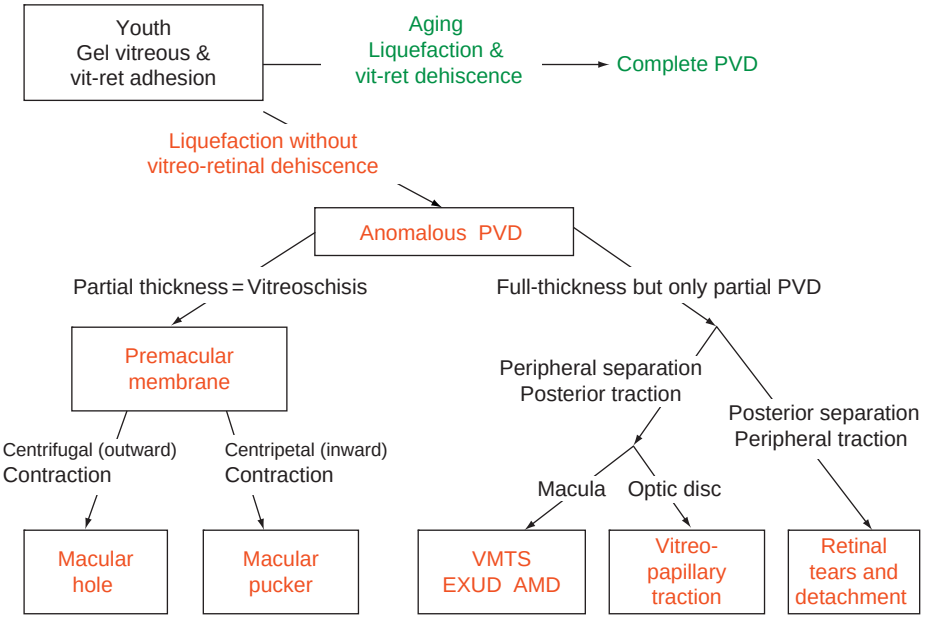

Figure 10 Schematic diagram of anomalous PVD. This schematic diagram demonstrates the various possible manifestations of anomalous PVD. When gel liquefaction and weakening of vitreoretinal adhesion occur concurrently, the vitreous separates away from the retina without sequela (top of diagram). If the separation of vitreous from retina is full-thickness but incomplete, there can be different forms of partial PVD (right side of diagram). Posterior separation with persistent peripheral vitreoretinal attachment can induce retinal breaks and detachments. Peripheral vitreoretinal separation with persistent full-thickness attachment of vitreous to the retina posteriorly can induce traction upon the macula, known as the vitreo-macular traction syndrome (VMTS). This phenomenon appears to be highly associated with exudative age-related macular degeneration (AMD). Persistent attachment to the optic disk can induce vitreo-papillopathies and also contribute to neovascularization and vitreous hemorrhage in ischemic retinopathies. If, during PVD, the posterior vitreous cortex splits (vitreoschisis), there can be differences depending upon the level of the split. Vitreoschsis anterior to the level of the hyalocytes leaves a relatively thick, cellular membrane attached to the macula. Inward (centripetal) contraction of this membrane induces macular pucker. If the split occurs at a level posterior to the hyalocytes, the remaining premacular membrane is relatively thin and hypocellular. Outward (centrifugal) tangential traction can induce a macular hole.

Vitreo-Macular Traction Syndrome

Vitreo-macular traction syndrome (VMTS) results when there is peripheral PVD but persistent attachment of full-thickness (i.e., not split) posterior vitreous cortex to the macula. This induces axial traction upon the macula with thickening due to both the effects of traction as well as edema. Full-thickness vitreo-macular adhesion may also be important in patients with age-related macular degeneration (AMD). Recent studies have identified that true PVD is protective against wet AMD, while anomalous PVD with persistent vitreo-macular adhesion may promote choroidal neovascularization.

Vitreoschisis

PVD is associated with vitreous cortex remnants at the fovea in 44% of human eyes studied at autopsy with scanning electron microscopy. When these remnants are a layer or sheet of posterior vitreous cortex, the term vitreoschisis is appropriate. On clinical examination, the inner wall of the vitreoschisis cavity may be clinically confused with a PVD when the posterior layer of the split vitreous cortex remains attached to the ILL of the retina.

Ulltrasonography (Figure 11) can, at times, detect the split layers in vitreoschisis – depending upon the thickness of the layers. Vitreoschisis has been detected by ultrasound in 20% of eyes with proliferative diabetic retinopathy and optical coherence tomography detected vitreoschisis in about one-half of patients with macular pucker and macular holes.

Figure 11 Ultrasonography of vitreoschisis. B-scan ultrasound of vitreoschisis in a human demonstrates the inner (I) and outer (P) walls of a split posterior vitreous cortex. The arrow indicates the schisis cavity created by the split.

Macular Pucker

Following vitreoschisis, premacular membranes can contract and cause significant visual impairment and metamorphopsia, sometimes necessitating surgical intervention. Studies of excised tissue have demonstrated the presence of astrocytes and retinal pigmentary epithelium (RPE) cells, but there can likely be other cells that can have similar appearances – such as hyalocytes. It has been hypothesized that macular pucker results when vitreoschisis splits the cortex anterior to hyalocytes leaving this cellular membrane attached to the macula.

Recent studies have identified that nearly one-half of all eyes with macular pucker have more than one site of retinal contraction (Figure 12). There is a higher incidence of intra-retinal cysts and significantly more macular thickening with increasing foci of retinal contraction.

Macular Holes

The precise pathogenesis of macular holes is unknown, although several hypotheses have been presented over the years. Initial theories cited anteroposterior traction by vitreous fibers, while more recent hypotheses incriminate tangential traction upon the macula. Advanced imaging using combined optical coherence tomography and scanning laser ophthalmoscopy has determined that nearly all subjects with macular holes have vitreo-papillary adhesion – suggesting that this might alter the vectors of force upon the macula inducing outward (centrifugal) tangential traction inducing a central hole.

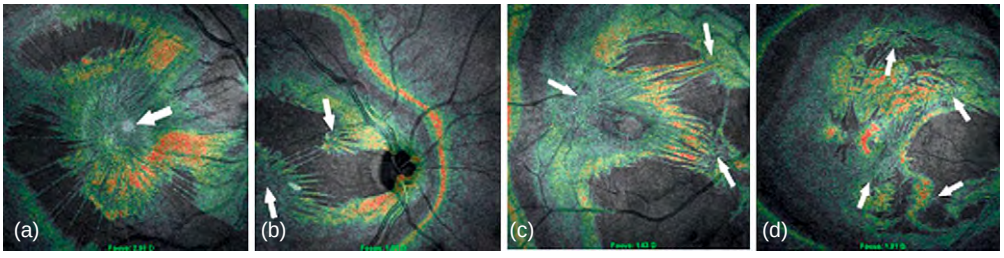

Figure 12 Multi-focal retinal contraction in macular pucker. Superimposed coronal plane OCT images upon the SLO fundus images reveal multi-focality (arrows) in the pattern of macular pucker. (a) 1 pucker center, (b) 2 pucker centers, (c) 3 pucker centers, and (d) 4 puckers centers.

X

Xenopus laevis as a Model for Understanding Retinal Diseases

O L Moritz and D C Lee, University of British Columbia, Vancouver, BC, Canada

Glossary

AP20187 – A small molecule modeled on a dimer of the immunosuppressive drug FK506. One molecule of AP20187 can bind with high affinity to two FK506-binding protein (Fv) domains. Thus, Fv domains can be used to produce fusion proteins that will dimerize in the presence of AP20187. This in turn can be used to control the activity of proteins or enzymes whose activities are influenced by dimerization, such as caspases.

Bardet–Biedl syndrome – An autosomal recessive disorder characterized by obesity, retinal degeneration, polydactyly, hypogonadism, developmental delay, and mental retardation. Genes implicated in this syndrome are involved in ciliary transport processes.

Caspase-9 – An initiator caspase in the apoptotic cascade. Caspases are a family of cysteine proteases, which play essential roles in programmed cell death. Once activated, caspase-9 triggers activation of other caspases, precipitating the apoptotic process.

Optical coherence tomography (OCT) – A technique that permits three-dimensional imaging within tissues that scatter light. The technique is frequently used in ophthalmology to noninvasively image the cell layers of the retina.

Peripherin/RDS – A transmembrane glycoprotein found in the outer segment of both rod and cone photoreceptor cells. It is thought to be a structural protein important for disk morphogenesis. Mutations in the gene encoding peripherin/RDS are associated with a variety of autosomal dominant retinal dystrophies; also referred to in publications as rds, peripherin, or peripherin-2.

Rab proteins and Arf4 – The members of the Ras superfamily of monomeric guanine-nucleotide-binding proteins (G proteins), which are involved in the regulation of membrane trafficking.

Retinal degeneration – A phenotype associated with many different retinal disorders, involving progressive death of retinal cells, usually of a specific cell type.

Retinitis pigmentosa – A hereditary retinal dystrophy characterized by defective dark adaptation, progressive loss of peripheral vision that may eventually extend to loss of central vision, and the appearance of black pigment in the fundus.

RNA helicase Ddx39 – A member of the DEAD box protein family of putative RNA helicases. Family members are characterized by the conserved motif Asp-Glu-Ala-Asp (D-E-A-D), and are involved in RNA metabolism.

Stargardt's disease – An autosomal recessive juvenile-onset form of macular dystrophy arising from mutations in the *ABCA4* gene. The *ABCA4* gene product is expressed in photoreceptor cells and is thought to be an ATP-dependent transporter for N-retinylidene-PE.

Introduction

The amphibian retina has many unique properties that have intrigued visual scientists for decades. Many studies have been conducted on the retina of *Xenopus laevis*, a frog species commonly used as a laboratory animal. These frogs were introduced to the research community in the 1930s and soon became widely available, after the discovery that they can be induced to lay eggs by injection of human chorionic gonadotropin (known as the Hogben test for pregnancy). As a research subject, *X. laevis* have advantages over other amphibians in that they have low maintenance

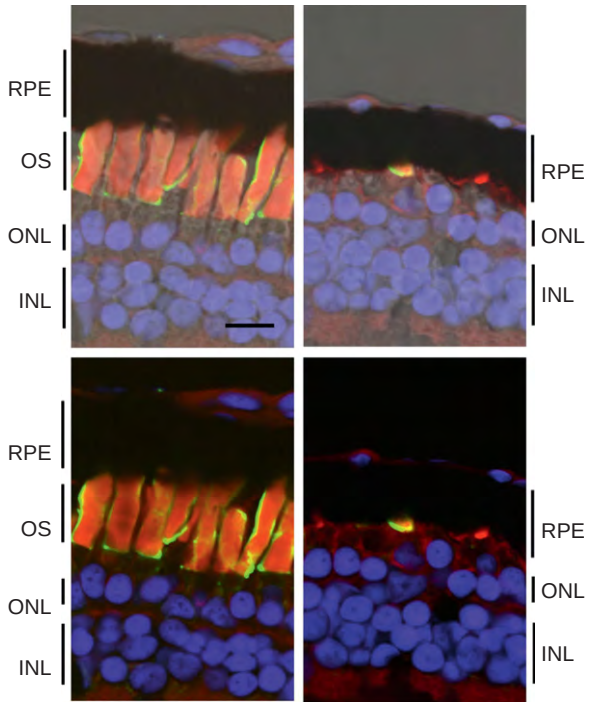

Figure 1 Expression of a bovine rhodopsin P23H mutant transgene causes retinal degeneration in *Xenopus laevis*. Combined confocal/DIC (upper panels) or confocal micrographs (lower panels) of developmental stage 47/48 wild-type retinas (left panels) or transgenic retinas expressing bovine-rhoP23H (right panels). Animals were raised in bright cyclic light for 2 weeks, beginning at fertilization. The 12-μm retinal cyrosections were stained with wheat germ agglutinin (red), B630N anti-rhodopsin (green), and Hoechst 33342 nuclear stain (blue). The central retinas of animals expressing bovine P23H rhodopsin (right panels) have almost no remaining rods, with those that remain having short and irregular outer segments. Note the relatively large diameter (7 μm) of the rod photoreceptors relative to those of the mammalian retina. Due to the relatively large diameter of the photoreceptors, only a single row of nuclei is required in the ONL. RPE, retinal pigment epithelium; OS, outer segment; INL, inner nuclear layer; ONL, outer nuclear layer. Scale = 10 μm.

requirements (they are entirely aquatic and do not require live food), and they can easily be induced to lay eggs. This made them a desirable model organism for developmental biologists studying fertilization and embryonic development; however, they have also been adopted by vision researchers as a model amphibian retina. The large size of the principle rod photoreceptors makes them highly amenable to biochemical, morphological, and electrophysiological studies (**Figure 1**). Early studies on the properties of the *X. laevis* visual system laid the groundwork for the use of this animal as a model organism for the study of visual disorders, while more recently developed techniques for genetic manipulation have resulted in *X. laevis* models of inherited retinal disease that are particularly amenable to certain forms of analysis.

Early Work on *X. laevis* – Biochemistry, Electrophysiology, and Microscopy

Modern research on the amphibian retina dates back to the extraordinary anatomical studies of Cajal and others in the 1800s that defined many of the principal cell types of the retina. Most early studies dealt with *Rana* and *Bufo* species. However, *X. laevis* have been used as a subject of retinal research dating back more than 50 years. In the 1950s, Wald and co-workers used *X. laevis* for investigations of visual pigment biochemistry. From the most abundant rod photoreceptors, it was found that the principal pigment exhibited maximal absorbance at 523 nm.

The amphibian retina is also of interest to electrophysiologists. Although the first electroretinogram (ERG) was recorded by Holmgren in the 1860s from a frog eye, *X. laevis* frogs were not used extensively for electrophysiological studies until the 1970s, with initial studies of *X. laevis* retinal physiology performed by Ripps and co-workers, correlating visual pigment content and photoreceptor threshold.

In the 1950s and 1960s, detailed analysis of the ultrastructure of photoreceptors was obtained by electron microscopy, leading to the current understanding of photoreceptor disk membrane structure, and the mechanisms of disk membrane synthesis and renewal. Many of these studies utilized amphibian retina, again typically *Rana* species, although Lanzavecchia examined the ultrastructure of *X. laevis* rods and cones in 1960. Further studies by Kinney and Fisher further characterized the morphogenesis and ultrastucture of the principal rod photoreceptor in *X. laevis*.

In the 1940s and 1950s, work by Sperry and co-workers demonstrated regeneration of the optic nerve after transection in various amphibians. Beginning in the late 1960s, Jacobson and co-workers conducted investigations of retinal development in *X. laevis*, with particular emphasis on the development of retinotectal projections. These studies employed embryonic surgery (e.g., inversion of the eye) to identify the origin of signals for optic nerve axon guidance, and demonstrated that the location of synapses of ganglion cell axons in the optic tectum are specified by the location (dorsal, ventral, nasal, or temporal) of the cell bodies in the retina.

These early investigations established the *X. laevis* retina as a viable subject for retinal research that is still in use, including ongoing studies of *X. laevis* disk shedding and renewal, electrophysiology, biochemistry, and retinal development, that are further improving our understanding of retinal function. Additionally, several studies discussed below have directly modeled human retinal disorders in *X. laevis*, in order to better understand retinal dysfunction.

X. laevis as a Model for Vitamin A Deprivation

One of the first instances of modeling retinal disease in *X. laevis* was a study by Witkovsky and co-workers on vitamin A deprivation in tadpoles. This model reproduced features of night blindness (i.e., decreased rod sensitivity) seen in vitamin-A-deprived patients. Among other novel findings, the authors demonstrated that bleaching of photopigment causes a greater reduction in photoreceptor sensitivity than can be accounted for by reduction in pigment quantity alone. This was accounted for in later studies, which demonstrated that opsin has a greater tendency to activate the visual transduction cascade than rhodopsin. More recently, studies on vitamin A deprivation in *X. laevis* have been continued by Solessio and co-workers, who have also pioneered the use of psychophysical measurements of *X. laevis* visual sensitivity.

X. laevis as a Model for Glaucoma

Early studies by Jacobson and Keating involving optic nerve transection in *X. laevis* are similar to paradigms currently used in research of optic nerve injury or glaucoma, although more typically the research subject is a mammal. However, unlike a mammalian optic nerve, a severed *X. laevis* optic nerve regenerates (a property that would be highly desirable in glaucoma patients). Research focused on *X. laevis* models of retinal regeneration of this type is currently being continued by Belecky-Adams and co-workers, who recently identified a possible role of the RNA helicase Ddx39 in the regulation of stem cells in the retina.

X. laevis and Studies of the Transport of Rhodopsin

The first investigations of the mechanism of outer segment renewal utilized amphibians injected with radioactive amino acids in a pulse–chase paradigm that allowed newly synthesized membranes to be visualized by autoradiography. The original experiments by Young and coworkers demonstrated that new disks were formed at the base of the rod outer segment, and subsequently became discontinuous with the outer segment plasma membrane. These studies were further extended by Besharse and Hollyfield, who examined the influence of light on disk synthesis in *X. laevis* photoreceptors, demonstrating diurnal regulation of disk membrane synthesis. Collectively, these studies demonstrated the extremely high rate of rod photoreceptor disk membrane synthesis in *X. laevis* retina, estimated at roughly 50-fold higher than in mammalian photoreceptors.

These findings suggested that, due to the enormous rate of outer segment membrane synthesis, the amphibian retina would be an excellent choice for studying the biosynthesis of rhodopsin. This work was pioneered by Papermaster and Dreyer, and subsequently continued by Papermaster and co-workers. These studies largely used *Rana* and *Xenopus* species, and resulted in identification of molecular and ultrastructural details of the rhodopsin transport pathway. Components of the biosynthetic machinery and transport mechanisms first identified in amphibia included associated features of the connecting cilium (the pericilliary ridge complex), and vesicles transporting rhodopsin (RTCs or rhodopsin transport carriers). Deretic was able to reconstitute rhodopsin transport in amphibian retinal extracts, and using this assay demonstrated that the rhodopsin transport signal was located in the cytoplasmic C-terminal domain. This *in vitro* assay and associated methodologies subsequently led to identification of a number of molecules associated with rhodopsin transport, including the small G proteins, rab6, rab8, rab11, and arf4.

However, due to the lack of an effective system for culturing photoreceptors, it was not possible to incorporate molecular biology approaches into the study of amphibian rhodopsin transport pathways until the 1990s, when techniques for the production of transgenic *X. laevis* developed by Kroll and Amaya, and cloning of promoters suitable for driving expression in *X. laevis* rods, allowed the study of rhodopsin transport in a genetically manipulated amphibian retina. Tam and colleagues found that rhodopsin-green fluorescent protein (GFP) fusion proteins expressed in *X. laevis* retina were transported correctly to rod outer segments. This allowed further identification and *in-vivo* demonstration of the function of the outer segment localization signal QVAPA, located at the extreme C-terminus of rhodopsin. Several mutations affecting this region cause retinitis pigmentosa (RP). These studies also demonstrated the extraordinary utility of transgenic *X. laevis* for conducting comparisons between transgenic animals, as numerous primary transgenic animals carrying different transgenes can be generated in a relatively short amount of time. For example, the rhodopsin outer segment localization signal was identified and refined using 15 distinct transgene constructs.

Using the same transgenic *X. laevis* system, the function of rab8 in rhodopsin transport was explored using dominant-negative and constitutively active mutants. Expression of these mutant rab8-GFP fusion proteins in *X. laevis* rods generated the first *X. laevis* models with an inherited retinal degeneration (RD) phenotype, as these fusion proteins proved to be quite toxic to retinal rods,

and the phenotype was passed to F1 offspring. The expression of dominant-negative GFP-rab8T22N caused a particularly rapid death of photoreceptors associated with accumulation of rhodopsin-containing intracellular vesicles in the vicinity of the base of the connecting cilium. Although it was not clear at the time, subsequent studies indicate that the resulting phenotype may be closely related to the RD associated with Bardet–Biedel syndrome (BBS). Similar investigations of the small G-protein Arf4, which binds the rhodopsin outer segment localization signal, are ongoing.

The RD observed in this study demonstrated a unique central-to-peripheral distribution subsequently seen in all other *X. laevis* models of RD. This is associated with the rapid growth of the eye in young *X. laevis*, which results in continuous addition of new photoreceptors to the peripheral retina. Thus, a single cryosection can demonstrate all stages of photoreceptor degeneration moving from central retina to periphery.

Modeling RP in Transgenic *X. laevis*

Subsequently, genetically modified transgenic *X. laevis* was used in a number of studies that directly examined mutations associated with the human disorder RP, an inherited form of RD. The pioneering study involved transgenic expression of mutant forms of peripherin/rds, a protein found at the periphery of rod outer segment disks. Peripherin/rds and its mutants were expressed as GFP fusion proteins using the rod opsin promoter to drive expression in retinal rods, at levels sufficiently high to cause RD in some cases. Confocal microscopy of the intrinsic GFP fluorescence showed that several fusion proteins had unique localization patterns distinct from wild type that respectively suggested either specific disruptions in normal function, or misfolding and endoplasmic reticulum (ER) retention. Furthermore, electron microscopy revealed unique abnormalities in disk organization, possibly associated with disruption of the normal functions of the peripherin/rds C-terminus.

Previous attempts to use rhodopsin-GFP fusion proteins to develop similar models of RP were unsuccessful, most likely due to low expression levels. In order to adapt the system for the study of RD induced by rhodopsin mutants, a system was devised for detection of nonfluorescent transgene products based on nonconserved rhodopsin antibody epitopes, such that epitope tags involving minimal (or no) sequence changes could be introduced. Initially, this system was applied to the study of an RP-causing mutation (Q348ter) that disrupts the previously identified rhodopsin outer segment localization signal. In these studies, the power of the *X. laevis* system for drawing comparisons between transgenes was further expanded. Rhodopsin mutants defective in signal transduction properties were combined with rhodopsin mutants responsible for RP to dissect the role of rhodopsin signal transduction in rod cell death pathways. The results demonstrated rhodopsin mislocalization was associated with axonal sprouting and cell death, regardless of whether rhodopsin signal transduction properties were inhibited.

The same system was subsequently applied to the study of the rhodopsin mutation P23H, the most common cause of autosomal dominant RP in North America. Despite numerous studies of this rhodopsin mutant in cultured cells and transgenic rodents, there was no clear consensus as to the effects of this mutation on rhodopsin function; in cultured cells, it was classified as a mutant defective in folding and ER exit, while transgenic animal studies suggested it was transported correctly to rod outer segments, where it caused RD that was exacerbated by light.

Studies in transgenic *X. laevis* compared several different forms of P23H rhodopsin, including P23H rhodopsins based on different species, and P23H rhodopsins defective in signal transduction and chromophore binding. Interestingly, all forms of P23H rhodopsin caused RD, but varied in terms of ER retention, expression level, and light sensitivity. P23H rhodopsins that exhibited dramatic ER retention (*X. laevis* P23H rhodopsin) caused RD under all circumstances, while P23H rhodopsins that were transported in small quantities to the OS (bovine P23H rhodopsin) caused RD only on light exposure (**Figure 1**). Furthermore, for bovine P23H rhodopsin, disruption of the chromophore-binding site was associated with reduced expression levels and RD, regardless of light exposure. This result reconciles the differences seen between previous studies, suggesting that in some forms of P23H-induced RD, chromophore binding promotes ER exit of newly synthesized rhodopsin. The dramatic sensitivity of these phenotypes to the underlying rhodopsin sequence was confirmed by Zhang and colleagues, who demonstrated light-sensitive RD in an *X. laevis* rhodopsin that differed from that used previously only in the sequences of the epitope tags. In addition to providing insight into the mechanisms underlying RD, these studies dramatically emphasize the difficulties in extrapolating results reported from a single disease model to human disease states.

A unique finding in this system was the presence of considerable quantities of truncated P23H rhodopsin, in which a significant portion of the N-terminal domain (including the mutated H23 residue) was removed; in fact, this was the dominant species observed in retinas expressing bovine P23H rhodopsin. This truncated species was also previously observed in cultured cells, although in smaller quantities. Identification of this species in other transgenic models would be difficult due to lack of a suitable reagent for detection, but was readily

achieved in *X. laevis* due to the availability of both N- and C-terminal specific antibodies that did not cross-react with endogenous rhodopsin.

Subsequent studies of the same *X. laevis* models of P23H-rhodopsin-induced RD probed the association of chromophore binding and ER exit. In order to address the question of whether the causative factor in light-induced RD was a reduction in the supply of free 11-*cis* retinal, or isomerization of 11-*cis* retinal bound to P23H rhodopsin as chromophore, the sensitivity of RD to different wavelengths of light was examined. It was determined that the profile of light sensitivity was consistent with photoisomerization of rhodopsin (which maximally absorbs green light) rather than free chromophore (with maximal absorbance in the UV). This also brings to mind similar studies of the constitutively active rhodopsin mutant K296E, classified as misfolding by some studies in cultured cells, suggesting that the active conformation of rhodopsin and/or loss of chromophore can be associated with altered kinetics of ER exit.

Studies of additional RP-causing rhodopsin mutations in transgenic *X. laevis* are ongoing, and have been reported at international meetings, including K296E rhodopsin and the glycosylation-defective mutants T4K and T17M. Glycosylation-defective rhodopsin mutants are also reported to be associated with light-exacerbated RD in *X. laevis*.

Inducible RD

In an alternate approach to modeling RP in the transgenic *X. laevis* retina, Hamm and co-workers designed a drug-inducible model of RD driven by a modified form of caspase-9. Dimerization and subsequent activation of this caspase-9 transgene is driven by AP20187, a small molecule based on a dimer of FK506. Administration of AP20187 to these transgenic *X. laevis* induces rapid RD that is not dependent on any particular environmental condition (such as special lighting). The system is designed to examine the effects of rod degeneration on other cell types, including cone photoreceptors and cells of the inner nuclear layer, and to examine the capacity for regeneration of rods in the *X. laevis* retina. This study was also the first to provide functional (i.e., electrophysiological) data for an *X. laevis* model of RD.

Interestingly, this model demonstrated a dramatic reduction in electrophysiological responses to stimuli designed to isolate cone function (e.g., a rapid flicker stimulus), despite the fact that no associated cone death was detected. This reduction in cone sensitivity may be associated with the cones themselves, or with other cells associated with the cone pathway and the ERG B-wave (e.g., cone bipolar cells and/or Müller glia). The restoration of responses to flicker stimuli was associated with a thickening of the inner nuclear layer, and a similar thickening can be observed by optical coherence tomography (OCT) in human RP patients.

Other Transgenic *X. laevis* Models of Retinal Disease

In addition to rhodopsin and peripherin/rds mutations responsible for RP, gene products related to Stargardt's disease have been expressed in *X. laevis* retina as GFP fusion proteins in order to examine their localization properties, although this has not yet resulted in a replication of a RD phenotype.

In studies by Kefalov and colleagues, cone opsins were expressed in *X. laevis* rods. As cone photoreceptors are considerably noisier than rod photoreceptors, this allowed a determination of the proportion of cone dark noise (activation of transduction in the absence of photons) that is purely due to the cone pigment sequence, and not other aspects of the transduction cascade or photoreceptor environment. Although generating a model of disease was not a goal of this study, the resulting animals could be considered a model for congenital stationary night blindness, which is due to abnormally high activity of the visual transduction cascade in the absence of photons.

X. laevis as a Model for Eye Development/ Developmental Disorders

The rapid development of the *X. laevis* embryos makes these animals of particular interest to developmental biologists, including those concerned with eye development. The first studies of the development of the *X. laevis* eye were conducted by Hollyfield through radioactive monitoring of the growth of the developing retina. Chung and colleagues histologically monitored the structural changes in the developing larval *X. laevis* retina and correlated these changes with electrophysiological changes, notably that while the receptive field of a ganglion cell remains constant in the developing larvae through metamorphosis, the inhibitory peripheral region expands to the entire retina of the adult *X. laevis*.

The development of the *X. laevis* eye has been manipulated by both the overexpression and by the knockdown of transcription factors. El-Hodiri and colleagues have extensively studied the transcriptional regulation of photoreceptor development. More recently, they identified a retinal homeobox gene family member, Rx-L, which regulates photoreceptor-specific gene expression. Expressed in developing embryos, the knockdown of Rx-L expression

adversely affected photoreceptor development, causing subtle phenotypes of altered photoreceptor morphology.

Using a similar embryonic transfection paradigm, Knox and colleagues found that overexpression of the transcription factors, *Nrl* and *Nr2e3*, in *X. laevis* retina resulted in an increase in numbers of rods, with concomitant reduction in cone photoreceptors, indicative of the roles of these factors in determining the developing photoreceptor cell fate. This system may prove extremely useful in modeling developmental disorders of the retina with similar underlying mechanisms.

X. laevis Models of Retinal Regeneration

Some recent studies have investigated the fascinating capacity of the *X. laevis* retina to repair itself after severe traumatic injury. In these studies, the entire retina is excised from an *X. laevis* tadpole eye. The retina subsequently demonstrates a dramatic capacity to completely regenerate by transdifferentiation of the remaining cells of the retinal pigment epithelium (RPE). Certain aspects of this transdifferentiation can be reproduced in culture, and it appears to be dependent on diffusible factors (possibly fibroblast growth factor 2 (FGF2)) released from the choroid. These results could have implications for traumatic eye injuries such as retinal detachment, retinal degenerative disorders, and glaucoma.

Summary

As an unconventional system for modeling retinal disease, *X. laevis* presents a number of advantages. As it is quite easy to generate transgenic *X. laevis*, they are an excellent system for comparing the effects of multiple transgenes. Other advantages include the relative ease of microscopic and electrophysiological studies due to the large size of the photoreceptor cells, regenerative capacity of the retina, and non-cross-reactivity of mammalian antibodies. However, there are also significant disadvantages, such as the current lack of knock-out or gene-replacement capabilities, long generation time (1 year), pseudotetraploid genome, and relatively small eyes, such that it is clearly not an ideal system appropriate for all experiments. Rather, *X. laevis* models of retinal disease are a very useful addition to the library of systems and models available to vision researchers.

Z

Zebrafish as a Model for Understanding Retinal Diseases: Pde6, Apoptosis, and the Bystander Effects

A A Lewis, C C Heikaus, and S E Brockerhoff, University of Washington, Seattle, WA, USA

Glossary

Achromatopsia – A disease characterized by defects in the cone photoreceptors resulting in extreme light sensitivity and color blindness or rod monochromacy.
Apoptosis or programmed cell death – A form of cell death characterized by a series of biochemical and morphological changes resulting in the formation of apoptotic bodies and removal by the immune system.
Bystander effect – This describes the transmission of death from mutant or injured cells to healthy neighboring cells.
Cyclic guanosine monophosphate (cGMP) – A cyclic nucleotide derived from guanosine triphosphate (GTP). cGMP acts as a regulator of the cyclic-nucleotide-gated ion channels in photoreceptors.
Cyclic nucleotide phosphodiesterases (Pde) – A family of enzymes that hydrolyze the phosphodiester bond in the second-messenger molecules cAMP and cGMP. They regulate the localization, duration, and amplitude of cyclic nucleotide signaling.
Electroretinography (ERG) – A method for evaluating visual response. Electrodes are placed against the cornea and used to measure the electrical responses of various cell types in the retina to a light flash of varying intensity.
GAF domains – A large group of protein domains that bind small molecules; in the Pde proteins these domains bind cyclic nucleotides. The GAF acronym comes from the names of the first three different classes of proteins identified to contain them: cGMP-specific and-regulated cyclic nucleotide phosphodiesterase, adenylyl cyclase, and *E. coli* transcription factor FhlA.
Gap junctions – The intercellular connections that occur between some types of cells. These junctions allow the movement of various molecules and ions between cells.
Optokinetic response (OKR) – A method for evaluating zebrafish vision. Fish are placed in a small dish in the center of a rotating drum decorated with vertical stripes. If the fish can see, its eyes will follow the rotating stripes with regular reflexive saccades.
Retinitus pigmentosa (RP) – A group of diseases characterized by defects in the rod photoreceptors resulting in night blindness. Progressive RP often results in cone loss and tunnel vision in some cases progressing to total blindness.
Scotopic vision – The low light vision that is produced exclusively by rod function.
Zebrafish or *Danio rerio* – A tropical freshwater fish of the minnow family that has gained prominence as a scientific animal model. For further information see the Zebrafish Information Network (ZFIN), an online database of zebrafish genetic, genomic, and developmental information.

Introduction

Inherited photoreceptor degenerations are a major cause of incurable blindness. Degenerations can affect rods, causing night blindness, cones, causing color and daylight blindness, or both cell types, leading to complete blindness. Although there are many models of retinal degeneration caused by variety of mutations in different genes, it is still not possible to completely describe the molecular cascade causing cell death in any of these disorders and therefore it is equally difficult to prevent the degenerative

process. Fundamental new information about the biochemistry of photoreceptor cell death is required to enhance our understanding of retinal degeneration and to develop new successful therapies. Zebrafish have gained prominence as a model organism for studies of retinal development, disease, and vision because they offer some distinct advantages over other genetically tractable systems. Zebrafish develop rapidly *ex utero* and can be maintained transparent allowing cells in the retina to be visualized in live larvae in real time using confocal and multiphoton imaging techniques. This provides the opportunity to visualize morphological and biochemical changes occurring in diseased photoreceptors with cellular and subcellular resolution. Here, we describe two mutations in the zebrafish cone phosphodiesterase (*pde6c*) gene that result in retinal degeneration. These mutants provide a unique opportunity to learn more about the biochemical triggers and inhibitors of cell death within the retina.

Retinal Disease

Photoreceptors are the primary sensory cells within the visual system. There are two main types of photoreceptors within the vertebrate eye: rods, which are monochromatic and respond in low light levels, and cones, which respond to higher light levels and specific wavelengths within the visual spectrum. The system of light absorption, ion fluctuation, and neuronal transmission are processes that require significant energy and, thus, the retina is one of the highest-energy-consuming tissues in the body. The high level of oxygen consumption by photoreceptors makes them particularly susceptible to injury and perturbation often resulting in cell death. Retinal degeneration is a leading cause of blindness in the developed world. The most common form of degeneration is age-related macular degeneration, which first affects the cones within the central retina (macula) and then progresses to the periphery.

Retinal degeneration can also occur as a result of genetic mutations. Achromatopsia and Retinitis pigmentosa (RP) together define a large class of heritable diseases that affect vision in humans. Both of these diseases are caused by a wide variety of mutations that disrupt visual transduction and photoreceptor maintenance. Achromatopsia is characterized by defects in the cone photoreceptors while rods remain functional, resulting in extreme light sensitivity and color blindness or rod monochromacy. Achromatopsia symptoms are generally seen at birth and the vision loss is only rarely progressive. RP, in contrast, develops during childhood and in later stages of life starting with degeneration of the rod photoreceptors, and progressing in some cases to total blindness. RP is estimated to affect 1 in 10 000 people. Due to the diversity of genes associated with these disease states, most therapeutics have focused on the general prevention of cell death as a method for limiting progressive vision loss.

Animal Models of Vision

Many animal models are used to study the visual system, and each possesses various strengths and weaknesses. By using a variety of systems scientists are able to capitalize on the strengths of all of them. The two most common systems for retinal modeling have been the fruit fly, *Drosophila melanogaster*, and mice, with a variety of work occurring in related species such as rabbit or ferret.

Drosophilae have mainly been used to study ocular development and patterning. Surprisingly, despite the obvious structural differences between the insect compound eye and our own, many of the same signaling cascades are used to establish the structure and patterning of the *Drosophila* eye. *Drosophilae* have an extremely short gestation period and well-established methods for rapid genetic manipulation, and these features have been used to understand the roles of multiple genes in eye development. However, there are still many limitations in the use of this organism, particularly in the modeling of retinal disease. Several differences exist between the insect and mammalian phototransduction cascade, and the structural differences of the compound eye also limit the applicability of this organism for disease studies.

The most commonly used mammalian animal model of the retina is the mouse. Mice have a number of advantages as a model system. There is an extensive literature on a variety of mutants that have been studied for many years. There are also multiple techniques for genetic manipulation, including the ability to modify genes and genomic loci and several techniques for retinal explantation for *in vivo* imaging. However, mice are nocturnal creatures and depend primarily on their olfactory system for foraging and predator identification. As a result, unlike the human retina, the mouse retina is dominated by rod photoreceptors and contains only 3% cone photoreceptors. While this makes mice ideal for studying rod photoreceptor disease and function, the study of cone physiology and function is less straightforward in this system. Additionally, mouse eye development occurs *in utero*, making it difficult to image and understand the early stages of eye development and retinal perturbation.

The Advantages and Techniques of the Zebrafish Model System

The zebrafish system has a number of benefits for studying visual development and disease. First, zebrafish vision, similar to humans, is cone dominated. They rely upon their vision for food acquisition and have four different

cone types: red, green, blue, and ultraviolet. In the zebrafish, ocular development occurs externally over the first 5 days postfertilization (dpf). During zebrafish development, the cone photoreceptors mature first between 3–5 dpf followed by the rods, which mature between 15–20 dpf. Thus, early zebrafish vision is dependent solely on cone-mediated vision. The rapid development of the visual system and early cone dominance have facilitated several genetic screens using young embryos to select specifically for cone related defects (see below).

Zebrafish were originally developed as a model system because they are inexpensive to keep, and take only 3 months to reach sexual maturity after which a mating pair will produce 200–300 eggs per week for at least a year. Further, development of many different genetic tools has added greatly to the versatility of this model for scientific study. In particular, mutagenesis protocols were optimized in the mid-1990s to introduce high frequencies of mutations. This made it possible to conduct large-scale forward genetic screens. Hundreds of different mutants affecting many aspects of vertebrate development and function have been identified. The constantly improving annotation of the nearly completed genome makes identifying mutated genes straightforward, and an impressive collection of vision mutants is available.

Another advantage is that cellular behavior can be observed in the intact, living organism. During the first 2 weeks of development, zebrafish larvae can be maintained in a translucent state and visualized live using either exogenous or genetically encoded fluorescent markers (see examples in **Figure 1**). Zebrafish can be maintained alive and healthy in agar on the microscope stage for days. Thus, cells can be imaged over the course of development or degeneration without perturbing the extracellular environment. At this point, transgenic lines containing fluorescent markers in various cell types are simple to generate and maintain. Transient injection of plasmid DNA at the one-cell stage will also produce a mosaic expression of genes throughout the fish allowing for the study of isolated cells within the intact animal. Multiple promoters have been developed to drive expression in various types of cells within the eye.

While no procedures exist to manipulate specific genes within the genome, several methods have been developed which allow scientists to circumvent this limitation. Morpholinos are synthetic RNA-like oligonucleotides that can be injected at the one-cell stage or electroporated into the fish at later stages. These morpholinos bind to corresponding RNA sequences within the cell, resulting in the degradation of the RNA and loss of protein expression. The loss-of-protein function is not as complete as is seen in knockouts and is only transient, but it has allowed researchers to study the effects of specific knockdowns during development. Additionally, several labs have developed a method known as targeting-induced local lesions in genomes (TILLING) in which high-throughput polymerase chain reaction (PCR) methods are used to identify specific gene mutations from libraries of randomly mutagenized fish.

Very recently, another method has been established in which nucleases are used to produce double-strand breaks at specific loci within the genome. These double-strand breaks are repaired by nonhomologous end joining, often resulting in deletions or insertions at the break site that can lead to frame-shift mutations in the target gene. The targeting specificity of these double-strand breaks is established by fusion to an array of zinc finger domains that bind to specific DNA sequences. Each zinc finger recognizes a 3-bp sequence and three zinc fingers are fused together to create a 9-bp recognition domain. Further, these zinc finger nuclease arrays must dimerize to activate the nuclease such that a total 18-bp recognition sequence is required.

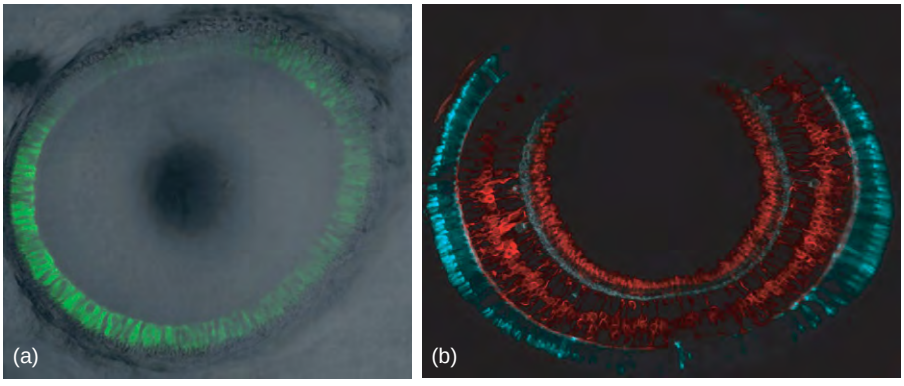

Figure 1 The zebrafish eye. These images illustrate the translucence of the eye and the ability to image the eye *in vivo*. For these experiments, zebrafish are anesthetized and embedded in a 0.5% agar solution during imaging. The zebrafish can survive under these conditions for up to 2 days. (a) A fluorescent image of the eye with the cone photoreceptors expressing the transgene for green fluorescent protein (*GFP*) under the control of a cone-specific promoter (*TαCP*), shown over the differential interference contrast (DIC) image of the eye. (b) An eye showing the photoreceptors in blue, expressing the transgene for cyan fluorescent protein under a cone-specific promoter (*Tg(TαCP:MmCFP)*) and the secondary layer of neurons or bipolar cells in red, expressing yellow fluorescent protein under a bipolar-specific promoter, (*Tg(nyc:mYFP)*).

Currently, the technology for generating the zinc finger arrays is cumbersome, but soon this will be a rapid and convenient way to generate targeted zebrafish mutants.

Methods have also been developed to create chimeric fish allowing for the rapid evaluation of the cell autonomous nature of genetic phenotypes. To produce these fish, eggs are grown to the blastula stage and then cells from one egg are removed and inserted into another egg. This procedure does not affect fish development and wild-type chimeras grow normally. The production of chimeric fish can be used to determine the critical cell population for the phenotypic changes associated with a mutation. It can also be useful for the evaluation of neighboring and surrounding effects.

Zebrafish have one other major advantage for the study of disease, which is the aqueous environment in which they reside. Methods are being developed for rapid high-throughput drug screens using zebrafish by adding compounds to their water and evaluating the effects. Most of the current studies with this method use fluorescent cell markers to indicate the presence or absence of various cells. This technique has been used with fluorescent hair cells to identify compounds that prevent hair cell death in the presence of the ototoxic agent neomycin. As zebrafish are small and easy to maintain, they are the best vertebrate model for this type of shotgun approach to drug development.

Evaluating zebrafish vision

There are several ways of evaluating zebrafish vision. The simplest involves a manipulation of the fish instinct to maintain its position within a moving stream. In this test, groups of fish can be placed in a long dish with a series of moving bars along its side. As the bars move, the fish respond to the apparent current by swimming to maintain their position with the bars. Thus, shoals of fish can be tested simultaneously for their ability to see and respond to the moving lines. This is known as the optomotor response. A related test called the optokinetic response (OKR) is done with a single fish placed in a small dish in the center of a rotating drum decorated with vertical stripes. In this test, the fish's eye will follow the stripes with periodic involuntary saccades. This is a very sensitive measure of an individual fish's ability to perceive its visual environment. Several labs have identified blind fish in mutagenesis screens using the optomotor response and/or the OKR. These screens have yielded a variety of mutants that can be used as models for retinal disease.

Another method that has been used to measure fish vision is the electroretinogram (ERG), which is a stimulated measure of the electrical response of the eye to a flash of light. In these measurements, the fish are dark adapted and a small electrode is placed on the cornea. The eye is then stimulated with a light flash and the electrical response is recorded. This technique records both the primary photoreceptor response, which appears as a negative spike at the beginning of the recording known as the a-wave, and the response of the secondary neurons, which is a large secondary positive response following the a-wave, known as the b-wave.

The Visual System: Phosphodiesterase and Phototransduction

Cyclic GMP (cGMP) phosphodiesterase (Pde) is an important enzyme in the process of phototransduction. During phototransduction the 11-*cis* retinal absorbs a single photon of light and alters the conformation of the opsin protein to activate the associated heterotrimeric guanosine triphosphate (GTP)-binding protein, transducin. The activated transducin removes the inhibitory gamma subunit from phosphodiesterase, which then degrades cGMP in the outer segments (for a schematic see Figure2).

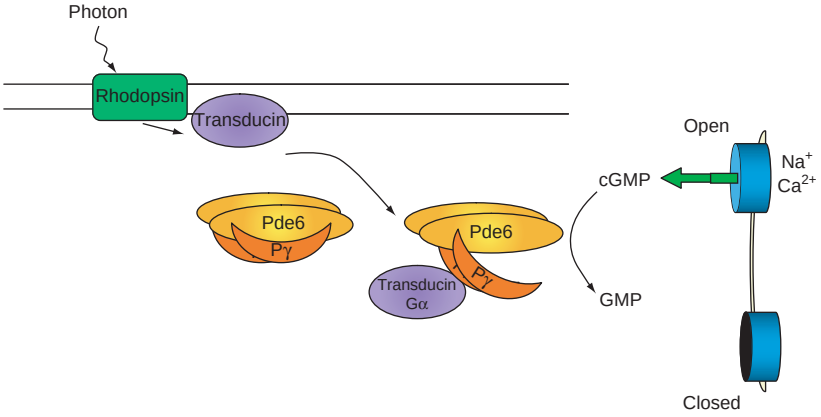

Figure 2 A schematic of the initial steps of phototransduction. The absorbance of a photon activates the 11-*cis* retinal of rhodopsin, which in turn activates the heterotrimeric GTP-binding protein, transducin. The Gα subunit of transducin binds to the inhibitory Pγ subunit of the Pde6 holoenzyme and relieves the inhibition of the catalytic domain. Pde6 then cleaves cGMP, resulting in a drop in cGMP levels that causes the closure of cGMP-gated ion channels in the plasma membrane.

The lowering of cGMP levels stimulates the closure of cyclic-nucleotide-gated ion channels in the plasma membrane, causing hyperpolarization and a decrease in neurotransmitter release at the synapse, initiating light signaling to downstream neurons. Channel closure also interrupts Ca^{2+} influx leading to a decrease in intracellular $[Ca^{2+}]_i$. The drop in intracellular $[Ca^{2+}]_i$ activates a Ca^{2+}-sensitive guanylyl cyclase, restoring cGMP to presignaling levels. Both types of photoreceptors have a similar phototransduction cascade, but use different genetically encoded enzymes to accomplish each task. Therefore, a mutation in the cone phosphodiesterase will not affect rod phototransduction.

The photoreceptor Pde (Pde6) is a multisubunit enzyme that differs slightly in rods and cones. In both cells the catalytic domain is a dimer that is bound and inhibited by the regulatory gamma subunit called Pγ. During phototransduction, activated transducin binds to Pγ and exposes the catalytic cGMP-binding site allowing the catalytic domain to cleave cGMP. In rod photoreceptors, two related but different proteins, Pα and Pβ, form the Pde6 catalytic domain. In cones, the catalytic domain consists of a dimer of one protein Pα', also known as Pde6c.

Retinal Degeneration in *pde6* Mutants: Primary Degeneration

Mutations in the Pde gene (*pde6)* are found in several families with RP and similar mutations have been used for many years as a model for RP in mice. The oldest and most commonly used mouse model of RP is the retinal degeneration 1 (*rd1*) mouse that contains a mutation in the Pβ rod-specific subunit of Pde6, the *pde6b* gene. In this model, rod degeneration is apparent by postnatal day 8 and nearly all of the rods are lost by 3 weeks of age. Despite many years of study, the process of primary photoreceptor degeneration in the *rd1* mouse is not well understood. Initial work has implicated programmed cell death pathways. The death of rods is associated with the extreme DNA cleavage that accompanies apoptosis, and this DNA cleavage can be detected with the terminal deoxynucleotidyl transferase biotin-dUTP nick end labeling (TUNEL) assay. However, several studies suggest that the standard apoptotic cascades, including a group of cysteine proteases known as the caspases, and other typical apoptotic effectors, are not involved. Instead, recent work implicates intracellular calcium concentration ($[Ca^{2+}]_i$) and the calpains, a calcium-activated set of proteases found in the mitochondria, as the relevant initiators of photoreceptor programmed cell death.

In *rd1* mice, the absence of Pde6 results in elevated levels of cGMP even under dark conditions, and it has been hypothesized that this results in the greater open probability of the cyclic-nucleotide-gated ion channels leading to increased $[Ca^{2+}]_i$ levels and apoptosis. However, little is known about the distribution of $[Ca^{2+}]_i$ during the death of cones. An initial report using the Ca^{2+} channel blocker, D-*cis*-diltiazem, to inhibit $[Ca^{2+}]_i$ accumulation showed a decrease in apoptosis. However, other labs using the same and other Ca^{2+} channel blockers have been unable to repeat these results. Due to the difficulty of imaging a mouse retina *in vivo* over long time periods, none of these studies has examined the levels of $[Ca^{2+}]_i$ within the cells *in vivo*. The translucence of the zebrafish retina enables *in vivo* imaging of both the morphological changes of degeneration as well as changes in levels of signaling molecules, such as Ca^{2+} or cGMP.

Retinal Degeneration in *pde6* Mutants: Secondary Retinal Degeneration, the Bystander Effect – Models and Mechanisms

In humans, RP is characterized by a lack of night vision, but often progresses over time to tunnel vision and, in some cases, complete blindness. This progression of the disease is due a gradual death of cones by apoptosis. Cell death begins in the peripheral retina where the number of rods is highest and moves toward the central retina. The cone photoreceptors are fully functional and do not use the mutated genes for phototransduction. However, the death of the mutant rods causes healthy cones to die apoptotically. This transmission of death to healthy neighboring cells is a process known as the bystander effect. The death of these cones represents the most debilitating part of this disease, and has significant potential for therapeutic intervention.

In addition to retinal degeneration, the bystander effect has been seen in a variety of diseases, including cancerous tumors, and can be either beneficial or detrimental to therapeutic efforts. One of the first descriptions of the bystander effect occurred during studies of gene therapy for cancer in which malignant tumors were injected with viruses containing suicide genes, which convert a prodrug into a lethal compound inside cells. Researchers found that, although only a small population within the tumor expressed the detrimental genes, significant portions of the tumor mass still died, suggesting that virally transfected cells were able to induce death in untransfected neighboring cells. Recently, researchers have found a similar occurrence in cells exposed to radiation therapy. In this case, cells that have not been irradiated show the genetic instability associated with radiation exposure.

In general, apoptosis does not affect the health of neighboring cells and it is unclear why in some instances there is a spread of death across a population. There are currently several hypotheses for how healthy cells are

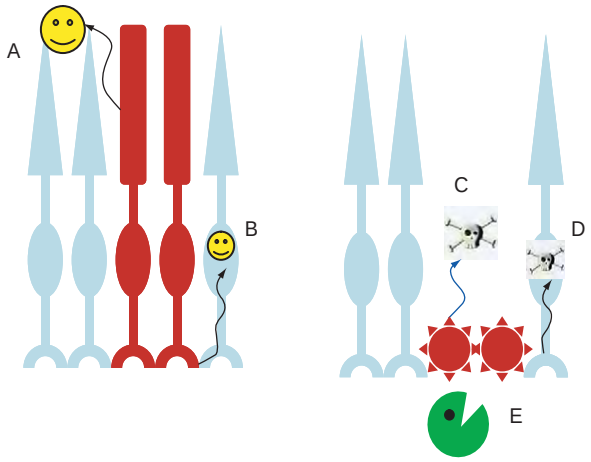

Figure 3 Schematic of some of the possible sources of the bystander effect. (a, b) Live cells release trophic factors (happy faces) that help neighboring cells and are lost when the mutant cells (in red) die. These factors could be released exogenously (a) or through gap junctions between cells (b). (c, d) Dying cells release toxic factors (skulls) that kill neighboring cells, again either exogenously (c) or through gap junctions (d). (e) The immune response to the presence of dying cells could have a deleterious effect on the remaining healthy cells.

induced to die. One possibility is that live cells release a trophic factor that stimulates the growth and differentiation of their neighbors and is required for their proper maintenance. For instance, it has been suggested that rods release a factor that stimulates the growth of cones. Another possibility is that dying cells release toxic factors that kill neighboring cells. A potential corollary to both of these hypotheses is that either toxic or trophic factors are released to neighboring cells through gap junctions. It is also possible that the immune response triggered by the removal of apoptotic cells has a deleterious effect on the neighboring cells. See Figure 3 for a schematic of these possibilities. Understanding the source of the bystander effect will suggest other methods by which it might be prevented.

Levels of the Bystander Effect in Photoreceptor Degeneration

The extent of bystander cell death is not the same for all cases of retinal degeneration. The death of cones in rod–cone dystrophies has been extensively studied in human patients and in a variety of animal models, including the *rd1* mouse. Mutations in rod phototransduction, resulting in rod death, almost always lead to some cone degeneration. However, the number of cells that die within the central fovea varies significantly from patient to patient. Mutations in genes required for cone phototransduction and their effects on rods are less well studied. Cone–rod dystrophies are conditions in which degeneration of the cones causes a decrease in scotopic vision, low light vision that is produced exclusively by rod function. Little is known about the state of rods in these patients, but it is thought that there is some degeneration associated with the visual loss. In contrast, some patients with cone dystrophies have cone death without affecting the rods or scotopic vision.

Differences in the connections between cells in a population might account for the variable levels of bystander death. In particular, it is thought that gap junctions between rods and cones in mammals may be predisposed to allow the flow of materials from the rods to the cones, but not from the cones to the rods. Thus, it may be possible that the flow of information would be asymmetrical between cell types and this could lead to differences in the effects on neighboring cells.

In order to better understand the bystander effect, an important first step is to determine how death progresses throughout the population and which populations of cells are capable of propagating apoptotic signals to healthy neighbors. For this type of analysis, zebrafish provide an ideal system. Not only are mosaic animals easy to generate, but the transparency of the embryo make it possible to analyze the transmission of death *in vivo*. This feature combined with the other tools described above provides a novel and powerful approach to examining the bystander effect within the photoreceptor population.

Zebrafish Models of Retinal Degeneration: Mutations in *pde6c*

Mutations in the zebrafish cone phosphodiesterase have been identified in two separate genetic screens for fish lacking OKR at 5 dpf. One of the mutations is a null mutant (*w59*), while the other is a missense mutation in a conserved amino acid (*els*). Recently, recessive mutations in *pde6c* were also identified in mice and in three human families with achromatopsia. Preliminary results indicate that in humans this form of achromatopsia may be progressive, suggesting the possibility of a bystander-associated death of rods.

pde6c^{w59}

pde6c^{w59} is a mutation in the splice site between exons 11 and 12 in the *pde6c* gene. The abnormal splicing caused by this mutation introduces a premature stop codon generating a null mutant. Zebrafish, homozygous for the *pde6c*^{w59} mutation, are viable and form normal swim bladders, a marker of general fish health, but must be raised with higher-than-normal food concentrations, as their visual defects impair acquisition of food (Figure 4(a)). In these fish, cone photoreceptors initially develop normally. However, at 4 dpf, when fish first respond to light, the cone photoreceptors in the central retina begin to

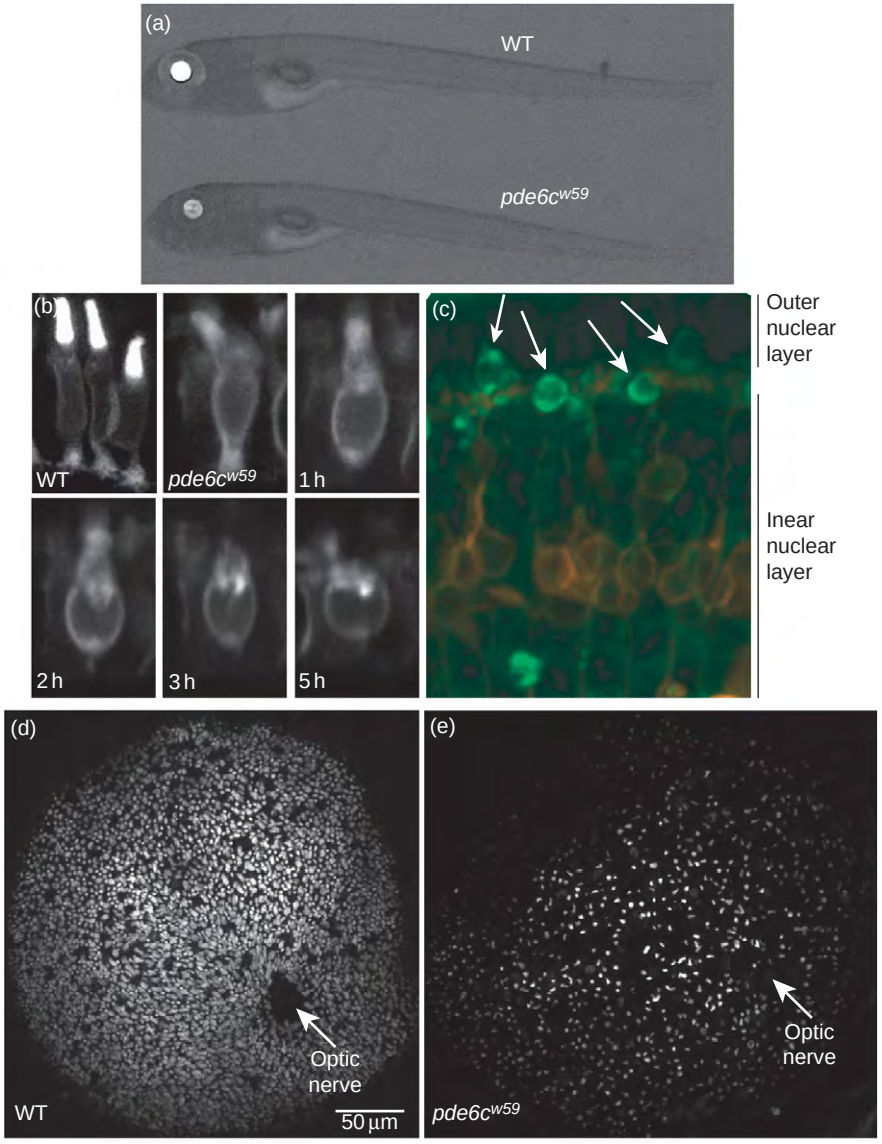

Figure 4 Images of the *pde6c*^{w59} mutant fish. (a) Homozygous *pde6c*^{w59} mutant fish have swim bladders, and are generally healthy. These fish contain the transgene *Tg(TαCP:MmCFP)*, which causes expression of membrane-tagged cyan fluorescent protein (MmCFP) specifically in cone photoreceptors. The level of fluorescence in the mutant eye is decreased due to the degeneration of cone photoreceptors. (b) A time-lapse sequence of a single mutant cone photoreceptor undergoing apoptosis. The initial picture is an image of wild-type cones. The subsequent pictures are a single *pde6c*^{w59} mutant cell over a 5-h time course. As the cells die, they retract their synaptic connections and round up to form apoptotic bodies which are eventually removed by the immune system. (c) Apoptotic photoreceptors (green) viewed using the membrane label boron-dipyrromethene (BODIPY), which labels all cellular membranes in the fish. Apoptotic bodies are clearly visible in the outer nuclear layer (arrows). Bipolar cells express yellow fluorescent protein (*Tg(nyc:mYFP)*) and are shown here in red. (d, e) The dramatic loss of fluorescently labeled photoreceptors in the whole eye of *Tg(TαCP:MmCFP) pde6c*^{w59} mutant. Eyes were removed from euthanized and fixed 6-day-old *Tg(TαCP:MmCFP)* WT (d) and *pde6c*^{w59} (e) mutant animals. Fluorescently labeled cone photoreceptors were viewed with confocal microscopy. From Lewis, Wong and Brockerhoff, in preparation.

degenerate. The *pde6c*^{w59} mutants exhibit a flat ERG at 5 dpf, indicating a total lack of photoreceptor response to light and no signaling to downstream neurons. At this stage in development, zebrafish vision relies on cones, so a flat ERG is consistent with the rapid cone degeneration observed in these fish. As the cone photoreceptors die, they retract their synaptic connections and outer segments and become spherical. Time-lapse images of this process are shown in **Figure 4(b)**. In the final stages of cell death, only the rounded apoptotic bodies remain (**Figure 4(c)**, arrows). This cell debris travels out of the outer nuclear layer and is disposed of by the macrophages of the immune system.

Within the central retina of the *pde6c*^{w59} mutant, a majority of cones die by 5 dpf. **Figures 4(d)** and **4(e)**

show the central retina of a wild-type (d) and mutant (e) eye, expressing membrane-tagged cyan fluorescent protein (MmCFP) specifically in the cone photoreceptors. The MmCFP accumulates in the outer segments of the cones. In **Figures 4(d)** and **4(e)**, the eye is visualized by removing it from a day-6 zebrafish larva and inverting it onto a microscope slide. In the wild-type eye, the central retina is densely populated with cones that show a regular mosaic pattern (**Figure 4(d)**). In the *pde6c*^{w59} eye, most of the cone photoreceptors have died and been removed from the retina, and many of the remaining outer segments appear dystrophic (**Figure 4(e)**).

Unlike humans or mice, fish continue to produce photoreceptor cells throughout their life. At the periphery of the eye is a region of cells known as the circumferential marginal zone, in which new photoreceptors are generated by multipotent stem cells. In this zone, young cones are constantly differentiating throughout the life of the animal. Even in adult *pde6c*^{w59} mutants, there are always cones in this region of the eye, indicating that there is no defect in cone morphogenesis or differentiation, but that cones die as they mature. The circumferential marginal zone is not visible in **Figures 4(d)** and **4(e)** but can be seen in **Figure 4(a)** as a faint ring of fluorescence around the periphery of the *pde6c*^{w59} eye.

The rods in the central retina also deteriorate during early development in *pde6c*^{w59} mutants but later recover. At 7 dpf, the rods appear normal and are slightly more clustered than in wild type, but not reduced in number. At 8–9 dpf, the number of rods begins to decrease in the central retina. The outer segments of the remaining rods in the central retina appear dystrophic. The deterioration of the rods continues through at least 6 weeks postfertilization. These data were the first evidence that zebrafish can undergo a bystander effect in the retina (i.e., mutant cones kill neighboring healthy rods).

The multipotent stem cells in the circumferential marginal zones of the eye can differentiate into rods throughout the life of the animal. Additionally, in cases of damage or injury, the Müller glia can also enter a mitotic state and produce stem cells capable of forming all types of retinal neurons. In the *pde6c*^{w59} mutants, this continuous regeneration eventually replenishes the small number of rods that have died. Thus, by 3 months postfertilization, the retina is completely populated with rods. Interestingly the *pde6c*^{w59} mutants never develop a scotopic ERG or OKR, indicating that even the remaining rods are unable to form proper connections with the downstream neurons in the eye. Unlike human and mouse eyes, zebrafish do not have separate rod and cone bipolar cells. The bipolar cells that connect to rods also connect to cone photoreceptors. The lack of scotopic vision in the *pde6c*^{w59} mutant suggests that the cones are necessary for the proper connections of the rods with their bipolar targets. In support of this theory, the bipolar cells of the *pde6c*^{w59} embryos often show an altered morphology with axons that extend into the ganglion cell layer and dendritic branches that send filopodia into the photoreceptor layer.

The *pde6c*^{w59} mutant allows for exceptional visibility of photoreceptor degeneration. Due to the rapid degeneration of the cones and rods in the central retina, it is possible to monitor many aspects of cell death as they are occurring. However, in the human diseases of RP and Achromatopsia, retinal degeneration can be a slow process occurring over several years. Thus, although it is easier to visualize cell death and develop drugs that will combat the rapid loss of photoreceptors in the *pde6c*^{w59} mutation, it would also be useful to have a mutant where degeneration occurred over a more protracted period of time. Recently the *els* mutant was identified as a mutation in *pde6c* that results in slow cone degeneration.

els

The *els* mutation produces a single amino acid change; methionine (M) 175 is mutated to an arginine (R) (M175R) in the first GAF domain of Pde6c. At 5 dpf, when zebrafish vision is cone dependent, fish that are homozygous for the *els* mutation have a flat ERG and no OKR, although initially the cones appear morphologically normal. This indicates that phototransduction is disrupted but surprisingly cell death has not been triggered. This finding suggests that the *els* allele is not null for the Pde6c protein, but that secondary defects within the *els* cones may be disrupting phototransduction, resulting in a flat ERG. One finding in support of this idea is that, although all four types of cones are initially present in the *els* mutant, the localization of various opsins within the photoreceptors is abnormal. Generally, opsins are found only in the outer segments, but in the *els* mutant, opsin proteins are found throughout the cell. At this stage, there is also a small but significant increase in the number of apoptotic cells in the *els* retinas. By 3 weeks postfertilization, the cones and rods in the central retina have begun to show an altered morphology, and the number of cone cells has decreased. However, despite their slightly altered morphology, rod maturation occurs in these fish and by 3 weeks postfertilization the fish respond to OKR under scotopic conditions.

As the *els* fish matures, the cones continue to deteriorate and by 6 months postfertilization the retina no longer contains cones, but consists entirely of rods. The rods are morphologically normal and, unlike those found in *pde6c*^{w59}, functional. This suggests that the significantly slower death of cones in *els* compared to *pde6c*^{w59} fish allows rods to form proper synaptic connections with bipolar cells. Interestingly, the total number of cells in the inner retina is decreased in this mutant; however, the ratio of inner retinal cells to rods has increased over wild type, suggesting that the rods are forming more

connections in the mutant than they do in the wild-type retina. The number of mitotically dividing cells in the retina is also increased in the mutant, suggesting that there is an increase in cellular proliferation probably resulting from the death of the cone photoreceptors.

Pde6 Structure

Recent work on the structure and function of Pde6c has shed some light on the potential effects of the *els* mutant for the Pde6c holoenzyme. The catalytic subunit of the Pde6 protein consists of two domains: a regulatory domain with two GAF domains, one of which (GAF A) binds cGMP, and a catalytic domain that has phosphodiesterase activity. The inhibitory subunit Pγ binds to the GAF A domain though its C terminus and the catalytic domain through interactions with its N terminus. Recent work with the rod Pde6 has suggested that the binding of cGMP to the GAF A domain may increase the binding affinity of the N terminus of Pγ for the catalytic domain. Thus, the binding of cGMP to the GAF A domain may help to regulate the activity of Pde6c *in vivo*. Met175 is located within the allosteric cGMP-binding site of the GAF A domain of Pde6c (**Figure 5(a)**). A recently determined crystal structure of the GAF A domain from chicken Pde6c reveals that the side chain of Met175 (equivalent to Met179 in chicken Pde6c) is in close proximity to the cyclic phosphate group of cGMP, although it does not directly interact with the cyclic nucleotide. As in other cyclic-nucleotide-binding Pde GAF domains, the phosphate group of the ligand is stabilized through the positive dipole of helix α3 (**Figure 5(b)**). The mutation M175R (equivalent to M179R in chicken Pde6c) introduces a larger and positively charged side chain into the binding pocket and thereby changes the cGMP-binding environment and, potentially, the binding affinity for the allosteric regulator cGMP (**Figure 5(c)**). A model in which a methionine side chain is substituted for an arginine side chain suggests three potential consequences of the M175R mutation. First, the R175 side chain clashes with helix α3, which may disrupt the dipole interaction between the helix and the phosphate group. Second, the R175 side chain clashes directly with the phosphate group of cGMP. Third, R175 might form a salt bridge with the phosphate group. In the former two scenarios, R175 would disrupt cGMP binding and lower the binding affinity of the GAF domain for cGMP, whereas in the latter scenario, R175 may cause a higher affinity for cGMP.

In either model, it is likely that the M175R mutation interferes significantly with cGMP binding and the sensitive regulatory mechanism of Pde6 through its GAF A domain. This, in turn, may lead to impaired Pde6 function and cause over- or underexpression of Pde6 protein, thereby disrupting the cone photoreceptor function. No data are available on the stability or functionality

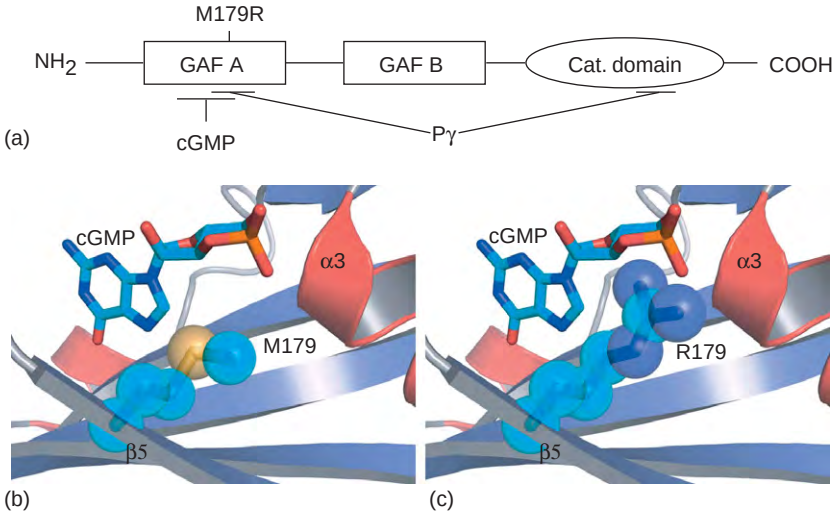

Figure 5 Structural consequences of M179R mutant in Pde6c GAF A. (a) Domain organization of Pde6c. The C-terminal catalytic domain is regulated by allosteric noncatalytic binding of cGMP to the N-terminal GAF A domain and binding of the inhibitory Pγ-subunit. The methionine (M)179 to arginine (R) mutation in chicken Pde6c, for which there is a crystal structure, is equivalent to the *els* Met175R mutation in zebrafish. (b) Experimentally determined structure of wild-type cGMP-binding pocket of chicken Pde6c GAF A (pdb-code: 3dba). α-Helices are shown in red, β-strands are shown in blue. cGMP and Met179 are shown in sticks with carbon atoms in cyan. Met179 is also highlighted through spheres. The figure was prepared with PyMOL, a molecular modeling program. (c) Model of M179R mutant cGMP-binding pocket of Pde6c GAF A. M179 was mutated to R179 through the mutation-function of PyMOL. In the absence of some structural rearrangements in the binding pocket, the longer side chain of R179 clashes with the phosphate group of cGMP and helix α3. α-Helices are shown in red; β-strands are shown in blue. cGMP and R179 are shown in sticks with carbon atoms in *cyan*. R179 is also highlighted through spheres.

of the *els* mutant protein. However, the phenotypic comparison with the *w59* mutant suggest that the *els* mutant is not a null mutation, but creates a more subtle effect on the levels or activity of the Pde6c protein. The proximity of the mutation to the cGMP-binding site in the GAF A domain implicates a possible disruption of the intramolecular allosteric regulation of catalytic activity ascribed to this portion of Pde6c.

The *els* mutant represents a unique opportunity to understand more about the enzymatic functions of Pde6 and its role in retinal degeneration. The slower degeneration of this mutation compared to the *w59* allele more accurately reflects slower human forms of degeneration. These two zebrafish *pde6c* mutants will provide complementary tools for studying Achromatopsia and apoptosis due to phosphodiesterase deficiency.

Conclusion

Zebrafish have gained prominence as a model for retinal disease. Cone-based vision, visual translucence, inexpensive maintenance, and rapid external embryologic development help make this model particularly exciting for retinal studies. Several genetic screens for blind fish have identified a variety of mutants that mimic human retinal disease. Among these, the *pde6c* mutants are a particularly good example of a retinal model that has been studied for many years in mice, and will benefit from the types of study available in the zebrafish system. In particular, the potential for live imaging of cells *in vivo* in an intact animal presents a novel opportunity to visualize and understand the source of photoreceptor degeneration.

One of the largest differences between the eyes of zebrafish and humans is the continuous growth of the zebrafish eye, and its regenerative ability in response to damage. Although this regenerative potential can complicate the evaluation of zebrafish as a model organism, it also presents a novel possibility to understand and imitate a natural system of retinal stem cell regeneration. By studying the differences between the zebrafish and mammalian systems it may be possible to stimulate our own potential for retinal regeneration.

The zebrafish model also offers an unprecedented potential for high-throughput drug screening. Using fluorescent cell markers and fluorescent plate readers, it will soon be possible to do large-scale screening of drugs that affect the levels of retinal degeneration. This method can also be used to test permeability and the toxicity of drugs. This is the first vertebrate animal model that provides a method for this type of rapid drug development.

Zebrafish: Retinal Development and Regeneration

T J Bailey and D R Hyde, University of Notre Dame, Notre Dame, IN, USA

Glossary

BrdU (bromodeoxyuridine) labeling – The synthetic nucleoside which is incorporated into nascent DNA during replication and is detectable by antibodies to indicate what cells have divided since exposure to BrdU.

CMZ (circumferential marginal zone) – The region of the retina distal to the optic stalk and proximal to the ciliary margin and lens. Here, retinal cells are continually born throughout the life of the zebrafish. CMZ cells express genes found in the neuroretina of the developing zebrafish embryo.

Homeobox transcription factors – The proteins that pattern tissue in that they regulate gene transcription by binding to a specific DNA sequence, the homeobox, in the target gene promoter.

Morpholino – Similar to RNA, this polymerized oligomer with a morpholino (rather than ribose) backbone, can base pair with ribonucleic acid (RNA) molecules, and persists in the cell as it is not easily degraded by RNases. Morpholinos interfere either with ribosomal processing of the messenger RNA into protein or spliceosome processing of premessenger RNA into mRNA, thus depleting the amount of protein produced.

Notch signaling – The plasma membrane-bound receptor that regulates the cell fate choice of individual neurons. Intracellular cleavage product can act as a transcription factor and regulate the expression of pro-neural genes such as basic helix–loop–helix (bHLH) transcription factors.

Pcna (proliferating cell nuclear antigen) – A marker for DNA replication in that it is a protein that functions as a trimer to promote DNA polymerase δ processivity.

Shh (sonic hedgehog) signaling – The Shh family members act as morphogens to pattern tissue. Signaling pathway proteins and pathways are reutilized in more specific cell fate specification as tissues are patterned.

TUNEL (terminal deoxynucleotidyl transferase dUTP nick end labeling) – A hallmark of apoptotic cells is genomic DNA fragmentation by specific nucleases that cleave DNA between histones. This process results in semi-uniform lengths of DNA with overhanging hydroxyl groups. Terminal transferase efficiently polymerizes labeled nucleotides to DNA hydroxyl groups without the need of a template. TUNEL is used to detect the genomic fragmentation of an apoptotic cell.

Introduction

Zebrafish has rapidly become a leading model system to study a variety of developmental processes, due to its large clutch size, external development of transparent embryos, and the rapid development of the embryo. Large and small genetic screens identified hundreds of mutants that affect the development of various tissues, including the retina. The ease in generating transgenic zebrafish lines has permitted a detailed cellular analysis of organ development without harm to the embryo. For example, transgenes that label specific cells are used to follow cell fates in the transparent embryo during tissue development. Alternatively, transgenes that express molecules that lead to cell death have been used to ablate cells to study either the disruption of development or organization of a tissue. Furthermore, the nearly complete sequence of the zebrafish genome has allowed comparative analyses with other vertebrate genomes to predict the presence of orthologous genes and developmental processes. Combined with the ability to direct the transient reduction in expression of desired proteins, it is possible to functionally analyze the potential role of different signaling pathways in the development of various tissues. Our understanding of zebrafish retinal development, from a sheet of neuroepithelial cells to a laminated and functional neural tissue, has benefited significantly from all of these approaches.

In addition to being an excellent model system to study early development, zebrafish has quickly become the premier model system to study tissue regeneration. In addition to exhibiting rapid and functional regeneration of the fin, liver, and heart, zebrafish also regenerate neuronal tissues, including the spinal cord, brain, and retina. Using mutants and transgenic lines that are readily available in zebrafish, a detailed comparison of the genes, molecules, and process that are required for retinal development and retinal regeneration is starting to be generated. While it may initially seem reasonable that regeneration would recapitulate the mechanisms that are involved in retinal development, recent studies revealed that regeneration may utilize the same genes and proteins as

development, but in a different context. This becomes most obvious when one compares the development of a laminated retina from an unpatterned neuroepithelium to the regeneration of single neuronal cell type from an existing laminated retina. To fully appreciate the differences between these two processes and the mechanisms involved in regeneration, it is important to contrast our understanding of the general events involved in retinal development with our recently acquired knowledge of the processes underlying retinal regeneration.

Embryonic Eye Patterning

Zebrafish Eyes Form from a Single Field in the Anterior Neural Plate

There is a large body of knowledge regarding the genes and genetic pathways that are required for the proper formation of the vertebrate eye. Around 10 h postfertilization (hpf), several secreted proteins induce the most anterior region of the anterior ectoderm to become the neural plate. Several signaling pathways (wingless (Wnt), fibroblast growth factor, and insulin-like growth factor) then further subdivide the anterior neural plate to produce the presumptive eye field. Some anterior-most cells then begin expressing several homeobox transcription factors, such as the retinal progenitor genes visual system homeobox 2 (*vsx2*), paired box gene 6 (*pax6*), and retinal homeobox (*rx*), which further restrict their fates to be retinal progenitor cells. The midline of the underlying head mesoderm then expresses several secreted, signaling molecules (such as the sonic hedgehog-related protein, sonic-you), which induces the eye field in the anterior neural plate to split into two distinct regions. This yields the first morphological sign of the developing visual system, the bilateral evagination of a single-cell thick epithelium from the anterior end of the neural keel, which will develop into the optic lobe. The optic lobes are morphologically visible by 12 hpf (**Figure 1(a)**). Each optic lobe expresses diffusible signals that induce the overlying naïve epithelium to commit to form the lens. As the lens placode starts to thicken (18 hpf, **Figure 1(b)**), it produces soluble signaling molecules that promote the underlying optic lobe to proliferate and invaginate, which results in the formation of a concave neuroepithelium – the optic cup. Expression of the transcription factor genes microphthalmia-associated transcription factor (*mitf*) in the ventral optic cup and *vsx2* in the dorsal optic cup commits those cells to develop into the retinal pigmented epithelium and neural retina, respectively. The region that lies at the junction of the *mitf* and *vsx2* expressing cells later becomes one region of persistent retinal neurogenesis in the adult retina, the circumferential marginal zone (CMZ, discussed below).

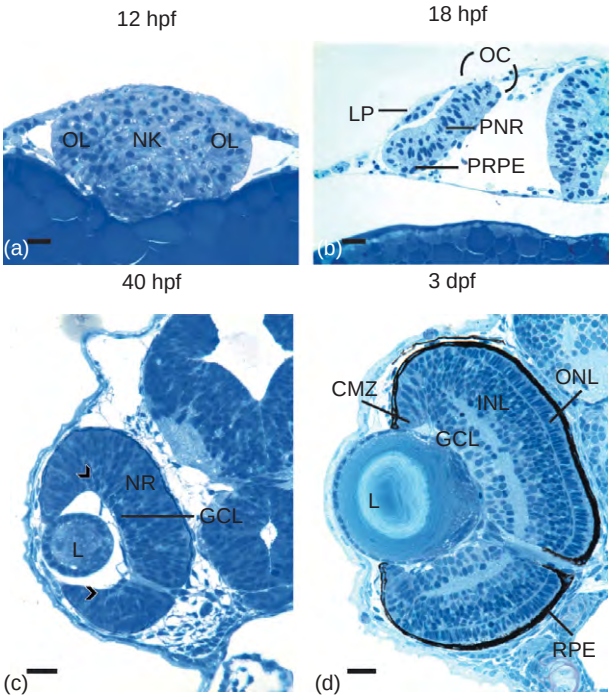

Figure 1 Zebrafish retinal development. (a) Cells evaginate bilaterally from the anterior neural keel (NK) to form the optic lobes (OL), which are morphologically distinguishable by 10–12 h postfertilization (hpf). (b) By 18 hpf, the proliferating cells of the presumptive neuroretina (PNR) have induced the overlying ectoderm to thicken into the lens placode (LP). The retina then invaginates to form the OC, with the thicker dorsal cells, or presumptive neuroretina, expressing *vsx2* and the thinner ventral cells, or presumptive retinal pigmented epithelium (PRPE), expressing *mitf*. (c) The cells in the neural retina continue to proliferate until a wave of sonic hedgehog (Shh) signaling induces the first retinal ganglion cells (RGCs) in the most basal nuclear layer, the ganglion cell layer (GCL: between the arrowheads), to differentiate around 40 hpf in the center of the retina, whereas cells in the retinal margin remain in an uncommitted state. (d) Additional waves of Shh signaling produce three nuclear layers, the ganglion cell layer (GCL), inner nuclear layer (INL), and outer nuclear layer (ONL). The ONL is immediately below the retinal pigmented epithelium (RPE), which is now darkened with pigment granules by 3 days postfertilization (dpf). Scale bars represent 20 μm. OC, optic cup; NK, neural keel; NR, neural retina; RPE, retinal pigmented epithelium; CMZ, circumferential marginal zone; GCL, ganglion cell layer; INL, inner nuclear layer; L, lens; LP, lens placode; OL, optic lobe; ONL, outer nuclear layer; PNR, presumptive neuroretina; PRPE, presumptive retinal pigmented epithelium.

The Laminar Structure of the Retina Forms as Cells Exit the Cell Cycle and Differentiate

The number of cells in the NR increases through cell proliferation until the diffusible signaling protein sonic hedgehog (Shh) is produced in a ventronasal patch of the NR. The Shh protein initiates a wave of expression of the basic helix–loop–helix (bHLH) transcription factor atonal homolog 7 (Atoh7) that sweeps radially toward the dorsal retina that induces the differentiation of the retinal

ganglion cells (RGCs) (**Figure 1(c)**). Shh is then secreted from the newly specified RGCs to sequentially induce the apically located naïve mitotic cells to exit the cell cycle and commit to the other retinal neuronal identities. Later, Shh signaling from the RPE is required for proper photoreceptor differentiation. This process results in the formation of the terminally laminated retina, which is composed of three nuclear layers (ganglion cell layer, inner nuclear layer (INL), and outer nuclear layer) and two synaptic layers (inner plexiform layer and outer plexiform layer) by 72 hpf (**Figure 1(d)**).

Intrinsic commitment and specification of the different retinal cell types also requires the expression of homeobox transcription factors and pro-neural genes of the Notch signaling pathway. Experiments aimed at determining when the different retinal cell types are committed (neuronal birthdating) established a bias of early committing cells to the RGC, amacrine cell, cone, and horizontal cell classes, followed by the bipolar and rod photoreceptor cells, and lastly the Müller glial cells. The reproducible timing observed with these different cell types suggests that a molecular clock modulates their commitment and differentiation. This model proposes that the commitment of a retinal progenitor cell to a particular neuronal cell type corresponds to when the progenitor cell exits the cell cycle, with early committed cells localizing more basally in the retina. Thus, retinal progenitor cells divide and some daughter cells become ganglion cells, while the remaining daughter cells continue to divide. Some of these retinal progenitors exit the cell cycle and differentiate as amacrine cells and others continue as retinal progenitors. These progenitors continue their asymmetrical cell division to produce some retinal neurons with each round of cell division, until the final retinal progenitors are committed to become Müller glial cells. This suggests that the Müller glia is the retinal cell type that is most recently differentiated from the retinal progenitor cell. This model also allows for the presence of external signals to influence the commitment of the cell, which also changes over time. These mechanisms appear to be conserved across species.

Addition of Retinal Cells Throughout the Life of a Zebrafish

Unlike mammals, the zebrafish eye continuously grows throughout the lifetime of the fish. This growth requires the continual generation of new retinal neurons in a process called persistent neurogenesis. These additional retinal cells are produced from two adult stem cell niches, the CMZ (**Figure 1(d)** and **Figure 2(a)**) and an INL stem cell niche (**Figure 2(a)**). The stem cells within the CMZ continue to express the cell cycle genes and the embryonic retinal progenitor genes, such as orthodenticle homolog 2 *otx2*, *pax6*, and *rx,* throughout the life of the fish. These stem cells proliferate to yield daughter cells that ultimately differentiate into ganglion cells, amacrine cells, horizontal cells, cone photoreceptors, bipolar neurons, and Müller glial cells, but not rod photoreceptors. Rods arise from the INL stem cell niche as described below. The addition of these newly differentiated cells to the region adjacent to the CMZ (**Figure 2(c)** and **2(d)**) results in the radial growth of the adult retina.

The INL stem cells have recently been demonstrated to correspond to the Müller glial cells. Unlike the CMZ stem cells, however, the asymmetric division of the Müller glia ultimately produce only rod photoreceptors during persistent neurogenesis (**Figure 2**). Relatively few Müller glia are actively dividing at any given moment. The asymmetric division of the Müller glial cell produces neuronal progenitor cells (**Figure 2(a)**), which continue to proliferate as they migrate to the outer nuclear layer, where they are called rod precursor cells and continue to undergo cell division (**Figure 2(b)**). Unlike the pluripotent CMZ stem cells, these Müller glial-derived rod precursor cells are committed to differentiate into only rod photoreceptors during persistent neurogenesis (**Figure 2(c)**). As the adult eye enlarges, the distance between the originally differentiated rod photoreceptors increases. The Müller glial-derived rods fill in this space. Thus, persistent neurogenesis in the zebrafish retina encompasses both the radial growth of the retina by addition of all retinal cell types by the CMZ and the slow production of additional rod photoreceptors by the Müller glia (**Figure 2(d)**).

Regeneration in the Zebrafish Retina

Zebrafish regenerate all retinal neurons

Persistent neurogenesis involves the continual generation of new neurons in the adult retina, without any prior loss of retinal neurons that must be replaced. It should be noted that the scientific literature often uses retinal regeneration to define the reprojection of axons from viable neuronal soma to replace damaged axons, such as the reprojection of axons from RGCs subsequent to an optic nerve crush or severing. For this discussion, retinal regeneration refers to the replacement of entire neuronal cells that were lost through retinal insult or genetic causes. Zebrafish respond to the loss of retinal neurons by significantly increasing both the number of Müller glia that reenter the cell cycle and the rate of proliferation in the neuronal progenitor cells, relative to that observed during persistent neurogenesis. This amplified proliferation response appears to be proportional to the amount of damage suffered. In contrast to persistent neurogenesis, these Müller-glial-derived neuronal progenitors are not committed to become only rod photoreceptors. These neuronal progenitors proliferate, migrate to the retinal layer that contains the missing neurons, and differentiate specifically into the lost neurons. Thus, the damage response alters the persistent neurogenesis program to

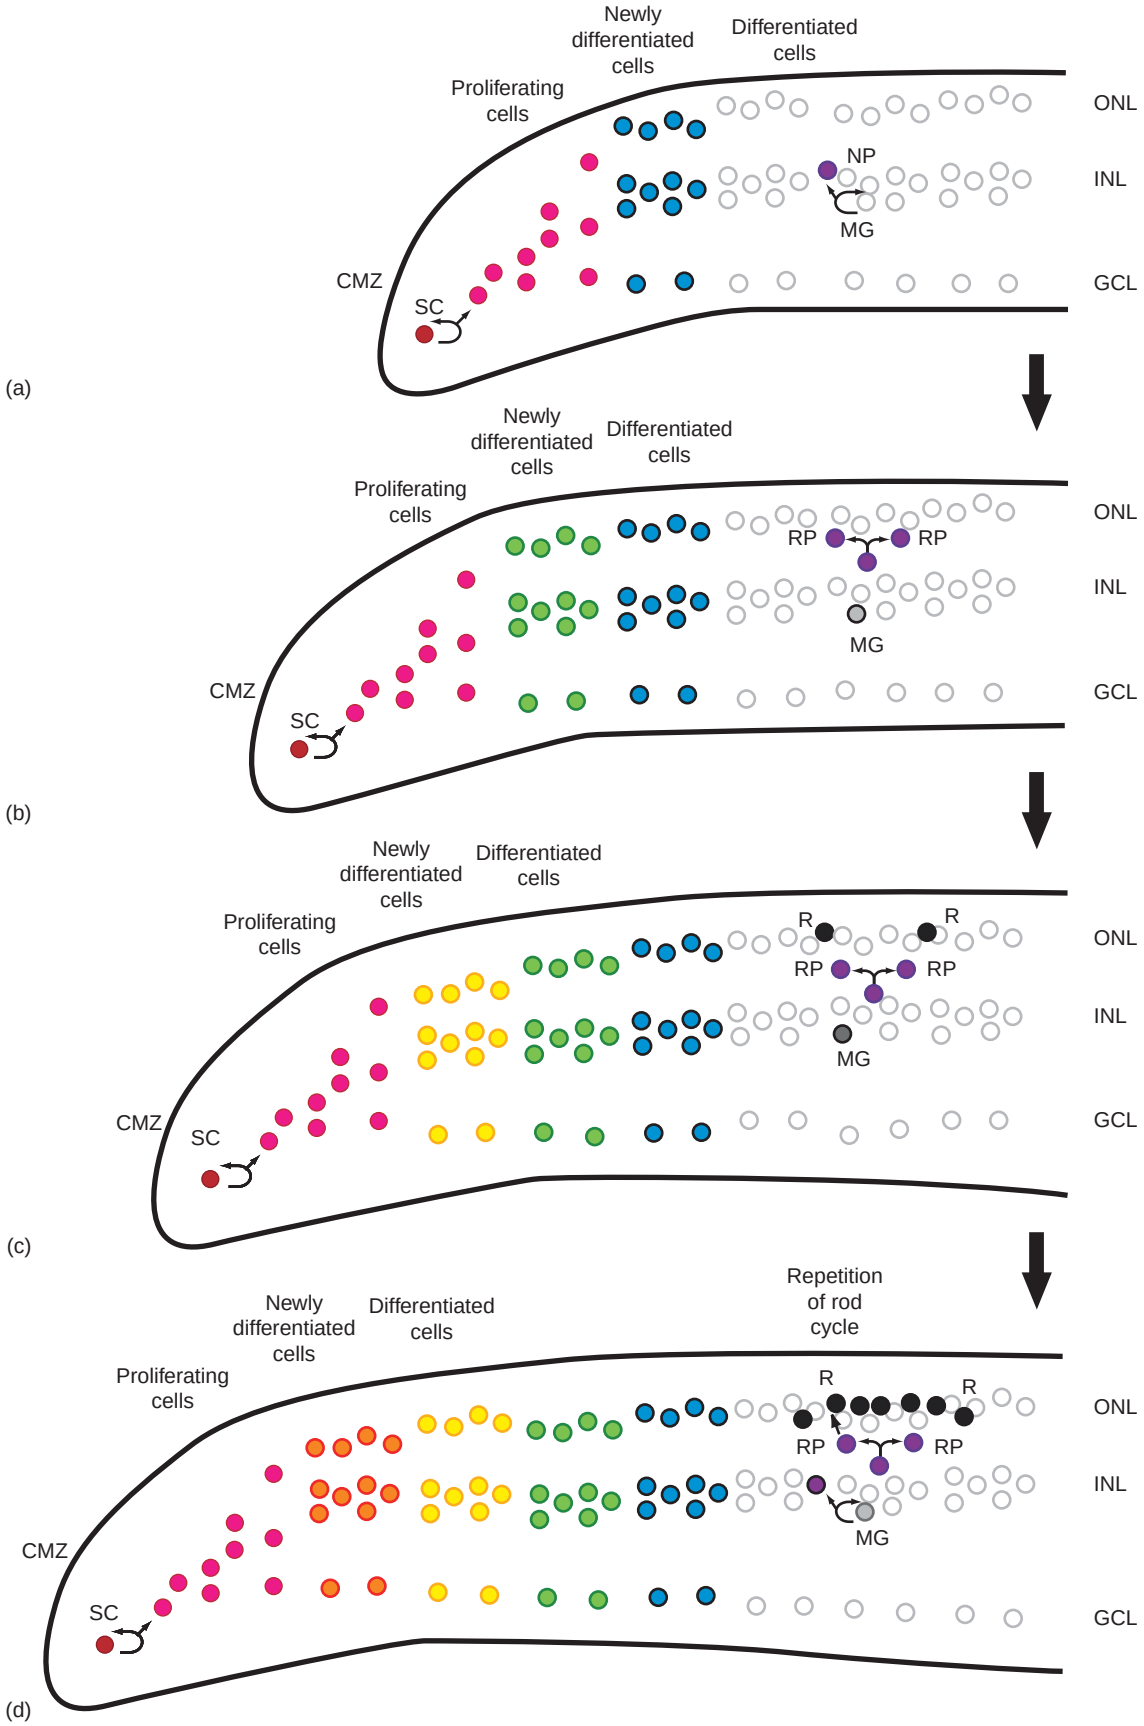

Figure 2 Continued

significantly increase the number of neuronal progenitors and allow them a greater breadth of cell differentiation potential.

A variety of damage paradigms have been studied in the zebrafish retina. For example, simple surgical lesion induces cells proximal to the cut site to die, which usually results in the death of all the retinal cell types in a small area of the retina. Similarly, heat caused by either a high temperature probe or laser ablation, or high concentrations of ouabain (Na, K-ATPase inhibitor), often causes loss of cells from all three retinal layers. In contrast, other damage models exhibit more restricted cell-type loss. For example, intravitreal injection of low concentrations of ouabain causes the loss of ganglion cells and INL neurons, without the loss of significant numbers of rod and cone photoreceptors. Constant intense light, in contrast, causes apoptosis of only the rod and cone photoreceptors, primarily in the dorsal and central retina, with no detectable cell death in the INL or GCL layers. An advantage of the light damage model is that only two neuronal classes are lost, rod and cone photoreceptors, which limits the complexity of the regeneration response. Furthermore, the light damage extends across a large region of the retina, which induces the participation of a very large number of Müller glia and neuronal progenitor cells. This results in an amplification of the signals and processes that are required for regeneration, which should increase the likelihood of their identification.

Constant Intense Light Kills Photoreceptors, Which Are then Regenerated by Müller Glia

Zebrafish rods and cones die by apoptosis upon exposure to prolonged high-intensity light. Apoptosis is a genetically programmed cell death mechanism, in which the dying cell fragments its DNA and the cell body (blebs) to produce easily phagocytosed cell corpses. Terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL), is a standard method to detect this fragmented genomic DNA. Fragmentation of the DNA produces large numbers of free 3′-hydroxyl ends that can be used by terminal deoxynucleotidyl transferase to add dUTP nucleotides that are covalently modified to a detectable molecule, such as biotin or fluorescein (**Figure 3**).

The light-induced photoreceptor cell death is rapid, with TUNEL-positive cells first detected in the ONL as early as 3 h after initiating the light treatment. By 16 h of constant light, the photoreceptor cell death is evident based on the reduction in the number of ONL nuclei relative to undamaged retina and is striking by 3 days of constant light (**Figure 4(a)** and **4(b)**). In addition to the strong TUNEL-positive signal that is detected in the ONL, a weaker TUNEL signal is observed throughout the Müller glial cells in the INL. Strikingly, this INL TUNEL signal is neither restricted to, nor predominantly localized in, the Müller glia nuclei, which demonstrates that the Müller glial cells are not apoptotic. Rather, the colocalization of some proteins derived from apoptotic rods with the TUNEL signal in the Müller glia suggests that the Müller glia selectively engulf dying rod photoreceptors. These data are consistent with results in the degeneration model of the *Tg*(*Xops:mCFP*) transgenic line, which expresses membrane-bound cyan fluorescent protein (mCFP) from the *Xenopus rod opsin* promoter (*Xops*) in only zebrafish rods. The *Tg*(*Xops:mCFP*) retina exhibits a persistent loss of only rod photoreceptors, even in the absence of any retinal insult, such as constant bright light. Furthermore, the *Tg*(*Xops:mCFP*) retina revealed TUNEL labeling in the INL in a morphology similar to Müller glia. Thus, the engulfment of apoptotic rod photoreceptors by Müller glia is a common early feature of the damaged zebrafish retina and may be required for regenerative Müller glial cell stimulation. TUNEL labeling in the Müller glia can be detected early, within the first 12 h of light treatment, and represents one of the earliest signs of Müller glial response to apoptotic photoreceptor damage. Robust regeneration of the light-damaged zebrafish retina follows and a normal complement of rod and cone photoreceptors reform within 28 days after terminating the constant light treatment (**Figure 4(c)**).

Figure 2 Schematic of persistent neurogenesis in the adult zebrafish retina. (a) In the adult retina, stem cells (SC) in the circumferential marginal zone (CMZ) continue to proliferate through asymmetric cell division to produce neuronal progenitor cells (pink circles), which then exit the cell cycle to become newly differentiated cells (blue circles). These CMZ-derived cells differentiate into cone, horizontal, bipolar, amacrine, and ganglion neurons, as well as Müller glia (not labeled), but not rod cells. Throughout the remainder of the retina, a limited number of Müller glial cells (MG) divide asymmetrically to produce a Müller glial cell and a neuronal progenitor cell (NP). (b) As the CMZ stem cells continue to produce neuronal progenitors (pink circles), there is a radial growth of the adult retina, with the most recently differentiated neurons (green circles) located closer to the CMZ than the older neurons (blue circles). In the central region of differentiated retina, the new NP cell continues to divide and migrates to the ONL. Once these NP cells reach the ONL, they are termed rod precursor cells (RP). (c) The CMZ continues producing new retinal cells (yellow circles), which are located closest to the CMZ. The RP cells in the ONL continue to proliferate, with some of the daughter cells differentiating into rod photoreceptors (purple circles). The newly differentiated rod cell intercalates between differentiated cone cells to maintain the density of rod photoreceptors during the radial expansion of the retina. (d) Persistent neurogenesis continues as the CMZ-based retinal stem cells and the Müller-glial-derived neuronal progenitors continue to produce new neurons at the margin and central retina, respectively. CMZ, circumferential marginal zone; GCL, ganglion cell layer; INL, inner nuclear layer; MG, Müller glial cell; ONL, outer nuclear layer; NP, neuronal progenitor; RP, rod precursor cell; SC, stem cell.

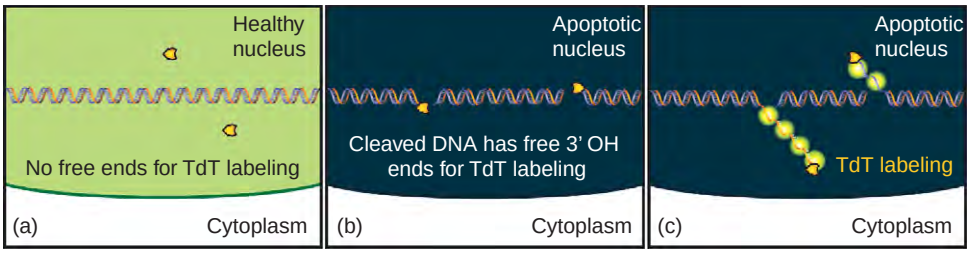

Figure 3 TUNEL assay detects the fragmented DNA in apoptotic nuclei. (a) A healthy nucleus contains intact DNA, which contains only a single 3′ hydroxyl group at the end of each chromosome. The terminal deoxynucleotidyl transferase enzyme (TdT), which can add polymerized stretches of deoxyuridine triphosphate (dUTP), without the need for a complementary strand of DNA with which to pair nucleotides (template-independent). TdT binds to both ends of the linear chromosomal DNA and adds only a few dUTPs per healthy nucleus. (b) Apoptosis results in the fragmentation of the DNA, which generates a very large number of free 3′ hydroxyl ends. (c) TdT adds dUTPs to each of the now many generated 3′ hydroxyl ends. The large number of dUTP molecules can either directly fluoresce because they are tagged with a fluorochrome or, in the case of biotinylated-dUTP, are detected by tagged Streptavidin molecule to generate a strong fluorescent signal in the apoptotic nucleus. Because of the absence of the genomic DNA in the cytoplasm, little, if any, fluorescent signal is present in the cytoplasm of an apoptotic cell.

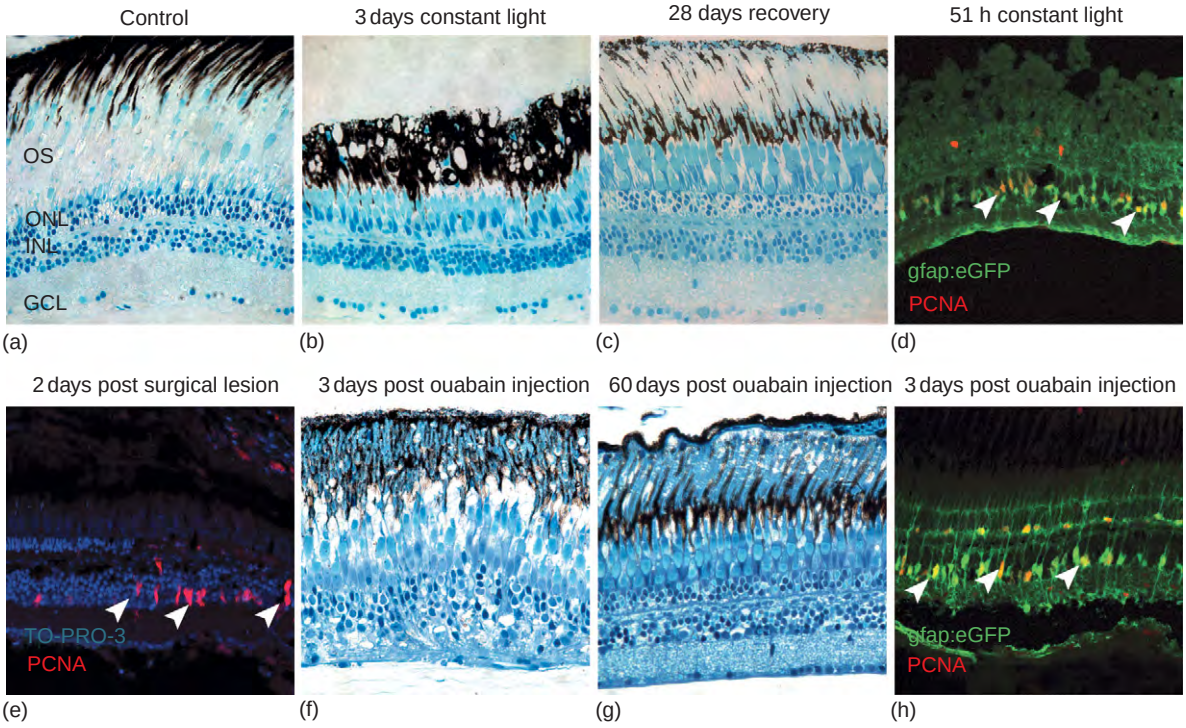

Figure 4 Cell-type restricted retinal damage in zebrafish. (a) Histological section of an undamaged zebrafish retina (control) with the following labeled: outer segments (OS), outer nuclear layer (ONL), inner nuclear layer (INL), and ganglion cell layer (GCL). (b) After 3 days of constant light, the loss of photoreceptor nuclei in the ONL and reduced outer segment integrity relative to the control are evident. (c) Photoreceptors are regenerated only 28 days post light treatment based on the nuclear density and thickness of photoreceptor nuclei in the ONL and the restoration of the photoreceptor outer segments. (d) A transgenic zebrafish line, *Tg*(*gfap:eGFP*), expresses EGFP in the Müller glia from the *gfap* promoter. Light-induced damage of this transgenic line induces proliferating cell nuclear antigen (Pcna-red) in a subset (arrowheads) of the Müller glial cells (green) after only 51 h of constant intense light. (e) Proliferating cell nuclear antigen (Pcna-red) immunolabeling Müller glial cells (arrowheads) at 2 days after a surgical lesion (TO-PRO-3 labeling of nuclei-blue) is very similar to the response observed in the light-damaged retina (d). (f) Three days after intraocular injection of ouabain, the damaged retina revealed lost retinal ganglion cells and INL neurons, without significant loss of ONL photoreceptors. (g) Sixty days after ouabain injection, the regenerated retina revealed a GCL and INL that is nearly indistinguishable from wild type (a). (h) The *Tg(gfap:eGFP)* line revealed that Pcna was detected in a subset of Müller glial cells (arrowheads) at 3 days after intraocular injection of ouabain.

In light-damaged zebrafish retinas, the Müller glia exhibit increased expression of proliferating cell nuclear antigen (Pcna), which is a component of the DNA replication machinery. The expression of this protein in the Müller glia indicates their reentry into the cell cycle (**Figure 4(d)**). To confirm that the Müller glia were proliferating, light-damaged *Tg*(*gfap:EGFP*) retinas, which express enhanced green fluorescent protein (EGFP) specifically in the Müller glial cells from the zebrafish glial fibrillary acidic protein (*gfap*) promoter, were coimmunolabeled for the expression of the proliferation marker Pcna. The number of actively dividing Müller glia, coexpressing EGFP and the red fluorescing anti-Pcna antibody, increases through 51 h of constant intense light treatment (**Figure 4 (d)**), at which point the Müller glial-derived INL neuronal progenitor cells continue to proliferate to produce clusters of 8–12 progenitor cells associated with a single Müller glial cell. While this suggests that all the neuronal progenitor cells in a cluster are derived from a single Müller glial cell and remain associated with that glial cell, this has not been formally demonstrated. This Müller glial cell-based regeneration response is conserved throughout a number of different damage models. For example, either surgical lesion or ouabain injection results in the death of many different neuronal cell types in the retina, and they both exhibit increased proliferation of the Müller glial cells (**Figure 4(e)–4(h)**).

Curiously, not all of the Müller glial cells proliferate in response to constant intense light treatment. Earlier reports suggested that a threshold of rod cell death was required to induce the Müller glial proliferation response. However, intravitreal injection of a low concentration of ouabain into the zebrafish retina resulted in massive death of the neurons in both the ganglion cell and INLs, with minimal cell death of photoreceptors (**Figure 4(f)**). Regeneration of the ouabain-damaged retina takes longer than the light-damaged retina, but still produces a relatively normal retina by 60 days post ouabain injection (**Figure 4(g)**). This demonstrates that significant rod or cone cell death is not required to induce retinal regeneration from the Müller glia (**Figure 4(h)**). Furthermore, this suggested that the number of apoptotic neurons, rather than the type of neuron, was critical for inducing this regeneration response.

To address if only rod photoreceptor cell death was sufficient to induce a Müller glial-derived regeneration response, the *Tg*(*Xops:mCFP*) transgenic line and the phosphodiesterase 6c (*pde6c*) mutant line were analyzed. The *pdge6* mutant line fails to maintain cone cells, in contrast to the rod photoreceptor cell death in the *Tg*(*Xops:mCFP*) fish. While no detectable Müller glial proliferation response was observed in the *Tg*(*Xops:mCFP*) line, a small, but significant, Müller glial proliferation response was detected in the *pdge6* mutant line. This suggested that loss of rods requires only increased proliferation of the ONL rod precursor cells that were derived from the neuronal progenitor cells during persistent neurogenesis, while loss of cones requires the increased proliferation of the pluripotent Müller glia.

To further test this hypothesis, a *Tg*(*zop:ntr*) transgenic line was generated that expresses the bacterial *nitroreductase b* (*ntr*) gene from the zebrafish *rhodopsin promoter* (*zop*). The NTR enzyme converts the prodrug, metronidazole, into a cell-autonomous toxin within NTR producing cells. Exposing a *Tg*(*zop:ntr*) transgenic line, expressing NTR in all rod photoreceptors, to metronidazole results in the death of only rod photoreceptors and the induction of a Müller glial proliferation response. Addition of metronidazole to a similar transgenic line that expresses NTR in only a subset of rods, however, failed to induce the Müller glial response. These data suggest that it is the magnitude of the cell death that determines if the Müller glia exhibit a robust proliferation response. The failure of the *Tg*(*Xops:mCFP*) transgenic line to induce the Müller glial proliferation response may be due to the rod cell death being small and chronic relative to the massive and acute cell death observed in the metronidazole-treated *Tg*(*zop:ntr*) transgenic retinas that express NTR protein in all the rod photoreceptors.

Discovery and Analysis of Candidate Genes Involved in Retinal Regeneration

Several groups have performed microarray analyses of mRNA expression patterns in different retinal damage models to determine what genes might change their expression during specific points of regeneration. In both the surgical-lesioned and light-damaged models, signal transducer and activator of transcription 3 (*stat3*) and its negative regulator suppressor of cytokine signaling 3 (*socs3*) exhibited increased expression shortly after the retinal insult (e.g., within 16 h of starting the constant intense light treatment). The increased *stat3* expression suggests that Gp130 receptor signaling is involved in the early damage response. Gp130 is a promiscuous receptor that binds a number of different extracellular signaling molecules, such as cytokines, to activate the Stat3 transcription factor in neuronal niches to promote cell proliferation in the adult vertebrate brain. The *socs3* gene, which is transcriptionally activated by the Stat3 protein, encodes a protein that binds the activated receptor to prevent further Stat3 activation. Increased *stat3 expression* is also known to occur in RGCs following optic nerve crush, further supporting Stat3's role in the damage response. Microarrays also revealed that both the achaete-scute complex-like 1a (*ascl1a*) pro-neural gene and the notch pathway genes were upregulated in the surgical-lesioned and light-damaged retinal models. By contrast, retinal progenitor genes, such as *rx* and *vsx2*, whose expression are maintained in the CMZ throughout life, are not significantly increased in expression in the damaged retina.

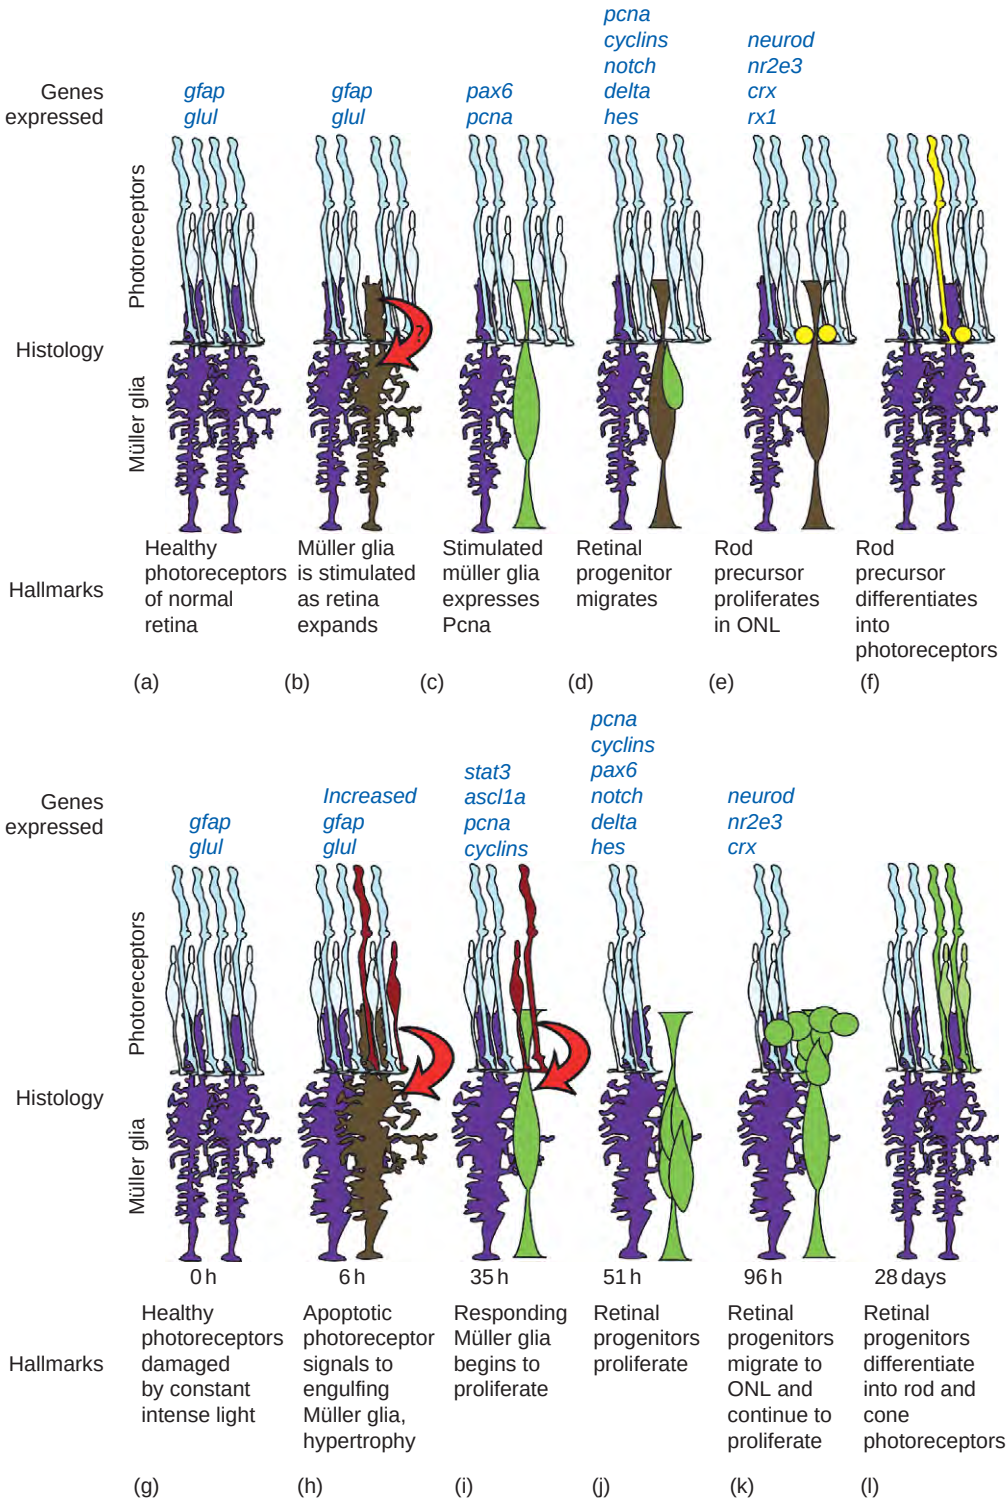

Figure 5 Schematic comparison of zebrafish retinal development and regeneration. (a) The healthy retina is made up of rod (tall dark blue) and cone (short light blue) photoreceptors interdigitating with the processes of Müller glial cells (purple). Other retinal neurons are neglected for simplicity. Müller glial cells express genes indicative of their differentiated state, glial fibrillary acidic protein (gfap) and glutamine synthetase (glul). (b) As the retina expands, a Müller glial cell becomes stimulated to proliferate (brown), possibly due only to slow or sporadic progression through the cell cycle. (c) The stimulated Müller glial cell (green) expresses *pcna* and *pax6* as it begins to divide. (d) The cell division in panel C produces a daughter Müller glial cell (brown) and a neuronal progenitor cell (green), which expresses *pcna, cyclins, notch, delta*, and *hes* genes as it migrates to the photoreceptor layer. (e) This neuronal progenitor cell reaches the ONL and is now called a rod precursor cell (yellow), as it expresses *neurod* and the rod specification genes *nr2e3, crx,* and *rx1*. (f) The rod precursor cell divides with one daughter cell differentiating into a rod photoreceptor (green). (g) The undamaged retina,

This suggests that Müller glia exhibit a state of competency that is downstream of the CMZ stem cells, but upstream of retinal neuron differentiation.

The ability to test the function of these various candidate genes in the regenerating retina has been recently advanced by the development of a method to electroporate morpholinos into the adult retina. Morpholinos are modified oligonucleotides that contain a morpholine ring, rather than deoxyribose. The morpholinos, which are complementary to a specific mRNA sequence, can base pair with and transiently block the efficient translation of the target mRNA. Because some protein could still be correctly translated in the presence of a morpholino, these loss-of-function experiments and organisms are termed knockdowns and morphants, respectively. Morpholinos have traditionally been introduced into zebrafish embryos by direct injection into either the relatively large cells of the early embryo (1–32 cell stage) or the yolk. The morpholinos then diffuse into the daughter cells as they divide during embryonic development. This approach has tested the function of numerous proteins in zebrafish development. Recently, morpholinos that are covalently attached to a positively charged fluorochrome, lissamine, have been injected into the vitreous and then electroporated into the adult retina. These morpholinos can disrupt retinal regeneration if they are electroporated into the retina to knockdown the expression of a target protein prior to its role in regeneration.

Proof-of-principle experiments to test the effectiveness of this method were shown for the requirement of Pcna in retinal regeneration. Morpholino-induced knockdown of Pcna expression resulted in the Müller glia failing to proliferate in the light-damaged retina, which led to the premature death of the stimulated Müller glial cells due to their inability to proceed through the S phase of the cell cycle. Retinas that were injected and electroporated with anti-Pcna morpholinos also failed to upregulate expression of the retinal progenitor cell marker *pax6* in the Müller glial-derived neuronal progenitor cells. Similar morpholino knockdown studies revealed that Stat3 and Pax6 are also required at different steps in the regeneration process. Microarray analyses of mRNA expression at different time points during regeneration of the surgical-lesioned and light-damaged retinas have revealed numerous candidate genes for functional study. The electroporation of morpholinos will permit a relatively rapid loss-of-function analysis to elucidate the genes that are required for regeneration and the key steps and processes underlying retinal regeneration.

Events Underlying Regeneration of the Light-Damaged Retina

Adult Müller glial cells are characterized by the expression of cell-specific markers (**Figure 5(a)**), such as glutamine synthetase (Glul) and glial fibrillary acidic protein (Gfap) among others. During persistent retinogenesis, rods are added to the established repeating mosaic of cone and rod photoreceptors from the Müller glial cell population. It is not clear if there is a signal (arrow) to stimulate Müller glia proliferation or if a small subset of Müller glia remain in a slow cell cycle (**Figure 5(b)**). This limited number of proliferating Müller glia can be detected by Pcna and Pax6 expression (**Figure 5(c)**). The small number of dividing Müller glial cells produce a daughter Müller glial cell (**Figure 5(d)**, brown) and a neuronal progenitor cell (green), which continues to express genes important in the cell cycle (Pcna and cyclins) and genes required for cell specification signaling (*notch, delta,* and *hes*). The neuronal progenitor continues to proliferate and migrates to the ONL. As the neuronal progenitor reaches the ONL (where it is now called a rod precursor), it continues dividing or begins to differentiate, expressing rod specification genes (neurogenic differentiation (*neurod*), nuclear receptor subfamily 2e3 *nr2e3, crx,* and *rx1*) and giving rise only to rod photoreceptors (**Figure 5(f)**, green).

Upon light-induced retinal damage (or other forms of retinal insult), Müller glia hypertrophy and transiently increase their expression of Glul and Gfap (**Figure 5(h)**). If the number of dying rods and cones (**Figure 5(h)**, red) is sufficiently large, the Müller glial cells increase their expression of the *ascl1a* and *signal transducer* (*stat3* genes (**Figure 5(i)**) through unclear mechanisms. Electroporation of morpholinos into the retina prior to inducing retinal damage revealed that both *stat3* and *ascl1a* are independently required for the Müller glial proliferation response. The reentry of these Müller glia into the cell cycle is accompanied by the increased expression of the

identical as in 4A is repeated here for comparison. (h) Photoreceptors (light blue) begin to undergo apoptosis (red) within 6 h of entering constant intense light treatment (rod precursors have been ignored for simplicity). The damaged photoreceptors signal (arrow) a subset of the Müller glial cells (brown) to hypertrophy, increase expression of *gfap,* and *glul,* and phagocytose the apoptotic rod cell bodies. (i) At 35 h, responding Müller glial cells (green) increase expression of the early response genes, such as *stat3* and *ascl1a,* and the cell cycle regulatory genes, the *cyclins.* Loss of Pcna expression by morpholino-induced knockdown, results in the failure of responding Müller glial cells to proliferate and regenerate the lost rods and cones. Similarly, morpholino-induced knockdown of Stat3 expression significantly reduces the number of proliferating Müller glial cells. (j) Pcna-positive neuronal progenitor cells are clustered around a Müller glial cell and exhibit increased expression of retinal progenitor genes, such as *pax6*, and genes involved in intracellular signaling pathways, such as Notch. (k) Pcna-positive neuronal progenitors display several neuronal and photoreceptor differentiation markers, including *neurod, nr2e3*, and *crx*, as they migrate to the damaged ONL. (l) One month after exiting the constant intense light treatment, regenerated photoreceptors (green) have differentiated and are indistinguishable from the undamaged photoreceptors.

cell cycle regulatory proteins, the cyclins. The Müller glial cell divisions produce neuronal progenitor cells, which continue to proliferate (expressing Pcna and the cyclins) and begin to express the retinal progenitor gene *pax6* and genes in the Notch and Delta neuronal signaling pathways (**Figure 5(j)**). As the neuronal progenitor cells migrate toward the ONL, they begin to express genes that are required for the commitment and differentiation of rod and cone photoreceptors (*neuroD, nr2e3*, and *crx*; **Figure 5(k)**). Within 28 days of ending the constant intense light treatment, the rod and cone photoreceptors have regenerated (**Figure 5(l)**).

Vestigial Retinal Regeneration Activity in Mammals

The finding that the Müller glial cell acts as an adult neuronal stem cell in the regeneration of the damaged zebrafish retina suggests that it potentially could produce a similar regeneration response in the damaged mammalian retina. Recent studies support the hypothesis that mammalian Müller glia possess some of the features of adult neuronal stem cells. Transplanted rodent Müller glia into a damaged retina will produce rhodopsin-positive cells. As expected, intraocular injection of neurotoxic doses of *N*-methyl-D-aspartic acid (NMDA), which is a synthetic amino acid that binds a glutamate receptor, results in the death of many retinal cell types. However, NMDA damage in the rat retina is followed by a small number of Müller glia proceeding through one cell division to yield a limited number of cells that differentiate into photoreceptors and bipolar cells. This Müller glial cell proliferation and regeneration response can be slightly enhanced with the addition of various growth factors. Injection of the toxin *N*-methyl-N-nitrosourea (NMU) into the adult rat eye, which specifically kills photoreceptors, induces Müller glial hypertrophy and increased expression of GFAP and the neural stem cell marker, nestin, followed by the proliferation of some Müller glia. While BrdU labeling confirmed that the Müller glia actively divided in response to the NMU damage, only 42% of the BrdU-labeled cells remained 2 weeks after the NMU injection. Of these surviving BrdU-labeled cells, which were all located in the INL, 58% expressed glutamine synthetase (suggesting they corresponded to Müller glial cells that initially divided) and only 8% expressed rhodopsin. Thus, there were very few rhodopsin-positive cells produced by this Müller cell division and the ones that were generated, failed to properly migrate to the ONL. Expression or addition of various growth factors increased the number of proliferating Müller glia only to a small extent. Activation of various signaling pathways, such as Notch, similarly resulted in only a slight increase in the number of Müller glial-derived neuronal progenitors in the damaged rodent retina. While retinal damage induced some mammalian Müller glia to proliferate and various growth factors or signaling pathways slightly increased that number, there remained an insufficient number of proliferating Müller glial cells and neuronal progenitor cells to properly regenerate all the neurons lost from the retinal damage. Analyzing the mechanisms underlying the robust Müller glial proliferation response in the light-damaged zebrafish retina will provide important clues as to why the regenerative capacity of the mammalian retina is so limited.

Similarities and Differences of Development with Retinal Ontogeny/Genesis

As discussed above, Müller glia and the neuronal progenitor cells respond to retinal damage by increasing the expression of many of the retinal progenitor genes, such as *pax6*, that are expressed during embryogenesis and near the CMZ throughout the life of the fish. The inability of the mammalian Müller glial cells to mount a sufficiently robust proliferative and regenerative response may be due to differences in the signals that stimulate the Müller glia to respond. All attempts to stimulate sufficient levels of Müller glial proliferation in the mammalian retina have met with very limited success. Conversely, the failure to robustly proliferate may be due to intrinsic differences between the mammalian and zebrafish Müller glial cells. For example, transplanted mammalian Müller glial cells into a damaged retina will differentiate into rhodopsin-positive cells that are predominantly restricted to the INL, rather than repopulating the ONL. Thus, a further understanding of the signals that stimulate the zebrafish Müller glial and neuronal progenitor cells to proliferate and migrate may reveal insights into how to better manipulate the mammalian retina, and by extension, potentiate human retinal regeneration.
