Commonly encountered bacterial TLR ligands, such as LPS (also termed endotoxin) and flagellin among others can activate endothelial sprouting directly by signaling through TLRs, even in the absence of additional cytokines. The molecular pharmacology contributing to enhanced angiogenesis includes, for example, increased local tissue concentrations of adenosine and adenine nucleotides, autacoids (i.e., nonpeptidic, intercellular small molecule signals) that increase rapidly following cellular injury or ischemia. Animals with targeted disruption – also termed a gene knock-out – of adenosine A2A receptors, for example, exhibit not only less inflammation but also less wound-related angiogenesis following injury, suggesting that release of locally acting autacoids such as adenosine does contribute to accelerated wound healing. Indeed, several mammalian TLRs (specifically TLR2, -4, -7, and -9), in the presence of activating ligands such as LPS or unmethylated CpG motifs, synergistically induce the synthesis and release of multiple families of vascular endothelial growth factor (VEGF) isoforms, in the presence of adenosine acting at A2A receptors. As a consequence, the induction and extent of inflammation-induced angiogenesis is accelerated, while any further release of inflammatory cytokines (e.g., TNF-α, and IL-1β among others) may be moderated or even suppressed. In contrast, in the absence of adenosine release, although TLR activation continues to increase inflammatory cytokine expression, VEGF-A is suppressed (at least in murine macrophages *in vivo*).

This adenosine-mediated angiogenic switch triggers downstream intracellular signal transduction cascades involving intermediate adapter proteins such as MyD88, IRAK4, and TRAF6, among others (see **Figure 1**). Indeed, macrophages from mice with targeted disruption of MyD88 (i.e., MyD88 knock-outs), an essential component of intracellular TLR signaling cascades, as expected did not express any VEGF-A isoforms in response to either TLRs or to adenosine A2AR agonists. These results provide additional insight into the molecular pathways that contribute to wound healing. Skin wounds in $MyD88^{-/-}$ mice, for example, healed at a markedly slower rate than wounds in wild-type animals. Wound contraction and stabilization also decreased, which in turn delayed granulation tissue formation, in part, due to reduced microvascular blood vessel density, each of which was due in large part to a reduction in the expression of several VEGF isoforms, when compared to wild-type (i.e., $MyD88^{+/+}$) animals.

Another signaling pathway involved in innate immunity and the response to tissue injury is high mobility group box-1 (HMGB1), a protein which is released from cells in response to infection or injury. Activated HMGB1 triggers a cascade of innate immunity signaling pathways, including TLR4, as well as activation of several families of pro-angiogenic proteins. This cascade of signaling proteins is manifested, in large part, by the

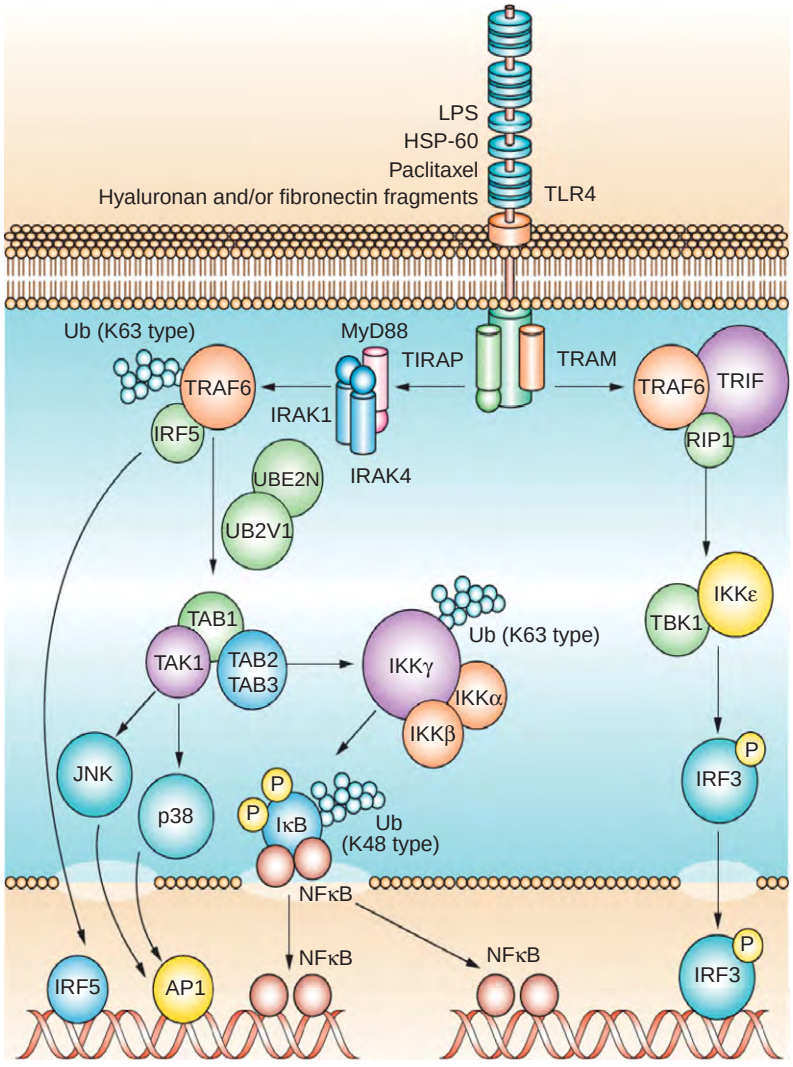

Figure 1 The toll-like receptor signaling pathway. Abbreviations: AP1, activator protein 1; HSP-60, heat shock protein 60; IκB, inhibitor of nuclear factor κ B; IKKα, inhibitor of nuclear factor κ B kinase α; IKKβ, inhibitor of nuclear factor κ B kinase β; IKKε, inhibitor of nuclear factor κ B kinase ε; IKKγ, inhibitor of nuclear factor κ B kinase γ; IRAK1, interleukin 1 receptor-associated kinase 1; IRAK4, interleukin 1 receptor-associated kinase 4; IRF3, interferon regulatory factor 3; IRF5, interferon regulatory factor 5; JNK, c-jun N-terminal kinase; LPS, lipopolysaccharide; MyD88, myeloid differentiation primary response protein; NFκB, nuclear factor κ B; RIP1, receptor-interacting protein 1; TAB1, TAK1-binding protein 1; TAB2–TAB3, TAK1-binding proteins 2 and 3; TAK1 (M3K7), transforming growth factor-β-activated kinase 1; TBK1, serine–threonine-protein kinase; TIRAP, TIR domain-containing adaptor protein; TLR4, toll-like receptor 4; TRAF6, tumor necrosis factor receptor-associated factor 6; TRAM, TRIF-related adaptor molecule; TRIF, TIR-domain-containing adaptor inducing interferon β; Ub, ubiquitin; UB2V1, ubiquitin-conjugating enzyme E2 variant 1; UBE2N, ubiquitin-conjugating enzyme E2N.

RAGEs. Animals with targeted disruption of RAGE, for example, have significantly less heart muscle damage in ischemia-reperfusion assays when compared to normal, wild-type, control animals.

HIF-1α: At the Intersection of Angiogenesis and Innate Immunity

The transcription factor HIF-1α and its related isoforms play a relatively unique role following development, in that they regulate, either directly or indirectly, a series of physiologic regulatory pathways that include both oxidative phosphorylation as well as glycolytic pathways for the generation of ATP. All three HIF isoforms require binding (i.e., dimerization) to a protein termed the arylhydrocarbon receptor nuclear translocator or ARNT for short (also termed HIF-1β), in order to initiate gene transcription. Hypoxia-dependent activity of all of the HIF-1 isoforms is regulated via hydroxylation of highly conserved proline residues, a reaction catalyzed by oxygen-sensing prolylhydroxlyases (PHDs). Induction of

HIF-1α signaling is well known to orchestrate the expression of genes that regulate multiple families of proteins that are involved in angiogenesis and tissue repair. These include most VEGF family members and their related subisoforms, as well as other angiogenic cytokines, including, but not limited to, platelet-derived growth factor (PDGF), PlGF, and the several known angiopoeitin isoforms, among others.

Importantly, the appropriate physiologic suppression of HIF-dependent signaling is equally important with regard to this family of pro-angiogenic transcription factors, depending on the cellular and physiologic context. For example, excessive and/or continuous activation of HIF signaling may lead to vascular malformations, or facilitate the development of a blood supply to a nascent, hypoxic subclinical tumor. There are, therefore, a number of autoregulatory mechanisms that limit HIF isoform activity as tissue hypoxia improves, including upregulation of PHD gene expression, which acts as a feedback mechanism to suppress HIF activity in the short term. During sustained or chronic hypoxia, however, continuous overactivation of PHD signaling appears to induce a new set point or equilibrium for intracellular O_2 homeostasis. This is characterized by sustained low levels of HIF isoform expression despite continuously low intracellular levels of tissue oxygen content, thereby prolonging cell survival.

HIF-1 activation in many cell types also regulates the expression of a number of proteins involved in apoptosis. In endothelial cells studied *in vitro* for example, HIF-1α decreased apoptosis in response to hypoxic stress followed by rapid re-oxygenation (often termed reperfusion injury). This models the common clinical scenario observed in patients who develop a rapidly occlusive clot in, for example, a large coronary artery, resulting in myocardial ischemia or infarction. These are then treated by a clot-dissolving, thrombolytic drug or by coronary artery catheterization and physical removal of the clot. Rapid restoration of oxygenated blood flow into an area of ischemic tissue is essential – particularly in tissues such as the brain, kidney, and the heart – that have a continuously high metabolic demand for oxygen. However, the extent of tissue injury following ischemia is also impacted by the generation of reactive oxygen species (ROSs) which, somewhat counter intuitively perhaps, may result in additional damage to cells despite adequate tissue oxygen levels.

Genomic analyses of selected cell types transfected with constitutively active HIF-1α transgenes have also identified unconventional pro-angiogenic peptides that are regulated by HIF-1α, such as the natriuretic peptides atrial and brain natriuretic factor (ANP and BNP), for example, as well as growth factors such as insulin-like growth factor 1 (IGF-1), IGF-2, insulin-like growth factor binding protein 3 (IGFBP3), fibroblast growth factor 2 (FGF-2), TGFβ1 and epidermal growth factor (EGF), as well as neuregulins and inflammatory cytokines, including TNF-α and interleukin (IL)-1β, among other innate immunity agonists. LPS (i.e., endotoxin) alone, for example, even in the absence of inflammatory cytokines, has been shown to directly activate HIF-1α signaling to a greater extent than hypoxia. Indeed, a central role for HIF-1α in sustaining, if not initiating, inflammation was first revealed by selectively deleting HIF-1α only in leukocytes, using the enzyme *cre*-recombinase. The phenotype of the resulting leukocytes was surprisingly normal, but the affected cells did have reductions in many pro-angiogenic cytokines – all VEGF-A isoforms for example – as well as in genes involved in gluconeogenesis, a reflection of the essential role that the HIF isoforms play in maintaining and regulating energy homeostasis within most cell types. Genetically engineered, myeloid tissue-specific, VHL-deficient (VHL-LysM-CRE) mice lack the ability to suppress HIF-1α activation when oxygen is not limiting. These animals exhibited an exaggerated response to a number of pro-inflammatory signals in several tissues, such as arthritic changes in synovial joint tissue, even in the absence of any documented infectious etiology. Indeed, biopsies from patients with active arthritis exhibited increased levels of HIF-1α and HIF-2α expression in tissue sections, as well as increased bioactivity (i.e., increases in angiogenic cytokines such as VEGF-A isoforms, in synovial biopsies). Also, HIF-1α is known to regulate the expression of the inflammation-inducible isoform of nitric oxide synthase (i.e., iNOS), an effector arm of innate immunity. Levels of NO generated by iNOS are sufficient to induce bacteriostasis, as well as facilitating local vasodilation, both of which would tend to suppress infection and permit more rapid recruitment of inflammatory cells.

Another recently recognized link between HIF signaling and innate immunity was the discovery that induction of HIF-1α is dependent upon, among other pathways discussed above, the activation of NFκB signaling, and in particular IKK-β. More efficient utilization of glycolytic pathways may be one other potential benefit of the physiologic link between HIF-1 and IKK β-mediated regulation of inflammation, both of which are evolutionarily ancient signaling pathways. Consistent with this model are recent data that document increases in expression and transcriptional activity of both HIF-1α *and* HIF-1β (i.e., ARNT) in monocytes during differentiation into tissue macrophages. Indeed, activation of HIF-1α appears to be essential for the functional maturation of macrophage activity. Furthermore, several forms of ROSs – generated by H_2O_2 or by a nicotinamide adenine dinucleotide phosphate (NADPH) oxidase for example – are known to trigger stabilization and nuclear translocation of HIF-1α/ARNT heterodimers, a process that requires initiation of activation of NFκB.

Wound repair also requires sources of energy in the relatively hypoxic, inflammatory milieu of the healing tissue, a process termed metabolic reprogramming, that

is, switching from the use of oxygen as the primary electron donor to anaerobic metabolism. This metabolic switch depends in large part on the activation of the transcription factor peroxisome proliferator activated receptor (PPARα). This adaptation, perhaps somewhat counter-intuitively, results in the restriction of glycolytic intermediates entering into the tri-carboxylic acid cycle (TCA) cycle, while concurrently decreasing oxidative phosphorylation. This adaptation should diminish the risk of severe tissue ischemia, while concurrently minimizing oxygen radical damage to, in this case, skeletal muscle fibers.

Other, related transcriptional regulators that have recently been shown to mitigate tissue hypoxia, by inducing activation of several angiogenenic signaling cascades, include the peroxisome–proliferator-activated receptor coactivator-1α (PCG-1) which, following dimerization with the orphan receptor ERR-α, regulates oxidative phosphorylation, induces gluconeogenesis, and upregulates all VEGF-A isoforms, although by a mechanism that is distinct from HIF-1α/ARNT heterodimer signaling. For example, iron chelators such as desferoxamine, which reliably induce HIFα expression and activation, do not enhance PCG-1α-dependent VEGF isoform secretion).

There is also epigenetic regulatory control of numerous inflammatory and pro-angiogenenic pathways in the context the pathophysiology of cardiovascular diseases. Histone deacetylase (HDAC) inhibitors suppress, for example, TNF-α signaling in monocytes *in vitro*, but not necessarily *in vivo*, depending on the intracellular context. There are also important inter-species differences among mammals, such as the modest activation of human iNOS *in vitro* in response to inflammatory cytokines when compared to the much more robust responses observed in rodents, for example. As these authors note, our understanding of the epigenetic regulation of promoter specificity for many genes targeting innate immunity pathways remain poorly understood. Investigation of these regulatory signaling pathways will obviously continue to inform our knowledge of the roles of epigenetic factors at the interface of inflammation and angiogenesis.

Another area of increasingly focused investigation is the role of RNA silencing in the regulation of host defense, including the function of microRNAs (miRNA) and small interfering RNAs (siRNAs) in controlling gene expression in general. A recent study documented the phenotype of animals with an endothelial cell restricted, targeted deletion of mi-126, a miRNA expressed predominantly in areas of high vascular density, such as the heart and lungs. Deletion of mi-126 results in a number of vascular abnormalities, including, among others, severe ischemic injury in several vascular beds – including the heart – compared to control animals. Similar results with mi-126 were reported by Fish and collaborators in a zebra-fish model.

One of the more remarkable results noted recently are data from Kleinman and colleagues in the context of choroidal neovascularization (CNV). While testing a variety of siRNA constructs targeted to suppress neovascularization (i.e., VEGF-A isoform secretion) in the retina, these investigators noted that even non-targeted 21 nucleotide duplex siRNAs were able to suppress intraocular vascular proliferation as well as targeted constructs. For example, firefly luciferase siRNA, among several other siRNA's tested, was as effective in suppressing VEGF production in the retina as isoform-targeted, VEGF-A siRNA constructs. Given that naked siRNAs are not known to be internalized by mammalian cells, the most tractable hypothesis based on these data suggests that the innate immunity PRRs , and, in particular, TLR-3, recognize 21-mer or longer double-stranded RNA (dsRNAs) and suppress transcription. This additional activity of TLR3 was unanticipated, given that the majority of the work to date on the inflammatory effects downstream of the toll isoforms results in increased, not decreased, inflammation.

Summary

Activation of an innate immune response is among the first lines of defense following tissue injury. Restoration of blood flow to the site of injured tissue (i.e., angiogenesis) is a necessary prerequisite for successful tissue remodeling and wound repair. The HIF families of transcription factors play a pivotal role in both the induction of an innate immune response as well as the triggering of multiple pro-angiogenic signaling cascades that participate in wound repair and regeneration. The coordinated activation of these, among other innate immunity signaling cascades, are essential for initial suppression of pathogen growth, and are required for the release of multiple pro-angiogenic and innate immunity signaling pathways that facilitate tissue repair process which, when successful, results in a gradual return to normal tissue homeostasis.

Intraocular Pressure and Damage of Optic Nerve Axons

R W Nickells, University of Wisconsin, Madison, WI, USA

Glossary

Apoptosis – The molecular and biochemical process by which a cell soma (cell body) is able to disassemble all of its organelles and break apart to be engulfed by neighboring cells. As the process is intrinsic, and tightly regulated by the cell itself, it has often been called a cell suicide program. Apoptosis is the mechanism of cell elimination during development (programmed cell death) and is often the end-stage result of cell loss in a variety of diseases, particularly chronic neurodegenerative disorders. Retinal ganglion cell soma apoptosis is the mechanism of cell loss in glaucoma.

Axons – The single extensions of neurons that act as the conduit for an electrical impulse or signal originating from the soma of the same neuron. They typically terminate in a synapse that contacts one of many dendrites of other neurons. In reference to glaucoma, axons of the retinal ganglion cells pass out of the eye into the optic nerve.

Glia – The abundant non-neuronal cell types in the nervous system. There are many different classifications of glia, but principally they are made up of astrocytes, Müller cells (in the retina), oligodendrocytes or Schwann cells (which synthesize myelin in the central and peripheral nervous systems, respectively), and microglia. Astrocytes and Müller cells are thought to function as neuronal support cells under normal conditions. Microglia are thought to play an important role in the innate immune response of neural tissue.

Lamina cribrosa – In higher primates, it is the connective tissue and neuronal structure comprising the scleral canal at the site where the optic nerve exits the eye. The connective tissue is formed as plates of collagen and basement membrane and the surface of these plates are occupied by astrocytes and a secondary cell type called lamina cribrosa cells. Pore structures exist between the plates through which retinal ganglion cell axons are bundled as they exit the eye. Rodents do not have a lamina cribrosa, but instead have columns of astrocytes that surround the bundles of exiting axons. Because of the lack of connective tissue, this structure has been termed the cellular lamina in these animals.

Optic nerve – It is anatomically described as the second of the 12 paired cranial nerves and is an extension of the central nervous system. The nerve begins at the lamina cribrosa and extends to the lateral geniculate nucleus in higher primates and the superior colliculus in rodents. Shortly after it exits the eye, the fibers of the nerve, which are axons of retinal ganglion cells, become myelinated.

Retinal ganglion cells – The projection neurons that reside in the innermost layer of the retina, and extend axons out of the eye and into the optic nerve. They receive electrical stimulation from photoreceptors by way of bipolar neurons and then convey that stimulus to optical centers in the brain.

Soma – Also known as the cell body, it is anatomically and functionally distinct from the dendrites, axon, and synapse, even though these compartments are all part of the same cell. The soma contains the basic cellular organelles including the nucleus and the majority of endoplasmic reticulum and Golgi bodies. Retinal ganglion cell somas reside in the ganglion cell layer of the retina.

Introduction – Intraocular Pressure as a Risk Factor for Glaucoma

Glaucoma is one of the world's leading causes of blindness, estimated to affect over 60 million people worldwide by the year 2010. It is typically a disease of the elderly and often goes undetected until later stages because progression is usually not associated with pain, or the devastating loss of central vision. Instead, glaucoma progresses slowly, creating a series of small peripheral defects in vision (called scotomas) that are compensated for by processing in the visual centers of an affected individual. The development of these pathological blind spots is principally the result of the regional degeneration of the retinal ganglion cells, involving the loss of both the axon in the optic nerve, and the cell body (soma) in the retina. Once a critical number of cells are lost in the retina, light information from that specific region is unable to be transmitted to the brain.

Because of the slow progressive nature of the disease, early detection is paramount to establish treatments that can attenuate further damage to the retina and optic nerve. A critical part of the early detection arsenal is the association between elevated intraocular pressure (IOP) and glaucoma. Nearly every person with glaucoma has

either elevated IOP, or benefits from having existing levels of IOP lowered. In addition, experimentally induced ocular hypertension is a staple of virtually all animal models of the disease, while lowering elevated IOP in these models is associated with slowing the progression of glaucoma, thus providing experimental evidence for the causal relationship between eye pressure and optic nerve disease.

Currently, there is no clear mechanism that associates elevated IOP with the activation of optic nerve and retinal damage; however, studies over the last several decades have pointed to a viable model linking the two. At present, this model serves as a framework for both current and future hypothesis-driven studies that may help resolve this important question. Understanding the model requires a brief tutorial on the relevant anatomical structures of the eye. In essence, the mammalian eye is a closed hydrostatic system. The optics, which are designed to focus incoming light from the anterior segment of the eye onto the sensory retina lining the posterior segment of the eye, require that the globe be properly inflated. To do this, aqueous humor is secreted by cells of the ciliary body posterior to the iris and drained through the trabecular meshwork and Schlemm's canal, anterior to the iris. As light passes into the eye, and is focused onto the sensory retina, photons are captured by photoreceptors, where they are converted into chemical signals that are then processed by the neural network of the retina until finally reaching the retinal ganglion cells. Ganglion cells transmit these signals through axons that exit the globe, enter the optic nerve, and connect to neurons in visual centers in the brain. Anatomically, the axons from the ganglion cells typically form bundles and exit the globe through a posterior hole in the sclera called the lamina. In small mammals, such as rodents, the axon bundles in the laminar region are supported by columns of glial cells, principally astrocytes. This structure has been called the cellular lamina by some researchers to distinguish it from the lamina cribrosa (LC) found in the eyes of larger mammals such as primates. The LC accommodates larger numbers of ganglion cell axons (in the range of 1 million in higher primates versus 50 000–100 000 in rodents), which necessitates the presence of collagenous beams and plates that support the spaces through which the axon bundles pass (**Figure 1**). Similar to rodents, this region of the optic nerve is also populated with cells, including astrocytes, specialized cells referred to as LC cells, and microglia.

Biomechanical Engineering Studies

In a consideration of how elevated IOP causes the death of retinal ganglion cells, the lamina plays a central role. Several seminal studies on the pathophysiology of glaucoma have pointed to the laminar region of the optic nerve head as the first site of damage in glaucoma. The evidence for this comes from a variety of observations, notably classical studies showing the disruption of both retrograde and anterograde axoplasmic transport in response to elevated IOP (**Figure 2**), and more recent electron microscopic studies showing very early axonal disruption in the nerve head of a mouse model of glaucoma.

Intuitively, the lamina causes something of a dilemma when considering that the eye must be under some kind of pressure in order to maintain normal function, since it is essentially a hole in an otherwise closed, spherical, hydrostatic system. Thus, one might expect that forces generated by hydrostatic pressure within this system would be focused onto the weakest point, such as this small hole. Given the requirement for some level of pressure in the eye, it is likely that the evolutionary development of the lamina would be sufficiently strong enough to support the axons passing through it, so that they are not adversely affected by the forces concentrated on this area. However, in the face of above-normal levels of IOP, which would increase the forces directed at the laminar structure, axons could be damaged if the forces focused on this region exceeded the structural capacity it was designed to withstand.

This rather speculative model has been tested by biomechanical engineers using finite element modeling. In this complicated field of applied engineering, real-life measurements of the tensile strength of biological tissues are taken and used to design small elements that are pieced together to create a three-dimensional model of the biological system in question. Early finite element models of the eye were created based on mathematics of a simple sphere under pressure, and these models helped confirm the basic intuitive idea that forces created by pressure inside the globe create stress and strain on the structural integrity of the lamina (**Figure 1**). Important advances in the field finite element modeling in the study of glaucoma have come from detailed element modeling of both the sclera of the eye and the different components of the primate LC.

Modulation of Glia Behavior at the Optic Nerve Head and Dysfunction of Ganglion Cell Axons

When IOP becomes elevated, resulting in an increase in the stress placed in the laminar region, the cells in this region respond. The precise nature of this response is not fully understood, but detailed gene expression profiles of the optic nerve head region of rats with experimental glaucoma clearly indicate that the glial cells in this region upregulate the expression of genes involved in proliferation and remodeling of the extracellular matrix (ECM). Similar changes in gene expression have been noted in optic nerve astroctytes and LC cells in higher primates

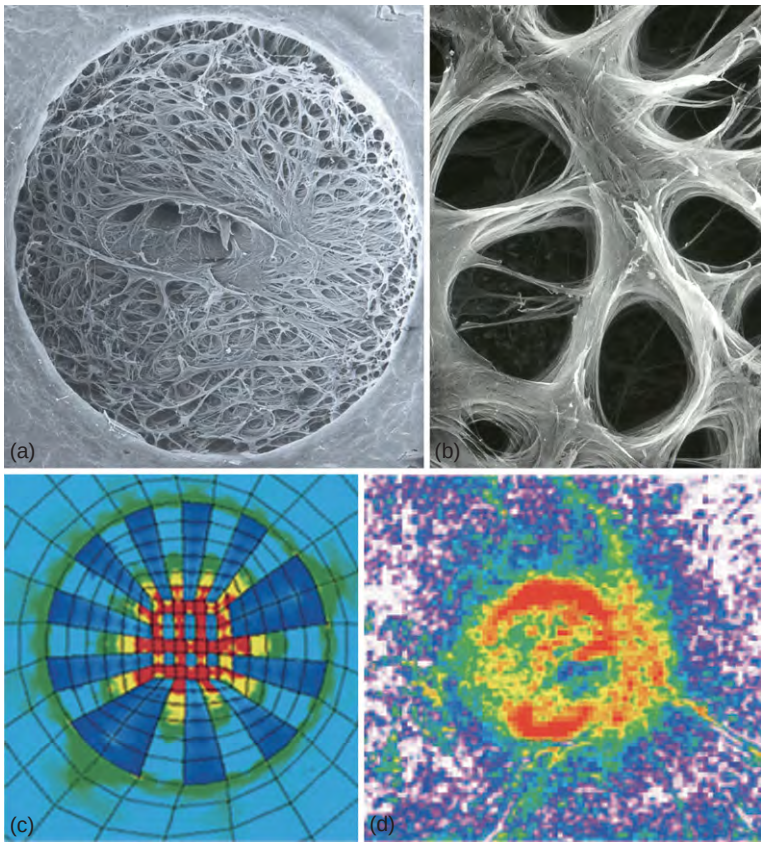

Figure 1 Increased strain associated with elevated IOP is directed onto the lamina cribrosa. (a) Scanning electron micrograph of a human lamina cribrosa after alkali treatment to remove soft tissue. The collagen-based laminar beams create an interacting network of plates and pores (higher magnification in (b)), through which bundles of retinal ganglion cell axons pass as they exit the eye and extend through the optic nerve. The diameter of the human scleral canal is approximately 1.7 mm, and the image shown is from the perspective of the vitreoretinal surface. (c) A contour stress plot of a finite element model of a human lamina. Models such as these predict that stresses generated by elevated IOP are concentrated on the laminar beams, with the highest stress (warm colors) occurring within the central beams. In addition to stress being applied to the beams, detailed histological studies also show an enlargement of the scleral canal. (d) A contour plot of tissue deformation of the lamina of a human donor eye. In this experiment, deformation was calculated as the topographical difference between the vitreoretinal interface when exposed to 15 and 50 mmHg. Experimentally, maximal deformation does not take place at the center of the lamina. (a and b) Courtesy of Dr. Harry A. Quigley, Wilmer Eye Institute, Johns Hopkins School of Medicine. with experimental glaucoma and in the human disease. Early interpretations of these changes in gene expression generally assumed that cells in this region were responding to the loss of ganglion cell nerve fibers by laying down a glial scar. This notion has recently been challenged by biomechanical studies of the connective tissue composition of the laminas isolated from monkeys at the very early stages of experimental glaucomatous damage. In detailed three-dimensional reconstructions of serially sectioned nerve heads, in which each section was individually stained for ECM components, this group showed that connective tissue content increased in the laminar region well in advance of the loss of neuronal tissue. Surprisingly, the ratio of connective tissue to neural tissue remained relatively constant, indicative of an increase in the thickness of the laminar region caused by the addition of new ECM material in the posterior region of the lamina and an actual widening of the scleral canal. Progressively, the connective tissue lamina begins to deform posteriorly partly as a function of the loss of ECM material in the anterior portion of the lamina, and, at later stages of glaucomatous progression, partly as a function of the loss of ganglion cell axons entering the optic nerve head. Eventually, the posterior deformation becomes permanent, resulting in the classic cupping of the optic nerve head observed clinically.

The interpretation of these changes in the optic nerve head in early glaucoma is that the glial cells in this region are responding to the tremendous increase in stress and strain induced by the elevation in IOP, by laying down

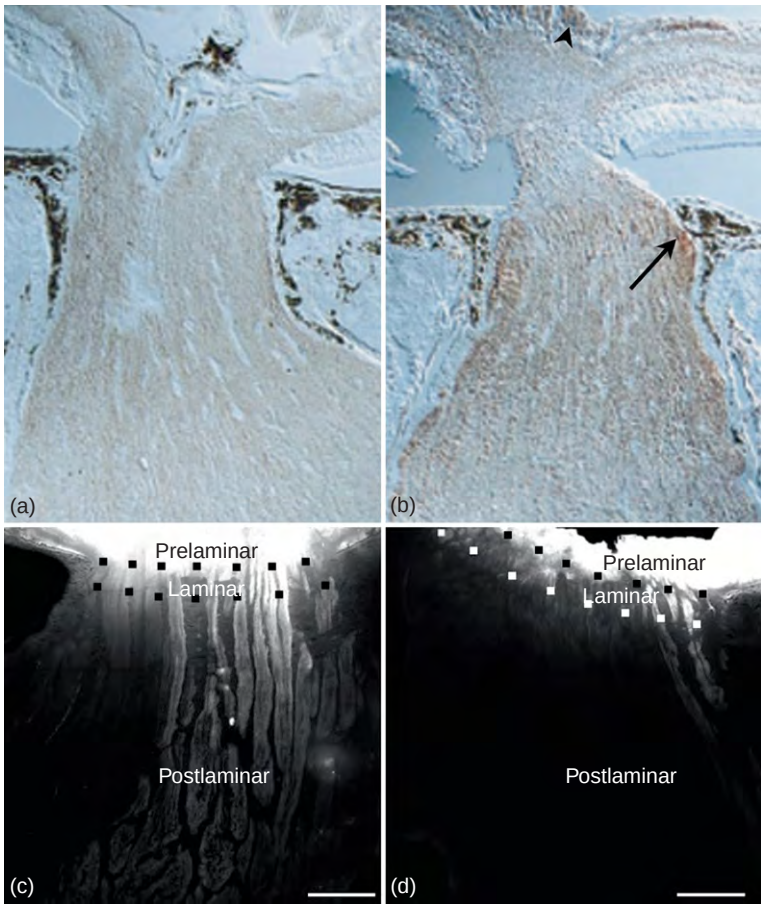

Figure 2 Ocular hypertension and glaucoma are associated with a blockage of axonal transport. (a and b) Immunohistochemical staining for the TrkB neurotrophin receptor in the optic nerve of rat eyes under normal IOP (a) or experimentally induced ocular hypertension (b). The TrkB receptor typically binds neurotrophic factors, such as brain-derived neurotrophic factor (BDNF), at ganglion cell synaptic connections in the brain. Once bound, TrkB is internalized and transported retrogradely to the ganglion cell somas. During periods of ocular hypertension, TrkB receptor accumulates at the level of the cellular lamina in the rat eye (arrow), while focal accumulations of this receptor can also be detected in the nerve fiber layer of the retina (arrowhead). These findings are consistent with a blockade of retrograde axonal transport during ocular hypertension. (c and d) Blockade of anterograde axonal transport in a porcine model of ocular hypertension. In this experiment, rhodamine β-isothiocyanate (RITC) was injected into the vitreous of pig eyes, which were then subjected to elevations in IOP for 6 h (d). Eyes under normal IOP (c) show uptake and transport of the RITC along the axons of the optic nerve. Ocular hypertensive eyes exhibit little to no transport of this dye past the laminar region. (a and b) Reproduced from Pease, M. E., McKinnon, S. J., Quigley, H. A., Kerrigan-Baumrind, L. A., and Zack, D. J. (2000) Obstructed axonal transport of BDNF and its receptor TrkB in experimental glaucoma. *Investigative Ophthalmology and Visual Science* 41: 764–774, with permission from the Association for Research in Vision and Ophthalmology. (c and d) Reproduced from Balaratnasingam, C., Morgan, W. H., Bass, L., et al. (2007) Axonal transport and cytoskeletal changes in the laminar regions after elevated intraocular pressure. *Investigative Ophthalmology and Visual Science* 48: 3632–3644, with permission from the Association for Research in Vision and Ophthalmology. Scale (in (c) and (d)) = 400 μm.

new connective tissue in an effort to increase the mechanical strength of the lamina. Addition of material to the posterior surface of the lamina ensures, at least in the short term, that axons will be minimally damaged in the process. Ultimately, this process appears to be a losing battle, as axons become progressively more damaged and begin to degenerate, the optic nerve head becomes a series of collapsed connective tissue plates. A critical question in the pathophysiology of glaucoma is what ultimately causes the damage to the axons in this region.

Several theories have been postulated for the source of the axonal damage. The earliest of these were contradictory models that postulated either (1) a decrease in blood flow to the optic nerve head, creating an ischemic environment for the ganglion cell axons, or (2) direct mechanical damage to the axons as they passed through the connective tissue plates of the lamina such that they were being crimped as the plates underwent the process of posterior deformation. More recent models have predicted that the altered function of the astrocytes and microglia in this region leads to the release of toxic molecules. Several studies have suggested that these toxins could range from highly reactive nitric oxide radicals mediated by the activity of nitric oxide synthase-(NOS)-2 to tumor necrosis factor α (TNFα), which is produced by astrocytes under stress conditions and can activate retinal ganglion

cell death. Regarding this hypothesis, although many questions remain unanswered, experimental evidence is clear that astrocytes, microglia, and possibly LC cells become reactive in the glaucomatous optic nerve head (Figure 3), leading to molecular and behavioral changes that have been associated with pathology in several other neurodegenerative disorders.

Others, however, have reasoned that the initial responses of glia in the nerve head are just as likely trying to protect the axons as they compensate for the increased mechanical strain. Protective effects of astrocytes can include becoming a source of trophic factors for damaged neurons. In addition, they also act as the principal source of glycogen stores in the central nervous system (CNS), and are typically involved in monitoring and balancing extracellular pH and ionic conditions, which both support neurons and prevent damaging effects. Thus, central questions in our understanding of glaucoma pathology are whether the optic nerve glia simply become unable to continue their role in supporting the ganglion cell axons, or do they instead change to a molecular behavior that contributes to axonal pathology?

Another important consideration in our understanding of the effects of elevated IOP on the optic nerve head is the differential between IOP and arteriolar blood pressure. From a biomechanical standpoint, perfusion pressure to the small capillaries in the nerve head could meet much higher resistance in the face of elevated IOP. Thus, it is reasonable to predict that reduced blood flow would lead to micro-ischemic environments in this region. A similar consideration could also be made for the process of axoplasmic transport, particularly retrograde transport. Taken together, the pressure differential encountered at the lamina of a glaucomatous eye may consummate in a catastrophic stress where neurons are consuming greater amounts of adenosine triphosphate (ATP) to maintain

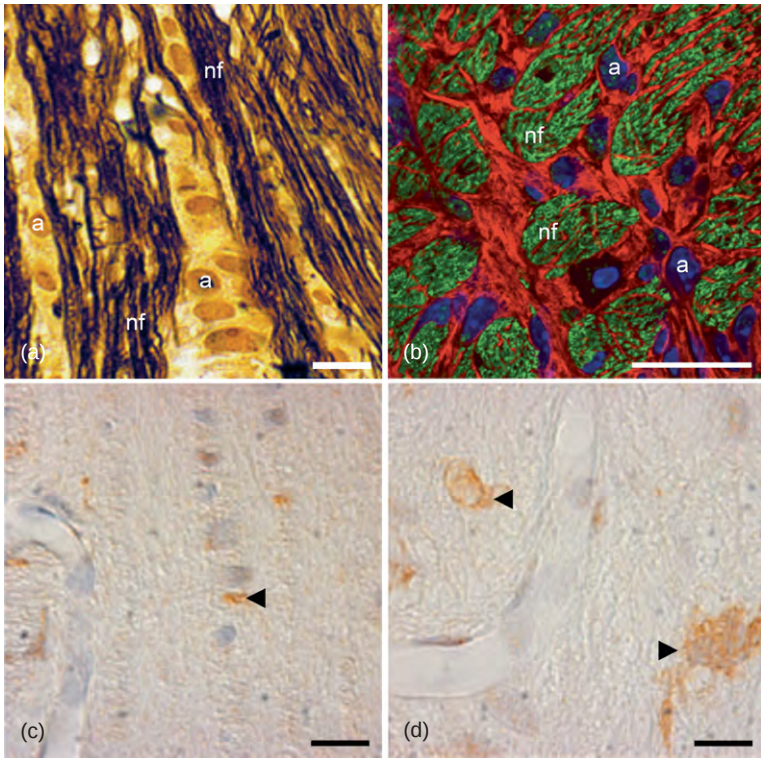

Figure 3 Ocular hypertension is associated with reactive astrocytes and microglia in the optic nerve head. (A) Columns of astrocytes (a) separate bundles of nerve fibers (nf) of ganglion cell axons in the cellular lamina of a young DBA/2J mouse without glaucoma. Longitudinal section, stained with silver impregnation. Scale = 10 μm. (B) In a mouse eye with glaucoma, astrocytes (a) become reactive and express the glial fibrillary acidic protein intermediate filament (stained red). This expression occurs early in disease, as evidenced by nerve fiber bundles (nf: stained green) still mostly intact. Transverse section through the lamina. Scale = 20 μm. (C, D) Images showing microglia expressing the marker gene IBA1 (brown reaction product) in a normal control rat lamina (C), or in the lamina of an eye with experimental glaucoma (D). Arrowheads point to immunopositive cells. Reactive microglia upregulate IBA1 expression. Scale (in (C) and (D)) = 3 μm. (A) Reproduced from Schlamp, C. L., Li, Y., Dietz, J. A., Janssen, K. T., and Nickells, R. W. (2006). Progressive ganglion cell loss and optic nerve degeneration in DBA/2J mice is variable and asymmetric. *BMC Neuroscience* 7: 66. (B) Reproduced from Howell, G. axoplasmic transport in the face of reduced access to nutrients and oxygen from both compromised astrocytes and reduced arteriolar blood flow. Ultimately, a scenario may develop where energy supplies are no longer sufficient to sustain transport against the pressure gradient and the axon is forced to execute a self-destruct pathway.

Compartmentalized Self-Destruct Pathways and the Pathology of Glaucoma

A major factor in understanding how elevated IOP leads to ganglion cell death is understanding how ganglion cells die in the first place. Ganglion cells are projection neurons of the CNS. The cell body, or soma, is located in the inner retina, where they take input from neurons in the outer retina through a complex network of dendrites located in the inner plexiform layer. The soma then projects an axon through the nerve fiber layer, which is adjacent to the vitreous, exiting the eye through the lamina into the optic nerve. In simple terms, a ganglion cell has four distinct compartments: the soma, the axon, a synapse at the end of the axon, and the dendritic tree.

Recently, the death of retinal ganglion cells has been evaluated in the context of effects on their individual compartments. Several studies, using genetically engineered mice, in which mutations in specific genes selectively affect the degenerative process of individual compartments, have shown that ganglion cell death can occur in an autonomous, compartment-specific, fashion. Two mutations, in particular, have contributed to the understanding of the process of ganglion cell death in glaucoma. The first of these is a knock-out mutation created in a gene called *Bax*, which is a member of a larger gene family that regulates the intrinsic apoptotic pathway by affecting permeability changes and dysfunction in mitochondria. Although apoptosis is generally considered in the same context as cell death, the term actually describes the self-destruct pathway executed by cell somas. In a defined, naturally occurring form of glaucoma in the DBA/2J inbred line of mouse, *Bax* deficiency was found to completely abrogate ganglion cell soma loss, but not the degeneration of the ganglion cell axons. A second mutant gene, which occurs naturally in mice, is called Wallerian degeneration slow (Wld^S). This mutant gene dramatically reduces the degenerative process called Wallerian degeneration, which is the self-destruct pathway executed by dying axons. In DBA/2J mice carrying the Wld^S mutation, ganglion cell axons are dramatically preserved in the face of ocular hypertension that causes glaucoma in wild-type mice. Importantly, in these mice, ganglion cell somas are also spared compared to wild-type animals. These data provide insight on the timing of events associated with ganglion cell loss. They indicate that axon loss is not prevented by blocking soma loss, while soma loss can be attenuated if axon loss is prevented. Together, this strongly implicates glaucoma as an axogenic disease, distinct from other neurodegenerative disorders where the soma is the fist site of injury. Supporting this model, all studies examining the timing and progression of both optic nerve degeneration and retinal disease in the DBA/2J mouse (**Figure 4**), point to axonal damage preceding the loss of ganglion cell somas.

In a scheme that links elevated IOP to ganglion cell damage and death, the activation of an autonomous self-destruct pathway in the ganglion cell axon will, in turn, lead to the activation of the autonomous apoptotic pathway in the ganglion cell soma. The mechanism by which this occurs is also unknown, but several studies suggest that the loss of axonal transport will reduce the flow of neurotrophic growth factors to ganglion cell somas. This model for the activation of soma death in glaucoma has been coined the neurotrophin hypothesis. During development, the normal pruning of retinal ganglion cells, in which approximately 50% of the cells are eliminated, coincides with an increased dependence on neurotrophic factors for survival. Similarly, application of exogenous neurotrophins, after acute or chronic damage to the optic nerve, is able to prolong ganglion cell survival.

Although these studies are consistent with the neurotrophin hypothesis, there are several caveats that require further explanation and reveal the need for continued study. First, the level of protective effect of exogenous neurotrophins is transient, even if efforts are made to introduce a continuous supply of any given factor over a long period. Second, injury to the optic nerve is known to stimulate the expression of endogenous trophic factors by other cells, particularly macroglia, in the retina, leading to the question of why this increase is not an expression sufficient to sustain ganglion cell somas in the absence of retrograde transport? Part of the reason for this effect may lie within molecular changes occurring in the ganglion cell somas once they have become injured. An early component of the injury process is the silencing of normal gene expression and some of the genes that are downregulated appear to be for the receptors that neurotrophic factors bind to. An alternative explanation is that many of the studies showing the transient effects of exongenous trophic factors are usually examining the effects of only a single factor at a time. Compelling available data suggest that treatments that elicit the infiltration of cells, such as macrophages, provide a much greater and longer-term effect on the survival of ganglion cell somas. In this case, infiltrating cells are likely producing and secreting much more complex mixtures of trophic factors than could be applied by experimental manipulation. Lastly, the signaling pathways activated by neurotrophic factors are variable and highly regulated. One such level of regulation is by the localization of target receptors on neurons, such that receptors bound at the synapse are likely to activate distinct mitogen-activated protein kinase

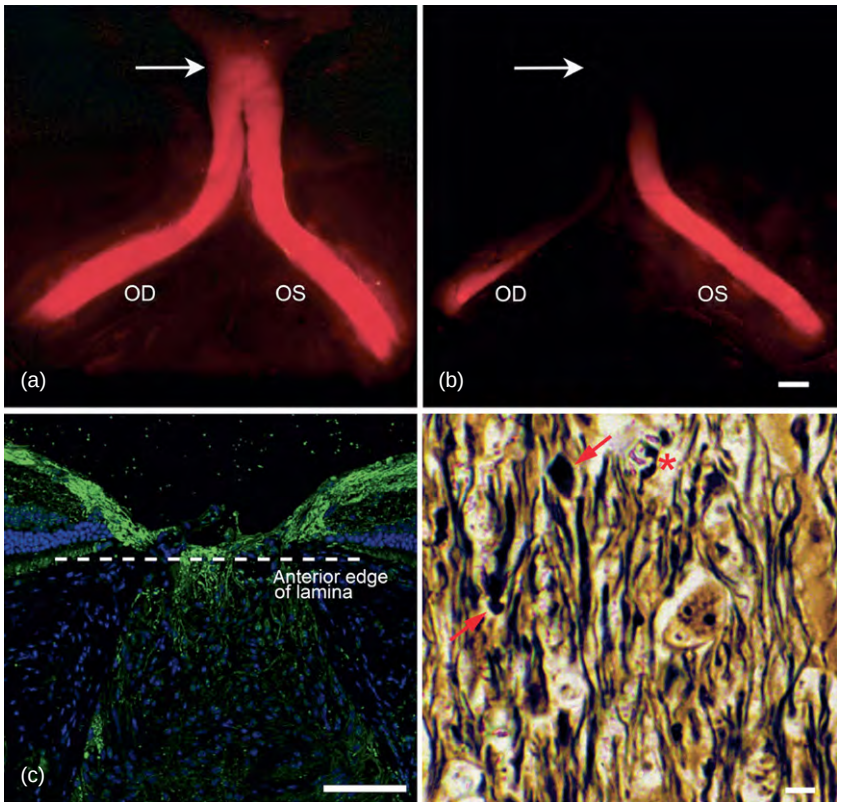

Figure 4 Axon degeneration in the optic nerves of DBA/2J mice with glaucoma. (a and b) Optic nerve tracts of a young mouse without disease (a) or an older mouse with bilateral disease (b). Axons are labeled using a postmortem technique in which DiI is allowed to diffuse along intact axonal tracts from the globe to the optic chiasm (denoted by arrow in both). Both nerves of young mice can be labeled all the way to the chiasm, while mice with glaucoma show partial or incomplete labeling that is typically asymmetric. Scale = 0.5 mm. (c) Axon loss in a DBA/2J mouse mutant for the proapoptotic *Bax* gene (*Bax*$^{-/-}$). Axons of retinal ganglion cells are labeled green. Mice lacking a functional *Bax* gene exhibit complete resistance of ganglion cell somas to glaucoma, but still undergo optic nerve degeneration. In this severe case, axons originating in the nerve fiber layer extend only to the laminar region. Past this point, axons have mostly degenerated, indicating that the point of axonal lesion is at the level of the lamina. Scale = 75 μm. (d) Silver-stained longitudinal section of the post-laminar region of a DBA/2J mouse with glaucoma. Axons, which are stained dark brown to black, are tortuous (asterisk) and often end in bulbous swellings (arrows) indicative of degeneration. Scale = 5 μm. (c) Reproduced from Howell, G. R., Libby, R. T., Jakobs, T.C., et al. (2007) Axons of retinal ganglion cells are insulted in the optic nerve early in DBA/2J glaucoma. *Journal of Cell Biology* 179: 1523–1537, with permission from the Rockefeller University Press.

(MAPK) pathways than the same receptors if they interact with a neurotrophin ligand at the plasma membrane of the cell soma. The activation of distinct MAPK pathways could certainly yield different effects on ganglion cell survival. This was demonstrated by recent studies showing increased survival and gain of function of ganglion cells in cat eyes after a partial optic nerve crush, when the neurotrophic factor, brain-derived neurotrophic factor (BDNF), was applied both as an intravitreal injection and simultaneously infused into the visual cortex.

Intraretinal Circuit Formation

J L Morgan, P R Williams, and R O L Wong, University of Washington, Seattle, WA, USA

Introduction

The vertebrate retina is a laminated tissue in which the various component cell types and their synaptic connections are arranged in distinct layers or laminae. This laminar organization, together with a high correspondence between structure and function, makes the vertebrate retina an excellent model system for studying the development of neuronal circuits. The development of retinal circuits generally follows the same sequence of major events for all vertebrates studied thus far. In this article, we provide an overview of the assembly of circuits in the vertebrate retina, primarily focusing on the mouse and zebrafish that have in recent years become key model systems because of the availability of transgenic animals. Circuit assembly involving retinal neurons requires that each cell type forms connections with their appropriate synaptic partners and establishes the correct density of synaptic connections with these synaptic partners. We first briefly review the overall organization of the mature retinal circuitry and then provide the current views on how these circuits are assembled during the development.

Organization of Retinal Circuits of Vertebrates

Figure 1 shows the general morphological organization of the mature vertebrate retina. Cone photoreceptors transmit light-evoked signals to bipolar cells that relay these signals to the output neurons of the retina, the retinal ganglion cells. There are two major functional subclasses of bipolar cells: ON bipolar cells are depolarized by increased illumination, whereas OFF bipolar cells are hyperpolarized. Cone photoreceptors contact cone bipolar cells whereas in general, rod photoreceptors contact a single class of rod bipolar cells, which form a circuit dedicated to low light vision (the rod pathway). Unlike cone bipolar cells, rod bipolar cells do not contact retinal ganglion cells directly, and instead contact AII amacrine cells. Neurotransmission along the vertical pathway comprising photoreceptors–bipolar cells–retinal ganglion cells is mediated by glutamate. Signals transmitted along the vertical pathway are modulated by amacrine interneurons that provide feedforward inhibition directly onto retinal ganglion cells and feedback inhibition onto bipolar cells. In the inner plexiform layer (IPL), lateral inhibition is mediated by either gamma aminobutyric acid (GABA)-ergic or glycinergic transmission from the amacrine cells. In the outer plexiform layer (OPL), photoreceptor transmission is modulated by horizontal cells, although the exact mechanism(s) by which this modulation occurs remains highly debated.

Formation of Retinal Synaptic Laminae

The exquisite lamination of cell bodies and synaptic connections of the vertebrate retina have long attracted investigations into the mechanisms that organize this orderly arrangement. Lamination first emerges in the inner retina where retinal ganglion cells, the first-born neurons, migrate to the basal surface of the retina after cell division at the apical surface. As a ganglion cell layer forms, amacrine interneurons are generated and migrate to the inner retina where the majority of these cells accumulate and form a cell layer next to the ganglion cell layer. As amacrine cells and ganglion cells elaborate their processes, an IPL takes shape. An OPL becomes apparent later as the axons and dendrites of the photoreceptors, bipolar cells and horizontal cells differentiate and become confined to a narrow lamina. Interestingly, horizontal cells differentiate early, at around the time of amacrine and ganglion cell genesis, but they do not reach their laminar position until after the IPL emerges. This sequence of lamination, from inner to outer, thus does not depend strictly on the time course of cell generation and the subsequent migration of the various cell types (summarized in Figure 2). The lamination of the axons and dendrites of each cell type of the retina is described in detail in the following sections in the context of circuit assembly.

Assembly of the Vertical Pathway

The vertical pathway of the retina is the major excitatory pathway, conveying light information from the outer to inner retina through glutamatergic transmission. This pathway from photoreceptors to bipolar cells to retinal ganglion cells develops later than circuits involving lateral connections from amacrine cells and horizontal cells.

In order to understand how vertical circuits in the retina are assembled, many studies have focused on the mechanisms that organize the presynaptic axons and postsynaptic dendrites of cellular components of the vertical pathway into their appropriate laminae. How the axonal

R, rods; C, cones, RBC, rod bipolar cell, CB, cone bipolar cell, H, horizontal cell, A, amacrine cell, AII, AII amacrine cell, G, ganglion cell, IPL, inner plexiform layer, OPL, outer plexiform layer. The IPL is approximately divided into OFF (outer two-fifths) and ON (inner three-fifths) sublaminae.

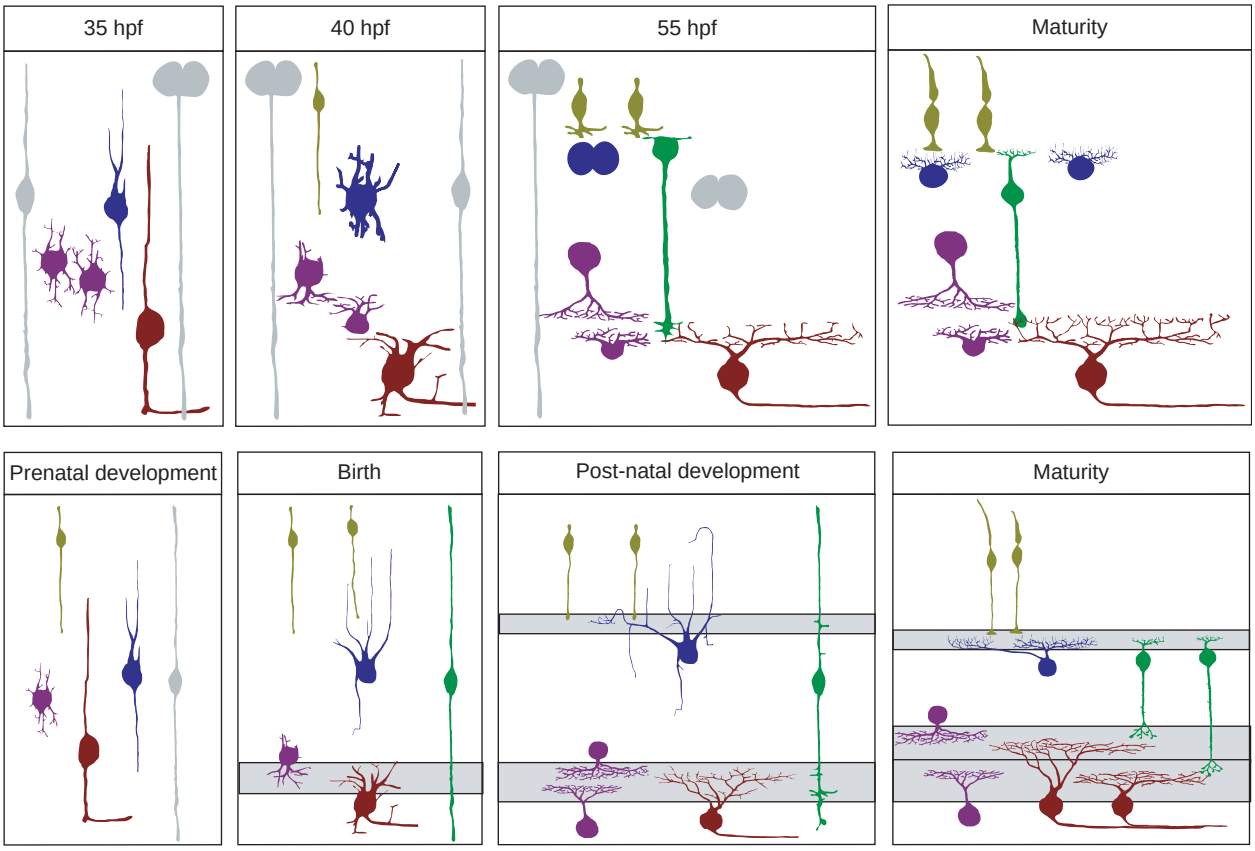

Figure 2 Developmental time-line in retinal circuit assembly. Schematic diagrams illustrating the developmental time-line in the structural assembly of the verteberate retina of mice (below) and zebrafish (above). Development in both species shares some common features, for example, the inner retinal circuits emerge before outer retinal circuits. However, there are some species differences in the developmental organization of the neuronal processes of some cells, especially the developmental remodeling of horizontal cell and ganglion cell dendrites. hpf: hours postfertilization; IPL: inner plexiform layer; OPL: outer plexiform layer.

and dendritic arbors of retinal ganglion cells, bipolar cells, and photoreceptors develop has largely been investigated by imaging labeled cells by light microscopy and by reconstructions from serial electron microscopy. Despite the static nature of the observations, these studies have collectively provided insightful views of how retinal ganglion cells, bipolar cells, and photoreceptors acquire the mature forms of their neuronal processes. More recently, live imaging approaches have captured the dynamic changes in axonal and dendritic architecture of developing retinal neurons, including the retinal ganglion cells and bipolar cells. These time-lapse studies confirmed previous observations and also revealed surprising cellular behaviors resulting in the stratified processes of some types of ganglion cells and bipolar cells.

Retinal Ganglion Cells

Dendritic stratification of retinal ganglion cells has been studied extensively in a variety of species. The stratification level of retinal ganglion cell dendrites is correlated with the type of functional input these neurons receive from cone bipolar cells. As indicated in **Figure 1**, retinal ganglion cells that depolarize to increased illumination have dendritic arbors stratifying in the inner three-fifths of the IPL, whereas ganglion cells stratifying in the outer two-fifths of the IPL hyperpolarize to illumination. In mammalian retinas including cat, rabbit, ferret, mouse, rat, and quokka, immature retinal ganglion cells have dendrites that course through the entire depth of the forming IPL (**Figure 3(a)**). This initially diffuse arrangement is altered with maturation, giving rise to laminated arbors that stratify at depths unique to each subtype of retinal ganglion cell. Such studies have largely focused on ganglion cells that later possess a single monostratified arbor. Retinal ganglion cells that have two stratified arbors in mammalian retina (the bistratified ganglion cells) have not been followed throughout their early differentiation, mainly because of a lack of cell-specific markers for ganglion cell subtypes prior to when their dendrites stratify.

In zebrafish, a large proportion of retinal ganglion cells possess more than one stratified dendritic arbor. Because *in vivo* time-lapse imaging of individual retinal ganglion cells is possible in the transparent zebrafish, the sequence of events leading to the stratification of ganglion cell dendrites can be monitored. Such imaging studies demonstrated that ganglion cells with multiple stratified arbors appear to form each arbor, one stratum at a time (**Figure 3(b)**). These observations in zebrafish raise the possibility that dendrites in mammals and fish may adopt distinct mechanisms to achieve their stratification patterns. Alternatively, retinal ganglion cells that have multiple stratified arbors may develop differently from cells that become monostratified. Thus, future experiments in which bistratified ganglion cells in mammalian retinas can be identified early in their development are needed to distinguish between these possibilities.

What regulates retinal ganglion cell dendritic stratification? Studies in cat and ferret suggested that blockade of neurotransmission affects the emergence of stratified dendritic arbors of the retinal ganglion cells. Chronic application of the amino-phosphonobutyric acid (APB) agonist of the metabotropic glutamate receptor 6 (mGluR6) receptor found on the dendrites of mature ON bipolar cells led to a failure of ganglion cell dendrites to become stratified. However, APB has been shown to suppress the activity of all retinal ganglion cells in the immature ferret retina and thus its site of action is unclear. Examination of mice in which transmission along the vertical pathway is expected to be perturbed led to different observations. In mice lacking

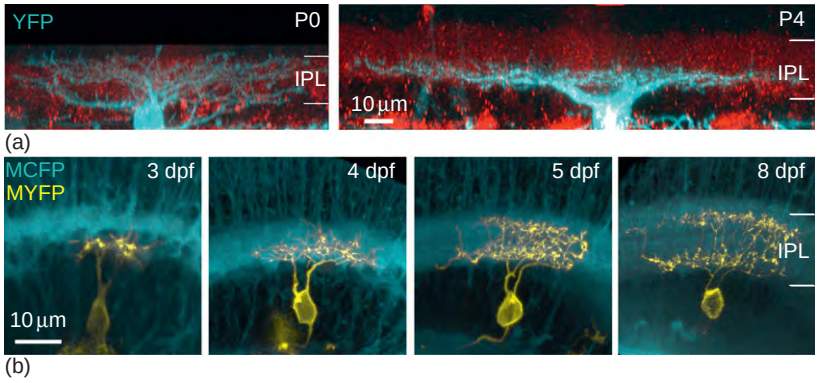

Figure 3 Dendritic stratification of retinal ganglion cells. (a) The dendritic arbors of neonatal retinal ganglion cells (blue) in the mouse retina become stratified with maturation; Red signal is reflected light. P: postnatal day; YFP: yellow fluorescent protein. (b) Dendritic stratification in many zebrafish retinal ganglion cells (yellow) emerges by progressive addition of new strata, one at a time. S., Williams, P. R., Godinho, L., et al. (2006). *In vivo* imaging reveals dendritic targeting of laminated afferents by zebrafish retinal ganglion cells. *Neuron* 52: 609–621, with permission from Elsevier.

the mGluR6 receptor, ganglion cell dendritic stratification is normal – in this case, however, one might expect that spontaneous release of neurotransmitter from the bipolar cells is unaffected even though visual stimulation along the ON pathway is abolished. Numerous studies have since been carried out to assess the role of visual experience in regulating dendritic stratification of retinal ganglion cells. Dark-rearing appears to decrease the developmental reduction in the proportion of ON–OFF retinal ganglion cells in mice. This developmental reduction is also less prevalent in mice lacking glycine receptors. In contrast, factors independent of activity have been found to guide dendritic lamination of ganglion cells. In particular, recent studies of the chick retina showed that members of the superfamily of immunoglobulin family of adhesion molecules (sidekicks and DsCam) influence the lamination patterns of retinal ganglion cells and amacrine cells. Although not yet completely worked out, it appears that molecular guidance cues involving adhesion molecules initially guide stratification of ganglion cell dendrites but later visually evoked activity may continue to shape the final lamination patterns of the ganglion cell dendrites.

Bipolar Cells

The development of the axonal terminals of bipolar cells has mostly been studied in a variety of species by single cell labeling methods using Golgi techniques and immunolabeling. Golgi-labeled cells that were presumed to be bipolar cells based on their radial morphology and terminal ending in the IPL appear to confine their axon terminals to specific depths within the IPL even before these cells form dendrites. Immunostaining for recoverin also suggested that ON and OFF bipolar cells stratify early in their differentiation. In transgenic mice, the mGluR6 promoter drives expression of green fluorescent protein in a subset of bipolar cells (ON bipolar cells). Expression is observed when these cells still possess apical and basal processes that are attached to the outer and inner limiting membranes, respectively. Time-lapse imaging of the retinas from these transgenic mice unequivocally demonstrated that axons and dendrites extend from the neuroepithelial-like processes as the bipolar cells differentiate (**Figure 4(a)**). Whether axons and dendrites in other species including zebrafish also develop in a similar manner is yet to be determined. Both axons and dendrites of the mouse ON bipolar cells explore retinal

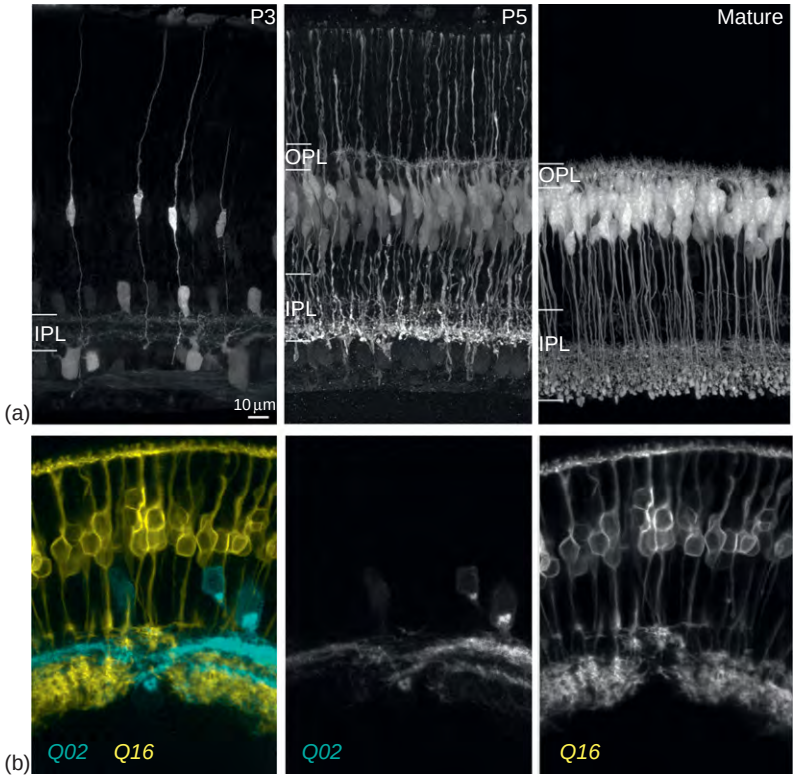

Figure 4 Lamination of bipolar cell axons and dendrites. (a) Green fluorescent protein driven by the mGluR6 promoter in bipolar cells at P3, P5 and mature retina. GFP expressing bipolar cells elaborate dendrites from apical and basal processes oriented vertically and neuroepithelial-like. IPL, inner plexiform layer. Note that upon maturation, dendrites are confined to the OPL (outer plexiform layer) and axons to the IPL. (b) Local perturbation in amacrine cell (blue) and bipolar cell (yellow) lamination visualized in a transgenic zebrafish in which a subset of amacrine cells express cyan fluorescent protein (Q02) and ON bipolar cells express yellow fluorescent protein (Q16) in the background of the *lakritz* mutant, which lacks ganglion cells.

depths outside their final lamination locations, but processes within the appropriate lamina are selectively stabilized with maturation. Process stabilization cues may be provided by other retinal neurons that have already grown stratified arbors in the forming plexiform layers. For example, the axonal terminals of the ON bipolar cells are largely distributed within the inner half of the IPL where they later contact ON ganglion cells. At this stage of axonal elaboration, as discussed later, amacrine cells that stratify in the ON sublamina have already contacted their target ganglion cells. Because amacrine cells can stratify independently of the presence of retinal ganglion cells, it is possible that these interneurons provide laminar cues for the bipolar axons. This hypothesis receives some support from observations in the zebrafish *lakritz* mutant that lacks retinal ganglion cells, in which there are local patches with lamination defects in the amacrine cell neurites although lamination largely occurs across the retina. In these locally perturbed regions, bipolar axon terminals are also abnormally placed (**Figure 4(b)**).

Photoreceptors

Photoreceptors connect to the bipolar cell dendrites once horizontal cells have already entered into synaptic partnerships with the photoreceptors (**Figure 2**). Apart from early Golgi studies, relatively little is known about how individual photoreceptors terminate their axons to form a single lamina in the outer retina during development although several studies have described the maturation of their outer segments. Observations in the ferret retina showed that some photoreceptors even transiently project into the IPL during development, although the functional significance of these projections is not yet known.

Synaptogenesis in the Vertical Pathway

Synaptic connections in the vertical pathway have only recently been studied in detail by light microscopy. Early ultrastructural studies of the IPL and OPL of mammals and zebrafish suggest that ribbon synapses are formed between bipolar cells and retinal ganglion cells after conventional synapses are present (**Figures 5** and **6**). In rodents and zebrafish, contact between photoreceptors and bipolar cells occur about the same time as bipolar cells contact the retinal ganglion cells. However, ribbons appear late at bipolar synapses in the IPL. Detailed serial reconstruction of immature bipolar cell axon terminals in primate retina suggest that ribbons appear after clusters of vesicles are found at appositions between bipolar cell axonal processes and a neighboring process. Interestingly,

the earliest bipolar synapses appear to be monads, that is, there is only one postsynaptic process, whereas with maturation, bipolar cells synapses occur at junctions with two processes, forming a dyad synapse. The postsynaptic processes may comprise processes from two amacrine cells, an amacrine and a ganglion cell, or two ganglion cells. That bipolar synapses are already present on ganglion cell dendrites prior to the appearance of ribbons is supported by electrophysiological recordings from immature retinal ganglion cells. As discussed in more depth later, spontaneous excitatory postsynaptic currents (sEPSCs) can be recorded from ganglion cells in mammals prior to when ribbons appear. Electron microscope observations of developing mouse retina also suggest that bipolar synapses are present in the outer half (OFF) of the inner plexiform layer prior to their appearance in the inner half (ON) of the inner plexiform layer. There is support for the relatively earlier differentiation of synaptic connections, or at least their structures, in the OFF sublamina of the inner plelxiform layer. For example, in mice, VGluT1 (vesicular glutamate transporter) immunolableing is first observed in the OFF sublamina prior to its appearance in the ON sublamina (**Figure 5**). The significance of this sequence in maturation of the ON and OFF vertical pathways is unclear because light-evoked activity does not emerge until several days later.

Reconstructions of bipolar cell synapses at the ultrastructural level, however, cannot provide a view of the spatial distribution of such inputs on individual ganglion cell dendritic arbors unless extensive serial reconstructions are performed on immature ganglion cells. Using transient transfection methods, recent studies have successfully explored the spatial distribution of bipolar cell inputs on the dendritic arbors of retinal ganglion cells using light microscopy. Expression of fluorescently tagged postsynaptic density protein 95 (PSD95), a scaffolding protein found at glutamatergic postsynaptic sites, revealed the distribution of bipolar cell contacts across the dendritic arbors of ganglion cells in the mouse retina. Quantification of the spatial maps of these synaptic puncta

indicated that in mice, there is a rapid acquisition of glutamatergic postsynaptic sites from postnatal day 5 until eye-opening (Figure 7). Synaptogenesis between bipolar cells and retinal ganglion cells thus appears to proceed mostly prior to eye-opening (around 2 weeks after birth). Interestingly, the density of connections across the dendritic territory of the ganglion cells appears to be fairly invariant with age, even though there is significant structural remodeling (largely reduced dendritic branching density) of the dendritic arbors with maturation. This may reflect the developmental increase in the number of contact sites along the dendrites as dendritic density decreases with age.

Electron microscopy studies clearly indicate that cones form synaptic connections prior to rods. However, to date, there is little information concerning how bipolar cells and photoreceptors establish the specificity in their connectivity patterns during synaptogenesis. Retinas in which rod or cone populations are perturbed provide important insight into the specificity of wiring between rod and cone photoreceptors and their target bipolar cell types. In *nrl*-knockout mice in which rods fail to form and all photoreceptors become cones, rod bipolar cells are contacted by cones. Conversely, in in cyclic nucleotide gated channel A3 (CNGA3) knock-out mice in which cones are present but nonfunctional, cone bipolar cells form synaptic connections with rods. Thus, rod and cone bipolar cells can be targeted nonspecifically by cones and rods in the absence of proper interactions between these pre- and postsynaptic cell types. However, it is not yet clear whether specificity in the wiring between rods and cones and their target bipolar cells is obtained during development after a period of rewiring, or whether there is target selectivity during synaptogenesis. One way to address this question is to follow the development of photoreceptor-bipolar synaptogenesis over time *in vivo*. This can be readily achieved in zebrafish but is more difficult to perform for mammalian retinas. Furthermore, experiments that will determine how the different color cones wire up to the appropriate bipolar cells during development will be important in determining how color circuits are established in cone-dominated retinas.

Assembly of Lateral Circuits

Compared to the vertical pathway, the assembly of circuits that modulate transmission in the inner and outer retina are not as well understood. However, recent studies in which amacrine cells and horizontal cells can be identified early in development have shed new insight into the cellular behaviors of these cells as they form circuits.

Inner Retina – Amacrine Cells

Amacrine cells migrate freely toward the inner retina and appear to stratify shortly upon reaching the border with the forming ganglion cell layer (Figure 2). Serial electron microscopy suggested this pattern of amacrine cell migration and neurite development, which has

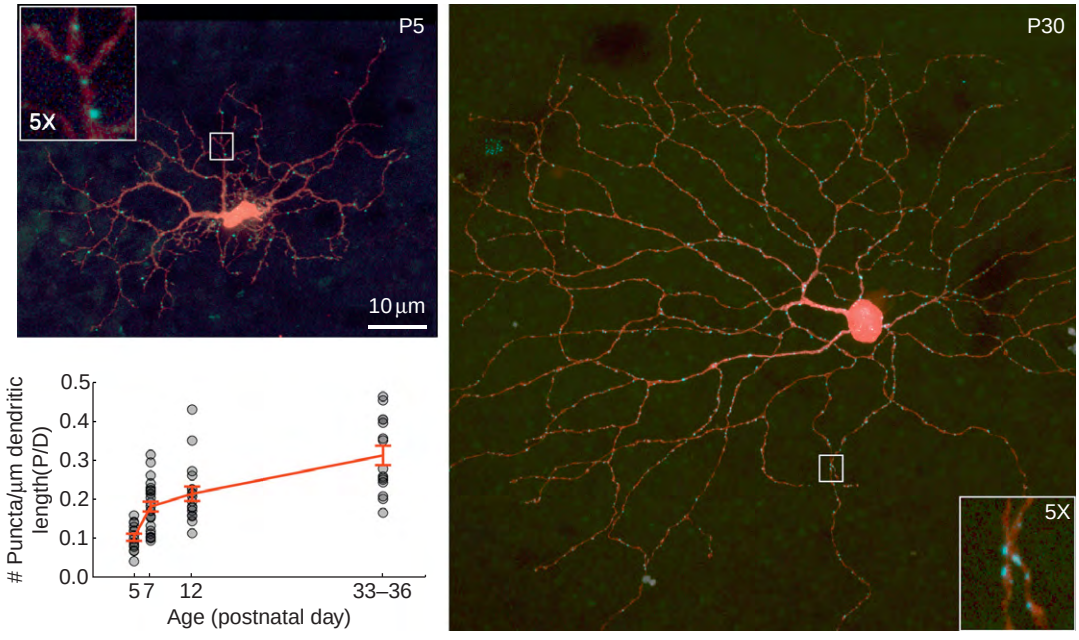

Figure 7 Spatial distribution of glutamatergic postsynaptic sites on developing ganglion cells. Examples of ganglion cells from an immature (postnatal day, P5) and a juvenile (postnatal day, P30) retina for which glutamatergic postsynaptic sites are labeled (blue). Dendrites are labeled by expression of the red fluorescent protein, td-Tomato, and gluamatergic postysnaptic sites by fluorescently tagged postsynaptic density 95 PSD95. Insets in upper left and lower right are 5× magnifications of the areas indicated by the boxes. Lower left: The density of PSD95-YFP (blue) puncta along the dendrites is plotted across ages studied.

subsequently been visualized in real time by *in vivo* imaging of these neurons in the zebrafish retina. Zebrafish amacrine cells very quickly stratify their neurites within the inner or outer half of the IPL as soon as their cell bodies reach their final locations. Thus, amacrine cell neurites do not appear to undergo a period of indiscriminate occupation of the IPL. Whether this pattern of neurite growth also occurs for mammalian amacrine cells, however, is not known although in rodents, cholinergic amacrine cells appear to form their mirror-symmetric laminations at two distinct depths in the IPL early in IPL formation.

The cues that influence the neuritic stratification of amacrine cells are not completely known, but it is evident that ganglion cells are not necessary for this process to occur. In mouse atonal 5 (*Math5*) knock-out mice and in the zebrafish mutant, *lakritz*, both lacking retinal ganglion cells, amacrine cells form stratified arbors. Because bipolar cells differentiate later than amacrine cells, these interneurons are unlikely to provide lamination cues for amacrine cells. The influence of adhesion molecules in the stratification of amacrine cell neurites has, however, been shown in the chick retina. The immunoglobulin superfamily of adhesion molecules, Down syndrome cell adhesion molecule (DsCam), DsCam-like, Sidekick-1 and Sidekick-2 are expressed in nonoverlapping strata in the chick inner plexiform layer. Manipulating the expression of these adhesion molecules in ovo suggests that they are involved in specifying the laminae within which amacrine cells and their target retinal ganglion cells stratify.

As yet, it is unknown what factors regulate synapse density between the amacrine cells and their target retinal ganglion cells. This issue can potentially be investigated by serial reconstructions of the IPL but because there are at least two dozen types of amacrine cells in the mammalian retina, and perhaps an even greater variety in the fish retina, mapping the inputs of specific subtypes of amacrine cells on the dendrites of their postsynaptic ganglion cells is extremely challenging. No doubt, future studies using transgenic approaches to visualize specific amacrine subtypes will be invaluable. Amacrine cells also provide feedback inhibition onto bipolar axon terminals. These feedback synapses have largely been studied in the rod bipolar cell pathway where A17 amacrine cells are known to contact the large axon terminals of rod bipolar cells (see **Figure 6 (a)**). The development of this highly localized reciprocal synapse has yet to be examined in detail but its well-characterized function makes this synapse a good model for studying the development of feedback circuits in general.

Outer Retina – Horizontal Cells

In the outer retina, modulation of transmission along the vertical pathway is provided by horizontal cells. In rodents, horizontal cell dendrites attain a laminated arbor after a period of reorganization (**Figure 2**). Cajal described immature horizontal cells as having a radial rather than lateral arbor. Since then, horizontal cells in rodents have been identified by immunolabeling for the GABA synthesizing enzyme, glutamic acid decarboxylase 67 (GAD67), and by calbindin immunoreactivity. Such labeling confirmed Cajal's early observations and also showed that horizontal cell dendritic stratification occurs as photoreceptors form synaptic connections onto the horizontal cells. Dendritic stratification of horizontal cells does not appear to rely on neurotransmission from photoreceptors because this process occurs even when cone photoreceptors are ablated during development. However, long-term loss of photoreceptor transmission does lead to elaboration of horizontal cell dendrites into the outer nuclear layer where they can receive ectopic contact.

Horizontal cells form contacts with cone photoreceptor terminals prior to the elaboration of bipolar cell dendrites that later invaginate into the cone terminal to form a synaptic triad (**Figure 6(c)** and **6(d)**). The triad comprises a single bipolar cell dendritic tip flanked by two horizontal cell processes at a location opposite to the ribbon in the cone terminal. The assembly of this triad structure has been described by elegant ultrastructural studies in the past but the cues that coordinate the assembly of each component of this synapse are still unknown. **Figure 5** summarizes the time-line of synaptogenesis between the various cell elements contributing to the OPL.

Emergence of Function – Spontaneous and Light-Evoked Activity

Visually evoked signals in the mammalian retina emerge shortly before eye-opening when photoreceptors have formed synaptic connections with the bipolar cells. However, the retina generates its own pattern of activity prior to photoreceptor transmission. In many mammalian species studied thus far, retinal ganglion cells have been found to exhibit bursts of action potentials that occur rhythmically and are synchronized among neighboring cells (**Figure 8**). This synchronized activity takes on the form of propagating waves that spread across the retina in different directions. The wave-like activity pattern has been linked to the refinement of the axonal projection patterns of the retinal ganglion cells to their subcortical targets, but as yet waves have not been found to influence the development of intraretinal circuits in mammals.

Changes in the properties of retinal waves, however, have been informative with regard to the organization and development of retinal circuits. For example, studies of retinal activity in chick, mice, ferret, and rabbit all suggest that early synchronized activity is mediated by gap junctions, then by cholinergic drive and later by glutamatergic transmission. Moreover, ON and OFF retinal

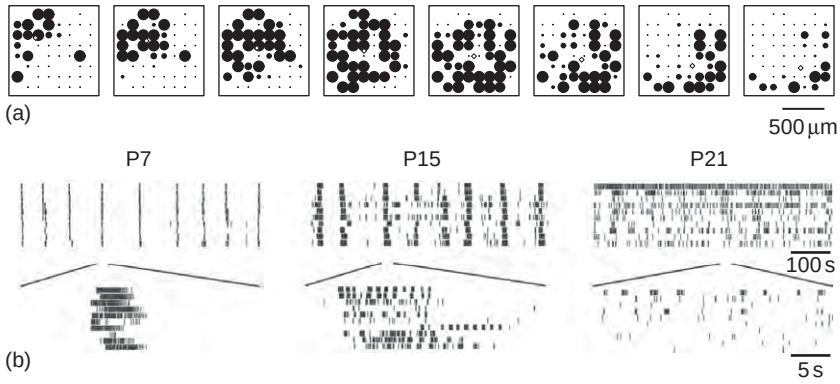

Figure 8 Immature retinal circuits spontaneously generate waves of activity. (a) Multielectrode array recordings (squares) for neonatal mouse retinas showing propagation of a retinal wave over time (left to right). Time between frames is 0.5 s. Each dot represents an electrode site and the size of the dot corresponds to spike rate. (b) Spike rasters from 10 representative cells recorded simultaneously on the array for three postnatal ages; P7, P15, and P21.

ganglion cells are synchronized in their bursting activity during the period when cholinergic drive is necessary for the wave activity. However, as glutamatergic drive takes over, the spontaneous bursting activity of ON and OFF mouse ganglion cells becomes desynchronized: ON ganglion cells burst before OFF ganglion cells. This asynchrony is generated by cross-over inhibition between these parallel pathways. Thus, prior to eye-opening, retinal circuits undergo changes in spontaneous activity patterns of the ganglion cells largely due to alterations in the type of excitatory drive (cholinergic then glutamatergic) and the maturation of inhibitory circuits. At the level of synapses, measurements of synaptic currents from individual retinal ganglion cells show that the amplitudes and frequency of sEPSCs increase with age, even after eye-opening.

Few studies have directly measured the early visual response properties of retinal ganglion cells. Such studies have been difficult to carry out *in vivo* because of the poor optics of the immature eye. As soon as it is possible to record light responses from the retina *ex vivo*, generally a few days before eye-opening, the characteristic center-surround organization of ganglion cell receptive fields can be identified in cat and rabbit. Although the antagonistic surround, mediated by inner and/or outer retinal inhibition, is present when the receptive field centers are first detected, the response properties of the early surrounds appear to be species dependent. The early light responses are weak and adapt rapidly but become robust several days later. However, ON and OFF responses are evident and there is no significant developmental change in the percentage of cells with ON- and OFF-center receptive fields in the cat. In contrast, in ferret and mice, there is a higher proportion of ganglion cells that receives converging ON and OFF input during development. The reduction in the incidence of ON–OFF cells in the ferret has been attributed to dendritic pruning, whereas in mice this reduction is considered to be the result of a decrease in the number of cells with dendritic arbors located at the border of the ON and OFF sublaminae of the IPL. However, in mice, direct correlation between structure and function of individual ganglion cells that have converging ON and OFF input has yet to be obtained. Direction-selective ganglion cells can be found in rabbit retina before eye-opening and the development of the circuitry underlying this visual response property in mouse retinal ganglion cells does not depend on spontaneous retinal wave activity or visual experience. In contrast, the spatial receptive fields of turtle retinal ganglion cells appear to reorganize with maturation. Direction selectivity, orientation preference, and receptive field sizes of turtle ganglion cells are shaped by spontaneous and light-driven activity. Thus, the influence of neurotransmission, especially visual experience, in establishing the precision in wiring of intraretinal circuits appears to vary across species, perhaps due to different developmental constraints that are species specific. Alternatively, such differences may be due to how neurotransmission is altered *in vivo* and the consequence of each manipulation in the transmission of signals between specific cell types.

Conclusions

Much remains to be done in order to elucidate the molecular and cellular mechanisms that are responsible for establishing the many circuits within the vertebrate retina dedicated to the processing of light information. In recent years there have been significant technological advances that allow probing the structural and functional development of retinal circuits. However, cell-type specific markers that will enable tracking the same cell type throughout development are necessary for many future studies. With the increasing availability of transgenic models, it should be possible to directly address the mechanisms that are essential to circuit assembly *in vivo*. Investigating the development of intraretinal circuits is certainly well aided by the immense knowledge of the structure and function of the

adult vertebrate retina, and the comparative anatomy and physiology of its circuits across many species.

Ion Transport in the Ciliary Epithelium

O Strauß, Klinikum der Universität Regensburg, Regensburg, Germany

Glossary

Functional syncytium – In cells that are coupled to each other by gap junctions, small molecules can freely diffuse between the cells, an effect that synchronizes the cells to a functional unit. A true syncytium is a cell-like body filled with cytoplasm and multiple nuclei.
Primary active transport – A transport of molecules against a concentration gradient which directly uses energy from hydrolysis of adenosine triphosphate.
Secondary active transport – A transport of a molecule against a concentration gradient in which the transport is coupled to the active transport of another molecule. Since the concentration difference of the downhill-transported molecule stems from primary active transport, the transport is then termed secondary active transport.
Transepithelial potential – The voltage difference across an epithelium.
Transepithelial resistance – The electrical resistance across an epithelium.

Introduction

A stably and finely regulated intraocular pressure is of fundamental importance for the maintenance of visual function. The balance between aqueous humor production and outflow defines intraocular pressure. The understanding of the regulation of aqueous humor production represents an important base to lower intraocular pressure in glaucoma. Aqueous humor is produced by active ion transport across the ciliary epithelium. In the course of this active ion transport, anions are transferred from the stromal to the chamber side. The transport of solutes drives a transcellular transport of water through aquaporin water channels. In this article, the basic transport mechanism across the ciliary epithelium is described. When possible, the article focuses on the mechanisms known in primate species, because there are great variations among different species.

Aqueous Humor Production: Active Transport

The ciliary stroma contains fenestrated capillaries which provide the substrate for aqueous humor production. The formation of aqueous humor occurs in an estimated rate of 2–4 $\mu l\,min^{-1}$. Aqueous humor has a defined composition. For example, in aqueous humor there is a much higher ascorbate concentration compared to that in the plasma. Furthermore, it contains only very minor amounts of proteins when compared to plasma, but a variety of signaling molecules. This indicates that a selective active secretion process is responsible for the production of aqueous humor. The secretion process across the ciliary epithelium (**Figure 1**) results in a transepithelial potential of −2.5 mV at the aqueous side (measured in monkey). This transepithelial potential results from the fact that the transport mainly involves movement of anions, in humans mainly Cl^-, across the ciliary epithelium. The net transport of Cl^- is coupled to a net transport of Na^+, K^+, and ascorbate. The transport of solutes across the ciliary epithelium drives osmotically the flow of water across the epithelium through water channels in the nonpigmented epithelium. It should be mentioned that it might be possible that not all of the aqueous humor is produced by the ciliary epithelium only. Concentration differences of, for example, ascorbate between the posterior and the anterior chamber might be explained by a passive volume influx from other epithelia.

The Ciliary Epithelium: A Double-Layered Epithelium Forms a Functional Syncytium

The ciliary epithelium separates the stroma of the ciliary body from the posterior chamber. It is a double-layered epithelium consisting of a pigmented epithelium facing the ciliary body stroma and a nonpigmented epithelium facing the posterior chamber. The two epithelia are in contact with each other through their apical cell membranes. The basolateral membrane of the pigmented epithelium is orientated toward the stromal side, whereas the basolateral membrane of the nonpigmented epithelium faces the side of the aqueous humor. In region of the borders of the ciliary body, posteriorly at the flat pars plana zone close to the ora serrata, and anteriorly at the transition zone between iris and ciliary body, the human ciliary epithelium shows regional structural variations. In the pars plicata, the ciliary epithelium shows deep infoldings and large numbers of mitochondria, indicating the zone of active transepithelial ion transport. Furthermore, the analysis of the intracellular ion composition in the ciliary epithelium using X-ray microprobe analysis also revealed functional variations in the transport activity

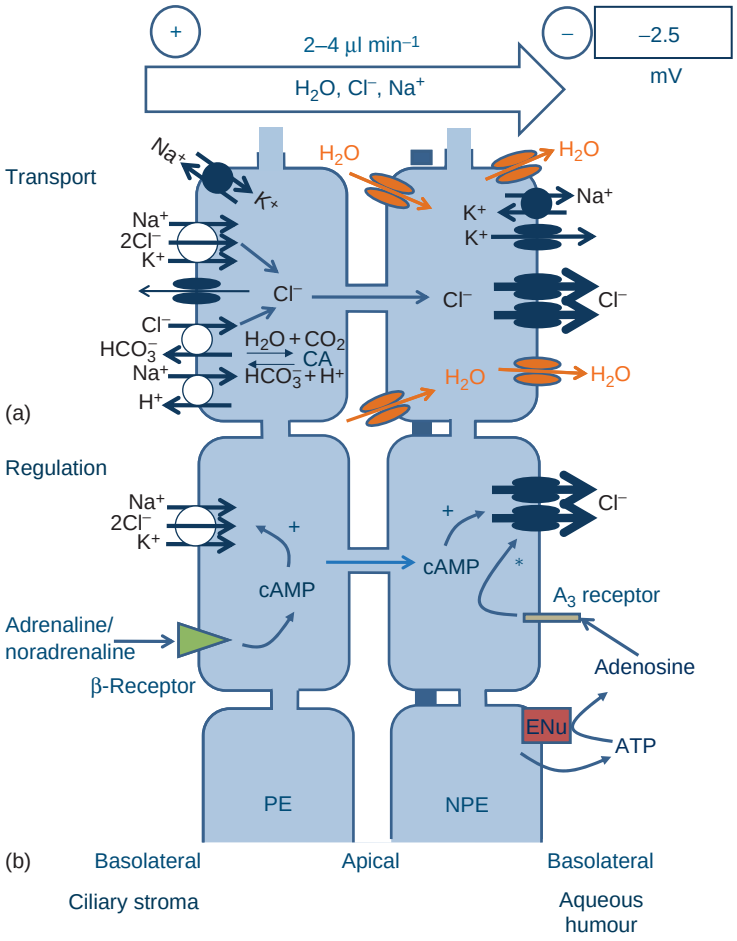

Figure 1 Summary of ion and water transport mechanisms of the ciliary epithelium. (a) Transport of ions. The ciliary epithelium is a functional syncytium: gap junctions (open connections) connect the cells of the pigmented and the nonpigmented epithelium and tight junctions (dark blue bars) between the cells of the nonpigmented epithelium form a barrier. Mainly Cl^- and Na^+ are taken up by the pigmented epithelium by transport mechanisms located in its basolateral membrane. The Na^+/K^+-ATPase establishes a gradient for Na^+ by transporting Na^+ out of the cell. The gradient for sodium is used by the $Na^+/K^+/2Cl^-$ co-transporter to take up Na^+, K^+, and Cl^- into the cell. A second transport mechanism further accumulates Cl^- in the cell: intracellular carbonic anhydrase accelerates the reaction of CO_2 and water into HCO_3^- and H^+; using the gradient for Na^+, H^+ is extracted from the cytosol by the activity of the Na^+/H^+ exchanger which further accelerates the reaction by carbonic anhydrase, leading to accumulation of HCO_3^-; HCO_3^- is transported out of the cell in exchange with Cl^- which increases the amount of Cl^- in the cytosol. Cl^- diffuses through gap junctions into the nonpigmented epithelium and leaves the cell through basolateral Cl channels. Na^+ is eliminated from the cytosol of the nonpigmented epithelium by the activity of the Na^+/K^+-ATPase. K^+ recycles across the basolateral membrane through K^+ channels. This transport of osmolytes drives the transport of water which follows the osmotic gradient though aquaporin water channels across the nonpigmented epithelium. (b) Major regulatory pathways. Activation of β-adrenergic receptors in the pigmented epithelium leads to an increases in intracellular cAMP which activates both the $Na^+/K^+/2Cl^-$ transporter in the basolateral membrane of the pigmented epithelium and the Cl^- channels in the basolateral membrane of the nonpigmented epithelium. ATP, which is released from the ciliary epithelium or adjacent tissues, is degraded into adenosine by ecto-nucleotidases. Adenosine stimulates A_3-receptors which activates an intracellular signaling cascade, resulting in stimulation of the Cl channels in the basolateral membranes of the nonpigmented epithelium. CA, carbonic anhydrase; ENu, ecto-nucleotidase; NPE, nonpigmented epithelium; PE, pigmented epithelium.

of the different regions. The turnover of Na^+, K^+, and Cl^- appeared to be considerably higher in the anterior than in the posterior ciliary epithelium.

The barrier function of the epithelium is provided by the formation of tight junctions between cells of the non-pigmented epithelium at their apical borders. The tight junctions form a major part of the blood–aqueous barrier of the ciliary body. The cells of the pigmented and of the nonpigmented epithelium are functionally connected to each other by gap junctions to form a functional syncytium. Thus, the transport across the ciliary epithelium requires the following steps (**Figure 1(a)**): (1) the pigmented epithelium takes up ions from the stroma of the ciliary body; (2) the ions pass through the gap junctions to the nonpigmented epithelium; and (3) the ions are released into the aqueous humor across the basolateral membranes of the nonpigmented epithelium. Functionally, the ciliary epithelium could be characterized as a tight epithelium,

which means that the major part of the ion transport has to pass through the cells of the epithelium. Due to the low conductance of the tight junctions, only few molecules can pass the paracellular pathway. In fact, flux studies in the bovine ciliary epithelium using L-glucose showed paracellular flux rates comparable to those known in tight epithelia. However, fresh iris–ciliary body preparations from many species showed rather low transepithelial resistances of values lower than 100 Ω cm^2. The explanation for such a small value likely stems from an underestimation of the surface area of the deeply folded ciliary epithelium in these preparations. When the measurements were corrected for the true surface of the unfolded tissue, the resistances reaches values of more than 1000 Ω cm^2, which is comparable to that of other tight epithelia, such as the retinal pigment epithelium. Using transport inhibitors the rate of aqueous humor production can be reduced by 80 %, which indicates the amount of water and solutes transported through the transcellular route.

The Energy for Active Transport

As in all transporting epithelia, the basic drive for active ion transport is provided by the activity of the Na^+/K^+-adenosine triphosphate (ATP)ase. Inhibition of Na^+/K^+-ATPase decreases intraocular pressure and transport of Na^+ in experimental animals. The Na^+/K^+-ATPase uses the energy of ATP hydrolysis to transport Na^+ and K^+ across the cell membrane against a concentration gradient. In this transport, the Na^+/K^+-ATPase removes Na^+ from the intracellular space and transports K^+ into the cell. This primary active transport of Na^+ establishes a gradient for Na^+ across the membrane which is used by secondary active transporters for many substances by coupling their transport to a movement of Na^+ along the established gradient. In the ciliary epithelium, both the pigmented and the nonpigmented epithelium express Na^+/K^+-ATPase. The Na^+/K^+-ATPase is localized in the basolateral membranes and the interdigitations of both the nonpigmented and the pigmented epithelium. Due to a higher expression rate in the nonpigmented epithelium and because of regional variations in the expression of different isoforms, the Na^+/K^+-ATPase activity of the nonpigmented epithelium overcomes the one of the pigmented epithelium. Thus, the transport across the double-layered epithelium is mainly driven by the activity of the Na^+/K^+-ATPase in the nonpigmented epithelium. The activity of the Na^+/K^+-ATPase in the pigmented epithelium may serve housekeeping functions. The activity of the Na^+/K^+-ATPase in the nonpigmented epithelium is further supported by the close neighborhood to basolateral K^+ channels. K^+, which is transported by the Na^+/K^+-ATPase into the cell, recycles across the basolateral membrane into the extracellular space through these K^+ channels. This keeps the gradient for K^+ across the basolateral membrane small and facilitates the Na^+ transport by Na^+/K^+-ATPase. The transport direction, in general, is then defined by the asymmetrically distributed Na^+-dependent co-transporter molecules in the ciliary epithelium.

The Transport Mechanisms

The Uptake of Ions at the Basolateral Membrane of the Pigmented Epithelium

Cl^- is taken up from the stromal side across the basolateral membrane of the pigmented epithelium and accumulates in the cytosol basically by two transport mechanisms which use the Na^+ gradient established by Na^+/K^+-ATPase. The bumetanide-sensitive electroneutral $Na^+/K^+/2Cl^-$ co-transporter takes up Na^+, K^+, and Cl^- from the stromal fluid. Since K^+ can flow back from the cytosol into the stromal extracellular space through K^+ channels, it is mainly Cl^- that accumulates in the cytosol of the pigmented epithelium. The second transport mechanism is provided by the coupled activity of both a Na^+/H^+ exchanger and a Cl^-/HCO_3^- exchanger. The Na^+/H^+ exchanger again uses the gradient for Na^+ to remove protons from the cytosol of the pigmented epithelium. This increases the amount of HCO_3^- in the cytosol from the reaction of H_2O and CO_2. HCO_3^- is then transported out of the cell across the basolateral membrane by the Cl^-/HCO_3^- exchanger by whom an additional influx of Cl^- ions from the stromal side into the cell is generated. The proportion of the two transport mechanisms in the entire transport of the ciliary epithelium is not clear and may vary between different species. However, the combined transport activity of these two transport mechanisms is counterbalanced by basolaterally localized Cl^- channels. Cl^-, which has accumulated in the cytosol of the pigmented epithelium, can recycle back into the stroma through these channels. This decreases the amount of transported Cl^- into the cytosol of the pigmented epithelium and across the ciliary epithelium. As described later, the control of the ratio of transported and recycled Cl^- ions is important for the modulation of the ion and water transport by the ciliary epithelium.

The Transport from the Pigmented Epithelium to the Nonpigmented Epithelium

As described above, the two epithelia are coupled through intercellular gap junctions to form a functional syncytium. The gap junctions are localized between the pigmented and the nonpigmented epithelium, and between the cells of the nonpigmented epithelium. The two combined transport mechanisms, $Na^+/K^+/2Cl^-$ exchanger and Na^+/H^+ exchanger plus Cl^-/HCO_3^- exchanger, lead to a transport of Na^+ and Cl^- into the pigmented epithelium. The ions

flow from the cytosol of the pigmented epithelium into the cytosol of the nonpigmented epithelium through the gap-junction channels which are formed by connexins. So far, different subtypes of connexins were found to be expressed by either the pigmented or the nonpigmented epithelium. Analysis of the gap junctions in the rat showed that Cx40 and Cx43 form gap junctions between the pigmented and the nonpigmented epithelium, whereas Cx26 and Cx31 form the gap junctions between the cells of the nonpigmented epithelium. The identity of the connexins forming gap junctions between the cells of the pigmented epithelium is unclear. Unspecific inhibition of the conductance of gap junction channels by inhibitors, such as oactanol of heptanol, revealed the importance of the gap junctional complexes for the epithelial transport of ions across the ciliary epithelium. Using these blockers, the active ion transport across the ciliary epithelium is reduced by 80%.

The Efflux of Ions across the Basolateral Membrane of the Nonpigmented Epithelium

Under physiological conditions, the efflux of ions across the basolateral membrane of the nonpigmented epithelium into the eye chamber represents the rate-limiting step of the transport of ions by the ciliary epithelium. This is mainly concluded by the difference of driving forces for Cl^- between the cytosol of pigmented and the nonpigmented epithelium and by the fact that the transport activity of the Na^+/K^+-ATPase of the nonpigmented epithelium is dominating over that of the pigmented epithelium. This conclusion means that the uptake of Cl^- by the pigmented epithelium is always larger than the efflux of Cl^- from the cytosol of the nonpigmented epithelium into the eye chamber. Na^+, which reaches the nonpigmented epithelium, is transported out of the cell by the activity of the Na^+/K^+-ATPase. Additionally, it is possible that a part of Na^+ leaves the cell through epithelial Na^+ channels (ENaCs), which were found to be expressed by the nonpigmented epithelium. Cl^- ions leave the cells of the nonpigmented epithelium through basolateral Cl channels. Since the Cl^- efflux out of the nonpigmented epithelium represents the rate-limiting step in the transepithelial transport, the regulation of the Cl channel activity represents a major mechanism in the regulation of aqueous humor formation. So far, it seems to be that the basolateral Cl^- conductance of the nonpigmented epithelium is primarily provided by ClC-3 Cl channels. These Cl channels are regulated by a multitude of different stimuli such as cell swelling or reduced protein kinase C activity. However, data from other stimulatory pathways, such as elevation of intracellular cyclic adenosine monophosphate (cAMP), imply the functional presence of other Cl channels which are so far not identified. Data from the isolated nonpigmented ciliary epithelium imply also the presence of a recycling pathway for Na^+ and Cl^- back from the aqueous side into the cytosol of the nonpigmented epithelium. This recycling pathway could be again provided by the coupled activity of both Na^+/H^+ exchanger and Cl^-/HCO_3^- exchanger in the basolateral membrane of the nonpigmented epithelium.

Aquaporins of the Ciliary Epithelium

The active transport of osmolytes drives the transport of water by osmosis. As mentioned above, the ciliary epithelium has a low paracellular permeability so that every transport has to pass the transcellular route. This transport route is provided by aquaporins, the so-called water channels, which are transmembrane proteins that form a pore to pass water across the cell membrane. In the ciliary epithelium, only the nonpigmented epithelium was found to express aquaporins: aquaporin-1 (AQP1) and aquaporin-4 (AQP4). These aquaporins are likely located in the membranes on both sides, apically and basolaterally, of the tight-junction belt of the nonpigmented epithelium. Thus, the transport route for water consists of the following steps: Since the pigmented epithelium does not express tight junctions, water can freely reach the tight-junction belt of the nonpigmented epithelium. Na^+ and Cl^-, which reach the nonpigmented epithelium through gap junctions from the pigmented epithelium, increase intracellular osmolarity. This drives an osmotic uptake of water through aquaporins. The ATP-driven transport of osmolytes across the basolateral membrane of the nonpigmented epithelium drives the transport of water through aquaporins across the basolateral membrane. Analysis of aquaporin-deficient mice revealed a decreased intraocular pressure due to reduced water transport by the ciliary epithelium.

Regulation of Aqueous Humor Formation

A large variety of signaling molecules was detected which regulate aqueous humor formation. Extracellular stimuli are catecholamines, antinatriuretic peptide, cannabinoids, endothelin, muscarinic agonists, glucocorticoids, prostanoids, and tumor necrosis factor-alpha. These extracellular signaling molecules activate intracellular signaling pathways, which involve cAMP, cyclic guanosine monophosphate (cGMP), NO, Ca^{2+}, pH, protein kinases A and C, tyrosine kinase, or mitogen-activated protein (MAP) kinase.

Regulation of Na^+ and Cl^- Uptake by the Pigmented Epithelium

As mentioned above, the efficiency by which the pigmented epithelium takes up Na^+ and Cl^- is reduced by a recycling pathway for these ions. This pathway is

represented by the combined activity of the Na^+/K^+-ATPase of the pigmented epithelium and the presence of basolateral Cl channels in the pigmented epithelium. These two transporting transmembrane proteins move Na^+ and Cl^- back to the extracellular space of the stromal side. As a pathway which counterbalances the uptake of ions from the stromal side, the recycling pathway can increase or decrease the net uptake of Na^+ and Cl^- and is, thus, important for the regulation of aqueous humor production. Although the Cl^- efflux at the nonpigmented epithelium represents the rate-limiting step in the aqueous humor production, the recycling pathway of the pigmented epithelium is of importance by the fact that the pigmented epithelium is accessible to many signaling molecules from the blood stream or from sympathetic nerve endings. ATP was found to increase the activity of the Cl channels and is therefore a regulator which decreases aqueous humor formation. Stimulation of the ATP receptors, P_2Y_2, triggers the formation of prostaglandin E2, and increases intracellular free Ca^{2+} as well as cytosolic cAMP. The latter second messenger directly activates the so-called maxiCl channels, which have a large Cl conductance and would transport the major proportion of recycled Cl^-.

Modulation of Cl^- Efflux out of the Nonpigmented Epithelium

The Cl^- is the rate-limiting step for the aqueous humor formation by the ciliary epithelium. Thus, the regulation of the Cl channel activity in the nonpigmented epithelium represents an important side for the regulation of aqueous humor production. Since the nonpigmented epithelium is not reachable to mediators from outside of the eye, the regulation of Cl channel activity can only involve intrinsic factors such as cell swelling or autocrine regulatory pathways; indeed, cell swelling appeared as a strong regulator to increase aqueous humor secretion. Furthermore, the stimulation of the A_3 adenosine receptors, inhibition of protein kinase C, or an increase of cytosolic cAMP increases the Cl channel activity and subsequently the formation of aqueous humor.

The Regulation of the Aqueous Humor Formation at the Double-Layered Epithelium

As mentioned above, a multitude of different factors modulate the formation of aqueous humor. Since a clear picture which integrates these pathways into one scenario is lacking, the two most important pathways are described in more detail subsequently (**Figure 1(b)**).

In the isolated epithelia, cAMP appeared as an important regulator. On the one hand, cAMP might reduce the aqueous humor production by activation of Cl channels in the pigmented epithelium and, on the other hand, it might increase the formation of aqueous humor by activation of the basolateral Cl conductance of the nonpigmented epithelium. Indeed, an increase by different cAMP-stimulating mediators had adverse effects on the Cl^- transport of the double-layered epithelium. β-Adrenergic stimulation, which leads to formation of cAMP, increases the aqueous humor production by stimulation of the $Na^+/K^+/2Cl^-$ co-transporter and the Cl channels in the pigmented and the nonpigmented epithelia, respectively. This mechanism is in accordance with the effects of clinically administered β-adrenergic antagonists, which lower the aqueous humor inflow. However, a more general increase in intracellular cAMP production by forskolin activates the cAMP-producing enzyme, adenylyl cyclase, leading to a reduction in the aqueous humor inflow. These effects of cAMP might result from the inhibition of the Na^+/K^+-ATPase in the nonpigmented epithelium, uncoupling of the gap junctional connection between the pigmented and the nonpigmented epithelium and the above-mentioned activation of Cl channels in the pigmented epithelium. It is likely the final response of the double-layered epithelium to cAMP stimulation results from a spatial distribution of local increases in the cAMP concentration, especially for the effects of β-adrenergic stimulation.

A second important pathway that regulates the formation of aqueous humor is that of the stimulation of A_3 adenosine receptors. Knock-out mice, lacking the expression of the adenosine A_3 receptor, were found to show decreased intraocular pressure probably resulting from a decreased transport through the ciliary epithelium. In addition, A_3-receptor-selective agonists increase intraocular pressure, while A_3-receptor-selective antagonists block the effects of adenosine to increase intraocular pressure. Furthermore, a disease-dependent overexpression of A_3 receptors seems to play a role in the development of glaucoma in pseudoexfoliation syndrome. The agonist of the adenosine receptors is either secreted from the adjacent tissue or generated by the presence of ecto-enzymes on the surface of both the pigmented and the nonpigmented epithelium. These enzymes hydrolyze ATP which is released from both the pigmented and the nonpigmented epithelium. Thus, the adenosine-dependent regulation of aqueous humor production represents an intrinsic autocrine pathway, which is of critical importance for the regulation of the transport activity by the nonpigmented epithelium. Indeed, the most profound effect of A_3 receptor stimulation is the increase in the Cl^- conductance of the nonpigmented epithelium.

The Transport of HCO_3^-

As shown above, an HCO_3^--dependent transport pathway seems to increase uptake rates for Na^+ and Cl^- by the

pigmented epithelium and to counterbalance the Cl^- efflux across the basolateral membrane of the nonpigmented epithelium. The role of the HCO_3^- transport in epithelial ion transport across the ciliary epithelium is not fully understood. In humans, the transport by the ciliary epithelium does accumulate Cl^- in the aqueous humor, but not HCO_3^-. However, there are implications for a role of HCO_3^- in the regulation of aqueous humor formation in humans. These implications come from the treatment of glaucoma by lowering intraocular pressure using inhibitors of carbonic anhydrase, which were found to reduce inflow of aqueous humor in monkey. Carbonic anhydrase strongly accelerates the reaction of CO_2 and H_2O to HCO_3^- and H^+ and the reaction vice versa. Indeed, the presence of cytosolic and of membrane-bound carbonic anhydrase has been demonstrated in the ciliary epithelium. In humans, the administration of inhibitors for carbonic anhydrase leads to an increase in the aqueous-to-plasma ratio for HCO_3^- and a decrease in the aqueous-to-plasma ratio for Cl^-. This means that inhibition of carbonic anhydrase seems to decrease the Cl^- transport by the ciliary epithelium and to increase the HCO_3^- transport. Since the Cl^- transport by the human ciliary epithelium seems to be the dominating transport, the reduced inflow of aqueous humor in response to inhibition of carbonic anhydrase results from a decreased transport of Cl^- and water. Thus, in humans the effects of carbonic anhydrase seem to work at the side of the pigmented epithelium. The activity of the membrane-bound carbonic anhydrase would deliver CO_2 and water. CO_2 diffuses into the cell where the cytosolic carbonic anhydrase accelerates the reaction of CO_2 and H_2O to H^+ and HCO_3^-, which enhances the transport by the combined activity of the Na^+/H^+ exchanger and the Cl^-/HCO_3^- exchanger. These two transporter systems accumulate Na^+ and Cl^- in addition to the transport activity of the $Na^+/K^+/2Cl^-$ co-transporter and would increase the net transport of Na^+ and Cl^-. Thus, although the transport across the ciliary epithelium does not accumulate HCO_3^- in the aqueous humor, the modulation of HCO_3^- transport across the basolateral membrane of the pigmented epithelium is of clinical importance, being a target for drugs to lower intraocular pressure.

Ionic Permeability and Currents in the Lens

P J Donaldson, University of Auckland, Auckland, New Zealand
K F Webb, University of Nottingham, Nottingham, UK

Glossary

Advection – The transport of a substance by a moving fluid. In the lens the circulating ionic currents create a fluid flow that causes the advection of neutral solutes such as glucose and amino acids into the lens faster than would be predicted by passive diffusion alone.
Conductance – A measure of current (in Amperes (A)) divided by voltage (in Volts (V)) and refers to the rate of ion travel through an ion channel and is often measured in Siemens (S). Most ion channels have a conductance of between 1 and 150 pS (10^{-12} S).
Impedance analysis – An electrophysiological technique which utilizes broadband voltage stimuli delivered and recorded by spatially separated microelectrodes to provide location-specific measurements of resistive pathways within a tissue. This technique has been used to monitor the propagation of these stimuli through the ocular lens, providing information on the resistive coupling of electrical compartments between and around radial columns of lens cells. This analysis is dependent upon the fitting and refinement of a detailed three-dimensional equivalent circuit model, incorporating the relative contributions of membranes and conductive spaces within different lens locations.
Isotonic fluid transport – The theoretical limiting velocity of water flow that is approached as the membrane water permeability approaches infinity and the transmembrane osmotic gradient approaches zero.
Patch clamping – An electrophysiological technique whose discovery made it possible to record currents flowing through individual ion channels. Patch clamp recording utilises a glass micropipette, with a tip diameter of $\sim$ 1mm, to enclose a patch of membrane that often contains just one or a few ion channels. The micropipette is pressed against a cell membrane and suction is applied to assist in the formation of a high resistance ($>10^9$ ohm, GΩ) seal between the glass and the cell membrane. The high resistance of this seal makes it possible to electrically isolate the ion channel currents measured across the membrane patch with little competing noise. Erwin Neher and Bert Sakmann received the Nobel prize in physiology or medicine in 1991 for their contributions to the development of this technique.
Permeability – A description of how fast ions are able to move through an ion channel (the rate of movement). The depth of the energy well for a particular ion generally determines its permeability, or conductance. However, if an energy well is too deep, it can slow down the ion's rate of travel.
Ussing chamber – A physiological recording apparatus consisting of two halves that are clamped together to isolate the apical and basolateral surfaces of an epithelial tissue. The two half chambers are filled with physiological media in order to remove any chemical, mechanical, and electrical driving forces. The vectorial transport of ions across an epithelial tissue produces a potential (voltage) difference across the tissue that is measured using a pair of voltage electrodes placed on either side of the epithelial tissue. Current is injected to balance the potential difference measured across the voltage electrodes via a second pair of current passing electrodes. This so-called short-circuit current (I_{sc}) is a precise measure of net ion transport taking place across the tissue.
Vibrating current probe – An electrophysiological technique used to measure ionic current flowing in the extracellular compartment surrounding tissues. The vibrating probe consists of a voltage-sensitive electrode which is rapidly vibrated between spatially separated locations adjacent to the tissue surface. Calibrating for the resistivity of the bathing fluid allows measurements of current density and direction to be made at locations across an epithelial surface or around a tissue.

The Physiology of Lens Transparency: A Unique Structure and Function

The transparency of the lens is closely linked to the unique structure and function of its component cells. The highly differentiated lens fiber cells which compose the bulk of the lens are derived from an overlying anterior layer of epithelial cells, which exit the cell cycle at the equator to embark upon a differentiation process involving extensive cellular elongation, loss of cellular organelles and nuclei, and the expression of fiber-cell-specific proteins. Fiber cells elongate until they meet other fibers extending

from their opposite hemisphere, meeting and interdigitating at the anterior and posterior poles to form the sutures. Since this process continues throughout life, a gradient of fiber cells at different stages of differentiation is established around an internalized core (the lens nucleus) of mature, anucleate fiber cells. While the transparent properties of the lens are a direct result of its highly ordered tissue architecture, the lens may not be a purely passive optical element. Maintenance of its architecture could require special mechanisms to supply the deeper lying fiber cells with nutrients and remove metabolic waste and to control the volume of these cells.

Because of its size, it has been proposed that the avascular lens cannot rely on passive diffusion alone to transport nutrients to deeper lying cells, or to transport waste products back to the surface. Calculated diffusion rates for substrate entry to the lens center preclude simple diffusional delivery of glucose and other nutrients, whereas passive redistribution of metabolic waste products and ionic entry could lead to excessive accumulation of toxic metabolites in the lens interior. Outer cell layers, lying near the surface and closer to supply of oxygen and nutrients, derive energy from aerobic glycolysis conducted by mitochondria in the anterior epithelium and differentiating fiber cells. In contrast, internalized mature fiber cells are reliant on anaerobic glycolysis for energy production, which produces lactate whose accumulation in the deep lens lowers tissue pH. Thus, opposing gradients of metabolic substrates and waste products are found across the lens radius. In the absence of a blood supply some other transport system must exist by which glucose and other nutrients supply the metabolic needs of mature fiber cells and by which waste products can be removed from the lens interior.

It has been proposed that the lens operates an internal microcirculatory system that preserves tissue architecture and transparency by supplying fiber cells with nutrients, removing wastes, and controlling the volume of fiber cells. Our understanding of this system is not yet complete and is still somewhat controversial. To put the current model of lens transport into perspective it is pertinent to review the historical developments that have led to its formulation.

Early Views of Lens Physiology

Early investigations in lens physiology treated the organ as a kind of giant cell, due to its apparently amorphous interior, high global internal K^+, and low Na^+ concentrations (**Figure 1(a)**). The physiological characterization of the lens began with techniques designed to estimate its global functional properties – such as ion concentrations, intrinsic potential, specific resistances, and current–voltage relationships. Such experiments did not attempt to localize or apportion functional measurements to intralenticular structures, due to the prevalent view that the lens was a homogeneous bag of proteinaceous gel, and was not cellular in nature. As histological and electrophysiological techniques improved, there was a slow paradigm shift driven largely by the growing study of fluid transport and homeostatic mechanisms in other epithelial tissues. Since the anterior surface of the lens is covered by an epithelial cell layer while the posterior surface is not, early studies of lens physiology focused on hypothetical anterior–posterior differences in ion transport (**Figure 1(b)**). By mounting the lens in an Ussing chamber an anteriorly directed positive electrical potential was detected, which appeared to result from Na^+/K^+ exchange mechanisms located at the lens anterior. Thus, the anterior epithelial layer was thought to maintain the welfare of the fiber cell mass by setting and maintaining the lens intrinsic potential and ion balance, creating a functional syncytium driven by a pump-leak mechanism (**Figure 1(b)**). The lens epithelium was thought to contain all active transport and selective ion permeation pathways, while the fiber cells were thought to exist as a distributed leak, against which epithelial transport worked to maintain lens homeostasis. Two-electrode voltage clamp methods, in which separate voltage-sensing and current-passing electrodes were inserted into different locations within a single lens, found that wherever the electrodes were placed a similar potential could be recorded. This was interpreted as evidence of membrane degeneracy in the lens core, where cells were seen as electrochemically passive, or even dead. By contrast, the anterior epithelium was amenable to direct functional study – being capable of maintaining its integrity and structural composition even when stripped from the lens. The fiber mass left behind depolarized and rapidly degenerated on removal of the epithelium, and was thus viewed as functionally inert.

The role of fiber cells in lens physiology remained uncertain, although data hinted at a more defined contribution of inner lens membranes than a simple homogeneous leak. Some of the first data on the internal structure and resistive contribution of cell membranes within the internalized lens came from the application of impedance analysis to the lens which allowed the relative contributions of peripheral and deep fiber cell membranes, connected by a tortuous, resistive extracellular space to be estimated. It was found that internalized fiber cells possessed very high resistance membranes, and the majority of the ion conducting pathways lay within the outer cell layers. In combination with ion replacement experiments, it was found that surface cells contained a large permeability pathway to K^+ ions, while inner fiber membranes were dominated by Na^+ and Cl^- conductances of much lower density. The large amount of fiber cell membrane in the internalized lens ($\sim$100 cm^2 in a small frog lens, vs. $\sim$0.5 cm^2 of epithelial membrane) translates into a significant leakage pathway for Na^+ and Cl^-, which is offset by

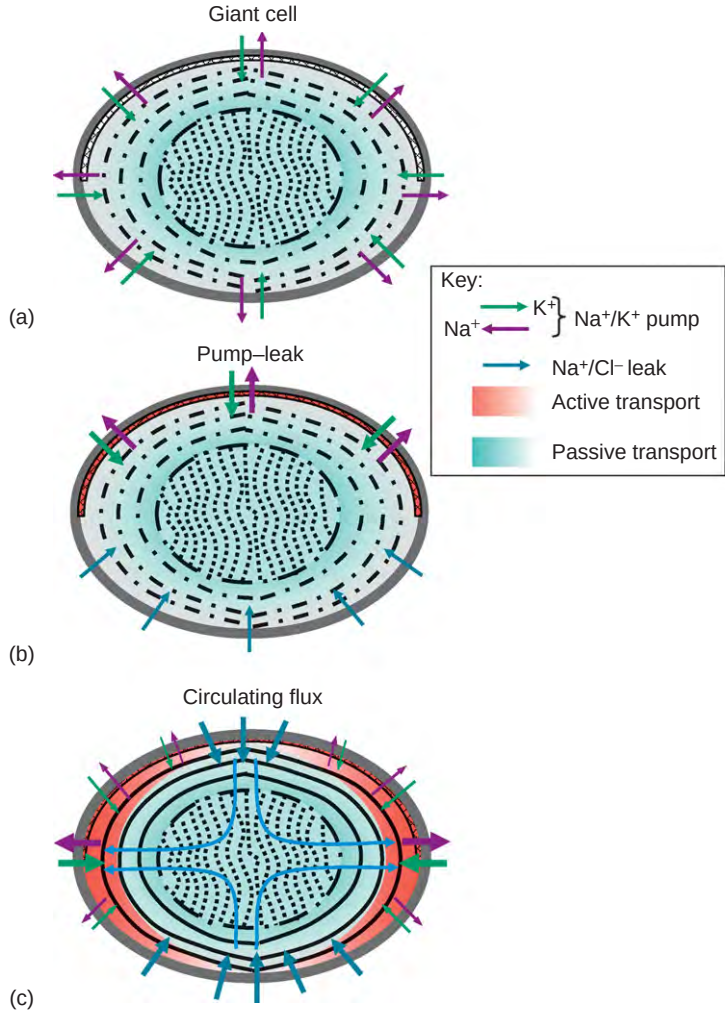

Figure 1 Historical views of lens physiology. (a) The lens was originally thought of as a homogeneous, acellular ''giant cell'' due to the degeneration of fiber cell membranes. Transport across the lens capsule was thought to create an outwardly-directed K^+ and an inwardly-directed Na^+ gradients. (b) In the pump-leak model active transport by the anterior epithelium was believed to drive a posterior–anterior ion flux that compensated for a distributed Na^+/Cl^- leak in the fiber cell mass. (c) The circulating flux model was proposed to account for impedance and vibrating probe data that collectively showed that current flows are directed into the lens at the poles and out of the lens at the equator.

pumping activity at the lens surface. In this revised model transport activity was no longer restricted solely to the anterior epithelium, but to surface cells which includes differentiating fiber cells that retain contact with the capsule.

The next advance in understanding of lens physiology came from the application of a novel electrophysiological approach, the so-called vibrating probe, which measured the magnitude and direction of ionic current flowing in the extracellular compartment around the lens circumference. This technique revealed an outwardly-directed current exited the lens at the equator, whereas inward current was detected at both the anterior and posterior poles (**Figure 1(c)**). In intermediate positions, the current direction appeared to undergo a gradual shift from strongly inwardly-directed over the polar sutures, to strongly outwardly directed at the lens equator (**Figure 2(b)**). The equatorial outward current was found to respond to manipulations in bathing $[K^+]$, and could be reversed in direction by voltage clamping the lens to potentials more negative than E_K. Blockade of Na^+/K^+ ATPase activity by exposure to ouabain lead to a small initial current reduction, that was followed by a slow decline to zero. Decreasing bathing $[Ca^{2+}]$, which lead to large depolarizations in lens potential, caused a sharp rise in equatorially measured current. Radiolabeled Na^+ in the bath solution entered the lens at the poles and eventually exited at the lens equator. Since the equatorial current was outwardly directed, and Na^+/K^+ ATPase activity extrudes Na^+, it was proposed that the measured pattern of lenticular current flow represented a re-entrant cycle of Na^+ movement through the lens structure, entering via the extracellular space and leaving via Na^+/K^+ ATPase activity at the lens equator.

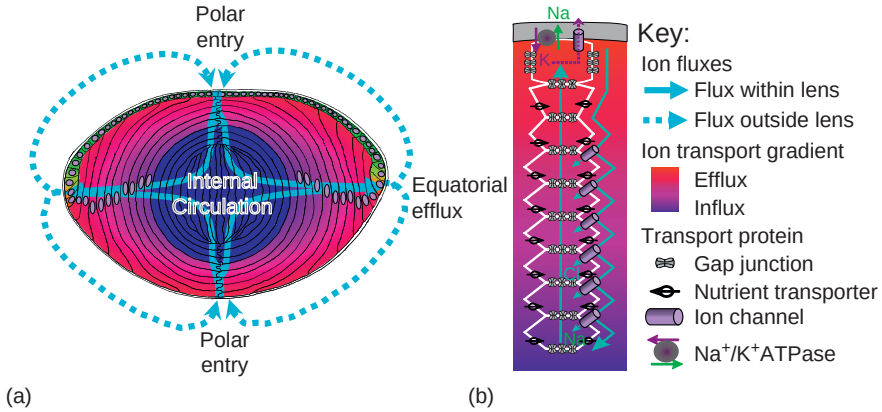

Figure 2 The lens internal micro-circulation system. (a) Current flow pathways around and through the lens carried by circulating ionic fluxes. (b) Schematic diagram showing a column of fiber cells cut in cross section at the lens equator. Current and solutes are proposed to flow into the lens via the extracellular space, to cross fiber cell membranes and to flow outward via an intracellular pathway mediated by gap junction channels. The surface local of Na^+/K^+ ATPase and K^+ channels which is connected to the Na^+ and Cl^- leak pathways in deeper fiber cells via gap junctions generates a circulating flux of ions that drives the circulation system.

K^+ accumulated by pumping activity was allowed to leave equatorial cells by K^+ selective channels, setting a negative membrane potential which was transmitted to the entire lens via gap junctions.

The results obtained by the vibrating probe were eventually verified using a modified Ussing chamber that measured ion fluxes in specific regions of the lens surface. These studies showed patterns of current flow that were spatially similar to those recorded via the vibrating probe. Efflux currents were dominant at the lens equator and an area immediately anterior. Application of the K^+ channel blocker Ba^{2+} eliminated measured currents only if applied to regions including the most equatorial zone, while ouabain produced measurable inhibition of Na^+/K^+ ATPase currents in the equatorial and immediately anterior segment, but not at the lens anterior pole. This location-specific effect of pharmacological agents strongly supports the notion that the physiologically relevant transport processes are concentrated in the equatorial lens.

The Lens Internal Circulation System

Having described from a historical perspective the techniques underpinning the formulation of the lens internal circulation hypothesis, this article now describes the current understanding of the model. Spatial segregation of transport functions within the lens creates a continuous flux of ions through the tissue structure (**Figure 2(a)**). Na^+ and Cl^- enter the lens at both poles via the extracellular space, enter internalized fiber cells via a distributed low level entry pathway, and leave the lens via an intercellular route mediated by gap junctions (**Figure 2(b)**). Mathias and co-workers have shown by biophysical modeling that this vectorial flux of ions produces a continuous flux of fluid and solute through the lens tissue, which appears to act as a lens internal microcirculation. The circulating flux of ions creates an extracellular fluid flow by solvent drag, whose rate has been estimated in the frog lens at approximately 1 μm s^{-1}. This flowing fluid carries with it other solutes, including antioxidants, glucose, and other nutrients; causing them to reach the lens core at a rate exceeding that results from simple diffusion alone. The operation of this lens internal circulation system appears essential to lens transparency since it controls ionic and volume homeostasis in all lens cells, and nutrient delivery and waste removal from the lens core. The constantly moving fluid flux prevents excessive accumulation of lactate and other metabolic products, prevents depletion of Na^+ and other ions from the extracellular space, and prevents the slow leakage of Na^+ and Ca^{2+} into fiber cells from triggering pathological change in the lens core.

Key Membrane Transport Components of the Lens Circulation System

The lens internal circulation system is hypothesized to achieve a constitutive flux of ions and fluid through the lens structure by the concerted action of spatially separated membrane transport pathways. Key components are listed below:

Localization of Active Transport Mechanisms to the Lens Surface

In the lens the active transport of Na^+ ions is achieved by concentrating the expression of functionally active Na^+/K^+ ATPase in the membranes of the surface cells, including the anterior epithelium and equatorial fiber cells. However, ouabain-sensitive pump currents at the equator have been shown to be at least 20-fold higher than those

measured at the poles. Na^+/K^+ ATPase pump proteins are detected throughout the fiber cell mass, but these proteins detected in cortical and nuclear fiber membranes appear to be nonfunctional due to tyrosine phosphorylation. The restriction of functional Na^+/K^+ ATPase pumps to the lens surface makes sense anatomically, since the pumping of ions requires energy, which is in short supply in deeper fiber cells that rely on anaerobic metabolism. Hence, it is the Na^+/K^+ ATPase activity that sets up the ion gradients which become the driving force for passive ion movement within the lens. The intracellular potential and cation gradient thus created are transmitted to the fiber cell mass by extensive gap junctional coupling, allowing secondary active uptake of nutrients and electroneutral ion exchange in internalized cells, which do not themselves maintain a functional pool of Na^+ pumps.

Spatially Differences in Membrane Permeability

Electrical measurement conducted on whole lenses exposed to changes in extracellular ion concentrations have shown that the K^+ permeability is restricted to the surface of the lens, while deeper fiber cells contain Na^+ and Cl^- permeability pathways. Using the patch clamp technique, the lens epithelium was subsequently found to contain K^+ channels which are thought to play a key role in setting lens membrane potential by providing a permeation pathway for K^+ accumulated by Na^+/K^+ ATPase activity in the lens periphery. A variety of inwardly and outwardly rectifying K^+ channels that were differentially sensitive to blockade by agents such as Ba^{2+} and tetraethylammonium (TEA) have been reported to be expressed in the lens epithelium. Not all of these identified channels are found in every species, or even in any one cell. However, despite this diversity of lens epithelial K^+ channel expression, in all species of lens these K^+ channels are important in setting the membrane potential for the underlying fiber cells, which are electrically connected to the epithelial surface via gap junctions. This dependency of the fiber cells on the surface epithelium is graphically illustrated by the inability of fibre cells once isolated to maintain their structural integrity. Fiber cells dissociated from the epithelium depolarize and activate a nonselective leak conductance that allows Ca^{2+} influx, which in turn activates Ca^{2+}-dependent proteases that compromise the structural integrity of these isolated cells.

Equatorial epithelial cells differentiate into fiber cells, and as part of this process there needs to be a switch in cation permeability from a predominantly outwardly directed K^+ conductance at the lens surface, to an inwardly directed Na^+ conductance in deeper fiber cells. Consistent with this switch in cation permeability the Cl^- conductance is expected to change from a peripheral efflux to a deeper influx to preserve electroneutrality. To determine how these changes occur as a function of fiber cell differentiation, fiber cells were isolated from the outer lens cortex in the presence of Gd^{3+}, a general inhibitor of nonselective cation channels, that prevented the membrane depolarization and Ca^{2+} influx that usually occurs when fiber cells are dissociated from the overlying epithelium. In the presence of Gd^{3+} it is possible to measure the membrane properties of isolated fiber cells using the whole cell patch clamp technique and to compare their membrane properties to those of the epithelium. Since fiber cell length *in vitro* has been shown to be predictive of *in vivo* location, length-dependent trends in the electrical properties of isolated fiber cells are able to be related to differentiation-dependent changes in membrane permeability.

Using this approach it was shown that the membrane properties of isolated fiber cells resemble a continuum (**Figure 3**). Short newly differentiated fiber cells tend to have membrane properties that resemble those of their progenitor epithelial cells, being hyperpolarized, electrically tight and dominated by K^+ conductances that are sensitive to Ba^{2+} and TEA (**Figure 3(a)**). As fiber cells elongate, these epithelioid K^+ conductances appear to become buried beneath an outwardly rectifying lyotropic anion channel, which increasingly dominates membrane behavior in longer cells. In short fiber cells this anion conductance was found to be not normally active, but it could be activated by cell swelling. In longer cells the anion conductance appeared to be constitutively active. The lyotropic selectivity sequence of these anion conductances observed in isolated cells appears similar to that measured in intact lenses under isotonic conditions, suggesting that these conductances may have a physiological role within the lens under resting conditions. Two classes of nonselective cation (NSC) channels could be distinguished by their sensitivity to trivalent cations, and were present in parallel to the anion conductance. The presence of these NSC conductances introduced a variable Na^+-permeable leak pathway that depolarized current reversal potentials and contributed a linear component to whole-cell current recordings. If this conductance was allowed to remain active, cell degradation rapidly ensued, triggered by catastrophic membrane influx of Ca^{2+} ions. While one NSC conductance was effectively minimized by the addition of Gd^{3+} to the bathing media, an additional NSC conductance, which proved to be sensitive to La^{3+}, was shown to activate upon isotonic cell shrinkage. Thus, it appears that while epithelial and short fiber cells are dominated by K^+ conductances, longer fiber cells become increasingly dominated by an anion conductance with a low level of cationic leak, which appear differentially sensitive to cell volume in longer cells. These spatially localized differences in ionic permeability, because they are electrically coupled by gap junctions, are believed to drive the internal ionic circulation system.

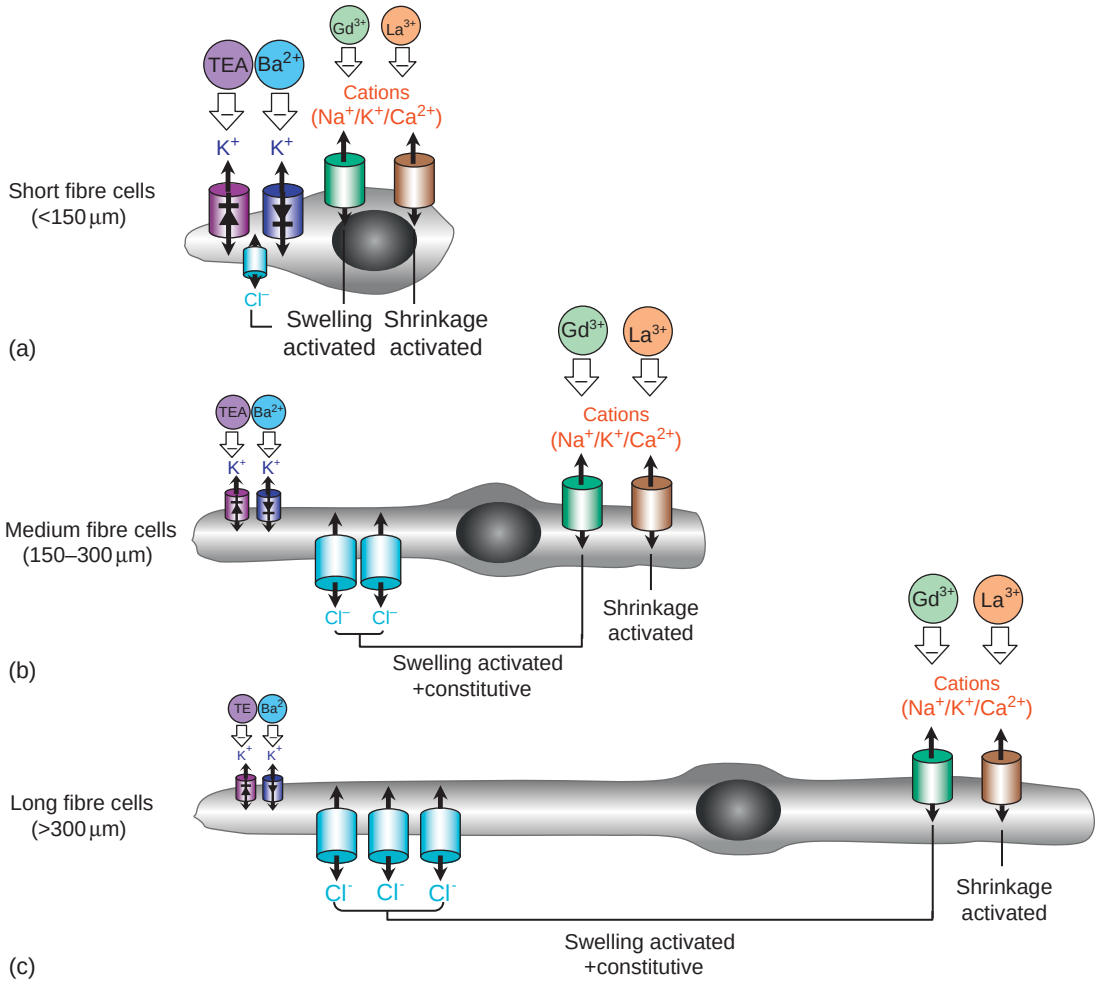

Figure 3 Spatial differences in membrane permeability develop as fiber cell differentiate. (a) The membrane properties of short fiber cells that have just undergone elongation from their progenitor epithelial cells tend to be dominated by Ba^{2+}- and TEA-sensitive K^+ channels, although they contain at least two distinct classes of nonselective cation (NSC) channels and a lyotropic Cl^- channel. The activity of NSC and Cl^- channels is usually low in these short cells but can be activated by changes in cell volume. Medium (b) and longer (c) fiber cells begin to accumulate more Cl^- channels, which, while retaining their volume sensitivity, become constitutively active under isotonic conditions. This increase in Cl^- conductance in longer cells overwhelms the K^+ conductances originally present in the shorter epithelial-like fiber cells.

Directing Gap Junctional Coupling to the Equator

Due to the abundance of gap junction channels, the lens can be considered a syncytium in which all cells have a similar membrane potential. However, regional differences in the distribution and regulation of the gap junction channels exist. In the outer fiber cells, gap junctions are particularly concentrated on the broad sides of the equatorial region of fiber cells, thus providing communication pathways preferentially in a radial direction toward the equator. In the inner fiber cells, the gap junctions are more evenly distributed throughout the cell membrane and provide a more isotropic coupling. This differential distribution of gap junctions helps to direct the outward component of the circulating current to the lens equator where the Na^+ pumps are preferentially localized (**Figure 2(b)**).

Fiber cells throughout the lens are connected to each other via gap junction channels composed of two related connexins, α_3 (Cx46) and α_8 (Cx50). Despite the fact that both of these connexins have the ability to form functional channels when expressed in *Xenopus* oocytes, inherited mutations and null mutants have shown that the presence of both is essential for the maintenance of tissue transparency. Briefly, α_8 appears to be involved in modulating the growth of the lens, while α_3 is important for maintaining cell-to-cell coupling in the lens core. In a wild-type lens the gap junctional coupling in differentiating fiber cells of the outer cortex is about 1.0 S cm^{-2} and falls to around 0.4 S cm^{-2} in the mature fiber cells of the lens core. In the lenses from the α_3 knock-out mice, the conductance is reduced by about 50% in the outer differentiating fibers and can be accounted for by the presence of α_8. However,

in central mature fibers of the α_3 knock-out mouse the coupling conductance drops to zero. This indicates that α_3 is solely responsible for mediating intercellular coupling in the lens core.

Water Permeability and Fluid Flow

The lens circulation model proposes that water follows the circulating Na^+. This requires that the lens fiber and epithelial cell membranes have significant water permeability. The most abundant membrane protein in lens fiber cells, Major Intrinsic Protein 26 (MIP26), was subsequently shown to be a member of the aquaporin (AQP) family of water channels and was renamed AQP0. When exogenously expressed in oocytes, AQP0 forms a water channel, but unlike many other members of the AQP family, it is not sensitive to Hg^{2+} and exhibits a relatively low water permeability. Using vesicles prepared from the rat lens, it was subsequently shown that the water permeability of AQP0 containing vesicles was some 45 μm s^{-1}, was Hg^{2+}-insensitive, and was dramatically reduced by the extraction of AQP0 from the vesicles. AQP0 water permeability has been shown to be sensitive to alterations in intracellular pH and $[Ca^{2+}]_i$, reflecting a potential mechanism to enhance water transport and rectify osmotic imbalances. In contrast, lens epithelial cells that express AQP1 had a membrane water permeability of some 135 μm s^{-1}, which was blocked by Hg^{2+}. Based on the lens circulation model, the water flowing out of each epithelial cell is due to the cumulative entry into many fiber cells. Hence, the water permeability of the epithelial cell membrane needs to be greater than that of fiber cell membrane, as indeed is the case.

Since water fluxes in the lens have been proposed to be isotonic in nature and the Na^+ influx across fiber cell membrane has been measured as 0.3×10^{-11} mol cm^{-2} s^{-1}, then the water flow generated by this solute flux needs to be some 10^{-8} cm s^{-1} to maintain lens osmolarity. Given the water permeability above 45 μm s^{-1}, the fiber cell transmembrane osmotic gradient necessary to generate this flow velocity is only about 0.1 mOsm. Thus, one does indeed expect the circulation to generate a near maximal water flow that approaches isotonic.

Secondary Active Transport of Nutrients

The internal circulation system is hypothesized to generate a bulk flow of fluid and solute which enhances the delivery of substrates to internalized lens cells by accelerating the movement of solute via the extracellular space. Consistent with this view, molecular studies (Table 1) have shown that fiber cells express a full repertoire of transporters that mediate the uptake of glucose and the amino acids involved in the synthesis of the glutathione (GSH), the key antioxidant in the lens.

Furthermore, immunocytochemical localization of these transporters has shown that differences exist in the complement of transporters expressed in the cortex and nucleus of the lens, suggesting that regional differences in nutrient uptake may exist. For example while lens epithelial cells express the facilitative glucose transporter GLUT1, fiber cells express the higher-affinity GLUT3

Table 1 Molecular inventory of nutrient transporter protein expression in different regions of the lens

		Localization					
Transporters	*Species*	*CE*	*NE*	*OC*	*IC*	*C*	*Mode of action*
Glucose transporters							
GLUT1	Rat		√				Facilitative diffusion
GLUT3	Rat			√	√		
SGLUT2	Rat			√	√	√	Secondary active transport
Cystine/glutamate exchanger (Xc-)							
xCT	Rat			√	√	√	Sodium independent antiporter
Glutamate transporters							
EAAT1	Rat			√	√		Secondary active transport
EAAT2	Rat		√	√

Vitamin C transporters							
SVCT2	Human	√					Secondary active transport

CE, cultured epithelial cells; NE, native epithelial cells; OC, outer cortex; IC, inner cortex; C, core; A, anterior surface; E, equatorial surface.

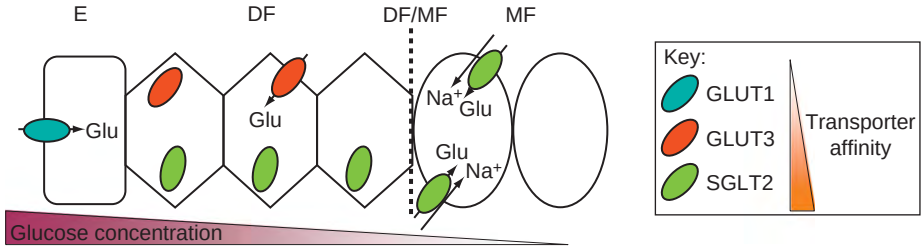

Figure 4 Regional differences in nutrient uptake in the lens. (a) Glucose uptake in the lens is mediated by at least three different transporters. In the epithelium GLUT1 is expressed, while in fiber cells GLUT3 and SGLT2 are expressed. During the course of fiber cell differentiation GLUT3 first becomes inserted into the narrow sides of differentiating fiber cells (DF) in the outer cortex. By contrast, SGLT2 is inserted into membranes of mature fiber cells (MF) from a cytoplasmic pool at the DF/MF transition. It is proposed that this differential expression of glucose transporters establishes an affinity gradient, which increases the ability of deeper fiber cells to extract a diminishing supply of glucose from the extracellular space.

isoform and the sodium-dependent glucose transporter SGLT2 (Figure 4). Both GLUT3 and SGLT2 transporters appear to be present predominantly in the cytoplasm of peripheral fibre cells and become inserted into the plasma membrane at different stages of fiber cell differentiation. GLUT3 is initially inserted into the narrow sides of the differentiating fiber cells, while SGLT2 is abruptly inserted into the membranes of mature fiber cells at the transition zone between differentiating and mature fiber cells that coincides with the loss of cell nuclei. Thus, the differential expression of glucose transporters establishes an affinity gradient which increases the ability of deeper fiber cells to extract a diminishing supply of glucose from the extracellular space. A similar change in the complement of transporters that mediate amino acid uptake in the cortex and nucleus has also been observed.

The expression of sodium-dependent transporters such as SGLT2 in the lens nucleus means that mature fiber cells are able to utilize the energy stored in the sodium gradient to accumulate metabolites such as glucose above their concentration gradients. Reference to the circulation model shows that the Na^+ gradient is ultimately maintained by the active removal of Na^+ at the lens surface. Thus in addition to generating the circulating ion fluxes that underpin the convective delivery of the nutrients to deeper fiber cells, Na^+ efflux at the lens surface also serves to maintain the Na^+ gradient utilized by secondary active transporters to accumulate nutrients in the lens nucleus.

Steady-State Volume Regulation: Balancing Ion Influx and Efflux

Lens transparency is a direct result of its unique cellular structure and any disruption of this structure by either cellular swelling or dilation of the normally tight spaces between the cells increases intralenticular light scattering, and can eventually lead to cataract. Thus, volume regulation at both the cellular and tissue levels is of critical importance for the maintenance of lens transparency. The regulation of lens volume in turn depends on maintaining an appropriate balance between ion influx and efflux so as to prevent the intracellular or extracellular fluid accumulations that induce light scattering. This balance has been experimentally manipulated by utilizing pharmacological reagents to modulate the activity of Cl^- transport proteins implicated in mediating ion influx and efflux in the lens.

The histological analysis of lenses treated with a variety of inhibitors revealed that blocking Cl^- transport induced either one of two spatially distinct tissue damage phenotypes, or on occasions a combination of the two phenotypes (Figure 5). In contrast to the regular cellular architecture observed in control lenses, lenses cultured in the presence of either the Cl^- channel inhibitor 5-nitro-2-(phenylpropylamino)-benzoate (NPPB), or the sodium potassium dependent chloride cotransporter (NKCC) blocker bumetanide, exhibited a localized band of tissue damage (Figure 5(a)). This damage manifests itself as extracellular fluid accumulations between fiber cells located some 150 μm from the lens capsule. In contrast, the predominant effect of culturing lenses in the $K^+/2Cl^-$ co-transporter (KCC) inhibitor [(dihydroninindenyl)oxy] alkanoic acid (DIOA) was a swelling of fiber cells located at the lens periphery, although some deeper extracellular space dilations were evident (Figure 5(b)).

The two distinct damage phenotypes generated by the different inhibitors can be explained with reference to previous experimental measurements of lens membrane potential (Figure 5(c)). By measuring radial differences in the transmembrane potential and the concentration of Cl^- in the whole lens, the electrochemical gradient for Cl^- ion movement (E_{Cl}) can be calculated at different depths into the lens. This analysis predicts that Cl^- will move from the extracellular space into fiber cells in the inner lens, but will be driven from the cytoplasm of fiber cells to the extracellular space in the lens periphery (Figure 5(c)). Therefore, one would expect that an inhibition of Cl^- fluxes would block the uptake of Cl^- from the extracellular space by fiber cells in the inner lens. This would cause an accumulation of Cl^- ions and water in the

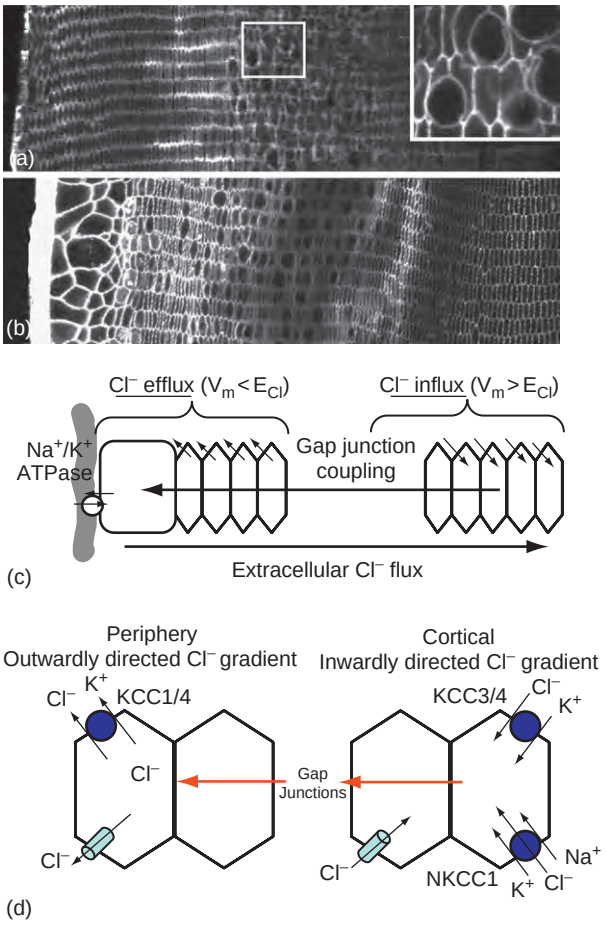

Figure 5 A circulating flux of Cl^- ions contributes to steady-state volume regulation in the rat lens. Confocal images of equatorial sections taken from lenses organ cultured under isotonic conditions showing the distinct morphological effects of blocking either (a) Cl^- channels with 10 μM NPPB or (b) KCC with 10 μM DIOA. (a) Blocking Cl^- influx mediated by Cl^- channels resulted in the accumulation of Cl^- ions and water between deeper fibre cells and the formation of extracellular space dilations in a distinct zone of the lens (insert). (b) Blocking Cl^- channel efflux mediated by KCC produced the intracellular accumulation of osmolytes and the swelling of peripheral fiber cells. Some deeper extracellular space dilations were also evident. (c) Measurements of membrane potential and E_{Cl} predict that in deeper fiber cells the electrochemical gradient favors Cl^- influx while in the periphery it promotes Cl^- efflux. (d) Emerging molecular model of transporters and channels that contribute to volume regulation by mediating ion influx and efflux in different regions of the lens. Since the zones of ion influx and efflux are connected by gap junction channels a circulating flux is established which helps to maintain cell volume. Patch clamp studies indicate that in peripheral fibre cells a volume-sensitive Cl^- channel becomes activated following cell swelling induced by either blockage of KCC (isosmotic cell swelling) or exposure to hyposmotic solutions.

tortuous extracellular space and lead to the formation of extracellular space dilations (Figure 5(a), insert). In the lens periphery, the passive efflux of Cl^- ions from fiber cells would be blocked, thereby causing an intracellular accumulation of osmolytes and resultant fiber cell swelling. These two spatially segregated zones of cell swelling and extracellular space dilations were deemed to be due to the inhibition of Cl^- influx and efflux in deeper and peripheral fiber cells, respectively. Since these pathways are coupled together by gap junctions, they generate a circulating flux of Cl^- ions, which contributes to the maintenance of steady-state lens volume. The two spatially distinct phenotypes observed from pharmacological experiments with anion transport inhibitors indicate that NKCC, KCC, and Cl^- channels all mediate ion uptake in the deeper cells, while KCC mediates ion efflux in peripheral fiber cells.

This relative simple view of circulating Cl^- fluxes derived from these morphological experiments has been confirmed and extended by a series of molecular localization, electrophysiological, and additional morphological studies. Molecular experiments designed to identify the specific proteins responsible for Cl^- influx and efflux have shown that NKCC1 and three of the four known KCC isoforms are expressed in a differentiation-dependent manner in the rat lens, supporting their initial pharmacological detection (Figure 5(d)). KCC1 was restricted to peripheral cells in the efflux zone, NKCC1 and KCC3 were found in both zones in the outer cortex, while KCC4 was expressed throughout the entire lens including the lens core. Although the molecular identity of the Cl^- channels that mediate the circulating Cl^- fluxes remains unclear, patch clamp experiments on longer fiber cells (>120 μm) isolated from the zone of ion influx exhibited a lyotropic anion selectivity sequence ($I^- > Cl^-$), reminiscent of volume-sensitive Cl^- conductances seen in many cell types. In contrast, the membrane properties of shorter fiber cells (<120 μm) isolated from the efflux zone were dominated by a K^+ conductance, and under isotonic conditions appeared to lack a constitutively active Cl^- conductance. Additional morphological experiments performed on organ cultured lenses using the KCC activator *N*-ethylmaleimide (NEM) support a role for KCC isoforms in both Cl^- influx and efflux pathways. NEM-induced stimulation of KCC-mediated Cl^- fluxes caused cell shrinkage in peripheral cells within the efflux zone, but cell swelling in deeper fiber cells of the influx zone. Taken together these data suggest that under isotonic conditions, NKCC1, KCC3/4, and a constitutively active lyotropic Cl^- channel all appear capable of contributing to Cl^- influx in deeper cells. This Cl^- influx in the deeper cells is then conveyed to the more peripheral cells by an intracellular pathway mediated by gap junction channels, where the Cl^- is removed from the lens by KCC transporters (Figure 5(d)). In these peripheral cells if the KCC-mediated efflux is blocked, these cells swell and a normally quiescent Cl^- channel is activated by the cellular swelling that allows Cl^- to efflux the lens.

From this model it is apparent that, under steady-state conditions, if fiber cell volume, and therefore lens transparency, is to be maintained, ion influx and efflux in the

two zones needs to be balanced. Furthermore, since the fluid flows associated with these two zones are dependent on the circulation model, any pathological insult to the circulation system will result in a loss of lens homeostasis that will initiate a cascade of events that ultimately leads to lens cataract.

Ischemic Optic Neuropathy

S S Hayreh, University of Iowa, Iowa City, IA, USA

Glossary

Afferent pupillary defect – Reduction in the response of the pupil to direct light.
Giant cell arteritis – An inflammation of the arterial wall, affecting medium and large size arteries.

Ischemic optic neuropathy constitutes one of the major causes of blindness or seriously impaired vision among the middle-aged and elderly population, although no age is immune. Its pathogenesis, clinical features, and management are discussed in this article.

Classification

Ischemic optic neuropathy is an acute ischemic disorder of the optic nerve. Based on the blood-supply pattern, the optic nerve can be divided into two very distinct parts: (1) the anterior part (called the optic nerve head) and (2) the rest of the optic nerve (Figure 1). Ischemic optic neuropathy is of two distinct types.

1. *Anterior ischemic optic neuropathy (AION).* This is due to ischemia of the anterior part of the optic nerve, which is supplied by the posterior ciliary artery (PCA) circulation. Etiologically and pathogenetically, AION is of the following two types: (a) arteritic AION (A-AION), which is due to giant cell arteritis (GCA), and (b) nonarteritic AION (NA-AION), which is due to all other causes and not GCA.
2. *Posterior ischemic optic neuropathy (PION).* This is due to ischemia of a segment of the rest of the optic nerve, which is supplied by multiple sources but not the PCA (Figure 1).

Nonarteritic Anterior Ischemic Optic Neuropathy

This is the most common type of ischemic optic neuropathy and has attracted the most controversy about its pathogenesis and management.

Pathogenesis

Nonarteritic anterior ischemic optic neuropathy (NA-AION) is caused by acute ischemia of the optic nerve head, whose main source of blood supply is from the PCA circulation (Figure 1). Marked interindividual variations in the blood supply of the optic nerve head and its blood-flow patterns profoundly influence the pathogenesis and clinical features of NA-AION.

Etiologically and pathogenetically, NA-AION is of two types:

1. *Transient nonperfusion or hypoperfusion of the optic nerve head circulation.* This is by far the most common cause of NA-AION. All the available evidence indicates that NA-AION is not a thromboembolic disorder. The mechanism causing transient nonperfusion or hypoperfusion of the optic nerve head circulation in NA-AION is multifactorial in nature. In the vast majority of cases, it is a transient fall of blood pressure, most commonly during sleep (nocturnal arterial hypotension – Figure 2) or a nap during the day. Any kind of shock also can cause a transient marked fall of blood pressure. A sharp rise in the intraocular pressure to high levels, as in neovascular glaucoma associated with ocular ischemia, or angle closure glaucoma, can also cause a transient fall in perfusion pressure in the optic nerve head, where perfusion pressure is equal to mean blood pressure minus the intraocular pressure.

   A transient fall of perfusion pressure in the optic nerve head vessels below the critical autoregulatory range level in susceptible persons results in ischemia of the optic nerve head and development of NA-AION. The severity of the ischemia may vary from mild to marked, depending upon the severity and duration of the transient ischemia, and upon other factors influencing the blood flow in the optic nerve head.
2. *Embolic lesions of the arteries/arterioles feeding the optic nerve head.* This is a rare cause of NA-AION. Compared to the hypotensive type of NA-AION, the extent of optic nerve head damage in this type is usually massive, severe, and permanent.

Risk Factors for Development of NA-AION

All available evidence indicates that NA-AION is multifactorial in nature. The risk factors fall into two main categories:

1. Predisposing risk factors:
   (a) *Systemic.* These include arterial hypertension, nocturnal arterial hypotension, diabetes mellitus, ischemic heart disease, hyperlipidemia, atherosclerosis

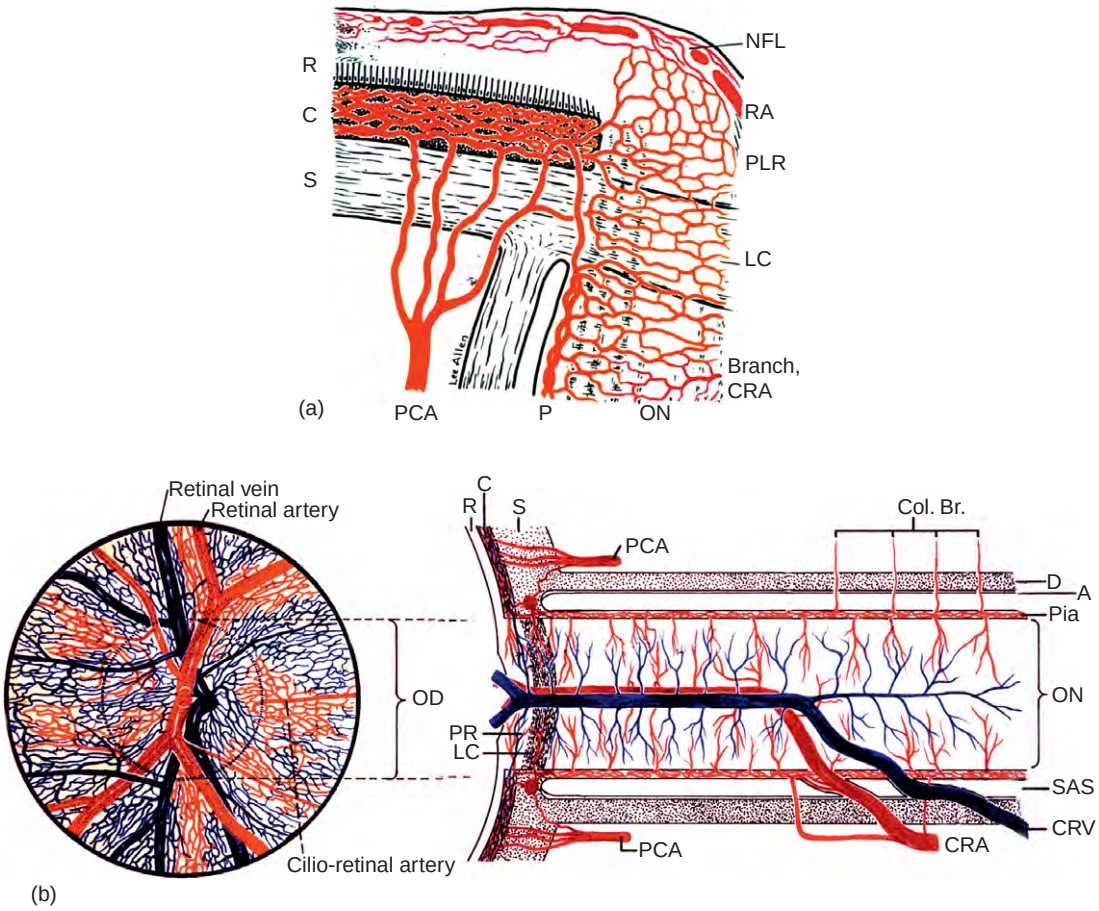

Figure 1 Schematic representation of blood supply of: (a) the optic nerve head and (b) the optic nerve. A, arachnoid; C, choroid; CRA, central retinal artery; Col. Figure 2 Ambulatory blood pressure monitoring records (based on individual readings) over a 24-h period, starting from about 11 a.m., in a 58-year-old woman with bilateral NA-AION, and on no medication. The blood pressure is perfectly normal during the waking hours but there is marked nocturnal arterial hypotension during sleep. Reproduced from Hayreh et al. (1999) *Ophthalmologica* 213: 76–96.

and arteriosclerosis, sleep apnea, arterial hypotension due to any cause, and migraine.

(b) *Risk factors in the eye and/or the optic nerve head.* These include absent or small cup in the optic disk, marked optic disk edema, raised intraocular pressure, and optic disk drusen. There is a misconception in the ophthalmic community that a small or absent cup is actually the primary factor in the development of the disease; this has resulted in catchy terms like "disk at risk". However, in the multifactorial scenario of the pathogenesis of NA-AION, an absent or small cup is simply a secondary contributing factor once the process of NA-AION has started.

2. Precipitating risk factor(s): in a person with predisposing risk factors present, a precipitating risk factor acts as the final insult (last straw), resulting in ischemia of the optic nerve head and NA-AION. Nocturnal arterial hypotension (**Figure 2**) is the most important factor in this category. Studies have shown that patients with NA-AION typically discover visual loss on waking in the morning, indicating that NA-AION developed during sleep when there is invariably a fall of blood pressure.

Conclusion

A host of systemic and local factors, acting in different combinations and to different extents, may derange the optic nerve head circulation, with some increasing optic nerve head susceptibility to ischemia and others acting as the final insult. Nocturnal arterial hypotension seems to be an important precipitating factor in the susceptible patient. Thus, the pathogenesis of NA-AION is complex but, not, as often stated, unknown.

There is a common perception among ophthalmologists and neurologists that NA-AION and cerebral stroke are similar in nature pathogenetically and in management. It is well established that stroke is a thromboembolic disorder. However, available evidence indicates that NA-AION is pathogenetically a hypotensive disorder, not a thromboembolic disorder. In NA-AION, unlike stroke, (1) there is no association between smoking and NA-AION; (2) aspirin has no beneficial effects in NA-AION; (3) no significant association has been found between NA-AION and thrombophilic risk factors; (4) fluorescein fundus angiography during the early stages of onset of visual loss invariably shows no evidence of complete occlusion of the vessels supplying the optic nerve head (**Figures 3(a) and 3(b)**); and (5) 41% of NA-AION eyes show spontaneous visual improvement, which is rare in a thromboembolic disorder.

Its importance in various ischemic disorders of the optic nerve head, and glaucoma, low-tension glaucoma and allied disorders. *Documenta Ophthalmologica* 59: 217–246.

Clinical Features of NA-AION

NA-AION is the most common type of ischemic optic neuropathy. It usually has classical symptoms and signs. NA-AION is mostly a disease of the middle-aged and elderly population, although no age is immune. It has been reported in twenty-three percent of patients with NA-AION are under the age of 50 years. It is far more common among the white population than in other racial groups.

1. *Symptoms.* In the vast majority of patients, there is a sudden and painless deterioration of vision, usually discovered on waking in the morning. NA-AION patients often complain of loss of vision toward the nose and less often in the lower part. Later on,

photophobia is a common complaint. Simultaneous bilateral onset of NA-AION is extremely rare.

2. *Signs.* Initial visual acuity may vary from 20/20 (better than 20/40 in 33%) to marked loss. Therefore, a normal visual acuity does not rule out NA-AION. An inferior nasal visual field defect is the most common, followed by an inferior altitudinal defect; a combination of a relative inferior altitudinal defect with absolute inferior nasal defect is the most common pattern in NA-AION (**Figures 4(a) and 4(b)**). The eye shows the presence of a relative afferent pupillary defect in unilateral NA-AION cases, and in some there may be raised intraocular pressure.

At the onset of visual loss, there is always optic disk edema (**Figures 5 and 6(a)**). There are several misconceptions about optic disk edema in NA-AION. The most common one is that in NA-AION the optic disk edema is always pale, which is not at all true initially because the color of optic disk edema in NA-ION initially does not differ from that due to other causes; in some cases there may even be hyperemia of the optic disk (**Figures 5 and 6(a)**). A splinter hemorrhage at the disk margin is common (**Figure 7**). The optic disk edema resolves spontaneously in about 8 weeks, and the disk develops segmental or generalized pallor (**Figure 6(b)**). In the normal fellow eye, the optic disk usually shows either no cup or a small cup, which can be a helpful clue in the diagnosis of NA-AION in doubtful cases.

In diabetics, optic disk changes in NA-AION may have some characteristic diagnostic features. During the initial stages, the optic disk edema is usually, but not always, associated with characteristic prominent, dilated, and frequently telangiectatic vessels over the disk and many more peripapillary retinal hemorrhages than in nondiabetics (**Figures 8(a) and 8(c)**). Because of these disk changes, NA-AION in diabetics has been mistakenly diagnosed as diabetic papillopathy. With the resolution of optic disk edema, vascular changes and hemorrhages also resolve spontaneously (**Figures 8(b) and 8(d)**).

Fluorescein fundus angiography, at the onset of NA-AION, during the very early phase of dye filling in the fundus almost invariably shows delayed filling of the prelaminar region and the peripapillary choroid (**Figure 3(a)**) and/or choroidal watershed zone (**Figure 3(b)**).

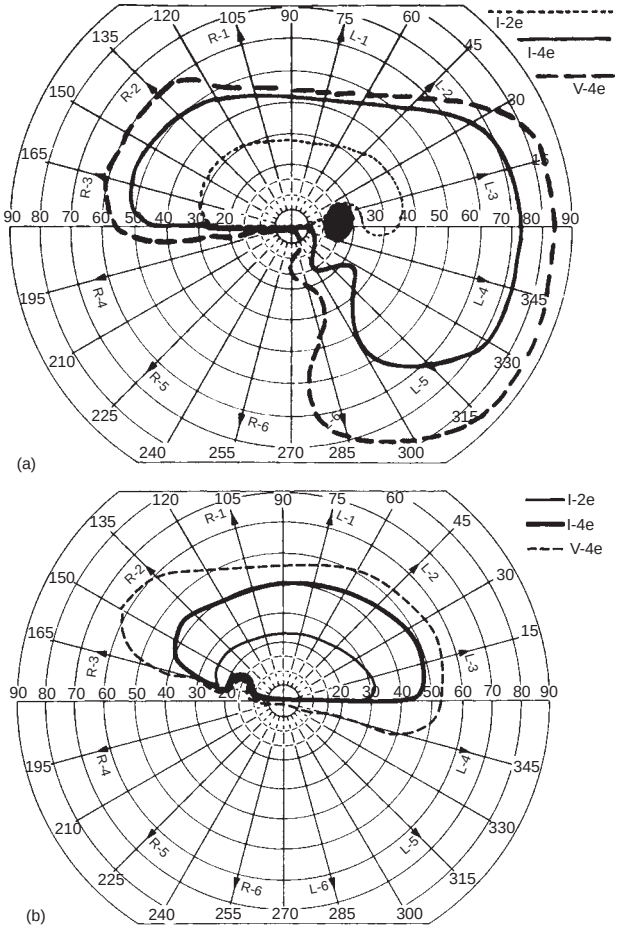

Figure 4 Visual-field defects in NA-AION, plotted with Goldmann perimeter using I-2e, I-4e, and V-4e targets, where the Roman numeral indicates target size, the Arabic numeral indicates relative intensity, and the lowercase letter indicates minor filter adjustment of the light intensity. (a) Shows an inferior altitudinal defect with I-2e and an inferior nasal defect with I-4e and V-4e. (b) Shows an absolute inferior altitudinal defect with I-2e, I-4e, and V-4e. The visual acuity in both eyes was 20/20. Reproduced from Hayreh et al. (2005) *Archives of Ophthalmology* 123:1554–1562.

Bilateral NA-AION

The cumulative probability of the fellow eye developing NA-AION has varied among different studies: 25%

Figure 5 Left fundus photograph showing optic disk edema and hyperemia during the acute phase of NA-AION.

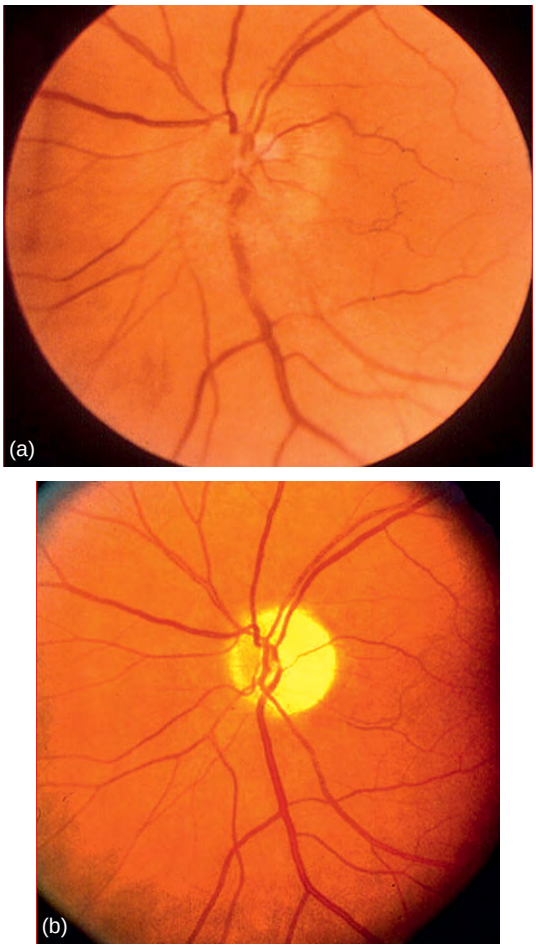

Figure 6 Fundus photographs of left eye of a 53-year-old man. (a) With optic disk edema during the active phase of NA-AION. (b) After resolution of optic disk edema and development of optic disk pallor – more marked in the temporal part than in the nasal part.

within 3 years, 17% in 5 years, and 15% over 5 years. Diabetics have a significantly ($p = 0.003$) greater risk than non-diabetics of NA-AION in the second eye as well as earlier involvement. Simultaneous bilateral onset of NA-AION is extremely rare, except in patients who develop sudden, severe arterial hypotension, for example during hemodialysis or surgical shock.

Recurrence of NA-AION in the same eye

In a study of 829 NA-AION eyes, the overall cumulative percentage of recurrence of NA-AION in the same eye at 2 years was 5.8%. The only significant association for recurrence of NA-AION was with nocturnal arterial hypotension.

NA-AION and phosphodiesterase-5 inhibitors

These agents are currently popular for erectile dysfunction. A critical review of all the reported cases usually shows a good temporal relationship between the ingestion of Viagra and other phosphodiesterase-5 inhibitors and the development of NA-AION, in persons who already have predisposing risk factors.

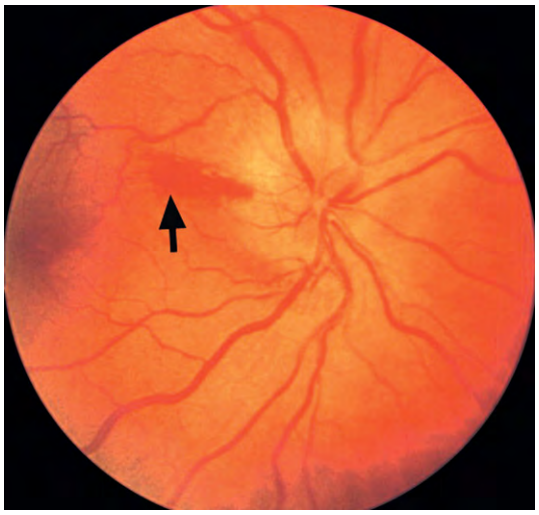

Figure 7 Right fundus photograph showing optic disk edema and hyperemia, with a splinter hemorrhage (arrow) during the acute phase of NA-AION.

Amiodarone and NA-AION

There is a universal belief that amiodarone causes optic neuropathy, called "amiodarone-induced optic neuropathy". However, it is NA-AION produced in the multifactorial scenario by the systemic cardiovascular risk factors for which the drug is given rather than amiodarone *per se* causing it.

Familial NA-AION

There are five reports in the literature representing 10 unrelated families in which more than one member developed NA-AION. It is clinically similar to the classical non-familial NA-AION, with the exception that familial NA-AION occurs in younger patients and has much higher involvement of both eyes than the classical NA-AION. The role of genetic factors in familial NA-AION is not known.

Management of NA-AION

The outcome of all advocated treatments has to be compared with the natural history of a disease, so that natural recovery is not attributed to the beneficial effect of a mode of treatment. Therefore, it is essential to first consider the natural history of visual outcome in NA-AION. This has been investigated by two prospective studies in patients seen within 2 weeks of onset of visual loss and initial visual acuity of 20/70 or worse. Both showed spontaneous visual acuity improvement in 41–43% of the patients and worsening in 15–19% at 6 months. Evaluation of visual fields

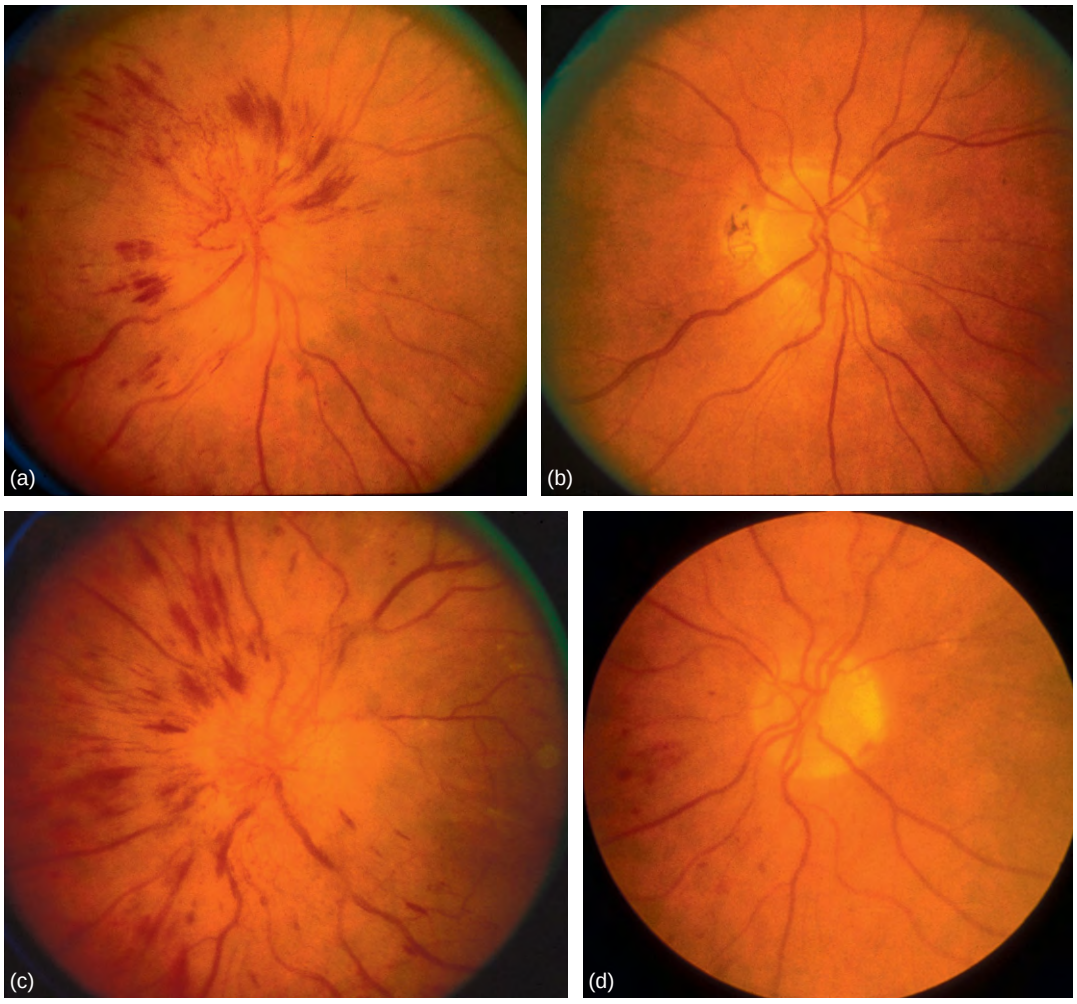

Figure 8 Fundus photographs of both eyes of a 51-year-old woman with adult-onset diabetes mellitus. She developed bilateral NA-AION, first in the right eye ((a) and (b)) and 8 months later in the left eye (c, d). (a, c) On first visit: Fundus photographs show massive optic disk edema with marked telangiectatic vessels on the optic disk, and many retinal hemorrhages. Visual acuity was 20/20 in the left and 20/15 in the right eye. Both eyes had an inferior nasal visual-field defect. (b, d) On resolution of optic disk edema: Fundus photographs show no optic disk edema but mild temporal pallor, no abnormal vessels on optic disk, and no retinal hemorrhages in the right eye (b), and a few resolving hemorrhages in the left eye (d). Reproduced from Hayreh et al. (1981) *Ophthalmologica* 182: 13–28.

with kinetic perimetry showed that of those with moderate-to-severe visual field defect, 26% showed improvement at 6 months. Visual acuity and visual fields showed improvement or further deterioration mainly up to 6 months, with no significant change thereafter.

Management of NA-AION has been a highly controversial subject. A number of treatments have been advocated. Following are the principal ones.

Optic nerve sheath decompression. A study in 1989 claimed that optic nerve sheath decompression improved visual function in "progressive" NA-AION. However, a recent multicenter clinical trial showed that this procedure is not effective and may be harmful, and thus is an inappropriate treatment for NA-AION, because 24% of the eyes with the optic nerve sheath decompression suffered further visual loss as compared to only 12% of eyes simply left alone.

Aspirin. Studies have shown that aspirin in NA-AION provides no long-term benefit in reducing the risk of NA-AION in the fellow eye.

Systemic corticosteroid therapy. A recent large, prospective study evaluated the role of steroid therapy in 696 NA-AION eyes, comparing the visual outcome in treated (364 eyes) versus untreated control (332 eyes) groups. In eyes with initial visual acuity of 20/70 or worse and seen within 2 weeks of onset, there was visual acuity improvement in 70% the treated group compared to 41% the untreated group (odds ratio of improvement: 3.39; 95% CI:1.62, 7.11; $p = 0.001$). Similarly, among those seen within 2 weeks of NA-AION onset and moderate to severe initial visual-field defect, there was improvement in 40% of the treated group and 25% of the untreated group (odds ratio: 2.06, 95% CI: 1.24, 3.40; $p = 0.005$). In

both treated and untreated groups, the visual acuity and visual fields kept improving for up to about 6 months after the onset of NA-AION, but very little thereafter.

Reduction of risk factors. As NA-AION is a multifactorial disease and many risk factors contribute to it, the correct strategy is to try reducing as many risk factors as possible to reduce the risk of developing NA-AION in the second eye or any further episode in the same eye. Nocturnal arterial hypotension is a precipitating risk factor in NA-AION patients with predisposing risk factors. In view of this, management of nocturnal arterial hypotension is an important step in both the management of NA-AION and the prevention of its development in the second eye. It seems NA-AION is emerging in some cases as an iatrogenic disease due to the use of currently available highly potent arterial hypotensive drugs.

Incipient NA-ION

This clinical entity initially presents with asymptomatic optic disk edema and no visual loss attributable to NA-AION. Available evidence indicates that it represents the earliest, asymptomatic clinical stage in the evolution of the NA-AION disease process; therefore, it shares most clinical features with classical NA-AION except for the visual loss initially.

Arteritic AION

The primary cause of A-AION is GCA, although other types of vasculitis can also cause it.

Pathogenesis

The primary cause is GCA, which has a special predilection to involve the PCA, resulting in its thrombotic occlusion. Since the PCA is the main source of blood supply to the optic nerve head (**Figure 1**), occlusion of the PCA results in infarction of a segment or the entire optic nerve head, depending upon the area of the optic nerve head supplied by the occluded PCA. This, in turn, results in development of A-AION.

Clinical Features of GCA and A-AION

GCA is a disease of late middle-aged and elderly persons and is almost 3 times more common in women than in men. There is evidence that GCA is far more common among Caucasians than other races.

Symptoms

GCA patients usually present with systemic symptoms, including anorexia, weight loss, jaw claudication, headache, scalp tenderness, abnormal temporal artery, neck pain, myalgia, malaise, and anemia. However, a study showed that 21% of patients with visual loss due to GCA have no systemic symptoms whatsoever (i.e., occult GCA).

One visual symptom of GCA is episodic transient visual loss, which is an important and an ominous sign of impending visual loss. In one series, it occurred in about one-third of the patients. Most patients with GCA develop visual loss due to A-AION suddenly without any warning. Occasionally there may be diplopia or ocular pain. A rare patient with GCA can suffer from euphoria and even deny any visual loss.

Signs

Visual acuity in eyes with A-AION varies between 20/20 and no light perception, but overall it is much worse than in NA-AION. The extent and severity of visual field defects depends upon the extent of optic nerve head damage caused by ischemia, usually much more extensive and severe than in NA-AION. When there is diplopia, there is extraocular motility abnormality. In uniocular A-AION, there is a relative afferent pupillary defect.

The optic disk always shows edema initially, which usually has a chalky white color (**Figure 9**) – a diagnostic characteristic of A-AION. When disk edema resolves, the optic disk in the vast majority shows cupping which is indistinguishable from that seen in glaucomatous optic neuropathy. In addition to optic disk edema, the fundus may show retinal cotton wool spots, central retinal artery occlusion, cilioretinal artery occlusion (**Figure 10(a)**), and/or choroidal ischemic lesions. Fluorescein fundus angiography done during the early acute stage of the disease shows evidence of occlusion of the PCAs (**Figures 10(b)** and **11**).

Laboratory investigations

Evaluation of erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are the most important immediate diagnostic tests in the diagnosis of A-AION and its

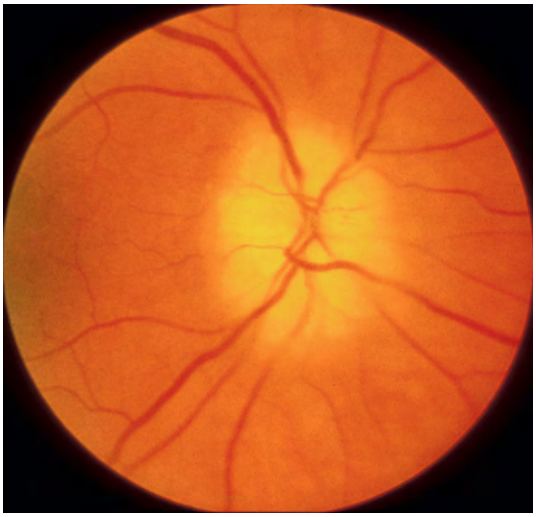

Figure 9 Fundus photograph of right eye with A-AION showing chalky white optic disk edema during the initial stages.

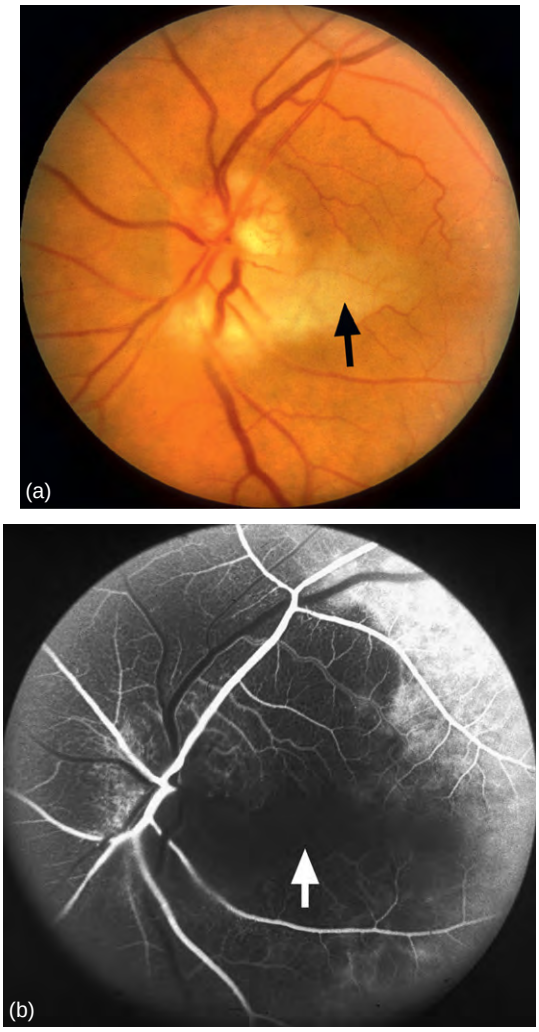

Figure 10 Fundus photograph (a) and fluorescein angiogram (b) of left eye with A-AION associated with cilioretinal artery occlusion. (a) Fundus photograph shows optic disk edema and retinal infarct (arrow) in the distribution of cilioretinal artery. (b) Fluorescein angiogram shows no filling of the choroid and entire optic disk supplied by the medial PCA and of the cilioretinal artery (arrow), but normal filling of the area supplied by the lateral PCA. (a) Reproduced from Hayreh, S. S. (1990). Anterior ischaemic optic neuropathy. Differentiation of arteritic from non-arteritic type and its management. *Eye* 4: 25–41; (b) reproduced from Hayreh S. S. (1978) *International Ophthalmology* 1: 9–l8.

differentiation from NA-AION. Although high ESR is traditionally emphasized as a *sine qua non* for diagnosis of GCA, there are numerous reports of "normal" or "low" ESR in patients with positive temporal artery biopsy for GCA. Normal ESR does not rule out GCA. CRP, on the other hand, is a much more reliable test to diagnose GCA. Thus, both tests should be used for diagnosis of GCA and monitoring of steroid therapy in all patients. Other hematological tests which can help in the diagnosis of GCA include the presence of thrombocytosis, anemia, elevated white blood cell count, and low hemoglobin and hematocrit levels.

Figure 11 Fluorescein fundus angiogram of a right eye with A-AION, showing normal filling of the area supplied by the lateral PCA (including the temporal one-fourth of the optic disk) but no filling of the area supplied by the medial PCA (including the nasal three-fourth of the disk). Reproduced from Hayreh S. S. (1978) *International Ophthalmology* 1: 9–l8.

Management of A-AION

Management of A-AION is actually the management of GCA. Visual loss is preventable with (1) early diagnosis of GCA and (2) immediate and adequate steroid therapy. To establish a definite diagnosis of GCA without delay is the most critical step in the management of GCA. Classically the gold standard for diagnosis of GCA is the five criteria advocated by the American College of Rheumatologists: (1) age $\geq$ 50 years at onset, (2) new onset of localized headache, (3) temporal artery tenderness or decreased temporal artery pulse, (4) elevated ESR (Westergren) $\geq$ 50 mm/hour, and (5) positive temporal artery biopsy. The American College of Rheumatologists states: "A patient shall be classified as having GCA if at least 3 of these 5 criteria are met." However, studies indicate that these criteria are inadequate to prevent blindness in all GCA patients, particularly patients with occult GCA (21%) who never develop any systemic symptoms of GCA. Use of a positive temporal artery biopsy as the definite diagnostic criterion for GCA showed that the odds of a positive temporal artery biopsy were 9 times greater with jaw claudication ($p < 0.0001$), 3.4 times with neck pain ($p = 0.0085$), 2.0 times with ESR (Westergren) 47–107 mm/hour relative to those with ESR <47 mm/hour ($p = 0.0454$), and 3.2 times with CRP >2.45 mg dl compared to CRP <2.45 mg dl ($p = 0.0208$), and 2.0 times when the patients were aged $\geq$75 years as compared to those $\leq$75 years ($p = 0.0105$). Among the other systemic signs and symptoms, the only significant one was anorexia/weight loss ($p = 0.0005$); the rest showed no significant difference from those with negative temporal artery biopsy.

Differentiation of A-AION from NA-AION

When a patient is diagnosed as having AION, the first crucial step in patients aged 50 and over is to identify immediately whether it is arteritic or nonarteritic – missing A-AION can result in disastrous visual loss which is entirely preventable. Collective information provided by the following criteria helps to differentiate the two types of AION reliably.

1. *Systemic symptoms of GCA.* These are discussed above. However, 21% with occult GCA have no systemic symptoms of any kind at all. Patients with NA-AION have no systemic symptoms of GCA.
2. *Visual symptoms.* Amaurosis fugax is highly suggestive of A-AION and is extremely rare in NA-AION.
3. *Hematologic abnormalities.* Immediate evaluation of ESR and CRP is vital in all patients aged 50 and over. As discussed above, elevated ESR and CRP, particularly CRP, is helpful in the diagnosis of GCA. Patients with NA-AION do not show any of these abnormalities, except when a patient has some other concurrent systemic disease.
4. *Early massive visual loss.* There is a much more massive visual loss in A-AION than in NA-AION; however, the presence of perfectly normal visual acuity does not rule out A-AION.
5. *Chalky white optic disk edema* (**Figure 9**). This is almost always diagnostic of arteritic AION and is seen in the majority, but not all, of A-AION eyes.
6. *A-AION associated with cilioretinal artery occlusion* (**Figure 10**). This is almost always diagnostic of A-AION.
7. *Evidence of PCA occlusion on fluorescein fundus angiography* (**Figures 10(b) and 11**). If angiography is performed during the first few days after the onset of A-AION, and the choroid supplied by one or more of the PCAs does not fill, this once again is almost diagnostic of A-AION.
8. *Temporal artery biopsy.* This finally establishes the diagnosis; however, the possibility of an occasional false negative biopsy has to be kept in mind.

Steroid Therapy to Prevent Blindness in GCA

This is a highly controversial subject because practically all the available information is from the rheumatologic literature. Rheumatologists and ophthalmologists have different perspectives which influence their recommendations on steroid therapy for GCA – the regimen advocated by the former primarily concerns managing benign rheumatologic symptoms and signs, whereas the latter confront the probability of blindness. In our 27-year prospective study on steroid therapy in GCA, marked differences were seen between the rheumatologic and ophthalmic steroid therapy regimens. In the light of information from that study, the following guidelines to prevent visual loss are suggested.

1. If there is a reasonable suspicion of GCA, as judged from systemic symptoms, high ESR and CRP (particularly high CRP) and sudden visual loss from A-AION or central retinal artery occlusion, high doses of systemic corticosteroid therapy must be started immediately as an emergency measure.
2. The physician should not wait for the result of the temporal artery biopsy because by the time it is available, the patient may have irreversibly lost further vision.
3. A high-dose steroid therapy (80–120 mg) must be maintained until both the ESR and CRP settle down to stable levels, which usually takes 2–3 weeks, with CRP reducing much earlier than ESR levels (**Figure 12**), followed by gradual tapering of steroid therapy.
4. A titration of the steroid dosage with the levels of ESR and CRP is the only safe and reliable method for tapering down and follow-up of steroid therapy; using clinical symptoms and signs of GCA as a guide, as often recommended by rheumatologists, is a dangerous practice for the prevention of blindness.
5. Patients with GCA show marked interindividual variation in the dosage of corticosteroids they require, their response to steroid therapy, and their therapeutic and tapering regimens of steroid therapy; therefore therapy must always be individualized. No generalization is possible; *NO* one size fits all.
6. The vast majority of GCA patients require a lifelong small dose of steroids to prevent blindness. As our study found no evidence that intravenous mega-dose steroid therapy was more effective than large-dose oral therapy in improving vision or preventing visual deterioration due to GCA, it is recommended that patients initially receive one intravenous mega dose (equivalent to 1 g of prednisone) followed by a high-dose (80–120 mg) of oral prednisone if that patient presents with: (a) a history of amaurosis fugax, (b) complete or marked loss of vision in one eye, or (c) early signs of involvement of the second eye.

Conclusion

If GCA patients are treated promptly and aggressively with an adequate dose of corticosteroids, and reduction of steroid therapy is regulated by using ESR and CRP as the only criteria, not a single patient will suffer any further visual loss 5 days after starting adequate steroid therapy. However, in our study, in spite of early high-dose steroid therapy, only 4% of GCA patients with visual loss showed any visual improvement, and during the first 5 days after the start of the therapy 4% developed further visual loss; but there was no further visual loss after that.

Posterior Ischemic Optic Neuropathy

PION is much less common than AION and is due to ischemia of the optic nerve posterior to the optic nerve head, which is supplied by multiple sources but not the PCA (**Figure 1(b)**). It is a diagnosis of exclusion, and it should be made only after all other possibilities have been carefully ruled out, for example, macular and retinal lesions, NA-AION, retrobulbar optic neuritis, compressive optic neuropathy, other optic disk and optic nerve lesions, neurological lesions, hysteria, even malingering, and a host of other lesions.

Classification

Etiologically, PION can be classified into three types: (1) arteritic PION (A-PION), (2) nonarteritic PION (NA-PION), and (3) surgical PION.

Pathogenesis

Arteritic PION

This is due to GCA when arteritis involves the orbital arteries, which supply the posterior part of the optic nerve (**Figure 1(b)**). A-PION occurs much less commonly than A-AION.

Nonarteritic PION

An association between NA-PION and a variety of systemic diseases has been reported in the literature. In one series, comparison of NA-PION cases with a control population showed a significantly higher prevalence of arterial hypertension, diabetes mellitus, ischemic heart disease, cerebrovascular disease, carotid artery and peripheral vascular disease, and migraine than in NA-PION patients. Thus, the pathogenesis of NA-PION, similar to NA-AION, is multifactorial in nature, with a variety of systemic diseases, other vascular risk factors, and/or local risk factors predisposing an optic nerve to develop PION; defective autoregulation of the optic nerve may also play a role. Finally, some precipitating risk factor acts as the "last straw" to produce PION.

Surgical PION

This type of PION usually tends to cause bilateral, massive visual loss or even complete blindness, which is usually permanent; therefore, it has great medicolegal importance. It is almost invariably associated with prolonged systemic surgical procedures for a variety of conditions, including spinal and other orthopedic surgical procedures, radical neck dissection, coronary artery bypass, hip surgery, nasal surgery, and so on. The pathogenesis of surgical PION is multifactorial in nature. The main factors include severe and prolonged arterial hypotension, hemodilution from administration of a large amount of intravenous fluids to compensate for the blood loss, orbital and periorbital edema, chemosis and anemia, and even direct orbital compression due to the prone position.

Clinical Features of PION

NA-PION, similar to NA-AION, is seen mostly in the middle-aged and elderly population, but no age is immune.

Symptoms

Clinically, patients with A-PION and NA-PION typically present with acute, painless visual loss in one or both eyes, sometimes discovered upon waking up in the morning. In some eyes, it may initially be progressive. Patients with surgical PION discover visual loss as soon as they are alert postoperatively, which may be several days after surgery. Surgical PION usually tends to cause bilateral massive visual loss or even complete blindness, which is usually permanent.

Signs

Visual acuity may vary from 20/20 to no light perception. The most common visual-field defect is central scotoma, alone or in combination with other types of visual-field defects (**Figure 13**). A small number of PION eyes show the reverse pattern, that is, a normal central field with marked loss of peripheral fields (**Figure 14**).

Initially, apart from relative afferent pupillary defect in unilateral PION, the anterior segment, intraocular pressure, and optic disk and fundus are normal on ophthalmoscopy and fluorescein fundus angiography. The disk generally develops pallor within 6–8 weeks, usually more marked in the temporal part. The criteria to differentiate arteritic from nonarteritic PION are basically the same as those for arteritic and nonarteritic AION,

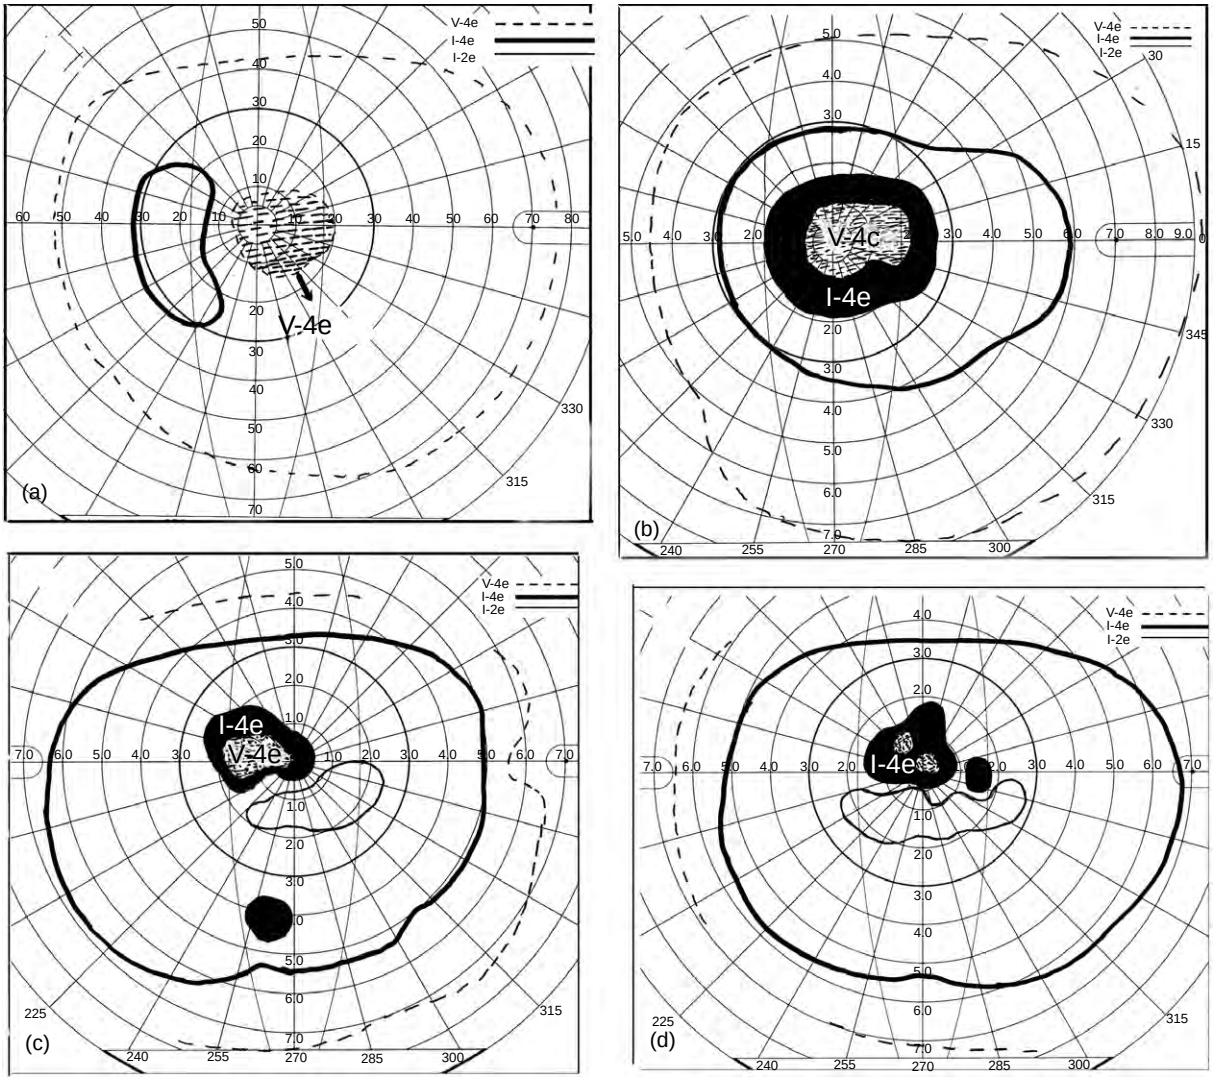

Figure 13 Four visual fields in nonarteritic PION showing varying sizes and densities of central scotoma and other field defects, with normal peripheral visual fields, where the Roman numeral indicates target size, the Arabic numeral indicates relative intensity, and the lowercase letter indicates minor filter adjustment of the light intensity. Reproduced from Hayreh, S. S. (2004). Posterior ischemic optic neuropathy: Clinical features, pathogenesis, and management. *Eye* 18: 1188–1206.

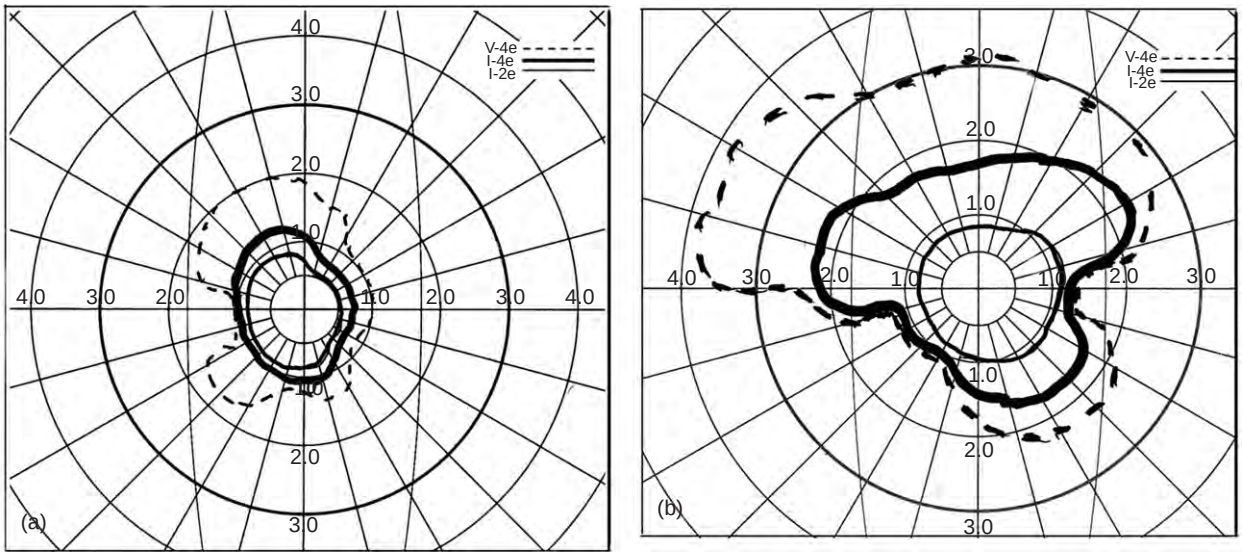

Figure 14 Visual fields of (a) right and (b) left eyes with arteritic PION, showing markedly constricted central visual fields, with complete loss of peripheral fields in both eyes. From Hayreh, S. S. (2004). Posterior ischaemic optic neuropathy: Clinical features, pathogenesis, and management. *Eye* 18: 1188–1206.

discussed above, except that the optic disk and fundus are initially normal in both types of PION.

Management of PION

The management of PION depends upon the type of PION. In all cases other than surgical PION, as in AION, the most important first step in persons aged 50 years or older is always to rule out GCA.

Arteritic PION

Management is similar to that of A-AION discussed above. However, there is usually no visual improvement with systemic steroid therapy.

Nonarteritic PION

The eyes of patients treated with high-dose systemic steroid therapy during the very early stages of the disease show significant improvement in visual acuity and visual field, compared to untreated eyes. However, spontaneous improvement in visual acuity and visual field may also occur to some extent in some eyes without steroid therapy. Since systemic risk factors may play a part in the development of NA-PION, in the management of these patients one should try to reduce as many risk factors as possible so as to reduce the risk of second eye involvement.

Surgical PION

Management amounts to prophylactic measures to prevent development, because once the visual loss occurs, it is usually bilateral, severe, and irreversible. No treatment has been found to be effective to recover or improve the lost vision. Prophylactic measures during surgery include shortening the duration of surgery to a minimum and avoiding: arterial hypotension, excessive fluid replacement and hemodilution, pressure on the eyeball and orbit, and dependent position of the head. Since systemic cardiovascular risk factors may predispose a patient to a higher risk of developing surgical PION, it may be advisable to consider those factors in the decision to perform surgery.

Conclusions

Ischemic optic neuropathy is not a singular disease but a spectrum of several different types, each with its own etiology, pathogenesis, and management. Each must be considered a separate clinical entity. Overall, they constitute one of the major causes of blindness or seriously impaired vision, yet there is marked controversy on their pathogeneses, clinical features, and management. As the signs and symptoms can overlap, correct diagnosis is the key to producing the best visual outcome.

Knock-Out Mice Models: Cornea, Conjunctiva, Eyelids and Lacrimal Gland

W W-Y Kao, C-Y Liu, and H Liu, University of Cincinnati, Cincinnati, OH, USA

Glossary

Cre – The phage recombinase that catalyzes cyclization recombination of LoxP elements.
EGF – The epidermal growth factor which binds to its receptor, EGFR.
FGF – The family of growth factors involved in angiogenesis, wound healing, and development.
Keratins – The family of structural proteins that are tough and insoluble. Keratin 12 is specific to the cornea.
Keratocan – A member of keratan sulfate proteoglycans that is important for transparency of the cornea.
LoxP – The locus of crossover within P1 phage.
Reverse tetracycline transcriptional activator (rtTA) – Binds to Tet operator sequence 7 and activates transcription of the target gene in the presence of tetracycline (Tet-on system).
Tetracycline operator element – The tetracycline-regulated promoter that contains tetracycline operator sequences, which regulate expression of a downstream gene.

Introduction

Transgenesis, that is, the insertion of an exogenesis gene into an organism such that the gene is transmitted to the offspring, and gene targeting are among the most important biological techniques developed in the twentieth century. The studies of genetically modified mutant mice by transgenesis and gene targeting are of great value to elucidate the pathophysiology of altered gene functions and have greatly increased our knowledge of normal physiology and diseases in humans. They not only provide the means for the generation of animal models that are used to examine the pathogenesis of human diseases caused by altered genetic functions, but also allow the development of gene and cell therapy strategies to treat diseases. For example, the application of transgenesis and gene-targeting techniques opens the door of targeted introduction of genes to cells of diseased tissues, that is, gene therapy. Thus, lost cellular and tissue functions can be restored and diseases are cured.

Transgenesis

Transgenesis through microinjection of cloned DNA into fertilized mouse eggs was first accomplished in the laboratories of Brinster, Costantini, Ruddle, Mintz, and Wagner. The availability of a cell-type-specific promoter is a prerequisite for the success of creating transgenic mouse lines that exhibit altered phenotypes caused by the presence of such reporter gene product in tissues of interest. Since then, the technology of transgenesis has advanced to create inducible transgenic mouse lines in which a reporter gene has a unique spatial and temporal expression pattern by administering antibiotics, hormones, and pheromones to experimental animals. The system usually consists of two transgenic mouse lines, one of which employs a tissue-specific promoter for the expression of a transgene that encodes a fusion protein of a transcription factor and hormone receptor and antibiotic suppressor. The other is a transgenic mouse carrying a reporter gene following the responsive elements of a transcription factors and suppressor. In the bitransgenic offspring from the mating of the two transgenic mice, the reporter genes can be turned on and off when ligands bind to the fusion proteins of transcription factor/receptor and transcription factor/suppressor fusion proteins. For example, tet-ON and tet-OFF system in overexpression of *tet-O-FGF7* by epidermal epithelium under the control of reverse tetracycline transcription activator (rtTA) driven by keratin 5 (K5) and K14 promoters of bitransgenic *K5-rtTA/tet-O-FGF7* and/or *K14-tTA/tet-O-FGF7* mice.

Gene Targeting

In late 1980, Doetschman et al. and Thomas et al. demonstrated that the mouse genome could be modified *in vitro* in embryonic stem cells by homologous recombination. It was subsequently demonstrated that the modified mouse genome could be transmitted to offspring through injection of such genetically modified embryonic stem cells into blastocysts. Since then, many gene-targeting strategies have been developed not only to ablate functional genes (i.e., knock-out), but also to replace target genes with another functional gene and/or a mutant gene of interest (knock-in). These strategies allow us to examine gene function in experimental mouse lines that mimic pathogenesis of human diseases and yield useful information, leading to a better understanding of normal physiology and pathophysiology in humans.

However, many of the altered genes often lead to embryonic lethality and detrimental effects on animal development, limiting their use in studying biology of the ocular surface tissues. To circumvent the pitfalls, one of the strategies is conditional gene knock-out that employs Cre–LoxP system to ablate gene in a cell-type-specific manner.

Tissue-specific gene ablation using Cre–LoxP system

The Cre–LoxP system was developed to avoid embryonic lethality as well as to confine the inactivation of the target gene in a cell- or tissue-specific manner. Cre is a phage recombinase that specifically deletes any DNA sequence flanked by two LoxP elements. The Cre–LoxP system consists of two mouse lines, one of which uses a tissue-/cell-type-specific promoter for the expression of Cre. The other mouse line contains a modified genome in which two LoxP elements are inserted in two introns flanking functionally important exon(s) of the targeted gene by gene-targeting techniques. The LoxP-modified (floxed) gene remains fully functional, except in cells expressing Cre that is under the control of a tissue-specific promoter. Thus, the offspring are characterized by the ablation of the gene in a tissue-/cell-type-specific manner. The system allows the inactivation of the target gene in a single cell type and/or a limited number of cell types, depending on the specificity of the promoter, and reduces the probability of embryonic lethality of the experimental mice. Thus, it permits the analysis of physiological and pathophysiological consequences of the genetic alteration in mature animals.

Pitfalls of Cre–LoxP system: Cryptic Cre expression by germ cells during gametogenesis

We have recently discovered that recombination of floxed genes happens during gametogenesis in several Cre/LoxP bitransgenic mouse lines that express tissue-specific Cre outside the gonads, for example, *Kera-Cre*, *Krt12-Cre*, and *BF1-Cre* mice. The frequency of the promiscuous LoxP/Cre recombination varied in different lines of Cre driver mice and sex of the same driver mice with higher penetrance in male than in female double transgenic mice as well (**Table 1**). Polymerase chain reaction (PCR) and recombination analysis demonstrate recombination of floxed allele occurs during transition from spermatogonia (diploid) to primary spermatocyte (tetraploid) in testis. Thus, target floxed allele(s) are ubiquitously ablated in Cre/LoxP mice intended for tissue-specific gene

Table 1 Excision of floxed alleles during gametogenesis of double transgenic Cre/floxed mice

Father	Mother	Number of Cre^{tg}/floxed mice Total	Δ	Number of Cre^{0}/floxed mice Total	Δ	Percentage of penetrance[c]
KC4.3/ZEG	*C57BL/6*	10	10	10	10	100
KC4.1/ROSAR	*C57BL/6*	4	4	6	6	100
KC1/ZEG	*C57BL/6*	15	15	16	16	100
C57BL/6	*KC4.3/ROSAR*	4	2	1	1	60
$K12^{Cre/w}$/*ZEG*	C57BL/6	NA[a]	NA[a]	13	6	46
C57BL/6	$K12^{Cre/w}$/*ZEG*	NA[a]	NA[a]	27	2	7
$BF1^{Cre}$/*R26R*	*CD-1*	7	5	9	6	69
C57BL/6	*Wnt1-Cre/R26R*	1	0	5	0	0
WntlCre/R26R	*C57BL/6*	1	0	7	0	0
$Tbr2^{f/f}$	$KC4/Tbr2^{f/w}$	18[b]	5	26[b]	5	23
$Smad4^{f/f}$	$KC4.3/Smad4^{f/w}$	6[b]	2	7[b]	3	38

[a]ZEG transgene is on chromosome 11 same as *Krt12*. Thus, the ZEG allele is always co-segregated with the $Krt12^{Cre}$ allele
[b]Homozygous floxed *Tbr2* and *Smad4* alleles
[c]Percentage of penetrance is calculated by number of mice with excised floxed allele divided by the total number of mice carrying floxed allele in each experimental group.
Double transgenic mice were crossbred with wild-type mice, and homozygous $Tbr2^{f/f}$ and $Smad4^{f/f}$ mice. The excision event was determined by the expression of respective reporter gene activities or by PCR of the excised floxed alleles as described in Methods. Cre^{Tg}: hemizygous Cre transgenic mice; Cre^{0}: non-Cre transgenic mice. Reproduced from Weng, D. Y., Zhang, Y., Hayashi, Y. et al., (2008). Promiscuous recombination of *LoxP* alleles during gametogenesis in cornea *Cre* driver mice. *Molecular Vision* 14: 562–571.

deletion. Increasing evidence indicates that many cell-type-specific genes in adults are promiscuously expressed in gonad during gametogenesis. Therefore, the promiscuous expression of Cre recombinase driven by cell-type-specific promoters should always be examined to avoid misinterpretation resulting from haploid deficiency.

Inducible Cre–LoxP system

To overcome the pitfalls of promiscuous Cre expression during gametogenesis, we have developed a doxycycline-inducible tet-ON system to spatially and temporally ablate gene of interest in ocular surface tissues. This tet-ON system employs triple transgenic mice consisting of an ocular-surface tissue-specific promoter rtTA (*Kera-rtTA (KR)*), *Krt12-rtTA* (K12R), and *Pax6$_{OS}$-rtTA* (P6R) (**Table 2**), and tet-O-Cre (TC) transgenes, as well as an $X^{f/f}$ (a LoxP-modified gene). Administration of doxycycline will activate rtTA that subsequently turns on the tet-O-Cre transgenes for the synthesis of Cre recombinase, which then excises the $X^{f/f}$ gene in an ocular-surface tissue-specific manner (as described below).

Strategies of Cornea-Specific Genetic Modification: Transgenic and Knock-Out/Knock-In Mice

Identification of Ocular-Surface Tissue-Specific Promoter

The availability of ocular-surface tissue-specific promoter is a prerequisite for the preparation of experimental animal models in which genetic modifications are made to study the consequence of the loss and/or gain of functions of genes in ocular surface tissues, that is, cornea, conjunctiva, lacrimal glands, and eyelids. To date, our laboratory has identified and characterized two cornea-specific genes: keratin 12 (*Krt12*) and keratocan (*Kera*) genes of corneal epithelium and stroma, respectively, and used transgenesis and gene-targeting techniques to create mouse lines in which the gene functions are altered in a cornea-specific manner. However, it should be noted that many systemic genetically modified mouse lines that were created by conventional systemic gene-targeting techniques and/or transgenesis with non-ocular-surface tissue-specific promoters also manifested pathogenesis in ocular surface tissues. Naturally, these mouse lines often exhibited pathogenesis in other tissues than ocular surface tissues as well. To date, only a few promoters that exhibit ocular surface tissue specificity have been identified, for example, keratocan (*Kera*), keratin 12 (*Krt12*), and modified *Pax6* promoters. It should be noted that there is no tissue-specific promoter available that can be used to create mouse lines in which genetic modifications are limited to conjunctiva, cornea endothelium, and lacrimal gland.

Stromal keratocyte-specific promoter

Keratan sulfate proteoglycans (KSPGs) play a pivotal role in the development and maintenance of corneal transparency. Keratocan, lumican, and mimecan (osteoglycin) are the major KSPGs in vertebrate corneas. We have cloned both the mouse keratocan gene and its complementary DNA (cDNA). The mouse keratocan gene spans approximately 6.5 kb of the mouse genome and contains three exons and two introns. Northern blotting and *in situ* hybridization were employed to examine keratocan gene expression during mouse development. Unlike lumican gene, which is expressed by many tissues other than cornea, keratocan messenger RNA (mRNA) is more selectively expressed in the corneal tissue of the adult mouse. During embryonic development, keratocan mRNA was first detected in periocular mesenchymal cells migrating toward developing corneas on embryonic day 13.5 (E13.5). Its expression was then gradually restricted to corneal stromal cells in between E14.5 and E18.5. Interestingly, keratocan mRNA can be detected in scleral cells of E15.5 embryos, but not in

Table 2 Mouse lines for cornea-specific genetic modification

Mouse lines	*Tissue/cell specificity*	*Induction*	*Function*
Kera-rtTA/tet-*O*-reporter	Stromal keratocytes in adult and neural crest cells in embryo	Doxycycline	Overexpression
Kera-Cre	Stromal keratocytes in adult and neural crest cells in embryo	Not inducible	Gene ablation
Kera-rtTA/tet-*O*-Cre/$X^{f/f}$	Stromal keratocytes in adult and neural crest cells in embryo	Doxycycline	Spatial and temporal gene ablation
Krt12-rtTA/tet-*O*-reporter	Corneal epithelium	Doxycycline	Overexpression
Krt12-Cre	Corneal epithelium	Not inducible	Gene ablation

E18.5 embryos. In adult eyes, keratocan mRNA can be detected in corneal keratocytes, but not in scleral cells.

To identify and characterize a keratocyte-specific promoter, we have cloned a 3.2-kb genomic DNA fragment 5′of the mouse *Kera* gene, which has promoter activities in driving the expression of reporter genes, for example, β-galactosidase *(β-Gal)*, reverse tetracycline transcription activator (*rtTA*), Cre recombinase (*Cre*), by migrating periocular mesenchymal cells of neural crest origin during embryonic development and by cornea stromal keratocytes in adults. For example, in adult *Kera-βGal* transgenic mice, *β*-galactosidase activity was detected only in cornea, not in other tissues (e.g., lens, retina, sclera, lung, heart, liver, diaphragm, kidney, and brain). In contrast, during ocular development, the spatial–temporal expression patterns of *βGal* reporter gene recapitulated that of endogenous *Kera* expression in mice. Using X-Gal staining, strong *β*-galactosidase activity was first detected in periocular tissues of E13.5 embryos, and restricted to corneal keratocytes at E14.5 and thereafter. Interestingly, in addition to cornea, *β*-galactosidase activity was transiently found in some nonocular tissues, that is, ears, snout, and limbs of embryos of E13.5 and E14.5, but was no longer detected in those tissues of E16.5 embryos. The transient expression of endogenous keratocan in nonocular tissues during embryonic development was confirmed by *in situ* hybridization. Taken together, the observations suggest that the 3.2-kb *Kera* promoter contains sufficient *cis*-regulatory elements to drive heterologous minigene expression in cells expressing keratocan.

Corneal-epithelium-specific promoter

Keratins are a group of water-insoluble proteins that form 10-nm intermediate filaments in all epithelial cells. Approximately 30 different keratin molecules have been identified, which can be divided into acidic and basic neutral subfamilies. *In vivo*, a basic keratin is usually coexpressed and paired with a particular acidic keratin. The expression of keratin pairs is tissue specific, differentiation dependent, and developmentally regulated. Expression of keratin 3/keratin 12 pair has been found in human, bovine, guinea pig, rabbit, and chicken corneas and is regarded as a marker for corneal-type epithelial differentiation. The expression of keratin 12 is restricted to the corneal epithelium. We have identified and cloned the corneal-epithelium-specific K12 keratin (*Krt12*) gene. Using gene gun to deliver *Krt12-LacZ* reporter gene constructs to rabbit corneal epithelium, we have identified the *cis*-regulatory element that is sufficient and necessary for corneal-epithelium-specific expression of the reporter genes. However, the use of conventional transgenesis techniques failed to identify a functional *Krt12* promoter that was capable of driving the expression of reporter genes, for example, *β-Gal*, chloramphenicol acetyl transferase (*CAT*), and green fluorescent proteins (*GFP*s) in corneal epithelium. Transgenesis using lentiviral *Krt12-lacZ* vectors had successfully generated mouse lines that expressed the reporter *LacZ* gene by corneal epithelium, but multiple insertions by the use of lentivirus vector compromised the efficiency of obtaining stable transgenic mice. To overcome the pitfalls, a gene-targeting construct containing an internal ribosomal entry site–reverse tetracycline transcription activator (IRES-rtTA) cassette was inserted into the *Krt12* allele to produce knock-in *Krt12-rtTA* and Krt12-Cre driver mouse lines through gene-targeting techniques (see below).

Ocular-surface epithelium-specific Pax6 promoter ($Pax6_{OS}$)

Pax6 is a regulatory gene with restricted expression and essential functions in the developing eye and pancreas and distinct domains of the central nervous system (CNS). Three conserved transcription start sites (P0, P1, and a) have been identified in the murine *Pax6* locus. Furthermore, the use of transgenic mouse technology has identified the *cis*-regulatory elements controlling the tissue-specific expression of *Pax6*. Specifically, a 107-bp enhancer and a 1.1-kb sequence within the 4.6-kb untranslated region upstream of exon 0 are required to mediate *Pax6* expression in the lens, cornea, lacrimal gland, conjunctiva, or pancreas. Another 530-bp enhancer fragment located downstream of the *Pax6* translational start site is required for expression in the neural retina, the pigment layer of the retina, and the iris. Finally, a 5-kb fragment located between the promoters P0 and P1 can mediate expression into the dorsal telencephalon, the hindbrain, and the spinal cord. The identified *Pax6/cis*-essential elements are highly conserved in pufferfish, mouse, and human DNA and contain binding sites for several transcription factors indicative of the cascade of control events. Corresponding regulatory elements from pufferfish are able to mimic the reporter expression in transgenic mice. Thus, the results indicate a structural and functional conservation of the *Pax6* regulatory elements in the vertebrate genome. This segment of the mouse Pax-6 gene 5′ flanking region is necessary and sufficient for reporter construct expression in components of the eye derived from non-neural ectoderm, for example, lens epithelium and ocular surface epithelium. This transcriptional control element has been used to prepare $Pax6_{OS}$-rtTA (P6R) driver mouse lines for transgene expression.

Ocular Surface Tissue-Specific Driver Mouse Lines

Corneal stroma-specific mouse lines

The mouse keratocan gene (*Kera*) expression tracks the corneal morphogenesis during eye development and becomes restricted to keratocytes of the adult, implicating a cornea-specific gene regulation of the mouse *Kera*. We

have identified and cloned a 3.2-kb genomic DNA fragment 5′ of the mouse *Kera* gene, which is capable of driving the expression of *LacZ* reporter gene that recapitulates the expression patterns of *Kera*. The keratocan promoter has been used to create transgenic mice, for example, *Kera-biglycan*, and *Kera-Cre* and *Kera-rtTA* driver mouse lines. The *Kera-rtTA* (KR) mice can be used to create bitransgenic Kera-rtTA/tet-O-reporter construct and tritransgenic *KR/TC (tet-O-Cre)/X$^{f/f}$* (X, gene of interest) mice for keratocyte-specific doxycycline-inducible transgene expression and gene ablation (**Table 2**).

Corneal-epithelium-specific mouse lines

A similar strategy employing Cre–LoxP and tet-ON systems with keratin 12 promoter (*Krt12*) would allow us to prepare experimental mouse lines that express transgenes and ablate genes in a corneal-epithelium-specific manner. Thus, for many years we tried to identify and isolate a functional keratin 12 promoter for the preparation of corneal-epithelium-specific transgenic and Cre–LoxP mouse lines without success. To circumvent these difficulties, we have prepared mouse lines carrying IRES-Cre and IRES-rtTA reporter genes into the *Krt12* locus through a targeted knock-in strategy.

Unlike prokaryotes, most mammalian mRNAs are monocistronic (i.e., one message encodes one protein). However, some viral mRNAs and/or translationally regulated mRNAs (e.g., fibroblast growth factor 2 (FGF-2) and c-myc) are bicistronic in that they have IRESs in the mRNA that allows a second initiation of translation after the stop codon of the first reading frame for the synthesis of a second protein from the mRNA. Inclusion of such IRES elements in the reporter gene constructs has allowed the generation of transgenic mouse lines that express two proteins encoded by a single transgene.

To create corneal-epithelium-specific gene ablation in mice, a targeting construct containing intron 2 to exon 8 of *Krt12* gene was prepared in which an IRES-Cre and the phosphoglycerate kinase-neomyocin resistance gene (PGK-Neo) reporter genes were inserted right after the stop codon within exon 8 as shown in **Figure 1**. Germ line chimera mice were obtained through conventional gene-targeting techniques using embryonic stem cells. The K12-Cre mice were crossed with reporter Tg(CAG-Bgeo/ALPP)1Lbe (*ZAP*) mice that harbor a transgene containing a chicken β-actin promoter, a floxed *LacZ* gene (two LoxP elements flanked at 5′ and 3′ ends of *LacZ*), and followed by alkaline phosphatase (*AP*) gene in tandem. The Cre activity was assessed by the detection of *LacZ* and expression of *AP* in corneas of the offspring as shown in **Figure 2**. Thus, the K12-Cre knock-in mice can be used to create mouse lines in which any floxed genes are ablated in corneal epithelium. Thus, it will allow us to investigate the role of a gene in corneal morphogenesis and homeostasis through the loss of function without threatening the life of the experimental animals. Using a similar strategy, a gene-targeting construct containing an IRES-rtTA cassette was inserted into the *Krt12* allele to produce a knock-in *Krt12$^{rtTA/w}$* mouse line through gene-targeting techniques (**Figure 1**). The *Krt12$^{rtTA/w}$* knock-in mice were bred with *tet-O-LacZ* reporter mice to obtain *Krt12$^{rtTA/w}$/tet-O-LacZ* bitransgenic mice. The corneal-epithelium-specific expression of the *LacZ* gene was induced in bitransgenic mice by administration of doxycycline in the drinking water and chow as shown in **Figure 3**. To further expand the usefulness of Krt12-rtTA knock-in mice, a tritransgenic *Krt12$^{rtTA/w}$/tet-O-Cre/ZEG* mouse line was prepared in which the expression of enhanced green fluorescence protein (EGFP) was activated by feeding mice doxycycline that subsequently excised the *LacZ* gene from the *ZEG* allele and allowed the expression of EGFP. **Figure 4** shows the doxycycline-induced expression of EGFP by corneal epithelial cells of *Krt12$^{rtTA/w}$/TC/ZEG* mice. ZEG is a transgenic mouse line that has dual reporter genes of a *LacZ* flanked by LoxP, followed by *EGFP* driven by a chicken actin promoter. Chicken actin promoter drives the expression of *LacZ* in all cells except those of which express Cre and show green fluorescence due to the excision of *LacZ* and expression of *EGFP*. Using the strategies, we have prepared several mouse lines that can be used to overexpress transgenes and ablate genes of interest in a cornea-specific manner as summarized in **Table 2**.

Ocular surface tissue-specific Pax6$_{OS}$-rtTA mouse line

We have recently prepared an ocular surface epithelium-rtTA (Pax6$_{OS}$-rtTA) driver mouse line with *cis*-regulatory elements of the 4.6-kb un-translated region upstream of exon 0 of *Pax6*, which mediate *Pax6* expression in the lens, cornea, lacrimal gland, conjunctiva, or pancreas. The bitransgenic *Pax6$_{OS}$-rtTA/Tet-O-EGFP* mice express EGFP upon doxycycline induction (data not shown). This *Pax6$_{OS}$-rtTA* mouse line is useful for generating experimental mice of overexpression of tet-O-transgene and ablation of floxed gene of tritransgenic (*Pax6$_{OS}$-rtTA/tet-O-Cre/X$^{f/f}$*) mice.

Roles of Growth Factors on Ocular Surface Tissue Morphogenesis during Development and Wound Healing Elucidated from Transgenic Mice

Corneal morphogenesis during eye development of vertebrates involves the differentiation of cells from surface ectoderm and the migration of periocular mesenchymal cells of neural crest origin. The differentiation of surface ectoderm gives rise to corneal and conjunctival epithelia of the ocular surface as well as to glandular epithelium, for example, lacrimal and meibomian glands. The

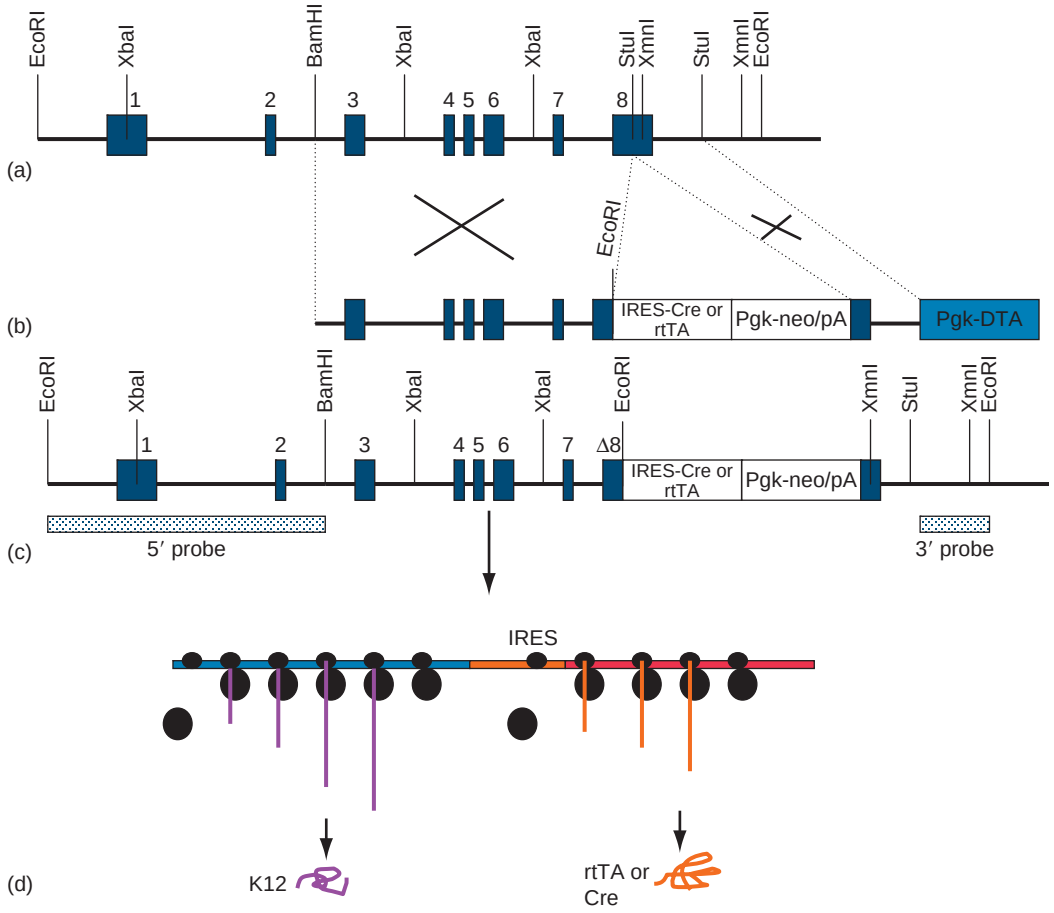

Figure 1 Generation of *Krt12*$^{rtTA/+}$ and *Krt12*$^{Cre/+}$ knock-in mice through gene targeting. (a) Krt12 allele. (b) Targeting vector: the IRES-rtTA (and IRES-Cre) cassette, containing IRES, rtTA (Cre), and SV40-polyA, was cloned in-frame into the corresponding EcoRI/EcoRV site of pKrt12-4.8 3′ to the stop codon in exon 8 of *Krt12*, creating a modified exon 8 that contains the entire 3′ coding region of *Krt12*, IRES-rtTA, and SV4-polyA signals. This was followed by pgk-Neo minigene, untranslated exon 8, and polyadenylation (pA) of *Krt12.* Finally, a negative selection marker gene, diphtheria toxin A fragment (pgkpr-DTA) cassette, was placed on the 5′ end of the targeting vector. Knock-in' shows the predicted structure of a targeted knock-in allele after homologous recombination. (c) Knock-in Krt12 allele through homologous recombination. (d) Bi-cistronic mRNA derived from the Knock-in Krt12 allele. Panels (a), (b), and (c) of this figure are reprinted from Chikama, T. -L., Hayashi, Y., Liu, C. -Y. et al. (2005). Characterization of tetracycline inducible *Krt12*$^{rtTA/+}$/*tet-O-LacZ* mice. *Investigative Ophthalmology and Visual Science* 46: 1966–1972.

mesenchymal cells of neural crest origin become corneal endothelial cells and keratocytes, and the stromal cells of other ocular surface tissues, that is, eyelids, iris, ciliary body, and trabecular meshworks.

The corneal epithelium synthesizes components of extracellular matrix (ECM) for the formation of primary stroma when the lens detaches from the ectoderm during development. In vertebrate corneal development, the first wave of mesenchymal cells that migrate underneath the primary stroma forms the endothelium. The mesenchymal cells of the second wave invade the primary stroma and become keratocytes, which are responsible for the formation of secondary stroma of adult vertebrates. The third waves of mesenchymal cells contribute to the stromas of eyelids, iris, ciliary body, and trabecular meshworks. This orderly cellular migration and differentiation are controlled by cues from various cytokines and the components of ECM, which are under constant remodeling during embryonic development. For example, members of the transforming growth factor beta (TGFβ) superfamily play pivotal roles in embryonic development. However, the precise cytokines and their functions that modulate corneal morphogenesis remain unknown. It is very likely that cytokine signaling may modulate the expression of specific transcription factors that contribute to this orderly corneal morphogenesis during development or vice versa.

TGFβ Receptor Signaling Pathways during Development and Corneal Wound Healing

Role of TGFβ2 on development

TGFβ has a pivotal role in embryonic development. In mammals, three isoforms of TGFβ (β1, -2, and -3) are

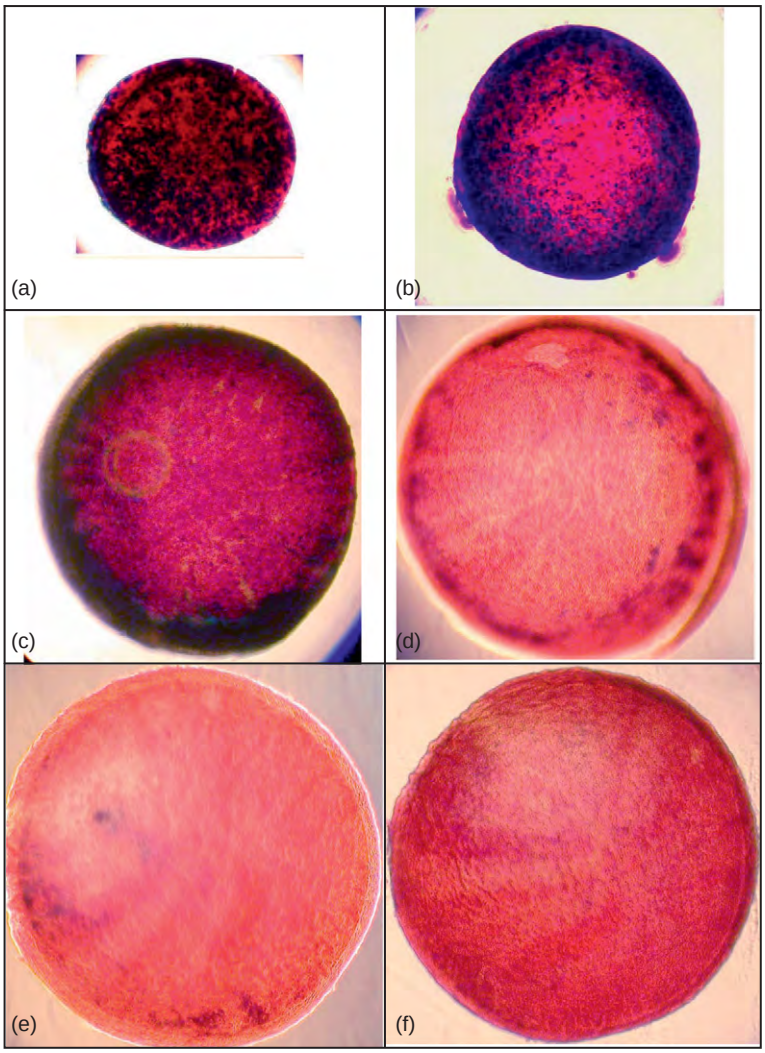

Figure 2 Histograms of X-gal and AP staining of *Krt12*$^{Cre/Cre}$/*ZAP* bitransgenic mice. Corneas from bitransgenic mice at different ages were subjected to histochemistry staining for X-gal and alkaline phosphatase activities. (a) P15 (postnatal day 15); (b) P30; (c) P60; (d) P90; (e), P180; (f) P300. Cells express K12 and AP (alkaline phosphatase) positive were stained red, whereas the K12 negative cells were *LacZ* positive and stained blue. At P15, the expression of *LacZ* (blue) and *AP* (red) shows a mosaic pattern. At P90, almost all central cornea epithelia express K12 and stained red with sporadic blue cells. At P180 and P300, central corneas were stained red with blue cells located at limbus. Reproduced from Tanifuji-Terai, N., Terai, K., Hayashi, Y., et al. (2006). Expression of keratin 12 and maturation of corneal epithelium during development and postnatal growth. *Investigative Ophthalmology and Visual Science* 47: 545–551.

known. Members of TGFβ family are multifunctional cytokines involved in development, tissue repair, and other physiological or pathologic processes. Among the knock-out mice of the three *Tgfb* isoforms, only *Tgfb2*$^{-/-}$ mice exhibit ocular pathology of thin corneal stroma, absence of corneal endothelium, fusion of cornea to lens, a phenotype resembling Peter's and Axenfeld anomaly in humans, and accumulation of hyaline cells in vitreous. Delayed appearance of macrophages in ocular tissues was observed in *Tgfb2*$^{-/-}$mice. Malfunctioning macrophages may account for accumulation of cell mass in vitreous of *Tgfb2*-null mice. In *Tgfb2*$^{-/-}$mice, fewer keratocytes were found in stroma that have a decreased accumulation of ECM; for example, lumican, keratocan, and collagen I were greatly diminished. The thinner stroma resulting from decreased ECM synthesis may account for the decreased cell number in the stroma of *Tgfb2*-null mice. The absence of TGFβ2 did not compromise corneal epithelial cell proliferation, nor enhance apoptosis. Keratin 12 expression was not altered in *Tgfb2*$^{-/-}$mice, implicating that TGFβ signaling is not essential for cornea-type epithelium differentiation. This suggestion is further supported by the observation that ablation of TGFβ type II receptor in *Krt12*$^{Cre/Cre}$/*Tbr2*$^{f/f}$ mice does not cause corneal epithelium anomaly (our unpublished observation).

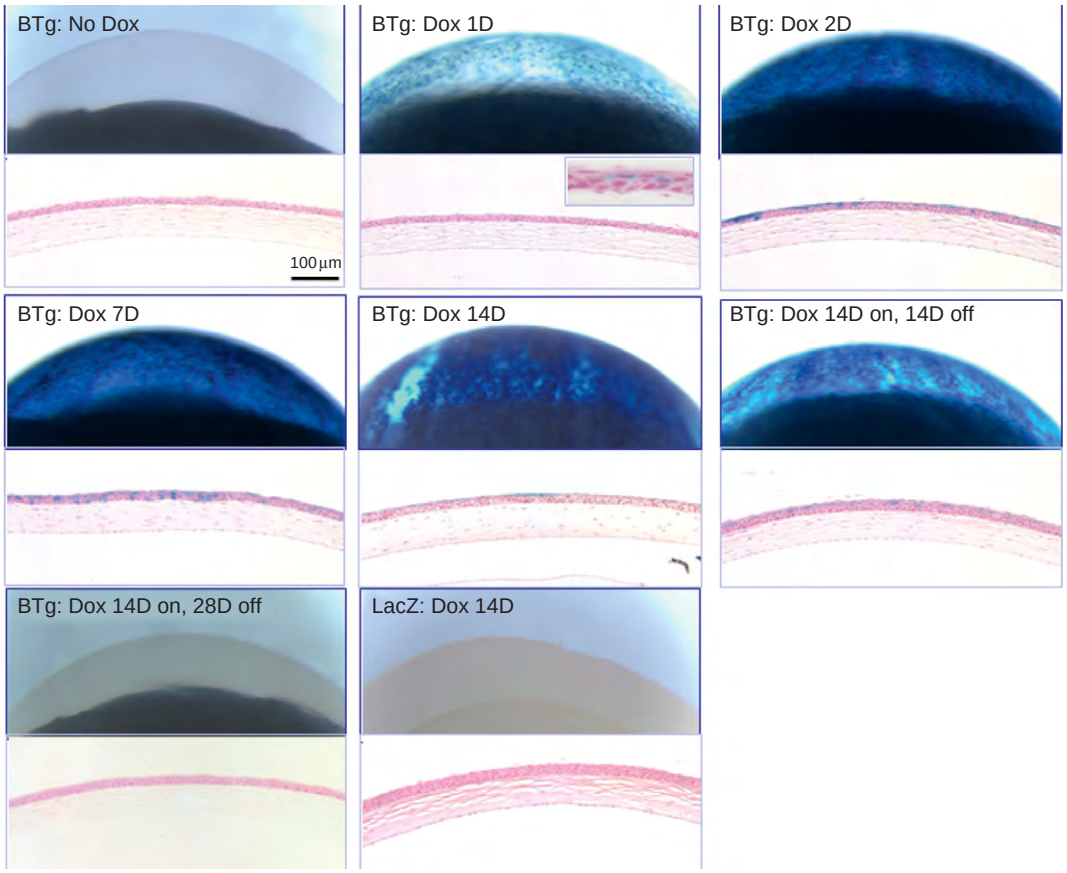

Figure 3 *In situ* analysis of β-galactosidase enzyme activity induction by doxycycline in corneas of *Krt12*$^{rtTA/+}$*/tet-O-LacZ* bitransgenic mice. Stereomicroscopy showed a side view of each eye after whole-mount β-galactosidase staining. Histological examination (lower image of each panel) of the same samples revealed that the β-galactosidase expression was restricted to corneal epithelium. Corneal epithelial cells began to express β-galactosidase in 24 h after doxycycline administration. The number of β-galactosidase expressing cells in BTg mouse with doxycycline increased in the course of time. Not all corneal epithelial cells expressed β-galactosidase was observed even in the maximum level. BTg, bitransgenic; *LacZ*, *tet-O-LacZ* single transgenic. Role of TGF-β signaling in wound healing of corneal epithelium

Corneal epithelial defects must be rapidly resurfaced to avoid microbial infection and further damage to the underlying stroma. Epithelial healing is achieved by migration of the epithelial sheet to cover the denuded surface and enhanced cell proliferation to reestablish the epithelial stratification quickly after resurfacing. It is of interest to note that in the early phase of healing only one of the two cellular responses, cell migration, takes place, whereas cell proliferation is suppressed. Although cell migration promotes rapid re-epithelialization, the cessation of cell proliferation may impede healing if such cessation is prolonged.

Various growth factors, including TGFβ, orchestrate the behavior of healing corneal epithelium: for example, cell migration and/or proliferation, cell death, and protein synthesis. It has been demonstrated that the TGFβ isoforms and their receptors are present in corneal and limbal epithelia and other supporting tissues (e.g., conjunctiva and tear fluid). Therefore, it has long been speculated that the TGFβ isoforms play pivotal roles in maintaining corneal homeostasis in a paracrine and autocrine fashion as TGFβ inhibits cell proliferation of cultured keratinocytes and corneal epithelial cells *in vitro*, thus it may suppress corneal epithelial cell proliferation *in vivo*. This notion is further supported by the observation in which the administration of anti-TGFβ-neutralizing antibodies reduces scar tissue formation in injured corneas. Recently, it was shown that epithelial debridement causes an upregulation of TGFβ receptor expression on migrating corneal epithelial cells, suggesting that this ligand may have a pivotal role in modulation of functions of migrating corneal epithelial cells during wound healing.

We recently examined the roles of TGF-β signaling pathways in regulating cell migration and proliferation of the healing of corneal epithelium debridement. TGF-β type II receptor (*Tbr2*) floxed mice were bred

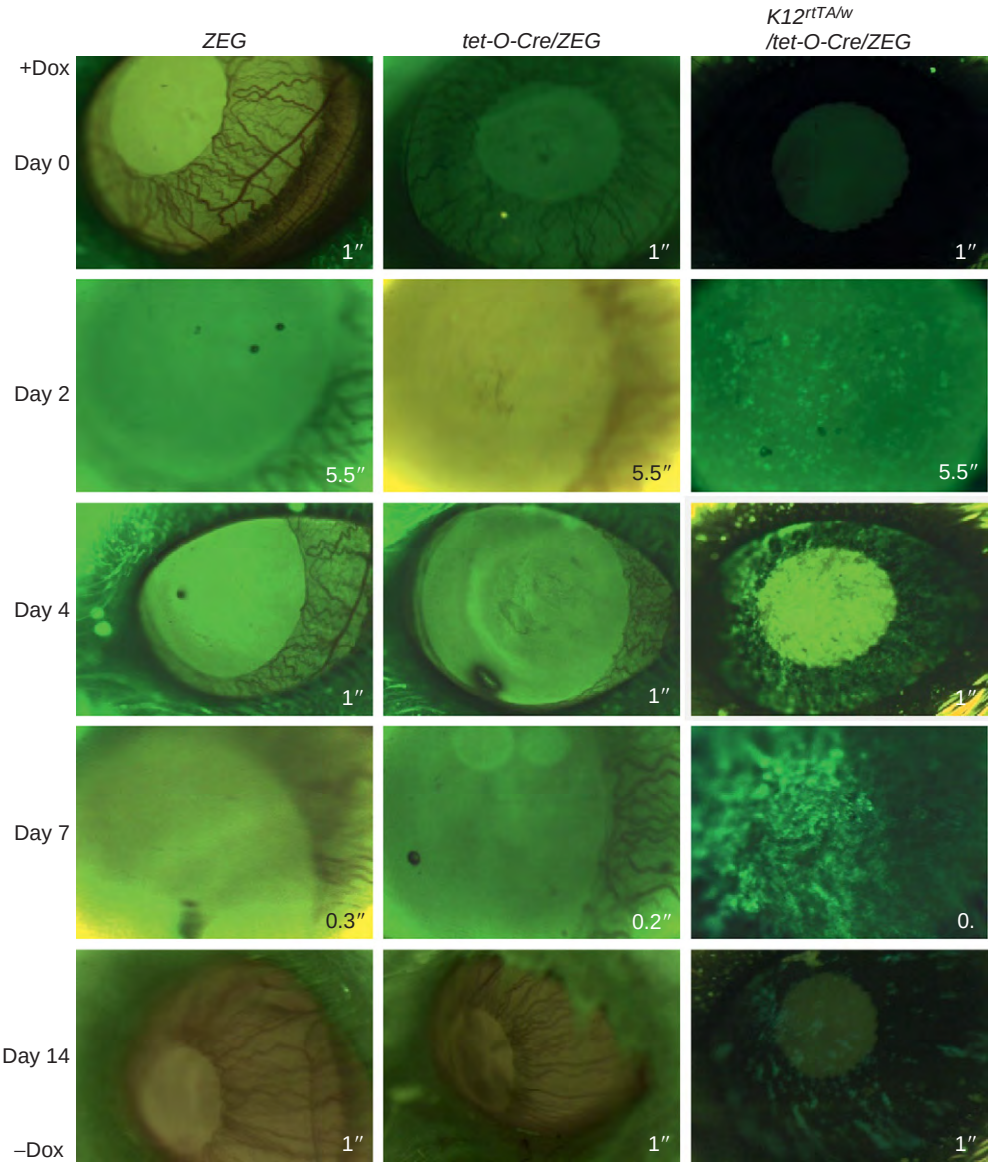

Figure 4 Expression of floxed reporter gene by doxycycline induction Tritransgenic *Krt12/tet-O-Cre/ZEG* mice were fed doxycycline chow for various periods of time. The experimental animals were examined under a ZEISS stereomicrscope with epi-fluorescence attachment. Strong green fluorescence was observed in tritransgenic *Krt12/tet-O-Cre/ZEG* mice after 2 days induction and then declined in 14 days after removal of doxycycline in the diet.

with *Krt12-Cre* mice to generate bitransgenic mice in which the *Tbr2* gene was disrupted selectively in the corneal epithelial cells. Corneal epithelial debridement (2 mm in diameter) was created in 2-month-old bitransgenic $Krt12^{Cre/Cre}/Tbr2^{f/f}$ mice and their littermates as controls $Krt12^{Cre/Cre}/Tbr2^{f/w}$ and $Krt12^{Cre/Cre}/Tbr2^{w/w}$. Our results indicated that corneal epithelium of $Krt12^{Cre/Cre}/Tbr2^{f/f}$ mice exhibited delayed healing of debridement in comparison to that of control littermates that were heterozygous floxed and wild-type *Tbr2*. The naive uninjured corneal epithelium of $Krt12^{Cre/Cre}/Tbr2^{f/f}$ mice exhibited higher cell proliferative activities than controls as determined by BrdU incorporation. It is of interest to note that corneal epithelium debridement caused cessation of epithelial cell proliferation of all experimental mice in 6–12 h, irrespective of whether the *Tbr2* was ablated or not.

Immunohistochemistry using anti-phospho-p38 mitogen-activated protein kinase (MAPK) revealed, following epithelium debridement, that the activation of p38MAPK was seen in 6 h of injury in control mice. In contrast, phosphorylation and nuclear translocation of p38MAPK were markedly delayed in mice lacking Tbr2 in corneal epithelium compared to control mice. The observation is consistent with results of our previous studies, in which we demonstrated that addition of p38MAPK inhibitors blocked cell migration more markedly than

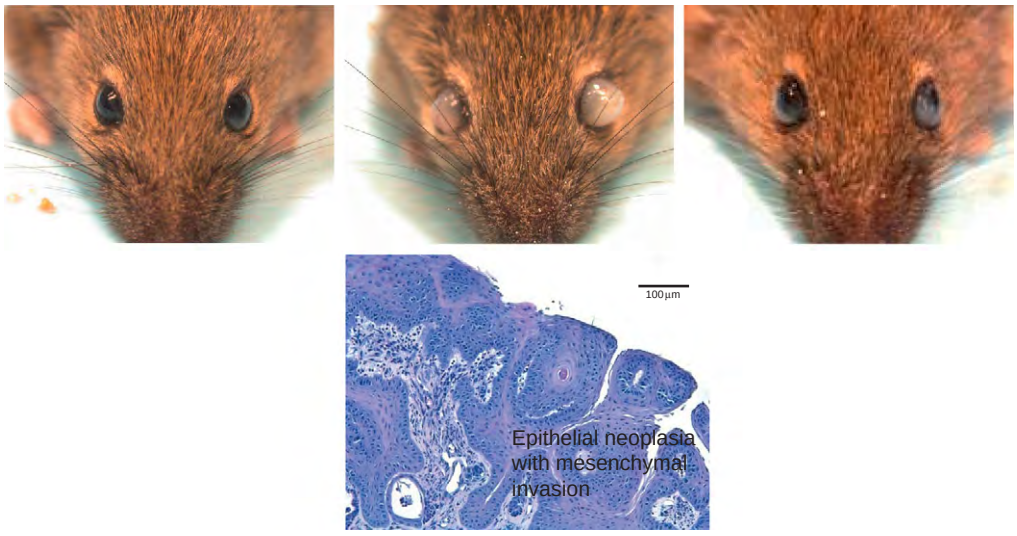

Figure 5 Excess expression of FGF7 by corneal epithelium causing ocular surface squamous neoplasia (OSSN). Krt12-rtTA/tet-*O*-FGF7 bitransgenic mice were obtained by crossbreeding single Krt12-rtTA and tet-*O*-FGF7 mice. The progeny were induced by feeding mothers doxycycline chow at the beginning of mating (E0.5) and until weaning of the pups at postnatal day 18 (P18). The pups were continuously fed doxycycline chow after weaning until sacrifice at P21. Enucleated eyes were subjected to histological examination. The bitransgenic Krt12-rtTA/tet-*O*-FGF7 mice showed bilateral OSSN.

neutralizing anti-TGFβ antibody and enhanced cell proliferation in the injured corneal epithelium. The observation suggested that p38MAPK, but not the mothers against decapentaplegic (Smad, another signaling cascade active by TGFβ) cascade, plays a major role in promoting cell migration and in suppressing cell proliferation in migrating epithelium.

Role of FGF7 in Maintenance of Corneal Homeostasis

During mammalian embryogenesis, epithelial–mesenchymal interactions play a determining role in normal tissue patterning and development. FGF7 (also known as keratinocyte growth factor, KGF), a member of the FGF family, is a mesenchymally derived mitogen for epithelial cells in regulating epithelial cell behavior, as the FGF7 receptor is expressed by epithelial cells. Overexpression of human FGF7 by a crystalline promoter in the eye caused hyperproliferation of embryonic corneal epithelial cells and their subsequent differentiation into functional lacrimal gland-like tissues. This indicates that stimulation of the FGF7 receptor early in development, in surface ectoderm normally destined to form corneal epithelium, is sufficient to alter the fate of these cells. This further suggests that the correct spatial and temporal expression of FGFs plays a critical role in normal lacrimal gland induction. It is of interest to note that overexpression of FGF7 in $Krt12^{rtTA/wt}/tetO\text{-}FGF7$ bitransgenic mice by doxycycline induction during embryonic development resulted in the formation of vascularized cornea with epithelium hyperplasia, resembling human ocular surface squamous neoplasia (OSSN) as shown in Figure 5. The phenotype variations of the two mouse models can be explained by the fact that α-crystalline expression by lens commences at E10–E11.5, whereas the expression of keratin by corneal epithelium begins at E14.5.

EGFR/EGF, TGFα Signaling Pathways on Eyelids Morphogenesis

Transgenic *Kera-Bgn* mice overexpressing biglycan, driven by keratocan promoter under the keratocan promoter, exhibit exposure keratitis and premature eye opening from noninfectious eyelid ulceration due to perturbation of eyelid muscle formation and the failure of meibomian-gland formation. In addition, *in vitro* analysis revealed that biglycan binds to TGFα, thus interrupting epidermal growth factor receptor (EGFR) signaling pathways essential for mesenchymal cell migration induced by eyelid epithelium. The defects of TGFα signaling by excess biglycan were further augmented by the interruption of the autocrine or paracrine loop of the EGFR signaling pathway of heparin-binding (HB)-EGF expression elicited by TGFα.[10] These results are consistent with the notion that under physiological conditions, biglycan secreted by mesenchymal cells serves as a regulatory molecule for the formation of a TGFα gradient serving as a morphogen of eyelid morphogenesis (Figure 6).

MEK kinase 1 (MEKK1) is an MAPK originally identified as an upstream activator for several MAPK pathways. During mouse embryogenesis, MEKK1 controls cell

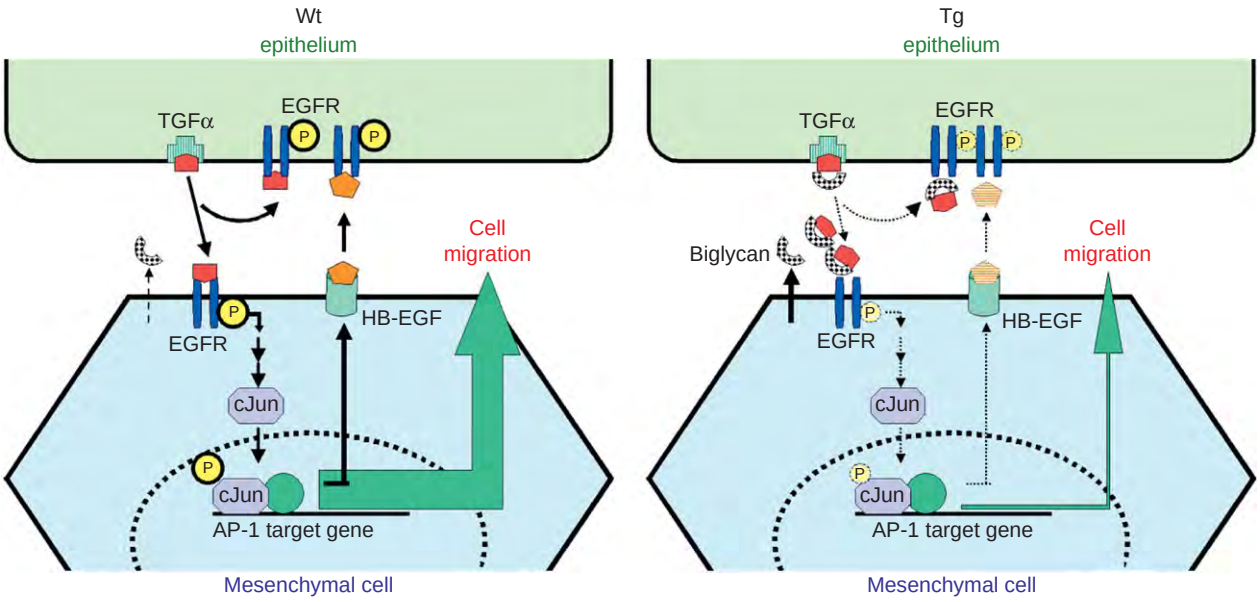

Figure 6 The EGFR signaling mediated by TGF-α during eyelid morphogenesis. The presence of excess biglycan in the *Kera-Bgn* transgenic mice sequesters TGF-α and consequently perturbs the autocrine and/or paracrine loop of EGFR signaling pathways through HB-EGF and impairs mesenchymal cell migration. Reproduced from Hayashi, Y., Liu, C. -Y., Jester, J. V. et al. (2005). Excess biglycan interferes TGF-α signaling required for eyelid morphogenesis. *Developmental Biology* 277: 222–234.

shape changes and formation of actin stress fibers that are required for sealing epidermis in the embryos in a process known as eyelid closure. MEKK1-null mice display eye-open at birth (EOB), a phenotype found also in mice impaired in activin, a subgroup of the TGFβ family, or in EGFR or its ligand TGFα, or in transcription factor c-Jun. Molecular analyses have revealed at least two signaling mechanisms in the control of eyelid closure. One is originated from the activins and is transduced through MEKK1, leading to transcription-independent actin stress fiber formation and transcription-dependent keratinocyte migration. Another is the TGFα/EGFR signal that is transduced through an MEKK1-independent pathway to the activation of the extracellular signal-regulated kinase (ERK) MAPK, which also leads to keratinocyte migration. c-Jun might serve as a connection between the two pathways. As embryonic eyelid closure is a specific morphogenetic process that is easily detectable, genetic mutant mice with EOB will be ideal models to understand the signaling mechanisms in the control of epithelial cell migration and the morphogenetic process of epithelial sheet movement.

Thus, the observation supports the hypothesis that tissue morphogenesis during development is regulated by growth factors and cytokines, and is characterized by constant remodeling of ECM in response to signaling molecules, for example, growth factors, cytokines, and so forth. Proteoglycans that bind growth factors are potential regulators of tissue morphogenesis during embryonic development.

Conclusion: The Clinical Relevance of Tet-ON Mouse Models in Elucidating Pathophysiology of Ocular Surfaces Diseases

Many transgenic and knock-out mice exhibit pathogenesis resembling human ocular surface diseases. Thus, the clinical manifestations of mouse lines can be used as clues for identifying inherited human disease of unknown etiology. However, embryonic lethality and congenital defects of the mouse lines do not allow further examination of the effects of altered genetic functions on pathophysiology of acquired diseases in adults. The difficulties can be overcome by preparing mouse lines of inducible transgene expression, tissue-specific gene ablation, and inducible tissue-specific gene ablation. The conditional transgenic mouse lines will live normally until the administration of doxycycline, which induces expression of the transgene and/or ablation of gene of interest. Use of these genetically modified mouse lines can simulate the pathophysiology of ocular surface diseases, for example, wound healing, tumorigenesis, and irregular hormone and cytokine signaling that offsets homeostasis in adults.

Glossary

CD86 – A co-receptor expressed on the surfaces of antigen-presenting cells. When engaging either of its cognate receptors – CD28 and CTLA-4 – on the surface of T cells, it generates signals essential for T-cell activation and activates signaling cascades within the antigen-presenting cells.
Chemokines – The proteins that promote recruitment of lymphocytes and leukocytes to inflamed tissues and to lymphoid tissues.
Hypophysectomy – The surgical removal of the pituitary gland.
Interferon gamma (IFN-γ) – A cytokine released primarily by T cells and natural killer cells that induces T cells to express the T_H1 phenotype, activates macrophage to express microbicidal functions, and induces B cells to switch from immunoglobulin M (IgM) to complement-fixing IgG isotypes.
Interleukin 1 alpha and 1 beta (IL-1α, IL-1β) – The related cytokines released primarily from macrophages, endothelial cells, and epithelial cells that induce inflammatory responses.
Interleukin 6 (IL-6) – A cytokine that promotes inflammatory responses and supports survival of T and B cells.
Interleukin 12a (IL-12a) – A cytokine released in innate immune responses that induces expression of IFN-γ and, thereby, promotes the evolution of adaptive responses mediated by T_H1 cells.
Lactation – The production and secretion of milk.
Lactogenesis – The secretory differentiation of the mammary epithelium.
Orchiectomy – The surgical removal of the testes.
Sex hormone-binding globulin (SHBG) – A protein which binds estrogens and androgens. It is produced by the liver and secreted into the blood. Estrogens stimulate its production and androgens suppress its production.
Sodium-potassium-dependent ATPase (Na,K-ATPase) – The sodium–potassium pump enzyme; it generates the chemiosmotic energy essential for lacrimal fluid production by pumping Na^+ out of, and K^+ into, the cytosol.
Transforming growth factor-beta (TGF-β) – A cytokine released by T cells and macrophages, as well as by some epithelial cells and mesenchymal cells. Its actions on immune cells include: inhibiting T-cell proliferation and expression of effector functions; inhibiting B cells from proliferating and inducing them to undergo IgM-to-IgA isotype class-switch recombination; and suppressing macrophage activation. It often exerts antiproliferative or pro-apoptotic influences on epithelial cells.

Gender-Related Dimorphisms

The lacrimal glands produce most of the aqueous fluid that comprises the *milieu extérieur* sustaining the live, metabolically active cells of the superficial layers of the cornea and conjunctiva, and insufficient production of this fluid and alterations of its composition are associated with dry eye disease. Because dry eye disease is considerably more prevalent among women, it has seemed intriguing that morphological differences can be readily discerned between the acini – that is, the primary secretory structures of the lacrimal glands – of male and female rats. The structural dimorphisms were, some years ago, found to be accompanied by equally striking biochemical and functional dimorphisms. Classic work by Sullivan and colleagues showed that many of the evident dimorphisms are supported by the higher levels of androgens characteristic of males. However, it is taking much longer to learn how, in mechanistic terms, the gender-related dimorphisms might relate to females' greater predilection

for lacrimal dysfunction. Indeed, one of the first functional dimorphisms to be documented appeared paradoxical: basal precorneal tear volume is smaller in intact male rats than in females, and it increases in males after they are castrated – a surgical maneuver that causes the size of the acini to decrease, that is, to become more female like.

One of the products that the lacrimal glands contribute to the ocular surface fluid is secretory immunoglobulin A (sIgA), which is the effector of the adaptive mucosal immune defense against microbial infection. The lacrimal glands of rats exhibit several readily quantified dimorphisms relating to the production and secretion of dimeric IgA (dIgA). The stromal spaces of the lacrimal glands of male rats are populated by larger numbers of dimeric IgA-secreting plasmacytes. Whole gland extracts contain greater masses of dIgA. Glandular epithelial cells express higher levels of the polymeric Ig receptor (pIgR), which mediates uptake of dimeric dIgA at the stromal-facing surface of the lacrimal epithelium, chaperones it through the cells' transcytotic apparatus, and provides the secretory component (SC) portion of secretory IgA (sIgA). Lacrimal gland fluid from sexually mature male rats contains both more sIgA and SC.

Sex Steroids

Androgens

As noted above, it was established early on that the androgens support the gender-related dimorphisms of acinar size and of precorneal tear volume, which is presumably related to basal rates of lacrimal fluid production. It was also found that the androgens also support epithelial cell expression of pIgR and secretion of SC. However, androgen effects on the numbers of IgA^+-plasmacytes populating the glands' stromal spaces varied considerably among individual animals.

Although different laboratories have reported discrepant findings, there is some evidence for the theoretical paradigm that the androgens exert general trophic influences on the glandular epithelium. Hypophysectomizing rats decreases circulating levels of gonadal and adrenal steroids, as well as pituitary hormones (see **Box 1**). This maneuver reduces the lacrimal glands' gross weight and their weight as a fraction of total body weight. In some studies, administration of dihydrotestosterone (DHT) did not change lacrimal gland weight appreciably. In other studies, administration of DHT partially reversed hypophysectomy-induced decreases in the total amounts of protein and Na,K-ATPase catalytic activity measured in lacrimal gland lysates. Ovariectomizing female rabbits decreases serum sex steroid levels. This maneuver decreased the total protein and DNA contents of lacrimal gland lysates. Administration of DHT prevented the ovariectomy-induced decreases, and it increased the Na,K-ATPase catalytic activity measured in lacrimal gland lysates. Surprisingly, in view of the role Na,K-ATPase plays in lacrimal fluid production, DHT did not increase the basal rate of lacrimal fluid production. However, it significantly increased the volume of fluid intact glands produced when they were stimulated with cholinergic agonists. These findings make it clear that several independent layers of regulation determine lacrimal fluid production: long-term regulation of the mass of cells comprising the glandular epithelium and of the levels at which the epithelial cells transcribe the genes specifying Na,K-ATPase and other ion-transport proteins, and acute regulation – presumably neurally mediated – of the transport proteins' functional states. A more complex paradigm, however, is needed to account for why the magnitude of the lacrimal gland regression caused by ovariectomy is small compared to the extent of atrophy that nuclear magnetic resonance (NMR) imaging studies have documented in the lacrimal glands of aging females. One possible paradigm is that in mature, but not aged, female rabbits the lacrimal glands compensate for ovariectomy-induced loss of testosterone by converting the weak androgen, dihydroepiandrosterone (DHEA) – which is produced by the adrenal cortex (see **Box 1**) – to testosterone and DHT. A second is that the loss of a small trophic influence must be compounded over time before its consequences become evident. A third is that androgens influence other parameters in addition to the cellular mass of the epithelium, and that it is the consequences of loss of those influences that are compounded over time.

In *ex vivo* studies, DHT increased proliferation in models of acinar cells from rabbit lacrimal glands. Compared to the action of epidermal growth factor (EGF), however, the influence of DHT was relatively modest. When Azzarolo and colleagues tested the hypothesis that androgens support the number of cells in the epithelium by preventing apoptosis, as well as by promoting cell proliferation, they found that epithelial cell apoptosis is relatively rare, but plasmacytes in the glands' stromal space began apoptosing within an hour following ovariectomy. Moreover, administration of DHT prevented ovariectomy-induced plasmacyte apoptosis.

The finding that androgen withdrawal leads to a wave of apoptosis in the lacrimal gland plasmacyte population is one of several that accord with the paradigm that their higher levels of androgens protect men both from Sjögren's autoimmune dacryoadenitis and from the histopathophysiological syndrome commonly found in aging women by influencing immunophysiological processes within the gland. Indeed, it has been found that administration of DHT suppresses lacrimal gland disease in certain mouse models for Sjögren's syndrome, and preliminary clinical experiences suggest that androgen supplementation of hormone replacement therapy may improve symptoms and clinical signs in menopausal women with inflammatory autoimmune lacrimal diseases. In the models in which androgen administration is therapeutic, the responses are

Box 1. Regulation of reproductive hormone bioavailability

Figure 1 summarizes factors and feedback interactions that determine the bioavailabilities and local actions of the steroid reproductive hormones.

Hypothalamic neurons release gonadotropin-releasing hormone (GNRH), which stimulates release of LH and FSH by the anterior pituitary. LH and FSH, in turn, stimulate synthesis of estradiol and progesterone in the ovaries, and synthesis of testosterone in the testes. Notably, testosterone is an obligatory precursor in the syntheses of estradiol and progesterone, and total serum testosterone levels increase as estradiol and progesterone levels increase. Progesterone can be converted to testosterone, but estradiol cannot.

The anterior pituitary also produces adrenal corticotropic hormone (ACTH), which is induced by corticotrophin releasing hormone from hypothalamic neurons. ACTH, in turn, increases adrenal synthesis of the glucocorticoids and dihydroepiandrosterone (DHEA). DHEA can be converted to testosterone in peripheral tissues. Androgen target tissues frequently convert testosterone to dihydrotestosterone, a higher affinity ligand for androgen receptors.

The liver plays an indirect but critical role in determining testosterone bioavailability, producing sex hormone binding globulin (SHBG) in response to increasing levels of estradiol and testosterone in the serum. In some cases SHBG sequesters the hormones, reducing their bioavailability. In other cases SHBG-sex steroid hormone complexes exert biological activities by interacting with nonclassical receptors at the surfaces of target cells, rather than with the classical receptors that traffic from the cytosol to the nucleus.

After menopause, the ovarian stroma continues to produce some testosterone and androstenedione. During hormone replacement therapy, however, the exogenous estrogens suppress GnRH release, thus reducing ovarian testosterone production. Exogenous estrogens further decrease testosterone bioavailability by stimulating increased hepatic production of SHGB.

Production of testosterone declines gradually as men age. Production of DHEA declines similarly in women and men. In women, reproductive steroid hormone and prolactin levels vary systematically during the menstrual cycle. They fluctuate, with more individual variation, during the perimenopause. They then remain consistently low postmenopausally, while prolactin levels are decreased only modestly. Estradiol, progesterone, and prolactin levels increase markedly over the course of a pregnancy. The steroid levels decrease abruptly at parturition; prolactin declines more gradually during a nonlactating puerperium, and it remains elevated during lactation.

In contrast to positive regulation of LH, FSH, and ACTH by hypothalamic factors, the release of prolactin by the anterior pituitary is negatively regulated, that is, suppressed, by dopamine produced by hypothalamic neurons. Estradiol increases production of prolactin in the anterior pituitary, while prolactin suppresses estradiol production by acting upstream to suppress release of GNRH. As noted in the text, a number of peripheral tissues in addition to the pituitary produce prolactin.

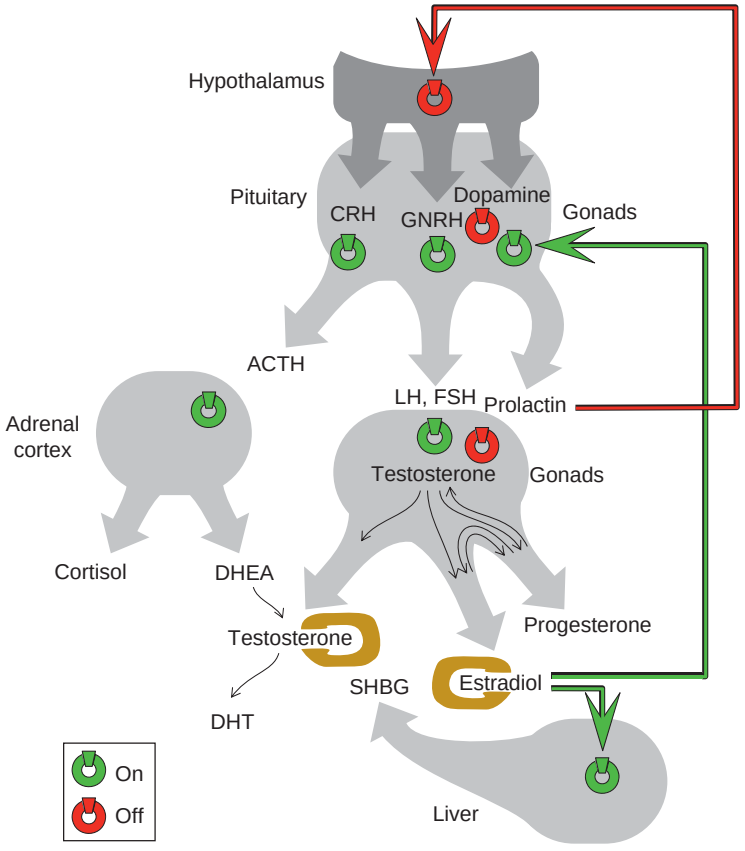

Figure 1 Production, regulation, and interactions of reproductive hormones. The pituitary produces the protein hormones, LH (luteinizing hormone), FSH (follicle stimulating hormone), ACTH (adrenalcorticotropic hormone), and prolactin. LH and FSH stimulate gonadal production of estradiol, progesterone, and testosterone. ACTH stimulates production of cortisol, as well as dihydroepiandrosterone (DHEA). Estradiol stimulates hepatic production of sex hormone binding globulins, which may either sequester steroids, particularly testosterone, reducing their bioavailability, or potentiate their actions by allowing them to bind to unconventional receptors at the surfaces of target cells. Estradiol also increases pituitary production of prolactin. Both prolactin and estrogen mediate negative feedback signals that decrease LH and FSH production.

more pronounced in the lacrimal glands than in other affected organs. This finding led Sullivan and coworkers to propose that the androgens control the expression of critical immunoregulatory paracrine mediators by lacrimal gland epithelial cells. Recent microarray analyses indicate that androgens influence the expression of large numbers of gene transcripts in the lacrimal glands and corneas of mice. Some of the androgen actions might be expected to diminish inflammatory processes. For example, testosterone decreases expression of certain chemokines; interferon (IFN) response factors 4 and 7; caspase-1, which converts the inactive interleukin (IL)-1β precursor to active IL-1β; and the prolactin receptor, which – as discussed below – mediates mitogenic responses both in B and T cells and induces T cells to express IFN-γ. However, other testosterone actions might be expected to enhance inflammatory processes. For example, testosterone increases expression of IL-6; IL-12a; the chemokines CCL1, CCL8, CCL28, CCL5, and CXCL4; CD86; and interferon response factor 5.

Before considering tentative theoretical paradigms that might explain how the androgens might confer protection against dry eye disease, it is necessary to first review the influences other reproductive hormones exert on the lacrimal glands.

Estradiol and Progesterone

Whereas estradiol and testosterone often have opposing actions, Azzarolo and coworkers found that estradiol – like DHT – prevents ovariectomy-induced apoptosis of lacrimal gland plasmacytes. Estradiol does not appear to influence pIgR expression in rat lacrimal epithelial cells. However, tear lactoperoxidase levels vary during the estrus cycle in rats and the menstrual cycle in humans – correlating with the changes in estradiol and progesterone levels. Microarray analyses of mouse lacrimal gland extracts indicate that estradiol and progesterone influence the expression of numerous gene transcripts. They increase expression of the chemokines CCL2 and CXCL15 and decrease expression of FoxP3 – a central transcription factor in regulatory lymphocyte function; these influences might seem consistent with the greater risk for inflammatory lacrimal gland disease in females. However, estradiol and progesterone also decrease expression of CD86, IL-12, and the chemokines CCL6, CCL12, and CCL28 – influences which might be expected to diminish inflammatory responses.

Prolactin

Prolactin is produced by the pituitary gland; as its name implies, its first discovered function was support of lactogenesis and lactation. However, prolactin has also been found to function as an autocrine/intracrine and paracrine mediator in a number of physiological systems. In the immune system, it acts as a mitogenic cytokine for T cells and B cells, and as a differentiation factor for T cells – inducing them to express the prototypical T_H1 cytokine, IFN-γ. Administration of prolactin to hypophysectomized male rats increased Na, K-ATPase catalytic activity in lacrimal gland. However, a number of reports indicate that serum prolactin levels are elevated in women with Sjögren's syndrome and other autoimmune diseases. A study of reproductive hormone influences on lacrimal function revealed that increasing serum prolactin levels within the normal range of values for nonpregnant, nonlactating women were strongly correlated with decreasing lacrimal function – independently of menopausal status and use of estrogen replacement therapy.

Exocrine Products and Autocrine/Intracrine and Paracrine Mediators

While they respond to prolactin as a classic hormone, lacrimal gland epithelial cells also express prolactin, and they secrete it both as an exocrine secretory product and as a paracrine mediator. In the lacrimal glands of normal, nonpregnant female rabbits, immunopositivities for prolactin, as well as for transforming growth factor-beta (TGF-β), EGF, fibroblast growth factor (FGF)-2, are localized preferentially – but not exclusively – in ductal epithelial cells. In both acinar and ductal cells, the cytokine and growth factor immunopositivities are concentrated in the apical cytoplasm. Prolactin is localized in the regulated exocrine secretory vesicles; the mechanisms by which epithelial cells of the rabbit lacrimal gland secrete the other cytokines and growth factors have not been elucidated. Like prolactin and other secretory vesicle-content proteins, TGF-β is released to the fluid forming within the lumen of the acinus-duct system in response to stimulation with cholinergic agonists.

As illustrated in **Figure 1**, lacrimal epithelial cells use their apical recycling endosome and early basolateral endosome as a transcytotic secretory apparatus. It is this apparatus which secretes sIgA and some free SC into the lumena of the acinus-duct system. They also use the early and recycling endosomes as a paracrine secretory apparatus that delivers products to the underlying stromal space. Both transcytotic secretion and paracrine secretion occur constitutively; although they can be accelerated by stimulation with cholinergic agonists, the steady-state pools of secreted products in the endosomes are quite small compared to the pools of products stored in regulated exocrine secretory vesicles. Experiments with *ex vivo* acinar cell models showed that increasing the concentration of prolactin in the ambient medium induces increased transcription of prolactin messenger RNA (mRNA). Increasing epithelial cell prolactin expression or increasing the prolactin concentration in the ambient medium decreased the amount of secretory proteins stored in apical secretory vesicles, and it

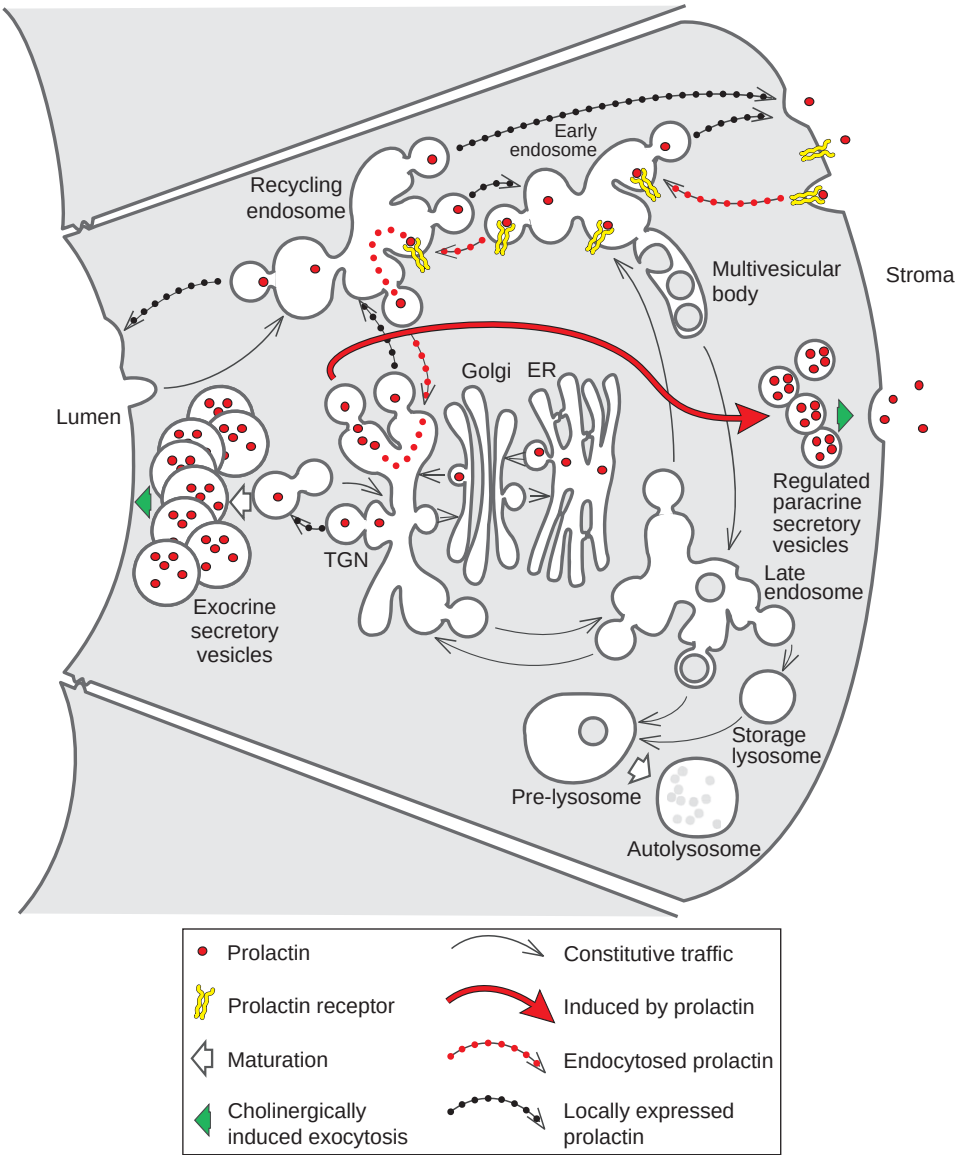

Figure 1 As in other exocrine glands, lacrimal gland epithelial cells use secretory vesicles to secrete proteins into the fluid being produced in the lumena of the acinus-duct system. They also use their early basolateral endosomes and apical recycling endosomes as a transcytotic apparatus to secrete SC and sIgA. Furthermore, the constitutive traffic of transport vesicles from the endosomes to the basolateral plasma membranes secreted paracrine mediators to underlying stromal space. Elevated levels of prolactin induce the cells to express a novel population of regulated paracrine secretory vesicles and decrease their population of exocrine secretory vesicles. The induced paracrine secretory vesicles allow ductal epithelial cells to secrete more prolactin and TGF-β to the stroma, and they allow acinar cells that have endocytosed prolactin from the stroma to recycle it as a paracrine secretory product.

induced the cells to express a novel population of regulated secretory vesicles that accumulated in the basal cytoplasm and released their contents at the basolateral plasma membrane in response to acute cholinergic stimulation.

Immunogold localization studies demonstrated that when acinar cells endocytose prolactin from their ambient medium, they traffic it dually to the endosomes that comprise their constitutive transcytotic-paracrine apparatus and to the secretory vesicles of the novel, induced paracrine apparatus. Thus, when acinar epithelial cells internalize prolactin secreted from the pituitary or from ductal epithelial cells, they may recycle it as a paracrine mediator.

Serum prolactin levels do not differ greatly between normal men and normal, nonpregnant women. However, serum prolactin levels increase markedly during pregnancy, and, by the time a pregnancy reaches term, mean serum prolactin levels are 10- to 20-fold greater than the levels in nonpregnant, nonlactating females. Thus, the physiological hyperprolactinemia of pregnancy has seemed to offer a natural model in which to study prolactin's influences on the lacrimal glands.

Influences of Prolactin, Estradiol, and Progesterone during Pregnancy

The lacrimal glands of nonpregnant, sexually mature female rabbits normally contain small aggregates of lymphocytes and plasmacytes, localized in the stromal spaces surrounding and spanning between venules and interlobular ducts. It might be noted that these are the same sites where the ectopic lymphoid tissues characteristic of Sjögren's dacryoadenitis develop. The immunoarchitecture undergoes a remarkable change during pregnancy, and it remains in the altered state throughout lactation and for some weeks following weaning. By the time a pregnancy reaches term, the aggregates have largely dissipated, and lymphocytes and plasmacytes are primarily located in the thin stromal spaces surrounding acini.

The immunoarchitectural change is associated with several notable cytophysiological changes and functional changes. The basal rate of lacrimal gland fluid production decreases, while the rate of fluid production under cholinergic stimulation increases. Immunopositivities for TGF-β and prolactin increase substantially, and their localizations shift from the apical cytoplasm to the basal cytoplasm. It now appears that these redistributions occur because the novel paracrine secretory apparatus induced by the increased serum prolactin level captures prolactin and TGF-β away from the regulated exocrine secretory pathway. Accordingly, the level of prolactin excreted in lacrimal gland fluid decreases, and TGF-β becomes scarcely detectable.

Experiments that have not yet been published indicate that when ovariectomized rabbits are implanted with sustained-release pellets establishing pregnancy-like serum levels of estradiol and progesterone, the patterns of lymphocyte organization and of TGF-β and prolactin expression and localization change to resemble the patterns characteristic of pregnancy. Thus, estradiol, progesterone, or the two steroid hormones in concert act on ductal epithelial cells to increase their expression TGF-β. They may increase ductal epithelial cell prolactin expression either directly, or indirectly, that is, by increasing pituitary prolactin secretion (see **Box 1**). The increased level of prolactin then directs both mediators away from the regulated exocrine protein-secretion apparatus and directs prolactin into the novel paracrine apparatus.

As discussed below, the changes that occur in the lacrimal glands during pregnancy are analogous to those which occur over roughly the same time in the mammary glands. While the lacrimal glands are accessory organ of the visual system, the mammary glands are accessory organs of the reproductive system. Both glands also are effector organs of the mucosal immune system. Other organs of the male and female reproductive systems also play parallel roles as adaptive mucosal immune system effector organs, and their immunophysiological functions are, likewise, influenced by the reproductive hormones.

Reproductive Hormone Influences on Other Mucosal Immune System Tissues

Neither the testes nor the ovaries are normally populated by IgA^+-plasmacytes. However, in males, IgA^+ cells are abundant in the urethral glands and prostate; they are also present in the seminal vesicles in some species, but not others. Orchiectomizing male rats has little effect on the amount of IgA in the prostate and seminal vesicles; subsequent administration of DHT causes a slight increase of the IgA content of the prostate, but not the seminal vesicle. There is little pIgR expression in the testes, vas deferens, or epididymis, but a significant level of expression in the seminal vesicles and a 20-fold greater level in the prostate. Orchiectomy decreases pIgR expression, and subsequent administration of DHT increases it threefold in the seminal vesicles and fourfold in the prostate. Interestingly, estradiol has no effect on pIgR expression in the seminal vesicles but doubles it in the prostate.

In females, IgA^+ immune cells are abundant in the lamina propria of the fallopian tubes. They are sparse in the endometrium. Since endometrial gland epithelial cells contain IgM^+ and IgA^+, as well as J chain, it may be that the uterine lining secretes Igs derived primarily from the serum, rather than from local plasmacytes. In contrast, IgA^+ cells are abundant within the epithelia and lamina propria of the endocervix, although somewhat less abundant in the ectocervix and vagina. Epithelial expression of pIgR roughly parallels the abundance of IgA^+ cells. The level is significant in the fallopian tubes and endocervix. While there seems to be no clear evidence that pIgR is expressed in the ectocervix and vagina, the level of sIgA in cervical mucus increases just prior to ovulation and remains elevated throughout the luteal phase, and the uterine fluid contains a high level of sIgA throughout pregnancy.

As the alveolar epithelium of the mammary glands develops during pregnancy, ductal epithelial cells are induced to express pIgR, and the glands' stromal spaces become populated by $dIgA^+$-plasmacytes. During lactation, the mammary epithelium secretes sIgA as well as lactoperoxidase and other innate mucosal immune effector molecules. Like the other changes occurring during lactogenesis, the induction of mucosal immune effector functions is controlled by interacting influences of estradiol, progesterone, and prolactin. Most studies of hormonal influences on the mammary glands have been motivated by interest in normal lactogenesis, lactation, and postweaning involution, and in mammary carcinoma – rather than focused on the mammary glands' mucosal immune functions. This work has shown that the systemic hormones orchestrate lactogenesis and lactation, in part, by regulating the expression of autocrine/intracrine and paracrine mediators. The ductal network of the mammary gland develops

during puberty, largely under the influence of estradiol. Prior to pregnancy, TGF-β – which is expressed both by ductal epithelial cells and periductal mesenchymal cells – exerts pro-apoptotic and antiproliferative influences that prevent development of the alveoli – and, during pregnancy, alveolar development depends on the concerted influences of prolactin and progesterone. Increasing progesterone levels increase the abundance of TGF-β, but they also increase expression of EGF, FGF-2, and TGF-alpha (TGF-α) – which abrogate TGF-β's anti proliferative and pro-apoptotic influences. Notably, the expression of prolactin by mammary epithelial cells also increases at this time. Despite its evident synergy with prolactin in promoting lactogenesis, the elevated level of progesterone inhibits lactation. Recent evidence suggests it does so by increasing expression of Wnt-5b, which is thought to maintain the undifferentiated state by promoting nuclear translocation of β-catenin, and by increasing expression of insulin-like growth factor-binding protein (IGFBP-5) – which suppresses insulin-like growth factor signaling. These inhibitory influences are removed and lactation becomes possible at parturition, when production of progesterone is abruptly suppressed.

Certain of the estradiol-, progesterone-, and prolactin-induced mediators that determine development of the mammary epithelium also determine expression of the mammary glands' mucosal immune functions. As reviewed elsewhere in the encyclopedia, TGF-β typically acts as a differentiation factor for immature $dIgA^+$-expressing plasmablasts, inducing them to mature into dIgA-secreting plasmacytes as they arrive at mucosal immune effector sites. Normal plasmacytes – like other bone-marrow-derived cells – express an intrinsic apoptotic program, and their ongoing survival requires that this program be abrogated by survival signals from the local milieu. As noted above, prolactin plays a role in inducing ductal epithelial cells to express pIgR. Its known mitogenic influences on T cells and B cells suggest that it may also act as one of the factors which support the mature plasmacytes' survival. Thus, prolactin may contribute to a counterpoise against plasmacyte's apoptotic program as well as against the pro-apoptotic and antiproliferative influences TGF-β would otherwise exert on both the plasmacytes and the alveolar epithelium. Evidently, this counterpoise is maintained as the levels of TGF-β, prolactin, and other estrogen- and progesterone-dependent factors increase during pregnancy, and it supports expansion of the population of plasmacytes that will produce dIgA for secretion in the milk.

Similar interactions between the sex steroids and prolactin may account for the reproductive hormones' influences on the other mucosal effector organs of the female and male reproductive systems, and the data available so far indicate that they do so for the lacrimal glands, as well.

Counterpoises between Contradictory Signals

Figure 2 summarizes the spatial and temporal actions of the differentiation and survival factors, as they are organized in the lacrimal glands. The notions that plasmacytes express an intrinsic apoptotic program which must constantly be abrogated and that the steady-state pools of paracrine secretory products in lacrimal epithelial cells are small may help explain why they begin undergoing apoptosis so abruptly after ovariectomy. The pools of paracrine secretory products would deplete rapidly after the signals that support their ongoing expression are removed. Unpublished findings that prolactin immunoreactivity is present in the nuclei of plasmacytes seem to confirm that prolactin is one of the lacrimal epithelial paracrine mediators the influence plasmacytes. This may only be part of the explanation; however, and it is possible that testosterone, estradiol, and, perhaps, progesterone as well also might interact with prolactin and other survival factors to generate synergistic signals that maintain plasmacyte survival.

While prolactin may be one of several factors that provide mitogenic signals abrogating TGF-β's pro-apoptotic and antiproliferative influences, it appears that TGF-β may provide a counterpoise to prolactin's lymphoproliferative and proinflammatory influences. As reviewed elsewhere in the encyclopedia, there is evidence that the transcytotic apparatus mucosal epithelial cells use to internalize dIgA and release sIgA into the fluid they produce inevitably secretes a significant burden of autoantigens to the underlying stromal spaces. Thus, newly matured dendritic cells that emigrate from the lacrimal glands to the draining lymph nodes carry with them lacrimal epithelial autoantigens. They process the autoantigens to generate epitopes that their surface MHC class-II molecules will present to $CD4^+$ T cells, and they also release the autoantigens for sampling by IgM^+-B-cell antigen receptors. There is now evidence that TGF-β induces immature dendritic cells to mature into immunosuppressive antigen-presenting cells that prevent proliferation of autoreactive lymphocytes within the lacrimal glands and draining lymph node. Moreover, it is possible that dendritic cells that have matured within the lacrimal glands might also function as tolerogenic antigen-presenting cells – inducing the generation of T_H3 or T_R1 regulatory cells.

Microarray studies have clarified that the reproductive hormones influence the expression of other cytokines and growth factors apart from TGF-β and prolactin in the lacrimal glands. Further work will be needed to determine the extents to which the various mediators are expressed by infiltrating immune cells, acinar and ductal epithelial cells, and mesenchymal cells. Other factors in addition to the reproductive hormones are likely to influence epithelial expression of TGF-β and of prolactin and the plasmacyte

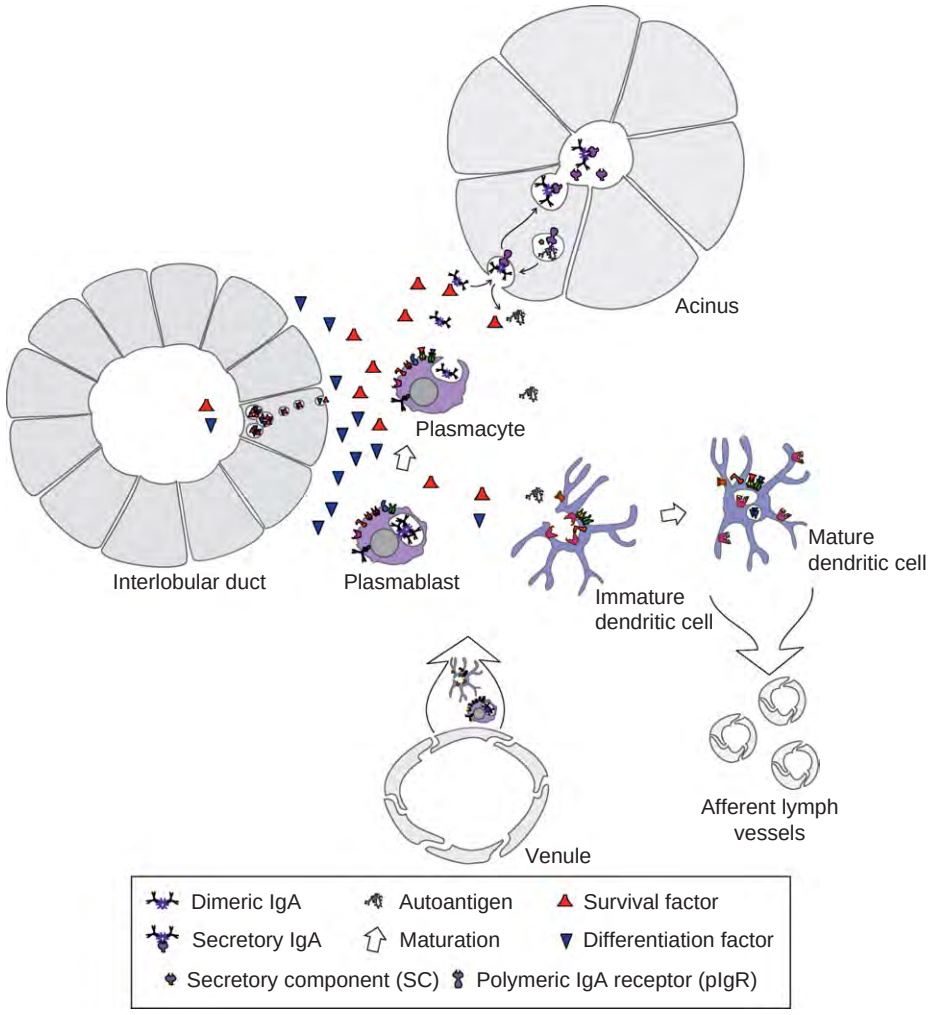

Figure 2 Interlobular duct epithelial cells produce both differentiation factors, such as TGF-β and IL-10, which may also exert pro-apoptotic and immunoregulatory influences. They also produce survival factors, such as EGF, FGF, and prolactin, some of which also may exert mitogenic and proinflammatory influences. The counterpoises of contradictory influences maintain for the lacrimal glands' exocrine functions as well as their mucosal immune functions. For example, TGF-β may support expression of the ductal epithelial phenotype, while FGF, EGF, and prolactin may support both survival of the ductal epithelium and development and survival of the acini. TGF-β induces plasmablasts to undergo terminal differentiation to dIgA-secreting plasmacytes, while prolactin may be one of several mediators that support the plasmacytes' ongoing survival. TGF-β also induces immature dendritic cells that have taken up lacrimal autoantigens to differentiate as regulatory antigen presenting cells.

survival factors. Nevertheless, the concept that the reproductive hormones orchestrate counterpoises between contradictory signals, summarized in **Figure 3**, may lead to detailed paradigms that explain why Sjögren's dacryoadenitis and the common histopathological syndrome are both so much more prevalent among women, and why the onset of clinical dry eye disease is associated with events of the reproductive cycle and life cycle. There are several physiological states during which prolactin-mediated influences might become excessive with respect to the available counterpoises (see **Box 1**). Given the burden of epithelial autoantigens constitutively present in the stromal space of the lacrimal glands, one might predict that such states favor the accumulation of autoreactive T cells and B cells. In a direct experimental test of the hypothesis, an adenovirus vector was used to transiently increase prolactin expression in lacrimal glands of mature female rabbits. As has been reported in preliminary form, increased abundance of prolactin transcripts was accompanied by increased abundances of mRNAs for IFN-γ and TGF-α, as well as accumulation of large lymphocytic infiltrates and apparent formation of germinal centers. Moreover, the lymphocytic foci persisted for weeks after the prolactin mRNA levels returned to normal. Of interest also is a recent report that, after having a primary relative with an autoimmune disease, carrying a pregnancy to term is the second greatest risk factor for Sjögren's syndrome appears to accord with this prediction. Both findings suggest that autoimmune activation can be suppressed after systemic hormone levels have returned to normal, but that autoreactive memory cells

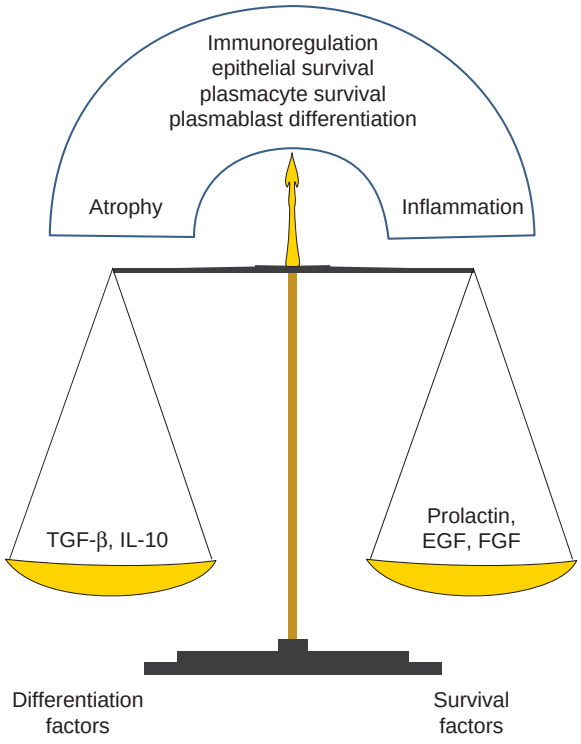

Figure 3 The capacity of the lacrimal gland to perform its exocrine functions – that is, secretion of electrolytes, water, and proteins – and its mucosal immune functions – that is, maintenance of a population of mature, dIgA-secreting plasmablasts and transcytotic delivery of sIgA into the fluid being produced, while avoiding autoimmune inflammatory processes – depends on a system of counterpoises between contradictory influences. The reproductive hormones influence expression of many of the paracrine mediators that exert those influences.

may persist and become activated as the age-related loss of reproductive steroids changes the immunoregulatory signaling milieu within the lacrimal glands.

Lacrimal Gland Overview

M C Edman, R R Marchelletta, and S F Hamm-Alvarez, University of Southern California School of Pharmacy, Los Angeles, CA, USA

Glossary

Acinus – Originating from the Latin word grape, it refers to the sac-like ending of a secretory exocrine gland.
Endocytosis – The process of internalization of plasma membrane as well as membrane-bound constituents and extracellular fluid by invagination of the plasma membrane, budding of the membrane vesicle, and its movement to the interior. Different types of endocytosis are known, including clathrin-mediated and caveolar endocytosis.
Exocytosis – The process by which a cell releases the contents of secretory vesicles to the extracellular environment by fusion of secretory vesicles with a plasma membrane domain.
Motor proteins – Mechanochemical proteins that utilize the energy of ATP hydrolysis to generate motive force along a polar surface, typically an actin filament or a microtubule.
Rab proteins – Small GTP-binding proteins that utilize the GTP binding and hydrolysis cycle to trigger protein on and off states, and which serve as molecular zip codes to specify the accurate sorting and targeting of membranes.
SNARE proteins – Proteins associated with donor and acceptor membranes which associate to form a fusion pore, allowing the contents of opposing membrane vesicles to intermingle, or allowing the extrusion of membrane-encapsulated contents to the cell exterior.
Transcytosis – The process by which macromolecules are transported through a polarized cell.
***trans*-Golgi network** – A post-Golgi processing compartment responsible for the accurate segregation of contents into membrane vesicles destined for regulated exocytosis, constitutive exocytosis, or for targeting to intracellular membrane compartments.

Anatomy of the Main Lacrimal Gland

The human main lacrimal gland, located laterally above the eye, measures approximately $20 \times 12 \times 5$ mm and has an almond-like shape. The major part of the gland, designated as the orbital portion, or the intraorbital gland, is located in the shallow lacrimal fossa of the frontal bone, while the smaller palpebral, or extraorbital portion, which is separated from the orbital portion by the lateral horn of the levator palpebrae muscle, is located above the temporal segment of the superior conjunctival fornix. In contrast, the mouse and rat have two pairs of lacrimal glands including a small orbital gland which is located laterally beneath the upper lid and a larger extraorbital gland which is located ventral and anterior to the eye. The rabbit lacrimal gland is unusually large and is comprised of a larger portion (4 cm) located below the eye and a smaller portion (0.5 cm) located above the eye. The lacrimal gland is constituted largely (80%) of acinar epithelial cells organized within the tubuloacinar units that are arranged into multiple globuli surrounded by fibrovascular septa. The remaining 20% of the mass of the lacrimal gland is composed of ducts, nerves, myoepithelial cells, leukocytes, and connective tissue. A schematic diagram showing the positioning of the gland relative to the ocular surface and the organization of several of the cell types within the gland is shown in **Figure 1**.

Cell Types within the Lacrimal Gland

Acinar Cells

The acinar epithelial cells within the lacrimal gland are triangular-shaped cuboidal cells organized in single cell layers in clusters with a narrow microvillus-covered apical domain oriented toward a central lumen and a more extensive basolateral domain which faces the tissue interstitium. Tight junctions near the apices segregate these two domains and result in polarization of the cells, which also are cytoplasmically coupled through gap junctions, thus making the acinus a single functional unit. The apical side of the cell is enriched in numerous large (1–2 μm) secretory granules or vesicles, containing proteins released upon cell stimulation, while the Golgi apparatus and endoplasmatic reticulum compartments are located more toward the basolateral side adjacent to the basolateral nucleus. **Figure 2** shows the characteristic distribution of secretory vesicles and other organelles within an acinar cell from mouse lacrimal gland.

Ductal Cells

The lumena of several acini come together to form a duct; each duct merges with others into gradually larger ducts

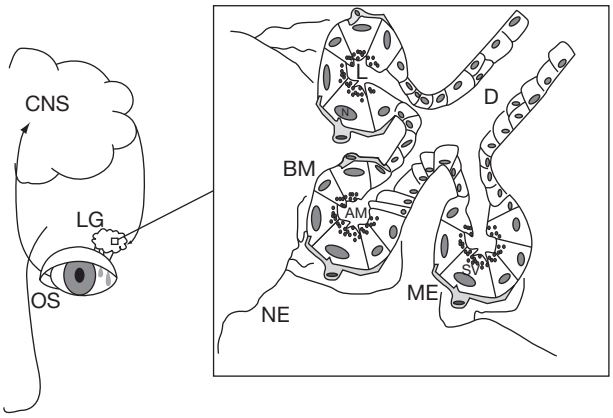

Figure 1 Schematic diagram showing the positioning of the human main lacrimal gland relative to the ocular surface and the organization of several of the cell types within the gland. AM, apical membrane; BM, basolateral membrane; CNS, central nervous system; D, duct; L, lumen; LG, lacrimal gland; ME, myoepithelial cell; N, nucleus; NE, nerve ending; OS, ocular surface; SV, secretory vesicle.

that finally, in humans, drain into 6–12 major ducts with openings in the upper lateral fornix. In rat and mice, the ducts from the extraorbital gland join to a single major duct that then joins the duct from the intraorbital gland before it empties onto the conjunctiva in the lateral canthus of the eye. In rabbit, a single duct each forms from the upper and lower portions of the gland, which empty onto the conjunctiva of the upper and lower lids, respectively, near the temporal angle. The ducts are formed by one to two layers of cuboidal epithelial cells. Similar to the acinar cell, the ductal epithelial cells of small ducts are polarized by tight junctions in the apical area. However, in these cells, the Golgi and endoplasmic reticulum are located more apically, and secretory vesicle content is lower. Interlobular ducts are embedded with and supported by perivasculoductal connective tissue containing associated structures such as nerve fibers, capillaries, and mast cells and a dense population of fibroblast-associated collagen fibrils.

Myoepithelial Cells

The acini are surrounded by stellate-shaped myoepithelial cells with long slender processes. The myoepithelial cells not only exhibit characteristics of other epithelial cells, such as expression of cytokeratin, but also exhibit properties of smooth muscle cells such as expression of α-smooth muscle actin. The exact role of the myoepithelial cells in the regulation and maintenance of the lacrimal gland remains unclear, but it has been shown that they express receptors for neurotransmitters, suggesting that they play a role in facilitating the secretion from the lacrimal gland. It is also likely that an important role is to support and maintain the structure of the lacrimal gland.

Bone-marrow-derived Cell Population

The lacrimal gland is a part of the mucosal-associated lymphoid tissue (MALT). The bone-marrow-derived cells in the lacrimal gland are mainly immunoglobulin A (IgA)-producing plasma cells and T and B lymphocytes, but macrophages and mast cells are also present. The bone-marrow-derived cells are clustered into lymphoid follicles scattered in the stroma surrounding the acini.

Innervation of the Lacrimal Gland

The lacrimal gland is innervated by parasympathetic, sympathetic, and sensory nerves. Parasympathetic nerves originate in the lacrimal nucleus of the pons and travel along the nervus intermedius, the deep and superficial petrosal nerves, and the vividian nerve before they synapse in the pterygopalatine ganglion. The postganglionic parasympathetic fibers can take different routes to the lacrimal gland. They leave the ganglion through the pterygopalatine nerves but can also reach the lacrimal gland via the maxillary portion of the trigeminal, the zygomatic, or the lacrimal nerves. Parasympathetic fibers can also travel along a branch of the middle meningeal artery to join the ophthalmic or lacrimal artery *en route* to the lacrimal gland. Sympathetic nerves originate from the superior cervical ganglion and travel along with the parasympathetic nerves through the pterygopalatine ganglion, reaching the lacrimal gland through the lacrimal branch of the zygomatic branch of the maxillary trigeminal nerve that joins the ophthalmic branch of the trigeminal nerve. The sensory nerves innervating the lacrimal gland carry sensory information from the gland through the ophthalmic branch of the trigeminal nerve to the trigeminal ganglion.

The parasympathetic nerves, being the most abundant, regulate the lacrimal gland mainly through the release of neurotransmitters, acetylcholine and vasoactive intestinal

peptide (VIP), with a possible co-secretion of nitric oxide (NO). Acetylcholine activates M_3 muscarinic receptors located in the basolateral membrane of the lacrimal cells, while VIP binds to VIP receptors that are similarly located. The sympathetic nerves exert their effects on the lacrimal gland through release of norepinephrine that binds to α- and β-adrenergic receptors, and possibly through neuropeptide Y receptors also located at the acinar cell basolateral membranes. The sensory nerves release substance P and calcitonin gene-related peptide. Not every individual acinar cell is independently innervated; rather cells that are not directly innervated can respond to stimulation of neighboring cells due to the intercellular gap junctions that connect the cells. The density of synapses within each acinus varies according to the species: in the rat, orbital glands fewer than 15% of acinar cells have an adjoining nerve fiber in contrast to the mouse orbital glands where close to 100% of the cells have an adjoining nerve fiber.

Blood Supply

The main blood supply to the lacrimal gland is not only through the lacrimal artery, a branch of the ophthalmic artery, but it also receives minor contributions from the infraorbital and the meningeal arteries. The veins mainly follow the same pathways as the arteries inside the orbit and drain into the superior ophthalmic vein.

Contents of Lacrimal Fluid

The tear film consists of three layers: a mucus layer located directly above the ocular surface epithelium, an aqueous layer, and a thin external lipid layer. The lacrimal fluid produced by the main lacrimal gland constitutes the major part of the aqueous layer of the tear film, to which the accessory glands of Krause and Wolfring and the ocular surface epithelium also contribute, in a minor fashion. Although the major part of the aqueous layer is water, it also contains electrolytes and a high concentration of proteins. Human tear fluid, for instance, has a protein concentration of about $8\,\mu g\,\mu l^{-1}$. Although the three layers of the tear film largely originate from different sources, these sources can contribute in part to each layer; therefore, it is hard to determine the origin of a specific protein. Recently, researchers identified 419 different proteins in human tear fluid; however, many of these may not have an active function in the tear fluid but are simply debris shed from epithelial cells. Three proteins constitute 80% of the total protein within the aqueous tear film, that is, lipocalin, lysozyme C, and lactoferrin. The functions of the different proteins in the tear fluid are varied. For instance, many proteins contribute to the antimicrobial properties of the tear fluid. Secretory IgA and cytokines are involved in immune responses, while others such as lysozyme C and lactoferrin provide a more direct defense against bacteria. The novel protein, lacritin, acts as a mitogen in corneal regeneration. Other proteins in the lacrimal fluid are involved in diverse activities in wound healing, blood coagulation, and oxidative stress reduction – all functions essential to maintain a healthy ocular surface. The protein pattern of both active and inactive proteins in the tear fluid can reflect disease states, including diabetes, dry eye, and cystic fibrosis.

Mechanisms of Protein Secretion in the Lacrimal Gland

The acinar cells of the lacrimal gland are professional excretory cells that engage in several types of secretion that collectively contribute to the lacrimal fluid. Protein secretion at the apical membrane into lacrimal fluid can be subdivided into several types: regulated exocytosis, constitutive exocytosis, and transcytosis. Regulated exocytosis is a process in which proteins destined for a particular plasma membrane domain are sorted into secretory vesicles after their biosynthesis within a post-Golgi sorting compartment called the *trans*-Golgi network. These secretory vesicles mature and migrate toward the site of release, where they are stored until the appropriate signal triggers their movement and fusion with the acceptor membrane domain. Examples of content proteins thought to be released from the lacrimal acini in animal model systems through regulated exocytosis at the apical plasma membrane include peroxidase and β-hexosaminidase. Constitutive exocytosis occurs, similarly, as components for release to the exterior of the cell are sequestered into vesicles at the *trans*-Golgi network that are immediately targeted to the acceptor membrane. Unlike regulated exocytosis, constitutive exocytosis is not reliant on extracellular activation of receptors by a ligand (such as a hormone or a neurotransmitter) to elicit the event. Although both forms of exocytosis have been observed in lacrimal acini, most studies have focused on the role of regulated exocytosis in the release of proteins at the apical plasma membrane of the acinar cell into lacrimal fluid. The secretory vesicles in the lacrimal gland acinar cells are generally larger (1–2 μm) and considerably more heterogeneous in both size and content compared to vesicles in other exocrine glands such as exocrine pancreas and the salivary gland. The spectrum of proteins secreted from the lacrimal acinar secretory vesicles appear to span a greater functional range than the spectrum release from other exocrine tissues as well, including nutrient and protective factors as well as factors that protect the mucosal surface from pathogens. This is an area of very active research since there are an unusually large number of

proteins of unknown function in the lacrimal gland secretory proteome.

Transcytosis is a process in which material internalized at the basolateral membrane is recruited into vesicles by endocytosis, followed by the movement of these vesicles to apically located compartments, and ultimately their targeting to the apical plasma membrane for release. Major cargo known to be carried through this pathway includes dimeric IgA, through association with the polymeric IgA receptor. Although not specifically characterized in lacrimal acini, other abundant tear proteins, including albumin and transferrin, are known to be transported through transcytotic pathways in other epithelial cells, suggesting that these proteins may be comparably transcytosed into lacrimal fluid by lacrimal acini.

Regulated exocytosis and transcytosis utilize a number of different processes, globally referred to as membrane trafficking, to achieve the unidirectional transport of cargo-laden vesicles over short and long distances followed by their targeted release. Several of these processes have been studied in acinar cells, including cytoskeleton and motor proteins, rab proteins, and soluble *N*-ethylmaleimide-sensitive factor attachment protein receptors or SNARE proteins. All mammalian cells contain filamentous structures collectively referred to as the 'cytoskeleton', which includes actin filaments, intermediate filaments, and microtubules. Each of these structures is formed from individual subunit proteins that exist in equilibrium with polymeric assemblies. Cytoskeletal filaments are critical in maintaining the integrity of cell shape as well as conferring cellular polarity or asymmetry, a function critical in aiding the movement of materials to different membrane domains in a polarized cell. Filamentous actin and microtubules, in particular, participate in several capacities in the movement of membrane vesicles to the apical plasma membrane, where the release of proteins into lacrimal fluid takes place. Microtubule- and actin-dependent membrane transport events can be facilitated either by the use of compressive force associated with cytoskeletal assembly to physically compress or direct membrane traffic, and/or by the use of these polymers as tracks which support the movement of motor proteins which carry membrane vesicles to specific destinations.

In lacrimal acini, actin filaments are localized in a dense network below the apical membrane called the subapical actin network, and this network is also present to a lesser extent below the basolateral membrane. Beneath the subapical actin, the ends of microtubules are anchored. Microtubules extend from the subapical region to the basolateral membrane. Both actin filaments and microtubules sustain aspects of protein secretion in lacrimal acinar cells. When microtubules are disrupted in acinar cells using the agent, nocodazole, stimulated protein secretion is reduced because the microtubule scaffolding required for vesicle motility has been disrupted. Other studies have suggested that a particular motor protein, cytoplasmic dynein, is required for the movement of membrane vesicles involved in secretory vesicle maturation and, possibly, transcytotic vesicle transport, to the subapical cytoplasm.

The subapical actin cytoskeleton plays complex roles in lacrimal acinar secretion. With its location immediately beneath the apical plasma membrane in a dense network, it poses an intracellular barrier for vesicle fusion to the apical membrane. For fusion to occur, this actin barrier must be disassembled to allow access of large secretory vesicle to the apical plasma membrane. Recent work has shown in fact that regions of the actin cytoskeleton located immediately beneath the regions of apical plasma membrane do disassemble, but that actin filaments also reassemble and contract around the base of multiple fusing secretory vesicles. The force generated through compression and retraction of actin filaments toward the apical membrane aids in compound fusion and content extrusion from the fusing vesicles. Regulated exocytosis can therefore be further characterized in lacrimal acini into a type known as multivesicular exocytosis. Two specific actin-dependent motors have been implicated so far in this actin remodeling and compound fusion of activated secretory vesicles, a conventional myosin motor known as nonmuscle myosin 2 and an unconventional myosin motor known as myosin 5c, with the possibility that other members of the myosin motor superfamily may also participate in this complex process.

Other major membrane trafficking effectors that have been implicated in acinar cell protein secretion include rab proteins. Rabs are major effectors of all intracellular steps of membrane trafficking and fusion in the eukaryotic cell, serving as the molecular address code on donor membrane vesicles which specify the acceptor compartment destination. GTP binding and hydrolysis serves as the on/off switch that activates these proteins. Specific rabs are localized to distinct compartments, conferring identity to these compartments. For instance, rab3D is enriched in secretory vesicles in lacrimal acinar cells and appears to regulate compound fusion of these vesicles. Other data suggest that rab27 isoforms also participate in the maturation and fusion of secretory vesicles during regulated exocytosis in lacrimal acini. By analogy with other systems, rab4 and rab5 isoforms are likely to participate in early events in acinar transcytosis, specifically basolateral endocytosis and sorting, while rab 11 isoforms are enriched in apical endosomes and may facilitate terminal transcytotic traffic of materials destined for the lacrimal fluid.

Specific types of SNARE proteins are located on donor and acceptor membranes and interact to form fusion pores which allow membrane contents to mingle or secretory vesicle contents to be extruded to the cell exterior. Several types of SNARE proteins have been demonstrated in lacrimal acini. Regulated exocytosis of secretory vesicles in acini is thought to use both vesicle-associated

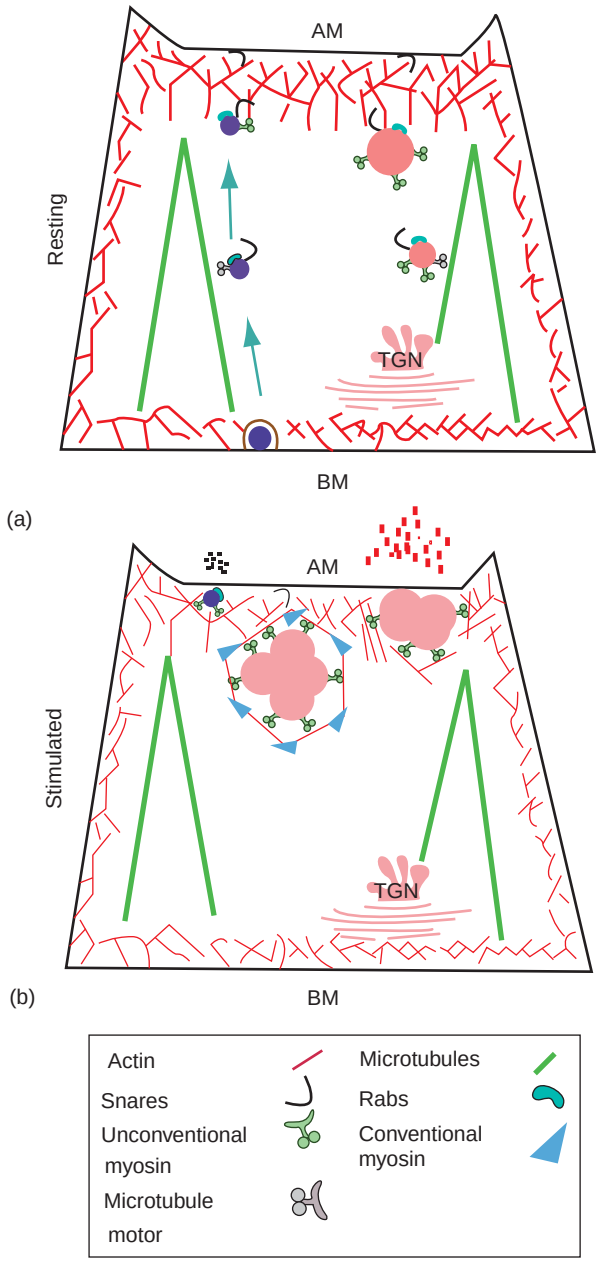

Figure 3 Protein secretion in lacrimal acinar cells at the apical membrane. (a) Depicts vesicles participating in the transcytotic pathway from the basolateral membrane (BM) to the apical membrane (AM) as shown in blue vesicles. Depicted as well is the maturation and movement to the AM of secretory vesicles after budding from the *trans*-Golgi network (TGN) as shown in red vesicles. Initially both transcytosis from the BM and movement from the TGN are reliant on microtubule-based motor proteins. As the vesicles move to the actin-rich subapical region, unconventional myosin motors become important in actin-based movement through the subapical actin network. (b) Depicts multivesicular exocytosis after stimulation with secretogogs such as carbachol. Unconventional myosins such as myosin 5c have been shown to have an important role in the reorganization of actin filaments around clusters of secretory vesicles primed for fusion. Actin and conventional myosins then work together to compress the fusing secretory vesicles and to promote content extrusion. Rab and SNARE proteins participate in the targeting and fusion events in each pathway. It should be noted that the rabs and the SNAREs participating in transcytosis and exocytosis are different for each pathway.

membrane protein 2 (VAMP 2) and VAMP 8 on donor membranes, and syntaxin 2 and SNAP23 on acceptor membranes. Figure 3 shows the organization of the two major protein secretory pathways that contribute proteins to lacrimal fluid: regulated exocytosis and transcytosis, as well as some of the effectors within each pathway.

Morphological analysis of ductal epithelial cells has revealed the presence of large secretory vesicles, presumably containing additional constituents destined for release into the lacrimal fluid. However, due to limitations in the ability to isolate these individual cells and conduct cellular investigations into the membrane trafficking mechanisms, little is known about the precise mechanisms involved in ductal cell exocytosis and transcytosis.

Mechanisms and Regulation of Electrolyte and Water Secretion by the Lacrimal Gland

Acinar Cells

The lacrimal fluid is hypertonic due to a high Cl^- and K^+ content, whereas the levels of Na^+, HCO_3^-, and Ca^{2+} are similar to the plasma levels. The electrolyte concentration of the lacrimal fluid is however not static, but varies with the flow rate to become more isotonic with an accelerated flow rate. Fluid secretion is an osmotic process driven by ion movement through the membrane of the acinar cells. Parasympathetic stimulation of the acinar cells triggers an acute increase of cytosolic Ca^{2+} and adenosine 3′,5′-cyclic monophosphate (cAMP) which opens Cl^- channels in the apical membrane, resulting in a movement of Cl^- into the lumen. The increase in cytosolic Ca^{2+} also activates K^+ channels in the apical as well as the basolateral membrane, causing K^+ to move out of the cell. Na^+ follows the flux of Cl^- and K^+, moving from the basolateral side toward the lumen traveling through paracellular channels between the cells. To maintain an isotonic secretion, water exits the cell through water-channel proteins called aquaporins. The movement of Cl^- and K^+ out of the cell is dependent on their electrochemical gradient, that is, the intracellular concentration of these ions must be higher than in the extracellular fluid. This is made possible by ion pumps and co-transporters located in the basolateral membrane. Na^+/K^+-ATPase transports K^+ into the cell and Na^+ out of the cell; the $Na^+/K^+/2Cl^-$ co-transporter (NKCC1) moves all three ion types into the cell; and Cl^-/HCO_3^- and Na^+/H^+ anti-porters transport Cl^- and Na^+ into the cell and H^+ and HCO_3^- out of the cell. Figure 4 illustrates the ion channels and transporters present in the lacrimal acinar cell.

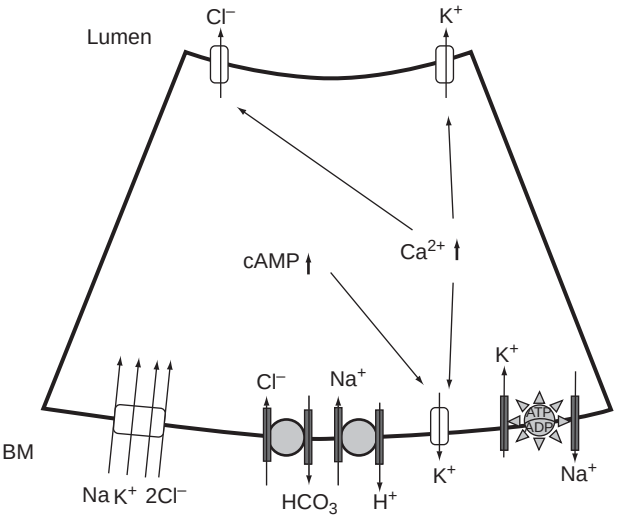

Figure 4 Schematic diagram showing the major ion transporters active in the electrolyte and water release from the lacrimal gland acinar cell. Increases in cytosolic Ca^{2+} and cAMP following neural stimulation opens K^+ and C^- channels, resulting in an outward flux of these ions. Na^+/K^+-ATPase transports K^+ into the cell and Na^+ out of the cell, the $Na^+/K^+/2Cl^-$ co-transporter moves all three ion types into the cell, and Cl^-/HCO_3^- and Na^+/H^+ anti-porters transport Cl^- and Na^+ into the cell and H^+ and HCO_3^- out of the cell.

Ductal Cells

Due to difficulties in specifically isolating the ductal cells, the ion transport mechanisms have not been extensively studied. However, it has been hypothesized that the water and ion transport events continue as the lacrimal fluid travels through the ductal system in a pattern comparable to that in the acinar cells. Recently, several approaches to study the ductal cells have been developed, including microdissection and culturing of individual ducts and laser capture microdissection of individual ductal cells. In these studies, some of the most common acid/base transporters were characterized in the ductal cells. The same work also showed that the ion transport in the ductal cells can be regulated by parasympathetic neurotransmitters. Furthermore, studies showed that the lacrimal fluid released from the acinar cells is isotonic, leading to the hypothesis that the ductal cells are responsible for the high K^+ levels in tears. The finding that Na^+K^+-ATPase and NKCC1 are expressed at higher levels in the ductal cells than in the acinar cells supports this hypothesis.

Conclusion

Previous and ongoing studies have established many of the functions of the principal cells of the lacrimal gland. The major cell type, the acinar cell, is responsible for the regulated release of proteins, fluid, and electrolytes into the lacrimal fluid, while ductal cells appear to further modify the electrolyte composition and likely also contribute additional proteins to the aqueous tear film. Some of the signaling pathways have been elucidated that stimulate the production of lacrimal fluid, while some of the molecular mechanisms involved in the fundamental exocytotic and transcytotic events have likewise been elucidated. However, the complexity of the signaling and membrane trafficking events even in lacrimal acinar cells, the best-studied cell type in this complex organ, means that considerable work remains to be done. Although some insights regarding changes in signaling and membrane trafficking pathways that result in altered production of lacrimal fluid have been obtained in dry eye disorders, considerable additional work is required in order to truly understand the etiology of these disorders. In some studies, changes in tear protein composition have been associated with dry eye disorders, so future challenges also include the identification of tear biomarkers that can be used to diagnose different types of dry eye disorders to aid in determination of the appropriate course of treatment.

Lacrimal Gland Signaling: Neural

D Zoukhri, Tufts University, Boston, MA, USA

Glossary

Acinar cells – Highly polarized epithelial cells that form an acinus and whose primary function is to secrete proteins, electrolytes, and water.
Exocytosis – The process in which molecules (such as secretory proteins) in a membrane-enclosed vesicle (secretory vesicle or granule) fuse with the plasma membrane and are then released outside the cell.
Muscarinic receptors – A subtype of receptors for the neurotransmitter acetylcholine that is more responsive to muscarine than nicotine.
Neurotransmitters – Chemicals released by neurons to modulate the function of a target cell.
Preocular tear film – A complex and highly structured moist film which covers the bulbar and palpebral conjunctiva, and the cornea. It is composed of water, electrolytes, proteins, mucins, and lipids.
Signal transduction – The biochemical events that conduct the signal of an external stimulus from the cell exterior, through the cell membrane, and into the cytoplasm.

Anatomy of the Lacrimal Gland

The lacrimal gland is a compound tubuloalveolar serous gland composed primarily of acinar, ductal, and myoepithelial cells (Figure 1). Acinar cells account for over 80% of the cell type present in the lacrimal gland and form the site for synthesis, storage, and secretion of proteins. Several of these proteins have antibacterial or growth factor properties and are crucial to the health of the ocular surface. Acinar cells are highly polarized cells with tight junctions surrounding each acinar cell on the luminal side and thus separating the plasma membrane into apical (luminal) and basolateral (serosal) components. The basal portion of the cell contains a large nucleus, rough endoplasmic reticulum, mitochondria, and Golgi apparatus, while the apical portion is filled with secretory granules.

Like the acinar cells, the duct cells are also polarized with the nuclei located basolaterally, whereas the rough endoplasmic reticulum and mitochondria are more apical. The primary function of the ductal cells is to modify the primary fluid secreted by the acinar cells by absorbing or secreting water and electrolytes. The duct cells secrete a KCl-rich solution so that the final secreted lacrimal gland fluid is rich in K^+. It has been estimated that as much as 30% of the volume of the final lacrimal gland fluid is secreted by the duct cells.

The myoepithelial cells lie scattered between the acinar and ducts cells and the basement membrane and are interconnected by gap junctions and desmosomes. These cells are highly branched and contain multiple processes which surround the basal area of the acinar cells (Figure 1). The myoepithelial cells are thought to contract because they contain muscle contractile proteins (α-smooth muscle actin, myosin, and tropomyosin). The contraction of these cells would help expel the fluid out of the acini and the ducts onto the ocular surface. In support of a functional role of lacrimal gland myoepithelial cells, receptors and intracellular signaling molecules for parasympathetic neurotransmitters have been described.

The lacrimal gland contains other cells: plasma cells, B and T cells, dendritic cells, macrophages, and mast cells. Immunoglobulin A (IgA)-positive plasma cells account for the majority of the mononuclear cells in the lacrimal gland. These cells synthesize and secrete IgA, which then is transported into acinar and ductal cells and secreted by these epithelial cells as secretory IgA.

Neural Control of Lacrimal Gland Secretion

To ensure adequate production of the aqueous component of the preocular tear film, lacrimal gland secretion is under tight neural control. To this end, the lacrimal gland is densely innervated by the parasympathetic and sympathetic nervous system (Figure 2). Although scarce, sensory nerves are also present in the lacrimal gland (Figure 2). Nerves are located in close proximity to acinar, ductal, and myoepithelial cells, as well as blood vessels, and hence can control a wide variety of lacrimal gland functions. While each individual cell may not be innervated, gap junctions electrically and chemically connect cells within an acinus so that even noninnervated cells can respond to the neural stimulus.

In the lacrimal gland, parasympathetic nerves contain the neurotransmitters acetylcholine and vasoactive intestinal peptide (VIP). Sympathetic nerves contain the neurotransmitters norepinephrine and neuropeptide Y (NPY).

Sensory nerves contain the neurotransmitters substance P and calcitonin gene-related peptide (CGRP). Acetylcholine and VIP are potent stimuli of lacrimal gland protein and electrolyte/water secretion. Norepinephrine is also a potent stimulus of protein secretion, but a weak stimulus of electrolyte/water secretion. In contrast, NPY and CGRP are weak stimuli of protein secretion, while substance P does not appear to stimulate either protein or electrolyte/water secretion.

The stimulation of lacrimal gland secretion occurs through a neural reflex arc originating from the ocular surface (Figure 3). Neural reflexes are initiated by stimulation of the afferent sensory nerves of the cornea and conjunctiva or by activation of the optic nerve in response to intense light. Efferent parasympathetic and sympathetic nerves of the lacrimal gland are then activated to release their neurotransmitters (Figure 3). The neurotransmitters interact with and activate specific receptors located on the basolateral membranes of acinar and duct cells, which then initiates a cascade of intracellular events known as signal transduction. Activation of these signal transduction pathways induces fusion of the preformed secretory granules with the apical membrane to release secretory proteins into the lumen (Figure 3). To trigger electrolyte and water secretion, ion channels and pumps, located in the apical and basolateral membranes, are also activated.

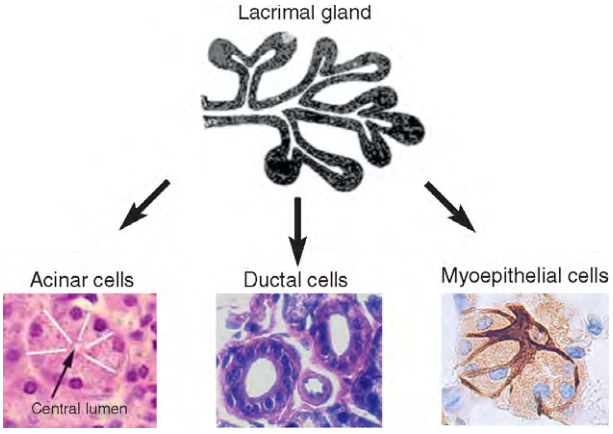

Figure 1 Schematic of the lacrimal gland and photomicrographs showing the three major cell types that it is composed of. The acinar cells, which account for 80% of the cell type present in the lacrimal gland, and ductal cells were stained with hematoxylin and eosin. The myoepithelial cells were identified immunohistochemically (brown stain) using an antibody against α-smooth muscle actin.

Signal Transduction Pathways Activated in the Lacrimal Gland

Signal transduction proceeds in three steps: (1) initiation of the signal by interaction of the ligand (neurotransmitter, neuropeptide, or hormone) with its receptor; (2) amplification of the signal through the interaction of the receptor/G protein/effector enzyme leading to the generation of second-messenger molecules; and (3) termination of the signal through the action of protein phosphatases and membrane pumps to bring the amount of phosphorylated proteins and ions, respectively, back to resting levels (Figure 4).

Cholinergic Agonist-Activated Signal Transduction Pathways

Acetylcholine, released from parasympathetic nerves, activates muscarinic receptors on the basolateral membrane of lacrimal gland cells. Of the five receptor subtypes (M_{1-5}) identified, only the M_3 or glandular subtype is present in the lacrimal gland. These receptors are coupled to the activation of phospholipases C and D (PLC and PLD, respectively) and the activation of the p42/p44 mitogen-activated protein kinase (p42/p44 MAPK, also known as extracellular signal-regulated kinase (ERK)) pathway (Figure 5).

PLC-coupled signaling pathway

Lacrimal gland M_3 receptors are coupled, via the G-protein Gαq, to the effector enzyme PLC. Activated PLC hydrolyzes the plasma membrane lipid, phosphatidylinositol 4,5-bisphosphate (PIP_2), to generate two

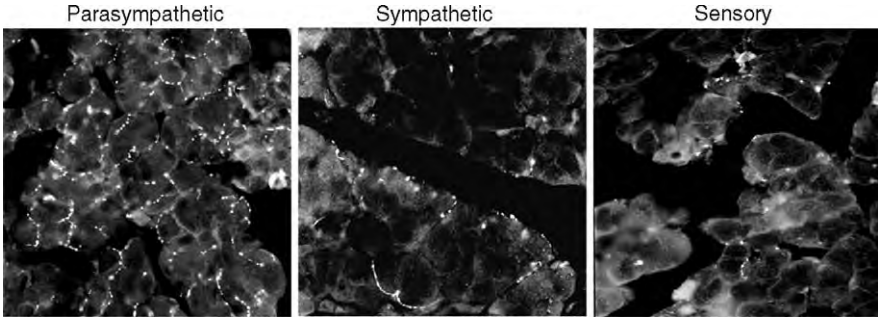

Figure 2 Photomicrographs depicting the innervation of murine lacrimal gland. Nerves were visualized using antibodies against the following neurotransmitters or enzymes: VIP for the parasympathetic nerves, dopamine β-hydroxylase for the sympathetic nerves, and CGRP for the sensory nerves.

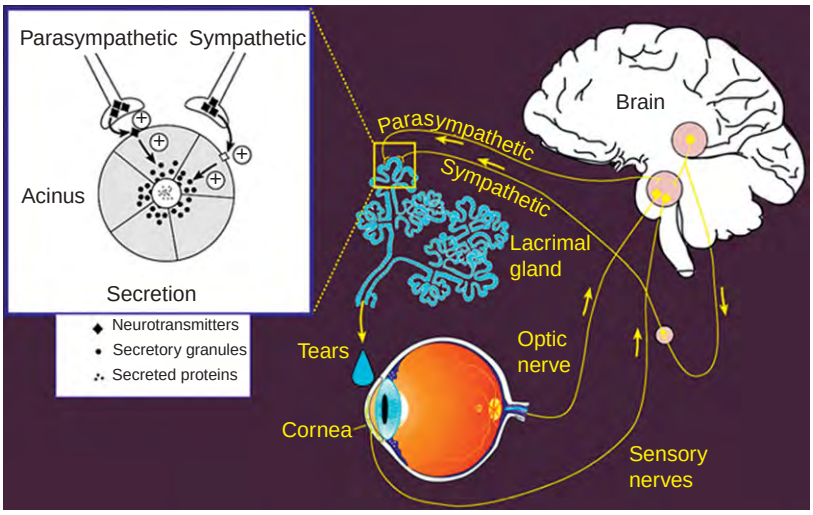

Figure 3 Schematic of the neural reflex arc that controls lacrimal gland secretion. Neural reflexes are initiated by the stimulation of the afferent sensory nerves of the cornea and conjunctiva or by activation of the optic nerve. Efferent parasympathetic and sympathetic nerves of the lacrimal gland are then activated to release their neurotransmitters. The neurotransmitters activate specific receptors located on the basolateral membranes of acinar cells to stimulate secretion.

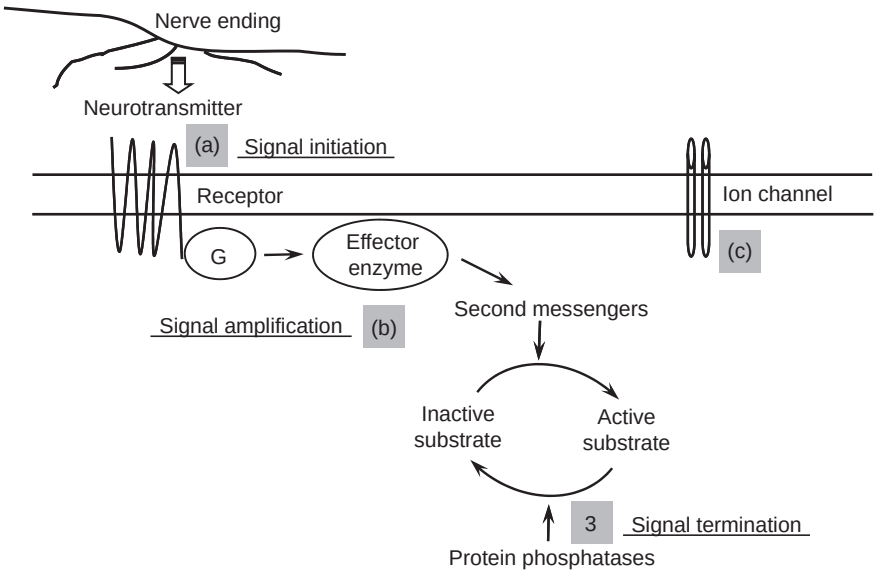

Figure 4 Schematic depicting the three steps involved in signal transduction in response to a neural stimulus: (a) signal initiation by interaction of the neurotransmitter with its receptor; (b) signal amplification through the interaction of the receptor with the G protein and effector enzyme to generate second-messenger molecules; and (c) signal termination through activation of protein phosphatases and membrane pumps.

second-messenger molecules, inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG; **Figure 5**).

IP_3, a water-soluble molecule, diffuses to the endoplasmic reticulum where Ca^{2+} is stored in an inactive, bound form. It also interacts with specific receptors located on the endoplasmic reticulum to release Ca^{2+} into the cytosol. Depletion of these Ca^{2+} stores leads to an increase in the influx of extracellular Ca^{2+} across the plasma membrane. The IP_3 receptor is a homotetramer of ≈310 kDa each and constitutes one of the largest of all known ion channels. Binding sites for IP_3 are located within the N-terminal domain, whereas the C-terminal regions form the intrinsic Ca^{2+} channel. Multiple isoforms of IP_3 receptor have been cloned. They share significant similarity to each other and are encoded by at least four genes.

The activation of lacrimal gland cholinergic M_3 receptors triggers a biphasic Ca^{2+} response: a rapid (usually referred to as peak) increase in $[Ca^{2+}]_i$ due to IP_3-induced release of Ca^{2+} from intracellular stores, followed by a slow and sustained (usually referred to as plateau) increase in $[Ca^{2+}]_i$ due to influx of Ca^{2+} from the extracellular milieu. Both Ca^{2+} responses are necessary for cholinergic

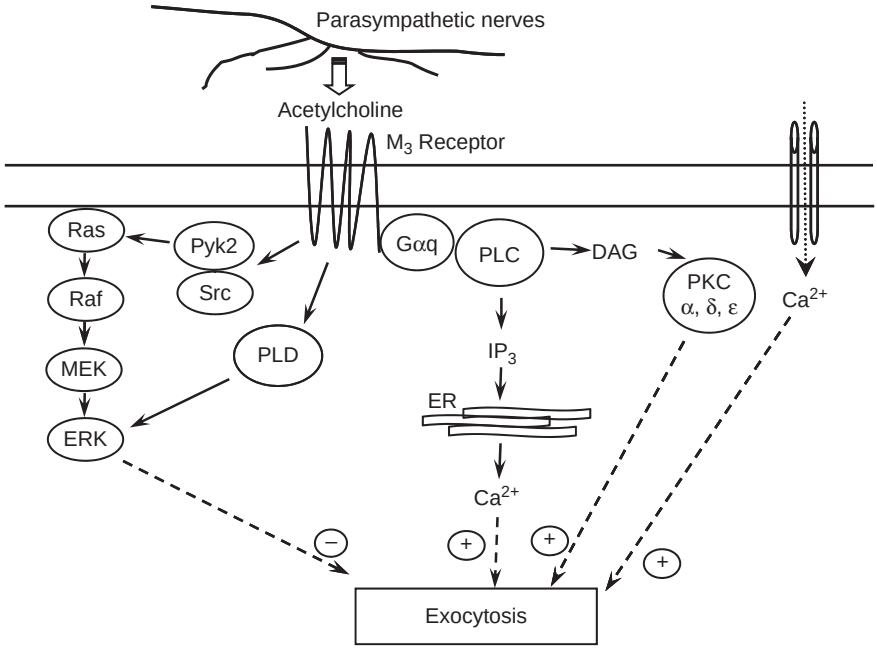

Figure 5 Schematic depicting the main signal transduction pathways activated by acetylcholine to stimulate protein secretion. The activation of lacrimal gland cholinergic receptors activates three main signaling pathways that either enhance (PKC, Ca^{2+}) or attenuate (ERK) protein secretion. The net protein secretory output in response to acetylcholine stimulation will likely depend on the relative contribution of the stimulatory versus the inhibitory signal transduction pathways.

agonist-stimulated protein secretion since chelation of either the intracellular or the extracellular Ca^{2+} leads to complete inhibition of secretion. Ca^{2+} can stimulate secretion alone or do so by activating Ca^{2+} and calmodulin-dependent protein kinases to phosphorylate-specific substrates to cause secretion.

The DAG formed from the hydrolysis of PIP_2 activates protein kinase C (PKC, Figure 5). PKC is a family of closely related isozymes that has been divided into three categories based on structural and functional criteria. A first group, termed conventional PKCs (cPKCs), includes PKCα, -βI, -βII, and -γ isoforms, which have a Ca^{2+}- and DAG-dependent kinase activity. A second group, termed novel PKCs (nPKCs), includes PKCϵ, -δ, -θ, and -η isoforms, which are Ca^{2+}-independent and DAG-stimulated kinases. A third group, termed atypical PKCs (aPKCs), includes PKCζ and -ι/λ isoforms, which are Ca^{2+}- and DAG-independent kinases.

Four isoforms of PKC are expressed in the rat lacrimal gland: one classical, PKCα; two novel, PKCδ, and -ϵ; and one atypical, PKCι/λ. In an attempt to define the role that individual PKC isoforms might play in regulating lacrimal gland functions in response to cholinergic stimulation, isoform-specific peptide inhibitors of PKC were synthesized. These peptides were derived from the unique pseudosubstrate sequences of PKCα, -δ, and -ϵ, and were myristoylated at their N-terminus to make them cell permeant. Indeed, all PKC isoforms have a pseudosubstrate sequence in their N-terminal part, which interacts with the catalytic domain to keep the enzyme inactive in resting cells. Using these peptides, it was shown that cholinergic agonists activate PKCα and -ϵ to a larger extent and PKCδ to a lesser extent, to induce protein secretion. It was also shown that PKCδ and -ϵ, but not -α, negatively modulate cholinergic-induced Ca^{2+} elevation in the lacrimal gland.

PLD-coupled signaling pathway

PLD catalyzes the hydrolysis of membrane phospholipids (preferably phosphatidylcholine), producing phosphatidic acid and the free polar head group. Phosphatidic acid, by itself or after its conversion to DAG by a phosphohydrolase, is an important second-messenger molecule. Besides its hydrolytic activity, PLD possesses the unique ability to catalyze a transphosphatidylation reaction, in the presence of a primary alcohol, in which the phosphatidyl moiety of the phospholipid substrate is transferred to the primary alcohol producing the corresponding phosphatidylalcohol. Accumulation of such unique transphosphatidylation products has been used to detect PLD activity unambiguously in diverse cell types.

Depending on the cell's type, the receptor activation of PLD was shown to occur through mechanisms involving PKC activity, Ca^{2+}, G proteins, or receptor-linked tyrosine kinases. Since PKC activation and Ca^{2+} mobilization are downstream to PLC stimulation, it has been suggested that PLD activation may be secondary to receptor activation of PLC.

Taking advantage of the transphosphatidyl reaction catalyzed by PLD, it was shown that the lacrimal gland contains a PLD activity. Cholinergic agonists, through the muscarinic receptor, stimulate both the hydrolytic activity of PLD to produce phopshatidic acid, as well as the transphosphatidyl reaction. However, if either Ca^{2+} is mobilized or PKC is activated, only the transphosphatidyl reaction is stimulated. This finding implied that cholinergic agonist activation of PLD in the lacrimal gland is not secondary to the activation of PLC by these agonists.

MAPK-coupled signaling pathway

MAPK, also known as ERK, is a dual serine/threonine and tyrosine protein kinase. It is activated through phosphorylation by an MAPK kinase (known as MEK). MEK is also activated through phosphorylation by its upstream MAPK kinase kinase (known as Raf). Raf is activated when the small GTP-binding protein, Ras, is in its GTP-bound form. Depending on the cell's type, Ras can be activated by several mechanisms, including the nonreceptor tyrosine kinases Pyk2 and Src, growth factors receptors, and PKC.

In the lacrimal gland, the activation of MAPK attenuates protein secretion. The activation of MAPK by the M_3 receptor was shown to involve the nonreceptor tyrosine kinases Pyk2 and Src, which in turn activate Ras and, ultimately, MAPK (**Figure 5**). Recent evidence showed that the activation of MAPK by cholinergic agonists is downstream of PLD activation. The mechanisms involved in PLD-mediated activation of MAPK in the lacrimal gland remain to be elucidated.

The termination of the cholinergic signaling pathway involves receptor desensitization, activation of protein phosphatases to dephosphorylate ERK and other phosphorylated substrates, and the activation of ion channels/pumps to return the concentration of cytosolic Ca^{2+} to its resting levels.

In summary, the activation of lacrimal gland cholinergic receptors in response to the parasympathetic neurotransmitter acetylcholine activates three main signaling pathways that either enhance (PKC, Ca^{2+}) or attenuate (ERK) protein secretion (**Figure 5**). The net protein secretory output in response to acetylcholine stimulation will likely depend on the relative contribution of the stimulatory versus the inhibitory signal transduction pathways.

VIP-Activated Signal Transduction Pathways

VIP interacts with specific VIP receptors located on the basolateral membranes of lacrimal gland cells. Two types of VIP receptors have been identified, VIPRI and VIPRII, which are also known as VIPACR1 and VIPACR2, and both of them are expressed in the lacrimal gland, with VIPRI being the predominant type.

Adenylate cyclase-coupled signaling pathway

The VIP receptor uses the G protein $G_{\alpha s}$ to activate the effector enzyme adenylyl cyclase (AC), which produces the second-messenger molecule, cyclic adenosine monophosphate (cAMP) (**Figure 6**). Molecular cloning has identified several isoforms of mammalian AC forming a family of at least 10 enzymes (ACI-X). There are at least three isoforms of AC (ACII, ACIII, and ACIV) present in the lacrimal gland, each having a unique localization.

Although the regulation of AC enzymatic activity is complex and isoform specific, all AC isoforms are activated

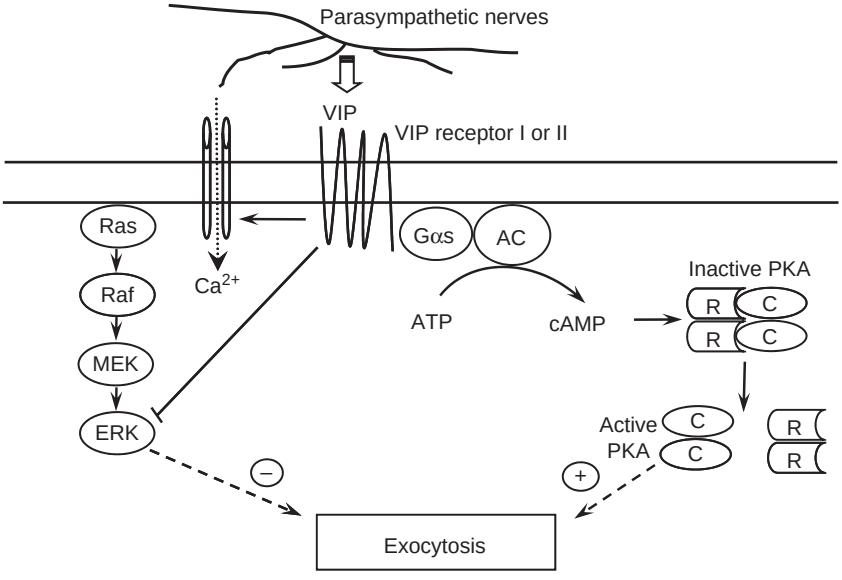

Figure 6 Schematic depicting the main signal transduction pathways activated by the VIP to stimulate protein secretion. The activation of lacrimal gland VIP receptors activates two main signaling pathways that enhance protein secretion.

by Gαs. Increases in the intracellular levels of cAMP lead to activation of protein kinase A (PKA), a ubiquitous serine and threonine protein kinase. In its inactive state, PKA consists of a complex of two catalytic (C) subunits and two regulatory (R) subunits (Figure 6). Binding of cAMP to the R subunit alleviates an autoinhibitory contact that releases the active C subunit (Figure 6). The active kinase is then free to phosphorylate specific protein substrates to stimulate lacrimal gland protein and fluid secretion.

MAPK-coupled signaling pathway

Recently, it has been shown that addition of VIP, exogenous cAMP, or analogs that increase cAMP levels inhibited both basal as well as cholinergic induced activation of MAPK in the lacrimal gland. One implication of these findings is that it could help explain the well-documented synergistic effect that addition of a cAMP along with a Ca^{2+}-/PKC-dependent agonist have on lacrimal gland protein secretion. Indeed, cholinergic agonists activate MAPK, which attenuates protein secretion. When the cAMP pathway is activated, MAPK activity is inhibited; this should alleviate the inhibitory effect that MAPK has on secretion and as a result, protein secretion will be potentiated if both the Ca^{2+}/PKC and the cAMP pathways are activated simultaneously.

The termination of VIP-activated signaling pathways likely includes activation of the cAMP-phosphodiesterase, which converts cAMP to the inactive 5'-AMP. Other signal-terminating mechanisms include desensitization of the VIPR and AC, sequestration of the PKA C subunits by the naturally occurring protein kinase inhibitor (PKI), and activation of protein phosphatases.

α_1-Adrenergic Agonist-Activated Signal Transduction Pathways

Norepinephrine, released from the sympathetic nerves, binds to α_1- and β-adrenergic receptors on lacrimal gland cells. β-Adrenergic receptors are coupled to activation of AC to activate a cAMP-dependent signal transduction pathway, as discussed for VIP. Of the three α_1-adrenergic receptor subtypes (α_{1A}, α_{1C}, and α_{1D}) identified, only the α_{1D} subtype is expressed in the lacrimal gland.

Ca^{2+}- and PKC-coupled signaling pathways

In most exocrine tissues, α_1-adrenergic agonists activate the same pathway as cholinergic agonists (i.e., activation of PLC and PLD). Surprisingly, in the lacrimal gland, α_1-adrenergic agonists do not activate PLC or PLD, although their activation leads to a slight increase in cytosolic Ca^{2+} and to activation of PKC isoforms (Figure 7). To date, the effector enzyme(s) activated by lacrimal gland α_{1D}-adrenergic receptors to mobilize Ca^{2+} and activate PKC is still unknown.

Although Ca^{2+} mobilization in the lacrimal gland in response to adrenergic agonist stimulation is well

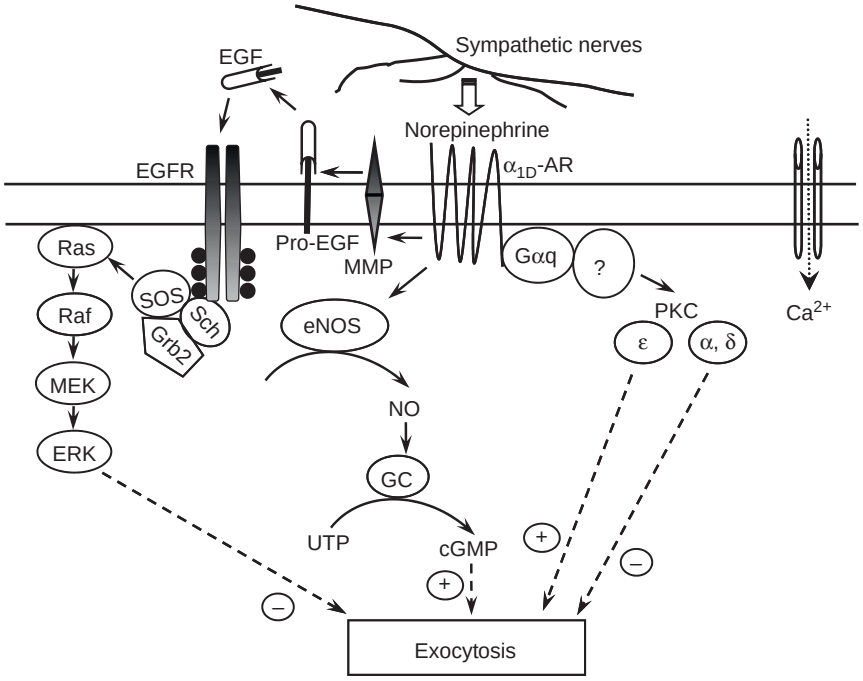

Figure 7 Schematic depicting the main signal transduction pathways activated by the norepinephrine to stimulate protein secretion. The activation of lacrimal gland α_{1D}-adrenergic receptors activates stimulatory pathways, including PKCε and cGMP, and inhibitory pathways, including PKCα, PKCδ, and ERK. It is likely that the net lacrimal gland protein secretion in response to sympathetic stimulation is a balance between these stimulatory and inhibitory signal transduction pathways.

documented, the mechanisms involved are poorly understood. A role for IP_3 has been ruled out since adrenergic agonists do not increase its production as they fail to activate PLC. It has been proposed that cyclic ADP ribose, which activates ryanodine receptors to release Ca^{2+} into the cytosol, might be involved. Other investigators proposed that nitric oxide (NO)-induced generation of cyclic guanosine monophosphate (cGMP) is involved in α_1-adrenergic agonist-induced mobilization of Ca^{2+}.

The role of PKC in α_1-adrenergic agonist-induced lacrimal gland protein secretion has been studied using the myristoylated pseudosubstrate-derived peptides. It was shown that α_1-adrenergic agonists activate three PKC isoforms – PKCα, -δ, and -ϵ. Activation of PKCϵ enhances protein secretion, whereas activation of PKCα and -δ attenuates protein secretion. This is in contrast to the stimulatory effect that PKCα and -δ isoforms have on protein secretion when activated by cholinergic agonists. These findings imply that the effect (inhibitory or stimulatory) of a given isoform of PKC in the lacrimal gland is stimulus dependent and might be dictated by the cellular location of PKC isoforms.

MAPK-coupled signaling pathway

Similar to cholinergic agonists, α_1-adrenergic agonists activate MAPK to attenuate lacrimal gland protein secretion. However, in contrast to the cholinergic pathway, activation of MAPK by the α_{1D}-adrenergic receptor does not involve the nonreceptor tyrosine kinases Pyk2 and Src, but involves activation of the epidermal growth factor receptor (EGFR; **Figure 7**). The EGFR, also known as Erb1, is the prototypical member of the ErbB/EGFR family of receptors which consists of three additional members (ErbB2–4). EGFR is a type 1 transmembrane tyrosine kinase receptor consisting of an extracellular domain (ligand-binding site), a transmembrane domain, and the carboxy-terminal, an intracellular domain containing the tyrosine kinase motif. In addition, the carboxy-terminal domain contains tyrosine residues that become phosphorylated following ligand binding and receptor dimerization. Following receptor activation, several exogenous substrates that contain either Src homology 2 (SH2) or protein tyrosine binding (PTB) motifs are recruited to specific phosphorylated tyrosine residue.

In the lacrimal gland, the activation of the EGFR by α_1-adrenergic agonists occurs through a process termed as transactivation and involves the activation of a metalloproteinase and shedding of EGF (**Figure 7**). Following activation, Shc (an SH2 motif-containing protein) is recruited to the EGFR, followed by recruitment of Grb2 and the guanine nucleotide exchange factor protein, SOS (**Figure 7**). SOS stimulates the exchange of GDP for GTP on Ras and hence leads to its activation. Activated Ras triggers the activation of the MAPK cascade, leading to activation of ERK (**Figure 7**). Similar to the cholinergic pathway, α_1-adrenergic-activated ERK has been shown to attenuate lacrimal gland protein secretion.

NO-coupled signaling pathway

NO, along with L-citruline, is produced from L-arginine in the presence of O_2- and NADPH-derived electrons. This reaction is catalyzed by the enzyme NO synthase (NOS). There are three well-characterized isoforms of NOS expressed by mammalian cells: neuronal NOS (nNOS also known as NOS1), inducible NOS (iNOS or NOS2), and endothelial NOS (eNOS or NOS3). Activation of nNOS and eNOS, but not iNOS, requires calmodulin and an increase in $[Ca^{2+}]$.

It has been shown recently that lacrimal gland α_1-adrenergic receptors are coupled to the NO/cGMP pathway (**Figure 7**). Indeed, it was found that both nNOS and eNOS are expressed in the lacrimal gland. The addition of α_1-adrenergic agonists led to generation of NO, presumably through activation of eNOS and not nNOS. NO, in turn, activates soluble guanylate cyclase to generate cGMP which enhances lacrimal gland protein secretion.

The termination of the α_1-adrenergic signaling pathway is likely to involve receptor desensitization, activation of protein phosphatases to dephosphorylate ERK and other phosphorylated substrates, and the activation cGMP-phosphodiesterase, which converts cGMP to the inactive 5'-GMP.

In summary, the activation of lacrimal gland α_{1D}-adrenergic receptors, in response to the sympathetic neurotransmitter norepinephrine, activates stimulatory pathways (including PKCϵ and cGMP) and inhibitory pathways (including PKCα, PKCδ, and ERK; **Figure 7**). It is likely that the net lacrimal gland protein secretion in response to sympathetic stimulation is a balance between these stimulatory and inhibitory signal transduction pathways.

Lens Determination and Induction

T J Plageman, B Chauhan, and R A Lang, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA and University of Cincinnati, Cincinnati, OH, USA

Glossary

Induction – A process that occurs during embryonic development in which one tissue signals to an adjacent tissue, altering the differentiation of the responding cells.

Lens fiber cells – Terminally differentiated cells that first form at the posterior of the lens vesicle, the side closest to the developing retina. Fiber cells become highly specialized for light refraction and transparency by the accumulation of large amounts of proteins, called crystallins.

Optic cup – A bilayered structure derived from the optic vesicle, an outpocketing of the forebrain. Invagination of the optic cup occurs at the same time that the lens is invaginating from the lens placode. Cells of the inner layer of the optic cup produce the retina.

Placode – A region of thickened epithelium caused by the crowding and elongation of the epithelial cells. Placodes are the source of several structures in the embryo, including the neural tube, inner ear, and lens.

Introduction

The Lens Is One Type of Light-Focusing Structure

Animals have developed many different types of eyes. These range from the multifaceted ommatidial eyes of insects to the camera eyes of vertebrates. There are some remarkable variations on these basic themes. For example, flies have evolved with their eyes positioned on long stalks as a mechanism of improved peripheral vision and of attracting a mate. There also exists a species of fish with bifocal corneas for simultaneous air and water viewing. These unusual examples indicate the remarkable plasticity, over evolutionary timescales, of the visual system.

In most types of eyes, there is a mechanism for focusing light on photoreceptors. In the familiar vertebrates, both cornea and lens are transparent and refractile and serve together to focus light on the retina. However, other solutions are possible and include variations like the Spookfish where a downward-looking eye uses a mirror-like surface to direct light onto photoreceptors or the solution that evolved in a species of turtle where a thickened cornea serves as the sole means for focusing light. The compound eyes of insects have lenses that are a complex of proteins secreted from the so-called cone cells. In the Duke-Elder volumes, one drawing suggests that a unicellular organism has a subcellular organelle with a lens-like component. These examples suggest that most species have some form of refracting lens and recommend these structures as an interesting subject for analysis. In this article, we review our understanding of development of the vertebrate lens. Most of the analysis has been performed in the popular experimental organisms such as the African clawed frog *Xenopus laevis*, the chick, *Gallus gallus*, the zebrafish *Danio rerio*, and the mouse, *Mus musculus*.

Lens Induction: An Auspicious Beginning

In 1901, Hans Spemann performed optic cup ablation experiments in amphibian embryos that resulted in the failure of a lens to form on the operated side. These experiments led directly to the concept of embryonic induction – the ability of one tissue to direct the fate of another – and began the study of lens induction. The interpretation of these experiments was initially controversial when Mencl identified a mutant salmon with lenses but no other eye components. Since then, many investigators performed similar optic cup ablation experiments, which have shown varying results that probably reflect the delivery of critical lens induction signals at different developmental stages in the different species used. In the mouse, it has become very clear that the retinal primordium and optic cup do provide signals that direct lens development, although over several stages of development and not exclusively. Understanding the nature of these signals is a major goal of the lens induction research field.

The Developmental Biology of Lens Formation

The Lens Undergoes Complex Morphogenesis

Studies in many different vertebrate species have shown that the lens of the eye is derived from the embryonic surface ectoderm (**Figure 1**). Morphologically, lens structures first become apparent when the surface ectoderm overlying the optic cup forms the thickened domain of

epithelium known as a placode, which develops when epithelial cells elongate through mechanisms that are currently not understood.

After placode formation, the presumptive lens begins invagination. This epithelial movement occurs in close coordination with the invagination of the presumptive retina. When the presumptive retina invaginates into the optic vesicle, the bilayered optic cup is formed. During coordinated invagination of the lens placode and presumptive retina, the two epithelia are joined by fine cytoplasmic processes (**Figure 2**). These were originally described in 1902 by Lenhossek and Magitot, then by Mann in 1950, and most recently, in 1980, by McAvoy. These cytoplasmic processes are transient in that they form in the mouse at about E9.0 just before invagination begins, increase in numbers to about one per cell by E10.5, and then disappear by E11.5. It may be that these structures are physical tethers that have a structural function in

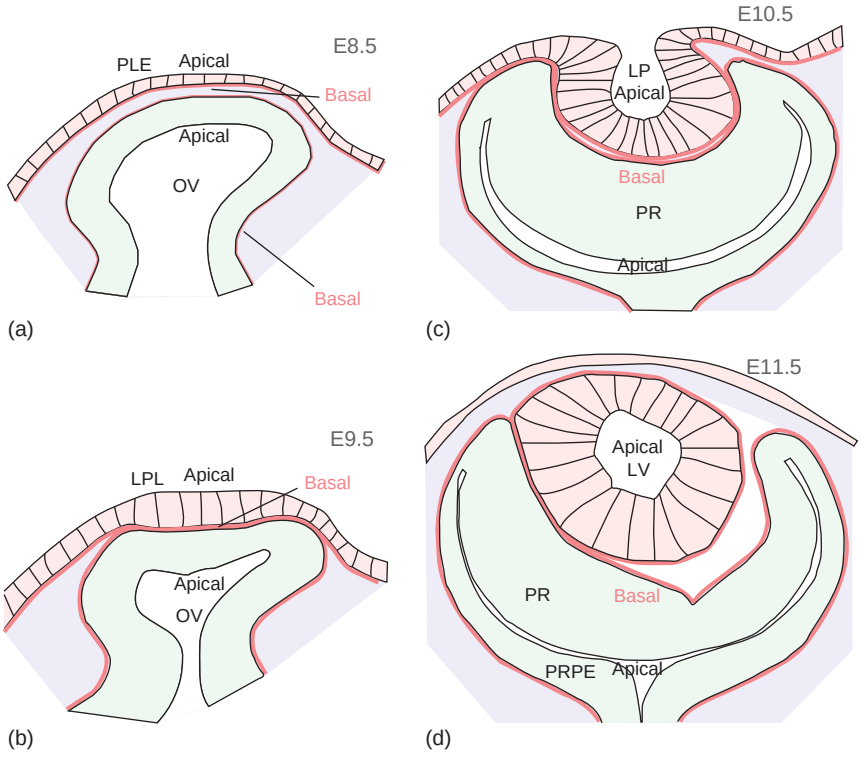

Figure 1 Early morphogenesis of the mouse eye. (a–d) Mouse eye development stages from E8.5 to E11.5 in daily intervals. The three tissue layers involved in eye development include the surface ectoderm (red) the mesenchyme (mauve), and the neuroepithelium of the optic vesicle (green). The apical and basal faces of the epithelia are indicated. PLE, presumptive lens ectoderm; OV, optic vesicle; LPL, lens placode; PR, presumptive retina; LV, lens vesicle; PRPE, presumptive retinal pigmented epithelium.

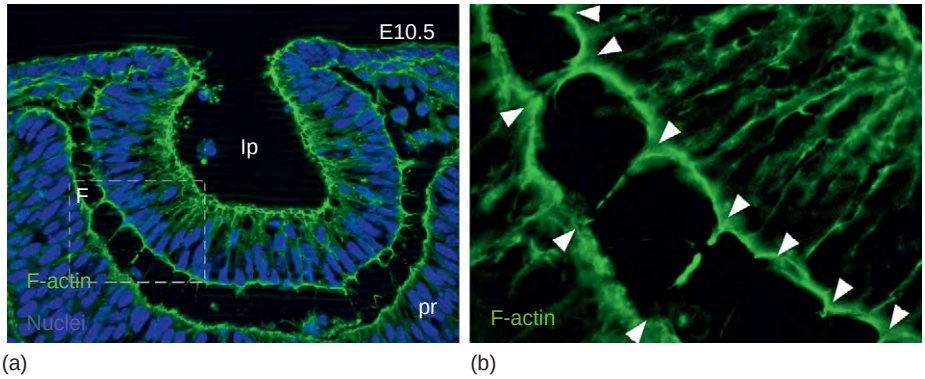

Figure 2 Cytoplasmic processes connect presumptive lens and retina during invagination. (a) An E10.5 mouse eye in section, labeled for F-actin with phalloidin (green) and nuclei (blue). A subregion of (a), indicated by the white dashed line, is shown at higher magnification in (b). The white arrowheads point to the cytoplasmic extension that connects presumptive lens and retinal epithelia. lp, lens pit; pr, presumptive retina.

coordinating epithelial morphogenesis or that they have an active signaling role.

The presumptive lens and retina are epithelia with apposed basal surfaces (**Figure 1**). Transmission electron microscopy studies have shown that fine basal laminae can be detected on both sides of the presumptive lens–presumptive retina interface. This arrangement of epithelial polarity means that during invagination of presumptive lens and retina, presumptive lens is invaginating basally and presumptive retina in the apical direction. Although the mechanisms of invagination are not understood, this opposite epithelial polarity may mean that the mechanisms of invagination in each epithelium are fundamentally distinct.

Johaan Zwaan and Richard Hendrix performed mathematical modeling of cell shape during invagination of the lens placode. Their major goal was to understand the forces required for invagination, but as part of this analysis, they carefully measured changes in epithelial cell shape. They concluded that lens placode invagination is accompanied by a change from cylindrically shaped to conically shaped epithelial cells. Since apical constriction can be an active process imposed, for example, by the Shroom3 molecule, it is tempting to speculate that apical constriction and the formation of conically shaped lens epithelial cells is the driving force behind invagination.

At E10.5 in the mouse, the lens pit is fully invaginated (**Figure 1**). After this, the major morphogenetic movement is the anterior extension of the lens pit epithelium to form a closure pore at the embryo surface. Fusion of the junction epithelium, that is, surface ectoderm distally and lens pit ectoderm proximally, forms the lens stalk, a structure that persists in a variety of mutants with mild lens development defects. Involution of the lens stalk by mechanisms that are not understood results in the formation of separated lens vesicle and the surface ectoderm that will become the corneal epithelium.

Within the lens vesicle, the lens fiber cells, which are the differentiated cell type, begin to form from the posterior wall of the lens vesicle at approximately E12.5. These are the primary lens fiber cells that go on to form the nucleus of the lens. Secondary lens fiber cells differentiate starting at approximately E14.5 from cells at the lens equator. These have migrated to the lens equator and originated in lens epithelial cells that proliferate to provide lens fiber progenitors. The formation of lens fiber cells and the nature of their differentiation program are addressed elsewhere in this encyclopedia.

Is There a Common Placodal Precursor Domain?

It has been suggested that in vertebrates, placode-derived structures such as the olfactory epithelium, lens, ear, and pituitary might all begin their existence at a common placodal region with uniform characteristics that later becomes further regionalized. The idea of a common placodal precursor derives partly from the morphology of some vertebrates – such as frogs – where the U-shaped region at the edge of the neural plate has uniform morphology and also gives rise to all the placodes. In addition, more recent analysis has suggested that there are common molecular characteristics across the placodal progenitor domain. These include expression of certain genes such as Pitx3 (in the zebrafish) and Six1, 2, and Eya2 (in the chick). Indeed, investigations using the chick have suggested that the common placodal precursor first has the characteristics of lens and, then later, under the influence of additional genes, becomes modified regionally to other structures. This whole idea has given further credibility to experiments showing that lenses can arise in unusual places when gene function is modified. These examples include the *you too* mutant zebrafish, where a *Gli2* gene mutation results in an ectopic lens forming from the adenohypophyseal (pituitary) placode, and misexpression of the *Six3* gene in Medaka, which results in an ectopic lens forming from the olfactory placode. Furthermore, in chicks with neural crest elimination, ectopic lenses arise close to the eye and in mice with fibroblast growth factor 4 (Fgf4) overexpression in the head ectoderm, ectopic lenses form in corresponding regions.

Genetic Regulation of Lens Development

Transcription Factors

After more than a decade of analysis, a reasonably sophisticated model has been generated that describes the genetic regulation of lens development in the mouse (**Figure 3** is a simplified version). Central to these pathways is paired box 6 (Pax6), the paired domain and homeodomain-containing transcription factor that has been implicated generally in metazoan eye development. Various experiments show that Pax6 is essential for lens development and that there are two distinct phases of expression. These include the so-called pre-placodal phase in the head surface ectoderm and the placodal phase that can be detected when the placodal morphology is obvious. According to an assessment of Pax6 gene transcription in a Pax6 point mutant, the placodal phase of Pax6 expression is dependent on functional gene product from the earlier, pre-placodal phase. For this reason, the Pax6 gene is often described as autoregulated (**Figure 3**).

The Pax6 gene is large and complex with multiple transcripts that are the consequence of multiple promoters and alternative exon splicing. Long-range sequence alignments of Pax6 gene sequences from a variety of species reveal that there are more than 30 highly conserved regions that presumably have a regulatory function. A few of these have been characterized. The so-called ectoderm enhancer

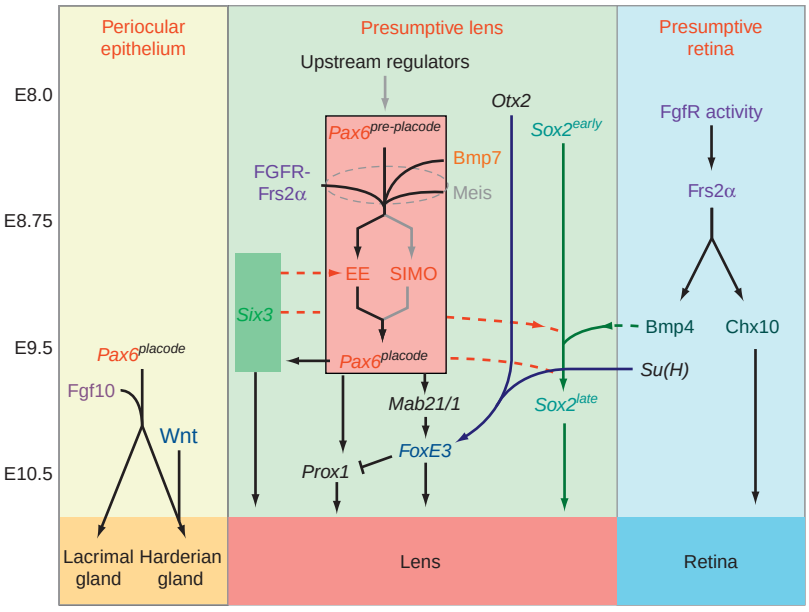

Figure 3 A model for genetic regulation of lens induction in the mouse. In this model, solid arrows represent expression dependency and dashed arrows a direct action. For example, evidence suggests that Six3 can directly bind the ectoderm enhancer (EE) of Pax6. A detailed description of this model is provided in the text.

of Pax6 not only is active in the lens placode but is also active in the surrounding ectoderm that includes the epithelia of the presumptive Harderian gland, lacrimal gland, and conjunctiva. This enhancer is just over 300 bp in length and is more than 90% conserved when comparing mouse and human. Thus far, it has been suggested that the myeloid ecotropic viral insertion site (Meis) transcription factors bind to this enhancer and activate Pax6. Furthermore, it has also been suggested that Six3 regulates Pax6 by binding to the ectoderm enhancer (**Figure 3**).

The so-called single input multiple output (SIMO) element of Pax6 is an enhancer that resides 240 kb downstream of Pax6 in the final intron of the adjacent gene. Heterozygous deletion of the SIMO element in humans or in mice results in an aniridia (without a lens) phenotype like Pax6 heterozygosity. This implies that SIMO is required for Pax6 expression. Since the SIMO element is sufficient to drive gene expression in the presumptive lens, it likely functions in concert with the ectoderm enhancer. This may explain why targeted deletion of the ectoderm enhancer still allows lens formation, albeit a small one.

In a Pax6 somatic mutant where Pax6 is rendered nonfunctional in the lens placode, no lens forms. Furthermore, Pax6 misexpression can lead to the formation of ectopic lenses in many locations. These data have indicated that Pax6 is necessary and sufficient for lens development.

Downstream of Pax6, there are other transcription factors that include Prox1, Six3, and FoxE3 (**Figure 3**). Analysis of Six3 somatic mutants has suggested that Pax6 and Six3 function in a positive-feedback loop that may serve to raise expression levels of both in the early lens. These same Six3 somatic mutants also show that Six3 is required for lens development from the placode stage onward. FoxE3 is a *forkhead* family transcription factor that is mutated in the *dysgenetic lens* mouse. In this mutant, the lens does not separate from the surface ectoderm and remains small. Prox1 is a homeodomain transcription factor that is critical for the development of lens fiber cells in the later lens. FoxE3 suppresses Prox1 expression and regulates the balance of proliferating and differentiating cells in the lens.

The Grainger group has also provided evidence to suggest that inducibility of the FoxE3 in the lens placode is dependent on an Otx2-binding site in a FoxE3 gene enhancer. Otx2 is not sufficient for FoxE3 expression but appears to be a necessary prerequisite. A critical activating signal for FoxE3 is believed to be the suppressor of Hairless (Su(H)) transcription factor that is a transducer of Notch signaling. The finding that the Notch ligand Delta2 is expressed in the optic vesicle explains the source of the Notch signal and is consistent with many years of developmental biology implicating the optic vesicle in lens induction. These findings are also very interesting because they suggest that Otx2, which is expressed broadly in head ectoderm, may be, in part, the basis of lens competence.

FoxE3 expression is also dependent on Pax6, as mentioned above, but analysis of Mab21l1 mutants suggests that this transcription factor acts as an intermediate between Pax6 and FoxE3. It is not yet understood whether Mab21l1 is a direct regulator of FoxE3. We can conclude that FoxE3 expression is dependent on at least three inputs – Otx2, Mab21l1, and Su(H) (**Figure 3**). It is likely

that this type of combinatorial regulation will be commonplace as we dissect lens induction and development mechanisms further.

The sex-determining region (Sry) family transcription factors, Sox1, 2, and 3, have all been implicated in lens development. For example, according to embryological manipulations in the chick, expression of Sox2 in the lens placode is dependent on the underlying optic vesicle. Furthermore, when Sox2 is mutated in the presumptive lens, with a few exceptions, lens development is arrested at the lens pit stage. Since Sox2 expression is unchanged in pre-placodal ectoderm of Pax6 mutant mice (and vice versa), Sox2 and Pax6 are believed to function in parallel at this stage (**Figure 3**). Recent data indicate that after the lens placode has formed, expression of Sox2 is dependent on Pax6. Investigation from the Kondoh group has shown that Pax6 and Sox2 can form a physical complex and, in one important element of lens development, regulate the expression of crystallin genes.

Signaling Pathways Involved in Lens Induction and Development

Bone Morphogenetic Protein

The bone morphogenetic proteins (BMPs) have important roles in the development of many structures in vertebrates. Although a germ-line mouse mutant is difficult to analyze because of early lethality, BMP4 has been implicated in lens induction. The BMP4 mutant does not increase the expression of the transcription factor Sox2 in the early lens, although the expression of Pax6 is unchanged. Since Sox2 has an important role in lens development, the regulation of Sox2 by BMP4 is further confirmation that BMP4 is also an important regulator. These data place BMP4 signaling upstream of Sox2 expression in the current model of the genetic regulation of mouse lens induction (**Figure 3**).

The eye phenotype apparent in the Bmp7 germ-line null mouse is highly variable, but does implicate this signaling molecule in lens induction. In Bmp7-null embryos that show a severe phenotype, there is a failure of the lens placode to form and arrest of eye development that includes the absence of lens fate acquisition and morphogenesis. Consistent with the absence of lens formation, Pax6 is not upregulated in the lens placode and remains at the low level normally observed earlier in the head surface ectoderm. Since Sox2 expression is unaffected in the Bmp7 mutant, it appears to have a function that is distinct from Bmp4. Indeed, the regulation of Pax6 by Bmp7 and Sox2 by BMP4 suggests that these two signaling molecules may function in parallel (**Figure 3**). In some Bmp7-null mutants, the phenotype is very much less severe and results only in a small eye. It is unclear why the Bmp7 phenotype is so variable but phenotypic variability is a characteristic of several of eye development mutants.

Fibroblast Growth Factor

Early work on the role of Fgf signaling in lens fiber cell differentiation prompted investigators to determine whether Fgf signaling might also be required for lens induction. This turned out to be the case with multiple methods of Fgf signaling suppression, indicating that this pathway was involved in lens induction. In particular, mutation of the fibroblast growth factor receptor substrate 2-alpha (Frs2α) adapter protein resulted in reduced Pax6 expression in the lens placode. Since lens placode-specific somatic mutation of Fgf receptors also results in a failure of lens development, it is clear that placodal cells respond to Fgf signaling during induction (other experiments have shown that the presumptive retina is also Fgf pathway responsive) (**Figure 3**).

In Frs2$\alpha^{2F/2F}$ mutants, the FGF signaling pathway is compromised in both presumptive lens and retina. One interesting feature of these mutants is the loss of Bmp4 expression within the optic vesicle and of Six3 expression in optic vesicle and presumptive lens. First, this places Six3 downstream of Fgf signaling. Since Pax6 in the presumptive lens is also dependent on Fgf signaling and Six3 is downstream of Pax6, these findings are consistent with a model in which FGF signaling–Pax6–Six3 is a linear pathway (**Figure 3**).

The dependence of BMP4 expression on FGF signaling is particularly interesting because it might explain how the two pathways are integrated during lens induction. Since BMP4 signaling increases the expression of Sox2, we can argue that BMP4 produced by the presumptive retina stimulates Sox2 expression in the surface ectoderm. Since Pax6 expression in presumptive lens is FGF pathway dependent, this would mean that FGF activates both Pax6 and Sox2 in presumptive lens (**Figure 3**). Recent investigations show that Pax6 and Sox2 cooperate functionally in early lens development.

Wnt

Wnt pathway signaling responses are generally referred to as canonical (involving β-catenin) and noncanonical. There are now many varieties of noncanonical Wnt signaling and although noncanonical Wnt signaling has been implicated in lens development, it is currently unclear which of these varieties. The canonical Wnt signaling system is well characterized but complex (**Figure 4**). Wnt ligands are lipid modified and are thus poorly soluble. Consistent with this, range-of-action experiments suggest that in many settings, Wnt signaling may occur through cell–cell contact. Canonical Wnt signaling requires two membrane components, the *frizzled* receptors and the Drosophila *arrow*-related co-receptors Lrp5 or Lrp6. In the mouse, there are nine Frizzled receptors. Lrp5 and Lrp6 are members of the larger class of low-density

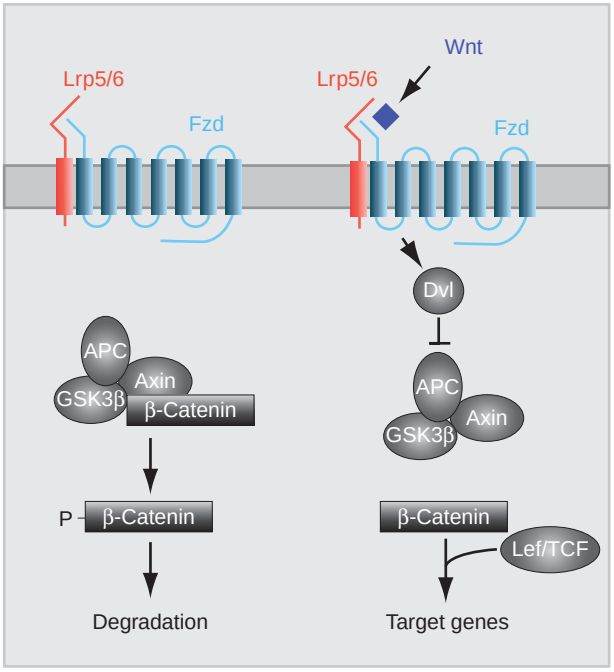

Figure 4 The canonical Wnt signaling system. In the absence of a Wnt ligand, a complex consisting of APC, axin, and GSK3β causes the phosphorylation-mediated degradation of β-catenin. In the presence of a Wnt ligand, Disheveled (Dvl) is activated by the receptor complex and suppresses the APC–axin–GSK3β complex allowing β-catenin to stabilize. In turn, β-catenin associates with transcription factors of the Lef/TCF family and regulates target gene transcription.

lipoprotein receptors, but Lrp5 and Lrp6 are the only ones closely related to arrow, the co-receptor for *Drosophila* Wnt signaling. Wnt ligand engagement by Frizzled/Lrp5/6 complex results activates Dishevelled (Dvl) and suppresses the glycogen synthase kinase-3β (GSK3β), axin, adenomatosis polyposis coli (APC) degradation complex. In the absence of ligands, GSK3β phosphorylates β-catenin and results in its degradation through APC and the proteasome. When Dvl suppresses GSK3β, β-catenin is stabilized, binds TCF/Lef transcription factors and regulates target genes.

Canonical Wnt signaling pathways have been implicated in the regulation of lens development. The McAvoy group has provided evidence that canonical Wnt signaling reporters are expressed in the lens epithelium and that there is a lens epithelial defect in the few *Lrp6* mutant embryos that survive to later stages of lens development. The canonical Wnt signaling pathway has also been implicated in restricting the domain of surface ectoderm that can form lens. This activity is demonstrated when β-catenin function – an essential Wnt pathway component – is functionally deleted from the surface ectoderm. This results in the formation of not only small ectopic lentoid bodies throughout the head ectoderm, but also a large ectopic lentoid structure immediately nasal to the eye. Since there is normally a small region of Wnt-responsive ectoderm that forms the Harderian gland nasal to the eye, this leads to the suggestion that canonical Wnt pathway activity normally redirects ectoderm from a lens fate to a Harderian gland fate (**Figure 3**). This is quite consistent with general conclusion that the canonical Wnt pathway often functions to suppress differentiation. There is a set of genes known to be directly regulated level by the canonical Wnt signaling pathway and presumably some of these participate in lens development.

There are a number of mutant mice in which the optic vesicle fails to develop and, as a consequence, no lens is formed. This is the modern-day equivalent of Spemann's optic cup ablation experiments. The Lhx2 and Rx mutant mice both have this characteristic. In an interesting extension of our understanding of β-catenin function, the Jamrich group has shown that the lens development failure of the Rx mutant mice can be largely rescued by deletion of β-catenin in the presumptive lens. This might mean that the optic vesicle normally suppresses Wnt signaling to permit lens development or that the adhesion function of β-catenin is an important regulator. However, further work is required to understand this in detail.

Notch

The Notch pathway is a well-characterized means to regulate cell fate decision. In many cases, Notch signaling is employed in binary cell fate decisions where two distinct cell types are produced. As touched on above, the Notch signaling pathway has been implicated in lens induction with evidence suggesting that Delta2 in the optic vesicle signals to the overlying presumptive lens ectoderm to initiate expression of FoxE3. It has also been shown that the Notch pathway has a role in later lens development in regulating the balance between lens epithelial and lens fiber cells. This is an appealing setting for the Notch pathway because, again, it represents a binary cell fate decision.

Concluding Comments

The lens has proven an excellent model system for developmental biologists because of its relative simplicity. With the increasing sophistication of genetic tools in the vertebrate models, we can anticipate that our understanding of lens development will become increasingly sophisticated. In particular, the lens is likely to serve as an excellent model system in which to understand the processes of morphogenesis that are such a prominent component of its development.

Lens Fiber Cell Differentiation

M L Robinson, Miami University, Oxford, OH, USA

Glossary

Connexins – The membrane proteins which form gap-junction channels that connect the cytoplasm of adjacent cells. Lens fiber cells have abundant fiber-specific connexins (Cx46 or Gja3 and Cx50 or Gja8) that are found in few other tissues.

Lens capsule – An extracellular matrix, secreted by the epithelial and superficial fiber cells, which surrounds the lens. The capsule can be thought of as a multilayered basal lamina, composed of the proteins laminin, type 4 collagen, entactin, and other typical components of basal laminae.

Lens vesicle – The hollow sphere of epithelial cells that results from the invagination of the lens placode early in eye development. Lens epithelial cells are derived from half of the vesicle closest to the surface ectoderm, while primary fiber cells are derived from the half nearest the future retina. These cells elongate and fill the lumen of the vesicle.

Secondary fiber cells – The fiber cells derived from the equatorial region of the lens epithelium. These cells are formed in successive waves throughout life, burying primary fiber cells and older secondary fiber cells deeper in the lens fiber mass.

Primary Fiber Cell Differentiation

In terrestrial vertebrates, the first morphological sign of lens development is the thickening of the surface ectoderm overlying the optic vesicle to form a lens placode (**Figure 1(a)**). The placode subsequently invaginates, forming the lens pit (**Figure 1(b)**). The lens pit deepens and eventually the connection of the pit to the surface, known as the lens stalk, narrows, closes off, and disintegrates, forming the initially hollow lens vesicle (**Figure 1(c)**). All of the cells of the lens vesicle are polarized, with basal surfaces facing outward and apical surfaces facing the lumen of the vesicle.

The lens vesicle contains the precursors of all the cells in the lens. Initially, all cells of the lens vesicle are capable of proliferation, with the fate of each cell determined by its position within the vesicle. The most posterior cells of the vesicle (closest to the developing neural retina) begin elongating as they become the primary lens fiber cells, while the cells lining the anterior hemisphere of the lens will differentiate into the lens epithelium (**Figure 1(d)**). The elongation of the primary fiber cells will continue until the apical ends of the fiber cells have reached the apical surface of the lens epithelial cells lining the anterior of the vesicle. As the lens grows, elongating secondary fiber cells will displace the attachment of the primary fiber cells to their basement membrane (the lens capsule), at the posterior, and to the lens epithelial cells, at the anterior. This process forms the embryonic lens nucleus, which remains in the center of the lens throughout life. During differentiation, all lens fiber cells, whether primary or secondary, withdraw from the cell cycle, elongate, express several fiber-cell-specific proteins (including differentiation-specific crystallins), and will ultimately degrade all intracellular organelles.

The Lens is a Stratified Epithelium

Pax6 is a transcription factor essential for the development of all surface-ectoderm-derived eye structures, including the lens. The Pax6-expressing surface ectoderm, overlying the lens vesicle, will differentiate into the corneal epithelium, conjuctiva, and eyelid epithelium, and the surrounding surface ectoderm that does not express Pax6 will differentiate into epidermis. All of these tissues are stratified epithelia, defined as having multiple layers of cells with only the basal cells remaining in contact with the basement membrane. The lens can also be thought of as a stratified epithelial tissue. Although all of the cells of the lens vesicle and the lens epithelial cells remain attached to the basement membrane (lens capsule), fiber cells eventually lose their attachment to the lens capsule and eventually form layers of fiber cells with the oldest (primary) fiber cells in the center with progressively younger layers of secondary fiber cells, derived from the lens epithelium, at the periphery.

Secondary Fiber Cell Differentiation

Primary fiber cells are only those fiber cells derived from the posterior cells of the lens vesicle. The majority of fiber cells present in the mature lens are derived from the continuous differentiation of lens epithelial cells, which takes place at the lens equator.

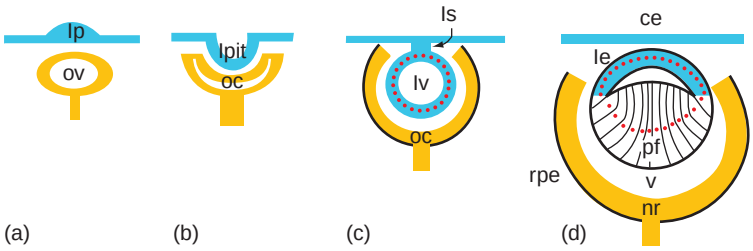

Figure 1 Early stages of terrestrial vertebrate lens development. (a) The first morphological sign of lens development is a thickening of surface ectoderm overlying the optic vesicle (ov) into a lens placode (lp). (b) The lens placode subsequently invaginates to form a lens pit (lpit) as the optic vesicle invaginates to form the optic cup (oc). (c) The lens pit eventually forms a hollow, closed lens vesicle (lv) consisting of a single layer of cells initially joined to the overlying surface ectoderm through a transient lens stalk (ls). At this time, the outer layer of the optic cup starts differentiating into the retina pigment epithelium (rpe). (d) The cells making up the posterior half of the lens vesicle begin the process of elongation signaling the initial differentiation of the primary lens fiber cells (pf). The anterior cells of the lens vesicle will differentiate into the lens epithelium (le) and the overlying surface ectoderm is fated to become the corneal epithelium (ce). The inner layer of the optic cup will subsequently differentiate into the neural retina (nr). The space between the lens and neural retina is where the vitreous (v) will eventually form.

Cell-Cycle Withdrawal

As the lens epithelium differentiates from the anterior lens vesicle cells, lens cell proliferation becomes restricted to a narrow band of cells slightly anterior to the lens equator known as the germinative zone. As cell proliferation in the germinative zone continues, some epithelial cells are displaced toward the equator into a region of postmitotic cells called the transitional zone (in most mammals) or the annular pad (in birds and most reptiles). In mice, the transitional zone is only six to seven cells wide. It is while the cells are in the transitional zone that the very first molecular signs of secondary fiber cell differentiation become apparent. These cells increase their synthesis of the transcription factor Prox1 and the cyclin-dependent kinase inhibitor p57Kip2. The *p57Kip2* gene is paternally imprinted in mammals and is essential for proper cell-cycle withdrawal during fiber differentiation. As cells move through the transitional zone toward the equator, their nuclei go from being randomly arranged to lining up in radial columns called meridional rows (**Figure 2(a)**). This establishment of regular packing order is the first morphological evidence of secondary fiber cell formation and is the genesis of the hexagonal shape (easily seen in lens cross sections along the equatorial plane) maintained by secondary fiber cells throughout their subsequent differentiation stages (**Figure 2(b)**). In contrast, primary fiber cells in the embryonic lens nucleus do not exhibit a regular hexagonal packing shape in cross section (**Figure 2(c)**).

Fiber Cell Elongation

As meridional rows are forming, these differentiating cells begin the process of elongation. There is evidence from chick lens epithelial explants that primary fiber cell elongation is driven by increased cytoplasmic volume resulting both from increased intracellular potassium and by increased protein synthesis. In contrast, morphometric confocal microscopy studies on living mouse lenses demonstrated that initial elongation of secondary fiber cells is not coupled with a directly proportional increase in cell volume. Although fiber cells are much longer than epithelial cells, they are also much thinner, and exhibit a ribbon-like morphology. The driving force for the initial elongation of lens epithelial cells appears to be changes in cell shape mediated by cytoskeletal remodeling. The precise mechanism of this remodeling is not known, but fiber cell elongation is insensitive to nocodazole, suggesting that microtubules are not essential for the process. These young differentiating secondary fiber cells are found at the lens equator and the arrangement of the nuclei of differentiating cells in this region (seen in transverse lens sections) resembles the arc of a bow from which the bow region of the lens received its name (**Figure 2**).

Crystallin Synthesis

Upon differentiation, fiber cells begin synthesizing large quantities of fiber-cell-specific (or fiber-cell-preferred) crystallins, most notably the β-crystallins (in all vertebrate lenses) and γ-crystallins (which are largely missing from birds) and several other taxon-specific crystallins. Crystallins are typically very stable proteins, and collectively crystallins accumulate to extremely high concentrations in the lens fiber cells. The extremely high protein content of lens crystallins is thought to be necessary for short-range order required for the transparency and refractive power of the lens.

Fiber Cell Membranes

As lens fiber cells mature, several membrane specializations occur. There are a number of membrane proteins that are only found in lens fiber cells. The most abundant of these is aquaporin 0 (AQP0); also known as major

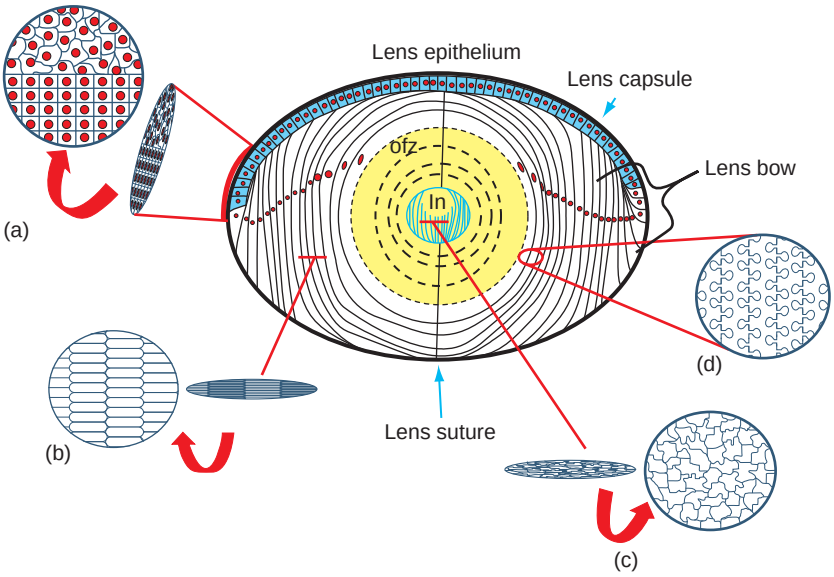

Figure 2 A transverse view of a section of mature lens. The lens epithelium occupies a single layer of cuboidal cells lining the anterior hemisphere of the lens (shaded cells). The entire lens surface is covered with a lens capsule. (a) The first morphological sign of secondary fiber differentiation is the formation of meridional rows of lens cells as previously randomly arranged transitional zone lens epithelial cells approach the equator. These meridional rows of cells begin elongating with basal fiber ends remaining in contact with the lens capsule and apical ends contacting the lens epithelium. The arrangement of nuclei (red circles) when viewed in transverse section form the characteristic lens bow representing the differentiation zone of cortical secondary fiber cells. (b) Cross sections through the lens cortex demonstrate the hexagonal arrangement typical of secondary lens fiber cells. (c) Cross sections through the embryonic lens nucleus (ln) containing the primary lens fiber cells do not resemble the hexagonal arrangement of secondary fiber cell membranes. Eventually, the cortical fiber cells detach from the lens capsule and the lens epithelium and join oppositely oriented lens fiber cells to form anterior and posterior lens sutures, the pattern of which is characteristic for a given species. (d) Fiber cell membranes become progressively more intertwined by ball-and-socket joints as they mature. Just before the destruction of nuclei and other cytoplasmic organelles mature, fiber cell membranes fuse and open large cytoplasmic pores that allow for the movement of proteins and other materials throughout the syncytium of the lens organelle free zone (ofz).

intrinsic protein (MIP) or MIP26, it is the founding member of the aquaporin water channel family of proteins, but its water permeability is much less than that of AQP1 (present in epithelial cells including lens epithelium). AQP0 is also pH dependent, being more active at low pH. It contributes as much as 60% of total fiber cell membrane protein and is responsible for the bulk of water transport between fiber cells. The relatively low water permeability and high abundance of AQP0 suggest that it serves a dual role of both a cell–cell channel and adhesion molecule in the lens. MP20 (also known as lens intrinsic membrane protein 2 (LIM2)) is also an abundant fiber-cell-specific membrane protein. It is a tetraspanin protein thought to act as a transmembrane scaffolding protein aiding in the assembly of membrane signaling complexes. In contrast to AQP0, which is always membrane associated, MP20 is cytoplasmic in young fiber cells and is exclusively localized to the membrane corresponding to the stage when lens nuclei are degraded. Mutations in either AQP0 or MP20 cause cataracts in mice.

The membranes of both lens epithelial cells and lens fiber cells are connected through gap junctions formed by connexin proteins. Although the nomenclature and molecular size of gap-junction orthologs differ among vertebrate species, the lens contains three gap-junction proteins that demonstrate differential expression patterns. The lens epithelium expresses two of these, known as connexin 43 (also known as gap-junction protein, alpha 1 (Gja1)) and connexin 50 (also known as Gja8), in mice and humans. Upon fiber differentiation, connexin 43 expression ceases, connexin 50 expression continues and connexin 46 (also known as Gja3) expression initiates. Connexin 43 is expressed in many tissues, but connexins 46 and 50 are found only in the lens. Subunits of connexins 46 and 50 may mix in fiber cells to form heteromeric gap-junction channels. Mice lacking either connexin 46 or 50 develop cataracts. Connexin 50 also plays a specific role in lens growth as lenses lacking this connexin are significantly smaller than wild-type lenses. While connexins are generally thought to function specifically through the formation of gap junctions, there is some evidence that expression of connexin 45.6 (the chick ortholog of connexin 50) is capable of stimulating fiber cell differentiation, independent of its ability to form a functional gap-junction channel.

As fiber cells mature, several structural membrane modifications develop. Among these is the formation of interdigitations between the lateral surfaces of neighboring fiber cells known as ball-and-socket junctions (**Figure 2(d)**).

These junctions interlock the fiber cells together and help keep adjacent fibers from sliding past each other when the lens stretches during accommodation. In the deeper (older) secondary fiber cells, this interlocking nature is exaggerated by the formation of paddle-like extensions that are formed after organelles are eliminated, suggesting that their formation does not require *de novo* protein synthesis. Finally, in the oldest nuclear fiber cells, a further level of compression is achieved by the formation of accordion-like folds of fiber cells in the plane of the visual axis.

Fiber cells also have both basal and apical membranes. The basal membrane is initially in contact with the lens capsule through an extensive basal membrane complex consisting of a lattice-like network of neural cadherin (N-cadherin), fibrous actin (F-actin), and myosin. The basal ends of the fiber cells adhere to the capsule through α6β1 integrin interaction with capsular laminin-1. The contractile proteins present in the basal membrane complex allow fiber cells to migrate in a posterior direction along the capsule as they mature. The apical membrane of young fiber cells is apposed to the apical membrane of lens epithelial cells. Although there are some gap junctions connecting the apical–apical fiber–epithelial interface, these are relatively rare and it is thought that little molecular transport occurs across this interface. The apical membrane does contain an actin network, but the organization is not as regular as seen in the basal membrane complex. Nevertheless, the apical fiber cell membrane also migrates in an anterior direction as fiber cells mature. As secondary fiber cells elongate in mammals, they assume an opposite-end curvature giving them a three-dimensional S-shape. The basal membrane complex breaks down as the posterior end of the fiber cell reaches the lens suture branch. Likewise, the apical membrane loses its attachment to the epithelium near the anterior suture branch. The basal and apical ends of oppositely oriented fiber cells flare outward relative to their mid-portions and join to form posterior and anterior lens sutures, the pattern of which is characteristic for any given species. In the final phases of lens fiber differentiation, lens cell membranes partially fuse and large pores form creating cytoplasmic connections between fiber cells. This process takes place shortly before intracellular organelles are destroyed and results in what is known as the lens syncytium. Large molecules, including proteins, can diffuse from cell to cell within this most central region of the lens.

Fiber Cell Cytoskeleton

Fiber cells also develop an extensive cytoskeletal network. Although the cell adhesion molecule, N-cadherin, is found in both epithelial cells and fiber cells, it specifically localizes to fiber cell membranes upon differentiation. N-cadherin also co-localizes with F-actin and β-catenin on the lateral membranes of the hexagonally packed fiber cells. In contrast, N-cadherin associates with γ-catenin at the vertices of the fiber cell hexagons. γ-Catenin also associates with desmoplakin and vimentin intermediate filaments in this N-cadherin-based junctional complex. Lens fiber cells also uniquely express components of intermediate beaded filaments, filensin (CP115) and phakinin (CP49). Proteomic studies have demonstrated an interaction of both filensin and phakinin with AQP0 at the cell membrane. Phakinin and vimentin also associate with lengsin at fiber cell membranes. Lengsin is a lens-specific protein related to glutamine synthase which appears to have been evolutionarily recruited to serve as a lens cytoskeletal protein in vertebrates. In mice, lengsin expression initiates in fiber cells just prior to organelle loss. Interestingly, this is precisely the time when beaded filaments undergo a redistribution from being primarily associated with the plasma membrane to being distributed throughout the cytoplasm. Cytoskeletal remodeling is an essential component of both fiber cell elongation and migration. Networks of F-actin and myosin IIB, predominantly localized at the basal membrane complex, are likely regulated by myosin light-chain kinase and small guanosine triphosphate (GTP)-binding proteins such as Rho. Protrusive lamellipodia-like processes have also been observed on both basal and apical fiber cell tips, suggesting that these cellular extensions may play a direct role in the migration of the ends of the fiber cells.

Organelle Elimination

The lack of organelles is one of the most striking features of a fully mature fiber cell. Failure to eliminate organelles from mature fiber cells results in light scattering and cataract formation. Fiber cells are transcriptionally and translationally active until shortly before the loss of nuclei. Evidence for this comes from the expression of at least two proteins (lengsin and hop) in mouse fiber cells between the time of capsule detachment and nuclear loss. The process of nuclear breakdown takes place over some period of time and the morphological events associated with nuclear destruction vary among species. In contrast, the loss of mitochondria and other organelles takes place very rapidly, over the course of a few hours. The end of the nuclear breakdown and loss of other cytoplasmic organelles are coordinated such that there is a sharp boundary between organelle-containing fiber cells and the organelle-free zone (**Figure 2**). The destruction of the nucleus and other cytoplasmic organelles has been compared to the process of apoptosis, but in contrast to apoptosis, fiber cells must remain in place to ensure transparency of the lens as a whole. Recent evidence has also demonstrated that the proteases that initiate the destructive processes in apoptosis (caspase-3, caspase-6, and caspase-7) are not required for organelle breakdown in lens fiber cells. In contrast, DNase IIβ, which is not essential for apoptosis, is required fiber cell denucleation.

Mice lacking this enzyme develop nuclear cataracts and retain DNA-containing nuclear remnants in mature fiber cells. However, mature fiber cells deficient in DNase IIβ do not contain mitochondria and other organelles, suggesting that DNase IIβ is not required to initiate organelle loss. Lactacystin (an inhibitor of the ubiquitin–proteosome pathway) is able to inhibit mitochondrial breakdown in lens fiber cells *in vivo*, suggesting that the ubiquitin–proteosome pathway is required for the creation of the organelle-free zone. The regulatory mechanism that triggers organelle breakdown in the lens is not known. A number of different mutations and perturbations of the lens appear to inhibit nuclear breakdown, but these may be secondary to their disruption of fiber cell homeostasis, as organelle loss is a late event in fiber cell maturation. It has been hypothesized that organelle loss may be triggered by a combination of decreasing oxygen concentration and increasing calcium concentration as fiber cells move further from the superficial layers of the lens cortex, but the resolution of the precise trigger for organelle breakdown remains a matter of debate.

The entire lens is surrounded by a lens capsule which is secreted by the lens cells. This capsule starts out as the basement membrane of the lens vesicle cells and thickens as the lens matures. The capsule ensures that no cells enter or leave the intact lens. Occasional apoptotic cells appear within the lens epithelium during normal development. However, most lens cells remain in the lens for the life of the organism. Analogous to the way the history of a tree is retained within its rings, the developmental history of a lens is also retained within the tissue. The primary fiber cells remain at the center of the lens, forming the embryonic lens nucleus. Therefore, the cells within the embryonic lens nucleus are among the oldest cells in the body. The embryonic lens nucleus is enveloped by layer upon layer of secondary fiber cells with progressively younger cells being found in a central to peripheral gradient. The lens epithelium remains as a single layer of cells lining the anterior lens hemisphere.

Experimental Approaches to Study Lens Fiber Cell Differentiation

Classical experiments by Coulombre and Coulombre in the 1960s provided the first direct evidence that the polarity of the lens (with the epithelium on the anterior lens surface and the differentiated fiber cells posterior to the epithelium) was dictated by extrinsic factors. In these experiments, embryonic chick lenses were surgically reversed such that the lens epithelium faced the retina and the posterior surface of the lens faced the cornea. Within a few days, the epithelial cells on the reversed lens surface formed a new fiber cell mass and the equatorial epithelium migrated anteriorly to form a new epithelium on what had been the posterior face of the lens. This suggested that factors in the vitreous (the gel-like material between the retina and lens) promoted lens fiber differentiation and that factors in the aqueous (fluid between the cornea and lens) promoted lens epithelial maintenance. Similar experiments conducted with mouse eyes by Yamamoto in 1976 reached similar conclusions.

Most of the current molecular understanding of the regulation of fiber differentiation comes from three basic types of experiments. The first of these is the study of primary dissociated lens epithelial cells in culture; the second experimental system is the lens explant; and the third is direct studies in living embryos or genetically manipulated animals.

Dissociated lens epithelial experiments are often done with isolated chick lens epithelial cells grown on different substrates that differentially promote migration or differentiation of these epithelial cells to fiber-like cells present in aggregations of cells called lentoid bodies. These lentoid bodies express fiber-preferred crystallins and exhibit many of the features of normal lens fiber cells. The advantages of these experiments include the relative ease by which these cells can be transfected and grown in culture. The most common criticism of this experimental approach lies in the fact that epithelial cells often behave abnormally when separated from their normal basement membrane.

Lens explants are prepared by removing the fiber cells from the lens while leaving epithelial cells attached to the lens capsule. As the attachment of the lens epithelial cells to the capsule is quite strong, this can be accomplished simply by peeling off the capsule and removing the fiber cell mass. The capsule can then be pinned to a culture dish with the epithelium either above or below the capsule. Epithelial cells cultured in this way can go through all of the stages of fiber differentiation including organelle loss. Another similar approach is the lens capsular bag, where the lens fiber cell mass is removed through a hole in the capsule much the way cataracts are surgically removed in the clinic. Epithelial cells will remain attached to the capsule and the whole capsule with epithelial cells attached can be grown in culture. These approaches have the advantage of being amenable to defined culture conditions without disrupting lens epithelial cell polarity, cell–cell interaction, or cell–basement-membrane interaction.

It is always most powerful to be able to elucidate developmental pathways in the context of normal development. Unfortunately embryonic development *in vivo* is complicated and achieving defined experimental conditions is difficult. Modern genetic techniques that specifically add or subtract genetic information during development have contributed a great deal to our present understanding about regulatory networks involved in lens fiber differentiation. RNA interference (RNAi), morpholinos, and gene targeting in embryonic stem cells can be used to knock down or knock out specific gene expression, while transgenic, *in vivo* electroporation and viral vector strategies can easily add genetic

information to the developing embryo. Although many modern genetic strategies are amenable to manipulating development in a wide variety of species, unless otherwise noted, the references about the role of specific genes during *in vivo* fiber differentiation for the remainder of this article are derived from studies in using transgenic or gene-targeted mice.

Regulation of Fiber Cell Differentiation

Although the precise molecular events initiating primary lens fiber cell differentiation *in vivo* are not known, gene deletion studies in mice have revealed several genes essential for this process. Obviously, transcription factors essential for lens induction (e.g., Pax6) will secondarily be essential for lens fiber cell differentiation. Cells of the lens vesicle initially express a set of characteristic transcription factors, including Foxe3, c-Maf (or L-Maf in the case of chickens and Xenopus), Pax6, Pitx3, Prox1, Six3, and at least one member of the group B1 Sox genes (Sox1, Sox2, and/or Sox3, depending on the species). Genetic studies in several organisms demonstrate that each of these transcription factors is required for lens formation and/or development. While it is sometimes difficult to discern where to draw the line between those genes necessary for lens induction and those required for later stages of lens development, there are genes that appear to be specifically important for fiber cell differentiation. Defects in many of these disrupt normal primary lens fiber differentiation, often resulting in a lens where the fiber cells fail to fill the lumen of the lens vesicle.

Transcription Factors

Primary fiber cells in mice deficient for the transcription factors, c-Maf, Prox1, and Sox1, fail to completely elongate, inefficiently withdraw from the cell cycle, and are missing specific subsets of crystallin proteins. In particular, c-Maf-deficient mice have very low-to-undetectable levels of β- and γ-crystallin expression. The discovery of functional c-Maf-binding sites in the promoters of many crystallin genes suggests that these crystallins are directly regulated by c-Maf. c-Maf-binding sites have not been identified in the promoters of filensin, phakinin, and AQ0, but the expression of all of these genes is greatly reduced in *c-Maf* knock-out mice, suggesting that these genes are indirectly regulated by c-Maf. Likewise, Sox-binding sites are present in the promoters of all of the genes in the mouse gamma crystallin cluster (γA, γB, γC, γD, γE, and γF) and none of these genes is expressed in *Sox1* knock-out mice despite persistence of β-crystallin gene expression. Sox2 and/or Sox3 are important in lens induction of several species as well, but it appears that the role of Sox1 is most important during the fiber differentiation stage of development, at least in mice. Prox1-deficient mice do not express γB or γD crystallins and fail to increase the levels of the cyclin-dependent kinase inhibitor, p57Kip2, which likely explains the failure of lens cells from this mutant to withdraw from the cell cycle. Another transcription factor, Pitx3, is expressed in the lens placode and vesicle and Pitx3 expression within the lens is highest in the bow region. Lenses in mice homozygous for the spontaneous *Pitx3* mutation, *aphakia*, degenerate shortly after the initiation of primary fiber cell differentiation. The phenotype of the Pitx3 mutant mice differs from that of the c-Maf, Sox1, and Prox1 mutants in that there is no persistence of a hollow lens vesicle. It is likely that defective lens development of Pitx3 mutants is more a problem of lens specification/induction than specifically with fiber cell differentiation. Experiments in zebrafish suggesting that Pitx3 is in a genetic pathway upstream of Foxe3, which is required for the normal development of lens epithelial cells, support this notion.

Several other transcription factors need to be down-regulated during fiber cell differentiation. Notably, Pax6, and Foxe3 expression falls during lens fiber cell differentiation and transgene-mediated overexpression of either of these transcription factors in maturing fiber cells results in abnormal differentiation.

Growth Factors

The search for the fiber cell differentiation factor has been going on at least since the experiments of Coulombre and Coulombre demonstrated that factors supplied by the ocular environment control lens fiber differentiation. Vitreous fluid is a rich source of factors that can induce lens fiber differentiation in lens epithelial explants. Multiple lines of evidence suggest that both bone morphogenetic proteins (Bmps) and fibroblast growth factors (Fgfs) are present in the vitreous fluid and play a role in lens fiber differentiation. Experiments performed with dissociated chick lens epithelial cell monolayers have demonstrated that both Fgfs and Bmps are capable of stimulating lens epithelial cell elongation as well as the expression of several fiber-cell-specific genes.

The importance of both Fgf- and Bmp-mediated signal transduction cascades in fiber cell differentiation is also supported by genetic studies in mice. Clearly, Bmp4 and Bmp7 are important for lens induction, as lens formation is inhibited in mice lacking either of these growth factors. The role of Bmps, specifically in fiber cell differentiation, has been more difficult to discern. Mice lacking the type I Bmp receptor, *Acvr1* (*Alk2*), develop elongated fiber cells that express many characteristic fiber cell proteins. These Acvr1-deficient cells did display a defect in cell-cycle withdrawal that normally accompanies fiber cell differentiation, likely due, at least in part, to decreased expression of p57Kip2 (**Figure 3**). Similarly, mouse lenses lacking

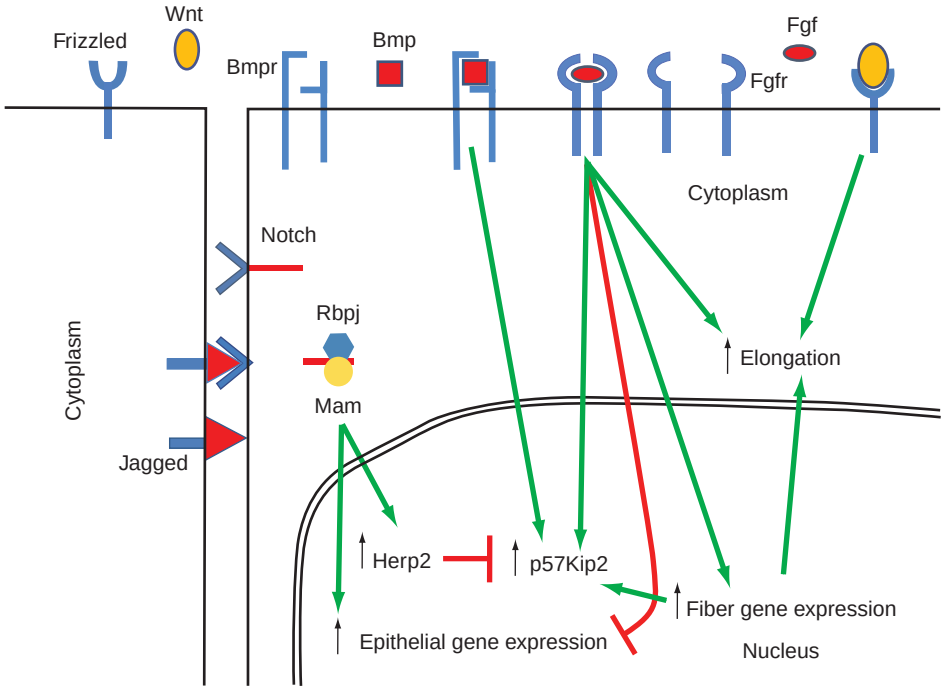

Figure 3 Ligand–receptor signaling controlling fiber differentiation in lens epithelial cells. Adjacent lens epithelial cells are shown with Bmp receptors (Bmprs), Fgf receptors (Fgfrs), Frizzled receptors and Notch receptors embedded in the plasma membrane and soluble Bmp, Fgf, and Wnt ligands as well as cell-associated Jagged ligands. Upon Jagged activation of Notch receptors present on the plasma membrane, the intracellular domain of Notch disassociates with the membrane and associates with Rbpj and Mam proteins to form a transcriptional signaling complex that directly activates expression of Herp2 and directly or indirectly promotes lens epithelial gene expression. Herp2 directly inhibits the promoter for p57Kip2, thus keeping lens epithelial cells in the cell cycle. Bmp and Fgf signaling increase p57Kip2 expression and cell-cycle withdrawal. Fgf signaling also promotes the expression of several lens fiber-cell-specific genes and aids in the repression of gene expression associated with lens epithelial cells. Fgf signaling also promotes lens fiber elongation as does Wnt signaling, most likely acting through the Wnt/planar cell polarity pathway.

intracellular mothers against decapentaplegic (Smad) proteins necessary for canonical Bmp signaling (Smad1, Smad4, or Smad5) exhibit elongating fiber cells that fail to completely exit the cell cycle. Transgenic mice expressing the Bmp inhibitor, noggin, in the lens undergo morphologically normal primary fiber cell differentiation, but display inhibition of secondary fiber cell differentiation. These noggin transgenic mice eventually display a lens epithelial layer that covers most of the lens surface with a loss of the characteristic lens bow. Similar defects in secondary lens fiber differentiation were seen in transgenic mice expressing a soluble Fgf receptor (Fgfr), designed to interfere with endogenous lens Fgfr activity. Fgfs have been shown to promote lens fiber differentiation in dissociated lens epithelial cell monolayers, lens epithelial explants, and in transgenic mice. Lens fiber cells lacking *Fgfr2* elongate and express many genes consistent with fiber cell differentiation but exhibit defects in cell-cycle withdrawal associated with incomplete induction of p57Kip2. Combined deletion of *Fgfr1, Fgfr2*, and *Fgfr3* in the lens vesicle inhibits multiple aspects of both primary and secondary fiber cell differentiation (**Figure 3**). Presumptive fiber cells from these triple *Fgfr* knock-out mice fail to induce p57Kip2 and thus remain in the cell cycle. These cells also do not properly elongate or initiate fiber-cell-specific gene expression; instead, they express genes characteristic of lens epithelial cells, including E-cadherin, Pax6, and Foxe3.

There is also evidence that Wnt signaling plays a role in lens fiber cell differentiation. Although canonical Wnt signaling, through stabilization of β-catenin, has been shown to suppress lens fate in the ectoderm surrounding the lens placode, the lens later expresses a number of Wnt ligands, Wnt (frizzled) receptors and modulators of Wnt signaling. The role of canonical Wnt signaling in fiber cell differentiation is controversial. Reporter mice indicate only a brief period of canonical Wnt signaling in the anterior cells of the lens vesicle and in the early embryonic lens epithelium. Despite this, Wnt3a-conditioned media or overexpression of β-catenin has been shown to activate β-crystallin expression in lens cell cultures. Recent evidence with transgenic mice overexpressing a secreted frizzled-related protein (Sfrp2), a protein that interferes with Wnt signaling, suggests that Wnts play a role in lens development through the noncanonical Wnt/planar cell polarity pathway (**Figure 3**). Fiber cells in Sfrp2 transgenic mice do not elongate completely, leaving a lumen between the primary fiber cells and the lens epithelium. Secondary

fiber cells from the Sfrp2 transgenic mice also exhibited nuclear retention and cytoskeletal disruption. Both the anterior and posterior tips of the fiber cells lacked filopodia-like protrusive processes and failed to appropriately migrate, detach from the capsule, and form sutures, leading to an abnormally shaped lens with fiber cells exhibiting abnormal curvatures.

Notch Signaling

Notch is a cell surface receptor that interacts with membrane-associated ligands, such as Jagged, on neighboring cells. Activation of Notch receptors leads to the release of the intracellular domain which forms a DNA-binding complex in association with Rbpj and Mam proteins to activate transcription. Notch signaling during development typically acts to prevent differentiation, while Notch signaling in the lens epithelium activates the expression of Herp2, which binds to and represses the promoter of p57Kip2, thus maintaining lens epithelial cells in a proliferative state (**Figure 3**). Lens epithelial cells with conditional deletion of Rbpj lose expression of Herp2 and prematurely express p57Kip2, leading to cell-cycle withdrawal and fiber differentiation. These findings are consistent with Notch signaling playing a critical role in the regulation of the choice between proliferation and differentiation in the lens.

Conclusion

Lens fiber differentiation is a complex process that is undoubtedly supported by a number of growth factors, receptors, and transcription factors, only a few of which have been highlighted here. Likewise, these ligand–receptor complexes initiate many intracellular signal transduction cascades that ultimately turn on genes required for fiber cell formation and turn off genes required for lens epithelial maintenance. The elucidation of the complete molecular mechanics of these processes remains an active area of research that is far from complete.

Lens Gap Junctions

E C Beyer and V M Berthoud, University of Chicago, Chicago, IL, USA

Glossary

Connexin – A subunit protein component of gap junction channels.
Gap junction – The plasma membrane specialization characterized by the close apposition of the plasma membranes of adjacent cells leaving a gap of 2–3 nm that contains clusters of intercellular channels made of connexins.
Gap junction-mediated intercellular communication – The direct transfer of ions and molecules between the cytoplasm of adjacent cells through gap junction channels.
Lentoid cultures – Lens cells that, in culture, begin to differentiate into fiber cells. In this process, the cells aggregate to form clusters that express increased levels of markers of fiber cell differentiation. Lentoid cultures can be used to study the assembly and regulation of gap junctions in lens fiber-like cells.

Lens Structure and Importance of Intercellular Communication for Lens Function

The lens is a transparent organ suspended between the aqueous humor and the vitreous whose main function is to transmit light and focus it onto the retina. The lens is comprised of two cell types: epithelial cells that form a single layer along the anterior surface and fiber cells that form the bulk of the organ (Figure 1). At the lens equator, epithelial cells differentiate into fiber cells, a process that involves cell elongation and loss of nuclei and organelles. Most of the synthetic and active transport machinery of the lens is present only in the nucleated surface cells. Mature fiber cells have limited metabolic activities, are nondividing, and must survive for the life span of the organism.

As there is no direct blood supply to the organ, specialized mechanisms are required to allow survival of the cells in the interior of the lens. Nutrients for the entire organ derive from the aqueous humor through uptake by the epithelial cells. The lens may have an internal circulation in which flow of ions drives the movement of solutes throughout the organ. A model of this circulation has been developed based on surface currents recorded from lenses. In this model, current (i.e., flow of ions and associated water and solutes) enters the lens along the extracellular spaces at the anterior and posterior poles, it crosses fiber cell membranes in the lens interior, and it flows back to the surface at the equator (through a cell-to-cell pathway). The lens circulatory system provides a pathway for internal fiber cells to obtain essential nutrients, remove potentially toxic metabolites, and maintain resting potentials. Thus, fiber cell survival and the maintenance of transparency depend on the function of epithelial cells and on communication between cells.

Structure and Components of Gap Junctions

Intercellular communication among lens cells is facilitated by an extensive network of gap junction channels. Gap junctions are plasma membrane specializations that contain clusters of intercellular channels that allow direct exchange of cytoplasmic ions and small molecules (<1 kDa) between coupled cells without encountering the extracellular space (Figure 2(a)). A gap junction channel is formed by docking of two hexameric hemichannels or connexons (Figure 2(b)) located in the plasma membranes of apposing cells. The subunit gap junction proteins are members of a family of related polytopic membrane proteins called connexins (CX). The proteins that form vertebrate gap junctions are called connexins. The official names of the human genes encoding these proteins are *GJA1* for CX43, *GJA3* for CX46, and *GJA8* for CX50. This article utilizes only the connexin nomenclature in which different connexins are identified based on their predicted molecular masses in kDa (e.g., CX43 is a 43-kDa protein). To avoid the confusion that arises due to different masses of the orthologous connexins in other species, this article identifies each connexin using the name for its human isoform. There is a second family of vertebrate proteins called pannexins that are related to the innexins which form gap junctions in invertebrates. Although there is pannexin expression in the lens, the pannexins may not form intercellular channels; therefore, they are not included in this article. Connexins contain four transmembrane domains and have both their amino and carboxyl termini located in the cytoplasm (Figure 2(c)). Among connexin family members, the extracellular and transmembrane domains are the most conserved, while the cytoplasmic domains are the most divergent.

Distribution of Connexins within the Lens

Three connexins have been identified in the lens with different, but overlapping, expression patterns (Figure 1). CX43 is produced in lens epithelial cells, but its expression is turned off as epithelial cells in the equatorial region differentiate into fiber cells. CX50 is also expressed in epithelial cells. CX46 and CX50 are abundantly expressed in the differentiating cells and are the only connexins found in lens fiber cells. CX46 and CX50 co-localize at gap junctional plaques and form mixed (hetero-oligomeric) connexons. Despite their similar expression patterns, CX46 and CX50 must have some differences in function, since substitution of CX46 for CX50 in genetically engineered mice does not result in entirely normal lenses.

Transcripts encoding a fourth connexin, CX23, have been detected in lenses of zebrafish embryos and mice. CX23 may be expressed in lens cells of other mammalian species, since it has been identified as an expressed sequence in messenger RNA (mRNA) from whole eyes or lenses. However, no transcripts have been detected in human lenses. This connexin may be involved in fiber cell differentiation, since elongation of fiber cells is abnormal in mice expressing a missense mutant of CX23. However, several issues regarding CX23 have not yet been resolved, including detection of CX23 protein in lens cells, determination of its abundance and, more importantly, its contribution to lens intercellular communication, relative to other connexins. Therefore, CX23 is not included in Figure 1.

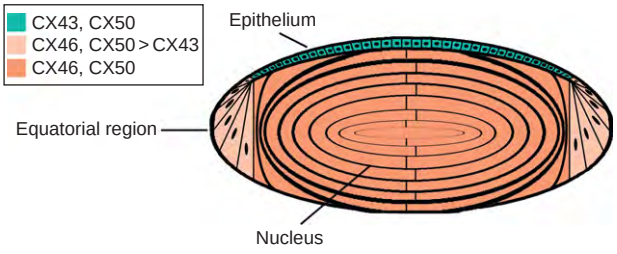

Figure 1 Diagram of the lens showing the distribution of three connexin isoforms. Different colors indicate regions with different connexin expression patterns. Cells from the anterior epithelial layer express CX43 and CX50; cells from the equatorial region express CX43, CX46, and CX50; and fiber cells (including those of the nucleus) contain CX46 and CX50.

Physiology and Pharmacology of Gap Junction-Mediated Intercellular Communication

The behavior of intercellular channels formed of connexins has been studied in expression systems, including paired *Xenopus* oocytes and transfected mammalian cells, using electrophysiological techniques such as voltage clamp and patch clamp. The gap junction conductance between a pair of cells depends on the number of channels, their open probabilities, and their single-channel conductances.

Each connexin forms channels with distinct properties, including unitary conductance, permeability, charge selectivity, gating, and regulation by different protein kinase-dependent pathways. CX43 gap junction channels are permeable to larger molecules than channels formed of CX46 or CX50. Thus, the permeability of gap junction channels in different regions of the lens is determined, in part, by the repertoire of connexins expressed.

Although there are connexin-specific differences in sensitivity to these agents, all gap junction channels are regulated by voltage (transjunctional and sometimes transmembrane), calcium, and pH. High transjunctional voltage, high concentrations of intracellular calcium, and low cytoplasmic pH close gap junction channels. Regulation by transjunctional voltage is not significant in the lens where cells have similar resting potentials. Both calcium- and pH-dependent regulation of gap junctions may be important in the lens, because calcium concentration is higher in the lens perinuclear region and pH decreases toward the lens interior. As in other tissues/organs, closure of gap junctions by voltage, calcium, and pH may contribute to the cellular response to injury in the lens,

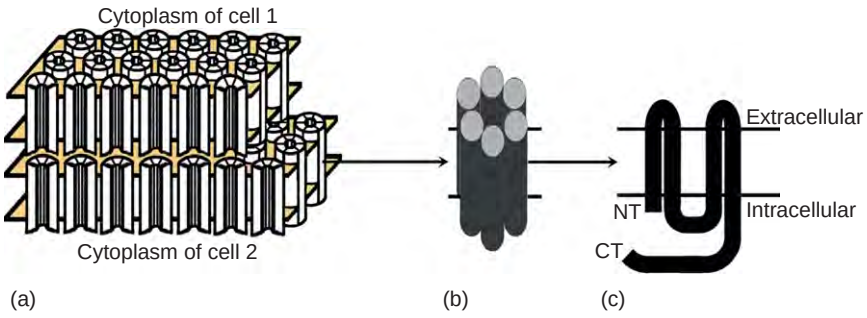

Figure 2 Diagram of a gap junction (a), a hemichannel or connexon (b), and the subunit gap junction protein, connexin (c). NT, amino terminus; CT, carboxyl terminus.

since the resulting disruption of intercellular communication would isolate intact cells from damaged ones.

Gap junction channels can also be closed by several pharmacologic agents, including long-chain alkanols (e.g., heptanol and octanol), anesthetics (e.g., halothane), glycyrrhetinic acid derivatives, oleamide, arachidonic acid or its metabolites, and the antimalarial compounds quinine and mefloquine. All of these are rather nonselective agents that also affect other channels or cellular functions; therefore, they are unlikely to be of therapeutic utility as selective lens gap junction blockers. However, mefloquine inhibits CX50 channels at much lower concentrations than it blocks other connexins; therefore, it has been used to determine the physiological role of CX50 in the lens.

Connexin Functions beyond Intercellular Communication

In addition to forming intercellular channels, connexins can also form hemichannels that introduce large, relatively nonselective conductances in single plasma membranes. (These conductances appear to represent permeation through undocked single connexons.) This phenomenon has been best demonstrated in primary cultures of various cells and in expression systems. One of the most dramatic examples is the large permeability induced by expression of CX46 in single *Xenopus* oocytes that can be gated by modulation of extracellular concentrations of divalent cations, including calcium. As CX46 hemichannels are mechanosensitive, it has been proposed that their opening plays a physiological role during lens accommodation. Opening of such hemichannels has not yet been demonstrated in intact tissues.

Connexins may also be involved in functions not directly associated with their channel-forming ability. Expression of the chicken CX50 ortholog (including nonfunctional mutants) or a chicken CX46 chimera containing the CX50 carboxyl terminus promotes differentiation of chicken lens cells in culture. The mechanism for these nonchannel-induced effects of CX50 has not been clarified, but it has been suggested that it involves interactions of its carboxyl terminus with other cellular proteins to modulate intracellular signaling critical for lens cell differentiation.

CX50 is also required for normal growth of the lens. Mice that are null for CX50 (but not those null for CX46) have small lenses. The decreased lens size appears to result from reduced proliferation of lens epithelial cells, especially during the first few days of postnatal life. It has been speculated that this proliferative deficiency is due to some connexin function other than intercellular exchange of ions, since introduction of CX46 into the CX50 locus does not restore normal lens growth to CX50-null mice. Overexpression of CX50 also leads to a decrease in lens size; thus, the proper level of CX50 expression is required for normal lens development and growth.

Regulation of Connexin Functions by Protein Modification

Similar to many other proteins, connexins are subject to post-translational modifications. A variety of modifications has been detected in the connexins found in different cells and tissues, including phosphorylation, acetylation, ubiquitinylation, S-nitrosylation, fatty acylation, hydroxylation, γ-carboxyglutamylation, and cleavage/partial proteolysis. The functional consequences of many of these protein modifications remain to be determined. Phosphorylation and proteolytic cleavage are the most extensively studied modifications of lens connexins and may be associated with physiological effects on connexin function.

Phosphorylation

Many of the connexins, including CX43, CX46, and CX50, are phosphoproteins. A number of phosphorylated residues and the responsible kinases have been identified. These phosphorylation events are involved in the regulation of channel function or of various steps during formation and degradation of gap junction channels.

CX43 phosphorylation has been extensively studied. In many cell types, the immunoblot pattern of CX43 contains at least three major immunoreactive bands designated NP, P1, and P2. The NP band has the fastest electrophoretic mobility and, in some cases, corresponds to CX43 that is not phosphorylated. P1 and P2 correspond to different phosphorylated forms. The P2 form shows a slower electrophoretic mobility than P1, and its presence has been correlated with localization of the protein to gap junctional plaques and insolubility in Triton X-100. A P3 form with an electrophoretic mobility slower than P2 is observed in some cell lines during mitosis. At least 12 serines and two tyrosines in the carboxyl terminus of CX43 can be phosphorylated by different protein kinases.

In many cell types that express CX43 (including lens epithelial cells), treatment with activators of protein kinase C, PKC, (e.g., 12-*O*-tetradecanoyl phorbol ester, TPA) decreases intercellular communication. In most cases, this treatment is associated with a relative increase in the P1 and P2 forms of CX43 and a decrease in NP. Studies have suggested several different mechanisms for the reduction of gap junction function, including changes in single-channel conductance, channel permeability, connexin trafficking/assembly, and turnover/redistribution of gap junctions.

Several immunoreactive bands corresponding to different phosphorylated forms of CX46 and CX50 are

detectable in lens homogenates. Phosphorylation of the lens fiber cell connexins has been implicated in regulation of intercellular communication, protein stability, and proteolytic cleavage. The sheep CX50 is phosphorylated by casein kinase I, and inhibition of casein kinase I increases intercellular communication between cultured lens cells. Casein-kinase II-mediated phosphorylation of Ser363 in the chicken CX50 regulates its cleavage by a caspase-3-like protease. Phosphorylation may regulate the stability of chicken CX46, since its slowest migrating phosphorylated forms have longer half-lives.

The effects of phorbol esters and PKC activation on fiber cell connexins have been studied in lentoid-containing cultures and lens organ cultures. TPA treatment of cultures from chicken lenses decreases dye coupling between lentoid cells. The TPA-induced decrease in dye coupling is associated with activation of PKCγ and an increase in phosphorylation of chicken CX46 at Ser118, suggesting that phosphorylation leads to channel closure. Rat CX46 hemichannels are also modulated by PKC phosphorylation. A PKC activator reduces the amplitude of hemichannel currents and leads to their inactivation after prolonged incubation, an effect that can be inhibited by PKC inhibitors. Treatment of whole rat lenses with TPA results in increased PKCγ activity, decreased intercellular coupling in the lens cortex, decreased anti-CX50 immunoreactivity in gap junctions, and increased anti-CX50 immunoreactivity in the nonjunctional plasma membrane, suggesting that PKC activation leads to undocking and dispersion of CX50 hemichannels. However, in sheep lentoids, PKC activators have no effects on intercellular communication. These divergent findings may be explained by species differences, because the ovine CX50 ortholog is not a PKC substrate.

Cleavage/Proteolysis

In lens sections, immunofluorescent staining (performed using antibodies directed against epitopes in the carboxyl terminus of fiber cell connexins) shows a substantial decrease of staining intensity in the nuclear region. This reduction has been interpreted as due to proteolysis of this part of the connexin. In agreement with this interpretation, preparations of isolated lens gap junctions contain immunoreactive bands with electrophoretic mobilities corresponding to connexin polypeptides that are full length and to proteolytically cleaved products. While such connexin proteolysis is not seen in all systems, several investigators have suggested that cleavage of lens fiber connexins occurs *in vivo*. Calpains and a caspase-3-like protease have been implicated in connexin cleavage in different species.

The carboxyl terminus of connexins may play an important role in regulating channel activity. Intercellular coupling between lens fibers (but not between epithelial cells) is insensitive to acidification. It has been speculated that the lack of sensitivity results from cleavage of lens fiber connexins. When expressed in exogenous systems, truncated forms of CX50 are unresponsive to pH gating, whereas truncated forms of CX46 show a slight change in acid dissociation constant (K_a), but are still sensitive to pH. These results imply that the pH sensitivity of gap junctions in lens fiber cells is dominated by CX50. Therefore, it has been proposed that the cleavage of fiber cell connexins in the lens interior would allow gap junction channels to stay open in this rather acidic environment, facilitating the exchange of small molecules between fiber cells.

Connexins and Lens Pathologies

Cataracts in Mice with Genetically Manipulated Connexin Levels

The importance of gap junction-mediated lens intercellular communication for the maintenance of lens transparency has been substantiated by a number of genetic studies in mice. Targeted deletion of CX46 or CX50 results in the development of cataracts in homozygous but not heterozygous mice. The CX50-null mice have a more severe cataract than the CX46-null mice. The onset of the cataract phenotype in CX50 knock-out mice occurs within the first postnatal week, and results in a mild nuclear cataract that is characterized by a relative decrease in the solubility of crystallins. The cataracts in CX46-null mice are visible by the third week of age; they are associated with decreased solubility of several crystallins and proteolysis of γ-crystallins. In mice deficient in either of the lens fiber connexins, cataract severity varies with genetic background, suggesting the influence of additional genes. Double knock-out mice lacking both the CX46 and CX50 genes show dense opacities that are far more extensive than those observed in either the CX46- or CX50-single null mice. The increased severity of the opacities in these mice likely reflects the total absence of gap junction-mediated intercellular communication between lens fiber cells. Transgenic mice overexpressing CX50 in differentiating and lens fiber cells also develop severe cataracts, suggesting that any significant alteration of connexin levels in these cells (either absence or a major increase) may lead to cataract formation. The role of CX43 for normal lens function is uncertain. The lenses of prenatal or newborn CX43-null mice appear normal and transparent; however, the long-term effects of the loss of CX43 in the lens have not been determined in these mice, because global deletion of CX43 results in neonatal lethality. (Lens-specific deletion of CX43 has not been studied.)

Cataracts due to Connexin Mutations

The cataract trait in several mutant mouse strains has been mapped to the lens connexin gene loci. The *No2*

mouse, which develops congenital cataracts (especially in homozygotes), carries a missense mutation within the coding region of CX50, resulting in a change of amino acid residue 47 from aspartate to alanine (CX50D47A). Another mouse with cataracts, *lop10*, carries a missense mutation at amino acid residue 22 of CX50 (CX50G22R). Mice carrying a CX50 mutation at amino acid residue 64 (changing it from valine to alanine, CX50V64A) exhibit dominantly inherited cataracts.

More importantly, mutations in lens connexins have been associated with human disease. Missense and frameshift mutations of the CX46 and CX50 genes have been identified in members of families with inherited (usually dominant) cataracts of various different phenotypes. The identified mutations and their positions within the connexin proteins are summarized in **Figure 3**. Mutations in CX43 have been associated with oculodentodigital dysplasia, a disease which is rarely accompanied by cataracts.

Studies of connexin mutants identified in association with a variety of diseases have revealed that the molecular mechanism responsible for cellular pathology may differ among mutants. Mutant connexins could form nonfunctional channels or channels with altered properties (such as gating, conductance, or permeability).

Several cataract-associated mutant connexins have been examined in expression systems to elucidate cell biological and/or functional abnormalities that may lead to cataract formation. The CX46 and CX50 mutants that have been analyzed exhibit loss of function; no gap junction conductance is detected when they are expressed in paired *Xenopus* oocytes or in transfected cells. When co-expressed with wild-type connexins, some mutants exert a dominant-negative effect abolishing gap junction conductance. This behavior may explain the autosomal dominant inheritance of the cataract trait associated with these mutants, since this inhibition would render these individuals effectively null for function of that connexin despite the presence of a wild-type allele. However, co-expression of some other mutants with their wild-type counterparts has no inhibitory effect. Thus, there is an apparent difference in the phenotypic consequences of partial loss of fiber cell connexin function between mice and men; heterozygous connexin-null mice are unaffected, whereas people that are heterozygous for a loss-of-function mutant develop cataracts. Another explanation is that the presence of mutant connexin protein (at about 50% levels due to heterozygosity) is worse for lens transparency than a 50% reduction in expression of that connexin.

In some cases, the loss of function may reflect defects in connexin trafficking, since several mutants do not form gap junction plaques when expressed in transfected cells; rather, the proteins are found in the cytoplasm. In one mutant, CX46fs380, a unique sequence in the mutant CX46 protein (generated by a frame shift) impairs protein trafficking to the plasma membrane.

While cataract formation due to connexin mutations may occur due to impaired intercellular communication, cytoplasmic accumulation of the mutant protein or formation of mutant protein aggregates may also contribute to the phenotype. The CX50 mutant, CX50P88S, forms cytoplasmic multilamellar accumulations. These accumulations may be detrimental to lens function by scattering light and interfering with its transmission and focusing onto the retina. Cytoplasmic accumulations of mutant connexins may also contribute to the loss of lens transparency by acting as nucleation particles for accumulation/aggregation of other proteins or by directly causing cellular damage.

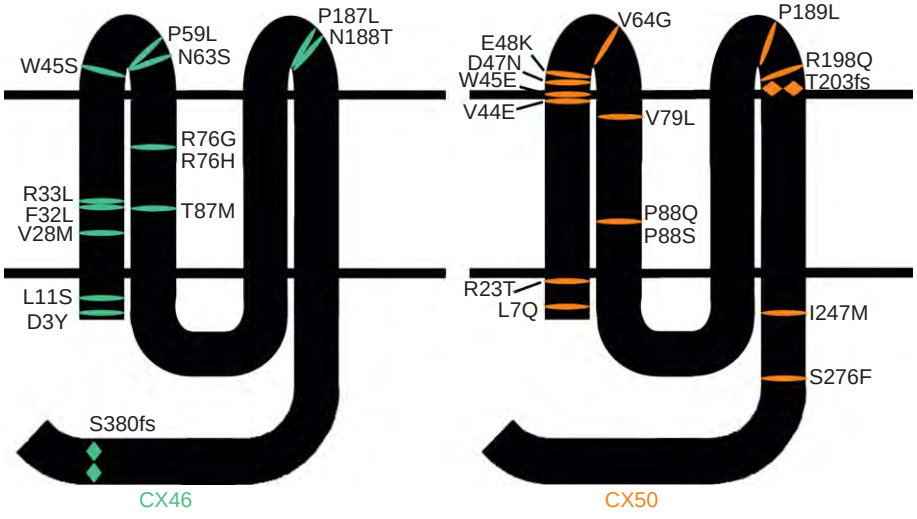

Figure 3 Diagram illustrating the topology of the human lens connexins, CX46 and CX50, is illustrated. The locations of missense (⬭) or frame shift (♦♦) mutations identified in members of families with inherited cataracts are indicated.

Cataract-Causing Insults and Damage to Lens Connexins

Lens proteins, including connexins, can accumulate a variety of post-translational modifications with aging or in association with cataract formation. Oxidation of methionine has been detected in the bovine orthologs of CX46 and CX50. Deamidation of asparagine121 has been detected in the CX50 ortholog. However, it is not certain that these modifications actually occur *in vivo*, since both methionine oxidation and deamidation may occur during sample preparation. The effects of most of these modifications on gap junction-mediated intercellular communication are unknown.

One of the most-studied etiologies of cataract formation is oxidative stress, which may be linked to changes in connexins and gap junctions. Several studies have used H_2O_2 treatment of cultured lens cells or isolated lenses to examine the consequences of oxidative stress. Treatment of chicken lentoid-containing cultures with H_2O_2 leads to dose- and time-dependent changes in the immunoblot pattern of chicken CX46, suggesting that H_2O_2 leads to its differential phosphorylation. A cleaved form of this connexin has been observed following treatment with high concentrations of H_2O_2; this is also associated with cell death. Treatment of a CX43-expressing lens cell line with H_2O_2 leads to an increase in PKCγ activity, an increase in phosphorylation of CX43 in Ser368 as detected by immunoblotting, a decrease in the number of gap junction plaques, and a decrease in dye coupling. Similar effects have also been observed when rat lenses are treated with H_2O_2. Thus, several pieces of data suggest that oxidative stress leads to alterations in lens intercellular communication through activation of protein kinases and alterations in connexin phosphorylation, which may contribute to cataract formation.

Lens Regeneration

P A Tsonis, University of Dayton, Dayton, OH, USA

Glossary

Axolotls – Species of aquatic salamanders, *Ambystoma mexicanum,* that do not undergo metamorphosis, retaining gills into adulthood.
Dedifferentiation – Loss of differentiated cellular characteristics, including cell shape and characteristic gene-expression profiles; it may be followed by reacquisition of differentiated characteristics or transdifferentiation to another cell type. In lens regeneration in urodeles, iris cells dedifferentiate, then transdifferentiate to lens.
Dorsalize – Malformed quality in which the gross morphology contains only what are normally dorsal structures.
Epistasis – The effects of one gene are modified by one or several other genes.
Lentectomy – Removal of the lens. This is usually a requirement to initiate the process of lens regeneration.
Urodeles – Living members of the amphibian order *Caudata*, many of which can regenerate multiple body parts.
Ventralizer – Relating to or situated on or close to the anterior aspect of the human body or the lower surface of the body of an animal.

A General Background of Lens Regeneration

Some urodele amphibians are the only animals that, throughout their life, are capable of regenerating their lens following removal of the lens (lentectomy). Regeneration of the lens in adult newts was observed first by Collucci, in 1891, and independently by Wolff, in 1895, after whom the process is often called Wolffian regeneration. A few species of fish and premetamorphic frogs can also regenerate the lens. In the fish and newts, the regenerating lens is derived from the pigment epithelial cells (PECs) of the dorsal iris, whereas in the frog it is derived from the larval cornea. Mammals possess an ability to regenerate the lens, but only when the capsule and associated lens epithelial cells are left behind. This has been studied extensively in rabbits, and recently such studies have been extended to mice and rats. The source of the regenerated lens is the adherent lens epithelial cells that cannot be completely removed. This article concentrates only on the mechanism underlying lens regeneration in newts.

Over the past several decades, many reports have provided important insights about the process and its restriction to only some adult salamanders. First, not all salamanders are capable of lens regeneration. The axolotl, which can regenerate its limbs and tail very well, is unable to regenerate the lens. This mystery might unveil crucial mechanisms (see below). Second, for regeneration to occur, the iris PECs must re-enter the cell cycle and dedifferentiate. These dedifferentiated cells can then differentiate to lens cells. This process has been called lens transdifferentiation. That the regenerate was derived from dedifferentiated cells and not from a contaminating undifferentiated progenitor cell, was convincingly demonstrated by Professor Goro Eguchi and colleagues in studies using clonal cell culture. The ability of the dorsal and not the ventral PECs to transdifferentiate *in vivo* provides another valuable comparison. This is especially true, since ventral PECs are able to transdifferentiate to lens following prolonged culturing. Indeed, newt PECs from the ventral iris as well as retinal pigmented epithelium (RPE) cells from many different vertebrates are capable of transdifferentiation to lentoids after being cultured under certain condition. This is true for even aged human PECs. Much work, especially using chick RPE, has led to the identification of factors that seem to mediate this ability of PECs to transdifferentiate following culture. The most notable of these factors are fibroblast growth factors (FGFs), hyaluronidase, phenylthiourea, and vitamin C. Thus, it appears that the ability for transdifferentiation is present in all PECs, but, *in vivo*, this ability is only expressed by the dorsal iris PECs of the adult newt. This calls for extensive search for factors restricted to the dorsal or ventral iris and for comparative studies with the axolotl. These features have made lens regeneration a primary paradigm in the study of cell plasticity, cell determination, aging, and reprogramming.

The Process of Transdifferentiation and Lens Regeneration

PECs must proliferate to create the lens vesicle and the subsequent lens. Previous studies clearly showed that both the dorsal and ventral iris PECs re-enter the cell cycle, although the ventral PECs do so at a lower rate. These showed that proliferation begins at about 4 days post-lentectomy and that, at that time, both dorsal and ventral

PECs show comparable levels of cell proliferation. Later, proliferation rates are higher in dorsal PECs, but obviously this must correlate with the process of lens regeneration, which has been initiated from the dorsal iris. In relation to this, expression of a hyperphosphorylated form of retinoblastoma (Rb) has been found in the PECs of both the dorsal and ventral iris. Rb is a paramount player in cell-cycle regulation. When it is hyperphosphorylated, it is inactivated and dissociates from E2F transcription factors. Activation of E2Fs allows cells to re-enter the cell cycle. However, treatment with a cyclin-dependent kinase (CDK) inhibitor (which reduces Rb phosphorylation and inhibits proliferation) does not completely inhibit transdifferentiation. In addition, when ventral cells are cultured for about 2 weeks and then implanted as aggregates in the eye cavity, they can never transdifferentiate to lens – even though they undergo considerable proliferation. In different studies, it has been demonstrated that activation of the protease – thrombin – is predominant in the dorsal iris and that inhibition of thrombin activity results in loss of proliferating cells. Nevertheless, PECs from both dorsal and ventral iris are responsive to thrombin when stimulated *in vitro*. This might imply that, while proliferation is necessary to prepare cells for the process of regeneration, it might not be sufficient for their subsequent transdifferentiation. Thus, events other than those involved in cell-cycle re-entry are decisive for transdifferentiation and lens regeneration.

The histological events leading to de-differentiation have been well studied at the microscopic level. Soon after lentectomy, the PECs shed their pigment. Macrophages recruited to the site mediate such a process. Four days postlentectomy (a time frame that coincides with the onset of cell proliferation), the iris is decondensing and the PECs begin to elongate. At about 8–10 days postlentectomy, these cells become columnar and depigmented. The first depigmented cells are obvious at the tip of the dorsal iris. At about 10 days, a lens vesicle has been formed, but no crystallin expression is yet apparent. Many of the genes that are known to be expressed and involved in lens development, such as pax-6, FGFs, FGF receptors, and prox-1 are expressed in the early lens vesicle. After the vesicle is formed, the events of lens differentiation are initiated. At the posterior edge of the vesicle, elongation of the cells ensues with concomitant induction of crystallin synthesis. The elongated cells differentiate to lens fibers and the anterior part of the vesicle becomes the lens epithelium, which continues to contribute by proliferation and differentiation to the growing of the lens (**Figure 1**). Once lens differentiation has started, the process is remarkably similar to embryonic lens development (as far as the sequential appearance of the different crystallins is concerned). Indeed, studies using antibodies to crystallins or cDNA probes have conclusively shown that there is a parallel of their synthesis in the developing and regenerating lens. The crystallins examined were αA, βB1, and γ. All these crystallins appeared, at the same time, at the ventral portion of the lens vesicle (Sato stage IV; nearly 10 days postlentectomy), with γ-crystallin (in contrast with the other two) being specific for the lens fibers and not the lens epithelial cells. The lens epithelium proliferates extensively throughout. As in normal lens development, when lens epithelial cells differentiate to lens fibers, they stop dividing. At the same time events of apoptosis are also observed, but at a minimal rate. It is interesting to note that, even at stages prior to completion of regeneration of the lens, cell death is part of the normal routine.

Gene Expression and Induction of Lens Regeneration

Because lens regeneration normally occurs only from the dorsal iris (and never the ventral) by transdifferentiation of the iris PECs, research focused on finding key differences between the positive cells (dorsal) and the negative ones (ventral). It was hoped that understanding these differences could help induce the ventral iris (as a first step) to regenerate a lens. Studies concentrated on genes that were important for eye development and axis formation. It was first shown that *pax-6*, a known eye master gene, is expressed during dedifferentiation of the PECs and lens regeneration. These initial expression studies indicated that lens regeneration could recapitulate lens development and that, in the adult newt, developmental genes are not irreversibly turned off. FGFs and FGF receptors were also expressed in lens regeneration, with

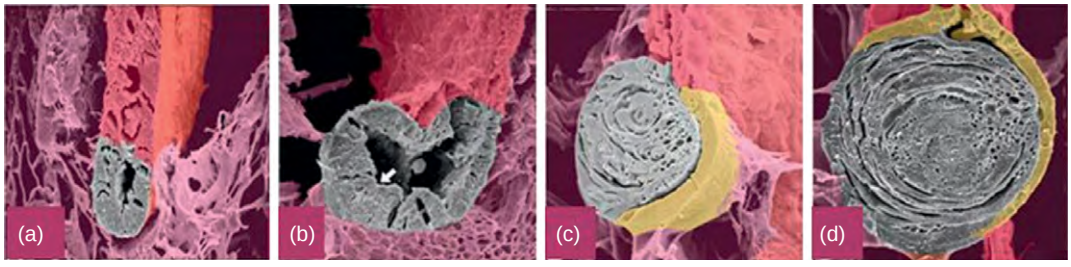

Figure 1 Lens formation from the dorsal iris during regeneration shown through SEM. (a) Day 10 postlentectomy, a lens vesicle forms at the dorsal margin. (b) Day 14, elongation and further lens development as differentiation of lens fibers occur at the posterior part (arrow) of the vesicle. (c) Day 20 of lens reformation. The anterior part becomes the lens epithelium (colored yellow). (d) Day 30, regeneration has concluded.

a preference for expression in the dorsal iris. When exogenous FGF was given to the eye, a second lens could be elicited from the dorsal, but not from the ventral iris. When FGF-receptor signaling was specifically inhibited, lens regeneration was abolished. These data clearly showed that FGF signaling is imperative for normal regeneration.

Other important factors were studied for specific expression and function during lens regeneration. These included key regulators, such as *Hox* genes, *Prox-1*, retinoic acid receptors, cyclin-dependent kinases, complement components, and components of the hedgehog pathway, which played a novel role in lens regeneration. The goal of all these studies was to identify factor(s) that might be good candidates for the induction of lens regeneration and to apply them to the ventral iris to induce regeneration from that site. This was initially accomplished by forced expression in the ventral iris of the transcription factor, six-3, and treatment with retinoic acid. As mentioned above, six-3 is a major eye-development regulator that collaborates with pax-6. Inhibition of the bone morphogenetic protein (BMP) pathway – which lies upstream of the pax-6/six-3 loop – could do exactly the same (**Figure 2**). BMPs are known to influence tissues to become more ventral fates during development. It seems likely that their function controls the identity of dorsal and ventral iris. The basic events and possible pathways that regulate this process are depicted in **Figure 3**.

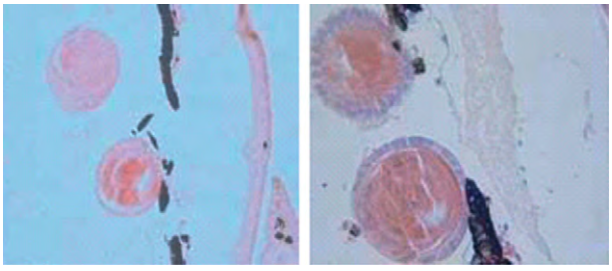

Figure 2 Induction of lens transdifferentiation from a ventral iris implant. On the left panel, the lens was induced by transfecting the ventral iris PECs with six-3 and treated with retinoic acid. On the right panel, the lens was induced by inhibiting the BMPR-1A. Top lens is the host regenerating lens.

Gene Regulation in the Induction of Lens Regeneration

Induction of lens regeneration from the ventral iris was a major accomplishment, which opened new avenues of experimentation. To understand more about the mechanism of induction, a detailed analysis of the expression of six-3, pax-6, and BMP receptors was undertaken. RNA was isolated from the intact dorsal and ventral irises, as well as at days 2, 4, and 8 postlentectomy. This time range was chosen to observe the regulation of these genes throughout the process of dedifferentiation. The results were quite surprising. All of these genes were expressed in the intact dorsal and ventral iris. In fact, levels in the intact ventral iris were higher than in the intact dorsal. However, as dedifferentiation progressed, these genes (especially six-3; **Figure 4(c)** and **(d)**) were selectively upregulated in the dorsal iris. The levels were elevated in the induced ventral irises as well (**Figure 4(f)**). These patterns suggested a mechanism whereby regeneration might be achieved: levels of gene expression must be elevated above a certain threshold. The genes involved are not just absent in the intact irises and specifically appear in the dorsal iris during regeneration.

Epistasis experiments showed that the BMP pathway was upstream the six-3/pax-6 loop. Treatment with the BMP antagonist chordin elevated both pax-6 and six-3 in the ventral iris postlentectomy (**Figure 4(g)**). As during normal eye development, an inhibitor of the BMP pathway (in that case, the BMP antagonist noggin) seems to be the upstream regulator of the eye-forming genetic network.

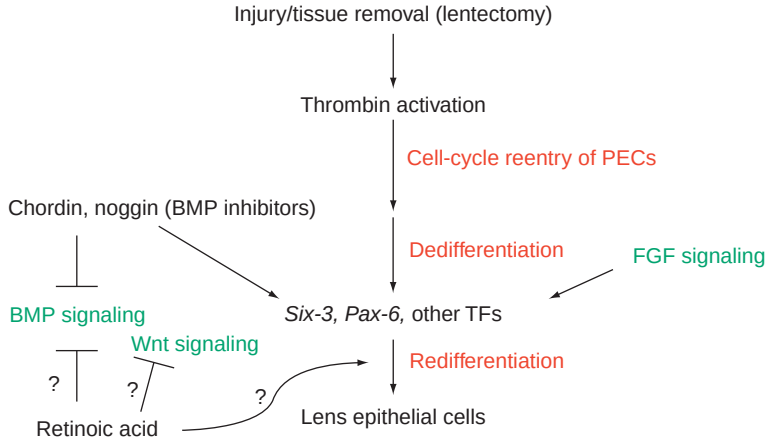

Figure 3 A diagram indicating the basic events and factors whose function has been associated with lens regeneration.

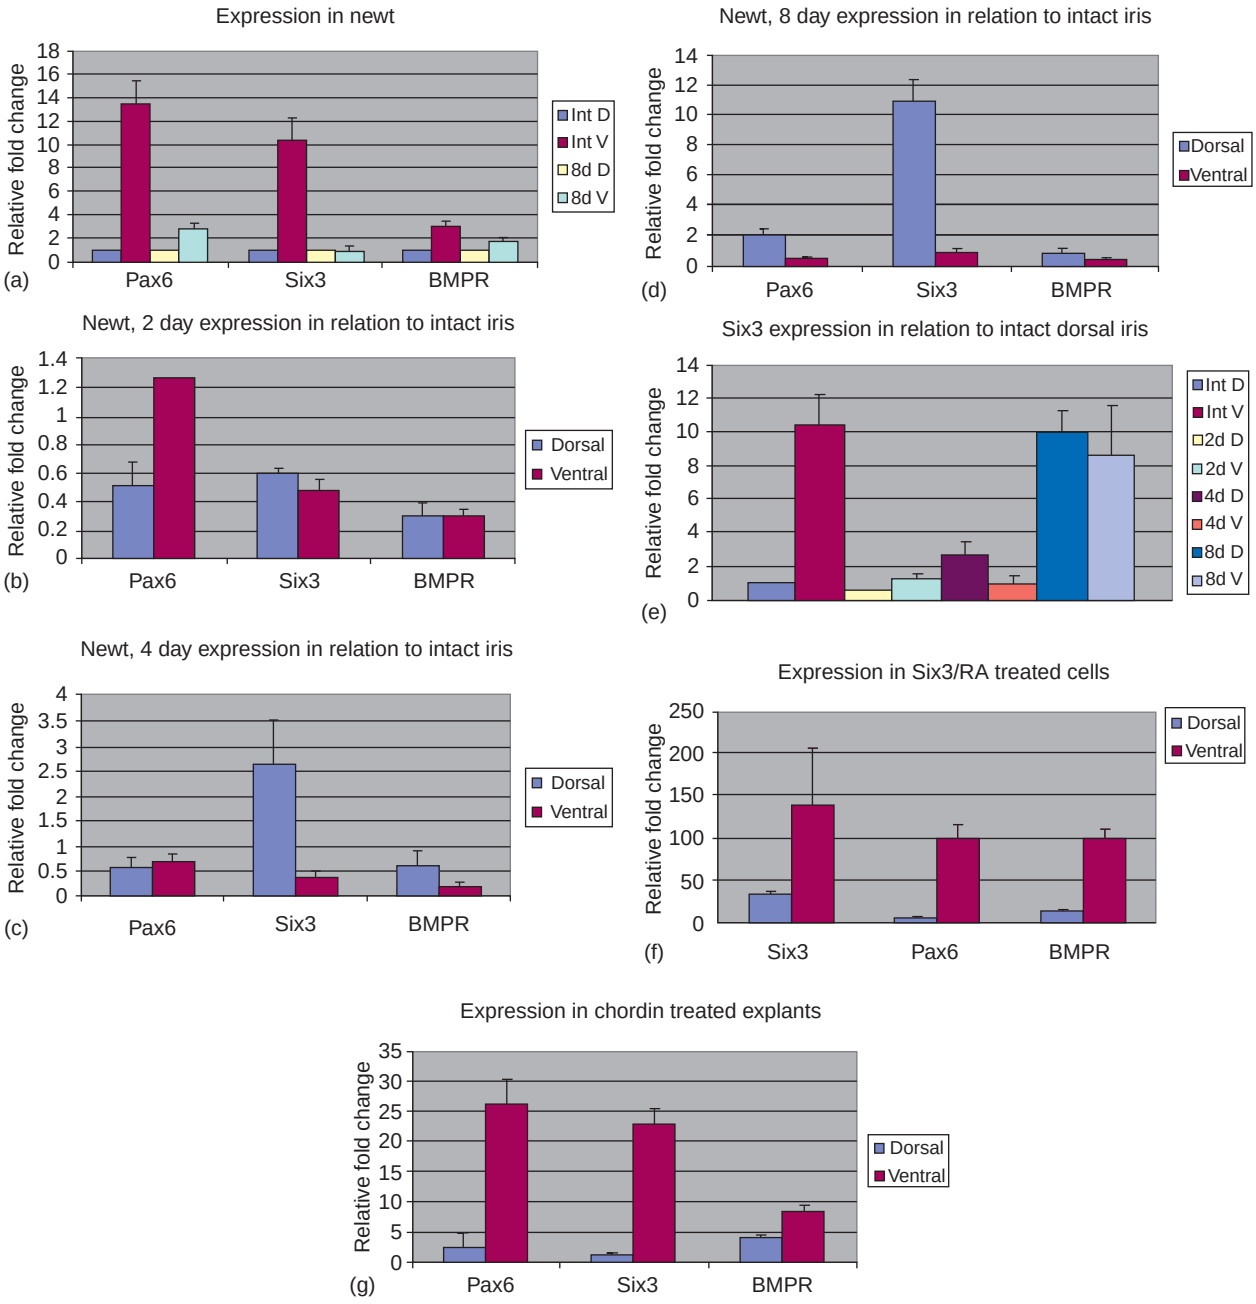

Figure 4 (a–d) Expression of pax-6, six-3, and BMPR-IA during the initial stages of regeneration – 2, 4, and 8 days following lentectomy. Expression in both dorsal and ventral iris is compared with the levels of the intact iris. Gradual increase in the dorsal iris can be seen, especially for six-3. (e) A summary of six-3 expression in relation to the one in intact iris. (f) Expression in six-3/RA treated cells. (g) Expression following chordin treatment. Note upregulation of pax-6 and six-3. Right panels: Comparison of expression levels in the dorsal and ventral iris for newt BMP-1, BMP2/4, and snail. Comparisons are between intact dorsal iris (ND), intact ventral iris (NV), dorsal iris at day 8 following lentectomy (RD) and ventral iris at day 8 following lentectomy (RV). Note a pattern of upregulation in the ventral iris during regeneration (RV vs. NV).

Several interesting points can be stated from the above induction and expression experiments (apart for the already mentioned activity in the ventral iris). First, six-3 was the first of these genes to be upregulated in the dorsal iris at day 4, while pax-6 levels increased at day 8. It was somewhat surprising that pax-6 did not induce regeneration. Second, because BMPs are ventralizers during embryogenesis and their inhibition dorsalizes the embryo, similar events might regulate lens regeneration. In fact, treatment of the dorsal iris with BMPs inhibited its ability for transdifferentiation. Because of this and the obvious involvement of the BMP pathway in lens regeneration, the expression of some BMP-signaling factors was examined to ascertain whether any of these genes would

recapitulate their expression pattern during embryogenesis. This network in *Drosophila* has nearly 90 genes involved in elaborate interactions. To obtain some insight into this idea, expression of the newt orthologs of decapentaplegic (dpp) – BMP2/4 and tolloid-related metalloproteinase (BMP-1) – were examined. BMP2/4 is an activator of ventral-specific genes during embryogenesis. The expression of snail was also evaluated. BMP-1 is ventral specific; it inhibits chordin and thus allows release of BMPs. This action is blocked by its antagonist, sizzled. Snail is activated by dorsal and is a repressor of ventral, neurogenic territory during development. For BMP2/4, BMP1, and snail, a very similar pattern emerged when their expression was examined with quantitative polymerase chain reaction (PCR) during regeneration (**Figure 4**, right panel). While their levels are higher in the intact dorsal iris when compared to the ventral (ND vs. NV in **Figure 4**), during regeneration, this difference became smaller. This might indicate downregulation in the regenerating dorsal iris, which would be consistent with dorsalization. Notably, levels in the ventral iris were increased during regeneration, consistent with ventralization.

Large-Scale Expression Studies

Microarray Analysis

The surprising results of genetic activity in the ventral iris provided new insights with regard to the mechanisms of lens regeneration. Was this a more general pattern, or was it restricted to only a few genes? The expression of nearly 370 cDNAs cloned from the newt was examined via microarray. The results showed that most were expressed in the dorsal and ventral iris. It was interesting to see that genes for tissue remodeling, for example, those for metalloproteinases (**Figure 5**), were expressed in both the dorsal and ventral iris! Clearly, the regeneration-incompetent ventral iris is remodeling in the same way as the dorsal iris.

MicroRNA Regulation During Lens Regeneration

The information available so far indicates that the ventral iris is not really dormant in genetic activity and that, in general, genes that are expressed in the regeneration-competent dorsal iris are also expressed in the regeneration-incompetent ventral iris. In addition, the gene expression data show that the levels of expression are upregulated in the dorsal iris in response to the process of regeneration. To delineate the underlying mechanism of such global regulation, attention turned to microRNAs (miRNAs). miRNAs are short RNAs of about 20–22 neucleotides in length that have sequences complementary to sequences in the 3′-untranslated regions (UTRs) of many different mRNAs. Thus, one miRNA can target hundreds of mRNAs. When a miRNA forms a duplex with its target sequence, protein synthesis is inhibited. Since one miRNA can regulate many mRNAs, it can exert massive effects on gene expression.

The first step was to clone miRNAs from the newt eye. Several miRNAs were identified, among them miRNAs known to be expressed in the eyes of other animals. The newt miRNAs were almost identical to their mouse or to human counterparts. This astonishing sequence conservation among many species is another characteristic of miRNAs and implies conservation of regulation as well. Following this initial step, detailed expression study was performed, using microarrays containing all the mouse and human miRNAs. RNA was isolated from intact and day-8 postlentectomy dorsal and ventral irises. Indeed, it was found that several miRNAs are regulated in the intact irises as well as during regeneration (**Figure 6**).

Table 1 summarizes some of the results of the microarray analysis. Several miRNAs – such as miR124, miR181, and miR184 – are known to be expressed in the eye. In addition, a particular pattern was seen for members of the let7 family. While these miRNAs were expressed at higher levels in the intact dorsal iris, they were all decreased during dedifferentiation. Interestingly, same patterns were seen during regeneration of another tissue, that of hair cells.

These results were the first to associate miRNA expression with regenerative processes and provide great promise for understanding gene regulation. For example, miR148 seems to be ventral-specific (this was verified by quantitative polymerase chain reaction (QPCR); **Figure 7**). Its inhibition might dorsalize the ventral iris and induce regeneration. Likewise, opposite experiments should inhibit regeneration.

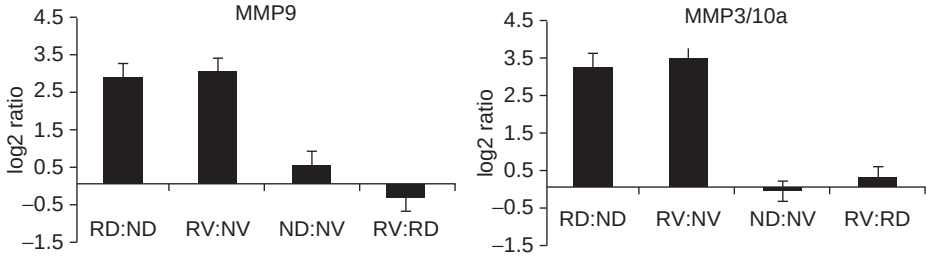

Figure 5 Quantitative PCR results on the expression of MMP9 and MMP3/10a in normal and regeneration-undergoing dorsal and ventral iris. RV:NV means comparison between regenerating ventral iris and normal ventral iris. Note that both in ventral and dorsal irises these genes are upregulated in relation to the values of their normal (intact counterparts), without much differences between each other.

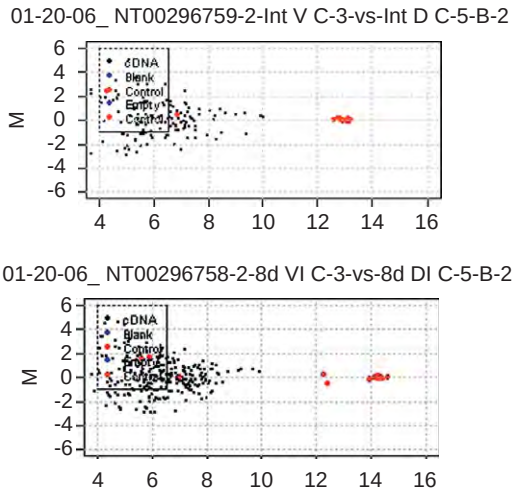

Figure 6 miRNA expression as revealed by microarray analysis. Comparison between intact dorsal and ventral iris (left) and between day 8 dorsal iris (DI) and ventral iris (VI) (right). Each black dot indicates a particular miRNA and, if it is above 0, is upregulated and, below 0, is downregulated. The red dots correspond to controls and as the reader can see they are mostly around value 0.

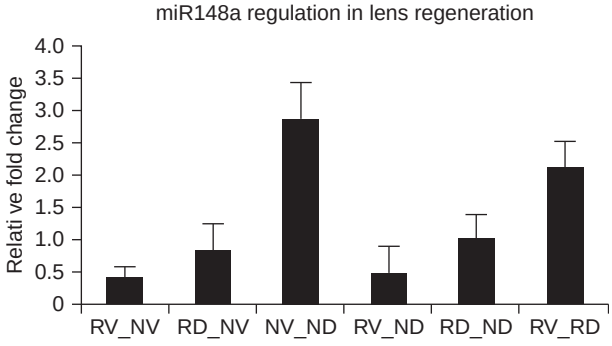

Figure 7 Quantitative PCR analysis of miR148 during lens regeneration. Note that this miRNA is expressed higher in the normal ventral iris as compared with the normal dorsal (NV_ND) and during regeneration (RV_RD).

Comparison with the Axolotl

Gene expression was also investigated in the axolotl – another urodele – but one that cannot regenerate the lens. We were, in particular, interested to check gene

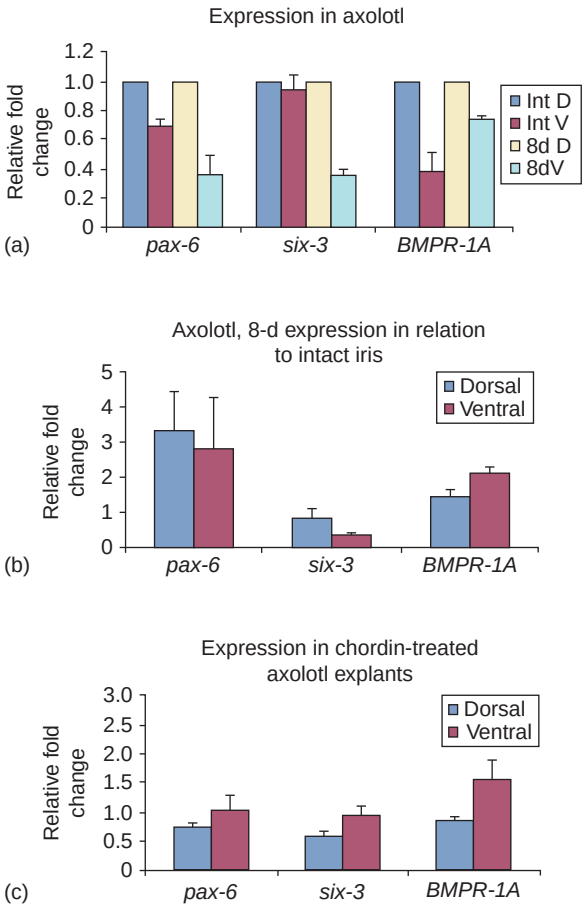

Figure 8 Expression in axolotl. (a) Comparison of pax-6, six-3, and BMPR-IA expression between the axolotl dorsal and ventral iris. Expression is shown in intact irises and 8 days following lentectomy. Values in the dorsal iris have been set to 1 and those in the ventral iris are shown as relative fold changes.
(b) Comparison of expression in 8th-day irises with intact irises.
(c) Expression in chordin-treated iris explants relative to untreated explants.

expression as it pertains to the induction we achieved in the newt ventral iris. QPCR for six-3, pax-6, and BMPR-1A was performed. The results were quite instructive. Unlike the newt, there was no differential expression detected between the intact dorsal or ventral iris (**Figure 8(a)**) and no upregulation of these genes following lentectomy (**Figure 8(b)**). Even though these genes are expressed, they do not follow a pattern similar to the one seen in the newts. Similarly, treatment with chordin did not increase the levels of pax-6 or six-3, as was shown previously in newts (**Figure 8(c)**; compare with **Figure 4(g)**).

This suggests that the axolotl irises cannot really be equated with the newt ventral iris. To corroborate this observation, the expression of several proteins involved in signaling was examined using antibodies that cross-react with both newt and axolotl tissues (verified by Western blot analysis). Some proteins showed increased expression in the newt ventral iris when compared with the newt

Table 2 Expression of proteins and their association with regenerative capabilities in newt and axolotl

Protein	*Abbreviation*	*Newt dorsal vs ventral iris (higher)*	*Newt dorsal vs Axolotl (higher)*	*Consistent with regeneration potential*
Calcium/calmodulin-dependent protein serine kinase 2α	CaMK2a	D	axolotl	NO
Catenin beta 1	Catenin b	V	equal	NO
Epidermal growth factor receptor	EGFR	D	newt	YES
Integrin-linked protein-serine kinase 1	ILK1	equal	newt	NO
Interleukin 1 receptor-associated kinase 4	IRAK4	V	equal	NO
Jun proto-oncogene	jun	V	axolotl	YES
Macrophage-stimulating protein receptor α chain	RONa	D	axolotl	NO
MAP kinase phosphatase 1	MKP1	D	newt	YES
Mitogen-activated protein serine kinase p38 α	P38aMAPK	equal	equal	NO
p21 activated serine kinase 3	PAK3	D	newt	YES
Protein-serine kinase C α	PKCa	D	newt	YES
Suppressor of cytokine signaling 4	SOCS4	V	axolotl	YES
TNF-related apoptosis-inducing ligand	Trail	equal	newt	NO

dorsal iris. These were similarly regulated in the axolotl irises, indicating a similarity of axolotl irises to newt ventral iris. However, many other proteins did not follow this pattern, indicating that the axolotl irises show patterns of protein expression that are different from that seen in the ventral iris of the newt (see **Table 2**).

These observations may have important implications for the potential of the axolotl (or another animal) iris to be induced with the same treatment that induced the newt ventral iris to form a lens. It is, of course, a major goal to induce lens regeneration in other species, but one must be cautious of how to apply the knowledge gained from the newt. Attempts to induce the axolotl irises to transdifferentiate to lens have not yet been successful. With the knowledge described above, this is hardly surprising. It seems most likely that global suppression of regeneration must occur in the newt ventral iris. Induction of lens regeneration in other animals, such as the axolotl, will depend on manipulating this exact molecular signature. The induction of the newt ventral iris is a good starting point, but achieving a similar result in the axolotl may require additional manipulation. Similar issues apply in mice. Even though the jump from amphibian to mammals is a big one, the ultimate goal of this research is to apply it in higher animals. In truth, not much is known about the expression of regulatory genes in adult mouse eye tissues. Most of what is known is derived from studies during development. As an initial step, pax-6 and six-3 mRNA levels were examined in mouse irises by PCR. Several genes that are important in pigment synthesis and in pigment stem cells – among them pax-3, beta-catenin, Sox10, and endothelin – were also studied. Interestingly, pax-6, six-3, and the other genes examined were expressed in the adult mouse dorsal and ventral iris (**Figure 9**) and, as in the axolotl, without apparent regulation following lentectomy. Thus, similar deductions can be drawn for the induction of lens regeneration in mice.

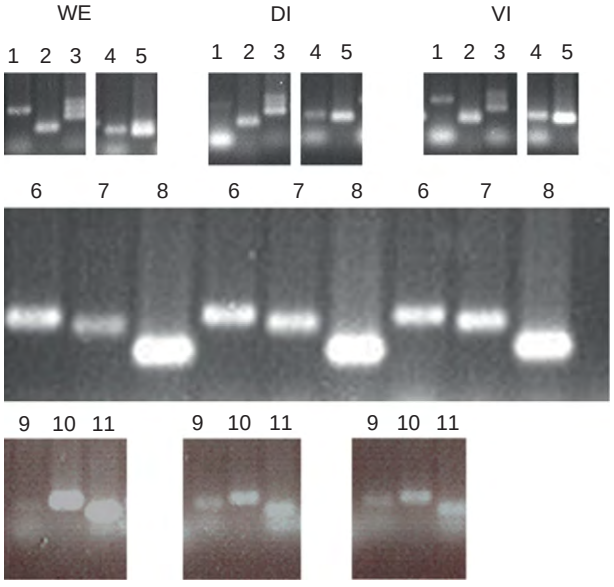

Figure 9 Expression of several genes in mouse whole eye (WE), dorsal iris (DI), and ventral iris (VI). 1: endothelin 3; 2: Endothelin B receptor; 3: pax-6; 4: mitf; 5 and 8: ATP5e (housekeeping); 6: six-3; 7: Sox10; 9: pax-3; 10: beta-catenin; 11: beta-integrin.

Regeneration of the lens in newts has provided a paradigm for regenerative research, in general. The inability of the ventral iris to form a lens is most likely due to a general repression mechanism that prevents it from transdifferentiating to lens. Since many of the mechanisms that are involved in gene repression are quite conserved to be extended and compared in other species than the newt.

Lens Structure

D C Beebe, Washington University, Saint Louis, MO, USA

Glossary

Lens capsule – The thick extracellular matrix that surrounds the lens.
Lens fibers – Elongated cells that make up the bulk of the lens. During their terminal differentiation fiber cells lose all membrane-bound organelles. The absence of organelles and their high protein concentration accounts for the transparency and high refractive index of the lens.
Sutures – Elongated fiber cells cannot taper to infinite thinness as they approach the anterior and posterior poles of the lens. Sutures are structural modifications that adjust for this physical dilemma. Elongating fiber cells may meet cells from the opposite side of the lens at planes (suture planes), or most cells may extend only part way to the pole, forming an umbilical suture.
Zonules – Thin fibrils that anchor the lens capsule to the ciliary epithelium, thereby suspending the lens in the anterior of the eye.

The function of the lens depends on its transparency, its refractive index, the curvature of its refractive surfaces, and its ability to change shape during accommodation. Accommodation is the process by which the power of the lens is increased for near vision. Transparency depends on minimizing light scattering and absorption. Some aspects of lens transparency are addressed below and in the sections on lens fiber cell differentiation and lens protein aging. The lens refractive index depends on the concentration of proteins in the fiber cells, a topic that is discussed below. Lenses may be nearly round or oblate and their anterior and posterior surfaces may have different radii of curvature. Surprisingly, the factors that determine lens shape are poorly understood, although it is clear that, during development and growth, signals from outside the lens influence its shape.

The mature lens is an unusual structure, compared to most in the body, being constructed only from epithelial cells. These cells exist in two states of differentiation, lens epithelial cells and fiber cells (**Figure 1**). The lens is surrounded by a tough, flexible layer of extracellular matrix, the lens capsule, which is secreted by the lens cells at the lens surface. Thin fibrils, the zonules, connect the capsule to the ciliary epithelium to suspend the lens in the anterior of the eye.

The anterior surface of the lens, the surface that faces the cornea, is covered by a monolayer of cuboidal epithelial cells, lying beneath the anterior capsule. The bulk of the lens is formed from a mass of elongated fiber cells. In the adult lens, cells in the central region of the epithelium rarely divide. However, epithelial cells in a narrow band near the lens equator – the germinative zone – proliferate slowly. The daughter cells of these mitotic divisions move toward the lens equator, where, in response to signals from the posterior of the eye, they permanently withdraw from the cell cycle in a region called the transition zone. Cells at the posterior edge of the transition zone elongate to form fiber cells. The elongation of successive waves of fiber cells buries earlier-born fiber cells deeper in the lens. Since new fiber cells are formed all around the lens equator, fiber cell formation generates concentric shells of fiber cells that are formed at the same time. Because no cells are removed from the fiber mass, the lens grows in cell number and size throughout life. Thus, the rate of cell proliferation in the germinative zone determines the rate of fiber cell formation and the size of the lens.

During fiber cell elongation, the basal ends of the fiber cells, which contact the posterior capsule, extend toward the posterior pole of the lens, whereas the apical ends extend anteriorly beneath the lens epithelium. The posterior ends of the fiber cells extend more rapidly than the anterior ends and reach the posterior pole of the lens before the apical ends reach the anterior pole. Fiber cell nuclei tend to remain in the center of the cells. The more rapid elongation of fiber cells toward the posterior pole causes the nuclei to become located more posteriorly in the lens. When the posterior ends reach the posterior pole of the lens, they stop migrating; however, the anterior ends of the fiber cells are still elongating. Therefore, the nuclei gradually shift back in a more anterior direction. The movement of the nuclei during fiber cell elongation, first in a posterior direction and then anteriorly, traces the shape of a bow, which gives this region of elongating fiber cells its name, the lens bow.

When the ends of the fiber cells extend, they encounter a geometric problem. The basal and apical ends of all of the fiber cells in a shell are elongating toward two points, one at the posterior pole and one at the anterior pole. In a practical sense, the ends of the cells can never be narrow enough for all cells to reach the poles.

The lenses of different species deal with this topological problem in one of two ways. In most mammals, amphibians, and some fish, elongating fiber cells meet cells from the opposite side of the lens along planes,

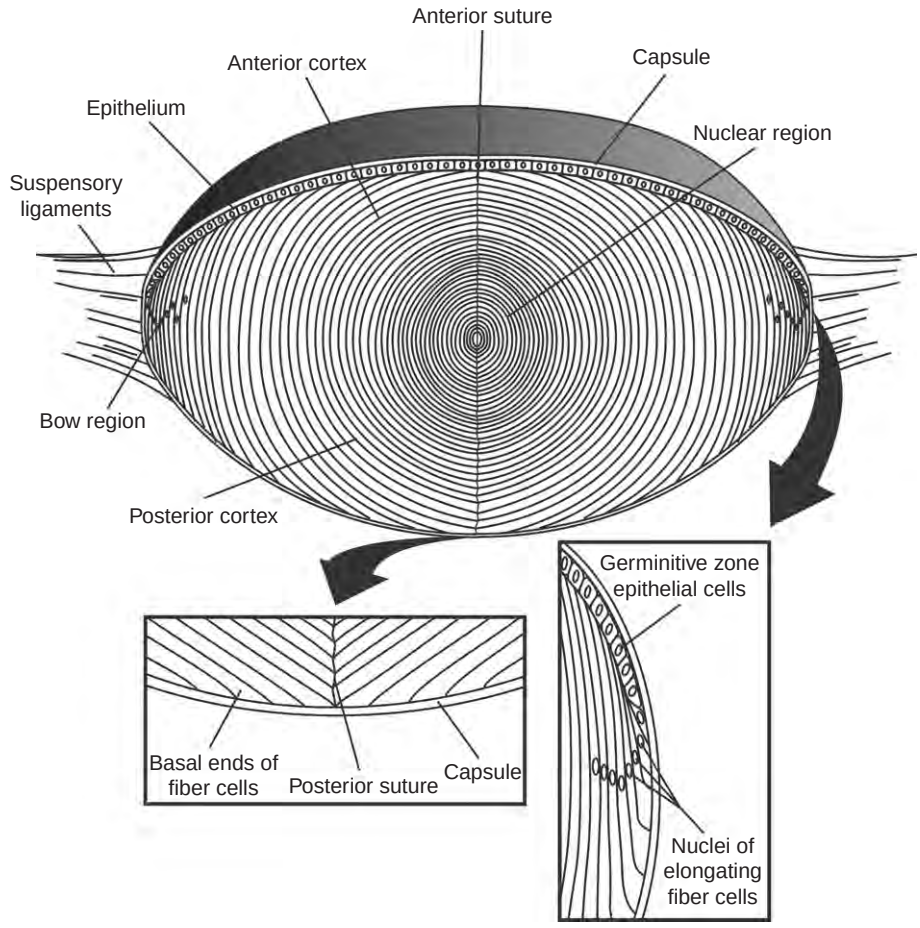

Figure 1 A schematic diagram of the structure of the lens. The inset on the left shows fiber cells meeting at the posterior of the lens, where the sutures are forming. The inset on the right shows detail of the lens equator, where epithelial cells divide, move posteriorly, elongate to form fiber cells, and eventually lose all membrane-bound organelles, including their nuclei. From Beebe, D. (2003). Lens. In: Kaufman, P. L. and Alm, A. (eds.) *Adler's Physiology of the Eye*, 10th edn, pp. 117–158. St. Louis, MO: Mosby.

called sutures. The simplest suture pattern is a line suture, in which the ends of fiber cells meet along a single plane at each pole of the lens. In a more complex variation, the ends of fiber cells meet along three planes, which take the shape of the letter Y (**Figure 2**). In humans and other primates, Y sutures initially form, but become more complex as the lens grows. In humans, the ends of the suture branches bifurcate soon after birth, generating six suture planes from the original three. This process occurs again later in life, resulting in 12 suture branches. In birds and some fish, suture planes do not form; instead, elongating fiber cells gradually taper as they elongate, with most fiber cells stopping before they reach the poles. The few cells that reach the poles contact the ends of cells from the opposite side of the lens, forming an umbilical or point suture.

Line and Y sutures are oriented precisely with respect to the axes of the eye. Y sutures form an upright Y in the anterior of the lens, the side toward the cornea, and an inverted Y at the posterior of the lens. Line sutures have a vertical orientation at the anterior of the lens and are horizontal at its posterior.

The suture patterns may have optical and structural consequences for the lens. Comparison of the optical properties of lenses with Y sutures with the more complex pattern found in primates showed that the more complex suture pattern results in lenses with fewer optical aberrations. The optical properties of lenses with umbilical and Y sutures have not been directly compared. Bird lenses undergo rapid and extensive change of shape during accommodation, suggesting that umbilical sutures may contribute to the ability of the lens to withstand the forces generated in this process. However, fish do not accommodate by changing the shape of the lens, but some have umbilical sutures. Thus, the extent to which the lens changes shape during accommodation is not the only factor that determines the suture pattern.

Sutures are not present early in lens formation. They only form later, as the lens grows and lays down shells of secondary fiber cells. The mechanisms that determine the

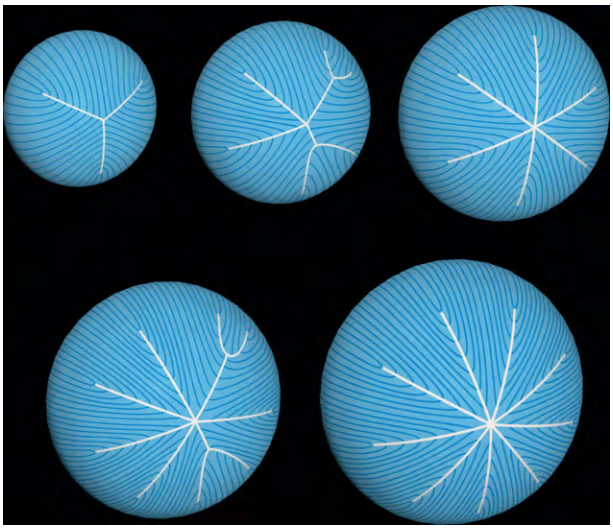

Figure 2 A diagram showing the development of the suture pattern in the human lens. The lens begins with a Y suture pattern. As it grows, newly formed sutures branch near the tips of the existing suture planes. These branch points migrate toward the pole, eventually doubling the number of suture planes. This process continues as the lens grows throughout life with the deposition of successive layers of fiber cells. This figure was kindly provided by Dr. Jer Kuszak. From Beebe, D. (2003). Lens. In: Kaufman, P. L. and Alm, A. (eds.) *Adler's Physiology of the Eye*, 10th edn, pp. 117–158. St. Louis, MO: Mosby.

type of suture pattern and that assure the stereotypical orientation of the sutures in the eye are not known. Similarly, we do not know why different species have acquired different suture patterns during evolution.

After the anterior and posterior ends of the fiber cells reach the sutures, they stop elongating. The lateral membranes of the fiber cells interdigitate, forming interlocking junctions between adjacent cells. These specializations appear to stabilize lens structure. At this stage in their development, fiber cells also partially fuse along their lateral membranes with their neighbors in the same shell. This may assure that the cytoplasm of cells at similar depth in the lens is of uniform refractive index. Soon after fusing, the fiber cells degrade all intracellular, membrane-bound organelles, including the nucleus, mitochondria, and endoplasmic reticulum. Mouse mutants in which nuclear degradation is inhibited have diffuse nuclear cataracts, supporting the idea that organelle degradation increases transparency by reducing light scattering.

Refractive Index

To focus light, any lens must have a refractive index that is different from the medium in which it is suspended. The refractive index of the eye lens is higher than the aqueous and vitreous humors that surround it because it has a higher protein concentration than these fluids. The higher protein content of the lens results largely from the synthesis and stability of the proteins of the lens fiber cells, the lens crystallins. Information about the structure, complexity, and stability of the crystallins is covered elsewhere in this encyclopedia.

Numerous studies have documented the extreme specialization in protein content that occurs during fiber cell differentiation. During lens development, a single crystallin can account for as much as 70% of the total protein content of the lens. There are about 12 crystallin polypeptides in the adult lens, but these account for about 95% of the soluble protein. The abundance of any protein depends on the level to which its mRNA accumulates, the efficiency with which the mRNA is translated, and the relative stability of the resulting protein. The abundance of the crystallins results, in part, from the high level of expression of crystallin mRNAs. This aspect of lens molecular biology is the one most studied. The relative contribution of selective translational efficiency to crystallin accumulation is not known. Although crystallins persist for the life of the lens, experimental studies have not revealed whether they are intrinsically more stable than other cytoplasmic proteins, whether the cytoplasmic environment within the lens fiber cells generally protects against protein degradation, or a combination of these factors.

The protein concentration of the lens cytoplasm increases two- to threefold from the lens surface to its center. This protein gradient creates a gradient of refractive index that largely compensates for the spherical aberration of the lens. Although the existence and importance of this gradient has been appreciated for many years, its origin is not clear. Cells at the surface of a young lens are buried deeper in the lens as it ages. Thus, the protein concentration in their cytoplasm must increase as lens cells age. However, protein synthesis is confined to cells near the lens surface. Therefore, for the most part, the increase in protein concentration in the deeper cells does not result from continued synthesis.

The solubility or osmotic activity of the lens proteins must change as they become more concentrated. If the crystallins were free in solution, the increase in their concentration would result in a decrease in water concentration, creating an osmotic gradient that would draw water into the lens nucleus. Since this does not occur, proteins deeper in the lens must exist in a state that reduces their osmotic activity. This might be accomplished by partial association or gel formation. The mechanisms responsible for the decrease in osmotic activity of the crystallins are not well understood.

Transparency

The high protein concentration in the lens cytoplasm may seem inconsistent with transparency, since light scattering

tends to increase with an increase in protein concentration. Classical studies by Delaye and Tardieu resolved this apparent contradiction by showing that, at the high concentrations present in the lens, short-range interactions between the proteins minimize light scattering. Whether these interactions also account for the reduced osmotic activity of the cytoplasm deep within the lens remains an unanswered question.

The Zonules

Thin fibrils connect the lens capsule to a ring of ciliary epithelial cells on the inner surface of the eye near its anterior margin. These fibrils form the suspensory ligament or zonular apparatus. They are composed largely of the protein fibrillin, a component of the elastic fibrils found throughout connective tissues. However, the zonular fibers are not extensible. In addition to positioning the lens in the visual axis, they transmit force from the ciliary muscles, altering lens shape during accommodation.

Lids: Anatomy, Pathophysiology, Mucocutaneous Junction

T Wojno, The Emory Clinic, Atlanta, GA, USA

Glossary

Actinic lesion – Dry, scaly, rough-textured patches that form after years of exposure to ultraviolet light, such as sunlight.
Amblyopia – Disorder of the visual system that is characterized by poor or indistinct vision in an eye that is otherwise physically normal.
Anisometropia – Condition in which the two eyes have unequal refractive power.
Blepharitis – Chronic inflammation of the eyelids.
Blepharoplasty – Surgical procedure intended to reshape the upper eyelid or lower eyelid by the removal or repositioning of excess tissue as well as by reinforcement of surrounding muscles and tendons.
Dermatochalasis – Redundant, baggy eyelids.
Ectopion – Outward malposition of the eyelid.
Entropion – Inward malposition of the eyelid.
Lagophthalmos – Inability to close the eye.
Ptosis – Downward malposition of the upper eyelid.
Strabismus – A condition in which the eyes are not properly aligned with each other.
Trichiasis – Misdirected eyelashes.

Anatomy

From a functional perspective, the upper lid can be divided into anterior, middle, and posterior lamellae (Figure 1). In the upper lid, the anterior lamella consists of the skin and orbicularis muscle while the posterior lamella consists of the conjunctiva, tarsus, levator, and Müller's muscle. The middle lamella is the orbital septum and orbital fat. The thin eyelid skin covers the orbicularis muscle, which is functionally divided into the pretarsal, preseptal, and orbital parts. There is no discreet anatomic border to these components of the orbicularis. The levator muscle originates just superior to the annulus of Zinn at the orbital apex and changes from striated muscle to fibrous apponeurosis 15 mm above the superior border of tarsus. The levator inserts into the superior border and anterior surface of the tarsal plate. It is innervated by the third cranial nerve. Müller's muscle is only 10–14 mm long and arises from the underbelly of the levator and inserts into the superior border of tarsus. It is composed of smooth muscle fibers and is adrenergically innervated. The levator and Müller's muscles function to open the upper lid while the orbicularis muscle closes it. The orbital septum is a thin, multilayered sheet of fibrous tissue separating the lid from the orbit. It arises from the superior orbital rim and inserts onto the levator aponeurosis 2–10 mm above the superior border of tarsus in Caucasians, 15 mm or more in blacks and at or below the superior border of tarsus in Asians. Small, fine, fibrous attachments extend from the levator to the subcutaneous tissue. These attachments and the insertion of the septum form the lid crease while the skin above the crease forms the lid fold. There are two fat pockets in the upper lid found nasally and centrally. The upper tarsus is a firm connective tissue usually 10–12 mm in height and 1 mm in thickness.

The lower lid is likewise divided into three functional lamellae: an anterior layer of skin and orbicularis, a posterior layer of conjunctiva and lower lid retractors, and a middle layer of septum and orbital fat (Figure 2). The lower lid retractors are composed of the capsulopalpebral fascia (the equivalent of the levator in the upper lid) and the inferior tarsal muscle (the equivalent of the Müller's muscle in the upper lid). The capsulopalpebral fascia is a fibrous band originating from the underbelly of the inferior rectus muscle that courses anteriorly, enveloping the inferior oblique, and inserts onto the inferior border of tarsus. It is functionally controlled by its origin from the inferior rectus muscle to retract the lower lid inferiorly when the eye looks downward, preserving unobstructed vision. The inferior tarsal muscle is often just scattered smooth muscle fibers intermixed with the capsulopalpebral fascia. As in the upper lid, the septum arises from the orbital rim and inserts on the inferior border of tarsus, often blending with the lower lid retractors. A lower lid crease occasionally exists but is usually less obvious. There are three fat pockets in the lower lid: nasal, central, and temporal (or lateral). The lower tarsus is usually 4–5 mm in height.

The lid margin is the border between the anterior skin–muscle layer and the posterior tarsoconjunctival layer. There are two to three irregular rows of lashes, whose bulbs are embedded just below the skin surface within the orbicularis muscle. Posterior to the lash line are the meibomian gland orifices. These sebaceous glands are embedded within the tarsal plates and run the entire vertical length of the tarsus. There are about 25 of these glands in the upper lid and 20 in the lower lid. The mucocutaneous junction is just posterior to the meibomian

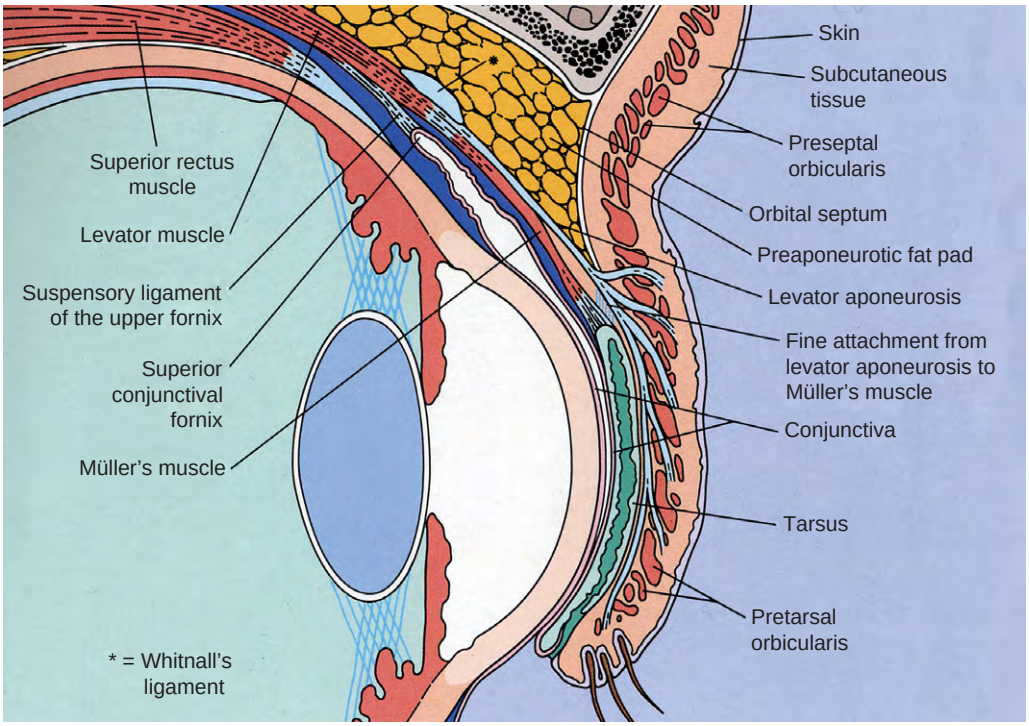

Figure 1 Cross-section of the upper eyelid.

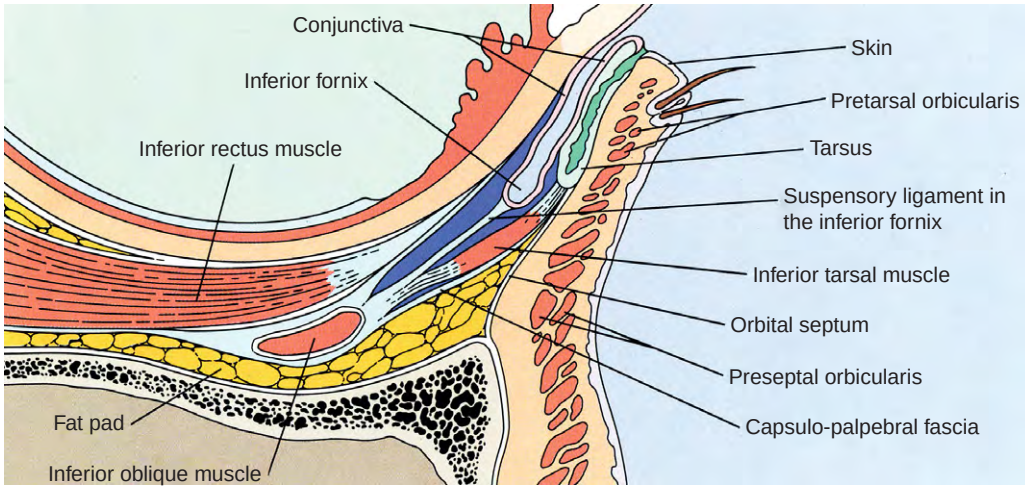

Figure 2 Cross-section of the lower eyelid.

gland orifices. The gray line is a variably visible section of pretarsal muscle (muscle of Riolan) just anterior to the tarsus. Embedded within the lid margin are the apocrine glands of Moll and the sebaceous glands of Zeiss associated with the lash follicles.

The upper and lower lids join laterally where the pretarsal heads of the orbicularis muscle form the lateral canthal tendon, which inserts into the orbital tubercle just posterior to the lateral orbital rim. Medially, the preseptal and pretarsal muscle form the medial canthal tendon, whose anterior and posterior heads surround the lacrimal sac. The lacrimal puncta open on the lid margin 6 mm from the medial commissure of the lids.

Pathophysiology

Dermatochalasis

Dermatochalasis is the normal aging change in the upper and lower lids characterized by loose, redundant skin and

orbicularis muscle often with bulging of the orbital fat pockets (Figure 3). It may be associated with ptosis of the eyebrows and forehead relaxation. When severe in the upper lids, it can limit peripheral vision and obstruct the central visual axis. Lower lid dermatochalasis rarely affects the vision, but in rare cases, fat bulging can be so extreme so as to contact the patient's glasses. Surgical treatment is aimed at removal of the excess skin, orbicularis, and fat.

Ptosis

Lid ptosis is a lower-than-normal position of the upper lid margin (Figure 4). When the lid margin is 2 mm or less from the center of the pupil, the superior visual field is usually significantly obstructed. Ptosis is either congenital or acquired. Congenital ptosis is usually the result of a malformed levator muscle often with a family history. It is unilateral in 75% of cases and bilateral (although often asymmetric) in 25% of cases. It is associated with anisometropia, amblyopia, or strabismus in 30% of cases. In general, the more severe the ptosis, the more dystrophic appears the muscle histologically. In cases of severe congenital ptosis, striated muscle fibers are usually completely absent, totally replaced by fibro-fatty connective tissue.

Figure 3 Dermatochalasis of all four eyelids.

Figure 4 Ptosis of the right upper lid.

Treatment for mild-to-moderate congenital ptosis is to perform levator resection surgery, wherein 12–18 mm of the distal levator and the underlying Müller's muscle is resected and the cut end resewn to the superior border of tarsus. This effectively shortens the muscle, resulting in a higher resting level of the lid on the globe but does not improve the overall movement of the lid. The most common problems post-operatively are undercorrection, overcorrection, or asymmetry of the lids often necessitating reoperation. Surgery induces lagophthalmos that increases with the amount of levator resected. Surprisingly, if done during childhood, lagophthalmos is usually well tolerated throughout the patient's lifetime.

In severe congenital ptosis, the levator is usually so dystrophic that resection is ineffective. In such cases a sling must be performed. In this surgery, autogenous or banked fascia or some alloplastic material is sewn into the tarsus and then threaded under the skin to the frontalis muscle in the forehead. The patient then elevates the lid by contracting the frontalis muscle, which pulls up the lid margin. Most patients do so automatically, resulting in effective lid opening.

Acquired ptosis, usually seen with aging, results from thinning or dehiscence of the levator aponeurosis from the tarsal plate. Any condition, however, that causes lid swelling or stretching (cataract surgery, trauma, contact lens wear, etc.) can result in acquired ptosis. Much less frequently, acquired ptosis is due to actual deterioration of the levator muscle or true muscular dystrophy. The usual treatment of acquired ptosis is to shorten the levator aponeurosis but to a much smaller degree than done with congenital ptosis (usually 4–10 mm). In adults, ptosis repair, when performed bilaterally, is often combined with blepharoplasty surgery for optimal cosmesis. Like in congenital ptosis, undercorrection, overcorrection, and asymmetry are common problems. In adults, however, adjustments can often be accomplished in the office under local anesthesia. Lagophthalmos is generally to be avoided in adult surgery, since the cornea is usually very intolerant of any chronic exposure and can rapidly result in discomfort and even ulceration.

Retraction

The opposite of ptosis, retraction is abnormal elevation of the upper lid or downward positioning of the lower lid (Figure 5). Most cases of upper lid retraction are due to thyroid eye disease resulting from contracture of the upper and lower lid retractors secondary to inflammation.

Figure 5 Retraction of all four lids secondary to thyroid eye disease.

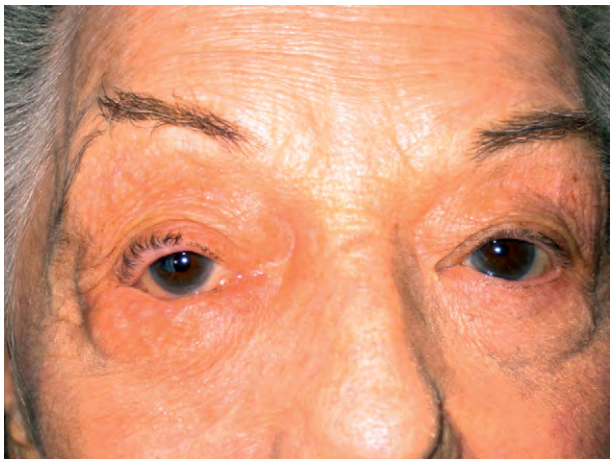

Figure 6 Involutional entropion of the right lower lid.

The lower lids may also retract due to age, associated with poor support from the cheekbones. Retraction due to thyroid eye disease is often associated with exopthalmos or an abnormal anterior displacement of the globe, which further increases the stare – so characteristic of this disease. Patients with retraction often have lagophthalmos, resulting in corneal exposure and irritation. Lower lid retraction is often seen as a normal physiologic variant in people with shallow orbits, especially common in black patients. Retraction is occasionally seen with overexcessive skin excision in blepharoplasty surgery.

Treatment of upper lid retraction in thyroid eye disease consists of graded recession of the levator–Müller's muscle complex superiorly so as to drop the upper lid margin down. Some surgeons insert spacers (autologous or banked tissues) between the recessed, cut edge of the levator–Mueller's muscle complex and the superior border of the tarsus when performing this surgery. In the lower lid, retraction is treated with recession of the lower lid retractors very frequently combined with spacer grafts for additional support of the lower lid. In the upper lid, gravity works in favor of the correction while it works against it in the lower lid. If the retraction is due to skin shortage after blepharoplasty, then skin grafting may be necessary.

Entropion

Entropion is an inward turning of the upper or lower lid margin (**Figure 6**). This results in the lashes rubbing on the globe, causing irritation and even corneal ulceration. Senile or involutional lower lid entropion is common with age and is due to excess horizontal (canthal tendons) and vertical laxity (the lower lid retractors).

This may be intermittent at first but usually progresses to a chronic condition. The lid margin appears to have a distinctive rolled-in appearance and can be reduced by pulling the lid against the lateral orbital rim, effectively tightening the lid. Surgical correction is aimed at correcting the horizontal laxity by resection of the redundant lid margin with resuspension at the lateral canthus. The vertical lid laxity may be corrected by plication of the lower lid retractors to the inferior border of tarsus. An effective repair is one which combines both of these procedures often performed through a lower lid blepharoplasty incision.

Involutional entropion usually does not occur in the upper lid. Such aging changes usually result in ptosis, as discussed above, or in lash ptosis – a downward angulation of the lashes due to relaxation of the anterior lamella of the eyelid in which the lash follicles are embedded. Lash ptosis is often corrected as part of an upper lid blepharoplasty procedure.

Cicatricial entropion may occur in both the upper and lower lids. It is due to vertical shortening of the posterior lamella of the eyelid, the tarsoconjunctival layer. It may be due to autoimmune disorders of the mucous membranes, inflammation, infection, surgery, trauma, or long-term use of glaucoma drops. Often, however, the cause is unclear. All surgeries for cicatricial entropion can be conceptualized as falling into three categories. The first are those that act by outward rotation of the lid margin (prototypical Weis procedure) usually involving a full-thickness, horizontal blepharotomy 4 mm from the lid margin. The second category involves expanding the shortened posterior lamella of the eyelid with grafts (usually buccal mucosa, amniotic membrane, or banked sclera). The third category involves procedures that split the lid margin at the gray line often with insertion of a spacer material, such as mucous membrane, to thicken the lid margin to the point that the lashes no longer rub against the globe. In some cases, the lash-bearing segment of the lid margin may simply be resected after splitting the lid margin.

Trichiasis

Often confused with entropion, trichiasis is inward misdirection of lashes against the globe in the presence of normal lid margin position. Trichiasis may, however, coexist with cicatricial entropion. Trichiasis is caused by the same factors that cause cicatricial entropion but is often idiopathic. Focal trichiasis is often treated by simple epilation of the offending lashes. If recurrent, electrolysis, cryotherapy, or laser may be used. Repeat treatment is often necessary since these modalities will kill the visible offending lashes but not the lashes that are about to bud. For large areas of the lid margin, surgery as outlined above for ciciatricial entropion may be needed. Alternatively, if focal, a segmental resection of the involved lid margin can be performed.

Distichiasis

Distichiasis is an additional row of lashes that grow from the meibomian orifices on the posterior lid margin. Such lashes will rub against the globe causing corneal irritation. Distichiasis may be congenital, often with a family history or acquired due to lid inflammation causing metaplasia of the cells in the posterior layer of the lid margin. It is treated with electrolysis or cryotherapy often after splitting the lid margin to prevent damage to the normal lashes. It may also be treated by direct surgical excision of the offending lashes.

Ectropion

Ectropion is outward rotation of the lower lid margin away from the globe (**Figure 7**). The exposure of the globe and the palpebral conjunctiva results in irritation, corneal damage, and keratinization of the conjunctiva. Epiphora, increased tear production, often results when the lower punctum stands off the globe and cannot adequately drain tears from the eye. Involutional ectropion occurs as an aging change secondary to horizontal lid laxity, mainly in the medial and lateral canthal tendons. Repair is accomplished by horizontal shortening of the redundant lid margin, usually at the lateral canthus, sometimes combined with vertical shortening of the lower lid retractors. When the problem is mainly medial, punctual ectropion, a spindle of conjunctiva and lower lid retractors is resected immediately below the lower punctum. Lower lid ectropion may coexist with retraction, as was discussed above. Involutional ectropion usually does not occur in the upper lid.

Figure 7 Involutional ectropion of the lower lids, worse on the right.

Cicatricial ectropion is due to vertical shortening of the anterior, skin–muscle lamella of the upper or lower lid. It is usually secondary to trauma or skin disorders. In the upper lid, release of the scarred tissue is followed by skin grafting from the opposite upper lid, the retroauricular area, supraclavicular area, or forearm. In the lower lid, horizontal lid shortening is also often required since the chronically ectropic lid often has or develops a component of excess horizontal laxity. In the lower lid, a skin graft may be replaced by advancement of a skin–muscle flap from the surrounding area.

Paralytic ectropion is due to paralysis of the seventh nerve. There is also lagophthalmos due to inability of the upper and lower lids to close. Exposure can be severe and can lead to corneal ulceration. Conservative treatment consists of ocular lubrication, moist chamber devices and lid taping. Tarsorrhaphy may be needed if the cornea dries out in spite of conservative measures. For those cases in which seventh nerve function will not return a gold weight or spring may be placed in the upper lid to counter the lagophthalmos. The lower lid usually needs to be tightened horizontally and often lifted vertically with a posterior lamellar graft or suspension sling of fascia or silicone. Although such treatments are helpful, patients never have a normal blink with any of these procedures.

Floppy Lid Syndrome

This uncommon syndrome is most frequently seen in obese, middle-aged males (**Figure 8**). The upper lid is extremely lax and spontaneously everts often while the patient sleeps and rubs against the pillow. Those affected have a severe papillary conjunctivitis, ropey mucoid discharge, and irritation. Floppy lid syndrome is accompanied by sleep apnea and hypertension. Symptoms can sometimes be controlled by having the patient wear a Fox shield over the eye while sleeping to reduce nocturnal eversion of the lid. Most often, horizontal upper lid shortening is needed along with tightening of the lower lid for control of symptoms.

Common Malignant Eyelid Tumors

Basal cell carcinoma (BCC) is the most common eyelid malignancy accounting for 85–90% of such lesions.

Figure 8 Demonstration of the floppy eyelid syndrome on the left.

Figure 9 Nodular basal cell carcinoma of the left lower lid.

BCC is an actinic lesion and is more common in fair-skinned individuals on sun-exposed parts of the body. It is most common on the lower lid, followed by the medial canthus, upper lid, and lateral canthus. The tumor is classically a firm, nodular lesion with a central ulcer and pearly, vascular border (**Figure 9**). It may also present as an irritating, erythematous patch or rarely be entirely subcutaneous. Lesions of the medial canthus have a propensity for deep invasion into the eye socket. BCC only rarely metastasizes and generally grows very slowly. The preferred treatment is complete excision with frozen section control or by Mohs micrographic surgery usually performed by a specially trained dermatologist. It provides the best cure rate (98–99%) while saving as much normal tissue as possible. Excision is followed by reconstruction of the eyelid defect or occasionally by spontaneous healing if the defect is small or does not involve the lid margin. Radiation therapy is an alternative to surgery but not as effective due to the relatively high recurrence rate (5–20%). Recurrence is also difficult to detect after radiation due to tissue alteration from the treatment. Cryotherapy is sometimes used for small lesions but has similar problems with a relatively high recurrence rate (20–30%) and depigmentation and atrophy of treated tissue.

Squamous cell carcinoma (SCC) accounts for about 5% of periocular malignancies. It too is an actinic lesion, being more common on sun-exposed areas of fair-skinned individuals. Again, the lower lid is the most common location. It most frequently presents as an erythematous, thickened patch with erosion of the involved tissue (**Figure 10**). A nodular subtype is occasionally observed. It may arise from preexisting actinic keratoses, which undergoes malignant transformation 20% of the time. SCC can metastasize through the regional lymphatics or spread along involved sensory nerves. Mohs removal and reconstruction are the preferred therapy. Radiation

Figure 10 Squamous cell carcinoma of the left medial canthus.

therapy is much less effective in SCC and thus is used only for palliation of surgically unresectable tumors. Topical therapy with 5-fluorouracil or imiquimod is a frequent treatment of the premalignant actinic keratosis.

Sebaceous cell carcinoma accounts for about 5% of periocular malignancies but is increasing in frequency, which may be due in part to better pathological diagnosis. It arises from the meibomian glands, the glands of Zeiss, and sebaceous glands of the caruncle. It presents as a nodular lesion, which is often mistaken for a chalazion or a diffuse intraepithelial pattern that looks like a chronic conjunctivitis (pagetoid spread) (**Figure 11**). Because of this, the diagnosis is often delayed until biopsied. It is capable of both regional lymphatic and vascular spread. It is considered deadlier than SCC. Mohs microsurgery may be effective in tumor removal if the tumor is nodular, but pagetoid spread and skip lesions often necessitate wide sampling of the bulbar and palpebral conjunctiva (map biopsy). If diffusely spread, orbital exenteration is

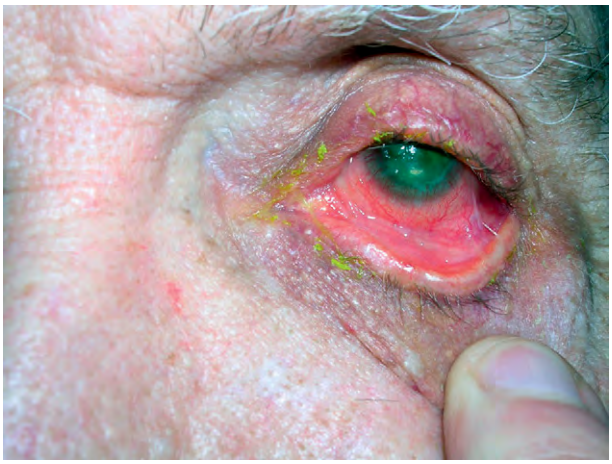

Figure 11 Pagetoid spread of sebaceous cell carcinoma of the conjunctiva of the left lower lid.

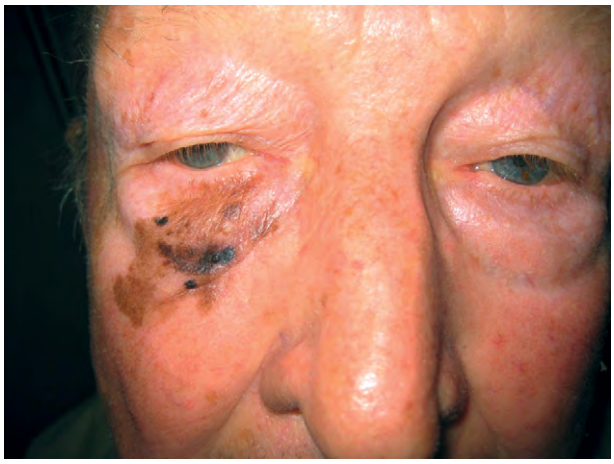

Figure 12 Malignant melanoma of the right lower lid.

usually required. Sebaceous cell carcinoma is relatively radio resistant and responds poorly to chemotherapy.

Malignant melanoma accounts for less than 5% of periocular malignancies, but it too is increasing in frequency (**Figure 12**). It too is an actinic lesion but other less well-defined causes play a role. It arises spontaneously usually as a nodule or in an existing nevus or area of lentigo maligna (intraepithelial tumor). It too is capable of spread through the regional lymphatics and the blood stream. Surgical excision is the treatment of choice, but requires permanent section histology to adequately assess tumor margins. Because of this, the resection of the tumor is often spread over several days (Slow Mohs) followed by reconstruction when margins are clear.

Benign Eyelid Tumors

A variety of benign lesions are found on the lids and periocular skin. The vast majority are of minimal functional significance, but patients frequently request removal for cosmetic reasons. The most common are nevi, inclusion and glandular cysts, seborrheic keratoses, verruca, skin tags, and benign glandular tumors. Simple excision can usually be carried out in the office under local anesthesia.

Inflammatory and Infectious Disorders of the Lids

Chalazion is a lipogranuloma of one of the meibomian glands of the tarsal plate. They arise relatively rapidly over a period of a few days, often with inflammation and discomfort. They can progress to form a chronic pea-sized, firm nodule in the lid (**Figure 13**). The initial treatment is to hot compress the involved lid frequently in the first few days in hopes of opening the obstructed gland. If not effective many will resolve spontaneously over the next several weeks to few months. Patients often request removal for cosmetic reasons. This can usually be done in the office with local anesthesia. An alternative is to inject the chalazion with steroid, which is effective about 50% of the time.

Figure 13 Chalazion of the right upper lid.

Hordeolum is a staphylococcal infection of one of the sebaceous glands of the lid. It presents as an acutely swollen, erythematous, painful nodule on the lid margin (external hordeolum) or on the palpebral conjunctiva (internal hordeolum). Hot compress, topical antibiotics, and surgical drainage are effective. Oral antibiotics may be needed if cellulitis occurs.

Blepharitis is the most common inflammatory disorder of the eyelids characterized by redness, swelling, and irritation with visible crusting. It is a chronic condition characterized by intermittent exacerbations. There are three subtypes, but many patients show combinations of all three. In staphylococcal blepharitis, chronic colonization of the lid margin leads to inflammation from the bacterial toxins and antigens. Slit-lamp examination

reveals characteristic white collarettes around the base of the lashes. In seborrheic blepharitis, there are greasy scales (scurf) found on the lashes and often associated seborrheic dermatitis of the face and scalp. The third form, posterior blepharits (posterior lid margin disease, meibomian gland dysfunction, and meibomianits) is characterized by a change in the normal clear meibomian gland secretion to a thick, cloudy to yellow, oily discharge. Posterior blepharitis is often associated with acne rosacea and chalazia. All forms of blepharitis lead to chronic redness of the conjunctiva, sometimes with papillary hypertrophy. The tear film is often unstable as manifested by a rapid tear break-up time. Dry eye is a frequent association. In addition to the above findings, slit-lamp examination may reveal punctate epithelial erosions (PEEs) of the cornea and marginal corneal erosions due to staphylococcal hypersensitivity. There may be small, rounded domes on the meibomian orifices, manifestations of the thick, inspissated secretions. Digital pressure on the lid may cause the meibomian glands to express material that can, in severe cases, have a cheesy consistency.

Treatment consists of warm compresses to thin the meibomian secretions and eyelid scrubs with baby shampoo or commercially available products to clean the lid margin and express the meibomian glands. Topical antibiotic drops or ointment reduces the bacterial colonization of the lid margin and topical steroids help to control the inflammation. Oral, low-dose tetracycline (50 mg doxycycline per day) is helpful in reducing the meibomian gland discharge and normalizing the pH of the tear film. Oral erythromycin can be used if the patient is intolerant to tetracyclines, pregnant, nursing, or under the age of 12.

Light-Driven Translocation of Signaling Proteins in Vertebrate Photoreceptors

P D Calvert, SUNY Upstate Medical University, Syracuse, NY, USA
V Y Arshavsky, Duke University, Durham, NC, USA

Glossary

Arrestin – A protein which binds to and inactivates photoactivated rhodopsin. Arrestin binding results in termination of transducin activation.
Light adaptation – The ability of photoreceptors (and the visual system as a whole) to adapt the speed and sensitivity of light responses to ever-changing conditions of ambient illumination.
Phosducin – A protein which interacts with the $\beta\gamma$-subunit of transducin and reduces its membrane affinity.
Recoverin – A regulatory protein which is thought to regulate the speed at which arrestin can bind to photoactivated rhodopsin.
RGS9 – A protein responsible for returning activated transducin in its inactive form.
Transducin – A G protein that mediates the visual signal between the photoactivated visual pigment, rhodopsin, and the downstream effector enzyme, cGMP phosphodiesterase. Transducin consists of two functional subunits, α and $\beta\gamma$.

Introduction

Rod and cone photoreceptors are highly polarized cells which transduce information encoded by photons into electrical activity that can be processed by higher-order neurons. At the one end, photoreceptors have specialized ciliary organelles, outer segments, which are enriched in proteins directly involved in light detection and signal transduction. At the opposite end, synapses convey the information gathered by outer segments to downstream neurons. Vision begins when a molecule of rhodopsin in the outer segment becomes excited by light and activates a G protein, transducin. The transducin α-subunit stimulates its effector, cyclic guanosine monophosphate (cGMP) phosphodiesterase (PDE), which leads to the reduction in intracellular cGMP and to the electrical response mediated by the closure of the cGMP-gated cationic channels in the plasma membrane. The recovery of the photoresponse requires complete inactivation of all these molecular components. Photoexcited rhodopsin is inactivated through its phosphorylation by rhodopsin kinase and arrestin binding, which blocks transducin activation. The rate of rhodopsin phosphorylation, and thus its active lifetime, is regulated by the Ca^{2+}-binding protein, recoverin. Transducin (and accordingly PDE) activation is terminated upon the hydrolysis of GTP tightly bound to transducin α-subunit, a process markedly accelerated by the GTPase activating protein RGS9.

Importantly, three of the above-mentioned proteins (transducin, arrestin, and recoverin) undergo massive light-driven translocation between the major subcellular compartments of photoreceptors (**Figure 1**). In rods, transducin moves out of the outer segment and accumulates primarily in the inner segment, arrestin moves in the opposite direction, and recoverin shifts from the outer segment toward the synapse. In cones, in light arrestin moves in the same direction, whereas transducin moves very little, if at all. Recoverin translocation has not yet been analyzed in cones. A similar phenomenon involving the G protein (G_q), arrestin, and the transient receptor potential-like (TRPL) channel takes place in rhabdomeric invertebrate photoreceptors.

Light Dependency of Protein Translocation

Quantitative experiments revealed that the translocations of arrestin and transducin in rods take place in bright light. The outer segments of the rod contain very little arrestin (estimated under 7% of its total cellular content) in the dark and under moderate illumination. In mouse rods, arrestin begins to move to outer segments when the light intensity reaches a critical threshold, exciting over ~1000 rhodopsins per rod per second, which is within the upper limit at which mammalian rods can signal variations in light. Transducin translocation is also triggered at a threshold light intensity, although brighter, exciting ~5000 rhodopsins per rod per second, an intensity that completely saturates rods. The time required for the completion of protein translocation in saturating light in rods is on the order of tens of minutes. Although no such quantitative measurements are available for cones, available data indicate that cone arrestin translocation also requires fairly bright light. The existence of cone transducin translocation in intact cells remains somewhat

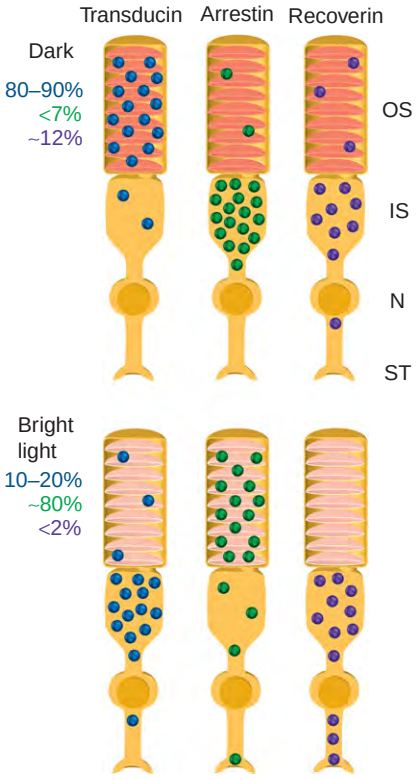

Figure 1 Schematic illustration of transducin, arrestin, and recoverin distribution in dark- and light-adapted rods. The numbers on the left, color-coded to the corresponding translocating proteins, represent the percentage of the proteins found in the outer segments in the dark or following bright light illumination. The subcellular rod compartments are abbreviated on the right: OS – outer segment; IS – inner segment; N – nucleus; ST – synaptic terminal. Reproduced from Calvert, P. D., Strissel, K. J., Schiesser, W. E., Pugh, E. N., Jr., and Arshavsky, V. Y. (2006). Light-driven translocation of signaling proteins in vertebrate photoreceptors. *Trends in Cell Biology* 16: 560–568.

controversial. Most investigators do not see it at any light intensity, whereas one group reports small degree of translocation observed in extremely bright light. The most recent report argues that the inability of cone transducin to efficiently translocate in light reflects specific physicochemical properties of its individual subunits.

Hypotheses on the Functional Roles of Protein Translocation

Photoreceptors adjust their sensitivity over a broad range of ambient light intensities, and protein translocation has been proposed to contribute to this process at the high end of adaptive light intensities. The reduction of transducin content in outer segments of rod in bright light correlates with a reduction in signal amplification in the rhodopsin–transducin–phosphodiesterase cascade, likely due to the reduction in transducin activation rate. This is likely to move the dynamic range over which rods operate to higher light intensities. Although transducin translocation takes place in light that is saturating for rods, this range adjustment may be adaptive after the light is dimmed or extinguished. For example, such a mechanism could be useful as dusk approaches when vision is switching from being cone-dominant to rod-dominant. The fact that transducin translocation is triggered by light intensities that completely saturate rods makes it plausible to suggest that both phenomena, transducin translocation and response saturation, occur for essentially the same reason, the inability of rods to inactivate vast amounts of transducin beyond a certain light intensity. In this context, transducin translocation can be viewed as an elegant self-regulating mechanism triggered at the point where the rod exhausts other means of avoiding response saturation.

Although not yet tested experimentally, arrestin translocation is thought to be adaptive as well. Its increased concentration in the outer segment could reduce the response amplitude and/or accelerate recovery. It could also allow rods and cones to prepare for inactivation of large amounts of photoexcited rhodopsin and its bleach products produced in bright light. Similarly, recoverin translocation from outer segments may increase the amount of rhodopsin kinase available to phosphorylate rhodopsin, thus further reducing light sensitivity.

Light-driven protein translocation, particularly in rods, may also play a neuroprotective role. Rod saturation marks the transition from mesopic (mixed rod/cone) to cone-dominated photopic vision. Under these conditions, rods contribute little to vision and transducin translocation may prevent excessive energy consumption by rods by reducing the number of transducin molecules undergoing the cycle of activation/inactivation. This may, in turn, reduce the metabolic stress in the retina commonly believed to contribute to pathological processes. A reduced level of cellular signaling caused by transducin translocation may also reduce the chance of apoptotic death of the rod. At least in rodents, some forms of apoptosis are suggested to be caused by excessive signaling through the phototransduction cascade. The same argument may be applied to arrestin translocation, whose accumulation in the outer segment in bright light is likely to preamplify rhodopsin shutoff on a sunny day.

Finally, when vision is dominated by cones, rods may perform more of their housekeeping functions, such as checking the integrity of proteins by the ubiquitin proteasome system located in the inner segments.

What Is the Mode of Protein Translocation: Active Transport or Diffusion?

A major currently explored area in this field is whether phototransduction proteins translocate by diffusion or by

active transport via molecular motors. In principle, the mode of translocation of each protein could be different between the light- and dark-induced directions. Most investigators argue against the involvement of molecular motors. One major argument is that all of these proteins (or at least individual subunits in the case of transducin) are fairly soluble and any of their relocation by molecular motors may be negated by the subsequent diffusion throughout the entire cellular volume. Another argument is that, although protein translocation by motors is rapid, it could be easily saturated by the very large number of translocation protein molecules. On the other hand, intracellular diffusion of soluble proteins in rods is also sufficiently rapid to explain the observed protein translocation rates and, unlike molecular motors, could not be saturated by the amount of protein molecules undergoing light-induced translocation. Yet, it should be noted that, based on the impediment of translocation by the cytoskeleton disrupting drugs, some believe that motor systems are involved, particularly in protein translocations in the dark-induced directions.

However, diffusion alone cannot account for the phenomenon because it does not explain any disequilibrium of protein distributions with the free cytoplasmic volume of the rod or cone. Thus, while diffusion serves as the mode of protein movement, the observed patterns of light-dependent protein redistribution may be explained by light-dependent appearance or disappearance of specific protein-binding sites in individual subcellular compartments. The next two sections illustrate these ideas in regard to transducin and arrestin.

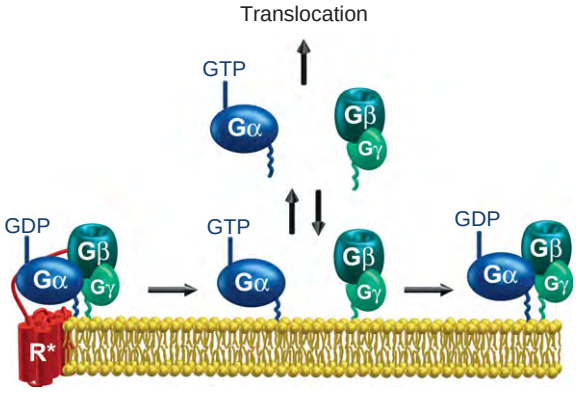

Figure 2 The putative role of transducin subunit dissociation in its translocation. When transducin is activated by photoexcited rhodopsin (R*), its α- and βγ-subunits become separated from one another and the membrane affinity of each is less than that of the heterotrimer. In this state, subunits may dissociate from photoreceptor disk membranes and translocate from the outer segment. The efficiency of translocation is dependent on the time during which transducin subunits stay apart before re-formation of the trimer. This time is determined by the rate of the GTP hydrolysis on the α-subunit and is dependent on the absolute amount of activated transducin. Reproduced from Calvert, P. D., Strissel, K. J., Schiesser, W. E., Pugh, E. N., Jr., and Arshavsky, V. Y. (2006). Light-driven translocation of signaling proteins in vertebrate photoreceptors. *Trends in Cell Biology* 16: 560–568.

Specific Mechanisms of Protein Translocation

Transducin

Recent reports suggest that transducin translocation could be explained by the differences in the membrane affinities of its αβγ heterotrimer compared to the individual α- and βγ-subunits. The heterotrimer is strongly membrane-associated due to the combined action of two lipid modifications: a farnesyl group on the γ-subunit and an acyl group on the α-subunit. Thus, in the dark-adapted rod, transducin heterotrimer is predicted to be concentrated on the disk membranes of the outer segment. When transducin is activated in light, α-subunits bind GTP and dissociate from the βγ-subunits (**Figure 2**). Both subunits become more soluble since each has only one lipid modification, allowing them to diffuse throughout the cytoplasm. Inevitably, GTP hydrolysis by the α-subunit would result in the restoration of the poorly soluble trimer. When this happens in the outer segment, transducin becomes re-attached to the disk membranes; but when it happens in the inner segment, the trimer may adhere to the membranous structures there, causing its transient accumulation. The central assumption of this hypothesis, that transducin subunits move apart from one another, is supported by the difference in their translocation rates and by transducin translocation being facilitated by transgenic or pharmacological manipulations promoting transducin subunits to remain in the dissociated state. The translocation of transducin βγ-subunit is further enhanced by the protein called phosducin. Phosducin reduces membrane association of the βγ-subunit, which presumably allows it to more easily diffuse throughout the cytoplasm.

Another important mechanistic feature of transducin translocation is its light-intensity threshold. This threshold reflects the fact that the cellular content of transducin significantly exceeds that of RGS9, a protein responsible for rapid inactivation of transducin. Light of the threshold intensity produces activated transducin in the amount exceeding the capacity of RGS9 to inactivate it. Consequently, a fraction of activated transducin stays in the active, GTP-bound form (with α- and βγ-subunits dissociated) for a longer time, sufficient for dissociation from the disk membranes and diffusion through the photoreceptor cytoplasm. Accordingly, the knockout of RGS9 allows transducin translocation at a lower light intensity, whereas RGS9 overexpression shifts the threshold to brighter light.

Arrestin

It was first suggested that arrestin is equilibrated throughout the rod cytoplasm in the dark and is trapped in the outer segment in light upon binding to photoexcited rhodopsin. However, recent observations argue that the dark-adapted distribution of arrestin does not match the distribution of the free cytoplasm volume, indicating that most arrestin is bound to sites located in the inner segment. One hypothesis is that these sites are formed by microtubules. It was further proposed that arrestin translocation is explained by a simple competition between constitutive, low-affinity microtubule sites in the inner segment and transient, high-affinity sites in the outer segment formed upon rhodopsin photoexcitation. However, quantitative measurements indicated that, at the minimal light intensity sufficient to trigger arrestin translocation, the number of translocated arrestin molecules exceeds the number of photoactivated rhodopsin molecules by ~30-fold. Even less rhodopsin activation is required to trigger arrestin translocation in knockout mice lacking RGS9 where transducin activation persists longer than normally. Therefore, triggering arrestin translocation is not dependent on the absolute amount of rhodopsin excited by light, but is rather dependent on arrestin release from the inner segment sites by a yet-to-be-identified signaling mechanism downstream from phototransduction.

Proteins' Return in the Dark

The rates of transducin and arrestin return to their dark-adapted locations upon switching from light to dark are much slower than their movement in the light-induced direction, with most measurements indicating that it takes at least an hour. This may be slow enough to be within the capacity of molecular motors, and indeed transducin and arrestin return can be blocked by cytoskeleton disrupting drugs. The specificity of these treatments remains unknown and artifacts such as clogging the connecting cilium could not be ruled out. On the other hand, arrestin and transducin return could also be explained by a combination of diffusion, removal of the light-induced binding sites, and restoration of the dark-adapted sites. Current evidence is insufficient to discriminate between the potential roles of molecular motors and diffusion in transducin and arrestin return to their dark-adapted cellular distributions.

Limulus Eyes and Their Circadian Regulation

B-A Battelle, University of Florida, St. Augustine, FL, USA

Glossary

Arhabdomeric cell – The secondary visual cell in *Limulus* median eyes that is not photoreceptive but is electrically coupled to photoreceptors and generates action potentials in response to photoreceptor depolarization.
Chelicerate – A type of arthropod belonging to the group Chelicerata that includes horseshoe crabs, scorpions, spiders, ticks, and mites.
Circadian clock – A biological clock that oscillates with a period of about 24 h even under constant conditions.
Compound eye – An eye that contains a few to many separate photoreceptive units.
Eccentric cell – A secondary visual cell in *Limulus* lateral eye that is not photoreceptive but is electrically coupled to photoreceptors and generates action potentials in response to photoreceptor depolarization.
Lateral inhibition – A mechanism of information processing in nervous systems that increases contrast and resolving power.
Ocellus – A type of eye with a single lens.
Octopamine – A major amine neurotransmitter in invertebrates that is the phenol analog of norepinephrine.
Ommatidium – The photoreceptive unit of compound eyes.
Quantum bump – The response of photoreceptors to a single photon of light.
Rhabdom – A photoreceptive membrane typically elaborated by arthropod photoreceptors that is composed of tightly packed microvilli.

The retinas of animals that live in cyclic light environments typically undergo rhythmic, daily changes in structure and function. These changes underlie the ability of animals to detect images over the large daily fluctuations in ambient illumination, and therefore they are critical for normal vision. Some of these changes, such as light and dark adaptation, are driven solely by fluctuations in illumination, while others are driven solely by signals from internal circadian clocks. Still other changes require interactions between light- and clock-driven biochemical cascades.

In the American horseshoe crab *Limulus polyphemus*, a chelicerate arthropod, circadian changes in vision are dramatic, and as a result, *Limulus* can see at night nearly as well as it can during the day. Since the circadian organization of the *Limulus* visual system is also advantageous for experimental manipulation, *Limulus* has been used to examine in detail the separate and combined effects of diurnal light and the clock on the retina.

The first part of this article describes the organization of the *Limulus* visual system and the circadian input to the eyes. The second part describes the impact of the circadian clock on *Limulus* retinal structure, the photoresponse, photosensitive membrane shedding, and gene expression. The synaptic mechanisms through which the clock influences the eyes are described as well as a clock-driven biochemical cascade in photoreceptors that may underlie some of the observed circadian changes in visual function.

Organization of the *Limulus* Visual System

Limulus has three major types of eyes: lateral, median, and rudimentary (**Figure 1**). The eyes that are obvious by examining the dorsal side of an adult animal are the lateral compound eyes (LE) on the dorsolataral carapace, and a pair of median eyes located on either side of the median dorsal spine near the front of the animal. Rudimentary eyes are found at three different locations, and in an adult animal they are largely hidden from view. Lateral rudimentary eyes are located below the cornea at the posterior edge of each LE, and a pair of fused median rudimentary eyes is located below the carapace between the two median ocelli. Ventral rudimentary eyes consist of a pair of optic nerves that extend anteriorly from the brain just below the cuticle on the ventral side of the animal. They terminate in an end organ located below a wart-like structure visible on the ventral cuticle in front of the mouth.

Lateral Compound Eyes

In an adult animal, each LE contains over 1000 conical lenses, and below each lens there is a single ommatidium, or mini-retina, that is aligned with the long axis of the overlying lens (**Figure 2(a)**) Each ommatidium is composed of 8–12 photoreceptors clustered like the sections of an orange around the dendrite of usually one secondary visual cell called the eccentric cell (**Figures 2(b)** and **2(c)**). The photoreceptors are electrically coupled to the dendrite of the eccentric cell. Two major non-neuronal cells types

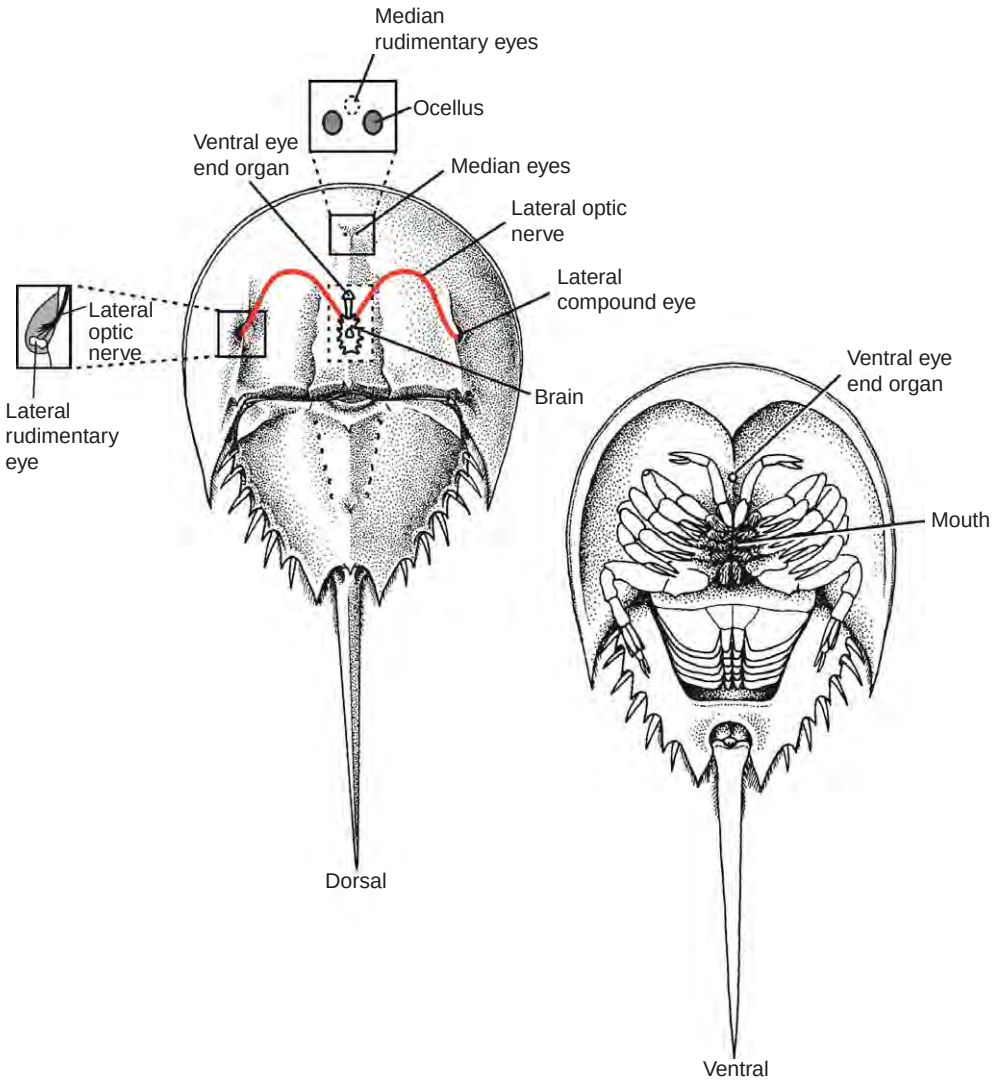

Figure 1 Schematics of dorsal and ventral views of an adult *Limulus* showing the locations of the eyes. The lateral compound eyes and median ocelli are visible on the dorsal carapace. The box at the left shows the location of a lateral rudimentary eye below the cornea at the posterior edge of the lateral compound eye. The box at the top shows the location of the fused median rudimentary eyes below the carapace between the median ocelli. The cutaway in the center shows the position of the brain and ventral rudimentary eyes. Ventral optic nerves extend anteriorly from the brain and terminate in an end organ located just beneath a wart-like structure that is visible on the ventral cuticle in front of the mouth. The long lateral optic nerves are shown in red. Modified from Calman, B. G. et al. (1991). *Journal of Comparative Neurology* 313: 553–562.

are present in ommatidia: cone cells and pigment cells. Cone cell processes occupy the aperture at the base of the lens and separate the lens from photoreceptors. Pigment cells surround each ommatidium and form partitions between photoreceptors.

LE photoreceptors respond with graded depolarizations to visible light, and the eccentric cells to which they are electrically coupled, encode these graded depolarizations as action potentials. Both photoreceptors and eccentric cells have axons that project to optic ganglia in the brain (lamina and medulla) through the lateral optic nerve (**Figure 3(a)**). However, because the lateral optic nerve in an adult animal is long, often over 10 cm, it is unlikely that the graded photoreceptor potentials reach the brain. Therefore, information from LEs is thought to reach the brain only through the activity of the eccentric cells.

In addition to projecting to the brain, eccentric cells extend axon collaterals laterally within the eye to form a neural plexus just below the ommatidia (**Figure 2(a)**). Within this plexus, eccentric cell collaterals from neighboring and even distant ommatidia make reciprocal inhibitory synapses which are the basis for lateral inhibition in the eye. Lateral inhibition, a fundamental mechanism of information processing in nervous systems that increases contrast

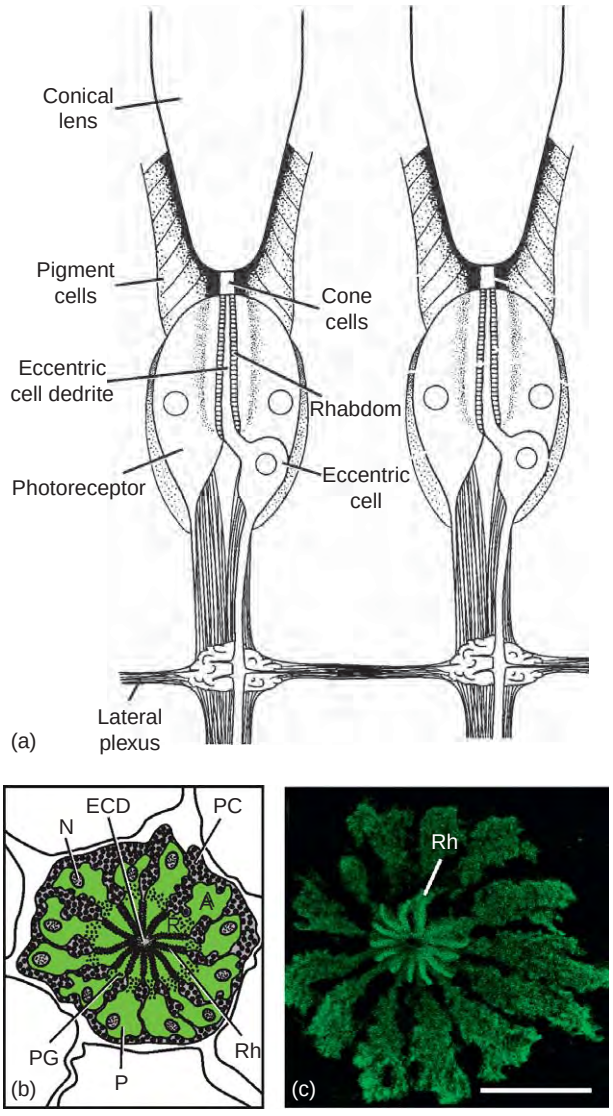

Figure 2 (a) Schematic of a longitudinal section through two ommatidia of the lateral eye, illustrating major cell types. The photoreceptors and eccentric cells project axons into the lateral optic nerve. Eccentric cell axons also project collaterals into a lateral plexus within the eye where they form the reciprocal inhibitory synapses that underlie lateral inhibition. (b) Schematic of a cross section through one ommatidium showing the arrangement of photoreceptors (P), shown in green, around a central eccentric cell dendrite (ECD). The nuclei (N) located in the arhabdomeral lobes (A) of photoreceptors is shown. Screening pigment granules within the photoreceptors (PG) define the junction between the arhabdomeral and rhabdomeral (R) lobes. The asterisk-like structure at the center of the ommatidium is the rhabdom (Rh) formed from the fused photosensitive membranes of neighboring photoreceptors. Pigment cells (PC) surround the ommatidium and form partitions between photoreceptors. (c) Confocal image of one ommatidium from a light-adapted daytime animal immunostained for LpMyo3. LpMyo3 distributes through photoreceptor cell bodies and concentrates at the rhabdom (Rh). Scale bar = 50 μm. (a) and (c) from Battelle, B-A. and resolving power, was first detected experimentally in *Limulus* LE. In vertebrate retinas, this same mechanism is known as center-surround inhibition.

Median Eyes

Median eyes are called ocelli because they have a single spherical lens (**Figure 4**). In median eye retinas, groups of 5–11 photoreceptors are typically associated with at least one secondary visual cell or arhabdomeric cell, but unlike LE ommatidia, these groups are not highly organized and difficult to discern anatomically. The photoreceptors and arhabdomeric cells are embedded in guanophores, cells that contain reflective guanine crystals, and the retina is surrounded by pigment cells.

An interesting feature of median eyes is that they contain two different types of photoreceptors: one that responds to visible light and another that is sensitive to ultraviolet (UV) light. These two photoreceptor types have not yet been distinguished anatomically. Median eye arhabdomeric cells are thought equivalent to LE eccentric cells because, similar to eccentric cells, they are electrically coupled to photoreceptors and generate action potentials in response to graded photoreceptor depolarizations. Median eye photoreceptors and arhabdomeric cells both project axons to ocellar ganglia in the brain through the median optic nerve (**Figure 3(a)**), but only the action potentials of the arhabdomeric cell are thought to reach the brain. Interestingly, arhabdomeric cell action potentials have been detected only in response to UV illumination.

Rudimentary Eyes

The lateral, median, and ventral rudimentary eyes differentiate in the embryo before the more complex LEs and median ocelli, and they presumably provide photic information to the developing embryo. Each rudimentary eye consists of a cluster of large photoreceptors (100 × 160 μm) that are sensitive to visible light. Ventral eye photoreceptors are typically scattered along the length of the ventral optic nerves as well as clustered near the brain and in the end organ (**Figure 3(a)**).

Similar to the photoreceptors in lateral and median eyes, rudimentary eye photoreceptors produce graded depolarizations in response to illuminations, but they have no associated secondary visual cells. Rudimentary photoreceptors project axons to the brain through the lateral, median, or ventral optic nerves, and although their axon diameters are considerably larger than those of lateral and median eye photoreceptors, it still seems unlikely that their graded depolarizations reach the brain in an adult animal. An exception may be the graded

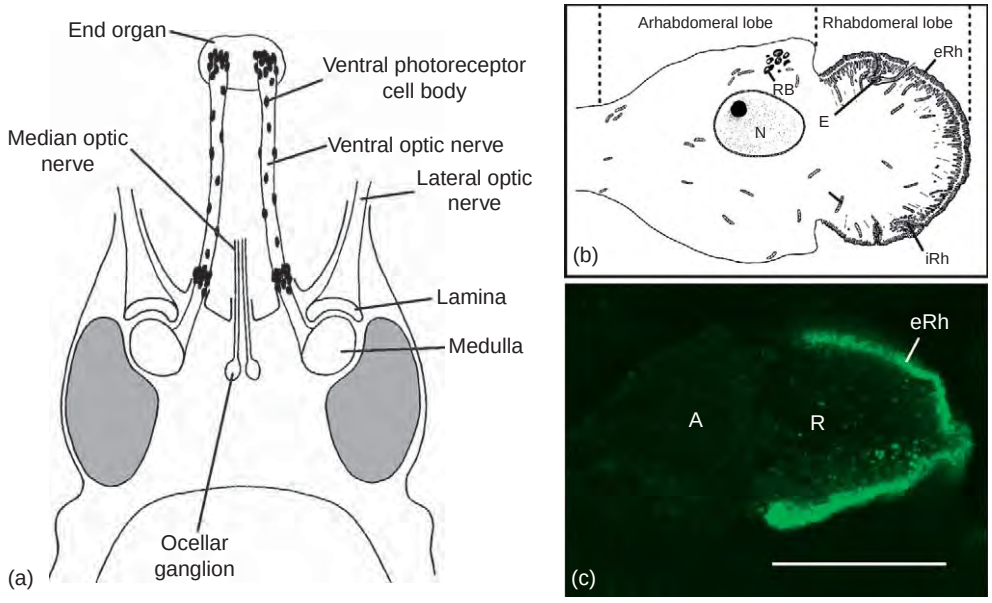

Figure 3 (a) Schematic of a dorsal view of the brain and ventral optic nerves. Ventral photoreceptor cell bodies (dark ovals) are scattered along the ventral optic nerves and clustered at their ends. Also shown are the median and lateral optic nerves and the optic ganglia. (b) Schematic of a ventral photoreceptor showing the rhabdomeral (R) and arhabdomeral (A) lobes, external rhabdom (eRh), internal rhabdom (iRh), efferent terminals near the rhabdom (E), mitochondria (M), ribosomes (RB), and nucleus (N). (c) Confocal image of a 1 μM optical section through a light-adapted ventral photoreceptor immunostained for visual arrestin. Visual arrestin concentrates at the rhabdom in the R lobe. Scale = 50 μm. Figure 4 Schematic of a median ocellus cut perpendicular to the carapace. Most of the area proximal to the lens is filled with photoreceptor cells. The dark areas below the lens represent the rhabdoms, which are not highly organized in this eye. Arhabdomeric cells are interspersed among the photoreceptors. Pigment cells surround the structure and reflective guanophores lie nearer the base of the retina. Modified from Jones, J. N. and Brown, J. E. (1971). *Z. Zellforsch* 118: 297–309, with permission from Springer Verlag.

depolarizations produced by ventral photoreceptors located close to the brain.

The Photoreceptors

The photoreceptors are fundamentally similar in the three types of *Limulus* eyes. All are composed of two major compartments: a rhabdomeral lobe and an arhabdomeral lobe (**Figures 2(b), 3(b),** and **3(c)**). The rhabdomeral lobe contains the photosensitive membrane or rhabdom, which in *Limulus*, as in other arthropods, is composed of tightly packed actin-rich microvilli. The arhabdomeral lobe is not photosensitive and contains the nucleus and metabolic machinery of the cell. As described above, all *Limulus* photoreceptors produce graded depolarizations in response to illumination, and with the exception of the median eye UV-sensitive photoreceptors, all respond to visible light with an absorption maximum of about 525 nm. Finally, all *Limulus* photoreceptors, as well as the eccentric cells of the LE and arhabdomeric cells of the median eye, release the inhibitory neurotransmitter histamine. Histamine is also the neurotransmitter used by the photoreceptors of insects and crustaceans.

The rhabdoms in the three types of eyes are organized differently, however, and they are highly organized only in LE ommatidia. In LEs, the rhabdoms of neighboring photoreceptors are fused so that in a cross section of an ommatidium, they appear like an asterisk with the eccentric cell dendrite at the center (**Figures 2(c)** and **2(c)**). The highly complex rhabdoms in median ocelli may project proximally into neighboring photoreceptors or infoldings of photoreceptor membranes may form internal rhabdoms (**Figure 4**). Rudimentary photoreceptors typically have both external and internal rhabdoms (**Figures 3(b)** and

3(c)) and often have more than one rhabdomeral lobe. In addition, rhabdoms of adjacent rudimentary photoreceptors frequently fuse forming a double layer of microvilli.

Among *Limulus* photoreceptors, those of the ventral eyes are the best studied, and their physiology is probably the most thoroughly characterized of any rhabdomeral photoreceptor. Ventral photoreceptors are also significant in the history of vision research. The first intracellular recordings of a photoresponse were made from ventral eye photoreceptors, and physiological studies of these photoreceptors provided the first evidence for the importance of Ca^{++} in light adaptation and a role for phospholipids in the photoresponse.

Circadian Organization of the *Limulus* Visual System

The circadian organization of the *Limulus* visual system is significantly different from that of vertebrates. In vertebrates, one or more circadian oscillators are present within the retina, and in some species, circadian oscillators are present in photoreceptors. In *Limulus*, the circadian oscillators that influence the eyes are located in the brain, not in the eyes. The *Limulus* brain contains bilateral circadian oscillators that remain synchronous through neuronal coupling, and they drive the activity of efferent neurons that project from the brain to all of the eyes.

The cell bodies of clock-driven efferent neurons that project to the eyes are clustered in the cheliceral ganglia located on either side of the base of the brain, and there are about 20 efferent neurons in each ganglion. The axon of each efferent neuron is thought to branch several times in the brain and its branches to project bilaterally out all of the optic nerves and innervate all of the eyes (**Figure 5(a)**). In the eyes, the efferent axons have neurosecretory-like terminals containing both clear vesicles and large, dense, crystalline granules. In LE ommatidia, efferent terminals innervate all cell types (**Figure 5(b)**). In median eyes, efferent terminals contact photoreceptors near the rhabdom, and in rudimentary eyes, efferent axons project to the rhabdomeral lobes of photoreceptors where they terminate directly adjacent to rhabdoms (**Figures 3(b)** and **5(c)**). Circadian efferent neurons, similar to those described in the *Limulus* visual system, also innervate the eyes of scorpions and spiders; therefore, the type of circadian regulation described for *Limulus* eyes appears to be a feature common to chelicerate arthropods, but not to crustaceans and insects.

In *Limulus*, efferent neurons innervating the eyes are active at night and silent during the day. They begin firing bursts of action potentials about 45 min before sunset. These bursts, which are synchronous in all optic nerves, reach a maximum frequency of about 2 Hz during the early evening. The burst rate slows after midnight, and then stops after dawn. This pattern of efferent nerve activity persists in constant darkness, and its phase (the time of day it starts and stops) can be shifted by changing the time of light onset. Thus, efferent nerve activity is clearly circadian.

Effects of the Clock on *Limulus* Eyes

Clock input increases the sensitivity of *Limulus* eyes to light at night, and this effect is most dramatic in LEs. In animals maintained in cyclic light, LEs become about 1 million times more sensitive to light at night compared to the day from the combined effects of dark adaptation and clock input. The effect of the clock is to roughly double the sensitivity obtained with dark adaptation alone.

In animals maintained in constant darkness, the onset of efferent nerve activity near dusk correlates with the increase in LE sensitivity. If the lateral optic nerve is cut during the day, severing the efferent axons and thus preventing clock signals from reaching the LE during the night, there is no nighttime increase in sensitivity. If the lateral optic nerve is cut during the night, interrupting clock input to the eyes, LE sensitivity falls rapidly toward the daytime level. However, if the distal end of a cut lateral optic nerve is stimulated electrically to activate the efferent axons, LE sensitivity increases even during the subjective day. Thus, increased LE sensitivity directly correlates with the activity of the efferent neurons.

In LEs, where the effects of the clock have been studied most thoroughly, the clock influences almost every aspect of retinal function, and studies with these eyes have revealed that the full range of some of the diurnal changes observed involves complex interactions between effects of clock and light (**Table 1**).

Structure

Much of the nighttime increase in LE sensitivity can be attributed to the changes in the structure of ommatidia (**Figure 5(b)**). As the LE transitions into the nighttime state, the aperture at the base of the lens, which is constricted during the day, widens and shortens permitting more photons to reach the underlying photoreceptors. The rhabdom also becomes shorter and wider, adjusting to the larger aperture. These structural changes, which increase photon catch during the night, persist with reduced amplitude in constant darkness in response to clock input alone. However, if clock input is eliminated, all of these rhythmic structural changes are abolished, even in cyclic light. Without clock input, ommatidia assume a structure that is never seen in an intact animal. Thus, these structural changes require clock input, and the effects of the clock are enhanced by cyclic light.

Another diurnal structural change observed in LE photoreceptors that probably contributes to increased nighttime sensitivity is the migration of photoreceptor screening pigment granules. However, unlike the

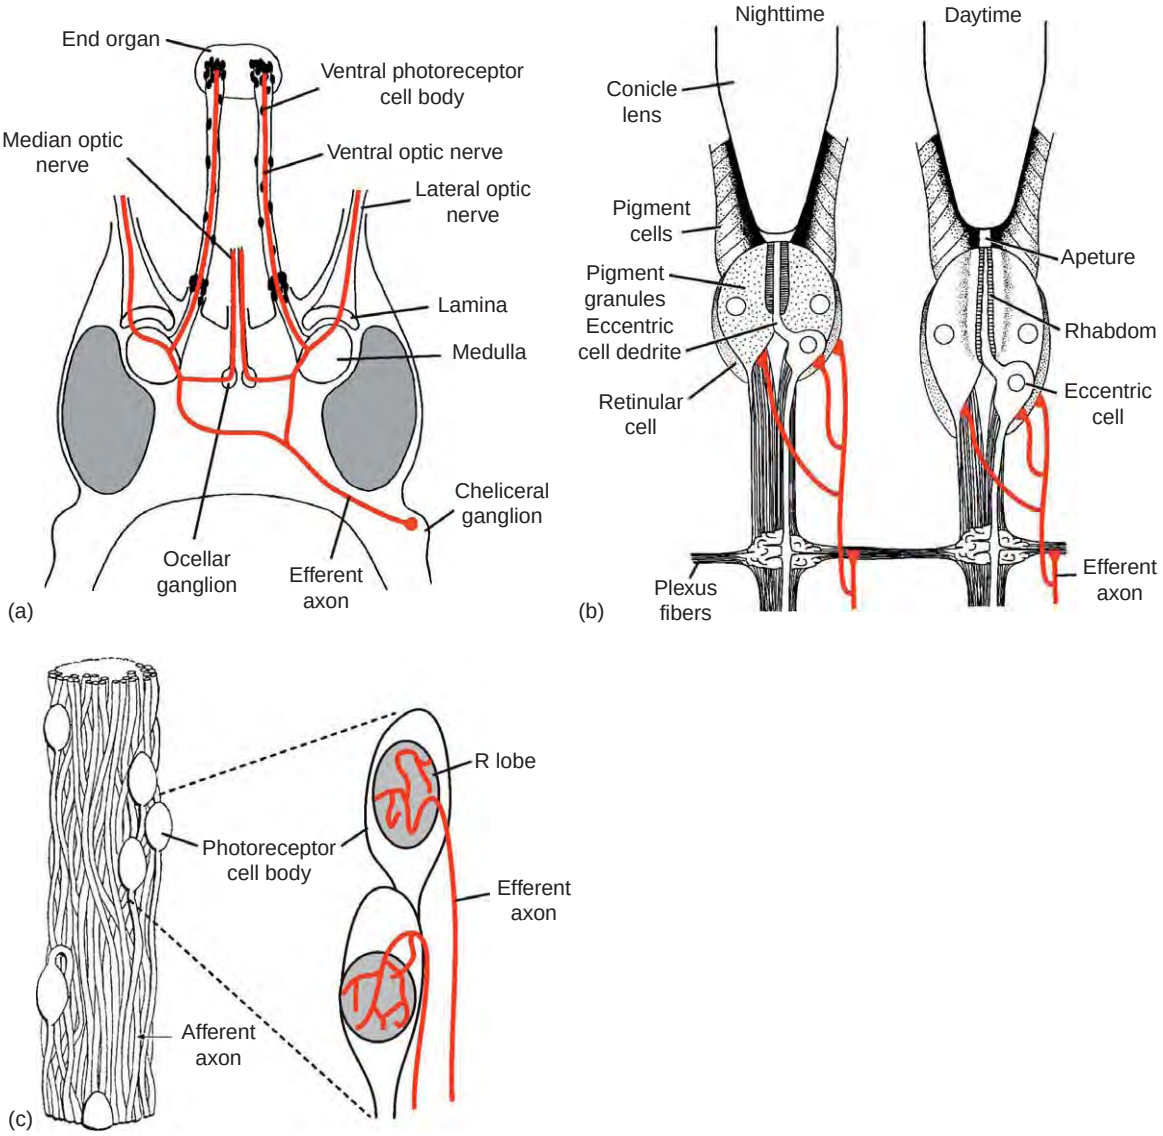

Figure 5 Schematics of circadian efferent neuron projections (shown in red). (a) The cell bodies of the circadian efferent neurons are located in the cheliceral ganglia at the base of the brain. A single idealized efferent neuron branches several times in the brain to project out all of the optic nerves. Modified from Calman, B. G. and Battelle, B-A. (1991). *Visual Neuroscience* 6: 481–495, with permission from Cambridge University Press. (b) Schematic of a longitudinal section through an ommatidium of the lateral eye illustrating projections and terminations of clock-driven efferent neurons, and the nighttime and daytime structure of ommatidia observed when the lateral eye is exposed to cyclic light and clock input. Modified from Barlow and Chamberlain (1979). *Science* 210: 1037–1039. (c) Schematic of efferent projections to ventral photoreceptors. On the left is an enlarged view of a portion of a ventral optic nerve showing ventral photoreceptor cell bodies and axons. On the right, a schematic of the two ventral photoreceptor cell bodies illustrates that the axons of the circadian efferent neurons project specifically to photoreceptor R lobes (shaded areas) and then ramify extensively. Modified from Evans et al. (1983). *Journal of Comparative Neurology* 219: 369–383.

structural changes in the aperture described above, pigment granule migration appears to be regulated entirely by the clock and is not significantly influenced by light. Photoreceptor pigment granules cluster near the junction of the rhabdomeral and arhabdomeral lobes during the day and disperse toward the periphery of the cell during the night (**Figure 5(b)**). This rhythm continues undiminished in eyes maintained in constant darkness and is eliminated in eyes deprived of clock input even when the eyes are exposed to cyclic light.

Physiology

Clock-driven physiological changes in photoreceptors also contribute to increased LE sensitivity. Clock input at night increases the amplitude (gain) and duration of the

Table 1 Lateral eye responses to clock input are influenced by light and mimicked by octopamine and elevated cAMP.

Retinal response to clock input	*Effect of light*	*Mimicked by octopamine and cAMP*
Sensitivity increases	Enhances	Yes
Aperture widens and shortens	Enhances	Inferred[a]
Rhabdom widens and shortens	Enhances	Inferred[a]
Screening pigments disperse		Not tested
Quantum bump gain increases		Yes
Quantum bump duration increases		Yes
Noise decreases		Yes
Transient shedding primed	Triggers	Yes
Arrestin mRNA levels decrease		Yes

[a]Infusions of OA into the LE *in situ* increase LE sensitivity. Since increased sensitivity is largely due to a wider aperture and repositioned rhabdom, the effects of OA on these two parameters are inferred.

response to a single photon (the quantum bump) and decreases the frequency of spontaneous membrane depolarizations recorded in the dark (noise). Thus, the clock increases the signal-to-noise ratio of photoreceptors at night. The onset of these physiological changes correlates directly with the onset of efferent nerve activity and occurs well before the structural changes described above are detected.

Rhabdom Shedding

Similar to the photoreceptors of vertebrates, invertebrate photoreceptors shed some of their photosensitive membrane every day. *Limulus* photoreceptors exhibit two distinct mechanisms for rhabdom shedding: light-triggered transient membrane shedding and light-driven shedding (Figure 6). Both result in the internalization of photosensitive membrane into photoreceptors. Light-driven shedding is similar to the clathrin-mediated endocytosis of activated G-protein coupled receptors described in many other systems, including insect photoreceptors. It continues throughout the day in the light and is mediated by clathrin and arrestin. The clock does not influence this process. On the other hand, light-triggered transient shedding is a unique, synchronous process that rapidly removes membrane from the rhabdom at dawn. During light-triggered transient shedding, large whorls of rhabdomeral membrane are internalized from the base of rhabdomeral microvilli and trafficked into multivesicular bodies. The process is triggered by the dim light of dawn and is complete within an hour after first light. The mechanism for membrane internalization during transient shedding is not yet known. However, importantly from the perspective of this discussion,

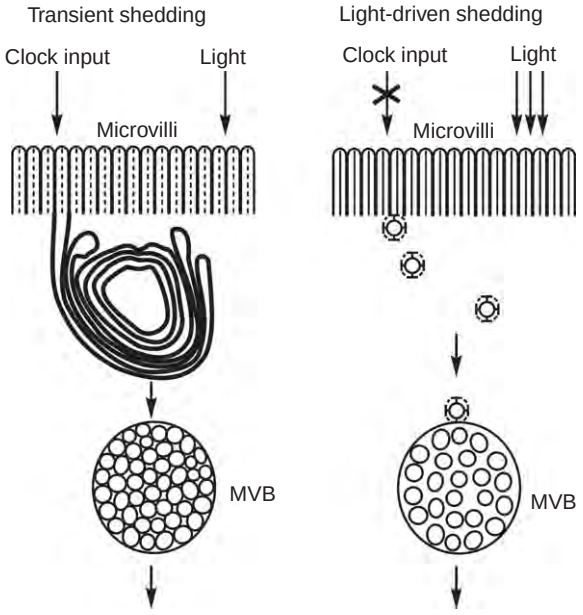

Figure 6 Schematic of transient rhabdom shedding and light-driven shedding. Transient rhabdom shedding must be primed by clock input during the night. It is triggered by the first light of dawn and characterized by the formation of large whorls of rhabdomeral membrane, which subsequently are processed in densely packed multivesicular bodies (MVBs). Light-driven shedding does not require clock input. This progressive process, which continues throughout the day, requires brighter light and involves the clathrin-mediated endocytosis of microvillar membrane from the base of the microvilli. The membranes endocytosed by this process aggregate and form loosely packed MVB. From Sacunas et al. (2002). *Journal of Comparative Neurology* 449: 26–42, with permission from John Wiley & Sons, Inc.

although transient shedding is triggered by light and probably involves the activation of protein kinase (PK) C, it occurs only after photoreceptors have received at least 3 h of clock input and the activation of cyclic adenosine monophosphate (cAMP)-dependent PK.

Gene Expression

In addition to driving structural and physiological changes in photoreceptors and priming transient rhabdom shedding, clock input influences the expression of at least one gene important for the photoresponse. Specifically, clock input to the LE controls an early step in the expression of the gene for visual arrestin (varr). Varr is the protein in photoreceptors responsible for quenching the phototransduction cascade, and as described above, it is also involved in the internalization of rhabdomeral membrane during light-driven shedding. In LEs maintained in constant darkness, clock input during the subjective night causes varr messenger RNA (mRNA) levels in photoreceptors to fall. Circadian fluctuations in varr mRNA levels may lead to a circadian fluctuation in varr

protein levels and thus contribute to some of the circadian changes in the photoresponse described above.

The expression of other photoreceptor proteins probably is also under circadian control, but the clock does not regulate the expression of all proteins important for the photoresponse. For example, *Limulus* opsin mRNA levels are regulated by light, not by the clock. In LEs that receive normal clock input and are exposed to cyclic light, opsin mRNA levels rise during the late afternoon and fall during the night. This rhythm continues in LEs deprived of clock input if they are exposed to cyclic light, and it is eliminated in LEs maintained in the dark even when they receive normal clock input.

Biochemical Processes Mediating Clock Effects on *Limulus* Eyes

Octopamine and the Activation of a cAMP Cascade

When circadian efferent neurons are active during the night, they release the biogenic amine octopamine (OA) from their terminals, and OA, the phenol analog of norepinephrine, is probably most responsible for initiating the circadian changes observed in the eyes. The application of OA to *Limulus* eyes mimics many effects of the clock (Table 1). Other molecules are also released from efferent terminals. Specifically, γ-glutamyl conjugates of OA and tyramine, the precursor of OA, are released, but their physiological relevance is not yet clear. The presence of crystalline granules in efferent terminals suggests that one or more neuropeptides may be released. Crystalline granules are often associated with peptidergic synaptic terminals in invertebrates, but presumptive neuropeptides in the circadian efferent terminals in *Limulus* eyes have not been identified.

In *Limulus* eyes, OA activates membrane receptors that are coupled to adenylyl cyclase stimulating a rise in cAMP in photoreceptors, and any effects of the clock are mediated through the activation of this cAMP cascade (Table 1). There is no evidence for a direct effect of cAMP on *Limulus* photoreceptor physiology; however, there is good evidence that some of the clock-driven changes in the eye require the activation of cAMP-dependent PKA. Therefore, investigations of mechanisms underlying the circadian regulation of photoreceptor function have focused on identifying and characterizing clock-regulated photoreceptor phosphoproteins.

Clock-Driven Protein Phosphorylation

To date, one clock-regulated phosphoprotein in *Limulus* photoreceptors has been identified and partially characterized. It is an unconventional myosin III (LpMyo3), a homolog of the *Drosophila ninaC* gene product that is required in *Drosophila* for normal photoreceptor function and survival. Since their discovery in *Drosophila* and *Limulus* photoreceptors, class III myosins also have been detected in photoreceptors of a variety of invertebrates and vertebrates, including octopus, fish, mice, and humans; thus, these proteins may be important for photoreceptor function in both vertebrates and invertebrates.

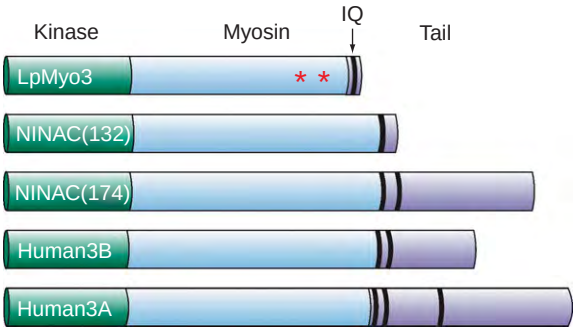

Figure 7 Schematic comparing the domain structure of LpMyo3 with that of the class III myosins expressed in *Drosophila* and humans. One isoform of myo3 has been found in *Limulus*. The two isoforms of myo3 expressed in *Drosophila* are splice variants of the same *ninaC* gene. Human class III myosins are products of two separate genes, *myo3A* and *myo3B*. Each protein contains an N-terminal kinase domain, a myosin domain, and one or more IQ calmodulin-binding motifs (black bars). The tail domains are most variable in length and sequence. LpMyo3 is a target of clock-stimulated phosphorylation within an actin-binding region near the C-terminus of its myosin-like domain (red asterisks).

Class III unconventional myosins are characterized by having an N-terminal kinase domain, a myosin-motor-like domain, one or more IQ calmodulin-binding motifs, and a C-terminal tail of varying lengths (Figure 7). Thus, they are potential signaling molecules as well as potential molecular motors. LpMyo3 is photoreceptor specific, quantitatively a major protein in photoreceptors and distributed throughout the photoreceptor from its cell body to its terminals. During the day in the light, LpMyo3 concentrates over the rays of the photosensitive rhabdom (Figure 2(c)).

LpMyo3 becomes more highly phosphorylated in LEs *in vivo* in response to activation of the circadian efferent input. Its phosphorylation also becomes elevated when intact photoreceptors are incubated *in vitro* with OA, drugs that elevate intracellular cAMP levels and that activate PKA, respectively. Since LpMyo3 is also phosphorylated in response to light, this protein may be particularly important as a substrate upon which light- and clock-driven cascades converge.

Some biochemical properties of LpMyo3 are known. It is a kinase that phosphorylates its own myosin domain as well as other substrates, and its substrate specificity is similar, but not identical, to PKA. LpMyo3 also binds actin, but since its actin binding is insensitive to adenosine triphosphate (ATP) and the protein lacks ATPase activity,

it probably does not function as a molecular motor. Clock-regulated phosphorylation sites in LpMyo3 have also been identified. This information provides clues to how the clock might regulate LpMyo3 and leads to speculations regarding how the phosphorylation of LpMyo3 might influence photoreceptor function.

Clock input to LEs increases the phosphorylation of two sites within the motor-like domain of LpMyo3 within and near an actin-binding interface called loop2 (**Figure 7**). Interestingly, LpMyo3 autophosphorylates these same sites through an intermolecular mechanism. The presence of phosphorylation sites within the actin-binding interface of a myosin is surprising. None of the other 22 classes of myosins that have been described to date becomes phosphorylated in this region. However, mutagenesis studies using other unconventional myosins indicate that changing the net charge in loop2 alters the affinity of myosin for actin. Phosphorylation of LpMyo3 within its actin-binding interface is predicted to reduce its actin affinity.

Actin is concentrated in the rhabdomeral microvilli. Functional consequences of a possible nighttime decrease in the affinity of LpMyo3 for microvillar actin are not yet known, but could be diverse. The Myo3 in *Drosophila* photoreceptors (neither inactivation nor afterpotential C (NINAC)) is thought to bind to and stabilize actin in rhabdomeral microvilli, and in *Drosophila* lacking NINAC, microvillar actin is fragmented or absent. These observations lead to speculations that LpMyo3 phosphorylation participates in circadian processes involving changes in the stability of rhabdomeral actin. One such process is light-triggered transient rhabdom shedding, which involves a transient breakdown of rhabdomeral actin. As described above, although this process is triggered by light, it must be primed by clock input and the activation of PKA. The clock-driven phosphorylation of LpMyo3 by PKA may contribute to the priming event.

LpMyo3 is also a kinase that may phosphorylate one or more proteins involved in the photoresponse. This idea is consistent with observations from *Drosophila*, which show that the photoresponse is abnormal in flies expressing NINAC without its kinase domain. If a change in the affinity of LpMyo3 for actin produces a nighttime decrease in the concentration of LpMyo3 at the rhabdom, the level of phosphorylation of LpMyo3 substrates may also fall and modify the photoresponse. Thus, multiple effects of the clock could be mediated through the modulation of LpMyo3.

Conclusion

The eyes of *Limulus*, with their diverse structures, large photoreceptors, and relatively simple organization, have long served as useful preparations for studying basic mechanisms of vision. Fundamental and broadly relevant aspects of photoreceptor function and sensory information processing were discovered through studies of the *Limulus* visual system. Moreover, studies using *Limulus* have revealed the fundamental importance of circadian rhythms for vision and the complex ways in which clock- and light-driven processes can interact to produce the full range of diurnal changes in retinas. The effects of circadian rhythms observed in *Limulus* LE have many parallels in vertebrate retinas, including those on photoreceptor structure, the photoresponse, and membrane shedding. In addition, circadian clocks in both *Limulus* and vertebrates exert their influence in retinas by regulating the release of biogenic amines and the activity of cyclic-nucleotide-signaling pathways. Mechanisms through which clock-driven signaling pathways influence specific retinal functions are just beginning to be identified, and their discovery remains an important challenge.

M

Macular Edema

R N Frank and I Glybina, Kresge Eye Institute, Wayne State University School of Medicine, Detroit, MI, USA

Glossary

Circinate lipid exudates – A round or oval assemblage of intraretinal lipid deposits that is often seen in macular edema, especially in diabetic macular edema. This presumably occurs because plasma exudes from a small retinal blood vessel, or a cluster of retina vessels, in a circular pattern around the abnormal vessel. The portion of this circle, farthest from the leaking vessels, is the thinnest, and as reabsorption of the fluid occurs at that location, the lipoproteins precipitate into the tissues, forming the visible exudates.

Cystoid macular edema – A form of macular edema in which much of the extracellular fluid collects in loculated spaces between the photoreceptor axons of Henle's fiber layer, forming round or oval, fluid-filled spaces. These are called cystoid because they are not lined with a layer of epithelial cells, which would make them true cysts; hence, these spaces are cystoid and not cystic.

Fovea – The central portion of the macula that contains only specialized cone photoreceptors, whose outer segments are narrow and elongated, rather than cone shaped as are extrafoveal cones.

Foveal avascular zone (FAZ) – A specialization of the capillary network in the foveal region of the retinal vasculature in humans and higher primates. There are no blood vessels in the FAZ, presumably as an evolutionary development to permit unimpeded access of light rays to the foveal cone photoreceptors. The FAZ can be readily seen as an approximately circular avascular zone about 1 mm in diameter in retinal vascular digest preparations from enucleated eyes or in good-quality fluorescein angiograms in living eyes.

Foveola – The central portion of the fovea, in which the axons of the cone photoreceptors are swept to the side, leaving only their inner and outer segments exposed to the incoming rays of light.

Henle's fiber layer – The obliquely directed axons of the foveal cone photoreceptors.

Irvine–Gass syndrome (aphakia, or pseudophakia, cystoid macular edema) – This entity was first described during the 1960s by the individuals whose eponymous names it bears. Presumably because of postoperative inflammation after cataract surgery, perifoveal capillaries begin to leak and edema fluid collects in a cystoid pattern in the central macula. The condition is often self-limited but may lead to considerably reduced vision. As demonstrated by fluorescein angiography, it may be accompanied by breakdown of the blood–retinal barrier in the capillary circulation of the optic nerve head.

Macula – The central region of the retina that is specialized for high-resolution vision. It is found in humans and higher primates and is notable histologically for the fact that it contains multiple layers of ganglion cells, while the extramacular retina contains only a single layer.

Macular edema – The thickening of the macular retina by extravasation of fluid, often containing lipid components (which may precipitate into the tissues) from breakdown of the normal blood–tissue barrier at the level of the endothelial cells of the retinal blood vessels in the macula. Fluid can also extravasate from the choroidal capillaries through the retinal pigment epithelium barrier, but this usually produces collections of subretinal fluid, which is distinguishable from the intraretinal fluid of macular edema.

Randomized controlled clinical trial (RCT) – A method of evaluating the efficacy of a new therapeutic procedure in which subjects with a disease under investigation volunteer to be allocated by random selection to a treatment group, or groups,

which will receive the new therapy or therapies under investigation, or to a control group that receives either no treatment or treatment with a placebo or treatment by the method that has been accepted as the current standard of care. Evaluation of the results for each subject is done by observers who are masked, that is, who do not know to which of the treatment, or control, groups the various subjects belong. This method is considered the definitive way to determine the efficacy, or lack of efficacy, of a putative new therapy.

Macular edema, a swelling of the central portion of the human retina, or macula, is a common feature in many diseases. It is a widely recognized complication of diabetic retinopathy, where its prevalence (in the United States) may be of the order of 10% of all individuals with diabetes, varying somewhat by ethnic group but not by type of diabetes (i.e., type 1 or type 2). Macular edema also occurs commonly in retinal vein occlusions, in uveitis, following cataract surgery, as an accompanying feature of some ocular tumors, in hereditary retinal degenerations, such as the retinitis pigmentosa syndromes and, rarely, as an isolated genetic entity apparently in and of itself.

Diagnosis of Macular Edema

Recognition of macular edema as an important clinical entity has been increasing in recent years, and, in particular, since the 1960s with the advent of a variety of new diagnostic techniques. These have included high-magnification, stereoscopic ophthalmoscopy using the slit lamp and several types of contact and noncontact lenses that allow the observer to visualize the edematous macula in a better manner; stereoscopic retinal photography; fluorescein angiography to enable visualization of circulatory dynamics and the physiology/pathology of the macular circulation, even at the capillary level; and, most recently, optical coherence tomography (OCT), a rapid, noninvasive technique that permits accurate measurement of the thickness of the macula, and yields high-resolution tissue sections of the maculae of living subjects with almost histologic clarity.

Anatomy of the Macula

The macula is an anatomic specialization of the neural retina that is unique to humans and to higher primates (**Figure 1(a)–(d)**). It is defined histologically by the presence of multiple layers of retinal ganglion cells (there is only a single layer of ganglion cells in the extramacular retina), and ophthalmoscopically as the region extending from the temporal margin of the optic nerve head to the center of the macula (the foveola, the central depression that is evident clinically in the normal retina), and then for an equal distance temporal to the foveola. In the superior–inferior direction, the macula extends between the two major temporal retinal vascular arcades. It is not clear why, of the entire extent of the human retina, the macula is particularly susceptible to such a large number of disorders, for example, the macular degenerations, or to edema in a large variety of diseases. Speculations entail the likelihood that the macular retina, including both its neural elements and also the macular retinal pigment epithelium, has a higher level of metabolic activity because of its enhanced visual function, including a greater density of cone photoreceptors, a thicker ganglion cell layer, and a greater thickness of retinal pigment epithelial (RPE) cells; or that this enhanced activity necessitates greater blood flow with a greater likelihood of circulatory breakdown, especially in view of the very rich retinal capillary network within the macula and, particularly, in the perifoveal region. Finally, the anatomic specialization of the foveola, in which the foveolar cone axonal and synaptic processes are swept obliquely to all sides, permitting direct access of photic stimuli to the photoreceptor outer segments, may lead pathologically to the accumulation of extracellular edema fluid into ballooning spaces in this axonal region in the entity known as cystoid macular edema.

In studying macular edema in an experimental setting, investigators are hampered by the fact that the macula is an anatomic specialization of the retina that is limited to humans and some higher primates. While certain birds, for example, hawks and eagles, have a fovea, there is no macula in the sense that it is present in the human eye, and the blood circulation of the posterior avian globe is entirely different from that of humans.

Clinical Findings in Macular Edema

The thickening of the central retina is best appreciated by stereoscopic viewing methods, for example, slit-lamp ophthalmoscopy with a contact lens or a handheld high dioptric indirect ophthalmoscope lens. Until recently, multicenter clinical research studies, for example, the Early Treatment Diabetic Retinopathy Study (ETDRS) used stereoscopic retinal photography to evaluate macular thickening. However, relatively minimal central retinal thickening may not be apparent even to the experienced examiner and photographic methods are subject to variability. Therefore, the introduction of OCT, which is discussed in more detail below, has held recent very great interest, but it has also raised some unexpected questions.

In the absence of stereoscopic viewing methods, one can suspect the presence of macular edema by the

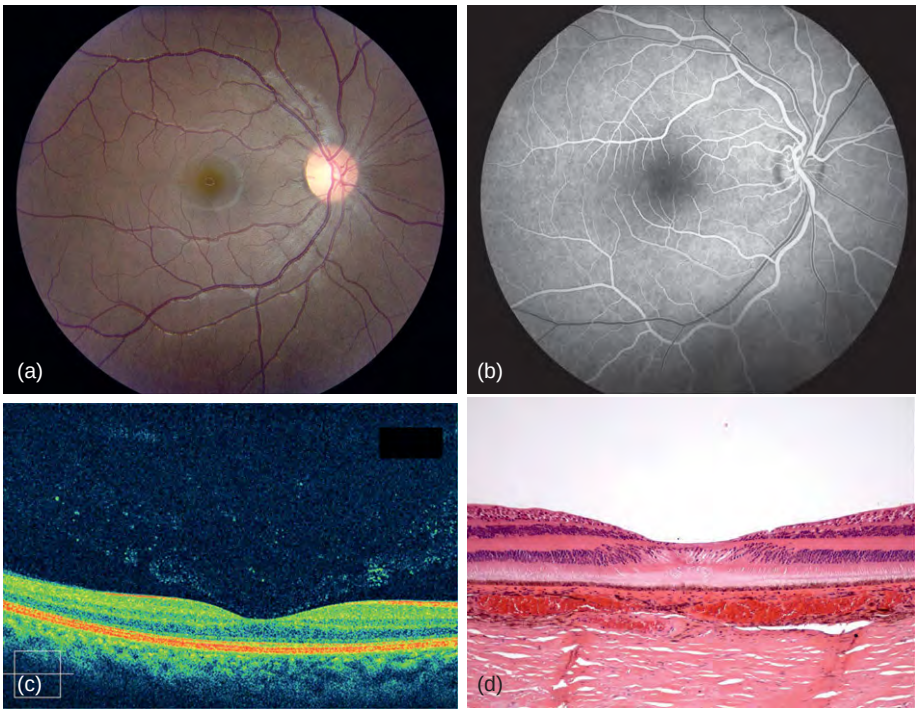

Figure 1 The normal human macula. (a) Color photograph of a normal macula. (b) Fluorescein angiogram of a normal macula. Note the striped pattern of blood flow in the retinal venule. This laminar flow, with the nonfluorescent column of blood cells in the center of the vessel, is typical of early flow in retinal venules. In later phases of the angiogram, the entire vessel will fill in. Note also the sharp margins of the vessels in this normal angiogram, in the normal retinal vasculature, the endothelial lining of the vessels is tight, even to the small (M.W. 327) fluorescein molecule, which is only about 65% bound to plasma proteins. (c) A spectral domain optical coherence tomogram (OCT) of a normal macula. In this high-resolution OCT scan, one can clearly see the cellular layers of the retina. (d) A histologic section of a normal human macula, stained with hematoxylin–eosin. This photomicrograph is courtesy of Ralph Eagle, M.D., Wills Eye Institute, Philadelphia, PA.

presence of certain characteristic retinal lesions. Extensive intraretinal hemorrhages or microaneurysms (dilations of capillary-sized blood vessels, which appear ophthalmoscopically as tiny red dots) in the macular region are indicators of extravascular blood or plasma leakage with resultant macular edema (**Figure 2(a)** and **(b)**). An especially characteristic abnormality, particularly in individuals with diabetes, is the presence of intraretinal lipid deposits. These often have a circular (circinate) configuration (**Figure 2(a)**), which presumably is the result of leakage of plasma from a central vascular lesion, or cluster of lesions (**Figure 2(b)**), with resorption of the edema fluid but not its lipid components around the periphery of the 360° circumference of the zone of leakage, where the thickness of the fluid layer is least and the less-soluble lipid therefore precipitates out of solution. Macular lipid, and edema, have characteristic appearances by OCT, and histologically, as demonstrated in **Figure 2(c)** and **(d)**. It has been known for a number of years that lower blood-lipid values are associated with lesser degrees of macular edema in diabetic subjects, although it is not clear that normalizing blood lipids can entirely prevent the development of macular edema in diabetic subjects.

There have been reports, at least one of which preceded by a number of years the development of OCT for objective measurements of macular thickness, that macular edema can vary over the course of a day. Some patients have noted that their vision, on arising in the morning, was much poorer than later in the day. Several investigators, using OCT, have found that macular thickness in at least some patients with diabetic macular edema is greater immediately after arising from a night's sleep than it is later. Although there are a number of possible causes, the most plausible is a simple gravitational effect, with edema fluid remaining in the upper body during recumbent posture and draining to the lower body when the individual is sitting or standing. However, although this diurnal effect does occur in some individuals, the Diabetic Retinopathy Clinical Research Network, in a study involving many institutions, found it to be infrequent.

Clinically Significant Diabetic Macular Edema

The ETDRS also introduced the term "clinically significant macular edema" to describe those cases in which the

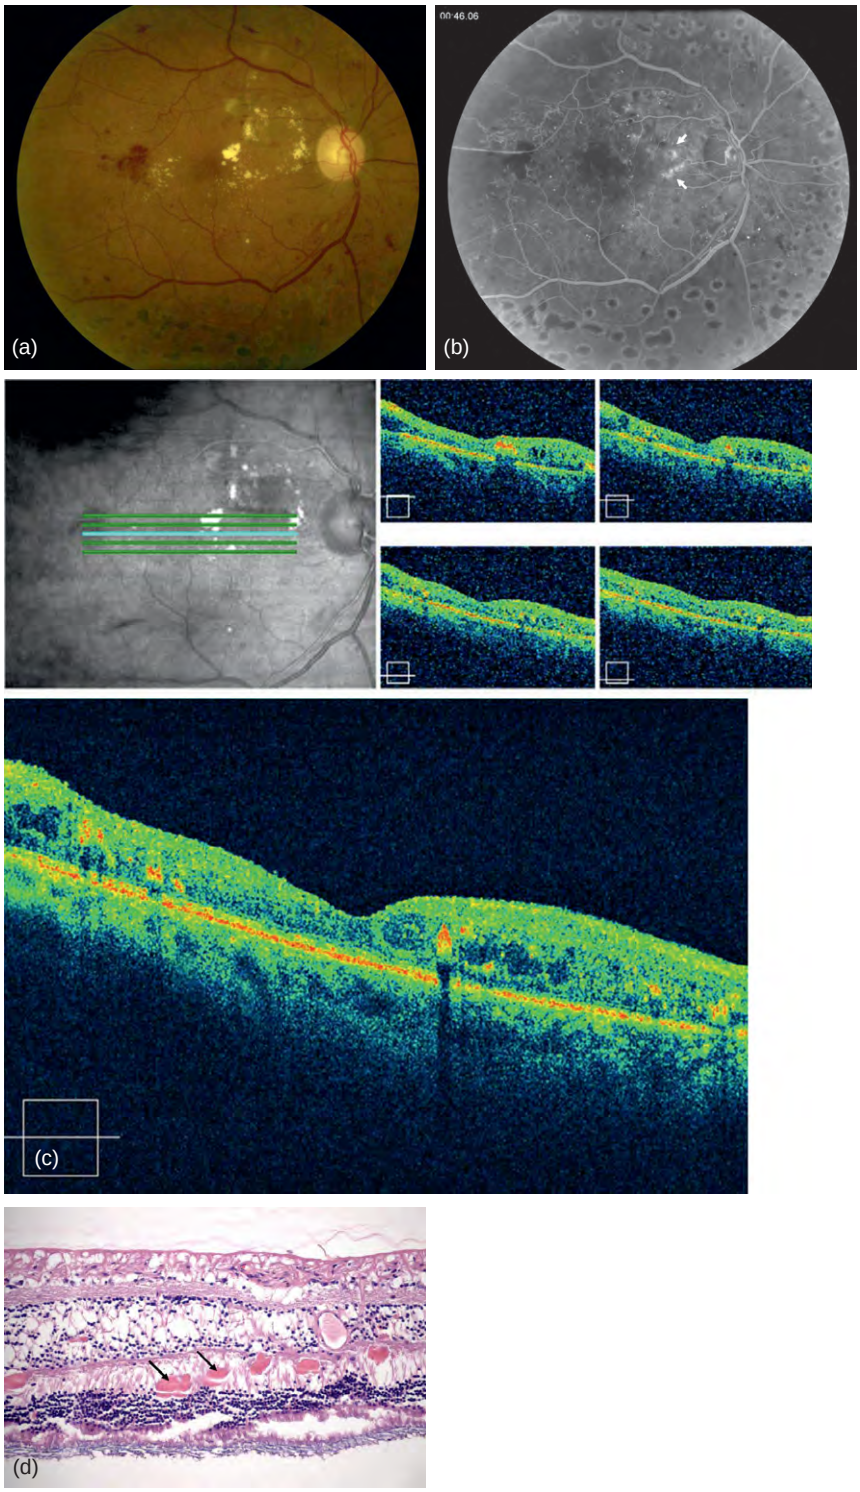

Figure 2 (a) Circinate lipid deposits form a ring in a case of diabetic macular edema. Multiple dot and blot hemorrhages and microaneurysms are also present. (b) A frame from a fluorescein angiogram from this patient, showing a cluster of leaking microaneurysms (arrows) at the center of the lipid ring. (c) Spectral domain OCT scans of this patient, showing intraretinal edema fluid, which appears as round, hollow spaces, and lipid plaques (red-orange densities). The vertical, empty spaces beneath the plaques occur because the plaques absorb the scanning laser beams, producing optical shadows. (d) Histologic section of the neurosensory retina, lacking retinal pigment epithelium and choroid, from an eye with diabetic macular edema (round or/and intraretinal lipid plaques, some of which are shown by arrows). The edema fluid appears as round or oval spaces with smooth borders, while the irregular spaces with ragged edges at the bottom of the micrograph are artifacts created by histologic sectioning. Hematoxylin–eosin stain. Photomicrograph courtesy of Ralph Eagle, M.D., Wills Eye Institute, Philadelphia, PA.

retinal thickening either involved the center of the macula (the fovea and foveola), or was sufficiently close to the center as to constitute a potential threat to the center with likely loss of central vision. The definition of clinically significant diabetic macular edema, as established by the ETDRS, is presented in **Table 1**.

Table 1 Clinically Significant Diabetic Macular Edema

1. Thickening of the retina at or within 500 μm (approximately one-half optic disk diameter) of the center of the macula.
2. Hard exudates at or within 500 μm of the center of the macula, if associated with thickening of adjacent retina (not residual hard exudates remaining after disappearance of retinal thickening).
3. A zone or zones of retinal thickening 1 optic disk area or larger, any part of which is within one disk diameter of the center of the macula.

From Early Treatment Diabetic Retinopathy Study Research Group (1985). Photocoagulation for diabetic macular edema. Early Treatment Diabetic Retinopathy Study Report No. 1. *Archives of Ophthalmology* 103: 1795–1805.

Findings by Fluorescein Angiography

By intravenous fluorescein angiography, in which a solution of sodium fluorescein is injected intravenously through an antecubital vein and rapid sequence photographs are taken using fluorescence optics, it is possible to visualize some of the vascular dynamics of macular edema. Fluorescein is a small molecule (M.W. 327) that is only loosely bound to plasma proteins, for example, only about 65% to albumin, and this small size enables it to leak readily through patent interendothelial cell junctions. Hence, in successive frames of a fluorescein angiogram in patients with diabetic retinopathy or other edema-producing retinal vascular diseases, one can see an increasing fluorescent haze surrounding the microvascular lesions (**Figure 3**). These leaking lesions are often (though surprisingly, not always) associated with macular thickening by OCT examination.

Fluorescein angiography has also demonstrated a specific type of macular edema, so-called cystoid macular edema. The axons of foveal cone photoreceptors are displaced laterally in human and higher primate retinas, thereby permitting light to strike the foveal cone outer

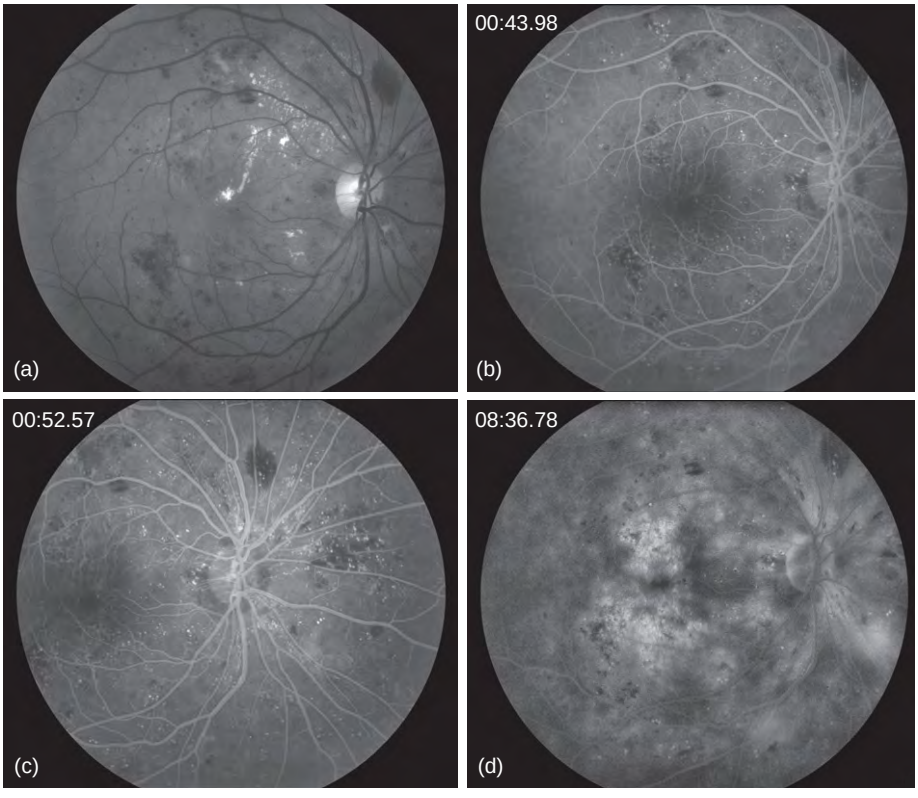

Figure 3 Sequence of angiographic frames showing increasing dye leakage in diabetic macular edema. (a) Red-free initial photograph of the right eye, taken before injection of the dye to show features of the posterior retina. (b) Frame from the fluorescein angiogram taken approximately 44 s from the time of dye injection (timing is indicated by numbers at the top left of the photograph). Arteries and veins have filled, and multiple microaneurysms, which appear as tiny white dots, are apparent. (c) Frame from the fluorescein angiogram taken at approximately 53 s after injection. Dye in the microaneurysms has intensified and has begun to leak from the vessel walls, creating a somewhat blurred appearance. (d) Frame from the angiogram taken approximately 8 min and 37 s from the time of injection. Dye and plasma have leaked profusely from the abnormal vessels into retinal tissue, contributing to the tissue edema.

segments directly, without traversing the inner retinal layers. This lateral displacement produces a unique anatomic arrangement that is known as Henle's fiber layer. The center of the fovea itself is avascular; however, cyst-like extracellular fluid spaces collect within Henle's fiber layer. These can, although often with some difficulty, be visualized by white light ophthalmoscopy using a slit lamp and handheld or contact lens, or sometimes by ophthalmoscopy using a green filter to increase contrast. The characteristic appearance, using fluorescein angiography, is one or more oval, uniformly fluorescent spaces oriented radially around the foveal center similar to petals on a flower, giving rise to the term "petaloid appearance." A single such large cystoid cavity is shown in the fluorescein angiographic frame of **Figure 4(a)**. The cyst-like nature of this cavity is evident on OCT scans (**Figure 4(b)**). Although macular edema may produce severe loss of central visual acuity, vision is often surprisingly preserved in many instances. **Figure 4(c)** shows OCT scans of a patient with bilateral cystoid macular edema, with corresponding microperimetric data printed underneath. This very sensitive visual sensitivity mapping device demonstrates only modest sensitivity loss in each eye, located almost directly corresponding to the position of the cystoid cavities. Visual acuity in each eye, also printed on the figure, is quite good. These cystoid cavities are, of course, not true cysts, since when histologic sections are available, they demonstrate that these fluid-filled spaces are not lined by layers of epithelium (**Figure 4(d)**). Cystoid edema may occur with any of the disorders that produce macular edema. One notable entity was first described during the 1960s, after fluorescein angiography had become widely used, when cystoid macular edema was observed angiographically in many patients who had just undergone seemingly uneventful intracapsular cataract surgery. Often, the postoperative visual acuity in these patients did not recover as fully as might have been expected, and fluorescein angiography revealed a pattern of cystoid macular edema, frequently accompanied by leaking of fluorescent dye from the optic nerve head. This pattern has been called the Irvine–Gass syndrome, after the individuals who initially reported it. With the advent of advanced extracapsular cataract surgical techniques, in which the posterior lens capsule is left in place and a posterior chamber intraocular lens is inserted, the incidence of postcataract surgical cystoid macular edema has been considerably reduced, but it still occurs. While this entity has been associated with various complications of the surgery, it often appears in cases where the surgical procedure was entirely uneventful.

Causes of Macular Edema

All investigators agree that the proximate cause of macular edema, associated with any systemic or ocular disease or drug, is a breakdown of the inner blood–retinal barrier, which is composed of junctional complexes of the endothelial cells of the retinal blood vessels, as opposed to the outer blood–retinal barrier, consisting of the retinal pigment epithelium, which serves as a boundary layer between the neural retina and the choroidal vasculature. Although contents of the vascular lumina can reach the extravascular space by transcellular mechanisms, directly through endothelial cell cytoplasm, most investigators believe that the most frequent pathologic mechanism is the breakdown of intercellular junctional complexes, which normally form a tight boundary between the vascular lumen and the extravascular milieu. This may be caused by specific molecular mechanisms, such as increased levels of vascular endothelial growth factor (VEGF, originally called vascular permeability factor because it was through that function that this molecular family was first discovered), or various inflammatory molecules or cytokines, or through the use of certain topical drugs in the treatment of glaucoma, such as epinephrine or, more recently, prostanoid compounds. Another molecular mechanism that has been of interest is the family of carbonic anhydrase enzymes. A recent paper, which describes proteomic analysis of the vitreous fluid in a series of patients with proliferative diabetic retinopathy and vitreous hemorrhage, who underwent vitrectomy surgery, has reported that these vitreous samples demonstrated a substantial upregulation of the CA-1 isoform of carbonic anhydrase. Injection of this molecule into the vitreous cavity of rats produced generalized retinal edema. Another recent paper cast some doubt on the role of VEGF in diabetic macular edema. These investigators examined the relationship between various single nucleotide polymorphisms (SNPs) in the VEGF gene and its promoter in individuals with various levels of diabetic retinopathy severity in the very large and well-characterized Diabetes Control and Complications Trial/Epidemiology of Diabetes Interventions and Complications (DCCT/EDIC) cohort. They found that there were 18 SNPs in the VEGF gene and its promoter that were significantly associated with severe preproliferative and proliferative retinopathy, but no detectable significant associations of VEGF gene or promoter polymorphisms with diabetic macular edema.

Treatment of Macular Edema

Results from the ETDRS

The ETDRS, a randomized, controlled clinical trial (RCT) of laser treatment and aspirin therapy that involved over 3000 patients with moderate to severe nonproliferative and early proliferative diabetic retinopathy, and/or with macular edema, reported in 1985 that treatment with focal applications of small-diameter

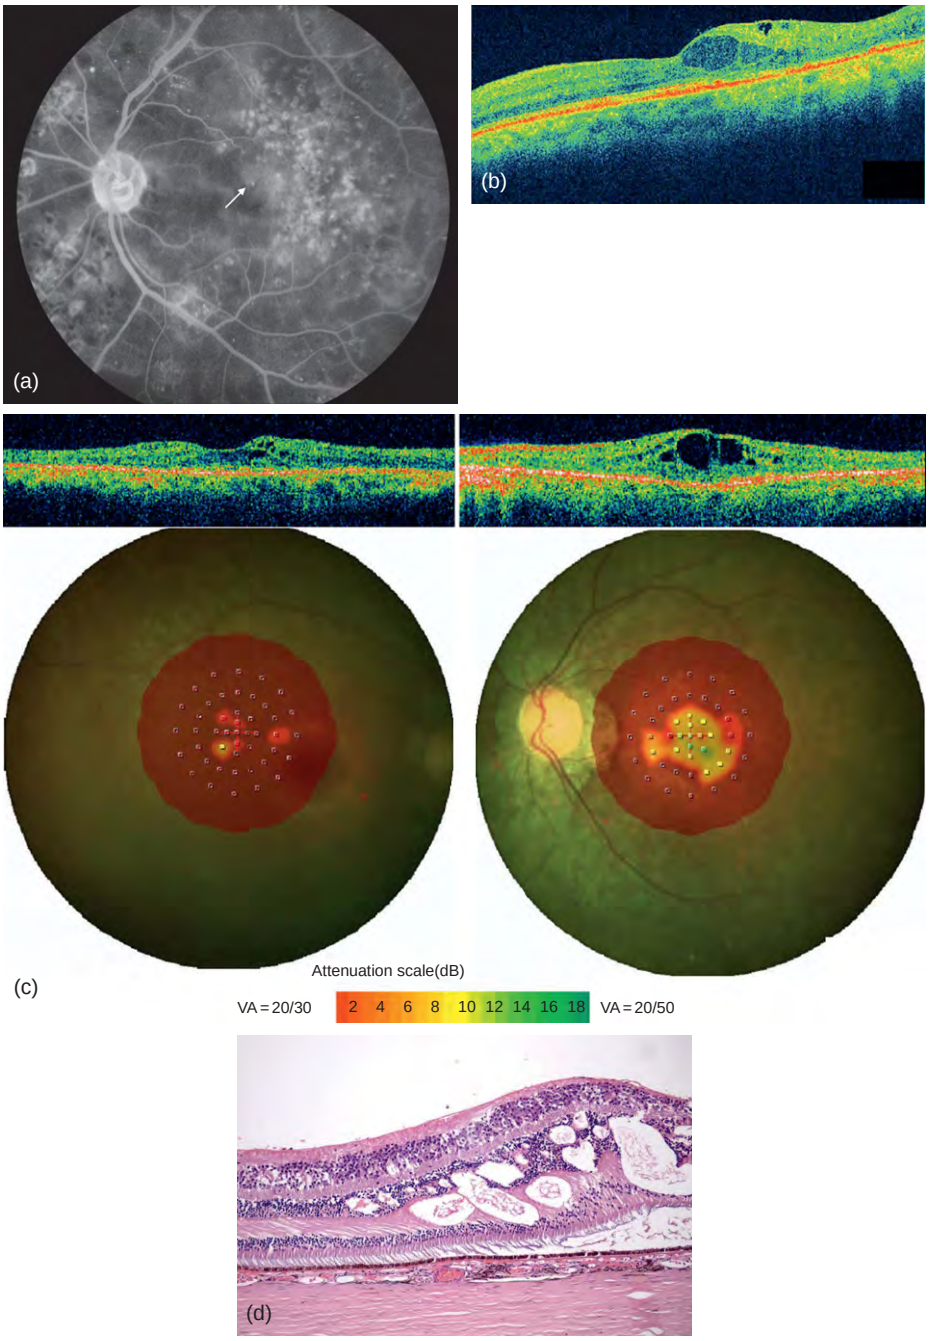

Figure 4 (a) Frame from a fluorescein angiogram of a patient with cystoid macular edema. Edema fluid containing the dye may fill many balloon-like spaces surrounding the center of the macula, producing an appearance similar to multiple radial petals on of flower, a so-called petaloid appearance. Only one such large space, indicated by the arrow, is seen in this photograph. The multiple small, round spots are previous laser treatment burns, which have been placed in a grid pattern. (b) Spectral domain OCT scan of this patient, showing the large cystoid spaces that appear in the angiographic frame in **Figure 4(a)**. (c) Microperimetric study of a patient of Dr. Tamer Mahmoud, who presented with bilateral cystoid macular edema. The microperimetry scans are here placed beneath OCT scans of the corresponding eyes. The color scale at the bottom of the illustration shows increasing loss of retinal sensitivity as one moves from left to right on the scale. (d) H-and-E-stained histopathological section of a retina with macular edema. Note the large fluid-filled vacuoles in the macula. This photomicrograph is courtesy of Ralph Eagle, M.D., Wills Eye Institute, Philadelphia, PA.

(50–100 μm) argon laser burns directly to macular microaneurysms (**Figure 5(a)–(c)**), or with grid laser applications could slow down or arrest the progress of diabetic macular edema with substantial preservation of vision by as much as 50% more in eyes that received treatment than in eyes that were randomly allocated to the no laser treatment group. The ETDRS results are frequently cited as showing that such laser treatment preserves

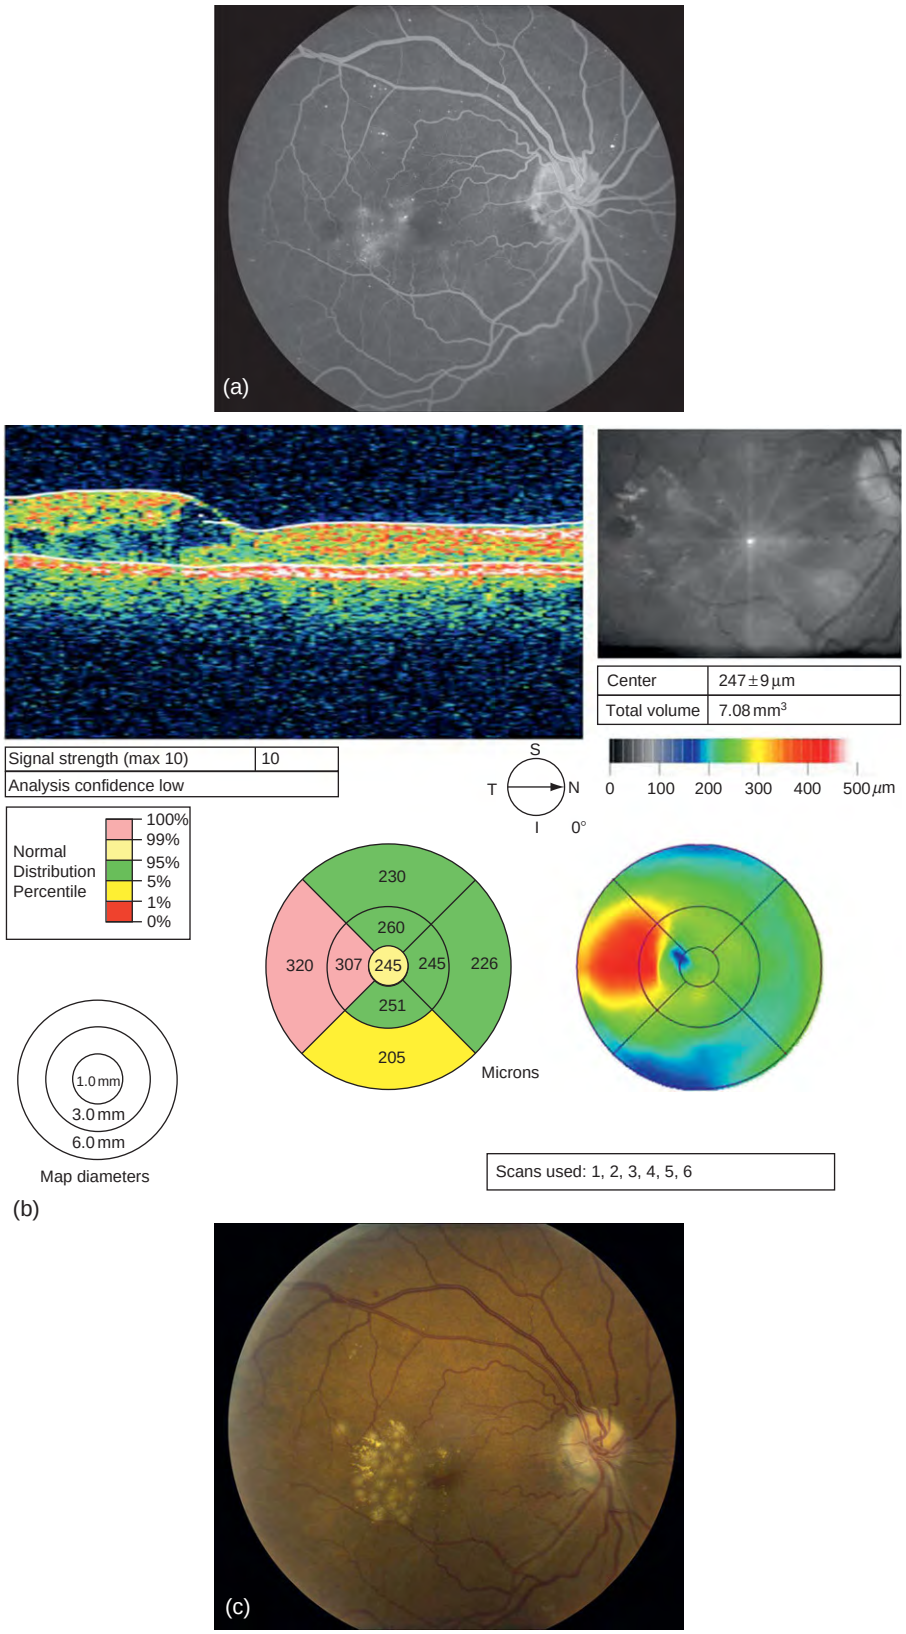

Figure 5 (a) Frame from a fluorescein angiogram showing intense leakage in the right eye of a patient with relatively focal macular edema; (b) Time domain OCT scan showing the region of edema (red-filled zone in the macular map). Color scales indicate retinal thickness. (c) Photograph taken immediately after application of focal argon laser burns, showing localization of the laser treatment to the edematous area.

vision, but does not improve it. However, in this study, a substantial number of the patients initially had good (i.e., better than 20/40) vision and hence were not likely to improve substantially. When one examines the results of the ETDRS patients whose initial vision was less than 20/40, it becomes apparent that laser treatment produced an actual improvement of visual acuity by more than one line on the ETDRS visual acuity chart in more than 40% of these subjects, compared to approximately 25% in the control group. In a more recent RCT, which compared two different techniques for applying focal argon laser treatment for diabetic macular edema, the Diabetic Retinopathy Clinical Research Network found that approximately 30% of patients with initial visual acuity less than 20/40 who received the modified ETDRS laser technique improved their visual acuity by more than three lines on the ETDRS vision chart, a halving of the visual angle, over a 1-year follow-up. At that time (fall, 2008), therefore, laser treatment, involving focal application of small, relatively light-intensity argon laser burns to areas of vascular leakage in the maculae of eyes with diabetic macular edema, and in particular clinically significant macular edema, was considered the treatment of choice. Application of this treatment, however, requires a degree of caution. Because eyes with clinically significant macular edema may not have suffered a loss of central vision (and most eyes with macular edema in the ETDRS had visual acuity at, or better than, 20/40), and because the laser treatment technique employed in this study involves the placement of moderately intense, small-diameter laser burns directly to microaneurysms identified ophthalmoscopically or by fluorescein angiography, placement of such burns to lesions very close to the center of the macula may result in damage to central vision. The use of focal laser photocoagulation for lesions very close to the macular center therefore does require an element of clinical judgment. Hence, the ETDRS recommended that laser treatment for clinically significant macular edema should be considered, but did not establish such treatment as an absolute standard of care.

Results of Other Clinical Trials

Another multicenter RCT, the Branch Vein Occlusion Study, found a significant beneficial effect of focal argon laser photocoagulation for macular edema, and for retinal neovascularization, in this disorder. However, eyes with central retinal vein occlusion, a much more severe condition, received no benefit from focal laser photocoagulation in the Central Vein Occlusion Study.

Focal laser treatment was also shown to be of clear benefit for the treatment of macular edema resulting from branch retinal vein occlusion in another RCT, the Branch Vein Occlusion Study. However, it was ineffective for central retinal vein occlusion in the Central Vein Occlusion Study, yet another RCT. There is no evidence for a beneficial effect of laser treatment for macular edema from any other cause.

As the pathogenesis of macular edema appears to have an inflammatory component, anti-inflammatory therapies have been widely used as treatment for some forms of this disorder. The ETDRS evaluated aspirin at a dose of 650 mg day^{-1}, compared to placebo for severe nonproliferative diabetic retinopathy and for diabetic macular edema and found no beneficial effect. In aphakia or pseudophakia cystoid macular edema, one RCT has demonstrated the efficacy of treatment with a topical nonsteroidal anti-inflammatory eyedrop, although some clinicians combine this with a topical steroid. More recently, a number of investigators have used intravitreal injections of triamcinolone, a steroid molecule, for several forms of macular edema. Although several papers have reported good results of this procedure for diabetic macular edema, a very recent paper detailing the results of a large, multi-institutional RCT in the Diabetic Retinopathy Clinical Research Network found that, over a 2-year follow-up, intravitreal triamcinolone, at 1 and 4 mg doses, was significantly less effective in this disorder than focal laser treatment. These doses of intravitreal triamcinolone have been evaluated for their efficacy in treating macular edema resulting from branch or central retinal vein occlusion in the Standard Care versus COrticosteroid for REtinal vein occlusion (SCORE) study, two multi-institutional randomized, controlled clinical trials sponsored by the U.S. National Eye Institute. For central retinal vein occlusion, these studies found that triamcinolone injected intravitreally in either a 1 or a 4 mg dose produced a significantly higher number of eyes that gained three or more lines of vision over a 1-year follow-up interval than observation alone. One milligram was concluded to be the preferred dose for this indication because of its smaller number of adverse effects. This result is the first time that any treatment has been reported as significantly effective in improving vision in macular edema from a central retinal vein occlusion. However, the concurrent SCORE clinical trial showed that neither of these two steroid doses injected intravitreally produced gains in vision for eyes with macular edema secondary to branch retinal vein occlusion that were superior to those obtained by focal argon laser photocoagulation, the previously accepted standard of care for that entity. Reasons for the different efficacies of steroids and laser for macular edema in diabetic retinopathy and in central and branch retinal vein occlusions remain to be explained.

Another intravitreal steroid, fluocinolone, has been used successfully as a long-term, slow-release implant inserted surgically in the treatment of macular edema resulting from chronic uveitis. Like other steroids, but to a somewhat greater degree, the fluocinolone implant can result in substantial elevations of intraocular pressure, and

in cataract formation. A full evaluation by RCT of the fluocinolone implant for macular edema in diabetes is underway, but clinical trials using this steroid implant involving other disorders in which macular edema is present have not yet been carried out.

Anti-VEGF Therapies and Macular Edema

Because the VEGFs were first recognized as a family of molecules that enhanced vascular permeability and the breakdown of blood–tissue barriers, before their recognition as angiogenic agents, the development of anti-VEGF agents with efficacy against neovascular retinal and choroidal diseases has been followed by clinical studies of these agents as potential treatments for macular edema. RCTs involving ranibizumab (Lucentis, Genentech), a humanized anti-VEGF monoclonal antibody injected intravitreally for diabetic macular edema and for macular edema in retinal vein occlusions are currently underway. A very similar monoclonal antibody, bevacizumab (Avastin, Genentech), developed initially as a cancer therapy, has also been employed in some preliminary clinical trials. One possible objection to the putative role of VEGF in diabetic macular edema, relating to the absence of significant VEGF gene polymorphisms in diabetic macular edema cases, compared to the presence of such changes in cases of severe preproliferative and proliferative diabetic retinopathy, has been discussed above. Another is the clinical observation that diabetic macular edema often occurs in the absence of retinal neovascularization and, conversely, neovascularization may occur without macular edema. If excessive VEGF secretion is essential to the cause of both types of diabetic retinal lesion, then both should occur together much more often than not. However, the issue may be much more complex, and its resolution will require, among other things, the completion of the ongoing clinical trials. There have been a number of reports describing encouraging results from much smaller trials. A report of a small, phase 2 trial of bevacizumab for diabetic macular edema from the Diabetic Retinopathy Clinical Research Network described suggestive evidence of a beneficial effect on macular thickness by OCT and visual acuity in patients injected with this agent, compared to focal argon laser photocoagulation. This trial, however, was quite small and complex in organization (a total of 100 patients, randomized into five treatment groups of 20 each, receiving various combinations of different doses of bevacizumab with or without laser therapy). A final determination of the efficacy of this mode of therapy must therefore await the completion of larger, longer controlled clinical trials.

Other agents that are currently being investigated for the treatment of diabetic macular edema include VEGF-TNF receptor-associated protein (TRAP; aflibercept, Regeneron), a VEGF receptor that is solubilized by being complexed to an immunoglobulin and that, upon intravitreal injection, acts by sponging VEGF molecules from the vitreous, and sirolimus (rapamycin), an antibiotic with immunomodulatory and anti-inflammatory properties, that is also capable of interfering with neovascularization.

A Puzzling Question

The use of OCT evaluations to measure macular thickness and to determine pathologic changes in macular anatomy has led to an unexpected finding. It has been generally assumed, that macular thickness beyond the normal range, and visual acuity, were inversely, and fairly closely, correlated, and central macular thickness determined by OCT has been used as an endpoint (usually a secondary endpoint) of several clinical trials of new therapies for diabetic retinopathy and some other diseases. Although a rough correlation does exist, the Diabetic Retinopathy Clinical Research Network and others who have investigated this question have found that, for diabetic macular edema, the correlation is surprisingly poor (**Figure 6**). We, and others, have found that this poor correlation extends to macular edema in other disorders as well, and our own preliminary results suggest that the slope of the correlation curve of central macular thickness

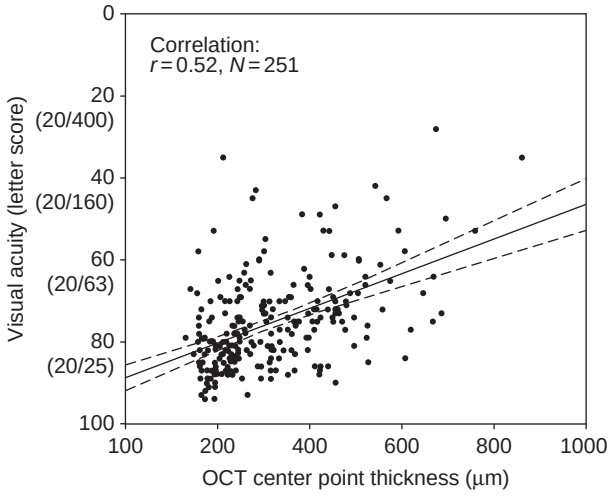

Figure 6 Best-corrected visual acuity, measured on the Early Treatment Diabetic Retinopathy Study (ETDRS) chart, of a large series of patients from the multicenter Diabetic Retinopathy Clinical Research Network, and correlated with macular central point thickness (measured by time domain OCT). The solid line indicates the best-fitting linear correlation curve, while the dashed lines indicate the 95% confidence interval. Although a correlation exists, it is surprisingly poor. Reprinted from DRCR.net Study Group (2007). Relationship between optical coherence tomography-measured central retinal thickness and visual acuity in diabetic macular edema. *Ophthalmology* 114: 525–536, with permission from Elsevier.

versus visual acuity differs for diabetic macular edema and for pseudophakia macular edema (Irvine–Gass syndrome).

The reasons for this unexpected observation are yet to be established. What is the effect of intracellular fluid accumulation versus large amounts of intercellular edema fluid, as in cystoid macular edema? Does edema of much longer duration have an adverse effect on visual acuity, by contrast with more acute occurrences? What kinds of anatomic alterations have an adverse effect on the visual acuity outcome? As a rule, patients whose fluorescein angiograms show extensive nonperfusion of the perifoveal capillary network, or who have a large lipid plaque in the center of the macula, will have poor visual acuity regardless of macular thickness. Are there more subtle

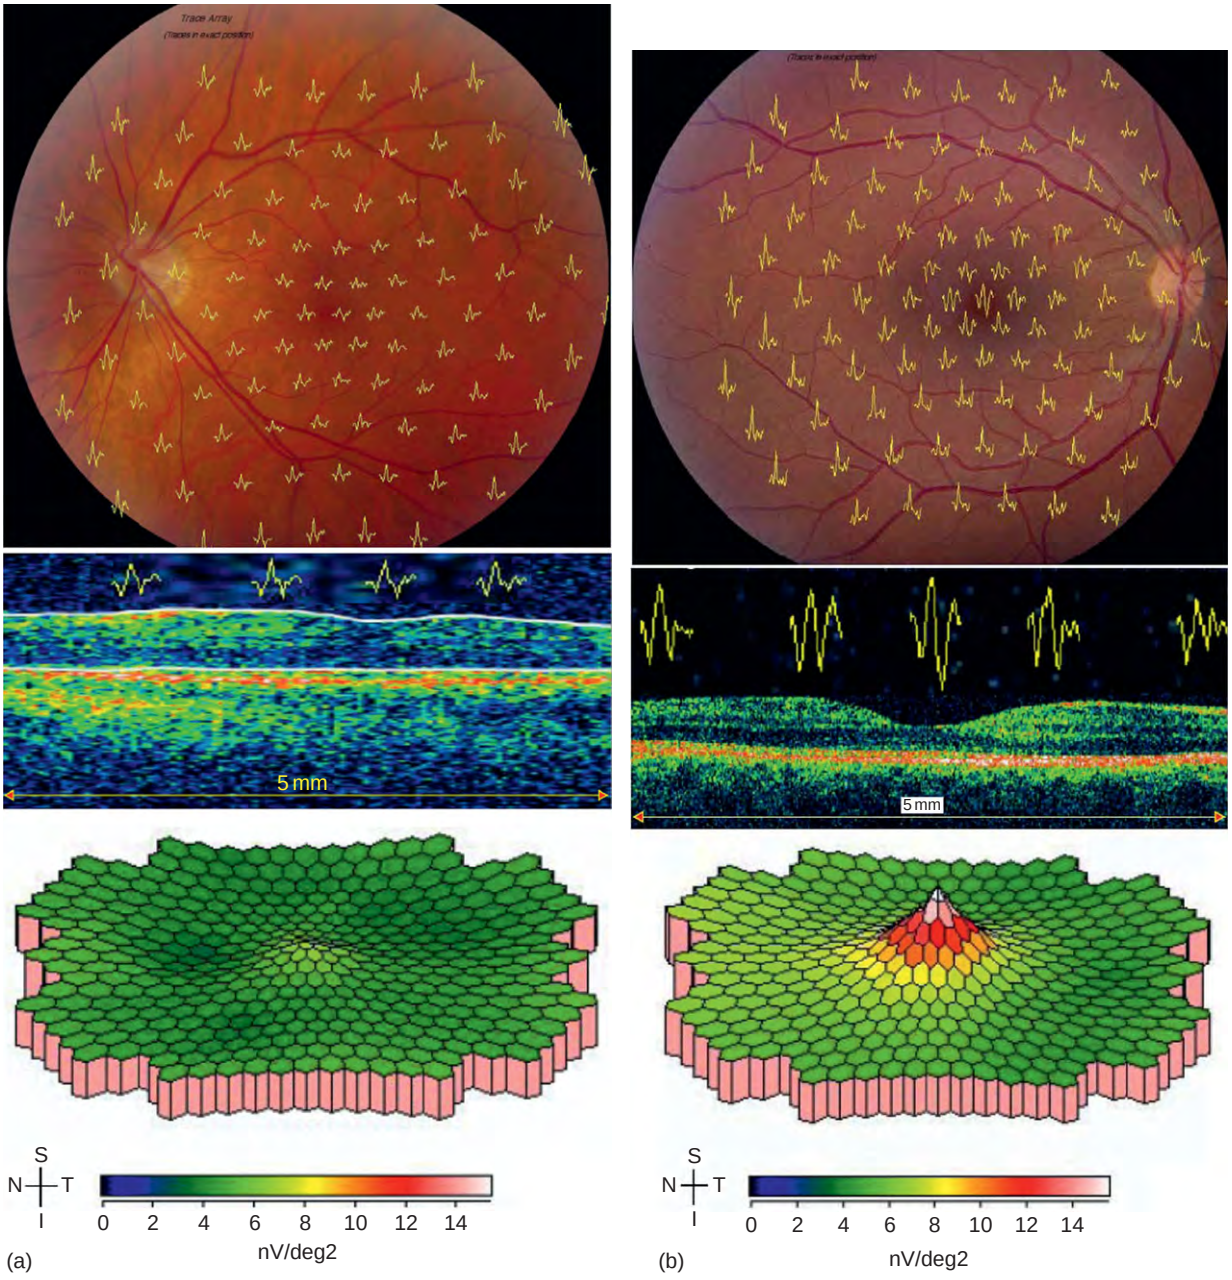

Figure 7 Multifocal electroretinogram (mfERG) traces of (a) A patient with diffuse macular edema and (b) a normal subject. In both figures, the mfERG traces are placed overlying a digital photograph of the individual's posterior retina, such that the site of the mfERG trace corresponds to its anatomic location. Note the diminution of the amplitudes and widening of the traces, indicating a prolongation of the latencies (implicit times) of the electrophysiologic responses to the light stimulus, in the retina with macular edema compared to the normal. Underneath the fundus images are placed time domain OCT scans of the normal and edematous retinas taken in the 180° meridian with overlying, corresponding mfERG responses. At the bottom of each figure is a three-dimensional pseudocolor map of mfERG P1 amplitudes (corresponding to the positive b-wave of a full-field ERG).

anatomic changes that can be detected by newer, high-resolution OCT methods (**Figures 1(c), 2(c)**, and **5(b) and (c)**; compare with **Figure 4(b)**)? Are there aberrations in photoreceptor structure or orientation that can be detected by high-resolution OCT, or by adaptive optics techniques? What prognostic information can be obtained by electrophysiologic methods such as the multifocal electroretinogram (**Figure 7**), that can detect functional alterations in very small regions of the macula? These and other questions remain subjects for investigation in the study of macular edema.

Meibomian Glands and Lipid Layer

T J Millar, P Mudgil, and S Khanal, University of Western Sydney, NSW, Australia

Glossary

Acinus – A gland that is shaped like a hollow sphere with the gland cells lining the sphere and secreting into the center of the sphere. The secretions are removed from the center of the sphere by a duct.
HMG-CoA – The 3-hydroxy-3-methyl-glutaryl-coenzyme A is a precursor molecule for lipid synthesis with the small precursor molecule attached to a carrier molecule, coenzyme A.
Holocrine – A mechanism of secretion by a gland wherein the whole gland cell is secreted.
Hydrophilic – A substance that dissolves readily in water (water loving).
Hydrophobic – A substance that does not like water. Fats, lipids, and oils are common hydrophobic substances.
mN m^{-1}(millinewtons per meter) – A unit used for measuring surface pressure relative to that of water which is regarded as 0 mN m^{-1}.
Osmolarity – A measure of the number of individual molecules dissolved in water. It is important to cells because water can pass readily through a cell membrane, but the dissolved chemicals in the cytoplasm cannot. Hence, a cell will either take on water or release water depending upon whether its osmolarity is more (hyperosmolar) or less (hypoosmolar) than its environment, respectively.
Refractive index – When light travels from one medium to another, for example, from air into water, it is bent. The refractive index is a measure of the extent to which the light is bent and is a constant for a particular substance.
Tarsal plate – A sheet of fibrous cartilage in the eyelids of mammals that gives the eyelids their stiffness and shape.

Overview

Meibomian glands are a series of fat (lipid)-producing glands found in the upper and lower eyelids of mammals, named after a German anatomist, Heinrich Meibom (1638–1700), who recorded their presence in *De Vasis Palpebrarum Novis Epistola* (1666). In humans, there are 30–40 evenly spread glands in the upper lid and 20–30 in the lower lid (**Figure 1**). Each gland is aligned vertically in the eyelid and located within the tarsal plate (a sheet of fibrous cartilage that gives the eyelids their stiffness and shape) which lies closer to the ocular surface than the dermal surface. Structurally, meibomian glands have a central tubular duct surrounded by grape-like acini (glands). The duct is blind at one end and the other end opens onto the eyelid margin. By everting the lower eyelid, the openings can be readily seen as a row of small dots behind the eyelashes (**Figure 2**).

Phylogenetically, meibomian glands are present in marsupials, but are absent in the two monotremes (echidna, *Tachyglossus aculeatus*; platypus, *Ornithorhynchus anatinus*) that we have studied. They are not present in reptiles or birds. It is believed that many of these animals use a different gland, the harderian gland, to secrete lipids onto the ocular surface. While the distribution and appearance of meibomian glands in other mammals are generally similar to those of humans, this is not always the case. Some species of voles and musk rats have few glands, for example, *Microtus pinetorum*, which has only two large glands in the upper eyelid – one at the medial canthus and the other at the lateral canthus. Whales have neither meibomian glands nor a tarsal plate in the eyelid. Dolphins and sea lions have a very oily secretion in their tears, but this is thought to originate from the harderian gland. Currently, the literature is not clear about the presence or absence of meibomian glands in sea-dwelling mammals. However, it is of interest to note that dolphins, sea lions, and sea otters have no eyelashes (or eyebrows), which means that they also lack the other major sebaceous glands in the eyelid, for example, the glands of Zeis which are the sebaceous glands of the eyelashes.

The major function of the meibomian gland is to supply the main components of the outer layer of the tear film. The tear film is a thin (7–10 μm thick), watery fluid that covers the exposed surface of our eyes (**Figure 3**). Lipids from the meibomian glands are secreted onto the inner margin of the eyelids where they contact and then spread over the aqueous part of the tear film to form a covering layer (~90 nm thick) in contact with the air. This layer is referred to as the lipid layer of the tear film. It is believed to decrease evaporation from the tear film and hence prevent dry eyes. However, this role for the meibomian lipids is by no means certain, and it is likely that it has other roles such as preventing tears from flowing onto the skin and skin lipids from flowing onto the ocular surface, assisting the spread of the tear film over the eye by lowering the surface tension, and forming a watertight seal when the lids are closed. The Meibomian lipids provide a smooth and

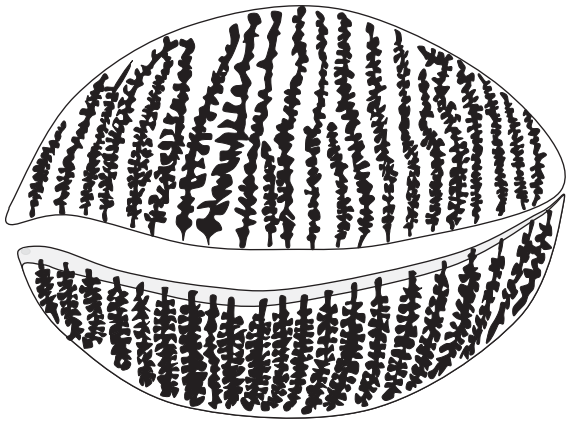

Figure 1 Arrangement of the meibomian glands in the upper and lower eyelids.

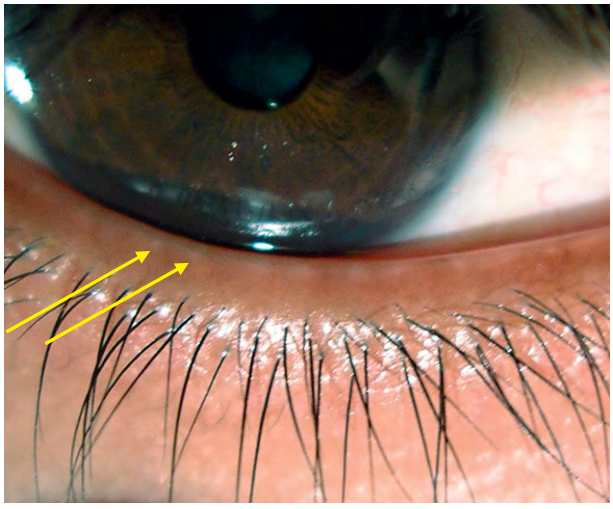

Figure 2 Meibomian gland orifices (arrows) in the lower lid margin.

highly refractive (1.4766 at 589 nm and 35°C) surface. Clinically, a mechanism for measuring tear breakup time (TBUT) is to observe changes to interference colors of the surface layer of the tear film. This can be used as one measure of the tear film performance.

The Lipid Layer of the Tear Film

The lipid layer of the tear film provides an optically smooth surface at the interface between the air and the aqueous part of the tear film. Although the structure of this layer has not been determined, the meibomian lipids form a major component (**Figure 3**). A useful model of the lipid layer, based on the idea that only lipids are present, was developed by McCulley and Shine. The model is presented as a crystalline array, and, while very useful for developing understanding, the lipid layer is unlikely to be crystalline in practice. This model proposed that the wax esters, steryl esters, triglycerides, and hydrocarbons (hydrophobic lipids) from the meibomian glands reside in the outermost layers and are linked to the aqueous subphase by polar lipids (phospholipids, free cholesterol, and free fatty acids). Some of these polar lipids may arise from the aqueous layer of the tear film and others from meibomian lipids and hydrolysis (cleavage) of the wax esters, steryl esters, and triglycerides. These polar lipids have a hydrophobic part which interacts with the hydrophobic lipids and a hydrophilic part that is able to interact with water (the aqueous layer). Assuming that the outer layer of the tear film is entirely made from lipids implies that the interfacial molecules (surfactants) must be polar lipids.

An alternate model proposing that proteins and mucins also contribute to this layer is more realistic. Strong evidence comes from surface tension measurements. It has been found that the surface tension of tears is 42–46 mN m^{-1} and this can only be achieved by a mixture of lipids and proteins and not with meibomian lipids alone. The interaction of meibomian lipids with tear proteins is often cautiously presented as lipids occupying the outer surface of the lipid layer, and the inner surface interacting with proteins from the aqueous layer. A more recent model includes proteins and mucins as integrated parts of this layer (**Figure 3**). Although there has been a focus on lipocalin, an abundant lipid-binding protein in tears, being the main tear protein interacting with the meibomian lipids, lysozyme and lactoferrin may be more involved. Lipocalin is thought to scavenge lipids that have adhered to the epithelial cells of the ocular surface and lipids that are in the aqueous layer. Although it has been claimed that these are then transported to the outer lipid layer, this may not be the case. Once a lipid is bound into the central pocket of lipocalin, lipocalin is in a low-energy state and unlikely to interact with the meibomian lipids at the outer surface of the tear film.

The presence of proteins in the lipid layer has important conceptual implications because they are large molecules with complex mixtures of hydrophobic, hydrophilic, and distinctly charged components. These properties mean that they can unfold and form a range of shapes according to their local molecular environment. Due to this unfolding, it is possible for them to extend across the lipid layer and interact with the hydrophobic lipids and other proteins. As the model suggests, this means that the layer comprises a complex mixture of islands of proteins, islands of lipids, islands of mucins, and various mixtures of these (**Figure 3**). This model is more akin to models for cell membranes and for lung surfactant. Some advantages of this model are that: the outer layer would be a noncollapsible viscoelastic gel; it would allow for the lowest free energy states of the proteins in contact with lipids; and the changes in salt concentrations in the tears

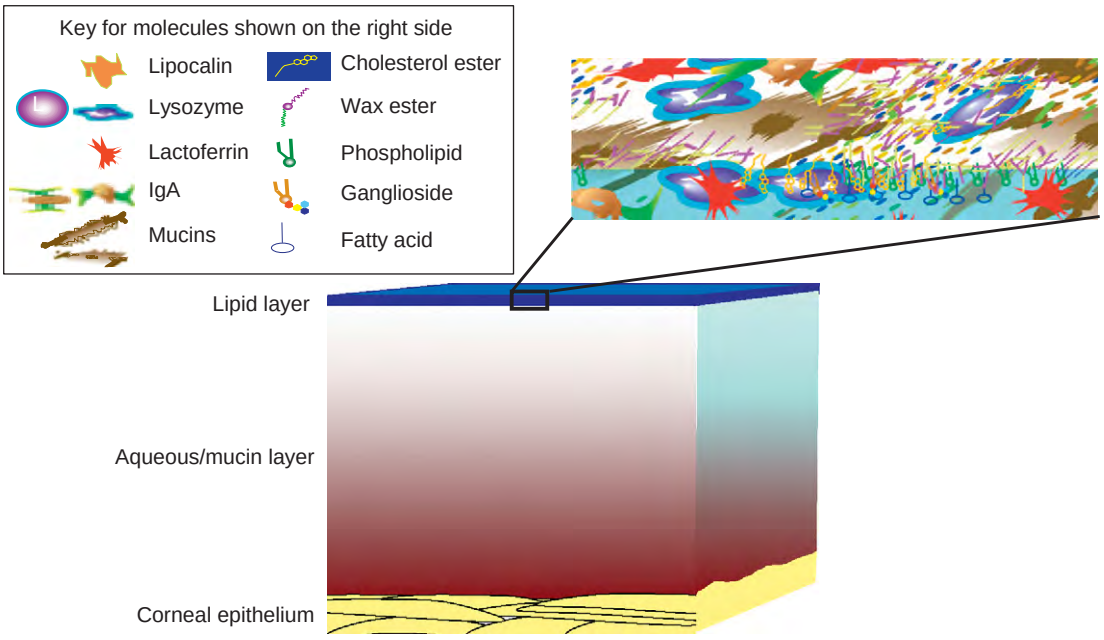

Figure 3 Tear film comprising an outer lipid layer covering an aqueous/mucin layer. The exploded view of the lipid layer shows a mixture of different lipids and denatured proteins (see key).

(e.g., hyperosmolarity) would affect the ability of the proteins to unfold and interact with lipids in the outer layer. Taking these one at a time, the lipid-only model needs some mechanism to spread the lipids over the aqueous surface after a blink. Both phospholipids and mucins have been proposed as enabling this by spreading slightly ahead of the hydrophobic lipids, and this concept also means that a new lipid layer is formed at each blink. Lack of change over a number of blinks to the interference patterns formed by the outer layer of the tear film does not support this concept. However, a noncollapsible viscoelastic gel that would be formed with proteins and mucins in the layer obviates the need for spreading and would account for the consistent interference pattern over a number of blinks. Furthermore, in other fields of study, mixtures of molecules in a liquid environment autoassemble into states of lowest free energy, which means that when lipids and proteins are placed together, they will mix at the molecular level rather than remain separate as the lipid-only model suggests. Some of the proteins can act as the surfactants, meaning that while phospholipids may co-jointly serve as surfactants, they are not absolutely necessary. It has also been found that while lipids alone are not capable of lowering the surface tension to the levels found in tears, mixtures of tear proteins and tear lipids possess that ability. Hyperosmolarity of the tears has the strongest correlation with a dry eye. Salt concentrations have strong effects on how proteins fold; therefore, it is possible that high salt concentrations would affect the folding of proteins and hence their ability to interact with the lipid layer to form a stable outer layer. In turn, this could affect the surface tension and spreading of the outer layer and, consequently, its protective function.

Meibomian Glands

Anatomy and Histology

There are no anatomical differences in the meibomian glands of human males and females. The ducts in humans are approximately 1.6 mm long with the central ducts being slightly longer than the nasal and temporal ducts, and are surrounded by a dense banding of elastic fibers. The ducts are lined by keratinized epithelium and lie nearly 780 µm from the dermal surface of the eyelid. A horny cell layer overlies one or two layers of intermediate cells that rest on cuboidal basal cells connected to a basement membrane, and there is no difference in this appearance between the proximal and distal portions of the duct (**Figure 4**). Acini are arranged circularly around the central duct and are connected to it by short ductules. The acinar cells are distinct from the ductal cells with no keratohyaline granules or lamellar bodies in the acinar cells, and no lipid vesicles in the ductal cells. The acinar cells continually differentiate into holocrine-secreting cells from basal acinar cells. They contain an abundance of smooth endoplasmic reticulum that surrounds the lipid vesicles. These cells also develop from the division of basal cells and move toward the center of the acinus (migration rate of 0.62 µm d^{-1} in rats), and slowly increase in neutral lipid content and in the size of the lipid-containing vesicles. The acinar cells die and gradually breakdown, leaving a

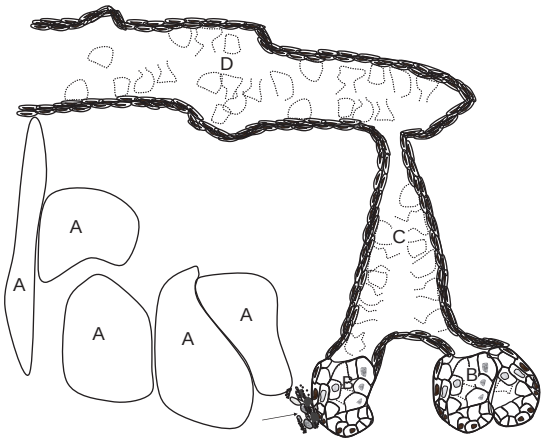

Figure 4 An illustration of meibomian glands and duct. A: Ghosts of acini not filled in with detail. B: Acini showing nucleated basal cells around the periphery which gradually lose their nuclei as they mature and move to the center of the acinus. C: Secondary duct surrounded by ductal cells (stratified epithelium) containing meibomian secretion and cell remnants. D: Main duct surrounded by ductal cells containing meibomian secretion and cell remnants. The arrow shows a bundle of nerve endings close to the acinus but separated by collagen fibers.

lipid mass that is secreted via the duct. In rats, it takes close to 9 days for a cell to migrate to the center of the acinus, and it probably divides twice during this time.

Surrounding the glands is a distinct extracellular matrix comprising collagen types I, II, and IV, aggrecan, dermatan sulfate, and chondroitin-6-sulfate. Close to the acini are numerous unmyelinated varicose nerve fibers with boutons in contact with collagen fibers within the basal lamina of the basal acinar cells. These are mainly parasympathetic fibers which contain the neurotransmitter, acetylcholine, and the neuropeptide vasoactive intestinal polypeptide. The cell bodies for these fibers lie in the pterygopalatine ganglion and their fibers reach the eyelid by the greater petrosal nerve. Preganglionic neurons are ipsilateral and cholinergic, and lie in the superior salivary nucleus located lateral, dorsal, and caudal to the superior olive and lateral, dorsal, and rostral to the facial nucleus. Sympathetic innervation is sparse and mainly associated with blood vessels. Sensory nerve fibers are also sparsely distributed close to the basal region of acini, and these are immunoreactive for the neuropeptides substance P and calcitonin gene-related peptide.

Development

Meibomian glands in humans develop as small, solid epithelial invaginations from the ocular face of the eyelid margin at approximately 9 weeks of development (crown-rump length of 40 mm). By 12 weeks (60 mm), the epithelial growth has extended the depth of the tarsal plate and has a central tube that was formed from apoptosis of the central epithelial cells. At 15 weeks (100 mm), cuboidal secretory cells line the ducts. The upper and lower eyelids are fused during this whole process. At 7.5 months (250 mm), after the eyelids have separated, acini are present, epithelial cells plugging the meibomian gland orifices disintegrate, and secretion begins just prior to birth. A similar process takes place in the mouse; however, in this case, the eyelids are still fused at birth, which is also the time when the first signs of meibomian gland development show, again from the eyelid margin. In contrast to meibomian gland development, eyelashes in humans begin development earlier at 8 weeks (35 mm) as solid epithelial invaginations from the external face of the eyelid margin.

Composition of Meibomian Lipids

The meibomian gland is often referred to as a modified sebaceous gland. In this case, the term sebaceous means lipid producing rather than sebum producing because the composition of the lipids differs from those produced by the sebaceous glands of hair follicles. The main lipid types produced by meibomian glands are wax and steryl esters (60–70%) which are very hydrophobic (dislike water). Wax esters are formed by linking a long-chain carboxylic acid (fatty acid) to a long-chain alcohol (fatty alcohol). Since different fatty acids and fatty alcohols are linked together, the wax esters are a complex family of lipids and their detailed structure varies between species. In humans, oleic acid is the most prevalent fatty acid found in these waxes. Similarly, the steryl esters are mainly cholesterol esters which are formed by linking cholesterol to a long-chain fatty acid. These fatty acids are generally longer than those found in the wax esters. Small amounts of other lipids (mainly polar) – such as mono-, di-, and triglycerides; fatty acids; fatty alcohols; free cholesterol; and phospholipids – make up the remainder. While phospholipids are readily detected in meibomian lipids of rabbits, there is contention as to whether they are a component of human meibomian lipids. This is important because in models of the lipid layer of the tear film, phospholipids are crucial as a link between the hydrophobic molecules (wax and cholesterol esters) and the aqueous layer. If they are not present in the meibomian lipids, then they must be derived from elsewhere, such as the aqueous layer of the tear film, or alternative surfactants need to be present in the model. The nature and mixture of the lipids give them a melting range of 19–33 °C, which means that they are fluid on the ocular surface.

Meibomian Lipid Turnover and Synthesis

Since the meibomian gland is a holocrine gland, lipid turnover is related to the cell turnover rate and the lipids are synthesized by the glands rather than being adsorbed from the bloodstream. For instance, the levels of

cholesterol found in meibomian lipids are independent of cholesterol levels in the blood. Synthesis of the straight-chain fatty acids is typical of elsewhere in the body, occurring in the cytoplasm using acetyl-coenzyme A (CoA) and malonyl-CoA as the starting molecules and fatty acid synthase as the major enzyme. Some of the fatty acids have branching and, at least in rabbits, the branched carbon chains are derived mainly from the amino acids valine and isoleucine. The acyltransferases seem to be nonselective and will connect any fatty acid to a fatty alcohol. Similarly, cholesterol synthesis is typical of other tissues converting β-hydroxy-β-methylglutaryl-CoA to mevalonate, isoprene, squalene, and cholesterol. The acylcholesterol transferase, involved with cholesterol ester synthesis, appears to be selective for longer-chain fatty acids based on the predominance of long-chain fatty acids in cholesterol esters.

The meibomian acinar cells have nuclear androgen receptors and the level of androgens or, more likely, the ratio between androgens and estrogens is critical for controlling lipid synthesis in the meibomian glands. Stimulating androgen receptors increases gene transcription in enzymes associated with fatty acid and cholesterol synthetic pathways (adenosine triphosphate (ATP)-citrate lyase, acetyl-CoA synthase, acetoacetyl-CoA synthase, 3-hydroxy-3-methyl-glutary (HMG)-CoA synthase 1, HMG-CoA reductase, acetyl-CoA carboxylase, glyceraldehyde-3-phosphate dehydrogenase, and sterol regulatory element-binding protein 1 and 2) and hence stimulates lipid production. Androgen deficiency has been associated with meibomian gland dysfunction (MGD) and dry eye. $P2Y_2$ receptor gene expression has also been detected in meibomian gland acini. This suggests that extracellular ATP or UTP might influence lipid synthesis or composition through activation of G proteins. Specific changes to lipid composition through this pathway have not been investigated.

The total amount of meibomian lipids on the lid margins has been estimated and children under 14 years of age showed the lowest levels ($1.5\,\mu g\,mm^{-2}$ lid margin). After puberty, there is a steady increment with age until the late 60s ($3.26\,\mu g\,mm^{-2}$) and throughout this period, males have nearly 10% greater levels than females. Given that one of the reasons for dry eye is insufficient meibomian lipid secretion and that there is an increase in the incidence of dry eye with age, it is surprising that the lowest levels of meibomian lipids have been found in children. Morning and afternoon basal levels are the same and there is no correlation between lid temperature (30–34 °C) and basal levels of meibomian lipids. However, deliberately increasing the eyelid temperature from 33 to 37 °C increases the lipid values on the lid margin by close to 25%. Despite the presence of parasympathetic nerves around the acini, lipid secretion is most likely due to the mechanical force of blinking which causes compression of the territorial fibrocartilaginous matrix that surrounds the meibomian glands. This has been shown by measuring the reappearance of lipids on the eyelid margin after cleaning with an organic solvent. No lipids appear until a blink occurs (3 min was the longest). After approximately 10 blinks, the levels return to nearly a third of their basal levels. It is estimated that close to 10 μg of lipids are delivered per blink and that there is approximately 20–40 times excess basal amount of lipids available on the eyelid margin than what is required for forming a complete lipid layer on the tear film.

How the lipids are removed from the eye is uncertain. It is believed that most of them flow over the eyelid margin onto the skin and eyelashes. This constant flow prevents the skin lipids from contaminating the tear film. It has been shown that skin lipids disrupt the tear film. Some lipids are likely to bind to proteins of the aqueous layer, particularly lipocalin, and are removed with the aqueous layer through the lacrimal ducts. The crusty buildup that collects in the corner of the eye during sleep is primarily a mixture of lipids and mucins and thus another mechanism for removing lipids from the ocular surface.

Pathology of the Meibomian Gland

Disorders of the meibomian glands are manifest by the obstruction of the gland orifices, inflammation, or loss of the glands. This is often associated with one or more of the following: thickening of the lid margin, exaggerated vascularization around the gland orifices, and hyperkeratinization. Meibomian gland diseases are usually more uncomfortable rather than painful and, when chronic, are associated with dry eye which can be very painful. Absence or deficiency of meibomian glands is often congenital.

Clinically, the state of meibomian glands is determined by examining their morphology and function. In eye clinics, the orifices of the glands lining both the upper and lower eyelids are observed through a slit lamp biomicroscope. If a gland is blocked, the orifice appears swollen on the lid margin. Some practitioners also squeeze the lower eyelid gently to expel meibomian lipids. A clear fluid is considered to be normal, whereas a thick, yellowy secretion is an indication of meibomian gland disorder. If excessive pressure is applied, a thick pasty expression can be obtained from people with normal meibomian gland function (**Figure 5**). This technique is used for obtaining meibomian lipids for experimental purposes or for analysis. In research settings, more specific tests are performed to assess meibomian gland function. Transillumination of the lower eyelids is widely used to evaluate the morphology of the glands. In particular, shorter-than-normal meibomian glands and meibomian gland dropout are strong indications of MGD (**Figure 6**). Changes to the shape and form of the glands do not occur with aging,

although expression of secretion is commonly more difficult. A clear, noninvasive view of meibomian glands can be achieved by using infrared light, but the need for specialized equipment means that this technique is only used in a few research laboratories.

Rather than examine the meibomian glands themselves, observation of the lipid layer of the tear film is regarded as an indirect measure of both the quantity and the quality of meibomian gland secretions. Using specialized interferometry, the lipid layer stability, distribution, dynamics, and thickness can be assessed. Generally, a thick amorphous layer is an indication of high-quality meibomian oil secretions and, hence, excellent meibomian gland function. Such a layer is also commonly associated with longer TBUTs, presumably because of the lowered surface tension. The results obtained from tear breakup tests have been shown to be comparable to interferometry findings, although a cause–effect relationship between the two is yet to be established.

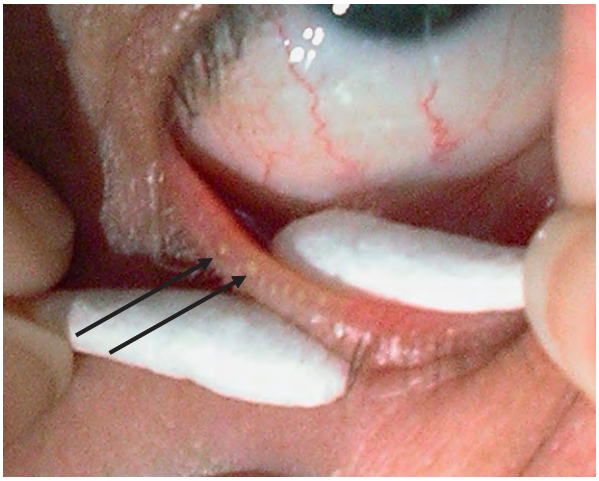

Figure 5 Hard squeezing of meibomian glands. The secretions are indicated by arrows.

Another method for evaluating meibomian gland function indirectly is to measure evaporation from the ocular surface. This is a difficult technique and is normally confined to research settings. Evaporimetry is based on the theory that evaporation from the ocular surface is normally minimal due to the well-spread lipid layer acting as a blanket, and that an inadequate lipid layer or disruption to this lipid layer causes tear evaporation to increase. It is thought to be the cause of evaporative dry eye. However, this idea has been difficult to substantiate and a wide variability in tear evaporation rates has been reported irrespective of the presence or absence of dry eye and, more importantly, the appearance of the lipid layer. Further, a large quantity of lipid on the tear surface does not necessarily correlate with an adequate barrier to evaporation. Evaporative dry eye can occur with an excessively thick lipid layer. Current areas of research center on whether the biochemical composition of the meibomian lipids can influence their surface activity and ability to diminish evaporation, but clear outcomes are still in the future.

Chronic Blepharitis

The term blepharitis has different meanings depending upon the user. Acute blepharitis (normally just called blepharitis) is an infection of the anterior eyelid and *Staphylococcus epidermidis* or *Staphylococcus aureus* are the most likely cause. Chronic blepharitis is caused by dysfunction of the meibomian glands and is synonymous with

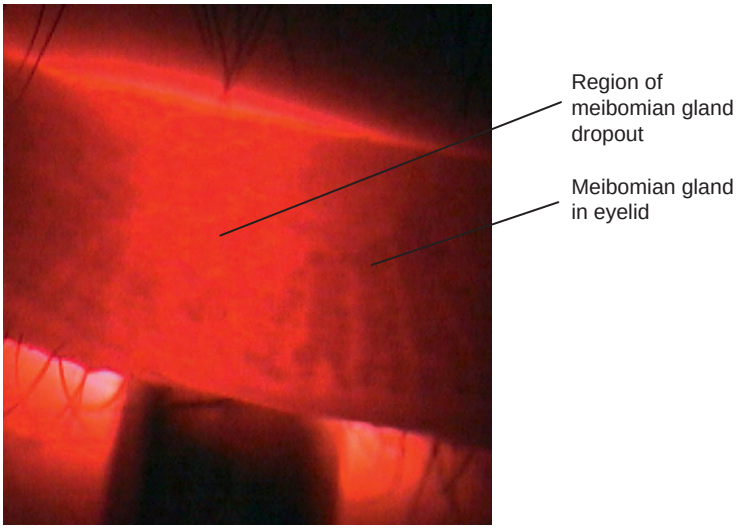

Figure 6 The transillumination of eyelid showing the dark meibomian gland acini. There is meibomian gland dropout in the middle region of the lid. Courtesy of Jerry Paugh, Southern California College of Optometry.

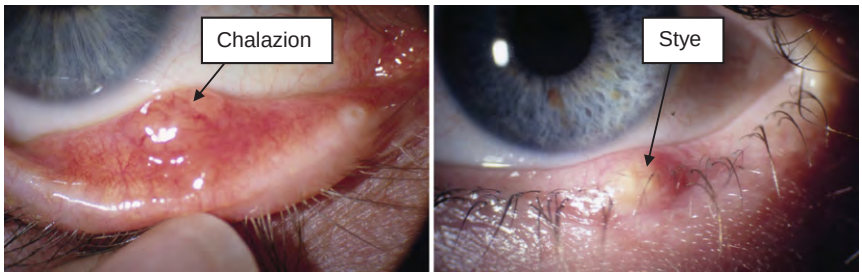

Figure 7 A chalazion appears as a swelling deep within the eyelid. A stye is associated with the eyelashes (infection of the eyelash follicle). Courtesy of Rob Terry, Institute of Eye Research, University of New South Wales.

MGD and posterior blepharitis. Many studies have looked at the association between blepharitis or chronic blepharitis and dry eye. However, the conclusions drawn about the association depend on the definitions being used in the study. Although MGD occurs in nearly three-quarters of patients with chronic blepharitis, it also occurs in approximately 20% of people with normal tear function. In MGD, the orifices of the meibomian glands are blocked, reducing the secretion of meibomian lipids onto the ocular surface. Regular warm compresses help to open the orifices and allow normal lipid secretion. Some patients with chronic blepharitis have similar symptoms to those of dry eye and are prescribed tear lubricants for palliative purposes, that is, they do not resolve the blepharitis.

Chalazion

The blockage of the meibomian glands can lead to formation of a chalazion (**Figure 7**). This is a cyst on the eyelid that is normally sterile and composed of a lipid granuloma. It looks similar to a stye, which is caused by an infected sebaceous gland of the eyelash, but can be easily distinguished clinically because a chalazion is painless and develops gradually, whereas a stye is always painful and forms over a few days. For both conditions, warm compresses are recommended. In extreme cases of chalazion, it is surgically incised and the granulomatous material is removed by curettage. Antibiotics are often prescribed to treat a stye.

Surgical Damage

Treatment of trachoma is a common cause for surgical damage to the meibomian gland. Trachoma, a leading cause of blindness, is an infectious disease of the palpebral conjunctiva that leads to the eyelids folding inward (entropion), causing the lashes to rub against the cornea. The lids, and hence the meibomian glands and ducts, are cut to relieve this condition. It is yet to be determined whether this compromises the functionality of the outer lipid layer of the tear film. Other surgical procedures such as correction of lid malpositioning, particularly ptosis (drooping of the upper eyelid) and genetic entropion, can also sometimes require the cutting of the meibomian glands.

Contact Lenses and the Lipid Layer

Anomalies of the lipid layer, in themselves, are not a deterrent for contact lens wear. Lipids or proteins or both are deposited on contact lenses during wear. These deposits can block the small pores of the contact lenses, which are essential for the passage of air to the cornea for its metabolism. It is impossible to ascertain beforehand how long a contact lens needs to be worn for it to be unsuitable for an individual as the amount and pattern of lipid deposition depends on the composition of the ocular lipids, which can vary between people, and the specific material the lens is made from. Contact lens cleaning agents are designed for the specific type of contact lens and normally contain a surface active agent that removes lipid deposits.

Glossary

Ciliary photoreceptors – Visual receptor cells in which the photosensitive region is derived from a cilium, a structure protruding from the cell body and characterized by the internal presence of nine longitudinal microtubules arranged in a circular fashion (and sometimes two additional microtubules in the center). Folding of the membrane of the cilium enhances its surface area to accommodate a great number of photopigment molecules.

Circumpallial nerve – Nerve that loops around the mantle of mollusks. It collects the axons from the eyes and projects to central neural ganglia of the animal.

Cyclic nucleotide-gated channels (CNG channels) – Family of ion channels that are ancestrally related to certain voltage-activated channels, but have evolved a different gating mechanism that responds to the binding of cGMP and cAMP to a site located in the intracellular side. They are responsible for generating the receptor potential in a variety of sensory cells, like olfactory neurons and many photoreceptors.

Diacylglycerol (DAG) – Product of the breakdown of phosphatidylinositol bisphosphate (PIP_2) by phospholipase C (PLC). This is the lipid moiety of the molecule and remains membrane bound. It is a prime activator of protein kinase C (PKC).

Guanylate cyclase (GC) – Enzyme responsible for generating the intracellular messenger cyclic guanosine monophosphate (cGMP), using guanosine trisphosphate (GTP) as substrate.

Inositol trisphosphate (IP_3) – Soluble, bioactive product of the breakdown of PIP_2, resulting from the cleavage of the polar head of this phospholipid. It can diffuse from the membrane to the endoplasmic reticulum (ER), where it binds to IP_3 receptors, causing them to expose a calcium-permeable pore and to release calcium contained within the endoplasmic reticulum (ER).

Microvillar photoreceptors – These are also called rhabdomeric photoreceptors. Photoreceptor cells in which the light-sensitive region presents evaginations of the cell membrane in the form of thin cylindrical protrusions, called microvilli. These are internally packed with longitudinal bundles of actin filaments that confer structural stability. The resulting increase in the surface area of the membrane makes it possible to accumulate a large population of photopigment molecules.

Phosphatidylinositol bisphosphate (PIP_2) – Minor phospholipid present in the inner leaflet of the cell membrane. Its enzymatic breakdown by phospholipase C (PLC) yields two bioactive products, namely inositol trisphosphate (IP_3) and diacylglycerol (DAG).

Phosphodiesterase (PDE) – Enzyme that cleaves a phosphodiester bond. In vertebrate photoreceptors, PDE breaks down cGMP, forming the inert compound 5′-GMP, thus leading to the closure of ion channels gated by cGMP.

Phospholipase C (PLC) – Enzyme that hydrolyzes inositol phospholipids in the membrane. A subclass, known as PLC-β, is activated by a guanine-binding protein (G-protein) of the G_q type.

Protein kinase C (PKC) – A class of enzymes capable of transferring a phosphate from an ATP molecule to a serine or threonine residue in a protein. Members of a subclass of these enzymes, known as conventional PKCs, are activated by calcium and/or diacylglycerol, two messenger molecules whose intracellular concentration increases in microvillar photoreceptors after stimulation with light.

pS, Pico-siemens (10^{-12} S) – A measurement unit of conductance. The conductance of a body is 1 S, such that upon applying 1 V across it, an electrical current of 1 A would flow.

Transient receptor potential (TRP), transient receptor potential like (TRPL) – Proteins first identified in the eyes of *Drosophila* as the ion channels subserving the late and the early phase, respectively, of the receptor potential. Genetic mutations leading to the failure to express TRP cause the receptor potential to consist of only the initial, transient phase, hence the name transient receptor potential (TRP).

Visual cells in the animal kingdom are usually partitioned into two distinct categories on the basis of the structure of the light-sensing organelle: in some photoreceptors, all the machinery necessary to absorb photons and generate a receptor potential is contained in a modified cilium; this is the case of the rods and cones in the vertebrate retina. In other cells, that function is subserved by microvilli, as it

occurs, for example, in the photoreceptors of the compound eye of insects. In both designs, the folding of the membrane greatly increases its surface area to accommodate a large number of photopigment molecules – which are integral membrane proteins – thus conferring a high optical density to the cell, making it an efficient and compact light collector.

It is generally accepted that this dichotomy also marks a sharp boundary between the design of vertebrate versus invertebrate retinae. However, the eyes of several marine mollusks, such as those of *Pecten irradians* (Figure 1) and *Lima scabra* challenge such dogma, because they possess a double retina, comprised of microvillar cells in the proximal layer, and ciliary cells in the distal layer. Because each retinal layer gives rise to a separate branch of the optic nerve, which in turn produces either ON or OFF neuronal discharges in response to light, both cell types were thought to be visual receptors. This conjecture was corroborated by intracellular recordings of light-evoked responses in the intact retina. Surprisingly, these light responses have opposite polarities: proximal cells depolarize – as all other invertebrate photoreceptors were known to do – while distal cells hyperpolarize. Because those measurements were conducted under conditions designed to hamper synaptic transmission, it was unlikely that some of the light responses may have been evoked indirectly. Lingering doubts about the coexistence of functionally and structurally different primary visual receptors were dispelled by recordings of light-dependent changes in membrane voltage and membrane current in enzymatically isolated microvillar and ciliary cells.

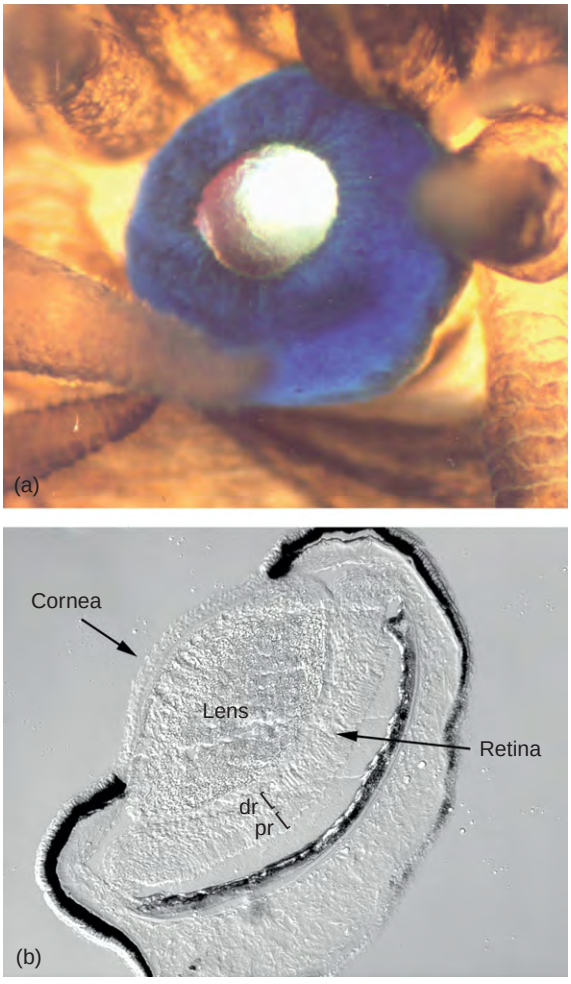

Figure 1 (a) The eye of the scallop, *Pecten irradian,* is of the simple type, possessing a single cornea and lens. The shiny appearance of the pupil is due to the presence of a reflector at the back of the eye, which helps focus light onto the retina. (b) Cryosection of a fixed eye. The retina is comprised of two separate layers, proximal (pr) and distal (dr), each giving rise to a separate branch of the optic nerve.

Microvillar (Rhabdomeric) Photoreceptors

Excitation

The basic properties of the light response in microvillar visual receptors of mollusks are generally similar to those found in other invertebrate eyes. Light produces a depolarizing receptor potential, which is due to an increase in membrane conductance. Because there are no local second-order neurons, light information must be directly encoded by action potentials (Figure 2) propagating along the axons

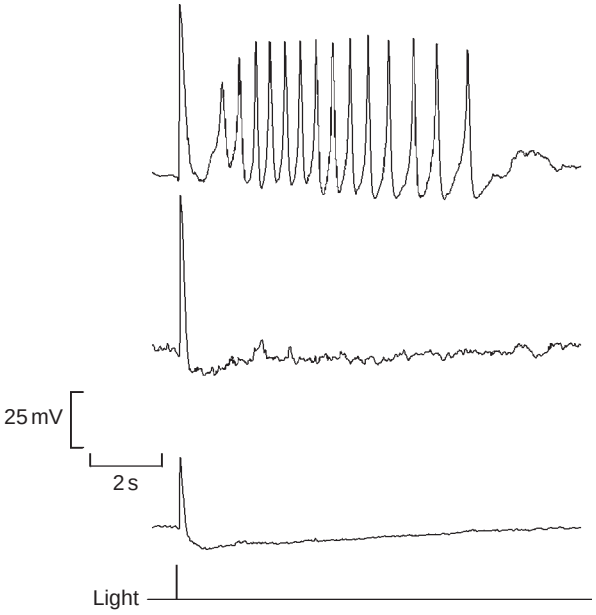

Figure 2 Current-clamp recording of the light response in an isolated microvillar photoreceptor of *Lima*. The membrane voltage was measured through a patch electrode in the whole-cell configuration. Flashes of 100-ms duration were presented, as indicated at the bottom, increasing their intensity at 0.6 log units (from bottom trace to top). A graded depolarization is evoked by light, eventually triggering one or more action potentials. The resting potential was ~–54 mV. Traces were offset vertically for clarity.

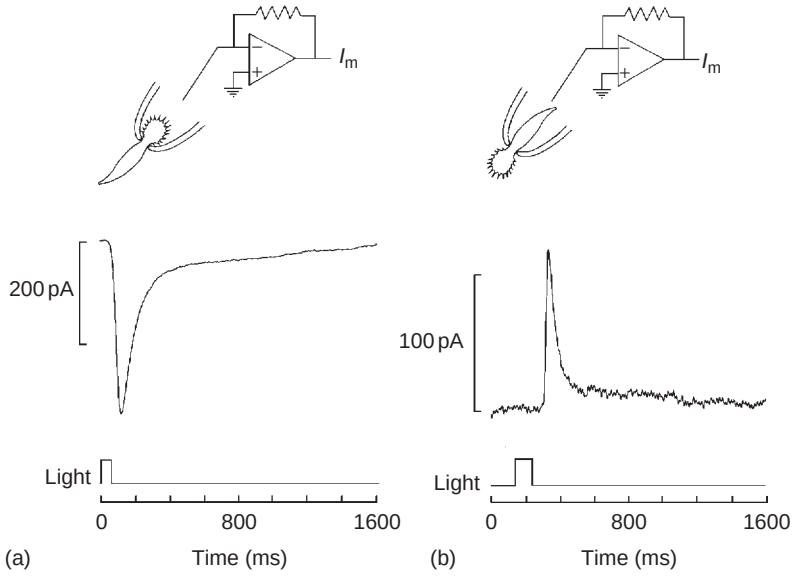

Figure 3 (a) Suction-electrode recording of light-evoked currents in isolated rhabdomeric photoreceptors of *Pecten* with the microvillar lobe inside the electrode. (b) Inverting the orientation of the cell in the pipette reverses the polarity of the recorded current. The active (inward) current is confined to the microvillar lobe of the cell.

that directly emanate from the photoreceptor cells and form the circumpallial nerve. The circumpallial nerve loops around the mantle of mollusks, collects the axons from the eyes, and projects to central neural ganglia of the animal. Voltage-dependent calcium currents contribute to the initiation of regenerative spikes, and, together with voltage- and calcium-dependent potassium currents, help shape the light response. The photocurrent is segregated to the photosensitive microvillar lobe, as clearly demonstrated by suction-electrode measurements (**Figure 3**). The light-sensitive conductance is cationic, permeable to sodium ions, and, to a lesser extent, to K (permeability ratio, p_{Na}:p_K, $\sim$ 1.8:1). Additionally, there is a small contribution of calcium ions, which, however, is quantitatively minute (<3% of the light-evoked inward current). In this respect, these cells differ from *Drosophila*, where the Ca:Na selectivity ratio of light-dependent channels may be as high as 40:1. Such discrepancy may point to the evolution of different strategies for light-triggered calcium mobilization (a phenomenon universally observed in all microvillar receptors tested to date): in *Pecten* and *Lima*, like in some other species (e.g., *Limulus*), photo-induced Ca transients are impervious to the removal of extracellular calcium and reflect release from IP_3-sensitive intracellular stores; such a scheme would have little use for a Ca influx pathway. By contrast, other photoreceptors display minimal – if any – internal release and must therefore depend essentially on Ca-permeable channels at the plasma membrane.

The photo-induced calcium transients of *Pecten* and *Lima* are very large, best monitored with low-affinity fluorescent indicators like Fluo 5F and Calcium Green 5N (K_D $\sim$ 2.3 and 14 μM, respectively; **Figure 4**); they are initiated

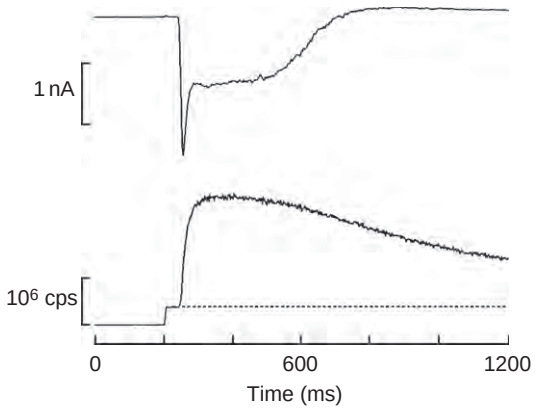

Figure 4 Simultaneous recording of membrane current under voltage clamp (top trace) and fluorescence of the indicator Calcium Green 5N, which was dialyzed through the patch pipette at a concentration of 75 μM (bottom trace). Emitted light was measured with a photomultiplier tube in photon-counting mode; the calibration bar at the bottom refers to counts per second (cps). A large increase in fluorescence above the initial level (indicated by the dashed line) occurred shortly after activating the epifluorescence beam, coincident with the beginning of the photocurrent.

in the light-transducing microvillar lobe, and precede the activation of the electrical response by $\sim$1 ms. Blunting the light-triggered Ca changes with Ca buffers (internal 1,2-bis(o-aminophenoxy)ethane-N,N,N′,N′-tetraacetic acid (BAPTA) or high concentration of ethylene glycol-bis-(β-amino-ethyl ether) N,N,N′,N′-tetraacetic acid (EGTA)) interferes with the light response, dramatically reducing its amplitude and slowing down its kinetics. However, although cytosolic Ca levels are controlled by light and

in turn exert a pivotal regulatory function, Ca does not, in all likelihood, directly activate light-dependent channels. Other events that follow phospholipase C (PLC) activation play a fundamental role; light-activated single-channel currents remain temporally viable in excised, perfused inside-out patches, pointing to membrane-bound signaling elements, rather than soluble messengers like inositol 1,4,5 triphosphate (IP_3) or Ca^{2+}. Diacylglycerol (DAG), the other, membrane-confined product of the breakdown of phosphatidylinositol-bisphosphate (PIP_2), is a plausible candidate. In *Lima*, a variety of DAG analogs, such as 2-dioctanoyl-sn-glycerol (DOG), phorbol 12-myristate 13-acetate (PMA), and (–)-indolactam, increase membrane conductance and evoke an inward current (**Figure 5**) with a similar ionic selectivity as the photoconductance; moreover, DAG analogs and light interact occlusively, suggesting that their effects converge onto a common target. Calcium elevation greatly potentiates and accelerates the effects of DAG analogs, an observation in line with the aforementioned effects of Ca manipulations. The generality of the role of DAG – or some metabolite thereof – in phototransduction remains to be systematically assessed in different species; moreover, even in *Lima*, the robust effects of DAG analogs fall quantitatively short of the speed and magnitude of the electrical response elicited by light. While the discrepancy could be ascribed to technical limitations in the application of chemicals to the cell, the participation of additional messenger molecules should not be ruled out. In other systems, phosphatidylinositol 4,5 bisphosphate (PIP_2), long viewed simply as the substrate of phosholipase C-β (PLC-β) and the precursor of IP_3 and DAG, has emerged as a signaling molecule in its own right. Because PIP_2 levels in the rhabdomeric membrane are bound to drop with light-triggered activation of PLC, a direct participation of this phospholipid in light signaling would call for a negative messenger role, one that helps maintain some element(s) of the transduction cascade in the inactive state. In *Lima*, intracellular administration of PIP_2 specifically antagonizes the light-evoked current while sparing voltage-dependent currents. Moreover, in excised patches of *Pecten* rhabdomeric membrane screened for the exclusive presence of light-activated channels, functional depletion of PIP_2 by antibodies (to avoid confounding by the concomitant generation of its bioactive hydrolysis products) induces the appearance of single-channel currents, which can be silenced by exogenous replenishment of PIP_2. Thus, the visual excitation process may be complex, and involve the interplay of several signaling and modulator molecules, rather than constituting a linear cascade.

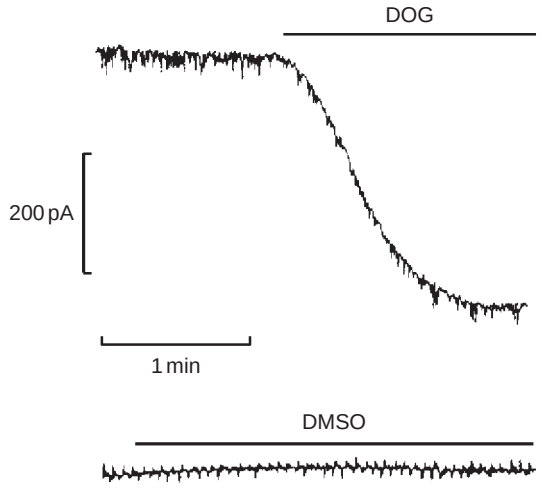

Figure 5 Diacylglycerol (DAG) analogs stimulate the light-sensitive conductance in *Lima* microvillar photoreceptors. Puffer-pipette application of the 2-dioctanoyl-sn-glycerol (DOG, 100 μM) activates an inward current, several hundreds of pA in amplitude, in a cell held under voltage clamp. Control application of dimethyl sulfoxide (DMSO) at the same concentration as that used to dissolve DOG is inert (bottom trace). The current activated by DOG and other diacylglycerol DAG analogs has the same ionic selectivity as the photocurrent; moreover, the analogs interact occlusively with light.

An additional complexity in the visual excitation scheme of molluskan microvillar receptors is the presence of separate populations of ion channels underlying the photocurrent, as subsequently corroborated in *Drosophila* where transient-receptor potential (TRP) and transient-receptor potential-like (TRPL) channels were molecularly identified. Two components of the macroscopic photocurrent of *Lima* can be distinguished by their time course and ion-conduction properties. In *Pecten*, cell-attached patch-clamp recordings in the exposed light-sensitive membrane reveal single-channel currents specifically activated by photostimulation (**Figure 6**) with a unitary conductance of ~48 pS and an additional population of smaller-amplitude currents ~18 pS. The identity of these single-channel currents as the constitutive elements of the macroscopic photoresponse was confirmed by the similarity of kinetics and light sensitivity, extending down to stimulation intensities that only evoke single-photon responses.

Light Adaptation

Modulation of sensitivity is a fundamental process in photoreceptor function, and enables the cell to maintain responsiveness over widely varying levels of ambient illumination. Once again, calcium had been singled out as a critical player as early as in the 1970s in *Limulus*, but its downstream effector(s) remained unclear. Protein kinase C (PKC) is a likely mediator, because some PKC subtypes are activated by calcium (and DAG), and also because in *Drosophila* it is associated with the macromolecular 'light-transduction complex'. Ca-dependent PKCα is selectively expressed in *Lima* eyes, as established by Western blot analysis using isoform-specific antibodies, and localizes in the light-sensing lobe of microvillar photoreceptors. Moreover, upon illumination it translocates from the cytosol to the membrane

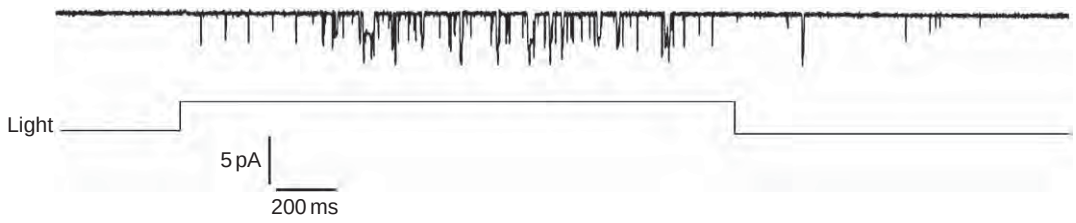

Figure 6 Cell-attached patch-electrode recording on the microvillar lobe of a *Pecten* rhabdomeric photoreceptor. Upon presenting a sustained, dim-light stimulus, single-channel inward currents are elicited. Two populations of light-activated currents are observed, one with a unitary conductance of ~≈48 pS and an additional population of smaller-amplitude currents ~18 pS. No responses are produced by voltage stimulation in the dark (not shown).

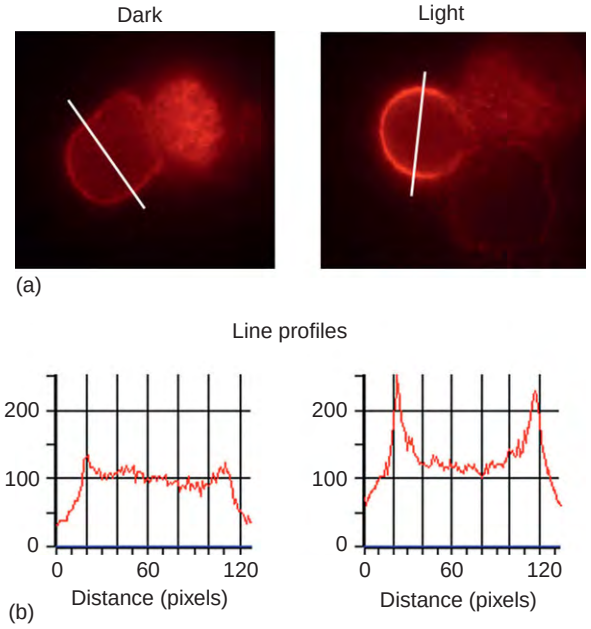

Figure 7 Light-induced translocation of PKCα. (a) Photoreceptor dark adapted for 1 h and directly fixed in paraformaldehyde (left), or illuminated for 3 s just before fixation (right). Anti-PKCα antibodies revealed a different spatial pattern of immunofluorescence in the two conditions, whereas in control cells PKCα is largely distributed diffusely in the cytosol of the microvillar lobe, after light the fluorescence forms a much more pronounced ring around the edges and is nearly absent from the central portion. (b) Intensity profiles of the immunofluorescence, measured along a line cutting across the rhabdomeric lobe.

(a functional assay of its activation), on a similar timescale as the onset of light adaptation (Figure 7). Chemical stimulation of PKC specifically depresses the light response, consistent with its role in desensitization, while pharmacological antagonists of PKC reduced light adaptation. These observations strongly support the involvement of PKC in the calcium-dependent regulation of response sensitivity.

Ciliary Photoreceptors

Photoreceptors of the distal retina function in a profoundly different way. Their resting potential is relatively depolarized (~−35 mV) owing to a high resting g_{Na}/g_K

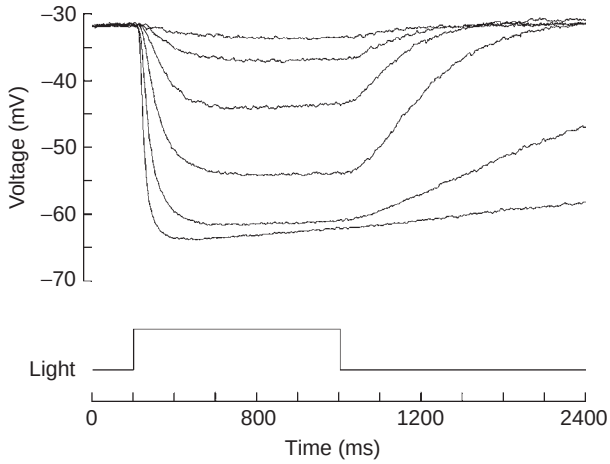

Figure 8 Hyperpolarizing receptor potentials elicited by a 1-s light of increasing intensity (top to bottom trace) in a dissociated ciliary photoreceptor of *Pecten*, measured with a patch electrode in whole-cell current-clamp mode.

ratio, and illumination produces a hyperpolarizing receptor potential graded with light intensity (Figure 8). The light sensitivity is significantly lower than in proximal photoreceptors, but the purpose here is not range fractionation (unlike rods and cones of the vertebrate retinas). Instead, ciliary photoreceptors play a fundamentally different role from that of their microvillar counterparts: the information output ultimately entails action potentials, which, of course, could not be caused by light-induced hyperpolarization. It is a reduction of illumination that causes firing in these axons: the effect of light is to remove, in a time- and intensity-dependent way, the steady-state inactivation of voltage-dependent calcium channels, such that when illumination is decreased (e.g., when an approaching predator casts a shadow on the animal's visual field), the return to a depolarized membrane potential triggers a Ca spike. As such, these cells function as dark detectors and activation of the phototransduction cascade serves the function of priming them to respond to light dimming.

Excitation

The hyperpolarizing receptor potential of ciliary visual receptors also arises from an increase in membrane

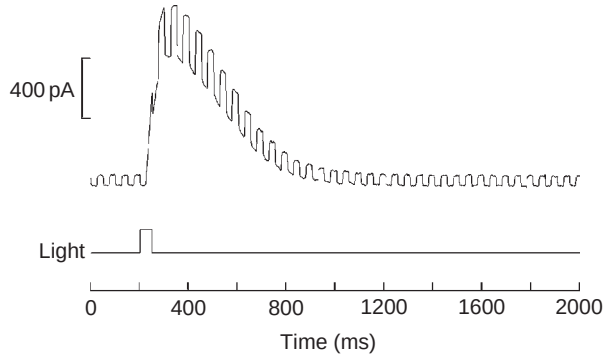

Figure 9 Light-induced increase in membrane conductance in a ciliary photoreceptor, assessed by superimposing a repetitive voltage step on the steady holding potential (10 mV, 100 Hz, and 0.5 duty cycle). When a light response was elicited, the size of membrane current perturbations grew several fold, indicating the opening of ion channels.

conductance (**Figure 9**). The reversal potential is ~–80 mV, close to the calculated value for E_K, the equilibrium potential for potassium, and exhibits a near-perfect Nernstian dependency on the concentration of extracellular potassium. Photostimulation, therefore, opens K-selective channels. Cell-attached patch recording on the ciliary appendages of the cell, presumably the light-sensitive organelles, reveals outwardly directed single-channel currents activated by light but not by voltage, with a unitary conductance ~26 pS.

Light-signaling in distal photoreceptors diverges sharply from that of their microvillar counterparts: the photoresponse is insensitive to both IP_3 and antagonists of the IP_3 receptor, and is also impervious to Ca elevation and to Ca buffering. Moreover, the guanine nucleotide-binding alpha Q protein ($G\alpha_q$) is not expressed in the distal photoreceptors of another member of the *Pectinidae*. These data strongly argue against the involvement of PLC – the canonical transduction cascade of invertebrate vision.

By contrast, substantial data have accumulated in support of a role for cGMP: intracellular application of cGMP or slowly hydrolyzing analogs (but not cAMP) elicits an outward current (**Figure 10(a)**) with similar ion-conduction properties as the light-evoked current: the reversal potential and its dependency on $[K]_o$ are the same (**Figure 10(a)**), and so is the characteristic outward rectification. Both the photocurrent and the current elicited by cGMP are inhibited by the same antagonists, such as l-*cis*-diltiazem. Furthermore, illumination and exogenous cGMP analogs interact occlusively. Activation of cGMP-dependent currents can be obtained in excised membrane patches, suggesting that cGMP operates directly on the channels. It can be concluded that cGMP is the internal final messenger for visual excitation, as it occurs in vertebrate photoreceptors.

Despite the structural and functional similarities of *Pecten* distal photoreceptors with rods and cones, a key difference places these receptors in a novel, distinct subcategory because the photoresponse is due to the opening, rather than the closing, of cGMP-gated channels. This implies that light must elevate cGMP levels, and this calls for an enzymatic machinery different from that of rods and cones. Several clues on the nature of this light-signaling pathway have emerged.

Photopigment, G Protein, and Arrestin

The molecular identity of the photopigment of ciliary receptors was elucidated in the Japanese scallop *Patinopecten yessoensis*, where a novel form of rhodopsin, dubbed SCOP2, was cloned and localized to the distal retinal layer by *in situ* hybridization. As in other invertebrates, the photopigment of scallop ciliary receptors is thermally stable upon illumination. The action spectrum, measured by both the late or the early receptor potential, peaks at 500 nm, and rhodopsin photoisomerization red-shifts its absorption curve by 75 nm; as a consequence, the fractional state of the pigment (rhodopsin (R)/metarhodopsin (M)) is a photoequilibrium that can be manipulated by varying the wavelength of illumination. A massive R to M conversion by blue-light illumination gives rise to prolonged hyperpolarizing after-potentials (or outward after-currents under voltage clamp) that can be reset by illumination with red light. Little is known about the detailed mechanisms that terminate the light response, but antibodies against bovine arrestin label a single band in Western blots of *Pecten* retinal homogenates and decorate ciliary photoreceptors both in cryosections of the eye and in dissociated retinas. Moreover, intracellular dialysis with the same antibodies slow down the falling phase of the photocurrent and allow prolonged after-currents to be elicited by spectrally neutral flashes, indicating that an arrestin-like molecule is implicated in visual excitation turn-off.

Seven transmembrane domain receptors (like rhodopsin), signal through a heterotrimeric G protein, and ciliary photoreceptors are no exception: GTP-γ-S, which interferes with G-protein deactivation, because it is resistant to the GTPase activity of Gα and associated GTPase activating proteins (GAPs), causes the flash response to become sustained. Conversely, GDP-β-S inhibits phototransduction. However, the identity of the G-protein is unusual for visual cells: the only detectable Gα form expressed in the distal retina was molecularly identified as a $G\alpha_o$, by Shichida and colleagues in *P. yessoensis*. A similar $G\alpha_o$, differing in a stretch of 22 amino acids but otherwise identical at the nucleotide level, has been cloned in *P. irradians*; this was also demonstrated to be confined to the layer of ciliary photoreceptors by *in situ* hybridization. Physiological and pharmacological data corroborate the participation of $G\alpha_o$ in light transduction: (1) mastoparan peptide activators of $G\alpha_o$ induce an outward current, which is suppressible by blockers of the light-sensitive conductance; (2) the light response is

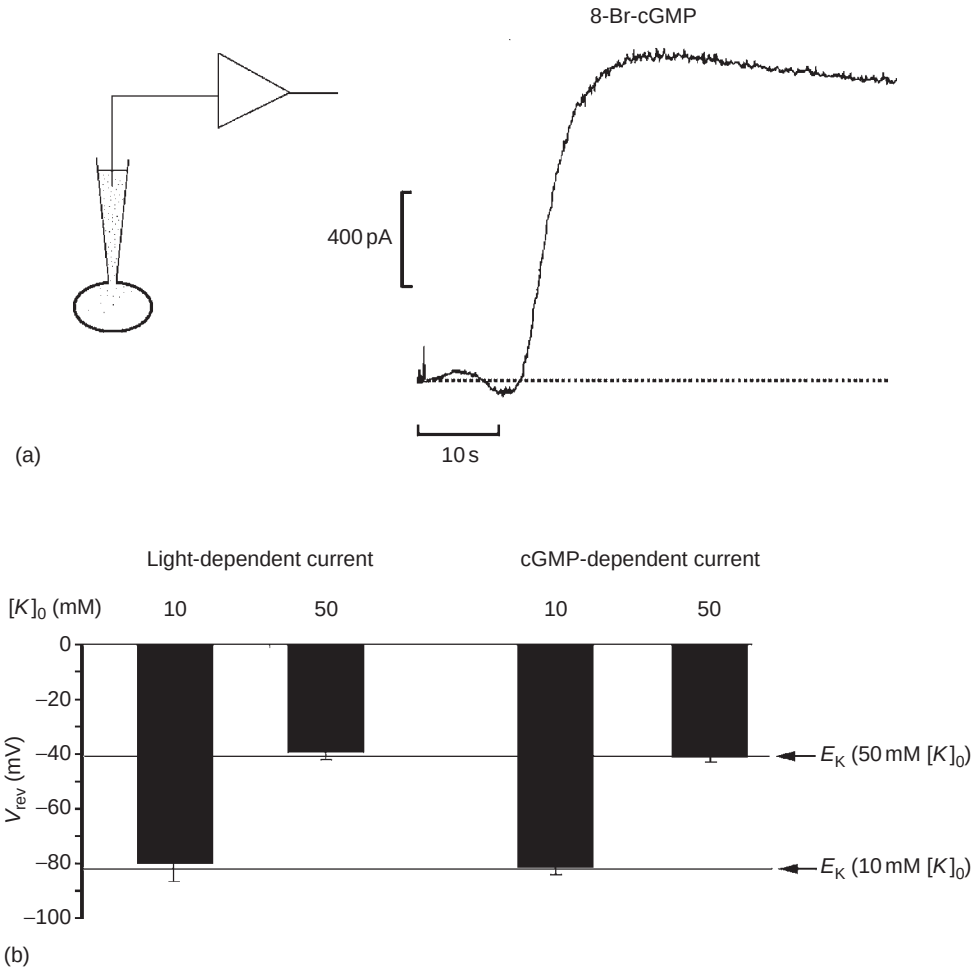

Figure 10 (a) Intracellular dialysis of an isolated ciliary photoreceptor cell with 20 μM of the cGMP analog, 8 bromo-cGMP (8Br-cGMP). Several seconds after rupturing the membrane patch to access the cell interior, a large outward current was evoked. (b) Similarity of the ion selectivity of the current elicited by light and by cGMP analogs. The reversal potential (V_{rev}) of the photocurrent was determined along with that of the current elicited by intracellular application of 8Br-cGMP. The measurements were conducted either in normal extracellular potassium (10 mM), or after elevating its concentration to 50 mM. In all cases, reversal potential V_{rev}, tracked exactly the predicted value of the *K* equilibrium potential, E_K.

inhibited by application of the A-protomer of pertussis toxin (the holotoxin moiety where the ribosyl-transferase activity resides), as predicted from the presence of a cysteine in the fourth position from the carboxy terminus of the $G\alpha_o$ sequence. This is the hallmark for susceptibility to ADP-ribosylation.

Guanylate Cyclase

The downstream mechanisms of visual excitation call for a light-induced elevation of cGMP, which could conceivably arise by either of two schemes: (1) inhibition of a phosphodiesterase (PDE) over a background of constitutive guanylate cyclase (GC) activity (i.e., the mirror image of the cGMP cascade of rods and cones) and (2) light-dependent stimulation of a cyclase (i.e., parallel to the cAMP cascade of olfactory neurons). Pharmacological antagonists of PDE fail to mimic the effects of light (i.e., they do not directly activate the photoconductance, although some of them augment the amplitude of the light response). By contrast, GC antagonists reversibly inhibit the photoresponse, suggesting that light may control cGMP production, rather than degradation (i.e., scheme (2)). Such a notion, unprecedented for visual cells, parallels the well-established role of adenylate cyclase in ciliary neurons of the olfactory epithelium, where cAMP is the internal messenger. The putative light-regulated GC, however, must not be one of the canonical soluble (sGC) or membrane (mGC) forms. First, the light response is impervious to manipulations of the nitric oxide (NO) pathway, which suggests exclusion of a soluble GC. Second, changes in intracellular Ca concentration do not alter the photocurrent, which indicates an essential divergence with respect to the regulatory mechanisms that operate in vertebrate membrane GCs. Most importantly, like in

all G-protein-coupled receptors, rhodopsin signals through a G-protein, and such a regulatory mechanism has not been reported by either class of GC. However, a new family of GCs has been uncovered in lower organisms (e.g., *Plasmodium*, *Paramecium*, and *Dictyostelium*), with the same topology as the G-protein-regulated adenylyl cyclase (class III) of olfactory neurons. In *Dictyostelium*, it has been reported that its activity is regulated by a heterotrimeric G-protein of the G_o subtype. G protein dependency for GC activity has recently been documented in Leydig tumor cells and may thus not be confined to protozoa. In *Pecten* retinal lysates, polyclonal antibodies against the multitransmembrane domain GC of *Paramecium* label a distinct band, with an apparent molecular mass of ~240 kDa, similar to that of the multitransmembrane domain GCs, and greatly exceeding that of either soluble (70–82 kDa) or other membrane-bound GCs (up to 140 kDa).

Light-Dependent Ion Channels

The molecular identity of the ion channels underlying the receptor potential of ciliary photoreceptors has yet to be established. Interestingly, in Western blots of *Pecten* retinal lysates, antibodies raised against CNG-2 (the α-subunit of the transduction channel of olfactory neurons) label a single band of the appropriate apparent molecular mass, 73 kDa; by contrast anti-CNG-1, the vertebrate retina form, and anti-CNG-3 (which is expressed in mammalian heart, kidney, and sperm) produce no signals. In whole-eye cryosections, the same antibodies selectively decorate the distal layer of the retina, where ciliary photoreceptors are found. By confocal fluorescence microscopy in dissociated cells, the target was localized in the ciliary appendages, presumed to be the light-transducing organelles. The results suggest the presence of an olfactory-like CNG channel in distal photoreceptors, with a subcellular distribution compatible with a role in visual excitation.

The light-dependent channels of distal photoreceptors are uniquely interesting because of their gating and ion-selectivity properties. It has long been known that CNG channels are homologous to some voltage-gated K channels, and a common evolutionary origin has been proposed. Nonetheless, the two classes differ sharply in terms of ion permeation, which in CNG channels is characteristically cationic nonselective. The light-dependent channels of hyperpolarizing invertebrate photoreceptors are remarkably similar to both voltage-gated K channels and CNG channels: on the one hand, they are strongly selective for potassium and highly susceptible to blockage by certain K-channel antagonists like 4-aminopyridine. On the other hand, they are gated by cGMP and blocked by various antagonists of the light-sensitive conductance of rods, such as l-*cis*-diltiazem. As such, they seemingly constitute a missing link, bridging the gap between these two superfamilies of ion channels. This raises a question about the origin of their gating mechanism. In *Pecten*, the light-dependent K conductance exhibits a pronounced outward rectification due to voltage-dependent occlusion of the permeation pathway by Ca^{2+} and Mg^{2+} ions, which bind at a site located about half-way through the membrane (electrical distance $\delta \sim 0.6$ from the external surface). Blockage by Ca^{2+} and Mg^{2+} requires an open pore, and the channels can close with a divalent ion trapped inside. These observations suggest that the cGMP-controlled gate must reside near the extracellular side of the channel protein, in sharp contrast with the intracellularly located gate of its voltage-dependent K channel relatives.

Light Adaptation

Because the primary function of ciliary cells is to produce an OFF discharge upon the dimming of a continuous light, the photoresponse is bound to have a prominent sustained component. Nonetheless, during prolonged light stimulation the photocurrent decays to a plateau, and background illumination or conditioning flashes produce all the classical manifestations of light adaptation: shift in the sensitivity curve, compression of the response amplitude range, and acceleration of response kinetics. However, the underlying modulatory mechanisms operate in an unusual way: the lack of a detectable Ca permeability of the light-activated channels and of a functional IP_3 signaling pathway implies that light stimulation is not coupled to either influx or internal release of calcium. In fact, unlike all other known photoreceptors, fluorescent Ca indicators report no discernible light-induced changes in cytosolic calcium. As a consequence, this ion would not be in a position to play a significant role in light adaptation. Not surprisingly, direct manipulations of intracellular Ca, either buffering it with the rapid Ca chelator BAPTA, or, conversely, elevating it to μM levels fails to significantly change basal light sensitivity or to alter adaptation. The Ca-independent signaling pathway responsible for light adaptation appears to implicate cGMP, the same messenger that governs visual excitation: application of cGMP analogs not only activates the photoconductance, but, on a slower timescale, also depresses the light response to an extent that far exceeds what one would expect from the decreased pool of available channels (i.e., a simple competition for a common effector mechanism). This excess reduction of the photoresponse amplitude is accompanied by a shift in the sensitivity curve and acceleration of response kinetics, the hallmark signs of light adaptation (**Figure 11**). Tests with pharmacological antagonists indicate that the changes in sensitivity during light adaptation mediated by cGMP may be in part controlled by a cGMP-dependent protein kinase.

In summary, ciliary photoreceptors found in the retina of several bivalve mollusks diverge sharply from classical (microvillar) invertebrate photoreceptors, and partake instead of several morphological and structural features of vertebrate rods and cones; nonetheless, they utilize a

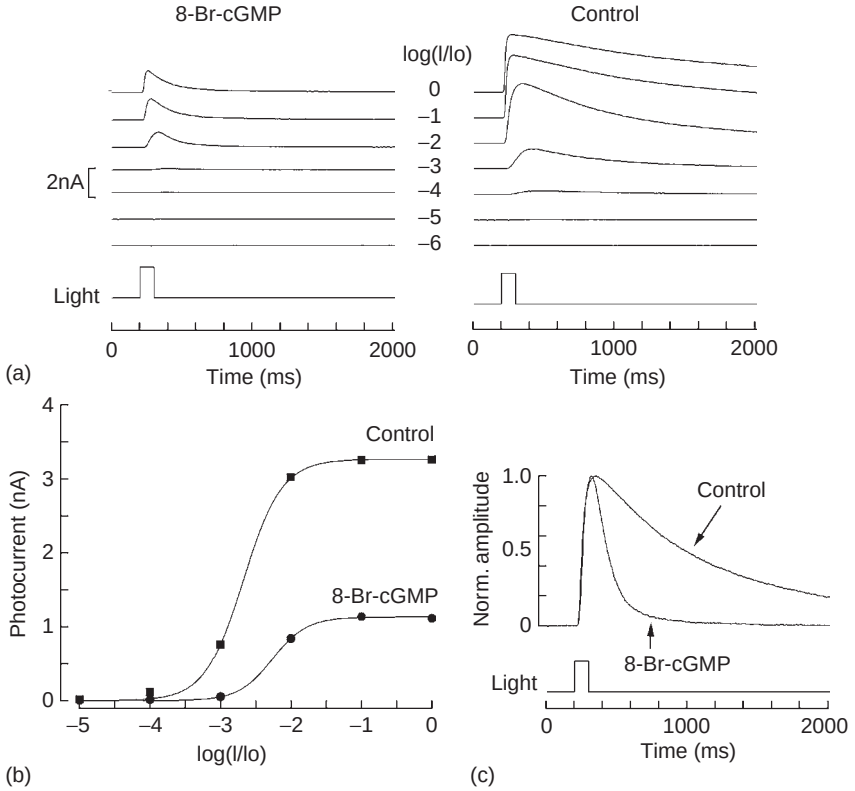

Figure 11 Photoresponse desensitization by cGMP analogs. (a) Current evoked by flashes of increasing intensity (bottom to top trace) delivered to ciliary photoreceptors internally dialyzed with 20 μM 8-Br-cGMP (left) vs. control solution (right). Log intensity for each trace indicated between two sets. (b) Intensity-response relation in the two cases in (a). In addition to the compression of response amplitude, 8-Br-cGMP shifts the curve to the right. (c) Normalized photocurrents (at –2 log) in control conditions vs. 8-Br-cGMP, highlighting the acceleration of the response decay.

fundamentally different cascade both for light transduction and for light adaptation, warranting their inclusion in a novel separate class of light-transducing cells. The parallelism with the odor-transduction cascade of olfactory neurons suggests a common lineage with an ancestral chemoreceptor cell.

Molecular and Cellular Mechanisms in Allergic Conjunctivitis

V L Calder, UCL Institute of Ophthalmology, London, UK

Glossary

Allergen – A protein to which the immune system responds.
Amblyopia – Vision disorder characterized by poor or indistinct vision in an eye that is otherwise physically normal.
Atopy – Allergic response in an area not in contact with allergen.
Conjunctiva – Tissue lining of the ocular surface comprised of epithelium and stromal layers. Bulbar conjunctiva covers the outer surface of the eye; tarsal (palpebral) conjunctiva lines the eyelids.
HLA-DR – A transmembrane human major histocompatibility complex 2 family member.
Hyperemia – Increase of blood flow to a portion of the body.
Photophobia – An abnormal sensitivity to light.
Rhinitis – Inflammation of some internal areas of the nose. The primary symptom of rhinitis is nasal dripping.

The term ocular allergy describes a spectrum of clinical conditions, ranging from the common, milder conditions of seasonal and perennial allergic conjunctivitis (SAC, PAC), to the rare but more severe diseases, vernal keratoconjunctivitis (VKC) and atopic keratoconjunctivitis (AKC). This article describes the clinically different subtypes of ocular allergy (classification summarized in Table 1) and our current understanding of the cellular and molecular pathways involved in the different forms of ocular allergy.

Ocular Allergies

Seasonal Allergic Conjunctivitis

SAC, or hay fever, is the most common form of ocular allergy and, in fact, the most common of all ocular disorders. SAC occurs only during the pollen season, the timing being dependent on which pollen is allergenic for that individual (e.g., tree, grass, weed). In countries where pollen seasons are extended, SAC can affect individuals for up to 10 months per year. It can occur at any age but is more frequently seen in children and young adults and the severity tends to lessen with age.

The symptoms of SAC include itching, watering, redness, and swelling of the eyes and lids, and there may be increased discharge. There is often an associated rhinitis and a history of atopy. During the pollen season, the ocular signs can be dramatic, usually affecting both eyes to a similar degree. Edema of the lids and conjunctiva can be mild and often outweighs the degree of hyperemia, giving a milky or pink appearance to the eye. In severe cases the swelling can be gross, with the inability to open the lids and a ballooning out of the conjunctiva termed chemosis, particularly after exposure to high aeroallergen concentrations or after rubbing of the eye. Eversion of the lids to reveal the tarsal conjunctiva demonstrates some hyperemia and mild infiltration of the conjunctiva, leading to a loss of transparency and thickening, with diffuse small inflammatory excrescences known as papillae. Since there is no serious limbal disease or conjunctival scarring, and the cornea is not involved, the visual acuity remains normal. Outside the pollen season the eye examination is normal.

Perennial Allergic Conjunctivitis

PAC is another common ocular allergy with many similarities to SAC but with a very different time course. Since the allergens in PAC are present for most or all of the year, PAC is not seasonal. The disorder is again most frequently and severely seen in children and young adults. House dust mite (*Dermatophagoides pteronyssinus*) is the most common sensitizing allergen but animal hair and dander, molds and other allergens can also induce PAC.

The symptoms are perennial and include ocular itch, discomfort, watering, redness, and some discharge. Patients may be able to correlate symptoms with exposure to an allergen. House dust mite allergy sufferers have a history of symptoms worse in the morning. Approximately one-third have an associated rhinitis, and a family and/or personal atopic history is very common. The clinical appearance is of a mild conjunctival inflammation and clinical signs may be very slight. The bulbar conjunctiva may be slightly red and edematous and the tarsal conjunctiva shows mild to moderate hyperemia, infiltration, and fine papillae. Lid edema is usually mild. Similar to SAC, in PAC there is no conjunctival scarring, or corneal involvement, such that vision is not affected. Due to the continuing presence of the allergens, the resultant inflammation in PAC is more chronic and hence the immunopathology of PAC differs from that of SAC.

Table 1 Classification of ocular allergic diseases

Disease	*Timing*	*Age group*	*Prevalance*	*Keratopathy*	*Sight threatening*	*Course*
SAC	Seasonal	Majority children and young adults	Very common	No	No	Mild, nonprogressive, often resolves
PAC	Perennial	Adult	Common	Common	No	Not serious, nonprogressive
VKC	Seasonal – Perennial if severe	Children	Uncommon	Yes	Yes	Serious, but usually resolves in 2–10 years with good outcome if well managed. Can change into AKC
AKC	Perennial	Adult	Rare	Yes	Yes	Serious and progressive, vision often reduced

SAC, seasonal allergic conjunctivitis; PAC, perennial allergic conjunctivitis; VKC, vernal keratoconjunctivitis; AKC, atopic keratoconjunctivitis.

Vernal Keratoconjunctivitis

VKC is a more serious ocular allergy of childhood. It makes up 0.1–0.5% of ocular disease in the developed world but is more common and much more severe in hot dry countries, especially the Middle East, West Africa, and the Mediterranean. It is a chronic form of conjunctivitis, usually with seasonal exacerbations. In the United Kingdom, VKC is a rare, self-limiting, often seasonal ocular allergy that affects children and young adults, most of which are male (85%) and many have a history of atopy.

The symptoms are worse in the spring and summer but, in severe disease, will last all year. Patients complain of severe itching, discomfort or pain, photophobia, stringy discharge, blurred vision, and difficulty opening the eyes in the morning. The ocular signs can be very asymmetrical. Conjunctival signs are maximal in the superior tarsal conjunctiva and limbus and the heavily inflamed lid may droop (ptosis). The conjunctival surfaces are hyperemic, edematous, and infiltrated, and a stringy mucoid discharge is present. The tarsal conjunctival tissues are densely infiltrated, with papillae that are often giant (>1 mm in diameter, known as cobblestone papillae). The limbus can have discrete swellings or, less often, diffuse hyperemia and inflammation, and the presence of small white chalky deposits (Trantas' dots) is typical of vernal limbitis. In the later stages, fine reticular white scarring may be seen, but this does not lead to significant shrinkage and distortion of the ocular surface as in some cicatrising conjunctival diseases such as AKC (see below).

Visual acuity can be affected by involvement of the cornea (keratopathy), which is most marked in the upper third of the cornea as a result of greater exposure to toxic inflammatory mediators, not mechanical rubbing by the papillae. At its mildest, there is a punctate disturbance of the epithelium, which may coalesce to form a discrete epithelial defect (macroerosion). Deposition of mucus, fibrin, and inflammatory debris can then result in the formation of a shallow oval plaque (or shield) ulcer, which repels the hydrophilic tears and the epithelial-healing response. Herpetic and bacterial corneal infection may occur. In the later stages, scarring of the cornea may lead to permanent visual reduction. Steroid treatment-related complications, and (because of the young age group) sensory-deprivation amblyopia also contribute to the potential for long-term visual loss.

Atopic Keratoconjunctivitis

AKC is the least common but most serious of the ocular allergies. It is a life-long condition that affects adults who have systemic atopic disease, either atopic dermatitis or chronic asthma. The usual onset is in the late teens but, unlike VKC, the disease is persistent and may be relentlessly progressive; occasionally the disease can begin in childhood. AKC is a highly symptomatic disorder with severe itching, pain, watering, stickiness, and redness.

There is usually facial atopic dermatitis involving the eyelids. The lid margins show severe blepharitis (chronic inflammation of the lash follicles and meibomian glands) and are thickened and hyperemic, posteriorly rounded, sometimes keratinized and the lid anatomy may be distorted with ectropion (outwardly turning eyelid), entropion (inwardly turning eyelid), trichiasis (inturning lashes), loss of lashes, and notching. The whole conjunctiva is affected and shows intense infiltration, papillae (which may be giant) and sometimes scarring with linear and reticular white scar tissue, lid to conjunctiva adhesions and shrinkage or loss of the conjunctival sac and secondary lid distortions. Marked limbal inflammation can develop and Trantas' dots may occur. The disease may never affect the cornea, in which case it is sometimes referred to as atopic blepharo-conjunctivitis (ABC); in this situation, the overall inflammation is generally less severe.

The cornea can be affected as a direct effect of the inflammatory process or may be damaged secondarily following extensive changes to the usually protective ocular surface by processes such as continual mechanical trauma, reduced lid protection, or severe loss of conjunctival tear

production. Significant visual acuity reduction due to corneal involvement occurs in 40–70% of the cases. Keratopathy may consist of punctate and macroscopic epithelial defects, filamentary keratitis, plaque ulcer, progressive scarring, neovascularization (with or without lipid deposition), thinning, and secondary corneal infections (herpetic, bacterial, and fungal). Associations between AKC and eye rubbing, keratoconus, atopic cataract, and retinal detachment have been reported.

Cellular Mechanisms in Ocular Allergy

The predominating immune mechanism occurring in SAC is an immediate (type 1) hypersensitivity response whereby conjunctival mast cells (MCs) (**Table 2**) and their secreted products primarily orchestrate the inflammatory response. In contrast, the cellular responses in PAC involve MC to a certain extent, although neutrophils and some T cells have also been detected in the conjunctival tissues, probably recruited as a result of the release of chemokines which attract these cells to the site of inflammation during the persistent allergen-driven inflammatory response. During VKC, studies have identified cells of both innate and adaptive immune responses becoming activated with T lymphocytes and eosinophils predominating, as well as MCs, neutrophils, and other cells infiltrating the conjunctival epithelium and stroma. In AKC, the predominant cell types infiltrating the conjunctival tissues are T cells, eosinophils, and neutrophils. In both VKC and AKC there are alterations to the epithelium and evidence of tissue remodeling and collagen deposition.

Conjunctival MCs

MCs are important effector cells at all mucosal sites including the conjunctiva, where rapid responses are necessary. During SAC, conjunctival MC become activated as a direct result of allergen cross-linking of surface IgE receptors (FcεR1), resulting in degranulation and release of histamine, leukotrienes, proteases, prostaglandins, cytokines, and chemokines (**Figure 1**). This rapid MC histamine response causes the itching characteristic of SAC. Upon binding to its receptors (H1 and H2), histamine induces vascular leakage, resulting in further cellular infiltration of eosinophils and neutrophils from the blood, leading to chemosis. Relative increases in mucosal MC (MC_T) were identified in tarsal conjunctival tissue specimens in SAC whereas increased numbers of both MC_T and connective tissue type (MC_{CT}) MC phenotypes have been detected in both tarsal conjunctival epithelial and substantia propria layers in PAC. The different pattern of MC subset activation occurring in PAC probably reflects the more persistent response to allergen.

Therapeutic intervention in SAC initially focused on the use of topical antihistamines in the form of eye drops, to neutralize the localized effects of the histamine secreted by the degranulating MC. Another therapeutic approach has used MC stabilizing drugs (e.g., sodium chromoglycate) to inhibit release of histamine and other secretagogues from the cells. Combinations of antihistamines with chromolyns have been used to treat the signs and symptoms of SAC for many years. However, more recent topical antiallergic drugs for treating SAC (e.g., azelastine, epinastine, ketotifen, olopatadine) combine antihistamine action with MC stabilization. The additional benefits of these drugs are in their ability to selectively prevent MC secretion of various inflammatory mediators including histamine, as well as cytokines and chemokines. Due to the presence of other cell types in the more chronic forms of ocular allergy, these antiallergic drugs are most effective in SAC and are not effective for the more severe forms of ocular allergy when used alone, but can be of some benefit when given in combination with other anti-inflammatory drugs such as steroids or cyclosporine A (see below). While specific allergen immunotherapy has been successfully used for treating other forms of allergy where the specific allergens are known, it has not been widely used for treating SAC since there is a wide variation among individuals affected with SAC in terms of their allergen responsiveness, with many

Table 2 Summary of cell types in conjunctival tissues in ocular allergy

Disease	*Predominant inflammatory cells*	*Involvement of tissue-resident cells*
SAC	MC_{CT}	None
PAC	MC_{CT} and MC_{CT}, neutrophils, T cells	None
VKC	Eosinophils, $CD4^+$T cells, neutrophils, MC	Fibroblasts, epithelium
AKC	$CD4^+$T cells, eosinophils, neutrophils, MC	Epithelium, fibroblasts

SAC, seasonal allergic conjunctivitis; PAC, perennial allergic conjunctivitis; VKC, vernal keratoconjunctivitis; AKC, atopic keratoconjunctivitis; MC, mast cells; MC_{CT}, mucosal mast cells; MC_{CT}, connective tissue mast cells.

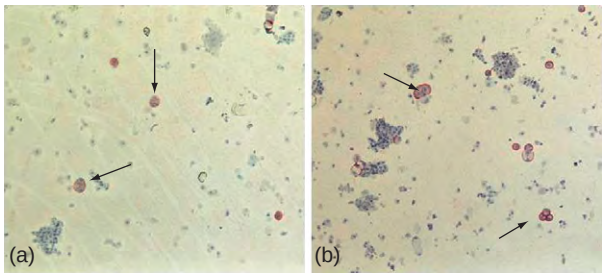

Figure 1 Conjunctival mast cells *in vitro* : (a) Unstimulated mast cells (small arrows); (b) mast cells stimulated via FecR cross-linking (large arrows). Stimulated mast cells form clusters prior to degranulating.

responding to more than one allergen. In the chronic forms of allergic eye disease (VKC, AKC), the conjunctivitis is due less to a direct allergen-specific response, but more an immune-mediated response involving local tissue resident cells, and other nonallergen-specific inflammatory cells. In those severe forms of ocular allergy, specific allergen immunotherapy would not be appropriate.

Conjunctival Eosinophils and Neutrophils

MCs are predominately responsible for SAC, but in more chronic forms of conjunctivitis other cell types have been identified as playing an important role. Some neutrophils and eosinophils have been found in less than half of symptomatic patients with SAC but little or no T cell infiltration was observed. In SAC and PAC, neutrophils and eosinophils have been observed at the site of inflammation, and both of these cell types are able to secrete a wide range of proinflammatory cytokines (interleukin (IL)-3, IL-4, IL-5, IL-6, transforming growth factor alpha (TGF-α), tumor necrosis factor alpha (TNF-α)), chemokines (IL-8, RANTES), and multiple mediators (granule proteins: eosinophil cationic protein, major basic protein, and eosinophil-derived cationic protein) to amplify the inflammatory response. In PAC, due to the presence of eosinophils, neutrophils, and some T cells, several cell-mediated processes are likely to be involved. MC-targeted therapy alone is not an effective treatment for PAC, supporting the hypothesis that there is a complex network of cells contributing to the chronic inflammation in this condition. Recently, intranasal corticosteroids have demonstrated a promising therapeutic effect in relieving the ocular symptoms associated with perennial allergic rhinitis.

In the more severe forms of ocular allergy (VKC and AKC), increased numbers of eosinophils have been detected in the conjunctival tissues, although it has also been found that it is the extent of eosinophil activation expressing intracellular adhesion molecule (ICAM)-1 or a transmembrane human major histocompatibility complex 2 family member (HLA-DR) that correlates more with disease severity than the overall numbers of eosinophils. There are differences between VKC and AKC in the patterns of cytokines which colocalize to conjunctival eosinophils, with those from VKC mainly expressing IL-3, IL-5, IL-6, and granulocyte/macrophage colony stimulating factor (GM-CSF) whereas, in AKC, eosinophils express mainly IL-4, IL-8, and GM-CSF. Although the specific cellular interactions are as yet unclear, these different cytokine profiles point to different eosinophil-mediated pathways being involved in each severe form of ocular allergy.

Conjunctival Lymphocytes

There are very few T cells detected in normal and in SAC conjunctival tissue specimens, which are mainly situated in the epithelial layer. There are a few T cells detectable in PAC but their phenotypes remain unknown. In contrast, immunostaining of tarsal conjunctival tissue specimens from VKC patients have found significantly increased numbers of lymphocytes which are mainly activated $CD4^+$ T cells, localized to the subepithelial layers of the affected tissue. There is also an increased HLA-DR expression within the epithelium and stromal layers of the conjunctival tissues as compared with normal subjects and increased numbers of Langerhans' cells and activated macrophages ($CD68^+$) were also observed. T cell clones, derived from VKC conjunctival tissues, were functionally characterized as Th2-type, since *in situ* hybridization staining demonstrated an increased Th2 cytokine (IL-3, IL-4, and IL-5) mRNA expression in VKC in areas of maximum T cell infiltration (**Figure 2**). In support of these studies, VKC tear samples were found to have increased intracellular T cell expression of IL-4 in more than 60% of the specimens. Further analysis of tear specimens using multiplex bead cytokine arrays, found that IL-4, interferon-gamma (IFN-γ), and IL-10 were all elevated in SAC and VKC in comparison with nonatopic controls. Although such studies do not identify the cellular source of the cytokines, nevertheless they illustrate the differentially activated cytokine pathways in each form of ocular allergy, perhaps due to the different cell types involved in each form of ocular allergy.

Similar to VKC, conjunctival biopsy specimens in AKC were found to have increased numbers of activated $CD4^+$T cells, HLA-DR expression, and cells of the monocyte/macrophage lineage as well as mRNA expression of the Th2 cytokines (IL-3, IL-4, and IL-5) in the stromal tissues. However, in contrast to VKC, there was also a significant increase in the expression of IL-2 mRNA, and in numbers of IFN-γ expressing T cells, suggesting a more Th1-type T cell response in the most severe of the ocular allergic diseases. In support of this, conjunctival biopsy specimen-derived T cell lines from AKC were found to secrete significantly increased levels of IFN-γ, indicative of Th1-T cells. It has thus been proposed that AKC is an

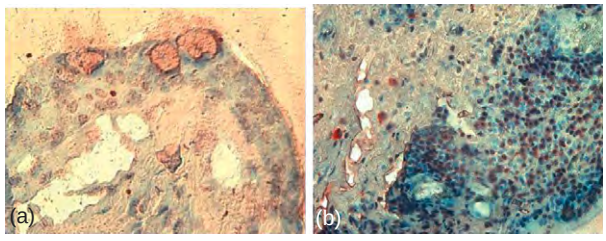

Figure 2 Light microscopy immunostaining of conjunctival biopsy tissue sections for IL-13 expression (brown): (a) weak staining for IL-13 localizing to goblet cells within the epithelial layer in SAC biopsy specimen; (b) intense staining for IL-13 (brown) localizing to mononuclear cells within the subepithelial and epithelial layers in VKC biopsy specimen (magnification ×200).

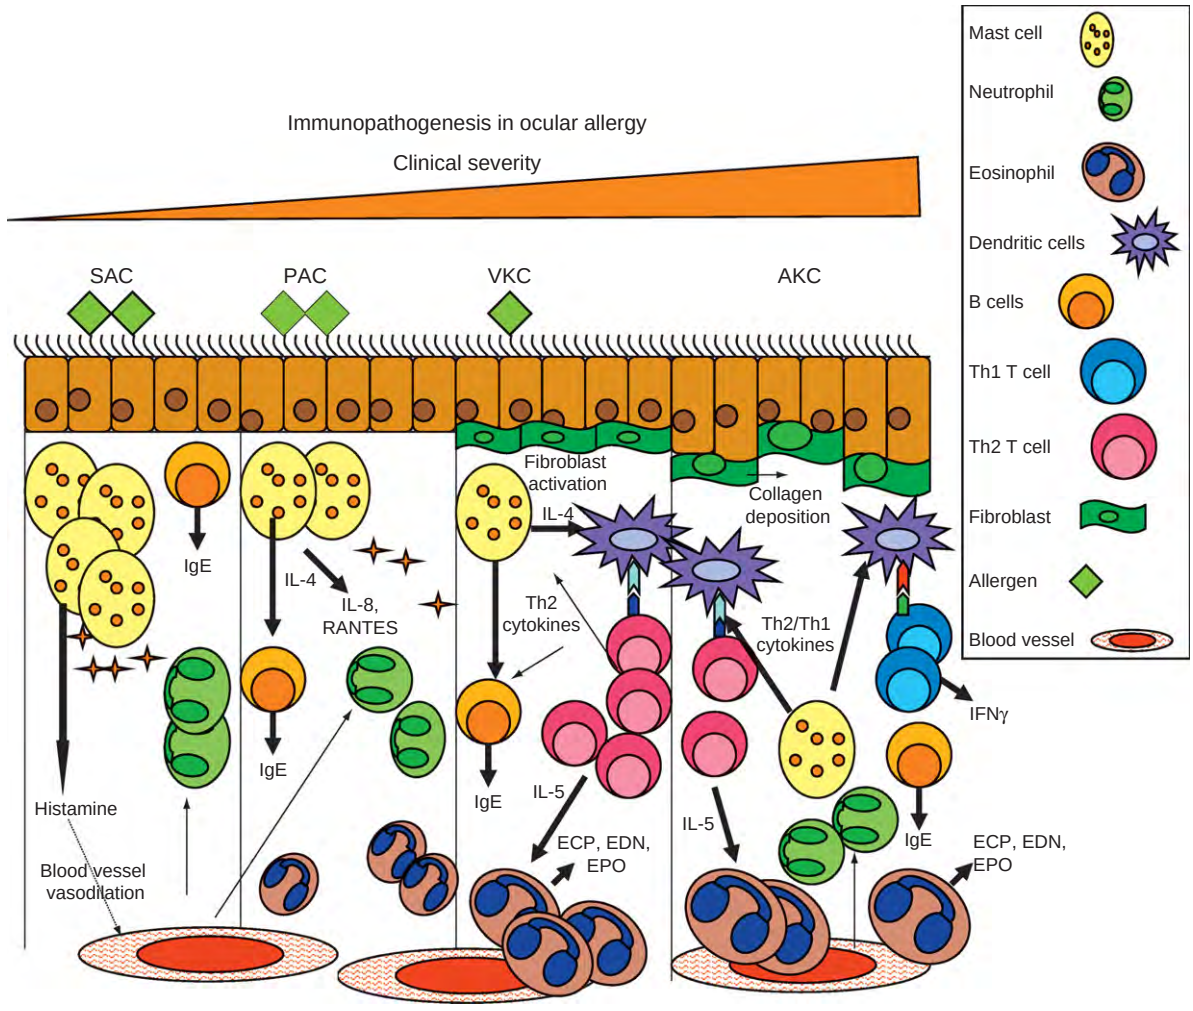

Figure 3 Schematic comparing the different types of immunopathogenis in ocular allergy. SAC, seasonal allergic conjunctivitis; PAC, perennial allergic conjunctivitis; VKC, vernal keratoconjunctivitis; AKC, atopic keratoconjunctivitis.

immune-mediated response involving Th1 T cells, whereas VKC involves a predominant Th2-type T cell response (Figure 3).

Due to the severity of the inflammation in VKC and AKC, immunosuppressive drugs (steroids) are used to dampen the immune response. However, long-term steroid treatment can have serious side effects in the eye, causing raised intraocular pressure which can lead to glaucoma, and cataract formation. Following the identification of T cells and their cytokines within the conjunctival tissues in VKC and AKC, cyclosporine A (CsA; 2% in maize oil) was tested and found to be an effective steroid-sparing treatment for VKC and AKC if administered locally as eye drops.

Conjunctival Epithelial Cells

As a consequence of chronic inflammation at the ocular surface, in particular in AKC, the epithelium can become thickened. Immunostaining of conjunctival epithelial cells from conjunctival biopsies have demonstrated an increased expression of ICAM-1 and HLA-DR, but only in the most severe forms of allergic eye disease (VKC and AKC) and almost no expression of these costimulatory molecules in noninflamed control conjunctival tissues. The ability of conjunctival epithelial cells to express ICAM-1 might allow greater adhesion and recruitment of leukocytes, while the expression of HLA-DR molecules could simply reflect the activation status of the cells, although the possibility of conjunctival epithelial cells presenting antigen to T cells is still to be confirmed. Several *in vitro* studies have used conjunctival epithelial cells, either as primary cultures of cells isolated from biopsy specimens, or as immortalized epithelial cell lines. Upon activation of conjunctival epithelial cells *in vitro*, there is an upregulation of costimulatory molecules, including ICAM-1 and HLA-DR and secretion of various cytokines such as IL-6, CCL8 (IL-8), a potent

Table 3 Summary of cytokines and molecules present in conjunctival tissues

	IL-2	*IL-4*	*IL-5*	*MMP-1, -3, -9*	*IFN γ*	*HLA-DR + epithelium*	*ICAM-1 + eosinophils*
Control	+	+	−/+	+	+	−	−
VKC	−/+	+++	+++	++	++	++	++
AKC	+++	++	+++	nd	+++	++	++

VKC, Vernal keratoconjunctivitis; AKC, atopic keratoconjunctivitis; IL, interleukin; MMP, matrix metalloproteinases; IFN, interferon; HLA-DR, a transmembrane human major histocompatibility complex 2 family member; ICAM, intracellular adhesion molecule.

chemokine for neutrophils. The ability of conjunctival epithelial cells to secrete proinflammatory cytokines and chemokines suggests an important proinflammatory role for these cells (Table 3).

Conjunctival Fibroblasts

In the severe forms of chronic ocular allergy, there is significant tissue remodeling involving collagen deposition and subepithelial fibrosis. Conjunctival biopsy-derived fibroblasts *in vitro* have been found to secrete cytokines (e.g., IL-6), chemokines (e.g., MCP-1), as well as matrix metalloproteinase (MMP)-1 and -9 and tissue inhibitor of matrix metalloproteinase (TIMP)-1. These cells were also found to respond to the Th2 cytokines IL-4 and IL-13, by secreting increased levels of eotaxin-1, IL-6, and RANTES, whereas there was a significant reduction of MMPs. Immunostaining of conjunctival biopsies from noninflamed controls and VKC identified a significant increase in MMP-1, -3, -9, and -13 expression in VKC tissues. Tear levels of MMP-1 and MMP-9 have also been found to be increased in VKC in comparison with controls, which is probably a reflection of the ongoing fibrotic tissue response.

Molecular Mechanisms

The ocular surface of the eye is a mucosal site and plays an important role in protecting the eye from infection through a mucosal barrier as well as supporting both innate and adaptive immune responses as described elsewhere in this encyclopedia. The ocular surface is protected by the presence and continuous production of tears and mucins to prevent binding of antigens, and within the tear fluid, antibodies can be found which will bind to, and activate opsonization of antigens by phagocytes. In addition, the expression of toll-like receptors (TLRs) provides another mechanism at the ocular surface, whereby binding of evolutionarily conserved microbial proteins (pathogen-associated molecular patterns, PAMPs) to these receptors induces innate and adaptive immune responses to break down and remove the invading pathogen. Immunostaining has been used to demonstrate expression of TLR-2, -4, and -9 in healthy conjunctival tissues, with expression mainly in the stromal layers. In comparison, in VKC, there is an increased expression of TLR-4 on both epithelium and stroma, together with a decrease in TLR-9. In AKC, TLR-2 expression has been found to be increased on human primary cultures of conjunctival epithelial cells following exposure to *Staphylococcus aureus*, as well as increases in ICAM-1 and HLA-DR expression and secretion of TNF-α and IL-8. This has been proposed as a mechanism whereby *S. aureus* infection at the ocular surface in AKC could activate a host epithelial cell response. In AKC, *S. aureus* colonization can occur at the ocular surface, probably due to a compromised mucosal barrier during this severe form of ocular allergy.

Costimulatory Molecules in Ocular Allergy

Immunohistochemical studies of tarsal and bulbar conjunctival biopsy specimens demonstrated expression of adhesion molecules, ICAM-1 and e-selectin, to be increased in SAC in comparison with controls. However, this increased expression was only detected during the pollen season and outside the pollen season, the levels returned to those of controls. This pattern of expression correlated with the degree of neutrophil or eosinophil infiltration in the bulbar tissue, suggesting an MC-mediated cell recruitment process.

Expression of HLA-DR and ICAM-1 molecules has been used as markers of cell activation. In AKC, there is an upregulation of HLA-DR expression and ICAM-1, localized to the epithelial cells, suggesting epithelial cell activation, probably as a result of exposure to proinflammatory cytokines as well as TLR activation. In both VKC and AKC there is an upregulation of HLA-DR expression and ICAM-1, localized to the eosinophils which correlated with an enhanced activation of these cells.

IgE in ocular allergy

Total serum IgE levels are significantly increased in VKC than in controls. However, IgE levels are variable among those with ocular allergy and cannot be used as a reliable indicator of disease activity or severity. Studies investigating allergen-specific serum IgE levels have detected a range of allergen specificities. A greater percentage of

VKC patients have specific serum IgE against *D. pteronyssinus* and *Dermatophagoides farinae*, whereas in SAC the specific serum IgE is against grass pollens. Allergen-specific IgE is also increased in tear specimens and there is a highly significant correlation with ocular allergy symptoms, supporting a diagnostic value for specific tear IgE, although limited tear volume restricts its use in routine immunoassays.

Cytokines and Chemokines in Ocular Allergy

Throughout this article, cytokines and chemokines have been discussed in relation to particular cell types. However, cell-free tear specimens have also been studied for the presence of cytokines and chemokines in the various forms of ocular allergy. Studies of VKC tear specimens have detected increased levels of IL-4, IL-10, IFN-γ, eotaxin, and TNF-α in comparison with noninflamed control tears. This correlates well with the enhanced expression of Th2-cytokines detected in isolated T cell clones from conjunctival biopsy specimens from VKC patients, as well as the increased percentages of intracellular IL-4-expressing T cells from tear specimens in VKC. In severe forms of AKC, increased tear levels of eotaxin-1 were found to correlate with increased numbers of eosinophils in tears, although the cellular source of the eotaxin was not identified.

The production of proinflammatory cytokines and chemokines by infiltrating conjunctival T cells could provide a mechanism whereby local tissue resident cells such as conjunctival fibroblasts become involved, since collagen deposition and conjunctival tissue remodeling is considerable in chronic allergic eye disease. Comparing conjunctival biopsy specimens from VKC patients with controls, increased expression of RANTES, eotaxin, monocyte chemotactic protein (MCP)-1, and MCP-3 was detected, reflecting the range of inflammatory cells present. VKC conjunctival tissue expression of the chemokine receptor CXCR3 was found to be specifically localized to T cells, and the CXC chemokine Mig was highly expressed, suggesting an important role for this ligand in recruitment of activated T cells.

In conclusion, tissue-based studies, combined with *in vitro* and *in vivo* models (not discussed in this article), have identified discrete cellular and molecular pathways in each form of ocular allergy, and this knowledge has allowed a more selective therapeutic approach. Nevertheless, currently available therapies for the more chronic forms of ocular allergic disease are limited by their side effects and there is an urgent need for improved treatments which can be given topically to reduce the impact of potential side effects.

Molecular Composition of the Vitreous and Aging Changes

P N Bishop, University of Manchester, Manchester, UK

Glossary

Collagen – This is the most abundant protein in the body and characteristically provides tissues with shape and tensile strength. Collagen molecules are composed of three polypeptide chains (called α-chains) that assemble into a triple helix. Collagen molecules form supramolecular structures such as fibrils and sheets.

Extracellular matrix – This is the material on the outside of cells that is composed of proteins, such as collagens, and carbohydrates, such as glycosaminoglycans. It provides mechanical support for cells. In addition, there is a two-way communication between cells and the extracellular matrix that regulates cellular functions, including fate, morphology, proliferation, and migration.

Glycosaminoglycans – These are long chains of carbohydrate consisting of repeating disaccharide units that are found in the extracellular matrix. Because they are highly charged, they attract ions and water, and this allows them to occupy large volumes and create a swelling pressure within tissues. All glycosaminoglycans are attached to a protein core, thereby forming proteoglycans, with the exception of hyaluronan.

Hyaluronan – Also called hyaluronic acid, hyaluronan is a unique glycosaminoglycan because it is not synthesized as attached to a protein core and is not sulfated. It exists as long unmodified chains of the repeating disaccharide units [β1-4 glucuronic acid-β1-3 *N*-acetylglucosamine]$_n$.

Posterior vitreous detachment – A collapse of the residual vitreous gel away from the inner surface of the retina as far anteriorly as the posterior border of the vitreous base. It results from a combination of vitreous liquefaction and weakening of postoral vitreoretinal adhesion. The main plane of cleavage is between the inner limiting lamina of the retina and the cortical vitreous gel, although vitreoschisis can also occur.

Introduction

The vitreous humor is a highly hydrated tissue with a water content of between 98% and 99.7%. It is surrounded by, and attached to, the retina, pars plana, and lens (Figure 1). At the vitreous base, which straddles the ora serrata, there is an unbreakable adhesion between the vitreous and peripheral retina/pars plana, but further posteriorly the adhesion is less strong and weakens with aging. When the vitreous (secondary vitreous in embryological terms) is formed, it is a gel. However, with aging, the vitreous gel gradually and inevitably liquefies. A combination of age-related gel liquefaction and weakening of postbasal vitreoretinal adhesion eventually results in posterior vitreous detachment (PVD) in 25–30% of the population during their lifetime (Figure 2). PVD is the separation of the cortical vitreous from the inner surface of the retina, which consists of a basement membrane called the inner limiting lamina (ILL), up to the posterior border of the vitreous base. PVD plays a central role in disease processes, including rhegmatogenous retinal detachment, macular hole formation, vitreomacular traction syndrome, and proliferative diabetic retinopathy. This article will discuss the macromolecular structure of the vitreous gel and the aging changes that can eventually result in PVD.

Molecular Composition of the Vitreous

Extracellular Matrix

The vitreous is in essence a dilute extracellular matrix. It contains a low number of macrophage-like cells called hyalocytes. These reside in the cortical vitreous and peripheral basal vitreous (Figure 1).

Extracellular matrices are composite structures containing network-forming macromolecules that possess complementary properties. There are fibrillar proteins that endow the tissue with shape, strength, flexibility, and resistance to tractional forces. Then there are charged carbohydrates, particularly glycosaminoglycans (GAGs), that attract counter-ions and water thereby providing a swelling pressure that spaces apart the fibrillar proteins, inflates the tissue and resists compressive forces. In vitreous the main fibrillar proteins are collagens and in mammalian vitreous the predominant GAG is hyaluronan (Figure 3).

Vitreous Collagens

The vitreous gel contains a low concentration of collagen, estimated to be approximately 300 μg ml^{-1} in the adult human eye. Vitreous collagen is mainly synthesized during

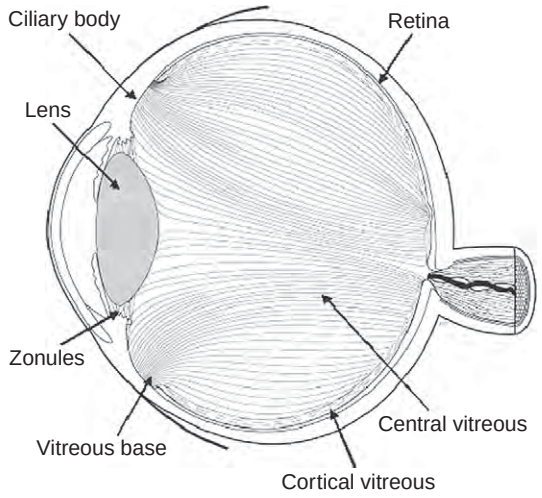

Figure 1 Anatomy of the vitreous. The vitreous is surrounded by and attached to the retina, ciliary body, and lens. The central vitreous forms the bulk of the vitreous body; in this region, the collagen fibrils are at their lowest concentration and tend to be orientated in an anterior–posterior direction. The collagen fibrils of the basal vitreous are at a higher concentration and are orientated perpendicular to the vitreous base, here they insert into the pars plana and the peripheral retina and form an unbreakable adhesion. The vitreous cortex is a thin layer (100–300 μm) that surrounds the central vitreous that has a higher concentration of collagen fibrils than the central vitreous. The anterior cortex courses from the anterior vitreous base across to the posterior surface of the lens. The posterior vitreous cortex lines the surface of the retina behind the vitreous base where it is adherent to the ILL. There is no vitreous cortex over the optic disk and it is thinned over the macula. The cortical collagen fibrils are orientated parallel with the inner retinal surface and they do not generally insert directly into the ILL. Reproduced from Le Goff, M. M., and Bishop, P. N. (2008). Adult vitreous structure and postnatal changes. *Eye* 22: 1214–1222, with permission of the Nature Publishing Group.

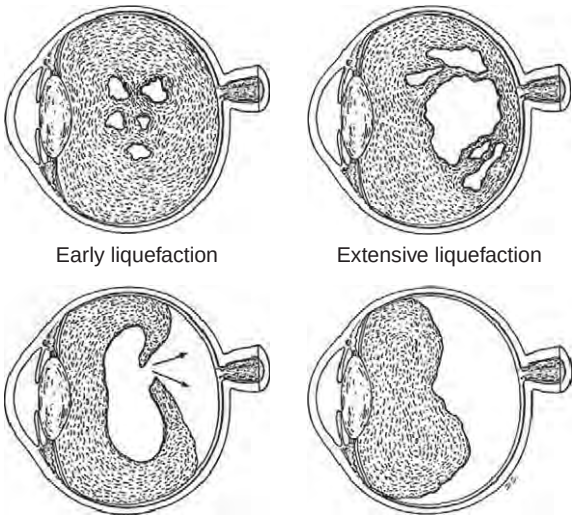

Figure 2 Age-related vitreous liquefaction and PVD. Pockets of liquefaction appear within the central vitreous and these gradually coalesce with aging. There is a concurrent weakening of postoral vitreoretinal adhesion. Eventually, these combined processes can result in PVD where the liquid vitreous dissects the residual cortical gel away from the ILL as far anteriorly as the posterior border of the vitreous base. Reproduced from Le Goff, M. M., and Bishop, P. N. (2008). Adult vitreous structure and postnatal changes. *Eye* 22: 1214–1222, with permission of the Nature Publishing Group.

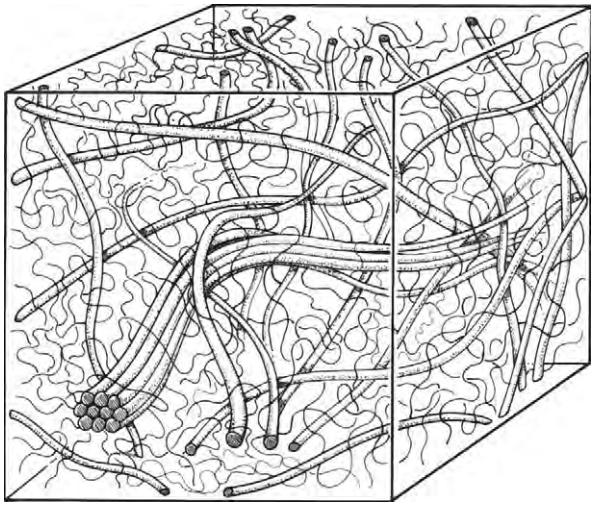

Figure 3 Schematic representation of the cooperation between two networks responsible for the gel structure of the vitreous. A network of collagen fibrils maintains the gel state and provides the vitreous with tensile strength. A network of hyaluronan (thin black lines) fills the spaces between these collagen fibrils and provides a swelling pressure to inflate the gel and help space apart the collagen fibrils. Reproduced from Le Goff, M. M., and Bishop, P. N. (2008). Adult vitreous structure and postnatal changes. *Eye* 22: 1214–1222, with permission of the Nature Publishing Group.

embryonic development and thereafter the rate of synthesis is low. It remains unclear how much degradation of vitreous collagen occurs, but it is likely that the rate of turnover is low and indeed it is possible that collagen fibrils that are formed during embryonic development last throughout life.

Collagen molecules are composed of three polypeptide chains (α-chains) that fold into a characteristic triple-helical configuration. They also contain nontriple helical regions of varying size that are present at each end of the molecule, and in some collagens interrupt the main triple-helical region. The triple-helical fold results from the α-chains having a glycine at every third amino acid, that is, a $(Gly–X–Y)_n$ sequence where X and Y can be any amino acids, but are frequently the imino acids proline and hydroxyproline. Hydroxyproline is important in stabilizing the structure of the collagen triple helix by forming extra hydrogen bonds, while lysine and hydroxylysine residues are necessary for the formation of cross-links which stabilize the collagen fibril.

There are at least 28 different types of collagen molecules (i.e., collagen types I – XXVIII). The commonest collagens are fibril-forming collagens, including types I, II, III and V/XI, but others such as type IV collagen form

sheets (in basement membranes). When fibril-forming collagens are secreted into the extracellular environment they are in a soluble precursor form, the procollagen, and have terminal extensions called N- and C-propeptides. Cleavage of these propeptides by specific enzymes produces a mature collagen with just short noncollagenous (NC) telopeptides at the ends of the triple-helical molecule; this removal (or processing) of the propeptides allows the mature collagen molecules to assemble into fibrils. In some instances the N-propeptides are not removed from fibrillar collagens, but these collagens can still participate in fibril formation and the N-propeptides are then retained on the fibril surfaces.

In vitreous humor nearly all of the collagen is in thin, uniform fibrils that are about 15 nm in diameter. These fibrils are heterotypic (of mixed composition) and contain the fibril-forming collagen types II and V/XI, along with type IX collagen (**Figure 4**). The molecules within the fibrils are cross-linked together to make the fibrils strong and resilient. The collagen fibrils of cartilage have a similar, but not identical, composition and contain collagen types II, XI, and IX. This explains why hereditary collagenopathies such as Stickler syndrome affect both vitreous and cartilage.

Type II collagen

Collagen type II is a fibril-forming collagen that forms the bulk of the vitreous collagen fibrils, accounting for 60–75% of the collagen within the fibrils. It is composed of three identical α-chains, that is, its α-chain composition is $\alpha1(II)_3$. The N-propeptide contains an additional domain that is present in some, but not all of the vitreous type II procollagen, but is absent from cartilage type II procollagen. The presence or absence of this von Willebrand type C domain is dependent on alternative splicing of exon 2 of the type II procollagen gene. Its function remains uncertain, but interestingly it binds transforming growth factor-β and bone morphogenic protein-2, so it may play a role in regulating eye development. This tissue-specific differential splicing of exon 2 explains why patients have been identified with mutations in exon 2 that have a predominantly ocular or ocular only form of Stickler syndrome.

Type V/XI collagen

Type V/XI collagen is a minor component (10–25%) of the heterotypic vitreous collagen fibrils. Its chain composition is probably $\alpha1(XI)_2\alpha2(V)$. The N-terminal domain of type V/XI collagen is not removed by processing and is retained on fibril surfaces where it may play a role in regulating fibril diameter by sterically hindering the lateral growth of the fibrils. There is evidence that a closely related collagen called type V collagen has an essential role in the initiation of collagen fibril formation in tissues where it forms heterotypic fibrils with type I collagen, so type V/XI collagen may have a similar role in initiating collagen fibril formation in the vitreous.

Type IX collagen

Type IX collagen represents up to 25% of the collagen in the heterotypic vitreous fibrils and it is made up of three distinct α-chains, that is, α1(IX)α2(IX)α3(IX). It is not a

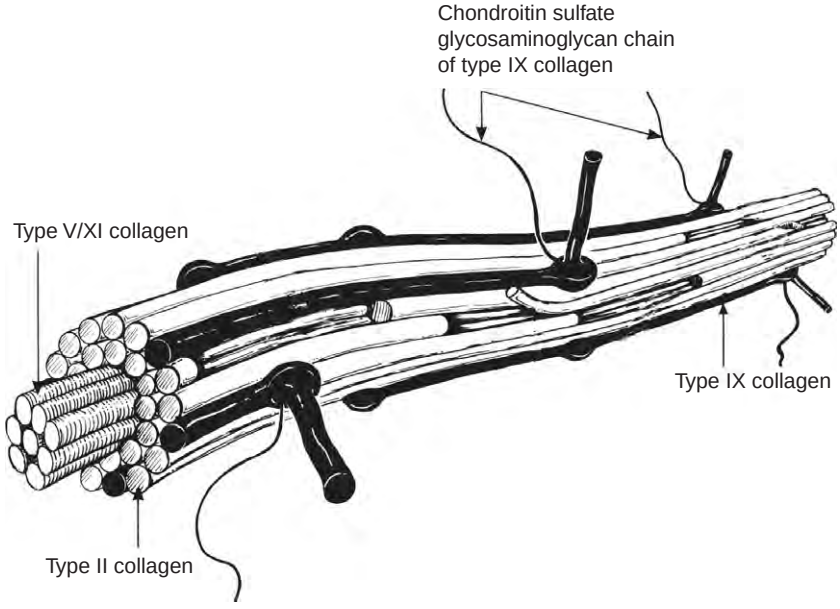

Figure 4 Cartoon representation of the heterotypic collagen fibrils of the vitreous. The fibrils contain collagen types II, V/XI, and IX. Collagen types II and V/XI are fibril-forming collagens that align in staggered arrays to form a central core to the fibrils. Type IX collagen is a chondroitin sulfate proteoglycan that is regularly distributed along the surface of the fibrils. The N-propeptides of type V/XI collagen are retained and located on the surface of the fibrils and some of the N-propeptides of type II collagen may be retained on the fibril surfaces. Reproduced from Bishop, P. (1996). The biochemical structure of mammalian vitreous. *Eye* 10: 664–670, with permission of Macmillan Publishers Ltd.

fibril-forming collagen. Instead it is regularly cross-linked to the surface of the collagen fibrils, which have a core formed by the type II and V/XI collagens. It is a member of the family of fibril-associated collagens with interrupted triple helices (FACIT), which also includes collagen types XII, XIV, and XVI. These collagens have (NC) domains interspersed between collagenous (COL) regions. In the case of type IX collagen there are three COL domains (COL1, COL2, and COL3) interspersed between four NC domains (NC1, NC2, NC3, and NC4). Further complexity is added by the α1(IX) collagen gene (COL9A1) using tissue-specific alternatively spliced transcription start sites, resulting in a form in cartilage that has a globular NC4 domain, but this domain is almost absent in vitreous. The functional significance of these differences remains unclear.

Type IX collagen can exist in proteoglycan and non-proteoglycan forms with the proteoglycan form having a single chondroitin sulfate chain attached to the α2(IX) chain in the NC3 domain. In vitreous, the type IX collagen is synthesized in a proteoglycan form, but the length and sulfation pattern of the chondroitin sulfate chain is species dependent. In mammalian vitreous it has a relatively short chondroitin sulfate chain (15–60 kDa), but in chick vitreous it is very long (approximately 350 kDa).

Synthesis of vitreous collagen

Evidence from a variety of studies suggests that during embryonic development vitreous collagens are mainly synthesized by the ciliary body. The posterior nonpigmented ciliary epithelium secretes the collagen molecules that assemble into fibrils in or around these cells. The fibrils are then extruded into the vitreous cavity. This provides an explanation for the perpendicular orientation of the collagen fibrils in the basal vitreous relative to the nonpigmented ciliary epithelium, and the unbreakable adhesion at the vitreous base.

While the levels are low, there is good evidence that some postnatal vitreous collagen synthesis occurs. Interestingly, this appears to carry on into adulthood and to take place in the peripheral retina. The cells responsible for collagen synthesis in the adult eye are yet to be conclusively identified. This new vitreous collagen synthesis in the adult eye results in the formation of a mat of collagen fibrils on the cellular side of the peripheral ILL. Some of these collagen fibrils break through the ILL and become intertwined with the preexisting cortical vitreous collagen. This process then results in the formation of new unbreakable vitreoretinal adhesions and thereby extends posteriorly at the posterior border of the vitreous base (**Figure 5**). At birth, the vitreous base is at the ora serrata, but it extends posteriorly with aging and has been shown to have migrated over 3.5 mm behind the ora serrata as a result of this process. Irregularities of the posterior border of the vitreous base resulting from uneven posterior extension will predispose to rhegmatogenous retinal detachment during PVD.

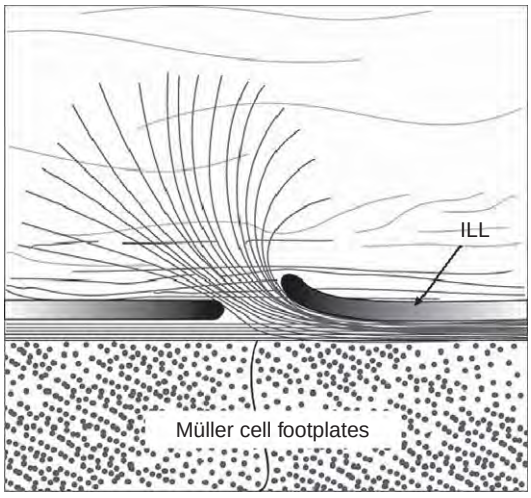

Figure 5 Extension of the posterior border of the vitreous base. There is a very strong adhesion at the vitreoretinal interface within the vitreous base because vitreous collagen fibrils insert directly into the posterior ciliary body and peripheral retina. The vitreous base extends posteriorly into the peripheral retina with aging as a result of the adult peripheral retina synthesizing new collagen. This new collagen forms a mat-like layer on the cellular side of the ILL, and some of this collagen breaks through defects in the ILL and intertwines with preexisting cortical vitreous collagen thereby creating new adhesions and extending the vitreous base posteriorly. Reproduced from Le Goff, M. M., and Bishop, P. N. (2008). Adult vitreous structure and postnatal changes. *Eye* 22: 1214–1222, with permission of the Nature Publishing Group.

NC Proteins and Glycoproteins

Opticin

The heterotypic collagen fibrils of the vitreous are coated with a molecule called opticin. It is a glycoprotein member of the extracellular matrix small leucine-rich repeat protein/proteoglycan (SLRP) family. This family comprises of approximately 11 members and are characterized by a domain containing a number of tandem leucine-rich repeats (LRRs) flanked by disulfide-bonded capping motifs. LRRs are 20–30 amino acid repeats that contain the consensus sequence LXXLXLXXNXL, where L can be a leucine, isoleucine, or valine residue, N is an asparagine, cysteine, or threonine residue and X can be any amino acid. Opticin possesses eight tandem LRRs and an N-terminal extension containing a cluster of sialylated O-linked oligosaccharides. Opticin exists as a dimer in solution as a result of interactions between the LRR domains. Other members of the SLRP family have been shown to play a role in regulating collagen fibril diameter, but this does not appear to be the case for opticin. Instead, opticin appears to modify the vitreous collagen fibril surfaces that are presented to invading cells during pathological processes, such as preretinal neovascularization, and thereby it can attenuate disease processes.

Other proteins and glycoproteins

Vitreous contains many other proteins. Some are derived from the serum and others are produced locally. As well as the molecules described above there are other extracellular matrix components in the vitreous, but their functions remain uncertain. Fibrillin-containing microfibrils have been demonstrated in vitreous. The zonules are composed of bundles of these fibrils and it is unclear whether the vitreous fibrillin-containing microfibrils have a structural role or whether they are a byproduct of zonular synthesis or breakdown. A small amount of type VI collagen is present, this forms its own distinctive microfibrils, but again it is unclear if these have a significant structural role. Fibronectin has been identified in vitreous and it has been postulated that it is involved in vitreoretinal adhesion. A number of other extracellular matrix components have been identified using proteomics in embryonic chick vitreous.

GAGs and Proteoglycans

GAGs are long chains of repeating disaccharide units that undergo varying degrees of modifications during their synthesis, including sulfation, epimerization, and acetylation/deacetylation. These modifications alter the charge of the GAGs and can create specific binding sites for other molecules. All GAGs are attached to a core protein, thereby forming proteoglycans, except hyaluronan which is uniquely synthesized at cell surfaces and is not linked to a core protein.

Hyaluronan

Hyaluronan is the predominant GAG in mammalian vitreous. It is composed of very long carbohydrate chains consisting of the repeating disaccharide [β1-4 glucuronic acid-β1-3 *N*-acetylglucosamine]$_n$. These chains are not modified by sulfation or epimerization. In adult human vitreous, the hyaluronan concentration has been estimated to be between 65 and 400 μg ml^{-1} and the average molecular weight to be 2–4 million.

Chondroitin sulfate proteoglycans

The repeating disaccharide unit of chondroitin sulfate is [β1-4 glucuronic acid-β1-3 *N*-acetylgalactosamine]$_n$. The C-4 and C-6 of the *N*-acetylgalactosamine residues are variably sulfated, and less frequently the C-2 of glucuronic acid. Vitreous is known to contain two chondroitin sulfate proteoglycans, type IX collagen (see section on collagens) and versican. Versican is a large proteoglycan with a central domain that carries multiple chondroitin sulfate chains. At its N-terminus it has a hyaluronan-binding domain that presumably binds vitreous hyaluronan and this binding is stabilized by a link protein. However, as the hyaluronan is in a 150:1 molar excess to the versican and link protein, the structural role of versican in vitreous remains uncertain. Nonetheless, it is of note that the hereditary vitreoretinopathy Wagner syndrome is caused by splice site mutations in versican.

Heparan sulfate proteoglycans

Heparan sulfate and heparin share the same repeating disaccharide unit [β1-4 glucuronic acid-α1-4 *N*-acetylglucosamine]$_n$. The GAG chain is variably modified by sulfation, deacetylation, and epimerization. The degree of modification determines whether the GAG is heparan sulfate or heparin. Heparan sulfate proteoglycans are major components of basement membranes, including the ILL. Heparan sulfate proteoglycans are present in the embryonic vitreous, possibly in transit to form the ILL, but the levels are very low in postnatal eyes.

Supramolecular Organization of the Vitreous

The vitreous collagen fibrils and hyaluronan form two interwoven networks (**Figure 3**). The network of (heterotypic) collagen fibrils is essential for the gel state of the vitreous, as removal of these collagen fibrils converts the vitreous into a viscous liquid. Furthermore, it is through this network of collagen fibrils that tractional forces are transmitted in vitreoretinal diseases. The hyaluronan network inflates the vitreous, increases its mechanical stability and contributes to the spacing of the collagen network, but surprisingly the hyaluronan network can be removed without destroying the vitreous gel, at least in the short term. The long hyaluronan chains form a network primarily through entanglement and this network probably interacts weakly with the collagen fibrillar network.

The vitreous collagen fibrils are long and unbranched. Analysis by freeze-etch rotary shadowing electron microscopy showed that the collagen fibrils are arranged in bundles within the vitreous and form an extended interconnected network by branching between these bundles (**Figure 6(a)**). In the young eye the vitreous collagen fibrils within the bundles appear to run closely together and in parallel, but are not fused. Morphological analyses suggest that the chondroitin sulfate chains of type IX collagen play a role in both connecting together and spacing apart the collagen fibrils within these bundles (**Figure 7**).

Aging Changes that Predispose to PVD

Age-Related Vitreous Liquefaction

The human vitreous humor undergoes an inevitable process of liquefaction (or syneresis) with aging. Initially

small pockets of liquefaction form, but these coalesce with aging to produce more extensive areas; so by the age of 80–90 years typically more than half of the vitreous cavity is filled with liquid. Ultrastructural studies have shown that vitreous collagen fibrils aggregate with aging into macroscopic strands. Age-related vitreous liquefaction is probably caused by this gradual and progressive aggregation of the collagen fibrils resulting in a redistribution of the collagen fibrils, with the aggregated collagen fibrils being concentrated in the residual gel and other areas therefore becoming devoid of collagen fibrils and consequently converted into liquid.

The spacing between the collagen fibrils appears to be maintained by the chondroitin sulfate chains of type IX collagen (**Figures 6** and 7). However, we have shown that there is a progressive loss of type IX collagen from the surface of the human vitreous collagen fibrils with aging, and that the half-life of type IX collagen on the fibril surfaces is just 11 years of age. This loss of type IX collagen (along with its chondroitin sulfate chains) will result in a loss of spacing between the collagen fibrils. Furthermore, the loss of type IX collagen results in the increased exposure of sticky type II collagen on the fibril surfaces, so when the collagen fibrils come into contact (as a result of eye movement) they will have a propensity to fuse irreversibly.

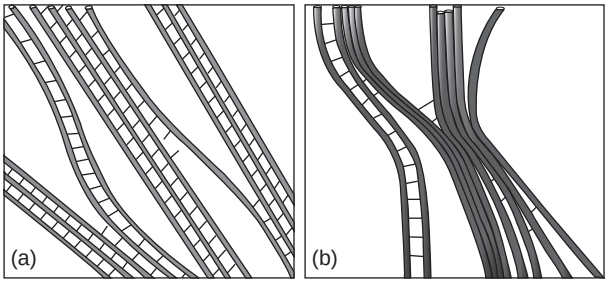

Figure 6 The collagen fibrillar network of the vitreous and aging changes. (a) The collagen fibrils (thick gray lines) form an extended network by being organized into small bundles that are interconnected by collagen fibrils running from one bundle to another. Within each bundle the collagen fibrils are both connected together and spaced apart by the chondroitin sulfate chains of type IX collagen (thin black lines). (b) With aging there is a loss of type IX collagen from the fibril surfaces. The loss of the type IX collagen from the fibril surfaces combined with an increased surface exposure of type II collagen results in aggregation of the collagen fibrils. Reproduced from Le Goff, M. M., and Bishop, P. N. (2008). Adult vitreous structure and postnatal changes. *Eye* 22: 1214–1222, with permission of the Nature Publishing Group.

Figure 7 The role of the chondroitin sulfate chains of type IX collagen in maintaining the spacing between vitreous collagen fibrils. Electron micrographs of vitreous collagen fibrils stained with uranyl acetate (to visualize the collagen fibrils) and the cationic dye Alcian blue (to visualize the chondroitin sulfate chains of type IX collagen). The Alcian blue-stained chondroitin sulfate chains appear to bridge between adjacent collagen fibrils and thereby both space the collagen fibrils apart and link them together. (Scale bar 300 nm).

Weakening of the Vitreoretinal Adhesion

In young eyes there is a relatively strong adhesion between the cortical vitreous and the ILL of the postoral retina, but this weakens with age. The cortical vitreous collagen fibrils do not generally insert directly into the postoral ILL, so it is assumed that the molecular basis of the vitreoretinal adhesion is interactions between components on the surface of cortical vitreous collagen fibrils and macromolecules on the inner surface of the ILL. There is evidence that type XVIII collagen is involved in vitreoretinal adhesion from studies of knockout mice and early PVD in patients with Knobloch syndrome, a rare autosomal recessive condition that results in a lack of type XVIII collagen. Type XVIII collagen is a heparan sulfate proteoglycan. It has been shown that opticin can bind heparan sulfates including those of type XVIII collagen and opticin and type XVIII collagen colocalize at the vitreoretinal interface. Therefore, the opticin on the surface of cortical vitreous collagen fibrils could bind heparan sulfate proteoglycans of the ILL including type XVIII collagen, thereby contributing to vitreoretinal adhesion. However, opticin knockout mice do not appear to develop spontaneous vitreoretinal disinsertion, suggesting that other molecular interactions also contribute to vitreoretinal adhesion, at least in the mouse eye.

Conclusions

Although the vitreous only contains a dilute dispersion of collagen fibrils, it is these fibrils that are central to the gel structure of the vitreous. Molecules on the surface of these collagen fibrils are essential for maintaining the gel state (such as type IX collagen) and play a key role in vitreoretinal adhesion. Alterations in the molecular interactions of the collagen fibrils lead to vitreous liquefaction, weakening of vitreoretinal adhesion, and a consequent predisposition to PVD.

Molecular Genetics of Congenital and Juvenile Glaucoma

M Acharya and M A Walter, University of Alberta, Edmonton, AB, Canada

Glossary

Congenital glaucoma – A rare genetic disorder that usually manifests itself at birth or within the first year of life, but may emerge up to the age of 3.
Glaucoma – A multifactorial optic disk neuropathy with a complex genetic basis, in which there is a characteristic acquired loss of retinal ganglion cells and atrophy of the optic nerve.
Juvenile glaucoma – Another subtype of glaucoma based on time of onset. Individuals presenting with open-angle glaucoma before the age of 35 are classified as having juvenile glaucoma.
Mutation – Mutations are changes in nucleotide sequences of an organism's genetic material. Mutations in a gene often have deleterious effects and are often associated with disease.
Open-angle glaucoma – The most common subtype of glaucoma based on anatomy of the anterior chamber of the eye. In open-angle glaucoma, the angle between iris and cornea, often referred to as the iridocorneal angle, remains open.
Trabecular meshwork – A mesh-like structure composed of endothelial cells located between the iris and cornea in the anterior chamber of the eye covering the Schlem's canal. The trabecular meshwork regulates aqueous outflow from the eye thereby maintaining the physical shape of the eye.

Definition of Glaucoma

Glaucoma is the second-largest blinding disorder after cataract. According to the latest estimates, glaucoma affects about 60 million people worldwide. Globally, 12.3% of all blind people suffer from glaucoma. Glaucoma refers to a heterogeneous group of optic neuropathies, with a complex genetic basis. It is a multifactorial optic disk neuropathy, in which there is a characteristic acquired loss of retinal ganglion cells and atrophy of the optic nerve. These neuropathies gradually reduce vision without warning and often without symptoms. At least half of patients with glaucoma do not know they have glaucoma due to lack of symptoms. Untreated glaucoma is a leading cause of irreversible blindness.

Major Subtypes of Glaucoma

Glaucoma is classified according to etiology (primary vs. secondary), anatomy of the anterior chamber (open angle vs. closed angle), and time of onset (infantile vs. juvenile vs. adult). In general, primary glaucoma is broadly classified into three major groups: (1) open-angle glaucoma (OAG), (2) angle-closure glaucoma, and (3) congenital glaucoma (CG) (**Figure 1**). OAG is further subdivided according to age of onset as (1) juvenile OAG (JOAG) and (2) adult-onset glaucoma. In addition, a number of ocular conditions, such as Axenfeld–Rieger syndrome (ARS), Peters anomaly, and nail–patella syndrome (NPS), which result from an abnormal differentiation of neural crest cells, are also reported to be associated with glaucoma (**Table 1**).

Secondary glaucoma can develop due to multiple reasons. The most common types are inflammatory or drug-induced glaucoma. In addition, exfoliation syndrome and pigment dispersion syndrome are two common disorders that can result in secondary glaucoma through blockage of the trabecular meshwork (TM).

Prevalence and Clinical Features of JOAG and CG

OAG is the most common type of glaucoma affecting about 33 million people worldwide. Individuals presenting with OAG before the age of 35 are classified as having JOAG. However, approximately 1% of JOAG patients present clinical symptom before 5 years of age. Almost 39% of JOAG patients present the symptoms between the age range of 15 and 20 and 21% between ages 20 and 25. The glaucoma symptoms of JOAG, which are usually associated with variable severity and phenotypic expression, are severe and respond poorly to treatment.

CG is a rare genetic disorder that usually manifests itself at birth or within the first year of life, but may emerge up to the age of 3. Characteristic clinical features of CG include tearing, photophobia, megalocornea, corneal opacity with characteristic Haab's striae, and enlargement of the eyeball (buphthalmos meaning ox eye) resulting from elevated intraocular pressure (IOP). Unless managed properly, the disease may eventually lead to optic-nerve damage and permanent loss of vision (**Figure 2**). The incidence of CG varies geographically, for example, 1 in 10 000 in Caucasians, 1 in 2500 in Middle East, 1 in 1250 in Romany population of Slovakia, and 1 in 3300 in the Indian state of Andhra Pradesh.

Molecular Genetics of JOAG: Mapped Loci and Identified Candidates

OAG (OMIM # 137760) is transmitted both as a monogenic as well as a complex disease. In juvenile- and adult-onset OAG, genetic linkage analysis in affected families clearly suggests autosomal-dominant inheritance with incomplete penetrance. Luntz, in 1979, already suggested that adult-onset OAG is inherited as a non-Mendelian trait, whereas juvenile-onset OAG exhibit autosomal-dominant inheritance. The genetic relationship of adult-onset OAG and JOAG is not yet clear since, while a given OAG family may show a predominant diagnosis of either OAG or JOAG, some family members may have either of the diagnoses. Three JOAG genetic loci have been identified so far (GLC1A or JOAG1, GLC1J or JOAG2, and GLC1K or JOAG3). Details with references have been cited in **Table 1**.

Myocilin (*MYOC*) as a Primary Candidate for JOAG

Overview

In 1993, the first genetic locus for OAG (GLC1A) was identified and, in 1997, the causal gene, myocilin (*MYOC*), (OMIM # 601652) was discovered. In 1997, Polansky and coworkers identified the protein now known as myocilin while studying the effects of steroids on the TM cells in culture. In the eye, the TM cells help regulate eye pressure by controlling the drainage of aqueous humor from the eye. The cultured cells when treated with steroids secreted the same protein, which was called TM-inducible glucocorticoid response protein (TIGR). The gene (*MYOC/TIGR*), located in chromosome 1q24.3, spans about 17 kb region in the genomic DNA and contains three exons. Fingert and coworkers showed by northern blot analysis that *MYOC* is expressed as a 2.3 kb transcript and the translated product is predicted to contain 504 amino acids (57 kDa). Myocilin is a glycoprotein that exists in glycosylated and nonglycosylated forms, with molecular weights of 66 and 55 kDa, respectively, in both intracellular and extracellular locations. Myocilin has two major domains: a myosin-like domain at the N-terminus encoded by exon 1 and an olfactomedin-like domain at the C-terminal region encoded by exon 3.

Analysis of Mutations and Polymorphisms Associated with JOAG in *MYOC*

Known mutations in *MYOC* causing OAG are listed in the Human Genome Mutation Database (HGMD). It is estimated that *MYOC* mutations occur in 2–4% of OAG patients from a variety of ethnic background. Among the three exons of *MYOC*, mutations are mostly clustered in exon 3 (56 mutations), located rarely in exon 1 (eight mutations) and none has been detected so far in exon 2. In 2001 null mice for *MYOC* were created. Interestingly, these null mice had normal morphology of the eye and no

Figure 2 Diminishing vision in glaucoma.

glaucomatous features, suggesting that *MYOC* mutation does not cause glaucoma through haplo-insufficiency but through a dominant negative effect.

An interesting *MYOC* mutation (Lys423Glu) was described in a French–Canadian family, which resulted in a dominant negative effect when present in single dosage but had no phenotypic effect when present in both copies of the gene. The findings represent the first example of autosomal dominant metabolic interference. In metabolic interference, homozygosity for the normal allele *XX*, or for the mutant allele *xx*, both result in a normal phenotype. Only the heterozygous condition *Xx* produces an abnormal phenotype because the two alleles, when present together, interact to produce a harmful effect. These mutant proteins, resulting from Lys423Glu and Gln368Stop, in *MYOC* remain sequestered within cells. Furthermore, irrespective of mutant proteins produced from two alleles (homo-oligomer) or formed between wild type and mutant (hetero-oligomer), both remain sequestered within the cell. These researchers suggested a hypothesis that altered biochemical properties of mutant *MYOC* interfere with its secretion, dimerization, or interaction with other extracellular matrix components of the TM. Consistent with this idea, Fan and coworkers reported, in 2006, a Cys245Tyr mutation in *MYOC* in a Chinese glaucoma family, where the Cys245Tyr mutant protein formed homo-multimeric complexes that migrated at molecular weights larger than their wild-type counterparts and remained sequestered intracellularly in COS-7 cells. These data led to the hypothesis that myocilin-associated glaucoma is an endoplasmic reticulum (ER) storage disease, whereby chronic expression of misfolded, nonsecreted myocilin leads to TM cell death, TM dysfunction and, ultimately, a dominant glaucoma phenotype. The potential beneficial effects of facilitating folding and secretion of mutant myocilin suggested a new type of treatment for this form of glaucoma. Recently, it has been shown that mutations in human *MYOC* induce exposure of a cryptic peroxisomal targeting sequence whose interaction with the peroxisomal targeting signal type 1 receptor is necessary for elevation of IOP in a mouse model for human OAG. IOP is considered to be one of the major characteristic features in glaucoma.

Autosomal recessive inheritance was reported to be caused by a nonsense mutation in *MYOC* exon 1 in Koreans. However, a subsequent study from China identified a normal individual who was homozygous for the same mutation, suggesting that this *MYOC* alteration might be a nondisease-causing polymorphism. Among 64 mutations in the *MYOC* identified so far, four (Arg46Stop, Arg82Cys, Pro370Leu, and Thr377Met) mutations occur in mutable DNA motifs (CpG). These mutable motifs in DNA are considered to be the hotspots for mutation. Cooper and Youssofian suggested that deamination of 5-methylcytosine in a CpG dinucleotide followed by DNA replication results in mutation of the CpG to TpG. As described earlier, only eight mutations (Gln19His, Cys25Arg, Arg46Stop, Gln48His, Arg82Cys, Arg91Stop, Arg126Trp, and Arg158Gln) of a total 64 reported in *MYOC* are located in exon 1 of the MYOC gene. With the exceptions of Arg126Trp and Arg158Gln all of these mutations have been detected only in sporadic cases. Since sporadic mutations lack familial segregation data, they have weaker potential to be considered as disease-causing mutations. These findings suggest that the N-terminal region of *MYOC* encoded by exon 1 might harbor functionally less important domain than that contained within exon 3 (the olfactomedin domain).

A number of upstream/promoter region polymorphisms in *MYOC*, for example, −1000 G > C in *MYOC* and −153 T > C in *MYOC* have been suggested to have significant association with POAG including the normal-tension glaucoma. So far, about 50 *MYOC* polymorphisms have been reported, among which two (−83 G > A and Arg76Lys) have been detected in most of the populations examined. In addition, polymorphisms of additional genes have been suggested to have a role in OAG. Lin and coworkers showed a significant association of the p53 polymorphism (Arg72Pro) with Chinese POAG patients. However, additional studies did not find any association of Arg72Pro polymorphism in POAG patients of Indian origin.

While *MYOC* remains the most commonly mutated gene for POAG, several additional genes may also play a role in the disease. It has been recently reported that the polymorphism in *OPA1* is a significant risk factor for normal-tension glaucoma. Besides *MYOC* there were two

more genes reported to be linked with OAG. Mutations in *OPTN* were found to be responsible for 17% normal-tension glaucoma patients while *WDR36* is a potential candidate for OAG.

Molecular Genetics of CG: Mapped Loci and Identified Candidates

Genetic linkage studies revealed that CG mapped to two different loci, GLC3A (OMIM # 231300) located at chromosome 2p21 and GLC3B (OMIM no. 600975, Genbank accession no. NM_000104) located at chromosome 1p36 (**Table 1**). The causal gene at GLC3A locus has been found to be *CYP1B1*, which encodes for the cytochrome P450 enzyme. The causative gene for GLC3B has yet to be identified despite mutational analyses of a large number of genes identified in the chromosomal region (1p36) that contains the GLC3B locus. Following the discovery of association between the *CYP1B1* gene (OMIM # 601771) and GLC3A locus, 55 mutations and 32 polymorphisms have been identified in CYP1B1 in different populations. It is interesting to note that substantial portions of the mutations reported (19 out of 55) are deletion/insertions, implying an inherent instability of the CYP1B1 gene.

Cytochrome P450 1B1 (*CYP1B1*) as a Primary Candidate for CG

Overview

The *CYP1B1* genomic region spans >12 kb and contains three exons. Exon 1 encodes an untranslated portion of the CYP1B1 gene, while exons 2 and 3 encode for a protein containing 543 amino acids. CYP1B1 protein is a membrane-bound cytochrome that contains a transmembrane domain located at the amino-terminal region, and a proline-rich hinge region, which permits flexibility between the membrane-spanning domain and cytoplasmic portion of the molecule. Induced mutations in the hinge region interfere with the proper folding and heme-binding properties of other cytochrome P450 molecules. The C-terminal ends of members of the cytochrome P450 superfamily is highly conserved and contains a set of conserved core structures (CCSs) responsible for the heme-binding ability of these molecules. Between the hinge and the CCS lies a less conserved substrate-binding region.

Analysis of Mutations Associated with CG in *CYP1B1*

The identification of *CYP1B1* mutations in CG is the first example in which mutations in a member of the cytochrome P450 superfamily result in a primary developmental defect. It is thought that *CYP1B1* participates in the metabolism of an as-yet-unknown biologically active molecule that is a participant in eye development. They demonstrated that a stable protein product is produced in the affected subjects of these families, and that the three mutations they described would be expected to result in a product lacking amino acids between 189 and 254 from the C-terminus. This segment harbors the invariant cysteine of all known cytochrome P450 amino sequences; in *CYP1B1* it is *Cys470*. A cytochrome-P450-dependent arachidonate metabolite has been implicated that inhibits Na^+-K^+-ATPase in the cornea in regulating corneal transparency and aqueous humor secretion. This finding is consistent with the clouding of the cornea and increased IOP, two major diagnostic criteria for primary CG.

The involvement of *CYP1B1* in CG populations varies from 20% in Indonesians and Japanese populations to 50% among the Brazilians and about 100% among the Saudi Arabians and Slovakian Gypsies. The Slovakian Gypsies and Saudi Arabian populations exhibited allelic homogeneity largely attributed to consanguinity. Consanguinity is also prevalent in different ethnic groups of India and thus provides an excellent motivation to explore the role of *CYP1B1* in CG in these populations. Interestingly, the involvement of *CYP1B1* in CG was found to be lower (37.50%) in Indian population. This could be due to a lower rate of consanguinity and allelic homogeneity in the Indian populations. Relatively lower frequencies of *CYP1B1* mutations have also been observed in Southeast Asian populations such as Japanese (20%) and Indonesians (about 34%). Interestingly, none of the *CYP1B1* mutations in Japanese and Indonesian populations were found in Indian CG patients. Since Japanese and Indonesian populations reportedly has similar allelic distribution for numerous SNPs in different genes, the overlap in the *CYP1B1* mutation spectrum could be the result of shared ancestry between these two populations.

Genetic Overlap between CG and Juvenile Glaucoma (JOAG)

Involvement of *CYP1B1* in JOAG

The first report of *CYP1B1* involvement in JOAG came in 2002, where Vincent and coworkers showed an Arg368His mutation in *CYP1B1* expedited disease progression in combination with a Gly399Val mutation in *MYOC*. Later, *CYP1B1* was screened in 236 unrelated French–Caucasian OAG patients. They found mutations in 4.6% ($n = 11$) of the patients with no mutation in *MYOC*. In two families, occurrence of CG and OAG in members of a single sibship was found, all of which were compound heterozygous for mutations in the *CYP1B1* gene. Mutations in *CYP1B1* were typically associated with juvenile- and middle-age-onset OAG. Except one, all mutations detected in OAG patients were previously associated with PCG.

It has also been reported that another *CYP1B1* mutation was present in 200 unrelated Indian OAG patients. A R523T mutation in *CYP1B1* is primarily responsible for JOAG. Altogether six *CYP1B1* mutations were found in nine OAG patients (4.5%), consistent with previous reports. Subsequently, heterozygous *CYP1B1* mutations in Spanish OAG patients are present with similar frequency. Thus, it appears that *CYP1B1* has a larger role to play in glaucoma pathogenesis that includes causation of CG, modifying the pathogenesis of OAG, and, on rare occasion, being the primary cause of JOAG.

Recently, it has been reported that an Leu432Val polymorphism in *CYP1B1* is a susceptible factor for OAG. They designated Val432 as susceptible allele and CGGTA as the risk haplotype for OAG. They have shown higher amount of reactive superoxide (ROS) generation in Val432 in *CYP1B1* leading to apoptotic condition that might progress toward OAG. These data suggest that other than *CYP1B1* mutations, cSNPs found in normal individuals could also be functionally associated with OAG.

Involvement of *MYOC* in CG

Involvement of *MYOC* in CG was first described when 200 CG cases were screened for the *MYOC* Gln48His mutation and identified five cases harboring the mutant allele, which also included one homozygote. Interestingly, four of the five PCG cases harboring *MYOC* mutations, including the individual with the homozygous Gln48His mutation lacked any *CYP1B1* defect. These data and other more recent reports are consistent with a direct role of *MYOC* mutations in CG.

Digenic Inheritance in Glaucoma

The concept of defects in two genes gave rise to glaucoma (digenic inheritance) where primarily *MYOC*-linked OAG segregated in a large Guyanese family with *CYP1B1* as potential modifier. In that pedigree, a heterozygous *CYP1B1* mutation (Arg368His) was associated with earlier onset of the disease in patients carrying the *MYOC* mutation (Gly399Val), indicating that a *CYP1B1* mutation might behave as a modifier of the *MYOC* gene. In this family the mean age of onset of carriers of the *MYOC* mutation alone was 51 years, whereas carriers of both the *MYOC* and *CYP1B1* mutations had an average age of onset of 27 years. Similar results were reported, where a combination of *MYOC* and P1B1 variations appeared to be necessary to cause JOAG in an Indian population. These observations suggested that *MYOC* and *CYP1B1* may interact through a common pathway and *MYOC* function may be influenced by changes in *CYP1B1* and mutations of *CYP1B1* might be a cause of POAG or at least a risk factor for this disease. A potential digenic inheritance of *MYOC* and *CYP1B1* mutations leading to CG has been reported. Such digenic interaction is also observed in retinitis pigmentosa (RP) individuals who harbor specific mutations in both the peripherin/RDS and ROM1 genes wherein neither of these mutations in single gene alone causes RP.

Developmental Anomalies and Glaucoma

Since some forms of glaucoma are congenital, it is expected that glaucoma could be associated with ocular conditions that are the result of an abnormal differentiation of the eye. This is born out as the abnormal differential of ocular neural crest cells results in diseases that include glaucoma – for example, ARS, Peters' anomaly, and NPS/hereditary onycho-osteodysplasia (HOOD). These diseases share the features of variable expression of ocular features with high degree of penetrance among affected family members.

ARS is an autosomal-dominant developmental defect of the anterior segment of the eye that often results in glaucomatous blindness. The systemic ARS phenotype variously includes any of small, missing or absent teeth, redundant periumbilical skin, sensory hearing loss, congenital heart defects, and skeletal limb anomalies. The gross changes in eye morphogenesis in ARS are highly penetrant and ARS is associated with an approximately 50% risk of glaucomatous optic nerve damage and visual field loss. ARS is associated with mutations in two transcription factor genes (*PITX2* and *FOXC1*) expressed throughout eye development. However, more than 50% of ARS patients are without any genetic variation in defined loci and genes for ARS, suggesting that ARS has considerable genetic heterogeneity.

The Peters' anomaly is another congenital abnormality associated with glaucoma, which shows a number of ocular phenotypes that include central corneal leukoma (opacity), absence of the posterior corneal stroma and Descemet membrane, and a variable degree of iris and lenticular attachments to the central aspect of the posterior cornea. A number of genes including *PITX2*, *FOXC1*, and *PAX6* have been reported to be associated with Peters' anomaly. A mutation in *CYP1B1* is also causal for Peters' anomaly, and mutations in *CYP1B1* could contribute to 20% of cases of Peters' anomaly. However, the genetic basis for this anomaly is still not clear and, to date, there are no major loci found to be linked with the anomaly.

In addition to these anomalies, several other developmental defects are associated with glaucoma. NPS or HOOD has been shown to be associated with glaucoma by Dryer and coworkers in 1998. NPS is an autosomal-dominant, pleiotropic disorder with features suggestive of a primary defect of connective tissue, and is caused by mutations in LMX1B gene. The encoded protein specifies the development of dorsal structures from mesoderm during limb development. In all of these developmental

abnormalities, the genes mutated in these conditions cause the developmental defects of the eye structure. However, the fact that these genes continue to be expressed in the adult eye suggests that a combination of structural defects that predispose to glaucoma pathogenesis and disruption of functions of these genes in the adult eye together result in glaucoma. It appears that the ARS gene *FOXC1* is involved in stress-response pathways in the adult eye, which is consistent with this hypothesis.

Future Directions

Taken together, these data suggest overlapping genetic mechanisms for causation of both JOAG and CG. Although JOAG and CG are different in terms of age of onset, they share many common anatomical (e.g., angle between iris and cornea remains open) as well as physiological (e.g., elevated IOP) features related to glaucoma. However, there are several distinct morphological features observed in the eye of a CG patient that are not present in patients affected with JOAG. In addition, digenic inheritance in JOAG suggested a genetic connection between *MYOC* and *CYP1B1* that requires thorough investigation at functional level. In 2001, Vincent and coworkers suggested that *MYOC* and *CYP1B1* might interact through a common pathway and proposed that *MYOC* function might be influenced by changes in *CYP1B1*. To date, however, there are no reports of a direct physical interaction between *MYOC* and *CYP1B1*. In all likelihood, there might be one or more unknown substrates of *CYP1B1* acting as missing link in the common pathway through which both *MYOC* and *CYP1B1* interact. Exploration of this area could be particularly fruitful.

From multiple genetic evidences it appears that JOAG and CG are parts of a larger disease spectrum where mutation in a single gene can cause either form of glaucoma. At the same time, some of these forms of glaucoma only result from simultaneous mutations of several genes. Current evidence indicates that *CYP1B1* has a larger role to play in glaucoma pathogenesis, which includes causation of CG, modification of the pathogenesis of OAG, and, on rare occasion, it might be the primary cause for JOAG. Therefore, from the viewpoint of glaucoma molecular diagnostics, both *MYOC* and *CYP1B1* should be routinely screened for disease-causing variants in both JOAG and CG patients.

Glossary

Basement membranes – Thin sheets of extracellular matrix at the interface between epithelial and mesenchymal tissues that contain type IV collagen, adhesive glycoproteins, and proteoglycans.
Caspase – A type of protein that is involved in apoptosis (a normal process in a cell that leads to its death).
Endothelial cell – Cell type responsible for blood vessel formation, forms inner lumen of blood vessels.
Extracellular matrix – Three-dimensional macromolecular network that forms a structural scaffold and an instructional cellular and tissue environment.
Focal adhesion kinase – An important intracellular mediator of integrin signaling. FAK is phosphorylated and activated on endothelial cell integrin engagement with various ligands.
Integrin – A large family of noncovalently linked, heterodimeric trans-membrane cell-adhesion receptors that also transduce signals from the outside to the inside of the cell and vice versa.
Matrix metalloproteinases – A large family of proteolytic enzymes that preferentially degrade collagens, basement membranes, and other extracellular matrices. They are extremely active during tissue remodeling, cancer and angiogenesis.
Mitogen-activated protein kinases – Important intracellular mediators of integrin signaling. They belong to two major classes, ERK1 and ERK2, and p38 MAPK (MAPKs function downstream of FAK).
Noncollagenous domain 1 – The C-terminal domain of type IV collagen. In type IV collagen, proteolytic cleavage from the parent molecule can release NC1 fragments that can become anti-angiogenic.
Phosphatidylinositol-3 kinase – Important intracellular mediators of integrin signaling (PI3K function downstream of FAK).
RGD – Proteins that contain the Arg–Gly–Asp (RGD) attachment site.

Introduction

Vascular basement membrane (VBM)-derived molecules are regulators of certain biological activities, such as cell growth, differentiation, and angiogenesis. Angiogenesis, the process by which neovasculature is created from native blood vessels, is essential in both normal development and several pathological conditions, such as cancer, rheumatoid arthritis, choroidal neovascularization (CNV) in age-related macular degeneration (AMD), and diabetes. Angiogenesis is regulated by a systematic controlled balance between VBM-derived angiostatic factors and proangiogenic growth factors. In the normal physiological state, equilibrium is maintained between the angiostatic and proangiogenic factors. In cancer, tumor cells require new blood vessels to sustain local growth and escape to distant sites through hematogenous spreading and metastasis. Without angiogenesis, tumor cells cannot survive for long, for this reason, endogenous angiostatic factors which do not engender the same sort of resistance and intolerance as exogenous compounds might be important candidates for anticancer or anti-CNV in AMD therapy, either by themselves or in combination with other agents that are used more routinely in the clinic.

Endogenous angiogenesis inhibitors from extracellular matrix (ECM) include large multifunctional ECM glycoproteins, such as thrombospondin, Endorepellin (a C-terminal end of perlecan), anastellin (a fibronectin fragment), fibulins (C-terminal fragments corresponding to fibulin 1D and the domain 111 of fibulin 5), and endostatin. The discovery of endostatin hastened the investigation to find other matrix components, such as collagen IV, that have the potential to modulate angiogenesis. The proteolytic cleavage of type IV collagen generates noncollagenous (NC1) domains which include: arresten (α1(IV)NC1), canstatin (α2(IV)NC1), tumstatin (α3(IV)NC1), and α6(IV)NC1 domains identified as angiostatic molecules discussed in this article. In this terminology, α indicates the chain in collagen IV (**Figure 1**). Thus, the molecules that are needed to assemble a basement membrane (BM) to maintain the integrity of blood vessels and to prevent the leakage of fluids and loss of proteins can do the opposite under the right circumstances; that is, they have both angiogenic and angiostatic activities. Interestingly, endogenous angiostatic proteins that are derived from type IV collagen

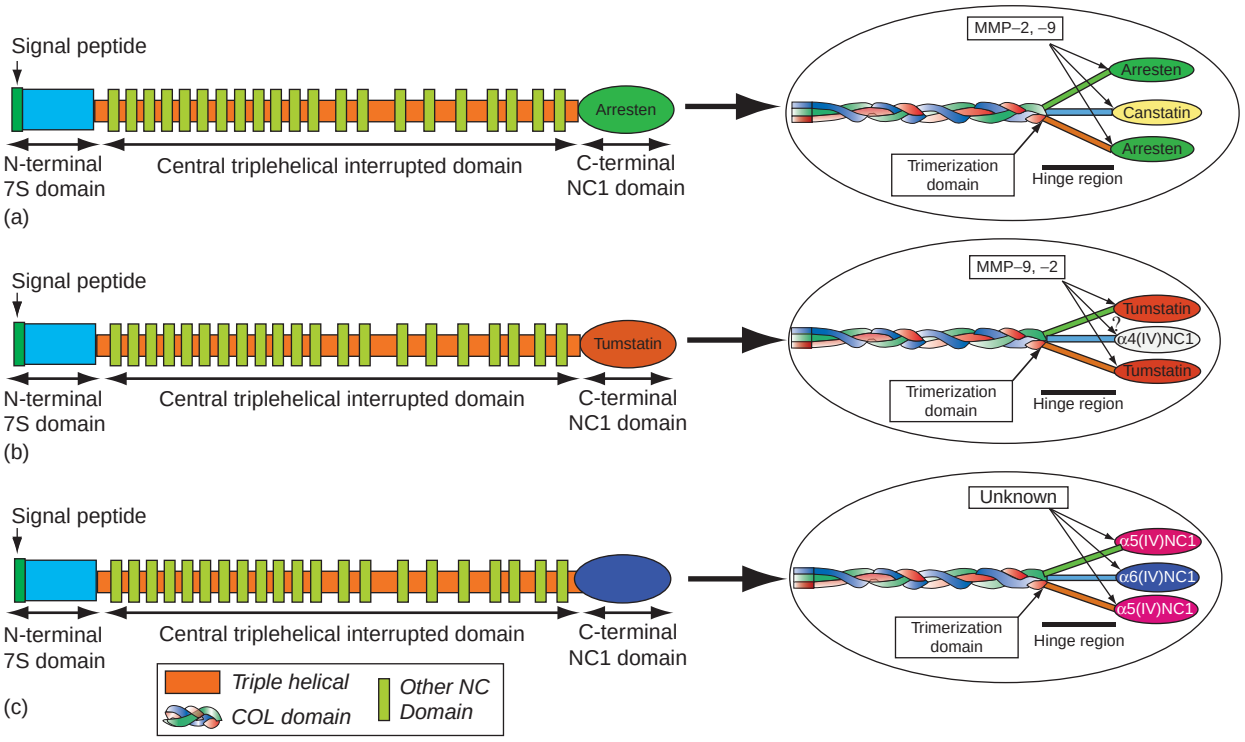

Figure 1 Structural domains of mammalian type IV collagen. (a) Type IV collagen (a single α1(IV) chain is depicted for simplicity) contains an N-terminal cysteine-rich 7S domain, a central triple-helical interrupted domain by noncollagenous (NC) domains, and a C-terminal NC1 domain. The NC1 domain is enlarged as a trimer of $[\alpha1(IV)]_2\alpha2(IV)$. α1(IV) and α2(IV) chains contain the antiangiogenic domains arresten (or α1(IV)NC1) and canstatin (or α2(IV)NC1) (labeled green and yellow oval). (b) α3(IV) chain contains an N-terminal cysteine-rich 7S domain, a triple-helical interrupted domain by NC domains, and a C-terminal NC1 domain shown. The NC1 domain is enlarged as a trimer of $[\alpha3(IV)]_2\alpha4(IV)$. α3(IV) contains the antiangiogenic domain tumstatin (or α3(IV)NC1) (labeled red oval). No antiangiogenic activity has been identified from α4(IV)NC1 domain (labeled white oval). (c) α5(IV) chain contains an N-terminal cysteine-rich 7S domain, a triple-helical domain interrupted by NC domains, and a C-terminal NC1 domain shown. The NC1 domain is enlarged as a trimer of $[\alpha5(IV)]_2\alpha6(IV)$. α6(IV) contains the antiangiogenic NC1 domain (α6(IV)NC1) (labeled blue oval). No antiangiogenic domain has been identified from α5(IV) (labeled pink oval).

possess similar structures that have striking differences in their angiostatic actions.

Type IV collagen NC1 domains exert their effects by interacting with cell-surface integrin receptors that help modulate how cells interact with and are affected by matrix components. The functional receptor for each angiostatic agent derived from type IV collagen is different and specific; α1β1, αVβ5/αVβ3, αVβ3/α3β1, and αVβ3 integrins for arresten, canstatin, tumstatin, and α6(IV)NC1, respectively. This indicates that the mechanism of receptor engagement and downstream signaling events might also be different and specific, although some common intracellular signaling components are modulated. Canstatin and tumstatin function by inhibiting endothelial protein synthesis and promoting apoptosis. Arresten and α6(IV)NC1 seem to interact differently with integrins compared with the typical native ligands from which they are derived. The four fragments are structurally related but differ functionally, which explains why they interact with different integrins and have different effects on angiogenesis. By restricting our focus to these four angiostatic molecules, we hope to emphasize similarities that might also apply to other (perhaps undiscovered) angiostatic matrix molecules and further our understanding of angiostatic activity with potential therapeutic benefit against diseases in which angiogenesis play role.

Physiological and Biological Functions of Type IV Collagen

Type IV collagen is the most abundant constituent of the BM that forms a network-like structure in the ECM. Type IV collagen provides a scaffold in the BM with other macromolecules, such as laminins, heparan sulfate proteoglycans, fibronectin, entactin, and regulates the interaction with adhering cells discussed separately in this article. Type IV collagen is ubiquitously present in VBM and is highly conserved among vertebrates and invertebrates, regulating cell adhesion and migration. Type IV collagen has six α-chains and can exist in atleast three hetero-trimeric triple helical forms $[\alpha1(IV)]_2\alpha2(IV)$, $[\alpha3(IV)]_2\alpha4(IV)$, and $[\alpha5(IV)]_2\alpha6(IV)$ and their genomic localization shows a pair-wise head-to-head arrangement with a

bi-directional promoter that were mapped onto three different chromosomes. Each α(IV) chain in type IV collagen is composed of three distinct domains: a cysteine-rich N-terminal 7S-domain, a central long triple helical collagenous domain with Gly–X–Y repeats (where X and Y represent any amino acids other than glycine, but are often proline and hydroxyproline) interrupted by short NC domain, and a globular C-terminal NC1 domain of ~ 230 amino acids (**Figure 1**). The NC1 domains are involved in the assembly of α-chains to form heterotrimers and the 7S-domains are involved in the covalent assembly of heterotrimers in a complex mesh-like network that serves as a scaffold for BM. Several human genetic diseases provided insights into the physiological role of type IV collagen discussed in this article. Mutations or deletions in Col4α5, Col4α3, and Col4α4 chains are involved in Alport syndrome (defective glomerular BM) and diffused leiomyomatosis (a benign smooth muscle tumor). The C-terminal region of α3 chain of type IV collagen has been identified as an autoantigen involved in Goodpasture syndrome (an immune disease characterized by glomerulonephritis and pulmonary hemorrhage). The α1(IV) and α2(IV) chains are ubiquitous and $[\alpha1(IV)]_2\alpha2(IV)$ heterotrimers are predominant. In humans, no disease is yet linked to mutations in the major α1(IV) and α2(IV) chains.

The $[\alpha1(IV)]_2\alpha2(IV)$ trimers contain a triple helical domain with binding sites for α1β1 and α2β1 integrins. Cells bind to type IV collagen and this binding inhibited by type IV collagen derived peptides was demonstrated in several cell types. A peptide that was derived from NC1 of the α1(IV) chain could promote adhesion of bovine aortic endothelial cells. The functional α1 and α2 type IV collagen chains isolated from the Engelbreth Holm Swarm Sarcoma tumors inhibited capillary endothelial cell proliferation. In primitive invertebrate Hydra vulgaris, addition of NC1 type IV collagen alters morphogenesis, blocking cell aggregate and development. These results confirm that the biological functions of NC1 domains are conformation dependent.

Generation of Angiostatic Domains from Type IV Collagen and Their Signaling Mechanisms

Proteolytic degradation of type IV collagen induces exposure of cryptic sites which is involved in binding of integrins and sends new signals between cells and BM. Several NC1 domains from type IV collagen were detected in the serum of patients suggesting that these domains exist due to physiological cleavage of ECM by proteases. Earlier we reported that arresten, canstatin and tumstatin are proteolytic NC1 peptides generated from α1, α2, and α3 chains of type IV collagen by matrix metalloproteinase (MMP)-9, -2, and -13. Although we gained some preliminary clues for *in vitro* processing of type IV collagen NC1 domains, the exact mechanisms of generation still need to be extensively investigated. In early 2000, several groups focused their attention on potential angiostatic properties of type IV collagen NC1 domains and identified their angiostatic effects.

Different Integrins Mediated Angiostatic Signaling by Tumstatin

Tumstatin, a 28 kDa protein from the C-terminal NC1 fragment of α3(IV) (**Figure 1**), was identified originally as an inhibitor of angiogenesis in early 2000. Inhibition of cell migration using peptide 185–205 amino acids from tumstatin was reported in melanoma and fibrosarcoma cells with a decrease in expression of membrane-bound metalloproteinase (MT1-MMP) and activated MMP-2. Tumstatin inhibits formation of tubular structures in mouse aortic endothelial cells embedded in Matrigel plugs and inhibits growth of different tumors in mouse models (renal cell carcinoma (786-O), CT26 (colon adenocarcinoma), prostate carcinoma (PC3), Lewis lung carcinoma (LLC), human lung cancer (H1299), human prostate cancer (DU145), human fibrosarcoma (HT1080), and teratocarcinoma (SCC-PSA1)). But what are the cell surface integrin receptor(s) involved in these angiostatic actions of tumstatin? It is clear that different integrins are key targets of tumstatin. Tumstatin interacts with endothelial cell via αVβ3 integrin in a vitronectin and RGD-independent fashion. Integrin αVβ3 interacts with tumstatin through two distinct regions, comprising residues 54–132 and 185–203 amino acids. The first site is involved in the angiostatic activity (is sufficient to inhibit *in vitro* and *in vivo* angiogenesis by increasing apoptosis in endothelial cells), whereas the second site is involved in antiproliferative activity on cancer cell lines. These results confirm specific regulatory subdomains in tumstatin control adhesion, proliferation, or apoptosis in various cell types. The functional specificity of these subdomains from tumstatin in endothelial or cancer cells is very interesting. Indeed, the recently published 3D crystal structure of type IV collagen NC1 domain reveals N- and C-homologous subdomains. The major difference between these subdomains for each chain is in the region from residues 86–95 in the N-subdomain and 196–209 in the C-subdomain. These regions overlap two sequences that were previously identified to be having angiostatic and antiproliferative effects in cancer cells. Tumstatin or its peptides interaction with integrins seems to be involved in the disruption of contacts between endothelial or tumor cells and the BM, leading to apoptosis in these cells. Tumstatin also binds to endothelial cells through α6β1 and αVβ5 integrins, but the significance of these integrins interaction is not yet clear.

Tumstatin induces endothelial cell apoptosis by interacting with αVβ3 integrin and inhibits adhesion to VEGF in the matrix, and this effect was potentiated by anti-αVβ3 blocking antibody. The angiostatic activity of tumstatin was conferred by its N-terminal end comprising amino acid residues 54–132 region interaction with integrin αVβ3 and inhibiting activation of focal adhesion kinase (FAK), phosphatidylinositol 3-kinase (PI3K), serine/threonine kinase (Akt/protein kinase B), mammalian target of rapamycin (mTOR), and prevents dissociation of eukaryotic translation initiation factor 4E (eIF4E) from 4E-binding protein 1 (4E-BP1) leading to the inhibition of Cap-dependent translation in proliferating endothelial cells (Figure 2). Furthermore, these findings indicate a specific role for integrins in mediating cell specific inhibition of protein translation suggesting a potential specific mechanism of tumstatin on endothelial cells. α3β1 integrin binds to C-terminal region 185–203 residues associated with

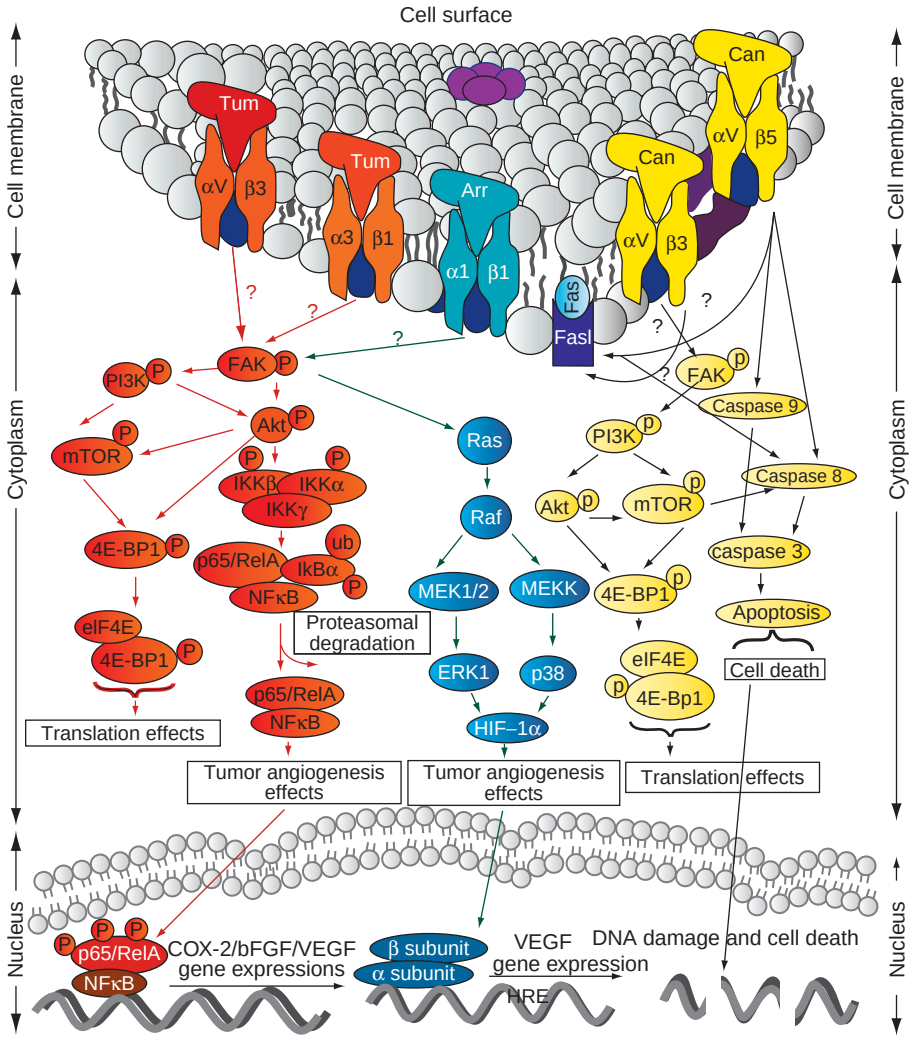

Figure 2 Schematic illustrations of the different integrins mediated signaling pathways evoked by tumstatin (Tum), arresten (Arr), and canstatin (Can) in endothelial cells. Tumstatin (signaling components shown as red ovals), arresten (signaling components depicted as blue ovals), and canstatin (signaling components depicted as yellow ovals) interact with αVβ3/α3β1, α1β1, and αVβ3/αVβ5 integrins, respectively, to inhibit the phosphorylation of FAK. Tumstatin: It binds to αVβ3 and α3β1 integrins and inhibits the pathway that includes phosphorylation of FAK, PI3K, serine/threonine kinase (Akt), mammalian target of rapamycin (mTOR), eIF4E-4E-BP1, and eIF4E to decrease endothelial cell protein synthesis and proliferation. In addition, tumstatin also inhibits NFκB-mediated signaling in hypoxic conditions and leads to inhibition of cyclo-oxygenase (COX-2), VEGF, bFGF expressions, resulting in inhibition of hypoxic tumor angiogenesis. Antagonism of the α3β1 integrin by tumstatin might also cause transdominant inhibition of αVβ3 integrin. Arresten: It binds to α1β1 integrin and inhibit phosphorylation FAK, causes inhibition of Ras (a small GTPase), Raf (a serine/threonine kinase), extracellular signal-related kinase 1 (ERK1), and p38 MAPK pathways that leads to inhibition of HIF-1α and VEGF expression resulting in inhibition of endothelial cell migration, proliferation, tube formation, and apoptosis in proliferating endothelial cells. Canstatin: It binds to αVβ3/αVβ5 integrins and inhibits two apoptotic pathways, involving activation of caspase-8 and casoase-9, leading to activation of caspase-3 on endothelial cells. Canstatin activates procaspase-9 not only through inhibition of the FAK/PI3K/AKT pathways, but also by cross talking mitochondrial pathway through Fas-dependent caspase-8 activation leads to endothelial cell apoptosis.

antitumor activity. These data correlate with earlier findings that tumstatin binds to α3β1 integrin and transdominantly inhibits expression of αVβ3 integrin. Interestingly, recent studies clearly show that in addition to tumor suppressive action of tumstatin or its peptide (T3; C-terminal end comprising amino acid residues 133–244 region of the tumstatin) directly inhibits growth of glioma cells. In addition, a cyclopeptide derived from tumstatin (YSNSG) was also shown to inhibit human melanoma cell proliferation.

Recently, Boosani and coworkers identified that tumstatin inhibits hypoxia-induced cyclo-oxygenase-2 (COX-2) expression in endothelial cells via FAK/Akt/NFκB (nuclear transcription factor-kappa B) pathways, leading to decreased tumor angiogenesis and tumor growth in an α3β1 integrin dependent manner. In addition to COX-2 inhibition, the down stream VEGF and basic fibroblast growth factor (bFGF) protein expression was also inhibited upon tumstatin treatment to endothelial cells. Moreover, several investigators have demonstrated that blockade of COX-2-mediated pathway serves as a therapeutic benefit in different cancer models and potential target for tumor angiogenesis. These findings indicate that there may be several targets for the inhibitory effects of tumstatin in tumor angiogenesis. The above studies support the angiostatic and antitumorogenic activity of tumstatin mediated through αVβ3 and α3β1 integrins (**Figure 2**). Surprisingly, abnormal tumorogenesis is observed in mice lacking tumstatin, indicating that it is playing a role in pathological angiogenesis to decrease tumor progression. However, in a controlled angiogenic process such as wound healing, tumstatin does not affect the overall neovascularization. Although tumstatin is efficient in reducing tumor neovascularization, its exact role needs to be deciphered.

Different Integrins Mediated Angiostatic Signaling by Canstatin

Proteolytic degradation of type IV collagen liberates a 24 kDa peptide from C-terminal NC1 domain of α2 chain, called canstatin [α2(IV)NC1], and this peptide was reported to inhibit tumor-associated angiogenesis. Canstatin binds to the endothelial and tumor cell surface in an αVβ3 and αVβ5 integrin-dependent manner. Canstatin competes with type IV collagen of ECM for cell surface integrin binding and reverses the proliferative and migratory effects induced by cell–ECM interactions. Thus, αVβ3 and αVβ5 integrins appear to mediate the angiostatic and antitumorgenic properties of canstatin. In addition, researchers also determined that canstatin binds to αVβ3 and αVβ5 integrins and induce apoptosis in endothelial and certain tumor cells. Canstatin inhibits the growth of many tumors in human xenograft mouse models, histological studies revealed decreased CD31 positive vasculature. Canstatin strongly inhibits the migration and proliferation of endothelial cells. Moreover, these events are mediated by an upstream event involving canstatin binding to αVβ3 and αVβ5 integrins. Recent findings have shown that canstatin inhibits the phosphorylation of FAK, Akt, mammalian target of rapamycin (mTOR), eukaryotic initiation factor 4E-BP1, and ribosomal S6 kinase in cells. Canstatin binds to αVβ3 and αVβ5 integrins and initiates two apoptotic pathways that include activation of caspase-8 and-9 (both initiators of the downstream apoptotic process), and leads to activation of caspase-3. Canstatin activates caspase-8 by downregulation of Flip levels. Upregulation of Fas/Fas ligand triggers not only cell death directly through caspase-3 activation, but also indirectly through mitochondrial damage via activation of caspase-9 within the apoptosome. On the other hand, phosphorylated FAK/PI3K is known to inactivate the mitochondrial apoptotic pathway by inhibition of caspase-9 (**Figure 2**). Canstatin directly activates procaspase-9 through inhibition of the FAK/PI3K pathway and amplifies the Fas-dependent pathway in mitochondria. Caspase activation in endothelial cells by canstatin might be exploited for treatment of CNV in AMD or therapy in the treatment of cancer.

Recently, the Campochiaro group reported that intravitreous or periocular injections of canstatin caused selective apoptosis of endothelial cells participating in neovascularization resulting in suppression of neovascularization when it was given prior to onset of new vessel sprouting. Importantly, when the canstatin was given after neovascularization had already developed, it caused the new vessels to regress. These results demonstrates that canstatin, which has previously been shown to suppress tumor angiogenesis in xenograft models, is also a strong angiostatic agent in the choroid and is a therapeutic candidate for treatment of choroidal nonvascular in AMD.

Canstatin inhibits FAK/Akt signaling by binding to αVβ3 and αVβ5 integrins and induces distinct signaling pathways to activate caspase-3 in endothelial or in tumor cells. Canstatin initiates two apoptotic pathways, involving activation of caspase-8 and -9, leading to activation of caspase-3. Canstatin activates (1) procaspase-9 directly through inhibition of the FAK/PI3K/Akt pathway and (2) caspase-3 by amplifying indirectly the mitochondrial pathway through Fas-dependent caspase-8 activation; whereas in tumor cells canstatin activates caspase-3 only the mitochondrial pathway (**Figure 2**). Collectively, the available research information suggests that, canstatin binds to αVβ3 and αVβ5 integrins and inactivates FAK downstream signaling, leading to suppression of cell proliferation and migration and thus leading to apoptosis.

Distinct Integrin-Mediated Angiostatic Signaling by Arresten

Arresten is a 26 kDa molecule derived from the NC1 domain of the α1 chain of type IV collagen by proteases. Not much is known yet about arresten, its angiostatic actions are presumably mediating through α1β1. Integrin

α1β1 is a collagen-binding receptor that also binds to other BM components, such as laminin. Blocking of α1β1 integrin interactions with ECM inhibits angiogenesis, which indicates that the integrin α1β1 acts as pro-angiogenic receptor. Among the integrin receptors for collagen, α1β1 integrin activates the Ras/Shc mitogen-activated protein kinase (MAPK) pathway promoting cell proliferation. Arresten binds to α1β1 integrin in a collagen type IV dependent manner and mediates its angiostatic and proapoptotic functions and inhibits angiogenesis by inhibiting endothelial cell proliferation, migration, and tube formation. Significant halt in pathological angiogenesis and tumor growth was reported in α1 integrin knockout mice. Whereas arresten had no effect in α1 integrin null endothelial cells, on the contrary, it significantly inhibited proliferation of wild-type mouse endothelial cells. This confirms the significance of integrin α1β1-mediated signaling of arresten. Arresten inhibits phosphorylation of FAK/Ras/Raf/MEK1/2 and p38 MAPK when mouse lung endothelial cells (MLECs) are plated on collagen type IV matrix. Similar inhibition of FAK/Ras/Raf/MEK1/2 and p38 MAPK phosphorylation was not observed with arresten treatment in α1 integrin null MLECs. Downstream to FAK, Akt/PKB plays an important role in endothelial cell survival signaling. Arresten does not inhibit Akt or phosphatidyl-3-kinase (PI3K) phosphorylation suggesting that arresten regulates migration of endothelial cells in an Akt-independent manner.

In addition, recently, Nyberg and coworkers identified arresten and its active peptides induce endothelial cell apoptosis via downregulation of Bcl-2 (antiapoptotic) and Bcl-xL (antiapoptotic) with no effect on Bax (proapoptotic) expression. These Bcl-family members are significantly involved in the balance of proapoptotic and antiapoptotic signals at the mitochondrial level. The balance of their expression determines whether cells undergo apoptosis. These studies demonstrate that activation of apoptotic signaling in proliferating endothelial cells is sufficient to inhibit or regulate new blood vessel formation. These results are consistent with earlier reports that angiostatic and antitumorogenic activity of arresten is partly mediated via integrin cross talk with a cell-intrinsic apoptotic pathway.

Interestingly hypoxia-induced factor alpha (HIF-1α) and VEGF expression was inhibited by treatment of arresten in hypoxic (lack of oxygen) endothelial cells in an α1β1 and FAK/Ras/Raf/MEK1/2 and p38 MAPK manner (**Figure 2**). HIF-1α is an oxygen-dependent transcriptional activator, which plays crucial roles in the tumor angiogenesis. HIF-1α regulates cellular responses to physiological and pathological hypoxia, and studies demonstrate that HIF-1α is a potential target for tumor angiogenesis. HIF-1α transcriptionally regulates VEGF expression in hypoxic cells and promotes angiogenesis in solid tumors. These findings suggest that HIF-1α is a prime target for anticancer therapies. This hypoxic inhibitory activity might be exploited for antiangiogenic therapy in the treatment of cancer, but more preclinical laboratory studies are needed.

Distinct Integrin-Mediated Angiostatic Signaling by α6(IV)NC1

Recombinant α6(IV)NC1 binds to αVβ3 integrin and inhibits human endothelial cell proliferation and neovascularization of Matrigel plugs in mice. The α6(IV)NC1 suppresses the growth of subcutaneously transplanted Lewis lung carcinoma and also spontaneous pancreatic insulomas that develop in the Rip1Tag2 mice. Inhibition of tumor growth is associated with significantly diminished microvascular density. Collectively, present scientific evidence suggested that α6(IV)NC1 is an another angiostatic molecule that are generated from type IV collagen showing antitumorogenic activity. How α6(IV)NC1 regulates angiostatic activities is not yet clear and further extensive studies are needed to address this molecule as an inhibitor of angiogenesis and to be considered for the future clinical trials

Conclusions and Perspectives

In the last decade, several different endogenous angiostatic molecules have been discovered and their pharmacological studies showed promising angiostatic activity, but their mechanism of action and physiological role are not yet understood. Type IV collagen derived angiostatic molecules binds to different integrins and exert their effects through multiple mechanisms including induction of endothelial cell apoptosis, inhibition of endothelial cell proliferation, migration and tube formation, and inhibition or alteration the functions of proangiogenic growth factors. Three possible conclusions drawn from the signaling mechanisms of type IV collagen derived angiostatic molecules that are shown in **Table 1**. (1) All these collagen type IV derived inhibitors appears to exert their angiostatic effects by binding to specific cell surface integrins. (2) These inhibitors also block the binding of natural ligand/binding partners for proangiogenic receptors/molecules. (3) In addition, possibly by binding to its receptors, these inhibitors cross talk with other cell surface receptors and activate specific caspase-mediated signaling to regulate cell functions.

In addition several angiogenic inhibitors including αV integrin antagonist EMD 121974, 2-methoxyestradiol (panzam) and MMP-2,-9 inhibitor COL-3 etc. are currently in half phases in human clinical trails. Recent study suggests that upregulation of specific proangiogenic factors is a common mechanism for colorectal and renal carcinoma cells to evade inhibition by several of extracellular derived

Table 1 Signaling Mechanisms Mediated by Type IV Collagen Derived Angiogenesis Inhibitors

Angiogenesis inhibitor name	**Arresten (α1(IV)NC1)**	**Canstatin (α2(IV)NC1)**	**Tumstatin (α3(IV)NC1)**	**α6(IV)NC1**
Inhibitor origin	Type IV collagen α1 chain NC1 domain	Type IV collagen α2 chain NC1 domain	Type IV collagen α3 chain NC1 domain	Type IV collagen α6 chain NC1 domain
Generated by	By MMP-2 and -9	By MMP-9 and -2	By MMP-9, -2, -3 and -13	Not known
Integrin binding	α1β1 ?	αVβ5, αVβ3, ?	αVβ3, α3β1, αVβ5, α6β1?	αVβ3, ?
Endothelial proliferation	Effect	Effect	Effect	Effect
Endothelial migration	Effect	Effect	No effect	Not known
Endothelial tube formation	Effect	Effect	Effect	Not known
Anti-angiogenic effects	Inhibits endothelial proliferation and migration	Inhibits endothelial proliferation by activating apoptosis	Inhibits endothelial proliferation and protein synthesis	Inhibits endothelial proliferation
Anti-angiogenic signaling mechanism	FAK/Ras/cRaf/MEK1/2/p38/ERK1/2/HIF1α mediated signaling and Bcl-2 mediated apoptosis.	FAK/Akt/PI3/mTOR/eIF-4E/4E-BP1 signaling and FasL mediated apoptosis	FAK/Akt/PI3K/mTOR/ eIF-4E/4E-BP1 and NFkB/COX-2 mediated signaling	Not known

endogenous angiogenesis inhibitors. Earlier lessons from preclinical trials of angiostatin, endostatin, 2-ME, etc. suggest that more basic research is required for better understanding of the mechanisms of action associated with these inhibitor molecules. Presently, some of the angiostatic agents, such as Bevacizumab, and several other VEGFR tyrosine kinase inhibitors, Vatalanib (PTK787/ZK 222584), Semaxanib (SU5416), Sunitinib (SU11248), Sorafenib (BAY 43-9006), etc., are in clinical trials. Further extensive evaluation of arresten, canstatin, tumstatin, and α6(IV)NC1 through pharmacokinetic studies is needed to address these molecules as an inhibitors of angiogenesis and to be considered for the clinical trials.

Morphology of Interneurons: Amacrine Cells

E Strettoi, Istituto di Neuroscienze CNR, Pisa, Italy

Glossary

Coverage factor – The product of mean dendritic field size and cell density. It gives a measure of the number of neurons of a particular type whose receptive fields overlap a particular point on the retina. Because of their great varieties in shapes and frequencies, amacrine cells of different types can have coverage factors anywhere between 1 and 500.
Retinal mosaic – The ordinate spatial pattern formed over the retinal surface by cells of a certain type, arranged regularly. Each retinal cell type has a unique mosaic that can be described formally in mathematical terms. Starburst amacrine cells tile the retinal surface very regularly, while dopaminergic amacrines have highly irregular mosaics.

Near the end of the nineteenth century, Santiago Ramon y Cajal named amacrine cells those retinal neurons whose cell bodies occupy the innermost tier of the inner nuclear layer (INL) and that ramify at various depths in the inner plexiform layer (IPL). Literally, their name means cells without an axon. From Cajal's initial observations and following early studies based on Golgi-impregnated neurons, the notion emerged that amacrine cells come in all shapes, sizes, and stratification patterns (**Figure 1**). In time, many morphological types were described thanks to the development of various techniques. These included intracellular recordings followed by dye injections, immunocytochemical staining, assorted anatomical tracing methods and, more recently, transgenic expression of fluorescent molecules. At present, it is accepted that the retina of mammals contains more than 26 varieties of amacrine cells; their catalog can be considered substantially complete. Classification schemes with a tendency to emphasize subtle differences among presumptive categories separate amacrine cells in as many as 40 different types. Surely enough, amacrine cells represent the most diverse cell types in the retina, as they comprise more varieties than bipolar and ganglion cells.

In the IPL, amacrine cells receive their excitatory input from bipolar cells and provide inhibitory output onto the dendrites of both other amacrine and ganglion cells. They also establish inhibitory synapses onto the axonal arborizations of bipolar cells. Functionally, amacrine cells are capable of modulating the activity of ganglion cells by direct inhibition, or by inhibiting the activity of bipolar cells that carry excitatory inputs to the inner retina. Many amacrine cells are also coupled by means of gap junctions.

Coupling can be with amacrine cells of the same (homologous) or different (heterologous) type. In addition, amacrine cell processes can be coupled to ganglion cell dendrites. Although many amacrine cells, such as the AIIs, generate graded signals in response to light, it has been shown that certain amacrine cells are capable of producing true action potentials that initiate locally and then propagate into every dendrite, exciting the entire cell. Thus, each amacrine cell can mediate both local as well as long-range lateral inhibition, regulating the spatial and temporal pattern of synaptic outputs from its dendrites.

Despite their name, certain wide-field amacrine cells have long, axon-like processes which probably function as true axons as they represent output fibers of the cell. These particular amacrines have been described as polyaxonal and their soma are often found in an interstitial position, that is, within the IPL. However, their long processes remain confined within the retina and do not contribute to the optic nerve as do the axons of ganglion cells.

Traditionally, amacrine cells have been divided into the broad categories of narrow-field (30–150 μm), small-field (150–300 μm), medium-field (300–500 μm), and wide-field (>500 μm) cells, based on the size of their dendritic field diameters. It is worth pointing out that the dendritic spread of the cells is correlated quite strongly with their degree of stratification. Hence, wide-field cells are highly stratified, medium-field cells are less so, and almost all narrow-field cells span radially across two or more levels of the IPL (**Figure 2**).

The mere size of their dendritic field, however, cannot account for the great variability in the morphology of these interneurons. Multiple classification schemes coexist: some amacrine cells have traditionally maintained numbers from old, partial nomenclatures (i.e., AII amacrines and A17 amacrines), while others are indicated with names reminiscent of their shapes, such as starburst cell, fountain amacrine, flag amacrine, or spider cell. As for bipolar and ganglion cells, a more functional, and therefore relevant criterion of identification involves knowing the stratification level of the cells. It is well known that the IPL can be subdivided into five equally thick strata or sublayers to which amacrine, bipolar, and ganglion cell processes can be assigned. The level of stratification of a given neuron in the IPL is predictive of the polarity of the cell response to light stimuli, so that neurons confined in the outermost two

layers of the IPL, the so-called sublamina a, are excited when the light goes off, while neurons ramified in the innermost three tiers of the IPL, the sublamina b, are excited at the light onset. This strong correlation between anatomy and function makes it convenient to classify neuronal types primarily according to the strata of the IPL in which their processes are confined. Altogether, the combination of dendritic field size, pattern, and depth of stratification within the IPL are sufficient criteria to separate cells into unique types. Supplementary information includes dendritic caliber, size and distribution of varicosities, and the course of dendrites.

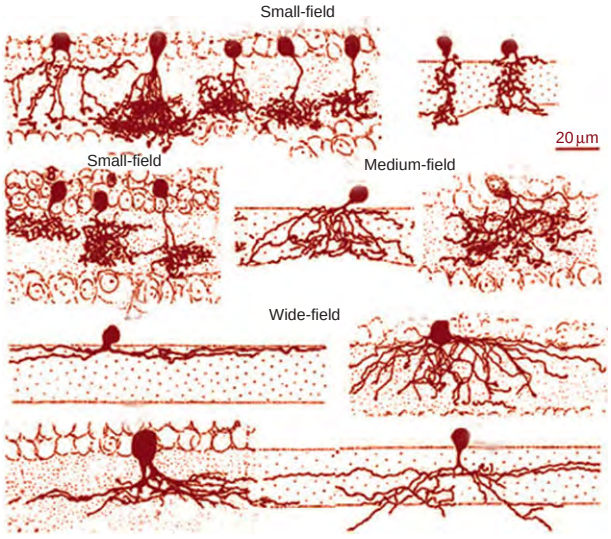

Figure 1 Small-, medium-, and wide-field amacrine cells from the human retina. Golgi silver impregnation. Modified from Poljak, S. (1941). The Retina.

The fact that branching of individual amacrine cells takes place at various levels in the IPL implicates that different amacrine cells contact different types of bipolar and ganglion cells and end up having different functional properties. Indeed, amacrine cells are major players in the retina's processing of visual information. They constitute at least 40% of all neurons in the INL of mammalian retinas and contribute to 64–87% of all synapses in the IPL according to the species. While it was once generally believed that primate retinas were more bipolar dominated as opposed to lower-mammal (i.e., rabbits) retinas, considered more amacrine dominated, quantitative morphology demonstrated that these cells represent some 40% of the INL cells in rabbits, mice, and primates.

Neurotransmitter immunocytochemistry (based on the localization of amino acids or rate-limiting enzymes) has shown that amacrine cells either contain gamma-aminobutyric acid (GABA) or glycine, two inhibitory amino acids used as neurotransmitters ubiquitously in the central nervous system. Remarkably, GABAergic amacrine cells are morphologically wide-field cells, while glycinergic amacrines are small- and medium-field neurons. Glycinergic amacrines are slightly more numerous, at least in the rabbit retina, in which they account for some 56% of all the amacrines. This fits well with the percentage of small-field amacrines (55%) revealed by the technique

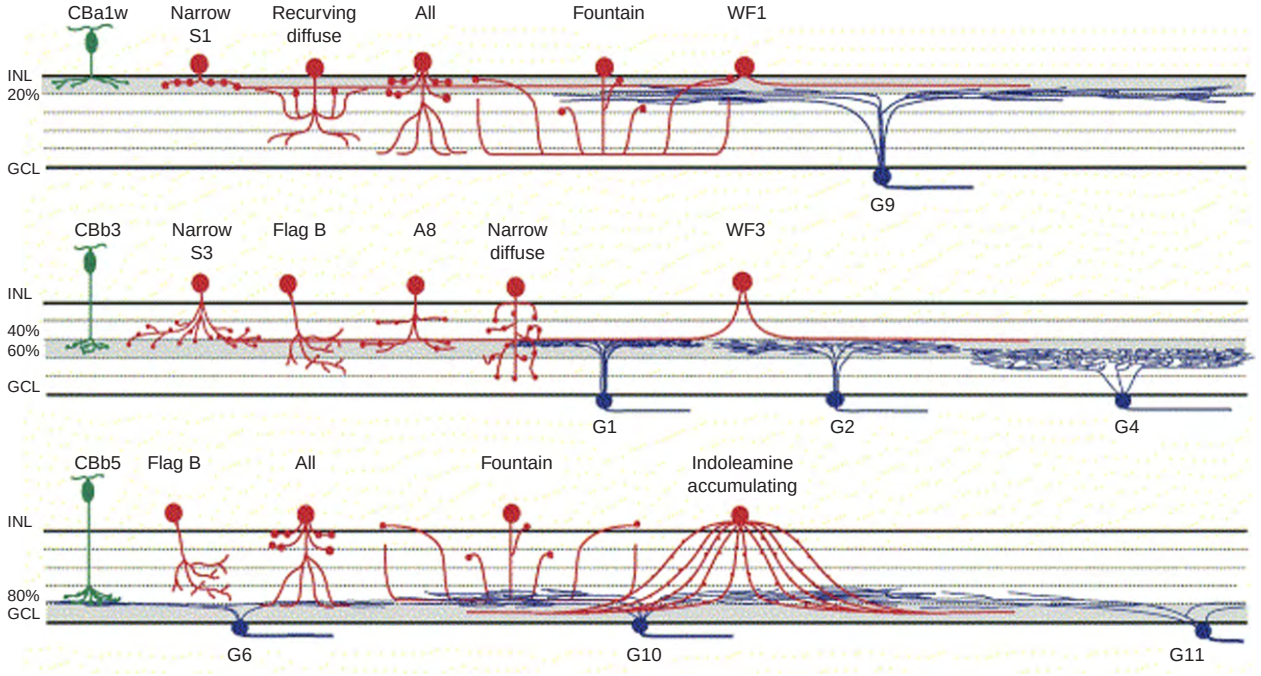

Figure 2 A schematic drawing of some amacrine cells (shown in red), and their spatial relations to known bipolar (green) and ganglion (blue) cell types. From Masland, R. H. (2004). Neuronal cell types. *Current Biology* 14, R497–R500.

of random photofilling. Glycinergic amacrines, with their narrow fields and little overlapping dendrites, mediate radial inhibition in the retina. These cells are meant for vertical transmission rather then for modulation of light signals.

GABAergic amacrines, instead, are more designated for later inhibition, a function traditionally ascribed to amacrine cells in general. In GABAergic amacrines, the fast neurotransmitter GABA usually coexists with another neurotransmitter or neuromodulator; this is typically a peptide, such as somatostatin, substance P, vasoactive intestinal peptide (VIP), and so on. Because they contain high levels of one amino acid, amacrine cells can be identified through their typical amino acidic signature in appropriately stained histological sections of the retina. Noticeably, cholinergic (starburst) amacrine cells are stained with methods revealing both GABA and acetylcholine and are known to corelease both transmitters.

Each particular point of the retina is covered by the dendritic trees of cells of the same type, overlapping to different extents. The parameter indicating the degree of overlapping is known as the coverage factor. This is obtained essentially by histological measurements and is defined as the product of cell density and area of the dendritic tree. A coverage factor of 10 means that a retinal point is covered by the dendritic trees of 10 cells of a given type. Amacrine cells have highly variable coverage factors. In general, small-field amacrine cells have lower coverage factors than wide-field amacrine cells. The well-known indoleamine-accumulating cells (IACs), which comprise two varieties of wide-field amacrines, narrowly stratified in the deepest stratum of the IPL, have coverage factors of 500–900. This means that in each point of the retina, a stack of processes from overlapping IAC cells are regularly piled in sublamina 5 of the IPL. Low-power electron microscopy shows bundles of IAC cells fasciculating in sublamina 5, running parallel to each other and interrupted by the large varicosities of rod bipolar axonal endings, also located at the border with ganglion cell bodies.

Individual types of retinal neuron exhibit regular spacing, such that cells of a certain type maintain a minimum distance from other neurons of the same type. Each cell is surrounded by an exclusion zone from which other cells of the same type are barred. On the contrary, spacing of neurons of different types is completely casual. Amacrine cells adhere to this rule. Because of the availability of cell-specific markers, the mosaics of certain amacrine cells have been described in detail. Starburst amacrine cells can be stained by antibodies against choline acetyl trasferase (ChAT), the rate-limiting enzyme in acetylcholine synthesis; their mosaic is highly characteristic. Similarly, AII amacrine cells can be labeled with antibodies against the protein disabled 1, or, in certain mammals including humans, by parvalbumin antibodies. Dopaminergic amacrines (historically, the first to be described, using enzyme histochemistry) can be revealed by antibodies against tyrosine hydroxylase. Each of these amacrine cells forms over the retinal surface a peculiar, well-recognizable mosaic that can be described formally in rigorous, mathematical terms. Whatever the mechanism leading to mosaic formation during retinal development might be, the regularity of a mosaic is a powerful means to assess that a given cell has been properly identified and correctly assigned to a type. Mutations in various genes controlling retinal development can alter mosaic formation and lead to retinal structural abnormalities.

Multidisciplinary studies on the currently well-known amacrine cell types have led to the notion that, as for other retinal neurons, diversity of shape means diversity of function. This concept is supported by a number of considerations: first, cells whose morphological features are very different have different membrane properties associated with the size of the dendritic tree, the caliber of individual dendrites, and the number and position of input and output synapses with respect to the cell soma. In addition, amacrine processes that occupy different sublayers of the IPL communicate with different sets of bipolar and ganglion cells. Since connectivity shapes function, the functional properties of amacrine cells with different patterns of connections must be different. Also, the area of the dendritic field (which varies greatly among various cells types) is strictly related to the retinal sampling capability (or area of visual space) of a given cell. A different coverage factor also reflects different sampling rates of cells.

The following sections describe two types of amacrine cells whose morphological and functional properties have been studied in detail and appear extremely different. They can be considered as paradigmatic of amacrine-cell-variegated structural and functional aspects.

AII Amacrine Cells

These small-field amacrines were first described in the cat retina by Kolb and co-workers in 1978 and can be considered as hallmark components of the retina of mammals. They bear a distinctive morphology as their dendrites are organized in two different layers: an ovoidal cell body gives rise to a thick, primary dendrite producing two orders of branches – a series of long, thin processes mostly restricted in sublamina 5 of the IPL, near the cell bodies of ganglion cells; and a second set of globose varicosities, called lobular appendages, clustered in a bushy and narrow ramification, spanning vertically through sublaminae 1–2 of the IPL (**Figure 3**). Electron microscopy has demonstrated that AII amacrine cells are placed in a pivotal position along the rod pathway. Scotopic signals transmitted from rods to rod bipolar cells (which belong to the category of ON-center, depolarizing neurons) are conveyed through sign-conserving, glutamatergic synapses to the vitreal dendrites of AII amacrine cells in sublamina 5 of the IPL. At this point, a dichotomy is generated in the rod pathway,

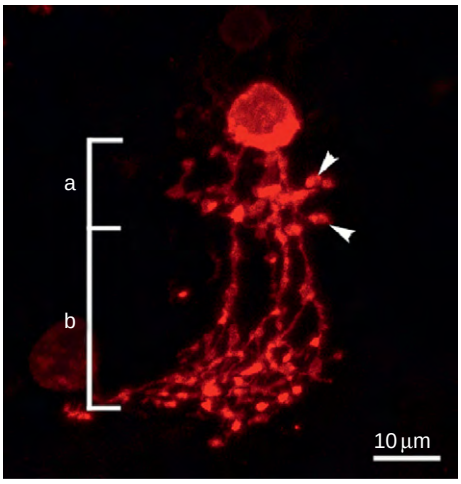

Figure 3 An individual AII amacrine cell from the mouse retina labeled after delivering the fluorescent probe DiI with a gene gun. Note the typical bistratified morphology, with lobular appendages (arrowheads) confined in the outermost part of the inner plexiform layer (IPL), the sublamina a. Long and thin processes of the same amacrine reach the innermost portion of the IPL, the sublamina b.

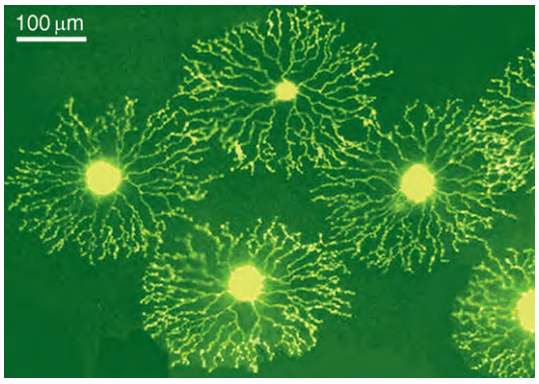

Figure 4 Example of three adjacent starburst amacrines stained by intracellular injection with Lucifer yellow. Reproduced from Vaney, D.I. (1999). Neuronal coupling in the central nervous system: Lessons from the retina. *Novartis Foundation Symposium* 219: 113–125.

as the signal is literally split into two channels by means of the connections of AII amacrines. These cells establish sign-conserving gap junctions with the axonal arbors of cone bipolar cells located in sublamina ON of the IPL, and glycinergic, sign-inverting synapses with axonal endings of cone bipolar cells terminating in sublamina OFF of the IPL. Finally, rod-initiated signals are transferred to the ganglion cell through sign-conserving chemical synapses established by axonal endings of cone bipolar cells in the ON and OFF halves of the IPL. Therefore, the rod pathway ultimately makes use of the axonal endings of cone bipolar cells to gain access to ganglion cells. The five-neuron chain in which the main rod pathway is organized is usually called piggyback arrangement, to indicate the fact that rod-generated signals use a common route, represented by cone bipolars, to exit the retina. AII amacrines are key elements of the piggyback pathway: because of their peculiar morphology and connectivity, they occupy a strategic position when illumination conditions switch from the scotopic range, in which rod photoreceptors are active, to the photopic range, in which cones become functional. AII amacrines, therefore, have to be informed about adaptation in the inner retina. This information is provided, among others, by dopaminergic amacrine cells, which play a relevant role in adaptation processes in the neural retina, and which provide a rich innervation of the primary dendrites of AII amacrine cells in sublamina 1 of the IPL.

Because of their synaptic circuitry, cells such as the AII do not conform to the general concept of amacrine cells as laterally placed, modulatory elements of the retinal connectivity, deputed to lateral transmission of electric signals. Within the rod pathway, AII amacrines occupy a vertical position and rod-generated signals cannot enter ganglion cells without this strategically placed neuronal type. Hence, in very dim light, the AII amacrine is an obligatory connection in the retina's through-pathway. Generally speaking, small-field amacrine cells introduce little more lateral conduction than bipolar cells do; besides the AII, the function of other small-field amacrines is yet to be clarified.

As rod photoreceptors are numerous, AII amacrine cells are also abundant in the retina. Indeed, they are the largest population of amacrine cells accounted for, reaching 11–13% of all the amacrines in the retina of rabbits and mice. The remaining amacrine cell types come at a lower frequency, each reaching 3% maximum of the total population.

Starburst Amacrines

Starburst amacrine cells, so defined thanks to the shape of their circular and rich dendritic tree, are the second, most numerous amacrine cells in mammals, accounting for about 3% of the whole amacrine population. They are a recurrent finding of vertebrate retinas, from dogfish to primates. These neurons have a characteristic, radially symmetric morphology, with higher-order dendritic branches emerging from dichotomous ramification of thicker fibers. In the rabbit retina, their dendritic field size is approximately 400 µm and therefore they belong to the category of wide-field cells (**Figure 4**). It has been shown that starburst amacrines overlap extensively and their dendrites occupy a large percentage of the volume of the IPL. In the rabbit, calculations show that each millimeter of IPL is covered by 6 m of dendrites from starburst amacrine cells, so that the whole retina contains some 2 km of processes from this neuronal type.

Starburst amacrines occur in two, mirror-symmetric populations, composed of almost equal numbers of cells.

In the first group, cell bodies reside in the innermost tier of the INL and dendrites form a narrow plexus in sublamina 2 of the IPL.

These are OFF-starburst cells. In the second population, cell bodies are located in the ganglion cell layer instead and therefore contribute to the heterogeneous group of displaced amacrine cells. Displaced starbursts can be easily identified in the ganglion cell layer even with simple nuclear staining because of the smaller nuclear size and visible regularity of their mosaic. Their dendrites form a second plexus in sublamina 4 of the IPL and are therefore ON-starbursts. Because of their early formation during retinal development and precise positions in the ON and OFF halves of the IPL, the two tiers of starburst dendrites (also known as cholinergic bands) are landmarks often used as references to define the stratification levels of other neurons in the IPL.

In the first days of postnatal development, when retinal neurons are being generated and assembled in regular tiers, waves of light-independent electrical activity traverse the inner retinal surface intermittently. Retinal waves can be recorded from the ganglion cell layer in the form of correlated activity of these neurons. Waves are thought to play an instructive role in the formation of topographic maps of projection neurons in the centralmost visual areas. Pharmacological experiments indicate that developmental waves require the presence of starburst amacrines, releasing both GABA and acetylcholine, the latter acting on nicotinic receptors. The action of both neurotransmitters is excitatory, since GABA has an excitatory role during development. During retinal maturation, starburst cells communicate directly with each other, so that electrical activity generated at one retinal location can propagate to distant areas. However, during the subsequent developmental stages, excitation between starbursts becomes almost undetectable while GABAergic synapses among starburst cells switch from being excitatory to inhibitory.

Starburst cells participate in transretinal waves during early development but their role is totally different in the adult retina. The exact cofasciculation of starburst processes and the dendrites of a highly distinctive ganglion cell type, the ON-OFF directional selective (DS) ganglion cell, which senses stimuli moving in one direction, led to the hypothesis that, in the adult retina, starburst amacrines could provide a major source of synaptic input to this category of neurons. A wealth of data generated the notion that acetylcholine and starburst amacrines in particular, do contribute to the functional properties of directional selectivity. A current view of this complex problem that has fascinated physiologists for decades is that starburst amacrines are capable of releasing the neurotransmitter in a directional fashion, contributing to the tuning of DS ganglion cells for the preferred direction of motion.

Only for a few other types of amacrine cells has a clear role been elucidated. Among them, dopaminergic amacrines, also known as interplexiform cells, have a crucial function in neural adaptation and circadian rhythms; A17 amacrine cells, a long-time known type of wide-field amacrine, are typical local interneurons, providing feedback inhibition to the axonal ending of rod bipolar cells. For most of the amacrine cell types, however, the role is simply inferred on the basis of their costratification with other retinal neurons. Obviously, the fact that our inventory of amacrine cells is presumably complete represents only the first stage in the comprehension of the role of these interneurons. The next step toward a true understanding of retinal architecture will be to learn synaptic and functional interactions of the amacrine cell with individual types of bipolar and ganglion cells, constituting parallel pathways across the retina – a challenge for future years.

Morphology of Interneurons: Bipolar Cells

S Haverkamp, Max-Planck-Institute for Brain Research, Frankfurt/Main, Germany

Glossary

Clomeleon – A ratiometric genetically encoded indicator comprising a fusion of cyan and yellow fluorescent protein that allows noninvasive chloride measurements in living tissue.
Dyad – Synaptic arrangement of the bipolar cell output synapses within the inner plexiform layer of the retina; the presynaptic ribbon of a dyad is surrounded by vesicles and two postsynaptic elements.
Genuine S-cones – In ventral mouse retina, the great majority of cones express both medium-wavelength (M) and short-wavelength (S) opsin. Blue cone bipolar cells contact only those cones, which express S-opsin only. These are the genuine S-cones.
Landolt club – Process that extends distally from many bipolar cells in cold-blooded vertebrates from the outer plexiform layer to the outer limiting membrane. The function of the Landolt club is not known in any retina.
Midget bipolar cell – The term midget refers to the small spread of their dendritic and axonal arbors. The one-to-one relationship between midget bipolar cells and cones on the dendritic end, and between midget bipolar cells and ganglion cells on the axonal end, is a distinctive property of midget bipolar cells around the fovea.
Type – Members of each cell type show very similar properties, that is, release the same transmitter, make the same connections to other cell types, and generally have the same morphology.

Introduction

The retina contains a large diversity of individual cell types, each carrying out a specific set of functions. They are mainly defined by their morphological appearance. Bipolar cells differ in their dendritic branching pattern, the number of photoreceptors contacted, and the shape and stratification level of their axons in the inner plexiform layer. The cells transfer the light signals from the photoreceptors to amacrine and ganglion cells. They can be subdivided, according to their light responses, into ON and OFF bipolar cells. This functional dichotomy is the result of the expression of different glutamate receptors at the synapses between photoreceptors and bipolar cell dendrites. OFF bipolar cells make flat or basal contacts with cone pedicles, ON bipolar cells make invaginating contacts. The axon terminals of OFF cone bipolar cells terminate in the outer half of the IPL and synapse with the dendrites of OFF ganglion cells, whereas those of ON bipolar cells terminate in the inner half of the IPL and contact the dendrites of ON ganglion cells.

Bipolar Cell Types of the Mammalian Retina

Bipolar cells of the mammalian retina can be subdivided into many different morphological types (**Figure 1**). There are at least nine types of cone bipolar cells and one type of rod bipolar cell. Most mammalian retinas are rod dominated. Therefore, rod bipolar cells form the numerically superior part of the bipolar cell population. Their dendrites make invaginating contacts with rod spherules (**Figure 3(b)**) and their axons terminate in the innermost part of the IPL (**Figure 1**: rod bipolar cell, RB). The number of rods converging on a single rod bipolar cell varies greatly between the species, and, within a species, with retinal eccentricity. In the peripheral human retina, each rod bipolar cell contacts 40–50 rods. Near to the fovea, the dendritic trees become smaller and 15–20 rods are connected. Regardless to retinal eccentricity, convergence in the rod pathway is usually higher than in the cone pathway.

Several types of cone bipolar cells have been recognized in different mammalian species (rabbit: 13, human: 10, cat: 8–10, rat: 9–11, ground squirrel: 6–8). The diagram in (**Figure 1**) compares the bipolar cells of the mouse retina with those of the peripheral macaque monkey retina. The nine putative cone bipolar cell types (labeled 1–9) and the rod bipolar cell of the mouse retina are arranged according to the stratification level of their axon terminals in the IPL. The cells were drawn from vertical sections following intracellular injections. Selective markers, which stain the whole population, are now available for most of the bipolar cell types of the mouse retina (see below). Types 1–4 are OFF cone bipolar cells; types 5–9 are ON cone bipolar cells. The cells contact on average between five and eight neighboring cone pedicles with one exception: type 9 has a wide dendritic tree that appears to be cone selective and it will be shown later that it contacts S-cones.

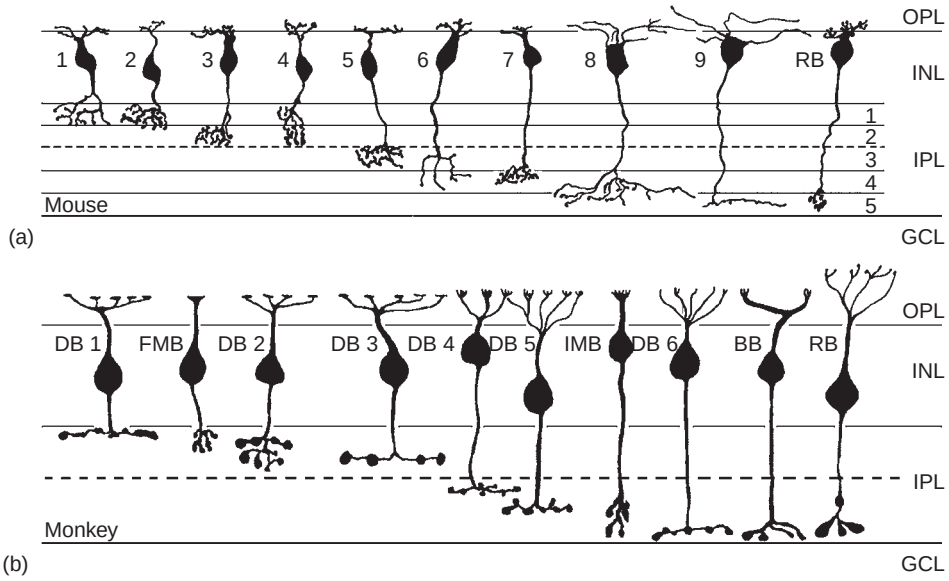

Figure 1 Schematic diagrams of bipolar cells of mouse (a) and primate retina (b). The retinal layers are indicated in (a) for the mouse retina. The inner plexiform layer (IPL) can be subdivided into five sublayers of equal width. The bipolar cell types of the mouse retina were named according to the level of stratification of their axon terminals in the IPL. The dashed horizontal lines dividing the IPL in (a) and (b) represent the border between the OFF-(upper) and the ON-(lower) sublayers. Bipolar cells with axons terminating above this line represent OFF bipolar cells, those with axons terminating below this line represent ON bipolar cells. DB, diffuse bipolar cells; FMB, flat midget bipolar cells; IMB, invaginating midget bipolar cells; BB, blue cone bipolar cells; RB, rod bipolar cells; OPL, outer plexiform layer; INL, inner nuclear layer; GCL, ganglion cell layer. Adapted from Ghosh, K. K., et al. (2004). See Erratum in *Journal of Comparative Neurology* 476: 202–203.

The mouse retina is considered to be rod dominated because only 3% of their photoreceptors are cones. However, the perspective changes if one examines the absolute number of cones; the cone density is about 13 000 cones/mm^2, similar to peripheral cat, rabbit, and macaque monkey retinas. Consequently, the types and retinal distributions of cone bipolar cells are closely similar between mammalian species. The bipolar cell types of the monkey retina (**Figure 1(b)**) were determined initially from Golgi-stained whole mounts. There is a striking similarity between mouse and monkey bipolar cells with respect to the shapes and stratification levels of their axons. However, there is also a clear difference; midget bipolar cells (flat midget bipolar cell (FMB); invaginating midget bipolar cell (IMB)) are only found in the monkey retina. FMB and IMB cells have dendritic trees, which contact a single cone. Bipolar cells contacting several neighboring cone pedicles were named diffuse bipolar cells (DB1–DB6).

Midget Bipolar Cells of the Primate Retina

Primates have trichromatic color vision based on three spectral types of cones: long-wavelength (red or L-), middle-wavelength (green or M-), and short-wavelength (blue or S-) sensitive cones. Midget bipolar cells receive inputs either from red or green cones. Thus, in terms of their input and the polarity of their response, there are four types of midget bipolar cells: red ON, red OFF, green ON, and green OFF. The term midget refers to the small spread of their dendritic and axonal arbors (**Figure 1b**: FMB, IMB). In the central retina, a midget bipolar cell receives direct input from just one cone (**Figure 2(a)**). The bipolar cell axon terminal, which contacts just one ganglion cell, is correspondingly small. This one-to-one relationship between midget bipolar cells and cones on the dendritic end, and between midget bipolar cells and ganglion cells on the axonal end, is a distinctive property of midget bipolar cells around the fovea. Four to five millimeters beyond the fovea, in the near periphery, the midget bipolar cells become two and three headed connecting to two and three cones, respectively (**Figure 2(b)**).

Reconstructions of Golgi-impregnated midget bipolar cells of the primate retina by serial electron microscopy (EM) revealed a clear dichotomy of their dendritic contacts at the cone pedicle base: IMB cells made exclusively invaginating contacts, whereas FMB cells made only flat contacts (**Figure 3(a)**). In central retina, they are all in the vicinity of the ribbons (triad associated, TA), and at eccentricities beyond 3–4 mm, approximately 20% are nontriad associated (NTA). Individual IMB bipolar cells make up to 25 contacts with a cone pedicle, and an FMB cell makes approximately 2–3.5 times that number of basal synapses.

Blue Cone Bipolar Cells

Placental mammals other than primates have only two types of cones: M-cones, in which the visual pigment has an absorption maximum of >500 nm and S-cones with an absorption maximum at <500 nm. They are, therefore, dichromats. In an evolutionary comparison of color

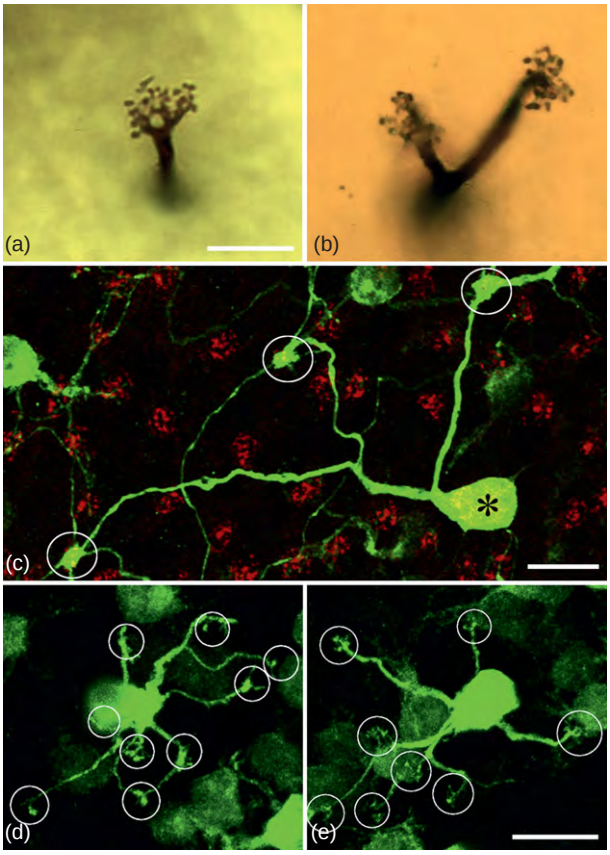

Figure 2 Bipolar cells and their cone contacts in the primate and mouse retina. (a, b) Horizontal view of Golgi-impregnated midget bipolar cells, with the plane of focus at their dendritic tips in the OPL. The micrographs show examples of a single-cone contacting (a) and a two-cone-contacting (b) midget bipolar cell. (c) Horizontal view of a Clomeleon mouse retina (Clm1 line) double labeled for GFP (green) and for GluR5 (red). The clusters of GluR5 puncta represent individual cone pedicles. The dendrites of the blue cone bipolar cell (asterisk) contact three-cone pedicles (circles) and avoid all other pedicles. The BB cell is cone-selective for S-opsin expressing cones. (d, e) Dendritic trees of two type 7 bipolar cells in the Gus-GFP mouse and their cone contacts (circles). Type 7 cells contact on average 8.4 cones. Scale bars = 10 μm. (a, b) Images: courtesy of H. Wässle. From Puller, C., Haverkamp, S., and Grünert, U. (2007). OFF midget bipolar cells in the retina of the marmoset, *Callithrix jacchus*, express AMPA receptors. *Journal of Comparative Neurology* 502: 442–454.

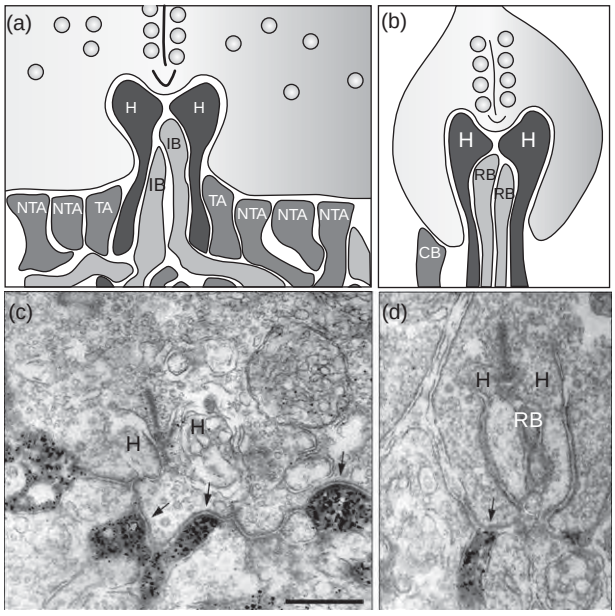

Figure 3 Bipolar cell contacts at photoreceptor terminals. (a, b) Schematic drawings showing the arrangement of contacts at a cone pedicle (a) and rod spherule (b). Horizontal cell processes (H) always end laterally and deeper in the invaginations of both rod and cone terminals. In cone pedicles, the central processes derive from invaginating ON bipolar cells (IB), whereas in rod spherules, the central elements derive from rod bipolar cells (RB). Flat contacts at the base of the cone pedicle are subdivided into triad associated (TA) or nontriad associated (NTA) contacts, depending on their relative distance from the triad. Some cone bipolar cells receive direct input from rods (CB in (b)). (c, d) Type 4 cone bipolar cells of the mouse retina express calsenilin and contact cones as well as rods. Preembedding electron micrographs showing several flat contacts of a calsenilin-positive dendrite at a cone pedicle base (arrows in (c)) and a calsenilin-positive dendrite making a flat contact on a rod spherule (arrow in (d)). Scale bar = 0.5 μm. (a, b) Schematic drawings: courtesy of C. Puller.

pigments, it has been estimated that the L/M separation in the old world primate lineage occurred ~35 million years ago. The separation of the M- and S-cone pigments occurred >500 million years ago and thus represents the phylogenetically ancient, primordial color system. The morphological substrate for the dichromatic color vision common to most placental mammals is the S-cone pathway. Bipolar cells selective for S-cones in the macaque monkey retina have long, smoothly curved dendrites and contact between one and three cone pedicles. Their axons terminate in rather large varicosities in the innermost part of the IPL, close to the ganglion cell layer (BB cells in Figure 1(b)) and innervate the inner tier of the dendritic tree of the small bistratified ganglion cells: These cells are color-opponent and respond to increasing blue light (blue – ON) and decreasing yellow light (yellow – OFF).

Immunostaining with antisera specific for S-opsin has shown that S-cones constitute approximately 10% of the cones in most mammalian retinas. However, in some species S-cones have a very uneven topographical distribution across the retina and many cones express both M- and S-opsin. Recently, a transgenic mouse line could be studied, where Clomeleon, a genetically encoded fluorescence indicator, was expressed under the thy1 promoter. Clomeleon was expressed in ganglion cells, amacrine cells, and bipolar cells.

Clomeleon-labeled ganglion cells, amacrine cells and bipolar cells

Among the bipolar cells the S-cone-selective (blue cone) type could be identified, and the cone-selective contacts

and the retinal distribution could be studied (**Figure 2(c)**). The morphological details of the blue cone bipolar cells match type 9 cells of mice (**Figure 1(a)**) and they are closely similar to the blue cone bipolar cell of the primate retina. It is interesting that in the ventral mouse retina, where most cones express both M- and S-opsin, blue cone bipolar cells contact only those cones, which express S-opsin only. They are the genuine S-cones of the mouse retina. Meanwhile, S-cone-selective bipolar cells have also been verified in ground squirrel and rabbit retina.

Diffuse Bipolar Cells

Most bipolar cell types of the mammalian retina contact between 5 and 10 neighboring cones (**Figure 2(d)** and **2(e)**). In mouse, the number of cone pedicles contacted by individual bipolar cells varied from an average of 5.6 for type 2 cells to an average of 8.4 for type 7 cells. Each and all cones are contacted by at least one member of any given type of bipolar cell (leaving aside the blue cone pathway). Consequently, each cone pedicle is connected to a minimum of eight different bipolar cells. They represent eight separate channels that transfer the light signal into the IPL. Parallel processing, therefore, starts at the first synapse of the retina, the cone pedicle.

Diffuse bipolar cells of the primate retina contact L- and M-cones in their dendritic field non-selectively. Whether all diffuse bipolar cell types also contact S-cones is still a matter of discussion, and it has been proposed that one type of diffuse bipolar cell avoids S-cones in the primate retina. This type would be a good candidate to transfer a yellow (L-plus M-cone) signal into the IPL, where it could contact the outer tier of the dendritic tree of the small bistratified ganglion cells. For the dichromatic ground squirrel retina, it has been shown that diffuse bipolar cells sample cone signals differently: some types receive mixed S/M-cone input and other types receive an almost pure M-cone signal. Bipolar cells that sum signals from S- to M-cones are therefore involved with the transfer of luminosity signals, whereas bipolar cells that carry M-cone signals can have, together with S-cone bipolar cells, a role in color discrimination. Alternatively, these bipolar cells may mediate – due to their relatively small dendritic fields – high acuity vision. This idea would correspond to the fact that the center of the human fovea, which mediates the highest acuity vision, also excludes S-cones.

Like the midget bipolar cells, diffuse bipolar cells also differ in their synaptic contacts with cone pedicles, making either flat or invaginating contacts. EM reconstructions of Golgi-impregnated diffuse bipolar cells of the macaque monkey retina revealed that DB1, DB2, and DB3, which have their axon terminals in the outer IPL and are putative OFF bipolar cells (**Figure 1(b)**), make exclusively basal junctions with the cone pedicle. They always have triad associated (TA) and nontriad associated (NTA) contacts (**Figure 3(a)**). The proportion of TA and NTA contacts varies according to the cell type, as does the average number of contacts per cone, which is between 10 and 20. Bipolar cells DB4, DB5, and DB6 have their axon terminals in the inner part of the IPL and are putative ON bipolar cells. They have an average of between four and eight invaginating synapses per cone pedicle. In addition, they also form basal junctions, in a predominantly TA position. Thus, while the dichotomy 'invaginating = ON, flat = OFF' holds for midget bipolar cells, it does not conform so clearly for diffuse bipolar cells. Therefore, the type of synapse made by a bipolar cell at a cone pedicle, flat versus invaginating, is not the decisive feature; it is rather the glutamate receptor expressed there.

Cone Bipolar Cells with Rod Input

Recent results from rodent and rabbit retina have shown that some OFF cone bipolar cells make also basal contacts with rod spherules and thus receive a direct input from rods. This represents a third route for the rod signal, in addition to the rod bipolar cell circuit, and the gap junctions between rods and cones. In mouse, true-cone-selective OFF bipolar cells (types 1 and 2, **Figure 1(a)**) can be distinguished from types with mixed rod-cone input (types 3 and 4, **Figure 1(a)**). Type 4 bipolar cells make several basal contacts at the cone pedicle base (**Figure 3(c)**) and an individual cell contacts five to eight cones. In addition, some dendrites extend further out into the OPL and contact rod spherules as flat contacts (**Figure 3(d)**). On average, we counted 10 rod spherule contacts per type 4 bipolar cell, and approximately 10% of rods contacted by type 4 bipolar cells.

Immunocytochemical Markers and Transgenic Mouse Lines

The morphological classification of bipolar cells has been made more objective and more quantitative by immunocytochemical markers that selectively label specific cell types. Some of the markers label the same cell types across different species. For instance, rod bipolar cells of all mammals are immunoreactive for protein kinase C α (PKCα). However, other markers, such as calcium-binding proteins, label different cell types in different mammals. Calbindin antibodies label the DB3 OFF cone bipolar cell in the primate retina. However, in the rabbit retina, the calbindin-immunoreactive cell is an ON cone bipolar cell, and in the rat and mouse retina, no bipolar cell expresses calbindin immunoreactivity. Recoverin is another example of a marker that selects different types of bipolar cells in different species. While

in rat and rabbit retinas two types of bipolar cell, an OFF and an ON cone bipolar cell, appear to be labeled, only the OFF midget bipolar cell is labeled in the macaque monkey retina. Even in closely related species, different bipolar cell types can be selected by the same marker. The antibody against the carbohydrate epitope CD15 labels a single population of ON bipolar cells (DB6) in macaque monkey, whereas DB6 cells and OFF midget bipolar cells are labeled in marmoset monkeys. In rabbit, CD15 antibodies label an ON cone bipolar cell, whereas in mouse CD15 is expressed in OFF cone bipolar cells. In contrast, antibodies against the calcium-binding protein CaB5 immunolabel at least three types of bipolar cells in a variety of mammalian species. In all species, rod bipolar cells, one ON cone bipolar cell and at least one OFF cone bipolar cell were labeled (**Figure 4**).

The IPL can be subdivided into five strata of equal thickness (**Figures 1** and **5**). In mouse, these strata can be easily defined by immunolabeling the retina for the calcium-binding protein calretinin (**Figure 5(b)**), which reveals three densely labeled horizontal bands of processes. The outer band (between stratum 1 and 2) contains the processes of the OFF cholinergic amacrine cells and the outer dendritic branches of direction-selective ganglion cells. The band in the inner IPL (between stratum 3 and 4) contains the processes of the ON cholinergic amacrine cells and the inner dendritic branches of direction-selective ganglion cells. The band in the middle of the IPL (between stratum 2 and 3) represents the level of stratification of a nitric oxide synthase (NOS) immunoreactive amacrine cell type and separates the OFF sublamina (outer) from the ON sublamina (inner). The calcium-binding protein 5 (CaB5)-immunoreactive bipolar cells stratify in three strata; in stratum 2 where the type 3 bipolar cells stratify, in stratum

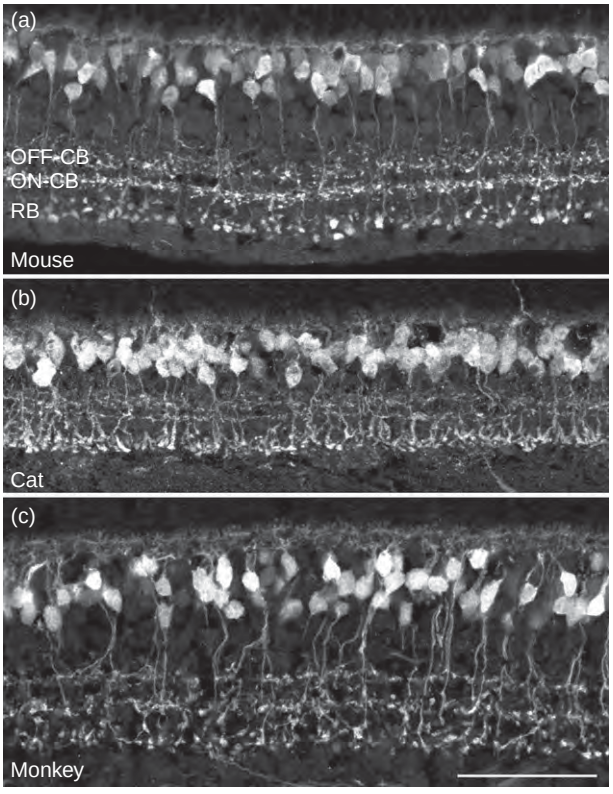

Figure 4 Comparison of CaB5 immunoreactivity in mouse (a), cat (b), and monkey (c) retina. In all three species, rod bipolar cells (RB) and at least one ON cone bipolar (ON-CB) and one OFF cone bipolar cell (OFF-CB) are labeled. Scale bar = 50 μm.

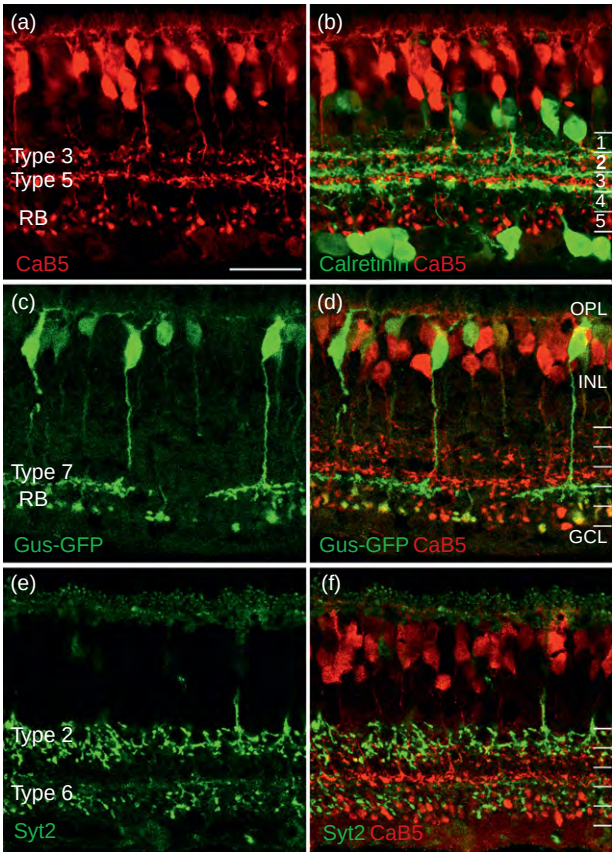

Figure 5 Immunocytochemical staining of mouse bipolar cells. (a, b) Vertical section through a mouse retina that was double immunostained for CaB5 (red) and calretinin (green). Three dendritic strata within the IPL express calretinin and subdivide the IPL into four sublaminae. Three bipolar cell types (type 3, type 5, and RB) express CaB5. Their axons terminate in the IPL in sublamina 2, sublamina 3, and sublamina 5, respectively. (c, d) Vertical section through the Gus–GFP mouse retina immunostained for GFP (green) and CaB5 (red). The retinal layers are indicated (OPL, INL, IPL, subdivided into five sublayers of equal thickness; GCL). Type 7 bipolar cells express high levels of GFP and their axons terminate at the border of sublaminae 3/4. Rod bipolar cells also express GFP, but weakly (double labeled with Cab5 in (d)). (e, f) Vertical section through the mouse retina immunostained for synaptotagmin 2 (Syt2 , green) and CaB5 (red). Type 2 and type 6 bipolar cells express Syt2. Type 2 axons terminate in sublamina 1/2, above the CaB5-labeled type 3 axons; type 6 axons terminate mainly in sublamina 4/5 and intermingle with CaB5-labeled RB axon terminals. Scale bar = 25 μm.

3 where type 5 cells stratify, and in stratum 4/5 where the rod bipolar cells terminate (**Figure 5(a)** and **5(b)**).

We have used several selective markers, either antibodies or the specific expression of fluorescent proteins in transgenic mouse lines, for analyzing the different types of bipolar cells in the mouse retina. Five putative OFF cone bipolar cells were analyzed by selective markers. Type 1 bipolar cells were found to be immunoreactive for the neurokinin 3 receptor (NK3R) and they could also be identified in Clm1 transgenic mice. Type 2 bipolar cells expressed NK3R and synaptotagmin II (Syt2) immunoreactivity (**Figure 5(e)** and **5(f)**). Type 3a and type 3b cells were immunostained for the hyperpolarization-activated cyclic nucleotide-gated potassium channel 4 (HCN4) and the protein kinase A regulatory subunit II β ($PKA_{RII\beta}$), respectively, and type 4 cells expressed the calcium-binding protein, calsenilin. In the case of ON cone bipolar cells, markers for four types were described. Type 5 bipolar cells were labeled in the 5-hydroxytryptamine 3 receptor-EGFP (5HT3R-EGFP) transgenic mouse; however, they represent two types (named 5a and 5b). Type 6 bipolar cells were partially identified because their axons express Syt2 (**Figure 5(e)** and **5(f)**). Type 7 bipolar cells were labeled in the Gus-GFP mouse, a transgenic mouse line where GFP is expressed under the control of the gustducin promoter (**Figures 2(d), 2(e), 5(c)** and **5(d)**) Type 9, the blue cone bipolar cell, has been identified in Clm1 mice. Rod bipolar cells have been immunostained for PKCα. This list suggests that, with the exception of type 8 bipolar cells, selective markers, which stain the whole population, are available for all bipolar cell types of the mouse retina.

Synaptic Contacts of Bipolar Cells in the Inner Plexiform Layer

The axons of bipolar cells terminate in the IPL in lobular swellings (**Figure 6(a)**). Some bipolar cell types, such as DB3 and DB6 of the primate retina and type 7 of the mouse retina, keep their axon terminals within a narrow stratum (**Figure 5(c)** and **5(d)**). Hence, their output will be restricted to the amacrine and ganglion cell dendrites they meet within that stratum. Other bipolar cells such as type 4 and type 6 of the mouse retina occupy with their axon terminals the complete OFF or ON sublamina respectively (**Figure 5(e)** and **5(f)**). They are possibly engaged in contacts with a wider variety of postsynaptic

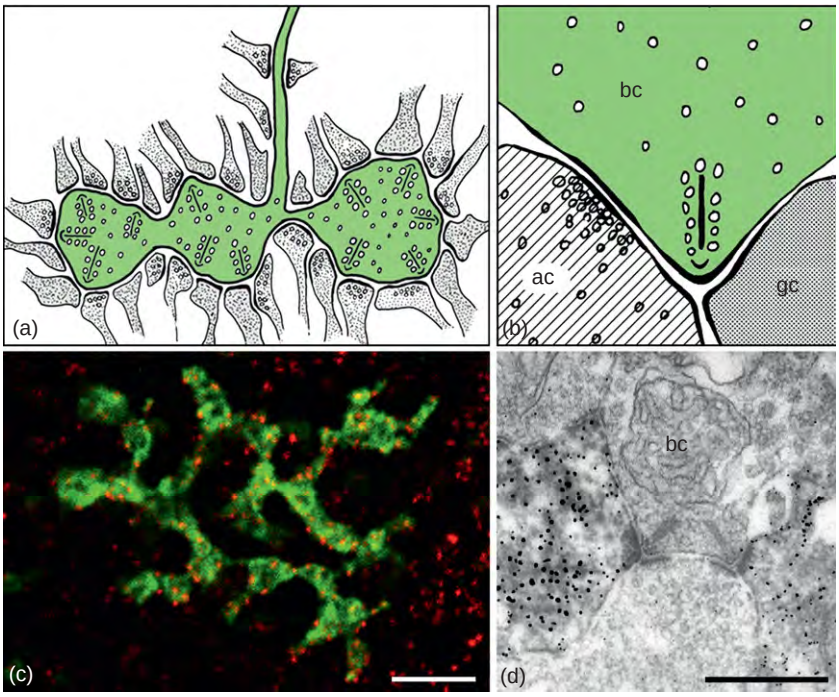

Figure 6 Synaptic output of bipolar cells in the IPL. (a) Schematic diagram of the axon terminal of a cone bipolar cell. It contains many presynaptic ribbons that are flanked by synaptic vesicles. (b) Magnified view of a cone bipolar cell ribbon synapse (dyad). The presynaptic bipolar cell (bc) releases glutamate and the two postsynaptic partners express different sets of glutamate receptors. The amacrine cell, in turn, makes a synapse back onto the bipolar cell terminal (reciprocal synapse). (c) Horizontal view of a GFP-labeled type 7 axon terminal (green) in a Gus-GFP retina. The output synapses are marked (red) by their expression of the ribbon associated C-terminal binding protein 2 (CtBP2/RIBEYE). Altogether, 128 output synapses have been counted at this axon terminal. (d) Electron micrograph of a bipolar cell axon terminal (bc) with two output synapses. Two of the postsynaptic elements are immunolabeled amacrine cell profiles (pre-embedding with glycogen phosphorylase in primate retina). Scale bar = 5 μm in (c), 0.5 μm in (d). ac, amacrine cell; gc, ganglion cell.

neurons. Midget bipolar cells of the primate retina represent a special case, because their axon terminals precisely match in width and depth the dendritic tops of midget ganglion cells, and they together form a densely interconnected glomerulus. The axon terminals of neighboring bipolar cells of a given type usually tile the retina without overlap in the horizontal direction. An interesting question is how the precisely layered and territorial arrangement of axon terminals is formed during embryonic development. Type-specific interactions have to be postulated because terminals of different types can overlap within the same sublamina. Proteins such as the Down's syndrome cell adhesion molecule (Dscam) and an immunoglobulin superfamily protein (Sidekick) are involved in lamina-specific segregations of neuronal processes within the IPL during embryonic development.

Bipolar cell axon terminals provide synaptic output through multiple ribbon synapses (**Figure 6(c)**). We have counted the number of output synapses of the type 7 bipolar cells in the Gus–GFP mouse. The numbers varied between 74 and 128 ($n = 8$) depending on the size of the axon terminals. The number of ribbon synapses made by rod bipolar cells of the rabbit retina was up to 30, compared to only 15 in the rat retina, which reflects the smaller size of rod bipolar axon terminals in rats. The fine structure of the bipolar cell output synapses is shown in **Figure 6(b)**. The presynaptic ribbon is surrounded by vesicles and two postsynaptic elements. This synaptic arrangement is named a dyad. One of the postsynaptic partners at cone bipolar cell dyads is usually a ganglion cell dendrite, while the other one is an amacrine cell process. The amacrine cell process often makes within about 0.5–1.0 μm of the dyad a conventional synapse back onto the bipolar cell axon terminal. This arrangement appears to be a reciprocal synapse and because most amacrine cells are inhibitory, it is the structural correlate of negative feedback at the dyad. Bipolar cell axons receive, in addition to reciprocal synapses, input from amacrine cells not related to the dyads. In the case of rod bipolar cell dyads, both postsynaptic partners are amacrine cells (AI and AII); and AI cells provide the reciprocal synapses.

Costratification of Pre- and Postsynaptic Partners in the Inner Plexiform Layer

Bipolar axons terminate at distinct levels within the IPL, and different types of amacrine and ganglion cells also keep their processes at specific levels within the IPL, which leads to the prediction that they are also engaged in mutual synaptic contacts (**Figure 7**). However, this simple rule has only been verified in a few instances. Midget bipolar cells of the primate retina – both ON and OFF midget – contact midget ganglion cells. Parasol

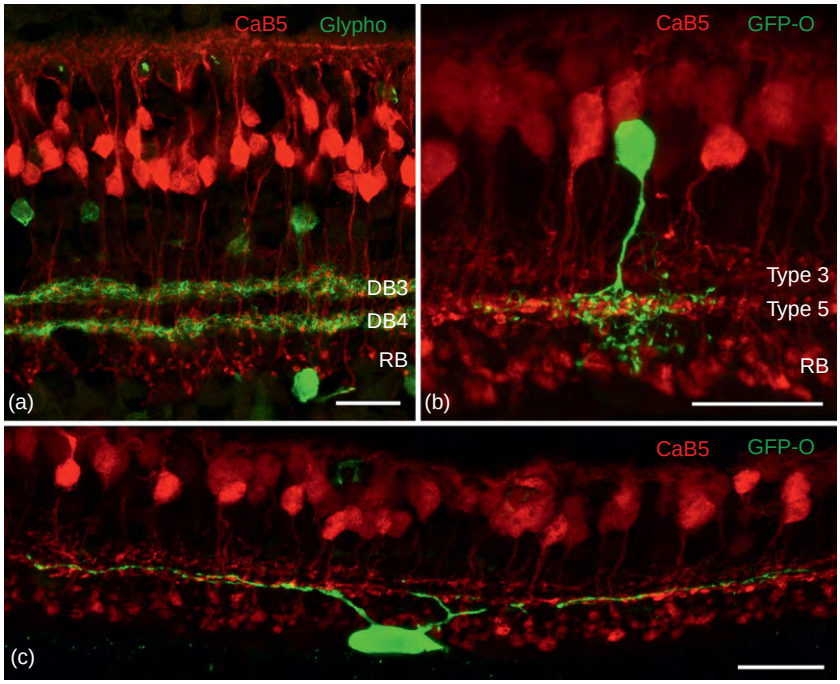

Figure 7 Costratification of pre- and postsynaptic partners in the inner plexiform layer. (a) Vertical section through a primate retina that was double immunostained for CaB5 (red) and glycogen phosphorylase (glypho, green). Axon terminals of CaB5-labeled DB3 and DB4 bipolar cells costratify with the glypho-immunoreactive amacrine cell processes. (b, c) Vertical sections through a transgenic mouse retina where a small set of small-field amacrine cells and ganglion cells express GFP under the control of the thy1 promotor (GFP-O line). Both the small-field amacrine cell with dendrites in the ON-sublamina (b) and the monostratified putative ON ganglion cell (c) costratify with the axon terminals of the type 5 ON bipolar cell. Scale bar = 20 μm.

ganglion cells of the primate retina also occur as OFF and ON pairs and their dendrites stratify in sublamina 2 and sublamina 4, respectively. The OFF parasol cells receive their major, excitatory input from DB3 bipolar cells, and ON-parasol cells most likely from DB5 bipolar cells. In rabbit, ON α ganglion cells stratify just below the ON cholinergic amacrine cells and cofasciculate (distribute together) with the axon terminals of the calbindin-immunoreactive bipolar cells.

The bistratified ON/OFF direction-selective (DS) ganglion cell coincides with the level of stratification of ON and OFF cholinergic amacrine cells. In the rabbit retina, DS ganglion cells receive the majority of their synaptic input from amacrine cells. The axon terminals of the CD15-immunoreactive bipolar cells stratify slightly more distally of the ON cholinergic band. In addition, they follow the pattern of the ON cholinergic dendrites, and are, therefore, good candidates for providing synaptic input to the DS circuitry.

Figure 7(a) shows a double labeling of glycogen phosphorylase (glypho) and CaB5 in the macaque monkey retina. The glypho-immunoreactive cells occur – like the cholinergic amacrine cells – as mirror-symmetrical populations of regular and displaced wide-field amacrine cells. The regular amacrine cells branch in sublamina 2 and co-stratify with DB3 cells; the displaced amacrine cells branch in sublamina 3 and co-stratify with DB4 cells.

Transgenic mouse lines are extremely helpful to study potential contacts between bipolar cells and their postsynaptic partners in the mouse retina. For instance, in the GFP-O line, each mouse expresses GFP in a small and variable set of ganglion cells and small-field amacrine cells. See **Figure 7(b)** for a small-field amacrine cell and **Figure 7(c)** for a monostratified ON ganglion cell, both of which coincide with the type 5 bipolar cell.

Bipolar Cells of Nonmammalian Vertebrates

It has been shown that bipolar cells of a particular cell are usually found in one-half of the IPL or the other, but not in both. In several nonmammalian vertebrates, however, the axon terminals of the bipolar cells are highly stratified, ending on one or several levels in the inner plexiform layer. Most cold-blooded vertebrate retinas contain large bipolar cells, long thought to be rod-related bipolar cells, and small bipolar cells, believed to be cone-related bipolar cells. In fish, it has been shown that many bipolar cells, particularly the larger ones, contact both rods and cones.

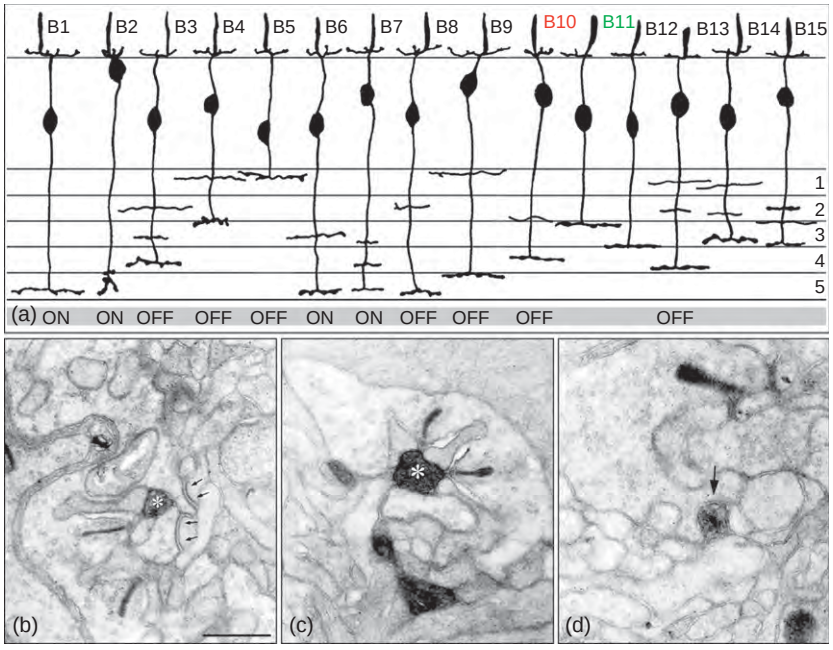

Figure 8 Bipolar cells of the turtle retina. (a) Bipolar cell types B1–B15 in the turtle retina. B1–B9 are from Golgi-impregnated retinae, B10, B11, and B13 from intracellular recordings with subsequent dye injection, and B12, B14, and B15 from Lucifer Yellow injections. The cells are drawn in vertical views with cell bodies, dendrites, and Landolt clubs in the outer retina and the stratification of their axons in the five strata (S1–S5). Several cells are bi- or tristratified. B1, B2, B6, and B7 are ON-center cells; B3, B4, B5, B8, B9, B10, and B13 are OFF-center cells. B10 and B11 are color-opponent cells (B10: red-ON, green/blue-OFF; B11: red-OFF, green/blue-ON). (b)–(d) Electron micrographs showing invaginating, ribbon-associated synapses of an HRP-stained B10 bipolar cell with L-cone pedicles (asterisks in (b) and (c)) and a noninvaginating, basal junction with an M-cone pedicle (arrow in (d)). Two unstained wide-scleft basal junctions in (b) are marked by small arrows. Scale bar = 0.5 μm.

It has also been shown that certain of these bipolar cells are likely to be color-coded, because they contact specific sets of cones. In turtle retina, at least 15 different morphological types of bipolar cells were found (**Figure 8(a)**). Some are monostratified with only a single axon terminal (B1, B2, B5, B11, and B12), several are bistratified (B4, B6, B8, B9, and B10), and some are tristratified (B3, B7, B13, B14, and B15). All seem to have Landolt clubs arising from their dendrites in the outer plexiform layer (OPL) to extend into the outer nuclear layer. A functional organization of the turtle IPL into OFF sublaminae (strata 1 and 2) and ON sublaminae (strata 3, 4, and 5), as has been described for other vertebrate retinas, is quite clear for two types of OFF bipolar cells, which stratify in the two distal strata (B4, B5) and for all four types of ON bipolar cells (B1, B2, B6, and B7). However, some OFF bipolar cells (B3, B9, B10, and B13) have axon terminals in strata 3–5 in addition to their terminations in stratum 1 or 2 (**Figure 8(a)**).

Color-Coded Bipolar Cells in the Turtle Retina

The turtle has excellent color vision, and is at least tetrachromatic. Three cones are sensitive to long wavelengths, one to medium wavelengths, one to short wavelengths, and a further cone to ultraviolet light. The chromatic types of cones can be morphologically identified by the presence and colors of their oil droplets and the shape of their pedicles. Two of the bipolar cell types in turtle are color-opponent: B10 is a red-ON, green/blue-OFF bipolar cell with axons in S2 and S4 and B11 is a red-OFF, green/blue-ON bipolar cell with an axon terminal in S3 (**Figure 8(a)**).

We have analyzed the cone contacts of a horse-radish peroxidase labeled B10 cell by serial EM reconstruction: 45 ribbon-associated synapses were found in single and double L-cones; basal junctions were found in M-cones (**Figure 8(b)–8(d)**). No contacts were found with rods, S-cones, and UV-cones. The results showed that invaginating synapses with L-cones and noninvaginating synapses with M-cones formed the basis of color opponency in an identified bipolar cell for red versus green light stimulation. We suggested sign-inverting transmission from L-cones at invaginating synapses mediated by G-protein-coupled metabotropic glutamate receptors, and sign-conserving transmission from M-cones at wide-cleft basal junctions mediated by ionotrophic (ion-gated) glutamate receptors. For B11 bipolar cells, we would predict that the dendrites express ionotropic glutamate receptors at their contacts with L-cones (red-OFF) and metabotropic glutamate receptors at their contacts with M-cones (green-ON).

Morphology of Interneurons: Horizontal Cells

L Peichl, Max Planck Institute for Brain Research, Frankfurt am Main, Germany

Glossary

Cone pedicle – The axonal synaptic ending of the cone photoreceptor in the outer plexiform layer of the retina; it is commonly a relatively large conical structure that contains about 30 synaptic sites (triads), each having a presynaptic ribbon and three postsynaptic processes.

Connexin – A transmembrane protein; six connexins form a connexon or hemichannel and two connexons form a gap junction. Connexins are a diverse family and can combine into homomeric or heteromeric connexons and gap junctions.

Ephaptic – An action mediated by an electrical contact between nerve cells, without the mediation of a neurotransmitter. In the case of horizontal cells it is mediated by a hemichannel.

Gap junction – A specialized connection between neighboring cells, forming an electrical synapse in the neurons. A gap junction consists of two connexons (hemichannels) that form an intercellular pore across the touching cell membranes. The connexons are connexin hexamers. The pore allows various ions and molecules (e.g., neurobiotin) to pass between the cells. Gap junctions can be regulated (opened and closed) by neuromodulators and thus implement a flexible functional syncytium.

Rod spherule – The axonal synaptic ending of the rod photoreceptor in the outer plexiform layer of the retina; it is a small globular structure that contains two synaptic sites with a presynaptic ribbon and four postsynaptic processes.

Triad – A synaptic arrangement at the synaptic ending of a photoreceptor, located at an invagination of the cone pedicle or rod spherule. The presynaptic side of the triad contains an electron-dense synaptic ribbon for the docking of transmitter vesicles. The postsynaptic side has three invaginating processes, a central bipolar cell dendritic terminal and two lateral horizontal cell terminals. Rod triads receive two biploar cell terminals and two horizontal cell terminals.

General Morphology and Connectivity

Basic Morphology

Horizontal cells are interneurons of the outer retina and the largest neurons present in that region. Their somata are located in the outer part of the inner nuclear layer. Their processes ramify in the outer plexiform layer and form synaptic contacts with the photoreceptors. The horizontal cells of mammals – to which this article is limited – comprise two types, commonly termed A-type and B-type; the terms A-HC or HA and B-HC or HB are also in use. The B-type has a smaller, densely branched dendritic tree with relatively fine dendrites and also has an axon ending in a profusely branched axon terminal system. The A-type has a larger, more sparsely branched dendritic tree with fewer and stouter primary dendrites, and has no axon (**Figure 1(a)**). The dendrites of both types carry clusters of terminals (terminal aggregates) that synapse exclusively with cones. The axon terminal system of the B-type has unclustered terminals that exclusively contact rods (**Figures 1(b)–1(g)**).

The horizontal cell terminals, together with the dendrites of invaginating bipolar cells (ON bipolar cells, depolarizing to the onset of light), insert into invaginations at the base of the photoreceptor terminal (cone pedicle or rod spherule). The synaptic complexes thus formed are referred to as triads. Each cone pedicle possesses a substantial number of invaginations with triads (20–50 in primates), whereas a rod spherule commonly only has one invagination with two triads (**Figures 1(e)–1(g)**). Presynaptically, the triad is marked by a synaptic ribbon that is thought to play a crucial role in the continuous vesicular release of the photoreceptor transmitter glutamate. Postsynaptically, each mammalian triad has a bipolar cell dendritic terminal (two at rod spherules) as a central element, flanked by two horizontal cell terminals as lateral elements. The bipolar cells, via their axonal contacts, pass their signals on to the inner retina. The horizontal cells have no spatially segregated output synapses. The only synaptic contacts they form are with the photoreceptors. These are their input and output sites, representing a local feedback mechanism for the cones (by A-type and B-type dendrites) and the rods (by B-type axon terminals).

Horizontal cells modulate signal transmission from the photoreceptor to the invaginating bipolar cell processes.

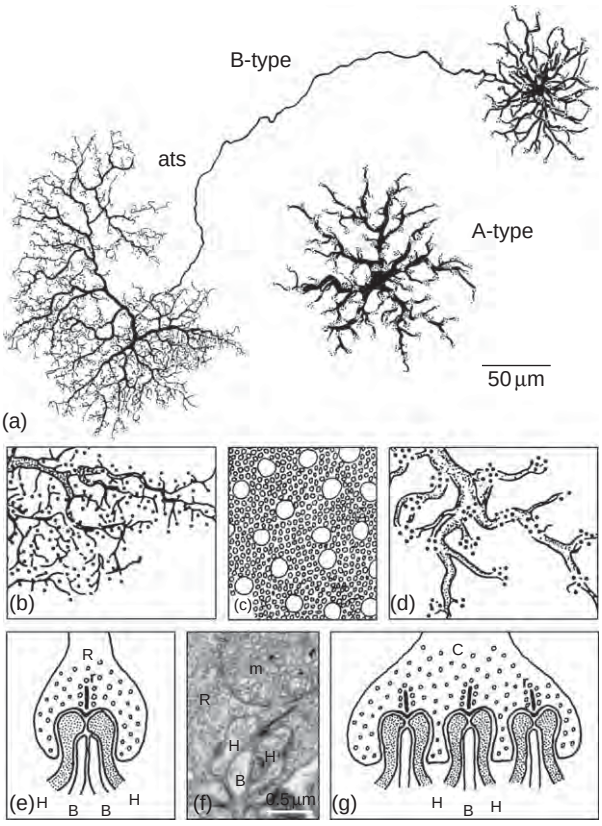

Figure 1 Basic mammalian horizontal cell morphologies. (a) Flat views of a Golgi-stained B-type horizontal cell with axon terminal system (ats) and axonless A-type horizontal cell of cat. Middle row: (b) enlarged part of the B-type ats with single terminals that are the contacts with rods; (c) a schematic photoreceptor pattern with the rather regularly spaced cones surrounded by the more numerous and smaller rods; and (d) part of an A-type dendrite with clustered terminals that are the contacts with cones. Bottom row: (e) schematic triad arrangements at a rod spherule; (f) electron micrograph of a triad in a mouse rod spherule; and (g) schematic triad arrangements at a cone pedicle. R, rod spherule; C, cone pedicle; H, horizontal cell process; B, bipolar cell process; r, presynaptic ribbon; and m, mitochondrion. For details, see text. Adapted from Figure 1 in Peichl, L., Sandmann, D., and Boycott, B. B. (1998). Comparative anatomy and function of mammalian horizontal cells. In: Chalupa, L. M. and Finlay, B. L. (eds.) *Development and Organization of the Retina*: *From Molecules to Function*, pp. 147–172. New York: Plenum Press. With kind permission of Springer Science and Business Media.

The horizontal cell feedback is inhibitory and supposedly creates the antagonistic receptive field surrounds of bipolar cells, thus contributing to the receptive field properties of the ganglion cells. However, the exact nature of the feedback synapse is unknown. There is some evidence that mammalian horizontal cells use the inhibitory transmitter gamma aminobutyric acid (GABA); however, a feedback mediated by electrical conduction (ephaptic, via hemichannels) and pH modulation (proton hypothesis) is also considered. In addition, the horizontal cells probably have feed-forward connections to ON bipolar cells. OFF bipolar cells, which make flat (noninvaginating) contacts at the photoreceptor base, are not in direct apposition to the horizontal cells. It is assumed that the horizontal cell modulation affects them indirectly via the changed photoreceptor output.

The dendritic spread of a horizontal cell is much larger than that of a cone bipolar cell, and activation by cones anywhere in its dendritic field results in an output across the entire dendritic field. Thus, information about the illumination state of cones outside a bipolar cell's input region is picked up by the overlying horizontal cells and negatively fed back to the few cones providing the direct bipolar cell input – the classical lateral inhibition that sharpens contrast sensitivity and acuity. Most likely, the same function is provided for the rod pathway by the B-type axon terminal system.

Photoreceptor Contacts

In the mammalian retina, the rod and cone signals are separately carried by cone and rod bipolar cells, respectively. These major rod and cone pathways only converge in the inner retina. In addition, there is gap-junctional coupling between rods and cones, and a few cone bipolar cells also synapse with rods. Mammalian horizontal cells separately serve the rod and cone pathways.

Contacts with cones

The dendritic fields of horizontal cells are commonly shaped round to oval. Depending on the retinal location, A-type dendritic trees in cat are 80–220 µm in diameter and contact 120–170 cones, whereas B-type dendritic trees are 70–120 µm in diameter and contact 60–90 cones. A- and B-type cells in rabbit are slightly larger but contact similar numbers of cones. In their cone connections, the two horizontal cell types share a common input. Most mammals are cone dichromats with an approximately 90% majority of medium-to-long-wavelength-sensitive (L) cones and a 10% minority of short-wavelength-sensitive (S) cones. In most studied species, both A- and B-type cells contact the vast majority of cones within their dendritic fields; this was considered as evidence that each spectral cone type contacted each horizontal cell type. Soma recordings from cat and rabbit horizontal cells with spectral stimuli confirmed that both types hyperpolarize to all wavelengths. Direct anatomical evidence for the nonselective contacts of both horizontal cell types with both spectral cone types has been obtained in rabbit and tree shrew (**Figures 2** and **3**). In cone triads, the two lateral elements are either two A-type terminals, two B-type terminals, or one A-type and one B-type terminal; in rabbit, these three combinations are found in equal numbers. The current

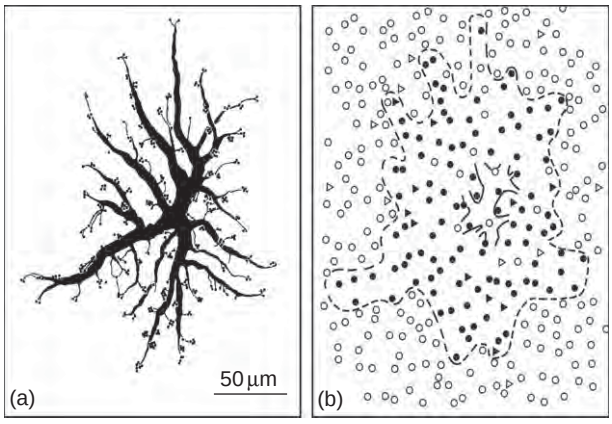

Figure 2 Cone contacts of an A-type horizontal cell in rabbit. (a) Drawing of the Lucifer yellow-injected cell. (b) Cone mosaic overlying the cell, revealed by labeling all cones with the marker peanut agglutinin and identifying the S-cones by an S-opsin antiserum. S-cones are shown as triangles and L-cones as circles. Cones contacted by the A-type cell (dendritic field outline given by broken line) are shown as filled symbols and noncontacted cones as open symbols. The cell contacts most of both spectral cone types in its reach. Reproduced from Figure 4 in Hack, I. and Peichl, L. (1999). Horizontal cells of the rabbit retina are non-selectively connected to the cones. *European Journal of Neuroscience* 11: 2261–2274. With kind permission of Wiley-Blackwell.

view is that mammalian horizontal cells do not participate in color opponency (i.e., the antagonistic interpretation of color opponent channels).

Contacts with rods

Mammalian rods have horizontal cell contacts only with B-type axonal terminals; conversely, B-type axonal terminals connect only to rods. The only reported exception is the cone-dominated gray squirrel retina, where the axon of an H1 cell (B-type equivalent) was described to contact cones and, perhaps, rods. Unlike some other vertebrates, mammals have no type of horizontal cell that is exclusively connected to rods. This role is taken over by the B-type axon terminal system. The B-type axon is not an axon in the functional sense; it does not conduct information from the dendrites and soma to the axon terminal system. The latter is electrically uncoupled from the dendritic part; apparently, the axon is too thin and long (several hundred microns) to conduct the graded potentials that horizontal cells use for signaling. The axonal synaptic connections with the rods resemble those of the dendrites with the cones (**Figures 1(e)–1(g)**). It is thought that the B-type axon terminal system is the independent rod horizontal cell of mammals. Thus, while being one metabolic entity, the B-type cell represents two functional units. Actually, a small rod input is found in soma recordings of both B- and A-type cells; however, this is attributed to direct rod/cone coupling and not to signal transfer through the B-type axon.

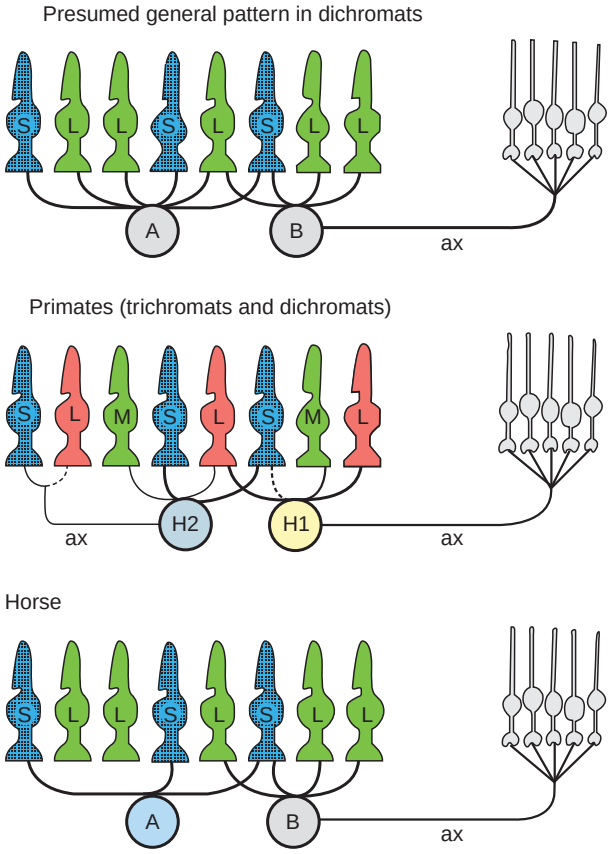

Figure 3 Scheme of the cone and rod contacts of horizontal cells in different mammals. (Top) The presumed general connectivity pattern in dichromats, confirmed in rabbit and tree shrew. A- and B-type cells indiscriminately contact S-cones and L-cones; the B-type axon terminal system contacts rods. (Middle) The connectivity pattern in primates. H1 cells contact M- and L-cones, but largely avoid S-cones (broken contact line); their axon contacts the rods. H2 cells contact S-cones strongly (thick contact line) and M/L-cones less strongly; their axon contacts S-cones, but may also contact M/L-cones. In dichromatic primates, M- and L-cones are only one spectral L type. (Bottom) The connectivity pattern in horse (and probably other equids). The A-type contacts S-cones exclusively, whereas the B-type makes indiscriminate contacts with S-cones and L-cones. The coloring of horizontal cell somata indicates their spectral tuning. Adapted from Figure 9 in Peichl, L., Sandmann, D., and Boycott, B. B. (1998). Comparative anatomy and function of mammalian horizontal cells. In: Chalupa, L. M. and Finlay, B. L. (eds.) *Development and Organization of the Retina*: *From Molecules to Function*, pp. 147–172. New York: Plenum Press. With kind permission of Springer Science and Business Media.

Why are the rods contacted by only one type of process (the B-type axonal terminals) and the cones by two types (A- and B-type dendrites) and what detailed functional difference does that make? An answer is currently not available. The receptive field surround of the ganglion cells becomes broader and shallower with decreasing light levels, and this is interpreted as a useful image-processing strategy. Nevertheless, it is unknown whether and how the rod/horizontal cell connections may be involved.

Population Properties and Gap-Junctional Coupling

The A- and B-type cells form populations that completely cover the retinal surface and thus provide their signals at all points of the retina. Within each population, the cells form a rather regular mosaic, that is, an even tiling of the retinal surface. The horizontal cells, similar to many other neurons, decrease their population density from the central to peripheral retina and conversely increase the size of the individual cells such that the dendritic overlap, or coverage factor, remains approximately constant across the retina. In cat, the density of A-type cells decreases from 800 mm^{-2} to 100 mm^{-2}, and that of B-type cells from 2300 mm^{-2} to 300 mm^{-2}. The coverage factor is approximately four for each type; therefore, each cone can, on average, contact eight horizontal cells. In rabbit, the central–peripheral density gradient is shallower (550 mm^{-2} to 250 mm^{-2} for the A-type and 1375 mm^{-2} to 400 mm^{-2} for the B-type); the coverage factor is approximately six for the A-type and 8–10 for the B-type, somewhat larger than in cat. Several staining methods can be used to stain entire horizontal cell populations. In many mammals, neurofibrillar stains and immunocytochemical staining of the neurofilament proteins specifically reveal the A-type population (**Figure 4(a)**), but in horse, the B-type population is specifically stained. Antibodies against the calcium-binding protein calbindin (CaBP 28 kDa) stain both horizontal cell populations in various mammals (**Figure 4(b)**).

Mammalian horizontal cells are electrically coupled by gap junctions. The coupling is homotypical; there are no gap junctions between A- and B-type cells (**Figure 5**). The gap junctions of A-type cells in rabbit are composed from connexin 50 (Cx50) subunits, and are larger than those of the B-type cells where the connexin is Cx57. The gap junctions of B-type cells in mouse are also formed by Cx57; therefore, the cell-type-specific connexins may be conserved across species. The rod connectivity is similar through the coupling of B-type axon terminals; notably, this coupling is segregated from that of the B-type dendrites (**Figure 5**). Thus, with respect to electrical coupling, the horizontal cells form three separate networks, even though A-type and B-type dendrites largely share their synaptic input and output partners, the cones. The gap junctions are regulated by the ambient light level in a triphasic manner. At intermediate light levels, the horizontal cells are strongly coupled and their signals spread over large distances; in bright and in very low light, the gap junctions are closed and the horizontal cells act as smaller inhibitory units. Dopamine and other neuromodulators are involved in this regulation. Horizontal cell coupling is thought to play an important role in photoreceptor adaptation to different ambient light levels as it serves to collect light information over large areas of the retina.

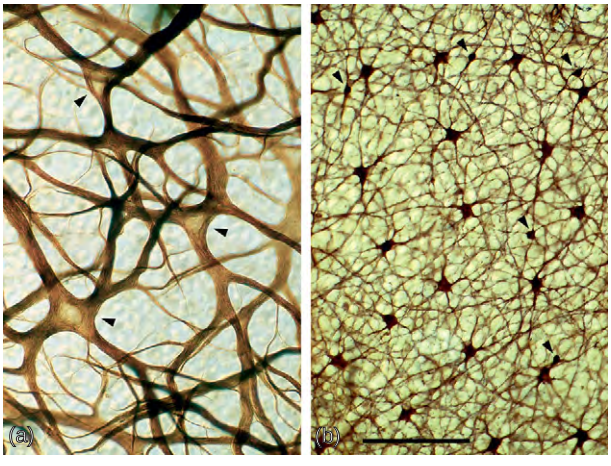

Figure 4 Flat views of population stains of horizontal cells. (a) Neurofibrillar staining of the A-type population in rabbit and (b) calbindin immunostaining of the A- and B-type populations in horse. In both images, the arrowheads indicate A-type somata. The scale bar = 50 μm for (a) and 100 μm for (b).

Diversity of Morphology and Connectivity across Species

None of the basic features listed so far has provided compelling arguments to explain why there should be two horizontal cell types in mammals. Are there really

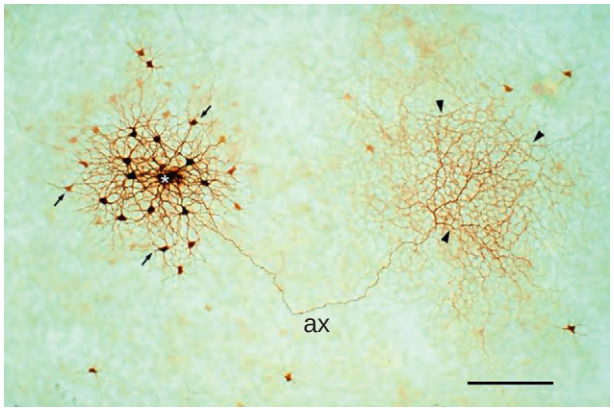

Figure 5 Gap-junctional coupling of rabbit B-type cells. After injection of neurobiotin into a B-type soma (asterisk), the dye spreads to neighboring B-type somata and dendritic trees (some arrowed) via gap junctions between dendrites, but not to neighboring B-type axon terminals or A-type cells. The dye that has diffused intracellularly through the axon (ax) to the axon terminal system of the injected cell then spreads to neighboring axon terminals via gap junctions (right side, arrowheads), and thereon diffuses to some B-type somata through their axons. This shows that gap-junctional coupling is type-specific (homotypic), and that coupling is segregated between B-type dendrites and axons. The scale bar = 100 μm. Image kindly provided by David I. Vaney.

two types in every mammal? Which morphological differences are of functional significance? Are there differences in their specific connection with the cones and, thus, in chromatic processing? A- and B-type horizontal cells have been identified in a range of orders including primates, carnivores, lagomorphs, rodents, and ungulates; both types are present in rod-dominated and cone-dominated retinas. On this basic pattern, an unexpected diversity in morphology and connectivity is superimposed, which has led to modifications in the general definition of mammalian A- and B-type cells.

Variations of Shape

Old World primates including humans were perceived early on as deviating from the general mammalian pattern. Both the H1 cell (B-type equivalent) and the H2 cell have an axon (**Figures 6(a) and 7**). Hence, H2 was regarded as unique to the primate retina. The axon of the H1 cell connects to rods, while that of the H2 cell connects to cones; the dendrites of both types only synapse with cones. As the H2 axon has no rod contacts, this cell can be equated to the A-type of other mammals. However, H2 cells have finer dendrites than H1 cells, the reverse of the presumed characteristic distinction between the A-type and B-type. Cells with the same morphologies also exist in New World monkeys. Moreover, the cone contacts of H1 and H2 cells in both Old World and New World primates differ from those of the B- and A-type cells of other mammals (see below).

In line with the overall more fine-grained processing in primate retina, particularly near the fovea, H1 and H2 cells have higher densities and smaller dendritic fields than the horizontal cells of other mammals. In macaque, H1 and H2 densities near the fovea are 18 400 mm^{-2} and 4,600 mm^{-2}, respectively, dropping to 1000 mm^{-2} and 500 mm^{-2}, respectively, in the peripheral retina. A central H1 cell only contacts 6–7 cones and a peripheral one, 40–50 cones. H2 cells have larger dendritic fields than H1 cells at corresponding locations, conforming to the A-type/B-type differences in other mammals.

In artiodactyls (ox, sheep, pig, and deer), the B-type cells have a robust dendritic tree, while the A-type dendritic tree is delicate (**Figures 8(c) and 7**); with regard to this, they resemble primates. The B-type has a single axon ending in an axon terminal system. The A-type has no axon; however, sometimes, one or a few dendritic processes extend beyond the perimeter of the dendritic field. Our evidence indicates that they are conventional dendrites connected to cones. The suggestion is that the artiodactyl A-type represents an intermediate shape between the roughly symmetric A-type dendritic fields of many mammals and the singular asymmetry of the primate H2 cell's axon, thus placing primate H2 cells at one end of a spectrum of A-type morphologies.

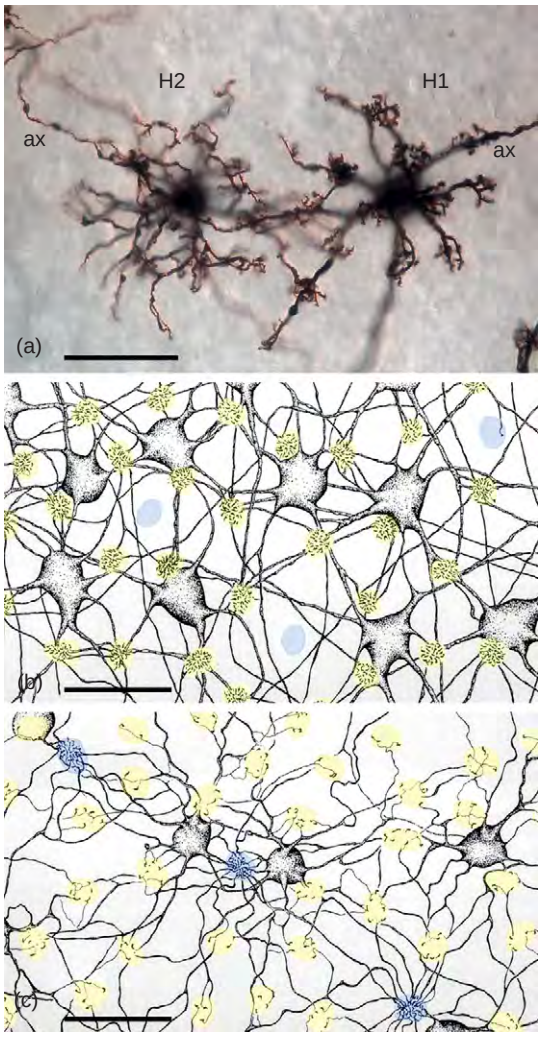

Figure 6 Primate horizontal cells and their cone contacts. (a) Golgi-stained macaque H1 and H2 cells in flat view, focused on the dendritic trees and terminal aggregates (ax, axon). (b) Plexus of macaque H1 cells, stained by a neurobiotin injection in one of the cells; tracer spread to the neighboring H1 cells occurred through the gap junctions. The H1 cells form dense terminal clusters at most cone pedicles (yellow, presumed M- and L-cones), but nearly completely miss the three presumed S-cones (blue). (c) Similarly neurobiotin-labeled macaque H2 cells. They not only strongly innervate the three presumed S-cones (blue), but also contact the other (M and L) cones. The scale bar = 25 μm. Images kindly provided by Dennis Dacey.

In perissodactyls (horse, ass, mule, and zebra), the B-type also has a robust dendritic tree. The single axon is very long, straight, and unusually thick (**Figures 8(d) and 7**). The dendrites of the A-type are very fine and sparsely branched, and there is no indication of an axon (**Figure 7**). The most interesting feature of this A-type cell, however, is its selective connection to the S-cones (see below).

The cone-dominated retina of the tree shrew (*Tupaia belangeri*, Scandentia) has particularly unusual A-type cells (**Figure 9**). They are large and have stout radial

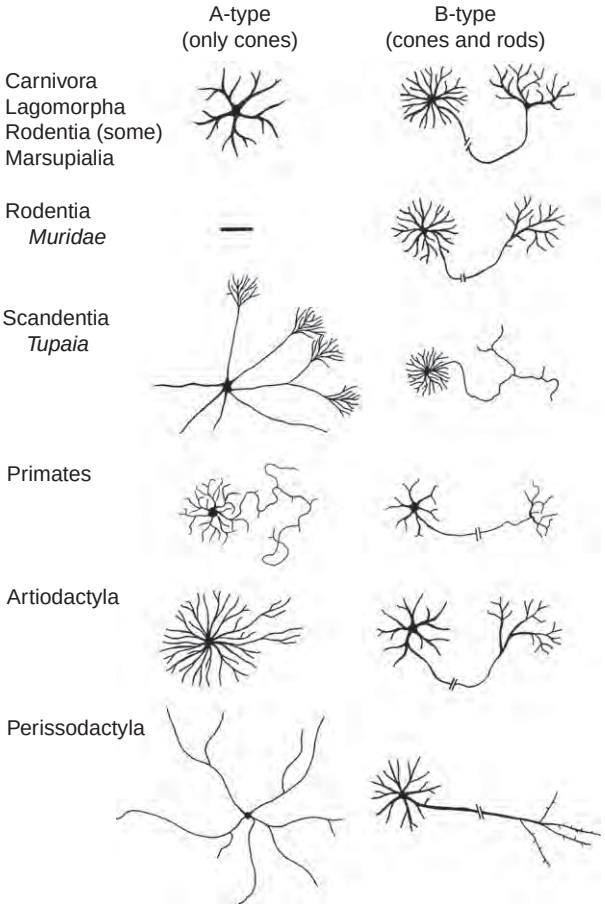

Figure 7 Schematic drawings to show interordinal variations in mammalian A- and B-type horizontal cell morphology. The diagram shows the basic branching patterns but not the synaptic terminals. Interruptions on B-type cells' axons indicate that the axons are longer than drawn. Adapted from Figure 5 in Peichl, L., Sandmann, D., and Boycott, B. B. (1998). primary dendrites that rarely branch until the periphery of the dendritic field, where some ramify into unique bushy arborizations. The first description of these cells termed them multiaxonal because the arborizations were reminiscent of B-type axon terminal systems. We then showed that all connections of these cells, including those at the peripheral arborizations, are with cones. The cells thus conform to the basic mammalian A-type connectivity and can be interpreted as a further variety of A-type shape. This shape is not overtly associated with the high cone density in the tree shrew retina because the H2 cell (A-type equivalent) of the equally cone-dominated ground squirrel retina has a rather conventional shape. The B-type cells of the tree shrew are small and have a conventional dendritic tree; however, the axon is very sparsely branched and has only a few terminals (**Figure 9**). This is to be expected because less than 10% of the tree shrew's photoreceptors are rods.

The rodents are the most diverse of the mammalian orders, and their horizontal cells have provided the biggest surprise. The muroid species rat, mouse, gerbil, and Syrian

hamster possess only one type, the axon-bearing B-type (**Figures 8(b)** and **7**); intracellular injections and population analysis gave no evidence for a further type of horizontal cell. So far, the muroid rodents are the only known instance where the basic mammalian pattern of two horizontal cell types has not been found. In some other rodent groups, for example, sciurids and caviomorphs, both types are present (**Figure 8(a)**). The absence of A-type cells does not appear to be associated with nocturnality since the gerbil has active phases at both day and night and possesses a rather high cone proportion of 10–20%. Rat and mouse have a lower cone proportion (1% and 3%, respectively), which is, however, comparable to the cone proportions found in cat and rabbit (2–4%). Apparently, there is no correlation between a low cone/rod ratio and the absence of the A-type.

The morphology of the B-type axon terminal system also varies significantly across mammalian species. Most species have a thin B-type axon of a few hundred microns length that meanders randomly; in horse, the axon is thick, straight, and a few millimeters long. In cat, rabbit, and rat, the axon terminal system is rather densely branched and appears to innervate most of the rods in its field (as many as 3000 in cat). In other species such as primates or horse, the branching is less dense or even sparse. Here, only a minority of the rods present are innervated by any one terminal system. However, as a population, the overlapping axons of several cells ensure full coverage of the rods.

The existence of a third type of horizontal cell has been claimed for primates, the rabbit, and the South American opossum on the basis of individual cells that markedly differed from the other two types in morphology and presumed connectivity. However, other studies have concluded that such cells are encompassed in the normal variation of the standard two types; the most parsimonious interpretation is that these cells are extreme individuals. If horizontal cells with new or unusual morphological features are to be classified as a new type, it should also be demonstrated that this type exists as a population and adequately covers the retina.

The species variations in horizontal cell morphology add to the recognition that the basic blueprint of the mammalian retina is more flexible than is commonly assumed (**Figure 7**). Currently, there is little clarity regarding the meaning of these variations. The absence of the A-type in murids is of practical significance since genetically modified mouse strains are heavily used to elucidate the general principles of mammalian retinal wiring and function. Researchers have to be aware that mouse data on the contribution of horizontal cells to retinal processing may not be readily transferable to other species. On the other hand, mice may provide key insights into the effects that one versus two horizontal cell types have on the properties of ganglion cell receptive fields.

Species with Selective Cone Contacts

Most mammals are cone dichromats with a majority of L-cones and a minority of S-cones. In Old World primates and man, the mammalian L opsin gene has diverged into separate genes for the M (green) and L (red) cone opsins, making these species cone trichromats with refined color vision. Most New World monkeys are cone dichromats by genotype; however, some species were shown to have an L opsin polymorphism that results in a trichromatic phenotype in many females, while the males are dichromats. Hence, the retina of primates was an interesting place to investigate whether the horizontal cells are chromatically selective and might contribute to color processing.

Observations on Golgi-stained human and monkey horizontal cells had indicated that H1 dendrites specifically avoid or undersample the S-cones, whereas H2 dendrites contact all cones and H2 axons exclusively contact S-cones. In a seminal study, Dennis Dacey and his colleagues recorded the responses of H1 and H2 cells to chromatic stimuli in the isolated living macaque retina and demonstrated that H2 cells show the same hyperpolarization at all wavelengths, whereas H1 cells hyperpolarize to M- and L-cone stimuli but do not respond to S-cone stimuli. The recorded cells were injected with the tracer neurobiotin, labeling all members of patches of H1 or H2 cells around an injected cell through the homotypic gap junctions. The population of H1 cells innervates the majority of the cones, but hardly contacts the small fraction of presumed S-cones (**Figure 6(b)**). The H2 population, on the other hand, connects to all cones, but makes particularly numerous contacts with the small fraction of presumed S-cones (**Figure 6(c)**). Studies combining dye-labeling of individual horizontal cells and cone opsin labeling confirmed this connectivity pattern for macaque, orangutan, and chimpanzee. They showed that only close to 15% of the H1 cells contact S-cones, but then only sparsely; the H2 cells contact all cones within reach and have more synapses with each S-cone than with each of the M- and L-cones contacted. The axon of the H2 cell definitely contacts S-cones, but whether it does so exclusively has yet to be determined. Despite the differences in cone connectivity, the physiological recordings indicate that neither the H1 nor the H2 cell is involved in creating spectrally opponent receptive fields of bipolar and ganglion cells.

New World monkeys (where there are dichromatic and trichromatic individuals) have the same cone connectivity pattern of H1 and H2 cell dendrites as macaque and man. This suggests that the special horizontal cell connectivity with S-cones is not correlated with the evolution of trichromacy in the Old World primates. Notably, both horizontal cell types of trichromatic primates are nonselective in their M-cone and L-cone contacts. Apparently, when the red/green processing pathway evolved from a

presumably dichromatic early primate retina, this did not involve alterations in horizontal cell connectivity.

A differential cone connectivity of horizontal cells was also found in the dichromatic horse (**Figure 3**). Its A-type cells have particularly large and sparsely branched dendritic fields with few and widely spaced terminal aggregates. In one Lucifer yellow-filled A-type cell, counterstained with an S-cone marker, all but one of its 45 contacts were with S-cones. Further cells need to be studied to confirm this finding. However, the A-type, similar to the B-type, is a consistently occurring cell population that covers the horse retina (**Figure 4(b)**). Therefore, the horse (and other equids) may possess an A-HC that is selectively connected to S-cones, while the B-type connects to both types of cone.

A similarly S–cone-selective horizontal cell may be present in the cone-dominated retinas of the dichromatic sciurids. The red squirrel and ground squirrel possess an axon-bearing H1 cell (B-type) and an axonless H2 cell (A-type). The density of dendritic terminal aggregates on the H1 cell is high enough to contact all cones present. In contrast, the terminal aggregates on H2 dendrites are spaced so far apart that they can only contact a small fraction of the cones, which presumably are S-cones. It would be worthwhile and now feasible to determine, experimentally, if an S-cone selective horizontal cell is present.

Conclusions and Open Questions

The principal horizontal cell dichotomy of an axon-bearing B-type, which serves rods and cones, and a commonly axonless A-type that only serves cones, holds for most mammals. Thus, the A-type and B-type cells represent basic components of the mammalian retinal blueprint, suggesting an indispensable function. The B-types are necessary in all mammals as they all have cones and rods. However, why is there an additional A-type in the cone pathway? What functional differences are there between the A-type and the B-type? Modeling suggests that the two types with their different dendritic field sizes and spatial summation properties can explain the assumed receptive field characteristics of the cones, and, hence, the receptive field organization of bipolar cells and ganglion cells. The requirements for temporal processing may be another reason for having more than one horizontal cell type. Indeed, horizontal cells in cat differ in their flicker-response properties. However, despite the absence of the A-type, rat and mouse have ganglion cells with center/surround receptive field organizations very similar to rabbit and cat.

Mammalian horizontal cells are rather diverse across species. This diversity encompasses morphological features as well as details of cone connectivity (**Figures 7** and **3**). Thus, some amendments to the textbook characterizations are necessary:

1. Dendritic thickness and dendritic branching pattern are not defining characteristics of either type, unless the order of mammal is specified. Within a given species, the two types differ in their dendritic morphology, which suggests some physiological difference. Does it matter whether the finer dendrites are on the B-type (as in cat and rabbit) or on the A-type (as in primates and artiodactyls)?
2. Across species and orders, the A-type is more variable than the B-type. A-type variability includes axon-like processes in primates, an S-cone preference in primates and horse, and a complete lack of the A-type in some rodents. B-type variability includes dendritic and axonal branching patterns and the near avoidance of S-cones by primate H1 cells.

There is no obvious correlation between these horizontal cell variations and the phylogenetic distance of the corresponding mammalian orders. For example, Carnivora and Lagomorpha are phylogenetically less close than Primates and Scandentia, but the former have very similar horizontal cell morphologies, while those of the latter differ significantly. The peculiarity of a B-type/H1 cell with fine dendrites and an A-type/H2 cell with stout dendrites is shared by artiodactyls, perissodactyls, and primates. Within any one taxon, horizontal cell features are commonly more conserved across species.

There is no obvious correlation between these horizontal cell variations and specific adaptations to different visual requirements and other retinal specializations. Different cone/rod ratios, indicative of a nocturnal or diurnal lifestyle, do not predict the presence of one or two horizontal cell types. Primates with highly developed trichromatic color vision have cone-selective horizontal cells, but so does the dichromatic horse. In addition, the cone selectivity of H1 and H2 cells is the same in New World and Old World primates, which have different levels of color vision.

Morphology of Interneurons: Interplexiform Cells

D G McMahon and D-Q Zhang, Vanderbilt University, Nashville, TN, USA

Glossary

Retinitis pigmentosa – A group of inherited disorders characterized by progressive loss of photoreceptors.
Sublamina of inner plexiform layer – Inner plexiform layer is divided into sublamina a (the distal sublamina) and sublamina b (the proximal sublamina). Sublamina a is further divided into two strata, 1 and 2, whereas sublamina b is divided into three strata, 3–5.

Introduction

The canonical flow of visual information in the retina is for light stimuli to be transduced into neurochemical signals by the rod and cone photoreceptors in the outer retina and then passed through the synaptic layers (outer plexiform layer, OPL; inner plexiform layer, IPL) to ganglion cells which then transmit them to the rest of the brain via the optic nerve. Interplexiform neurons are a unique class of retinal amacrine cells that form an intraretinal feedback pathway transmitting adaptational visual signals in the opposite direction, from the inner retina back to the outer retina (**Figure 1**). They receive their synaptic input in the IPL and make their output via interplexiform processes terminating in the OPL. These intraretinal feedback neurons are present in most vertebrate retinas, and in the majority of species these neurons secrete the neurotransmitter dopamine.

Dopaminergic interplexiform cells (IPCs) exert widespread influence on the physiology and function of the retina, reconfiguring retinal circuits and altering the processing of visual signals in the retina, by initiating slow and sustained changes in the physiology of retinal neurons and synapses. In particular, retinal dopamine has been found to act on electrical synapses, or gap junctions, to restrict the flow of visual signals in retinal neural networks at the level of photoreceptors, horizontal cells, and amacrine cells. In addition to the direct synaptic contacts from interplexiform processes in the outer plexiform layer, dopaminergic retinal neurons exert influence throughout the retina by volume transmission, via perfusion of dopamine beyond synaptic zones. Dopamine has been found to affect all major classes of retinal neurons, from photoreceptors to ganglion cells. An overall effect on retinal function of these feedback signals from dopaminergic IPCs is to enhance signaling in cone pathways and to decrease the signaling on rod pathways, optimizing retinal circuitry for photopic visual processing during periods of relatively high light levels. However, roles for dopamine in dark-adapted retinal responses have also been shown. Thus, dopamine and IPCs play key roles in optimizing retinal function over the wide dynamic range of light intensities encountered in the visual environment.

Secretion of dopamine by IPCs is controlled by two factors: background illumination and an intrinsic daily clock in the retina, enhancing cone signals in conditions of bright light and during the day, and rod signals in conditions of dim light and during the night. In addition to this adaptational effect on retinal neural networks, dopamine secreted from IPCs has trophic effects on photoreceptor survival and eye growth that are associated with eye diseases. In the following, we discuss the anatomy, physiology, and significance for human visual health of dopaminergic IPCs.

Morphology of Dopaminergic Interplexiform Neurons

Dopaminergic amacrine (DA) cells are a subpopulation of amacrine cells whose cell bodies lie in the innermost cell row of the inner nuclear layer (INL). DA cell processes ramify extensively in the outermost layer of the IPL where they are both presynaptic to and postsynaptic to other neurons. The total number of DA cells averages 500 per retina, although it varies slightly in different species. IPCs are a class of DA cells in which additional fine processes arising either from the cell body or from one of the dendrites ascend through the INL to the OPL where they form an output plexus for the secretion of dopamine in the outer retina. The IPC was first described in the retina of cat by Gallego in 1971, and was extensively studied by Dowling and co-authors. The percentage of DA-IPCs among DA cells is species dependent. In goldfish, Cebus monkey, and mouse retinas, almost all DA cells are likely to be DA-IPCs, whereas in rabbit, turtle, salamander, and human retinas, interplexiform processes are rarely observed on DA neurons. Approximately 50% of DA cells are DA-IPCs in the rat, *Xenopus* and *Rhesus* monkey retinas.

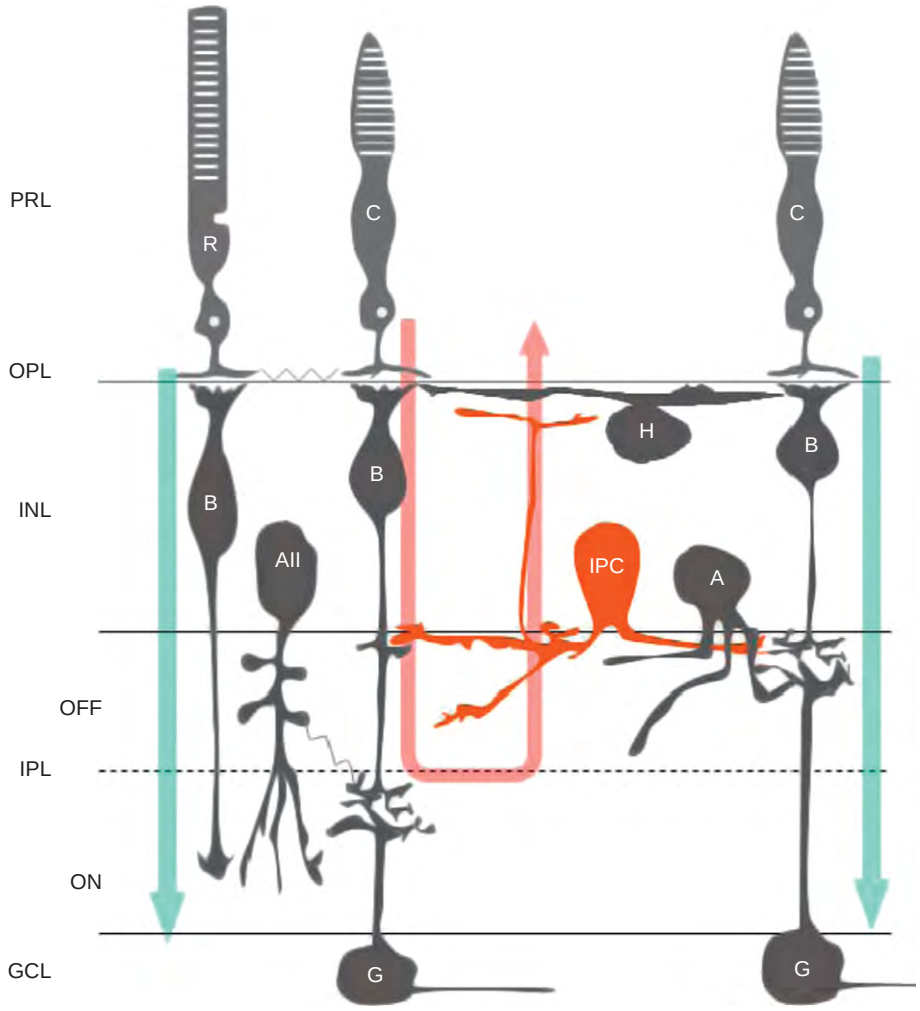

Figure 1 Interplexiform neurons mediate intraretinal feedback. An interplexiform cell (red) is located in the middle of the retina. Straight arrows indicate the canonical flow of visual signals from the outer retina to the inner retina. The U-shape arrow indicates an intraretinal feedback from the inner retina to the outer retina. R, rod; C, cone; H, horizontal cell; B, bipolar cell; AII, AII amacrine cell; IPC, interplexiform cell; A, inhibitory amacrine cell; G, ganglion cell, PRL, photoreceptor layer; OPL, outer plexiform layer; IPL, inner plexiform layer; GCL, ganglion cell layer; OFF, OFF sublamina of the IPL; ON, ON sublamina of the IPL.

Morphology and Distribution

Antibodies against tyrosine hydroxylase, the rate-limiting enzyme of catecholamine synthesis, are commonly used to detect DA cells for characterization of their localization, shape, size, dendritic arborization, and distribution (**Figure 2**). In order to enable targeting of living DA cells for morphological, functional, and molecular analysis, transgenic mouse lines have been created in which the DA cells are labeled with chemical or fluorescent protein reporters, driven by the tyrosine hydroxylase gene promoter. DA cells have three descriptive components to their morphology: soma, dendrites, and axon-like process. The morphology of dopaminergic IPCs is similar to that of other DA cells except for the presence of an additional axon-like process ascending to the OPL.

Soma

Somata of DA cells are either round or ovoid with diameters of 12–15 μm and areas of 100–150 μm^2 (**Figure 2**). In most species, DA cell somata are regularly and sparsely distributed in the innermost aspect of the INL across the entire extent of the retina. The distribution of the DA cells varies across the retina in the rat, with the peak density in the superior temporal quadrant and the lowest density in the inferior nasal quadrant. Occasionally, DA cells are displaced into the ganglion cell layer and, in this case, there is no evidence that these displaced amacrine cells have interplexiform processes.

Dendrites

Two to six primary dendrites arise from the cell body, and branch 4–6 times in the outermost aspect of the OFF

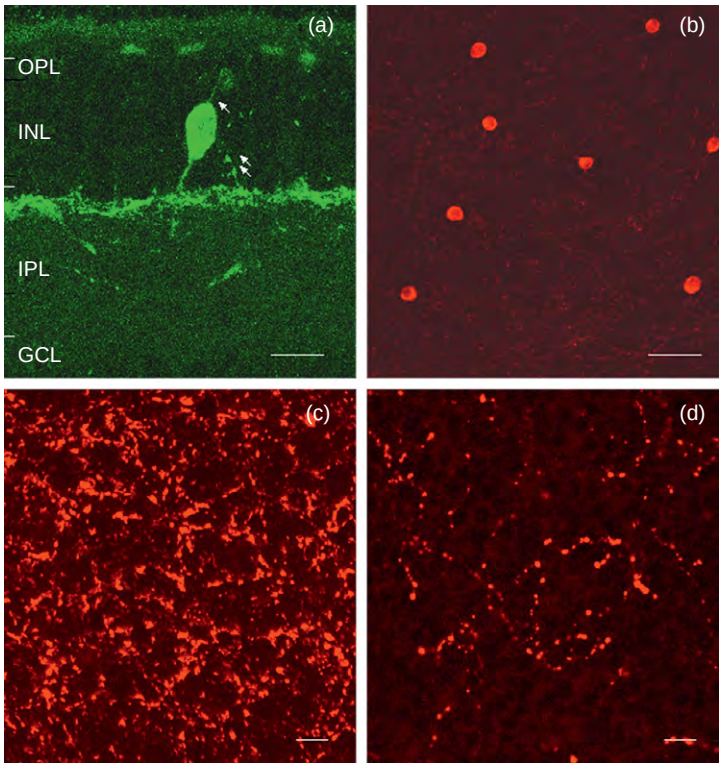

Figure 2 Immunohistochemical localization of TH in the mouse retina. (a) TH-positive soma situated in the INL stratifies at the border between the INL and the IPL in a vertical section. Single arrow and double arrows indicate ascending axon-like processes emerging from the DA cell body and from the plexus in the IPL, respectively. The axon-like processes traverse the INL toward the OPL. Scale bar: 20 μm. (b) Flat-mount view focused on the INL demonstrates the regular distribution of DA cells. Scale bar: 50 μm. (c) Flat-mount view focused on the border between the INL and the IPL shows a dense plexus of dopaminergic processes. Scale bar: 10 μm. (d) Flat-mount view focused on the OPL illustrates a loose plexus of fine dopaminergic processes. Scale bar: 10 μm.

sublamina (stratum 1) of the IPL. These branches radiate symmetrically from the soma and follow a straight somatofugal direction. The thickness of the primary dendrites is up to 4.5 μm and decreases at each bifurcation. The primary dendrites are usually smooth, whereas terminal branches exhibit varicosities (up to 0.5 μm in diameter). The long axis of the dendritic field of individual DA cells is approximately 800 μm. The dendritic fields of adjacent DA cells overlap extensively with a coverage factor of 2–4, forming a dense plexus in stratum 1 of the inner plexifom layer (**Figure 2**). Dendrites from teleost DA cells spread proximally throughout the IPL. In contrast, in mammalian retinas, only occasional processes from the plexus in stratum 1 run deeper into other stratums.

Axon-like fine process

Axon-like processes are quite distinct from the dendrites of DA cells. They are thin, straight, long, and sparsely branched at close to right angles. Teleost DA-IPC axon-like processes form a pronounced plexus in the OPL. DA-IPCs in Cebus monkey have dense plexuses of fine processes in both the outer and inner plexifom layer. In other species, DA cell processess form an extensive dense network in the IPL, whereas the ascending axon-like processes either do not branch or branch within clusters in the OPL. For instance, in the mouse retina, two to three axon-like processes arise either from the soma or from the primary dendrites. Each axon-like process, with multiple successive bifurcations, covers the extensive area of the retina: total length up to 10–25 mm. Thus, axon-like processes can overrun each other and, together with overlapping dendrite networks, form a particularly dense plexus of dopaminergic processes in stratum 1 of the IPL. This process network forms small rings around the origin of the primary dendrites of AII amacrine cells at the INL–IPL margin. Axon-like processes bear varicosities that are thought to be sites of dopamine release. Compared to the dense plexus in the IPL, the OPL plexus of fine dopaminergic processes is more loosely arranged. Axon-like processes also traverse the INL to the OPL, sometimes forming clusters of fine processes (**Figure 2**).

Synaptic Input to DA Neurons

Dopaminergic IPC processes extend widely into the outer and the IPLs. There is anatomical evidence that DA neurons receive synaptic input in the IPL from bipolar

and amacrines cells, as well as centrifugal fibers arising from brain nuclei, and there is functional evidence for retrograde input to DA neurons from ganglion cells.

Input from bipolar cells and amacrine cells

DA cell interplexiform processes are presynaptic to horizontal and bipolar cells in the OPL, and there is no evidence that interplexiform processes are postsynaptic to any cells in the OPL. Electron microscopy of tyrosine hydroxylase immunoreactivity in rhesus monkey, cat, and rabbit has shown that DA cells receive synaptic input from both bipolar cells and inhibitory amacrine cells in mammalian retinas. The size, structure, and position of the bipolar to DA neuron synapses in the IPL suggest that they are from bistratified bipolar cells. Bistratified bipolar cells have also been found in the mouse, fish, turtle, and salamander retinas. In addition, close apposition of bipolar and DA neuron processes has also been observed in deeper layers of the IPL. Therefore, light information generated by photoreceptors may reach DA cells directly from bipolar cells or indirectly from bipolar cells through inhibitory amacrine cells (**Figure 3**).

Input from intrinsically photoreceptive ganglion cells

Intrinsically photoreceptive ganglion cells (ipRGCs) are endogenously photosensitive because they express melanopsin, a photopigment first described in photosensitive dermal melanophores of the frog. They comprise 1–2% of retinal ganglion cells forming a photosensitive network in the inner retina. The ipRGC dendritic processes ramify in the OFF layer of the IPL where they have close contact with DA neuron processes (**Figure 3**). Physiological experiments have suggested that DA cells receive synaptic input from ipRGCs (below). Whether DA cells are postsynaptic to the dendrites of ipRGCs is under investigation.

Input from centrifugal fibers

Many vertebrate retinas receive input from other parts of the brain via retinopetal axons. The efferent input to the retina originates from the ventral thalamus in reptiles, the olfactory bulb in fish, the isthmo-optic nucleus in birds, and the tuberomammillary nucleus of the posterior hypothalamus in mammals. In fish centrifugal fibers make synapses directly onto DA-IPCs. Histamine has been localized to retinopetal axons in the guinea pig, monkey, and rat, and evidence suggests that DA cells receive input from histaminergic centrifugal fibers in mammalian retinas. Thus, IPCs likely form a conduit for feedback to the retina from the rest of the brain as well as for intraretinal feedback signals.

Physiology of Dopaminergic Interplexiform Neurons

Dopamine Reconfigures Retinal Circuits

DA neurons comprise the central neuromodulatory system of the retina, forming an intraretinal feedback

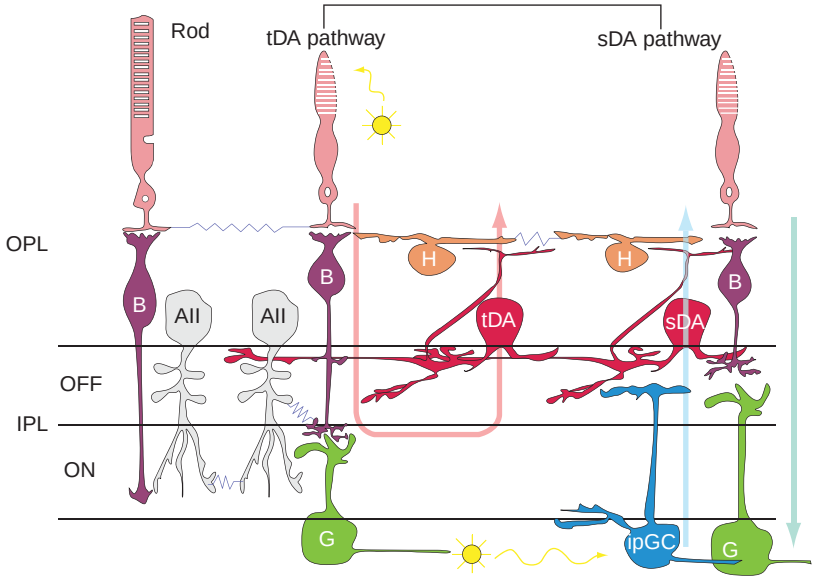

Figure 3 Dopamine neuron light response pathways. DA cells exhibit two classes of light responses: ON-transient and ON-sustained. ON-transient DA cells (tDA) are driven by rod or cone photoreceptors through ON-bipolar cells (tDA pathway), whereas ON-sustained DA neurons (sDA) are driven by melanopsin-expressing intrinsically photoreceptive ganglion cells (sDA pathway). Green straight arrow indicates the canonical flow of rod/cone visual signals from the outer retina to the inner retina. The U-shape red arrow indicates an intraretinal feedback of rod/cone initiated signals from the inner retina to the outer retina. The blue arrow indicates an intraretinal retrograde flow of ganglion cell photoreceptor signals from the inner retina to the outer retina. tDA, transient dopaminergic interplexiform cell; sDA, sustained dopaminergic interplexiform cell; ipGC, intrinsically photoreceptive ganglion cell.

pathway that reconfigures retinal circuits according to prevailing illumination conditions and signals from the retinal circadian clock. Through dopaminergic signaling, they restructure retinal function by modulation of chemical and electrical synapses, as well as by modification of the functional properties of retinal neurons. Both through direct synaptic contacts from interplexiform processes and through volume transmission, DA neurons influence all levels of retinal circuitry and all major classes of retinal neurons. In particular, dopamine regulates multiple neural circuits in the retina by modulating electrical synaptic transmission through gap junctions. This type of circuit modulation was first described in relation to dopaminergic uncoupling of gap junctions mediating electrical synaptic transmission between horizontal cells in teleost fish retinas, an action thought to reduce the size of retinal receptive fields. Subsequently, the regulatory action of dopamine on retinal gap junctions has been found to be a more general phenomenon, with coupling between rods and cones, AII amacrine cells and ganglion cells also being modulated by dopamine. Dopaminergic regulation of both rod–cone coupling and AII amacrine cell coupling serves to restrict the flow of visual signals from rods to retinal ganglion cells during light-adapted conditions in the day, while allowing flow of rod signals in the dark and at night.

In addition to regulating electrical synaptic transmission, retinal dopamine influences retinal circuit function by modifying chemical synaptic transmission, via modulation of glutamate and gamma aminobutyric acid (GABA) receptors. It also alters intrinsic functional properties of retinal neurons via modulation of membrane ion channels, such as voltage-gated sodium currents in bipolar and ganglion cells. Many of the synaptic and cellular changes induced by dopamine are consistent with a role for this transmitter in mediating light-adaptive changes in retinal function. For example, uncoupling of horizontal cells is consistent with a reduction in receptive field size and increased spatial resolution in light-adapted conditions. Restriction of rod signals from the cone pathways in the light and during the day is consistent with this notion as well. Modulation of sodium currents in bipolar cells and ganglion cells is consistent with accelerating light responses in cone pathways and shifting ganglion cell function from photon detection to contrast signaling, respectively. Finally, although IPCs do not directly synapse on photoreceptors, the outermost cells of the neural retina, they significantly influence their function, presumably through volume transmission of dopamine. In addition to regulating circadian rhythms in rod–cone coupling, dopamine influences regulation of the intracellular second messenger cyclic adenosine monophosphate and the timing of circadian secretion of melatonin by photoreceptors.

Light Drives Interplexiform Neurons via Both Conventional and Novel Pathways

One of the persistent puzzles regarding IPCs has been to understand the precise mechanisms by which they are affected by light and thus provide feedback signals within retinal circuits for background illumination. Studies of retinal dopamine release revealed a surprising heterogeneity in the lighting conditions that evoked dopamine release, including flickering light, steady light, and even prolonged darkness. Although studied intensively for more than three decades, the neural mechanisms by which light influences the activity of dopaminergic interplexiform neurons have remained incompletely understood, in part, because the sparse nature of retinal dopaminergic neurons had prevented analysis within intact retinal circuits with electrophysiological approaches that directly measure neuronal activity. Previous studies with anatomical approaches had suggested that retinal DA neurons are a homogeneous population of cells, that their primary input was from inhibitory GABA/glycine amacrine cells in the OFF sublamina of the IPL, and thus that their light responses could be due to disinhibition of OFF responses. Recently, the limitation on *in situ* electrophysiological recording of DA neurons was overcome by creating a transgenic mouse in which DA neurons were genetically marked with a fluorescent protein. Electrophysiological studies of dopaminergic interplexiform neuron light responses yielded the surprising finding that despite being considered a morphologically homogenous class, these neurons are functionally heterogeneous, with distinct neuronal subpopulations exhibiting transient and sustained light responses (**Figure 3**). This cellular heterogeneity is likely the substrate for the observed functional heterogeneity in dopamine regulation by light.

Light-responsive DA neurons fall into two distinct subpopulations (ON-transient and ON-sustained), which are driven by separate synaptic circuits. ON-transient cells are driven by rod or cone photoreceptors through ON-bipolar cells, in a conventional retinal ON-pathway circuit. ON-sustained DA neurons, however, are driven by melanopsin-expressing ipRGCs in a novel intraretinal retrograde light pathway in which ganglion cell photic signals are used for network adaptation within the retina. This novel intraretinal feedback pathway completely reverses the canonical direction of visual signaling, with photoreception being initiated in ganglion cells and dopaminergic signaling potentially modulating rod and cone photoreceptors (**Figure 3**). Thus, the dopaminergic interplexiform system is composed of two functional subpopulations of neurons tuned to distinct aspects of environmental light signals: transient DA neurons (t-DA, **Figure 3**), driven by rod and cone input through ON-bipolar cells that are tuned to rapidly changing background signals and which may mediate the observed dopamine release to flickering light, and sustained DA neurons (s-DA, Figure**3**), driven

by ipRGCs that are tuned to maintained background illumination and which may mediate the observed dopamine release to steady light.

While light stimulates dopamine secretion by dopaminergic retinal neurons, there is also basal release of dopamine in the dark. Studies by Raviola and colleagues showed that isolated DA neurons are spontaneously active, with sodium and calcium currents that support spontaneous spiking and dopamine secretion. Recordings from DA neurons in intact retinas have shown that DA neurons exhibit spontaneous bursts of spikes that are enhanced when input from inhibitory amacrine cells is blocked pharmacologically. In intact retinal circuits, the OFF-channel-driven GABA and glycine input from inhibitory amacrine cells partially suppresses the intrinsic bursting activity of DA neurons. As burst spiking is associated with increased dopamine secretion from midbrain dopaminergic neurons, the input from inhibitory amacrine neurons likely regulates basal secretion of dopamine by retinal DA neurons in the dark.

IPCs Signal Time of Day from the Retinal Clock

The retinal circadian clock shapes retinal function into 'day' and 'night' states timed to the local day–night cycle. This requires intraretinal signaling mechanisms for both the output of clock signals to the downstream retinal processes and the input of the local light cycle to set the phase of the retinal clock. Retinal dopamine, which is under both circadian and light-evoked control, appears to play a critical role in both of these processes. Among its manifold demonstrated effects on retinal neurons and circuits, dopamine regulates circadian rhythms in rod–cone coupling, and the resulting rhythms in spectral sensitivity and rod–cone balance of retinal responses. Several recent results also suggest that dopamine plays a key role in the signaling of light stimuli to the retinal circadian clock. Recent findings that retinal dopamine is a key component of light resetting of the retinal clock and that retinal dopaminergic neurons receive light input from ipRGCs suggest that retinal circadian photoreception is likely mediated by a novel intraretinal retrograde light-transmission circuit in which light signals originate in the ipRGCs and reset the circadian clock through their influence on sustained DA cells.

DA Neurons and Retinal Degenerative Disease

Parkinson's Disease

Parkinson's disease is a neurodegenerative disease caused by degeneration of doapminergic neurons in striatum and substantia nigra. Visual functions such as contrast sensitivity detected by pattern electroretinograms (PERGs) are also impaired in Parkinson's disease since there is concurrent loss of DA neurons in the retina. One possible cause is that dopamine deficiency increases receptive field size of horizontal cells in the outer retina, and of AII amacrine cells in the inner retina, through loss of dopaminergic control of gap junctions, which results in altering receptive field properties of ganglion cells (the primary origin of the PERG response).

Diabetic Retinopathy

Diabetic retinopathy, which is classically defined as a microvasculopathy, is now being viewed as a neurodegenerative disease of the retina. Functional visual deficits detected by electroretinogram (ERG) often occur before the appearance of overt retinal lesions in diabetic retinopathy. The most prominent change of the ERG in early diabetes is a distortion of oscillatory potentials that are thought to derive from the inner retinal neurons including DA cells. Indeed, DA cells initiate programmed cell death in early diabetes, and are lost during the later phases of the disease. Dysfunction of DA cells in diabetic retinas has also been suggested by studies examining retinal dopamine content and tyrosine hydroxylase activity. Together, these studies suggest that DA cells undergo degeneration in diabetes, but the cause remains unclear.

Human Health Implications of the Retinal Clock

Retinal circadian clock signaling modulates human vision, is associated with retinal degenerative diseases, and modifies photoreceptor survival in animal models of human ocular disease. Humans have daily psychophysical rhythms in absolute visual sensitivity, as well as the temporal resolution of vision, with peak scotopic sensitivity occurring at night and peak temporal resolution occurring during the day. These visual rhythms are mediated by corresponding rhythmic changes in retinal function with scotopic ERG b-wave sensitivity, and implicit time decreased during the day. Interestingly, these ERG rhythms are altered in patients with retinitis pigmentosa, indicating a link between circadian regulation of retinal function and this disease, which is a major cause of adult blindness. In addition, macular edema in diabetic retinopathy, intraocular pressure associated with glaucoma, and refractive errors associated with myopia in primates also exhibit circadian regulation. Finally, photoreceptors exhibit circadian-dependent vulnerability to light damage, being more susceptible in the night phase, and that dopamine and melatonin, two neurochemical messengers of the circadian clock, modulate photoreceptor survival in retinal degeneration animal models.

Summary

Retinal interplexiform neurons are a specialized subclass of amacrine cells that mediate intraretinal feedback of photic signals from photoreceptors, ganglion cells, and from brain nuclei to reconfigure retinal circuits according to prevailing illumination and circadian factors. They act primarily through the secretion of the neurotransmitter dopamine, both synaptically and via volume transmission. DA neurons and interplexiform neurons play critical roles in overall retinal function and in visual health by modulating retinal circuits, synchronizing the retinal clock and regulating eye and photoreceptor tropism.

Glossary

Extracellular matrix – The structural support for cells and tissues in animals or plants. It contains fibrous proteins, polysaccharides, and proteoglycans.
Gene – The portion of DNA that encodes a functional RNA or protein product.
Leucine zipper – The protein motif characterized by a short alpha-helix with a leucine amino acid at every seventh position.
Signal peptide – A short peptide sequence that directs proteins to organelles within a cell.
TATA box – A DNA sequence in the regulatory region of a gene where the transcription factors bind.
Trabecular meshwork – The tissue in the anterior segment of the eye located between the cornea and the ciliary body. It is responsible for filtering and draining aqueous humor from the anterior segment.
Unfolded protein response – A cellular stress response related to an accumulation of misfolded or unfolded proteins in the endoplasmic reticulum.

Discovery of the Glaucoma-Associated Myocilin Gene

The most common form of glaucoma is primary open-angle glaucoma (POAG). This disorder generally occurs between the sixth and eighth decades of life and is accompanied with alterations in visual acuity due to loss of optic nerve function. An early onset or juvenile form of primary open-angle glaucoma (JOAG) occurs between the second and fifth decades of life. In 1997, Edwin Stone and colleagues at the University of Iowa (USA) used genetic linkage studies to identify a glaucoma-associated region to chromosome 1q in a family with an autosomal dominant pedigree for JOAG. Additional studies in other JOAG family pedigrees confirmed chromosome 1q21-1q31 as a glaucoma susceptibility locus.

Concurrent to the genetic studies, Jon Polansky and colleagues studied a protein in human trabecular meshwork cells that was induced following glucocorticoid treatment (originally called trabecular meshwork inducible glucocorticoid response gene (TIGR)). Clinically, the administration of glucocorticoids can result in elevated intraocular pressure (IOP) and if not monitored, may lead to symptoms similar to POAG. Expression of TIGR from cultured human trabecular meshwork cells treated with dexamethasone increased in a time and dose-dependent manner that correlated with the elevated IOP increase observed in patients following steroid treatment. Additionally, studies aimed at identifying candidate genes for inherited retinal disease identified a novel protein with homology to nonmuscle myosin that was expressed in the ciliary rootlet and basal body of the connecting cilium in photoreceptor cells which was termed myocilin (myo- from myosin; -cilin from cilium). Sequence comparisons of both TIGR and myocilin proteins confirmed that these two proteins were identical and that both originated from the same gene *(MYOC/TIGR)*. The *MYOC/TIGR* gene was located within the chromosome 1q21-1q31 glaucoma susceptibility locus. Subsequent studies found that the *TIGR/MYOC* gene contained mutations in up to 36% and 4% of JOAG and POAG patients, respectively. Conventional nomenclature set forth by the Human Genome Organization Committee officially designated the *MYOC/TIGR* gene as *MYOC* and the protein product produced from this gene as myocilin.

MYOC Gene to Myocilin Protein

The gene for human myocilin contains three exons and two introns and spans nearly 17 kb of human genomic sequence at the chromosome 1q24.3-1q25.2 locus (**Figure 1**). The gene produces several transcripts, ranging in size from 1.8 to 2.3 kb, due to differential use of three polyadenylation sites at the 3′ end. The immediate upstream region of the myocilin gene contains several transcriptional regulatory elements, including a TATA-box, nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB), activating protein (AP)-1 and -2, and an E-box. The E-box is a DNA sequence which lies upstream of a gene in the promoter region. An E-box is bound by an upstream stimulatory factor (USF) and is critical for basal promoter activity. Several glucocorticoid-like response elements have also been identified upstream of the transcription initiation start site. However, none of these appears to function in myocilin's response to steroids. Furthermore, glucocorticoid induction of myocilin is dependent on new protein

*Adapted from Resch, Z. T. and Fautsch, M. P. (2009). Glaucoma-associated myocilin: A better understanding but much more to learn. *Experimental Eye Research* 88: 704–712.

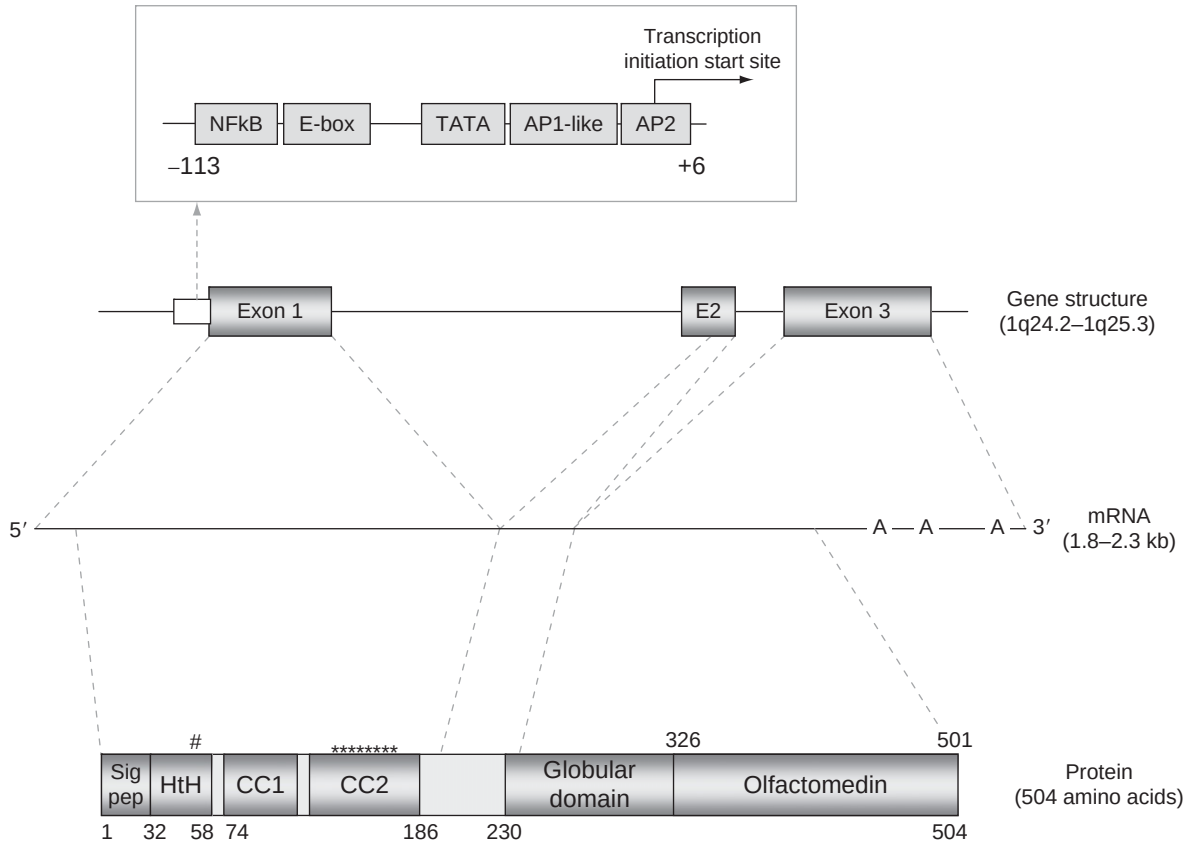

Figure 1 Structure of human *MYOC* gene and myocilin protein. The human *MYOC* gene contains three exons and two introns. The inset shows regions of homology to several promoter and enhancer sequences upstream of Exon 1. The mRNA produced from the *MYOC* gene ranges in size between 1.8 and 2.3 kb. The myocilin protein is 504-amino-acids (aa) long and contains several structural motifs: a signal peptide sequence (aa1–32), a helix–turn–helix (HtH) domain (aa18–58), two coil–coil (CC) domains (aa74–110 and aa118–186), and a C-terminal globular domain (aa230–504) that contains homology to olfactomedins (aa326–501), a protein family involved in many diverse functions. Asterisks represent leucine amino acids involved in the leucine zipper. Number sign denotes N-glycosylation site.

synthesis suggesting that the myocilin steroid response is a secondary effect, not a direct stimulation.

The protein product produced from the myocilin transcript is a 504-amino-acid glycoprotein with a predicted molecular weight of 55.3 kDa. On sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) gels, myocilin separates as a doublet between 53 and 57 kDa, with the larger of the two proteins migrating slower due to the N-glycosylation at amino acids (aa) 57–59 (Asn-Glu-Ser). A 66-kDa form of myocilin has also been reported. Not all myocilin antibodies recognize this product suggesting that the 66-kDa form of the protein is unique, potentially having several post-translational modifications. Alternatively, the 66-kDa form may not be myocilin, but may represent a myocilin-related protein. Truncated products of myocilin have also been identified. Cleavage of myocilin, possibly by the protease calpain II, can lead to a 23-kDa N-terminal fragment and a 35-kDa C-terminal fragment. The C-terminal form of myocilin has been identified in human aqueous humor and in conditioned media from human trabecular meshwork and embryonic kidney cells (HEK293) engineered to overexpress myocilin.

The N-terminal region of myocilin contains two translation initiation methionine amino acids at aa1 and aa15. A functional signal peptide sequence representing aa1-32 was confirmed for human myocilin by N-terminal sequencing of immunoprecipitated myocilin and *in vitro* using microsomal membranes. Phylogenetic comparison of other myocilin proteins shows that only rat myocilin contains two initiation codons similar to human myocilin. All other myocilin proteins have only one initiation codon that corresponds to the second initiation codon in humans and rat. All species, however, have an N-terminal region characteristic of a signal peptide sequence that suggests an evolutionary conserved function for this region.

In addition to the signal peptide sequence, the N-terminal region of myocilin contains leucine zipper motifs within two coiled-coiled domains (aa74–aa110 and aa118–aa186), the second of which is responsible for exosome-like vesicular binding. Dimerization with itself as well as other

intracellular and extracellular proteins can also occur within this region.

The C-terminal globular region of myocilin (aa230–504) contains homology to a family of proteins called olfactomedins. Over 100 proteins contain an olfactomedin domain. Within these proteins, the olfactomedin domain is highly conserved across species supporting an important role for this domain in the functional aspects of these proteins. Similarly, the olfactomedin domain of myocilin is highly conserved across species (>80%), suggesting this region is important for the structure and functional properties of the protein. The importance of the olfactomedin domain to myocilin function is highlighted by the presence of >90% of the identified glaucoma-associated mutations being found within this domain.

Myocilin Expression and Localization

Myocilin is expressed in a number of tissues within and outside the eye. Within the eye, myocilin expression has been identified in the sclera, ciliary body, choroid, cornea, iris, lamina cribosa, retina, optic nerve, and aqueous and vitreous humor (**Figure 2**). The trabecular meshwork is reported to have the highest level of expression within the eye with similar expression distribution within the uveal, corneoscleral, and juxtacanicular regions. Outside the eye, expression of myocilin is found in highest levels in the skeletal muscle and heart. Other tissues in humans, rats, and mice that express myocilin include the mammary gland, small intestine, thymus, prostate, testis, colon, stomach, thyroid, trachea, bone marrow, and brain. Myocilin has also been detected in Schwann cells and the myelin sheath of peripheral nerves, renal podocytes and mesangial cells, intervertebral disks, and plasma.

Expression of myocilin can be regulated by both its internal and external environment. In addition to mechanical and oxidative stress, transforming growth factor-beta1 (TGF-β1), optineurin, and steroids can stimulate myocilin expression. Conversely, glaucoma medications such as timolol and latanoprost can decrease myocilin expression, while basic fibroblast growth factor (bFGF) and thyroid hormone T_3 can reduce the steroid stimulation of myocilin.

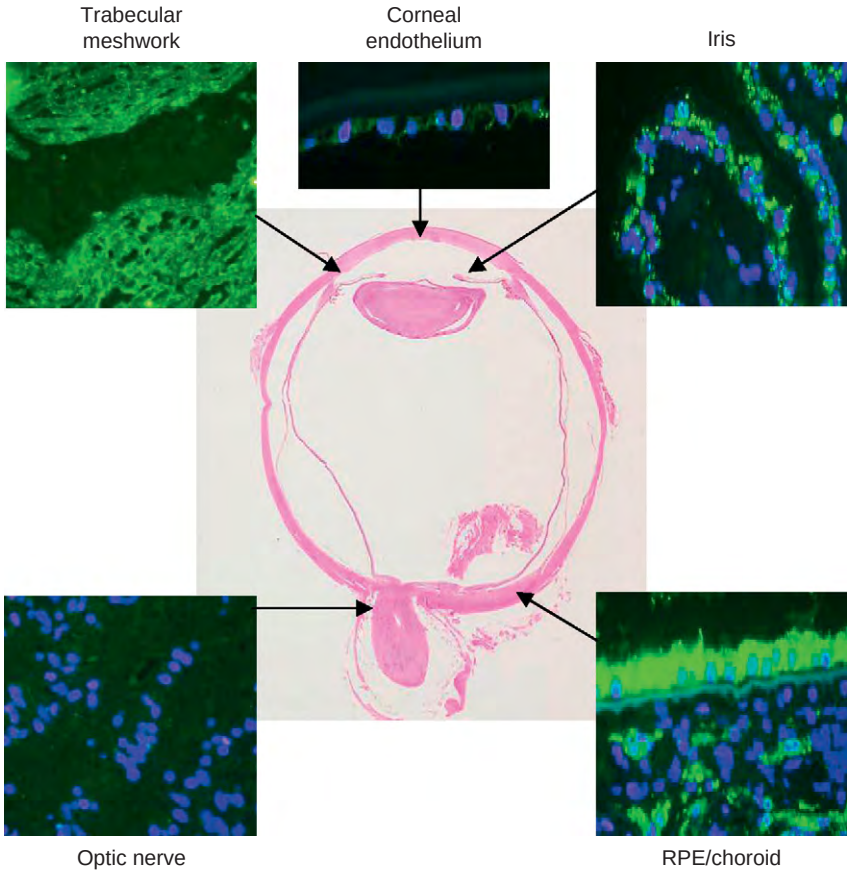

Figure 2 Representative images of myocilin expression within the human eye. Myocilin monoclonal antibodies were used to identify myocilin expression within the trabecular meshwork, corneal endothelium, iris, RPE/choroid, and optic nerve. Magnification: ×400. Blue: nuclei; green: myocilin.

The use of cultured primary human trabecular meshwork cells is an important model system to study the cellular and molecular aspects of these cells. Substrate and growth supplementation can effect the proliferation, morphology, and gene expression of cultured trabecular meshwork cells. Standard culture conditions (use of 10% fetal bovine serum as a growth supplement) can reduce myocilin expression and secretion from cultured trabecular meshwork cells. The use of aqueous humor as a growth supplement, and growth on soft extracellular matrices or on anisotropically ordered nanopatterned substrates can maintain myocilin levels in cultured trabecular meshwork cells similar to that observed *in vivo*. Additionally, topographic cues including shear forces present *in situ* may also play an important role in maintaining normal myocilin production from the trabecular meshwork.

Myocilin has been localized to both intracellular and extracellular compartments. The identification of an N-terminal signal peptide sequence and the presence in aqueous humor indicate that myocilin is secreted from the cell. Proteins with signal peptides are generally synthesized, folded, and processed through the endoplasmic reticulum and Golgi apparatus prior to exposure to the extracellular milieu. Myocilin has been localized within a variety of organelles associated with the secretory pathway, including the endoplasmic reticulum and Golgi apparatus.

In the extracellular matrix, myocilin associates with long-spacing collagens, elastic-like fibers, and sheath-derived plaque material within the trabecular meshwork. Structural components of the extracellular matrix, including fibronectin, laminin, decorin, and collagen types I, III, V, and VI, have all been associated with myocilin binding. Hevin, a member of the BM-40/SPARC/osteonectin family, has also been identified as a myocilin-binding protein.

Inside the cell, myocilin has been reported to associate with several intracellular proteins, including microtubules, myosin regulatory light chain, flotillin, gamma-synuclein, and actin stress fibers. Additionally, myocilin has been found associated with organelles. In the mitochondria, myocilin associates with the inner and outer membranes and in the intramembrane space, but not with mitochondrial matrix. The association between myocilin and mitochondria may be cell specific, having been seen in trabecular meshwork and astrocyte cells, but not in corneal fibroblasts. Furthermore, myocilin appears to associate with exosome-like vesicles. Exosomes are small microvesicles that are transported to the plasma membrane through microvesicular bodies, where they are released into the extracellular compartment. The association with exosomes not only suggests an intracellular localization for myocilin but also indicates that myocilin may be secreted from cells by a nontraditional mechanism.

Function of Myocilin

The normal, physiologic function of myocilin is currently unknown. However, myocilin has some properties consistent with matricellular proteins. Matricellular proteins are extracellular matrix proteins essential for modulating cell–matrix interactions, particularly those involved with cell attachment, cell spreading, inhibiting focal adhesion, and stress-fiber formation. Some matricellular proteins have a de-adhesive effect on cell–matrix attachment. Cells grown on matricellular substrates have altered cell attachments, cytoskeletal reorganization, and changes in cell shape. Most matricellular proteins are tightly regulated at the level of gene expression, especially during development and following cellular injury.

Similar to matricellular proteins, myocilin can be found extracellularly, bound to extracellular matrix, can influence cell–matrix interactions, and is a stress and injury response protein. Culturing of trabecular meshwork cells, skin fibroblasts, and neurons on myocilin substrates reduced cell–matrix adhesion and cell migration (i.e., de-adhesive activity). Furthermore, trabecular meshwork cells that have been wounded by physical disruption in culture exhibit decreased migratory ability and altered morphology, becoming more broad and stellate with the formation of cellular microspikes in the presence of exogenous myocilin treatment.

Intracellularly, myocilin may influence mitochondria function. Overexpression of myocilin in trabecular meshwork cells reduced mitochondrial respiration, potentially sensitizing cells and triggering apoptotic events. This may lead to a loss of trabecular meshwork cells, altering trabecular meshwork function and IOP maintenance.

Myocilin Mutations

Myocilin mutations have been found in up to 36% of JOAG patients and in approximately 4% of individuals with POAG. Over 70 glaucoma-causing mutations have been identified (**Figure 3**). Greater than 90% of these mutations are found in the C-terminal globular domain containing homology to olfactomedins. Myocilin mutations have a strong genotype–phenotype correlation. Individuals with the T377M mutation are generally diagnosed in their fourth decade, later than the P370L mutation (first and second decade) and Y437H (second decade), but earlier than the most common disease-associated mutation in Caucasians, Q368X, which has an average onset in the fifth and sixth decades. IOP differences have also been noted, with individuals carrying the Y437H mutation having mean maximal pressures of 44 mmHg and patients with the Q368X mutation having lower, but still elevated, mean maximal IOP (30 mmHg).

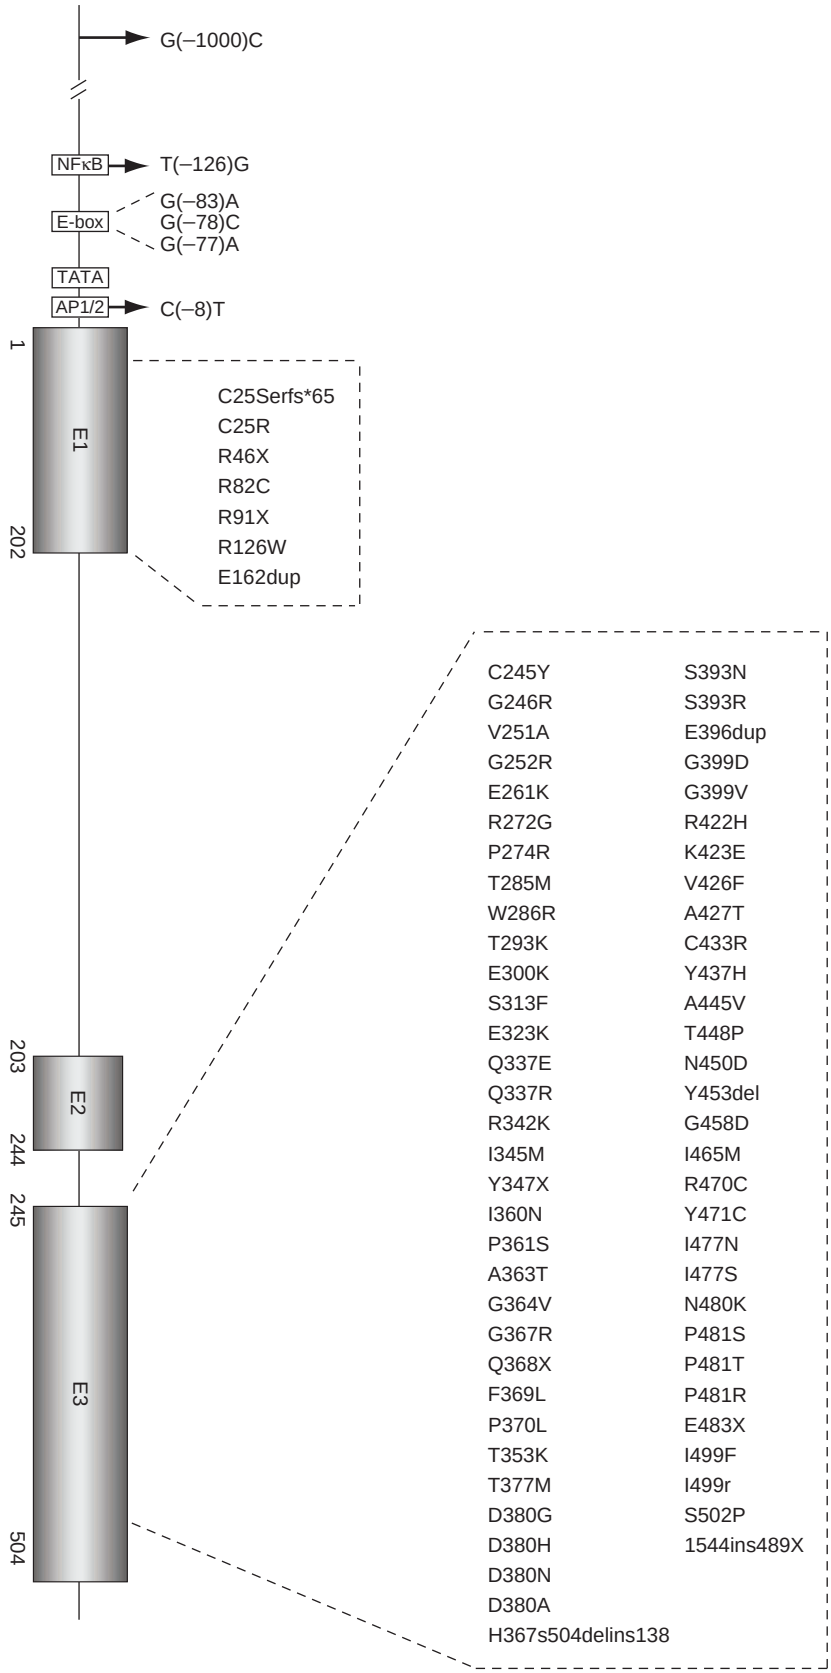

Figure 3 Glaucoma-causing mutations in myocilin. Over 70 glaucoma-causing mutations have been identified in myocilin, with >90% found in exon 3 that contains an olfactomedin-homology domain. Gene structure is shown on right. Numbers under the exons denote codon location in gene sequence. Reproduced from Resch, Z. T. and Fautsch, M. P. (2009). Glaucoma-associated myocilin: A better understanding but much more to learn. *Experimental Eye Research* 88: 704–712, with permission from Elsevier Ltd.

Less than 10% of the glaucoma-causing mutations in myocilin have been identified in the N-terminus. Two involve cysteine amino acids. C25R is in the signal peptide sequence and may interfere with secretion. Mutation of the cysteine amino acid at position 47 may disrupt normal homo- and heteromer disulfide bond formation. Three other mutations involve arginines at aa82, aa91, and aa126. These mutations may disrupt protein–protein interactions within the N-terminal leucine zipper motif.

A unique property of many of the mutant myocilin proteins is their inability to be secreted. Unlike normal myocilin which is secreted, mutant myocilin accumulates within the endoplasmic reticulum as homo- or heterodimers. The protein conformational changes caused by many mutants can be relaxed when cells overexpressing individual myocilin mutants are grown at 30°C. Interestingly, the more virulent glaucoma phenotypes (P370L, I477N, and Y437H) were less sensitive to secretion at 30°C compared to glaucoma phenotypes that are less virulent (T377M, G364V, I499F, and D380A). Additionally, treatment of cells with sodium 4-phenylbutrate increased the secretion of several myocilin mutants (C245Y, P370L, and Y437H), presumably by reducing aggregate formation.

Several sequence variations have been identified in the transcriptional regulatory region. Three of the sequence changes (−77G>C, −78G>C, and −83G>A) were identified in the E-box, a DNA sequence found to be essential for basal transcription regulation of myocilin. The most common sequence variation in the transcriptional control region is a cytosine to guanine base-pair substitution at position −1000 (mt.1(+)). This sequence variation has been reported in up to 20% of POAG patients with a suggestion that individuals with the mt.1(+) variation have a more rapid disease progression. Not all studies have confirmed the association of the mt.1(+) variant with POAG. A genetic test for the mt.1(+) variant (OcuGene) is available for clinical use.

How Does Myocilin Cause Glaucoma?

How myocilin increases IOP and causes glaucoma is unknown. Two theories, supported by clinical and laboratory observations, have been proposed. The first involves overproduction of normal myocilin, while the second focuses on a change of function for the glaucoma-associated mutations.

Normal Myocilin

The first hypothesis regarding myocilin's role in glaucoma revolves around the idea that elevated IOP may be caused by increased levels of normal myocilin, thus resulting in a reduction of outflow facility (increase in outflow resistance) within the trabecular meshwork. Several studies support this hypothesis: (1) the use of myocilin-specific antibodies in immunohistochemical studies indicates that some POAG eyes have elevated levels of myocilin in the trabecular meshwork; (2) dexamethasone treatment of trabecular meshwork monolayer cells or cultures of anterior segments increased myocilin in a time- and dose-dependent manner that correlated with the timing and increase of IOP seen in patients following steroid treatment; (3) primates treated with steroids for 1 year had elevated IOP and a threefold increase in trabecular meshwork myocilin levels; (4) recombinant myocilin overexpressed and isolated from either bacterial lysate or conditioned media from a human transformed trabecular meshwork cell line increased outflow resistance by >90% when perfused into human anterior segments; and (5) myocilin levels are statistically elevated in human aqueous humor by volume and as a percent of total protein in POAG when compared to normal controls (patients undergoing cataract surgery). Some animal models also support a correlation between elevated myocilin levels and IOP: (1) rats that spontaneously develop elevated IOP have a fourfold increase in myocilin transcription; (2) several canine breeds that have primary glaucoma show elevated levels of myocilin in aqueous humor, trabecular meshwork, and nonpigmented ciliary epithelium within regions of the ciliary processes; and (3) beagles genetically susceptible to develop glaucoma have increased levels of myocilin in aqueous humor with a direct relation to the severity of the disease.

Although evidence in human eyes and some animal models seemed to validate the hypothesis that overexpression of myocilin may contribute to elevated IOP, not all studies have confirmed this opinion. Expression of myocilin by an adenovirus in cultured anterior segments decreased IOP rather than increased IOP. Mice bred to overexpress either the mouse or human form of myocilin showed no change in IOP. Steroid-treated rats with elevated IOP contained normal levels of myocilin in the trabecular meshwork and a feline model overexpressing myocilin for >1 year did not show any change in IOP. Furthermore, deletion of one or both copies of myocilin in mice did not have any effect on IOP or ocular morphologies.

As myocilin is a protein induced by several forms of stress, it is reasonable to speculate that increased levels of myocilin may be a secondary effect of elevated IOP, not the primary cause. The overexpression of myocilin has been reported to alter gene expression of several molecules involved in cell adhesion and cell–matrix interactions. Therefore, increased levels of myocilin would not cause the elevated IOP, but may be the result of elevated IOP and potentially influence long-term changes in cellular adhesion.

Glaucoma-Associated Mutant Myocilin

While the mutations within the transcription regulatory region (promoter and enhancer region) may change myocilin messenger RNA (mRNA) and protein expression, the alterations in the protein-coding sequence can alter the three-dimensional structure, effectively masking important charges that regulate cleavage sites and presumably normal function. The sequestration of myocilin mutants in the endoplasmic reticulum may result in a gain of function unrelated to the normal function of myocilin. Clinical evidence supports this notion. Homozygous and heterozygous family members for myocilin mutant R46X, which truncates all but 13 amino acids of the processed protein, do not develop glaucoma. This suggests that normal myocilin may not be a key component in the causality of glaucoma. Furthermore, mice engineered to have zero or one copy of a functional myocilin gene did not have any ocular changes or elevation in IOP. These studies indicate that the lack of normal myocilin expression is not essential for the disease but that myocilin containing mutations may have a different function (gain of function) that may influence the physiologic development of glaucoma.

Mutant myocilin forms heterodimers with normal myocilin, effectively reducing the levels of secreted normal myocilin from trabecular meshwork cells. The sequestration of normal myocilin by mutant myocilin suggests that prolonged expression of mutant myocilin may lead to retention of the mutant (and normal myocilin), causing an endoplasmic reticulum overload response or unfolded protein response. Formation of normal and mutant myocilin heterodimers can form inclusion bodies, decreasing the heteromeric complex from translocating to the cytosol or extracellular milieu. Cells overexpressing myocilin mutants show expression changes in immunoglobulin heavy chain binding protein (BiP), endoplasmic-reticulum-localized eukaryotic initiation factor (eIF-2α) kinase, and activation of caspase 3 and 12. All of these factors are indicative of an endoplasmic reticulum storage disease process that can lead to apoptotic death. Furthermore, if normal myocilin functions as a de-adhesive molecule as postulated, then retention of normal myocilin in the endoplasmic reticulum by mutant myocilin would reduce the level of extracellular myocilin and cause a stiffer, less-pliable trabecular meshwork, possibly resulting in elevated IOP.

Glaucoma is mainly a human disease, with only sporadic cases found in other animals. Therefore, if myocilin is involved in glaucoma, specific characteristics of human myocilin may give us clues as to how mutated myocilin may function. Several lines of evidence support this hypothesis (summarized in **Table 1**). Mice engineered to express the human Y437H mutation have an increase in IOP. Conversely, mice or domestic cats expressing their species equivalent of the human Y437H mutation (Y423H) do not show a change in IOP. Unlike all forms of myocilin from different species, human myocilin contains a unique peroxisomal targeting signal-1 receptor binding site (PTS1R) at the C-terminus. Whether or not the PTS1R-binding site is functional in human cells remains to be determined. However, if the PTS1R site is functional, the shuttling of misfolded mutant myocilin to peroxisomes may lead to cellular stress and death.

Table 1

Myocilin animal models

Species	*Myocilin expressed*	*Effect on IOP*
Mouse	*MYOC* knockout	No effect
Mouse	*MYOC* overexpression[a,b]	No effect
Mouse	Mutant Y437H[a]	Increased
Mouse	Mutant G364V, Y437H[a]	Increased
Mouse	Mutant Q368X, S502P[a]	No effect
Mouse	Mutant Y423H[b]	No effect
Feline[d]	*MYOC* overexpression[c]	No effect
Feline[d]	Mutant Y423H[c]	No effect

Naturally occurring models

Species	*Phenotype*	*Myocilin levels*
Canine	Glaucomatous	Elevated
Beagle	Glaucomatous	Elevated
Rat	Elevated IOP	Elevated

Future Directions

Understanding the function of normal myocilin and the glaucoma-associated myocilin mutants is essential to our understanding of myocilin's role in the eye. Myocilin's expression throughout the eye and its secretion into the outflow pathway as part of aqueous humor suggest possible roles for myocilin in maintaining or influencing the aqueous outflow pathway. However, additional studies need to be done to fully elucidate myocilin's normal function and its role in the pathogenesis of JOAG and POAG. Analysis of stress conditions and growth factor/cytokine levels in aqueous humor needs to be assessed to determine whether they have a role in myocilin expression and function in outflow facility. An appreciation of myocilin in concert with other factors, such as the glaucoma-associated proteins cytochrome P450, subfamily 1, polypeptide 1

(CYP1B1), and WD repeat domain 36 (WDR36), is necessary to delineate myocilin's role in normal and disease processes. Future endeavors aimed at myocilin function will be essential to understanding myocilin's role in the eye as well as to other tissues of the body.

Myopia

F A Vera-Diaz, Schepens Eye Research Institute, Harvard Medical School, Boston, MA, USA

Glossary

Accommodation – The changes in optical power by the eye in order to maintain a clear image (focus) as objects are moved closer. This occurs through a process of ciliary muscle contraction and zonular relaxation that causes the elastic-like lens to round up and increase its optical power. Natural loss of accommodation with increasing age is called presbyopia.

Astigmatism – An optical defect in which refractive power is not uniform in all directions (meridians). Light rays entering the eye are bent unequally by different meridians that prevent formation of a sharp image focus on the retina.

Choroidal neovascularization – The creation of new, weak and leaky, blood vessels in the choroid layer of the eye. It is a common symptom of wet age-related macular degeneration and of pathological myopia.

Glaucoma – The neuropathy that affects the optic nerve of the eye and involves loss of retinal ganglion cells in a characteristic pattern causing peripheral visual-field defects.

Retinal detachment – A disorder of the eye in which some layers of the retina peel away from its underlying layers of support tissue. It is a medical emergency and if untreated it may cause partial or total vision loss.

Definition of Myopia: Health and Economic Implications

Myopia, also called near- or shortsightedness, refers to the refractive state of the eye whereby the images of distant objects are focused in front of the retina when the accommodation system is relaxed. It can also be described as the refractive error in which the point conjugate with the retina, the far point of the eye, is located at some finite point in front of the eye. Therefore, light entering the eye has to originate from near objects, within the eye's focal point, or diverged by concave lenses (minus power) in order to be focused on the retina of the myopic eye (**Figure 1**). Distant objects are otherwise perceived as blurred, hence the term nearsightedness. Squinting of the eyes is another symptom of myopia which can, rarely, produce headaches.

Myopia, in particular high myopia, is directly or indirectly associated with a number of ocular health complications that are potentially blinding. Moderate and high levels of myopia – greater than −5.00D – are a predisposing risk factor of reghmatogenous retinal detachment (lifetime risk is greater than 9%). High myopia is also a predisposing factor for open-angle glaucoma, myopic retinopathy, and myopic maculopathy. The increased elongation of the globe may be associated with degenerative changes in the sclera, choroid, Bruch's membrane, retinal pigment epithelium (RPE), and neurosensory retina. There is increased incidence of fundus (posterior part of the eye) lesions (**Figure 2**) such as posterior staphyloma, atrophy of RPE and choroid, lacquer cracks in Bruch's membrane, subretinal hemorrhages, lattice degeneration, pavingstone degeneration, pigmentary degeneration, white with or without pressure, retinal holes or tears, posterior vitreous detachment, macular holes, and choroidal neovascularization (CNV). Of these, CNV is the most common vision-threatening complication. Keratoconus, lens opacities, and increased complications following cataract surgery and pigmentary glaucoma are other associated complications. Although various methods of optical correction of myopia are possible, none changes the abnormally large size and shape of the myopic eye, with consequent thinning of the various layers, and therefore the risk of complications remains. Therefore, frequent complete eye health examinations, with pupillary dilation for comprehensive examination of the fundus, are necessary.

Myopia is a significant public health problem and its rapid increase in prevalence in recent decades is associated with a significant financial burden. In the United States, the annual direct cost of refractive correction with eye glasses alone is estimated to be at least $3.8 billion. Further adding to the cost of myopia are eye examinations, time off work, other optical corrections (e.g., contact lenses), refractive surgery, and other treatments. In the United States, correction of refractive errors, including the cost of glasses, contact lenses and refractive surgery, consumed over 12 billion dollars in 1990.

Although blurred vision resulting from myopia can often be corrected with visual aids, such as glasses, contact lenses, or refractive surgery, uncorrected refractive error is the major cause of visual impairment worldwide, accounting for at least 33% of visual impairments. In the United States, it is estimated that 5.3% of the visual impairments are due to uncorrected refractive errors. In addition, myopia – even if corrected – can be an impediment in certain professions; for example, military pilots and police officers.

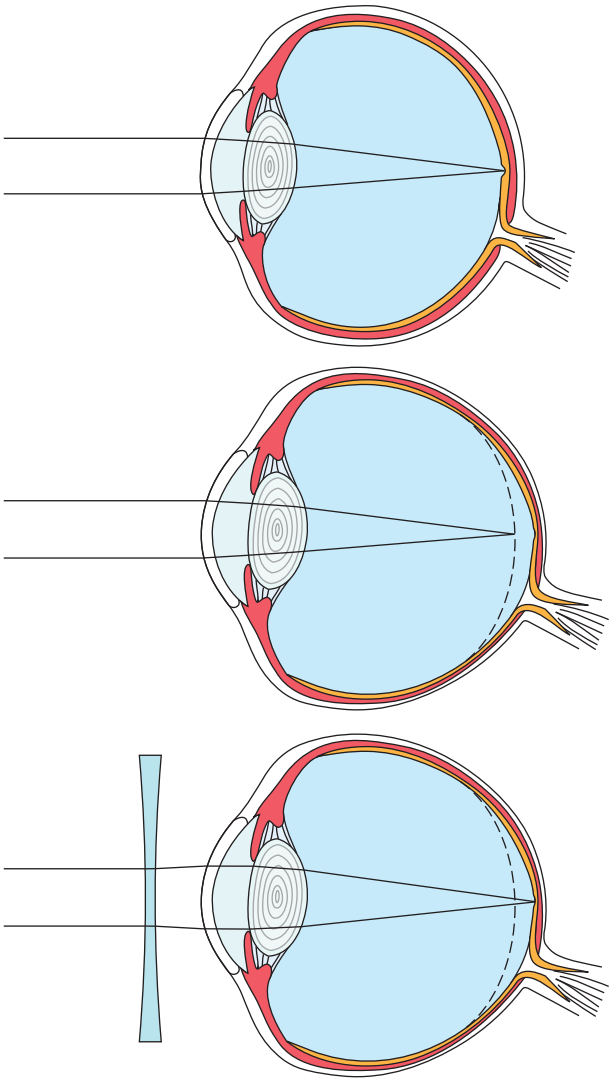

Figure 1 (From top to bottom) Schematic drawing (color) of an emmetropic eye (top) with parallel rays of light focusing at the retina; a longer myopic eye (middle) with parallel rays of light focusing in front of the retina; and a longer myopic eye corrected with a concave lens, the light rays are diverged and now focus at the retina (bottom).

Natural History of Myopia

Emmetropization is the process whereby the refractive components and the axial length of the eye come into balance during postnatal development in order to induce emmetropia (no refractive error). Most infants are hyperopic, and in those born myopic, the myopia typically decreases to reach emmetropia by toddler age. However, in a small population, for instance, premature infants with retinopathy of prematurity, myopia is present at birth and does not regress. By 12 months of age, the frequency distribution of the spherical equivalent becomes leptokurtic (as it is in adults) with the peak at low hyperopia. Results of a large longitudinal study by Gwiazda and colleagues, in 2000, showed that infantile astigmatism is associated with increased astigmatism and myopia during the school years.

Myopia typically develops during the school years, progressing until adulthood, but it may also develop in adults. Progression typically ceases in the teenage years, although it may continue into the 30s. Generally, the annual progression is close to −0.50D in juvenile (8–12-year-old) Caucasians and double that for juvenile Asians. There is a correlation with the age of onset and the final refractive status in adulthood, that is, children who become myopic at an earlier age (6 vs. 11 years) have a higher risk for myopia progression and higher degree of myopia later on.

Refractive error in the adult population follows a leptokurtic distribution with the peak around emmetropia. Later in life, a myopic refractive shift may result due to crystalline lens changes.

Structural Correlates, Molecular and Anatomical Changes in Myopia

In the Aristotelian writings (*c* 330 BC), the condition of shortsightedness was already documented. The optics of myopia, however, were first elucidated by Johannes

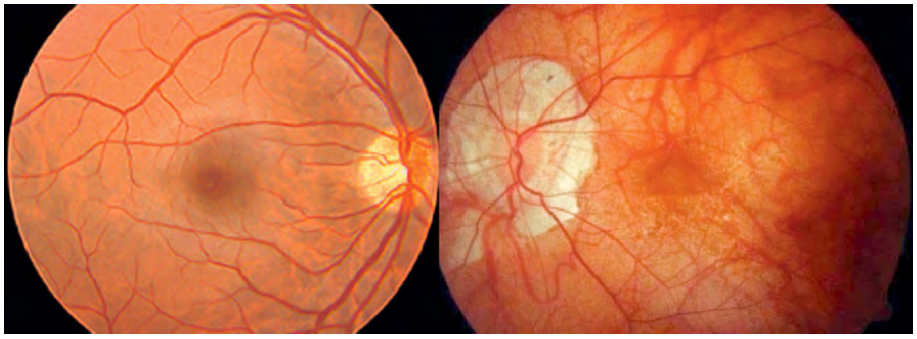

Figure 2 Fundus photograph of a normal emmetropic eye (left) and an eye with pathological myopia (right). Modified photographs from original images from images.google.com

Kepler in his initial *Clarification of Ophthalmic Dioptrics* (1604) when he correctly assumed that the incident light was brought to a focus in front of the retina. The reason for the displacement of the focus in myopic eyes elicited much attention. Some authors believed it was due to abnormal convexity of the lens; others attributed the defect either to an increased convexity of the cornea or to undue length of the globe, while some others described anatomically the unusual distance between the lens and the retina.

Biometric investigations of myopic eyes have confirmed that increased axial length of the eye, particularly vitreous chamber elongation, is the main structural correlate in human myopia. Steeper corneal radius, deeper anterior chambers, and thinner crystalline lenses have also been found; however, these are less consistent findings. The relationship between the eye's axial length and corneal radii (normally 3/1) is generally increased in myopic eyes. Retinal thickness is increased in the fovea, but decreases toward the periphery and it is significantly thinner in myopic eyes beyond the macula. In the 1990s, some studies showed that intraocular pressure (IOP) was related to myopia in children and therefore associated to the pathogenesis of myopia. However, a number of recent studies have refuted this theory with findings of no association between IOP and refractive error prior to or after the onset of myopia in children. Differences in the results may have resulted from ethnic differences.

The protein composition in aqueous humor is different in myopic eyes, suggesting that those proteins could indicate a potential biomarker for myopia development. However, most myopic changes are found in the posterior segment of the eye. The sclera of myopic eyes, even with low or moderate amounts of myopia, exhibits a number of structural changes due to the stretching of the eye, including increased extensibility, narrowing and dissociation of collagen fiber bundles, increased prevalence of stellate fibrils, severe thinning, and reduced collagen content, among others. These differences in scleral structure, and therefore its functionality, translate into a relatively thinned and weakened sclera. As myopic eyes expand during myopia development, the sclera must increase its surface area. Either new tissue must be added or existing tissue remodeled. Results of biochemical and histological studies are generally consistent with the hypothesis of active remodeling of the sclera during myopic growth. Regulatory changes in scleral metabolism could be rapidly evoked by a change in visual conditions which can also regulate the direction of change in eye size (toward hyperopia or myopia). The sclera's role on regulating eye growth and emmetropization and its potential role for preventing myopia warrant further investigation.

Signaling cascades link retinal image processing to scleral growth in myopia. Chemical messengers are released from the retina toward the RPE where secondary messengers are released through Bruch's membrane and transmitted through the choroid to the sclera. The role of substances and transmitters in the retina and choroid, such as glucagons, insulin, early growth response factor-1 (EGR1 or ZENK), dopamine, nitric oxide synthase (NOS) inhibitors, gamma aminobutyric acid (GABA), muscarinic receptor subtypes (M1 and M4), and acetylcholine, is being investigated. Jody Rada and Lisa Palmer have suggested that increased choroidal permeability may represent a mechanism for controlling the rate of delivery of bioactive factors to the sclera to regulate the rate of glycosaminoglycan synthesis in the posterior sclera. Changes in collagen subtype expression and turnover of the normal scleral matrix (matrix metalloproteinase-2) are ultimately responsible for the anatomical changes in collagen fibril morphology and tissue thinning found in myopia. A role of growth factors, such as transforming growth factor beta and specific matrix–cell receptors (integrins), and altered scleral cell phenotype (myofibroblasts), in the scleral regulation of myopia development has been suggested. In addition, several research centers are beginning to map the myopia-associated locus and to identify the gene(s) responsible for myopia (see the section titled 'Etiology of myopia').

Anthropometric measures such as body stature and weight have been associated to myopia. The Genes in Myopia (GEM) Twin Study group from Australia has recently (2008) reported that individuals in the heaviest quartile of weight of their study population had an increased incidence of myopia compared to those in the lightest weight quartile, but the relationship was significant only for females. Previous investigations have also associated myopia with taller and heavier individuals, but not all studies agree.

Classifications of Myopia

The pattern of myopia development is complex and variable; therefore, it makes more sense to refer to "myopias" rather than a single condition of myopia. This complex pattern makes a classification of myopia difficult and has resulted in numerous different classifications being postulated, including:

- *Classification according to the degree of myopia.* (1) Low, (2) moderate, and (3) high. The limits are still arbitrary, a consensus among experts is necessary if studies of prevalence are to be compared. Typically, low myopia refers to amounts between −0.50D and less than −3.00D; moderate refers to amounts between −3.00D and −6.00D; and high would be greater than −6.00D.
- *Ophthalmologic classification based on the fundus changes.* (1) Simple or physiological (no fundus changes) and (2) degenerative or pathological myopia (fundus anomalies).

- *Classification according to progression of myopia.* In 1984, Donders subdivided myopia progression into (1) stationary, (2) temporarily progressive, and (3) chronically progressive (also called malignant or deleterious) myopia. Nowadays, researchers classify myopia based on the progression of the refractive power: (1) stable myopia refers to the refractive error that has not increased more than -0.25D in a period greater than 2years, and (2) progressing myopia refers to greater increases over that period.
- *Classification according to the age of onset.* Typically classified as (1) congenital, (2) infantile, (3) juvenile, and (4) adult myopia. It may also be classified as (1) congenital versus (2) acquired. Research studies classify myopia based on the age of onset: (1) late-onset (15 years or older), and (2) early-onset myopia (14 years or younger).
- *Classification according to the combination of components of the eye.* (1) Refractive, correlation or combination myopia, and (2) component myopia (e.g., due to corneal curvature myopia, lens myopia, and axial myopia).
- *Classification according to presumed etiology.* (1) Environmental versus (2) genetic. Also: (1) physiological myopia, (2) school myopia (due to close work), and (3) excessive myopia (i.e., caused by diseases).
- *Genetic classification.* Dominant type, recessive type, a sex-linked recessive type, etc.
- *Biological classification of myopia.* (1) Physiological or simple myopia as a biological variation of the normal distribution of the eye components, and (2) pathological (progressive or magna) myopia as falling outside the normal distribution.

Clinical forms of myopia include: nocturnal myopia, due to drift in the accommodation state that increases the power of the eye under scotopic conditions, and pseudomyopia, false myopia due to physiological or pathological increased accommodation state.

Epidemiology of Myopia

In the early 1980s, more than 25% of the adult population in the United States and up to 75% in other developed countries, such as Taiwan, was myopic. Twenty years later, approximately 50% of general population in USA and up to 84% of the 16- to 18-year-old group in Taiwan was myopic. Based on a serial cross-sectional study from the Singapore Armed Forces, myopia prevalence has increased in military conscripts from 26% in the late 1970s, to 43% in the 1980s, 66% in the mid-1990s, and to 83% in the late 1990s.

The prevalence of myopia varies with age; it is low in young children, increases in school-age children and young adult cohorts, and decreases in older age groups. Within populations, myopia tends to be initially observed at the ages of 6–8 years with the average annual progression quoted as ranging from −0.10D to −0.60D. Chinese children are predominantly myopic; in 1990, the prevalence was 37% and 50% in the 6–12-year-old group and 13–18-year-old group, respectively. Recent studies in China and Sweden show that the prevalence of myopia is now higher for teenagers. Prevalence is even higher among Taiwanese children: 56% of 12-year-old children and 76% of 15-year-old children are myopes. In the later 1990s in Japan, 43.5% of 12-year-old children and 66% of 17-year-olds were myopes. It can be appreciated that there are racial differences within groups of same-age populations, for example, Chinese and Taiwanese populations show higher prevalence rates than other populations. Myopia prevalence declines to some extent in the population over 45 years of age, which is likely due to an increased prevalence rate in younger populations than an age difference.

The prevalence of myopia varies considerably between races, although it is difficult to ascertain the influence of environmental factors on these differences. In an attempt to account for environmental differences, a number of studies have investigated differences in racial groups living in the same location. In 1999, Lam and Edwards reviewed previous studies on myopia prevalence and concluded that the greatest prevalence of myopia occurs among Japanese, Chinese, and some Native American tribes. These studies take into account that the prevalence of myopia is lower in rural populations and it is affected by educational attainment and socioeconomic status.

Some studies have found a slightly higher prevalence of myopia in females than in males; however, not all agree on this. It seems that the differences in gender are found if the prevalence is measured in younger adults when males and females are not at the same growth level.

Etiology of Myopia

It is currently accepted that the etiology of myopia is complex with genetic and environmental factors playing a role. Understanding the relative contributions of genetic and environmental components is necessary to establish the mechanisms of myopia development and further attempt to arrest its progression. Separating these components is not trivial; for example, educational attainment is strongly influenced by genes, and therefore this risk factor should not solely be considered as an environmental risk factor; twins typically have the same environmental factors and hence should not be considered merely a genetic component.

A century ago, in 1913, Steiger showed that myopia is influenced by genetic factors and is an expression of a range within the normal distribution. A number of early

and recent studies with twins have shown that the concordance of refractive error is greater in monozygotic twins, indicating the existence of a genetic factor in myopia. Further, twin studies have provided evidence of correlation and heritability of a number of traits implicated in myopia. However, there are limitations associated to these studies.

The use of twin studies is also important in the identification of myopia's gene loci. A number of genetic loci have been identified as being linked with myopia. These include loci for high myopia occurring at Xq28 (MYP1), 18p11.31 (MYP 2), 12q23-24 (MYP3), 7q36 (MYP4), 17q21-22 (MYP 5), 4q22-27 (MYP11), and 2q37.1 (MYP12). Other candidate loci have been linked with low and moderate (common) myopia: 22q12 (MYP6), 11p13 (MYP7), 3q26 (MYP8), and 4q12 (MYP9). These linkages provide evidence that myopia is a polygenic disease with multiple and different alleles likely to contribute to different disease subtypes. Multiple familial studies also support a genetic component in myopia, suggesting a definite genetic basis for high myopia, and likely for low myopia. However, to date no candidate genes have been shown to account for even a modest fraction of the familial risk of myopia, and data are conflicting about whether a true association exists. It is likely that there is substantial genetic heterogeneity. In addition, further studies need to assess the relative roles of environmental factors and genetic influences, such as interactions of early-age nearwork and genotype, and the identification of phenotypes for etiologically different subgroups of myopia, for example, age of onset, presence of retinal degenerative changes, or response to treatments. See Schaeffel et al., Young, and the Genes of Myopia (GEM) Twin Group studies in the further reading section for reviews on the molecular basis of myopia.

Environmental factors, particularly nearwork, have been associated to myopia for centuries. Even though associated, nearwork has not yet been proven to be a causative factor. A number of aspects related to nearwork have been associated to myopia development and progression, including reading, cognitive effort during nearwork (with associated educational level and intelligence), lighting, and working distance. Accommodation and inaccuracies of the accommodation response are associated with myopia. Children who are to become myopic show greater inaccuracies of accommodation (greater lags) during near tasks. Accommodation effort, inaccuracies of the accommodation system during distance viewing, and accommodation flexibility have also been associated to myopia (nearwork-induced transient myopia (NITM) – a shift in refractive error due to inability to relax the accommodation).

Evidence for active and visually guided emmetropization (and its failures, such as myopia) is beyond refute. A number of animal models of myopia show that emmetropization can be manipulated and myopia can be induced. Manipulation of the environment can be achieved by imposing a close-work environment, or most commonly by lens-induced myopia (using high-power negative – concave – lenses) or form-deprivation myopia (using diffuser lenses, sutured lids, etc.; **Figure 3**). The most common animal models for myopia are chicks, mice, pigs, and tree shrews. Defocus blur is thought to be the primary cue for emmetropization and myopia. Emmetropization uses blur as visual feedback to regulate eye growth; the system requires detection of blur probably at the level of outer retina (perhaps amacrine and bipolar cells) – via diffusion of signals across RPE and choroid – to then alter scleral matrix (likely through a modulation of proteoglycan synthesis). The amount of defocus blur may increase in those

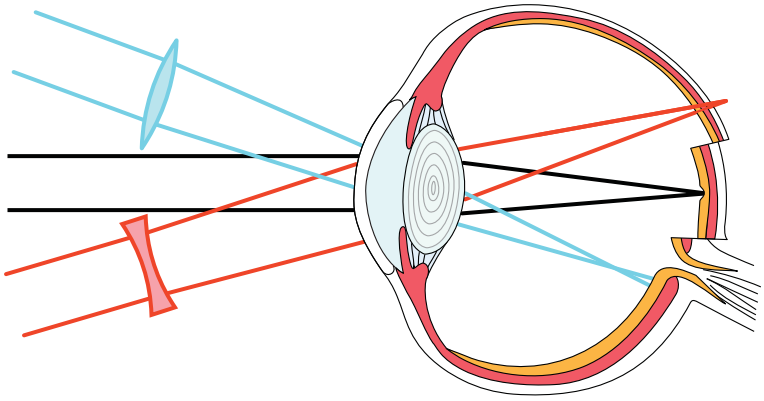

Figure 3 Schematic of an animal model of eye compensation for lens-induced defocus. Blue rays: a positive convex lens placed in front of a normal eye causes the image to form in front of the retina, the eye compensates by slowing down its growth rate and it hence becomes hyperopic (shorter); the eye layers become thickened. Red rays: a negative concave lens placed in front of a normal eye causes the image to form behind the retina, the eye compensates by accelerating its growth rate and it hence becomes myopic (longer); the eye layers become thinner. Black rays: the normal eye. Modified from Wallman, J. and Winawer, J. (2004). Homeostasis of eye growth and the question of myopia. *Neuron* 43, 447–468.

individuals who adapt more to blur, and hence blur adaptation may be a risk factor for myopia. The balance between central and peripheral defocus has been related to myopia, and animal models show that peripheral defocus alone can influence the rate of axial eye growth. Optical aberrations have been suggested to play a role in myopization, as some studies have found higher levels of aberrations in myopic eyes, but their association with myopia is not clear.

Among environmental factors, increasing educational demand seems to be a risk factor for development of myopia. When comparing university student populations with general populations, a much higher rate of myopia progression is found in the university populations. For example, significant differences have been found in the prevalence of myopia among Norwegian university students when compared to the general population of Norway and other Nordic countries. The prevalence of myopia has also been found to be greater in Greek university students and Scandinavian medical students than in the general population of the respective countries. In an interesting study in 1993, Zylbermann and coworkers showed that myopia was more prevalent in Orthodox Jewish boys in Jerusalem compared to Jewish girls, since boys spend up to 16 h day reading religious text, whereas girls receive a similar education to that in Western countries. Educational demands have also been cited as a risk factor in the prevalence of myopia in Young's 1969 work with Eskimo families in Alaska; while only two of the 130 Eskimo parents (all illiterate) were myopic, 60% of the children (required to attend school) became myopic.

Studies show that other environmental factors, such as light levels (related to latitude and the absence of ultraviolet (UV) radiation), contamination, diet, and parental smoking, have been associated to the development of myopia but there is no proven causation.

Children who spend more daytime outdoors are less likely to become myopic. This was a key discussion during the 12th International Myopia Conference in Australia. Following Jones and colleagues' first report in 2002 on the beneficial effects of outdoor exposure, others have found that it is the amount of time spent outdoors, rather than any particular physical activity as it was previously suggested, which may help retard myopia. There is consensus among myopia research groups (Orinda Longitudinal Study of Myopia, Sydney Myopia Study, and Singapore Sharable Content Object Reference Model (SCORM) study) that outdoor time is protective against myopia. The mechanism for this protective effect is unknown.

Mutti and coworkers (in 2002), the Correction of Myopia Evaluation Trial (COMET) group (in 2005), and others have found that parental myopia is a high-risk factor for myopia. Parental myopia may affect myopia with both genetic and environmental components. A theory of genetic predisposition to myopia with environmental triggers, such as nearwork, urban life, and reduced outdoor exposure, is commonly accepted at present. For an update on molecular, structural, and functional studies in humans and animals, including twin studies; prevalence, progression, and risk factors in myopia; the influence of nearwork and outdoor activity in myopia; and therapies for myopia see the 2009 work by McBrien and coworkers.

Correction and Prevention: Clinical Management of Myopia

Myopia may be corrected using visual optical aids such as spectacles, contact lenses, or, increasingly, refractive surgery. Correction of myopia is achieved by placing minor power (concave) lenses in front of the eye (**Figure 1**). The power of the lenses is measured in diopters (D) and corresponds to the inverse of the focal power of the lens. The eye care provider measures the refractive correction using objective (i.e., retinoscopy and autorefractometer) and subjective techniques to determine the lowest-power diverging lens that achieves best visual acuity. A binocular and eye health examination is required to establish the appropriate prescription.

As per the American Optometric Association guidelines, the goals for management of the patient with myopia are clear, comfortable, efficient binocular vision and good ocular health. Low levels of myopia (less than 3.00D) are not corrected in infants and toddlers as it may disappear within 2 years of age and their visual world is close anyway, that is, they can see as far as they need to. Older children or young children with higher amounts of myopia need to be corrected to allow the visual system appropriate development with clear visual input. For adolescents and adults, in general, any degree of myopia should be corrected any time the patient is adversely affected by the lack of clear distance vision; therefore, patients' needs are taken into account when prescribing a myopic correction. Astigmatism may occur in conjunction with myopia. When the degree of myopia is different ($\geq$2.00D) between the two eyes, the condition is called anisometropic myopia (anisomyopia). The material of choice for the eye glasses will also depend on the patient's characteristics (e.g., polycarbonate lenses are given to children) and the degree of the myopia (e.g., high-index, thinner lenses are recommended for higher prescriptions). Contact lenses (soft or gas permeable) are typically well accepted by myopic patients as the size of the retinal image is larger than with glasses, and they avoid visual-field restrictions. Whether spectacles or contact lenses are preferable in a given case depends upon numerous factors, including patient age, motivation, compliance, corneal physiology, and financial considerations. Orthokeratology is a technique of contact lens fitting which flattens the corneal surface over time to transiently reduce myopia.

A number of options to correct myopia with refractive surgery are available. Since the approval of the use of the excimer laser in the 1990s to reshape the cornea, there has been significant development in the correction of myopia. Laser refractive surgery has surpassed other conventional surgical techniques in safety and efficacy. The suitability of refractive surgery needs to be determined on a case-to-case basis and after a thoughtful discussion between the surgeon and the patient. Current refractive surgery options include:

1. *Excimer laser photorefractive keratectomy (PRK).* A procedure in which the corneal power is decreased by laser ablation of the central cornea, the corneal epithelium is scraped away to allow the reshaping of the corneal stroma.
2. *Laser in situ keratomileusis (LASIK).* This was introduced in the mid-1990s and largely replaced PRK. Unlike PRK, a flap is made in the epithelium to permit access to the stroma. LASIK avoids most of the problems of corneal haze, postoperative pain, and slow rehabilitation seen in PRK, but complications are sometimes associated with the flap. Some studies show that LASIK surgery has predictable and stable results in refractive and visual outcomes in correcting moderate to high myopia on long-term follow-up. Refractive stability is maintained over 7 years, with no evidence of progressive late-onset complications. Recently, an alternative mechanical, epi-LASIK technique has shown comparable effective results to LASEK.
3. *Laser epithelial keratomileusis (LASEK).* In this procedure, the epithelium is treated with alcohol and then peeled back to permit reshaping of the underlying layer. It avoids all flap-related complications associated with LASIK and has less postoperative pain and faster recovery than PRK.
4. *Wavefront-guided (WFG)*, or *custom LASIK.* This technique is used to avoid the induced positive spherical aberration typically found after conventional LASIK procedures. It is more advantageous with large pupils (most studies of conventional LASIK have shown a relationship between the diameter of the low-light pupil and complains of visual symptoms after surgery). However, WFG LASIK has all the same risks of conventional surgery.
5. A new procedure of PRK with intraoperative use of topical mitomicym C seems to be more effective than LASIK surgery for moderate myopia.
6. A number of surgical techniques use phakic intraocular lenses implanted in the posterior chamber. These are used for the correction of high myopia.

Despite significant advances, certain limitations and complications exist in these refractive surgery procedures and patient education is essential before a decision is taken. In this rapidly changing field, co-management of patients and consultation of most recent literature are necessary.

None of these correction techniques prevents or treats the condition. A number of approaches and techniques, which are discussed below, have been advocated over the years to prevent, inhibit, and attempt to reverse myopia development.

Positive Additions for Nearwork

The underlying principle of using positive additions is to reduce the accommodative demand at near, as increased accommodative effort is thought to play a role in the development of myopia. Positive additions may be achieved with the undercorrection of spectacles which also leads to a distance undercorrection and therefore defocused images; hence, the use of bifocals and progressive lenses has been suggested. The technique is supported by animal research that has shown that wearing positive lenses induces hyperopia. However, good results on the use of positive additions may not be only dependent on reducing the magnitude of accommodation, but on other oculomotor factors as well. Results of different studies are contradictory, although some reduction in the rate of myopia progression has been found to occur. In particular, the COMET group has found that the progression of myopia slows down in myopic children who have esophoria at near and are treated with positive additions in the form of progressive addition lenses (PALs). Ongoing longitudinal studies are being undertaken in this area.

Contact Lenses

Although some studies have shown that contact lenses (especially hard contact lenses) reduce myopia progression, the mechanism of action is not well understood. However, the success of these techniques is thought to result from corneal curvature changes produced by the contact lenses, which suggests that the changes may be transient.

Vision Therapy and Biofeedback Training

Various forms of accommodative vision therapy have been advocated in the treatment of myopia. The aim of a training program is to reinforce and establish control over the accommodative response. Although there are reports that these techniques can induce a reduction in myopia, there are no masked studies with objective data supporting the usefulness of vision therapy for correcting or preventing the progression of myopia. In most published reports the quantified test was solely unaided visual acuity which improvement may be explained by an improved ability to interpret a blurred retinal image. Myopes of low degree commonly report that their vision seems poorer upon removal of their spectacles compared to that after a period without spectacle wear. This phenomenon is called blur adaptation and accounts for very small to no additive improvement in visual performance.

Rigorous research studies are needed if accommodation biofeedback is to qualify as a method of clinical treatment of myopia.

Pharmacological Treatment

The first drugs to treat the progression of myopia were chosen based on the belief that myopia could be controlled either by the relaxation of accommodation or the reduction of IOP. Hence, cycloplegic agents such as tropicamide and atropine, and adrenergic antagonistic agents have been used in the past with no success. The difficulties resulting from the regular instillation of drugs, such as inconvenience, reading problems, discomfort, pupillary mydriasis, and the possibility of other adverse reactions to the drug, in addition to the lack of clear evidence of the effectiveness of these agents, provoked abandonment of these techniques. Although none of these pharmacological agents used has demonstrated an ability to control myopic progression successfully, for the past few years new approaches to myopia control are considering the importance of muscarinic receptors in myopia development. M1 antagonist pirenzepine and atropine are the newest drugs used in the attempt to slow down the progression of myopia. Atropine is the only pharmacological agent currently studied in clinical trials. Although the site of action of these drugs is unknown, studies in chicks suggest that these drugs act on the cartilaginous sclera to transiently inhibit glycosaminoglycan synthesis and slow down myopia development. Growth factors, such as insulin-like growth factor 1 (IGF-1), basic fibroblast growth factor (bFGF), and retinoic acid have been shown to be effective at controlling ocular growth in animal models and are promising therapeutic agents for high human myopia. Future therapies to slow down the progression of myopia in humans will be directed at altering the retinal–scleral signaling cascade involved in emmetropization.

Correction and Prevention: Clinical Management of Myopia?

In conclusion, the limited success achieved by the various methods of myopia control should not necessarily be interpreted as providing the absence of any relationship between myopia and nearwork. It is possible that once axial elongation has begun, continued visual feedback would produce additional axial elongation irrespective of any external intervention.

Neuroendocrine Properties of the Ciliary Epithelium

M Coca-Prados, Yale University School of Medicine, New Haven, CT, USA

Glossary

Aqueous humor – The fluid produced by the bilayered ciliary epithelium in the eye.
Endocrine system – An integrated system involving the release of extracellular signaling molecules such as hormones and neuropeptides in chemical communication between cells or tissues.
Intraocular pressure – The balance between the rate of aqueous humor secretion and its resistance to drainage through the trabecular meshwork.
Neuropeptide – A small chain of amino acids (i.e., 3–20 residues) formed from a large precursor (i.e., 200–300 residues) that is progressively cleaved by specific proteolytic enzymes into a biological active peptide.
Prohormone convertases – A group of protease enzymes that clip off the active segments from the larger peptide precursor at single, specific basic residues or pairs of basic residues.

The ciliary epithelium (CE) is a bilayer of polarized neuroepithelial cells, the pigmented epithelium (PE) and the nonpigmented epithelium (NPE), in the anterior segment of the mammalian eye. It forms with the underlying ciliary muscle (CM) and stroma, the ciliary body (CB), a multicellular unit playing multiple and essential functions in the physiology of the eye. The CE is involved in the secretion of aqueous humor and in the accommodation of the lens. It is also believed that the CE in conjunction with the trabecular meshwork (TM) plays a key role in the regulation of outflow of aqueous humor and intraocular pressure (IOP).

The gene expression profile of the CE has revealed the identification of prohormone convertases (PCs; PC1, PC2, PACE4, PC5, and furin) and enzymes (carboxypeptidase E (CPE); peptidylglycine α-amidating monoxygenase), usually restricted to neuroendocrine cells and tissues involved in the processing and maturation of neuroendocrine peptides and regulatory hormones. This finding has been supported by the identification of multiple neuropeptides (i.e., neurotensin (NT), galanin, and somatostatin (SST)) and peptide-hormones (i.e., natriuretic peptides (NPs), endothelin (ET), and angiotensin) in the intact CE, in aqueous humor and in the conditioned medium of cultured CE-derived cells *in vitro*. Some of these peptides are known to exert hypotensive effects in the cardiovascular system by lowering blood pressure, or ocular hypotension when injected in the eye, suggesting the presence of a local endocrine system in the CE that could influence inflow and outflow of aqueous humor and IOP. Although the development and differentiation of endocrine cells along the CE bilayer remain to be studied, peptide-producing cells have been localized in the NPE cell layer, including cells with molecular markers distinctive of neuronal differentiation involved in the biosynthesis of neurotransmitters.

The neuroendocrine peptides released by the CE are believed to act as either classical autocrine factors targeting their cognate receptors on the same peptide-producing cells, or as endocrine/paracrine signals on neighboring cells and tissues. In particular, cells of the conventional and the uveoscleral outflow pathways of aqueous humor are likely main targets of CE-secreted neuropeptides to influence their cellular function. These peptides may also function as neurohormones, neuromodulators, or neurotransmitters by linking inflow and outflow of aqueous by exerting positive and/or negative feedback control on IOP.

The Ciliary Epithelium

The mammalian CE is a bilayer of neuroepithelial cells, the NPE and PE, sharing the same embryological origin with the retina and the retinal pigment epithelium (RPE), respectively. The PE cell layer of the CE is continuous with the RPE and the NPE cell layer is related to the multiple neural and sensory cell layers of the retina.

At least, three anatomical regions have been distinguished along the CE: the pars plicata, the pars plana, and the ora serrata. The first region borders anteriorly with the iris and it is followed by the pars plana, whereas the ora serrata borders posteriorly with the peripheral margin of the retina. The cell polarity of NPE and PE cells along the entire CE is unique in the sense that their respective apical plasma membranes appose each other. Therefore, the basal membrane of NPE and PE cells face distinct microenvironments. The NPE cells face the aqueous humor, whereas the PE cells the stroma (**Figure 1**). Tight junctions, at the apical plasma membrane of NPE cells form a blood–aqueous barrier, preventing paracellular diffusion of plasma proteins from the stroma into the posterior chamber. The multiple gap-junction proteins, known as connexins, coupling NPE and PE cells facilitate the transfer of ions, electrolytes, and the propagation of intracellular signals along the CE as a functional syncytium.

A main function of the CE is the secretion of aqueous humor, a fluid that nourishes the avascular tissues (lens, cornea, and TM) in the anterior segment of the eye. The CE in conjunction with the filtering cells of the TM regulates the IOP, which reflects a balance between the rates of secretion of aqueous humor and its drainage through the outflow pathways. The secretion of aqueous humor and the regulation of IOP are essential for the integrity and normal function of the eye. An abnormal elevation in IOP is, for example, the best-known risk factor in the development of glaucoma, a neuropathy of the optic nerve characterized by the progressive axon degeneration and death of retinal ganglion cells, excavation of the optic nerve head, and loss of visual field, leading often to bilateral blindness. Today, a reduction in the rate of aqueous humor secretion is the most effective pharmacological approach in lowering IOP and in reducing the progression of the disease. Upon secretion, the aqueous humor moves from the posterior toward the anterior chamber through the pupil, leaving the eye through distinct outflow pathways, including the TM and Schlemm's canal, the uveoscleral, and the episcleral vein by mechanisms not totally understood.

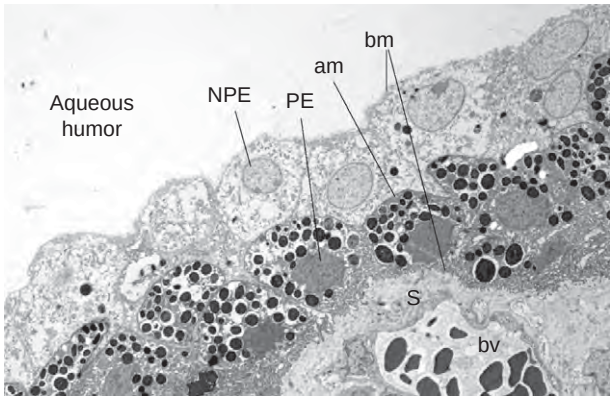

Figure 1 Electron micrograph of a cross section of the ciliary epithelium. The basal membrane (bm) of NPE cells faces the aqueous humor, whereas of the bm of PE cells abuts the stroma (S). The apical membranes (am) of NPE and PE cells appose each other. NPE, nonpigmented; PE, pigmented; bv, blood vessel.

Another function of the CE is accommodation, a mechanism that allows changing the focus of the eye field. Microfibril arrays, known as ciliary zonules, connect the CE and the equator of the lens, and through the contraction–relaxation of the CM, the underlying tissue of the CE, exerts tension in the zonular fibers by modifying the curvature of the lens and its refractive power. The elasticity of the zonular fibers is reduced over age, and in pseudoexfoliation glaucoma they appear to be subject to an increased proteolytic degradation.

In spite of the embryological relationship of the CE with the retina and RPE, little is known about the molecular signals that configure this tissue. Earlier studies have suggested that the lens formation may influence early events in the differentiation of the CE, and that specific signals such as BMP4, BMP7, and transcription factors (CHX10 and PAX6) are important determinants in that process. The PE cell layer of the CE is an extension of the RPE where there is a cellular redistribution of the Na^+/K^+-adenosine triphosphate (ATP)ase from the apical membrane in the RPE toward the basal membrane in PE cells without changing their cellular polarity. On the other hand, the NPE cell layer is related to the multiple cell layers of the retina and it becomes a single polarized cell layer apposing the PE cell layer. Although there is no evidence that the CE harbors photoreceptive cells capable of evoking light-mediated responses, the human CE continues to express (messenger RNA mR and protein) many components associated with the visual phototransduction and the retinoid cycle. The adult CE contains reduced levels of rhodopsin kinase, visual arrestin, cellular retinaldehyde-binding protein (CRALBP), all-*trans*-retinyl esters, and all-*trans*-retinol. Whether these retinal markers are indicative of the presence of presumptive retinal neurons or retinal progenitor cells along the CE is at present unknown.

In recent years, a large body of information has emerged on the cell and molecular biology of the human CE as well, based on the analysis of hundreds of expressed sequence tags (ESTs) isolated by subtractive hybridization from a human CB cDNA library. It has provided a deeper understanding of the multiple biological functions of the human CB (**Table 1**). This article emphasizes the neuroendocrine properties of the CE and the supporting evidences that it is the source of neuropeptides and transmitters in aqueous humor.

Neuroendocrine Genotype of the CE

Earlier studies have shown that the human CE expresses genes for neuropeptides, including NT, galanin, SST, and peptide-hormones and their receptors. These peptides usually are restricted to endocrine cells of the brain,

Table 1 Biological functions assigned to the human ciliary epithelium

1. Aqueous humor transport
2. Accommodation of the lens
3. Synthesis and secretion of plasma proteins, proteases, anti-proteases, and anti-angiogenic and growth factors.
4. Expression of neuropeptides, transmitters, peptide-hormones, and cognate receptors.
5. Expression of immunosuppressive factors: TGFβ2, somatostatin, substance-P.
6. Steroidogenic: steroid-converting enzymes (17β-HSDs and 11βHSDs).
7. Prostaglandins: Cyclooxigenase-2 (COX-2); prostaglandin D2 synthase.
8. Expression of components of rod-phototransduction including: rhodopsin, rhodopsin kinase, and visual arrestin.
9. Expression of components of the visual (retinoid) cycle including: CRALBP, IRBP, CRBP, 11-*cis*-RDH, and LRAT.
10. Expression of glutamate metabolizing enzymes, glutamate receptors (mGluR1b), and glutamate transporters (EAAT1, EAAT5).
11. Expression of GABA receptors (i.e., GABA-C)
12. Circadian clock genes, melatonin rhythm-generating enzymes, and melatonin receptors.
13. Expression of glaucoma genes: myocilin (*MYOC)*, cytochrome P450 *(CYP1B1)*, optineurin *(OPTN)*.

heart, and gastrointestinal tract. The neuronal-like peptides of the human CE (i.e., NT, galanin, and SST) should be considered separately from the peptides that originate from the sympathetic, parasympathetic or sensory ganglions for which nerve endings may be observed in the proximity of PE cells. Transcripts for galanin, NT, or SST, for example, have been detected by RT-PCR or Northern blot analysis on RNA extracted from dissected ciliary processes, a villi-like formation in the *pars plicata*, or from cultured NPE and PE cell lines established from this region. The peptides synthesized and released by the CE have been detected by radioimmunoassay. In many instances, human and bovine CE-derived cells under culture conditions *in vitro* maintain their peptide secretory activity. Therefore, it is unlike that the mRNA detected for each of the above peptides in the CE derives from the ganglia (i.e., ciliary ganglion, pterygopalatine ganglion, superior cervical ganglion, and trigeminal ganglion) innervating the CB.

It has been suggested that peptides released by the CE cells may display multiple functions including their potential influence in the regulation of the rate of aqueous humor secretion and IOP, while also serving as trophic or immunosuppressive factors.

Neuropeptides are synthesized as large precursor polypeptides or pre-propeptides containing the amino acid sequence of the neuropeptide, plus the signal sequence (also known as signal peptide) at its N-terminus that is found in precursor of hormones to be secreted. The precursors are first subjected to endoproteolytic cleavage on the C-terminal of basic residue pairs (Lys-Arg) by PCs, which are members of a family of serine proteinases related to the subtilisin/kexin-type. The C-terminal basic residues are then removed by the CPE, a neuropeptide-processing enzyme resulting in many cases the final step in the biosynthesis of mature peptides. However, some peptides undergo additional post-translational modifications, including amidation, N-terminal acetylation, and serine or threonine phosphorylation. Thus, if the peptide contains a glycine residue preceding the basic cleavage site, it can be further modified by the removal of the glycine residue, generating an amidated carboxyl group by the action of the peptidyl-glycine-α-amidating monooxygenase (PAM).

The capacity of the human CE to process neuropeptide precursors was initially suggested after the isolation and identification of a subtracted cDNA clone (CBS-294) encoding CPE. This finding followed the characterization in the CE of PAM, furin, the PCs PC1, PC2, PACE4, PC5, and the neuroendocrine peptide 7B2. PC1 and PC2 are endoproteolytic enzymes restricted to endocrine cells and neurons, whereas PACE4 and PC5 are found in a wide range of tissues and cells. PC1 and PC2 cleave precursors entering the regulated secretory pathway, while furin process precursors within the constitutive secretory pathway.

There is supporting evidence now that PCs are involved in a number of pathologies, including cancer, neurodegenerative diseases, endocrine disorders, and inflammation. Within the CE, PC1 has been found in the PE cell layer, whereas PC2 in the NPE cell layer. These studies also suggested that the intracellular proteolytic processing of peptide precursors is likely occurring in both cell layers of the CE in a cell-specific fashion. This is consistent with the view that CE cells may be able to process the same precursor into distinct biologically active peptides in PE from NPE cells. For example, the precursor of NT and neuromedin (NN), pre-proNT/NN, is a target of proteolytic processing of both PC1 and PC2 giving rise to distinct cleaved forms. In the brain, NT and NN are detected in equimolar levels, whereas in the intestine NN is detected in larger levels than NT. In the retina, the concentration of NN is higher than NT, whereas in the CB, NT is more abundant than NN. The distinct ratio of NT/NN found in endocrine tissues or cells is dependent on the PC-specific expressed. Precursors of neuropeptides and hormones released from the signal peptide are shuttled to the Golgi apparatus where they are sorted away from other proteins into granules of the regulated secretory pathway. Precursors are also co-packaged with their processing enzymes and they may be subjected to many additional enzymatic modifications (i.e., glycosylation and phosphorylation). The presence of a limited membrane around the secretory granules is characteristic of many secretory granules and their size may range from 20 to 30 nm to as large as 400 nm in diameter. Although neuropeptides and hormones can usually be stored within membrane-bound

Table 2 Expression of endocrine markers, neuropeptides, peptide-hormones, and transmitters in the human CE

Neuropeptide-processing enzymes
Prohormone convertases: PC1, PC2, PACE4, PC5, and furin
Carboxypeptidase E (CPE)
Peptidylglycine α-amidating monooxygenase (PAM)

Neuropeptide PY
Angiotensinogen (angiotensin II)
Endothelin (ET)
Substance-P

secretory dense-core granules, they can be also stored on translucent secretory vesicles (10–100 nm in diameter).

Protein 7B2 is an acidic protein that resides in the secretory granules of neuroendocrine cells and it functions as a specific chaperone for PC2. The co-expression of PC2/7B2 and additional neuroendocrine-processing enzymes in PE and NPE cells supports the hypothesis that the CE exhibits neuroendocrine properties. Table 2 summarizes a list of neuropeptide markers, peptides, and transmitters expressed in the human CE.

Neuropeptides and Peptide-Hormones of the CE

It is believed that the regulatory peptides released by the CE may exert positive and negative feedback actions on the secretion of aqueous humor and on the secretion of other neuropeptides and hormones. NPs and endothelin ET are among the most extensively studied peptides because of their potent ocular hypotensive effects evidenced by the lowering IOP in experimental animals and in humans. NPs and ET released by the CE exert important regulatory actions on both the site of secretion and the site of drainage of aqueous humor where NPs and ET receptors are present. A more recently identified neuropeptide expressed by the adult human CE is SST, which is also widely distributed in the central nervous system, gastrointestinal tract, and endocrine cells. Within the CE, SST immunoreactivity has been detected sparsely along the NPE cell layer, whereas SST receptors (SSTRs) are widely detected in the retina, iris, and CE. SST is regarded as a neurotransmitter and neuromodulator, exhibiting antisecretory and antiproliferative properties. SST is produced by neuroendocrine, inflammatory, and immune cells in response to a large and diverse number of exogenous and endogenous molecular signals. SST regulates many cellular functions, including the secretion of hormones, neuronal excitability, and vascular

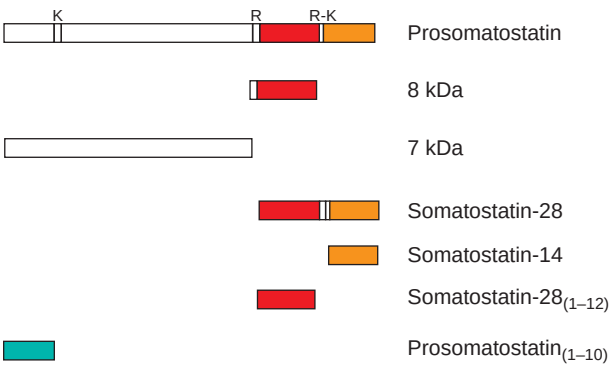

Figure 2 The polypeptide precursor of somatostatin, prosomatostatin, undergoes endoproteolytic cleavage at specific basic residue sites (i.e., arginine (R), lysine (K)), by proprotein convertases PC1 and PC2, to produce distinct biologically active peptides (i.e., somatostatin-28, somatostatin-14).

smooth muscle contractility. SST derives from a 92-amino-acid polypeptide precursor, known as prosomatostatin (pro-SST), which undergoes processing at both the amino and carboxyl-terminal sites of specific pair, basic amino acids into multiple shorter forms, including the biologically active peptides somatostatin-28 (SST-28), and somatostatin-14 (SST-14) (Figure 2).

It has been shown that the PCs, PC1 and PC2, cleave pro-SST into multiple forms, including SST-28 and SST-14, at specific residues with different efficiencies. The inhibitory activity exerted by SST on endocrine, exocrine secretions, and transmitter release, is mediated through at least five distinct SSTRs 1–5. These receptors are coupled to G_i-proteins and upon activation can negatively couple to the adenyl cyclase-cyclic adenosine monophosphate (cAMP) pathway to inhibit stimulated, but not basal, cAMP production, and inhibition of ion exchangers. In the iris, SST has been shown to induce mydriasis by attenuating cholinergic neurotransmitter release and may modulate pupil diameter. In other endocrine systems, activation of SSTRs mediates the inhibition of the growth hormone, glucagons, and insulin secretion.

The NP system has been shown to be present in the CE. It consists of three NPs (ANP, BNP, and CNP), and three distinct receptor subtypes (NPR-A, NPR-B, and NPR-C). Within the ciliary processes, ANP and BNP have been co-localized in the NPE cell layer, and CNP distributed in the vascular endothelium. CNP exhibits the most potent hypotensive effect in the eye when compared to ANP or BNP. The three NPs have been detected in the aqueous humor and in concentrations higher than in plasma, suggesting they are secreted. On the other hand, BNP levels are in higher levels than CNP or ANP. ANP receptors are downregulated in rabbits with experimental glaucoma and ANP levels in aqueous humor are increased as the IOP is increased. The mechanism of

action of the NPR-A and NPR-B receptors is associated with intrinsic guanylyl cyclase (GC) activities producing the second-messenger cyclic guanosine monophosphate (cGMP). In contrast, the NPR-C receptor does not have GC activity and functions as a clearance receptor regulating the level of NPs in aqueous humor.

The potential role of NPs as paracrine modulators of aqueous humor outflow has been suggested. Bremazocine, a relatively selective agonist of κ opioid receptors, lowered IOP by increasing the level of CNP in aqueous humor and increasing outflow. It has been also shown the effect of NPs on the transport systems believed to contribute to fluid secretion across the CE. Inhibitors of the Na^+/H^+-exchanger (NHE), for example, lower IOP when topically applied to the eye. On the other hand, NPs attenuate NHE activity in the CE by inhibiting the Na^+-dependent intracellular pH recovery upon an acid-load, in an order of potency that is similar to their ability to stimulate cGMP in cultured NPE cells. Thus, endogenous NPs could influence aqueous humor secretion by modulating the NHE activity in the CE.

ET is another example of a CE-released peptide in the aqueous humor with ocular hypotensive effects. The effect of lowering IOP has been suggested to occur as a result of the contraction of the CM, which inserts into the TM, resulting in an enhancement of the outflow facility. However, other studies support a potential reduction in aqueous humor secretion due to the inhibition of the Na^+/K^+-ATPase activity by acting on ETB receptors in NPE cells. Such an action could also result in a decrease in aqueous humor formation and contribute to the reduction of IOP.

Potential Neuroendocrine–Immune Circuitry in the Anterior Segment of the Eye

Neuropeptides released by the CE in the aqueous humor may exhibit multiple biological activities, including those associated with a putative neuroendocrine–immune circuit. It has been well recognized that the anterior segment of the mammalian eye is an immune-privileged site, and that antigens injected in the anterior chamber elicit deviant systemic immune responses that are devoid of immunogenic inflammation. This distinctive response, known as anterior chamber-associated immune deviation (ACAID), arises in part by the soluble immunosuppressive and anti-inflammatory factors released by the surrounding tissues in the aqueous humor. The aqueous humor, for example, is able to suppress interferon-γ (INF-γ) production by effector T cells, and neuropeptides present in the aqueous humor, including α-melanocyte stimulating hormone (α-MSH), calcitonin gene-related peptide (CGRP), vasoactive intestinal peptide (VIP), and SST, are capable of suppressing pathogen-induced inflammation in the anterior chamber of the eye. SST, for example, contributes to the immunosuppressive properties of the aqueous humor by promoting the production of the potent immunosuppressive cytokine α-MSH, and by inducing the activation of regulatory T cells. The presence of proinflammatory (i.e., substance-P and CGRP) and anti-inflammatory neuropeptides (i.e., SST) in aqueous humor indicates that there is likely a regulated balance between these factors that influence the ocular immune-privileged microenvironment of the anterior chamber. TGFβ2, a cytokine that promotes immune deviation and immunosuppressive activities, has been detected in high levels in the aqueous humor in approximately 50% of glaucoma patients with primary open-angle glaucoma. High levels of TGFβ2 mRNA are expressed in the human CE, and TM, suggesting that these tissues produce immunosuppressive factors into the aqueous humor. Recent studies have documented that T cells exposed to cultured PE cells of the iris-CB were induced to secrete large amounts of active and latent TGF-β2, a response that was mimicked by exposing T cells to aqueous humor. These observations confirmed that cells from the CE exhibit immunomodulatory functions of their own, since its ability to synthesize and release cytokine factors was independent of the involvement of T cells. The finding that the CE and TM cells expressed cognate receptors for many of the neuropeptides and cytokine released in the aqueous humor may not be coincidental, and it suggests that these factors may act upon autocrine and paracrine based mechanisms to promote immune privilege in the anterior chamber of the eye.

Potential Glutamatergic and Gamma-Aminobutyric Acid (GABA) Systems in the CE

Glutamate (L-Glu) and gamma-aminobutyric acid (GABA) are major excitatory and inhibitory neurotransmitters in the central nervous system (CNS) and retina. However, in recent years it has been shown that components of the glutamatergic are not restricted to the CNS. Glutamatergic systems have been found in peripheral tissues, including bone, pancreas, gastrointestinal tract, testis, and RPE, suggesting that L-Glu functions in these tissues as a chemical transmitter in an autocrine or paracrine fashion. There are observations supporting that NPE cells are pluripotent and capable of proliferating and differentiating into neurons when exposed *in vivo* to growth factors (i.e., insulin and EGF), or into presumptive photoreceptor precursors in response to retinal injury. Further studies have shown evidence supporting neuronal and glial differentiation within the adult CB. In comparison, PE cells from rodents and other adult

mammals in neurosphere-forming assays are capable of generating new neurons with retinal stem/progenitor cell characteristics. These PE-derived cells were shown to harbor stem/progenitor cells with the capacity to give rise to rod photoreceptors, bipolar neurons, and Müller glial cells.

Earlier studies have shown that the CE is capable of synthesizing and breaking down amino acid neurotransmitters. The enzyme glutamine synthetase, involved in the conversion of glutamate into glutamine, was described in NPE cells, and glutamate, GABA, taurine, glutamine, and glycine, and has been measured biochemically in the iris-CB extracts. Post-embedding immunocytochemistry techniques in the zebra fish eye have also revealed that CE cells contain significant basal levels of glutamate, glutamine, and taurine. Overall, these studies indicate that the CE stores neurotransmitter amino acids. Glutamate has been detected in the aqueous humor and in certain forms of retinal diseases and glutamate levels are high suggesting a disruption in glutamate homeostasis. The broad spectrum of peptide-, hormone-, and transmitter-producing cells in the human CE suggests that this tissue harbors a wide range of endocrine cells.

GABA exerts its regulatory actions through ionotropic $GABA_A$ and $GABA_C$, and metabotropic $GABA_B$ receptors. Preliminary studies indicate that $GABA_C$ ρho1- and ρho2-subunits are expressed in the adult human CB (**Table 1**). In the retina, for example, ρho1 transcripts have been identified only in bipolar cells, whereas ρho2 mRNA has shown a more widespread distribution, and ρho3 are in ganglion cells.

What is the putative function of GABAergic systems in non-neuronal tissues? One function that has been widely suggested is that GABA acts in these tissues as an autocrine or paracrine regulator of endocrine functions. Further studies are required to determine whether the $GABA_C$ receptors in the CE are functional and if so what role they play on the neuroendocrine functions of the CE.

Conclusion

The mammalian CE synthesizes and secretes neuropeptides, transmitters, and peptide-hormones into the aqueous humor. The peptides and the neuroendocrine-processing enzymes, so far identified, underscore potential novel neuroendocrine functions of the CE not exclusively restricted to the regulation of aqueous humor secretion and its absorption. The CE-released peptides may also represent functional components of multiple local interactive endocrine loops between the endocrine cells of the CE and the avascular tissues of the anterior segment of the eye. For example, the ocular hypotensive effect of several of CE-released peptides suggested that they may be involved in the local regulation of IOP by linking inflow with outflow of aqueous humor. The CE-peptides may also be involved in the cross talk between the CE and the immune homeostasis of the anterior segment of the eye. Finally, CE-peptides may represent key input/output factors in the circadian rhythm of aqueous humor and/or IOP.

Glossary

Calcium imaging physiology – An experimental technique used for detecting and measuring calcium (Ca^{2+}) levels in cells or tissues. Calcium imaging techniques take advantage of calcium indicator dyes, which are molecules that respond to the binding of Ca^{2+} ions by changing their spectral properties.
G-protein-coupled receptor – A large protein family of seven-pass transmembrane receptors that bind molecules and activate intracellular signal transduction pathways to generate cellular responses by coupling to heterotrimeric guanine-triphosphate-binding proteins.
Ion channels – The transmembrane protein complexes that form a water-filled channel across the plasma membrane through which specific inorganic ions can diffuse across their electrochemical gradients.
Paracrine – Acting by volume transmission of transmitters or modulators rather than at chemical synapses in a point-to-point fashion.
Patch-clamp electrophysiology – The study of the electrical properties of biological cells and tissues using electrodes with a high-impedance (gigaohm) seal that permits measurements of small (pA) current and voltage changes.

Introduction

The vertebrate retina contains numerous transmitters and related signaling molecules, including peptides and growth factors, which have multiple roles in the retina, including cellular signaling, growth, and maintenance. The presence, expression, and distribution of peptides, and their receptors in the retina are discussed elsewhere in the encyclopedia. This article mainly focuses on the cellular actions of peptides in the retina. Peptides are characterized by their small size, ranging from 5 to 35 amino acids, and their actions are mediated through guanine-nucleotide-binding protein (G-protein)-coupled receptors (GPCRs) to influence multiple intracellular effectors, including cyclic adenosine monophosphate (cAMP), cyclic guanosine monophosphate (cGMP), Ca^{2+}, protein kinases, and phosphatases. These intracellular effectors modulate ion channels, ligand-gated channels, gap junctions, transporters, and receptors, and affect nuclear transcription factors.

The presence of peptides in the retina was firmly established in the 1970s on the basis of peptide bioactivity and immunoreactivity in retinal extracts, and peptide immunostaining, mainly of amacrine cells. Consistent with the action of peptides in the retina, peptide receptor binding sites have been reported in retinal extracts, and later the expression of their receptors by different retinal cell populations was demonstrated. There is a wide distribution of receptors, with bipolar, amacrine, and ganglion cell populations, expressing different complements of peptide receptors. Interestingly, there is often a difference between the cellular distribution of peptide-containing amacrine cells and their processes compared to the cellular distribution of their receptors, which suggests that peptides can act in a paracrine manner to influence multiple retinal circuits in both the outer and inner retina.

Peptides modulate the cellular activity of retinal neurons and circuits by influencing intracellular signaling pathways. For instance, several different peptides reported in the retina have an effect on cAMP and Ca^{2+} levels, and somatostatin (somatotropin-release-inhibiting factor, SRIF) modulates K^+ and Ca^{2+} currents. SRIF and vasoactive intestinal polypeptide (VIP) also modulate gamma aminobutyric acid-A ($GABA_A$) receptor currents. Through these actions, peptides can change the efficacy of synaptic transmission in the retina by regulating cellular excitability as well as by modulating the release of the fast-acting transmitters, GABA and glutamate, from presynaptic axonal terminals. The overall actions of peptides on retinal neurons are generally characterized as being slow in onset, long lasting and potent at low concentrations, suggestive of a role in adaptive mechanisms. Together, these findings provide support for multiple physiological roles for peptides in the retina.

Peptide Receptor Expression

In general, peptide actions are mediated by GPCRs that influence intracellular signaling pathways, which in turn modulate neuronal excitability and transmitter secretion. Furthermore, there are multiple peptide receptor subtypes for most peptides that are differentially coupled to these intracellular effectors, which markedly increase the diversity of peptide action. For instance, numerous

receptor subtypes mediate the action of neuropeptide Y (NPY), somatostatin (SRIF), and VIP in the nervous system. In retina, there is a similar situation, with peptides expressed by a limited number of rarely occurring amacrine cell populations and multiple peptide receptor subtypes expressed by multiple and distinct retinal cell populations.

Numerous studies report the presence of numerous peptides in the vertebrate retina (**Table 1**). There are also multiple peptide receptors, including those for atrial natriuretic peptide, angiotensin II of the renin-angiotensin system, corticotropin-releasing hormone, NPY, opioid (enkephalin) and opioid-related peptides, SRIF, the tachykinin (TK) peptides (substance P (SP), neurokinin A (NKA), neurokinin B (NKB)), and VIP in some vertebrate retinas. These observations are based on biochemical, molecular biological, and immunohistochemical findings. The best-documented peptides and peptide receptors in the mammalian retina are currently, NPY, SRIF, the TK peptides, and VIP.

Peptide-Binding Sites and Localization

In the late 1980s and early 1990s, the presence of high-affinity peptide-binding sites was reported for several peptides in the vertebrate retina. Biochemical studies showed peptide-binding sites in retinal homogenates, and autoradiographic techniques reported their localization to the plexiform layers. These findings were suggestive of peptide-mediated actions through specific receptors in the retina, although at that time very few peptide receptors had been identified and cloned.

Peptide Receptor messenger RNAs

The identification and cloning of the key peptide receptor genes in the early to mid-1990s provided the tools for determining the expression of specific peptide receptors in the retina. NPY, SRIF, and the TK peptide receptors were reported in the mammalian retina. There are typically multiple subtypes of these receptors, based on both molecular and immunohistochemical findings, and these different subtypes vary in their abundance. These findings confirm that the mammalian retina, as indicated by binding and autoradiographic studies, synthesizes multiple peptide receptors.

Table 1 Peptides and peptide receptors in the retina

Peptides	*Preferred receptors*
Angiotensin II	AT_{1A}, AT_2
Enkephalin (leu_5- and met_5-enkephalin)	delta-, kappa-, mu-opioid receptors
CRH	CRH-binding sites
Neuropeptide Y	Y1, 2, 4, 5
Pituitary adenylate-cyclase-activating polypeptide	PAC1, VAC1, VAC2
Somatostatin	sst_{1-5}
Tachykinin peptides	
• Substance P	NK-1
• Neurokinin A	NK-2
• Neurokinin B	NK-3
Vasoactive intestinal polypeptide	VAC1, VAC2

Peptide Receptor Localization

Peptide receptors, including those that mediate the cellular actions of NPY, SRIF, and the TKs, have been principally studied in the mouse and rat retinas. Several receptor subtypes are expressed in the retina, often by one or more distinct cell types, including photoreceptors, bipolar, amacrine, and ganglion cells. For instance, in rat retina, the neurokinin-1 (NK-1) receptor, which is the preferred receptor for SP, is expressed by GABAergic amacrine cells, while, the NK-3 receptor, which is the preferred receptor for NKB, is expressed by OFF-type bipolar cells.

A frequent observation that has emerged from immunostaining studies is the mismatch between the distribution and number of peptide-containing processes and their receptors. For example, there is a differential distribution of SRIF processes and SRIF subtype (sst) receptors in the inner plexiform layer (IPL). There are examples of several peptides acting at receptors that are located away from the peptide-containing processes, which support the notion of a paracrine mode of action, although this does not rule out direct transmitter actions occurring at or near synaptic specializations where there is a close apposition of peptide- and peptide-receptor-expressing processes.

Intracellular Signaling

The activation of signal transduction cascades by peptides and related analogs in retinal extracts also supports the idea that endogenous peptides are present in the retina and their actions are mediated by specific receptors.

However, there are differences in observations concerning peptide actions on intracellular signaling pathways that may be due to the experimental approaches and sensitivity of the assays, as well as species differences. For instance, both NPY and SRIF inhibit forskolin-induced cAMP accumulation in some, but not all, vertebrate retinas. In contrast, VIP and VIP-related peptides potently stimulate adenylate cyclase activity in many vertebrate retinas. For example, SRIF is reported to stimulate cAMP accumulation in chick and ovine retinas, but SRIF does not affect cAMP accumulation in fish, pigeon, mouse, and rabbit retinas. Furthermore, SRIF inhibits VIP-stimulated adenylate cyclase activity in sheep retina. There is further complexity in evaluating SRIF's action in

retinal homogenates, based on a recent report using both wild-type and sst receptor knock-out mouse lines. This study reported that interactions of sst receptor subtypes as well as levels of sst receptors influenced SRIF potency on adenylate cyclase activity. Finally, the sst_2 receptor is reported to mediate SRIF inhibition of adenylate cyclase activity through a G protein of the $G_{o\alpha}$ type in both mouse and rabbit retina.

In contrast, VIP's potent stimulation of adenylate cyclase activity is well established in many vertebrate retinas. Peptide histidine isoleucine, which is co-expressed with VIP, also stimulates adenylate cyclase activity. In addition, the VIP-related peptides, pituitary adenylate-cyclase-activating polypeptide-27 (PACAP-27) and PACAP-38, are positively coupled to adenylate cyclase activity, and their actions are more potent than VIP, indicating the presence of the PAC1 receptor in retinal homogenates. Furthermore, in rat retinal homogenates, PACAP-27 and PACAP-38, but not VIP, show a dose-dependent stimulation of inositol phosphate levels, suggesting multiple signal transduction pathways for PACAP peptides.

SRIF acting through the sst_2 receptor is also reported to induce nitric oxide production in the retina. Nitric oxide, in turn, would activate soluble guanylate cyclase and increase levels of cGMP. The presence of functional NK receptors has been shown by the dose-dependent stimulation of inositol phosphate accumulation and intracellular Ca^{2+} ($[Ca^{2+}]_i$) mobilization by the TK peptides, SP, NKA, and NKB.

Cellular Signaling

Ca^{2+} Imaging and Ion Channel Physiology

Several peptides, including met_5-enkephalin, NPY, SP, and SRIF, have an action at the cellular level in both nonmammalian and mammalian retinas. For instance, in goldfish retina, met_5-enkephalin, SP, and SRIF partially inhibit voltage-dependent Ca^{2+} currents in isolated mixed bipolar cell axon terminals. In the mammalian retina, low concentrations of NPY, SRIF, or VIP modulate both voltage- and ligand-gated channels in multiple cell types, as discussed below.

Pharmacological studies used isolated rat rod bipolar cells in acute preparations, coupled with Ca^{2+} imaging techniques to characterize the cellular actions of NPY and SRIF. Low concentrations of NPY did not result in detectable changes in $[Ca^{2+}]_i$ levels in rod bipolar cell axon terminals, suggesting that NPY alone does not influence $[Ca^{2+}]_i$ levels. In contrast, there is a dose-dependent inhibition of K^+-evoked increases of $[Ca^{2+}]_i$ with NPY; inhibition is maximal with 1 μM NPY and is also observed with 0.1 nM NPY. Maximal inhibition is also seen with 1 μM C2-NPY and NPY(13–36), selective Y2 receptor agonists. In contrast, no inhibition is observed with Y1, Y4, and Y5 agonists. These findings indicate that NPY acts presynaptically through Y2 receptors to regulate glutamate release from rod bipolar cell axon terminals (**Figure 1**).

There have been several studies of SRIF action at the cellular level. In both isolated rat and rabbit rod bipolar cells, there is no detectable change in $[Ca^{2+}]_i$ levels following direct application of SRIF. However, SRIF strongly inhibits a K^+-stimulated increase of $[Ca^{2+}]_i$ through L-type Ca^{2+} channels in a dose-dependent manner in rat and rabbit rod bipolar cell axon terminals (**Figure 2**). SRIF also enhances GABA-evoked whole-cell currents in amacrine cells likely due to $GABA_A$ receptor phosphorylation, following activation of adenylate cyclase. In rabbit retina, SRIF and octreotide, a SRIF agonist, reduce a K^+-stimulated increase in $[Ca^{2+}]_i$ in rod bipolar cell axon terminals. In addition, SRIF inhibits Ca^+-activated K^+ currents (I_{BK}) in these cells. The octreotide effect is prevented by L-Tyr8Cyanamid 154806, an sst_2 receptor antagonist, indicating that these SRIF effects are likely to be mediated by sst_2 receptor activation.

In salamander photoreceptors, low concentrations of SRIF modulate both voltage-activated K^+ and L-type Ca^{2+} currents. SRIF enhances a delayed outwardly rectifying K^+ current in both rod and cone photoreceptors (**Figure 3**). It differentially modulates L-type Ca^{2+} channels currents: SRIF reduces the Ca^{2+} current in rods and increases the Ca^{2+} current in cones (**Figure 4**). Ca^{2+} imaging experiments of isolated rod and cone photoreceptors produce findings consistent with the electrophysiological findings. Together, these observations suggest that SRIF has a role in the regulation of glutamate release from photoreceptors based on its modulation of both voltage-gated K^+ and Ca^{2+} currents.

Membrane currents are not altered following direct application of VIP to isolated rat rod bipolar and ganglion cells. However, VIP does influence GABAs action at $GABA_A$ receptors. It potentiates GABA-evoked whole-cell currents in bipolar cells by 65% and ganglion cells by 54% (**Figure 5**). The onset of VIP action is slow with a long recovery period. VIP-induced potentiation of whole-cell GABA currents is mediated through phosphorylation of $GABA_A$ receptors, following adenylate cyclase activation. The activation of a cAMP-dependent pathway is consistent with biochemical findings that VIP increases cAMP levels in the mammalian retina. In contrast to these observations in rat, VIP reduces GABA-evoked whole-cell currents of rabbit bipolar cells by about 40%. Finally, in rat amacrine cells, VIP, SRIF, and enkephalin also enhance GABA-evoked whole-cell currents through $GABA_A$ receptor phosphorylation by protein kinase A to increase affinity of $GABA_A$ receptor for GABA. Thus, the peptides appear to fine-tune the inhibition by GABA.

These findings of NPY, SRIF, and VIP action at the cellular level are consistent with biochemical studies

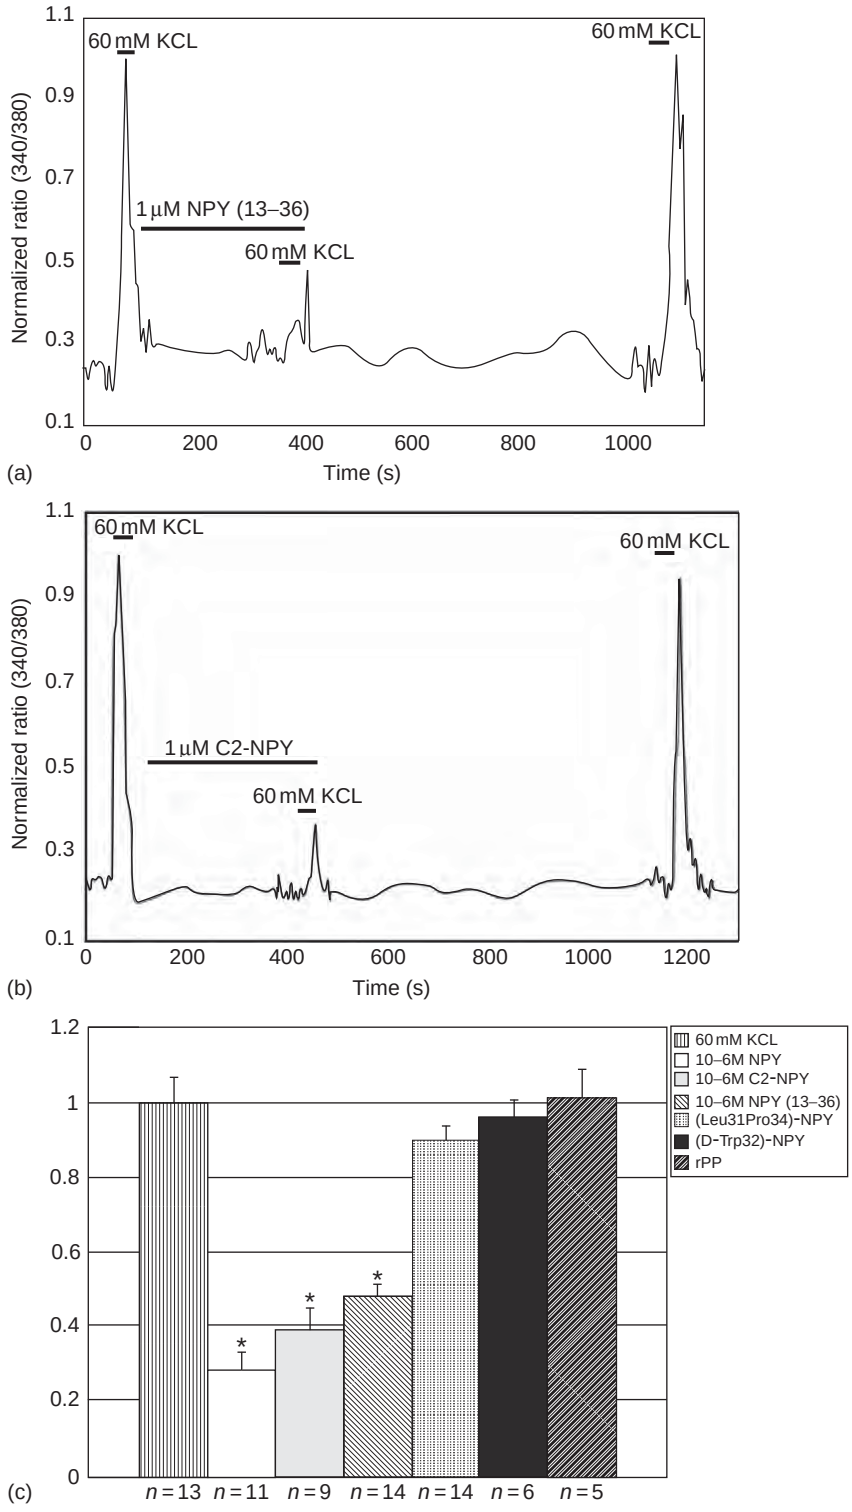

Figure 1 NPY inhibits Ca^{2+} influx into rod bipolar cells through Y2 receptor activation. (a) Micromolar concentrations of Y2 receptor selective agonists NPY (13–36) and (b) C2-NPY inhibits high K^+-induced increases in $[Ca^{2+}]_i$ in rod bipolar cell axonal terminals. The Ca^{2+} responses recover to baseline 10 min after the removal of the peptide. (c) Effect of NPY and selective Y-receptor agonists on depolarization-induced increases in intracellular calcium $[Ca^{2+}]_i$. Summary bar graph comparing the effects of NPY, Y2 receptor selective agonists NPY (13–36) and C2-NPY, Y1 receptor selective agonist $[Leu^{31}Pro^{34}]$-NPY, and Y5 receptor selective agonist $[D\text{-}Trp^{32}]$-NPY. (*) Significant inhibition when compared with high K^+ control ($P < 0.05$). From Figure 4 in D'Angelo, I. and Brecha, N. C. (2004). reporting the presence of peptide receptors and the activation of intracellular effectors in retinal homogenates. They are also consistent with the localization of peptide receptors to different retinal cell types. Together, they show that peptides have multiple cellular actions including modulation of voltage- and ligand-gated ion channels, which would influence intrinsic cellular properties and transmitter release from retinal cells.

Functional Studies

Electroretinogram Recording

A limited action of peptides in the retina has been shown using electroretinogram (ERG), which reflects the contribution of electrical activity from the different retinal cell types. The initial a-wave appears to arise from photoreceptors; the b-wave, the activity of primarily second-order bipolar cells and Müller glial cells; the slower c-wave, the activity of the retinal pigment epithelium and Müller cells; and the d-waves, the activity of the OFF pathway. In rabbit retina eyecups, low concentrations of SRIF decreased the amplitude of the b-wave in rabbit eyecup preparations, but several other peptides, including cholecystokinin (CCK) and SP do not appear to affect the ERG.

Extracellular Recordings

In contrast, extracellular recordings have shown that SP, SRIF, and VIP influence multiple retinal cell types in both nonmammalian and mammalian retinal eyecup preparations. Typically, low concentrations of peptides increase the general excitability of cells. In the mudpuppy eyecup preparation, neurotensin and SP increased the firing activity of ganglion cells; however, met_5-enkephalin inhibited them. However, the distribution of μ-opioid receptors is unknown in mudpuppy retina and the action of met_5-enkephalin could be an indirect effect on amacrine cells. These actions are characterized as slow and long lasting. There is also some specificity in peptide action. For example, using a rabbit eyecup preparation as described below, SRIF acts on all ganglion cell types; in contrast, SP acts on most brisk ganglion cells and VIP acts on ON- and OFF-center brisk ganglion cell types, respectively. Overall, peptide actions in this preparation are characterized as being modulatory and too slow to participate in fast, light-evoked responses.

Application of SP at low-to-moderate concentrations excites most brisk ganglion cells, including ON- and OFF-center and ON–OFF directionally selective ganglion cells in the rabbit retina (**Figure 6**). SP exerts these excitatory effects without affecting ganglion cell receptive field properties. The latency of the SP response

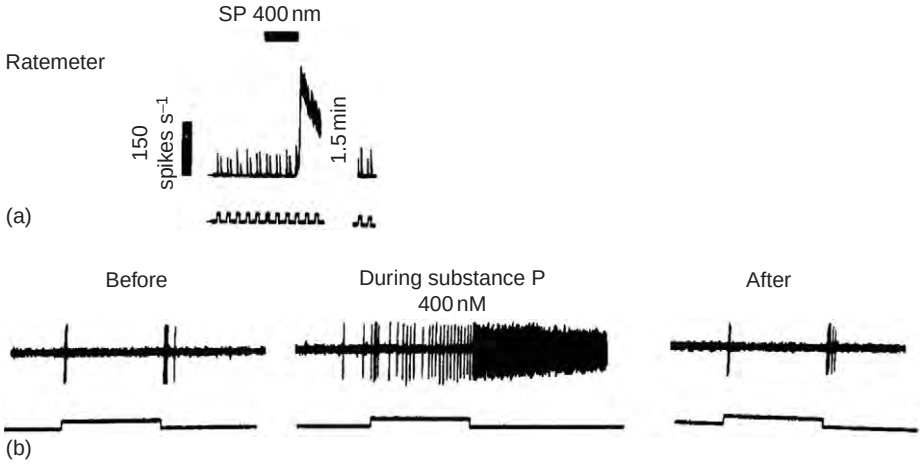

Figure 6 SP excitation of an ON–OFF direction selective ganglion cell responding to a stationary flashing spot. (a) Ratemeter records showing response to flashes (bottom trace) before, during and after application of 400 nM SP (upper bar); calibration bar on right is for 150 spikes s^{-1}. (b) Individual light responses before, during, and after application of SP. Bottom traces show duration of light response and upper traces show spikes. From Figure 1 in Zalutsky, R. A. and Miller, R. F. (1990). The physiology of substance P in the rabbit retina. *Journal of Neuroscience* 10: 394–402.

was shorter than that of SRIF. Furthermore, intracellular recordings show that SP depolarizes some amacrine cells, including GABA-containing amacrine cells. These experiments are consistent with the expression of the SP-specific NK-1 receptor by GABA-containing amacrine cells. SP did not affect horizontal cell activity, consistent with the lack of TK-binding sites and NK-1- or NK-3-receptor immunostaining of horizontal cells. Investigations also report that SP excites most ganglion cells in mudpuppy and fish retina. Together, these findings indicate that TK peptides act in the inner retina and affect the general excitability of ganglion cells and their level of spontaneous activity, rather than altering the characteristics of ganglion cell receptive field properties, as reported for SRIF and VIP in the rabbit retina.

In rabbit retina, low concentrations of SRIF excite all ganglion cell types, change their signal-to-noise ratio discharge activity and shift their center-surround balance toward a more dominant center (**Figure 7**). Similar to other peptides, SRIF actions are characterized as being slow in onset and having a long latency. SRIF is also reported to act on multiple cells in the inner and outer retina; it directly affects bipolar, amacrine, and ganglion cells and influences the horizontal cell network. Moreover, SRIF is reported to increase input resistance of amacrine and bipolar cells, suggesting an action on ion channels or gap junctions. This would be consistent with patch-clamp experiments showing that SRIF affects K^+ and Ca^{2+} currents in retinal neurons. In addition, modulation of gap junctions could be mediated by SRIF-induced dopamine release or nitric oxide production, as suggested by pharmacological studies. Together, these observations indicate that SRIF acts on multiple retinal circuits to produce long-lasting changes in ganglion cell activity and receptive field organization, consistent with the idea that this peptide acts as a modulator to mediate the effects of light adaptation in the retina.

VIP excites ON- and OFF-center brisk ganglion cells in the rabbit retina. Similar to observations using SRIF and SP, VIP is potent at low concentrations and there is a delay in the onset of its action on ganglion cells. The maintained activity of ON- and OFF-center ganglion cells is increased by VIP and their excitatory responses to flashes of light are unaffected or slightly reduced in the presence of VIP. In contrast, VIP has little effect on the maintained activity of ON/OFF directionally selective ganglion cells, and the response of these cells to a moving stimulus. Finally, the action of VIP on ganglion cells in rabbit retina is congruent with other reports of the action of VIP on GABA currents on isolated ganglion cells in the rat retina.

Peptide Influence on Transmitter Release

Several investigators have evaluated the influence of peptides on transmitter release from the retina. The general experimental paradigm is to preload the retina with a radiolabeled transmitter, such as GABA, glycine, or dopamine, and, following a washout period, to add the peptide and measure changes of radiolabeled transmitter levels induced by the peptide. An alternative experimental design is to measure endogenously released transmitter

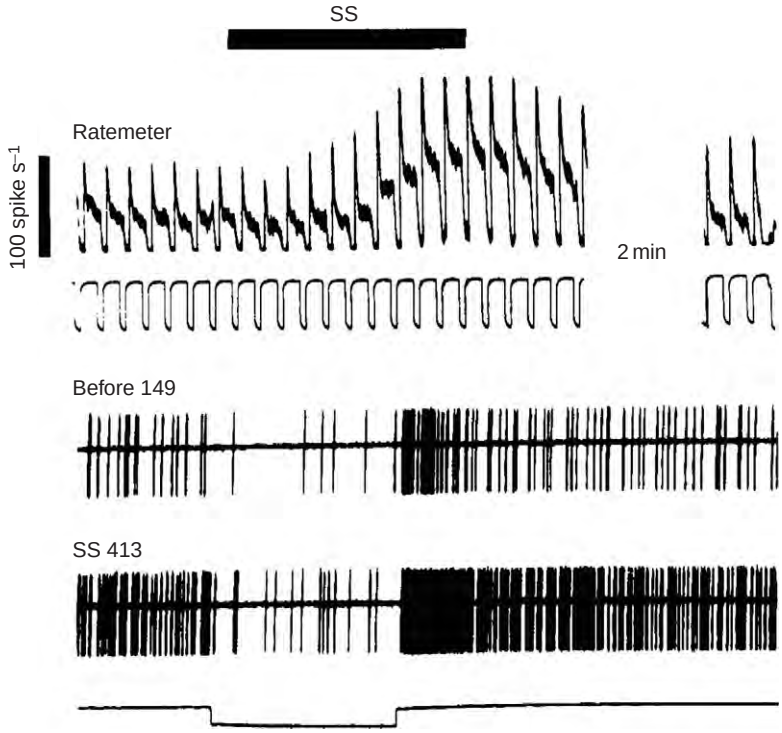

Figure 7 SRIF (somatostatin) excites most ganglion cells. (Top) Ratemeter record before, during, and after application of somatostatin indicated by the bar at top. (Middle and lower) An OFF ganglion cell response before and after 400-nM SRIF application. SS, somatostatin. From Figure 1 in Zalutsky, R. A. and Miller, R. F. (1990). The physiology of somatostatin in the rabbit retina. *Journal of Neuroscience* 10: 383–393.

levels, using radioimmunoassays or by high-pressure liquid chromatography.

Low concentrations of exogenously applied NPY stimulate the release of glycine, dopamine, acetylcholine, and 5-hydroxytryptamine from the vertebrate (frog and rabbit) retina. SRIF stimulates release of dopamine from the rat retina, and pharmacological studies indicate this action is mediated by sst receptors. SP also evoked the release of dopamine from rat retina, and the modulation of Ca^{2+} currents in fish bipolar cells by SP suggests that it may affect transmitter release.

A variant of this experimental approach involves the use of flashing light to stimulate transmitter release to determine if peptides influence light-evoked transmitter release. For example, the μ-opioid receptor agonist, (D-Ala2, MePhe4, Gly-ol5)-enkephalin (DAMGO), increases light-evoked release of acetylcholine from rabbit retina. These latter findings are consistent with-opioid-binding sites distributed homogenously over the IPL and GCL of the rat and monkey retina, and the localization of μ-opioid receptor immunoreactivity by bistratified ganglion cells of the rat retina. Furthermore in rabbit retina, nociceptin, the endogenous ligand for opioid-receptor-like 1, inhibits acetylcholine release evoked by flickering light. In contrast, SP and SRIF do not change the level of light-evoked release of acetylcholine from rabbit retina.

Peptide Function

Experimental findings are consistent with peptides acting as slow transmitters or modulators in the retina. For instance, NPY, PACAP, SP, SRIF, and VIP, acting through GPCRs, influence adenylate cyclase or phospholipase C activity in retinal homogenates and whole retina. Peptides also have potent modulatory effects on both Ca^{2+} and K^+ currents in retinal neurons. Furthermore, SRIF acting through sst_{2A} receptors inhibits the release of the excitatory transmitter glutamate from rod bipolar cells. In addition, the action of GABA at $GABA_A$ receptors is modulated by SRIF and VIP through phosphorylation of $GABA_A$ receptors by protein kinase A in rat rod bipolar, amacrine, and ganglion cells. These examples illustrate the functional role of peptides in regulating both transmitter release and the excitability of retinal neurons.

The concept that peptides act as modulators of retinal circuitry or networks is based on both anatomical and functional findings. Peptide-containing cells in most cases are wide-field amacrine cells that are characterized by a very-low–to-medium cell density. These cells ramify widely and have overlapping processes that cover the entire retinal surface. Therefore, they would have a broad influence on a large number of cells and are unlikely to mediate discrete point-to-point information

processing. Connectivity studies show that most synaptic input onto peptide-containing amacrine cell processes are from amacrine cells, and these cells in turn terminate mainly on amacrine and ganglion cells. Peptides released from these cells could therefore influence multiple cells in a local fashion. In addition, a consistent finding for several peptides is a distinct distribution of peptide-containing and peptide-receptor-bearing processes and cells. These findings suggest that peptides are likely to diffuse from their release sites and act at a distance in a paracrine fashion. Together, these observations support the concept that peptides have a widespread effect on multiple types of retinal neurons.

A feature of many wide-field amacrine cells is the co-expression of GABA and a peptide. For example, in rat, cat, and monkey retina, GABA is co-localized with NPY, SP, and VIP in different amacrine cell types. In addition, glutamate, the predominant ganglion cell transmitter, is co-expressed with PACAP in ganglion cells that innervate the suprachiasmatic nucleus of the hypothalamus. These observations are consistent with findings elsewhere in the nervous system reporting the co-expression and co-release of classical transmitters and peptides from the same cell. Interestingly, a differential release of classic transmitters and peptides depending on the frequency and pattern of cell firing has been shown for several neuronal systems. GABA or glutamate and peptides can act together at the same site, or the peptides can diffuse through the tissue and act at more distant cellular sites. There is evidence for both modes of action in the retina. GABA and peptides released from wide-field amacrine cells may act locally at $GABA_A$ receptors; for instance, both VIP and GABA act on $GABA_A$ receptors expressed by bipolar cell axons and ganglion cells. Peptides can also diffuse from their release site and act in a paracrine manner, as suggested for example, by the different distributions of SRIF immunoreactive processes and sst receptors, which are expressed by multiple retinal cell types.

Functional studies also support the concept that peptides act as modulators of retinal circuitry. In general, the cellular effects of peptides are slow, and they occur at multiple locations in the retina. Both SRIF and VIP produce excitatory changes in the range of seconds to minutes in the spontaneous activity and neuronal discharge patterns of ganglion cells. Moreover, SRIF affects the center-surround balance of all types of ganglion cells. This action of SRIF suggests a role in light/dark adaptation. The role of other peptides in visual function is less well understood. However, as their wide-ranging actions are also likely to be too slow to mediate fast signaling, these peptides will probably also act in modulatory processes that occur on longer timescales and participate in adaptive mechanisms that globally affect the state of retinal circuits and networks.

Conclusion

The vertebrate retina is richly endowed with multiple peptides and peptide receptors; peptides are often localized to a single or at the most a few amacrine cell types, and their receptors are typically expressed by multiple cell types. Peptides act through GPCRs to modulate voltage- and ligand-gated ion channels, and influence neuronal excitability and transmitter release. The pattern of peptide and peptide receptor expression, and the cellular action of peptides being slow in onset, long lasting and potent at low concentrations is congruent with a modulatory role of peptides that would influence multiple cells and cellular networks. This broad modulatory role is consistent with peptides participating in slow signaling events in the retina and influencing adaptive mechanisms.

Glossary

Autoradiography – A histochemical technique used to localize the binding site of a ligand in tissue using radiolabeled ligands (usually ^{131}I, ^{3}H, or ^{35}S) and photographic techniques to detect the isotope.
BAC – A bacterial artificial-chromosome-generated transgenic animals, which are a relatively potent way to generate knock-in transgenic mice that is thought to better recapitulate normal gene expression due to use of a large, chromosomal amount of regulatory genomic DNA surrounding the protein-coding region of the gene.
***In situ* hybridization histochemistry** – A histochemical technique used to localize the cellular localization of messenger RNA.
Isoforms – The different forms of a protein, derived from a single gene that result from alternative splicing or from a family of related genes.
Paracrine – Acting by volume transmission of diffuse messengers rather than at chemical synapses in a point-to-point fashion.

Introduction

The vertebrate retina contains numerous transmitters and related signaling molecules, including peptides and growth factors (Table 1). Peptides and growth factors have multiple roles in the retina, including cellular signaling, growth, and maintenance. This article focuses on the localization of peptides that are primarily involved in cellular signaling, including neurotransmission, and participate in retinal circuitry functions mediating visual information processing. Peptides are characterized by their small size ranging from 5 to 35 amino acids and slow actions that are mediated through multiple guanine-nucleotide-binding protein (G-protein)-coupled receptors (GPCRs), which influence intracellular signaling pathways.

The presence of peptides has been documented in both nonmammalian and mammalian retinas. The most studied peptides in the mammalian retina are neuropeptide Y (NPY), somatostatin (somatotropin-release-inhibiting factor, SRIF), the tachykinins (substance P (SP), neurokinin A (NKA) and neurokinin B (NKB)), and vasoactive intestinal polypeptide (VIP). This article primarily uses these peptides as exemplars of the pattern of peptide expression in the vertebrate retina.

Evidence for abundant peptide expression in the vertebrate retina began with multiple descriptions in the late 1970s of peptide activity in retinal extracts and peptide immunostaining of amacrine cells. These studies established that peptides are usually localized to low-density populations of wide-field amacrine cells; some ganglion cells also express peptides. Consistent with the presence of peptides in the retina is the expression of their receptors, which have a wide distribution, and have been reported in bipolar, amacrine, and ganglion cell populations. Interestingly, there is often a mismatch between the cellular distribution of peptide-containing amacrine cells and their processes compared to the cellular distribution of their receptors. A striking example is the distribution of SRIF and its receptor, SRIF subtype 2A (sst_{2A}, as discussed below), which suggests that peptides mainly act in a paracrine manner, and therefore influence multiple retinal circuits in both the outer and inner retina.

Peptides influence the cellular activity of retinal neurons and circuits by modulating multiple intracellular signaling pathways, which affect transmitter release and intrinsic neuronal properties. Peptide actions are characterized as being slow in onset, long-lasting, and potent at low concentrations, suggestive of a role in adaptive mechanisms. Together, these findings provide strong support for a functional role of peptides in the retina.

Peptide Expression

Bioassays and Radioimmunoassays

In the 1950s, Euler and his colleagues reported the presence of SP bioactivity in dog and bovine retinal extracts. However, it was not until the late 1970s with the development of additional bioassay systems and radioimmunoassays (RIAs) that a rich variety of peptides, including cholecystokinin, the enkephalin peptides, glucagon, SRIF, SP, thyrotropin-releasing hormone, and VIP, was described in vertebrate retinal extracts. At the present time, over 20 peptides have been reported in the vertebrate retina (Table 2) with a greater number of peptides and peptide families in nonmammalian compared to mammalian retinas.

In general, bioassay and RIA studies report low-to-moderate levels of peptides in retinal extracts compared to other tissues and brain regions. In most cases, findings

from these investigations are consistent with immunohistochemical studies showing that these peptides are expressed in amacrine and ganglion cells. For instance, SRIF bioactivity and immunoreactivity are in retinal extracts from numerous species, and this peptide is localized to sparsely occurring amacrine and displaced amacrine cells in all species studied to date. Similarly, SP bioactivity and immunoreactivity are reported in the retina of numerous species, and SP immunoreactivity is localized to both amacrine and ganglion cells.

Peptides detected in the retina correspond to those detected in other tissues as to their molecular structure based on gel electrophoresis or high-pressure liquid chromatography and, in more limited cases, on peptide sequencing. These studies revealed that both forms of SRIF, SRIF-14 and SRIF-28, are differentially expressed in the mammalian retina; SRIF-14 is the predominant form in the rat and human retina and SRIF-28, in addition to SRIF-14, is in guinea pig and rabbit retina. Functionally, this finding is likely to be of importance, since SRIF-14 and SRIF-28 preferentially bind to different SRIF receptor subtypes.

Peptide Localization

Peptide Messenger RNA

There have been few investigations documenting peptide messenger RNAs (mRNAs) in the retina. Most studies evaluated mouse, rat, and human retinal extracts using Northern blots and reverse transcription polymerase chain reaction (RT-PCR), and rat retinal sections using *in situ* hybridization histochemistry. A combination of these approaches have been used to show that preprotachykinin (PPT) I mRNA, which generates SP and NKA, and PPT II mRNA, which generates NKB, are expressed in rat retinal extracts. *In situ* hybridization histochemical studies have extended these findings to establish a differential distribution of the tachykinin mRNAs with PPT I mRNA in cells distributed to the inner nuclear layer (INL), inner plexiform layer (IPL), and ganglion cell layer (GCL), and PPT II mRNA in cells distributed to the GCL. *In situ* hybridization histochemical studies have also established the presence of sparsely distributed SRIF mRNA-containing cells in the INL and GCL, while another study showed the co-expression of SRIF mRNA and immunoreactivity in amacrine and displaced amacrine cells. Finally, VIP mRNA and immunoreactivity are in sparsely distributed cell bodies in the inner retina. These findings extend earlier biochemical studies showing that the mammalian retina synthesizes multiple peptides, and it is reasonable to assume that other peptides located in the retina by RIA or immunohistochemistry are also synthesized by retinal neurons.

An alternative approach to evaluating the cellular localization of a peptide is the employment of a transgenic mouse line with the peptide promoter driving the expression of a reporter gene. Although this type of genetic approach has been commonly used in other regions of the nervous system, there have been limited findings reported to date in the retina. The best example is the detection of NPY in amacrine cells in the INL and GCL of a mouse line with ß-galactosidase (ß-gal) expression driven by the NPY promoter. ß-Gal-containing amacrine and displaced amacrine cells are distributed to all retinal regions and they have widely ramifying processes. The pattern of ß-gal expression matched the pattern of NPY immunostaining established using a highly characterized antibody to NPY; there is about 85% co-localization between β-gal expression and NPY immunoreactivity. Thus, independent experimental approaches confirm the pattern of NPY expression in the retina.

Peptide Immunostaining

Beginning in the late 1970s and early 1980s, numerous peptide immunolabelings were described in both non-mammalian and mammalian retinas. Peptide immunostaining was usually localized to distinct populations of amacrine cells, and in some cases, to ganglion cells and their central-nervous-system projections.

Peptide immunoreactivity is commonly localized to wide-field amacrine cell populations distributed to both the proximal INL and the GCL. These cells are characterized by processes that ramify in one or more laminae of the IPL. In addition, these processes arborize widely and overlap to form a network across the retinal surface. Some wide-field amacrine cell types that contain peptide immunoreactivity also have axon-like processes. These amacrine cell types are likely to be polyaxonal amacrine cells characterized by a more restricted dendritic field and multiple axons that extend beyond their field of dendrites. Finally, there are several examples of sparse peptide-containing processes crossing the INL and ramifying in the outer plexiform layer (OPL). These processes are likely to be derived from interplexiform cells, which are characterized by processes that ramify in both the IPL and OPL, and they are often categorized as an amacrine cell variant. These peptide-containing amacrine cell populations are characterized by a very-low-to-moderate cell density. In most cases, their cell bodies are distributed to all retinal regions. In all cases, peptide-containing processes cover the entire retinal surface.

Three examples that illustrate the general features described above are the NPY-, SRIF- and VIP-containing amacrine cells in the mammalian retina.

NPY immunoreactivity is localized to wide-field amacrine cells that are located in both the proximal INL and the GCL. NPY cells have a similar appearance in different mammalian retinas. In the INL, most immunoreactive cells were characterized by small cell bodies and fine processes that ramify primarily in lamina 1 of the IPL. A few cells also ramified in lamina 3 of the IPL. In the GCL, small-to-medium immunoreactive cells ramify primarily in lamina 5 of the IPL. A few immunoreactive processes, originating from somata in the INL and processes in the IPL, ramified in the OPL (**Figure 1**). In rat retina, immunoreactive cells had a regular distribution across the retina and an overall cell density of 280 cells mm^{-2} in INL and 90 cells mm^{-2} in GCL.

SRIF immunoreactivity is localized to sparsely distributed, wide-field amacrine and displaced amacrine cells (**Figure 2**). Immunoreactive somata give rise to thin varicose fibers that form a narrow and continuous plexus in lamina 1 of the IPL. In many species, there is also a narrow plexus of varicose fibers in laminae 3 and 5 of the IPL. Frequently, a smooth, thin-caliber, axon-like process is observed to arise from a cell body or a primary process. A few immunoreactive fibers also cross the INL to ramify in the OPL in both ventral and dorsal retina. These fibers can be traced to the plexus in lamina 1 of the IPL. Finally, in rabbit and cat retinas, there is a dense accumulation of SRIF-immunoreactive fibers along the retinal margin, which form a circumferential band in all retinal regions.

A major feature of the SRIF expression in the mouse, rabbit, cat, and human retina is the predominant distribution of SRIF-containing cell bodies to the ventral retina. These cells form a very low-density cell population. For example, in rabbit retina, cell density ranges from 6 cells mm^{-2} in ventral retina to 11 cells mm^{-2} at the retinal margins. In addition, the total number of SRIF-immunoreactive amacrine cells in these retinas is correspondingly very low.

VIP immunoreactivity is localized to sparsely distributed wide-field amacrine cells, mainly located in the proximal INL. VIP cells have a similar appearance and

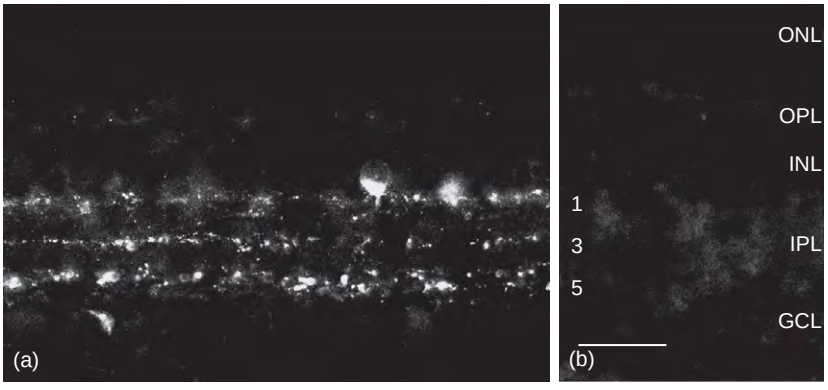

Figure 1 – NPY immunoreactivity in the rat retina. (a) NPY immunostaining of an amacrine cell body in the INL and varicose processes that ramify in laminae 1, 3, and 5 of the IPL. (b) Control experiment; NPY immunostaining was absent from a retinal section incubated with the NPY antibody that was preabsorbed with 10^{-6} M NPY. Vertical sections: scale bar = 30 μm. From Oh, S. J., D'Angelo, I., Lee, E. J., Chun, M. H., and Brecha, N. C. (2002). *Journal of Comparative Neurology* 446(3): 219–234. Copyright 2002, John Wiley & Sons, Inc. Figure 2 – SRIF immunoreactivity in the mouse retina. (a) SRIF immunoreactive processes are mainly in lamina 1 of the IPL. Sparse occurring processes also ramify in laminae 3 and 5 of the IPL, as well as crossing the INL and ramify in the OPL. (b) Plexus of SRIF immunoreactive processes in lamina 1 of the IPL. (a) Vertical section; scale = 50 μm; (b) Whole-mount preparation; scale = 50 μm.

distribution in different mammalian retinas. VIP immunoreactivity is distributed to multiple varicose processes and collaterals that ramify in laminae 1, 3, and 5 of the IPL in all retinal regions. VIP mRNA-containing and immunoreactive cells also form low-density cell populations in both the INL and GCL. For example, VIP-immunoreactive cells have an overall cell density of 25 cells mm^{-2} in rabbit retina, and there is an overall cell density of 50 cells mm^{-2} in the INL and 12 cells mm^{-2} in the GCL in the monkey retina.

Tachykinin and pituitary adenylate-cyclase-activating polypeptide (PACAP), a peptide in the VIP family, are reported in ganglion cells. These peptide-containing ganglion cells innervate multiple retinorecipient targets.

SP-immunoreactive ganglion cells are present in the frog, rat, hamster, rabbit, monkey, and human retina. These cells have been identified in co-staining experiments following either retrograde labeling of ganglion cells after fluorescent tracers are injected into retinorecipient nuclei or by the loss of ganglion cell immunostaining, following optic nerve section. In hamster, a small number of ganglion cells contain SP immunoreactivity; SP immunoreactivity in the lateral geniculate nucleus (LGN) is eliminated following optic nerve section. In rabbit, about 30% of the ganglion cells contain SP immunoreactivity. These cells have medium-to-large somata and dendrites that ramify extensively in the IPL. Their axons terminate in several retinorecipient nuclei, including the LGN, superior colliculus, and the accessory optic nuclei. In human retina, weakly staining SP-containing ganglion cells have also been identified on the basis of their morphology. Finally, in the *Macaca* monkey retina, the presence of SP-containing ganglion cells is suggested by the partial loss of SP immunostaining in the pregeniculate nucleus and the olivary pretectal nucleus, following bilateral eye enucleation.

There have been a modest number of ultrastructural investigations concerning the connectivity of peptide immunoreactive cells in rat, guinea pig, and primate retina. In general, the main input to peptide immunoreactive processes is from amacrine cells, whereas the major output formed by conventional synapses is onto amacrine and ganglion cells. There is a smaller percentage of input and output connections with bipolar cell axonal terminals. The large number of synaptic connections with amacrine cells indicates that peptide-containing cells are influenced principally by other amacrine cells and to a lesser degree by bipolar cells. There is more limited information about the connectivity of peptide-containing cells in other species, although overall the pattern of connectivity of these cells appears to be quite similar to that observed in monkey retina.

A feature of many wide-field amacrine cells is the co-expression of gamma aminobutyric acid (GABA) and a peptide. For example, in rat, cat, and monkey retina, GABA is co-localized with NPY, SRIF, and VIP. In addition, glutamate, the predominant ganglion cell transmitter, is reported to be co-expressed with PACAP in ganglion cells that innervate the suprachiasmatic nucleus of the hypothalamus. The co-expression of glutamate and SP in ganglion cells is also likely, although not formally demonstrated to date. These observations are consistent with findings elsewhere in the nervous system, reporting the co-expression and co-release of classical transmitters and peptides from the same cell. Interestingly, a differential release of classic transmitters and peptides, depending on the frequency and pattern of cell firing, has been shown in several systems. GABA or glutamate and peptides can act together at the same site, or the peptides can diffuse through the tissue and act at more distant cellular sites. There is evidence for both modes of action in the retina. GABA and peptides released from wide-field amacrine cells may act locally at $GABA_A$ receptors; for instance, both VIP and GABA act on $GABA_A$ receptors expressed by bipolar cell axons and ganglion cells. Peptides can also diffuse from their release site and act in a paracrine manner, as suggested, for example, by the differential distribution of SRIF-containing amacrine cell processes and SRIF receptors, which are expressed by multiple retinal cell types located away from the SRIF-containing processes.

Peptide Receptor Expression

As mentioned above, peptide actions are mediated by multiple GPCRs that influence intracellular signaling pathways, which regulate transmitter secretion and neuronal excitability. For instance, SRIF's cellular actions are mediated by five distinct GPCRs, sst_1–sst_5. There are also two sst_2 isoforms, sst_{2A} and sst_{2B}, from alternative splicing. The cellular actions of the tachykinin peptides are mediated by three receptors, known as NK-1, NK-2, and NK-3, whose preferred ligands are SP, NKA, and NKB, respectively.

Peptide-Binding Sites and Localization

The distribution of peptide receptors was initially evaluated using binding sites with autoradiographic approaches. In the late 1980s and early 1990s, the presence of high-affinity peptide-binding sites for several peptides, including SRIF, tachykinins, and VIP, was reported using radiolabeled peptides. Autoradiographic techniques were also used to define the regional distribution of peptide-binding sites. For example, SRIF-binding sites, identified with radiolabeled SRIF or a radiolabeled SRIF analog, were over the photoreceptor and both plexiform layers of the mouse and rat retina. High-affinity SP- and VIP-binding sites were homogeneously distributed over the IPL and GCL. In addition, NKA- and NKB-binding sites were evenly distributed over the IPL of the guinea pig retina. However, there are major difficulties in defining the cell types associated with these binding sites because of the low resolution of the autoradiographic technique. Furthermore, there are very few selective peptide agonists or antagonists available to distinguish among the different receptor isoforms. For example, octreotide binds to several SRIF receptor subtypes, and there is a high likelihood that multiple receptor subtypes were detected in these autoradiographic studies.

Peptide receptor mRNAs

The identification and cloning of peptide receptor genes in the 1990s have provided the tools for determining the expression of specific peptide receptors in the retina. NPY, SRIF, TK, and VIP receptors have been described most often in the mouse and rat retina. Multiple subtypes of these receptor mRNAs are found in the retina and they vary in their abundance; for example, in rat retina, the sst_2 and sst_4 mRNAs are the most abundant compared to the other sst mRNAs. Similarly, mRNAs of NPY and NK isoforms are present in retinal extracts with different levels of expression. Finally, mRNAs of the selective PACAP receptor, PAC1, and the VIP/PACAP-preferring receptors, VPAC1 and VPAC2, have been reported in retinal extracts. These findings illustrate that multiple peptide receptors are synthesized by the mammalian retina, in agreement with binding, autoradiographic, and immunohistochemical studies.

Pharmacological Studies

The activation of intracellular signaling pathways by peptides and related analogs in retinal extracts also supports the notion that endogenous peptides are present in the retina and they have a functional role that is mediated by specific receptors. For instance, both NPY and SRIF potently inhibit forskolin-induced cyclic adenosine monophosphate (AMP) accumulation, and VIP potently stimulates adenylate cyclase activity in retinal extracts. In addition, PACAP-27 and PACAP-38 are positively coupled to adenylate cyclase activity, and their actions are more potent than VIP, indicating the presence of PAC1. Furthermore, in rat retinal homogenates, PACAP-27 and PACAP-38, but not VIP, show a dose-dependent stimulation of inositol phosphate levels, suggesting multiple signal transduction pathways for PACAP peptides. Finally, the presence of functional NK receptors has been shown by the dose-dependent stimulation of inositol phosphate accumulation and $[Ca^{2+}]_i$ mobilization by the tachykinin peptides, SP, NKA, and NKB.

Pharmacological studies with isolated retinal cells and peptide receptor agonists and, in more limited cases, antagonists have also indicated the presence of pharmacological subtypes of peptide receptors. For instance, Y2, an NPY receptor, and sst_{2A} modulate L-type calcium channels expressed by rod bipolar cells. These investigations along with peptide binding and autoradiographic studies have been valuable in establishing the presence of functional peptide receptors in the retina.

Peptide Receptor Localization

Peptide Receptor mRNAs

In situ hybridization histochemical experiments have documented the cellular expression of NK-1 and NK-3 mRNAs in the rat retina. NK-1 mRNA is located in the INL and GCL, and NK-3 mRNA is mainly distributed to the middle and outer regions of the INL, corresponding to the location of bipolar cell bodies. This pattern of expression matches the NK-1- and NK-3-immunostaining patterns in the mouse and rat retina.

Peptide Receptor Localization

Peptide receptors, including those that mediate the actions of NPY, SRIF, and the TKs, have been mainly studied in the mouse and rat retinas. Several receptor subtypes are expressed in the retina, often by one or

more distinct cell types, including bipolar, amacrine, and ganglion cells.

Sst and NK receptor expressions illustrate the general pattern of cellular localization of peptide receptors, although many details of individual receptor expression remain to be determined in future studies. In some cases, there are marked differences in the pattern of expression of these receptors, when studied using different, well-characterized antibodies. These disparate observations suggest that antibody specificity is a major factor influencing the understanding of peptide receptor expression in the retina. To date, animal models using genetic reporters driven by peptide receptor promoters to localize the cellular expression of peptide receptors have not been reported in the retina. The use of molecular approaches and knock-out lines will be needed to fully characterize the antibodies used for the immunostaining studies, and bacterial artificial chromosome (BAC) transgenics and knock-in mouse lines will be important for establishing the cellular localization of these receptors, independent of immunostaining approaches.

There are major differences in the reported pattern of SRIF receptor expression. For instance, some groups report that numerous amacrine cells in the rat and rabbit retina express sst_1 immunoreactivity. In contrast, other groups using a different antibody report sst_1 immunoreactivity in a distinct population of ganglion cells based on their size, and distribution of dendrites to lamina 3 of the IPL. Several independent studies, using different antibodies, agree that sst_{2A} immunoreactivity is the most abundant SRIF receptor subtype, and it is mainly localized to bipolar cells in mouse, rat, and rabbit retinas (**Figure 3**). Sst_{2A} immunoreactivity is also reported in some wide-field amacrine cells, photoreceptor terminals, and horizontal cells in some species. All investigators agree that ganglion cells express sst_4 immunoreactivity. Sst_4 immunoreactivity is in multiple ganglion cells and numerous multistratified processes in the IPL. Consistent with the immunostaining studies are *in situ* hybridization histochemical experiments describing sst_4 mRNA expression in cells distributed to the INL and GCL. Together, these findings provide strong evidence for the expression of SRIF receptors by ganglion cells. There are no reports of the cellular localization of sst_3 to retinal cells and there is a single report of sst_5 expression in nearly all amacrine cells.

NK-1 immunoreactivity is in numerous amacrine cell bodies in the INL and in some small and large cell bodies in the GCL in the rat retina (**Figure 4**). Immunoreactivity is prominent in all IPL laminae, and in addition there are fine caliber and varicose processes in the OPL, and a few processes in the ganglion cell axon layer. NK-1 immunoreactivity is observed in tyrosine-hydroxylase-containing amacrine cell bodies and their processes. Finally, most NK-1 immunoreactive amacrine cells contain GABA immunoreactivity. The large number of NK-1 immunoreactive cell bodies and the distribution of processes to the IPL suggest that this receptor is expressed by multiple amacrine cell populations. Some ganglion cells, based on cell body size, appearance, and position, are also likely to express NK-1 immunoreactivity.

In contrast, NK-3 immunoreactivity is in bipolar cell bodies distributed to the middle of the INL, and in their dendritic and axonal processes in the OPL and IPL, respectively (**Figure 5**). In the IPL, they ramify in

PKC immunoreactivity in rod bipolar cells (green) that ramify in lamina 5 of the IPL. (b) The cell bodies of the NK-3 immunoreactive bipolar cells are clearly distinct from those of the rod bipolar cells. The pattern of NK-3 expression indicates OFF-type cone bipolar cells express this receptor. Vertical section: scale = 10 μm.

laminae 1 and 2, distal to where the type 3 cone bipolar cells stratify, suggesting NK-3 expression in OFF-type bipolar cells. A subset of the NK-3 immunoreactive bipolar cells expresses synaptotagmin 2. This same subgroup of NK-3 immunoreactive bipolar cells contains recoverin, a marker for type 2 bipolar cells. Together, these findings show that NK-3 immunoreactivity is localized to at least two types of OFF-type bipolar cells. In addition, NK-3 immunoreactivity is in tyrosine-hydroxylase-containing amacrine cells. There are no reports of specific NK-2 immunostaining in the retina, although NK-2 mRNA is detected in retinal extracts.

A frequent observation from these studies is the mismatch between the distribution of peptide-containing processes and their receptors. This mismatch supports the notion of a paracrine mode of action for peptides acting at receptors that are located away from the peptide-containing processes, although this does not rule out direct transmitter actions that could occur at synaptic specializations in areas of the IPL where there is apposition of peptide and peptide receptor processes.

Neurotransmitters and Receptors: Dopamine

P M Iuvone, Emory University School of Medicine, Atlanta, GA, USA

Glossary

Amacrine cells – Neurons with cell bodies located in the proximal part of the inner nuclear layer, and neuronal processes ramifying in the inner plexiform layer.
Circadian rhythms – Changes in biological processes that occur on a daily basis, are driven by autonomous circadian clocks, and provide selective advantage to organisms by allowing them to anticipate temporal changes in their environment.
Interplexiform cells – Neurons with cell bodies in the amacrine cell layer; they are distinguished from amacrine cells by having neuronal processes that project in both the inner and the outer plexiform layers.
Neuromodulators – Chemical transmitters that mediate slow, long-lasting modulatory effects on neurons and neuronal circuits through synaptic or extrasynaptic receptors; they usually have no effect on neuronal membrane potential alone, but modulate the response to other neurotransmitters.
Photopic vision – The vision in bright light that is mediated by cone photoreceptors and cone bipolar cell pathways.

Localization of Dopamine Neurons in the Retina

Dopamine is a member of the catecholamine family of neurotransmitters, which also includes norepinephrine (also known as noradrenaline) and epinephrine (also known as adrenaline). It is the primary catecholamine in the retina; only trace amounts of epinephrine and norepinephrine are found in this tissue. It was first detected in the retina in the 1960s and has been the subject of intensive study ever since.

Dopamine is released from a unique population of neurons with cell bodies in the innermost region of the inner nuclear layer (INL). These neurons have been visualized by formaldehyde-induced histofluorescence and by immunohistochemistry, with antibodies against tyrosine hydroxylase (see **Figure 1**), the rate-limiting enzyme in dopamine biosynthesis. The dopamine neurons have long axons that ramify in sublamina 1 of the inner plexiform layer (IPL), at the border of the INL. The axons contain varicosities (presumptive sites of dopamine release) along their entire length. Although the number of dopamine neurons is small (approximately 500 in mouse retina), the extensive length and branching of the axons result in considerable overlap of processes throughout the retina. Some of the axons form rings around the perikarya of AII amacrine cells, which transmit rod pathway signals in the inner retina. Some processes, likely dendritic, descend further into the IPL. In many species, the processes of the dopamine neurons project toward the outer plexiform layer (OPL; see arrow in **Figure 1(a)**), designating them as interplexiform cells.

Regulation of Dopamine Neuronal Activity

Retinal dopamine neurons spontaneously fire action potentials, stimulating the release of dopamine throughout the cell. Light increases the firing of action potentials and stimulates dopamine synthesis, release, and metabolism. Both transient and sustained light-evoked firing patterns have been observed.

Although the processes of dopamine neurons ramify in the outer portion of the IPL, where OFF bipolar cells make synapses, most evidence suggests that the light responses of dopamine neurons are driven by the ON pathway. Light-evoked dopamine release from monkey and frog retinas is inhibited by L-(+)-2-amino-4-phosphonobutyric acid (L-AP4), which pharmacologically blocks synapses between photoreceptors and ON bipolar cells. Light-evoked firing of most, but not all, dopamine cells in mouse retina is also blocked by L-AP4. In addition, light-evoked dopamine metabolism, commonly observed in the vertebrate retina, is absent in the no b-wave (*nob*) mouse; this mouse has no functional ON pathway due to a mutation in the nyctalopin (*nyx*) gene, but has an intact OFF pathway. Retinal dopamine neurons are excited by glutamate, a bipolar cell transmitter, and inhibited by the amacrine cell transmitters gamma aminobutyric acid (GABA) and glycine. Once released, dopamine diffuses to act on extrasynaptic receptors found on multiple cells types throughout the retina.

Dopamine Neuronal Activity Is Coupled to Dopamine Synthesis and Metabolism

The light-evoked increase in dopamine neuronal activity is not associated with a depletion of the neuromodulator,

and is sometimes correlated with an increase in the steady-state levels of dopamine and it's primary metabolite 3,4-dihydroxyphenylacetic acid (DOPAC). Several mechanisms appear to account for these observations. The dopamine neurons contain plasma membrane dopamine transporters, which recapture a fraction of the dopamine released into the extracellular space. Following reuptake, the dopamine can be repackaged into vesicles for subsequent release or metabolized by monoamine oxidase to form DOPAC. A light-evoked increase of DOPAC levels is a common feature among many vertebrate retinas. More important in maintaining a readily releasable pool of dopamine is a light-evoked increase of dopamine biosynthesis. This occurs through phosphorylation and activation of tyrosine hydroxylase, the rate-limiting enzyme in dopamine synthesis. While tyrosine hydroxylase can be phosphorylated by several protein kinases, the cyclic adenosine monophosphate (cAMP)-dependent kinase (protein kinase A (PKA)) appears to play a prominant role in the light-evoked regulation of tyrosine hydroxylase. The phosphorylation of the enzyme by PKA results in a conformational change that decreases the Km for tetrahydrobiopterin (BH4), the co-factor of tyrosine hydroxylase. This increases the activity of the enzyme at the subsaturating concentrations of BH4 found in retinal dopamine cells.

Circadian Control of Dopamine Release and Metabolism

In addition to being regulated by light, retinal dopamine release and metabolism, in many species, are controlled by circadian clocks that generate daily rhythms that persist in constant ($24\,h\ d^{-1}$) darkness. In these instances, dopamine release and DOPAC levels increase during the subjective day and decrease during the subjective night. In mouse retina, dopamine neurons express circadian clock genes and, therefore, may possess an autonomous circadian clock. However, evidence obtained in several species, including mouse, suggests that the circadian rhythms of dopamine release and metabolism are dependent on another neuromodulator, melatonin, which is synthesized in photoreceptor cells and released in a circadian fashion during the subjective night. Retinal dopamine neurons express melatonin receptors, the activation of which inhibits dopamine release. In turn, dopamine released in the daytime suppresses melatonin formation. Since dopamine receptors are widely distributed in the retina, dopamine plays important roles in the circadian organization of the retina.

Dopamine Receptors

Dopamine receptors are guanine nucleotide-binding protein (G-protein)-coupled receptors. There are five subtypes, organized into two families based on structural and pharmacological similarities: the D1-like and D2-like families (**Table 1**). The individual subtypes are named based on the chronological order in which they were cloned. The D1 family includes the D1 and D5 receptors, while the D2 family consists of D2, D3, and D4 receptors. The D1 and D5 (also known as D1B) receptors are derived from genes without introns; thus, there are no splice variants of the D1-like receptors. They show very similar pharmacologies with respect to selective agonists and antagonists; however, dopamine has a much higher affinity for the D5 receptor than for the D1 subtype. The D2, D3, and

Table 1 Dopamine receptors in the retina

Receptor name	*G protein*	*cAMP response*	*Cellular expression*
D1-like family			
D1	G_s	Δ↑	Horizontal cells, cone bipolar cells, and amacrine cells
D5	G_s	Δ↑	Retinal pigment epithelial cells
D2-like family			
D2	G_i	Δ↓	Dopamine neurons and amacrine cells
D4	G_i	Δ↓	Photoreceptor cells

D4 receptor genes contain introns, and splice variants of the D2 receptor have been characterized. They show similar pharmacologies; however, some selective agonists and antagonists have been identified. A common feature of all dopamine receptors is that they couple to G proteins that regulate cAMP. The D1 family receptors stimulate cAMP formation, while the D2 family members inhibit it. Dopamine receptors have also been reported to affect phospholipase C, Ca^{2+} currents, K^+ currents, and the protein kinases AKT, glycogen synthase kinase-3β (GSK3β), and extracellular signal-regulated kinases (ERK1/2).

Nearly all retinal cell types appear to express dopamine receptors, consistent with dopamine's role as a paracrine neuromodulator that acts on extrasynaptic receptors. Of the D1 family members, dopamine D1 receptor immunoreactivity is found on processes in both the OPL and IPL. The receptors are expressed by horizontal cells, subtypes of cone bipolar cells, and some amacrine cells. There is evidence for the expression of functional D1-like receptors in ganglion cells of goldfish. D5 receptors are expressed by mammalian retinal pigment epithelial (RPE) cells. Of the D2 family members, dopamine D2 receptors are highly expressed by retinal dopamine neurons, and function as autoreceptors that inhibit dopamine release. D2 receptors are also expressed by other unidentified amacrine cells and possibly by some bipolar and ganglion cells. D2 receptors have also been shown to be expressed and functional in guinea pig Müller cells. Dopamine D4 receptors are highly expressed by photoreceptor cells in mammals. The photoreceptors of nonmammalian vertebrates also have D2-like receptors; in addition, these are likely to be D4 receptors based on pharmacological criteria, but no molecular proof of this has been provided yet. D4 messenger ribonucleic acid (mRNA) expression has also been observed in the IPL and ganglion cell layer; however, due to the lack of specific antibodies, the types of cells in these layers have not been identified. Interestingly, neither mRNA nor protein for the dopamine D3 receptor has been found in retina.

Functions of Dopamine in the Retina

The widespread distribution of dopamine receptors coupled with the ability of dopamine to diffuse throughout the retina suggests that this neuromodulator has many functions in regulating retinal physiology, particularly in serving as a chemical signal promoting light adaptive functions. This section describes the effects of dopamine on different cell types within the retina, beginning with the distal retina, and gives examples on how dopamine impacts retinal network adaptation, circadian rhythmicity, and ocular growth.

Retinal Pigment Epithelium

Dopamine D5 receptors stimulate cAMP formation, which inhibits rod outer segment phagocytosis by RPE cells. Cultured bovine RPE cells express D5 receptors and dopamine inhibits phagocytosis by these cells. Thus, dopamine may function as a component of the regulatory mechanism that controls rod outer segment turnover.

Photoreceptor Cells

Dopamine D2/D4 receptors on photoreceptor cells have numerous effects due to their ability to inhibit cAMP formation and decrease intracellular Ca^{2+} concentrations. Dopamine receptor activation inhibits the synthesis of melatonin in photoreceptor cells by inhibiting cAMP formation. It regulates the amplitude of diurnal rhythms of phosphorylation of phosducin by cAMP- and Ca^{2+}-dependent protein kinases. Dopamine has been reported to increase the rate of dephosphorylation of rhodopsin, and probably affects the phosphorylation state of many photoreceptor proteins. Dopamine has been reported to inhibit the hyperpolarization-activated current (I_H) in rods, as well as the activity of Na^+/K^+-adenosine triphosphate (ATP)ase, which balances the dark current. It decreases the intracellular Ca^{2+} concentration of photoreceptor cells and also affects rod–cone coupling, but the effects may vary by species. These effects on currents, Ca^{2+}, and coupling may contribute to a reduction of rod synaptic transfer to bipolar and horizontal cells during the daytime.

Horizontal Cells

Horizontal cells mediate lateral inhibition and synaptic feedback to photoreceptor cells. Different horizontal cell subtypes couple together through gap junctions to form networks. In retinas of both mammalian and nonmammalian vertebrates, the activation of D1-like receptors uncouples the horizontal cells, narrowing their receptive fields. The activation of dopamine D1 receptors in dark-adapted retinas depolarizes horizontal cells and reduces

responses to flickering lights. The depolarization is due to the cAMP-dependent enhancement of glutamate-gated currents through α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA)/kainate glutamate receptors in the horizontal cell membrane; other voltage-gated channels may also be involved.

Bipolar Cells

Although dopamine receptor immunoreactivity has been observed in subtypes of mammalian cone bipolar cells, its function is yet to be investigated. In salamander retina, glutamate responses in OFF cone bipolar cells are enhanced by dopamine, similar to the enhancement observed in horizontal cells. In addition, dopamine has been shown to modulate gamma-aminobutyric acid (GABA)-mediated inhibition of Ca^{2+} influx and neurotransmitter release from bipolar cell terminals. GABAergic amacrine cells synapse onto bipolar cell terminals to provide feedback inhibition of glutamate release via GABA-C receptors. Dopamine, acting on D1 receptors, reverses this inhibition and increases glutamate release.

Amacrine Cells

AII amacrine cells are critical mediators of the rod pathway. They receive excitatory input from rod depolarizing bipolar cells and, thus, depolarize in response to light. They transmit hyperpolarizing light signals to OFF cone bipolar cells through inhibitory glycinergic synapses and depolarizing light signals to ON cone bipolar cells through gap junctions. In addition, AII amacrine cells form homotypic gap junctions with neighboring AII amacrines. The axons of the dopamine neurons surround the perikarya of AII amacrine cells. Dopamine and D1 receptor agonists promote the uncoupling of gap junctions in AII amacrine cells by cAMP-dependent phosphorylation of connexin proteins. The gap junctions between amacrine cells are more sensitive to the uncoupling action of dopamine than those between AII amacrine cells and ON cone bipolar cells. In addition to secreting dopamine, the dopamine amacrine/interplexiform cells also synthesize and release the inhibitory neurotransmitter GABA. The dopamine amacrine/interplexiform cells synapse onto the AII amacrines, where their processes form rings around the perikarya of the AII cells. The active zones of the synapses have GABA-A receptors. Thus, activation of the dopamine amacrine/interplexiform cells is likely to decrease the light response of AII amacrine cells through GABA. Interestingly, D1 dopamine receptors have not been observed in these active zones, suggesting that dopamine diffuses to distal receptors to promote AII–AII cell uncoupling.

Dopamine stimulates acetylcholine release in the retina through D1-like receptors; most acetylcholine in mammalian retina is released from starburst amacrine cells, which function in the circuitry regulating directional selectivity to moving stimuli.

Most of the synapses made by dopamine amacrine/interplexiform cells are onto other amacrine cells. Thus, it is likely that dopamine affects many other functions within the inner retinal circuitry, but the details and functional consequences for visual processing are less clear.

Ganglion Cells

The effects of dopamine on ganglion cells are complex and it is difficult to discern which responses result from direct actions on ganglion cells and which responses reflect effects on retinal circuitry. In the mammalian retina, dopamine appears to decrease the sensitivity to light and strengthen the center surround of ganglion cells. These effects are mediated by dopamine D1-like receptors, and D1 receptor antagonists have opposite effects. A D1 receptor blocker also reduces the response of ON–OFF directionally sensitive ganglion cells to the leading edge of a moving light stimulus. In addition, dopamine strengthens cone pathway input to ganglion cells and reduces rod pathway input.

A small subpopulation of ganglion cells is referred to as intrinsically photosensitive retinal ganglion cells (ipRGCs). These ganglion cells project to the suprachiasmatic nucleus (SCN) of the hypothalamus, the site of the master circadian clock in mammals; to the olivary pretectal nucleus, a relay nucleus in the pupillary light reflex circuit; and to other nuclei involved in nonimage forming vision. These ipRGCs mediate photic entrainment of the circadian clock and are essential for the normal pupillary light reflex. They contain a photopigment, melanopsin, and are directly responsive to light, showing a depolarizing response to illumination. The ipRGCs also receive input from rods and cones through retinal circuitry. In mammals, dopamine amacrine/interplexiform cells are a component of this circuitry and synapse directly onto the ipRGCs. In addition, dopamine drives a circadian rhythm of melanopsin expression in the ipRGCs, at least in rats.

Müller Glial Cells

Müller cells are giant glia that span the width of the neural retina from the outer limiting membrane to the inner limiting membrane. They play important roles in retinal physiology by regulating the extracellular ionic milieu, especially the K^+ concentration. Müller cells are also an important source of trophic factors within the retina. Mammalian Müller cells express dopamine D2 receptor immunoreactivity. The application of dopamine or a D2 receptor agonist decreases K^+ conductance through an inwardly rectifying K^+ channel. These findings indicate that dopamine may influence the extracellular K^+ clearance, thereby affecting neuronal excitability and visual processing in the retinal circuitry.

Role of Dopamine in Photopic Visual Processing

Overall, the effects of dopamine on individual retinal cell types are consistent with an important role for this neuromodulator in visual processing in light-adapted retinas. Dopamine facilitates cone input to the inner retina and diminishes rod input. Extensive rod–cone coupling at night may shunt cone currents to rods, accounting for the apparent lack of cone input at night in the absence of dopamine. The uncoupling of the rod–cone network in the daytime in response to dopamine isolates the cones, strengthening their input signals to the inner retina. The effect of dopamine on horizontal cell coupling narrows receptive fields and makes the center surround organization more compact, enhancing spatial contrast sensitivity. The enhancement of glutamate-gated currents on OFF cone bipolar cells would also be expected to strengthen cone input. In addition, the uncoupling of the AII amacrine cell network by dopamine, together with the inhibitory effect of co-released GABA on AII amacrine cell light responses, should further suppress information flow through the rod pathway. Collectively, activation of the dopamine amacrine/interplexiform cell appears to fine-tune the retinal circuitry for high-resolution, high-contrast, low-sensitivity visual processing under photopic conditions.

Dopamine and Circadian Organization of the Retina

Many cells types in the vertebrate retina express circadian clock genes, including the dopamine amacrine/interplexiform cells. Dopamine can entrain or phase-shift the circadian clock in amphibian photoreceptor cells that regulates melatonin biosynthesis. Dopamine affects the circadian expression of a clock gene reporter (period 2:: luciferase) in the inner retina of mice. In addition, circadian-clock-driven dopamine release drives circadian rhythms of rod–cone coupling in mice and fish, and photoreceptor protein phosphorylation in mouse photoreceptors. With the widespread distribution of dopamine receptors in retina, the ability of dopamine to diffuse throughout the retina, the expression of clock genes in the dopamine amacrine/interplexiform cells, and the large increase in dopaminergic activity at dawn, dopamine may play important, conserved roles in the circadian organization of the retina by entraining and coordinating multiple circadian oscillators.

Dopamine, Retinal Development, Ocular growth, and Myopia

In chick embryo retinal cell cultures, dopamine has been reported to inhibit growth cone motility. In addition, the signaling mechanisms utilized by dopamine receptors appear to change with the developmental stage. Dopamine may play a role in stabilizing synapses during retinal development. However, many of these studies were done with *in vitro* systems, and may not necessarily reflect the development of the retina *in vivo*.

Dopamine may also be involved in ocular development and establishing emmetropia (perfect, focused vision). At birth, most animals are hyperopic, with images focused posterior to the photoreceptors. During the postnatal period, the eye elongates, increasing its own focal length. Under normal conditions, the eye will elongate only to the point that the image is focused on the photoreceptor cells, yielding the condition referred to as emmetropia. However, if the eye grows excessively long, the image will focus in front of the retina, causing myopia (nearsightedness). The growth of the eye in the axial dimension is regulated by the retina through visually guided feedback mechanisms that coordinate the growth of the eye with its optics. If the retinal image is degraded, as in the case of congentital infant cataract, the eye grows excessively long, resulting in myopia. This process is referred to as form-deprivation myopia and has been studied extensively in chicken hatchlings. When a diffuser goggle is placed over the eye of a newly hatched chick, the eye will grow excessively long, resulting in a large myopic refractive error within 1–2 weeks. Interestingly, allowing short periods of vision each day without the diffusers prevents the development of myopia.

Although some controversy exists, dopamine appears to contribute to the retinal circuitry involved in the feedback mechanism controlling emmetropization. Retinal dopamine levels and metabolism are reduced in eyes of chicks exposed to form deprivation. The administration of apomorphine, a dopamine receptor agonist, prevents the development of form-deprivation myopia. Moreover, dopamine receptor antagonists block the ability of short periods of unobstructed vision to prevent the development of myopia.

Summary

Dopamine release is driven by light and regulated by circadian clocks. The neuromodulator regulates multiple functions within the retina primarily by extrasynaptic mechanisms. Dopamine receptors are widely distributed in the retina, and dopamine has the capacity to diffuse from sites of release to distant receptors. A primary function of dopamine is to regulate network adaptation within the retina to optimize vision during the daytime.

Neurotransmitters and Receptors: Melatonin Receptors

A F Wiechmann, University of Oklahoma College of Medicine, Oklahoma City, OK, USA

Glossary

Circadian rhythm – The term from the Latin *circa* which means around and *diem* which denotes day that is an approximate daily (24-h) periodicity in physiological processes of many organisms.
Diurnal – Activities that are repeated every 24 h, but are not necessarily under the control of a biological clock.
Orthologs – Homologous sequences which are similar to each other because they originated from a common ancestor.
Paracrine – The term from the Latin *para*, which means near, is a form of cell signaling in which the target cell is located within the same tissues as the cell that releases the chemical signal.
Pinealocytes – The main cells of the pineal gland that produce and secrete melatonin into the circulation.
Xenopus – The term from the Latin *strange foot*, which is a genus of frog native to Africa, and commonly used in research as a model organism.

Introduction

Melatonin (*N*-acetyl-5-methoxytryptamine) is an indolamine hormone synthesized by pinealocytes and retinal photoreceptors. The rate of melatonin synthesis, in most species studied, is highest at nighttime, and is considered to be a chemical signal of darkness that entrains circadian rhythms. This hormone synthesized in the pineal gland is secreted immediately into the circulation and acts as an endocrine hormone on distant target sites throughout the body. Melatonin produced in the retina, however, is thought to have a local, or paracrine role. It is thought that melatonin is synthesized and released by the photoreceptors at night, and diffuses throughout the retina to bind to melatonin receptors located on a variety of retinal cells. Since melatonin is a very lipophilic molecule, it diffuses freely through plasma membranes.

The three major subtypes of melatonin receptors are members of the superfamily of guanine nucleotide binding (G-protein)-coupled receptors. Most studies have shown that melatonin receptor activation is coupled to an inhibition of adenylate cyclase activity, although many reports demonstrate that other signaling mechanisms are conveyed by the melatonin signal. Melatonin receptors have been identified in many different retinal cells, including amacrine cells, horizontal cells, ganglion cells, photoreceptors, and the adjacent retinal pigment epithelium (RPE).

Sites of Retinal Melatonin Synthesis

Melatonin Synthesis by Photoreceptors

The photoreceptors appear to be the sites of melatonin synthesis in the retina. They express all of the enzymes involved in melatonin synthesis. Melatonin is synthesized from tryptophan in a series of four enzymatic steps: (1) tryptophan is converted into 5-hydroxytryptophan by tryptophan hydroxylase (TPH); (2) the 5-hydroxytryptophan is then converted into 5-hydroxytryptamine (serotonin) by aromatic amino acid decarboxylase; (3) serotonin is then converted into *N*-acetylserotonin by arylalkylamine N-acetyltransferase (AANAT); and (4) *N*-acetylserotonin is converted into melatonin (*N*-acetyl-5-methoxytryptamine) by hydroxyindole-O-methyltransferase (HIOMT). The enzyme activity and messenger RNA (mRNA) encoding TPH and AANAT exhibit circadian rhythms of expression, with highest levels occurring at night.

There is strong evidence that identifies the photoreceptors as the sites of retinal melatonin synthesis. Melatonin immunoreactivity is localized in the outer nuclear layer (ONL) of the retina which contains the cell soma of the photoreceptors. HIOMT and AANAT protein and mRNA are localized to photoreceptor cytoplasm, and a cyclic rhythm of AANAT activity persists following chemical lesion of the inner retina. The mRNA encoding TPH is localized to photoreceptors, and the photoreceptor layer of the amphibian retina continues to produce melatonin rhythmically in darkness after isolation from the inner retina.

In addition to the photoreceptors, some neurons of the inner retina may have the capacity to produce a small amount of melatonin. Melatonin immunoreactivity is observed in the inner retina, and a low level of AANAT mRNA has been detected in the inner nuclear layer (INL) and ganglion cell layer (GCL). The INL contains the cell soma of amacrine, horizontal, bipolar, and Müller cells. Since some cells in these layers also have melatonin receptors, the synthesis of melatonin by inner retinal neurons may be involved in the circadian activity of cells of the inner retina.

Phylogenetic Relationships between Photoreceptors and Pinealocytes

The ability of photoreceptors and pinealocytes to synthesize melatonin appears to be the consequence of an ancestral relationship between the retina and the pineal gland. Some primitive animals possessed three eyes which may have produced melatonin and were also capable of phototransduction. Pinealocytes of some lower vertebrates are morphologically very similar to retinal photoreceptors, and they synthesize melatonin as well as many proteins that are characteristic of retinal photoreceptors. Furthermore, the photoreceptors of the nonmammalian pineal gland are directly photosensitive, and during the embryologic development of the mammalian pineal gland, the pinealocytes undergo a transient photoreceptor-like differentiation.

It is suggested that the middle, or third eye, eventually evolved into an endocrine organ specialized for the secretion of melatonin into the circulation, in which the melatonin-producing pineal photoreceptors eventually lost their phototransduction capabilities, and the melatonin-producing cells of the lateral eyes evolved into photoreceptors specialized for phototransduction, but maintained their ability to synthesize melatonin. Genes expressing melatonin receptors in peripheral tissues may have also become expressed in ocular tissues, which enabled local paracrine signaling by melatonin in the retina.

Classification of Melatonin Receptors

Melatonin receptor expression has been identified in the retinas of several species. The major types of melatonin receptors that have been cloned are members of the superfamily of G-protein-coupled receptors. Melatonin receptors have been classified as Mel_{1a}, Mel_{1b}, and Mel_{1c} subtypes. These three subtypes are expressed in tissues, including the retinas, of lower vertebrates such as amphibians, fish, and birds. Mammalian melatonin receptors are classified according to their homology to the nonmammalian receptors, and according to their pharmacological properties. In mammals, the Mel_{1a} and Mel_{1b} receptor subtypes are designated as the MT1 and MT2 receptor subtypes, respectively. The mammalian ortholog of the Mel_{1c} subtype has been designated as GPR50, and does not bind melatonin. The G-alpha proteins coupled to melatonin receptors are inhibitory (G_i) to the activation of adenylate cyclase and cyclic adenosine monophosphate (cAMP) production in most tissues studied. However, receptor coupling to other G-alpha proteins ($G_{i\alpha 2}$, $G_{i\alpha 2}$, $G_{i\alpha q}$, $G_{i\alpha s}$, $G_{i\alpha z}$, and $G_{i\alpha 16}$), and hence other signaling pathways, have been reported. Nuclear melatonin receptors, which are members of the RAR-related RZR/ROR orphan nuclear receptor superfamily, have been reported to exist in some tissues, and a melatonin-binding site on the enzyme quinine reductase 2 has been identified and is referred to as the mammalian MT3 melatonin receptor.

Most G-protein-coupled receptors interact with each other to form homodimers or heterodimers. The mammalian MT1 and MT2 melatonin receptors can exist as homodimers and as heterodimers. Dimerization of G-protein-coupled receptors has important functional consequences in regard to receptor affinity, trafficking, and signaling. The relative expression levels of melatonin receptor subtypes in the retina may have a significant impact on the function of melatonin in the target cells.

Sites of Melatonin Receptors in the Retina

Melatonin receptors have been identified not only in several retinal neurons of the inner retina, but also in photoreceptors cells and RPE cells. The identification of melatonin receptors in photoreceptor cells was unanticipated, given that the photoreceptors are the site of retinal melatonin synthesis. The presence of melatonin receptors in photoreceptor cells suggests the possibility of what can be characterized as an intracrine (autocrine) signaling mechanism in response to melatonin, in which a cell synthesizes and releases a signaling molecule, and also has receptors to which the molecule binds and triggers an intracellular response. Another potential role of melatonin receptors in photoreceptor cells is that they may be involved in a negative-feedback mechanism which would enable melatonin to regulate the expression of the receptors to which it binds.

Melatonin Receptors in Photoreceptor Cells

Mel_{1a}, Mel_{1b}, and Mel_{1c} melatonin receptor subtype protein and mRNA have been identified in the photoreceptors of nonmammalian vertebrates, and MT1 receptors in photoreceptors of the mammalian retina. The receptor immunoreactivity has been identified primarily in the photoreceptor membranes of the inner segments, although some cytoplasmic immunoreactivity has been reported for some subtypes, and may represent newly synthesized receptors that have not yet been transported to the plasma membrane, or receptors that have been internalized after activation.

Mel_{1b} and Mel_{1c} melatonin receptor RNA and/or protein are expressed in *Xenopus* photoreceptors, and the MT1 (Mel_{1a}) receptor is localized to photoreceptors of the human retina. In the chicken retina, Mel_{1a} immunoreactivity and melatonin receptor mRNA expression (Mel_{1a}, Mel_{1b}, and Mel_{1c}) are localized to the photoreceptor layer. In the *Xenopus* retina, Mel_{1c} immunoreactivity is observed in the plasma membrane of photoreceptor

inner segments, whereas Mel_{1b} receptor immunoreactivity appears in a punctate pattern in the proximal portion of photoreceptor inner segments. The differential pattern of Mel_{1b} and Mel_{1c} may reflect differential regulation of expression or trafficking of melatonin receptors in photoreceptor cells.

Melatonin Receptors in RPE

The RPE is a monolayer of cuboidal cells located between the vascular choroid layer and the neural retina. It is very closely associated with the retinal photoreceptor cells. This close association reflects the vital function of the RPE to provide physical and metabolic support to the photoreceptors. Circadian signals may play a role in influencing the coordinated interactions between the RPE and its adjacent tissues. The RPE, photoreceptors, retinal neurons, and choroidal cells interact in a coordinated manner for optimal function. Melatonin may play a role in the timing of the circadian phagocytosis of shed photoreceptor outer segments. The distal tips of rod photoreceptor outer segments are shed on a circadian rhythm as part of a renewal process, with peak shedding occurring early in the light period. The shed outer segment tips are phagocytized by the RPE, and melatonin is thought to be involved in this process. Melatonin secreted from photoreceptors at night may activate melatonin receptors on the RPE to regulate some circadian activities of the RPE that are important for optimal photoreceptor activity.

Melatonin inhibits forskolin-stimulated cAMP synthesis in RPE cell cultures, and melatonin affects the RPE membrane potentials and resistances at the apical or basal membrane. The mRNA encoding all three melatonin receptor subtypes is expressed in *Xenopus laevis* RPE but the Mel_{1b} receptor protein is localized only to the apical surface of the *Xenopus* RPE, and is not present on the basal surface. The Mel_{1c} receptor protein has also been localized to the *Xenopus* RPE. The presence of melatonin receptors on the apical microvilli, which directly contact the photoreceptors, but not on the basal membrane of the RPE, suggests that the photoreceptors are more likely to be the source of melatonin that activate melatonin receptors on the RPE rather than melatonin that is produced by the pineal gland and secreted into the general circulation.

Melatonin Receptors in Inner Retinal Neurons

Using autoradiography with ^{125}I-melatonin, it has been demonstrated that melatonin binding occurs in the inner plexiform layer (IPL) of many species. The IPL contains the synaptic terminals between bipolar cells, amacrine cells, horizontal cells, and ganglion cells. Since melatonin inhibits dopamine release from the retina, and high-affinity melatonin binding occurs in the IPL of the retina, the dopaminergic amacrine cell, which forms synaptic contacts in the IPL, has long been considered to be a candidate for the site of action of melatonin in the inner retina. Another candidate cell for melatonin receptor expression is the GABAergic amacrine cell (GABA, gamma aminobutyric acid) of the INL since $GABA_A$ receptor antagonists block melatonin-induced suppression of dopamine release. This suggests that the effect of melatonin on dopamine release may not be mediated only by direct action on dopaminergic cells, but that indirect action on GABAergic amacrine cells may also contribute to the inhibition of dopamine release via melatonin.

The autoradiographic localization of melatonin-binding sites in cells of the inner retina has been confirmed by both *in situ* hybridization and immunocytochemistry. In *Xenopus*, Mel_{1b} and Mel_{1c} RNA expression is localized to the INL, GCL, and photoreceptor inner segments. In the chicken retina, the mRNA encoding the $Mel1_a$, Mel_{1b}, and Mel_{1c} receptor subtypes is present in the INL, GCL, and photoreceptor inner segments. The INL contains the cell soma of bipolar, amacrine, horizontal, and Müller cells. In the human retina, Mel_{1b} receptor mRNA is much more highly expressed than is Mel_{1a} receptor RNA, suggesting that the Mel_{1b} receptor has a more significant role in human retinal physiology.

Using antibodies against specific melatonin receptor subtypes for immunocytochemistry, all three melatonin receptor subtypes (Mel_{1a}, Mel_{1b}, and Mel_{1c}) have been observed in the outer plexiform layer (OPL; the layer that contains the synaptic contacts between photoreceptors, bipolar cells, and horizontal cells) and the IPL. The MT1 (Mel_{1a}) receptor has been localized to horizontal cells in several mammalian species, including human. All three melatonin receptor subtypes appear to be present in horizontal cells of fish and *Xenopus* retina. The MT1 (Mel_{1a}) receptor has also been localized to AII amacrine and GABAergic amacrine cells of the mammalian retina.

Some Mel_{1a} and Mel_{1c} receptor immunoreactivity co-localizes with GABAergic and dopaminergic amacrine cells in the *Xenopus* retina. The presence of Mel_{1a} and Mel_{1c} receptors on dopaminergic and GABAergic amacrine cells is consistent with the observation that melatonin modulates the cyclic release of GABA and dopamine from retinal amacrine cells. In contrast, Mel_{1b} receptor immunoreactivity does not appear to co-localize with markers for dopaminergic and GABAergic neurons in the *Xenopus* retina, suggesting that melatonin does not act directly on GABAergic and dopaminergic amacrine cells through the Mel_{1b} receptor in this species.

In the *Xenopus* retina, the Mel_{1a}, Mel_{1b}, and Mel_{1c} receptor proteins are differentially distributed throughout the retina. In the OPL, for example, presumptive horizontal cell processes are immunoreactive for Mel_{1a} and Mel_{1b} receptor subtypes, but the immunoreactive labels appear to be in different cell processes. Cell somas in the INL are immunoreactive either for Mel_{1b} or Mel_{1a}, or for Mel_{1a} or Mel_{1c}, but not for both. All three melatonin receptor

subtypes appear to be expressed in different populations of ganglion cells in the *Xenopus* retina, and the MT1 subtype is present in ganglion cells of the human and macaque retina.

Melatonin receptor mRNA and protein are rhythmically expressed in *Xenopus* and chicks, with peak levels of Mel_{1c} expression occurring in the day. In chicks, the rhythms of Mel_{1a} and Mel_{1b} receptor protein generally appear to be the opposite to that of Mel_{1c}, with lowest levels occurring in the early morning and higher levels in the evening. The patterns of cyclic rhythms appear to be distinctive for each receptor subtype in the retina. Circadian rhythms in melatonin receptor expression may perhaps be superimposed on the rhythm in retinal melatonin levels to provide an additional level of regulation of the responsiveness of retinal target to melatonin.

Effects of Melatonin on Retinal Function

Modulation of Neurotransmitter Release

Melatonin released from photoreceptors at night diffuses into the extracellular milieu and binds to melatonin receptors on dopaminergic amacrine cells. The activation of the melatonin receptors results in a decrease of dopamine release at nighttime. Thus, retinal dopamine levels are higher during the day and lowest during the night due to the circadian release of melatonin. Resultant lower dopamine levels at night cause a reduction in D_2 dopamine receptor activity on photoreceptors, causing an increase in photoreceptor intracellular cAMP levels that in turn causes an increase in coupling of gap junctions between rod and cone photoreceptors so that rod input dominates the cone horizontal cells. The increased sensitivity of horizontal cells to light at nighttime is therefore mediated at least in part by activation of D_2-like receptors by dopamine released from amacrine cells. A reduction in endogenous retinal dopamine levels causes hyperpolarization of horizontal cells and enhanced dark adaptation.

D_1 dopamine receptors, which are positively coupled to cAMP synthesis, are located on horizontal cells. Melatonin may therefore postsynaptically regulate horizontal cell activity by inhibiting the stimulation of cAMP synthesis in response to D_1 receptor activation. It may bind to receptors on GABAergic amacrine cells, stimulating them to inhibit dopamine release from nearby dopaminergic amacrine cells. In addition, since horizontal cells express melatonin receptors, and melatonin increases horizontal cell sensitivity to light, melatonin may act directly on horizontal cells to increase gap-junctional coupling of horizontal cells. Increased horizontal cell coupling would cause an increase in receptive field size, which would potentially increase the sensitivity of the retina to light during the dark period, since more second-order neurons would respond to a light stimulus.

Melatonin may therefore modulate dopaminergic transmission by a combination of directly reducing dopamine release from amacrine cells, and indirectly by stimulating GABAergic amacrine cells to inhibit dopamine release from dopaminergic amacrine cells, both of which would increase horizontal cell coupling. The resulting increased visual sensitivity at nighttime could be due to increased rod–cone coupling through dopamine binding to D_2 receptors on photoreceptors, or to horizontal cell coupling stimulated by the binding of melatonin to melatonin receptors on horizontal cells. A summary diagram of the known locations of melatonin receptors and the possible interactions with the various target cells is presented in **Figure 1**.

Melatonin increases horizontal cell sensitivity to light in salamander retina, and also potentiates glutamate-induced currents from isolated cone-driven horizontal cells in carp retina by increasing the efficacy and affinity of the glutamate receptor. These observations suggest that melatonin acts directly on melatonin receptors of horizontal cells. Melatonin modulates cyclic guanosine monophosphate (cGMP)-dependent glutaminergic transmission from cones to cone-driven horizontal cells by activation of the Mel_{1a} receptor, causes a depolarization of the H1 horizontal cell membrane potential, and reduces its light responses. These observations suggest that melatonin enhances the circadian sensitivity of rod photoreceptor signaling.

Melatonin has been shown in fish retina to potentiate responses of rod ON bipolar cells to simulated light flashes. This action of melatonin is mediated by the Mel_{1b} receptor, and increases cGMP levels by inhibiting phosphodiesterase activity. Melatonin may bind directly to Mel_{1b} receptors on rod ON bipolar cells to improve the signal/noise ratio for rod signals by enhancing signal transfer from rod photoreceptors to rod bipolar cells. The presence of melatonin receptors by immunocytochemistry has not yet been definitively established in bipolar cells.

Melatonin treatment of isolated rat retinal ganglion cells potentiates glycine-induced currents by increasing the efficacy and channel conductance of a glycine receptor. The inhibitory modulation of glycinergic inputs to ganglion cells may thus be strengthened by stimulation of melatonin receptor activation. This suggests that melatonin may regulate circadian changes in receptive field organization and light sensitivity by binding to melatonin receptors on ganglion cells.

Modulation of Photoreceptor Function

Several reports support the concept of a direct action of melatonin on retinal photoreceptor function. Melatonin induces membrane conductance changes in isolated frog rod photoreceptors, binds with low affinity to structures in the OPL in frog retina, enhances the rate of photoreceptor

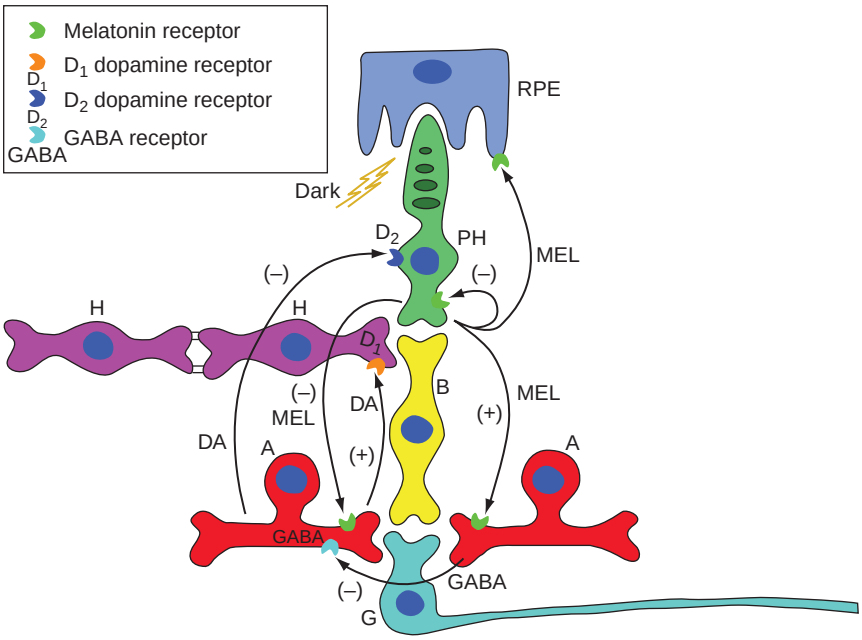

Figure 1 Summary diagram of locations of retinal melatonin receptors and potential interactions among target cells. Melatonin (MEL) is produced by photoreceptors (PH) at nighttime, and diffuses to target cells within the retina. Arrows represent the movement of melatonin to the target cells. The melatonin receptors are represented by a black crescent symbol. Dopamine and GABA receptors are represented by crescent symbols with D_1, D_2, or GABA as identifiers. Melatonin may bind to amacrine cells (A) that release GABA or dopamine (DA) as their neurotransmitter. Melatonin is thought to stimulate (+) GABA release and/or inhibit (–) dopamine release from these cells. GABA inhibits dopamine release from dopaminergic amacrine cells. A lower rate of dopamine release from amacrine cells at nighttime results in lower stimulation of D_1 receptors on horizontal cells (H), which leads to increased coupling of horizontal cells through gap junctions (=), which could cause an increase in receptive field size and increased retinal sensitivity to light. The decreased binding of dopamine at nighttime to D_2 receptors on photoreceptor cells results in an increase in melatonin synthesis, since dopamine inhibits melatonin synthesis in photoreceptors. Melatonin may potentially bind to horizontal cells to directly inhibit the cellular response to D_1 receptor binding. Melatonin may also bind to receptors located on the photoreceptor membrane, which could directly increase rod sensitivity to light, increase rod–cone coupling, and/or regulate synthesis of melatonin. Melatonin may bind to receptors on the apical membrane of retinal pigment epithelial (RPE) cells, to coordinate circadian interactions with photoreceptor outer segments. The possible expression of melatonin receptors on bipolar (B) cells, and the confirmed expression of melatonin receptors on ganglion cells (G) are not indicated by arrows.

outer segment disk shedding, and increases the degree of light-induced photoreceptor cell death. It causes a stimulation of the amplitude of the *a*-wave (rod photoreceptors) and the *b*-wave (inner retinal cells responding to the photoreceptor input) of electroretinogram (ERG) recordings of transgenic frogs that overexpress the Mel_{1c} receptor in rod photoreceptors. This suggests that melatonin acts directly on rod photoreceptors to increase retinal sensitivity to light as part of a dark-adaptation mechanism.

The role of melatonin in dark adaptation suggests a potential mechanism by which melatonin increases the degree of light-induced photoreceptor cell death. Since melatonin appears to increase the sensitivity of the retina to light as part of a dark-adaptation mechanism, an undesirable consequence of this may be an increased sensitivity to the deleterious effects of light. Although signals from the inner retina obviously play a significant role in the circadian activities of retinal photoreceptors, direct action of melatonin on receptors located on photoreceptors may contribute substantially to the functions of melatonin in circadian-regulated activities of the retina.

Noninvasive Testing Methods: Multifocal Electrophysiology

E E Sutter, The Smith-Kettlewell Eye Research Institute, San Francisco, CA, USA

Glossary

Base interval of stimulation – Stimuli are presented at intervals that are integral multiples of a base interval.
Binary stimulation – The stimulation that switches between two states such as flash/no flash, pattern–contrast-reversing pattern.
First-order kernel – This response component is computed by adding the response signal following base intervals with a stimulus and subtracting the signal following intervals without stimulus. If the response is linear, response contributions from subsequent stimuli must cancel as they are added and subtracted the same number of times. If the response is nonlinear, the following responses depend on the presence of the preceding stimulus. The difference that appears in the first-order kernel is called an induced component.
Inion – The prominent projection of the occipital bone at the lower rear part of the skull.
Lamina cribrosa – A mesh-like structure through which the optic nerve exits the sclera.
m-Sequence stimulation – The binary stimulation controlled by a special class of pseudorandom binary sequences called m-sequences. These sequences have ideal properties for the analysis of nonlinear systems.
Myelination – An electrically insulating material that forms a layer, surrounding the axons of many neurons. Axons of retinal ganglion cells become myelinated at the lamina cribrosa in the optic nerve head. Myelination of axons greatly increases the propagation velocity of action potentials.
Nonlinear response – In the case of binary stimulation, nonlinear means that the contribution of a response to the signal may depend on preceding and immediately following responses or responses in the neighboring areas.
Saltatory nerve conduction – The nerve conduction in myelinated fibers whereby the action potential jumps from gap to gap between the myelinated section.
Second-order, first slice – This response component can roughly be thought of as the difference between the response to two consecutive stimuli and the two stimuli individually presented.

Why Multifocal?

Visual electrophysiology has enjoyed decades of useful applications in the clinic and research. It provides objective measures of function at different stages of visual processing. Until relatively recently, it has been restricted to testing of a single area in the visual field. In the clinic it was generally used as a full field test or a test of a single area or spot in the field. This has greatly limited its sensitivity in diagnosis and in measuring progression and recovery from disease. It was clear from the start that mapping responses across the retina recording focal responses from one small area at a time would have taken very long and would not be practical. Multifocal techniques have overcome this limitation by stimulating a large number of areas concurrently whereby the response of each area is encoded in its temporal stimulation pattern. The special encoding using binary m-sequences permits clean extraction of the focal response contributions from a single signal derived from the cornea or from the scalp over the visual cortex of the brain. The m-sequence encoding has the additional benefit that it provides information on nonlinear response properties such as fast adaptation and recovery from photo stress that can be important clinical indicators.

There are many multifocal protocols available to clinicians. Some of them test the central visual field with lower spatial resolution and short recording times useful for screening. Others offer high resolution for the detection of small scotomata and sensitive assessment of changes in the spatial extent of dysfunction. Yet, other protocols enhance inner retinal and specifically ganglion-cell contributions. These tools permit tailoring the test for a specific clinical purpose. In many laboratories, only one protocol is commonly used and ordered by the clinicians as a multifocal electroretinogram (mfERG). Judicious selection of one of many available tests can lead to faster and more accurate diagnosis and, in some cases, avoid errors. Careful data analysis by a knowledgeable user can tease out local-response abnormalities that might otherwise be missed. A few examples shown below are selected to illustrate this point.

The Basic Principle

The basic principle of mfERG and multifocal visual-evoked potential (mfVEP) recording is schematically illustrated in Figure 1. With both types of recordings, the size of the focal stimuli is scaled with eccentricity to

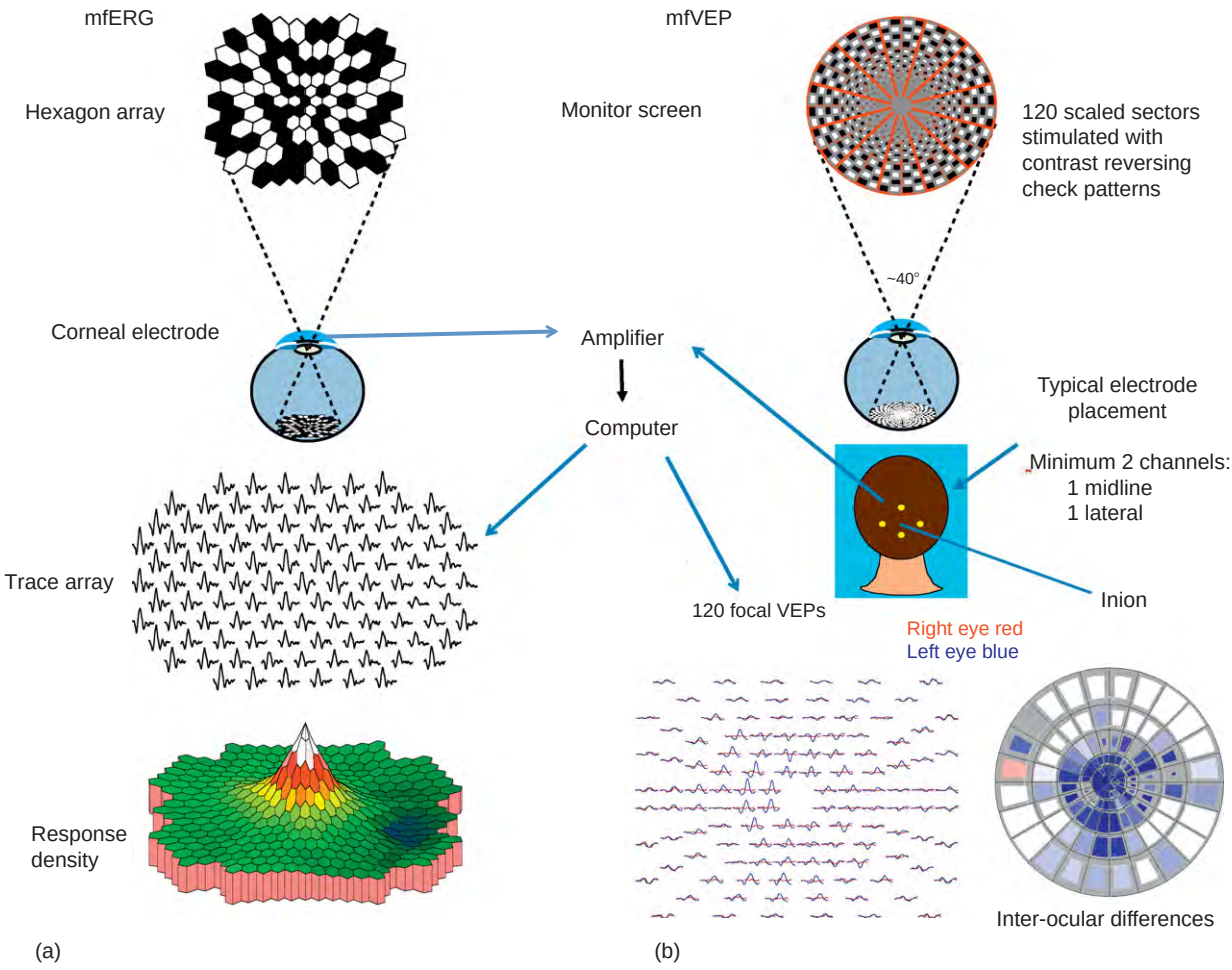

Figure 1 Schematic representation of the derivation of mfERG and mfVEP records. Commonly used stimulus arrays are shown on top. For the mfERG, hexagonal arrays are scaled with eccentricity to achieve similar signal-to-noise ratios across the stimulated field. The focal stimulation is m-sequence modulated flicker. The corneal signal can be derived with any of the available electrode techniques. For mfVEP, recording a dartboard pattern of stimulus elements is used to account for the steep eccentricity scaling of the representation of the visual field on the primary visual cortex. Each sector is stimulated with a contrast-reversing check pattern. Two perpendicular electrode pairs pasted to the scalp over the primary visual cortex cover the different directions of current flow. The data are presented as an expanded array of traces (bottom left) and as a pseudocolor field map (bottom right). The example is from an asymmetric patient. The left eye largely dominates (blue areas) except in the area of the right-eye blind spot (pink patch).

generate approximately the same signal amplitudes across the stimulated field. In the mfERG, we use scaled hexagonal arrays of the kind shown in **Figure 1(a)**. The steeper scaling of the cortical response requires the use of dartboard patterns **Figure 1(b)**. While the mfERG stimulus is usually focal flicker, the cortical responses of the multifocal visual-evoked cortical potential (mfVECP) are best elicited with focal contrast reversal of a check pattern.

Recording of Multifocal Data

All the data presented here have been recorded, analyzed, plotted, and exported with VERIS science 6.0 (Electro-Diagnostic Imaging, Inc, Redwood City, CA, USA). The mfERG data were recorded with a Burian–Allen bipolar contact lens electrode. This electrode and others of similar construction provide the best signal-to-noise ratio. Disposable monopolar electrodes such as the DTL fiber or the HK loop are considered less invasive but provide noisier signals and require longer recording times to achieve the same-quality data. Contact lens electrodes offer the advantage that they correct for corneal astigmatism and prevent drooping eyelids. However, care must be taken that the corneal ring of the electrode is reasonably well centered on the dilated pupil. To be comfortable, the electrode should be selected to fit the size of the eye.

All mfERG records shown here were recorded with a stimulus screen calibrated to produce multifocal flash intensities of 2.7 cd s m^{-2}. In most cases, the patient's fixation stability was monitored with an eye camera. For more recent recordings, fixation was monitored with an

infrared (IR) fundus camera that shows the position of the stimulus array on the fundus of the eye throughout the recording.

Multifocal Stimulators

Originally monochrome cathode ray tubes (CRTs) with a fast white phosphor were commonly used for stimulation. Few color CRTs could reach the required stimulus intensity. While, at this time, some suitable CRT monitors are still available, this technology is rapidly disappearing from the market and is being replaced by flat-panel liquid crystal display (LCD) monitors. The large panels are now bright enough, but achieve high brightness by leaving the pixels on during the entire display frame. This is ideal for pattern-reversal stimulation such as the mfVEPs, but it is not recommended for mfERGs. The switching speed of these panels is also marginal for ERG recording but adequate for mfVEPs. For multifocal flash ERG recording, we would like to have brief focal flash stimuli of no more than 2–3-ms duration at the beginning of each frame. This can be achieved with some of the available microdisplays. DLP projection displays can be used after substantial internal modifications.

Patient Positioning and Data Collection

In many laboratories chin rests are used for stabilization of the patient's head during recording. This is acceptable, but not the best solution. Patients are more comfortable in a reclining chair with a stable adjustable headrest. The reclined position helps to keep contact lens electrodes from dropping out. This arrangement works well in combination with a small stimulator mounted on an articulating arm. It allows adjustment of the angle of the stimulator so that the corneal ring of the contact lens electrode is centered on the patient's pupil.

The stimulus normally consists of a single cycle of a binary m-sequence. Using a longer m-sequence rather than averaging several shorter ones prevents contamination by higher-order kernels and, thus, provides cleaner separation of the local response contributions. For patient comfort, the record is collected in slightly overlapping segments that permit smooth splicing before data processing. Protocols for contact lens electrodes use a segment size of about 30 s. When recording with fiber electrodes, the patient must suppress blinks. To make this easier for the patient, the segment size is reduced to about 15 s.

Data Analysis and Presentation

Focal responses are extracted from the recorded signal using a cross-correlation executed by the fast m-transform. The focal responses may be contaminated with noise from blinks and small eye movements. A special artifact subtraction algorithm helps clean up the data. If the quality is not sufficient for this purpose, the operator can apply spatial filtering whereby each local waveform is averaged with a certain percentage of its nearest neighbors. This greatly improves the waveforms, but leads to some local smearing and is not recommended in cases where dysfunctional areas are suspected to be very small.

Clinically useful parameters of the local response waveforms can be extracted and presented as pseudo-color 2- or 3-dimensional topographic maps. The two most important ones are maps of response density and peak implicit time (time from the stimulus onset to the selected peak). Response densities are derived by dividing each focal-response amplitude by the solid visual angle of the corresponding stimulus patch. Estimating amplitudes of the often noisy focal responses using peak-to-trough measurements is very inaccurate. For this reason, a method of template matching is used. Each focal waveform is multiplied point by point with a normalized template of the underlying response. The template is derived as the average of waveforms in the same retinal region.

Implicit times of specific features of the response waveform, that is, the time from the stimulus onset to the feature are sensitive clinical measures. Of particular importance is the implicit time of the main positive peak *P*1. Estimating *P*1 implicit times using the highest point in the waveform is much too inaccurate when dealing with the noisy local responses. Much more accurate estimates are achieved by means of a template of the underlying waveform. On each focal waveform, the template is shifted into the position of best mean square fit. The location of the peak on the template waveform is then taken as the implicit time estimate. As with the amplitude estimation described above, the template waveform used at each location is the average of waveforms in the same neighborhood.

Dealing with Noisy Data

The main contaminations in mfERG responses are artifacts from blinks and small eye movements. It is possible to detect these artifacts and subtract them from the recorded signal. The process is capable of recovering some of the responses superimposed on the artifact, as long the artifact did not saturate data acquisition. This noise-reduction procedure works very well with mfERG records, but is less effective with mfVEPs where the contamination is usually noise from muscle tone required to maintain head posture rather than discrete artifacts. Here, it is more important to position the head in order to minimize tension.

How Long Does the Test Take?

The kernel extraction is an averaging procedure and, thus, follows the law of averages. Increasing the recording time

by a factor k improves the signal-to-noise ratio by $k^{1/2}$. The duration of a test must be determined by the amount of information to be gained and the signal-to-noise ratio of the derived response.

A multitude of tests can be designed from very short tests to tests lasting perhaps 1 h or more. The longer tests are used when more precise information is required. In the selection of a test, one should consider all the information already known regarding the patient.

Figure 2(a) and 2(b) show the results from two very short recordings derived from the same subject. Sixty-one patches stimulated the central field. Interpolating hexagons were inserted at plotting time to permit a more accurate estimation of the topography. The signal quality was very good in this case and does not reflect what one might get from an average patient in such ultra-short recording times. However, recordings of 2-min duration can be quite adequate for patient screening.

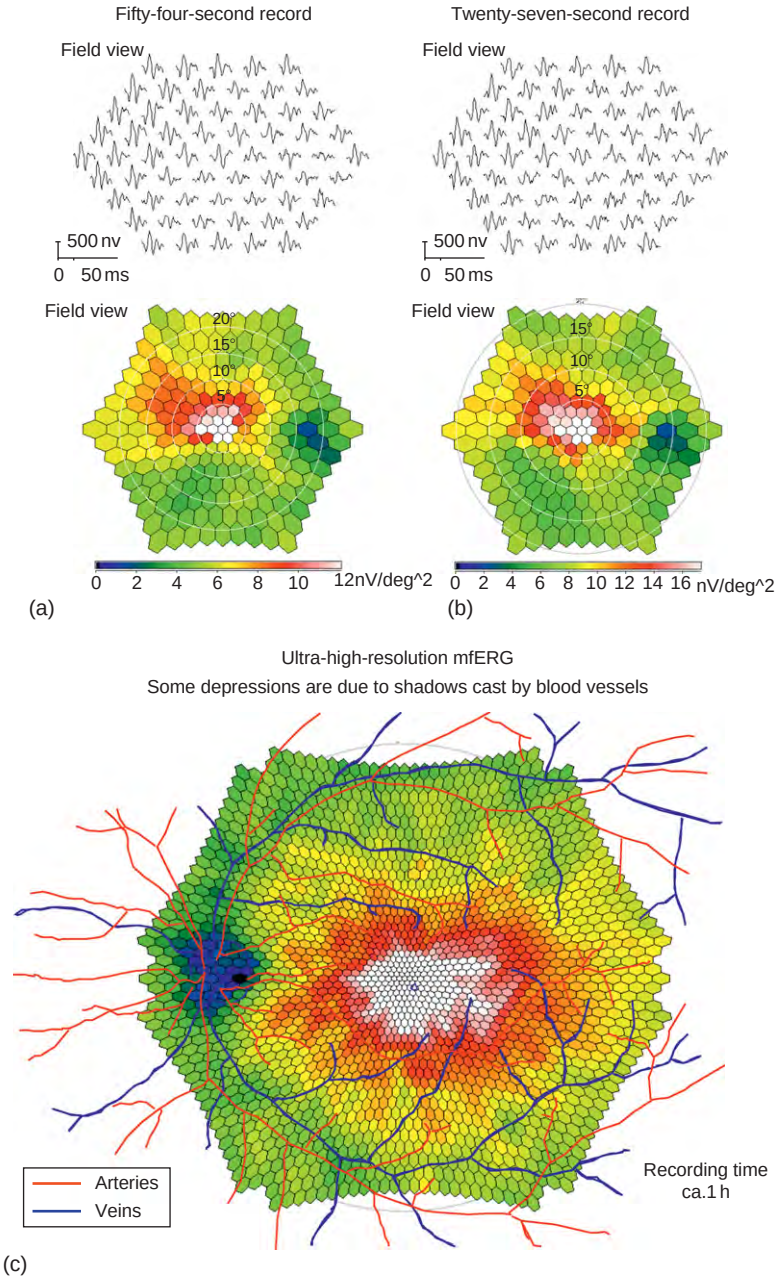

Figure 2 (a) Results from two very short multifocal recordings with 61 stimulus areas. The signals were derived with a bipolar Burian–Allen electrode. (b) High resolution recording using 509 stimulus areas within the central 45° of the visual field. The overlaid vasculature of the subject suggests that the depressed responses in some areas are caused by shadows of major blood vessels and their bifurcations.

Figure 2(c) illustrates a high-resolution recording with a stimulus array of 509 patches. The recording time of about 1 h necessary for this resolution is clearly not feasible in the clinic. The most popular array size uses 103 hexagons and records of 2–7 min length. Some clinics have used 241 hexagons in 7-min tests. Ideally, the spatial resolution of the test should be adjusted to meet the requirements of the clinical problem at hand.

Some Examples from the Retina Clinic

The samples presented below are selected to illustrate uses of different recording and analysis protocols. The clinical significance of the results cannot be discussed here due to space limitations.

Central Serous Retinopathy

The first example is from a male patient with central serous retinopathy (CSR). He was not diagnosed at the time of the recording but complained about a relative central scotoma in his left eye. We selected a 7-min test with 241 hexagonal patches because of the anticipated small spatial extent of the problem. The plots shown represent the average of two records. Individual records are slightly noisier, but would have been quite adequate in this case. Figure 3(a) shows the response density plots of the two eyes. The affected area in the left eye is clearly visible as an excavation in the central peak extending to the area surrounding the optic nerve head. The right eye is normal.

Some pathologies cause local delays in the main positive peak of the first-order waveform called the *P*1 peak indicated by the marks on the traces in Figure 3(c). Such delays are mainly attributed to photoreceptor sensitivity loss. Mapping the peak implicit time can help distinguish between different pathologies. In this CSR case, such delays are found in areas with reduced response density (Figure 3(b)).

Plots of *P*1 implicit time generally show delays in the vicinity of the disk. This feature must be ignored. It is attributed to a contribution to the focal response from scattered light. Some light from the focal stimulation of the highly reflective optic disk is scattered onto the peripheral retina where it elicits a delayed response contribution.

Hydroxychloroquine Retinopathy

A small percentage of patients who take this drug for autoimmune disease develop a bull's eye retinopathy. This dysfunction is, at best, only partially reversible when the patient is taken off the drug. For disease prevention, the mfERG is now proposed as a test for patient screening.

The left column in Figure 4(a) shows a typical example of hydrohychloroquine toxicity. Only the right eye is shown here as the presentation is usually bilaterally symmetric. The array of traces is shown at the top followed by the plots of response density and *P*1 implicit time below. Responses surrounding the center are substantially reduced to about 7–10° eccentricity with some relative sparing of the center.

The bottom plots shows that hydroxychloroquine toxicity does not cause significant changes in peak implicit times. This suggests that the changes are post-receptoral.

Amplitude ratios of ring averages around the fovea are used for diagnosis and assessment of severity of the bull's eye presentation. A plot from an automated screening protocol with statistical evaluation is shown in Figure 5. Ring averages are plotted in Figure 5(a). In Figure 5(b), response densities are plotted against eccentricity in degrees of visual angle and compared to data from a normal cohort. The data are interpolated with a cubic spline. For this analysis, ring averages have been normalized to the outermost ring that is usually minimally affected. The green bands around the normal mean (red line) represent the 2 standard deviation (SD) limit. The heavy black line is the patient's response amplitude. The area where the patient curve falls outside the 2-SD band is colored red. ICS is the index of central sparing used to evaluate the bull's eye configuration. It is computed as the ratio between the red area outside 3° eccentricity and the total red area below the 2-SD band. An ICS number of 1 indicates that all the losses in amplitude relative to the peripheral ring are outside 3° with complete sparing of the center. In a typical maculopathy patient, we find ICS values of around 0.2–0.4.

The importance of considering implicit times as well as response densities in standard clinical testing is illustrated with the example shown in the right-hand column of Figure 4 showing a patient with unknown vision loss.

The patient's visual fields showed a bilateral bull's eye configuration reminiscent of hydroxychloroquine toxicity of Figure 4(a). The perifoaveal relative scotoma seen in the visual field is confirmed by the response density distribution of the mfERG (Figure 4(a)). However, in this case we see substantial delays in the areas with depressed response amplitudes. This finding suggests loss in receptor sensitivity. In this case, topographic mapping of *P*1 implicit times was needed to clearly distinguish this case from hydroxychloroquine toxicity. Latency plots are often necessary to distinguish different pathologies with similar response density topography.

Juvenile X-Linked Retinoschisis

The first-order trace array (Figure 6(a)) and the first-order response density plots (Figure 6(b)) show two areas where amplitudes are still within normal range. However, closer scrutiny reveals that the two areas are very different in their functional properties. Area 1 is normal in the

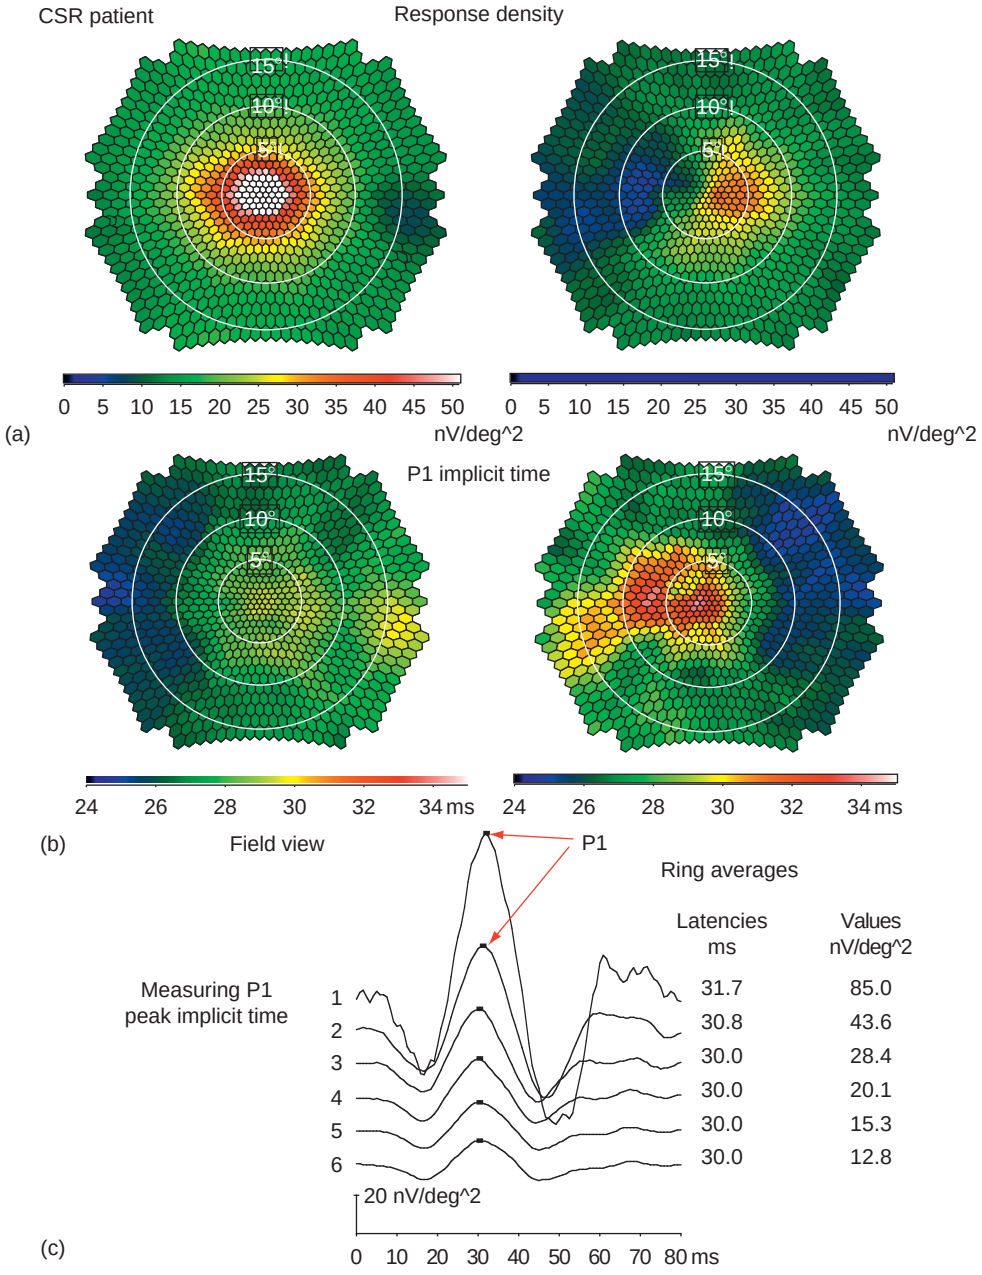

Figure 3 A patient complaining of a relative central scotoma diagnosed as central serous retinopathy with the help of this test. (a) A response density plot derived from two 7-min records. (b) The plot of *P*1 implicit time from the same record. *P*1 implicit times are measured from the time of the focal flash to the first positive peak as shown in (c).

first-order response amplitude as well as the *P*1 implicit time. The dominant higher-order component, the first slice of the second-order kernel, is also within normal range. This component reflects interactions between consecutive flash responses and is thought to originate predominantly in the inner retina. Area 2, on the other hand, has highly abnormal implicit times of close to 40 ms. The second-order component is almost completely absent in this area. This case illustrates the importance of looking not only at response densities but also at peak implicit times and the dominant higher-order kernel.

Detecting Small Central Dysfunction

The patient complained of a very small scotoma. It did not show in the visual field (**Figure 7(b)**) and there was no abnormal ophthalmoscopic finding. The patient drew the scotoma in the Amsler grid at 5° eccentricity (**Figure 7(a)**). Due to the small size of the suspected central dysfunction, we selected a protocol that places all 103 hexagons within the central 12°. The net recording time was 7 min. A distinct depression is seen at the location corresponding to the Amsler grid drawing (**Figure 7(a)**). In such cases, no spatial

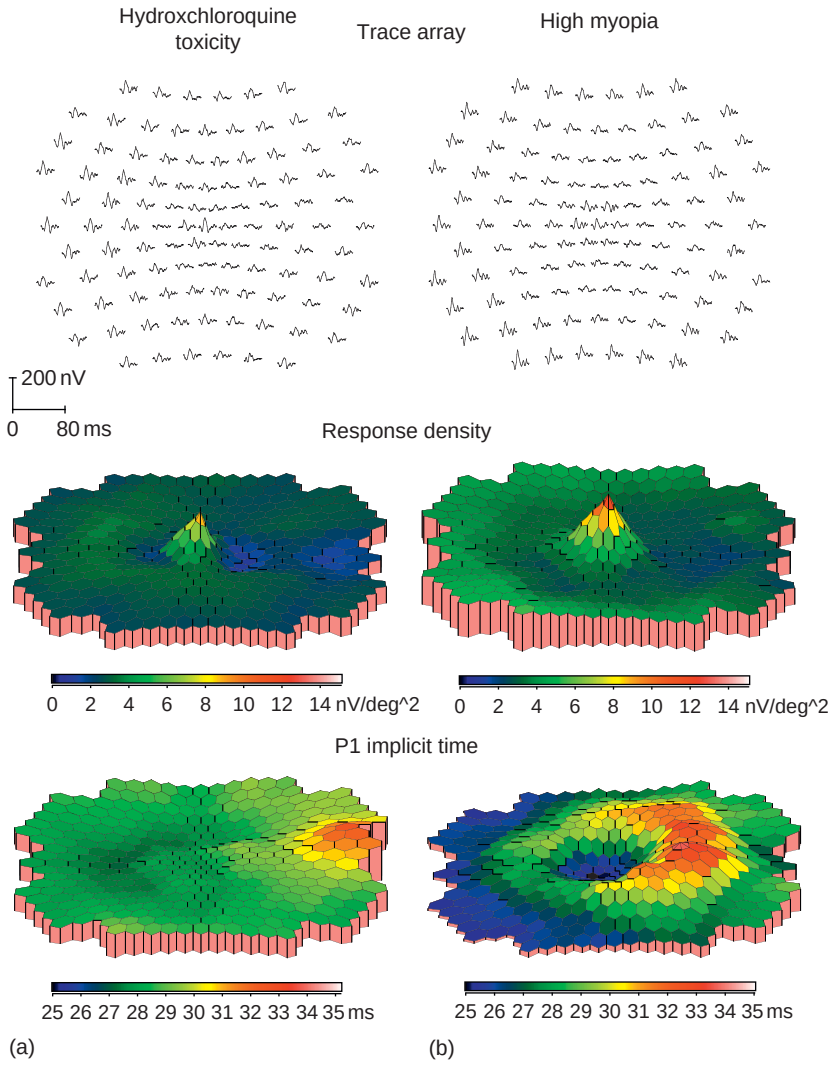

Figure 4 Column (a) shows a typical case of hydroxychloroquine toxicity. The characteristic peri-central amplitude loss is clearly seen in the trace array and the response density plot. The plot of *P*1 implicit time is normal suggesting inner retinal abnormalities. The enhancement in the area of the optic disc is due to scattered light and can be ignored. (b) a patient (high myopia) with a peri-central scotoma resembling hydroxychloroquine retinopathy. The increased implicit times in the depressed areas suggests a different pathogenesis, namely photoreceptor sensitivity loss. Plots of implicit time were needed to distinguish the two pathologies.

filtering could be applied to improve the quality of the focal waveforms as this would greatly reduce the small depression seen in the plot.

Another application of high-resolution central recording of this type is follow-up to macular hole surgery. OCT records document repair of structure, while the mfERG can be used to map recovery of function over time.

Applications to Neuro-Ophthalmology and Glaucoma

Some of the most important future clinical applications of multifocal electrophysiology are expected in the area of neuro-ophthalmology and glaucoma. The integrity of the optic pathway can be tested using the visual-evoked cortical response derived by means of electrodes placed over the visual cortex as schematically illustrated on the right in Figure 1. The response to contrast reversal of a check pattern has been shown to be most sensitive for the detection of conduction losses to the cortex. The introduction of the multifocal pattern visual-evoked response (mfVEP) raised hopes for objective visual field mapping. The main obstacle to this aim is found in the convoluted cortical anatomy onto which the visual field is mapped. Different patches in the visual field generate dipole signal sources of different orientations. Adequate coverage of the visual field requires at least two electrode pairs at perpendicular orientation as well as their sum and difference signals. Uniform coverage is not possible. Comparison

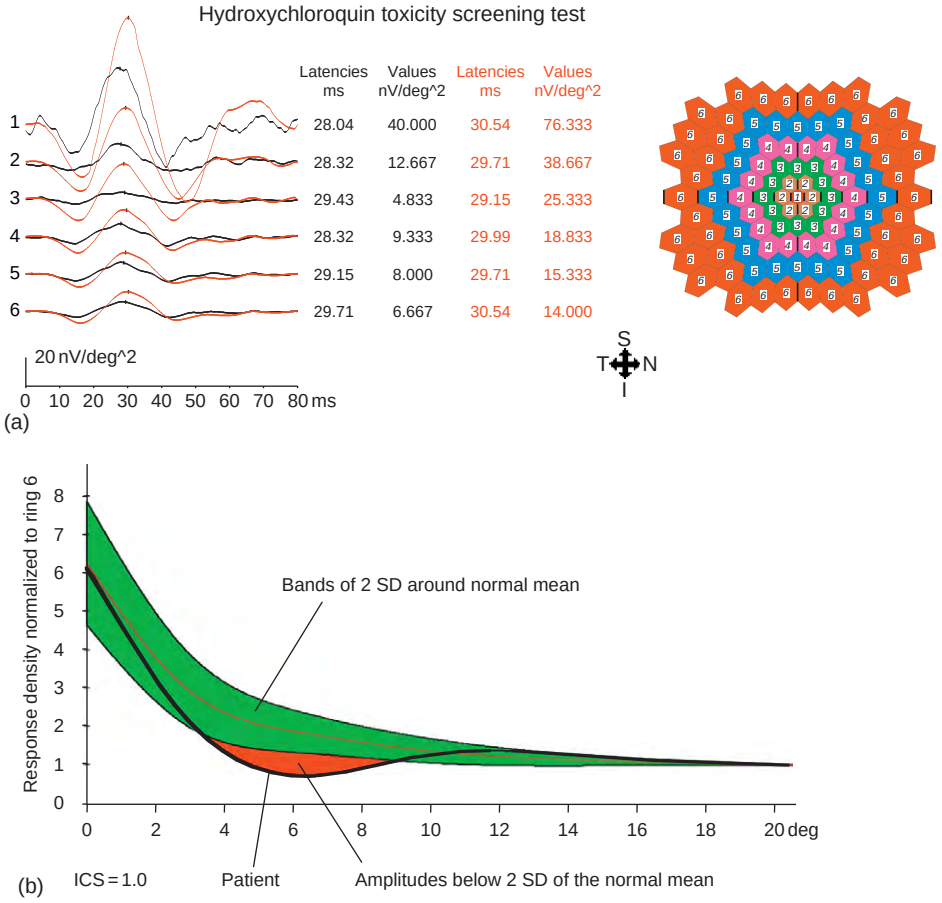

Figure 5 Automated statistical analysis for hydroxychloroquine toxicity screening. (a) responses in six rings for the patient (black) and the mean of 46 normal eyes (red). In (b), the amplitudes are plotted as a function of eccentricity. All data have been normalized to the outermost ring that is relatively unaffected in this condition. The ring averages of 5(a) are plotted as a function of eccentricity in degrees of visual angle with cubic spline interpolation. The green bands indicate 2-SD around the normal mean. The patient plot is in black.

with normative data is problematic due to the intersubject differences in the gross cortical anatomy. However, interocular comparison makes the mfVECP a powerful tool when the pathology is monocular or asymmetric between the eyes. Stimuli at corresponding locations in the visual field of the two eyes project to the same cortical patch and, in normal subjects, elicit virtually identical responses.

The cortical fold at the bottom of the calcarine fissure presents a problem that cannot be addressed with multiple electrodes. Sectors of the stimulus whose projections fall in this cortical area may wrap around the fold such that the same stimulus patch stimulates opposing surfaces of the sulcus generating mutually canceling dipole sources. This leads to characteristic signal dropout in the vicinity of the horizontal meridian. A substantial improvement was achieved by subdividing the sectors further and recording with 120 rather than 60 sectors. To compensate for resulting loss in signal to noise, the signal of each sector is averaged with a given percentage of the surrounding sectors after they have been brought to the same signal polarity. A typical plot of a trace array from a normal subject is shown in **Figure 8(a)**. Traces from the right eye are red, left eye traces blue. In this presentation, the position of the traces is not topographic. They are approximately equally spaced to best utilize the rectangular plot surface. The approximate eccentricities of the waveforms are indicated with black contour lines. The plot was derived from two perpendicular electrode placements, one from electrodes on the midline 4 cm apart and the other from electrodes 4 cm lateral to the inion on both sides. At each stimulus location, the signal-to-noise ratios of the two recorded channels and their sum and difference signals were compared and the best combination was selected. The pseudo-color topographic map of **Figure 8(b)** was derived from the same record. It graphically represents the local differences in response amplitude between the two eyes. The saturation of the color in each stimulus patch indicates the interocular difference while the amount of gray in each patch is a measure of uncertainty. It is derived from the noise level in the record. While some data can also be displayed in numeric form, this graphic representation permits us to capture

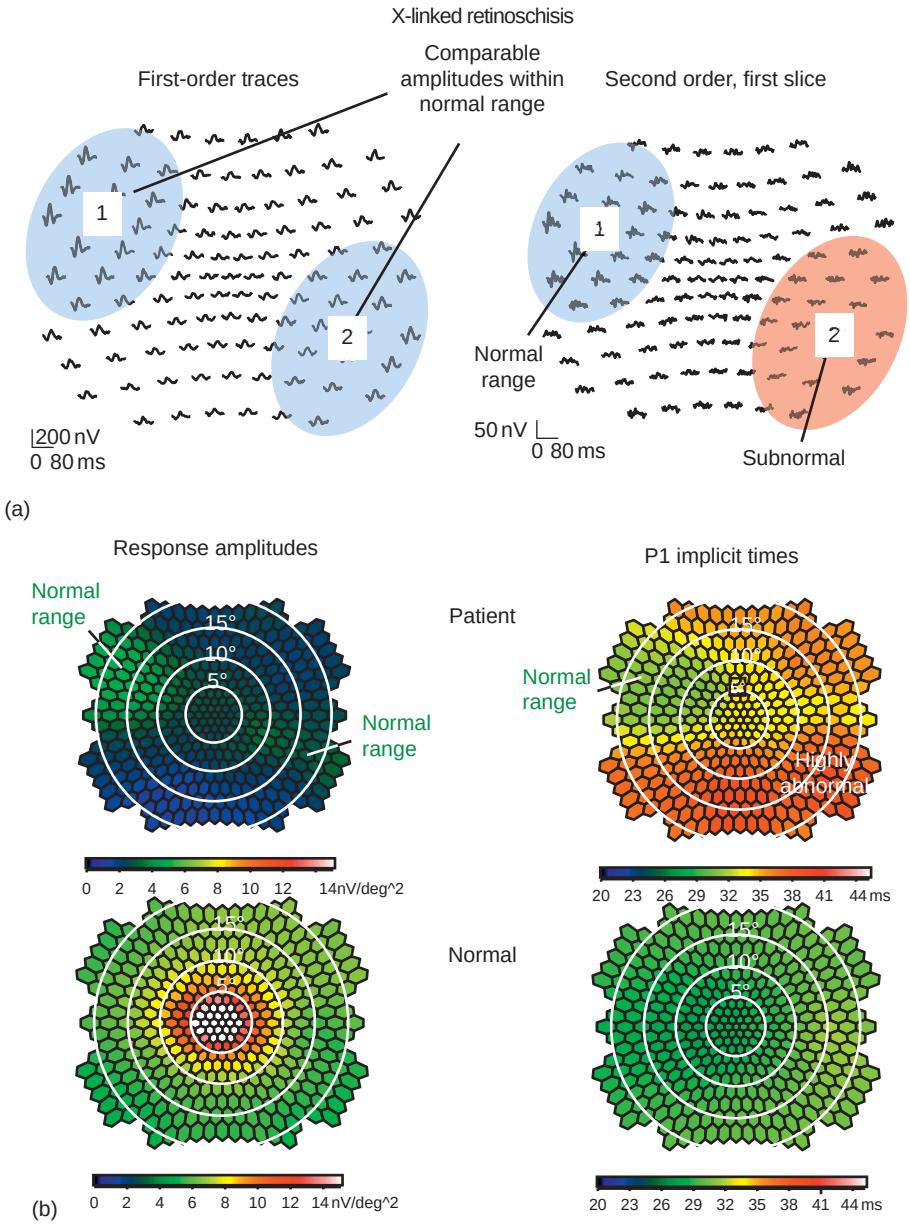

Figure 6 Record from right eye of a patient with x-linked juvenile retinoschisis. (a) The first-order traces show two areas with amplitudes within normal range. However, in area 2, the dominant second-order response contributions are almost completely extinct. (b) The response density plot shows two islands of relatively normal amplitudes. While the *P*1 implicit times are normal in area 1, they are highly abnormal in area 2.

the essence at a glance. Note that even in normal subjects, areas with small interocular differences in the peripheral areas are not unusual.

The mfVECP in Optic Neuritis

An obvious application of the mf VECP is in optic neuritis and multiple sclerosis. It is illustrated here with an example of acute optic neuritis. **Figure 9** shows mf VECP plots recorded in the acute phase and at 2-month intervals during recovery. In the acute phase, the responses within the central 3° of the affected eye are almost extinguished. The first follow-up record shows substantial recovery of amplitudes in this area, while increased implicit times indicate areas of demyelination. In the second follow-up record, the implicit times in the lower part of the fovea are back to normal, while in the upper field the delays persist.

Comparison of the mfVEP and the mf ERG in Optic Neuropathies and Glaucoma

It is well known that the ERG signal contains contributions from retinal ganglion cells and that losses of this cell population can, through a retrograde process, affect other

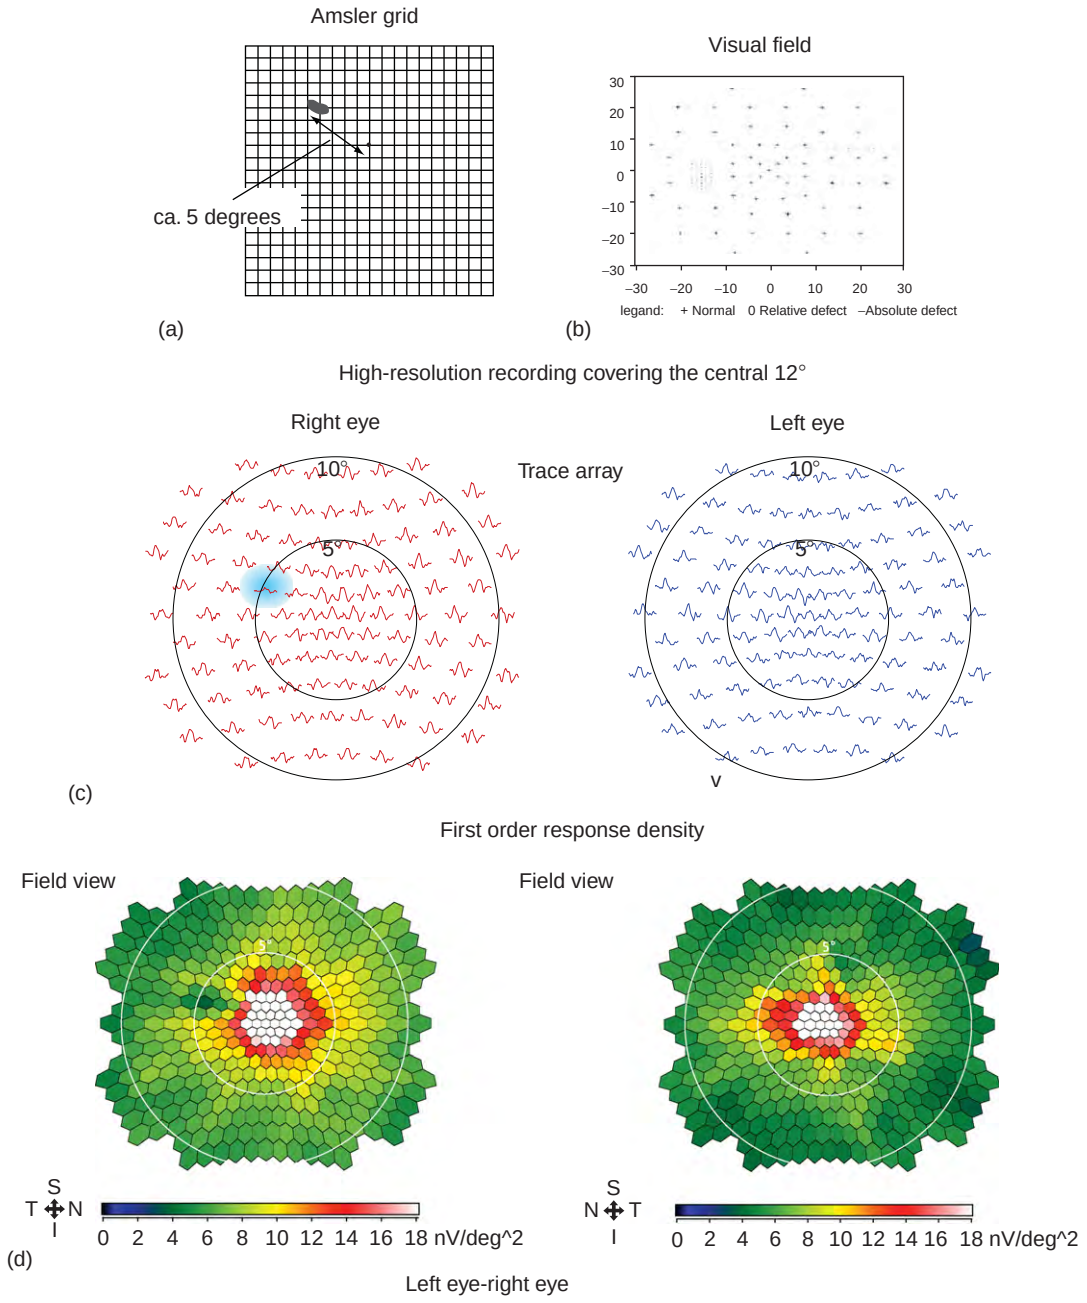

Figure 7 Patient complaining of a small scotoma not ophthalmoscopically visible or in the visual field. Patient draws it in the Amsler grid. A 7-min high resolution mfERG record reveals the dysfunctional patch objectively. (a) Amsler grid, (b) visual field, (c) trace arrays, (d) response density topography.

inner retinal response contributions. However, changes in the ERG signal are rather subtle and have proven difficult to detect in early stages of disease. The ganglion cell contributions to the ERG are small and overlap with signal contributions from other retinal sources, making their isolation and quantitative estimation extremely difficult. The discovery of the optic nerve head component (ONHC) of the ERG raised hope that isolation and mapping of ganglion cell function might become possible. The ONHC is a contribution from optic nerve fibers near the optic nerve head. Its generation is schematically illustrated in Figure 10. The contribution of the ONHC is delayed by the amount of time it takes action potentials to travel from the stimulated retinal patch to the nerve head. It is recognized by its timing, which varies depending on the length of the nerve fibers connecting the stimulus site with the disc. Possible mechanisms for its generation are the sharp bend in the axons where they descend into the cup, the beginning of myelination near the lamina cribrosa and conductive changes in the extracellular

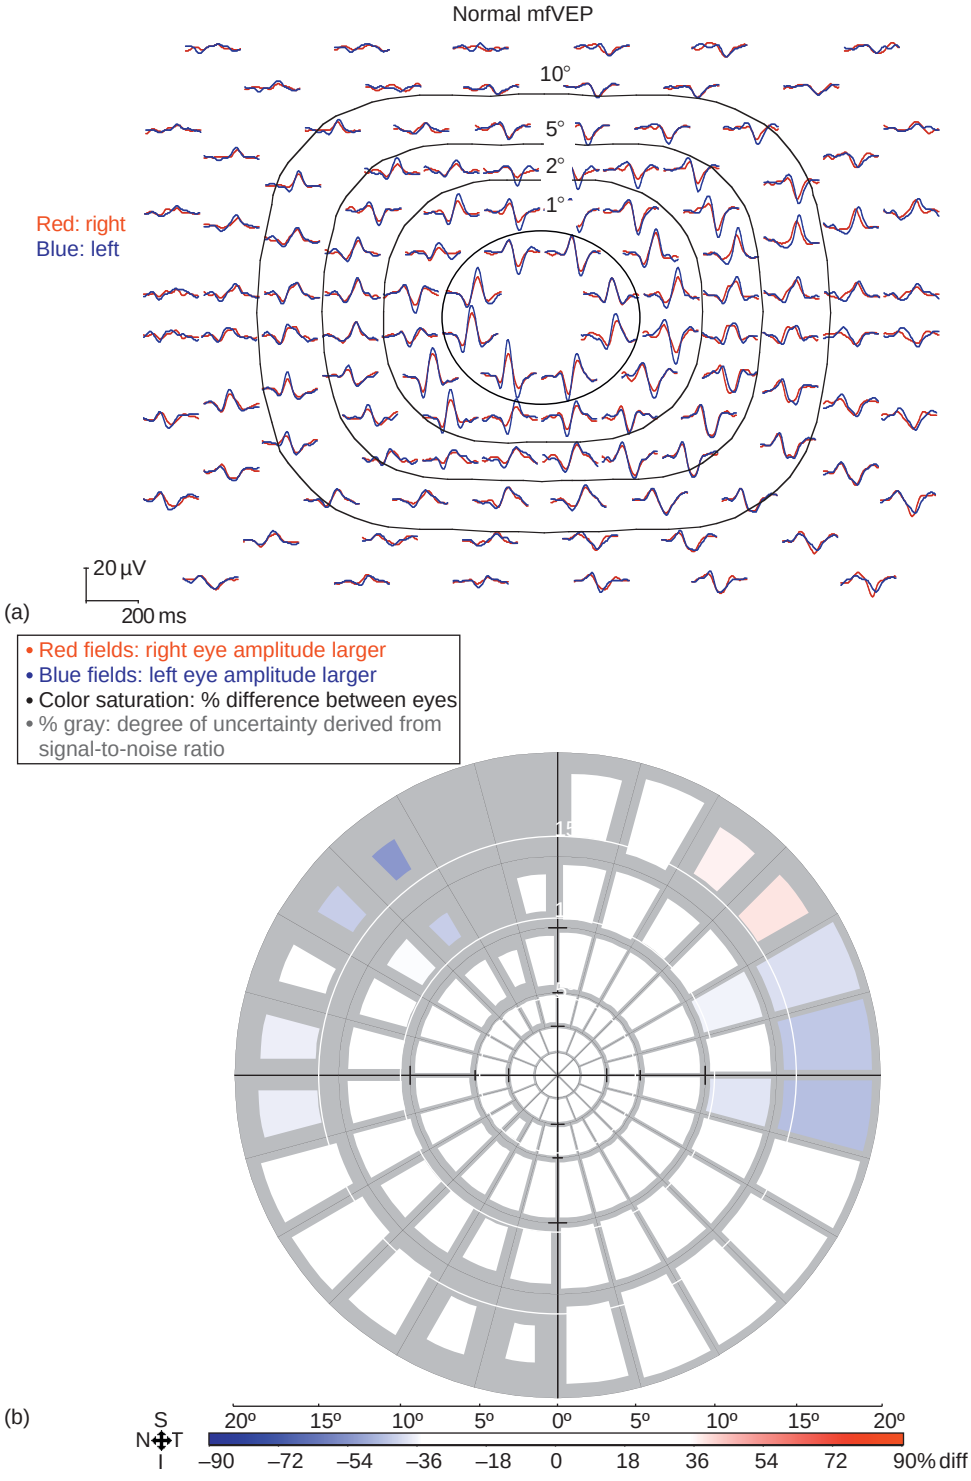

Figure 8 MfVEP of a normal subject. (a) interocular comparison of response traces: right eye red, left eye blue. The distribution of the traces is not topographic but has been arranged for best presentation of the traces in the rectangular plot area. Approximate eccentricities are indicated. (b) Pseudocolor topographic map of interocular differences.

medium. The observation that it can disappear in demyelinating disease while cortical responses are preserved, strongly points toward the transition from membrane conduction to saltatory conduction at the point where myelination begins as the main source of this signal. While mfVEP amplitudes are affected by the cortical anatomy, ONHC amplitudes directly reflect function. Their local evaluation does not require interocular response

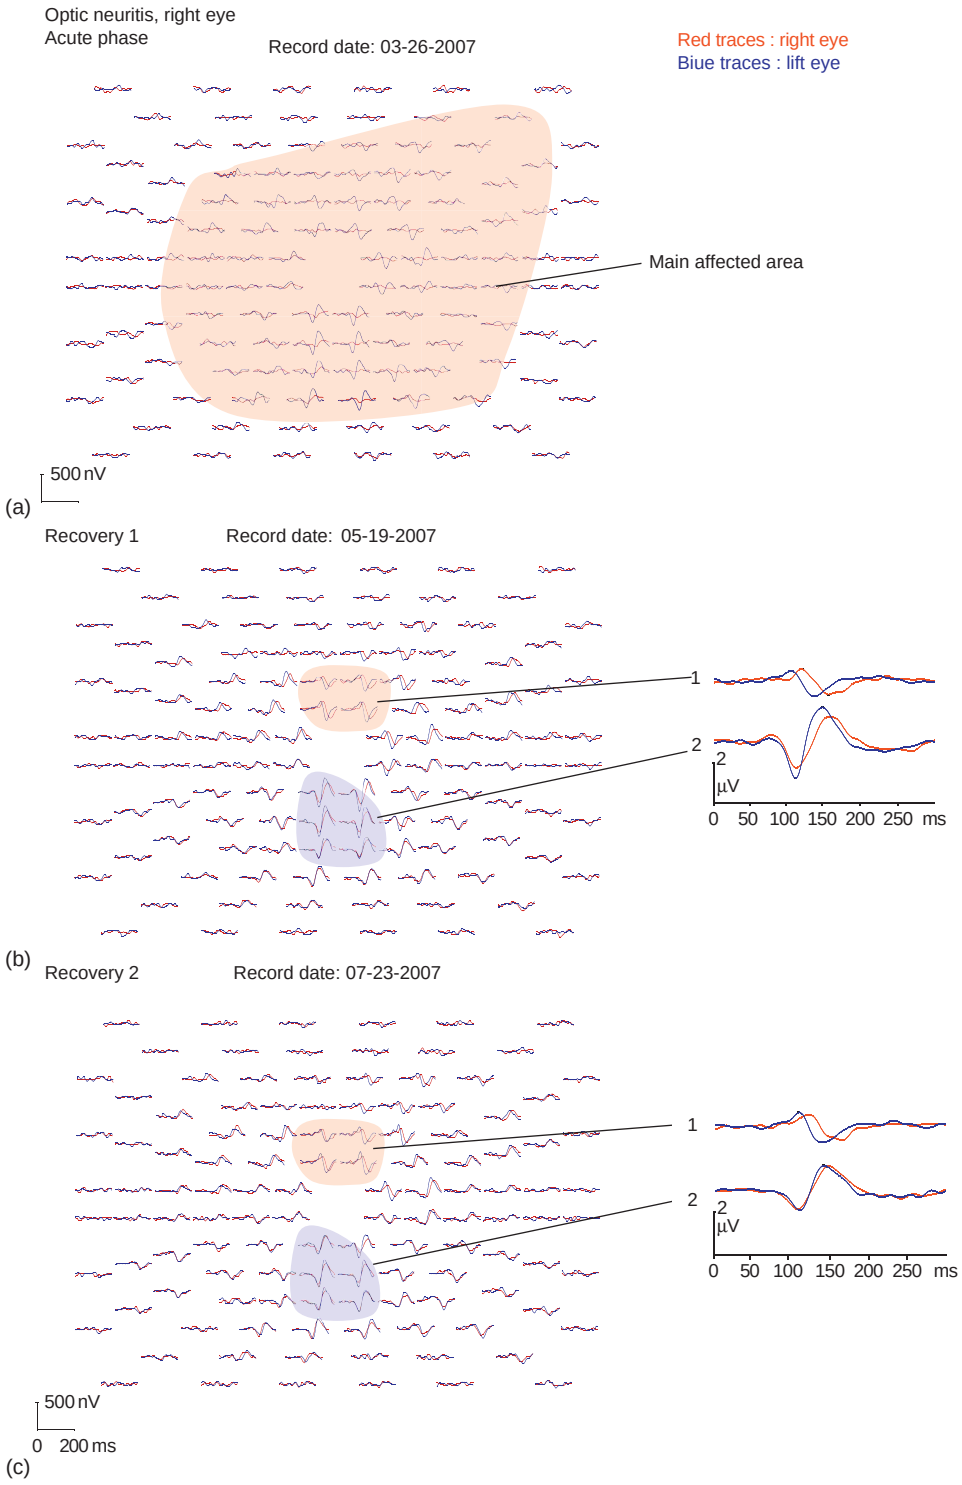

Figure 9 MfVEPs of a patient with optic neuritis. (a) during the acute phase: The red shading indicates the affected area. (b) After 2 months recovery: Amplitudes have largely recovered, but increased implicit times in the central area indicated demyelination. (c) After 4 months recovery: delays in the lower field have largely disappeared while those in the upper field remain.

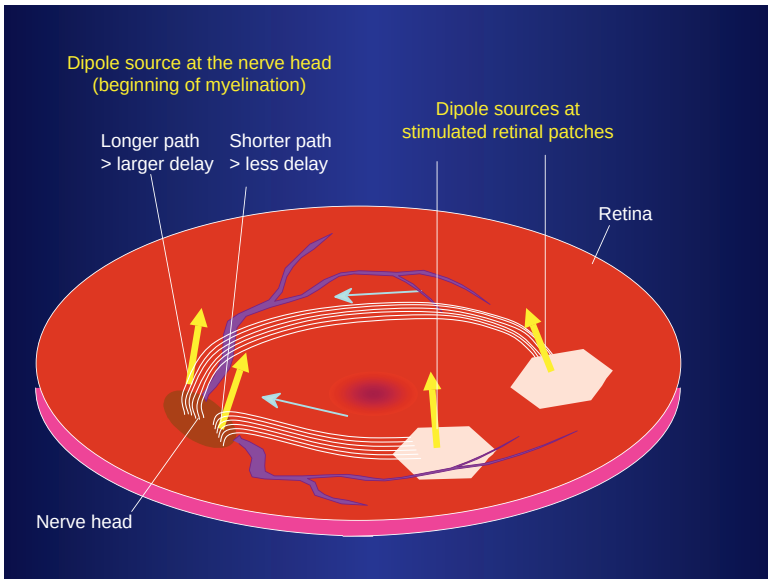
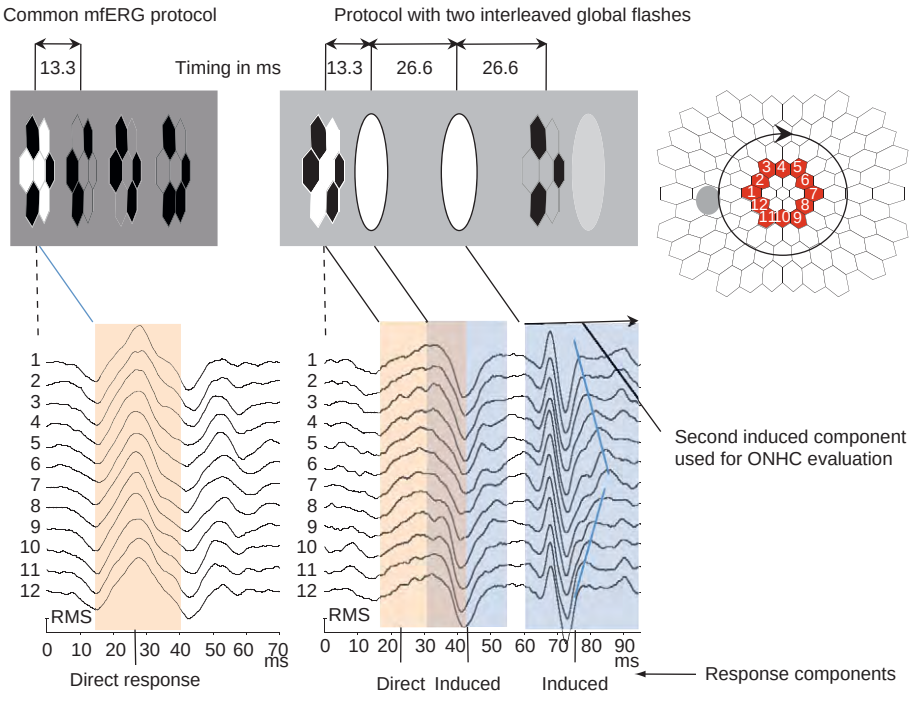
comparison. In bilateral disease, the ONHC, thus, promises to be more reliable than the mfVECP.

In records collected with the commonly used mfERG protocol, the ONHC is too small to be evaluated (**Figure10(b)** left). The traces are from a ring around the fovea starting from the area near the nerve head, proceeding through the upper field and returning through the lower field (insert on the right). The contributions



(a)



(b)

Figure 10 (a) This is a schematic illustration explaining the generation in the optic nerve head component (ONHC). Two signal sources are thought to contribute to the signal derived from the cornea, one from the stimulated retinal area and the second from the location in the nerve fibers where myelination begins. The latter is delayed relative to the retinal response by travel time of action potential from the stimulation site to the nerve head. It is recognized by this location-dependent delay. (b) Enhancement of the ONHC through the global flash paradigm. (Top) Schematic comparison of the stimulation used in the common m-sequence protocol on the left and the interleaved global flash protocol on the right. (Bottom) First-order traces derived from a normal subject: left, common protocol; and right, global flash protocol. The traces are from a ring around the fovea (insert on right) starting from the vicinity of the nerve head. The thin blue lines indicate the main feature of the ONHC contribution. The second induced component, epoch 60–90 ms, is normally used for visual evaluation.

from the ONHC should thus increase in implicit time to trace 7 and then decrease again. A stimulation protocol is now available that greatly enhances the ONHC as well as inner retinal response contributions. The protocol uses global flashes interleaved at specific intervals between the multifocal stimuli. The principle is illustrated on the right in Figure 10(b). The ONHC is now readily recognized. It consists of those features in the waveforms that shift

to longer implicit times with increasing distance of the stimulus patch from the nerve head. Its main peak is indicated with a thin blue line.

The ONHC can be visually evaluated when traces on rings around the fovea are plotted in vertical columns. A plot of this kind from a normal subject is shown in Figure 11(a). Traces in each ring are plotted starting from the patch nearest the disk, proceeding through the upper field and returning through the lower field.

The delays of the ONHC relative to the retinal contributions to the ERG are known. Propagation velocity of action potentials in the unmyelinated nerve fiber layer is determined by the fiber diameter and varies little between subjects. Aligning the traces to the ONHC before applying some spatial filtering further enhances its visibility and our ability to evaluate it by visual inspection. It is now seen as a vertical ridge in the columns of Figure 11(b).

Until an algorithm for estimation of the ONHC that performs better than a visual evaluation becomes available, the ONHC is mapped and scored as follows: using the computer mouse, traces are marked pink for moderately deficient and red for severely deficient in the ONHC. The corresponding areas automatically appear pink and red in the topographic insert below together with a numeric score (see example of Figure 12).

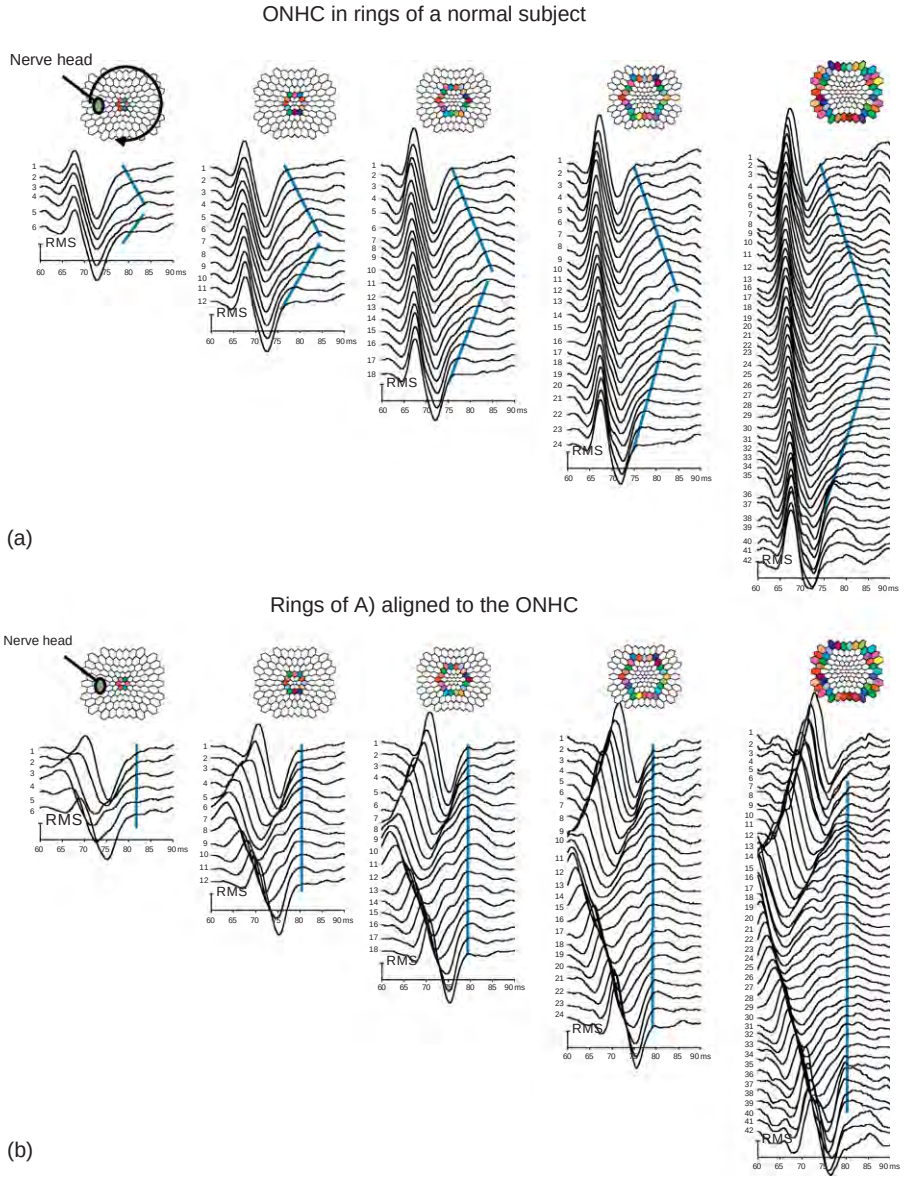


Figure 11 (a) Plots for visual evaluation of the ONHC. Traces on rings around the fovea are plotted in columns. Each ring begins on the side of the optic nerve head, proceeds through the upper field and returns through the lower field. (b) To enhance the appearance of the ONHC, the traces are aligned to ONHC implicit times.

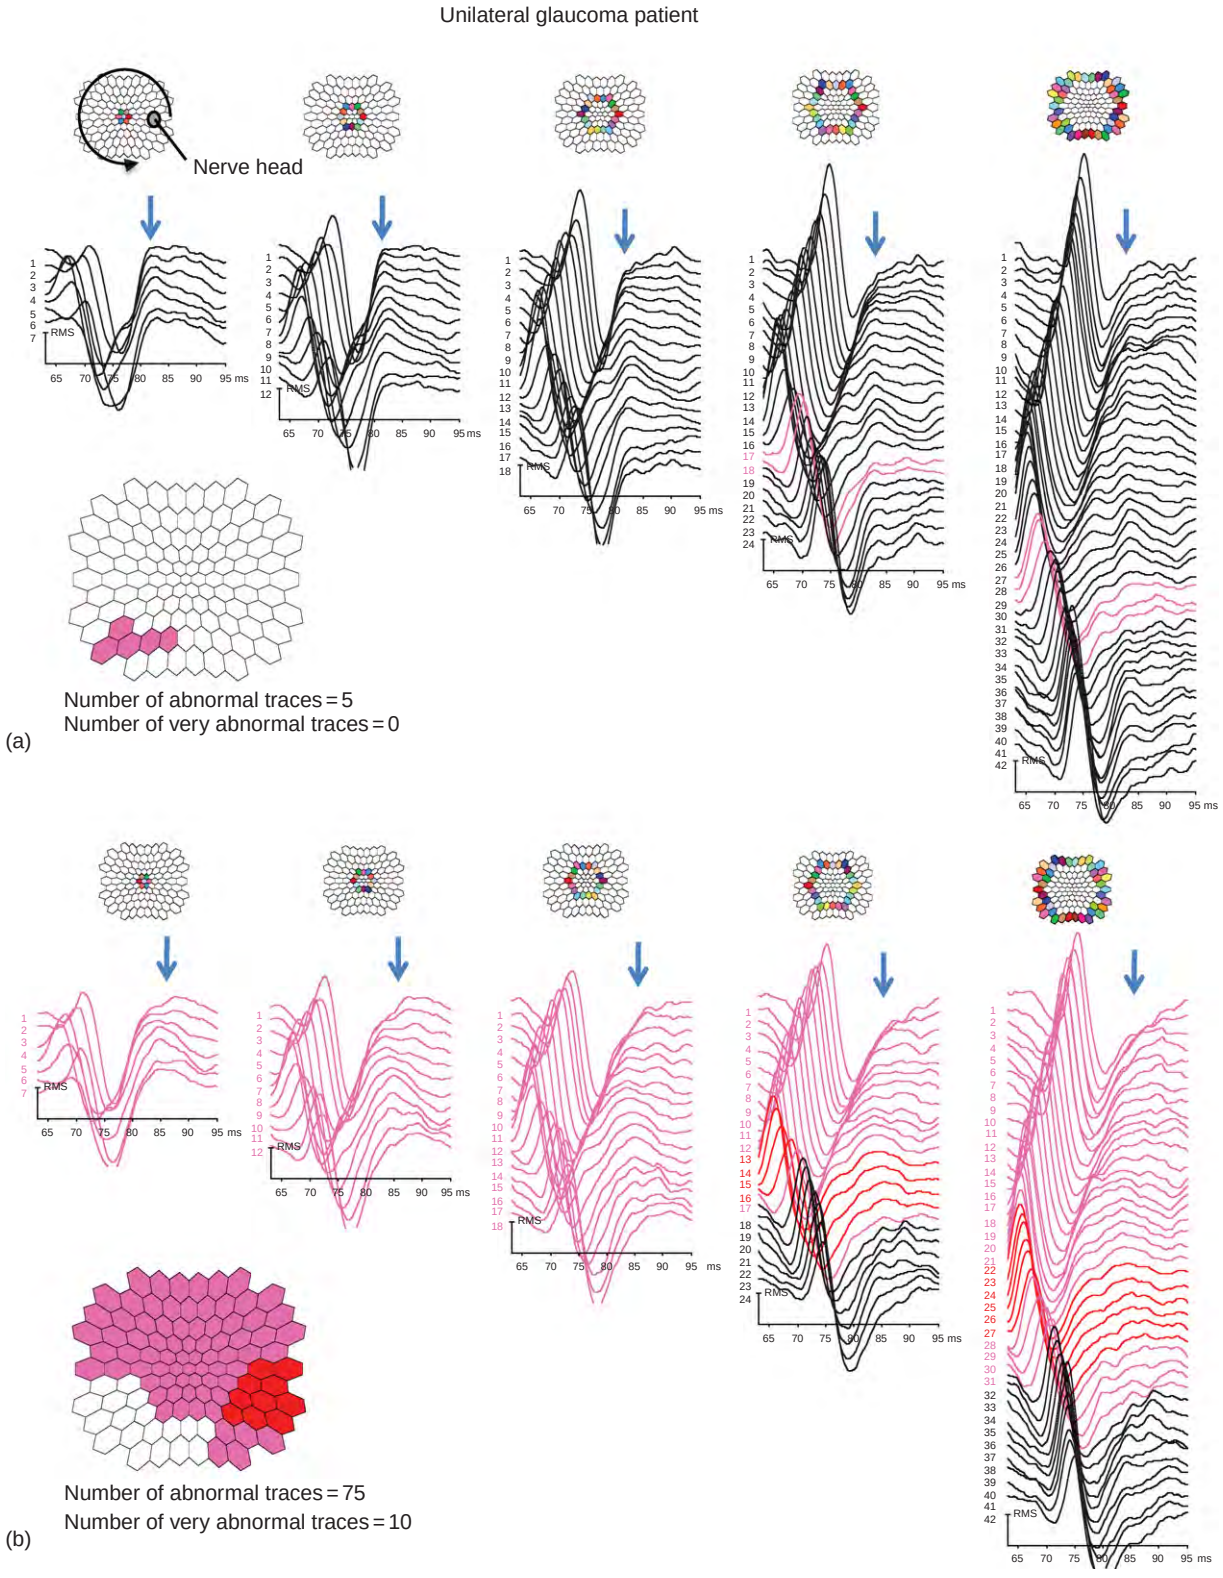

Figure 12 ONHC plots of the patient in **Figure 13**. (a) Unaffected right eye. The ridge from the ONHC contribution indicated with blue arrows is clearly visible and appears normal in most areas; (b) The ONHC ridge has largely disappeared. A residue is visible in the lower field.

Comparison of the mfVEP and the ONHC of the mf ERG in an Asymmetric Glaucoma Patient

To illustrate the performance of currently available electrophysiological function tests, a highly asymmetric glaucoma patient was selected. In Figure 13(a), the mfVEP trace arrays of the two eyes are compared. Figure 13(b) shows an automated topographic analysis of the same data set. The color of the field indicates the eye with the larger response, red for right, and blue for left. The color saturation indicates the percent difference in response amplitude

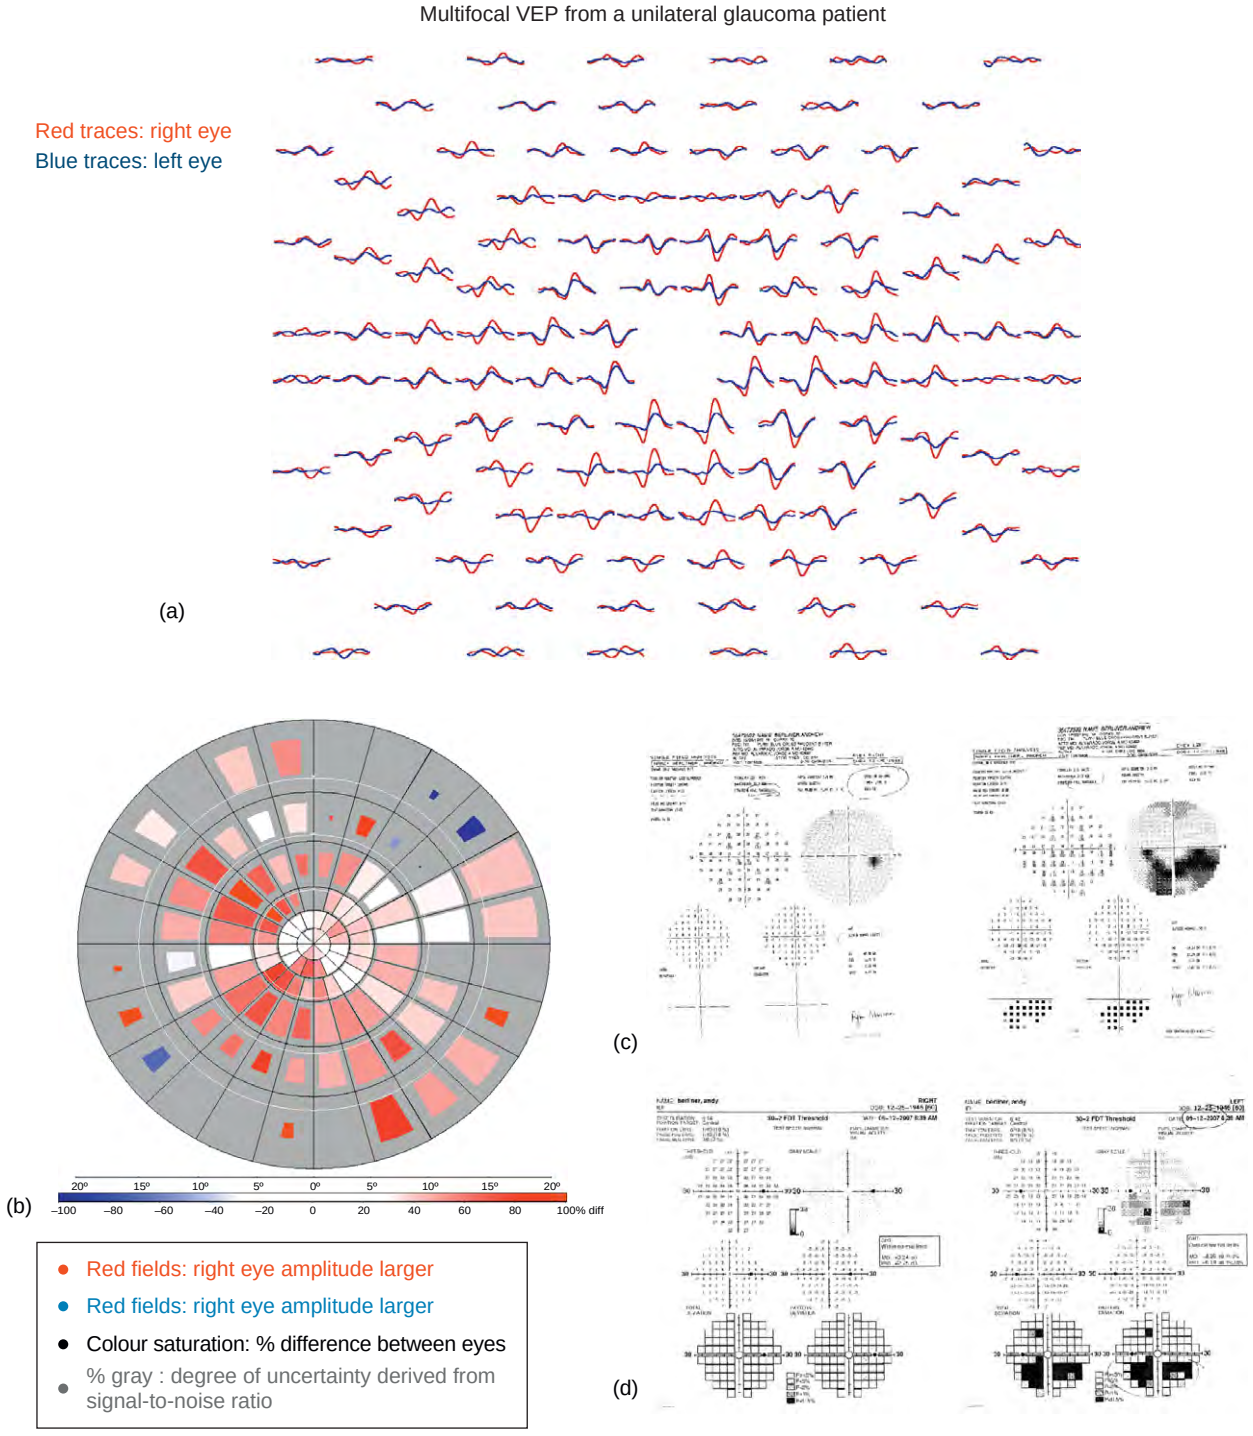

Figure 13 The mfVEP of an asymmetric glaucoma patient: (a) trace arrays of the two eyes; (b) topographic representation of interocular differences shows areas with response deficit in the left eye; (c) visual fields; and (d) perimetry using frequency-doubling technology (FDT) maps for comparison.

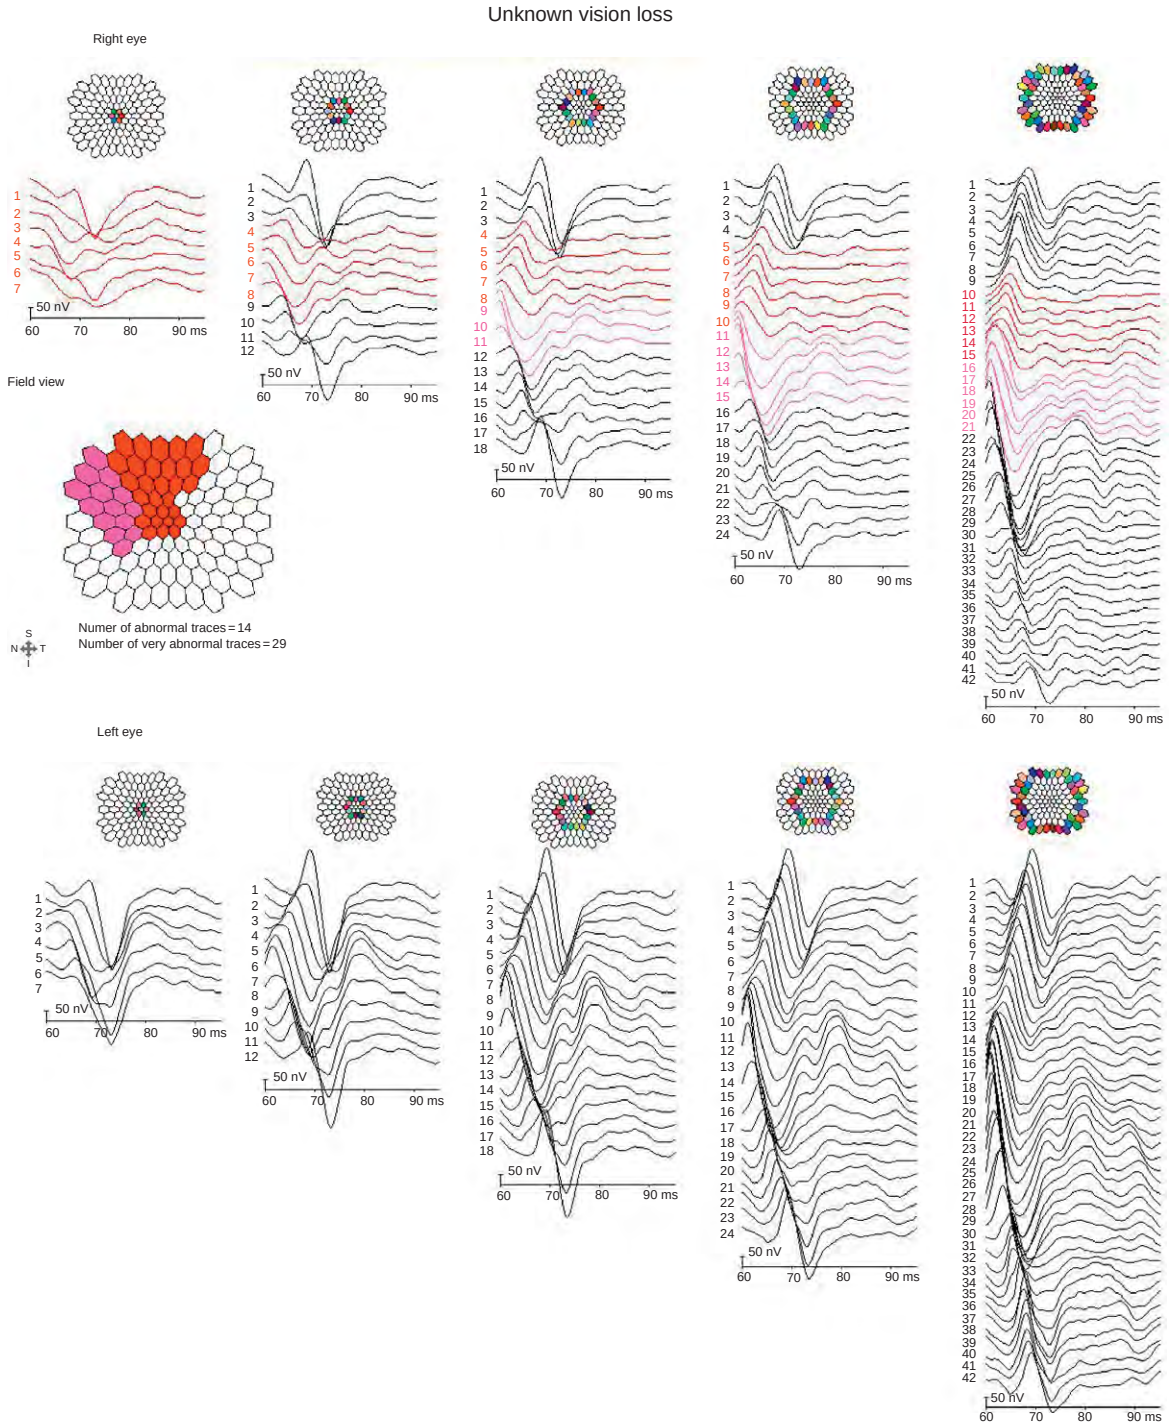

Figure 14 ONHC plots of a person with unknown vision loss. The complete disappearance of the ONHC in areas of the right eye is not consistent with the full visual field (not shown). Conclusion: The disappearance is due to loss of the transition from unmyelinated to myelinated fiber through retrolaminar demyelination rather than conduction loss.

between the eyes. The percentage of gray in each field represents the uncertainty in the estimate based on the signal-to-noise ratio in the record. The numeric version of the plot is not shown here. The inserts (c) and (d) show the visual field and the field mapped with the frequency-doubling technique (FDT) for comparison. **Figure 12(a)** and **12(b)** show the ONHC analysis of the mfERG for the two eyes of the same subject. Traces judged deficient in the ONHC are marked pink or red by the operator depending on the degree of abnormality. The corresponding stimulus areas are marked in the same color in the inset below.

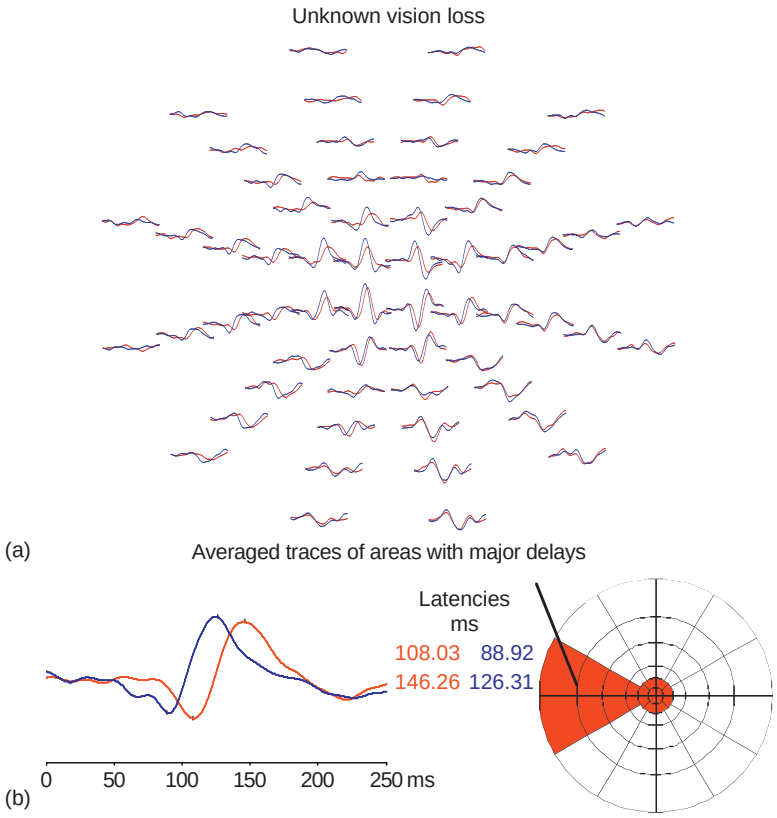

Figure 15 The conclusion from **Figure 14** is confirmed with an mfVEP. In the right eye, we find areas with substantial delays.

Both, the mfVECP and the ONHC data show more extensive losses than the two psychophysical function tests. In such highly asymmetric cases, the mfVECP can be a very sensitive test. It becomes more problematic when both eyes are affected. The ONHC, on the other hand, does not require interocular comparison.

Patient with Unknown Vision Loss

A 53-year-old male patient noticed blurring in his right eye. His visual acuity was V/A 20/30 on the right and 20/20 on the left. Visual fields were normal in both eyes. The common first-order response is somewhat lower in the right eye, but its topographic distribution is within normal range (not shown). The ONHC, on the other hand, is highly abnormal in the right eye, particularly in the center and in some portions of the upper field and completely absent in some areas (**Figure (14)**). The left eye is within normal range. The gross abnormalities in the ONHC are not consistent with the normal visual fields of the patient (not shown). This finding could, therefore, not be attributed to loss of nerve conduction. It could, however be explained by retrolaminar demyelination eliminating the source of the ONHC. This reasoning led to the mfVEP records shown in **Figure 15**. In the right eye, the responses are indeed substantially delayed in the areas with an abnormal ONHC confirming local demyelination. This case is interesting as electrophysiology led to the diagnosis of a patient not suspected of demyelinating disease.

Note that the ONHC is abnormal in some cases of optic neuritis even when substantial cortical delays are observed but not in others. In the above example, there are large cortical delays in areas where the ONHC is preserved. In the case of acute optic neuritis (**Figure 9**), the ONHC was judged within normal range in both eyes. In combination, the three tests (common mfERG, ONHC, and mfVEP protocols) allow us often to localize a dysfunction along the visual pathway.

Summary and Conclusion

Multifocal electrophysiology is not a single tool, but rather a collection of tools. Stimulation and analysis protocols can be optimized for specific clinical applications such as diabetes, AMD, optic neuropathies, etc. Much can still be done to shorten the tests and improve their efficiency. The protocols can be semiautomated to make clinical testing easy. However, the tools have to be paired with the expertise necessary to select the proper tool for each case and interpret the data.

There is a great deal of information contained in multifocal records that is only partially understood and still largely unexploited. Combining tests of function and structure promises to advance the understanding of both types of data and the pathogenesis of diseases. A case in point is the example of x-linked retinoschisis shown in **Figure 6**. The availability of OCT data on the different areas of the retina might have greatly helped our understanding of the connection between function and stricture in this and other similar cases.

Normal Age-Related Changes: Crystallin Modifications, Lens Hardening

P Wilmarth, L David, and K Lampi, Oregon Health and Science University, Portland, OR, USA

Glossary

Cataract – A clouding of the eye lens.
Cortex – The outer, soft lens material just inside the capsule.
Crystallins – The major structural proteins in the lens.
Deamidation – Loss of a tertiary amino group on glutamine or asparagines resulting in a carboxyl group and conversion to the corresponding acid.
Disulfide bonds – Oxidation of two cysteine residues resulting in a linkage between them.
Methylation – Addition (+14 Da) of a methyl group to an amino acid residue.
Nucleus – The inner, harder portion of the lens which has several layers.
Oxidation – Addition (+16 Da) of an oxygen atom to an amino acid residue.
Posttranslational modification (PTM) – A chemical or enzymatic alteration to amino acids in proteins that occurs after translation.
Presbyopia – Age-related problem with near vision.
Proteomics – The large-scale identification and quantification of proteins, and the effects of their modifications, interactions, and activities.
Truncation – Proteolytic or spontaneous cleavage of a protein's peptide backbone.

Introduction

The human lens is an avascular, clear tissue with unique protein composition and cellular organization. The bulk of the lens is comprised of terminally differentiated, elongated cells, called lens fiber cells. The most recently synthesized fiber cells are located in the outer (cortical) region of the lens and increasingly older fiber cells are located in the center (nuclear) region. As they mature during normal aging, fiber cells lose their ability to turnover and synthesize new proteins. Consequently, lens proteins persist for the life of the organism. They gradually become modified during aging with the greatest accumulation of modified proteins in the nuclear region. Protein modifications are thought to play major roles in presbyopia, the loss of the ability to focus on nearby objects, and age-related nuclear cataract.

The major proteins in the lens cytosol are called crystallins. Three major groups of crystallins exist in mammalian lenses – α-, β-, and γ-crystallins. α-Crystallins belong to the small heat shock family of proteins, form aggregates of approximately 800 000 Da molecular weight, and are composed of two types of subunits with molecular weights near 20 000 Da. Members of the β/γ-crystallin family contain a highly conserved tertiary structure made up of four Greek key motifs. They have subunit molecular weights ranging from 21 000 to 28 000 Da, due to variations in the length of their N- and C-terminal extensions. While the β-crystallin family forms aggregates containing from 2 to 8 subunits, the γ-crystallins remain as monomers. In young human lenses the major crystallin subunits have been identified as αA, αB, βA1, βA3, βA4, βB1, βB2, βB3, γC, γD, and γS.

Lens crystallins undergo extensive posttranslational modification as the lens ages, with the greatest abundance of modifications in the central nuclear region that contains some of the oldest proteins in the body. Modifications were first detected following protein separations using sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and isoelectric focusing. The earliest modifications observed were the truncations of β-crystallin extensions and an increase in acidic species, presumably due to deamidation. Once complete amino acid sequences for the crystallins had been determined, advances in separation and mass spectrometry techniques could be employed to identify specific crystallins and their sites of modifications.

The plasma membranes of fiber cells also have unique compositions. The dominant membrane protein is a water channel, aquaporin 0, expressed only in lens tissue. Aquaporin 0 undergoes a variety of modifications associated with aging and location within the lens. Lens membrane proteins are difficult to work with and little is known about how their functions change with age and whether they have a role in loss of transparency. In middle age, a barrier to diffusion forms that reduces the flow of nutrients and antioxidants to the nuclear region of the lens. This barrier has been suggested to be a precursor to age-related nuclear cataract formation.

Characterization of Lens Posttranslational Modifications

The techniques available to characterize proteins and their posttranslational modifications (PTMs) have changed

dramatically in the past 1–2 decades, as have the design and scale of lens PTM studies. Mass spectrometry has emerged as the method of choice for detecting and localizing PTMs in proteins. Early techniques relied on protein separations and purifications, and reported results were often devoted to a particular crystallin or crystallin family. Mass spectrometry was employed in these early studies to identify types of modifications and localize many of them to specific sites. However, lengthy protein separations may introduce protein modifications and enrich or deplete modified protein forms, possibly biasing the results.

Separations of intact lens protein mixtures by two-dimensional gel electrophoresis (2-DE) have been used frequently in studies of modifications that changed protein isoelectric points (phosphorylation, acetylation, deamidation, etc.) or molecular weight (proteolysis, alternative splicing, cross-linking, etc.). Mass spectrometry in combination with 2-DE allowed definitive protein identifications but frequently failed to localize sites of modifications in less abundant protein forms. The increasing sample complexity of aged lens proteins and their decreasing solubility limit the applicability of 2-DE in advanced age and cataractous lenses. It is not known to what extent 2-DE selects for different soluble protein forms. Proper controls are required to identify artifactual modifications, such as oxidized methionine, that are by-products of 2-DE.

More recently, complex mixture analyses of enzymatic digests of lens tissue have been used to perform large-scale PTM mapping for the first time. This bottom-up technique relies on the separation power and automation of modern liquid chromatography/mass spectrometer systems. Very complicated peptide mixtures can be separated by multidimensional liquid chromatography and the peptides sequenced by tandem mass spectrometry to identify proteins and localize sites of PTMs. This technique has been used in many recent large-scale studies of aged and cataractous lenses and has provided a truly global perspective on lens PTM changes. Recent advances in analysis of PTMs using tandem mass spectrometry have identified a large number of common *in vitro* sample processing artifacts which may have been incorrectly attributed to *in vivo* modifications in early studies. However, by using young lenses as controls, it is possible to discover which modifications are truly associated with lens aging and loss of protein solubility.

The newest application of mass spectrometry to lens research is using high mass accuracy and resolution to characterize intact protein mixtures without enzymatic digestion to peptides. This top-down approach has the potential to identify truncated protein forms, alternatively spliced proteins, and characterize PTMs. It has been used with great success in studies of histone modifications where whole protein purifications were possible. Current technology requires relatively low sample complexity, but water-soluble whole lens proteins, without separation, have been successfully studied using Fourier transform-ion cyclotron resonance mass spectrometry instrumentation. It will be interesting to see if limitations, such as increased protein heterogeneity with age or poor protein solubility in mass spectrometry compatible buffers, can be overcome.

Summary of Early PTM Studies

Modifications of αA and αB that have been reported include truncation of the C-terminal residues, deamidation of asparagine and glutamine residues to aspartic and glutamic acid, respectively, disulfide bond formation, oxidation of methionine and tryptophan residues, and phosphorylation of serine and threonine residues. Extensive racemization and isomerization of aspartate and asparagine residues in αA and αB also occur.

Early studies of human β- and γ-crystallins reported losses of β- and γ-subunits during aging and accumulation of more-acidic protein forms. Human βB1 and βA3/A1 are initially cleaved on their N-terminal extension with more extensive truncations occurring during aging. Forms of these proteins missing portions of their N-terminal extensions have been detected in human lenses of less than 1 year of age and may be associated more with maturation of the lens cells than with aging. The 2-DE patterns of protein from different lenses suggested that the concentration of truncated β-crystallins increased with age and that more truncated forms were localized in the more mature nuclear fibers of the lens. The acidic isoelectric points (pIs) of these truncated β-crystallins also suggested that they had undergone deamidation. The γ-crystallins are also extensively modified by deamidation and the formation of disulfide bonds.

These early studies established that the major modifications that occur in lens with age are N- and C-terminal truncations, deamidation (and associated isomerization/racemization), oxidation, possible disulfide bond formation, and phosphorylation. Available techniques allowed a relatively small number of specific PTM sites to be determined and quantitative information was generally lacking. Recent advances in proteomic techniques have allowed global PTM mapping in the lens and semiquantitative estimates of PTM abundances.

Review of Identified and Localized Lens PTMs

With the advent of biological mass spectrometry, advanced instrumentation, and sophisticated data analysis techniques, unambiguous identification and assignment of PTMs to specific lens protein sites can be performed. This article focuses on human lens modifications that have been localized to specific sites in lens proteins.

We also discuss which modifications are present *in vivo* and which modifications have the strongest correlations with aging. Most of the reported human lens PTM sites have been to the major crystallins. Lens membrane proteins, the beaded filament proteins filensin and phakinin, and many additional minor lens proteins have not received much attention. We limit our review to crystallins, although these other proteins are also likely involved in lens aging changes. Lastly, recent results probing the functional significance of some of these lens modifications will be discussed.

There are over 310 crystallin PTM sites that have been reported so far. A chart of the frequency of reported crystallin modifications is shown in **Figure 1**. Deamidation and oxidation have the largest numbers of reported sites followed by a gradual decrease for the remaining modifications. **Table 1** lists the reported modification sites in human lens crystallins for deamidation, methylation, oxidation, acetylation, and phosphorylation. Sites that have been reported in more than one study are highlighted in bold. We can draw a few conclusions from the patterns in the table. First, specific modifications are often present in multiple crystallins and at multiple sites. This supports the premise that mature fiber cells have few enzymatic processes and the modifications are probably chemically induced. Second, there are many deamidated asparagine and oxidized methionine residues that could have occurred during sample processing. Which modification sites truly occur *in vivo* and are associated with aging?

According to Wilmarth and colleagues, the technique of spectral counting was used to estimate the relative abundance of PTM sites and compare a young control lens to three aged lenses to identify sites that were more abundantly modified in the aged lens. This novel, unrestricted PTM searching strategy also clearly identified a wide variety of artifactual modifications caused by sample processing or electrospray ionization (such as in-source fragmentation, neutral loss of water and ammonia, N-terminal cyclization reactions, N-terminal carbamylation, deamidation, and oxidation). Comparative analysis of the young versus aged lenses identified carbamylation, deamidation, and oxidation sites that were likely to have occurred during sample processing, as these were present at both ages. Lens proteins were separated into water-soluble and water-insoluble fractions to identify which specific *in vivo* modifications could result in loss of crystallin solubility, a likely precursor to loss of lens protein function. Spectral count data taken from **Table 1** in Wilmarth *et al.* is presented in **Figure 2**. It is easy to see from the plot that deamidation is, by far, the most prevalent modification in aged human lens. It is also clear that no other type of modification, except deamidation, significantly increased in abundance with loss of crystallin solubility. The next sections will discuss these types of modifications and their possible roles in lens aging and loss of function.

Deamidation

Excluding the minor crystallins, βA2 and γB, there are 56 asparagines in the crystallins and 39 have been reported as deamidation sites (70%). Similarly, there are 111 glutamines, with 66 reported deamidations (59%). Surface accessibility, neighboring residues, and the three-dimensional structure all influence the rates of deamidation. To identify the sites that are detrimental to lens function, comparative quantitative studies will be required. Deamidation is expected to be faster for asparagine than glutamine and can occur during sample handling. Proper controls, such as comparison of modifications in old lenses with those in young lenses, with crystallin proteins expressed *in vitro*, or with synthetic peptides processed under identical conditions, are needed to ensure that deamidation sites in aged tissues accurately represent those present in the tissue *in vivo*.

As can be seen in **Figures 1** and **2** deamidation was the most prevalent modification in aged human lenses. Over 25 deamidation sites were found at higher frequency in the insoluble proteins than the soluble proteins, suggesting an association between deamidation and insolubilization.

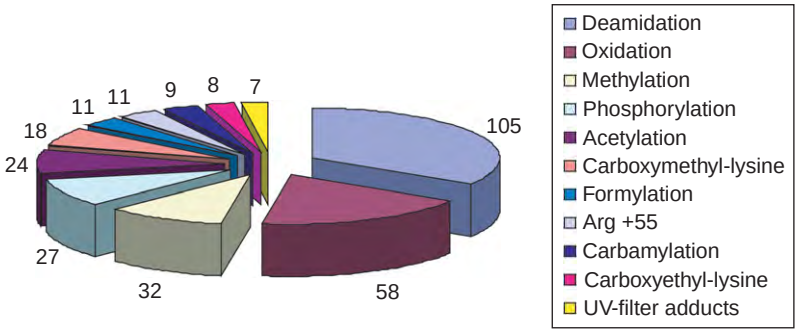

Figure 1 Frequency of reported human lens crystallin PTMs by modification type for 312 reported sites. Kynurenine-based UV filters can form unstable chemical species, react with lens proteins, and may contribute to coloration of aged lenses. The reported modification mass shifts of +28, +58, and +72 Da have been tentatively assigned to formylation, carboxymethyl lysine, and carboxyethyl lysine, respectively.

Table 1 Summary of reported posttranslational modification sites in human lens crystallin proteins for five common modifications

Crystallin	*Deamidation*	*Methylation*	*Oxidation*	*Acetylation*	*Phosphorylation*
Alpha A	**Q6, Q50, Q90, N101, Q104, N123, Q126, Q147**	R21, K88, H154	**M1,** W9, Y18, Y34, **M138**	**N-term, K70, K78,** K88, K145	T13, **S45, S122,** T140

[a]Gamma B peptide 60–76 is identical to the more-abundant gamma C peptide 60–76.
[b]The N-terminus of beta A1 is residue A18 of beta A3.
[c]Beta B3 sequence incorrectly contains the N-terminal Met residue.
Sites reported in more than one study are highlighted in bold type.

The number of deamidations in the water-soluble proteins increased up to 35 years of age, but then remained constant, while the number of deamidations in the water-insoluble proteins continued to increase with increasing age. This increase in deamidation, particularly between birth and middle age, suggests that deamidation may be a precondition for cataracts and may play a role in hardening of the lens. Hardening of the lens continues throughout life and is especially evident in nuclear sclerotic cataracts discussed elsewhere in this encyclopedia.

Methylation

Methylation is an abundant lens modification that has only recently been discovered. The main sites for crystallin methylation appear to be reactive cysteine residues. In early characterizations of this modification, there were unsuccessful attempts to find the methyltranferase responsible for the methylation. More recent large-scale PTM studies have shown that the number of methylation sites is quite large with methylated cysteine, histidine, and lysine sites all identified in aged lens or nuclear regions of aged lens. This points more and more toward nonenzymatic mechanisms. Currently, it has not been established when methylation is first observed in lens. It is absent in very young lenses and present at moderate levels in older lenses. Methylation was not significantly more abundant in the water-insoluble fractions (Figure 2), so the functional significance of methylation remains unknown. Future studies are needed to see if normally inaccessible cysteine residues become methylated with advance age or during cataract, which could indicate changes in crystallin conformations.

Oxidation

Oxidation is a defining feature of age-related nuclear cataract but the form of oxidation may not be a simple addition of oxygen (a +16 mass increase). Other forms of

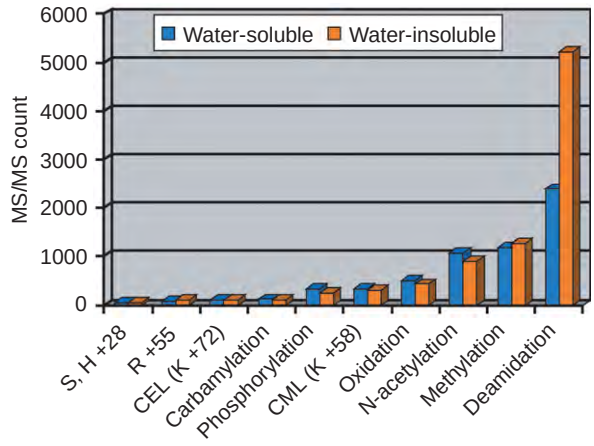

Figure 2 A spectral count comparison of modified peptides of three aged lens samples where water-soluble fractions were compared to water-insoluble fractions. Adapted from Wilmarth, P. A., Tanner, S., Dasari, S., et al. (2006) Age-related changes in human crystallins determined from comparative analysis of post-translational modifications in young and aged lens: Does deamidation contribute to crystallin insolubility? *Journal of Proteome Research* 5(10): 2554–2566.

oxidation, such as disulfides or mixed sulfhydryls, are more difficult to detect in mass spectrometry-based studies. There are 34 methionine residues in the major lens crystallins and 28 have been reported as oxidized (82%). There are 53 tryptophan residues and 42% (22) have been found to be oxidized. Oxidation of methionine can be caused by sample handling, especially in gel-based studies and many of the reported studies failed to demonstrate that methionine oxidation occurred *in vivo*. Tryptophan is much more resistant to artifactual oxidation and it is more likely that these sites, listed in **Table 1**, are true *in vivo* sites of oxidation. Spectral counting data shown in **Figure 2** indicated that the level of oxidation is relatively low in normal aged lenses and was not correlated with loss of solubility. An increase in tryptophan oxidation has been reported in cataractous lenses. The majority of these residues had low solvent accessibility, suggesting that oxidation of tryptophan may serve as a marker of protein unfolding with advanced age or during cataract formation.

Acetylation and Carbamylation

The majority of acetylation in lens occurs cotranslationally at the protein N-terminus for α- and β-crystallins. Data suggest that N-terminal acetylation is essentially quantitative for these proteins and protection of the reactive N-terminus may be advantageous for lens protein longevity. Interestingly, the γ-crystallins are not acetylated although N-terminal carbamylation has been reported. Lysine residues in the α-crystallins are the only other reported sites of acetylation in lens that have been seen in more than one study. It is not known if this modification occurs before, during, or after fiber cell differentiation and its biological significance remains unclear.

Carbamylation of several lysine residues were found to be more abundant in aged than young lens, but were present at similar low levels in water-soluble and water-insoluble fractions (**Figure 2**). Urea is commonly used to denature proteins prior to enzymatic digestion and its by-product (isocyanate) can cause carbamylation during sample processing. Thus, comparisons to control samples or avoiding urea use during sample processing steps are necessary to identify *in vivo* sites.

Phosphorylation

Phosphorylation has been reported at 27 sites in 10 crystallins, and only 7 sites in the α-crystallins have been detected in multiple studies. The reliability of most of these other sites remains unclear. It seems unlikely that phosphorylation would occur in mature fiber cells where enzymatic activities are presumed to be absent, and phosphorylation may be related to fiber cell differentiation or development. The data in **Figure 2** indicated that the levels of phosphorylation were comparable between water-soluble aged lens fractions and water-insoluble fractions. There are few reports that implicate phosphorylation in aging lens changes or cataract formation.

Other Lysine and Arginine Modifications

The unrestricted PTM search strategy used by Wilmarth and colleagues identified several previously unreported types of lens modifications. Lower levels of unusual lysine (+58 Da and +72 Da) and an unknown arginine (+55 Da) modifications were perhaps the most interesting of these modifications. It is speculated that these modification are advanced glycation end products such as carboxymethylation (+58 Da) or carboxyethylation (+72 Da) and may be markers of advanced age or oxidative stress.

Truncation

Extensive proteolysis of lens crystallins has been reported by several laboratories, and the N- and C-terminal extensions of the crystallins are the protein regions the most susceptible to truncation. It has been reported that high-molecular-weight lens protein complexes from aged lenses contain N- and C-terminally truncated fragments of αA and αB. Also, fragments of α-crystallins, β-crystallins, γ-crystallins, filensin, and vimentin have been found in the water-insoluble lens proteins. Increased high-molecular-weight protein complexes and water-insoluble proteins are thought to be detrimental to lens function.

While the bottom-up proteomic approach of digesting proteins by (typically) trypsin is by far the most successful

method to identify and assign PTM sites, it is not very effective in studies of proteolysis and truncation. Truncations, in principle, can be inferred from an atypical semitryptic peptide (either from the N-terminus or the C-terminus of the truncated protein form). However, those peptides may be too small to be detected or produced from other processes (in-source fragmentation, for instance). Gel-based separations have been used most often, but differential N-terminal labeling strategies or top-down methods may provide non-gel alternatives in truncation studies.

Functional Significance of Lens PTMs

The major age-related crystallin modification by far is deamidation. Yet, the functional significance of deamidation in the lens is not known. Deamidation occurs primarily by nonenzymatic reaction mechanisms. In addition to adding a negative charge, which by itself can alter protein structure and function, deamidation can lead to protein backbone cleavage, racemization, and isomerization.

The β-crystallins form complex hetero-oligomers partly due to hydrophobic interactions and hydrogen bonds that stabilize the interacting surfaces between subunits. The α-crystallins also form complex oligomers whose interactions have not been as clearly defined. Nonetheless, α-crystallins have chaperone activity *in vitro* and are likely to have chaperone activity in the lens. It is not surprising that the stabilizing interactions and functional activity of crystallins may be compromised by modifications, such as deamidation and truncation.

In support of the above, numerous studies have shown compromised biophysical properties of deamidated crystallins *in vitro*. Deamidation decreased β-crystallin stability *in vitro*, and similar findings have been reported for α- and γ-crystallins. Soluble aggregates were detected in βA3 when deamidations were introduced on the surface of the protein and surface deamidations in βA3 were more abundant in the insoluble proteins in aged and cataractous lenses. These *in vitro* and *in vivo* studies suggest that the accumulation of extensively modified crystallins and, in particular, deamidated crystallins, may be the reason for the increasing amount of insoluble lens protein that accumulates with age, compromising the transparency of the lens.

Accumulation of extensively modified crystallins during one's life may lead to impaired lens function such as inability to accommodate resulting in presbyopia and eventually to age-related cataracts. Little by little, we are discovering the mechanisms by which these modifications contribute (directly or indirectly) to lens hardening, presbyopia, and age-related nuclear cataract.

A fairly comprehensive tabulation is emerging of the major modifications of lens proteins. However, rigorous quantitative analysis of the differences in the abundance of these modifications in normal and pathologic conditions is still missing. Future experiments must focus on obtaining a large set of graded normal and cataractous human lenses on which a targeted quantitative analysis of the known modifications can be performed. Surprisingly, the biggest hurdle to overcome is not the methods of analysis, but obtaining a significant number of graded control and cataractous lenses to do the study properly.

Nuclear Cataract

R J W Truscott, Sydney University, Sydney, NSW, Australia

Glossary

Nuclear cataract – The opacification of the central region of the lens, usually associated with increased hardening of this region. For this reason, clinicians often refer to this as nuclear sclerotic cataract.
Presbyopia – The increasing loss of ability to focus on near objects with age. Stiffening of the lens cytoplasm is thought to play a major role in presbyopia.
Racemization – The randomization of direction of optical rotation of an optically active molecule. In lens proteins, some amino acids, notably aspartic acid, undergo time-dependent racemization from the L- to the D-form.

Cortical Cataract and Nuclear Cataract

There are two major types of age-related cataract: cortical which affects the outer half of the lens, and nuclear which involves opacification of the lens center. This central region consists of proteins that were synthesized *in utero*.

In contrast to cortical cataract, which is still ill-defined in terms of its molecular etiology, great strides in understanding have recently been made in the area of nuclear cataract. This is certainly not to say that we understand it completely, but there is now a framework.

Classification

It is generally easy to recognize nuclear cataract. The nucleus of the once transparent lens has become opaque and colored. In 1968, Antoinette Pirie used nuclear color as a means of classifying age-related nuclear cataract (ARNC) lenses. This semisubjective classification method has been remarkably successful. Nearly all of the biochemical correlates that are associated with ARNC have been derived using this method. For example, as will be illustrated below, moving from the earliest stage of ARNC (type II) to the most advanced (type IV) has been found to be associated with a progressive increase in urea-insoluble protein, oxidation of methionine, and cysteine and protein cross-linking. Later, other more detailed classification schemes (e.g., various iterations of the Lens Opacity Classification scale (LOCS)) have been introduced.

Cataract is Not the Same as Aging

Too often, even today, lens scientists occasionally lump these two quite distinct phenomena when compiling lists of changes that take place in older lenses. As will become clear later in this review, aging is almost certainly a prerequisite for ARNC, but the changes that take place in aging and ARNC, can and should, be distinguished. A summary outlining the proposed sequential steps in ARNC formation is shown in **Figure 1**.

Features that Distinguish ARNC from Normal Aging

At present, there are four key characteristics that can be used to differentiate ARNC lenses from age-matched normal lenses, and these are discussed below.

Insoluble Protein

Insolubility is a problematic feature since it requires the tissue of interest to be processed in some way, typically by homogenizing it, and the amount of protein that is deemed soluble will depend on the number of extractions, buffer, pH, etc. In normal lenses above the age of 50, approximately half of the total protein in the lens nucleus is no longer soluble in phosphate buffer, pH 7. Since such lenses are still transparent, it is likely that the proteins are not present as a precipitate in the intact lens. We can interpret the laboratory findings in this case to reflect changes in the state of the proteins in the lens.

The onset of ARNC sees the development of a quite separate phenomenon. In these lenses, a new protein fraction can be isolated, which is insoluble even in 8-M urea. This fraction contains most of the color of the ARNC lens and is composed of polypeptides cross-linked by nondisulfide links. The amount of this yellow protein fraction increases progressively in accord with the Pirie classification of ARNC from type II to type III and type IV lenses. In type IV lenses, it comes to represent half of the total nuclear protein. In order to solubilize this yellow protein fraction, a reducing agent such as mercaptoethanol or dithiothreitol must be added to the 8-M urea. In advanced ARNC lenses, a small quantity of protein remains insoluble even after this extraction procedure.

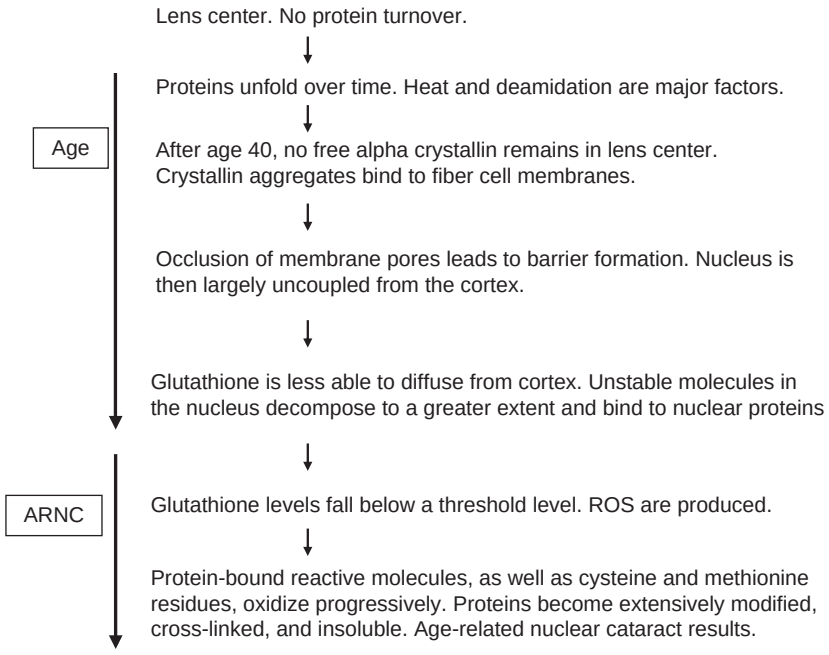

Figure 1 A summary of the sequential steps that take place in the center of the human lens, which may lead to age-related nuclear cataract formation. ROS, reactive oxygen species.

Oxidation

In advanced ARNC lenses, the extent of protein oxidation is unmatched by that of any other biological tissue. In type IV lenses, half of the methionine residues, and more than 90% of cysteines, are oxidized. Oxidation of sulfur-containing amino acids is a hallmark of ARNC. Methionine is oxidized to methionine sulfoxide and the cysteine residues to disulfides.

Oxidation of cysteine, and to a lesser extent methionine, is evident even at the earliest stage (type II) of ARNC and the extent increases as the cataract worsens. This oxidation of proteins can be used to differentiate ARNC lenses from normal lenses, since in aged normal lenses there is almost no methionine sulfoxide and protein thiol levels are typically within the normal range. In some older normal lenses, low amounts of crystallin disulfides can be detected; however, the levels in these lenses are always low, and may reflect the fact that these lenses are soon to become cataractous. All cysteine residues of the crystallins, with the exception of Cys 41 in gamma C and Cys 18 in gamma D crystallin, become oxidized once ARNC develops.

Cross-Linking

In ARNC lenses, two types of cross-links join the crystallins: disulfide and nondisulfide, and both are absent, or in much lower levels, in normal lenses. The extent of protein interchain disulfide bonding in ARNC lenses can be appreciated by the observation that cleavage of such links with reducing agents enables the vast majority of the urea-insoluble protein to become soluble in 8-M urea.

The structure of the nondisulfide bond in ARNC lenses is still unknown and its elucidation would add considerably to our understanding of the processes involved. It is not likely to be the same as that described in a 43-kDa peptide isolated from normal lenses by Spector's group. These authors reported that this novel species may contain a cross-link between crystallins; however, this was not confirmed.

Coloration

Normal human lenses become more colored as they age, and particularly so after age 50. This appears to be primarily due to the binding of breakdown products of reactive molecules, such as ascorbate and kynurenine ultraviolet (UV) filters, to nuclear crystallins. However, in all cases, a yellow hue results.

By contrast, ARNC lenses typically range in color from brown, orange/dark yellow to occasionally black. We still do not know the molecular structures responsible for this pigmentation. Since these colors are found in no other animal cataract, it may well be a human, or at least a primate-specific phenomenon. Since UV filters, such as 3-hydroxykynurenine, are present uniquely in primates, and such molecules readily bind to and tan proteins when exposed to oxygen, it has been postulated that these may be implicated. This hypothesis gained traction when it was discovered that all normal human lenses over the

age of 50 contain measurable levels of 3-hydroxykynurenine bound covalently to proteins in the nucleus. It could be imagined that this binding of reactive molecules to human nuclear crystallins is a potential time bomb waiting to be activated by the arrival of an oxidative environment. Cross-linking and coloration of crystallins would inevitably be the outcome.

Why is ARNC Age-Related?

Epidemiological data suggest that ARNC is inevitable if we are fortunate enough to live for a sufficiently long time. The incidence of ARNC increases substantially as we get older. What aspects of normal aging of the human lens facilitate the later onset of nuclear cataract? To a large extent, this question hinges on the definition of what constitutes normal aging. Substantial progress on the biochemistry of aging of the normal human lens has provided a platform for understanding those aspects that may be the preconditions responsible for subsequent ARNC.

It is now clear that massive changes take place in the normal human lens with age. For example, the stiffness of the center increases approximately 1000-fold in the first few decades of life and this is likely to be the feature that is responsible for presbyopia. Crystallin proteins become deamidated, denatured, and bound to fiber cell membranes. The ratio of free to bound water also changes progressively. After age 50, proteins in the lens center become loaded with covalently bound small molecules. Despite such huge changes, in most cases, the normal aged lens remains transparent. Therefore, which of these substantial alterations is important for the subsequent onset of ARNC?

A Model for ARNC: The Lens Center is an Enzyme-Free Region

In order to understand ARNC, it is first necessary to appreciate that the center of the mature adult lens is an enzyme-free zone. There is no turnover or synthesis of macromolecules in this region. For proteins, it is a life sentence. Although comprehensive data are not available, it would appear that after several decades, all enzymes that were present in the center of the lens, and were therefore synthesized prior to birth, have undergone denaturation and are now inactive. Two studies have demonstrated the presence of enzymes by immunohistochemical methods in the lens core, yet enzyme activity was undetectable. In effect, the center of the middle-aged lens is a chemical incubator where the processes governed in other cells of the body by enzymes, do not apply. The consequences of this are profound.

In order to minimize oxidation and covalent modification of proteins in the lens center, a high concentration of glutathione normally bathes these macromolecules. Glutathione is ideal since it acts not only as an antioxidant, but it can also intercept reactive intermediates and, by reacting with such molecules first, reduce the extent of covalent modification of proteins. Both synthesis of the tripeptide, as well as reduction of oxidized glutathione, takes place in the cortex. It is, therefore, obvious that any impediment to the exchange of glutathione between the cortex and lens nucleus would imperil the stability of nuclear proteins.

Uncoupling the Center from the Lens Cortex

Biophysical studies have demonstrated the onset of a barrier to the diffusion of small molecules within the lens at middle age. This barrier is not absolute, but it impedes the flow of small molecules from the outer parts of the lens into the interior. Interestingly, the existence of the lens barrier has been shown for both glutathione and water. These two molecules may move from cell to cell using quite different pores. In the case of glutathione, movement takes place via gap junctions composed of connexons, whereas water probably diffuses through pores made from the abundant integral membrane protein, aquaporin 0. Since the movement of both molecules are compromised by middle age, it suggests either that both types of channels become less active due possibly to posttranslational modification/cleavage or that a common process within the lens is affecting both types of membrane pores. Recent data suggest that it may be the latter explanation which best fits the data.

Unfolding Crystallins and the Importance of Alpha Crystallin

After age 40, no free alpha crystallin remains in the lens center: all of the chaperone have been used in binding to polypeptides that unfolded over a period of decades. The reasons for the denaturation and unfolding of the crystallins can be traced to the fact that proteins, and particularly some residues within them, are intrinsically unstable over a period of decades. Heat-induced denaturation of polypeptides, combined with deamidation of Gln and Asn residues and the isomerization of Asp/Asn sites, coupled with chemically mediated truncation, combine to destabilize lens proteins.

After age 40, when soluble alpha crystallin has been depleted in the lens center, some marked changes take place in the normal lens. It is at this time when nuclear proteins become increasingly insoluble, and it is noticeable that it is the decade between 40 and 50 in which most changes take place. In recent experiments, we have

demonstrated substantial binding of crystallins to fiber cell membranes during this 10-year period. It seems likely that the interaction of crystallin aggregates with the membranes may well act to clog the pores and, in this way, a barrier may form.

We do not yet understand exactly what processes are necessary to convert a clear middle-aged lens into an ARNC lens. Perhaps the degree of impermeability of the barrier is important in that if diffusion of glutathione from the cortex becomes progressively diminished, a stage may be reached where the environment in the lens core changes from being reducing to oxidative. Maintaining a concentration of glutathione above 1 mM may be crucial, as could be the ability to respond to an increased oxidative insult.

Another Impact of the Lens Barrier

Another feature of the barrier is its role in increasing the residence time of intrinsically unstable molecules in the center of the lens. This latter feature is not generally as well appreciated as the barrier's function in restricting glutathione penetration, but it may be just as important. As noted above, small molecules are able to enter the nucleus after age 50, but their rate of entry is reduced. Similarly, the ability of molecules to move in the reverse direction – from the nucleus to the cortex – will also be hindered. For some molecules that are unstable over a period of hours or days at neutral pH, this factor can be crucial. Two groups of lens constituents that are well known are the kynurenine UV filters and ascorbate. Ascorbate, when it acts as an antioxidant, oxidizes to the unstable triketone, dehydroascorbate. In the absence of sufficient glutathione, which would normally re-reduce the dehydroascorbate, this molecule can bind directly to proteins and it also decomposes to a variety of reactive aldehydes and ketones.

The kynurenine UV filters undergo spontaneous deamination at pH 7. The unsaturated ketones that are produced bind readily to His, Lys, and Cys residues of proteins through their side chains. One of the UV filters, 3-hydroxykynurenine, is an *o*-aminophenol and is therefore highly sensitive to oxidation. It has been proposed that oxidation of 3-hydroxykynurenine that is covalently bound to crystallins, may be responsible for the coloration and cross-linking of polypeptides that characterize ARNC.

Could Sunlight Play a Role in ARNC?

For many years, sunlight was thought to be the prime agent responsible for formation of ARNC. Indeed, it is still mentioned, together with skin cancer, as one of the conditions that will increase as a result of ozone depletion. The premise was that the lens is exposed every day to external light and that over a period of years it was not surprising that the proteins would oxidize. This was especially so since one could readily convert white lens proteins into brown aggregates by exposing them to UV light.

There were, however, some major problems with this hypothesis. First, irradiation destroyed tryptophan (Trp) residues in experimental systems and yet the brown proteins isolated from ARNC lenses did not show any significant reduction in content of Trp. Second, it was unclear why oxidation should be confined to the nuclear lens proteins when light must pass first through the anterior cortex. Third, epidemiology failed to demonstrate any conclusive link between exposure to sunlight and the incidence of ARNC.

The Resurrection of Sunlight?

It is ironic, therefore, that recent experimental data provide an explanation for how UV light could participate in the generation of ARNC. It should be emphasized that this is not evidence for a role of sunlight.

It turns out that protein-bound UV filters behave quite differently from their free kynurenine counterparts. Free UV filters appear to be benign once they absorb UVA light. By contrast, if UV filters are covalently bound, they sensitize the proteins to oxidation. When one considers this fact, in conjunction with the previously mentioned finding that all human lenses after age 50 contain measurable levels of protein-bound UV filters in the nucleus, it is possible to envisage why only the nuclear proteins may oxidize following exposure to ambient UV light. Cortical proteins are modified by UV filter molecules to a much lower degree, as are the nuclear proteins from lenses in people younger than 50. As a consequence, epidemiological evidence may need to be reevaluated. For example, exposure before the age of 50 may have no significant impact, whereas time spent in sunlight after 50 would be expected to be of much greater importance. This is accentuated by the fact that the levels of free UV filters decrease linearly over our life span at approximately 10% per decade. Therefore, older lenses are more susceptible to UV-induced damage.

What is the Primary Oxidant Involved in ARNC?

Oxidative processes are central to the formation of ARNC. It is less certain what the primary oxidant could be. Some oxygen, albeit at low levels, is present in the center of lenses. It has been proposed that increased liquefaction of the vitreous in older people, and in those patients exposed to vitrectomy, may facilitate the diffusion of oxygen from the retina into the lens and therefore

exacerbate ARNC. Such a proposal is supported by separate experimental data where intact lenses and animals, including human infants, have been exposed to hyperbaric oxygen. Experimental studies of UV-filter-modified proteins suggest that singlet oxygen is generated upon irradiation with biologically relevant doses of UVA in the presence of low concentrations of oxygen. Other work using human cataract lenses has revealed that the molecular markers associated with hydroxyl radical damage can be found in ARNC, but not in normal lenses.

Autoxidation of susceptible molecules within the nucleus could generate superoxide locally, which could dismutate into hydrogen peroxide. Peroxide could also potentially diffuse into the interior from mitochondrial electron leakage in the cortex. Certainly, the pattern of oxidation of sulfur-containing amino acids observed in ARNC is what would be expected by exposure of proteins to hydrogen peroxide.

Can ARNC be Prevented?

From the foregoing discussion it is apparent that if nuclear glutathione levels could be maintained in the center of the lens in older people, then it may be possible that ARNC could be delayed, if not prevented. Sadly, this does not seem easy to achieve. Even if one could boost antioxidant levels markedly through dietary or pharmacological means, there would remain the problem of these penetrating the interior of the lens where they are required.

Issues and Questions for the Future

One major impediment to future research on human ARNC is the difficulty in accessing cataract lenses. Phacoemulsification is now almost universal as the technique used to remove cataract lenses and so intact lenses, and even nuclear cores, are becoming increasingly difficult to obtain. This is a huge problem since there appears to be no appropriate nonprimate animal model system that can be employed. Human lenses are unique. As was apparent from the previous parts of this article, it is primarily the changes that take place in the lens over a period of several decades, which appear to be responsible for ARNC. It is, therefore, not an easy condition to model or replicate.

Other Questions

Could Lens Components Other than Crystallins be Involved?

This article has concentrated largely on protein changes as being the dominant factor underlying the etiology of ARNC. Bearing in mind the importance of the barrier and, in particular, membrane interactions of protein aggregates, it is clear that other factors, for example, changes to the lipid composition of the fiber cell membranes, may also play a part in facilitating the formation of the barrier. Preliminary data indicate that substantial changes can be documented in the lipid composition of human lens membranes as a function of age. This remains a topic for future studies, as is the degree to which membrane decomposition and oxidation may be implicated in ARNC.

It is also important to recognize that proteins, other than crystallins, are present in the lens center for all of our lives. The role of cytoskeletal proteins, the intrinsic membrane proteins in particular aquaporin 0, as well as the gap-junctional connexin proteins in ARNC may also be important.

Why Do Some People in India Develop ARNC Much Earlier than Those in Western Nations?

Since it has been reported that ARNC is observed in India more than a decade earlier than in the West, it would seem that a detailed study of people in some Indian regions may shed light on what factors may be responsible for delaying, or accelerating, the onset of ARNC.

Is ARNC Just a Problem that is Lens Specific?

A theme of this article has been that protein denaturation over a period of many decades is at the heart of understanding ARNC. It is becoming increasingly apparent that deducing the impact of changes in protein structure over a period of decades will be important in other human conditions that are associated with aging. The lens is not unique in the body in containing proteins that are present for many decades. Two facets of this longevity, and its relationship to protein unfolding, should be appreciated. First is the intrinsic instability of some amino acid residues. Some were noted briefly in an earlier part of this article, and are well known; others remain to be uncovered. The sites most affected within each protein will depend on the primary, secondary, and tertiary structures, as well as the packing of proteins within each tissue. For example, in the older human lens, deamidation of crystallins is abundant, but is localized to specific regions of each protein.

The second aspect is the role of chemical post-translational modification of proteins over a period of decades. In this sense, the long-lived crystallins of the lens can be viewed simplistically as resembling blotting paper. What are the most important chemical insults over a period of many decades to which proteins are exposed?

It is likely that proteomic investigations may shed light on this aspect.

The relative importance of extralenticular factors, such as the gel state of the vitreous and somatic metabolism, also remain to be established. For example, patients undergoing vitrectomy will, within 12 months, develop ARNC. In addition, patients with ARNC respond differently from age-matched normal subjects in terms of their serum response to an oral dose of Trp and their lenses contain higher-than-normal levels of amino acids. The explanations for these intriguing observations and, in particular, how such findings would relate to the etiology of ARNC, are not yet clear

Conclusion

In summary, there is now a coherent framework for understanding ARNC and why it is that this condition becomes apparent only in our later years. It may well be that the human lens is the ideal system for understanding more general aspects of human aging, particularly those that involve protein modification and denaturation. Lessons derived from the lens may, in the future, be applied more widely to other tissues of the body.

Ocular Media Clarity and Straylight

T J T P van den Berg, L Franssen, and J E Coppens, Netherlands Institute for Neuroscience of the Royal Netherlands Academy of Arts and Sciences, Amsterdam, The Netherlands

Glossary

Angle – In ophthalmology, it is usually measured in degrees (or °) and minutes of arc (or ′). A full circle encompasses 360°, and 1° = 60′. The horizontal human visual field encompasses ± 100°. The scientific standard for angle is the radian, with $2\pi = 360°$.
Commission internationale d'Eclairage **CIE, or International committee on illumination** – International standards committee with representative bodies in virtually all larger countries, acknowledged by ISO.
Disability glare – The effect of straylight on the eye whereby visibility and visual performance are reduced. Disability-glare sensitivity and straylight can be used synonymously according to CIE definition. Discomfort glare is glare that produces discomfort. It does not necessarily interfere with visual performance or visibility.
Glare – The effect produced by a luminance within the visual field that is sufficiently greater than the luminance to which the eyes are adapted to cause annoyance, discomfort (discomfort glare or psychological glare), or loss in visual performance and visibility (disability glare or physiological glare).
Light scatter – The physical effect of irregular material on the transmission of light, whereby part of the light is deflected. Most often scattering by isolated (often optically independent) and small irregularities is considered, resulting in straylight. Sometimes the word scatter is used for small-angle light spreading resulting from large-scale refractile aberrations.
Point-spread function or PSF – The (effective) distribution of light in the eye, deriving from an ideal point source of light, and delivering the unit amount of light to the eye. Properly defined, the PSF integrates to unity. When expressed with the visual angle θ as an independent variable, the functional (as seen) PSF equals $L_{eq}(\theta)/E_{bl}(\text{ster}^{-1})$, with $L_{eq}(\theta)$ the equivalent luminance (as seen), and E_{bl} the illuminance on the eye deriving from the point source.
Steradian – The unit for solid angle, shortened to ster. or sr. A half sphere encompasses 2π steradian.
Straylight – The outer part of the functional PSF of the human eye. As practical limits, values 1–100° are used. It is quantified by means of the straylight parameter $s(\theta)$, defined by $s(\theta) = \theta^2\,\text{PSF}(\theta) = \theta^2\,L_{eq}(\theta)/E_{bl}$. As for most eyes, the dependence on θ is weak, $s(\theta)$ is often shortened to s.
Straylight meter – An instrument for performing a psychophysical test to determine the straylight parameter. The psychophysical tests aim to establish the equivalent luminance L_{eq} deriving from a glare source with calibrated E_{bl} value. Originally, only threshold tests were employed, but more recently, equivalence is established by means of counter-phase flicker, as used in the current, only commercial, instrument (C-Quant by Oculus).

Introduction

Disturbances to the eye media may cause vision loss of several different types. With visual-acuity assessment using a letter chart and other means, the smallest detail that can be resolved is established. With the contrast sensitivity test, testing is extended to include not only the smallest distances, but also differences over somewhat larger distances, typically up to a few tenths of a degree. However, eye-media disturbance can also degrade vision because it may cause light scattering. This results in a veil of straylight over the image, strongly depending on the presence of brightness differences as typical in most visual scenes. The complaints

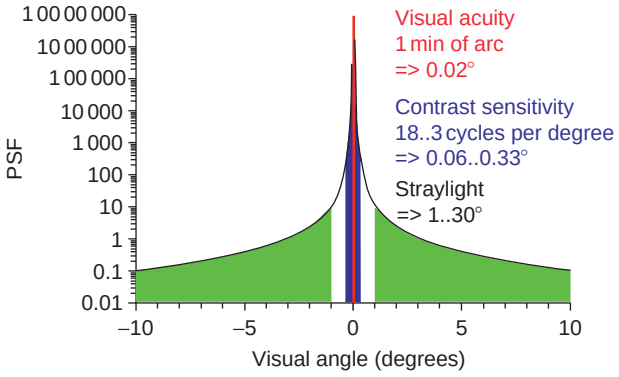

Figure 1 Point-spread function (PSF) of the normal human eye according to the standard formulated for the CIE in 1999. When the eye looks at a point source, the actual light distribution spreads out over the full retina. Different domains of this distribution are indicated, dominating different aspects of visual function. The PSF has steradian^{-1} as unit, and integrates to unity (steradian to be used as variable of integration).

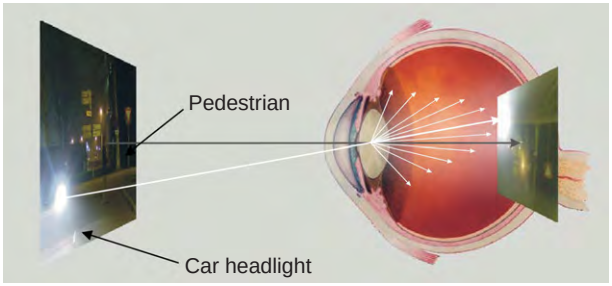

Figure 2 Visualization of retinal straylight. The optical components of the eye form an image of the outside world (left picture) on the retina (right picture). In the case of such a street scene, the picture on the retina is much degraded because part of the light coming from the car headlight is scattered in all forward directions (white arrows in the figure), projecting a veil of light over the retinal image. This veil of light is called straylight. Actually, the left picture simulates what a normal eye would see, and the right picture, what would be seen with an early cataract.

may include hazy vision, increased glare hindrance, loss of contrast and color, etc. These problems are much worsened if visual function is already low from retinal pathology, such as in macular degeneration or glaucoma.

It has long been realized that 20/20 is not enough. Contrast sensitivity was added to better assess full quality of vision. However, contrast sensitivity also was not enough. This can be understood on the basis of the large dynamics of the human eye, as illustrated in Figure 1. Figure 1 shows the point-spread function (PSF) of the normal human eye (for the average Caucasian at 62 years of age), according to the standard observer defined by the *Commission internationale d'Eclairage* (CIE). It gives the light distribution that follows from a point source of light. It shows that a point source does not project on the retina as a point, but strongly spreads out. This spreading of light is caused by several essentially different optical errors of the eye. The PSF dictates the effects of imperfect eye optics on vision. This has been studied over the years in many publications.

Different domains can be identified in the PSF. Ideally, light distribution should only be the central peak up to 1 min of arc, shown in red. The optically ideal PSF is called the Airy pattern, resulting from the fundamental diffractive properties of light, with a central disk extending to 1.22 × wavelength/pupil diameter. With a wavelength of 550 nm, and a pupil diameter of 4 mm, gives 1.2 min of arc for the central disk to become zero (this would be minus infinity in Figure 1 because of the logarithmic scale). However, actual eyes show aberrations causing this central peak to widen. This is the reason why Figure 1 does not show the very steep decline toward minus infinity at 1.2′. The most central area dominates visual acuity. The next area goes on to 10 min of arc (the blue area), which dominates contrast sensitivity (6 cpd corresponds to 5 min of arc band width). However, the light spreading continues over the full retina. The light spreading over 60 min of arc (1°) and more is called straylight. Every area of this PSF is important for quality of vision.

Straylight

Small-angle disturbances to the eye media may cause vision loss of small detail, determined with visual acuity assessment using a letter chart or contrast sensitivity. But how does the light scattered over larger distances affect vision? The light scattered results in a veil of straylight over the retinal image (see Figure 2). The patient's complaints may include hazy vision, increased glare hindrance, loss of contrast and color, etc. If concomitant retinal pathology exists, as macular degeneration, retinal dystrophy, or glaucoma, the problems experienced from straylight are much aggravated, calling for extra attention on straylight in such patients.

It is important to realize that the effect of straylight on vision is totally different from the effect of decreased visual acuity on vision. This is illustrated in the following examples, produced with known realistic means. Daily-life scenes were photographed under three conditions: normal, with a blurring lens, and with a light-scattering filter in front of the camera lens. The blurring lens simulates decreased visual acuity of about 0.4; the scattering filter simulates increased light scattering of around $\log(s) = 1.5$ (see Figure 3). Normal visual acuity would be around 1.5, and a normal straylight value would be around $\log(s) = 0.9$; therefore in both cases, the image is deteriorated by a factor of 4. These pictures illustrate that, in certain daily-life circumstances, increased light scattering has a much stronger effect on the quality of vision than decreased visual acuity.

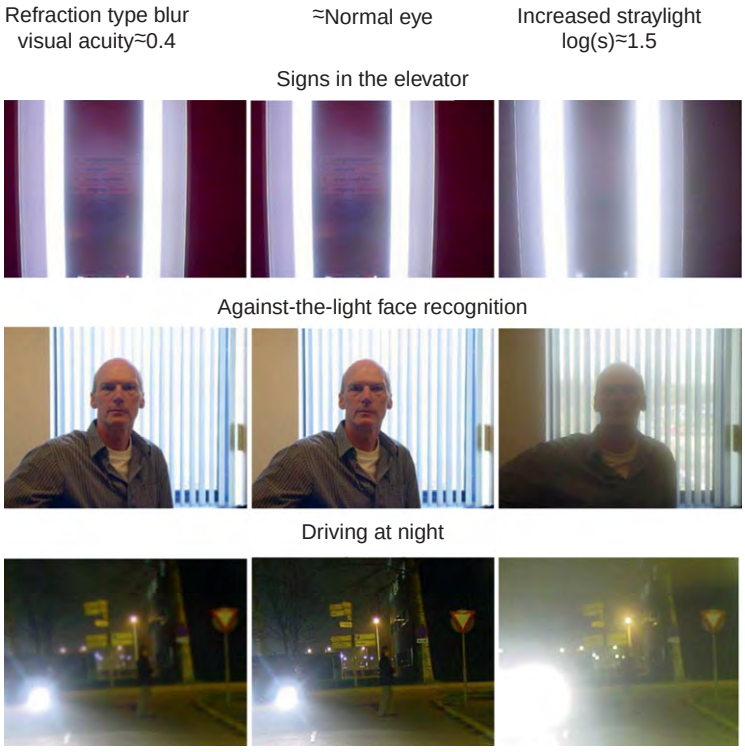

Figure 3 Comparison between refraction type blur (visual acuity around 0.4) and early straylight disturbance (log(s) around 1.5), for different daily-life situations.

History

Since the beginning of the twentieth century, the importance of retinal straylight for visual function has been recognized by several investigators. Cobb introduced the concept of equivalent veiling luminance (L_{eq}) as an apt way to define retinal straylight. Disability glare/retinal straylight, as defined by the CIE, is now quantified by means of this concept of equivalent luminance, that is, the (external) luminance that has the same visual effect as the glare source at some angular distance. Holladay and Stiles applied this concept in their measurements and formulated a disability glare formula, which has been widely used. Nowadays, retinal straylight can also be introduced as the outer skirt of the PSF, outside say, 1°. Since retinal straylight is defined in a functional sense by L_{eq}, the comparison with the PSF only holds if the PSF is also defined in the functional sense. Retinal straylight causes a veiling luminance over the whole retina that adds to the retinal projection of the visual scene, thereby reducing the contrast of the retinal image. Important overview papers were written by Vos. In 1999, a standard was proposed to the CIE (see **Figure 1**) for the normal eye, including age and pigmentation effects.

The first attempts to measure intraocular straylight by means of equivalent luminance involved two types of threshold measurements: thresholds in the presence of a distant glare source and those in the presence of a homogeneous background luminance. From such a series of measurements, the equivalent luminance could be derived, defined as the luminance giving identical thresholds as the glare source (equivalent veil method). This method did not gain practical use, such as in clinical or driver-licensing applications, because it was quite elaborate. As a result, variation was quite large between the older studies. However, the method continued to be used in experimental applications. Some approximate alternatives were designed to circumvent the measurement load. As even more easy-to-use alternatives, the so-called glare testers were introduced, which usually consisted of a visual acuity or contrast sensitivity test, with and without a glare source presented at some angular distance in the visual field. As a result of issues with glare testers, a standard way of glare measurement was never adopted.

To improve on this situation, a dedicated psychophysical method was designed, called the direct compensation (DC) method. In short, this method works as follows: A bright ring-shaped light source around a (dark) test field is presented flickering. Due to intraocular scatter, part of the light from the bright ring-shaped source will be projected on the retina at the location of the test field, inducing a (weak) flicker in the test field. To determine the exact amount of straylight, variable counterphase compensation light is presented in the test field. By adjustment of the amount of compensation light, the flicker perception in the test field

can be extinguished. In this way, the straylight modulation caused by light scattered from the glare source is directly compensated. In 1990, this technique was implemented in a small portable device, called straylight meter. Apart from the group of Van den Berg, this led to studies notably by the groups of Elliott, Kooijman, Schallhorn, and Alexander. However, outside the laboratory it proved to be a difficult technique. In 2003, a better psychophysical approach was defined, called compensation comparison (CC), and implemented in a commercial instrument, by the German firm Oculus, called C-Quant (see Figure 4). The essential difference was that this new approach is suitable for random subjects and for routine clinical use. Moreover, the CC approach enables control over the reliability of the assessment.

Figure 4 The C-Quant instrument from Oculus for measuring the amount of straylight in patient eyes.

Normal Eyes

Figure 5 shows the age dependence of straylight in the normal population. Straylight/disability glare increases with age A by a factor

$$\left[1+\left(\frac{A}{D}\right)^4\right],$$

where D is the age at which the amount of straylight doubles. Values for D were found to be between 62.5 and 70 years. This age dependence was later implemented in a more extensive model including pigmentation as a second parameter. The model was further refined, including age-dependency formulas of different levels of complexity, applicable in different angular-validity domains. This led to a proposal to the CIE for a standard glare observer in 1999, which was accepted as the CIE standard a few years later.

Angular dependence is classically described with the Stiles–Holladay approximation (proportionality to angle^{-2}), holding relatively well between 1° and 30°. As this approximation also holds for aging eyes, including cataracts and other conditions, for most applications, a measurement at one angle suffices. As a consequence, the PSF multiplied with θ^2 (the definition of the straylight parameter s) is more or less constant between 1° and 30°.

Pigmentation of the eye was found to be of importance for quality of vision. Blue-eyed Caucasians were found to have 0.1–0.4 log units higher straylight values compared to pigmented non-Caucasians, depending on angle. This pigmentation dependence is partly caused by variations in transmission of light through the ocular wall. For dark-brown eyes of pigmented individuals, transmission

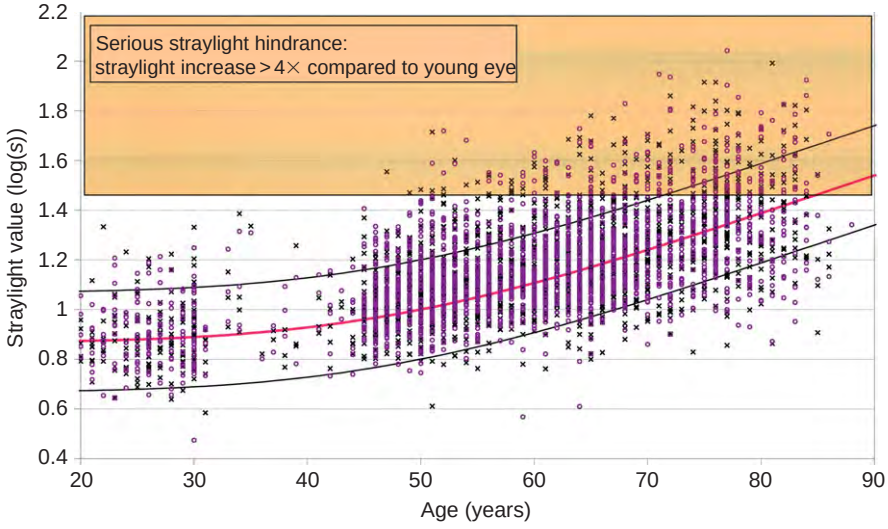

Figure 5 Log(*s*) values at 10° as a function of age for a population of European drivers. Keep in mind that, because of the logarithmic scale, a 0.3 increase in the log(*s*) value means in fact a doubling of the amount of straylight, and a log(*s*) increase of 1 means a tenfold increase in straylight.

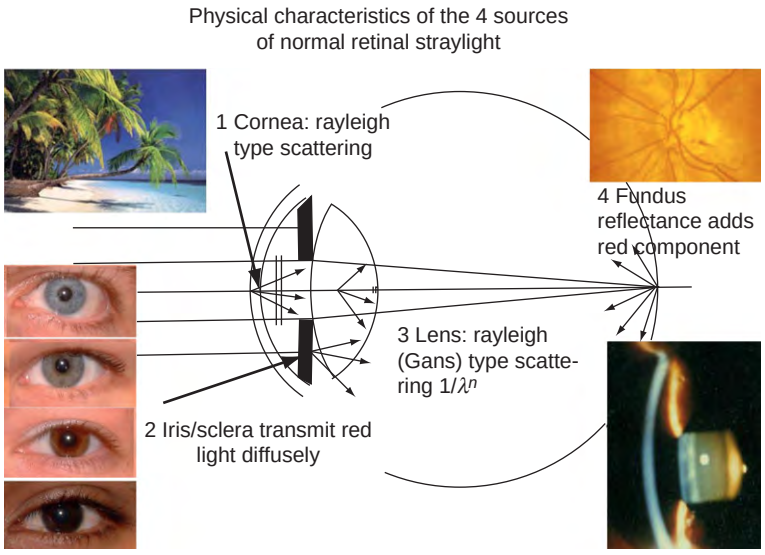

Figure 6 Primary sources of intraocular straylight in the normal eye: corneal scatter, iris, and sclera transparency, lens scatter, and fundus scatter.

was found to be orders of magnitude lower than that for blue-eyed individuals. Furthermore, variations in fundus reflectance are also partly responsible for pigmentation dependence of straylight. In albinism and other defects to pigmentation, the effects can be much stronger. Figure 6 gives an overview of the sources of straylight in the normal eye.

Wavelength dependence of straylight is important as a clue to what processes in the eye might cause straylight. A strong inverse wavelength dependence would signify scatter in the optical media to originate from particles of sizes in the same range as, or smaller than, the wavelength of light. (Like the blue of the sky originates from light scattering by very small irregularities in the air, which is called Rayleigh scatter.) However, depending on pigmentation, eye-wall transmittance and fundal reflections may introduce a straylight component with a wavelength dependence of the opposite sign (red dominant), negating the wavelength dependence from small particle scatter as identified in the lens and cornea.

Sources of straylight in the normal eye at young age are to about equal amounts, the cornea, the lens, and the pigmentation-dependent part. At older age only the lens component changes considerably, so as to dominate the other two, especially if (early) cataract develops. Often, straylight increase is the first complaint, before visual acuity changes.

Cataract

Cataract dependence of straylight was measured in patients with cortical, nuclear, or posterior subcapsular cataract. When compared to visual acuity, on average, the posterior subcapsular type showed the largest straylight increase, but individual results varied considerably. In all cataract types, straylight was often found to be increased considerably while visual acuity was still good; however, in other patients, the reverse was also possible. The important conclusion for ophthalmological practice is that straylight must be taken into account for just assessment of visual problems from cataract, and the decision for cataract surgery.

The angular dependence was found to be about the same for the different cataract types. The behavior was found to be similar to normal (extreme) aging, and it was concluded that, at least with respect to straylight, cataract can be modeled as early aging of the crystalline lens. Light-scattering filters that could be used to simulate the straylight characteristics of cataract were defined (used to create Figure 2). Straylight values after cataract surgery were found to be significantly decreased compared to preoperative values, but still about a factor of 2 above expected (best) levels. The reason is not yet resolved but may partly be due to the intraocular lenses or preclinical forms of posterior capsule opacification (PCO).

Cornea

The cornea proved to be a particularly sensitive organ for straylight increase. In experimentally hydrophilic contact-lens-induced corneal edema on average, a 10% corneal swelling induced a 50% increase in straylight. Variability in this relationship was speculated to be due to changes in the epithelium caused by the contact lens. After contact lens removal, individual straylight values decreased linearly with time, on a similar timescale as the decrease in

corneal swelling. Straylight scores in established contact-lens wearers were found to be significantly greater than in age-matched normals. Rigid gas permeable (RGP) contact lenses were shown to induce more straylight than hydrophilic contact lenses. Subclinical corneal edema seemed to be prevalent in some subjects.

Pathological conditions of the cornea may variably induce increased light scatter, strongly depending on the type of disease. In central crystalline dystrophy, straylight was found to be much increased while visual acuity was relatively well preserved. Alternatively, in posterior polymorphous dystrophy, straylight was not increased, even with impaired visual acuity. In macular and also lattice dystrophy, straylight and visual acuity were affected in a similar way. For deep lamellar endothelial keratoplasty (DLEK) and penetrating keratoplasty (PK), small differences on average between pre- and postoperative straylight values were found. Here the effects of habitual glasses must be mentioned. They were found to induce, as a rule, less straylight than is already present in the eye. The speculative conclusion is that the glass wearer has a tolerance against straylight from his glasses in dependence on his natural level. Higher straylight levels induce him to clean his glasses.

Since the introduction of laser refractive surgery, much concern has been expressed with respect to straylight problems regarding this type of corneal surgery. In radial keratotomy (RK), mean straylight increases by a factor of 1.4 (0.15 log units) in eyes with 4-mm-sized pupils and a factor of 2 (0.3 log units) for 8-mm-sized pupils. These values may be considered as functionally significant increases, but increases of a factor of 6 (0.8 log units) were also found. Studies on photorefractive keratectomy (different varieties are known by acronyms such as PRK, laser-assisted *in situ* keratomileusis (LASIK), and laser-assisted sub-epithelial keratomileusis (LASEK)) provided a less-clear picture. It is well known that a clear haze in the cornea or interface debris as result of the procedure gives subjective complaints, but with the advancement of techniques, these are not often seen. The emerging picture seems that in most cases, straylight does not increase, but that in 5–20% of the cases, depending on the study, significant straylight increase is found, without, in many cases, clear clinical signs.

Forward and Backward Scatter

Straylight reflects the effects of forward light scatter in the eye media. Several methods exist to assess the condition of the eye media using backward light scatter. In fact, the basic ophthalmological tool to evaluate the eye media (the slit lamp) is based on back scatter. Other examples are Scheimpflug slit-image photography, lens opacity meter, and lens opacities classification system (LOCS). One may wonder whether backward light scatter faithfully reflects the functional effect of light scatter in the eye, which is determined by forward light scatter. To address this question, *in vitro* measurements of light scatter in human donor lenses were performed, which showed that backward and forward light scatter are dominated by different light-scattering processes. In correspondence with these *in vitro* studies, patient studies on the comparison between different measures of backward light scatter and forward light scatter showed very variable results. It must be noted here that we consider forward scatter not in a very closely forward direction, but over angles of more than 1°. For more closely forward angles (smaller than 1°) we approach the domain that can be captured with other techniques, such as double-pass and wavefront-sensing approaches.

CIE Standard Observer

As mentioned above, the CIE has adopted standards for the glare of the normal observer. The CIE equations are given here. The total glare function proposed by Vos and Van den Berg (as eqn [8] in the CIE report) does actually give the complete PSF. It reads:

$$\mathrm{PSF} = [L_{\mathrm{eq}}/E_{\mathrm{gl}}]_{\mathrm{total}} = \left[(1-0.08)(A/70)^4\right]\left[\frac{9.2\times10^6}{\left[1+(\theta/0.0046)^2\right]^{1.5}}+\frac{1.5\times10^5}{\left[1+(\theta/0.045)^2\right]^{1.5}}\right] + \left[1+1.6(A/70)^4\right]\left\{\left[\frac{400}{1+(\theta/0.1)^2}+3\times10^{-8}\times\theta^2\right] + p\left[\frac{1300}{\left[1+(\theta/0.1)^2\right]^{1.5}}+\frac{0.8}{\left[1+(\theta/0.1)^2\right]^{0.5}}\right]\right\} + 2.5\times10^{-3}\times p[sr^{-1}],$$

where θ is the glare angle in degrees, A the age in years, and p a pigmentation factor ($p = 0$ for very dark eyes, $p = 0.5$ for brown eyes, and $p = 1.0$ for blue–green-eyed Caucasians).

Figure 1 shows the angular course of this function for $A = 62$ years and $p = 1$. Note that the total dynamics of the PSF span a range of about 10^9, or 1 000 000 000. Due to this enormous range, the differences for the various conditions appear to be very subtle, whereas, in fact, they are functionally very significant. These differences are more clearly represented when the curves are presented in terms of the straylight parameter s by multiplication of the PSF with θ^2. In this way, the approximate $1/\theta^2$ angular dependence is removed, so as to allow a better view of differences, see **Figure 7**.

For practical purposes, the CIE 1999 total glare equation is relatively complicated. Therefore, some simplified equations were formulated. The most simple (given as eqn [9] in the CIE report) version of a disability glare formula seems to be the classic Stiles–Holladay equation, in which the

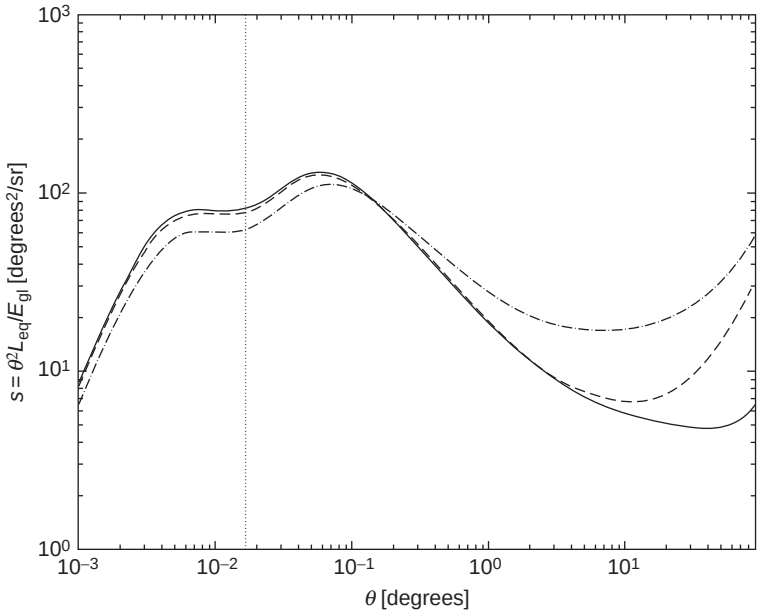

Figure 7 The CIE 1999 total glare function (PSF) multiplied by θ^2 to represent it in terms of the straylight parameter for a 35-year-old negroid (continuous line), a 35-year-old blue–green eyed Caucasian (dashed line), and a 80-year-old blue–green eyed Caucasian (dash–dotted line). The vertical dotted line indicates 1 min of arc. This is customarily assumed to be the smallest detail that can be resolved by an eye having a visual acuity of 1.

constant is multiplied by an age factor. It was called the age-adapted Stiles–Holladay equation:

$$\mathrm{PSF} = \left[L_{eq}/E_{gl}\right]_{S-H,agead} = \left\{1 + [A/70]^4\right\} 10/\theta^2$$

which has a validity domain that runs from 3° to 30°. As it is evident that the Stiles–Holladay equation falls short in particular below 1°, the following equation, the simplified glare equation (eqn [10] in the CIE report[131]), may serve in a more extended angular domain:

$$\mathrm{PSF} = \left[L_{eq}/E_{gl}\right]_{simpl} = 10/\theta^3 + \left\{1 + [A/62.5]^4\right\} 5/\theta^2,$$

which has a validity domain from 0.1° to 30°. To also cover the very large angle domain, more terms of the total glare equation should be taken into account; this is the general glare equation (eqn [11] in the CIE report):

$$\mathrm{PSF} = \left[L_{eq}/E_{gl}\right]_{gen} = 10/\theta^3 + \left[5/\theta^2 + 0.1 \times p/\theta\right] \cdot \left\{1 + [A/62.5]^4\right\} + 2.5 \times 10^{-3} \times p,$$

which has a validity domain that stretches from 0.1° all the way up to the very limit of the field of view, somewhere around 100°.

Relation between Straylight and Other Test Outcomes

Visual Acuity

There is only a weak relation between straylight and visual acuity. This is because straylight is determined by light scattering over larger angles (1–90°), whereas visual acuity is determined by light deflections over small angles (<0.1°, more commonly known as aberrations). Moreover, the physical processes that cause these light deflections are different for the two angular domains. Therefore, changes in one domain do not necessarily mean changes in the other domain. For example, putting a +2 dpt trial lens in front of a subject's eye will definitely change the subject's visual acuity, whereas his/her straylight value will stay precisely the same. On the other hand, putting a fog filter in front of the subject's eye will show a dramatically increased straylight value, whereas visual acuity will hardly decrease. This independence is also illustrated in the practical population by **Figure 8** for a large European-driver study.

Contrast Sensitivity

This is the subject of much misunderstanding. Contrary to what is often believed, straylight affects normal contrast sensitivity only very weakly. It is true that straylight reduces the contrast of the image of the outside world that is projected on the retina. Hence, increased straylight means lower contrast sensitivity. Only the decrease in contrast sensitivity is much smaller than the increase in straylight. This is illustrated in **Figure 9**. Five times increased light scattering lowers the contrast sensitivity function by only 20%; a very small amount, especially when compared to the contrast-lowering effect of blur (decreased visual acuity) or a bifocal implant or contact

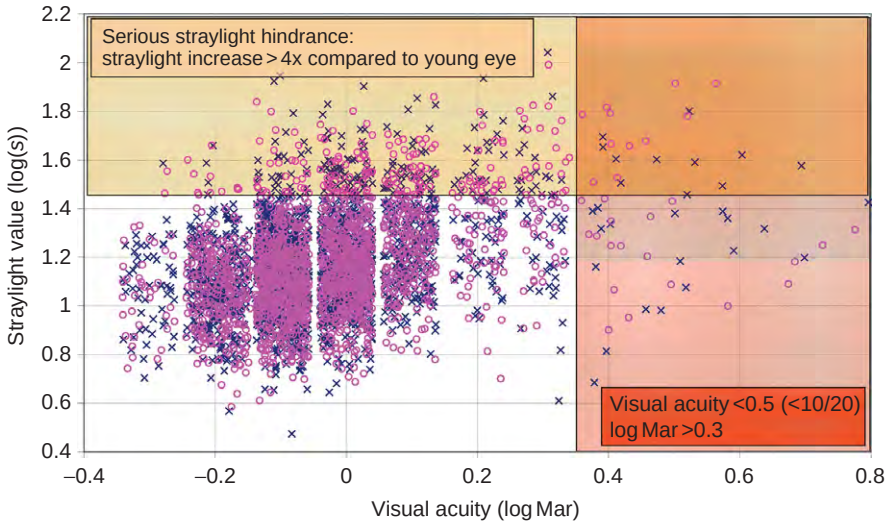

Figure 8 Straylight value as a function of visual acuity for a European driver population. Log(s) values > 1.47 and visual acuities < 0.5 (log MAR > 0.3) are considered serious visual impairments. A lot more individuals in this population are impaired by increased straylight than by decreased visual acuity. Only a very small subgroup suffers from both impairments.

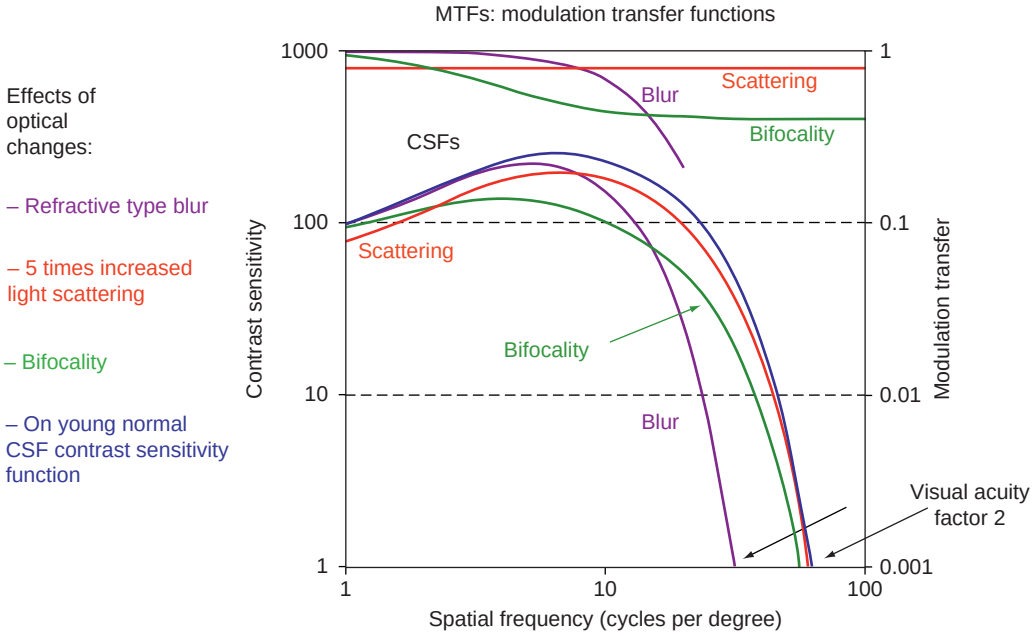

Figure 9 Effects of optical changes on the contrast sensitivity function.

lens. In other words, contrast sensitivity cannot be used as a valid means to assess the amount of straylight.

Glare Sensitivity

Maybe a reason for the misunderstanding is that it is still true that one of the most important effects of straylight is reduction of contrast sensitivity (see the examples in Figure 3). But the point to make here is that in our normal surroundings, huge intensity differences exist. Due to straylight, high-intensity areas influence effective contrasts and, as a consequence, effective contrast sensitivity in low-intensity areas. A better correlation between straylight and contrast sensitivity may be found when contrast sensitivity is measured with a glare source next to the measurement chart. But in that case, differences between subjects will also depend on differences in

contrast sensitivity that already exist without the glare source. Therefore, the parameter that would best relate to the straylight value is the decrease in contrast sensitivity caused by the glare source. There have been attempts to measure glare sensitivity in both ways with so-called glare testers. The Rodenstock Nyktotest, depicted in Figure 10, is an example of the first type (plain contrast sensitivity measurement with a glare source at the side). The second type is in fact a straylight measurement, but in an indirect, and therefore less accurate, way. In theory, it is a valid measurement, which may seem to relate more to all-day real-life circumstances, but in practice, the results appeared to be unreliable and could not be related to the patients' complaints.

Straylight and Slit-Lamp-Based Examination

Using backward light scatter, such as those based on the slit lamp examination principle (e.g., digital slit lamp, Scheimpflug system, lens opacity meter, LOCS), it is possible to assess opacities of the optical media of the eye. Figure 11 gives the LOCS III classification chart developed by Chylack and coworkers. These opacities are partly responsible for the amount of light scattering in the eye, so there may be a relation between the degree of opacity as observed with the slit lamp and the amount of straylight. However, this will not be a one-to-one relation for two reasons. First, as already mentioned, the opacities account for only a part of the total light scattering. For example, the transparency of the iris and sclera, as well as the amount of light reflected from the fundus, are not assessed by the slit lamp examination. Second, with the slit lamp one looks at light that is scattered back from the optical media. This is not the light that reaches the retina, which is the light that is scattered in forward direction. Studies showed that no direct relation exists between the forward and backward scatter. Therefore, it makes more sense to measure the amount of forward scatter, as this is what the patient actually sees and is bothered by.

Figure 10 Rodenstock Nyktotest.

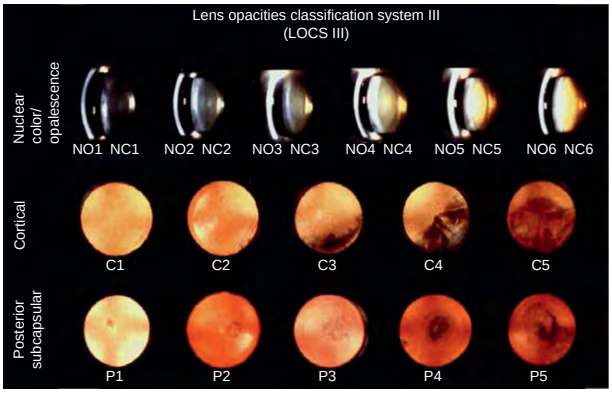

Figure 11 Lens opacities classification system (LOCS) III.

Straylight and Patient Complaints

Patient complaints from increased straylight may be voiced in a variety of ways. It is important to note that straylight defines a functional condition of the eye in a physical way, and the patient complaints will not always correspond with equal precision. As listed above, complaints may include hazy vision, increased glare hindrance, loss of contrast and color, halos around bright lights, and difficulties with against-the-light face recognition. The complaints mentioned or even the words used to describe them may strongly depend on the individual subject. Moreover, it must be mentioned that in the field of glare a particularly subjective type of patient response has been identified, called discomfort glare. As opposed to disability glare, which is the functional effect of glare, discomfort glare is a description of subjective glare. Complaints may be expressed in terms of discomfort, annoyance, fatigue, and even pain. On average, increased disability glare will also lead to more discomfort; however, in some cases, such as with the nowadays-abundant blue-light high-intensity discharge (HID) car headlamps, people might be severely annoyed by light sources that have only a moderate functional glare effect.

Frequently Asked Questions

What Are the Causes of Retinal Straylight?

The amount of retinal straylight is different for each individual, and may even be different for the two eyes of one individual. It depends on age, pigmentation, pathologies, such as cataract, and may change due to human interventions such as refractive surgery.

Normal eye

Within the eye, there are four major sources that contribute to the total amount of straylight: the cornea, the iris and sclera, the eye lens, and the fundus (see **Figure 3**). For a young, healthy, Caucasian eye, the total amount of straylight is, roughly speaking, 1/3 caused by the cornea, 1/3 by the lens, and 1/3 by the iris, sclera, and fundus. These ratios change with age and pigmentation:

- Corneal light scatter is more or less constant with age, but may increase as an unwanted side effect of refractive surgery.
- The iris and sclera are not completely opaque. Depending on the level of pigmentation, some of the light falling on the iris and sclera will be transmitted and contribute to the false light that reaches the retina. This contribution will be low for pigmented non-Caucasians (who have brown eyes), but might be considerable for lightly pigmented blond Caucasians with blue eyes.
- Light scattering by the crystalline lens increases with age, especially when people develop a cataract, which in terms of straylight can be seen as an accelerated aging of the eye lens.
- The fundus does not absorb all the light, so part of the light that reaches the retina will be reflected backward and scatter to different locations on the retina, thus contributing to the total amount of straylight. The amount of this scattered light is pigmentation dependent.

Important causes of increased retinal straylight

Some of the major causes for increase in retinal straylight are:

1. *Early cataract.* If cataract starts to develop, the earliest complaints often are from increased straylight, such as increased glare hindrance when driving at night. In fact, most often the first effect of cataract is that patients stop driving at night. Other complaints may include hazy vision, loss of contrast and color, halos around bright lights, and difficulties with against-the-light face recognition (see examples in **Figure 3**). Why should patients be allowed cataract surgery only on the basis of visual acuity loss?
2. *Corneal disturbances.* Most corneal disturbances as, for example, in corneal dystrophies cause strong increase in straylight. In some cases, visual acuity can be remarkably maintained while straylight deterioration is strong, such as in corneal edema.
3. *Refractive surgery.* In refractive surgery, there is a chance of haze in the cornea. Visual acuity hardly suffers, but complaints from straylight such as glare are of considerable concern.
4. *Contact lenses.* As a rule, contact lenses cause straylight to increase. Deposits or scratches can often be identified as a major cause of increased straylight, but if the cornea reacts to improper (use of) contact lenses, straylight increase can be huge.
5. *Turbidity in the vitreous.* This can cause large increases in straylight, often also without much effect on visual acuity.

What is the Reliability of a Straylight Measurement?

The CC method as implemented in the C-Quant straylight meter measures straylight as the subject actually sees it (and is disturbed by it). However, because it is a psychophysical technique, reliability of individual measurements needs to be checked (as with visual-field measurements). Therefore, a reliability parameter (estimated standard deviation (ESD)) was designed that predicts the accuracy of an individual measurement. In the C-Quant, a limit value of ESD $\leq$ 0.08 is used. In the large European-driver study an overall accuracy of 0.1 log units was found. These accuracies are more than sufficient compared to the effects to be measured (see above).

Does Pupil Size Affect the Straylight Measurement?

This subject is the cause of a lot of misunderstanding. As more glare is experienced at night, one might think that straylight is stronger at night. This may be believed to be caused by a larger pupil size. Indeed, the amount of straylight is higher because of the larger pupil, but also the nonscattered light (which is the light that forms the image on the retina) is increased, and by the same amount. Therefore, the straylight value will not change (the ratio stays the same). However, this is only true in general. On an individual basis, an increase as well as a decrease might happen, depending on the location-dependent scattering properties of the eye. For example, a patient with a centrally located lenticular opacity may get a lower straylight value with larger pupil size. In other words, to assess straylight hindrance at night, it is not needed as a rule to dilate the patient's eye when using the C-Quant.

Ocular Mucins

M Berry, Bristol Eye Hospital, Bristol, UK

Glossary

Alternative splicing – A variation mechanism in which linear combinations of exons are translated, resulting in a variety of mature products encoded by a single gene.
Atomic force microscopy (AFM) – A technique of high-resolution imaging through the measurement of forces between atoms in the sample and those on the instrument tip.
Glycan – The oligosaccharide portion of a glycoconjugate.
Glycocalyx – An outer, carbohydrate-rich coating on the surface of cells.
Glycoforms – Variations in the amount or compositions of oligosaccharides decorating the same peptide core.
Meibomian glands – The special sebaceous glands at the rim of the eyelids that supply the lipid layer of the tear film.
Mucins – A family of large, heavily glycosylated molecules, with most glycan chains O-linked to the peptide core.
Persistence length – A measure of polymer stiffness; it is the length over which correlations in the direction of the tangent are lost.
Reptation – Movement of a long polymer parallel to itself, similar to the movement of a snake.
Tandem repeats – The adjacent repetition of a pattern of two or more nucleotides.
Worm-like model – A model for the behavior of semiflexible polymers, considered continuously flexible.
Young's modulus – A measure of elasticity, defined as the ratio of stress to strain.

Introduction

In addition to the well-defined anatomical blind sac formed by the cornea and conjunctiva, the meibomian and lacrimal glands, the ocular surface comprises a mucosal immune system, rich neural and endocrine loops, as well as the blink reflex. As with other mucosal systems the ocular surface is further integrated into the adaptive immunity of the organism, and into the microbial richness of the outer environment. An additional and specific requirement of the ocular surface is the maintenance of transparency that applies to the cornea as well as to the preocular fluid.

Bathing the exposed part of the outer eye is a complex fluid whose elements are secreted by the wet epithelia, and the lacrimal and meibomian glands. Mucins are the main component of a mucus gel and responsible for its viscoelastic properties. They form a dynamic matrix wetted by a plasma dialysate enriched by secretions from the lacrimal glands and topped by a layer of waxes and lipids originating in the meibomian glands. This fluid is periodically sheared and mixed by the movement of the lids during blinking. Underneath the mucous gel, the epithelial glycocalyx anchors the tear film to the ocular surface: mucins and glycoproteins are the major components of this layer.

Mucin Architecture

A very rich glycosylation, with most sugar chains O-linked through *N*-acetylgalactosamine (GalNAc) to serine or threonine in the peptide core, is diagnostic of mucins. Sugar chains tend to be clustered in discrete regions resulting in concentrations of negative charges. In these high-charge regions the peptide core is rich in serine, threonine, and proline (PTS domains), and repeated sequences of aminoacids (variable number of tandem repeats, hence VNTR domains) are present, specific to the encoding gene. Other regions are less richly glycosylated and contain relatively more N-linked glycan chains, the latter necessary for mucin transit through intracellular microtubules during synthesis. In humans, ocular mucin regions of tens of nanometers seem to be almost naked: the molecular diameter measured in liquid with atomic force microscopy (AFM) is not significantly higher than that of aminoacids in a helix (**Figure 1(a)**), giving mucin polymers the appearance of strings of small beads, small beads of dense bottlebrushes.

Toward the N- and C-termini of mucins, the arrangement of moduli is similar to those found in proteins involved in coagulation (von Willebrand factor, VWF domains), cysteine knots, or SEA (sea urchin sperm protein, enterokinase, and agrin) domains. These are useful in tracing the evolution of mucin genes. Genes encoding for PTS domains and multiple VWF domains (D1–D2–D3 PTS, as in secreted mucins) can be found early in the evolution of metazoa, preceding hemostasis or coagulation

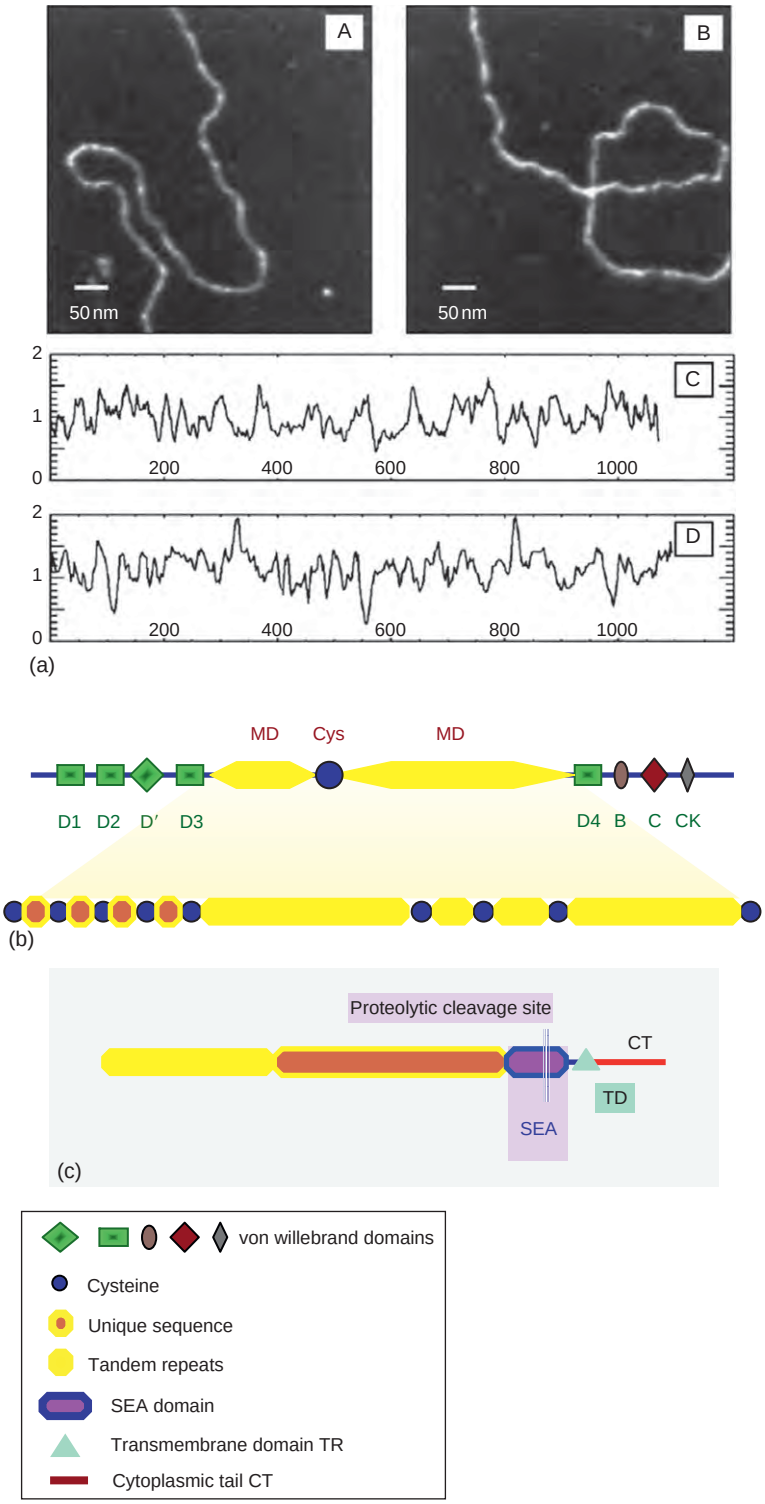

Figure 1 Architecture of ocular mucins deposited on mica (a) Portions of a hydrated human conjunctival mucin molecule imaged with AFM (A, B). The respective height profiles (C, D), highlight the short oligosaccharides of ocular mucins. All axes are in nanometres. Reproduced from McMaster, T. J. (1999). Atomic force microscopy of the submolecular architecture of hydrated ocular mucins. *Biophysical Journal* 77: 533–541. With permission from Biophysical Society. (b) Schematic of a mucin monomer, containing von Willebrand factor domains toward the C- and N-termini (D1, D2, D′, D3, and D4, B, C, and CK, indicated by green labels) and central mucin domains (yellow). A more detailed schematic of PTS domains reveals unique sequences (brown-filled octagons) and tandem repeat regions (yellow octagons) interspersed with cysteins (blue). Most secreted mucins polymerize by disulfide-bonded linear concatenation of such monomers.(c) Schematic of a cell-surface-associated mucin, containing an SEA domain (sea urchin sperm protein, enterokinase, agrin) within which there is a proteolytic cleavage site, a transmembrane domain (TD), and a cytoplasmic tail (CT).

(Figure 1(b)). SEA domain mucins appear in vertebrates, while the auto-catalytically cleaved SEA domain is restricted to mammals (Figure 1(c)).

Regions where the peptide core is extended by the insertion of the first sugar (GalNAc) and repulsion between negatively charged sugar chains alternate with more flexible polypeptide chain stretches, suggesting that mucins behave in solution like stiff random coils. Mucins occupy a large volume which indicates interpenetration of molecular domains at relatively low polymer concentrations. Using the worm-like model, calculations indicate that human ocular mucins are more flexible than DNA molecules of similar length; mucin persistence length is 35 nm and that of DNA is 50 nm. Polymer conformation and stiffness, for example, of human ocular MUC5AC glycoforms, are greatly influenced by the degree and nature of post-translational glycosylation.

Mucin architecture is determinant of mucin role and function at the mucosal surface and in the gel. The organ, developmental state, and physiological status, in turn, affect mucin expression and details of glycosylation. Ocular mucins have short oligosaccharide chains: in humans they are mostly less than six sugars long, negatively charged and terminated in sialic acid, with fucosylation representing less than one-fifth of the sugars (Figures 2 and 3). In dogs and rabbits, glycans are mainly neutral and terminated in fucose and/or GalNAc. The short oligosaccharides might be related to transparency and (relatively fast) turnover of mucins, and terminal sugars to environmental microbiota.

Mucin Families

Mucin genes appeared through a combination of moduli existing in other proteins. The close connection between mucin structure and function gives rise to a classification necessarily reflecting both.

Surface-associated mucins

Some mucins spend part of their life anchored into the apical cell membrane before they are shed into the luminal, that is, tear, fluid. Formerly known as membrane-bound mucins, they are now called cell-surface-associated mucins. These are heterodimers, with a large mucin subunit outside the cell, a (mostly hydrophobic) membrane-spanning region and an intracellular tail. A number of subfamilies are represented at the ocular surface: the mammalian-specific MUC1 with its SEA domain; the MUC16 that contains multiple SEA domains, not all of which are cleaved; and the MUC4 that has VWD but neither cysteine-rich domains nor SEA. Shedding of these mucins is thought to cause changes in the neighboring membrane domains, potentially transferring information to the cell interior. A further possibility is that information is conveyed through the cytoplasmic tail to the cytoskeleton. An important result of surface mucin release in the tear fluid is the renewal of the glycocalyx and the tear fluid itself.

This group of mucins is heterogeneous and most genes also encode splice variants that are secreted: MUC4, a cell-surface mucin in normal cornea and conjunctiva, is a goblet cell mucin in some pterygia (Figure 4). MUC1/SEC, a splice variant of MUC1 that lacks the transmembrane domain and, therefore, results in a soluble, secreted form of MUC1, is present in human cornea and conjunctiva.

Secreted mucins

Milliseconds after the secretion of mucins stored in granules, often in specialized epithelial cells, their volume

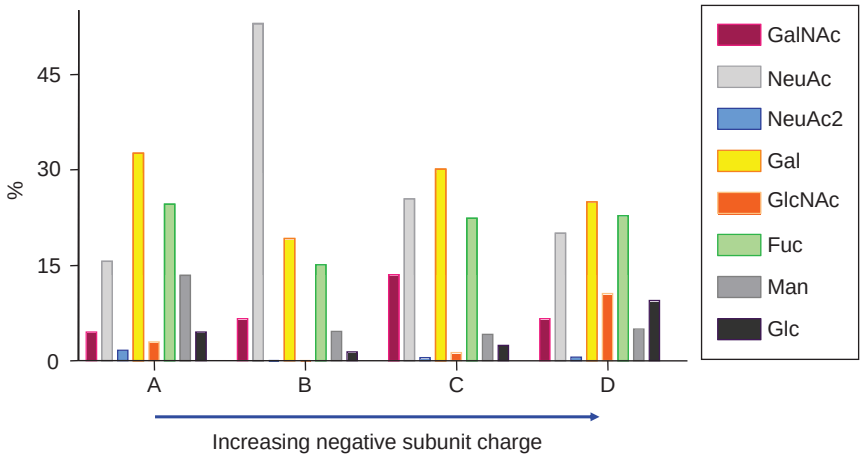

Figure 2 Monosaccharide composition of human ocular mucins. The increase in sialic acids, mono- or di-acetylated (NeuAc, or Neu-Ac2) did not parallel the increase in negative subunit charge (A<B<C<D). High negative charge was conferred by an the appearance and increase of sulfated oligosaccharides (not shown).

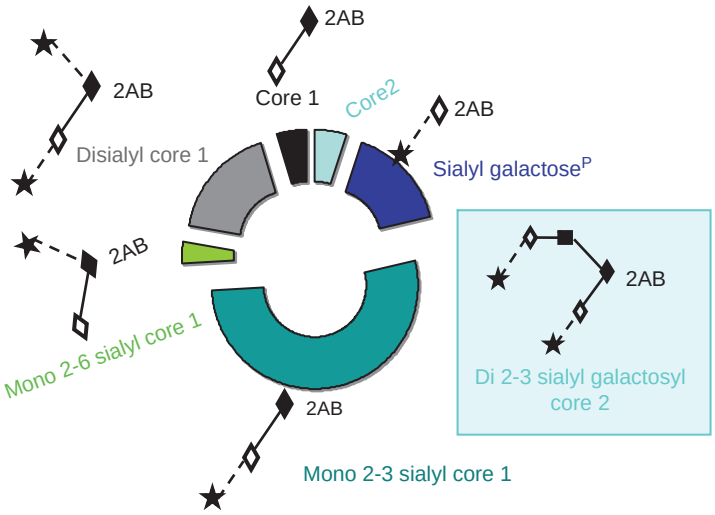

Figure 3 Oligosaccharide composition of human ocular mucins. This pie chart indicates the abundance of the different glycans of purified human ocular mucins obtained by hydrazinolysis. Each sequence is named in the color of its proportion in the total glyco-repertoire, while its structure is indicated in the sugar notation presented below. Notable is the high proportion of sialylated oligosaccharide chains, almost half of which contain α2-3-linked sialic acids. A cautionary note: at present the method used for determining O-linked glycan composition affects the results. Glycochip methods often estimate a higher proportion of core 2 glycans than obtained by hydrazinolysis and HPLC. Notation of sugars in the figure is as follows: ◆ *N*-acetylgalactosamine (GalNAc); ◊ galactose (Gal); ■ *N*-acetylglucosamine (GlcNAc); ★ *N*-acetylneuraminic acid (NeuAc). Solid lines denote β linkages, dashed lines mark α links.

increases 100-fold in the extracellular fluid as a result of hydration. These secreted mucins have a well-defined VWF-D2-D3 PTS architecture, and Cys-rich domains or Cys knots. VWF domains and Cys are involved in the concatenation of mucin subunits (Figure 5). The secreted mucins – MUC2, MUC5AC, MUC5B, MUC7, MUC19, and MUC23 – have been found at the ocular surface, in cells, impressions, and tears. MUC20 messenger RNA (mRNA) has also been identified in the conjunctiva. With the notable exception of MUC7, secreted mucins form linear polymers of subunits linked by disulfide bonds and form gels, and are thus called secreted gel-forming mucins. Polymers extracted from cells (and protected from proteolysis) may be few microns long; in the secretion, submicron lengths dominate. MUC7 oligomers are like spokes of a wheel around a central, yet to be fully described, entity. Though MUC7 is not gel forming, it is found in gels, for example, saliva, from which it has been originally described.

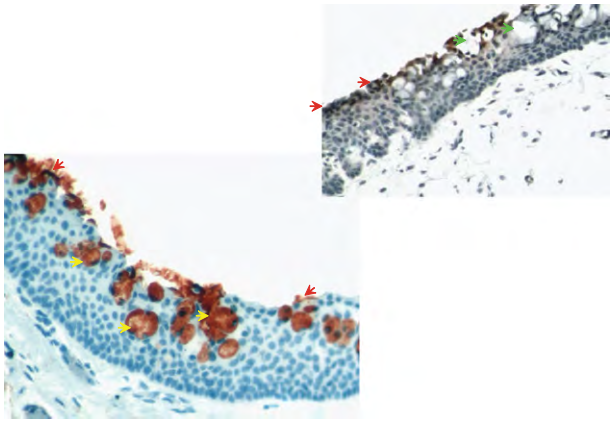

Figure 4 MUC4 alternative splicing in pterygium. In normal conjunctival tissue MUC4 is mainly a surface-associated mucin. In pterygia, triangular growths of the conjunctiva over the cornea, it can be present either as surface associated (red arrows) or secreted (yellow arrows) within prominent goblet cells. Where pterygial MUC4 is surface associated, goblet cells do not light up with anti-MUC4 antibodies (green arrows). MUC4 was visualized with antibody 4F12 (DSHB, Yowa, USA); counterstain: hemalum. Images: courtesy of Friedrich Paulsen, Halle University, Germany.

Biosynthesis and Turnover

Synthetic pathways

Mucin genes account for nearly 4% of genes expressed in the normal conjunctiva, with a further 29% dedicated to glycosyltransferases. During synthesis, molecular species with varying properties are transported to the location corresponding to their stage in this complex process. MUC5AC might take over 2 h from initiation to storage in the secretory granule. The making of secreted mucins starts with the synthesis of the peptide core in the endoplasmic reticulum, where N-linked sugars are also added. Following folding of the C- and N-termini, the peptides dimerize through S–S bonds between cysteine knot

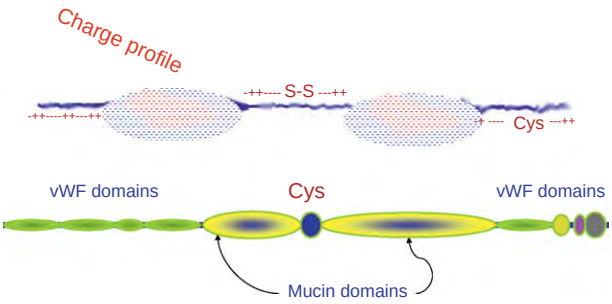

Figure 5 Schematic of secreted mucin structure. Secreted mucins have a well-conserved architecture. Within mucin domains, repeated sequence(s) called tandem repeats are gene specific. The concatenation of mucin subunits gives rise to a polymer with concentrated regions of negative charge, interspersed with less charged, less glycosylated regions. vWF, Von Willebrand factor domains; Cys, cysteine.

domains at the C-termini. O-glycosylation is initiated and elaborated in the *cis*- and medial Golgi. Further polymerization, S–S bonds between VWD3 domains at the N-terminal, occurs in the *trans*-Golgi and the secretory granule. Cell-surface mucins too acquire their N-linked sugars in the endoplasmic reticulum, where the peptide core is cleaved into the two domains, and further glycosylated as these mucins progress through the Golgi. A signal peptide in the N domain localizes cell-surface-associated mucins at the apical membrane; the cytoplasmic domain starts with a signal sequence involved in retention at the plasma membrane and mucin recycling.

Glycosylation

Glycosyltransferases

Mucin glycans are synthesized in the Golgi apparatus. The presence, activity, and localization of glycosyltransferases along the Golgi cisterns are the primary determinants of glycan chain density and sequence. The initial transfer of GalNAc from UDP-GalNAc to the hydroxyl group of Ser/Thr in the peptide backbone is catalyzed by uridine diphosphate GalNAc:polypeptide N-acetylgalactosaminyl transferases (ppGalNAcTs). Subsequent sequential sugar additions are catalyzed by glycosyltransferases (GalNAc-Ts). Nucleotide-sugar synthases and hydrolases, and genes encoding their transport proteins add further dimensions to the function and regulation of mucin molecules.

In other mucosae, for example, respiratory epithelium, epidermal growth factor (EGF), Th2 cytokines, and all-trans retinoic acid alter the expression of GalNAc-Ts, some of which are also downregulated in cancer. Molecular details of transcriptional regulation of glycosylating enzymes are not known for the eye. The final density of glycosylation and chain structure strongly depends on the availability of sugar nucleotides, and competition between enzymes for acceptor intermediates during glycan elongation, incorporating a measure of randomness in the glycan population.

At the human ocular surface, ppGalNAcTs are distributed in an epithelial layer and in a cell-type-specific manner. Isoform –T3 was detected in all the epithelial layers, while –T2 in restricted to basal cells; –T4 is expressed in all apical cells. One member of the family, ppGalNAcT-6, was found in goblet cells only in normal subjects, but in apical cells of conjunctival epithelia in patients with ocular cicatricial pemphigoid, together with the –T2 isoform.

How elongation of oligosaccharide chains is regulated is not yet understood: in humans, rabbit, and dog, ocular mucins have short sugar chains. The same mucin gene product in the respiratory or gastrointestinal mucosa is decorated by chains many tens of sugars long.

The ensemble of human ocular surface enzymes is such that mucin oligosaccharides are negatively charged and mostly terminated in sialylated structures, including the histo-blood Lewis group antigens (sialyl Le^x and sialyl Le^a). The number of different structures is low, barely in double figures, compared with many hundreds in respiratory epithelia from one subject, for example. Histo-blood group antigens are involved in neutrophil adherence and activation. Because of the short chains, sugar epitopes that are cryptic in other mucosae are overt in human ocular mucins, for example, Tn or SialylTn that are richly present in the normal conjunctival epithelium. Which sugars or end groups are exposed in the glycan envelope of the tissue remains to be clarified for the ocular surface. Variation in this envelope is likely to modulate both immune effector cells and bacterial adhesion to the conjunctiva or cornea.

Turnover

Quantities, species, and glycoform composition of mucin populations on the ocular surface are a dynamic result of mucin production, secretion, and degradation. Not all the factors involved in this process are known: immune and infective agents modulate synthesis and secretion, as do neural stimuli; enzymes in the tears contribute to mucin degradation, while tearing and blinking are believed to remove spent mucus from the surface.

There are no data on average half-life of mucins in the preocular fluid. Extraction of large and glycosylated mucin polymers from contact lenses suggests that some escape degradation during waking hours.

Recycling

There is evidence that surface-associated mucins are re-uptaken into the Golgi and re-glycosylated. In the cell lines where these experiments have been done, the final glycosylation of the mucin is different from its original, and, at least for MUC1, the uptake depends on mucin

palmitoylation. It is not known whether this also occurs at the surface of the eye.

Degradation

Bacteria are an essential player in mucin degradation: glycosidases and proteolytic enzymes contribute to mucus gel breakdown and renewal; adherent bacteria are probably wrapped in mucin epitopes (sacrificial epitopes) and removed from the surface. During sleep, neutrophil enzymes degrade the gel and cause or enhance the cleavage of surface-associated mucins, promoting recoating of epithelial surfaces with a mucus gel.

Control of Secretion

Mucins are a defensive secretion, augmented in response to pathogens and stimuli, including mechanical, thermal, and chemical insults (through nocioceptors in cornea and conjunctiva). Though the signaling pathway triggered by the external stimulus might be distinct, the involvement of protein tyrosine kinases, mitogen-activated protein kinases (MAPKs), and transcription factor NF-kappa B are relatively common.

In the conjunctiva, the eicosanoid 15-(*S*)-hydroxy-5,8,11,13-eicosatetraenoic acid (15(*S*)-HETE) stimulates MUC1, but not MUC2, MUC4 release, suggesting mucin-specific control of surface-associated mucin liberation in the tears. Further evidence for gene-product-specific modulation is derived from studies of a human corneal limbal epithelial cell line where matrix metalloproteinase-7 and neutrophil elastase induced the release of MUC16, but not of MUC1 or MUC4.

Nucleotide agonists acting locally through $P2Y_2$ purinoceptors (belonging to the major G-protein-coupled receptor (GPCR) family) on apical membranes of goblet cells provide a major regulatory system for mucin secretion. Cholinergic agonists are potent stimuli of mucin secretion. One of the pathways to secretion is through EGF receptor (EGFR) induction of MAPK. A fast Ca^{2+} sensor for the soluble NSF attachment protein receptor (SNARE) complex (the core machinery of membrane fusion) is essential for regulated secretion.

Individual Variation

It is not known whether the number of goblet cells varies in individuals. Their number, as assayed by impression cytology, represents those that are discharging in response to external stimuli, and depends on external factors, for example, wind, humidity, and spectacle wear. Goblet cell numbers decrease in severe, but not mild, dry eye disease.

Allelic variation, for example, in the number of tandem repeats, is but one source of individual variation. Additionally, variation in glycosyltransferases and in the availability of donor sugars in different physiological states gives rise to potentially large individual variation. However, the size-to-charge ratio of mucin populations is surprisingly well conserved: migration patterns of mucins from conjunctivas of men and women of different ages are similar, suggesting a tight control on the molecular size/charge ratio of intracellular mucins. Conservation of population parameters is also encountered in the largest mucins extracted from tears or contact lenses as shown in **Figures 6 and 7**. Ratios of the different mucin species sampled from the ocular surface showed little variation in asymptomatic contact lens wearers. The variation must therefore be more subtle and is yet to be understood.

Mucin Function

Mucins are essential for the defense of the organ from external factors. Mucins are: (1) lubricants easing the movement of the lids over the surface of the eye; (2) a physical barrier; (3) a trap for microbes; and (4) a matrix where tear constituents among which enzymes, antimicrobial peptides, and other signal molecules fulfill their physiological role. The surface mucins that are richly represented on cornea and conjunctiva are expected to fulfill signaling functions, which are yet to be clearly understood.

Adequate production of mucins is controlled by neural, hormonal, and other signaling networks. In addition,

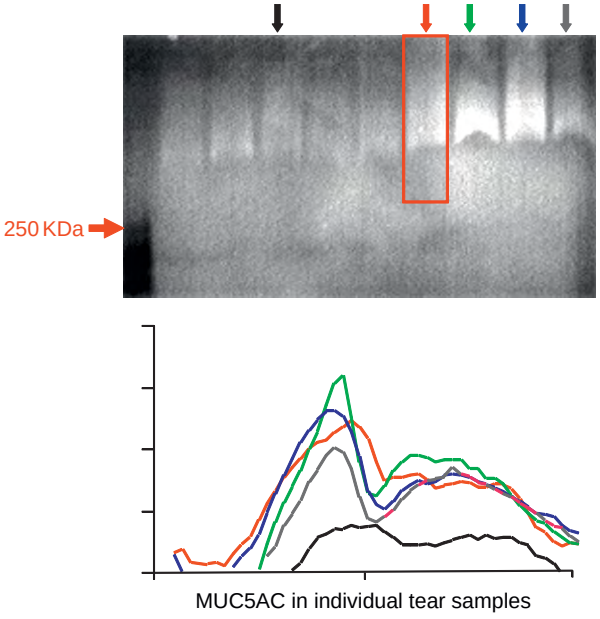

Figure 6 Electrophoresis of MUC5AC from individual tear samples. Very little variation was seen between the mobilities of the largest MUC5AC polymers in tears from nine individuals. Samples (not equalized for protein content) were run on 1% agarose electrophoresis, vacuum blotted, and visualized after incubation with antibody CLH2 to MUC5AC peptide core. The graphic underneath shows details of mobility for the color-coded respective lane.

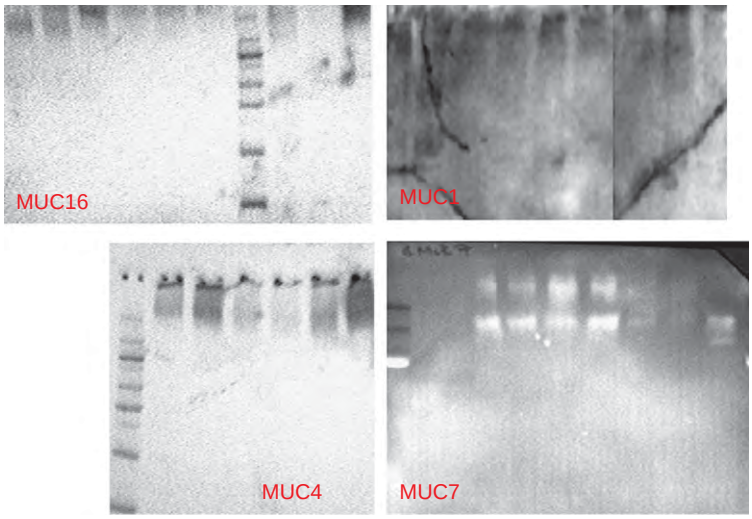

Figure 7 Electrophoretic profile of mucins in individual tear samples. Electrophoresis on NuPage Bis-Tris gels allows analysis of MUC1, MUC4, MUC7, and MUC16 and their fragmentation in individual samples. There are clear similarities in mobility, at least for species sufficiently represented to be detected with these methods.

a massive discharge of mucins occurs as a response to environmental stimuli, from mechanical stimulation to bacterial lipopolysaccharide.

Gel Formation

Mucins adhere to surfaces through either sugars or peptide sequences. In a physiological buffer, sequential adhesions of a mucin lowered onto mica were most often spaced similar to the atoms on this surface, indicating that no region of the molecule is barred from adhering to the substrate. The early events in adhesion are governed by random diffusion. Later (i.e., after the first polymers have adhered), cooperative sequential adsorption occurs, creating regions of high mucin density.

In dilute solutions, mucins reptate, that is, the polymer slides parallel to itself. A long mucin can thus extricate itself from entanglements, like a strand of spaghetti from a tangle.

Mucin polymers associate through long-range hydrogen bonds; they interact with like-charged moieties (e.g., sugars on another polymer) through bridging divalent cations, and form disulfide bonds between unpaired cysteins. Lectin-like site adhesions and hydrophobic domain interactions are also expected to contribute to gel formation, additional to the entanglement of these flexible polymers (**Figure 8**). The ocular surface is covered by a stable and dynamic mucous gel. *In vitro*, the elastic properties of the gel are conserved in time and recover after addition of purified ocular mucin – paralleling the discharge of granules from a goblet cell in the conjunctiva (**Figure 9**). The dynamic nature of the gel can be gleaned in changes in the roughness of its surface, and the temporary oscillations in elastic qualities after intervention. Calcium chelation weakens

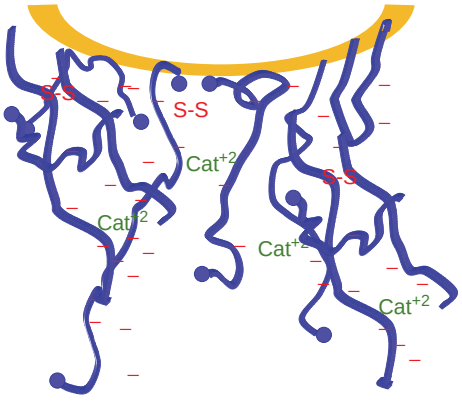

Figure 8 Mucin adsorption and intermolecular bonds. Schematic of mucin adsorption and association (animation). Sugar or peptide-core moieties can adhere to a surface; intermolecular long-range bonds are established between charged epitopes, bridged by divalent cations in solutions, and through unpaired Cys moieties.

human preocular mucus gels: subsequent addition of Ca restores their initial elastic qualities. The gel collapses on mucin depolymerization. Shorter mucins (i.e., $\leq$500 nm long) are more mobile in a model gel than the longest polymers ($\geq$1 µm long). It must be emphasized that the qualities of a gel depend not only on the mucins, but on all its constituents. Intracellular autocatalytic cleavage in the C-termini of MUC5AC is expected to generate reactive termini that form cross-links and enhance gel formation. The pattern of reactivities with antibodies to different parts of MUC5AC suggests that these cleavages occur in normal mucins, but not in those from dry eye patients.

Significant for mucin function is the fact that small entities (compared to pore size) gain more local mobility in a mucin gel than in viscous polymer solution, as

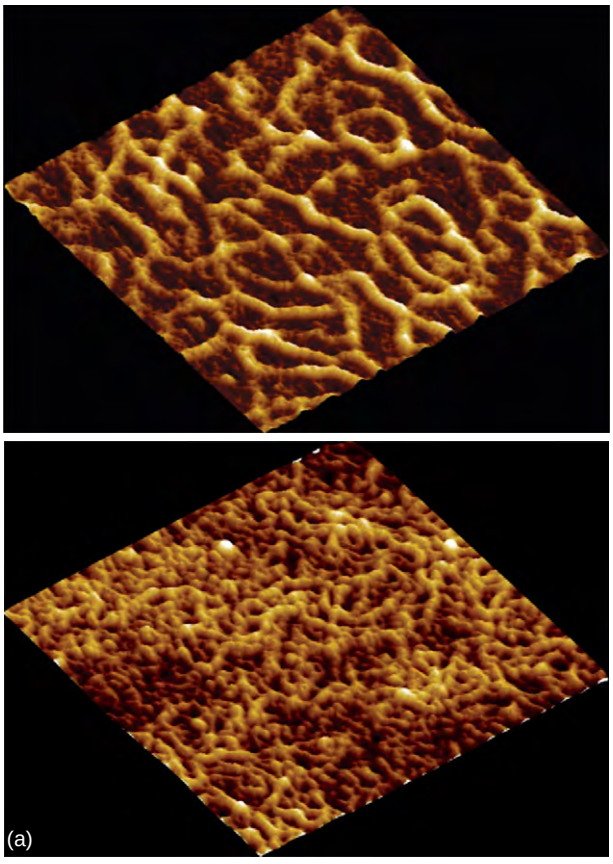

Figure 9 Purified mucin gels *in vitro*. (a) AFM topographical images during formation of mucin gels by repeated deposition of purified mucins on mica, in HEPES buffer (animation). (b) Characteristics of ocular mucin gels *in vitro*. Correlates of Young's modulus (elastic modulus, E*) of the gels were calculated from indenting the gel surface with an AFM tip. These elastic characteristics of the gel were calculated at different depths (of the order of nanometres) within the gel, and differences reflect the effect of the stiff substrate. Elasticity being conserved, as illustrated for three cycles of indentation separated by more than 1 h, indicates that the gel is a stable structure. Throughout this period the gel was kept hydrated in HEPES buffer.

relatively large, typically 200–400-nm, fluid-filled pores open up. Thus, the transport of biologically significant molecules is enhanced in the preocular gel, while micron-sized pathogens are still prevented from penetrating.

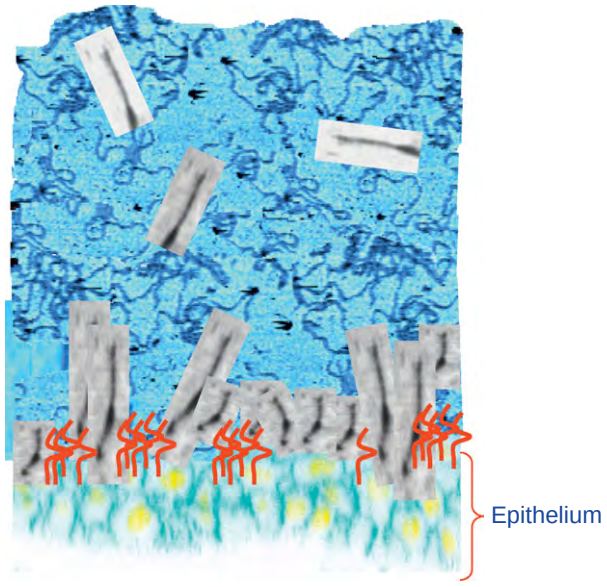

Figure 10 Schematic of the tear film anchoring to the ocular surface. Collage of confocal image of conjunctival epithelium and AFM images of cell surface associated (gray) and secreted mucins (blue). Glycocalyx is schematically shown in red.

Anchoring to the Ocular Surface

Surface tension is responsible for maintaining the tear film onto the ocular surface. Apical epithelial cells of the cornea and conjunctiva express a rich glycocalyx that interfaces with the secreted phase of the fluid. Entanglement, hydrogen bonding, sugar–sugar interactions, and lectin–sugar interactions are all involved in the interpenetration of the sessile and the stirred layer of the preocular fluid (**Figure 10**). Surface-associated mucins are longer than most other glycocalyx components and are expected to penetrate and entangle with elements of the secreted fluid.

Physical and Chemical Barriers

Particles (e.g., from mascara or cigarette smoke) can be seen trapped in the tear film for a period of time, after which they are eliminated from the ocular surface. This mechanism might involve wrapping in mucin or mucin aggregates, and it is also believed to be part of mucin turnover eliminating spent mucins. Sacrificial glycosylated epitopes, to which bacteria or viruses adhere before being eliminated, or which accept reactive molecular species, are also involved in the protective function of mucins.

Mucins are resistant to proteolysis because the peptide core is shielded by sugars. Degradation occurs at specific sites giving rise to small mucin polymers that are very mobile in the mucin gel. The presence of cleavage sites outside the cell membrane to which cell-surface mucins are anchored underlies the turnover of the glycocalyx and tear film itself, for example, through the action of neutrophil enzymes. The same mechanism has a protective

value, when, in response to bacterial enzymes, the cleavage of mucins and portions of gel removes invading organisms from the surface of the eye.

Lubrication

Water lubricates sliding soft surfaces densely covered with bottlebrushes of oligosaccharide chains. Mucin polymers incorporate large quantities of aqueous tears that bridge between negatively charged oligosaccharides. This cushioning layer sustains the pressure of the moving lids, thus decreasing friction. Furthermore, tears lower their viscosity with shear, further easing the blink. *In vitro*, in a physiological buffer, human ocular mucin macromolecular aggregates slide past each other without forming adhesions.

Tear Breakup

Evaporation is the organizing event of tear breakup. The evaporation of water from the liquid trapped in the pores of the gel may cause an increase in salts, and importantly in divalent cations, which causes a local salting-out of mucins and other polyelectrolytes, in turn causing a local collapse of the scaffold, and thus a dry spot on the ocular surface.

Antimicrobial Activity

The ocular surface is not sterile; it hosts commensal bacteria that are part of the normal ocular surface physiology. Mucins are considered to have co-evolved with bacteria. Their mutual relationships result in continued and effective protection of the underlying tissues. Signaling between microflora and host mucosa impacts on local metabolism and immune function in ways which are a current focus of research.

Carbohydrates, including mucin glycans, can be used as an energy source for bacteria. At the ocular surface, mucin oligosaccharides are protected from bacterial degradation by the acetylation of their terminal sugars: most sialic acids are mono-O-acetylated, and a minority di-acetylated. Acetylation prevents or restricts bacterial glycolytic enzymes. A proportion of mucin terminal sugars is sulfated, which also protects from cleavage of the glycan by bacterial enzymes.

For many bacteria, mucins are antiadhesive: denuding a cornea of mucins resulted in a large increase in the number of organisms attached to its surface. This effect can be achieved by mucin glycans interacting with bacterial adhesins and thus blocking them, and because bacteria coated in mucins do not bind to the mucosal surface. Mucins glide over those without any adhesions. In tears, *Pseudomonas aeruginosa* bind to specific oligosaccharide receptors containing sialic acids, and a substantial proportion of glycans are potential receptors. Mucin glycans, however, contain 10 times fewer sialic acids in the α2–6 linkage – the receptor for this bacterial species– than α2–3-linked sialic acids that are not adhesive (**Figure 3**). This example illustrates the two-pronged defensive mechanism of binding and removing in the bulk of the preocular fluid by dissolved moieties, and increasing antiadhesion closer to the epithelial surface.

To degrade complex substrates such as mucins, bacteria need an impressive array of glycosidases and peptidases acting in sequence. These are rarely in the arsenal of a single species, though they can be – and are – expressed by a bacterial community. Commensal bacteria degrade mucins: they cleave sugar chains and peptide backbones, changing the physicochemical characteristic of the mucin molecule. It is thought that in this way the commensal flora contributes to the renewal of the mucus component of the tear film.

Immune Protection

In large epithelial tracts, a link between mucins innate mucosal immunity and mucosal inflammatory responses is provided by modulation of mucin expression by inflammatory cytokines such as interleukins (IL)-1β, IL-4, IL-6, IL-9, IL-13, interferons, tumor necrosis factor-α, or nitric oxide. Neutrophils – the main patrolling cells of the closed eyes – can also stimulate increases in production of both gel-forming and cell-surface mucins through neutrophil elastase. *In vitro*, their degranulation and activation were shown to be different on normal and dry eye mucins.

Clinical Relevance and Pathology

Contact Lens Wear

If all species present in the preocular fluid also adhere to the contact lens without prejudice to its optical properties and gas permeability, a mucin coating should add cushioning, and provide added antimicrobial protection to the ocular surface.

Among mucins adhering to contact lenses there are very large and also (relatively) short mucin polymers, with both secreted and surface-associated mucins well represented. Mucins adherent to contact lenses might act as acceptors for reactive groups produced at the ocular surface. In these mucins, there exist subunits with much higher negative charge than observed in intracellular mucins. Naive wearers deposit more mucins on their lenses than experienced wearers, probably prior to habituation to the stimulus provided by the lens. Contact-lens-induced dry eye does not appear to alter the proportion of mucin species at the ocular surface.

Dry Eye Syndromes

Involvement of mucins in dry eye syndromes is suggested by a number of observations: (1) goblet cell numbers decrease in severe disease; (2) the quality of mucus can be manifestly affected with adherent plaques forming on the ocular surface; (3) ocular surface epithelia are (and feel) dry and even keratinized. The increase in squamous epithelial proliferation and relative (or absolute) decrease in goblet cells in dry eye syndromes highlight the different functions of surface-associated and secreted mucins in the preocular fluid.

Mucin genes are not altered in the conjunctiva of patients with moderate nonimmune (non-Sjögren) dry eye compared to normal conjunctiva. However, the expression of fucosyl- and sialyl-transferases is decreased, consistent with the decrease in sialylation observed in mucins of dry eye patients. Differences between neutrophil adherence and activation (dependent at least in part on fucosylated epitopes) on fields of normal mucins and mucins in Sjögren patients suggest that these differences become more severe with the severity of disease.

Optic Nerve: Optic Neuritis

K Hein and M Bähr, University of Göttingen, Göttingen, Germany

Glossary

Apoptosis – A genetically determined process of cell death that is marked by the fragmentation of nuclear DNA, occurs under both pathological and physiological conditions (known as programmed cell death).
Gadolinium – An element of the rare earth family of metals (atomic symbol Gd) used as a paramagnetic contrast agent in magnetic resonance imaging.
Isoelectric focusing – The most sensitive method for protein separation in serum and CSF using agarose gel electrophoresis.
Multiple sclerosis – A chronic autoimmune inflammatory demyelinating disease affecting the central nervous system (CNS) (synonym: encephalomyelitis disseminata).
P100 latency – The time it takes for the signal from the retina to reach the occipital cortex in the brain.
Plasmapheresis (plasma exchange) – A technology for removing pathologic plasma constituents from anticoagulated whole blood by a machine and returning the rest to the donor, usually with saline solution and albumin.
Snellen chart – Chart that contains rows of standardized letters, numbers, or symbols routinely used to assess visual acuity at a distance of 20 feet.
Visual evoked potential – A diagnostic test that measures alterations in the speed of responses to visual events. The patients watch a black-and-white checkerboard and an electroencephalogram (EEG) measures occipital cortex responses.

Definition

Optic neuritis (Latin – *neuritis nervi optici*) is defined as an inflammation of the optic nerve causing a relatively rapid onset of visual failure. Inflammation may occur in the portion of the nerve within the globe (neuropapillitis or anterior optic neuritis) or in the most commonly involved portion behind the globe (retrobulbar neuritis or posterior optic neuritis).

Optic Nerve Anatomy

The optic nerve, ~45 mm in length, can be divided into several segments: intraocular (1 mm), intraorbital (28 mm), canalicular (4–10 mm), and intracranial (3–16 mm). The diameter of the nerve increases from 1 mm at the intraocular point, 3–4 mm in the orbit, to 4–7 mm within the cranial cavity. The orbital section of the optic nerve has a slightly sinuous shape to allow for movements of the eyeball. As part of the brain, the optic nerve is surrounded by meninges. The outer dural sheath and inner arachnoid sheath merge with the sclera. Between the arachnoid sheath and pial sheath lies a cerebrospinal fluid (CSF)-filled space. The optic nerve consists mainly of fibers derived from the ganglion cells of the retina. The fibers emanating from the nasal part of each retina cross over to the other side in the optic chiasm. The nerve fibers originating in the temporal part of the retina do not cross over. From there, the mixed fibers from the two nerves become the optic tract passing through the thalamus and turning into the optic radiation until they reach the visual cortex located in the occipital cortex of the brain.

Immunopathogenesis

An early event in the development of inflammation is considered to be the activation of circulating autoreactive T lymphocytes by factors such as infection, superantigen stimulation, or effects of reactive metabolites or metabolic stress. Activated T lymphocytes interact with the venule endothelium surface to harm and break down the blood–brain barrier. Upregulation of vascular cell adhesion molecules (e.g., intercellular adhesion molecule-1 (ICAM-1)) increases vascular permeability and enables migration of T cells, B cells, and macrophages into the central nervous system (CNS). The activated antigen-specific T cells appear to develop a Th1-dominant profile with production of proinflammatory cytokines (e.g., IL-2, IFNγ, and TNFα). These cytokines exacerbate the inflammation resulting in further recruitment of pathogenic inflammatory cells, which play a direct role in demyelination. Other factors such as demyelinating antibodies, proinflammatory cytokines, and other soluble mediators contribute to myelin and axonal injury. Also the humoral immunity with autoreactive B-lymphocyte expansion with IgG production plays a relevant role in autoimmune inflammation. Despite significant research

progress in this field, the antigen driving the putative cascade of autoimmune inflammation has not been identified, leaving a substantial gap in the understanding of pathogenesis.

Epidemiology

Optic neuritis typically affects young adults with a mean age of 30–35 years. The majority of patients are female. The annual incidence of optic neuritis ranges from 1.4 to 6.4 new cases per 100 000 population. The prevalence is estimated to be 115 per 100 000 population.

Etiology

Various diseases and conditions may cause optic neuritis. The first description of a relationship of optic neuritis to multiple sclerosis (MS) came from Buzzard in 1893. Nowadays, MS is recognized to be the most common etiology for optic neuritis. Up to 50% of MS patients will develop an episode of optic neuritis.

Some other causes of optic neuritis include inflammation of vessels supplying the optic nerve, infectious diseases (e.g., viral encephalitis, sinusitis, meningitis, HIV, tuberculosis, and syphilis) and autoimmune disorders (e.g., lupus erythematosus). Toxic agents can clearly influence optic nerve and retinal function. Among the common offenders are tobacco and alcohol. Drugs (e.g., salicylates, digitalis, amiodaron, and some antibiotics) can also damage the optic nerve. Rarely, tumor metastasis to the optic nerve, diabetes, pernicious anemia, Graves' disease, and trauma lead to optic neuritis.

Some people, especially children, develop optic neuritis following a viral illness such as mumps, measles, or a cold.

Symptoms

Optic neuritis typically presents with a triad of symptoms: loss of vision, dyschromatopsia, and pain during eye movements. The major symptom is vision loss, which occurs over a period of 3–5 days and generally improves within 2–8 weeks. The visual deficit varies from a small central or paracentral scotoma to complete blindness. The initial attack is unilateral in 70% of adult patients and bilateral in 30%. Both eyes are affected with equal regularity. The visual symptoms are usually described as blurring or fogging of vision. Interestingly, some patients become aware of a unilateral visual disturbance by accident when, for some reason, the unaffected eye is covered.

Many patients with optic neuritis may lose some of their color vision in the affected eye, called dyschromatopsia. The colors appear slightly washed out compared to the other eye. In the majority of cases, patients experience tenderness in the eye, which is associated with pain at rest or on eye movement. In some cases, pain on eye movement precedes the visual loss. Positive visual phenomena, such as a sensation of sparks and flashes of light induced by certain eye movements, occur infrequently.

Symptoms of optic neuritis include one or more of the following:

- reduced visual acuity (near or far)
- pain on eye movement
- central scotoma
- dyschromatopsia or impaired color vision
- impaired contrast sensitivity
- afferent pupillary defect, and
- headache

Diagnosis

Optic neuritis can usually be diagnosed from a patient's history, clinical examination, visual-evoked potentials (VEP), CSF investigation and observations from magnetic resonance imaging (MRI).

Clinical Examination

Despite the wide use of MRI and electrophysiological techniques, the diagnosis of optic neuritis depends on accurate clinical assessment. The medical history should also be assessed to determine if exposure to toxins such as lead or methanol may have caused the visual disturbance. Patients with optic neuritis typically contact an ophthalmologist first. A complete visual examination, including a visual acuity test, color vision test, and visualization of the retina and optic disc by indirect ophthalmoscopy, should be performed. However, frequently there is no abnormal appearance of the optic disk during ophthalmoscopy. Occasionally, there may be hyperemia of the optic disk and distension of the large retinal veins. At later stages the margins of the optic disk are blurred and papilledema can be found. Clinical signs such as impaired pupil response may be apparent during an eye examination, but in some cases the eye may appear normal. Central field defects predominate in patients with optic neuritis.

Visual Evoked Potential

VEP is a noninvasive technique to detect pathological changes of the visual system during optic neuritis and is used as a routine clinical test. Commonly used visual stimuli are flashing lights or patterns (e.g., checker boards) on a video screen. The main interest in electrophysiological findings for optic neuritis focus on the so-called P100 latency and VEP amplitude. During the acute phase of the

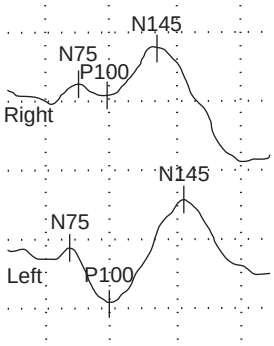

Figure 1 VEP from a 25-year-old woman with a 4-day history of acute right-sided optic neuritis. VEP shows a decrease in amplitude in the affected right eye. VEP amplitude consists of potentials originating in different parts of the brain (N75: area 17; P100: area 18, 19 and partially 17; N145: area 18 and 19).

disease, a decrease in the VEP amplitude, caused by a conduction block of inflamed optic nerve fibers, is a common pathological feature (Figure 1). The depression of the VEP amplitude correlates with the visual acuity and is associated with the degree of atrophy. The prolongation of P100 latency is the main characteristic in the chronic phase and persists over years in up to 70% of patients who suffer from optic neuritis.

Magnetic Resonance Imaging

The principal use of MRI is the evaluation of patients when optic neuritis is the first demyelinating disease event. In a typical case, if accurate clinical assessment has been done, MRI is not required to diagnose and distinguish optic neuritis from other common optic neuropathies. However, the patients with other pathologies such as ischemic or acute compressive optic neuropathy due to a cerebral aneurysm or pituitary tumor may not have the typical features that distinguish these disorders from optic neuritis. In these situations, MRI, when performed with the appropriate examination technique, can make a relevant contribution to the differential diagnosis. The small size and mobility of the optic nerve and artifacts caused by surrounding CSF and orbital fat are technically challenging in optic nerve imaging. Significant progress has been made in developing fat and CSF-suppressed high-resolution imaging. Use of these sequences increases the sensitivity in detecting inflammatory demyelination and optic nerve atrophy. Symptomatic lesions can be detected with sensitivities of 95% in fat-saturated fast spin-echo (FSE) imaging and 94% for the enhancing lesion on fat-saturated T1-weighted imaging following intravenous (IV) gadolinium administration (Figure 2). The abnormal gadolinium enhancement of the affected optic nerve indicates a blood–optic nerve barrier breakdown and is a consistent feature of acute optic neuritis.

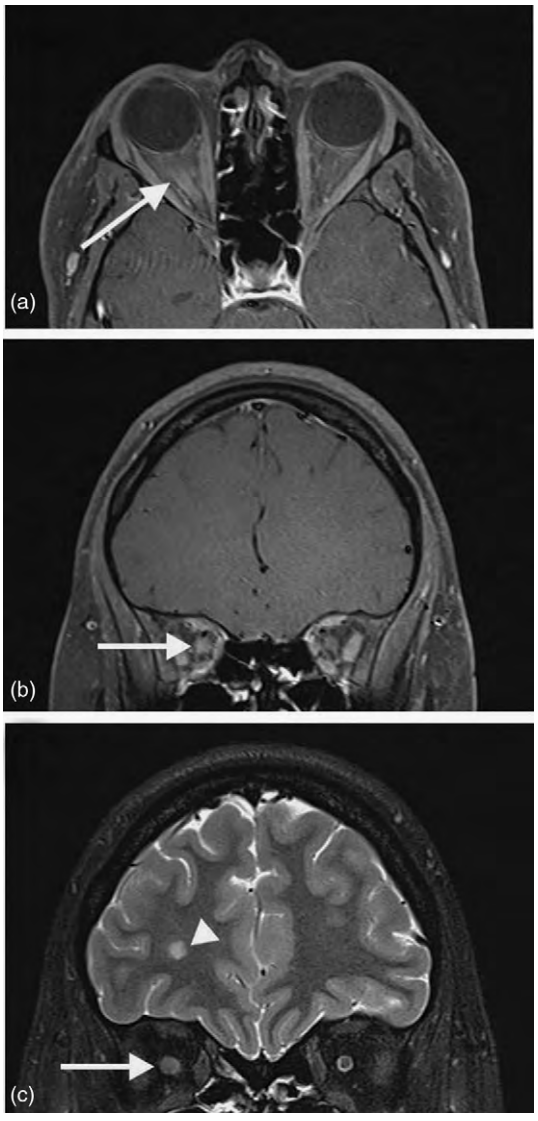

Figure 2 (a) Axial and (b) coronal T1-weighted magnetic resonance images after the IV application of gadolinium. (c) Coronal T2-weighted image from a 25-year-old woman with a 4-day history of acute right-sided optic neuritis demonstrating optic nerve swelling (arrow: diseased optic nerve; arrowhead: demyelinated cerebral lesion).

Cerebrospinal Fluid

CSF analysis is of great relevance to detect an inflammatory process in the brain. The diagnostic sensitivity of single parameters in CSF diagnostics depends on the quality of the applied techniques, especially with isoelectric focusing, and does not have a worldwide standard, such as MRI. In optic neuritis related to MS, typical changes are present in the CSF: slight pleocytosis (max. 50 leucocytes/μl), intrathecal (within the meningeal sheath) IgG production, and additional oligoclonal IgG bands, which are not present in the simultaneously examined serum. The so-called MRZ reaction (intrathecal synthesis of

antibodies against measles, rubella, and varicella-zoster) has a higher diagnostic specificity and is suggested in a European consensus report. Before the use of brain MRI, the detection of CSF pleocytosis and oligoclonal IgG bands provided paraclinical evidence of the dissemination of lesions and met the criteria for the diagnosis of laboratory-supported MS in isolated optic neuritis.

In other autoimmune disorders (e.g., lupus erythematosus and neurosarcoidosis) the cell count is moderately elevated. Verification of oligoclonal IgG bands can be achieved in up to 70% of the cases.

CSF abnormalities in optic neuritis resulting from a viral infection are not specific concerning number of cells, differential cell count, and total protein content and depend particularly on the stage of the disease.

Optical Coherence Tomography

OCT is a relatively new, noninvasive and easy-to-use technology that quantifies the thickness of the peripapillary retinal nerve fiber layer (RNFL), fovea, and macula in real time with highly refined resolution. Originally developed to investigate retinal axonal loss in glaucoma patients, OCT demonstrated a significant reduction of mean RNFL thickness in patients with optic neuritis. Hence, OCT may be useful for observing occult neurodegeneration and monitoring the efficacy of potential neuroprotective therapies in optic neuritis. Serial clinical studies in optic neuritis correlating MRI, clinical, and electrophysiological data are required to establish the use of OCT as an *in vivo* biomarker for axonal loss.

Differential Diagnosis

The differential diagnosis can be divided into several pathophysiological categories: inflammatory/autoimmune diseases, infectious diseases, genetic/hereditary disorders, neoplastic disease, and other demyelinating diseases. Errors in the diagnosis can be minimized if strict clinical criteria are applied and the neurologist is alert to discrepancies in the clinical picture presented (e.g., absence of pain, age of onset, and failure to remit). Also the character of visual symptoms and the type of field defect give additional important information. A slowly progressive unilateral visual failure should always suggest the possibility of compressive etiology. A central field defect can occur with a tumor but, with time, will extend to the periphery. Interestingly, spontaneous improvement in vision may occur in this case. Pain on eye movement is not confined to optic neuritis and can occur in optic nerve glioma, meningioma, and aneurysm. Any of the fundoscopic changes found in optic neuritis may be reproduced by compressive or infiltrative lesions. In such cases, MRI will significantly contribute to the correct diagnosis. The various vascular optic neuropathies generally affect a different age group from optic neuritis and tend to have a poor prognosis.

When both eyes are involved in optic neuritis, simultaneously or sequentially, the disorder must be distinguished from Devic's disease, Leber's hereditary optic neuropathy, nutritional/toxic amblyopia, and functional blindness. Devic's disease, neuromyelitis optica, is characterized by a combination of transverse myelitis and optic neuritis occurring within a finite period of time from each other, typically within weeks. Clinically, the disorder usually has monophasic presentation. The identification of serum anti-aquaphorin-4 antibodies should be helpful for differential diagnosis. Of the hereditary disorders, Leber's optic neuropathy causes optic atrophy with acute or subacute visual loss. This disorder is maternally transmitted and can be diagnosed through genetic testing. In optic neuropathies caused by toxic agents, the overlap of the visual symptoms with those due to optic neuritis is minimal. It often presents as a painless, progressive, bilateral, and symmetrical visual disturbance. Optic nerve pallor is often found in the ophthalmologic examination. Vision loss can be presented as a symptom of Lyme borreliosis optic neuropathy, syphilis, HIV-associated optic neuropathies, and other infectious disorders. In these cases optic nerve involvement tends to be bilateral and MRI and CSF examinations should show a reliable distinction.

Treatment

Treatment of optic neuritis depends on the underlying cause. In a MS-related episode of optic neuritis a course of IV methylprednosolone followed by oral steroids has been found to be helpful. No treatment is also a viable option. The optic neuritis treatment trial (ONTT) has shown that high dose IV steroids (250 mg prednisone every 6 h for 3 days) followed by oral prednisone (1 mg kg^{-1} d^{-1} for 11 days) accelerated visual recovery but did not have any impact on the 6-month and 1-year visual outcome compared with a placebo. An interesting finding of this study was that patients who received IV corticosteroids followed by oral corticosteroids had a temporarily reduced risk of development of a second demyelinating event consistent with MS compared with those who received an oral placebo or treatment with oral corticosteroids only. Oral prednisone has been found to increase the likelihood of recurrent episodes of optic neuritis, and is not recommended for treating the disorder. Patients with severe optic neuritis, who do not respond sufficiently to corticosteroids, can undergo escalating immunotherapy with plasma exchange within 1 month of the first symptoms. In clinical trials up to 60% of patients with optic neuritis had functional improvement after 5 plasmapheresis sessions with an exchange volume of 3000 ml. Long term prophylactic immunomodulatory

therapy with interferon-beta or glatiramer acetate is recommended in patients when optic neuritis is an event of demyelinating disease with a presence of further demyelinated brain lesions shown on the MRI.

Vision loss caused by viral or bacterial infection usually resolves itself once the virus/bacteria are treated. For herpes virus infection the IV treatment with aciclovir ($10\,mg\,kg^{-1}$ every 8 h for 14 days) is recommended. In cases of borrelia infection with neurological symptoms, patients should undergo a treatment session with doxycycline $200\,mg\,d^{-1}$ for 14–21 days. Optic neuritis resulting from toxin damage may improve once the source of the toxin is removed.

Neuroprotective Treatment Strategies

The increasing importance of axonal damage as a major substrate of clinical disability in autoimmune inflammation has led to ongoing research in developing treatment strategies that inhibit degeneration of axons and protect the neuronal cell body from apoptotic cell death. The hypothesis of achieving neuroprotective effects as a secondary phenomenon resulting from the treatment of inflammation and autoimmunity is supported by studies showing close association of axonal damage and inflammation. However, the elimination of the inflammatory component does not necessarily stop the disease progression. MRI studies showed that treatment with methylprednisolone did not limit ongoing lesion lengthening triggered by an episode of optic neuritis nor did it prevent optic nerve atrophy. A detrimental effect of corticosteroids on retinal ganglion cells (RGCs) has even been described in experimental optic neuritis. The effects of cytokines and trophic factors (e.g., erythropoietin, ciliary neurotrophic factor) on neuronal apoptosis appear to be limited; despite preventing neuronal apoptosis, these substances failed to improve visual acuity due to severe and ongoing degeneration of optic nerve fibers in autoimmune optic neuritis. For this reason, anti-inflammatory/immunomodulatory therapies should be combined with primary neuroprotective agents. The potential neuroprotective substances are still in the experimental stage of development, and controlled clinical trials are needed to prove the efficacy and tolerance of these agents.

Prognosis

The vision loss associated with optic neuritis is usually temporary. Spontaneous remission occurs within 2–8 weeks. The majority of patients (65–80%) recover visual acuity of 20/30 (on the Snellen chart) or better. Long-term prognosis depends on the underlying cause of the condition. If a viral infection has triggered the episode, it frequently resolves itself with no aftereffects. If optic neuritis is associated with MS, future episodes are common. Thirty-three percent of optic neuritis cases recur within five years. Each recurrence results in less recovery and worsening vision. There is a strong association between optic neuritis and MS. According to the latest literature, the probability of developing MS within 15 years after onset of optic neuritis is 50% and strongly related to the presence of lesions on a baseline non-contrast-enhanced magnetic resonance image of the brain.

Optical Coherence Tomography

W Drexler, Medical University Vienna, Vienna, Austria

Glossary

Adaptive optics (AO) – A technique originally developed for improving imaging performance in astronomy. Applied in vision sciences to correct wave front aberrations introduced by imperfect optics of the human eye to reduce the spot size in the retina and hence transverse resolution of retinal imaging.
Optical coherence tomography (OCT) – Optical analog to ultrasound, for noninvasive three-dimensional micrometer resolution visualization of superficial (up to 2 mm) tissue morphology.
Optophysiology – Optical analog to electrophysiology that enables noninvasive depth resolved optical probing of retinal physiology.

Optical coherence tomography (OCT) is a rapidly emerging noninvasive, optical diagnostic imaging modality enabling *in vivo* cross-sectional tomographic visualization of internal tissue microstructure in biological systems at resolution levels of a few micrometers. Novel high-speed detection techniques as well as development of ultrabroad bandwidth and tunable light sources have recently revolutionized imaging performance and clinical feasibility of OCT. In this view, OCT can now be considered as an optical analog to computed tomography (CT) and magnetic resonance imaging (MRI), not enabling full body imaging, but noninvasive optical biopsy, that is, micrometer/cellular resolution 3D visualization of tissue morphology.

The eye provides easy optical access to the anterior segment and the retina due to its essentially transparent nature. Axial and transverse resolutions are decoupled in OCT. While the axial one is mainly determined by the optical bandwidth of the employed light source, the transverse one is mainly given by the numerical aperture of the optics that is focusing the beam to the tissue. As a consequence, the axial OCT resolution for retinal imaging is not limited by the low-numerical aperture and large depth of focus of the human eye as it does in scanning laser ophthalmosocopy. For this reason, ophthalmic and especially retinal imaging has so far not only been the first, but also the most successful clinical application for OCT. Objectively this is evidenced by the fact that nearly 2500 (49%) of the 5000 OCT publications (including only peer-reviewed articles) have been published in ophthalmic journals. About 1300 (25%) have been published in optical or biomedical journals demonstrating the significant emphasis on OCT technology development since its invention. In addition, more than half a dozen companies offer this technology in its fourth generation for 3D retinal OCT. Considering the fact that OCT has been introduced only about two decades ago, retinal OCT therefore represents the fastest adopted imaging technology in the history of ophthalmology.

Figure 1 depicts an overview of OCT development with respect to axial resolution and data acquisition speed (measurement time) for morphologic (as opposed to functional) retinal imaging. After its first *in vitro* demonstration in 1991 and first *in vivo* imaging studies of the human retina in 1993 (cf. Figure 1(a)–1(d)), OCT has rapidly developed as a noninvasive, optical medical diagnostic imaging modality providing two-dimensional information of retinal structure with resolution about one order of magnitude better than ultrasound. Since its invention, the original idea of OCT was to enable noninvasive optical biopsy, that is, the *in situ* imaging of tissue microstructure with a resolution approaching that of histology, but without the need for tissue excision and postprocessing. As a consequence, two milestone developments that improved key technological OCT parameters – axial resolution and measurement time – significantly contributed to realize the optical biopsy idea of OCT. A first step toward this goal was the introduction of ultrahigh resolution OCT enabling a noticeably superior visualization of tissue microstructure, for example, all major intraretinal layers as well as cellular resolution OCT imaging in nontransparent tissue by improving axial OCT resolution by one order of magnitude from the 10–15 μm to the (sub)micrometer region, accomplishing 2–3 μm in the living human retina (cf. Figure 1(e)–1(g)). Advances in photonics technology including the development of ultrabroad bandwidth and high-speed tunable light sources as well as high-speed detection techniques have enabled a considerable improvement in data acquisition speed from several hundreds of A-scans/s to 30 000 A-scans/s and recently 300 000 A-scans/s (cf. Figure 1(h)–1(j)).

Despite numerous successful and clinically valuable OCT applications in the anterior eye segment (mainly in the cornea and anterior chamber angle), retinal OCT had a significantly higher clinical impact so far. This is mainly due to the lack of competing noninvasive techniques that can provide comparable wealth of information about the living human retina. Hence, the technological improvements that have been accomplished in the last decade not only enabled unprecedented OCT performance that is unique among noninvasive diagnostic

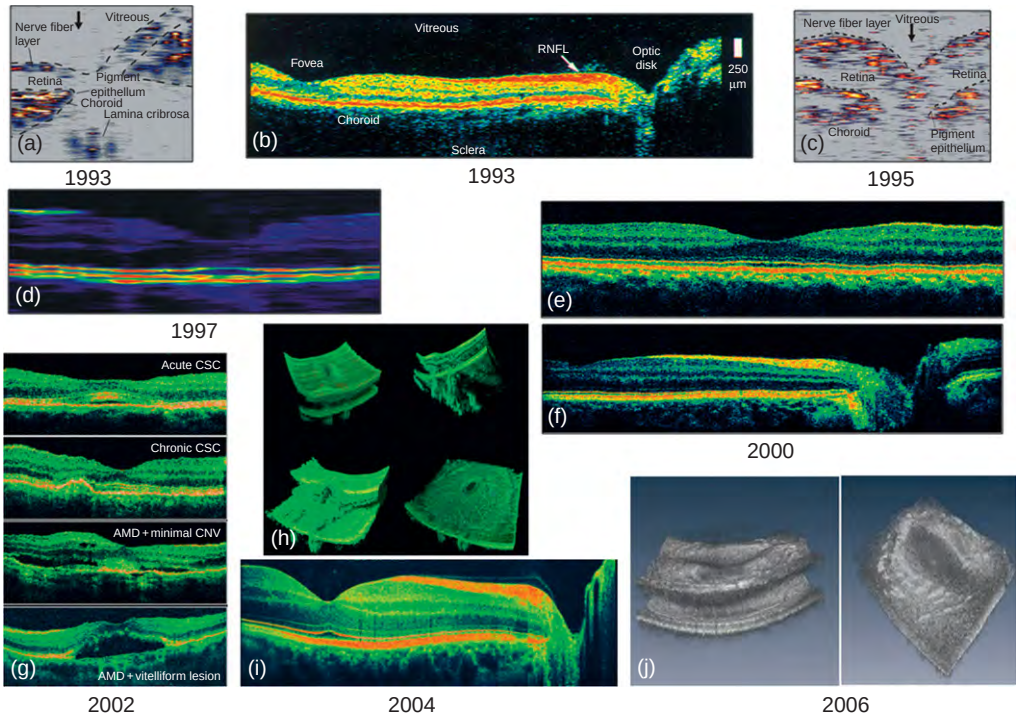

Figure 1 Development of retinal OCT regarding axial resolution and data acquisition. (a, c): First *in vivo* retinal OCT with 10–15 µm axial resolution and 2 A-scans/s; (b) 100 A-scans/s; (d): improved axial resolution (7–9 µm) with 2 A-scans/s; (e, f) first *in vivo* ultrahigh resolution (2–3 µm) with 160 A-scans/s of normal subjects; (g) first ultrahigh resolution OCT in patients; (h) three dimensional; (i) high definition ultrahigh resolution (2–3 µm) with 29 000 A-scans/s; (j) 300 000 A-scans/s and 10 µm axial resolution 3D retinal imaging at 1060 nm with enhanced penetration into the choroid.

techniques, but it also established retinal OCT as a state-of-the art noninvasive, complementary ophthalmic diagnostic methodology. For this reason, this article will mainly focus on retinal OCT.

3D Ultrahigh Resolution Retinal OCT

While third generation commercial retinal OCT systems (Stratus OCT) were based on the so-called time domain OCT, enabling up to 400 A-scans/s (one-dimensional (1D) measurements), fourth generation (spectral or Fourier-domain based) commercial retinal OCT systems, nowadays can perform up to 100 times more measurements enabling either highly sampled (high definition) 2D tomograms or 3D (volumetric) imaging of the retina. This is due to an alternative detection method that uses either a CCD camera-based spectrometer (spectral of Fourier domain), that can be read out quickly or a fast tuneable laser (swept source OCT or frequency domain OCT) as compared to a moving mirror (time domain) to perform a single A-scan. The first version is inherently more efficient and enables to raster scan the retina analog to a scanning laser ophthalmoscope (SLO) but thereby not only acquiring tissue information from a single 2D plane (in focus), but the full morphological depth information from an entire volume with a depth resolution mainly given by the optical bandwidth of the employed light source.

A volumetric data set is acquired for the imaged area that can then be viewed and analyzed in ways similar to those used with CT or MRI scans (cf. **Figure 2(a)** and **2(b)**). Hence, the imaged volume can arbitrarily be cut according to the necessary diagnostic needs, for example, like an ultrahigh resolution SLO in en face (C-mode) tomograms (cf. **Figure 2(c)** and **2(d)**). **Figure 2** demonstrates 3D UHR OCT in the foveal region of a patient with retinal pigment epithelium (RPE) atrophy. Note that the axial dimension is twofold enlarged as compared to the other two dimensions for better visualization. The 3D representation of the macular region is presented at different-angled views (cf. **Figure 2(a)**) depicting the pathological change in the topography of the foveal depression as well as enabling unprecedented views in which the retina can be observed from any direction, including from below (cf. **Figure 2(b)**). **Figure 2(e)–2(h)** present virtual biopsy/surgery using 3D UHR OCT in combination with 3D data rendering which allows the user to excise and remove any given layer or part of the retinal volume to visualize intraretinal morphology.

The clinical benefit of these spectral of Fourier domain-based OCT instruments is demonstrated in highly sampled 3D visualization of the retina during a reasonable short data-acquisition time resulting in more

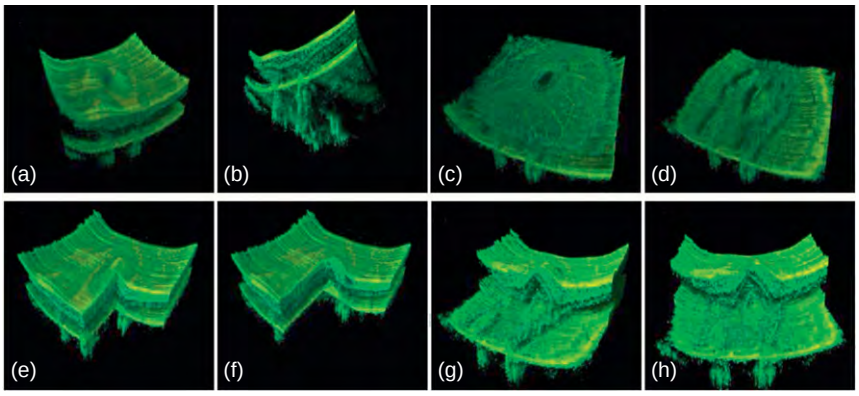

Figure 2 Three-dimensional ultrahigh resolution OCT of the macular region of a patient with retinal pigment epithelium atrophy; (a–d) at different-angled views; (e–h) virtual biopsy allows removal of any given layer or part of the retinal volume to visualize intraretinal morphology.

reliable and reproducible 2D thickness maps of (intra) retinal layers. Furthermore, retinal locations are less likely to be missed that are important for diagnosis since an entire volume is measured instead of deciding the location of B-scans during OCT acquisition. This might result in improved diagnosis of retinal pathologies, better understanding of retinal pathogenesis, as well as enhanced (objective) monitoring of novel therapy approaches.

3D Wide-Field Choroidal OCT

So far, commercially available retinal OCT has mainly been performed in the 800-nm wavelength region. This is mainly due to easy availability of broad bandwidth light sources and detectors (CCD cameras) in this wavelength region. Although OCT systems centered at 800 nm can resolve all major intraretinal layers, they only enable limited penetration beyond the retina, due to multiple scattering and absorption in the melanin-rich RPE. This results in limited visualization of the choriocapillaris and choroid. Moreover, in clinical OCT, turbid ocular media (e.g., cataract or corneal haze) represent a significant challenge when imaging the retina. Since scattering in biological tissues decreases monotonically with increasing wavelength, OCT imaging at 1060 nm can deliver deeper tissue penetration enabling delineation of choroidal structure. Being less sensitive to scattering eye media and enabling enhanced penetration into the choroid up to the choroidal–scleral interface at 1060 nm might therefore significantly improve the clinical feasibility of retinal OCT.

2D time domain-based OCT was initiated about 5 years ago demonstrating improved visualization of superficial choroidal structure. With the introduction of more efficient and hence more sensitive spectral of Fourier domain OCT, 3D OCT at 1060 nm demonstrated wide-field visualization of the entire choroid up to the sclera. In this approach, a cost-effective, easy-to-implement system based on a high-speed InGaAs linear 1024 pixel array (SUI-Goodrich) enabling 47 000 A-scans/s, 5–8 µm axial resolution, and 2.6 mm scanning depth in tissue was developed. **Figure 3** depicts the comparison of 3D OCT at 800 nm (cf. **Figure 3(a)** and **3(b)**) versus 1060 nm (cf. **Figure 3(c)** and **3(d)**) in the same normal eye. Enhanced visualization of the choroid up to the choroidal sclera interface is accomplished using 3D 1060-nm OCT as compared to 3D 800-nm OCT (cf. yellow arrows in **Figure 3(d)**). In the subject with light fundus pigmentation, 3D 1060-nm OCT enables penetration beyond the choroid into the sclera (cf. red arrows in **Figure 3(g)**). High-speed 3D 1060-nm OCT also enables en face visualization of the choroidal vasculature without the use of any contrast agent (cf. **Figure 3(c)**, **3(e)**, and **3(f)**).

High-speed 3D 1060-nm OCT therefore now enables unprecedented visualization of all three choroidal layers giving access to the entire choroidal vasculature. In addition, 2D choroidal thickness maps might have significant impact in the early diagnosis of retinal pathologies such as glaucoma, age-related macular degeneration and might contribute to a better understanding of myopigenesis.

Cellular Resolution Retinal OCT

For retinal OCT imaging, the cornea and the lens act as the imaging objective, thereby determining the numerical aperture and hence the beam diameter in the retina. This diameter specifies the transverse OCT resolution that is of the order of ~20 µm for a beam of ~1-mm diameter (at 800 nm) – approximately one order of magnitude worse than the best axial OCT resolutions accomplished so far. This can be improved by dilating the pupil and increasing the measurement beam diameter. In practice, however, for large pupil diameters, ocular aberrations limit the minimum focused spot size on the retina, even for monochromatic illumination. An alternative and promising

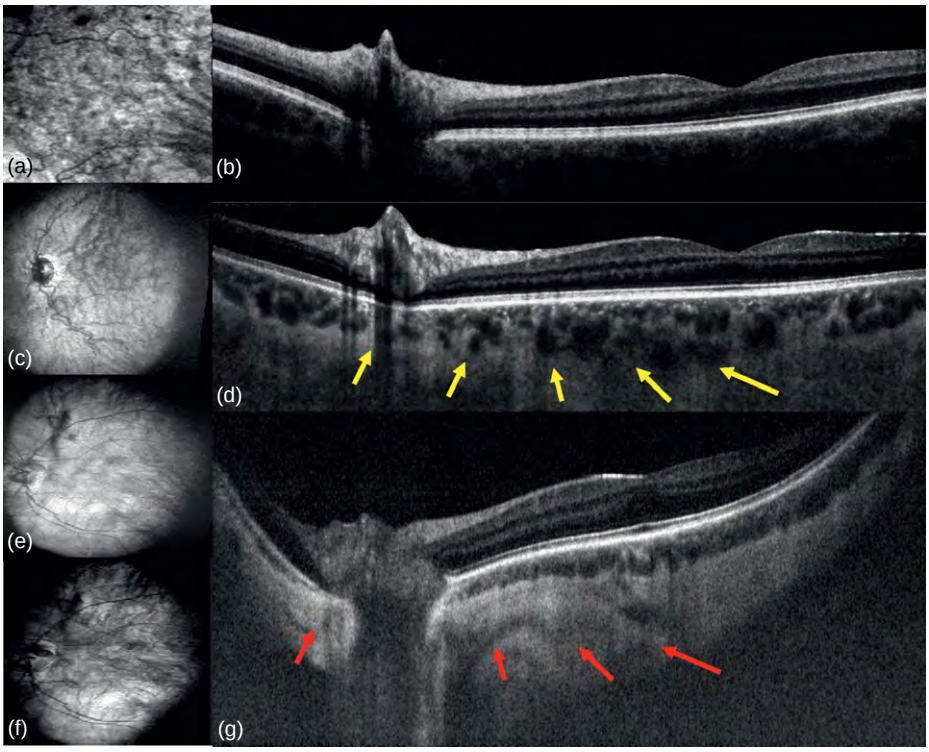

Figure 3 Wide-field three-dimensional choroidal OCT. (a, b) 3D-OCT at 800 nm and (c–g) 1060 nm of a normal retina: (b) high definition (4096 depth scans) 800-nm 3D-OCT scan over 35°; (d, g) high definition (2048 pixel) 1060-nm 3D-OCT scan over 35°; (a) en face view of the choroid using 3D OCT at 800 nm; (c, e, f) en face wide-field (35° × 35°) view using 3D OCT at 1060 nm; yellow arrows indicate enhanced choroidal visualization; red arrows indicate visualization of the sclera.

approach is to use adaptive optics (AO), which was originally developed to improve the resolution of astronomical imaging, to minimize ocular aberrations, reduce retinal spot size, and hence to improve transverse OCT resolution.

In ophthalmic AO a wave front sensor measures the individual ocular aberrations of the investigated eye, calculates an inverse wave front, and sends this information to a correcting device – a deformable mirror – for aberration correction. This procedure is performed in real time in a closed-loop configuration. In a couple of tenths of a second, ocular aberrations are compensated and continuously corrected during the entire measurement procedure. In the present approach, a deformable mirror (Mirao52, Imagine Eyes, France) with a unique performance in terms of amplitude (±50-µm stroke) and linearity was used, allowing for correcting highly aberrated normal or pathologic eyes. Furthermore a 140–160-nm Ti:sapphire laser (Femtolasers Integral, Femtolaser, Vienna, Austria) in combination with a CMOS Basler sprint spL4096-140k camera (Basler AG Germany) enabling 160 000 A-scans/s with 1536 pixels was used, resulting in ultrahigh speed cellular resolution retinal imaging with isotopic resolution of 2–3 µm. Furthermore, the chromatic aberrations of the eye in the 700–900 nm wavelength region of the employed light source have been compensated with a special lens.

The combination of high stroke deformable mirror-based AO, with ultrahigh speed, ultrahigh resolution OCT employing compensation of the eye's chromatic aberrations enabled isotropic OCT resolution of 2–3 µm. It is noteworthy that the extremely high measurement speed in combination with sufficient system sensitivity at this speed is essential to maintain cellular resolution morphology information despite motion artifacts. In analogy to AO, scanning laser ophthalmoscopy measurements, AO OCT raster scans a retinal area, but acquires full morphological information as a function of depth in the region of interest, without the need to scan the depth of focal plane. As a consequence, 3D morphology of single photoreceptor (PR) outer segments in addition to cellular microstructure at the level of the RPE and choriocapillaris can be visualized in the living human retina. **Figure 4** depicts *in vivo* cellular resolution retinal imaging in a normal human retina at about 4° parafoveal. A rendered volume of about 350 × 80 × 100 µm is presented. En face representations at different depths of the volume reveal cellular resolution intraretinal microstructure.

3D information of intraretinal morphology at cellular level might not only revolutionize ophthalmic diagnosis, but also significantly contribute to a more precise interpretation of OCT tomograms. Despite numerous clinical

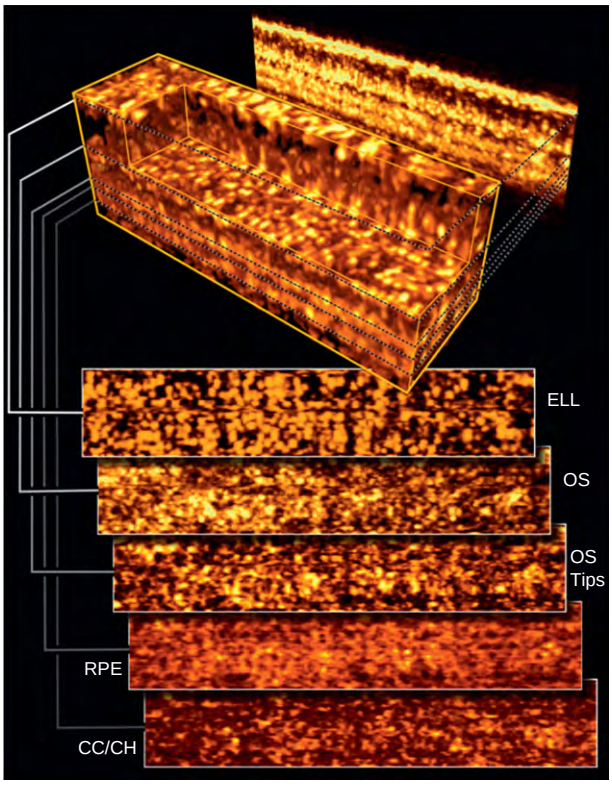

Figure 4 *In vivo* cellular resolution retinal adaptive optics OCT. 3D tomogram and en face cross sections of a normal human retina acquired at 4° parafoveal at 160 000 A-scans/s. Various retinal layers in photoreceptor layer may be distinguished with this technique. From top to bottom slice: ellipsoids (ELL), outer-segment tips (OS), outer segment tips (OS tips), retinal pigment epithelium (RPE), choriocapillaris (CC), and choriocapillaris/choroid (CC/CH). Width of slides corresponds to ~350 × 80 μm.

investigations using UHR OCT and systematic studies comparing histology with UHR OCT in *in vitro* animal models to correctly interpret OCT images, it is noteworthy that a comprehensive, reliable interpretation of all OCT intraretinal layers has not yet been accomplished. Although the state-of-the-art ophthalmic OCT technology enables significantly improved visualization of intraretinal layers, caution is therefore imperative regarding proper interpretation of OCT tomograms, especially of the distal part of the retina. **Figure 5** depicts state-of-the-art OCT interpretation of intraretinal layers in a high definition ultrahigh resolution OCT of the optic disk (a) and foveal (b) region of a normal subject. From the proximal to the distal part of the retina the nerve fiber layer (cf. **Figure 5(a)**, NFL) as well as plexiform layers (cf. **Figure 5(a)**, inner (IPL) and outer plexiform (OPL) layer) appear back-reflecting and therefore as a strong signal in the OCT tomogram. The ganglion cell layer (cf. **Figure 5(a)**, GCL) as well as nuclear layer (cf. **Figure 5(a)**, inner (INL) and outer nuclear (ONL) layer) appear less back-reflecting and therefore as a low signal in the OCT tomogram. The external limiting membrane (cf. **Figure 5(b)**, ELM), the inner and outer PR segments (cf. **Figure 5(b)**, IS PR, OS PR), as well as the choroid (cf. **Figure 5(b)**) are also properly confirmed by literature. Red-labeled layers indicate that caution is imperative and the correct interpretation needs more conclusive studies to confirm correctness. This applies to the internal limiting membrane (cf. **Figure 5(a)**, ILM) and the distal part of the retina involving probably the distal tips of the PRs – sometimes also referred to Verhoeff's membrane (cf. **Figure 5(b)**), the RPE including Bruch's membrane (cf. **Figure 5(b)**, RPE/BM) as well as choriocapillaris (cf. **Figure 5(b)**).

To date, the most distal layer, that is, strongest continuous distal signal in OCT tomograms, has been interpreted as the RPE layer. Although literature describing the light–RPE interaction in the near-infrared region around 800 nm would confirm this interpretation, the relatively thick (up to 30 μm) appearance in OCT tomograms is not supported by histological findings which describe the RPE as a monocellular layer. In addition, the appearance of the RPE and distally adjacent layers as visualized by OCT varies in eyes with different pathologies. **Figure 6** depicts the region indicated with a red rectangle in **Figure 5** but imaged with AO OCT. 3D information at cellular resolution level significantly helps to correlate OCT findings with well-known anatomy from histology and therefore more precisely interpret 2D OCT tomograms. Hence, from the external limiting membrane (cf. ELM in **Figure 6**) toward the distal part of the retina, the first bright (white) signal indicates the junction between inner and outer PR segments. En face cellular resolution representation clearly reveals single ellipsoids. After a thicker, less bright (black) layer indicating a part of the PR outer segment, five signal bands with alternating bright (white) and weak (black) signal appearance is revealed by AO OCT. En face information of the first bright (white) band suggests that this layer corresponds to the outer part/outer tips of the outer PR segments. It is noteworthy that this structure as well as the junction between the inner and outer segment of the PR cannot be resolved within a circular zone of less than 2° parafoveal. Their too-tight spacing and the limited numerical aperture of the human eye in addition to weak contrast has not yet allowed the visualization of PRs in the center (±2° central region) of the fovea. Nevertheless, they are included in this figure for more precise interpretation. The next weak (black) signal band might correspond to the RPE somas, since the adjacent bright (white) signal band is clearly identified to correspond to the RPE layer due to the hexagonal structure of single RPE cells as visualized by AO OCT in the indicated en face view. The next weak (black) signal band might correspond to Bruch's membrane, although literature describes the thickness of this membrane close to the resolution limits of AO OCT. This interpretation is nevertheless supported by the fact that the cellular resolution en face image of the next bright (white) signal band indicates that it might correspond to

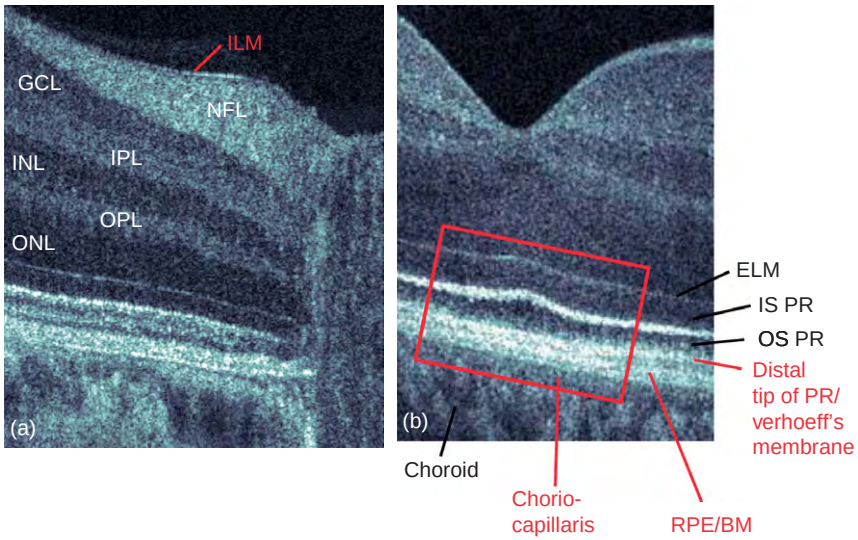

Figure 5 State-of-the-art interpretation of intraretinal layers in OCT. High definition ultrahigh resolution OCT of the optic disk (a) and foveal (b) region of a normal subject. Labeling of intraretinal layers that could properly confirmed by numerous previous studies are labeled white or black. Red-labeled layers indicate that caution is imperative and the correct interpretation needs more conclusive studies to confirm correctness. Nerve fiber layer (NFL), inner (IPL) and outer plexifrom layer (OPL), ganglion cell layer (GCL), inner (INL) and outer nuclear layer (ONL), external limiting membrane (ELM), inner (IS PR) and outer photoreceptor segment (OS PR), choroid, internal limiting membrane (ILM), and distal tips of the photoreceptors – sometimes also referred to Verhoeff's membrane, retinal pigment epithelium including Bruch's membrane (RPE/BM), choriocapillaris. Red square indicates region depicted in **Figure 5**.

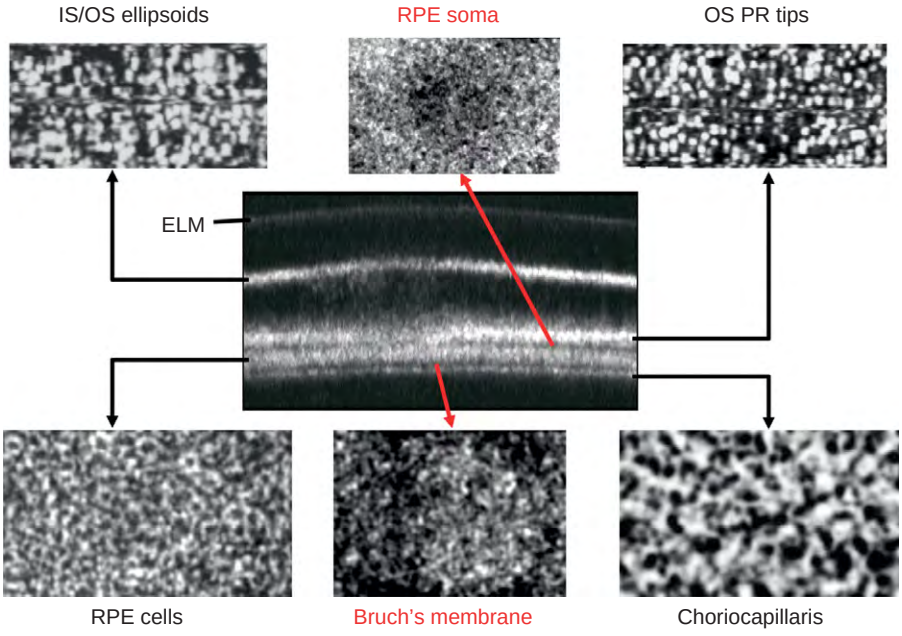

Figure 6 Revised interpretation of the RPE signal band in OCT. Three-dimensional information at cellular resolution level significantly helps to correlate OCT findings with well-known anatomy from histology and therefore more precisely interpret two-dimensional OCT tomograms; external limiting membrane (ELM); photoreceptors can only be resolved within a circular zone of less than 2° parafoveal. Nevertheless, they are included in this figure for more precise interpretation. Two layers are still labeled red indicating that more studies are needed to finally confirm their proper interpretation.

the choriocapillaris. It is noteworthy that despite the superb imaging performance of AO OCT, two layers are still labeled red in **Figure 6** indicating that more studies are needed to finally confirm their proper interpretation.

Figure 7 demonstrates the concept of clinical cellular resolution AO OCT in a patient with type 2 macular telangiectasia. A commercial 3D OCT is used to pre-screen a larger volume to identify suspicious locations.

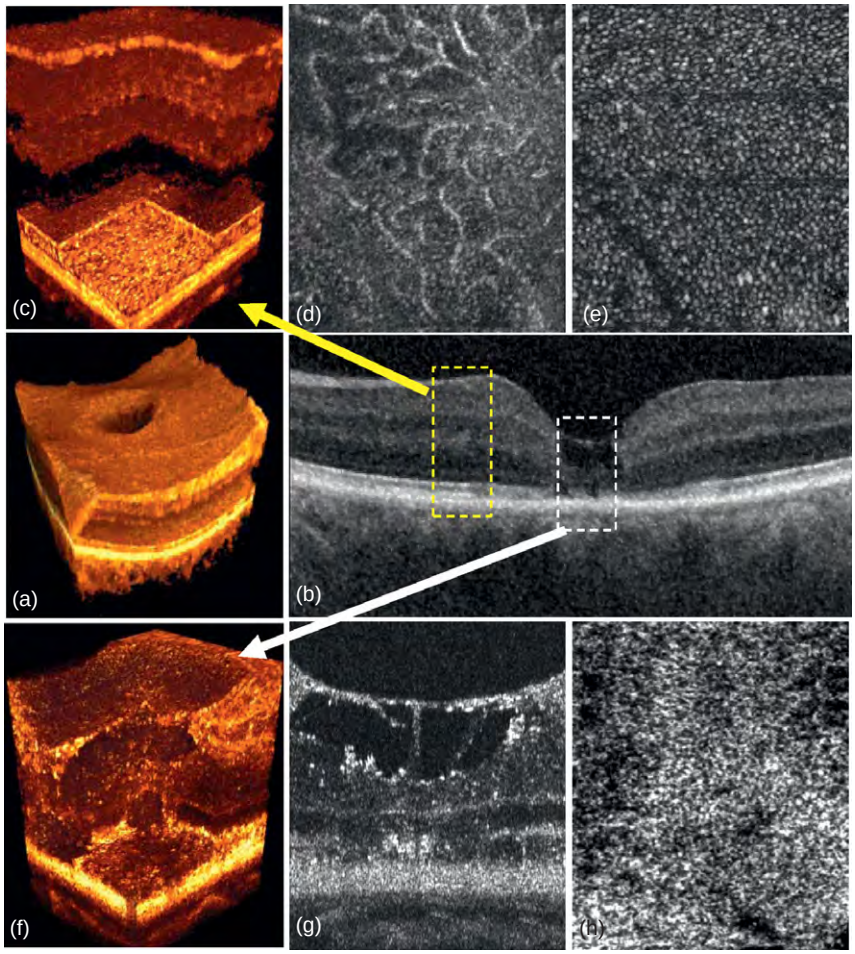

Figure 7 Possible strategy for clinical cellular resolution OCT in a patient with type 2 macular telangiectasia: (a) prescreening over 20°×20° (512 × 128 depth scans) using a commercially available 3D-OCT at 800 nm; (b) detection of impaired intraretinal morphology using a representative cross section from (a); zoom in at a normal (c–e, yellow-dashed square in (b)) and a pathologic ((f–h), white-dashed square in (b)) smaller volumes using cellular resolution OCT; volumetric rendering at 6° parafoveal (c) and 0° (f); en face images at the level of the capillaries in the inner nuclear layer at 6° (d) and at the level of the tips of the outer photoreceptors at 6° (e) extracted from (c); cross sections (g) and en face images at the level of the retinal pigment epithelium (h) extracted from (f).

These areas are then investigated (at the moment still with a separate system) with AO OCT at cellular resolution level revealing quite normal vasculature and PR appearance at 6° parafoveal whereas there is severe impairment at 0°.

Functional Retinal Imaging Using OCT

Numerous functional OCT extensions have been developed in the past of which Doppler OCT, measuring the blood flow velocity and polarization sensitive OCT, imaging depth resolved tissue birefringence have been the most developed and successfully applied in retinal imaging. Noncontact, depth-resolved optical probing of retinal responses to visual stimulation with 10 µm spatial resolution, achieved using functional ultrahigh resolution OCT, has recently been demonstrated. This method relies on the observation that physiological changes in dark-adapted retina caused by light stimulation can result in local variations in tissue reflectivity. This functional extension of OCT can be considered as an optical analog to electrophysiology and has therefore been called optophysiology.

To determine the sensitivity of optophysiology for the detection of changes in retinal reflectivity triggered by light stimulation, a dark-adapted living *in vitro* rabbit retina was exposed to a single flash of white light and optophysiology data were acquired synchronously with electroretinogram (ERG) recordings (cf. **Figure 8**). Throughout the functional experiments the isolated retinas were stimulated with single, 200-ms long white light flashes (cf. yellow rectangle in **Figure 8(c)**, **8(d)**, **8(f)–8(h)**, and **8(j)–8(l)**). A morphological B-scan was first taken from the measurement location (cf. **Figure 8(a)**). Multiple OCT depth reflectivity profiles (A-scans) were then acquired at one transverse location in the retina synchronously with ERG

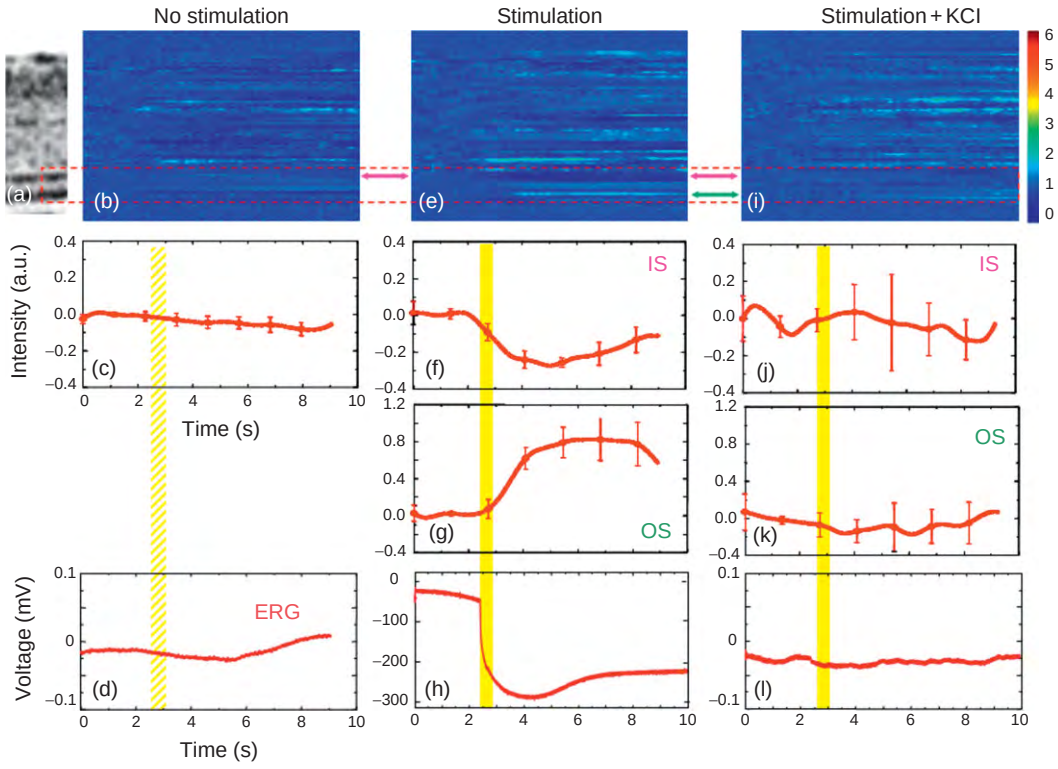

Figure 8 *In vitro* optophysiology in the rabbit retina – optical probing of depth resolved retinal physiology: (a) OCT retinal image of the rabbit retina; (b–d) response during no light stimulus; (e–h) representative single flash stimulus differential M-tomogram and extracted responses from the inner (f) and outer (g) photoreceptor layer; (i–l) case of KCL inhibited photoreceptor function; yellow boxes mark the time duration of the light stimulus; (d, h, l) simultaneous ERG recordings. OS: outer segment; IS: inner segment; ERG: electroretinogram; and KCL: potassium chloride.

recordings. The OCT A-scans were combined to form 2D raw data M-tomograms presenting the retina reflectivity profile as a function of time. The optical data were processed using a cross-correlation algorithm to account for any movement of the retina caused by the solution flow and for calculation of the optical background (average over the pre-stimulation A-scans of each M-tomogram) and generation of differential M-tomograms (cf. **Figure 8(b), 8(e)**, and **8(i)**). Optophysiological signals could be extracted from various retinal layers, so that depth-resolved optical back scattering changes that resulted from physiological processes induced by the optical stimulus could be detected. As expected, in the nonstimulated retina (cf. **Figure 8(b)–8(d)**) the optical reflectivity of the PR layer did not change significantly with time. When the retina is exposed to the light stimulus (marked by the yellow box), changes were seen in optical backscattering at locations corresponding to the inner (cf. **Figure 8(f)**) and outer (cf. **Figure 8(g)**) segment of the PR layer which correlated with changes in the corresponding ERG (cf. **Figure 8(h)**). When potassium chloride (KCL) was applied to the retinal sample to inhibit PR function (cf. **Figure 8(i)–8(l)**), the optical changes observed in the PR inner segment (IS) and outer segment (OS) of the PR layer were close to the optical background level and showed no correlation to the onset of the light stimulus. Depolarization of the cell membranes can occur during conduction of an action potential which could be detected by UHR OCT, but also by detection of spatially resolved change in backscattering over time. The exact origin of the detected optophysiologic signals is unclear but might be related to the dipole reorientation (and therefore refractive index changes) at the PR membrane. Alternatively they could arise from light-induced isomerization of Rhodopsin in the outer PR segment or metabolic changes in the mitochondria of the inner PR segments.

These optophysiological findings in the *in vitro* rabbit model have recently been tried to transfer to the *in vivo* human retina. Due to limitations in coordinating stimulus and data acquisition and the very slow time course of PR recovery after photobleaching stimulus, a protocol that included imaging a normal subject at intervals of about 1 min was used. Dark-adapted human eyes were briefly subjected to localized photobleach. For 20 min prior to, and 30 min after stimulus, volumetric optical coherence tomograms were collected partially overlapping with the bleached region. A location at the peak rod density at 11° temporal was scanned because rod responses are interesting in regards to dark adaptation and rod responses had been successfully observed the rabbit *in vitro* experiments.

The scanned patch was sampled at 512 A-scans in the long axis of the rectangle (fast axis) and 256 samples in the narrow axis (slow axis). Given the 47-kHz A-scan rate of the camera, this volume could be collected in 2.8 s. Twenty double volumes were completed before the subject was exposed to a white, 48 000 cd m^{-2} stimulus, bleaching over 99% of both photopic (duration 6 s) and scoptopic photopigments. As the eye recovered dark accommodation, 35 more double volumes were recorded at 1 min intervals. Tomograms were segmented into retinal layers by a newly described algorithm exploiting information in adjacent B-scans. En face fundus images extracted from major intraretinal layers were laterally registered manually. Time series summarizing the observed backscatter in selected layers for the bleached and unbleached areas are shown with a variety of corrections and normalizations applied: tomograms were corrected for inherent sensitivity roll off; the ratio between other layers and an assumed unchanging layer (RPE) as well as the ratio of stimulated area to unstimulated area were calculated.

Figure 9 depicts results obtained from one normal subject. For each tissue layer in each measured volume, the result of the experiment is summarized by the mean voxel intensity underneath the retinal surface receiving the

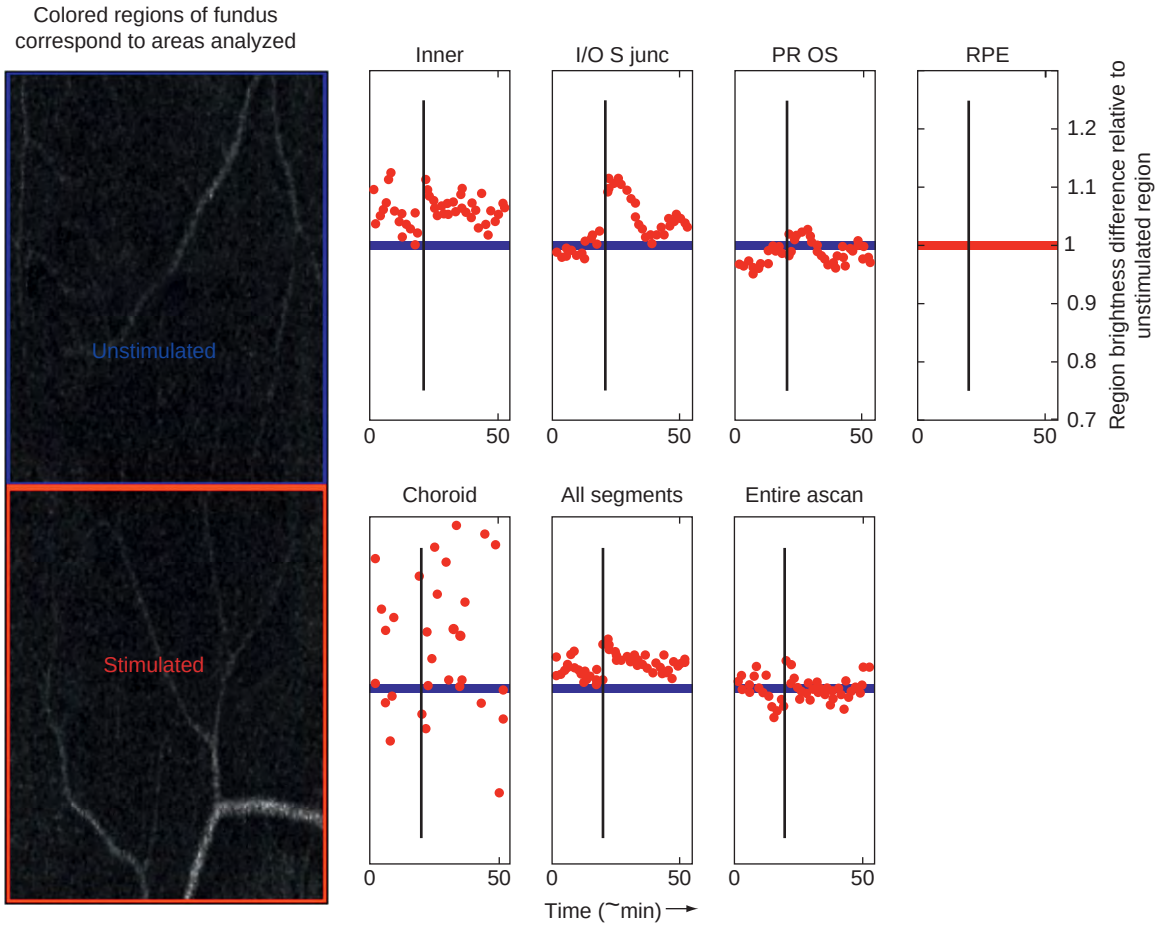

Figure 9 *In vivo* optophysiology in the human retina-A fundus image of the inner–outer segment junction layer is shown at the left to indicate the measured areas defined as unstimulated (blue) and stimulated (red). The volume has been segmented into five anatomical layers using only the most reliably segmented boundaries. The inner retina consists of the NFL, GCL, INL, IPL, and ONL. The choroid is defined from the lower RPE boundary to a thickness 20 pixels deeper (about the thickness of the RPE). All segments is defined from the inner boundary of the NFL to the outer boundary of the RPE. Entire A-scan ignores the segmented boundaries and finds an average pixel intensity over the entire thickness of the recorded A-scan. For each anatomical layer, the average intensity is computed in the stimulated and unstimulated areas and represented as a point in the time series. Twenty volumes acquired before the bleaching stimulus are represented by the points to the left of the vertical black line on each time series plot. Thirty-five volumes recorded after the bleaching stimulus are represented by the point on the right side of the vertical line. Time between acquisitions is about 1 min, so the time axis can be approximately read in units of minutes. Looking at the first four layers, the average pixel intensity appears to track roughly with the IOS distance from the zero delay indicated in the lower right plot. After RPE normalization and a ratio of the stimulated area compared to the unstimulated area, it again appears that there is a relative increase in average pixel intensity in the stimulated area after the stimulus that is most noticeable in the inner–outer segment junction layer that is decaying over a period of about 30 min after the stimulus.

stimulus, and a mean voxel intensity underneath the area without the stimulus. For any particular tissue layer, a time series of this plotted data is expected to show no change in the area without stimulus, and some change in the stimulated area, if there is a change to be observed. The hypothesis is that some layers will show change after stimulus while other layers will not. After the above mentioned normalizations, it appears that an increase larger than the noise level may occur in the inner outer segment region. The decay time for the change (20–30 min) is on the order of the time that the subject observed a persistent after image.

Although the experimental protocol differs from published protocols of studies performed *in vitro* in rabbit and *in vivo* in mouse, the key results are consistent in location and type of change. These, however, could not be convincingly repeated and are therefore presented as an illustration of the techniques used rather than an established observation. Furthermore, the results reported here were only observable in the data after several normalizations. These normalizations are logical, but should be applied with caution. Hence, measuring intrinsic optical signals with OCT in an awake human is challenging. Much needs to be done to deliver both clinically and neurologically significant results. Finally, and probably most importantly, because there is currently a lack of understanding of the physiology that produces intrinsic optical signals, it is difficult to search for the signal using the correct stimulus and measurement protocols. It seems likely that doing more work *in vitro* and with animal models where CCD camera techniques have been highly successful will help identify parameters that are most likely to yield a strong and relevant signal.

Conclusion

Currently, commercial fourth generation 3D ophthalmic OCT systems seem to have a significant diagnostic impact in daily clinical routine as well as novel therapeutic trials. After introducing 3D visualization of the healthy and pathologic human retina, the emphasis now shifts toward filtering out proper biomarkers from this significantly increased amount of information for improved diagnostic decisions. In this respect, it is at the moment not obvious where retinal OCT is heading. Recent developments in OCT technology significantly improved its potential for successful biomedical and clinical applications. These will also be important prerequisites for functional OCT extensions like Doppler OCT, polarization sensitive OCT, and optophysiology.

Despite several proof-of-principle demonstrations of significantly improved state-of-the-art retinal OCT imaging performance sound clinical studies on larger, properly selected patient cohorts are necessary to demonstrate the improved clinical impact and therefore verify the increased technological effort of these novel improvements in retinal OCT modalities.

Orbital Bony Anatomy and Orbital Fractures

R A Zaldívar, M S Lee, and A R Harrison, University of Minnesota, Minneapolis, MN, USA

Glossary

Cantholysis – A surgical section of a canthus or a canthal ligament.
Canthotomy – An incision of the canthus.
Dehiscence – The opening of a previously closed wound. It is often associated with contents emerging from the open wound.
Enophthalmos – A posterior displacement of the eyeball into the orbit.
Hypertelorism – An increase in the interorbital distance.
Hypoesthesia – Decreased tactile sensitivity.
Lagophthalmos – An incomplete or defective closure of the eyelids.
Meningitis – An inflammation of the protective membranes covering the central nervous system.
Mucocele – A soft mucus-filled enlargement.
Oculocardiac reflex – A decrease in the pulse rate associated with traction applied to the extraocular muscles and/or compression of the eyeball.
Proptosis – A forward displacement of the eye in the orbit.
Trochlea – The fibrous loop in the superiomedial orbit through which the tendon of the superior oblique muscle passes.

The Bony Orbit

Early in embryogenesis, the bony orbit develops from the mesenchyme that encircles the optic vesicle. Initially, the optic axes are positioned approximately 160–180° apart. The optic cups begin to rotate anteriorly at the same time as the orbital bones are formed. At birth, this angle is reduced to approximately 45°. Hypertelorism, or increased interorbital distance, may develop if there is incomplete rotation. Premature ossification of orbital bones may result in reduced orbital volume and proptosis, as seen in Crouzon's disease.

The adult bony orbit is four walled and pyramidal in shape. The average volume of the orbit is 30 cc. The orbital diameter measures approximately 4 cm in width and 3.5 cm in height at the base or anterior entrance, and has a depth of about 4.5 cm (Figure 1). The widest portion of the orbit is 1 cm just inside the bony rim. The lateral orbital walls subtend a 90° angle, and the medial walls are roughly parallel to each other.

The Orbital Rim

The orbital rim is formed superiorly from the frontal bone, laterally from the zygomatic bone, and inferiorly from the zygomatic and maxillary bones (Figure 2). The inferior-medial portion of the rim continues to form the anterior lacrimal crest on the frontal process of the maxilla, whereas the superior-medial rim continues to form the posterior lacrimal crest. Throughout, the rim is mainly rounded and thickened (greatest laterally). This serves to protect the eye from trauma.

A neurovascular bundle traverses through the medial third of the superior rim. Often (75%), it consists of a notch and the remainder of the time it travels through a true foramen, the supraorbital foramen. This is an important landmark both for brow surgery and to facilitate the identification of the inferior oblique. A vertical line from the notch to the inferior rim is the point anterior to where the inferior oblique originates. The infraorbital foramen, conducting the infraorbital artery, vein and nerve, is also located in this vertical plane, usually 4–10 mm below the central portion of the rim. When performing orbital floor surgery, care must be taken in elevating the periosteum below this level so as not to injure this bundle.

The Medial Orbital Wall

The medial walls are nearly parallel to each other and with the mid-sagittal plane. The wall measures approximately 4.5–5.0 cm from the orbital rim to the orbital apex. It is formed by the maxillary, lacrimal, ethmoid, and sphenoid bones (Figure 3). The maxillary and lacrimal bones join to form the anterior and posterior portions of the lacrimal sac fossa, respectively. Posterior to the lacrimal fossa is the lamina papyracea of the ethmoidal labyrinth. This is the thinnest bone of the bony orbit measuring approximately 0.2–0.4 mm in thickness. This is clinically important in that it is easily fractured in trauma and during surgery, and is a minimal barrier to the spread of infection from the adjacent ethmoid sinuses. Dehiscences or erosions of the bony wall secondary to chronic sinusitis may produce mucoceles either from the ethmoidal or frontal sinuses.

Superiorly, at the junction of the lamina papyracea and the orbital plate of the frontal bone is the frontoethmoid

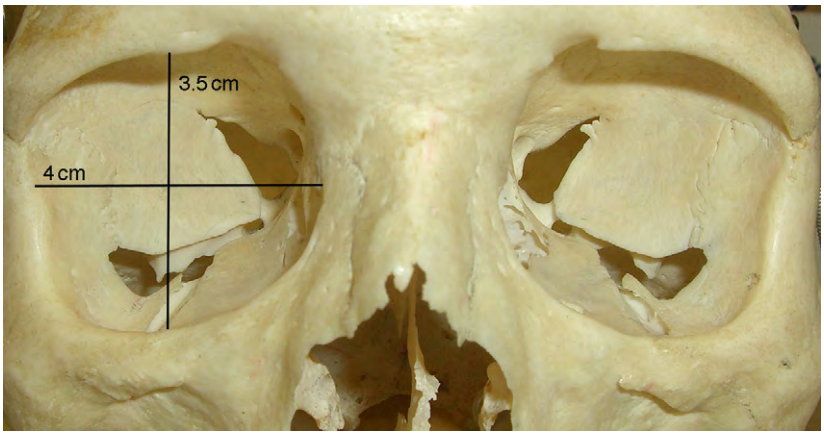

Figure 1 Anterior view of the bony orbit with horizontal and vertical dimensions indicated.

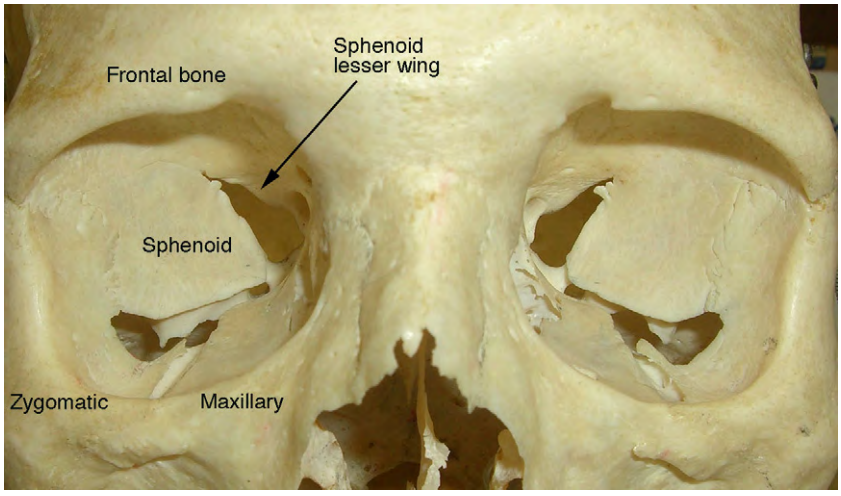

Figure 2 Anterior view of the bony orbit with the bones that form the orbital margin identified.

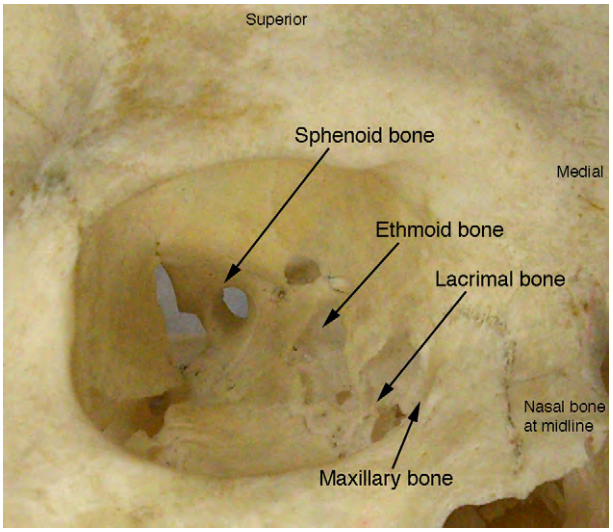

Figure 3 Lateral view of the medial wall of the bony orbit with the main bones identified.

suture line. This is the approximate roof of the ethmoid and floor of the anterior cranial fossa. There are openings at this level for the anterior and posterior ethmoidal vessels and nerves. The anterior foramen is an average of 24 mm behind the anterior lacrimal crest, whereas the posterior foramen is approximately 12 mm posterior to the anterior foramen and 6 mm from the optic canal. These foramina are clinically important as they serve as landmarks for the cribriform plate.

The Orbital Roof

The orbital roof is triangular in shape and formed by the frontal bone and the lesser wing of the sphenoid bone posteriorly (Figure 4). Superolaterally is a concave depression known as the lacrimal gland fossa. Approximately 4 mm posterior to the rim, along the superomedial portion of the roof, is a fibrocartilaginous trochlea for the superior oblique tendon. Careful repositioning of the

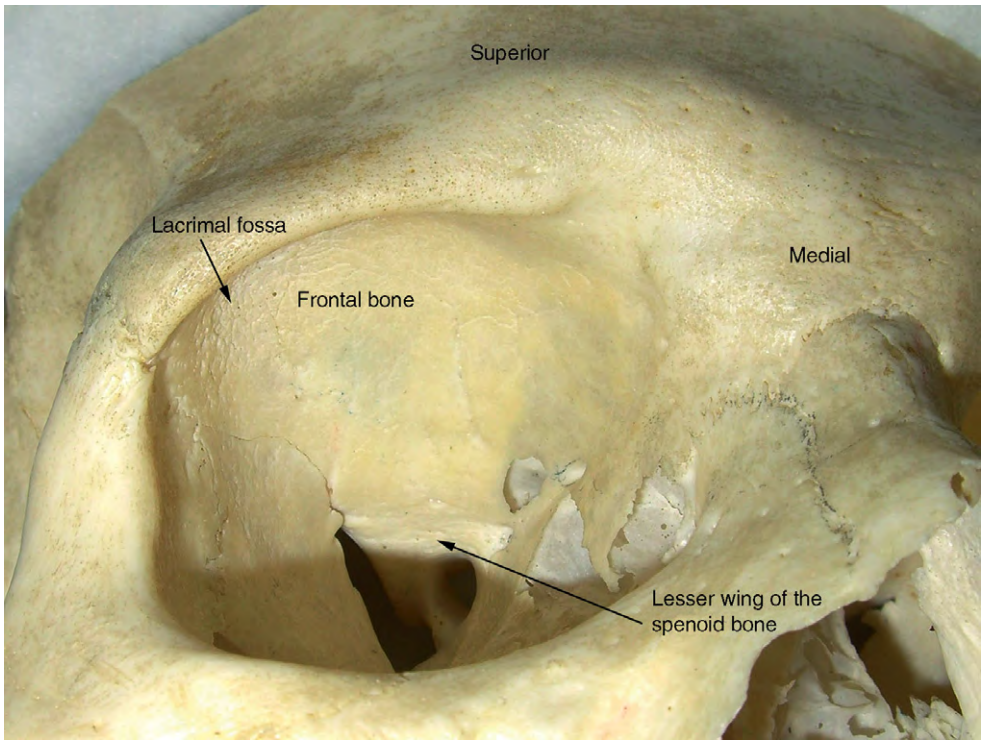

Figure 4 Inferior view of the roof of the bony orbit with the main bones identified.

trochlea on the superomedial surface of the orbit after surgery will help prevent postoperative motility disturbances.

The medial and superior aspects of the orbital roof are adjacent to the ethmoidal and frontal sinuses, respectively. Like the medial wall, the roof is thin and can become secondarily involved with chronic sinus disease. In addition, care must be taken during surgery as damage to the roof can result in a cerebrospinal fluid leak and meningitis. Along the apical, posteromedial portion of the roof lies the optic canal. It is bound by the sphenoid bone medially, the lesser wing of the sphenoid bone superiorly, and the optic strut laterally and inferiorly.

The Lateral Orbital Wall

The lateral orbital wall is the thickest and strongest of the orbital walls. It is composed of the zygomatic bone anteriorly and the greater wing of the sphenoid posteriorly (Figure 5). The medial and lateral walls are approximately the same length (45–50 mm); however, because the lateral wall is at 45° to the medial wall, the lateral orbital rim is approximately 1 cm posterior to the medial rim. The thinnest part of the lateral wall is at the zygomaticosphenoidal suture approximately 1 cm posterior to the orbital rim. This is important when taking off the lateral wall for deep orbital surgery as it allows for outfracture and removal for additional exposure.

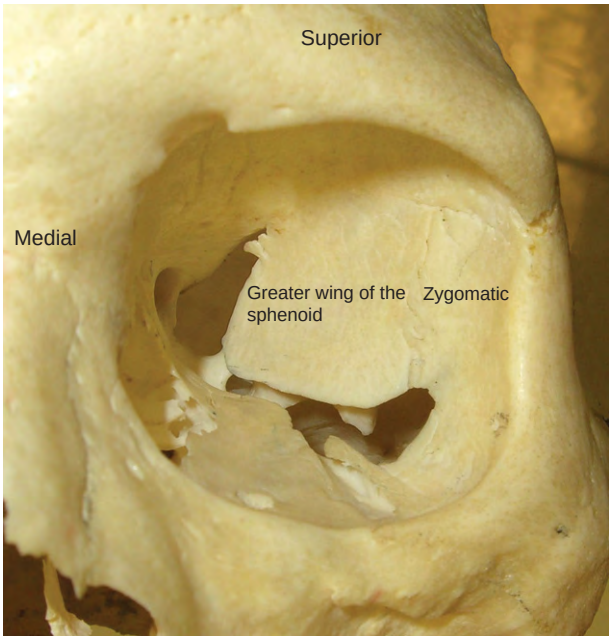

Figure 5 Medial view of the lateral wall of the bony orbit with the main bones identified.

The superior and inferior orbital fissures separate the lateral wall from the roof and floor, respectively. The superior orbital fissure lies between the greater and lesser wings of the sphenoid and transmits the third, fourth, ophthalmic division of the fifth and the sixth cranial

nerves from the middle crania fossa. The ophthalmic veins, a branch of the ophthalmic artery, and the sympathetic root of the ciliary ganglion are also transmitted through this fissure. The inferior orbital fissure transmits the zygomatic branch of the maxillary division of the fifth nerve, the infraorbital nerve and vessel, and the venous communications between the inferior ophthalmic veins and the pterygoid plexus. Along the lateral wall are also several small foramina that perforate the wall just behind the rim laterally and inferiorly. They transmit branches of the lacrimal artery and zygomatic nerve out of the orbit as the zygomaticotemporal and zygomaticofacial neurovascular bundles.

The Orbital Floor

The floor of the orbit is formed by the zygomatic bone, the orbital surface of the maxilla, and the orbital process of the palatine bone (**Figure 6**). It is the shortest of the orbital walls (~40 mm). Similar to the roof, it is triangular in shape. Posteriorly, the floor is separated from the lateral wall by the inferior orbital fissure. It continues anteriorly as the infraorbital groove and canal. The canal runs approximately in the center of the floor from posterior to anterior and carries the maxillary division of the trigeminal nerve and associated infraorbital artery. This bundle exits approximately 4–10 mm inferior to the orbital rim through the infraorbital foramen. The visualization of this groove during orbital floor surgery is important in preventing inadvertent trigeminal hypoesthesia. Medial to the infraorbital canal is the thinnest portion of the orbit where most blowout fractures occur. It is also where the floor is decompressed for surgical treatment of patients with thyroid eye disease.

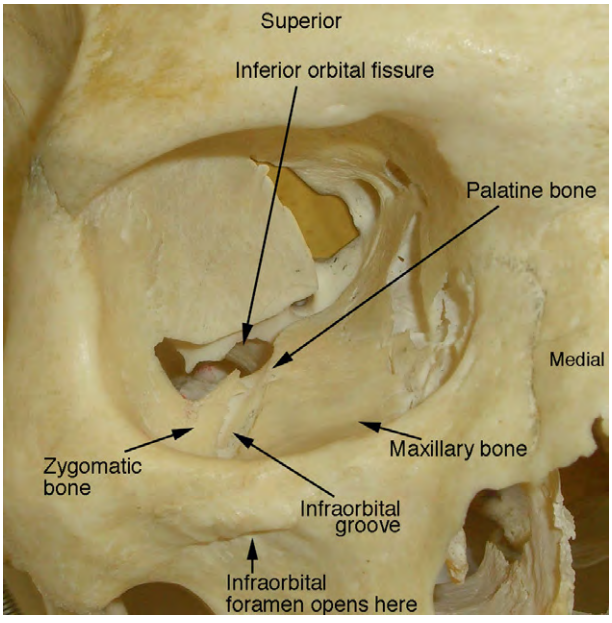

Figure 6 Superior view of the floor of the bony orbit with the main bones and fissures identified.

Orbital Fractures

Blunt trauma to the eye and orbit can cause injury to the thin orbital walls. It is believed that both direct and indirect forces are involved in injury to the orbital bones. The indirect injury occurs as a result of increased hydraulic forces in the confined area of the orbit causing the bone to buckle or blowout into the sinuses. The inferior and medial walls are the most susceptible to this injury. When the fracture is confined to the floor or medial wall, the term pure blowout fracture is used. With more severe injuries, the fractures can extend beyond the orbit, producing rim displacement and maxillary buttress fractures and even separation of the midface from the skull base (Le Fort III; **Figure 7**).

Indications for blowout fracture repair of the orbital floor include rectus muscle entrapment, enophthalmos greater than 2 mm, and large fractures (>50% of the floor or wall). These large floor fractures will often lead to enophthalmos, globe malposition, or both. Similar indications for medial wall repair are used. Repair is often performed within 2–3 weeks after injury. This allows time for the edema to subside, yet is within a window of time that postinflammatory adhesions are not well formed. However, in pediatric cases with clear entrapment, there is evidence that surgery should proceed as soon as possible to limit ischemic damage to the muscle. This group can present with various symptoms when there is a history of trauma. These may include bradycardia, nausea, or syncope secondary to the oculocardiac reflex and warrant early repair.

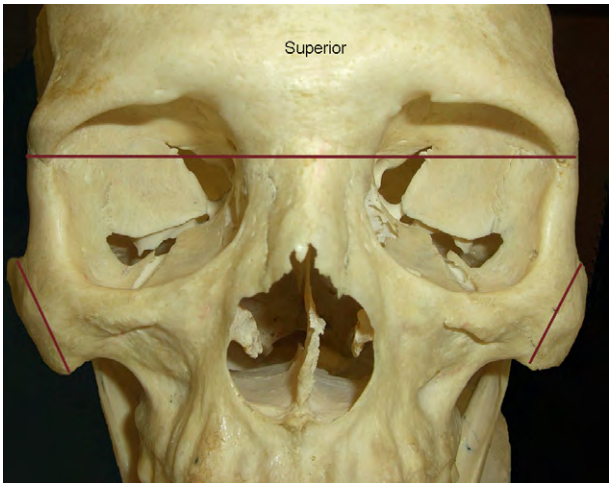

Figure 7 Maroon lines indicate location of a Le Fort III fracture, which is composed of a horizontal fracture that includes the frontozygomatic sutures, the greater wings of the sphenoid, the ethmoid and nasal bones, and a second fracture through the zygomatic arches. This results in a separation from the rest of the cranial bones of the maxillary and zygomatic bones.

Orbital Floor (Blowout) Fracture

Various approaches to the orbital floor have been described, including a subciliary incision or through a laceration of the lower lid sustained during the injury; however, the degree of postoperative sequelae, including lower-eyelid retraction and lagophthalmos, has led to a shift to a tranconjunctival approach. This approach is associated with fewer complications and has gained widespread acceptance.

First, local anesthesia is infiltrated into the lateral canthal and lower eyelid with 1% lidocaine with epinephrine (1:100 000) mixed 50:50 with 0.5% Marcaine (bupivacaine). Forced ductions are performed bilaterally to determine the amount of restriction prior to repair. A 10–15-mm lateral canthotomy is performed in a relaxed skin tension line using a No. 15 Bard-Parker blade (**Figure 8(a)**). Using a curved iris scissors or monopolar cautery, the incision is carried down to the lateral orbital rim periosteum over the zygoma. The inferior crus of the lateral canthal tendon is released (**Figure 8(b)**). The conjunctiva and inferior lid retractors are incised just below the tarsus from the lateral canthus incision to just lateral to the caruncle (**Figure 8(c)**). A Desmarres retractor can be used to retract the tarsal conjunctiva anteriorly. The incision is carried down to the orbital rim periosteum. A malleable retractor is then used to retract the orbital septum and fat. The inferior orbital rim periosteum is incised and gently dissected from the orbital floor with a periosteal elevator (Freer or Coddle elevator; **Figure 8(d)**). The malleable retractor is then repositioned in the subperiorbital plane, and using a hand-over-hand technique, the fracture is exposed (**Figure 8(e)**). Herniated orbital tissue is

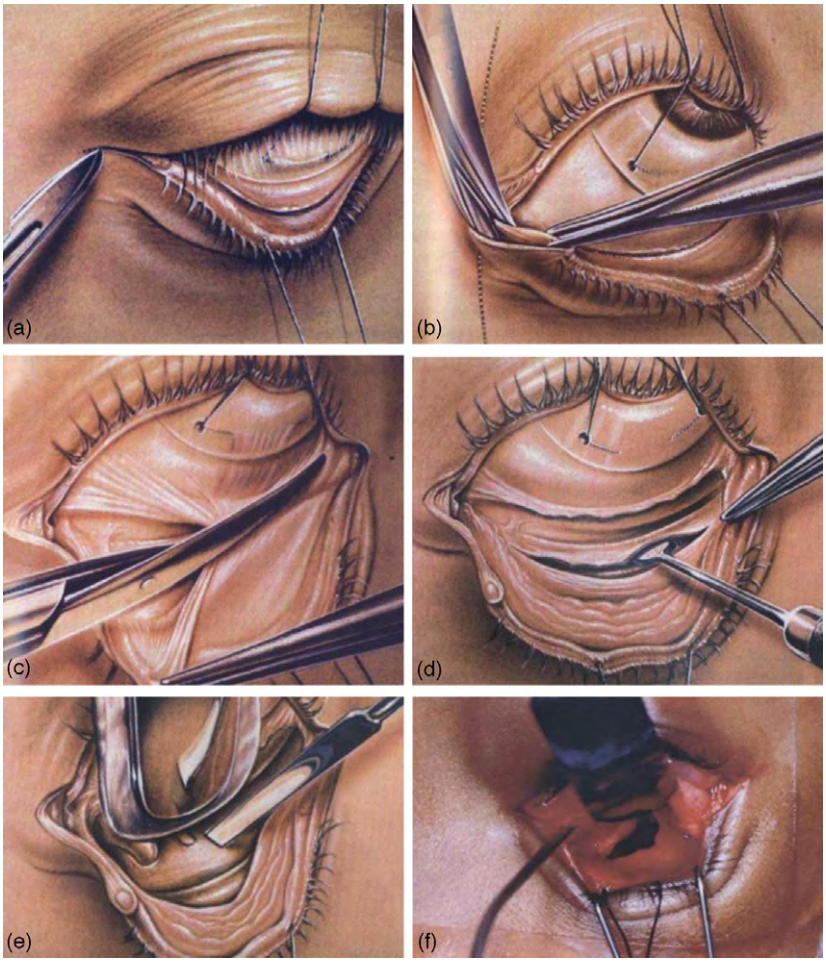

Figure 8 (a) A lateral canthotomy incision is made down to the periosteal level in order to expose the lateral canthal periosteum. This is important in order to be able to reattach the tarsoteninous strap. (b) Next, a lateral cantholysis is performed, which detaches the inferior crus of the lateral canthal tendon from the lateral orbital rim. (c) This incision is made transconjunctivally to extend the horizontal length of the eyelid to the caruncle medially, at a distance of 4 mm below the inferior border of the tarsus. (d) Using a periosteal elevator, the subperiosteal dissection is begun. The periosteum is thicker at the arcus marginalis, and can be grasped to aid dissection. (e) The retraction of the orbital contents superiorly is performed with a malleable retractor, and a subperiosteal pocket is formed. (f) Herniated orbital tissues are elevated in order to visualize the fracture site completely and ensure there is no remaining trapped tissue remaining at the fracture site.

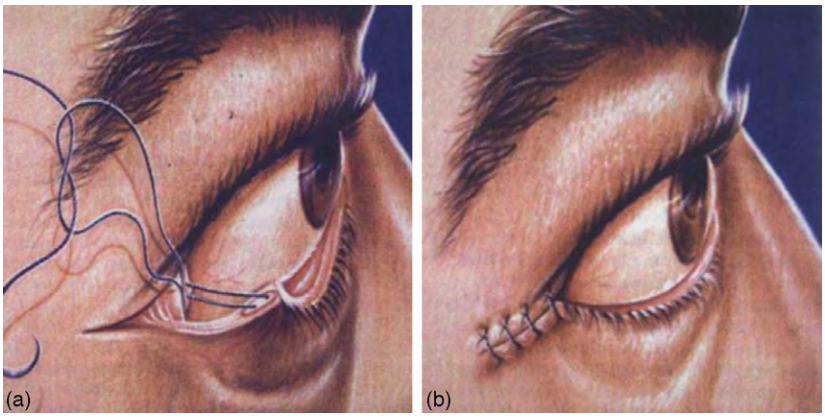

Figure 9 (a) The retractors and periosteum are closed, followed by reattachment of the lateral canthal tendon to the periosteum at the lateral orbital rim. (b) Careful approximation of the eyelid margins during closure is important, which are here closed using a horizontal mattress suture.

gently elevated through the fracture site with blunt dissection until the entire rim of the fracture can be identified (Figure 8(f)). It is important to ensure complete exposure of the fracture to avoid the possibility of leaving entrapped orbital tissue. If the orbital contents are entrapped, the fracture may be enlarged to free the tissue. Bony fragments may be removed with Takahashi forceps. Hemostasis is maintained with bipolar cautery. A paper or foil template is then cut and placed over the fracture site to adequately span the entire bony defect. An alloplastic sheet such as porous polyethylene Medpor (Porex, College Park, GA, USA) or nylon foil sheet SupraFoil (Supramid Alexandria, VA, USA) is then fashioned using the template as a guide. The volume can also be addressed by adding additional sheets. The implant should be positioned posterior to the anterior orbital rim to minimize extrusion. Usually, no fixation is required; however, if the implant tends to ride forward, one can create a small flap into the anterior part of the alloplastic sheet and tuck into the fracture site. Forced ductions are performed to demonstrate the free movement of the globe. The anterior periosteum is closed with a single 5-0 polyglactin suture centrally to prevent anterior migration of the implant. The inferior crus of the lateral canthal tendon is then sutured to the superolateral portion of the orbital rim in a mattress fashion with a double armed 5-0 polyglactin suture (Figure 9(a)). The lateral canthal angle is reformed with a 6-0 polyglactin suture placed through the gray line of the upper, and then lower, eyelid. The lateral canthotomy skin incision is reapproximated with 6-0 Fast Absorbing Plain Gut suture (Ethicon, Inc., Somerville, NJ, USA) in a running or interrupted fashion (Figure 9(b)). The conjunctival incision is not closed. Antibiotic ophthalmic ointment is placed along the lateral canthotomy incision, and antibiotic/steroid combination drops are used for 1 week postoperatively.

In cases where the entire floor is absent and no medial and or lateral edge exists to support the Medpor sheet, a Synthes titanium orbital floor implant (Synthes (USA), Paoli, PA, USA) or a Medpor Titan implant can be positioned over the defect and fixed rigidly to the orbital rim. If, however, the rim fractures are unstable, they should be stabilized first utilizing a screw and plating system, followed by repair of the orbit floor.

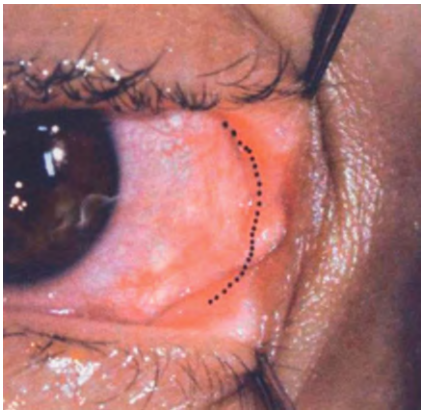

Figure 10 Access to the medial orbit by a transcaruncular incision line.

Medial Wall Fractures

Medial wall fractures often occur in combination with floor or other orbital trauma; however, isolated fractures of the medial wall can occur. If this is the case, they can be observed only if there is no evidence of medial rectus entrapment, the bony defect is nondisplaced or small, and enophthalmos greater than 2 mm is not present. Should it need repair, various approaches can be employed depending on the size.

A small fracture of the medial wall can be approached by a transcaruncular technique (Figure 10). The transcaruncular approach allows moderate access to the orbit without a visible skin incision. An incision is made

through the conjunctiva and Tenon's capsule just medial to the bulk of the caruncle and extends superiorly and inferiorly in the fornices. Dissection is then carried just posterior to the lacrimal sac. A malleable retractor is used to retract the globe and orbital tissues. The periosteum is incised posterior to the lacrimal sac, and periosteal elevators are used to expose the fracture. Once all edges of the fracture have been exposed, a Medpor sheet, or equivalent barrier sheet, can be placed to cover the entire fracture (**Figure 11**). No fixation screws or sutures are needed. Forced ductions are then checked to assure there is no entrapment of muscle.

Lynch incision or a direct approach can be used if the fracture is large or if combined with a large floor defect. The medial canthal area is infiltrated with local anesthetic. The Lynch incision is performed by marking a gull wing approximately 5 mm anterior to the medial canthus (**Figure 12**). Hemostasis is obtained with monopolar cautery and the periosteum is exposed. The periosteum is incised and elevated using a Freer elevator. The lacrimal sac and medial canthal tendon are elevated with the periosteum. A malleable retractor is positioned in the subperiosteal space, and the full extent of the fracture is exposed (**Figure 13**). Then, as with the smaller fractures, the herniated orbital tissue is gently elevated through the fracture site with blunt dissection until the entire rim of the fracture can be identified. The fracture can be enlarged if the orbital contents are entrapped. A template is cut and placed over the fracture site to adequately span the entire bony defect. An alloplastic sheet of Medpor is then cut using the template and placed over the defect. If the defect is greater than 50% of the medial wall or unstable, a combined titanium alloplastic sheet (MED TITAN) can be used to fix the defect. Care must be taken to protect the lacrimal sac by placing a notch in the sheet. Combined floor and medial wall fractures are repaired using the lateral canthotomy approach to the floor combined with the medial Lynch or transcaruncular approach. The anterior periorbita is closed with 5-0 polyglactin suture in an interrupted fashion, the deep tissues are closed with interrupted or running 5-0 polyglactin suture, and the skin is closed with a running 6-0 Fast Absorbing Plain Gut suture. Antibiotic ointment is applied over the wound.

Zygomatic–Maxillary Complex Fractures (Tripod)

Zygomatic–maxillary complex fractures involve the inferior and lateral orbital rim, zygomatic arch, and lateral

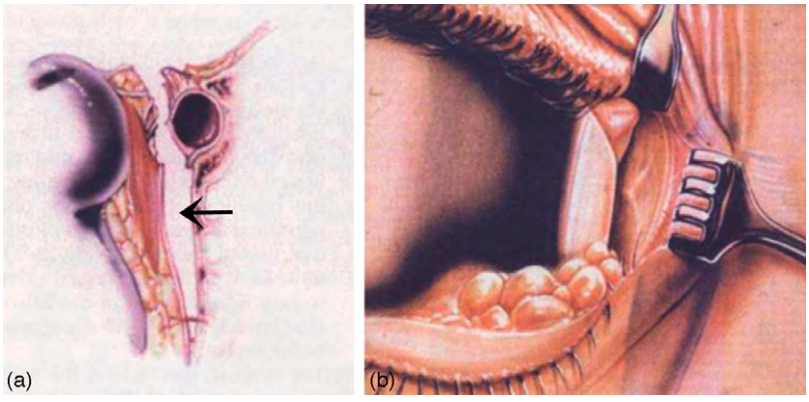

Figure 11 (a) Axial view of the transcaruncular approach to the medial extraperiosteal orbital space, indicated by the black arrow. (b) View of the medial orbital wall. Retractors are used to displace the lacrimal sac medially, while another retractor displaces the orbital contents temporally.

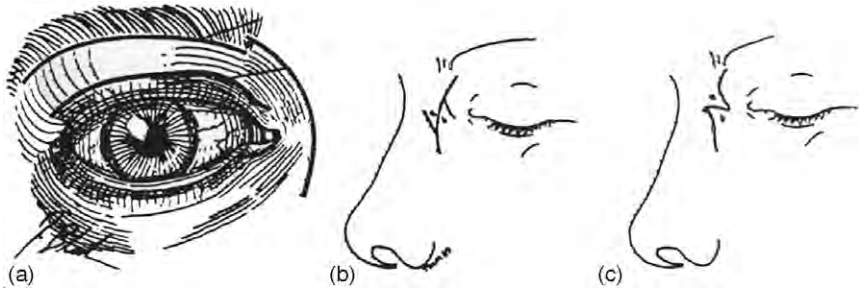

Figure 12 (a) Lynch incision. (b and c) Variations of the standard Lynch incision.

wall of the maxillary sinus. Left uncorrected, these fractures may produce flattening and depression of the cheek in addition to impingement on the coronoid process of the mandible, leading to pain and difficulty in opening the mouth. These fractures should be repaired within the first 2 weeks of injury with open, meticulous anatomic reduction of the fracture and fixation.

The lateral canthal and lower-eyelid areas are infiltrated with local anesthetic. A lateral canthotomy is performed as shown in **Figure 8**. Using the monopolar cautery, the incision is carried down to the lateral orbital rim periosteum over the zygoma. The upper and lower crus of the lateral canthal tendon are released, and the lateral wall periosteum is incised 2 mm lateral to the orbital rim and gently dissected from the zygoma and maxillary bone to define the fracture sites. The periosteum is then dissected from the lateral orbital wall. The conjunctiva and inferior lid retractors are incised below the tarsus from the lateral canthus to just lateral to the caruncle. A Desmarres retractor is used to retract the tarsal conjunctiva inferiorly, and the incision is deepened to the orbital periosteum. The orbital septum and fat are retracted with a malleable retractor and the inferior orbital rim periosteum is incised. A periosteal elevator is used to dissect the periosteum from the orbital floor and malleable retractors are then used to expose the full extent of the fracture using a hand-over-hand technique (**Figure 8**). To ensure the exact realignment and stabilization of the maxillary buttress, a superior buccal sulcus incision is made from the base of the canine to the base of the second bicuspid (**Figure 14**). The subperiosteal plane is created to expose the fracture. The displaced bone is reduced to the correct anatomic position using a towel clip or Kolker clamp. The fragments can be stabilized with miniplates. The periosteum over the lateral and inferior orbital rims is closed with interrupted 5-0 polyglactin sutures. The upper and lower crus of the lateral canthal tendon are reunited with a 5-0 polyglactin suture, and this suture is secured to the lateral orbital periosteum. The lateral canthal angle is reformed with a 6-0 polyglactin suture placed in the gray line of the upper, and then lower, eyelid. The lateral canthotomy skin incision is reapproximated with 6-0 Fast Absorbing Plain Gut suture in a running or interrupted fashion. The conjunctival incision is not closed, whereas the buccal incision is closed with 3-0 chromic sutures. Antibiotic ophthalmic ointment is placed in the inferior fornix and over the lateral canthus.

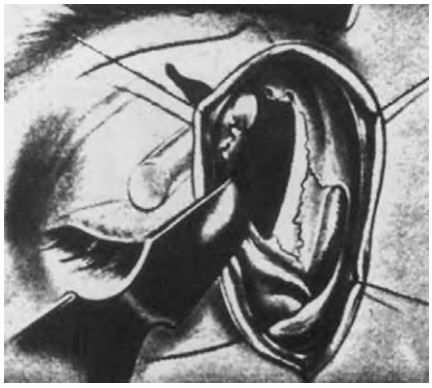

Figure 13 This dissection approach results in an extensive view of the medial orbital wall. The suture lines emerging laterally and medially represent the incision line.

Postoperative Care

In the immediate postoperative period, a delayed retrobulbar hemorrhage is the main concern. The patient and family should be made aware of these symptoms (increased pain and sudden proptosis) and if present, the vision should be checked one eye at a time to establish its presence. The inability of the patient to see or open the

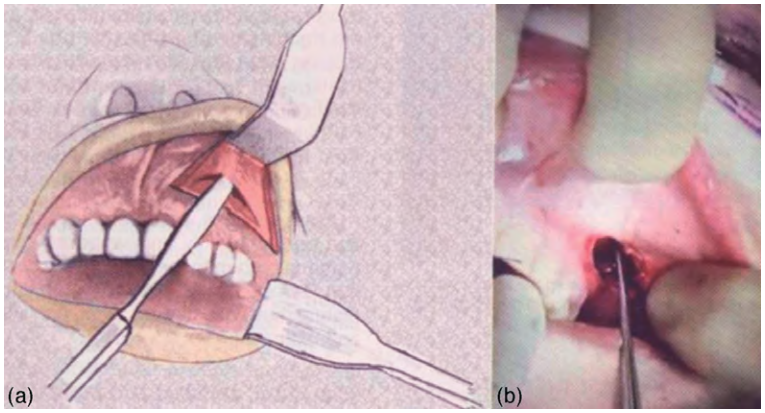

Figure 14 (a) At 10–15 mm superior to the mucogingival junction, a gingivobuccal (sublabial) incision is made at the level of the first molar tooth. (b) As the incision proceeds anteriorly, it is made for inferiorly as it nears the piriform rim. This is 5 mm superior to the mucogingival junction.

eyelid because of tense swelling should be evaluated immediately and may necessitate the release of sutures and a return to the operating room to manage any persistent bleeding. Pupils are often unreliable after surgery due to the effects of epinephrine in the local anesthetic and systemic medications given by the anesthesia staff.

As with care following orbital fractures, patients are warned not to blow their nose as air can enter into the orbit, and, if allowed to develop sufficient pressure, it can lead to vision loss via central retinal artery occlusion. Air in the orbit can be drained with a large bore needle and syringe of sterile water. The presence of bubbles in the water confirms the release of air. Intravenous antibiotics are recommended at the time of surgery if an implant is placed, and generally the patients are given postoperative antibiotics for 5–7 days. Antibiotic ointment is placed in the fornices and on any surgical wounds at the end of the surgery and then used twice a day for 1 week. Sports and significant exertion can be resumed around 6 weeks postoperatively.

Complications associated with orbital implants are infrequent; however, they may include fistula formation, migration, motility restriction, infection, globe elevation, cyst formation, proptosis, and optic nerve trauma. As mentioned earlier, care should be taken to avoid injury to the lacrimal sac by appropriately sizing the implant and cutting a notch as described. A thorough understanding of orbital and facial anatomy combined with appropriate surgical techniques will help limit these complications.

Glossary

Choristoma – A benign tumor, which contains normal tissues but is found in abnormal locations.
Ectopia – An abnormal congenital or acquired position of an organ or a part.
Hamartoma – A benign focal malformation that resembles a neoplasm in the tissue of its origin. It is composed of tissue elements normally found at that site, but which grow in a disorganized mass.
Mass effect – Damage to the globe, optic nerve, and/or tissues in the orbit due the bulk of a tumor, the blockage of fluid, or excess accumulation of the fluid within the bony orbit.
Mohs surgery – Created by a general surgeon, Dr. Fredrick E Mohs, it is a microscopically controlled surgery that is highly effective for common types of skin cancer.
Proptosis – Any nonendocrine-mediated protrusion of the globe.

This article discusses tumors and masses that occur in the human orbit. It is divided into sections based on the tissue origin of each tumor type and each disease entity.

Neoplasia

Neurogenic Tumors

Optic nerve gliomas

Juvenile pilocytic astrocytoma is a low-grade, slow-growing pilocytic astrocytoma of the optic nerve derived from glial cells, which usually presents before the second decade of age. Isolated lesions are more typical; however, diffuse tumors are found in conjunction with neurofibromatosis type 1 (NF1). Optic nerve gliomas (**Figure 1**) may involve any part of the optic nerve and can be subdivided according to location into orbital, orbitocranial, chiasmal, and diffuse/multifocal types. Clinical signs depend on the location; the more anterior tumors present with visual loss, increasing proptosis, and optic disk swelling or atrophy, whereas those nearer the chiasm cause a more insidious field of vision loss and hypothalamic symptoms or hydrocephalus. Imaging usually negates the need for biopsy due to the characteristic features of an enlarged fusiform optic nerve with smooth intact dural margins, kinking of the nerve, cystic degeneration of the tumor, and, rarely, sparse calcification seen on a computerized tomography (CT) scan. The management is generally conservative; however, chiasmal or parachiasmal tumors may need chemotherapy, radiotherapy, or shunting procedures, and more localized, accessible tumors of the optic nerve are excised if very large or rapidly progressive.

Malignant optic nerve glioma (glioblastoma) is an aggressive primary tumor of the optic nerve occurring in middle-aged adults. It may occur from a lower-grade astrocytoma but usually occurs *de novo* as glioblastoma multiforme and is not usually associated with neurofibromatosis. It displays rapid growth with local spread extending swiftly into the nervous system. Early visual deterioration progresses quickly into blindness and death. CT imaging demonstrates an enlargement of the optic nerve or chiasm in three-quarters of the patients; the diagnosis is by biopsy. Treatment options include radiotherapy, chemotherapy, or surgical excision, but these only offer a delay in fatality.

Meningioma is the most common primary tumor of the central nervous system in adulthood arising from meningothelial cap cells of the arachnoid villi. The orbital and visual effects are dependent on the location of the tumor – intracranial, within the optic canal, or along the optic nerve. Characteristic retinochoroidal (optociliary) shunts are seen at the optic disk margin with optic nerve sheath tumors. Growth along the optic nerve sheath may be extradural, subdural, or combined. Intracranial sites affecting the visual pathway commonly include the sphenoid ridge, suprasellar area, and the olfactory groove. There is a strong female preponderance, and the tumor typically presents in middle age. However, it can occur more aggressively in younger males. Imaging with CT may reveal hyperostosis of the adjacent bone, calcification of the tumor, railroad tracking (central lucent areas), and diffuse enlargement. Magnetic resonance imaging (MRI) scans show dense uniform enhancement with gadolinium. The management usually consists of regular observation and neuroimaging. If intervention is required, surgical excision or debulking offers a good prognosis. However, blindness frequently occurs due to direct damage of the optic nerve, and irradiation may be preferred.

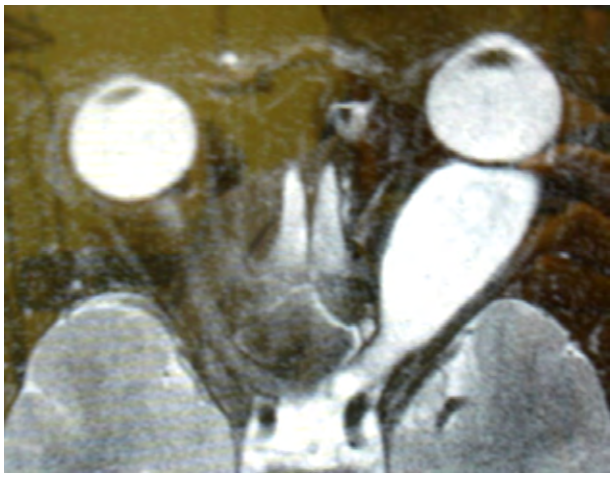

Figure 1 Axial T2-weighted magnetic resonance imaging with gadolinium enhancement of a left optic nerve glioma. Note the hyperintense fusiform mass that extends through the optic canal to the optic chiasm.

Medulloepitheliomas (neuroepitheliomas) of the optic nerve is a benign or malignant tumor of the optic nerve head found in children arising embryologically from the medullary epithelium of the optic vesicle. It needs to be distinguished from optic nerve glioma.

Hemangiopericytoma is an uncommon, noninfiltrative, vascular tumor of the pericytes that may be found in the orbit. It can be benign, intermediate, or malignant depending on the histopathological criteria, and is described as sinusoidal, solid, or mixed type. It causes a symptomatic mass effect within the orbit, but may also occur as an optic nerve lesion. Despite excision, it has a propensity to recur, and benign tumors may metastasize.

Peripheral nerve tumors

Neurofibroma is a benign nerve sheath tumor of the peripheral nervous system. Schwann cells are the neoplastic origin; however, other endoneurial cells and elements are present. The tumor may be plexiform, fusiform, or diffuse in shape. Neurofibromas of the orbit are broadly divided into dermal isolated lesions of a single nerve, diffuse infiltrations, and plexiform lesions of multiple nerve bundles. All types can be found in NF1. Localized isolated lesions can appear similar to schwannoma on imaging. The diffuse and plexiform lesions appear irregular with ill-defined borders and are best seen with fat suppression. No known treatment can stop the progression of neurofibromatosis or cure it. Individual neurofibromas can usually be removed surgically or shrunk with radiation therapy. Surgical removal often requires removing the nerve with the fibrous tumor.

NF1 is an autosomal-dominant disorder with low and variable expressivity affecting the nervous system, due to a mutation of neurofibromin chromosome 17q11.2. Diagnostic criteria require the presence of two or more classic features: at least six café au lait macules, two or more single neurofibromas or one plexiform neurofibroma, optic nerve glioma, axillary or inguinal freckling, Lisch nodules (iris hamartomas), a first degree relative with NF1, or distinct skeletal abnormalities such as sphenoid dysplasia.

NF2 is a rare autosomal-dominant disorder caused by mutation of merlin chromosome 22q12 and characterized by the development of bilateral acoustic neuromas, meningiomas, spinal schwannomas, and posterior subcapsular lens opacities. Combined retinal and pigment epithelial hamartomas, astrocytic hamartomas, and optic nerve gliomas may be visible on fundoscopy.

Plexiform neurofibroma is the most common peripheral nerve sheath tumor of the orbit involving multiple nerve bundles, causing periorbital and orbital soft-tissue hypertrophy, primary or compensatory bony changes, and ocular abnormalities. The management is usually cosmetic, but surgical excision is extremely difficult due to the high vascularity of these tumors and complex integration with surrounding structures. Malignant transformation is extremely rare.

Diffuse neurofibromas are rare, dermal, benign nerve sheath tumors that infiltrate normal surrounding structures. Subcutaneous involvement of the upper eyelid causes the classic S-shaped deformity.

Amputation neuroma is a disorganized overgrowth of regenerating severed peripheral nerves. Mechanical factors may precipitate the formation. Lesions can occur postenucleation causing proptosis and severe pain. Its management involves surgical excision.

Schwannoma (neurilemmoma) is a slowly progressive, noninfiltrative, benign tumor of the peripheral nerves arising from Schwann cells. Typically, the lesions are solitary, presenting in adulthood, and rarely occur within the periorbita. Orbital signs are related to the mass effect, dependent on location, and need to be distinguished from other slow-growing orbital tumors. Imaging shows well-delineated lesions with variable density dependent on intralesional cyst formation. If the patient requires intervention, then a complete surgical excision of the encapsulated tumor is preferential. Exceptionally rarely, schwannomas develop malignant change.

Malignant peripheral nerve sheath tumor (neurofibrosarcoma, neurogenic sarcoma, and malignant schwannoma) is a soft-tissue sarcoma of the nerve sheath, which may or may not arise from Schwann cells. Nearly half of them occur in patients with NF1. Due to the locally aggressive nature, radioresistance, and metastatic spread, the 5-year survival rate from this tumor is extremely low. Rarely, some tumors run a more indolent course. Radical surgical excision/exenteration offers the best prognosis.

Rare tumors of neuroectodermal origin

Alveolar soft part sarcoma is a soft-tissue tumor of uncertain cellular origin occurring in children and young

adults, more commonly female. It usually occurs on extremities but may occur in the orbit as a slow-growing mass. Its treatment is by wide surgical excision with a good prognosis for orbital primary lesions.

Granular cell tumor is a slow-growing, usually benign tumor of spindle cells dense in granular eosinophilic cytoplasm and thought to be of neural origin. Typically, the tumor occurs in the tongue or subcutaneous tissues, but can be orbital, ocular, or periorbital.

Paraganglioma (chemodectoma) is a rare, neuroendocrine tumor arising from glomus cells (chemoreceptors of blood vessels that are part of the paraganglion system) and is described according to their location within the abdomen, thorax, or the head and neck. Within the orbit, they are thought to arise from the ciliary ganglion. Tumors are usually encapsulated, comprising nests of cells (Zellballen), and have a low rate of malignancy or metastases. However, they tend to recur after incomplete orbital resection. Radiotherapy may have a role.

Primary orbital carcinoid tumors are slow-growing tumors of amine precursor uptake and decarboxylation (APUD) cells that are usually benign, but with malignant potential. A small proportion of these lesions are associated with the carcinoid syndrome. The majority arises in the gut, but primary and secondary lesions have been described within the orbit. Similar to other slow-growing tumors of the orbit, complete surgical excision is recommended.

Neuroepithelioma is an extremely rare neoplasm of the peripheral nerve that has an aggressive course and is difficult to treat.

Esthesioneuroblastoma (olfactory neuroblastoma) is a neuroectodermal tumor arising from the olfactory epithelium that commonly extends into the orbit. It differs from neuroblastoma in that it does not arise from the sympathetic nervous system; however, classification remains controversial. Those occurring in the cranium and orbit have a poorer prognosis. The management requires aggressive surgical excision with adjunctive radiotherapy and chemotherapy.

Primary neuroblastoma is a neuroendocrine tumor of varying levels of differentiation arising from the neuroblasts of the sympathetic nervous system. Of the orbit, it is typically metastatic from the adrenal gland and presents in children. However, primary orbital neuroblastoma has been reported, which needs to be distinguished from the less aggressive neuroendocrine tumors, such as carcinoid.

Primary ganglioneuroma is a benign neuroendocrine tumor of the sympathetic nerve fibers. Typically, older children present with a well-delineated mass of the posterior mediastinum or retroperitoneum, although it can rarely occur within the orbit.

Primary orbital melanoma is a rare, malignant tumor of orbital melanocytes that is a distinct clinical entity from secondary or metastatic melanomas that arise from the globe or melanocytes elsewhere. It presents more commonly in association with congenital ocular/oculodermal melanocytosis or hypercellular blue nevus. It starts off as a well-circumscribed lesion with enhancement on MRI; yet, prognosis is poor due to the propensity to metastasize. Its treatment is aggressive – wide excision/exenteration of the mass intact with adjuvant irradiation and chemotherapy.

Retinal anlage tumor (pigmented retinal choristoma/melanotic neuroectodermal tumor (MNET) of infancy/melanotic progonoma/congenital melanocarcinoma/melanotic adamantinoma/pigmented epulis of infancy) is a primary melanocytic tumor of infancy that usually begins in the jaw and occasionally affects the orbital soft tissue. It contains two cell types resembling retinal pigment epithelial cells (hence the name retinal anlage tumor) and neuroblastic cells. Complete wide excision, including bony removal, is usually required.

Ectomesenchymal tumor is a neoplasm derived from neural crest cell origin.

Mesenchymal Tumors

Striated muscle tumors

Rhabdomyosarcoma is the most common soft-tissue sarcoma (tumor of connective tissues) and primary malignancy of childhood arising from mesenchymal skeletal muscle development. Rhabdomyosarcoma commonly arises from within the orbit but can occur as a secondary extension from the sinuses or nasal cavity. Typical presentation is of rapidly advancing, nonaxial globe proptosis with eyelid swelling which may be painless. Histology reveals rhabdomyoblasts, and tumors are classified according to the cell pattern – embryonal, alveolar, undifferentiated, and anaplastic. Imaging assists in diagnosis; CT scans show moderately well-delineated homogenous tumors that usually spare bone and extraocular muscles and enhance with contrast. Prognosis depends on the cell type, the alveolar and undifferentiated sarcomas having the least favorable outcome. The management includes tissue diagnosis and tumor staging. If possible, the whole tumor should be excised intact. Most patients require adjuvant irradiation or chemotherapy.

Rhabdoid tumor is an extremely aggressive, malignant neoplasm of uncertain pathogenesis that appears similar to rhabdomyosarcoma but lacks rhabdomyoblasts. It occurs mainly in children and was initially described as a variant of Wilm's tumor of the kidney. Orbital involvement presents with rapid proptosis and globe displacement. Despite surgical excision, radiotherapy, and chemotherapy, the prognosis is generally very poor.

Rhabdomyoma is a benign tumor of skeletal muscle derivation occurring extremely rarely within the orbit. It is a well-differentiated, circumscribed tumor that can be excised, debulked, or observed. Cardiac rhabdomyomas are associated with tuberous sclerosis.

Endodermal sinus tumor (yolk sac tumor) is a malignant germ cell tumor which can not only occur within gonadal sites of young children as infantile embryonal carcinoma, but can also present as a fulminant neoplasm of the orbit. These malignant endodermal cells secrete α-fetoprotein, which helps to differentiate the tumor. The treatment includes a combination of surgery, and chemotherapy and recent advances of the latter have improved the prognosis.

Smooth muscle tumors

Leiomyoma is a benign, smooth muscle neoplasm that most commonly occurs within the uterus and gastrointestinal tract. It rarely occurs within the orbit as a well-defined, indolent mass, histologically similar in appearance to a nerve sheath tumor or fibrous histiocytoma. After incomplete excision, it may recur.

Leiomyosarcoma is a malignant, smooth muscle neoplasm that typically involves the uterus of women in their sixties. Orbital tumors have been reported and may occur postirradiation for retinoblastoma. It presents like other rapidly enlarging infiltrative orbital tumors with progressive nonaxial globe proptosis. Histology reveals anaplastic spindle cells positive for smooth muscle antigen (SMA). Wide excision/exenteration of orbital lesions combined with chemotherapy or irradiation may be required.

Adipose tumors

Lipoma is an extremely common, benign soft tissue tumor of the adipose tissue. Subtypes are classified according to cell type and location. Lipomas are rare within the orbit; however, if they do occur, they present as a distinct mass within the orbital fat and cause a localized displacement of tissues. The diagnosis is usually made postexcision, and the prognosis is excellent.

Liposarcoma is a malignant, soft tissue tumor arising from adipose cells. It has a widespread distribution, rarely occurring in the orbit where it causes a slowly progressive mass effect. Liposarcomas are classified into well-differentiated, myxoid, round cell, and pleomorphic cell types. Those in the orbit tend to be low-grade, well-differentiated, or myxoid types. The management is by complete surgical excision and may benefit from adjunctive radiotherapy.

Fibrous tissue tumors

Fibroma is a benign tumor of mesenchymal origin composed of fibrous tissue. It occasionally occurs as a non-infiltrative mass of the orbit. After surgical excision, it is found to be composed of a paucicellular population of fibroblasts separated by collagen with the absence of inflammatory cells.

Nodular fasciitis (nodular pseudosarcomatous fasciitis/subcutaneous pseudosarcomatous fibromatosis) is a benign nodular lesion, usually of the extremities, caused by a proliferation of connective tissue, and thought to be a reparative process secondary to trauma. It most commonly involves the superficial fascia and, as it develops rapidly, can be mistaken for sarcoma. Orbital nodular fasciitis is reported, usually occurring more anteriorly rather than deep in the orbit. The management is by complete surgical excision.

Fibromatosis is an infiltrative, nonmetastasizing, fibrous soft tissue tumor that sits in between a fibroma and a fibrosarcoma in the level of progression. Lesions are composed of well-differentiated fibroblasts. If smooth muscle elements are present, the term myofibromatosis is used. Congenital generalized fibromatosis is usually fatal, with multiple tumors occurring throughout the body of newborns. Orbital lesions occur, and treatment is by wide surgical excision followed by periodic monitoring. Myofibromas of the orbit tend to be solitary with a benign course. Regression of fibromatosis can occur.

Fibrosarcoma is a malignant, locally aggressive tumor of fibrous soft tissue comprised of immature spindle-shaped fibroblasts with a propensity to metastasize. Cells are typically aligned in a herringbone pattern. Reclassification of other spindle cell tumors has decreased the true incidence of this condition. Orbital tumors can be primary lesions or may arise secondary to spread from adjacent sinuses or after radiotherapy. Incomplete surgical removal from the orbit is common; thus, this tumor tends to recur. Wide excision/exenteration is needed.

Solitary fibrous tumor is a benign neoplasm of fibrous soft tissue that differs from other spindle cell tumors by the absence of a histopathological pattern. It occurs as a unilateral, well-circumscribed, orbital lesion of any age group and causes a slow mass effect. Malignant transformation is rare. Incomplete surgical excision can cause localized infiltrative recurrence.

Epithelioid sarcoma is a rare, aggressive mesenchymal malignancy with an epithelioid pattern. It commonly occurs in the extremities of young people, particularly the tendon sheaths, but has been reported in the orbit.

Myxoma is a benign tumor of mesenchymal origin, where connective tissue becomes filled with a mucinous matrix. The majority occurs within the heart, in particular the left atrium. Malignant tumors of myxoid appearance need to be excluded prior to diagnosis. True orbital myxomas are extremely rare. A complete surgical excision of this soft tumor is difficult due to the lack of a capsule, thus resulting in its recurrence.

Giant cell angiofibroma is a benign, spindle cell tumor of mesenchymal origin comprising multiple giant cells within the stroma and blood vessels. It very occasionally occurs within the orbit, presenting as an anterior mass.

Dermatofibrosarcoma protuberans is a neoplasm of fibroblasts affecting the dermis of the skin throughout the body. Local invasion, metastases, and recurrences are possible. It can occur in the periorbita and thus invade the orbital tissues. Mohs surgery is effective in excision of the sarcoma.

Histiocytic tumors

Fibrous histiocytoma is a tumor of mesenchymal origin containing fibroblasts and histiocytes that can be benign, locally aggressive, or malignant. It presents either as a superficial lesion, usually on lower extremities, or as a deep tumor – common within the adult orbit. Conventional fibrous histiocytoma tends to be a slow-growing, relatively firm mass, but more aggressive variants occur with infiltrative features and a tendency to recur, and rarely metastasize. Complete surgical resection is best.

Primary Bone Tumors

Benign fibro-osseous and cartilaginous lesions

Osteoma is a benign, slow-growing tumor of the bone, found most commonly in the paranasal and frontal sinuses but the tumor can extend into the orbit. It may take a sessile or pedunculated shape. The symptoms include a mass effect, and pain is common. Three histological subtypes exist – compact, cancellous, and fibrous. The management includes observation and surgical excision, recurrence being rare.

Fibrous dysplasia (Figure 2) is a benign, slowly progressive fibro-osseous malformation causing replacement of the medullary bone with fibrous tissue and osteoid, thought to be due to an arrest in the normal bone development. It may be monostotic (more common and often affecting the craniofacial bones) or polyostotic (involving many bones) as seen in McCune–Albright syndrome. Orbital symptoms reflect the gradual compressive effects. Imaging may reveal a ground-glass appearance to the expanded bone. Surgery tends to be reserved for cases with functional defects, rare malignant transformation, or pain.

Ossifying fibroma (fibro-osseous dysplasia) is a benign, acquired tumor of the bone that is most commonly found in the mandible but, occasionally, does present in the orbit. Typically, it starts as a monostotic lesion that gradually expands and spreads to adjacent bones. It is more aggressive in nature than fibrous dysplasia; thus, surgical excision should be performed early.

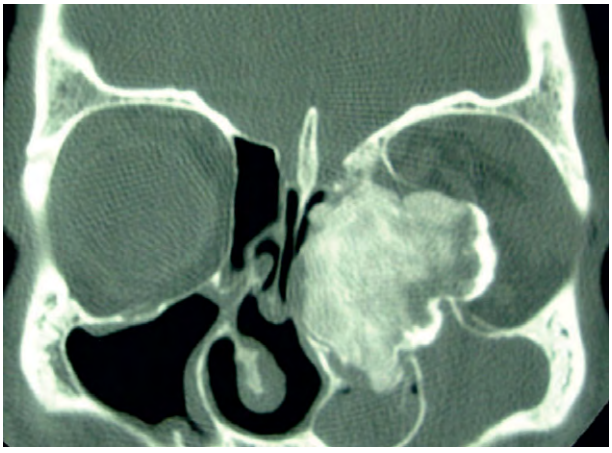

Figure 2 Coronal computed tomography bony view of an ill-defined, hyperdense lesion with a sclerotic margin arising from the ethmoid region and invading the left orbit. The lesion presents a characteristic pagetoid appearance with alternating areas of radiolucency and radiodensity. Histopathological examination revealed this lesion to be fibrous dysplasia.

Osteoblastoma is an uncommon, benign, primary tumor of the bone consisting of osteoblasts that produce the osteoid and primitive woven bone. While it predominantly arises in the spine and long tubular bones of young people, it is unusual for it to be found in the orbit. The mass effect causes compressive symptoms and pain. A rare, aggressive variant of this tumor that metastasizes exists. Complete direct surgical excision is generally curative.

Chondroma is an encapsulated, benign, indolent cartilaginous tumor of chondrocytes that commonly occurs in the bone. Occasionally, it becomes large enough to be symptomatic. It is rare in the orbit owing to the fact that the only normal cartilaginous material in the orbit is the trochlea of the superior oblique. Its management is by observation or excisional biopsy. Malignant change is possible.

Reactive lesions

Cholesterol granuloma is a benign, very slow growing tumor of the bone, formed by a reactive response to crystallized cholesterol and thought to be secondary to trauma or hemorrhage. It typically occurs in the middle ear and temporal bone, but may affect the orbit. Imaging reveals osteolysis, bony expansion, and erosion, and foreign body giant cells are seen microscopically. Curettage is curative.

An aneurysmal bone cyst is a rapidly expansile osteolytic lesion, usually of the long bones and spine and, typically, secondary to neoplasm or trauma. It may be intra- or extraosseus. Orbital cases cause mass and compressive effects. Curettage is generally successful in treatment.

Giant cell (reparative) granuloma is a benign, granulomatous proliferation of the bone, thought to be a reparative response to hemorrhage caused by trauma. It usually involves the maxilla, mandible, or phalanges, but can occur in the orbit. Localized bony destruction and collection of blood cysts are seen. It needs to be distinguished from the more aggressive giant cell tumor and brown tumor of hyperparathyroidism. Its treatment is usually by curettage.

The brown tumor of hyperparathyroidism is a benign, granulomatous proliferation of the bone in association with hyperparathyroidism. Increased osteoclastic activity causes bony destruction and hemorrhage. Treatment of the underlying hyperparathyroidism resolves the tumor.

Neoplasms

Osteosarcoma is the most common primary malignant neoplasm of the bone usually arising *de novo* and occurring in the long bones of children and young adults. It consists

of osteoblastic cell proliferation forming a tumoral bone that shows lysis, sclerosis, and expansion. It can arise secondary to underlying bone pathology, such as Paget's disease, prior irradiation, or a precursor tumor. In addition, it occurs as a secondary tumor in patients with familial retinoblastoma. Orbital lesions usually arise from the maxillary spread. Its management is by surgery with pre- and postoperative chemotherapy and subsequent irradiation. The prognosis depends on the stage, site, size, degree of induced necrosis by chemotherapy, and presence of metastases; however, generally, it is poor.

Chondrosarcoma is a malignant, locally aggressive tumor of the bone composed of anaplastic chondrocytes. It may develop from an underlying benign bony tumor. It most frequently occurs in long bones but can spread to the orbit from the adjacent sinuses. The symptoms are caused by mass effect and infiltration. Depending on the speed of growth and prognosis, the tumors are graded 1–3, with grade 1 being the slowest. If possible, ablative surgery is ideal. Adjunctive chemotherapy or irradiation may have a role.

Mesenchymal chondrosarcoma is a variant of chondrosarcoma that arises from the bone or extraskeletal soft tissue and is typically aggressive with a potential to metastasize.

Ewing's sarcoma is a malignant round-cell tumor found in the bone or soft tissue and thought to be of the same family as neuroectodermal tumors. It most commonly occurs in male teenagers. Orbital tumors arise from metastases or secondary spread, causing a fairly rapid mass effect. Treatment with neoadjuvent chemotherapy, radical surgical resection, and subsequent radiotherapy provides a reasonable prognosis for localized disease.

Myeloma (plasmacytoma) is a hematological malignancy of bone marrow plasma cells. The orbital bone may be affected and tends to present subacutely in older patients.

Langerhans' cell histiocytosis (old term histiocytosis X) is an unusual neoplasm of bone and soft tissues characterized by the clonal proliferation of Langerhans cells, a specialized histiocyte of the epidermal dendritic cell type. On histopathogical examination, these cells sit within an eosinophilic granuloma. The tumor may occur in localized or disseminated forms and can be seen in the orbit. The Hand–Schuller–Christian triad of diabetes insipidus, proptosis, and lytic bone lesions occurs due to multifocal lesions affecting the pituitary. Lettere–Siwe disease is caused by multifocal lesions of many tissues and has a poor prognosis. However, localized disease has a better outlook and is responsive to curettage and systemic or local steroid treatment.

Giant cell tumor (osteoclastoma) is a neoplasm of osteoclast-like giant cells that typically affects long bones in adulthood. Malignant change and metastases may occur. It rarely occurs in the orbit, usually being due to spread from the sphenoid bone.

Intraosseous hemangioma is a benign vascular tumor of the bone, hamartomatous in nature, similar to hemangiomas found elsewhere. It can present in the orbital, particularly frontal, bone as a slowly growing orbital mass associated with pain. Surgical excision is complicated by hemorrhage. Prior embolization may be possible.

Secondary Tumors of the Orbit

Neoplasia of the sinus and nasopharynx

Squamous cell carcinoma is a malignant tumor of anaplastic squamous epithelial cells. The tumor can remain *in situ* (Bowen's disease) or be invasive. Orbital lesions usually occur from direct extension of the eyelid, adnexal, and conjunctival tumors or invasion from the sinuses and nasopharynx. Posterior orbital tumors have a worse prognosis with a greater incidence of metastases at presentation.

Transitional carcinoma of the orbit is a neoplasm of the schneiderian epithelium of the nasal cavity or paranasal sinuses that has invaded the orbit. Tumors are usually multiple, benign, and papillomatous, although malignant transformation occurs in some individuals.

Adenoid cystic carcinoma is a malignant neoplasm of mixed glandular components usually seen in the head and neck region, in particular the salivary glands. Typically, these tumors stay indolent for a period before local invasion and, thus, are detected late. Orbital tumors occur due to spread from the lacrimal gland or paranasal sinuses. Perineural infiltration causes pain and parasthesia. The primary treatment is surgical excision. Adjuvant radiotherapy can be beneficial.

Adenocarcinoma is a malignant epithelial neoplasm of the exocrine glandular tissue. Orbital adenocarcinoma may occur due to the localized spread from the eyelid and adnexa, the sinuses and nasopharynx, or from metastases.

Odontogenic tumors are those arising from the mandible or maxilla that very rarely invade the orbit, for example: ameloblastoma, ameloblastic fibosarcoma, and calcifying epithelial odontogenic tumor.

Orbital extension of eyelid tumors

Basal cell carcinoma of the eyelid is a malignant, slow-growing epithelial tumor of the eyelid skin. Various forms are recognized: nodular, cystic, pigmented, sclerosing, superficial, or baso-squamoid. Orbital invasion is usually a result of advanced disease, recurrence, or the sclerosing (morpheiform) variant.

Sebaceous carcinoma of the ocular adnexa is an aggressive, malignant, epithelial tumor of the sebaceous glands of the eyelids and caruncle. Late diagnosis is typical due to mimicry of other common lid lesions. Orbital involvement is by secondary invasion and has a poor prognosis.

Merkel cell carcinoma is a rare, highly aggressive, and metastasizing malignant neuroendocrine tumor of the skin, usually occurring within the head and neck region.

Eyelid tumors are uncommon. Orbital invasion usually occurs after tumor recurrence.

Mucinous sweat gland adenocarcinoma is a rare, malignant carcinoma of sweat gland origin. An extension from the adnexa into the orbit is possible.

Infiltrating signet-ring carcinoma is an exceptionally rare, malignant carcinoma of eccrine gland origin with a diffuse, histiocytoid appearance microscopically. Orbital spread is possible.

Apocrine gland carcinoma is a rare, malignant carcinoma of apocrine gland origin, for example, an anaplastic cyst of Moll. Secondary orbital extension has been reported.

Secondary tumors arising from the conjunctiva

Conjunctival melanoma is an uncommon malignancy of melanocytes that arises in the conjunctiva. The neoplasms develop within underlying primary acquired melanosis (superficial epithelial pigmentation) or, less frequently, from underlying naevi, or can arise *de novo*. Orbital extension is more typical from other sites.

Orbital extension of ocular malignancies

Uveal melanoma is a malignant neoplasm of melanocytes occurring in the uveal tissue. Orbital involvement is from extrascleral spread and postenucleation orbital recurrence. Its treatment is by partial or complete enucleation/exenteration with plaque or orbital radiotherapy.

Retinoblastoma of the orbit is secondary to spread from a malignant intraocular tumor of the retina. After breach of Bruch's membrane, extension occurs via the choroid, optic nerve, and blood vessels, invading into the orbit and metastasizing. Orbital involvement is treated aggressively with radical excision of the tumor, chemotherapy, and radiotherapy.

Medulloepithelioma of ciliary body is a congenital neuroepithelial tumor of the ciliary body that may be benign or malignant. Medulloepithelioma may also very rarely occur adjacent to and within the optic nerve. Orbital, intracranial extension, and metastases are possible.

Orbital extension of lacrimal sac tumors

Lacrimal sac epithelial tumors occur as exophytic, inverted, or mixed papillomatous lesions, being further subdivided into squamous, transitional, or mixed cell type. They can also arise as *de novo* carcinomas. The histological cell types of those arising *de novo* include squamous cell, transitional cell, adenoid cystic, mucoepidermoid, adenocarcinoma, or poorly differentiated cells. Benign mixed tumors and oncocytomas can also occur from the lacrimal sac.

Lacrimal sac nonepithelial tumors include those of mesenchymal origin (fibrous histiocytoma, hemangiopericytoma, and lipoma), lymphomas, melanoma, granulocytic sarcomas, and neural tumors (neurilemmoma and neurofibroma).

Lacrimal Gland Neoplasia

Tumors of the lacrimal gland are usually classified as epithelial or nonepithelial in embryonic origin and can be benign or malignant. The more common epithelial tumors are the benign pleomorphic adenoma or carcinoma in pleomorphic adenoma and the malignant tumors such as adenoid cystic carcinoma, carcinoma ex pleomorphic adenoma, mucoepidermoid carcinoma, and adenocarcinoma. Nonepithelial tumors typically consist of mesenchymal neoplasms, lymphoproliferations, and metastases.

Pleomorphic adenoma (**Figure 3**) of the lacrimal gland (benign, mixed tumor) is a benign, slowly progressive, epithelial tumor of the lacrimal gland consisting of a mix of epithelial and mesenchymal elements. It usually arises from the orbital lobe and affects young to middle-aged adults. It clinically presents with a unilateral progressive mass in the superotemporal anterior orbit that is relatively pain free. Imaging reveals a round circumscribed mass without bony destruction. Complete extirpation is essential. Over time, this tumor can undergo malignant change.

Carcinoma in pleomorphic adenoma (circumscribed/carcinoma *in situ*) is a circumscribed, noninvasive focus of malignancy within a pleomorphic adenoma that is usually only diagnosed by histopathology. Clinically, there may be a sudden change in the behavior of a previously indolent lacrimal mass. The anaplastic focus is usually adenocarcinoma but may be adenoid cystic, squamous, or sarcomatoid.

Oncocytoma is a rare, benign, slow-growing epithelial tumor composed of oncoctyes – large polygonal granular eosinophilic cells with small, hyperchromatic nuclei. Tumors are found in the kidney, salivary glands, lacrimal sac, conjunctiva, accessory lacrimal glands, and, rarely, the lacrimal gland.

Warthin's tumor (papillary cystadenoma lymphomatosum) is a benign, epithelial tumor of the salivary glands – the second most common parotid gland tumor. It is rare in the lacrimal gland.

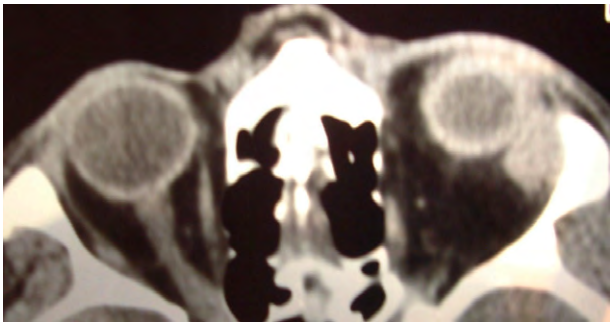

Figure 3 Axial computed tomography soft-tissue view showing an ovoid circumscribed mass in the left lacrimal fossa. Note the characteristic expansion of the lacrimal fossa. The tumor was removed en bloc and proved to be a pleomorphic adenoma.

Myoepithelioma is a benign, epithelial tumor of the lacrimal and salivary glands composed almost entirely of myoepithelial cells.

Adenoid cystic carcinoma of the lacrimal gland is the most common malignant epithelial tumor of the lacrimal gland. It usually presents around the age of 40 but has a bimodal occurrence in the second and fourth decade. Classic histopathological patterns are: cribriform (cystic spaces lined by malignant cells giving a swiss cheese appearance), solid (basaloid), tubular (ductal), sclerosing, and comedocarcinomatous. Tumors may display mixed patterns. In contrast to benign tumors, proptosis is rapid; pain is usually present and associated with ipsilateral parasthesia. Imaging reveals bony destruction. Management is difficult and prognosis is poor. Complete removal may be possible; however, if there is breach of the capsule, then orbital exenteration and bony removal with supplemental radiation and chemotherapy offer the best hope.

Carcinoma ex pleomorphic adenoma (noncircumscribed) is an invasive tumor of any lacrimal gland cell type originating from a pleomorphic adenoma – residual foci of the underlying pleomorphic tumor are evident on histology.

Mucoepidermoid carcinoma of the lacrimal gland is a malignant tumor of the lacrimal gland consisting of varying proportions of luminal epithelial and myoepithelial cell origin and mucin.

Adenocarcinoma of the lacrimal gland is a malignant, aggressively infiltrative epithelial tumor of the lacrimal gland that demonstrates glandular or ductal differentiation. Rapidly growing painful lacrimal masses occur with metastatic spread. Prompt exenteration and radiotherapy increase survival.

Polymorphous low-grade adenocarcinoma is a malignant, epithelial tumor that shows variable histological growth patterns and may be confused with adenoid cystic carcinoma. However, it is well circumscribed and less aggressive in nature. Metastases are less common.

Ductal adenocarcinoma of the lacrimal gland is a malignant epithelial tumor of the lacrimal gland showing proliferation of anaplastic luminal epithelial cells and cystic distension.

Sebaceous adenocarcinoma of the lacrimal gland is a rare, malignant, epithelial tumor of the lacrimal gland usually arising secondary to a preexisting benign mixed tumor or anaplastic carcinoma.

Acinic cell adenocarcinoma of the lacrimal gland is a rare, malignant, epithelial tumor of the lacrimal gland of acinar cell origin. This tumor is seen more typically from the sebaceous gland.

Basal cell adenocarcinoma of the lacrimal gland is a rare, malignant, epithelial tumor of the lacrimal gland of basal epithelioid cells that is slowly infiltrative and has low potential to metastasize.

Epithelial–myoepithelial carcinoma is a low-grade malignant tumor composed of a biphasic cell population of myoepithelial cells and ductal cells. It is more typical of the sebaceous gland but may occur in the lacrimal gland.

Lymphocytic Tumors

Lymphocytic processes in the orbit have received great attention in the last two decades with an increase in our understanding due to more sophisticated molecular and immunodiagnostic techniques. The most frequently encountered lymphocytic orbital tumors are low-grade, slowly-developing lymphoproliferations which tend to develop insidiously and, often, without any pain. They are frequently located anteriorly in the extraconal orbital compartment and tend to be cohesive and mould to adjacent structures on imaging. The underlying disease process is often that of a B-cell lymphoma (small cell), soft-tissue plasmacytoma, having atypical or reactive lymphoproliferations. Other types of orbital lymphocytic processes include: fulminant orbital infiltration by leukemic infiltrates, Hodgkin's lymphoma, or malignant histiocytosis; secondary orbital infiltration from bone or skin lesions; and neuro-ophthalmic lesions in the orbit usually from late disseminated leukemias or lymphomas. These are summarized in **Table 1** in terms of four clinical orbital lymphocytic processes, common mode of presentation, and the common disease processes involved.

If an orbital lesion is the primary presentation of a lymphoproliferative process, then a biopsy must be performed to establish histopathological diagnosis. This can be done by open-incision technique or fine-needle aspiration, the former being the preferred method where one cubic centimeter of tissue is adequate to aid in the diagnosis and allow for immunophenotyping and molecular studies.

A spectrum of lymphocytic processes exists, ranging from reactive lymphoid hyperplasia (RLH) through to frank lymphoma. RLH is a histological diagnosis where biopsy specimens typically show focal lymphoid aggregates. The lesions are usually slightly nodular with a firm to rubbery consistency most frequently in the anterior rather than deep orbit. They are often painless, frequently resemble other lymphoproliferative disorders on imaging, and usually respond well to corticosteroid immunosuppression. Indeterminate lesions are where the morphology is highly atypical but not quite lymphomatous, with lack of molecular or immunophenotypic evidence to suggest lymphoma. They are similar to low-grade lymphoma of the orbit in their presentation and clinical course.

The majority of orbital lymphoproliferations is of B-cell origin, with most lesions being composed of small B-cells that closely resemble normal lymphocytes, making the histological diagnosis particularly difficult.

Table 1 Orbital lymphocytic tumors

Orbital lymphocytic process	*Common mode of presentation*	*Common disease processes*
Orbital masses	Insidious, painless orbital masses, frequently anterior, little functional interference with cohesive appearance on imaging	B-cell lymphomas (small cell) Atypical lymphoproliferations Reactive lymphoid hyperplasia (RLH) Soft-tissue plamacytomas
Fulminant orbital infiltration	More rapid onset of orbital mass and infiltrative effect	Fungal infections Orbital cellulitis Secondary infections (immunocompromised host) Nonspecific orbital inflammatory syndromes
Secondary orbital infiltration	Diverse modes of presentation	B-cell lymphoma (large cell) Plasma cell tumors Burkitt's lymphoma Langerhans' cell histiocytosis T-cell lymphomas Myeloid leukemias
Neuro-ophthalmic lesions	CNS disturbance or invasion of ocular structures	Low-grade intracranial infections or inflammations Intracranial malignancies

The onset is usually in the sixth and seventh decade of life. These lesions are mostly found in the anterior orbit but sometimes have a subconjunctival component. On imaging, they tend to be extraconal and mould or encompass ocular and orbital structures typically without any associated functional deficit. A multidisciplinary approach to managing the patient is most appropriate. Localized disease can be targeted with local radiotherapy, whereas more widespread disease may warrant chemotherapeutic intervention. Emerging monoclonal antibodies against specific lymphocytes may prominently impact the management of lymphoma.

Diffuse large B-cell (DLBC) lymphoma is uncommon in the orbit but is the second most frequent orbital non-Hodgkin's lymphoma. Burkitt's lymphoma is a high-grade and high-risk lymphocytic undifferentiated neoplasm and is linked to Epstein–Barr virus, malaria, or human immunodeficiency virus infection. It is a rapidly disseminating lymphoma but usually presents as a solitary growth with a male preponderance. T-cell lymphomas refer to a broad spectrum of neoplasms in three main categories: precursor T-cell lymphoma, peripheral T-cell lymphomas, and cutaneous T-cell lymphomas. Ocular and orbital involvement usually indicates extracutaneous spread, and their management is based on the extent of involvement. Among childhood malignancies of the orbit, acute leukemia and granulocytic sarcoma are frequent causes of unilateral proptosis, second to rhabdomyosarcoma. Orbital involvement in such cases is a poor prognostic indicator.

Solitary plasma cell tumors are often slow-growing, circumscribed, soft-tissue tumors of the orbit and can be divided histopathologically into polyclonal reactive or monoclonal plasma cell tumors. Histologically, they are not too dissimilar to multiple myeloma, and the distinction comes from careful clinical evaluation and identifying the lack of other associated findings. Unlike non-Hodgkin's lymphoma, orbital involvement of Hodgkin's lymphoma is rare and mostly takes place during the final phases of the disease, reflecting dissemination and aggressive disease.

Langerhans' cell histiocytosis causes rare lesions occurring mostly in children, with a male predilection, and only 10% have any ophthalmic manifestations. It is thought to result from abnormal epidermal accumulations of specialized histiocytes from the dendritic cell family. It typically shows Birbeck granules (cytoplasmic racquet-shaped granules) on electron microscopy. The prognosis is related to the patient's age, extent of the disease, and likely progression, with mortality reducing as the age increases.

Structural Lesions

Cystic Lesions

The multitude of classifications of these lesions indicates their diversity. They can be either with or without epithelial lining. Further divisions can be based on the tissue type, location, and etiology. All cystic lesions share the common feature of a fairly spherical cavity containing material of a different density than the surrounding tissue. Various orbital lesions may have cystic components and may be multilocular. When cystic lesions involve or are adjacent to the bone, they tend to excavate and expand the bone locally if the lesions are encapsulated or cause bony lysis if the cyst margins are more irregular. Identifying cystic lesions from solid ones is part of the diagnostic process in such cases.

Congenital epithelial cysts include dermoid and epidermoid cysts. Orbital and periorbital dermoids are developmental choriostomas and are thought to arise from ectodermal nests pinched off at suture lines. They have a preponderance to be located in the upper outer quadrant of the orbit but may develop virtually anywhere within and adjacent to the orbit. They typically develop slowly and displace other structures by exerting a mass effect. They can be clinically subdivided into superficial

and deep lesions. They tend to have adnexal structures, such as pilosebaceous units, adjacent to the epithelial lining in contrast to epidermoids, which are only lined by the squamous epithelium. Overall, the majority requires complete extirpation, whereas some superficial lesions may be observed.

Acquired cysts include mucoceles and lacrimal cysts. Mucoceles are slowly expanding cystic lesions which originate from the sinuses. They mostly contain a clear to slightly yellow mucoid material, within which they can rarely form a pyocele if the contents become infected. They tend to be expansive and noninfiltrative, and exert a mass effect which can present clinically in a manner typical to the location of origin. For instance, frontal sinus mucoceles tend to displace the globe down and out with minimal proptosis, especially if located anteriorly. Various other ocular effects can result, such as diplopia, vision loss, and swelling, depending on which sinus is involved. The management is surgical and involves removing the cyst lining, re-establishing normal drainage, or obliterating the sinus. Lacrimal ductal cysts (**Figure 4**), otherwise known as dacryops, are uncommon and are classically mobile, tense, fluctuant, slowly growing swellings that become visible in the superior–temporal conjunctival cul-de-sac upon eversion of the upper lid. The management, if symptomatic or bothersome, is complete excision or marsupialization.

Tumors and Ectopias

Dermolipoma (**Figure 5**) is an ectopia of the skin to the conjunctiva and can cause frequent clinical confusion with true orbital dermoids. It often occurs in the area of the lacrimal ducts and, therefore, superficial excision to remove the lesion must ensure that these ducts are not damaged.

Lacrimal ectopia, although not infrequently found in the adnexal area, is rarely noted deep in the orbit. Surgical excision reduces the risk of progressive chronic inflammation of the orbit.

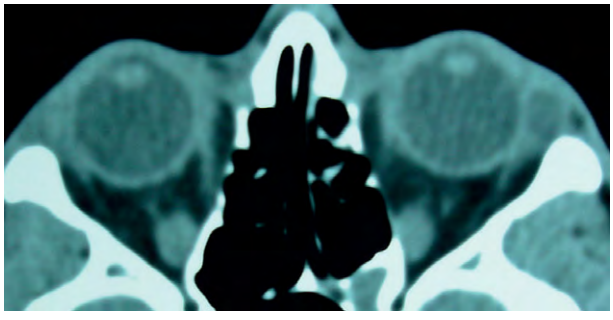

Figure 4 Axial computed tomography soft-tissue view demonstrating a cystic lesion (lacrimal ductal cyst) near the left anterior orbital rim.

Orbital teratoma is an uncommon tumor composed of tissues derived from more than one germ layer and usually from all three and, thus, is thought to arise from the pluripotential embryonic tissue. Aggressive excision or even exenteration may be required. It forms part of the differential diagnosis of a rapidly growing large orbital tumor in infancy along with lesions such as orbital hemangioma and rhabdomyosarcoma.

Inflammatory Diseases

Nonspecific Orbital Inflammations

This heterogeneous group of syndromes all have clinical hallmarks of inflammation, are generally acute or subacute in their onset, and are composed histologically of polymorphous inflammatory cell infiltrations. The location of inflammation often defines the clinical categories of these conditions. On imaging, they typically have an irregular margin adjacent to the primary focus of inflammation in addition to evidence of tissue swelling and enhancement with contrast media. An arbitrary but clinically useful subdivision of these conditions consists of five categories: myositic, lacrimal, anterior, apical, and diffuse. The rapid steroid responsiveness, especially as applied to pain, is almost pathognomonic of this group of conditions.

Myositic inflammation

Orbital myositis (**Figure 6**) is the most frequently encountered nonspecific inflammatory orbital syndrome. Clinically, it tends to have an isolated, recurrent, or atypical presentation. In the more common isolated or recurrent disease, typical presentation includes periorbital inflammation and swelling, retrobulbar pain, along with limitation and pain on eye movement. Visual acuity is often normal and focal conjunctival injection and proptosis may be clinically evident. Imaging reveals fusiform

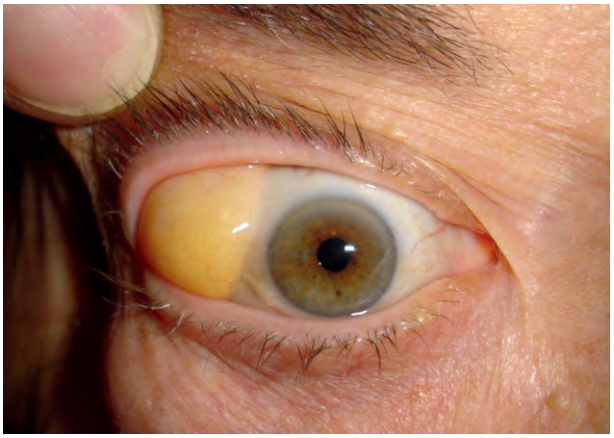

Figure 5 Rounded dermolipoma superotemporally in the right eye of a patient.

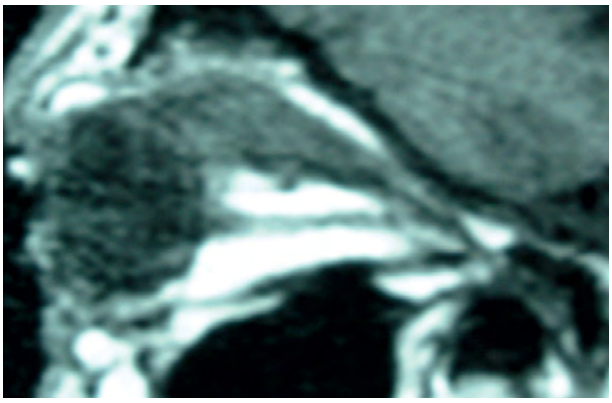

Figure 6 Sagital T2-weighted magnetic resonance imaging with gadolinium enhancement showing orbital myositis. Note the thickened superior rectus muscle and tendon.

enlargement of the whole muscle including the tendon, in contrast to thyroid orbitopathy. Typically, isolated cases tend to involve one muscle, whereas recurrent cases tend to involve multiple muscles and can be bilateral. In the atypical cases, pain may be absent without any limitation of ocular movement; however, abnormal or unusual imaging usually prompts the need for a diagnostic biopsy.

The predominant differential diagnosis for idiopathic myositis is Graves' orbitopathy. In contrast to idiopathic myositis, dysthyroid myopathy tends to be painless at onset, asymmetric, and slowly progressive with lid retraction and potential deterioration of visual function in addition to relative sparing of the tendon insertion of the muscle. The management for idiopathic myositis tends to range from simple nonsteroidal anti-inflammatory drugs in isolated unilateral cases, through to immunosuppressive agents and radiotherapy in bilateral, recurrent, or apex-involving cases.

Lacrimal inflammation

Dacryoadenitis describes inflammation of the lacrimal gland. The typical acute or subacute presentation consists of pain, tenderness, and injection of the temporal portion of the upper lid and conjunctival fornix giving an S-shaped deformity of the lid. The lacrimal gland itself is often palpable and tender, and pouting of the lacrimal ducts may be noted on biomicroscopy. Imaging shows irregular swelling of the lacrimal gland and adjacent tissues. Approximately 50% of nonspecific lacrimal gland inflammations may have an associated systemic disorder such as sarcoid, lymphoma, Wegener's granulomatosis, sclerosing inflammation, or any of a myriad of autoimmune disorders. This is more commonly identified in chronic presentations, and a biopsy is warranted in such situations.

Management for acute dacryoadenitis is to maintain a high index of suspicion for systemic disease and to promptly biopsy if justified. Oral corticosteroids in moderate tapering doses (starting with 40 mg prednisolone) will resolve the inflammatory episode within 1–3 months in the majority of nonspecific acute inflammatory cases.

Anterior and diffuse inflammation

In anterior orbital inflammation, the main focus involves the globe and adjacent orbit. Presenting features include moderate pain, ptosis, proptosis, and, in some cases, reduced vision. There may also be some ocular findings such as uveitis, papillitis, or exudative retinal detachments. This syndrome tends to present in children and young adults. Cases with diffuse disease not only have similar features, but also involve the extraocular muscles and neurosensory structures. On imaging, the infiltration is irregular and produces scleral and choroidal thickening. Ultrasonography may reveal prominence of the Tenon space with doubling of the optic nerve shadow (T sign). Treatment is generally with oral prednisone, usually starting at 60 mg and tapering over 2–3 months. This usually produces a dramatic response with a marked reduction in pain. Resolution can be monitored by repeat imaging. Recalcitrant cases, particularly in adults, should be considered for biopsy.

Apical inflammation

This condition presents with early pain on movement or diplopia in a disproportionate extent to the degree of inflammatory signs. Imaging displays the apical focus of inflammation. Apical disease should rarely be treated nonspecifically without a very careful follow-up, systemic evaluation, and consideration of biopsy, since a wide variety of diagnoses can present the same way.

Specific Inflammations of the Orbit

Infections – orbital cellulitis and sinusitis (microbial)

Clinically, orbital cellulitis is generally associated with axial displacement of the globe, whereas abscess formation within the orbit, particularly in the subperiosteal space, usually causes nonaxial displacement. Posterior subperiosteal tracking may lead to dramatic visual loss and neurosensory compromise due to apical compression. The increase in intraorbital tension may also lead to permanent visual loss. The most devastating complication is the spread to the cavernous sinus, leading to cavernous sinus thrombosis. Alternatively, the infection may spread into the intracranial cavity, leading to a subdural empyema or intracranial abscess. Current imaging technology allows for earlier recognition of orbital and periorbital involvement and is useful for evaluation of severity and guiding management. An abscess can be identified on imaging by a poorly defined mass with contrast enhancement of the rim.

The management and outcomes differ in adults and children. The majority of children do not need sinus or abscess drainage, whereas adults more frequently require this, particularly if there is orbital tension and threat to vision. The main principles of management consist of preventing ocular and nonocular complications, using appropriate antibiotics, surgical drainage when necessary (i.e., significant abscess with globe tenting, increased proptosis, deterioration of vision, or extraocular movements), and careful follow-up.

Fungal infections

Aspergillosis presents in the orbit in a disseminated form that causes microscopic angiitis or by the relatively slow development of a localized infiltrative mass usually originating from the adjacent sinus. It can occur in healthy people but is more common in predisposed individuals with recurrent sinusitis and polyps. Early diagnosis can be aided by the use of aspiration cytology. Once diagnosed, extensive debridement, local irrigation with antifungals, and systemic therapy are the hallmarks of management.

Tuberculosis and syphilis

Orbital tuberculoma is another manifestation of hematological spread and is associated with the development of an infiltrative orbital mass which may cause neurosensory deficits. Diagnosis may be aided by fine needle aspiration biopsy. Primary soft tissue gumma may occur with syphilitic orbital involvement which may also involve the extraocular muscles or lacrimal gland.

Parasitic infections

Hydatid cyst (Echinococcosis) is an infestation of the intestines of dogs, sheep, and other animals which may parasitize humans during its larval stage and spread around the body to form cystic spaces. Orbital cysts are seen infrequently. Onset is usually insidious and dominated by mass effect, but rupture of the cyst may be associated with a more acute fulminant inflammatory course and may be a complication of surgical incision or injury. Diagnosis is made by imaging of a cystic lesion within the orbit which may have evidence of calcification. Biological tests can substantiate these findings. Treatment is excision of an intact cyst either by a direct or lateral orbital route.

Vasculitis

Inflammatory diseases such as Wegner's granulomatosis may present by proptosis associated with a destructive orbital inflammatory mass. This is often bilateral and usually causes irreversible morbidity unless treated. An orbital biopsy can confirm the diagnosis prior to treating with aggressive immunosuppression.

Idiopathic sclerosing inflammation

The clinical features of this condition are dominated by a cicatricial infiltration associated with mass effect and mild inflammation. The characteristic imaging finding is a homogeneously enhancing mass with irregular margins. Prompt early biopsy and diagnosis followed by immunosuppression and immunomodulation are integral to the management of this condition.

Sarcoidosis

The clinical presentation usually consists of a mass effect, rarely associated with evidence of inflammation, with more than half of the patients presenting with lacrimal gland involvement. Other ocular findings may also be evident.

Other lesions

Less frequently encountered orbital inflammatory lesions such as orbital xanthogranulomas, consisting of chronic inflammatory infiltrate with lipid-laden histiocytes, predominantly respond initially to steroids. A reasonable degree of suspicion and suitable threshold for orbital biopsy must remain in the management of most orbital inflammatory lesions.

Vascular Lesions

Arteriovenous Malformations

High-flow arteriovenous malformations are characterized by antigrade arterial flow through the lesion to the venous side. Clinical features include pulsating exophthalmos and occasional episodes of hemorrhage or thrombosis. On imaging, these lesions are characterized by irregular, rapidly enhancing masses. For the most part, arteriovenous malformations are kept under observation; however, recurrent hemorrhaging or pain may require intervention.

Cavernous hemangiomas behave like low-flow arteriovenous malformations, although they are considered to be vascular hamartomas. Clinically, these lesions are benign noninfiltrating tumors that exert a slowly progressive mass effect. CT scans typically show a very well defined oval or rounded mass with distinct margins, which enhances with contrast. Intervention is unnecessary unless there is some functional or cosmetic concern.

Venous Malformations

Distensible venous malformations can be superficial, deep, combined, or complex lesions. The superficial malformations are seen as tortuous, epibulbar, or eyelid lesions, whereas the deeper ones are characterized by intermittent proptosis, evidence of enophthalmos due to fat atrophy, and pain on expansion brought about by physical effort or bending. Imaging features include

enlargement of the lesion on direct coronal CT, and expansion with Valsava maneuver during dynamic CT or MRI. Intervention is unnecessary unless there is pain, progressive expansion, or cosmetic concerns.

Nondistensible venous malformations are characterized by episodes of acute exacerbation and remission, due to hemorrhage or thrombosis within the lesion leading to sudden proptosis, echymosis, and pain. Indications for intervention include extreme orbital pressure and cosmetic disfigurement.

Lymphatic and Combined Venous Lymphatic Malformations (Lymphangioma)

These are no or low-flow vascular hamartomas that derive from the venous system embryologically and have differentiated, in part or whole, to lymphatic vessels. These lesions need to be separated hemodynamically from orbital varices. They can be superficial, deep, a combination of the above or complex if they involve the cheek, neck, face, and so on. The superficial are visible lesions of the conjunctiva or eyelid and consist of multiple clear cysts. If cosmetically unacceptable, they may be removed with relative ease. Deep lesions present with sudden proptosis due to spontaneous hemorrhage. In addition, they may have acute changes related to upper respiratory conditions. Imaging may demonstrate either a cyst with rim enhancement or a solid lesion with cystic components. Indications for intervention include acute orbital hemorrhage, cyst expansion, or significant cosmetic disfigurement.

Adult Lymphangiomas

These lesions are characterized by slowly evolving proptosis and the presence of a relatively homogenous intraconal mass, which is well defined anteriorly but poorly defined posteriorly, and may mimic cavernous hemangiomas clinically.

Capillary Hemangiomas

Capillary hemangiomas represent an abnormal growth of blood vessels with varying degrees of endothelial proliferation. They have a female predominance and usually present within the first months of life, starting as small, flat foci that undergo rapid expansion, followed typically by regression; this may take months to years. These lesions can be superficial, deep, combined, or complex. Superficial ones are the so-called strawberry nevi and are confined to the dermis. Steroid therapy or surgery may be needed if they bleed frequently or lead to obstruction of the visual axis. Deep lesions are characterized by proptosis or globe displacement. When palpable, they have a rubbery, soft consistency and may be collapsed to a degree with modest pressure. On imaging, the margins of these lesions vary from moderately well defined to infiltrating. The majority of these lesions regress spontaneously; however, larger lesions with considerable proptosis or visual axis obstruction may require treatment with systemic or local steroids and surgery.

Glossary

Anisotropic materials – These materials do not behave the same way in all directions. Muscle tissue, for example, has a different mechanical behavior in the fiber direction than in the directions perpendicular to the fiber direction.
Coulomb friction model – The frictional forces are determined by a coefficient of friction (either static or dynamic) and the normal forces that are exerted between the surfaces.
Continuum mechanics – It deals with the mechanical behavior of structures that can be modeled as a continuum. The microlevel behavior within a structure, for instance, cross-bridge dynamics within a muscle, is not modeled in detail but only the overall mechanical behavior is considered.
Friction – It is the force resisting the relative motion of two surfaces in contact. When the surfaces are moving, friction converts kinetic energy into thermal energy.
Inhomogeneous materials – These materials do not have the same composition throughout, and the mechanical properties depend on the location within the material. The orbital fat, for instance, is highly inhomogeneous as the connective tissue sheets orientation and density varies throughout the orbit.
Isotropic materials – These materials show the same mechanical behaviour in all directions.
Loss modulus – It is a measure for the energy that is dissipated in the material in deformation; this represents the viscous part of the energy needed for deformation.
Poisson's ratio – When a material is compressed in one direction, it will expand in the other two directions. A measure for this expansion is the Poisson's ratio. Incompressible media, like the orbital fat, have a Poisson's ratio close to the value of 0.5.
Storage modulus – It is a measure for the energy that is stored in the material in deformation; this represents the elastic part of the energy needed for deformation.
Stress – The intensity of the internal forces acting within a body across imaginary internal surfaces, as a reaction to external applied forces and body forces. Stress is a measure for the amount of force exerted per unit area.
Strain – The proportion of deformation to original size.
Viscoelastic behavior – The stress required for a certain deformation depends on the material properties. A viscoelastic material shows both elastic and viscous behavior. Elastic behavior entails that the energy that was used to deform the structure is returned when the structure is unloaded. Viscous behavior causes energy to be dissipated in the loading cycle and depends on the rate of deformation. Response (in terms of strain and stress) of a viscoelastic material to loading depends on the loading timescale and loading history. Hence, there is no direct relation between stress and strain.
A loading–unloading cycle of viscoelastic material will show a hysteresis loop in the stress–strain curve: more energy is required during the loading than returned during the unloading.
Young's modulus – The ratio of the stress to the strain, often also called the modulus of elasticity. Young's modulus is only meaningful in the range in which the stress is proportional to the strain.

Introduction

The human eye is suspended inside the orbit, a bony cavity in the skull. The orbit is filled with fat (adipose tissue) that supports the eye and eye muscles in different directions of gaze. Four rectus muscles control the horizontal and vertical position of the eye and two oblique muscles control the torsional position of the eye (**Figure 1**). The optic nerve, which transmits visual information from the retina to the brain, courses posteriorly from the eye to the apex of the orbit through the orbital fat.

A miraculous interaction between pressure and tensile forces in the soft tissues keeps the eye in place while a large range of rotational motion is enabled. For a correct

biomechanical representation of the three-dimensional shapes and volumes of the morphological structures, their material properties, and interactions, we can use continuum mechanics. The mechanical behavior is determined by (1) the geometrical shapes of the tissues, (2) their material properties, (3) their mechanical interactions, and (4) the mechanical load cases. In the following we discuss these four factors.

The first important factor is the geometry of the tissues. The three-dimensional shape of the muscle, for instance, influences the internal mechanics of the muscle fibers and also the resulting direction of pull of the muscles on the eye.

Second, orbital biomechanics depends on the material properties of the tissues. If external forces are applied to a material structure, it will undergo a deformation. The material properties of a structure determine the relation between stress and strain within the structure. Next, equilibrium equations determine the relation between stresses and external loads.

Sclera, for instance, shows less deformation under a certain stress than orbital fat. Most engineering materials, like steel, show a linear (i.e., proportional) relation between stress and strain, provided the deformations remain sufficiently small. The linear elastic material properties of isotropic materials are usually described by the Young's modulus and the Poisson's ratio.

Most biological soft tissues, however, show a more complex relation between stress and strain and usually do not have a linear relation. This is caused by rearrangements within the material that take place on a microscale; for instance, rearrangement of collagen fibers. In order to determine the exact material properties, experimental testing is needed. In addition to the nonlinear elasticity, the orbital tissues show viscoelastic behavior, and are anisotropic and inhomogeneous. The density of connective tissue sheets in the orbital fat, for instance, is much higher adjacent to the eye than directly behind the eye (inhomogeneity) and the sheets have a distinct direction which causes different mechanical behavior in that direction (anisotropy). This plays an important role, and cannot be disregarded when analyzing orbital biomechanics.

The third determinant of orbital biomechanics is mechanical contact interaction between tissues. The extraocular muscles, orbital fat, and the eye mechanically interact and exert forces on each other at every location where they contact. Clearly, contact has a large influence on the resulting strain and stress state, and the corresponding displacements found. The structures might also slide with respect to each other, in which the type and amount of friction becomes important as well. The medial rectus, for example, slides with respect to the medial orbital wall. In case of a trauma with an orbital fracture the muscle can get 'trapped' in the fracture. Sliding is not possible in this case, and eye movements are limited.

The final determinant of orbital biomechanics is the load case that is applied to the orbital structures. The most common load cases are muscle contractions, and blunt impact, tumor growth, or muscle expansion in Graves' disease can constitute application of a load to the orbital tissues as well.

In the following, we discuss the main factors (the geometries of the orbital structures, their material properties, their mechanical interactions, and load cases) that play a role in understanding soft tissue biomechanics and the suspension of the eye in the orbit.

Geometry of the Orbital Structures

The main structures that determine the biomechanical behavior in the orbit are the eye, the six extraocular muscles, the optic nerve, the orbital fat with its containing connective tissue sheets, and the bony orbit. Smaller structures, like blood vessels and nerves, have little influence on the overall mechanical behavior. Anteriorly, the eyelids exert a low pressure on the eye.

There is a large body of anatomical and histological literature that describes the anatomy of the orbit in detail. The currently available imaging techniques, like computed tomography (CT) and magnetic resonance imaging (MRI), enable a detailed view on the *in vivo* three-dimensional shapes of the geometries. In addition, the deformation of the structures can be visualized dynamically in different directions of gaze.

Material Properties

Eye Muscles

The oculomotor system has a diverse repertoire of actions, including steady fixation, slow vergence movements, pursuit movements at various speeds, and high-speed saccades over a wide range of angles. The functional requirements to the motor system are twofold. First, it must be able to keep the eye in a particular position of gaze and second, fast and directed movements must be possible. High eye velocities – velocities of over $600^\circ\,s^{-1}$ have been measured – impose specific requirements on the eye muscles.

The six extraocular muscles (EOMs) are structurally and functionally unique among the cross-striated muscles of vertebrates. For proper function, each muscle needs fatigue resistance, and force and velocity development. As these properties are not found in one fiber simultaneously, these conditions are met by deployment of different kinds of motor units. Most skeletal muscles have a mixed muscle-fiber-type composition, resulting in the functional properties of the muscle. The functional and structural requirements of the EOMs are reflected in complex muscle-fiber types described in mammalian EOMs. Their fibers have been classified into different types on the basis of their color, location, their enzyme- and immunohistochemistry, and their innervation. This system of classification differs markedly from that normally used to classify limb muscle fibers.

At optimum length (LO), that is, the length at which the muscle develops maximum force, the EOMs are the fastest among the cross-striated muscles. In animals, the contraction and the half-relaxation times are about 6 ms (range 4.5–7.0 ms). The maximum shortening velocity of the sarcomeres of EOMs is about $60\,\mu m\,s^{-1}$. This corresponds to an angular rotation velocity of the eye of about $850^\circ\,s^{-1}$ and is in the same order of magnitude as the fastest saccadic eye movements. Furthermore, the maximum shortening velocity appears to be virtually independent of the size of the animal, as has been observed in body and limb skeletal muscles.

The reasons for the uncommon combination of an exceptionally high shortening velocity and a high fatigue resistance are a high oxidative as well as a high glycolytic capacity in one and the same muscle fiber, in comparison with body skeletal muscles. The combination of a high shortening velocity and a high fatigue resistance in EOM is only possible with a relatively low force output. This is not so much of a problem, as inertia and rotational stiffness of the eye are relatively low. In general the EOMs produce a tension of about the half observed in skeletal muscles. These muscles EOMs have less contractile material per cross-sectional area; the fibers are thin and much room is taken by mitochondria, by capillaries needed for oxidative metabolism, and by a well-developed sarcotubular system. An additional reason for the relatively low force development is the presence of slow tonic fibres. EOMs also contain some multiply innervated slow-tonic muscle fibers. These are common in skeletal muscles of lower vertebrates, but rare in those of mammals.

In the classic way of looking at the action of EOMs, the mechanical behavior is regarded in terms of force–length and force–velocity relations. The force developed by a muscle during isometric contraction varies with the muscle's length and its contraction velocity (**Figure 2**). The passive, that is, without neural activation, length–tension relation shows an approximately exponential course. The length–tension relationship of stimulated muscles is approximately linear. The maximum tension development of single twitches is usually found at an extension of the muscle of approximately 1.15 times the rest length (range 1.1–1.2). This length, LO, is normally used as the working point to investigate the contractile properties of the muscles. Also the muscle tension developed in response to tetanic stimulation has maximum values at this extension.

Several lumped models have been developed to describe the mechanical behavior of muscles. Most of these models describe the developed force as a function of time, length, and activation, and the three-dimensional tissue behavior is disregarded. The future of modeling the mechanical eye muscle behavior lies in developing physically nonlinear continuum models. These models are being developed for limb muscles but this modeling approach has not yet been followed for EOMs. Such approaches allow, for instance, implementation of recruitment mechanisms or cross-bridge dynamics based upon Huxley-type models. These types of models have shown that muscles exhibit interesting mechanical behavior that has been neglected in the classic approach. Strain, for instance, is not uniform throughout the muscle: during muscle contraction it is possible that the muscle belly shortens while near the insertion the muscle is extended.

Orbital Fat

Orbital fat is an important entity within the orbital structures. In the human body, most fat is located beneath the skin and around internal organs. Around organs, it provides protective suspension and under the skin its main function is to provide thermal isolation and energy reserve. The main role of the orbital fat is to support the orbital structures but, at the same time, allow for eye rotations. It fills the orbital cavity, surrounding the eye and muscles and mechanically supports the globe and the nerves and vessels within the orbit.

Histological examinations have shown that the orbital fat is a loosely to strongly connected cellular material. The orbital fat consists of specialized connective tissue sheets that form small compartments that are filled with adipocytes, or fat cells (**Figure 3**). These cells contain a large lipid droplet surrounded by a ring of cytoplasm.

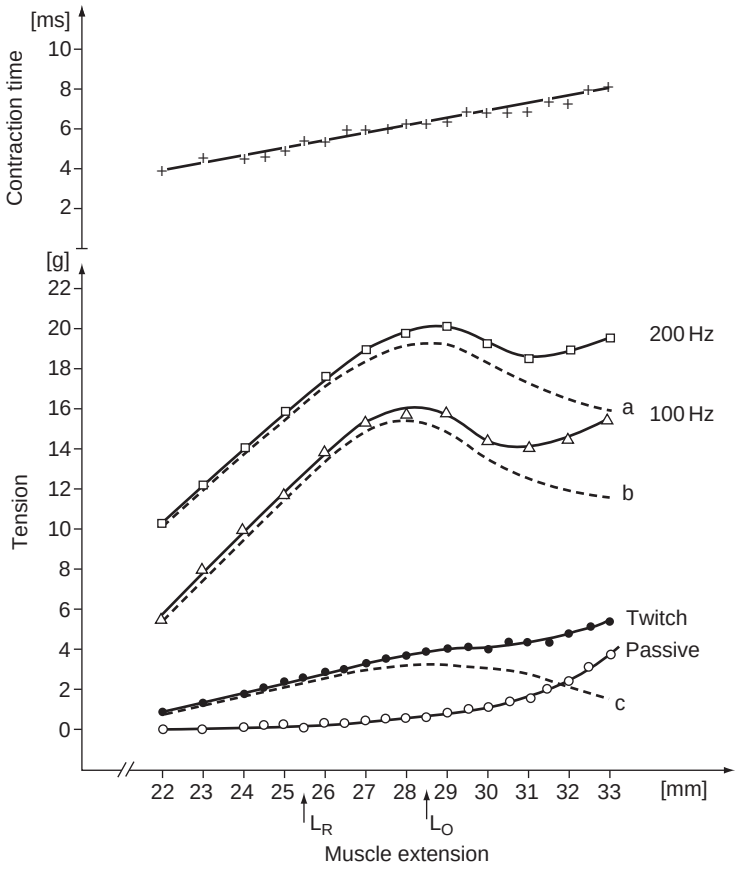

Figure 2 A force length diagram of a rabbit (♀; 4.2 kg body wt.) *in vitro* inferior oblique muscle at 35°C. Passive elongation (○–○) shows an exponential increase. The graph shows tetanic tension (●–●), tetanic tension at stimulation frequencies of 100 Hz (□–□) and 200 Hz (△ – △), and contraction time (+–+). The dashed lines illustrate the net tension of single twitches (c) and tetanic contractions (a, b). L_r – resting length of the muscle *in situ*; L_o optimum length. With permission from Springer.

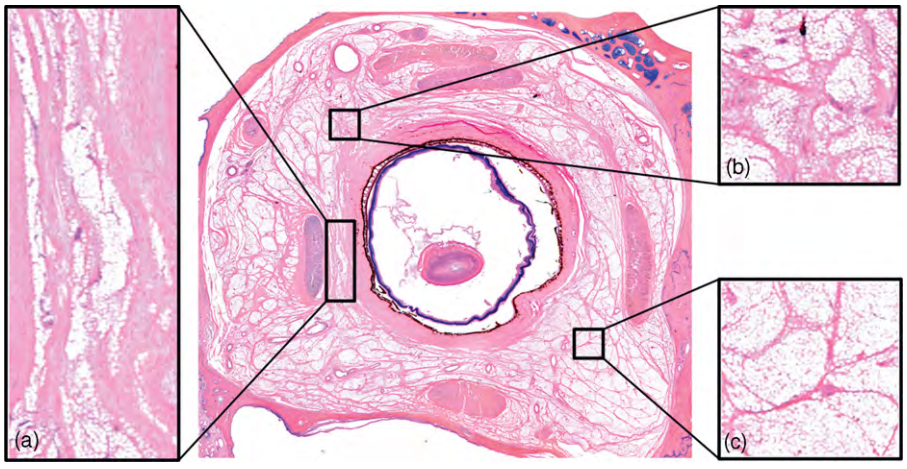

Figure 3 A frontal section of a human orbit (26-year-old person, 80 μm section, hematoxylin–eosin stain) by Koornneef (unpublished). The orbital fat consists of specialized connective tissue sheets that form small compartments that are filled with adipocytes, or fat cells. The orbital fat is a highly inhomogeneous structure, magnifications (b) and (c) show the varying size of the connective tissue compartments containing the fat. In addition, the orbital fat is highly anisotropic. Magnification (a) shows that connective tissue sheets between the medial rectus muscle and the eye, for instance, are oriented parallel to the muscle.

The orbital fat shows a highly anisotropic and inhomogeneous structure: the connective tissue compartments containing the fat vary in size, shape, and orientation. In the retrobulbar area, within the muscle cone, the compartments are large and have less fibrous sheets than anteriorly, in the area between the medial rectus muscle and the orbital wall, for instance. The structure of compartments containing the orbital fat seems to depend on the local mechanical requirements: behind the eye, where pressure is evenly distributed, they are large; adjacent to the eye, where the pressure gradient is steep, they are small. Connective tissue sheets between the medial rectus muscle and the eye, for instance, are oriented parallel to the muscle. This orientation allows the muscle to be quasi-rolled upon the eye when the eye abducts, while the orbital fat is squeezed out superiorly, inferiorly, and posteriorly.

Anterior in the orbit, the density of connective tissue sheets within the adipose tissue is higher and the sheets contain more collagen, elastin, and smooth muscle. The connective tissue sheets do not have a distinct geometry and show an amorphous structure.

The mechanical behavior of a viscoelastic material-like orbital fat can be described by its storage modulus (G') and loss modulus (G''). The storage and loss modulus can be determined in an experiment under oscillatory conditions, for instance, with a rheometer. Such a device applies a strain to the tissue in an oscillatory fashion at various frequencies and records the generated torque. From these recordings the moduli of the tissue can be estimated. In this type of experiment the anisotropy and inhomogenity of the tissues are neglected even though the orbital fat is highly anisotropic and inhomogeneous. The mechanical behavior of calf and monkey orbital fat has been measured (**Figure 4**). The elastic shear modulus (G') and viscous shear modulus (G'') of the orbital fat are low, and G'' is low compared to the G'. G' and G'' were found to be between 250 and 500 Pa for calves, and between 500 and 900 Pa for monkeys. The viscous shear modulus for calf orbital fat was found to be between 80 and 150 Pa, and for monkey orbital fat it was between 300 and 500 Pa.

As the viscous shear modulus is low, little energy is lost during eye movements. In kidney fat, G' and G'' are higher, possibly because this fat primarily has a dampening function. The viscous shear modulus remains approximately the same with increasing angular velocity during sinusoidal deformation. This means that relatively less energy is lost at higher velocities. In polymer mechanics, this phenomenon is called shear thinning.

Sclera

The human sclera performs several important functions for the visual and mechanical performance of the eye. It provides protection to the intraocular contents and its opacity ensures that internal light scattering does not affect the retinal image. The sclera is build up mainly out of collagen fibers with diameters ranging from 20 to 250 nm, entangled in bundles that vary in size.

The thickness of the sclera varies from approx. 1–1.3 mm at the posterior pole to 0.4–0.6 mm behind the insertions of the rectus muscles. From the insertion of extraocular muscles toward the limbus (the edge between the cornea and the sclera), the thickness gradually increases to 0.8 mm, where it blends with the cornea. The conjunctiva, a mucous membrane, attaches to the sclera at the limbus and covers the sclera.

The shape of the eye is maintained by the intraocular pressure that acts against the membrane stiffness of the scleral tissue. The pressure within the eye is approx 18 mmHg or 2.4 kPa. Due to the relatively high stiffness of sclera (2.60 ± 2.13 MPa; measured at 0.6 cm min^{-1}), the mechanical integrity of the eye is damaged after relatively small volume changes, for instance, after a perforation.

Optic Nerve

The optic nerve is contained within the optic nerve sheath that includes cerebrospinal fluid at intracranial pressure. The outermost sheath of the optic nerve resembles the epineurium of peripheral nerves and consists mainly of connective tissue that is the same as the meningeal ensheathments around the brain and spinal cord, dura, and arachnoid. In healthy subjects, the pressure inside the optic nerve sheath is higher than the pressure within the orbital fat. This causes the optic nerve sheath to behave like a protective tube around the optic nerve.

Contact Behavior at the Interface between Structures

An important determinant of the mechanics in the orbit is the contact behavior between the different structures. During eye rotations, the soft tissues in the orbit undergo displacements and deformations. At the interface layers between the tissues, sliding may occur, or the structures may be tautly connected. If tautly connected, the structures are able to transfer forces and moments in every direction. If structures are sliding, the transferred force is primarily in the direction perpendicular to the interface layer. In the direction of the interface layer, the transferred force depends on the type of friction that occurs. The type and amount of friction has to be found empirically. Friction can be described with a friction model. The most commonly used friction model is the model of Coulomb, in which the friction is described by a friction coefficient. However, a large number of friction models exist to describe the behavior of different types of friction

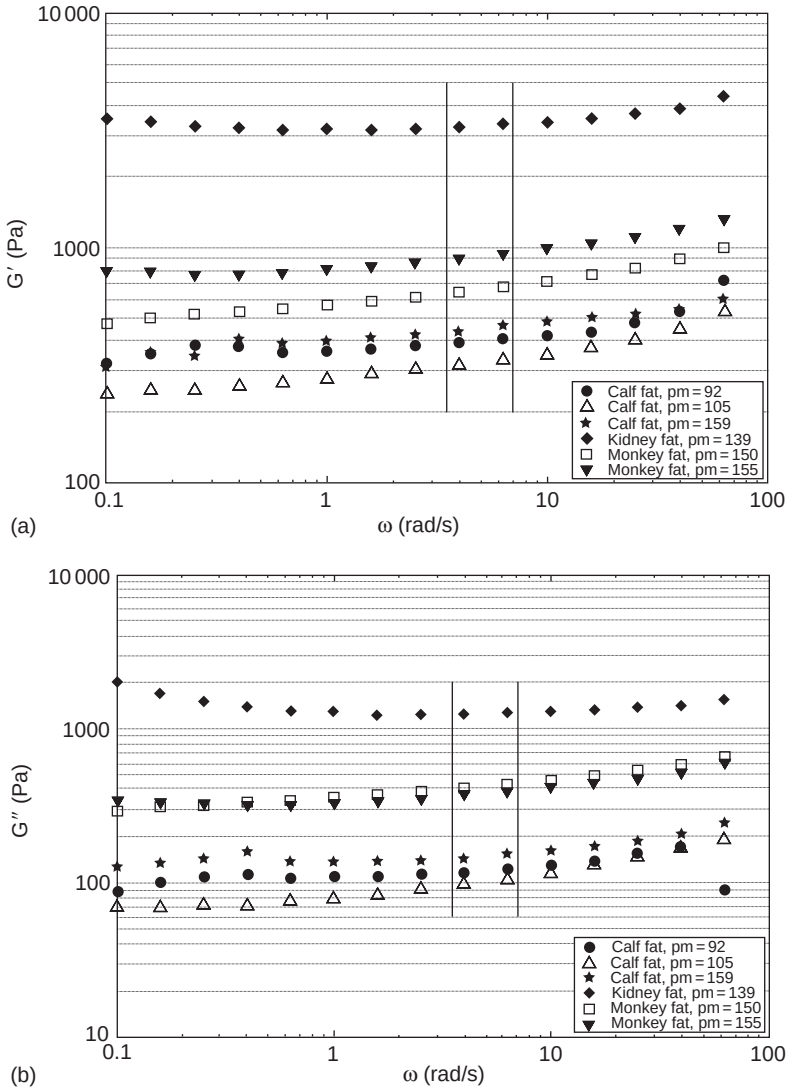

Figure 4 (a) Storage modulus (G′) and (b) loss modulus of the orbital fat of calves and rhesus monkey. Horizontal axis: angular velocity (ω) in rad s^{-1}. Vertical axis: storage modulus (a) and loss modulus (b) expressed in Pa. In order to illustrate the rate of deformation that occurs during eye movements, two vertical bars indicate approximate deformation that occurs during 100 and 200° s^{-1} saccades. Elasticity, viscosity, and deformation of orbital fat. *Investigative Ophthalmology and Visual Science* 47(11): 4819–4826. With permission from the Association for Research in Vision and Ophthalmology.

with different parameters. Frictional forces have a large influence on the resulting strain and stress state in the structures and their corresponding displacements. The nature of the lubricating fluid and the types of articular surfaces are important determinants for the friction. Little is known about the types of friction in the orbit. Sliding in synovial joints of the human body is usually facilitated by a synovial-fluid-like substance that is composed mainly of glycosaminoglycans and glycoproteins, which are long unbranched polysaccharides. These molecules are very large and can contain a large amount of water which makes them excellent lubricators.

Connected Structures

At a number of locations in the orbit, the mechanical interactions between the structures are clear. At the insertions of the six EOMs, the tendons are tautly connected to the sclera. Muscular fibers that connect directly to the sclera without a tendon have been described. At their origins, the proximal tendons of the EOMs are tautly connected to the tendinous annulus (of Zinn) in the apex. The origins of the EOMs are attached to the periorbit by interlocking of the tendinous and muscular fibers. The tendon of the superior oblique muscle courses from

its insertion through the trochlea to the apex of the orbit. The trochlea is a fibro-cartilage pulley that is attached to the medial wall of the orbit. A synovial membrane lines the inner surface of the trochlea. Possibly, synovial fluid lubricates the sliding interface between the trochlea and the superior oblique tendon. At the posterior pole of the eye, the optic nerve sheath is merged into the sclera. At its proximal end the optic nerve sheath is encompassed by the EOM origins at the tendinous annulus.

Sliding at the Interface between Structures

The human eye is able to rotate at high angular velocities and has an angular range of 100 degrees horizontally and 90 degrees vertically. It is able to do all of this with almost no translation of its center. It seems evident that the orbital fat plays an important role in keeping the eye in place during eye movements. The fat acts a supportive cushion for the eye and at the same time supports the optic nerve and other nerves, vessels, and the EOMs.

The large range of motion is partly facilitated by sliding at the interface between the sclera and Tenon's capsule, the connective tissue that surrounds the globe and the extraocular muscles. The interface is lubricated, and the eye is able to rotate within Tenon's capsule because of its spherical shape. On the other hand, free rotation of the eye within Tenon's capsule is impeded because the optic nerve leaves the eye posteriorly and crosses the potential subtenon's space. Further, the insertions of the eye muscles rotate with the eye and exert force on the orbital fat. These two effects and others cause the orbital fat to deform and to move, in part, with the eye rotation. The orbital fat directly behind the eye follows approximately half of the eye rotation. The remainder is accounted for by sliding of the eye in Tenon's capsule. Posterior in the orbit, the deformation resulting from eye rotations is less.

Contracting muscles move with respect to their surrounding tissues and sliding occurs between parts of the EOMs and the orbital fat. As the muscles are surrounded by connective tissues, just like the blood vessels and nerves, the mechanism of sliding comes down to sliding between connective tissue fascias. The EOMs slide with respect to the orbital wall. When sliding is hampered, for instance, in case of an orbital fracture when a muscle is trapped in the fracture, eye motility is limited.

MRI studies have demonstrated that the optic nerve slides with respect to the orbital fat. The amount of friction that exists between these structures has not been measured, but is likely to be low.

Connective Tissue Connections

The eye is covered by Tenon's capsule, a thin fibrous membrane that starts at the limbus and covers the eye to the optic nerve. To attach at their insertions, the EOMs course through portals in this capsule.

The inferior tarsal ligament (Lockwood's) is a connective tissue that connects the inferior side of the inferior rectus muscle and the inferior oblique. Posteriorly, this connects to the lacrimal crest. Anteriorly, this attaches to the capsulopalpebral fascia, lower eyelid retractors, and Tenon's capsule. Medially and laterally, it connects into the canthal tendons and orbital walls.

The superior tarsal ligament (Whitnall's) is a condensation of connective tissue sheets overlying the anterior superior part of the levator palpebrae that extends laterally and medially to the orbital walls.

At the level of the posterior pole of the eye, connective tissue bands (often referred to as pulley bands, or pulley slings) are connected to the rectus muscles and course anteriorly to the orbital wall. The function of these bands is heavily disputed. A function in stabilizing the muscle paths is claimed.

Other Interface Layers

The human orbit exhibits more interface layers that influence the overall mechanical behavior, for instance, between the rectus muscles and the orbital walls, between the superior oblique muscle tendon and the superior rectus, between the inferior oblique muscle and the inferior rectus muscle, the muscle tendons and the eye, and between the optic nerve sheath and the orbital fat. The frictional properties of these interactions are largely unknown.

Load Cases: Muscle Contraction, Orbital Disease, Blunt Impact, etc.

The most common load cases in the human orbit are muscle contractions. Neural activation of the EOMs results in force development in the muscles. The muscle forces act against inertia of the structures, stiffness and damping of the antagonistic muscle and of the orbital fat, and against friction in the contact layers. As a result of the muscle contraction, the eye starts to move. If the muscle activation remains constant, a new equilibrium position of the eye will be reached.

In primary gaze, the four rectus muscles have a base tension that causes pressure within the orbital fat. Such a pressure is contained by the connective tissue sheets. Directly behind the eye the pressure is at its highest, gradually diminishing in the anterior direction.

In Graves' disease the EOMs and orbital fat expand. As the bony orbit is stiff with respect to its contents and because the orbital fat is nearly incompressible, pressure in the orbit increases. As a result, the eye is pushed forward and pressure on the optic nerve rises. A similar

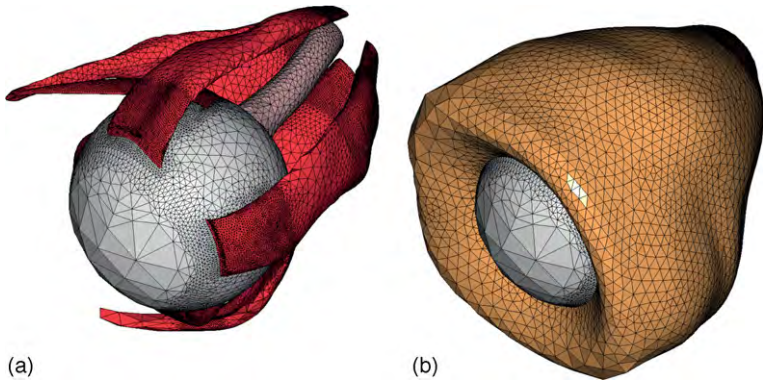

Figure 5 (a) The 3D mesh of the Delft finite-element model of orbital biomechanics. The geometry of the eye, the optic nerve, and the six extraocular muscles have been subdivided into a large number of tetrahedra. The orbital fat (b) encompasses the orbital structures.

process can occur when any other volume-increasing process takes place, like an orbital tumor.

After blunt impact on the orbit, for instance, a tennis ball on the eye, the pressure inside the orbit can rise to the extent that the mechanical load on the bony orbit exceeds its strength. A fracture can occur at the weakest spot, usually the orbital floor. In case of an orbital floor fracture, the inferior rectus muscle can get trapped in the fracture. This limits down gaze as the force developed by the inferior rectus muscle is transferred to the bony orbit. In upgaze, rotation of the eye is limited by the trapped muscle and the force developed by the superior rectus muscle pulls the eye back into the orbit.

Computational Modeling

In order to obtain better insight in orbital biomechanics, mechanical simulations can be employed to evaluate the effect of load cases. A simulation model can provide insight into the internal stress and strain distributions of tissues and contact forces, which cannot be derived from imaging data alone. A computational simulation method that is suited to numerically simulate the complex three-dimensional geometries, and anisotropic and inhomogeneous material properties, tissue interactions and load cases, is the finite-element analysis (FEA) method.

Several open source and commercially available software programs exist to develop FEA models. For an FEA model of orbital biomechanics, firstly the geometries, for example, eye, optic nerve, and EOMs, must be obtained from MRI. Subsequently, the geometries are segmented and mathematically described to be read into the FEA program. The complex geometries should then be subdivided into a number of simple elements, like tetrahedra (**Figure 5**) or hexagons. Each of the elements has to be assigned its material properties in accordance with the material properties of the actual structure, measured *in vivo* or post mortem. At the interface layers, for example, between the EOMs and the orbital fat, the optic nerve and the orbital fat, and the eye and the orbital fat, sliding should be simulated with a contact algorithm. Finally, load cases are applied to the model. After application of a load case, for instance, a base tension in the four rectus muscles, the resulting deformations and stresses in the tissue can be evaluated (**Figure 6**). An FEA model needs extensive validation, for instance, by comparing the deformations of the constituting tissues recorded with MRI (**Figure 7**) to the deformations predicted by the FEA model.

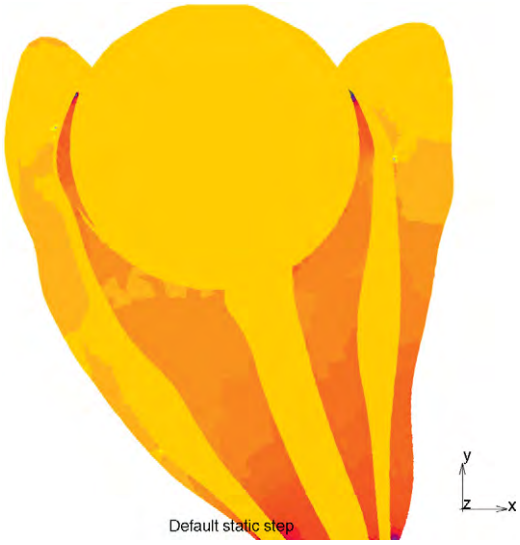

Figure 6 A transverse view on the results of a finite-element simulation at the level of the optic nerve. This simulation shows the pressure gradients in the orbital fat as a result of base tension in the rectus muscles. The yellow represents the globe, optic nerve, and extraocular muscles. The red represents the pressure gradients, with the darkest color representing the highest pressure. The orbital fat was modeled as an incompressible homogenous, isotropic material. The gradient is highest between the horizontal rectus muscles, which partly explains the outward curvature of the muscles. X represents medial and Y anterior.

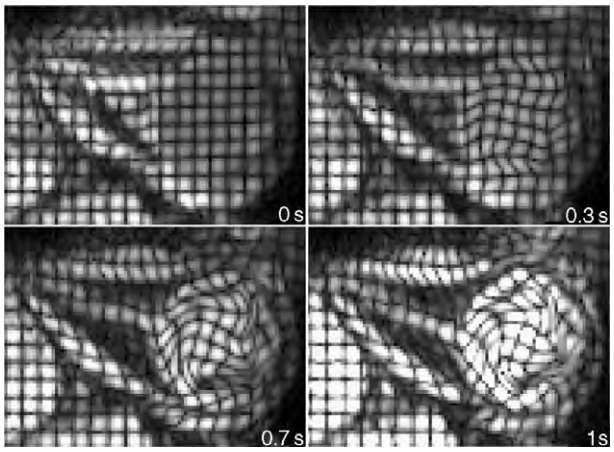

Figure 7 The tissue deformations in the orbit as a result of muscle contractions and relaxations are complex and nonuniform. The MRI sequence CSPAMM (Complementary SPAtial Modulation of Magnetization) can be used to study these deformations. Before the images are acquired, the magnetization of the tissue is periodically modulated in two perpendicular directions, so-called tissue tagging. The figure shows four CSPAMM MR images of the same transverse slice during eye movement. The magnetization is modulated to create a grid bind with the tissue (see time 0 s). The deformation of this grid (during time) depicts the differential movements within homogeneous tissues, such as in the extraocular muscles. Adapted from Piccirelli et al. (2007). Extraocular muscle deformation assessed by motion-encoded MRI during eye movement in healthy subjects. *Journal of Vision.* 7(14): 5.1–10. With permission from ARVO.

The coming years are likely to see improvement of the FEA models of the orbit and, thereby, our understanding of orbital biomechanics. *In vivo* or post mortem measurements of the mechanical behavior at contact layers and measurements of the inhomogeneity and anisotropy of the materials will allow improved modeling of orbital soft tissue biomechanics.

Orbital Vascular Anatomy

A E Semmer, L K McLoon, and M S Lee, University of Minnesota, Minneapolis, MN, USA

Glossary

Anastamosis – The collateral communication between blood vessels. They enlarge to facilitate compensatory blood flow when one of the vessels is obstructed.
Fistula – An abnormal communication between an artery and vein.

A thorough knowledge of the vascular anatomy in the orbit and periorbital tissues is critical for understanding alterations due to disease as well as avoiding these vessels during surgery in and around the orbit. The complexity and interindividual variability of the vessel anatomy is quite significant, and thus understanding the possible differences between orbits is particularly important for ensuring maximum preservation of blood supply and limiting bleeding within the orbit during surgical procedures.

The first major branch of the internal carotid, the ophthalmic artery, is the source of most of the orbital blood supply, with minor contributions from the external carotid circulation. Branching patterns of the ophthalmic artery may vary widely, but common patterns have been identified. Its distal branches form important anastomoses with the external carotid circulation that can sustain orbital blood flow in pathologic conditions involving the internal carotid artery (ICA). The orbital venous system is even more variable than the orbital arteries. Unlike the vasculature in most areas of the human body, the orbital arteries and veins do not run in parallel. Generally, the superior and inferior ophthalmic veins drain orbital blood into the cavernous sinus posteriorly. The orbital veins are valveless, so alternative drainage can occur through veins that connect to the facial veins anteriorly and the pterygoid venous system inferiorly.

Arterial Blood Supply

The ophthalmic artery provides the major blood supply to the orbit. It is the first major branch of the ICA. Branches of the ophthalmic artery anastomose with distal branches of the external carotid artery (ECA), creating important connections between the internal and external carotid circulations (**Figure 1**). The orbital arterial supply will be described first from the internal carotid contributions followed by the external carotid contributions. The most common anatomical configurations will be emphasized with discussions of common variants.

Internal Carotid Artery

At the upper limit of the thyroid cartilage, the common carotid artery bifurcates into the ICA and ECAs. The ICA ascends the neck without branching and enters the skull base through the carotid canal, an opening in the petrous portion of the temporal bone. The ICA runs anteromedially through the carotid canal, continuing through the foramen lacerum to emerge in the posterior cavernous sinus. The ICA winds through the cavernous sinus forming an elongated S shape referred to as the carotid siphon. From its entrance into the posterior cavernous sinus, the ICA travels slightly superiorly and then anteriorly before turning abruptly superiorly and piercing the dural roof of the cavernous sinus, just medial to the anterior clinoid process of the sphenoid bone. The carotid siphon then curves posteriorly, and then anterosuperiorly to reach the inferolateral optic nerve. Within the cavernous sinus, the ICA consistently gives off a meningohypophyseal trunk, which supplies the intracavernous oculomotor, trochlear, and abducens nerves, as well as portions of the pituitary gland. The artery of the inferior cavernous sinus and the capsular arteries are more variable intracavernous ICA branches.

The first major intradural branch of the ICA is the ophthalmic artery, which arises just distal to the carotid siphon. In 10% of cases, the ophthalmic artery actually arises from the ICA within the cavernous sinus external to the dura. Rarely, the external carotid circulation contributes to the ophthalmic artery's origin. The most common variant origin arises from the middle meningeal artery (MMA) either as a single trunk or from two separate ICA and MMA trunks. Isolated descriptions also exist of ophthalmic arteries arising from the middle cerebral artery, the anterior cerebral artery, the posterior communicating artery, and the basilar artery.

Usually, the ophthalmic artery arises from the anterior wall of the ICA inferior to the optic nerve. It then runs anterolaterally inferior to the optic nerve to enter the optic canal, running with the optic nerve. Multiple small arteries arise from the ICA near the origin of the ophthalmic artery. These arteries supply the pituitary infundibulum, the intracranial portion of the optic nerve, and the

Red indicates anastamoses with the facial artery, green indicates anastamoses with the maxillary artery, and blue arrows designate anastamoses with the superficial temporal artery. Based on Hayreh, S. S. (1963). Arteries of the orbit in the human being. *British Journal of Surgery* 50: 938–953.

optic chiasm. Distal to the ophthalmic artery, the ICA gives off the posterior communicating and anterior choroidal arteries to form the anterior circle of Willis. The terminal branches of the ICA are the anterior and middle cerebral arteries that supply blood to the brain parenchyma.

Ophthalmic Artery

The ophthalmic artery provides the major blood supply to the orbit. It is the first major branch of the ICA. Distal branches of the ICA form important anastamotic connections with the external carotid circulation that can provide collateral blood flow to the orbit. Branches of the ophthalmic artery are extremely variable, but common patterns have been identified. The ophthalmic artery will be described in three parts: (1) intracranial, (2) intracanalicular, and (3) intraorbital. The most common branching patterns will be discussed here along with common variants.

Intracranial

The intracranial segment of the ophthalmic artery describes the length of the vessel from its branch point off the internal carotid until it enters the optic canal. This portion of the ophthalmic artery is usually subdural (85%) and intimately associated with the ICA and the inferior aspect of the optic nerve. These structures are often linked by fibrous connective tissue. The average length of the intracranial ophthalmic artery is 2.6 mm, but can be as long as 7 mm. Typically, there are no branches off this arterial segment.

Intracanalicular

The intracanalicular ophthalmic artery runs in the optic canal, inferior to the optic nerve until it emerges in the orbit. The artery gradually pierces the dura surrounding the intraorbital optic nerve to enter the subdural space. Thus, within the optic canal, the artery becomes physically separated from the optic nerve by a dural barrier. The intracanalicular ophthalmic artery sends small branches to the intracanalicular optic nerve through fibrous bands connecting the dura to the optic nerve. Traumatic injury to the optic canal can tear these fibrous bands, interrupting the blood supply to the optic nerve and causes ischemic damage. Rarely, the ophthalmic artery enters the orbit through a separate bony canal.

Intraorbital

The extreme variability of the ophthalmic artery and its branches becomes evident in its intraorbital course. Hayreh has done the most comprehensive anatomical

descriptions of the ophthalmic artery. While their systematic dissections never revealed any identical intraorbital branching patterns of the ophthalmic arteries, they identified common patterns associated with whether the intraorbital ophthalmic artery crosses superior or inferior to the optic nerve.

The intraorbital ophthalmic artery can be divided into three segments (**Figure 2**). The first part begins at the orbital apex and is attached by loose connective tissue and fat to the inferior aspect of the optic nerve as it courses anteriorly along the inferolateral margin. The artery then crosses to the medial orbit. The point at which the artery turns medially to cross superior (83%) or inferior (17%) to the optic nerve is called the angle and marks the division between the first and second intraorbital ophthalmic artery segments. The second segment of the ophthalmic artery is defined as the length of artery that crosses the optic nerve from lateral to medial. It is only loosely connected to the dural nerve sheath. The vertical position of this arterial segment with respect to the optic nerve determines which arterial branching pattern will commonly be seen. The division between the second and third parts of the ophthalmic artery is called "the bend." This is a well-defined point on the superiomedial aspect of the optic nerve, where the ophthalmic artery turns to head anteromedially through the orbit. Distal to "the bend," the ophthalmic artery loses its intimate association with the optic nerve and is anchored to the medial orbital wall by the ethmoidal vessels. This arterial segment is quite tortuous, allowing the ophthalmic artery to withstand ocular movement without compromising blood supply. It heads medially and passes anterosuperiorly between the

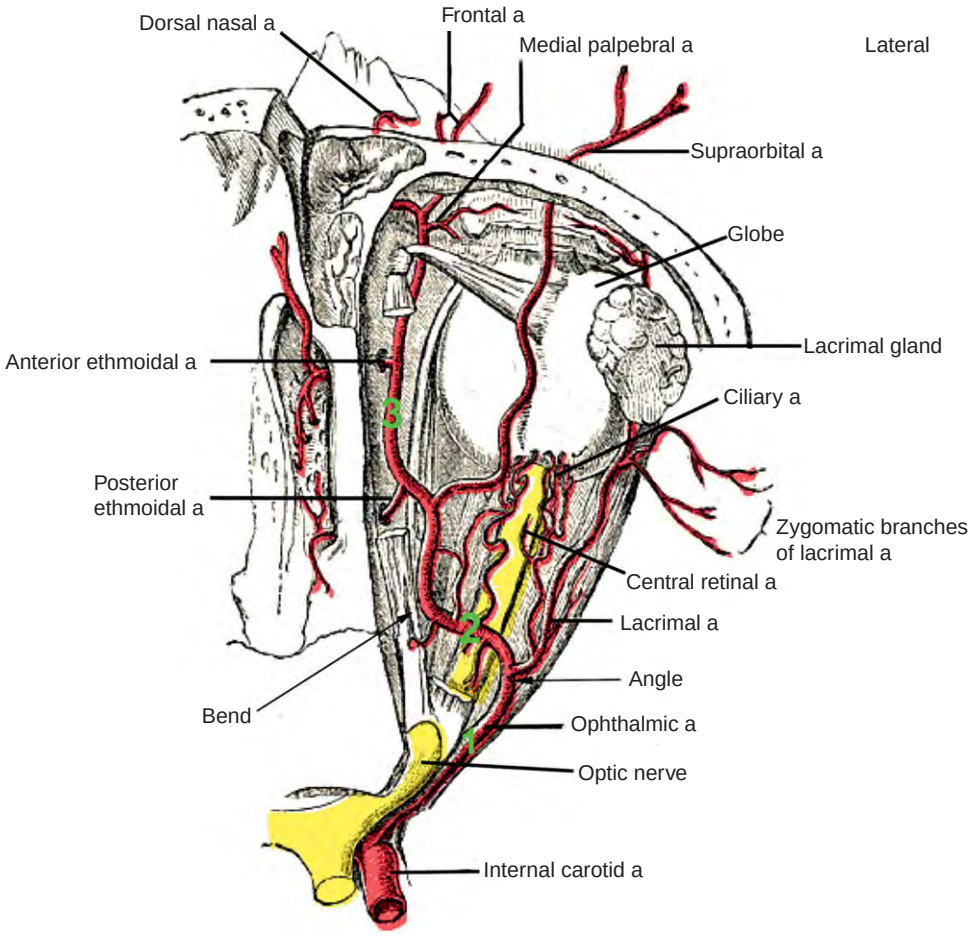

Figure 2 The intraorbital ophthalmic artery and its branches. The branching patterns of the ophthalmic artery are highly variable, but common patterns have been identified. This Figure illustrates the general course of the ophthalmic artery as is crosses over the optic nerve and courses through the medial orbit. The angle and the bend are important landmarks that separate the intraorbital ophthalmic artery into three sections. The first segment (1) runs from the orbital apex to the angle and is intimately associated with the optic nerve. The second segment (2) runs between the angle and the bend. It crosses medially either superior or inferior to the optic nerve. The spatial orientation of the second segment of the intraorbital ophthalmic artery dictates which common branching pattern may be expected in an individual orbit. The third segment runs from the bend along the medial orbital wall until the terminal arterial branches emerge from the orbit. This segment of the ophthalmic artery is the most tortuous. Adapted from Gray's Anatomy, 20th edition, copyright expired.

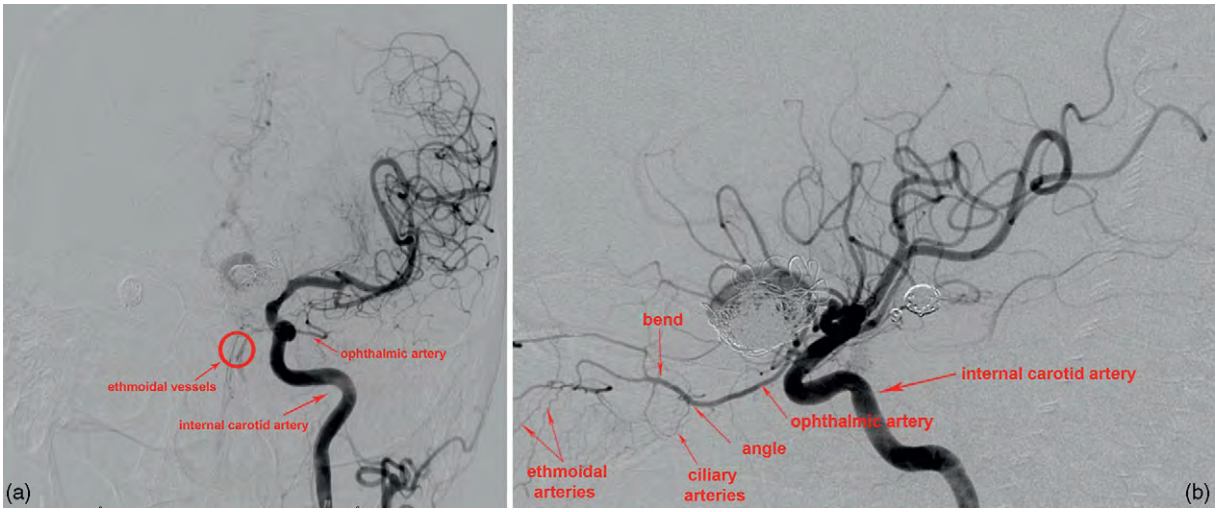

Figure 3 Angiograms depicting the orbital arterial vasculature. (a) Anterior–posterior view of the left internal carotid artery (ICA) shows the left ophthalmic artery coursing anterolaterally after its origin from the supraclinoid segment of the ICA. This ophthalmic artery has prominent ethmoidal branches (circle) coursing along the nasal septum. (b) Lateral projection of left ICA injection, early arterial phase showing most of the intraorbital course of the ophthalmic artery including the proximal, main trunk of the ophthalmic artery, the angle, the bend, and the anterior and posterior ethmoidal vessels. medial rectus and superior oblique muscles. It runs inferior to the trochlea before its terminal branches emerge from the superiomedial orbital angle, midway between the medial palpebral ligament and the superior orbital margin (Figure 3).

Branching patterns of the intraorbital ophthalmic artery are extremely variable. In Hayreh's systematic study of 59 human orbits, no identical ophthalmic artery branching patterns were seen. The main pattern distinction depends on whether the second segment of the ophthalmic artery crosses superior or inferior to the optic nerve and can be traced to varying patterns in fetal arterial development. As the ophthalmic artery develops, a vascular ring forms around the optic nerve. Typically, the larger dorsal portion of the vascular ring persists, while the ventral portion regresses, resulting in the ophthalmic artery crossing superior to the optic nerve 83% of the time. When the dorsal segment of the fetal vascular ring regresses, the ophthalmic artery crosses inferior to the optic nerve.

While the variability of the intraorbital branching pattern of the ophthalmic artery cannot be overemphasized, the most common branching patterns based on order of origin are outlined in Table 1. The following descriptions of the intraorbital ophthalmic arterial branches are organized topographically by the ocular, orbital, and extraorbital blood supplies.

Table 1 Common branching patterns of the ophthalmic artery

	Crossing pattern of ophthalmic artery	
Order of origin	*Superior to the optic nerve (83%)*	*Inferior to the optic nerve (17%)*
1	Central retinal	Lateral posterior ciliary
2	Lateral posterior ciliary	Central retinal
3	Lacrimal	Medial muscular
4	Muscular to superior rectus and/or levator	Medial posterior ciliary
5	Posterior ethmoid	Lacrimal
6	Supraorbital	Muscular to superior rectus and/or levator
7	Medial posterior ciliary	Posterior ethmoid
8	Medial muscular	Supraorbital
9	Muscular to superior oblique and medial rectus	Muscular to superior oblique and medial rectus
10	Anterior ethmoid	Anterior ethmoid
11	Medial palpebral	Medial palpebral
Terminal	Dorsal nasal	Dorsal nasal
Terminal	Supratrochlear	Supratrochlear

Based on Hayreh, S. S. (1962). The ophthalmic artery. III. Branches. *British Journal of Ophthalmology* 46: 212–247.

Ocular Branches

The ocular branches include the central retinal artery, the anterior ciliary arteries, the lateral and medial posterior ciliary arteries, and small collateral branches to the optic nerve. The central retinal artery is typically the first branch of the ophthalmic artery. It runs along the inferior aspect of the optic nerve before piercing the optic nerve sheath 5–15 mm posterior to the globe. Once the artery has entered the neural sheath, it makes its way to the

center of the optic nerve substance, supplying blood to the surrounding nerve as it courses toward the optic nerve head where its terminal branches divide to supply the inner retina. The central retinal artery is the sole blood supply to the inner two-thirds of the retina. The terminal branches of the central retinal artery are end arteries, meaning that a proximal occlusion will completely cut off blood supply to that portion of the retina. More distal occlusions can lead to segmental retinal ischemia.

The number of posterior ciliary arteries is variable. They typically arise as two to three trunks that divide into multiple short ciliary arteries and a medial and lateral long posterior ciliary artery that extend from the ophthalmic artery to the posterior globe. Up to five posterior ciliary artery branches have been described. The short ciliary arteries pierce the sclera near the optic nerve and directly supply the choroidal vessels that nourish the outer one-third of the retina. They form the anastamotic circle of Zinn and Haller, adjacent to the optic nerve that feeds the optic disc. In approximately 15% of the population, the short posterior ciliary arteries give off one or more cilioretinal arteries to supply the inner two-thirds of the macula in addition to the central retinal artery. When present, the cilioretinal artery can provide collateral circulation to the macula in a central retinal artery occlusion. The medial and lateral long posterior ciliary arteries run toward either side of the globe along the horizontal meridian, passing between the choroid and the sclera to anastamose with the anterior ciliary arteries. It supplies the ciliary muscle, iris, and part of the choroid.

Orbital Branches

The orbital branches of the ophthalmic artery include the lacrimal artery, extraocular muscular arteries, and small branches that supply the orbital periosteum and areolar tissue. The lacrimal artery typically branches from the second part of the ophthalmic artery between "the angle" and "the bend." It runs along the lateral orbital wall above the superior border of the lateral rectus muscle with the lacrimal nerve to supply the lacrimal gland. The lacrimal artery gives off the recurrent meningeal, zygomatic, and lateral palpebral arteries. The recurrent meningeal artery exits the orbit through the superior orbital fissure and anastamoses with branches of the MMA, connecting the internal and external carotid circulations. The lateral palpebral arteries supply the lateral eyelids and conjunctiva.

Multiple muscular arteries arise from the ophthalmic artery branches to supply the extraocular muscles. The lateral and medial muscular branches are the most prominent, and provide the major extraocular muscle blood supply. The lateral muscular artery typically arises from the second segment of the ophthalmic artery and supplies the lateral rectus, superior rectus, superior oblique, and levator palpebrae superioris. The medial muscular branch typically arises from the third segment of the ophthalmic artery medial to the optic nerve to supply the medial and inferior rectus, and the inferior oblique. After running the length of the muscle, the muscular branch in each rectus muscle gives off two anterior ciliary arteries, except for the lateral rectus that typically contributes only one, which run in the rectus tendons before piercing the sclera near the limbus to anastamose with the posterior ciliary arteries to supply anterior segment structures and choroid. Interruption of anterior ciliary blood flow can lead to a rare, but well-defined complication of strabismus surgery: anterior segment ischemia. This has typically been reported when three to four rectus muscles are removed during strabismus surgery, but has been reported in cases involving fewer muscles in patients with underlying predispositions to orbital ischemia. Anterior segment ischemia is more common in vertical muscle surgery, most likely because collateral flow from the long posterior ciliary arteries along the equator of the globe can compensate for lateral and medial anterior ciliary blood flow.

Extraorbital Branches

The extraorbital branches include the anterior and posterior ethmoidal arteries, the supraorbital artery, the medial palpebral artery, and the terminal ophthalmic artery branches: the dorsal nasal and supratrochlear arteries. The posterior and anterior ethmoidal arteries typically arise from the third segment of the ophthalmic artery and course through the medial orbit before passing through the posterior and anterior ethmoidal canals, respectively, into the ethmoid air cells. The presence of the posterior ethmoidal artery is variable. Hayreh reported absence of the posterior ethmoidal artery in 15% of specimens where the ophthalmic artery crosses under the optic nerve, and 19% of ophthalmic arteries that cross over the optic nerve. In the majority of cases, however, the posterior ethmoidal artery runs between the superior oblique muscle and the levator muscles. It enters the posterior ethmoidal canal with the posterior ethmoidal nerve to supply blood to the posterior ethmoid air cells, the meninges of the anterior cranial fossa, and the upper nasal mucosa.

The anterior ethmoidal artery is larger and more consistent than its posterior counterpart. It runs between the superior oblique and medial rectus and passes through the anterior ethmoidal canal with the anterior ethmoidal nerve to supply the anterior and middle ethmoidal air cells, the frontal sinus, and the anterior cranial fossa dura. Nasal branches supply skin on the lateral wall of the nose.

The supraorbital artery typically arises off the second portion of the ophthalmic artery. It joins the supraorbital nerve as is courses anterosuperiorly through the medial orbit. The supraorbital artery emerges on the face through the supraorbital notch or foramen to supply the levator

muscle aponeurosis anteriorly, upper eyelid, scalp, and forehead muscles.

Two medial palpebral arteries arise either directly from each ophthalmic artery or from a common trunk to supply the upper and low eyelids. They enter the eyelids superior and inferior to the medial palpebral ligaments and anastamose with the lateral palpebral arteries that branch off the lacrimal artery.

The dorsal nasal and supratrochlear arteries are the terminal branches of the ophthalmic artery. The dorsal nasal artery pierces the orbital septum above the medial canthal tendon to anastomose with the angular and nasal branches of the facial artery, connecting the external and internal carotid circulations. It supplies the scalp and forehead near the midline, and occasionally the lacrimal sac. The supratrochlear artery is typically the larger terminal branch of the ophthalmic artery. It pierces the orbital septum superior to the trochlea with the supratrochlear nerve and ascends the superior orbital margin to supply the skin, muscles, and scalp near the midline.

External Carotid Artery

The ECA provides minor vascular tributaries that form important anastamotic connections between the internal and external carotid circulations (**Figure 1**). In pathologic or anomalous anatomic conditions in which the internal carotid blood flow is slowly compromised, these anastomoses can enlarge to maintain orbital perfusion.

The common carotid artery bifurcates into the ICA and ECA at the upper border of the thyroid cartilage. As the ECA ascends the neck, it first curves slightly anteriorly, and then posteriorly as it courses toward the neck of the mandible, where it divides into its terminal branches: the superficial temporal and maxillary arteries. The major ECA branches are the superior thyroid, ascending pharyngeal, lingual, facial, occipital, posterior auricular, superficial temporal, and maxillary arteries. The facial, superficial temporal, and maxillary arteries supply orbital structures. Only these ECA branches are discussed further.

The facial artery supplies blood to oral, pharyngeal, and mid-lower facial structures. It is a very tortuous vessel, which allows it to withstand movement during speaking and chewing. The facial artery branches off the ECA near the angle of the mandible. It dives deep to the posterior belly of the digastric and stylohyoid muscles and enters a groove on the posterior aspect of the submandibular gland. The facial artery then emerges on the face, crosses superiorly over the body of the mandible to the angle of the mouth, and ascends lateral to the nose to terminate as the angular artery in the medial canthal region. The angular artery has an anastamotic connection with the dorsal nasal artery, a terminal branch of the ophthalmic artery off the ICA to connect the internal and external carotid circulations.

The superficial temporal artery is one of the two terminal ECA branches. It arises from the ECA within the substance of the parotid gland posterior to the neck of the mandible and ascends the scalp, anterior to the ear. Within the parotid gland, the superficial temporal artery gives off the transverse facial artery, which supplies the parotid gland and duct and the masseter muscle. The superficial temporal artery then ascends to cross above the posterior zygomatic process where it gives off two branches: (1) the middle temporal artery that supplies the temporalis muscle and (2) the zygomatic artery that supplies the orbicularis oculi muscle before anastomosing with the lacrimal and palpebral branches of the ophthalmic artery. Within 2–5 cm of crossing the zygomatic process, 90% of superficial temporal arteries split into a frontal and parietal branch. Anomalous patterns exist in approximately 10% of the population, with the most common variant being an additional frontal branch. Other variations include an additional parietal branch, a more proximal branch point off the superficial temporal artery, or no branching at all. The frontal branch supplies the facial muscles, skin, and pericranium of the anterior scalp and anastomoses with the supraorbital artery. The posterior branch anastomoses with the posterior auricular and occipital arteries to supply the posterior scalp.

The maxillary (internal maxillary) artery is the larger terminal ECA branch that supplies the deep structures of the face and sends intracranial branches to the dura and trigeminal ganglion. The artery can be split into three sections: (1) mandibular, (2) pterygoid, and (3) pterygopalatine. The mandibular portion of the maxillary artery runs anteriorly between the mandibular ramus and the sphenomandibular ligament insertion. It gives off the anterior tympanic, deep auricular, and middle meningeal arteries (MMA).

The MMA provides the largest dural blood supply. It ascends between the external pterygoid muscle and the sphenomandibular ligament and passes through the foramen spinosum in the sphenoid bone to enter the cranium. Blunt head trauma can result in MMA rupture leading to an epidural hematoma. Orbital branches of the MMA pass through the superior orbital fissure to anastomose with the lacrimal artery and/or other ophthalmic artery tributaries. Occasionally, the ophthalmic artery originates from one of these orbital MMA branches. Additional anastomoses between the internal and external carotid circulations may exist between small branches off the MMA that anastomose with the meningohypophyseal trunk within the cavernous sinus.

The pterygoid portion of the maxillary artery does not typically contribute blood supply to the orbit. It ascends the external surface of the medial pterygoid muscle medial to the ramus of the mandible, making its way

anteriorly, and entering the pterygoid fossa. It gives off branches to the pterygoid, masseter, and buccinator muscles as well as deep branches to the temporalis muscle and pericranium.

The pterygopalatine portion of the maxillary artery lies in the pterygopalatine fossa. It gives off six major branches: (1) the posterior superior alveolar artery, (2) the infraorbital artery, (3) the descending palatine artery, (4) the artery of the pterygoid canal, (5) a pharyngeal branch, and (6) the sphenopalatine artery. The infraorbital artery runs along the infraorbital groove and canal with the infraorbital nerve, where it gives off branches to the inferior oblique and inferior rectus muscles and anastomoses with the lacrimal and the third segment of the ophthalmic artery. This artery emerges on the face through the infraorbital foramen and ascends toward the medial canthal region to anastomose with the angular branch of the facial artery and the dorsal nasal artery off the internal carotid.

Venous Drainage

The orbital veins are extremely complex and variable. The exact number and configuration of the orbital veins are controversial because of their high variability. Unlike venous systems throughout the rest of the body, the orbital veins do not parallel the orbital arteries. One exception is the superior ophthalmic vein, which has a similar course to the ophthalmic artery. The superior and inferior ophthalmic veins represent the principal drainage systems of the orbit (**Figure 4**). Variably present orbital veins include the middle and medial ophthalmic veins and various collaterals that interconnect the superior and inferior orbital venous systems. Primary drainage is to the cavernous sinus; however, various interconnections also exist with the facial veins and the pterygoid plexus. The orbital veins are valveless, allowing pressure-dependent drainage through these alternative routes.

The superior ophthalmic vein is the largest and most consistently present orbital vein. Its diameter ranges from 2 mm to 1 cm. The superior ophthalmic vein is formed by the confluence of the supraorbital and angular veins near the superomedial orbital rim. The supraorbital vein enters the orbit and runs along the orbital roof superior to the trochlea. The angular vein pierces the orbicularis oculi muscle and enters the orbit through an opening in the orbital septum to join the supraorbital vein, just posterior to the trochlea in the anteromedial orbit. Various superior ophthalmic vein roots have been described, including a singular root formed by the convergence of the supraorbital and angular veins anterior to the trochlea.

The course of the superior ophthalmic vein is relatively constant compared to the rest of the orbital veins. In general, it follows the ophthalmic artery through the orbit. From the superomedial orbital angle, the superior ophthalmic vein enters the orbital cone near the medial border of the superior rectus muscle. It runs within the intraconal adipose tissue, crossing inferior to the superior rectus at the muscle's lateral border. The superior ophthalmic vein then runs posteriorly along the lateral aspect of the superior rectus before exiting the orbit through the superior

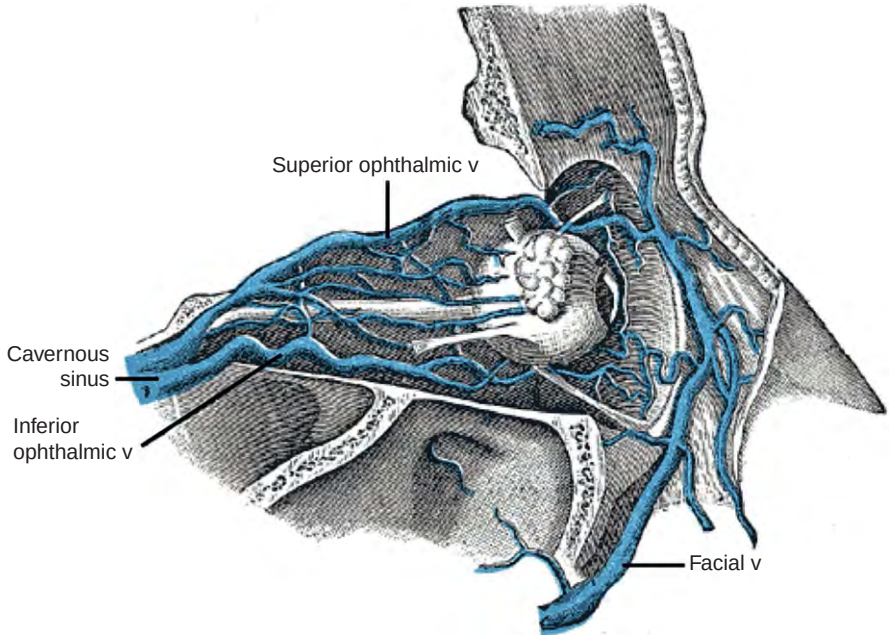

Figure 4 The orbital venous system. The orbital veins are highly variable; however, the superior and inferior ophthalmic veins are relatively constant. The inferior ophthalmic vein frequently empties into the superior ophthalmic vein prior to exiting the orbit through the superior orbital fissure to enter the cavernous sinus. Adapted from Gray's Anatomy, 20th edition, copyright expired.

orbital fissure and emptying into the cavernous sinus. The medial palpebral, superior vortex, anterior ethmoidal, lacrimal, central retinal, muscular, and inferior ophthalmic veins, typically, all drain into the superior ophthalmic. The muscular veins are often the most variable orbital veins; however, the veins from the superior rectus and superior oblique muscles consistently drain into the superior ophthalmic vein (**Figure 5**).

While there is some debate regarding the course and existence of the inferior orbital vein, most investigators agree that the venous drainage of the inferior orbit begins as a diffuse venous plexus on the orbital floor that receives venous blood from the inferior eyelid, lacrimal sac, inferior extraocular muscles, and the inferior vortex veins. When present, the inferior orbital vein typically arises from the posterior inferior venous plexus in the mid-orbit and runs posteriorly between the inferior rectus muscle and the optic nerve. In the posterior orbit, the inferior orbital vein commonly runs along the lateral border of the inferior rectus, before heading superiorly to join the superior ophthalmic vein, prior to its exiting the orbit through the superior orbital fissure into the cavernous sinus. The inferior orbital vein can also enter directly into the cavernous sinus without converging with the superior ophthalmic vein.

Inconstant orbital veins include the middle and medial ophthalmic veins. The middle ophthalmic vein drains the inferior orbit and runs between the superior and inferior ophthalmic veins in the posterior orbit before emptying into the superior ophthalmic vein. The medial ophthalmic vein arises from the angular vein or anterior superior ophthalmic vein. When present, the medial ophthalmic vein runs along the medial orbital wall and empties either into the superior ophthalmic vein or directly into the cavernous sinus. Cheung and McNab found that the medial ophthalmic vein consistently empties into the superior ophthalmic vein. The medial ophthalmic vein has been reported to connect the medial collateral, ethmoidal, and medial muscular veins to the superior ophthalmic vein through a venous loop.

Multiple, variable collateral veins typically connect the superior and inferior venous systems. Cheung and McNab described only medial and lateral collateral veins. Henry described anterior, medial, lateral, and posterior collateral veins that were also found identified by Brismar to be present in 91%, 97%, 72%, and 19% of individuals, respectively, based on orbital phlebography. A collateral branch that drains to the pterygoid plexus is another common variant.

The central retinal vein drains blood from the retina and intraorbital optic nerve. It runs with the central retinal artery within the substance of the optic nerve. It exits the optic nerve sheath 8–15 mm posterior to the globe and typically passes directly through the superior orbital fissure into the cavernous sinus. It can also join the superior or inferior ophthalmic veins within the orbit. Hayreh found that the central retinal vein runs within the surrounding dura after exiting the optic nerve. An optic nerve sheath meningioma involving the dura containing the central retinal vein gradually occludes it, which may cause development of the characteristic retinociliary collateral veins that are indicative of optic nerve sheath meningiomas.

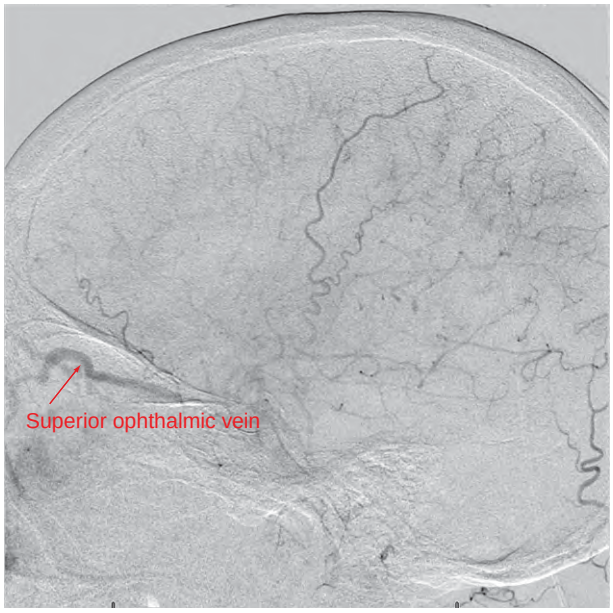

Figure 5 Angiogram depicting the superior ophthalmic vein. Lateral view of the early venous phase of the right internal carotid injection reveals a prominent superior ophthalmic vein providing collateral venous drainage into the cavernous sinus in a patient with a left temporal lob hemorrhage. The superior ophthalmic vein is typically only seen on angiography in pathological conditions. Images courtesy of Dr. Ramachandra Tummala, Department of Neurosurgery, University of Minnesota.

Cavernous Sinus

The cavernous sinuses are paired venous plexuses situated just lateral to the sella turcica on the superior aspect of the sphenoid bone. They receive the majority of orbital venous blood. Each cavernous sinus extends from the superior orbital fissure anteriorly to the apex of the petrous portion of the temporal bone posteriorly. Each cavernous sinus is approximately 3 cm long, 1 cm wide, and 0.5 cm high. Superiorly, the cavernous sinus is bordered by the anterior and posterior clinoid processes. The floor of the cavernous sinus contains the foramen lacerum, foramen ovale, and foramen rotundum.

The cavernous sinus receives venous blood from the orbit and drains posteriorly through the superior and inferior petrosal sinuses. It is the primary drainage reservoir for the orbital veins; however, the absence of valves in

the cavernous sinus and the orbital veins allows for alternative pressure-dependent drainage through the facial veins or pterygoid plexus. This is a potential path for facial infections to spread into the cavernous sinus and throughout the dura. Venous drainage into the cavernous sinus varies depending on the highly variable orbital venous configurations. The superior ophthalmic vein consistently drains through the superior orbital fissure. The inferior ophthalmic vein and the inconstant orbital veins variably drain into the superior ophthalmic vein, or directly into the cavernous sinus.

Contents of the Cavernous Sinus

The ICA runs through the medial cavernous sinus surrounded by a web of sympathetic fibers. The abducens nerve runs through the lateral cavernous sinus. Within the lateral wall of the sinus, from superior to inferior, lies the oculomotor nerve (CN III), trochlear nerve (CN IV), and the ophthalmic (CN V1) and maxillary (CN V2) divisions of the trigeminal nerve (Figure 6).

Clinical Correlate: Orbital Vascular Pathology

Arterial and Venous Occlusions

While the anastomoses between the internal and external carotid circulations can often compensate for a gradual compromise in orbital blood flow, acute interruptions in ocular blood flow can have clinically significant visual consequences.

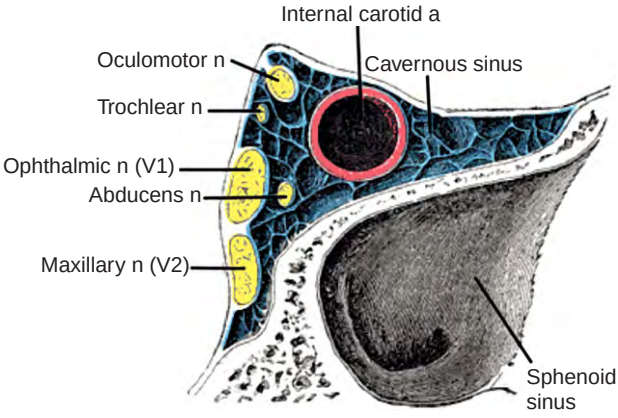

Figure 6 Contents of the cavernous sinus. The cavernous sinus is a venous network that serves as the primary drainage for orbital venous blood. The internal carotid artery, the oculomotor nerve, the trochlear nerve, abducens nerve, and the ophthalmic and maxillary divisions of the trigeminal nerve all run through the cavernous sinus. Adapted from Gray's Anatomy, 20th edition, copyright expired.

Transient monocular vision loss, or amaurosis fugax, results when blood flow in the central retinal artery, ophthalmic artery, or ciliary arteries is compromised. Common etiologies include embolic occlusion, vasospasm, and giant cell arteritis (GCA). Atherosclerotic disease proximal to the affected artery can cause an ocular transient ischemic attack (TIA) when cholesterol emboli released from an atherosclerotic lesion transiently occlude an ophthalmic vessel, or when a severely stenotic proximal vessel results in hypoperfusion. Cardiac emboli from atrial fibrillation, valvular heart disease, or atrial myxoma can cause the same obstructions but typically results in permanent occlusion.

Embolic occlusion of the central retinal artery (CRAO) or one of its branches (BRAO) typically resolves over time, but even transient ischemic retinal injury may result in permanent visual loss in the affected retinal areas. CRAO may result in peripheral field loss with spared central visual acuity if the cilioretinal arteries are spared. Granulomatous inflammation can also cause CRAO and BRAO. Furthermore, vasculitis of the short posterior ciliary arteries can result in arteritic anterior ischemic optic neuropathy (AION).

Occlusion of the central retinal vein (CRVO) or its branches (BRVO) causes loss of vision when venous congestion inhibits retinal capillary blood flow. Patients typically present with acute blurry vision and segmentally distributed intraretinal hemorrhages on examination. CRVO is associated with glaucoma, hypertension, diabetes mellitus, and cardiovascular disease. The strong association with atherosclerotic disease can be explained by the common sheath shared by the central retinal artery and vein, allowing easy compression the central retinal vein.

Cavernous Carotid Artery Aneurysm

ICA aneurysms within the cavernous sinus may present with visual complaints due to compression of the cranial nerves III, IV, and/or VI. Aneurysms can become quite large (>2 cm) before symptoms begin. If the aneurysm extends through the roof of the cavernous sinus into the subarachnoid space, there is a risk of subarachnoid hemorrhage. Aneurysmal involvement of the ophthalmic artery is also possible, putting the orbital circulation at risk. Treatment of these aneurysms involves coiling or ICA ligation to cause thrombosis within the aneurysm.

Carotid–Cavernous Sinus Fistula

A direct connection between the ICAs within the cavernous sinus can lead to the formation of a fistula between the ICA and venous cavernous sinus (Figure 7). Carotid–cavernous

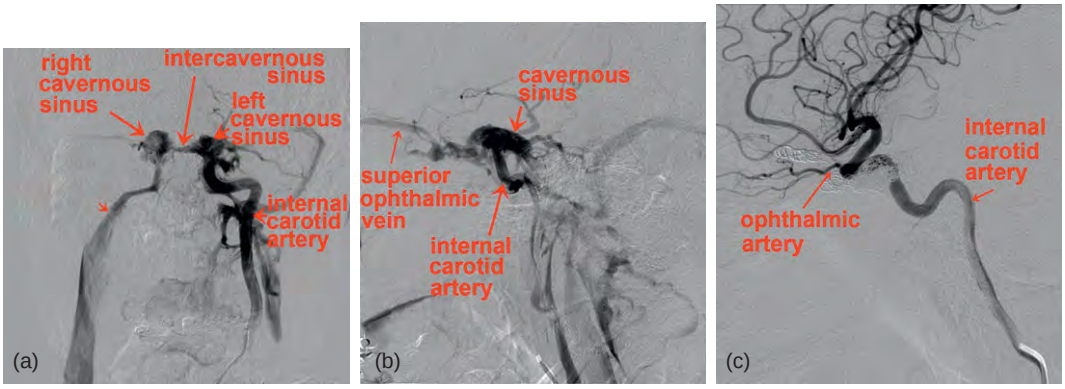

Figure 7 Angiograms depicting a carotid–cavernous sinus fistula (CCF) before and after treatment. (a) Anterior–posterior view of a left internal carotid artery (ICA) injection demonstrating a direct connection, or fistula, between the left cavernous sinus and the left internal carotid artery. The injection also shows filling of the intercavernous and right cavernous sinuses. (b) Lateral view of the CCF after ICA injection demonstrates collateral drainage of the cavernous sinus through the superior ophthalmic vein. (c) Following coil embolization repair of the CCF, ICA injection shows normal arterial filling of the internal carotid arterial vasculature, including the ophthalmic artery. Images courtesy of Dr. Ramachandra Tummala, Department of Neurosurgery, University of Minnesota.

Figure 8 Carotid–cavernous sinus fistula (CCF). These photos depict many of the common clinical features of a CCF, including chemosis, eyelid edema, proptosis, ophthalmoplegia, and arterialization of the conjunctival vessels. (a) The patient is unable to fully depress the left eye. Note that the upper eyelids are manually retracted by the clinician. (b) The patient is staring straight ahead.

Figure 9 Arterialization of the conjunctival veins. This close-up photograph demonstrates how a carotid–cavernous sinus fistula can lead to orbital venous congestion that arterializes the conjunctival veins in the right orbit of this patient. The veins seen here are injected and tortuous, indicating high blood flow and pressure in the orbital venous system.

sinus fistulas (CCFs) can be traumatic or spontaneous, rapid or insidious. The fistula between arterial and venous blood disrupts the orbital pressure gradient and causes a reversal of venous blood flow through the orbital veins. Signs and symptoms of a CCF include chemosis, eyelid edema, central retinal venous congestion, proptosis, arterialization of the conjunctival vessels (Figures 8 and 9), diplopia secondary to oculomotor, trochlear, or abducens nerve palsy, and an audible orbital bruit (the sound of turbulent blood flow heard by the patient or by a clinician with a stethoscope). Approximately 50% of CCFs with low-velocity blood flow will close spontaneously and may not require any intervention. In the presence of a neuro-ophthalmologic deficit or posterior venous drainage, coils can be placed in the cavernous sinus to occlude the fistula (Figure 7).

Cavernous Sinus Thrombosis

Infectious cavernous sinus thrombosis results from the progression of facial infections through the facial vein or pterygoid plexus to the cavernous sinus through the superior ophthalmic vein. Sinus and dental infections can also extend into the cavernous sinus. Signs and symptoms include fever, orbital congestion, lacrimation, conjunctival edema, swelling, proptosis, and ophthalmoparesis from compression of the abducens, oculomotor, or trochlear nerves. Progression of thrombosis to the rest of the cerebral venous sinuses can result in increased intracranial pressure and stroke. Treatment includes antibiotics, anticoagulation,

systemic steroids, and possibly surgery. Noninfectious cavernous sinus thrombosis can result from hypercoagulable states, including polycythemia, sickle cell crisis, and paroxymal nocturnal hemoglobinuria. However, the overwhelming majority of these are infectious.

Orbital Surgical Surface Anatomy

Dacryocystorhinostomy

Abnormal tearing, or epiphora, occurs when the nasolacrimal duct is obstructed and tears cannot drain normally from the lacrimal sac to the inferior meatus inferior to the inferior nasal turbinate. Obstruction can be congenital or acquired through recurrent dacrocystitis or cannaliculitis, dacrolithiasis, trauma, malignancy, or underlying nasal pathology. Surgical repair with dacryocystorhinostomy (DCR) creates a new direct connection between the lacrimal sac and the nasal mucosa for drainage. DCR approach can be external or endoscopic. Both techniques must take care to avoid the angular artery, which lies beneath the obicularis oculi muscle, 6–8 mm medial of the inner canthus and 5 mm anterior of the lacrimal sac.

Temporal Artery Biopsy

Giant cell arteritis (GCA) is a systemic vasculitis that can lead to rapid, irreversible blindness if left untreated. Classic symptoms include headache, scalp tenderness, and jaw claudication. Definitive diagnosis requires temporal artery biopsy. The superficial temporal artery is easily accessible for biopsy as it lies just under the skin while ascending the temporal region and anterior scalp. In cases where the ipsilateral ICA is occluded, collateral flow through the ECA occurs. Resection of the temporal artery in such cases may result in a stroke. Prior to biopsy, the vessel is compressed by hand and the patient is observed for focal neurologic deficits. A positive biopsy reveals lymphocyte, macrophage, and giant cell infiltration of the arterial wall. A negative biopsy does not rule out the possibility of disease.

Overview of Electrolyte and Fluid Transport Across the Conjunctiva

O A Candia and L J Alvarez, Mount Sinai School of Medicine, New York, NY, USA

Glossary

Short-circuit current – The short-circuit current (I_{sc}) across tissues isolated within an Ussing chamber is defined as the charge flow per time, per the cross-sectional area of the epithelium that is exposed to the bathing solutions, when the tissue is short-circuited by clamping the transepithelial voltage (PD_t) to zero with an external circuit. The I_{sc} is a current that circulates through the tissue and the external circuit thereby completing a closed loop. Because of this, the I_{sc} enters the tissue across one surface and leaves across the other. Monitoring the I_{sc} provides a continuous measure of the net charged flow of current across the transcellular pathways of the tissue. There is no net flow across the paracellular pathways in the short-circuited condition if the tissue is bathed bilaterally with solutions containing identical ionic concentrations. Adding drugs that affect the ionic channels or electrogenic elements within the membranes of the epithelium will affect the magnitude of the I_{sc}.

Transepithelial resistance – An epithelium can be considered to be comprised of an arrangement of resistance elements or resistors. This arrangement is most simply modeled in a multilayered epithelium as two resistors in series, namely R_a (the resistance of the apical membrane) and R_b (the resistance of the basolateral membrane). These resistances are shunted by a parallel resistor, R_{shunt}, which is the cumulative resistance of the paracellular pathways. As such, transepithelial resistance (R_t) is defined as follows:

$$R_t = \frac{(R_a + R_b) \times R_{shunt}}{R_a + R_b + R_{shunt}}$$

In the conjunctiva, R_{shunt} tends to be lower than the transcellular pathway. This leads to small measured changes in R_t when drugs that selectively affect either R_a or R_b are added. For example, potassium channel blockers should selectively increase R_b, but the effect on the measured R_t parameter is relatively smaller in the conjunctiva than in the corneal epithelium, which is a tight epithelium, that is, a tissue with a high R_{shunt}.

Transepithelial voltage – Epithelial cells transport ions and thereby generate a transepithelial voltage (PD_t). The generation of PD_t requires (i) an asymmetric distribution of ion channels and electrogenic transporters on the apical and basolateral sides of the tissue, and (ii) the presence of tight junction proteins between adjacent cells in the superficial epithelium to impede the flow of ions along the paracellular pathways.

Unidirectional fluxes – Across epithelia isolated in Ussing-type chambers, a unidirectional flux of a substance (e.g., a radiolabeled electrolyte or water molecule) is its rate of translocation across the tissue from the bathing solution within one hemichamber to the contralateral bath, disregarding any counterbalancing flux in the opposite direction. In practice, unidirectional fluxes are measured in the apical-to-basolateral direction, and again in the basolateral-to-apical direction. A difference in the magnitude of these two unidirectional fluxes provides a measure of the net flux, for example, there is a net chloride flux across the conjunctiva in the basolateral-to-apical direction.

Ussing chamber – A device designed by Hans Ussing in 1951 to originally study vectorial ion transport across the frog skin. It has since been modified (i.e., an Ussing-type arrangement) by many investigators to characterize electrolyte transport across various epithelial tissues including epithelia of the eye. This approach has significantly contributed to our understanding of how electrolytes are transported. The Ussing-type methodology entails two aspects. One is the chamber itself, which is constructed to hold the dimensions of a particular tissue, and enable it to be bathed bilaterally. The second aspect is the external electrical circuitry, which can be designed to measure transepithelial voltage, resistance, and current. The effects of pharmacological agents on the electrical parameters generated by the epithelium can be studied by applying test compounds unilaterally to either the apical-side or basolateral-side baths.

Introduction

The conjunctiva and the corneal epithelium together form the ocular surface. The conjunctiva (from late Latin, feminine of conjunctivus, or conjoining) is in essence a connection (conjunction) between the eyelids, the sclera of the eyeball, and the cornea. It lines the posterior surface of the

eyelids (the palpebral conjunctiva) and the exposed, anterior aspect of the globe (the bulbar conjunctiva). The latter is loosely attached to the sclera of the eyeball, and translucent, thereby exposing the so-called 'white of the eye'; it merges with the corneal epithelium at the limbus, which constitutes the edge of the cornea. The palpebral conjunctiva is tightly adherent to the eyelid.

The space, lined by the conjunctiva, between the lids and the globe is known as the conjunctival sac. The bottom of the sac, which is unattached to the eyelids or to the eyeball, is known as the fornix, forniceal region, or conjunctival fold. The untethered nature of the fornix allows the eyeball to move freely. The conjunctival sac varies in size depending upon the degree to which the lids are open. The depths of the unextended sac in humans are about 14–16 mm superiorly and 9–11 mm inferiorly. The total surface area of the conjunctiva is about 9 and 17 times larger than that of the cornea in rabbits and humans, respectively. The lacrimal glands, which secrete tears, open into the superior fornix.

The palpebral conjunctiva contains the openings of the lacrimal canaliculi, which allow tears within the conjunctival sac to drain into the nasal cavity. The vasculature of the palpebral conjunctiva is clearly visible within the tissue upon examining the posterior surface of the eyelid. In contrast, the bulbar conjunctiva is normally colorless, unless its vessels are dilated as a result of inflammation (conjunctivitis). The conjunctival vessels arise from a peripheral palpebral arcade and from the anterior ciliary arteries. Blood comes mostly from the orbit, but anastomoses with the facial system.

Conjunctival innervation is mediated by the ophthalmic division of the trigeminal nerve. The conjunctiva is extensively innervated with adrenergic, cholinergic, and peptidergic fibers identified in various species. In general, the largest numbers of nerves present are sympathetic, with fewer parasympathetic and sensory nerves. The parasympathetic nerves contain the neurotransmitters acetylcholine and vasoactive intestinal peptide; the sympathetic nerves, norepinephrine and neuropeptide Y; and the sensory nerves, substance P and calcitonin-gene-related peptide.

The major roles of the conjunctiva are:

(1) to contribute to tear production by secreting electrolytes and fluid;
(2) to modify the composition of the tear film by secreting mucins and lipids, and absorbing various organic compounds found in tears; and
(3) to contribute to the resistance of the eye to infection by providing protection against microorganisms.

The conjunctiva is comprised of an epithelium and an underlying stroma. The epithelium is embryologically related to, and anatomically continuous with, the epithelium of the upper airway. Within the conjunctival epithelium are goblet cells, which are specialized epithelial cells that function as unicellular mucus glands. The goblet cells secrete the mucin component of the tear film, which consists of three layers, each of which is secreted by different cells. Secreted mucins constitute the inner layer of the tear film and serve as wetting agents that keep the apical, hydrophobic aspects of the corneal and conjunctival epithelia hydrated. The middle, aqueous layer of the tear film contains water, electrolytes, immunoglobulin A (IgA), glucose, and proteins (including antibacterial enzymes). This layer is primarily secreted by the main and accessory lacrimal glands; the latter glands of Krause and Wolfring flank the main lacrimal duct near the superior fornix. It is possible that the conjunctiva also contributes to this layer under basal conditions when the lacrimal glands are not stimulated. The outer, lipid layer of the tear film contains a fat mixture that is secreted by the meibomian glands that line the eyelids. This layer functions to reduce evaporation of the aqueous layer.

Underlying the conjunctival epithelium, the connective tissue contains blood vessels, nerves, conjunctival glands, mast cells, and leukocytes including macrophages. The latter, defensive cells can be recruited in large numbers to an injury site on the ocular surface due to disruption of the barrier properties of the epithelium. They may also release paracrine-signaling agents that affect the transport properties of the epithelium, and certain leukocyte populations can also serve as antigen-presenting cells.

Recent work has characterized the active transport properties of the conjunctival epithelium. The epithelium is capable of transporting fluid as a consequence of a sufficiently high water permeability bestowed by endogenous water channels (aquaporins) and transepithelial solute movement due to active transport mechanisms. This article includes a synopsis of the current understanding of the electrolyte and fluid transport across the conjunctiva.

Conjunctival Epithelium

A primary role of all epithelial tissues, including those in the conjunctiva, is the absorption and/or secretion of fluid. In brief, two main elements are necessary for fluid movement across a membrane or a set of membranes: (1) the driving force represented by an osmotic gradient (or hydrostatic pressure), and (2) a water pathway represented by water channels (aquaporins) and the lipid bilayer. Thus, all fluid secretion or reabsorption is a consequence of the osmotic gradient created by active electrolyte transport, with the direction of fluid movement identical to that of the net transepithelial solute transport. To date, extensive, functional characterizations of the electrolyte transport properties of the conjunctival epithelium have been done only on the isolated rabbit conjunctiva. The epithelium of this species exhibits mechanisms that simultaneously mediate Na^+ absorption and Cl^- secretion. The relative proportions of these oppositely directed functions varies considerably from one individual rabbit conjunctival

specimen to another, for reasons that are unknown, but in general Cl^- transport is predominant. On average, the ratio of Cl^- secretion to Na^+ absorption is about 1.5 to 1, suggesting that the rabbit epithelium can function primarily as a chloride-secreting epithelium potentially capable of moving fluid into the conjunctival sac. However, it must also be noted that a small proportion of conjunctival specimens exhibited a Na^+ absorptive rate larger than the rate of Cl^- secretion.

Morphologically, the epithelia of the rabbit bulbar, forniceal, and palpebral regions have distinct appearances (**Figure 1**). The bulbar epithelium appears columnar and thinner than the other sections with goblet cells present. It is as thick as two to three cell layers and packed irregularly. In the forniceal area, the number of cell layers increases to three or four with a greater abundance of goblet cells. From this region to the lid margin, a transition within the palpebral epithelium is evident with the number of goblet cells diminishing, and the epithelial cells becoming more stratified. Species differences in morphology among mammalian conjunctivae have been described.

Excluding variations in the number of goblet cells, the epithelial cells within each conjunctival region appear homogeneous, which suggests that both absorptive and secretory activities coexist within an individual epithelial cell. If so, the conjunctival epithelium exhibits a rare property among epithelia in that the transport functions for Na^+ absorption and Cl^- secretion are not segregated in distinct cell types, and the transport rates for these oppositely directed functions are nearly equivalent in isolated conjunctivae under *in vitro* conditions.

Regardless of the normal, physiologic direction of fluid movement across the human conjunctiva, it is clear that inhibiting reabsorption and/or stimulating secretion may have a beneficial effect by increasing the aqueous layer of the tear film in individuals with a tear-fluid deficit due to various lacrimal gland deficiencies.

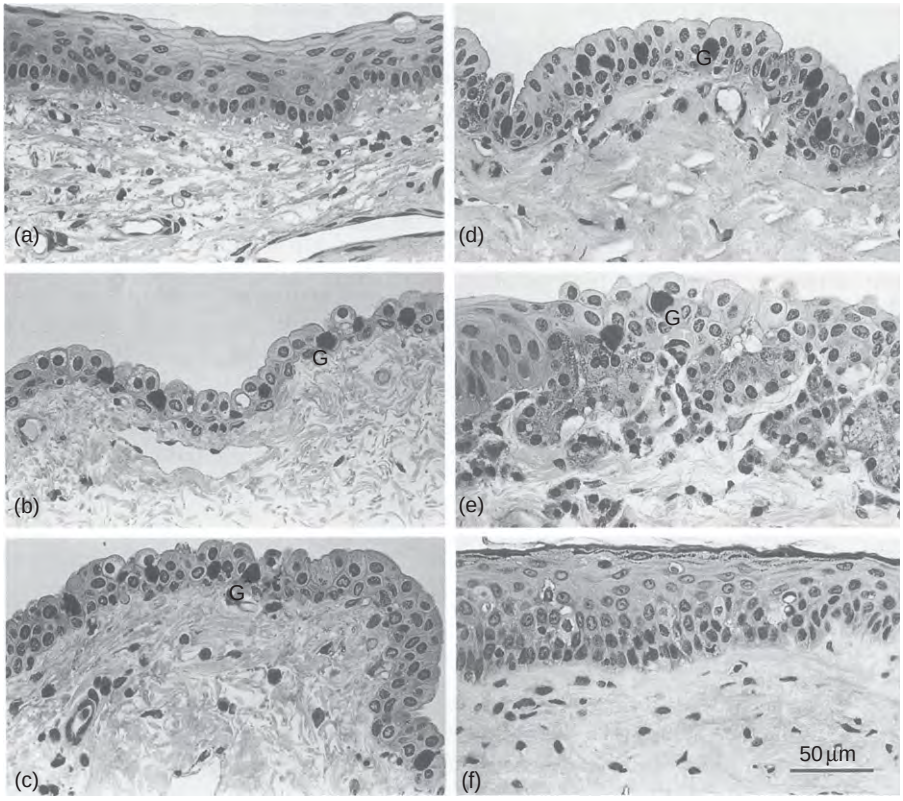

Figure 1 Histological sections of the rabbit limbal and conjunctival regions. (a) The limbal epithelium upon a highly vascularized stroma. (b) The bulbar conjunctival epithelium. There are goblet cells (G) present among the epithelial cells. (c) The forniceal epithelium nearest the bulbar region. (d) Another section of the forniceal epithelium, within which the goblet cells become more numerous relative to the bulbar region. The forniceal epithelium is thicker than the bulbar epithelium. (e) The palpebral epithelium near the forniceal region that is characterized by a decrease in the number of goblet cells and abundant lymphoid tissue. (f) The palpebral epithelium closer to the eyelid margin. It is more stratified than the other conjunctival regions and devoid of goblet cells. Adapted from Wei, Z. G., Sun, T. T., and Lavker, R. M. (1996). Rabbit conjunctival and corneal epithelial cells belong to two separate lineages. *Investigative Ophthalmology and Visual Science* 37: 523–533.

Bioelectric Studies on the Isolated Rabbit Conjunctiva

The ionic transport systems potentially mediating the absorptive and/or secretory functions of an epithelium can be efficiently characterized by isolating the epithelium under an Ussing-type arrangement. With this method, a flat piece of an epithelium is dissected with some of its underlying connective tissue or stroma maintained in place to provide structural support. The thickness of the entire dissected preparation is usually about 1 mm, of which about 0.05 mm represents the epithelial cellular compartment. The isolated tissue is then positioned between two hemichambers, which when closed together result in the tissue serving as a partition separating the cavities of the two hemichambers. In this situation, the apical surface of the epithelium interfaces with the cavity of one hemichamber, while the basal surface attached to the underlying stroma interfaces with the contralateral chamber. Each hemichamber is then filled with a physiological solution to simultaneously bathe the two surfaces of the *in vitro* preparation.

The rabbit conjunctiva serves as a fairly good specimen for this approach given its relatively large surface area, as well as the fact that the conjunctival sac can be removed nearly intact as a cylinder and then cut longitudinally to convert it to a flat epithelium that is easily mounted between Ussing-type hemichambers. Typically, about 0.5 cm^2 of cross-sectional area of tissue is bilaterally exposed to the bathing solutions within the chambers. A negative aspect of this approach with the conjunctiva is that the epithelium seems to be relatively frail (when compared to the corneal epithelium) as its integrity deteriorates following several hours of isolation within the chambers. Nevertheless, useful electrophysiological experiments can be designed and informative data are obtainable.

Upon isolation of an epithelial preparation, such as the conjunctiva, within the divided chambers, a potential difference (PD) develops across the tissue. The PD is a consequence of the active transport of electrolytes by the epithelium, which spends metabolic energy to maintain ionic gradients between the cellular compartment and the extracellular bath. An epithelium will exhibit a negative intracellular voltage with respect to both the apical-side bathing solution and the stromal-side (basolateral) solution. Typically, the positive voltage of the stromal-side bath (PD_s) with respect to the cellular compartment occurs because of the electrogenic Na^+–K^+ ATPase, which extrudes three Na^+ ions for two imported K^+ ions, and the fact that the cellular K^+ ion concentration is above equilibrium, so that K^+ will constantly efflux through K^+ channels toward the stromal (basolateral) bath (**Figure 2** shows an overview of the major transport elements found in the conjunctival epithelium). The Na^+–K^+ ATPase functions incessantly to maintain cellular K^+ above equilibrium. The positive voltage of the apical-side bath (PD_a) with respect to the cellular compartment is less positive than PD_s. As such, a transepithelial PD (PD_t) exists, which equals the difference between the PDs across the respective contralateral surfaces of the epithelium ($PD_t = PD_a - PD_s$; and has a negative sign with PD_s taken as reference). PD_a is less positive with respect to the cellular compartment than is PD_s because of the efflux of Cl^- via channels in the apical domain toward the apical-side bath, and in the case of the conjunctiva, an influx of Na^+ also occurs via electrogenic transporters that are in the apical membrane (**Figure 2**).

PD_t can only exist if tight junctions are present in the epithelium, which is the case in the conjunctiva. These elements are located between the lateral membranes of the most superficial epithelial cells and form a resistance barrier that impedes the diffusion of ions from the contralateral bathing solutions through the paracellular pathways between the epithelial cells. Without the presence of tight junctions, ionic flows in the paracellular pathway would

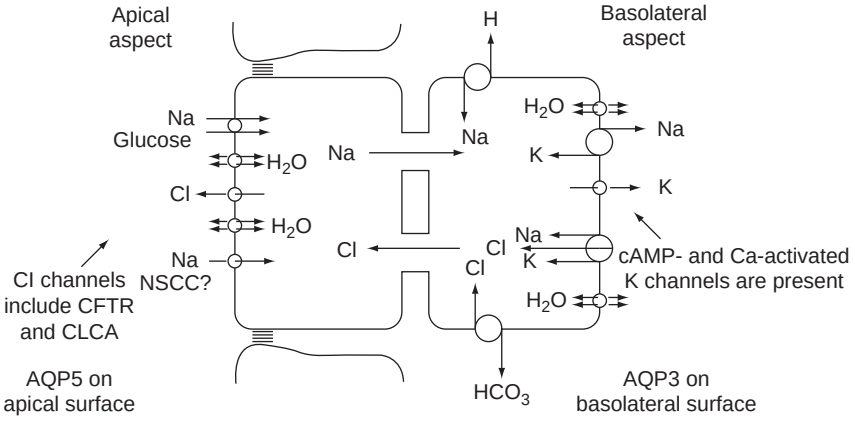

Figure 2 Summary cartoon of the major transport elements found in the rabbit conjunctiva with water fluxes indicated with double arrows. NSCC, nonselective cation channels; CFTR, cystic fibrosis transmembrane conductance regulator (which has chloride channel activity); CLCA, calcium-activated chloride channel; AQP5, aquaporins homolog type 5; AQP3, aquaporins homolog type 3.

short-circuit PD_t, because PD_a and PD_s would still exist and result in a net movement of anions from the apical-side bath to the stromal-side bath through the paracellular pathways, and a net movement of cations in the opposite direction through the paracellular pathways.

The Ussing-type chambers used to isolate the conjunctiva have ports for inserting electrodes into the bathing solutions to directly measure PD_t. In addition, there are ports for current-sending electrodes. These are used to short-circuit PD_t with an external circuit connected to an automatic voltage clamp that constantly maintains $PD_t = 0$ mV. The amount of current needed for this is continuously recorded and known as the short-circuit current (I_{sc}). The I_{sc} represents a real-time measure of the net transepithelial movement of electrolytes across the transcellular pathways of the tissue due to metabolically dependent active transport. As PD_t is maintained at 0 mV, there is no net movement of electrolytes through the paracellular pathways, even if tight junctions were, in principle, not present.

Transepithelial electrical resistance (R_t) can be determined by applying Ohm's law to the measured PD_t (under open-circuit conditions) and the measured I_{sc} (under short-circuited conditions), or by measuring the amount of current necessary to offset the short-circuited condition by a few mV for a few seconds. Either approach gives identical measures of R_t with the conjunctiva.

As alluded to above, the integrity of the conjunctival epithelium appears to degenerate following a prolonged period in the chamber. This is observed as a spontaneous, gradual decline in R_t. It appears that there is a loss in paracellular resistance (i.e., tight-junction structure may change with time *in vitro*) since the R_t decline occurs in the presence of a steady I_{sc}. As noted, under the short-circuited conditions, increases in paracellular ion movement do not result in a net flow across this pathway given the absence of a PD across the epithelium and identical electrolyte concentrations on each side of the preparation. As such, the I_{sc} continues to measure net transcellular flow of electrolytes in experiments with symmetrical solutions. However, changes in conjunctival R_t in response to the additions of various drugs frequently underestimate changes in membrane resistance. This is because transcellular resistance is proportionally larger than paracellular resistance, which means that large changes in transcellular resistance are recorded as smaller changes when measuring conjunctival R_t.

Nonetheless, the initial measurements of conjunctival R_t upon the isolation of fresh preparations within the divided chambers provide a good indication of the barrier properties of the epithelium. This is because the electrical resistances of both the cell membranes as well as the paracellular pathways contribute to the R_t measurement. The paracellular pathways of the *in situ* conjunctiva at the ocular surface allow for the passive diffusion of hydrophilic solutes across the conjunctiva. Passive paracellular transport of electrolytes across the conjunctiva *in vivo*, which is analogous to the open-circuit situation *in vitro*, occurs because of gradients created by the transcellular mechanisms. In addition, cell-impermeable, hydrophilic solutes applied to the conjunctival sac may diffuse across the epithelium through the paracellular route. The transepithelial permeability of such solutes decreases with increased solute size. Tight junctions located at the apical-most aspect of an epithelium create the major barrier for the movement of solutes across all epithelia including the conjunctiva. However, the paracellular route varies considerably among epithelia in terms of permeability to solutes and electrical resistance. R_t measurements can range at least 1000-fold between highly resistant and so-called leaky epithelia. In some tissues, electron microscopy studies have correlated the ultrastructure of the tight junctions with the measured R_t values obtained *in vitro*. In general, the number of tight-junction strands along the apical-basal axis is proportional to the junctional resistance. R_t values from freshly isolated rabbit conjunctival epithelia are in the range of 1–2 $k\Omega\ cm^2$, with many studies reporting an average value of $\approx$1 $k\Omega\ cm^2$. This suggests that the conjunctival epithelium is a moderately tight epithelium. For comparison, R_t measurements of the rabbit corneal epithelium and rabbit corneal endothelium are $\approx$7–9 $k\Omega\ cm^2$ and 0.01–0.07 $k\Omega\ cm^2$, respectively. As such, the electrical resistances of the corneal epithelium and endothelium vary over a range of about 100-fold, and the conjunctiva exhibits an intermediary value. The fact that the measured R_t of the freshly isolated conjunctiva is so high also indicates that tight junctions must exist between the surface goblet cells and the most superficial stratified epithelial cells. An explanation as to why R_t declines with prolonged time *in vitro* remains to be evinced, but barrier resistance is physiologically regulated in other systems. The stable I_{sc} recorded during the spontaneous R_t decline indicates that the epithelial cells have remained metabolically viable.

Electrolyte Transport Systems of the Rabbit Conjunctiva

The bioelectrical approach discussed above has been used to determine the major electrolyte transport systems present in the rabbit conjunctival epithelium. In work done to date, the short-circuiting methodology was used to characterize transcellular transport. Such transport is energy dependent, and controlled by the tissue-specific profile of transporters and channels along the apical and basolateral membranes of the epithelium. The conjunctival apical membranes interface with the tears and the basolateral membranes interface with the paracellular pathways from the tight junctions to the basement membranes at the

stroma. Transport mechanisms in the tissue are generally uncovered by electrolyte substitution experiments, and the application of relatively specific drugs (i.e., channel blockers, channel openers, transporter inhibitors, etc.) to the bathing solutions of conjunctiva isolated in the divided chambers. In some cases, the identity of channels and transporters that were identified in electrophysiological experiments were corroborated with immunoblotting and immunohistochemcial observations.

Identical to other Cl^--secreting epithelia, the rabbit conjunctival epithelium has a basolateral bumetanide-sensitive Cl^- uptake process (mediated by the Na^+–K^+–$2Cl^-$cotransporter, NKCC1) positioned in series with apical Cl^- channels, including cystic fibrosis transmembrane conductance regulator (CFTR). In addition, Na^+/H^+ and Cl^-/HCO_3^- exchangers exist in parallel in the basolateral membrane and can also mediate Cl^- uptake (**Figure 2**).

Oppositely directed, electrogenic Na^+ reabsorption is amiloride-insensitive, indicating the absence of the major epithelial Na^+ channel (ENaC) at the apical surface, and occurs through a Na^+-dependent cotransporter for glucose. Nonselective cation channels (NSCCs) were identified in whole-cell patch clamping of freshly isolated conjunctival epithelial cells and such channels may also reside at the apical surface. A transcellular Na^+ movement occurs because the apical uptake mechanisms for Na^+ exist in series with the basolaterally located Na^+–K^+ pump (**Figure 2**).

Other electrogenic Na^+-dependent uptake mechanisms at the apical surface were demonstrated by adding the transported substrates to the apical bath. Transport systems for amino acids, nucleosides, L-lactate, and di- and tri-peptides were evidenced in this manner because such compounds are normally not included in the physiological solutions used to bathe the *in vitro* preparations. The addition of such compounds to the apical bath results in a short-circuit current stimulation. In the cases of the amino acids and nucleosides, the largest I_{sc} stimulations occurred with L-arginine and uridine, respectively. The roles of these carriers are not firmly established. It is thought that these transport systems may clear the tear fluid of these compounds in either nonphysiologic or pathophysiological states of the ocular surface when excess amounts of such solutes might have leaked into tears.

Results from protocols for immunoblotting and the immunofluorescent labeling of frozen sections from separately isolated bulbar and palpebral regions of the conjunctival epithelium indicated that the proteins for the Na^+–glucose cotransporter, Na^+–K^+ ATPase, and Na^+–K^+–$2Cl^-$ cotransporter are uniformly distributed throughout the conjunctiva. These observations suggest that despite stark differences in the regional morphology of the bulbar and palpebral regions, the entire conjunctival epithelium exhibits the elements for transepithelial Na^+ and Cl^- transport.

Regulation of Epithelial Ion Transport in Rabbit Conjunctiva

Currently, information on the regulation of electrolyte transport by the conjunctival epithelium is somewhat limited. This is because the characterization of the macroscopic electrolyte transport properties of this tissue, as measured in bicameral Ussing-type chambers, was begun relatively recently. Hence, many fundamental aspects of the tissue have not been elucidated. One underlying rationale for studying conjunctival transport is to define the secretory functions of the epithelium. This effort could prove to have utility in ameliorating complications from dry-eye diseases, and some progress has been made in this regard. Because of the large surface area of the conjunctival epithelium, active transport by conjunctiva with accompanying fluid secretion could, hypothetically, contribute a significant fraction of tear production, which is normally provided in healthy individuals by the lacrimal gland. Upon stimulation, the transepithelial conjunctival contribution could be greater.

As commonly found in Cl^--secreting epithelia, the exposure of the conjunctiva to secretogogues that increase either cell calcium or cyclic adenosine monophosphate (cAMP) stimulates transepithelial Cl^- fluxes and the I_{sc}. The latter intracellular messenger can be increased in the conjunctival epithelium with forskolin (a direct stimulator of adenylyl cyclase), dibutyryl-cAMP (a cell permeable form of cAMP), 3-isobutyl-1-methyl-xanthine (IBMX, a nonselective phosphodiesterase inhibitor), rolipram (an inhibitor specific for cAMP-phosphodiesterase type IV), or epinephrine (a nonselective adrenergic agonist). In addition, these agents also increase the transconjunctival I_{sc} under Cl^--free conditions indicating that the increased cAMP levels also stimulate the Na^+ absorptive activity of the epithelium. The increase in Na^+ absorption has been attributed to a protein kinase A (PKA)-regulated, barium-inhibitable, basolateral K^+ conductance in the rabbit conjunctival epithelial cells. One or more different types of K^+ channels that have not yet been identified may mediate this K^+ conductance. The stimulation of the PKA-gated K^+ channels hyperpolarizes the negative cell potential relative to the bathing solutions and favors both the uptake of Na^+ across the apical face and the efflux of Cl^- into the tears. There is evidence that apical Cl^- channels are also gated by PKA, particularly in the case of CFTR. In the short-circuited conjunctiva, cAMP has a central role in coordinating simultaneous changes in apical Cl^- and basolateral K^+ conductances to enable stimulations in the transcellular transport of Cl^- in the stromal-to-apical direction and of Na^+ in the opposite direction.

Should both absorptive and secretory mechanisms coexist within the same cell, such cAMP-evoked stimulations of the *in vivo* conjunctiva would, in principle, deplete the epithelium of KCl and reduce cellular volume, while Na^+ and Cl^- move in opposite directions both trans- and

paracellularly. Experimental measurements of net water fluxes across the isolated conjunctiva (under open-circuit conditions) indicate an increased fluid movement in the stromal (basolateral)-to-apical direction in response to cAMP, likely due to the higher rate of Cl^- secretion relative to Na^+ absorption. Fluid flow occurs under open-circuit conditions, which is the situation *in vivo*. The dominant transport system, apparently Cl^-, will be transported mainly transcellularly, while Na^+ will reverse from its net tear-to-stroma direction found under short-circuit conditions to move paracellularly as a companion ion to neutralize the Cl^- charge and create a possible isotonic fluid at the apical surface. In open circuit, there would still be a transcellular movement of Na^+ toward the stroma, and a paracellular movement of Cl^- toward the stroma, but the magnitude of these flows will be less than the net of Na^+ and Cl^- secreted into tears (**Figure 3**). cAMP stimulates all flows and increases the net.

Other effective secretogogues in the rabbit conjunctiva are: (1) 1-ethyl-2-benzimidazolinone (EBIO), a Cl^- and K^+ channel opener that elicits electrophysiological effects similar to those of cAMP, although different subtypes of channels are likely involved; and (2) the nucleotide uridine 5′-triphosphate (UTP), which stimulates Cl^- secretion through $P2Y_2$ receptors upon exogenous application to the apical-side bath. Of these, only the latter has been tested on net fluid movement across isolated conjunctivae and found to be a useful stimulant. Recently, synthetic $P2Y_2$ agonists (e.g., diquafosol tetrasodium, which is also known as INS365) have been studied in clinical trials. Such agents are administered 4–5 times daily, and there is a time-dependent loss of efficacy that is observable in the data produced by such trials. This may be because $P2Y_2$-receptor activation is often transitory due to the nature of the Ca^{2+} signal itself (through the phospholipase C-sensitive calcium signaling pathways) and the fact that purinergic agonists produce receptor desensitization from which recovery is slow. Yet currently, the use of purinergic agonists appears a suitable approach to palliate dry eye because of not only the stimulatory effects on conjunctival Cl^- secretion and fluid transport, but also the fact that purinergics serve as mucin secretogogues from conjunctival goblet cells. As such, purinergics appear to have utility in conserving the composition of the tear film.

The established receptors that stimulate electrolyte and fluid secretion in the stromal-to-tear direction under open-circuit conditions are schematically presented in **Figure 4**. The specific channel subtypes activated by calcium and cAMP remain to be conclusively identified.

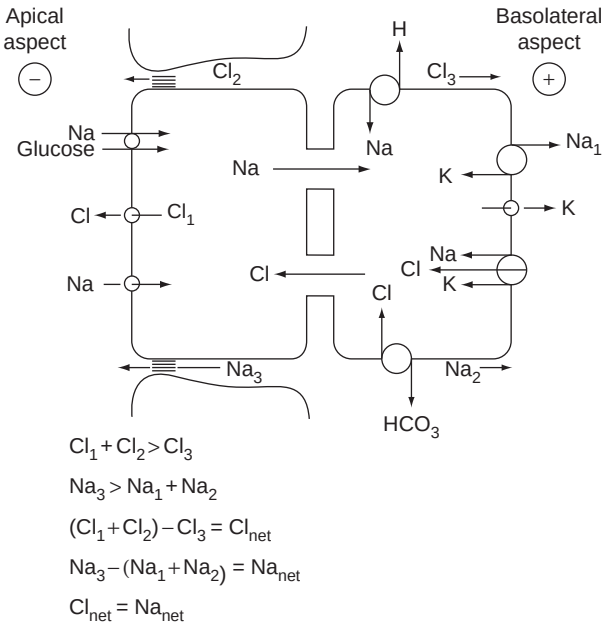

Figure 3 A simplified model of the sodium and chloride flows across the rabbit conjunctiva under open-circuit conditions, which are analogous to the *in vivo* situation. Some transporters present in the epithelium have been omitted for clarity. Cl_1 is the transcellular efflux of chloride via chloride channels in the apical domain. Cl_2 is the paracellular movement of chloride in the stromal-to-tear direction. Cl_3 is the paracellular movement of chloride in the tear-to-stromal direction. Na_1 is the sodium efflux mediated by the sodium-potassium ATPase pump. Na_2 is the paracellular movement of sodium in the tear-to-stromal direction, while Na_3 is the paracellular movement of sodium in the opposite direction. In open-circuit, the tear-side (apical) bath will have a negative potential relative to that of the basolateral-side bath. Cations will thus flow in the paracellular pathways toward the tear side, while anions will flow in the opposite direction. There is also the possibility that some potassium will move along the paracellular pathways toward the tears. The sodium–potassium–chloride cotransporter in the basolateral membranes drives the transcellular movement of chloride. The net flux of sodium and chloride into the tears results in a net fluid transport across the conjunctiva. Flux relationships are indicated at the bottom of the figure by equations.

Fluid Transport Studies across Isolated Rabbit Conjunctiva

Two commonly used methods to measure water fluxes across various epithelia have been applied to the excised, isolated rabbit conjunctiva: (1) unidirectional/diffusional flow with tritiated water (^3H_2O); and (2) net water flow by volumetric procedures.

With method 1, the diffusion permeability coefficient, P_{dw}, is expressed in cm s^{-1} and given by:

$$P_{dw} = \mathcal{J}_{dw}/A \cdot V_w \cdot C_w$$

where, A is the area of the membrane (cm^2), V_w is the partial volume of water (cm^3 mol^{-1}), C_w is the concentration of water (mol cm^{-3}), and $\mathcal{J}_{dw}$ is the measured unidirectional H_2O flux in cm^3 s^{-1}.

In this case, a two-compartment chamber is used. The tissue is mounted between compartments; ^3H_2O is added to one side and samples are taken periodically from both

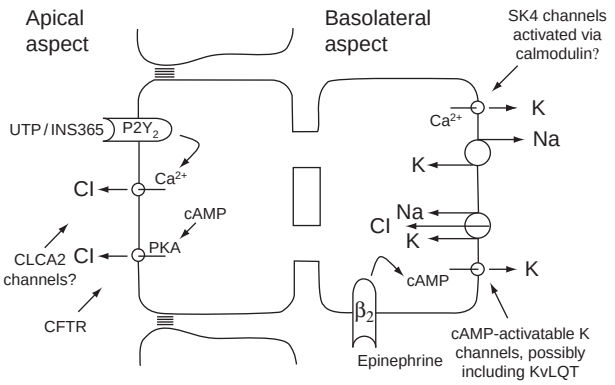

Figure 4 Cartoon of the established receptors that stimulate electrolyte and fluid secretion in the stromal-to-tear direction under open-circuit conditions, which are analogous to the *in vivo* situation. Some transporters present in the epithelium have been omitted for clarity. The specific channel subtypes activated by calcium and cAMP remain unverified. Abbreviations: UTP (uridine 5′-triphosphate); INS365 (a synthetic activator of the $P2Y_2$ receptor); $P2Y_2$ (a receptor subtype for the pyrimidine, UTP, that triggers calcium signaling via the phosphoinositide pathway); CLCA2 (a calcium-activated chloride channel subtype thought to be present in the conjunctiva); CFTR (cystic fibrosis transmembrane conductance regulator, which mediates a cAMP-gated chloride conductance via PKA); SK4 (a potassium channel subtype thought to be present in the conjunctiva that is activated by calcium, possibly via calmodulin, a calcium-regulatory protein); KvLQT (a potassium channel protein subunit linked to cAMP-activated potassium conductances). The presence of the above channel subtypes has been suggested from the expression levels of message in gene microarray assays of human conjunctiva, but the operational existence of the putative channel proteins has not yet been confirmed in functional experiments.

sides to determine the diffusion of ^3H_2O, which is proportional to $\mathcal{J}_{dw}$.

With method 2, the osmotic permeability coefficient, P_f, is expressed in cm s^{-1} and can be calculated from the following expression:

$$P_f = \mathcal{J}_v / A \cdot V_w \cdot \Delta C_s$$

where $\mathcal{J}_v$ (the measured net H_2O flux) is expressed in $cm^3\ s^{-1}$ and ΔC_s is the difference in solute concentration (mol cm^{-3}). For this approach, a two-compartment arrangement could also be used, along with a graduated capillary tube, or appropriate detection system, in order to directly measure $\mathcal{J}_v$ as a function of time.

Unidirectional fluxes of water determined with ^3H_2O (method 1) are usually large and similar in both directions. Thus, a small difference (the net volumetric flow, or $\mathcal{J}_v$, which is detected directly with method 2) is difficult to detect by method 1 and is usually not calculated as a difference between two unidirectional fluxes. For example, in the case of the conjunctival epithelium, unidirectional water fluxes ($\mathcal{J}_{dw}$) across the tissue are statistically identical in either direction, and have a magnitude ≈60-fold larger than the reported values for the net flux ($\mathcal{J}_v$) of fluid secreted to the tear side by the isolated conjunctiva (≈4–6 µl h^{-1} cm^{-2}, using method 2 (a volumetric approach). Because of this discrepancy in magnitude, it is unfeasible (if not impossible) to calculate $\mathcal{J}_v$ as the difference between the two, relatively large, unidirectional fluxes in the opposite directions. However, method 1 (a diffusional approach) is useful for determining the effects of agents or various experimental conditions on water permeability (P_{dw}); because although labeled water will cross cell membranes via all available pathways – lipid bilayer, aquaporins, and other channels, the measurements of $\mathcal{J}_{dw}$, which reflect P_{dw}, change equally in both directions when an experimental maneuver changes the water permeability of the epithelium.

From diffusional water fluxes ($\mathcal{J}_{dw}$) and mannitol fluxes it was determined that the conjunctival apical surface is highly permeable to water, and that the transepithelial water permeability (10^{-4} cm s^{-1}) exceeded the paracellular permeability (10^{-6} cm s^{-1}). A recently described element contributing to the water permeability of the apical surface is the water channel homolog known as aquaporin type 5 (AQP5). Generally, epithelia exhibit distinct AQPs in the apical and basolateral domains, and in the case of the conjunctiva, AQP3 is expressed in the lateral membranes. Together, AQP5 and AQP3 may be necessary in the conjunctiva for transepithelial fluid transport. AQP5 could serve as a potential target for pharmacological upregulation to enhance fluid secretion given that cAMP via PKA activity has been reported to increase the expression levels of this water channel at both transcriptional and posttranscriptional levels in other cell systems.

From measurements of $\mathcal{J}_v$, a spontaneous fluid transport across the isolated conjunctival epithelium in the basolateral-to-apical direction has been described, a property consistent with the more dominant Cl^- secretory activity of the tissue. As noted, the reported fluid secretion rates were ≈4–6 µl h^{-1} cm^{-2}. This flow was dependent upon transepithelial electrolyte transport given its abolition by ouabain, sensitivity to K^+ channel blockade, and Cl^- dependency. In addition, in experiments that increased the Na^+ absorptive activity by raising the glucose concentration (to 25 mM) of the apical bath, fluid transport was inhibited by 77%; an inhibition that did not occur with a similar concentration of mannitol. Studies found that the fluid transport rate was increased (≈50–100 %) by Cl^- secretogogues that included purinergic agonists acting via $P2Y_2$ receptors. As purinergic agonists stimulate mucin secretion by conjunctival goblet cells, it seems plausible that the roles of epithelial Cl^- transport include the hydration of mucins upon release.

Overall, the conjunctival epithelium has sufficient water permeability and the transporters necessary to contribute significant fluid to the tear film (≈50 µl h^{-1} based upon its total surface area). This level of fluid flow is sufficiently large that it may represent a baseline tear

secretion beyond that contributed by the lacrimal gland, which mediates reflex tearing under neuronal control. It is not yet clear if the innervation of the conjunctiva directly regulates the rate of fluid transported across the conjunctiva *in vivo*. However, the transport systems of the conjunctiva can potentially be manipulated pharmacologically.

Pathogenesis and Immunology of Bacterial Endophthalmitis

T Suzuki and M S Gilmore, Schepens Eye Research Institute, Boston, MA, USA

Glossary

Biofilm – A structured community of microorganisms encapsulated within a self-developed polymeric matrix.
Complement – A biochemical cascade that helps clear pathogens from contaminated tissue.
Quorum sensing – The regulation of gene expression in response to fluctuations in cell-population density.
Toll-like receptors – A family of pattern recognition receptors that initiate a rapid host innate immune response to microbial components.

Bacterial endophthalmitis is one of the most severe and sight-threatening ocular infectious diseases. It is characterized by massive inflammation and tissue damage caused by both bacteria and the subsequent immune response. Bacterial endophthalmitis is not common, and usually occurs in the context of ocular surgery, trauma, or hematogenous spread of organism to the eye. As an invariably sight-threatening infection, however, it is important to understand its pathogenesis and the host response.

Classification

Bacterial endophthalmitis is classified into two categories: exogenous, in which case bacteria enter into eye as a result of ocular surgery or trauma, or endogenous, caused by circulating organisms that migrate from other parts of body to the eye. The range of infectious pathogens depends on the causative trigger (Table 1).

Exogenous Endophthalmitis

Postoperative Endophthalmitis

Postoperative endophthalmitis is a severe complication of ocular surgeries, such as cataract surgery, glaucoma surgery, or vitrectomy. Endophthalmitis after cataract surgery usually occurs in the postoperative period, and the prevalence in most studies varies between 0.05% and 0.2%. Although the technical procedures used in cataract surgery are improving, the incidence of endophthalmitis has not changed and may be increasing. The leading causes of postoperative endophthalmitis include staphylococci, streptococci, *Enterococcus faecalis*, and *Propionibacterium acnes*. The visual prognosis depends on the kind of pathogen, and *Staphylococcus aureus*, streptococci, and *Enterococcus faecalis* infections often lead to significant vision loss. External bacterial flora is often the cause of acute postoperative endophthalmitis. External bacterial flora probably enters the anterior chamber through the surgical wound; in fact, contamination of the anterior chamber at the end of surgery has been noted to be as high as 5.7–21.1%.

Although intraoperative or postoperative contamination of the anterior chamber seems to be the initial step of endophthalmitis, the mechanisms by which a bacterium goes on to cause endophthalmitis relates to the pathogenicity of the organism and the host response. Endophthalmitis after cataract surgery usually follows one of two courses – early or late onset. The former occurs within days of surgery, presents with acute inflammation, and is often caused by *S. aureus*, streptococci, or enterococci. Late-onset endophthalmitis is characterized by chronic inflammation and is mainly caused by low-virulence microorganisms such as coagulase-negative staphylococci or *Propionibacterium acnes*.

Bleb-Related Endophthalmitis

The formation of a filtration bleb is often the next step for medically refractory glaucoma. The filtration bleb is formed between the conjunctiva and the sclera, and aqueous humor filters into the bleb. If the bleb is damaged, there can be direct communication between the anterior chamber and the external eye. Organisms infecting a bleb can easily spread into not only the anterior chamber, but also the posterior chamber, leading to endophthalmitis. The leading

Table 1 Classification of bacterial endophthalmitis and causative agents

Classification	*Causative agents*
Exogenous endophthalmitis	
Postoperative endophthalmitis	*Staphylococci, Streptococci, Enterococci, P. acnes*
Bleb-related endophthalmitis	*Staphylococci, Streptococci*
Post-traumatic endophthalmitis	*Staphylococci, Streptococci Bacillus* sp., *P. aeruginosa*
Endogenous endophthalmitis	*Staphylococci, Streptococci K. pneumoniae, E. coli*

causes of bleb-related endophthalmitis are toxigenic organisms *Streptococcus pneumoniae* and *Staphylococcus aureus*, and it is tempting to speculate that cytolysins expressed by these microbes may facilitate translocation through the bleb.

Post-Traumatic Endophthalmitis

Endophthalmitis is a complication of traumatic injury, and often progresses rapidly and leads to severe destruction of ocular tissue. Common etiologic agents of post-traumatic endophthalmitis include *Bacillus cereus, Pseudomonas aeruginosa,* fungi, and other organisms from the environment, along with staphylococci and streptococci from the ocular surface. In contrast to the causative agents of postoperative endophthalmitis, the number of bacterial cells which contaminates the eye during trauma may be large. The pathogenesis of endophthalmitis is often fulminant, which appears to stem from both microbial toxins and a robust host response. It may be that environmental organisms, such as *B. cereus* with little shared evolutionary history with humans, have not evolved mechanisms or properties that result in the type of tolerance that is seen to commensal organisms, and, as a result, they are quickly and robustly recognized as foreign.

Endophthalmitis Associated with Microbial Keratitis

Similar to post-traumatic endophthalmitis, endophthalmitis stemming from progression of microbial keratitis can cause severe damage to ocular tissue. Where healthcare is readily available, antimicrobial therapy against keratitis is usually effective in preventing the advance of the infection, and as a result bacterial endophthalmitis after keratitis is a rare complication. However, treatment failure in an era of advancing antibiotic resistance represents an important threat.

Endogenous Endophthalmitis

Little is known about the pathogenic mechanisms of endogenous endophthalmitis. It is mainly associated with immunocompromised patients, and those with liver abscess, pneumonia, or other serious underlying conditions. Precisely how these conditions contribute to the blood-borne spread of bacteria to eye in endogenous endophthalmitis is not well understood. The kinds of pathogens involved with this infection depend mainly on the predisposing condition. For example, *Klebsiella pneumoniae* is the predominant pathogen in patients with liver abscess. *E. coli,* staphylococci, and streptococci are also the major causative agents of endogenous bacterial endophthalmitis.

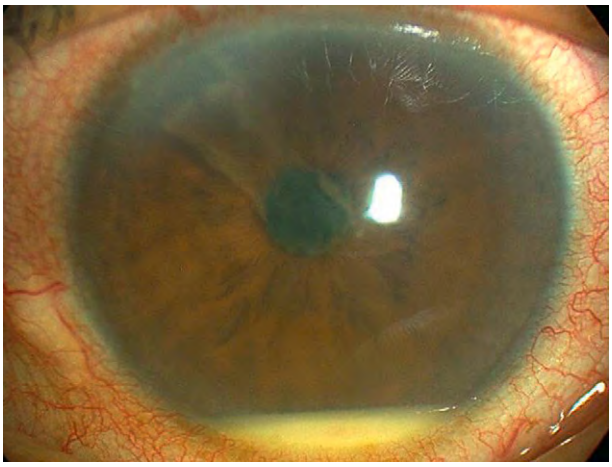

Figure 1 *E. faecalis* endophthalmitis following cataract surgery. Note the hypopyon and fibrin formation in the anterior chamber.

Clinical Findings

Patients who are suffering from acute endophthalmitis usually complain of blurred vision and/or pain. Slit lamp microscopy is used to detect characteristic hyperemia of conjunctiva vessels, ciliary injection, corneal opacity, hypopyon, and cell infiltration in the anterior chamber (**Figure 1**). A late clinical sign is the observation of vitreous opacity. Although it might be difficult to observe the fundus because of haziness in the visual path, retinal hemorrhage can also occur.

As for acute endophthalmitis, delayed-onset endophthalmitis may occur after cataract surgery with intraocular lens (IOL) implantation. This type of endophthalmitis is characterized by an indolent, subclinical inflammation that may evolve over weeks before keratoprecipitates, and a small number of inflammatory cells in anterior chamber raise the index of suspicion (**Figure 2**).

Virulence Factors of Bacteria Causing Endophthalmitis

Several microbial virulence factors that contribute to vision loss in endophthalmitis now have been identified and studied in molecular detail. Rabbit, rat, and mouse

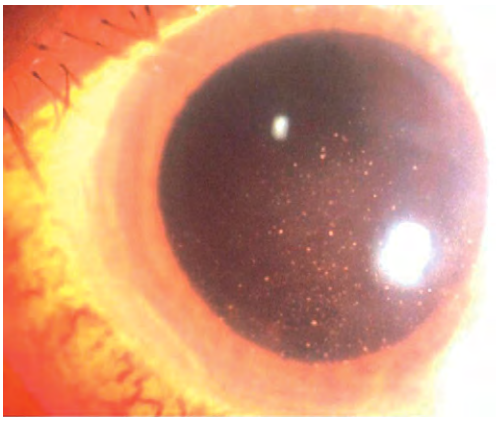

Figure 2 Low-grade endophthalmitis. Note the numerous keratic precipitates on the corneal endothelium. Reproduced from figure 1 in Suzuki, T. (2005). *Journal of Cataract and Refractive Surgery*, 31(10): 2019–2020, with permission from Elsevier.

Table 2 Virulence factor of pathogen in endophthalmitis

Pathogen	*Virulence factor*
S. aureus	Alpha-toxin, beta-toxin, *agr/sar* quorum sensing
E. faecalis	Cytolysin, gelatinase, serine protease, *fsr* quorum sensing
S. pneumoniae	Pneumolysin, autolysin
B. cereus	Motility, swarming, *plcR* quorum sensing
K. pneumoniae	Hypermucoviscosity

models of endophthalmitis have all been used to dissect the disease process. Studies using isogenic strains of bacteria differing only in the production of a toxin or virulence factor have been especially informative in unambiguously demonstrating the role of a particular toxin in contributing to the outcome of infection (Table 2).

Pathogenic Mechanisms

Quorum Sensing

A number of bacterial virulence factors involved in endophthalmitis are controlled by bacterial quorum-sensing systems. Quorum-regulated genes are induced or repressed, depending upon the local density of the bacterial population and accumulation of an extracellular signal. The extracellular signal, or autoinducer, may be a homoserine lactone, peptide, quinolone, or other metabolite. The low turnover of vitreous in the closed posterior segment may contribute to rapid accumulation of quorum molecules.

Biofilm Formation

A biofilm is a structured community of microorganisms encapsulated within a self-developed polymeric matrix, and adherent to a living or inert surface. Although little is known about a precise role of biofilms in bacterial endophthalmitis, biofilm-producing bacteria can attach firmly to the IOL lens. The role of biofilm formation as an impediment to clearance, or contributing to inflammation, is a subject of current study.

Toxin Production

As discussed below, toxin production is central to the pathogenesis of endophthalmitis. Toxins making important contributions to the pathogenesis of infection vary by organism, making it difficult to generalize. However, most of those for which a role has been demonstrated are membrane active.

Virulence Factors of Main Pathogen

Staphylococci

Staphylococci are major causes of postoperative and post-traumatic endophthalmitis. Coagulase-negative staphylococci express relatively few toxins, but are the most common causes of postoperative endophthalmitis. Those infections tend to be mild and usually resolve with limited visual loss. In contrast, infection caused by highly toxigenic *S. aureus*, which is only slightly less common, tends to be more severe, often resulting in visual loss, providing *prima facie* evidence for the role of toxins in endophthalmitis.

Although bacterial contamination of the anterior chamber during surgery is common, cases of endophthalmitis are rare. It has been speculated that biofilm formation, possibly on the implanted lens, may impede the clearance of these microorganisms. Biofilm formation may contribute to circumvention of an immune response and to limitation of the effectiveness of antibiotics. Coagulase-negative as well as *S. aureus* produce biofilms on biomaterials including the IOL lens (Figure 3). Case reports have correlated contaminated IOL lenses with endophthalmitis.

Staphylococcus epidermidis appears to attach to the IOL lens through a polysaccharide intercellular adhesin. The prevalence of potentially biofilm-forming *S. epidermidis* isolates is high in the conjunctival sac, which may be the source for biofilm-forming organisms on the IOL lens. Thus, development of materials that resist bacterial colonization is of high priority.

Once organisms are established, the next step in the pathogenesis of infection is damage to ocular tissue. Rabbit eyes infected with *S. aureus* strains deficient in alpha-toxin, beta-toxin, or both toxins were less inflamed and retained greater retinal function than eyes infected with wild-type toxigenic *S. aureus*. Furthermore, eyes infected with *S. aureus* strains deficient in quorum-sensing systems *agr* and *sar*, which control *S. aureus* toxins and adhesins,

exhibited reduced damage of ocular tissues. Staphylococci are increasingly resistant to a number of antimicrobials complicating rapid resolution of endophthalmitis potentially increasing exposure to toxin-mediated damage.

Enterococci

Enterococcus faecalis, a common cause of endophthalmitis after cataract surgery, is also associated with substantial loss of vision. The endophthalmitis vitrectomy study revealed that endophthalmitis caused by enterococci and streptococci was associated with the worst visual outcome. Several studies have examined the contribution of enterococcal virulence factors to the pathogenesis of *E. faecalis* endophthalmitis. The cytolysin expressed by some strains of *E. faecalis* was shown to be a key determinant of the severity and treatability of enterococcal endophthalmitis. If enterococci were nontoxigenic, the infection responded well to treatment with effective antimicrobials in combination with dexamethasone. However, if the infection was caused by an identical organism additionally expressing the cytolysin, this therapeutic regimen was rendered completely ineffective.

Gelatinase and serine protease are secreted proteases that are regulated by a quorum-sensing system termed *fsr*; in addition, they have been reported to be associated with the retinal destruction. These proteases further have been shown to play a role in endophthalmitis of aphakic eye after cataract surgery. *E. faecalis* proteases may promote organism spread by penetrating the posterior lens capsule. Bacterial migration from the anterior chamber to the posterior chamber is a key event in the progression of endophthalmitis; in the posterior segment, severe retinal damage may result (**Figure 4**). A surface adhesin of *E. faecalis*, aggregation substance, contributes to altered localization of the organism but otherwise appears to play a minor role.

In addition to these virulence traits, *E. faecalis* is intrinsically resistant to many antibiotics and is also capable of producing biofilm on IOL lens material. Both of these factors make infections with this organism very difficult to treat.

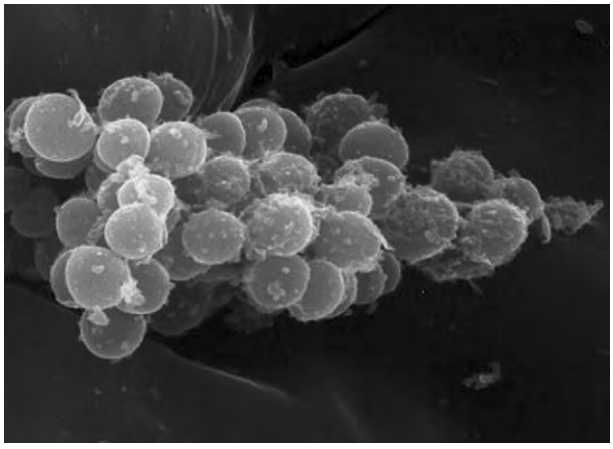

Figure 3 Biofilm-producing *Staphylococci.*

Streptococci

As noted above, streptococci can cause traumatic or postoperative endophthalmitis and are leading agents of bleb-related endophthalmitis. This infection results in severe visual loss. *S. pneumoniae* expresses pneumolysin and autolysin. These virulence factors contribute to the visual outcome of endophthalmitis.

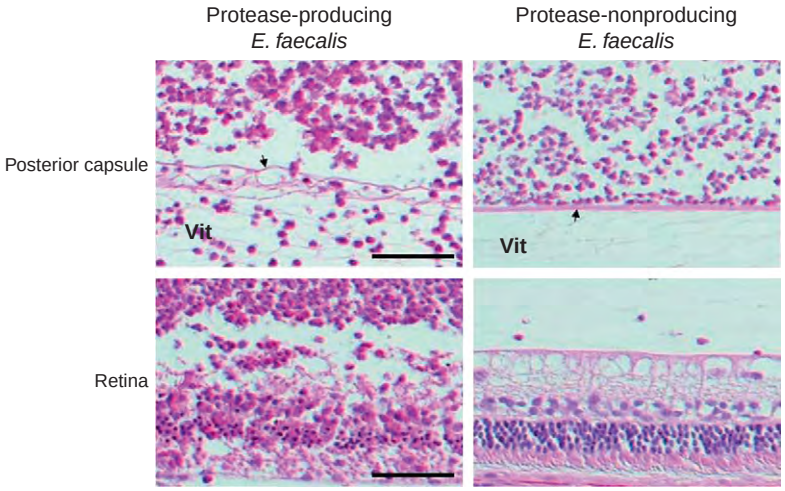

Figure 4 Histological analysis of experimental *E. faecalis* endophthalmitis. Degradation of posterior lens capsule (arrowhead) and destruction of photoreceptor segments were observed in eyes inoculated with protease-producing *E. faecalis*. Scale bar = 50 μm. Vit, vitreous cavity. Adapted from **figure 5** in Suzuki, T. (2008). *Journal of Cataract and Refractive Surgery*, 34(10): 1776–1784, with permission from Elsevier.

Bacillus

Bacillus spp. are leading agents of post-traumatic endophthalmitis, which is uniquely explosive in its evolution, leading rapidly to visual loss. Although speculated early to be an important contributor to the fulminance of *B. cereus* infection, one hemolysin termed hemolysin BL or HBL, was shown to make a relatively minor contribution to the course and severity of disease. *B. cereus* cytolytic factors are regulated by a quorum-sensing system termed *plcR*. Isogenic *plcR*-deficient mutants of *B. thuringiensis* (a derivative of *B. cereus* used as a surrogate in these tests) are significantly attenuated in severity in a rabbit model of endophthalmitis, but the infection nevertheless remains explosive, showing that these toxins collectively made a surprisingly minor contribution to the pathogenesis of infection. As *Bacillus* spp. are aerophilic and motile, it was hypothesized that chemotaxis along an oxygen gradient led to the margination of *B. cereus* to the blood–retina barrier, leading to its compromise and ensuing inflammation. This hypothesis was tested directly in a rabbit model, where motile and nonmotile *B. cereus* strains were compared. It was observed that deficiencies in swarming prevented *Bacillus* from migrating to the anterior segment, leading to less severe anterior segment disease.

Propionibacterium acnes

Propionibacterium acnes is the leading cause of late-onset postoperative endophthalmitis, which is characterized by a chronic indolent course, and is frequently associated with recurrence after standard endophthalmitis treatment. The precise role of *P. acnes* virulence traits, however, is unclear. *Propionibacterium acnes* produces a variety of chemotactic factors and proinflammatory molecules that are responsible for inflammatory and immunomodulatory properties. These factors may be associated with pathogenesis of endophthalmitis, but have not been tested directly.

Gram-Negative Rods

Gram-negative rods, such as *Pseudomonas aeruginosa*, *Klebsiella pneumoniae, Serratia marscescens*, and *Escherichia coli*, are rarer causes of postoperative endophthalmitis, but cause post-traumatic or endogenous endophthalmitis and are usually associated with poor visual outcome. Although there are few experimental studies regarding the pathogenesis of Gram-negative rods in endophthalmitis, hypermucoviscosity is an important phenotype in the pathogenesis of experimental *K. pneumoniae* endophthalmitis.

The Host Response in Endophthalmitis

As noted earlier, breach of the globe following surgery or trauma is a major predisposing factor for endophthalmitis. The low rates of endophthalmitis, compared to the rate of contaminated traumatic injury or contamination during surgery, suggest that the host response plays an important role in eliminating organisms, preventing many more endophthalmitis. The other side of an effective host defense, however, is that an overly exuberant inflammatory response can induce irreversible damage of ocular tissues, including the retina. The balance between defense and destructive inflammation is only beginning to be understood in the context of endophthalmitis.

Defense against Bacteria

Toll-Like Receptors

Toll-like receptors (TLRs) are a family of pattern recognition receptors that initiate a rapid host innate immune response to microbial components, known as pathogen-associated molecular patterns (PAMPs). Ligand binding to TLRs results in activation of cellular signaling pathways that regulate expression of genes involved in inflammation and immunity. In humans, 10 types of TLR family receptors (TLR1–10) have been identified. PAMPs recognized by TLR 2 and 4 are the lipoteicoic acid of Gram-positive bacteria and the lipopolysaccharide of Gram-negative bacteria, respectively. The precise action of TLR in endophthalmitis is still unclear; however, recent *in vitro* and *in vivo* studies have demonstrated the expression and function of TLRs in the eye. In these studies, it was noted that TLR-2, TLR-4, and TLR-9 are expressed in the retina and retinal pigment epithelial cells and could play a role in protecting against or responding to bacterial pathogens in posterior segment.

Complement

The complement system is a biochemical cascade that helps clear pathogens from contaminated tissue. It is part of the innate immune system, although it can be recruited and activated by the adaptive immune response. It is known that several aqueous humor factors possess complement-inhibitory activity. The level of complement components in the eye is lower than in the serum, even in inflamed eyes. Studies using guinea pigs, rendered deficient in complement by treatment with cobra venom factor, suggested a role for complement in defense against *S. aureus* IOL infection. However, when mice that were genetically deficient in the central complement component, C3, were used, complement was comparatively inconsequential in the outcome of endophthalmitis.

Cellular infiltration

Clinical findings, such as hypopyon and dense infiltration of cells in the anterior or posterior segments, are characteristic features of endophthalmitis. The cells present are

mainly polymorphonuclear cells and are found in highest numbers in the vitreous cavity, trabecular meshwork, anterior and posterior lens capsule, ciliary body, retina, and the choroid. Neutrophils are recruited into eye through several cytokine signals. However, the rate and magnitude of cellular infiltration depend on the pathogen. For example, endophthalmitis caused by *S. epidermidis* is often associated with delayed onset of infiltration. Little is known about what determines the onset of infiltration in the context of endophthalmitis. Although neutrophils play a large role in the killing of pathogens, they produce retinotoxic products, such as metalloprotease or oxyradicals, which result in severe damage of retina. Therefore, for successful treatment, it is important to control cellular infiltration in endophthalmitis.

Proinflammatory Cytokines

Tumor necrosis factor alpha (TNF-α) is a cytokine involved in systemic inflammation and is a member of a group of cytokines that stimulate the acute phase reaction. In the eye, TNF-α is produced by astrocytes and by histiocyte-like cells in the iris ciliary body. It induces apoptotic cell death, cellular proliferation, differentiation, and inflammation. The primary role of TNF-α is in the regulation of immune cells. TNF-α is a strong activator of nuclear factor kappa B (NF-κB), a universally present transcriptional regulator that regulates the expression of chemokines, growth factors, and cell adhesion molecules. This cytokine is important for IOL pathogen containment by PMNs during experimental *B. cereus* endophthalmitis. In the absence of TNF-α, fewer PMNs migrate into the eye, facilitating faster bacterial replication and loss of retinal function. Thus, TNF-α might play a critical role in endophthalmitis.

Similar to TNF-α, Fas ligand (FasL) belongs to the TNF family and is a type II transmembrane protein. The binding of FasL with its receptor induces apoptosis. The FasL–receptor interactions play an important role in limiting the response of the immune system. Although it was hypothesized that limiting FasL–receptor interactions would enhance the host response in the eye (by limiting a key factor that limits the host response), when directly tested in C57B6 mice it was found to have the opposite effect. FasL knockout mice were not more resistant to infection, but were more sensitive, suggesting that FasL has an important role in activating infiltrating polymorphonuclear neutrophils (PMNs).

Interleukin-1 (IL-1) is a pro-inflammatory cytokine that is produced by macrophages, monocytes, and dendritic cells and is involved in immune defense against infection. Inside of the eye, IL-1 is produced in the Müller cells and ciliary body cells in response to different uveitogenic stimuli, and induces other inflammatory mediators such as prostaglandins, phospholipase A_2, collagenases, and other proinflammatory cytokines (IL-6 and TNF).

IL-6 is produced by numerous cell types and acts as both a proinflammatory and anti-inflammatory cytokine. IL-6 is induced by other cytokines such as (IL-1, gamma-interferon, and TNF-α). In the eye, IL-6 is produced primarily by retinal pigment epithelial cells. The role of IL-6 as an anti-inflammatory cytokine is mediated through its inhibitory effects on TNF-α and IL-1, and these effects may influence bacterial endophthalmitis.

Immunosuppressive Microenvironment of the Eye

Anticomplement Factors

The ocular microenvironment maintains immune privilege by manipulating regional innate and adaptive immunity away from inflammatory responses. Aqueous humor contains a rich supply of constitutively produced immunosuppressive molecules that prevent pathogen-induced inflammation. The aqueous humor contains neuropeptides, such as α-melanocyte-stimulating hormone and calcitonin gene-related peptide, which along with transforming growth factor-β, suppress the activation and inflammatory activity of macrophages. Although these factors have important roles in minimizing ocular damage by inflammation in endophthalmitis, they might help bacteria avoid clearance.

Anterior-Chamber-Associated Immune Deviation

The anterior chamber is a unique immune-privileged site, governed by anterior-chamber-associated immune deviation (ACAID), as characterized by Streilein and associates. Generally, delayed-type hypersensitivity (DTH) induces a high degree of immunogenic inflammation in which interferon-γ is a principal effector; however, in ACAID, DTH is profoundly suppressed, whereas the humoral immune response is intact or even enhanced. The role of ACAID in limiting damage in IOL infection, either in the anterior or posterior segment, is not well characterized. As noted earlier, bacteria in most cases enter the eye through the anterior chamber, where they may be initially recognized. The extent to which ACAID delays or limits this or limits the host response in the posterior segment is only now being studied.

Conclusion

Severe cases of bacterial endophthalmitis are characterized by massive inflammation in the eye. Although the disease is not common, when it does occur, it can lead to significant damage in the ocular tissue. The visual prognosis of this disease depends on virulence factors of the pathogen and the resulting host response, but the details

of this are only beginning to be understood. It is clear that bacterial toxins and proteases are important in the pathogenesis of enterococcal and staphylococcal infection, but it appears that other cellular traits, such as motility, play more important roles in infections caused by *B. cereus*. Biofilms undoubtedly contribute to the challenge of eliminating an infection, either by antimicrobials or the host response, once it sets in. On the one hand, the multiplicity of factors makes it difficult to generalize and design a single therapeutic approach to improve visual outcome. On the other hand, having multiple targets increases the likelihood that at least some of them may prove to be points for successful intervention in mitigating the destruction that occurs in this infection.

Glossary

Biofilm – The microbial secretion of an extracellular matrix surrounding the organisms.
Conidia – These are fungal spores.
Matrix metalloproteinases (MMPs) – The proteases that participate in tissue remodeling, wound healing, and inflammation.
Multipurpose solution (MPS) – The contact lens care products that are used to disinfect daily-wear contact lenses.
Toll-like receptor (TLR) – A family of surface and endosomal receptors that recognize microbial products. TLR signaling induces production of proinflammatory and chemotactic cytokines and antimicrobial peptides.

Contact-Lens-Associated Fungal Keratitis

In June 2006, the Centers for Disease Control and Prevention (CDC) *Fusarium* investigation team (Chang and colleagues) reported 318 cases of *Fusarium* keratitis, with 164 confirmed cases in 33 states and one US territory, although smaller outbreaks were reported in Singapore, Hong Kong, and France. The age group was between 12 and 83, with a median age of 41; 94% wore soft contact lenses; and keratoplasty was needed for 34%. (Examples of contact-lens-associated *Fusarium* keratitis are shown by Alfonso and colleagues.) The CDC study demonstrated a clear relation to the use of Bausch and Lomb Renu with MoistureLock multipurpose solution (MPS), and the number of cases of *Fusarium* keratitis dropped shortly after withdrawal of this product. As unopened bottles were sterile, and *Fusarium* can be readily isolated from sink and shower drains, the CDC report concluded that the source of infection was in the patients' homes. However, although the report implies that poor lens care habits were involved, it became clear that *Fusarium* clinical isolates were more resistant to disinfectants in the lens care solution than CDC strains that were used for comparison. Moreover, resistance was related to the ability of the microorganism's capacity to form biofilm (see below). Reports from several regions of the USA, including Florida and San Francisco, described cases of contact-lens-associated *Fusarium* keratitis demonstrating severe corneal opacification and descemetocele formation (hernia of Descemet's membrane), most of which required keratoplasty. The CDC also reported that the number of cases of *Fusarium* keratitis dropped after Renu with Moisture Lock was voluntarily withdrawn from the market. However, several cases have been reported subsequently that were not due to this lens care product and were most likely due to increased awareness of *Fusarium*, although the causes were not always apparent.

Biofilm Formation in Contact-Lens-Associated Keratitis

Biofilm is defined as microbial secretion of an extracellular matrix surrounding the organisms. Biofilm formation allows the organisms to resist antibiotics (20–1000 times more resistant than planktonic forms), and to host immune responses. The CDC report on the contact-lens-associated outbreak of *Fusarium* keratitis also suggested that biofilm formation contributes to the resistance phenotype, as bacterial biofilm can form on contact lenses and lens cases. Bacterial biofilms can be generated rapidly on contact lenses and may therefore contribute to the pathogenesis of keratitis and endophthalmitis. Imamura and co-workers showed that *Fusarium* forms a biofilm on silicone hydrogel contact lenses; furthermore, the architecture, thickness, and composition of the biofilm differ according to the contact lens type. It is likely that the conidia germinate on the contact lens surface, and favorable conditions allow biofilm development. Once the biofilm is formed, the organisms are more resistant to antifungal agents, including those in multipurpose lens care solutions. Consistent with this notion, the *Fusarium* strain used to test lens care solutions did not form a biofilm and was more sensitive to lens care solutions (**Figure 1**).

Keratitis Caused by *Candida*

Candida species are the most common pathogenic yeast associated with keratitis. *Candida albicans* is part of the normal commensal flora; however, these organisms can cause opportunistic corneal infections in immunosuppressed

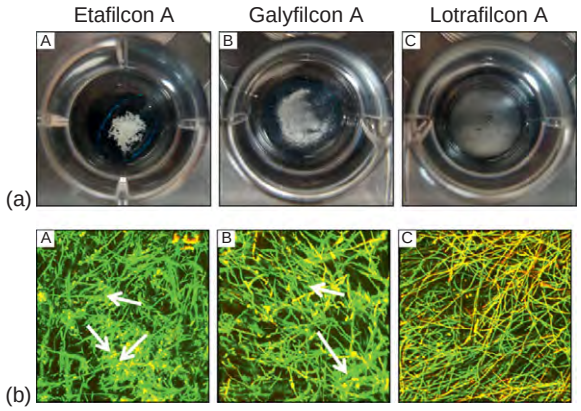

Figure 1 *Fusarium* biofilm formed on different soft contact lenses. (a) *Fusarium* conidia were incubated with each contact lens for 2 h, after which time the lenses were removed and incubated a further 48 h. Biofilms were formed by FSSC 1-b isolate MRL8609 on soft contact lenses, and their gross morphologies were imaged using a digital camera. All lenses tested supported biofilm formation by strain MRL8609. (b) The *Fusarium* FSSC 1-b strain MRL8609 was allowed to form mature biofilms on Etafilcon A silicon hydrogel contact lenses and then was stained with ConA and FUN1 dyes to show extracellular matrix (red) and live organisms (green). Stained lens-containing biofilms were analyzed by confocal scanning laser microscopy. Etafilcon A (A), galyfilcon A (B), lotrafilcon A (C), balafilcon A. Arrows indicate extracellular matrix in the biofilms. Similar results were found for *C. albicans* (not shown). Reprinted from Imamura, Y., Chandra, J., Mukherjee, P. K., et al. (2008). *Fusarium* and *Candida albicans* biofilms on soft contact lenses: Model development, influence of lens type, and susceptibility to lens care solutions. *Antimicrobial Agents and Chemotherapy* 52: 171–182.

individuals or following trauma or surgery. In contrast to filamentous fungi in which trauma is the major predisposing condition, *Candida* is primarily associated with therapeutic contact lenses, steroid use or immunosuppressive disease, and corneal surgery. In these dimorphic organisms, the yeast stage initially infects the cornea, and then germinates to form pseudohyphae in the corneal stroma. *Candida* produces a number of proteases and **phospholipases** (**particularly phospholipase B**) that facilitate their penetration through the cornea and contribute to tissue destruction. Using *C. albicans* mutants in a murine model of keratitis, Jackson and colleagues showed that *C. albicans* virulence depends on expression of genes encoding or regulating hyphal formation, but not genes regulating adherence.

Fungal Keratitis Associated with Trauma

Although relatively rare in North America and Europe, filamentous fungi are among the most common causes of microbial keratitis and corneal ulcers in India, China, and Ghana. In the southern USA, *Fusarium solani* and *Fusarium oxysporum* are the most common causes of mycotic keratitis, with *Aspergillus* species being the second most common cause, including *A. fumigatus*, *A. niger*, and *A. nidulans*.

Corneal trauma is the main predisposing factor, and the incidence of fungal keratitis increases during harvest season, which is consistent with the majority of cases associated with agricultural work, where it affects more males than females of working age. Trauma can be caused by numerous factors, such as airborne soil and plant material. Filamentous fungi are ubiquitous in the environment, especially on plants, and the fungal spores (conidia) can penetrate the corneal epithelium, germinate in the stroma, and if unchecked by the host response or effective antifungal therapy, fungal hyphae will grow in the corneal stroma, penetrate Descemet's membrane, and invade the anterior chamber.

Role of Matrix Metalloproteinases in Fungal Keratitis

Matrix metalloproteinases (MMPs) have an important role in tissue remodeling, wound healing, and inflammation. Rohini and co-workers examined human tears from fungal keratitis patients and corneal sections after keratoplasty and detected elevated collagenases MMP-2 and MMP-8, and the MMP-9 gelatinase, which is consistent with the activation and degranulation of infiltrating neutrophils. In addition to microbial killing, which is primarily mediated by oxygen radicals, neutrophils also prevent microbial dissemination by releasing MMPs and causing local tissue damage. Dong and co-workers as well as Mitchell and co-workers showed that MMP-2 and MMP-9 were also elevated in rabbit and mouse models of *Fusarium* and *Candida* keratitis, and Lin and colleagues demonstrated a role for MMP-8 in corneal inflammation by mediating breakdown of collagen and release of chemotactic Pro–Gly–Pro peptides, which then facilitate neutrophil migration through the cornea. Although differences between *Aspergillus* and *Fusarium* growth in the stroma have been reported by Xie and colleagues, it is not clear at present how this relates to MMP activity, or if there is a difference in protease production by these organisms.

Role of Innate Immunity in Fungal Keratitis

Since the 1960s, it has been apparent that the host immune response regulates fungal growth and the outcome of the infection. In rabbit and murine models of *Fusarium* and *Candida* keratitis in which either conidia or yeast is applied topically to the abraded epithelium, or is injected intrastromally, a neutrophil-rich cellular infiltrate into the corneal stroma ultimately clears the infection. However, subverting the host response by systemic

treatment with cyclophosphamide leads to increased hyphal penetration of the corneal stroma, decreased cellular infiltration, (especially neutrophils), and the unchecked growth of hyphae, causing corneal perforation. These results indicate that the host response plays a critical role in restricting fungal growth in the cornea. To characterize the host response to fungal challenge, *Candida*-infected corneas were processed for microarray analysis, which demonstrated that the proinflammatory cytokines, interleukin-1 (IL-1) and tumor necrosis factor-alpha (TNF-α), were upregulated. To characterize the innate immune response, Tarabishy and colleagues injected *Fusarium* conidia into the corneal stroma of immunocompetent C57BL/6 and mice on the same genetic background in which genes related to the Toll-Like Receptor (TLR) family of pathogen recognition molecules were knocked out. **Figure 2** shows that 6 h after intrastromal injection of 10 000 conidia, hyphae were detected in the corneal stroma of C57BL/6 mice and in mice in which the gene for the MyD88 adaptor molecule common to most TLRs and IL-1R1 is mutated. Although a cellular infiltrate was detected in the peripheral cornea of C57BL/6 mice, this infiltrate was absent in MyD88$^{-/-}$ mice. **Figure 3** shows that whereas C57BL/6 mice rapidly develop corneal opacification associated with a pronounced infiltrate and clear the organisms, MyD88$^{-/-}$ mice had delayed cellular infiltration, and even though neutrophils were recruited to the corneal stroma, they were unable to clear the organisms (**Figures 4** and **5**). *Fusarium* hyphae are detected throughout the cornea (**Figure 5**), which perforated within 4 days. Subsequent experiments showed that IL-1R1 is required for neutrophil recruitment to the cornea, whereas TLR4 is important for fungal killing.

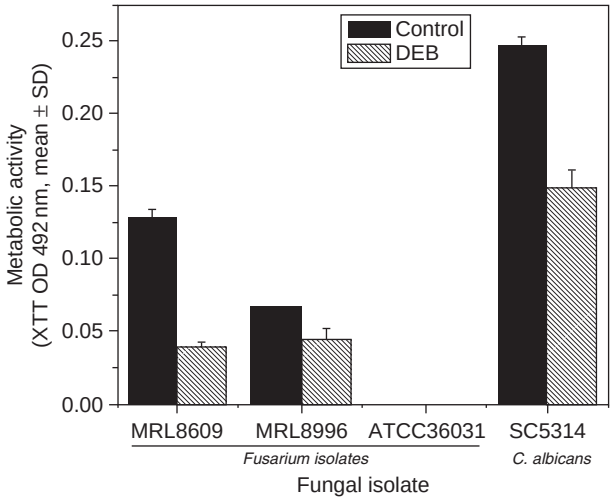

Figure 2 *Fusarium* strain differences in biofilm formation on lotrafilcon A lenses. Biofilms were formed in the absence or presence of DEB (which inhibits biofilm formation) on a lotrafilcon A lens using the FSSC 2-c ATCC 36031 reference isolate or clinical isolate FSSC 1-b (MRL8609), FOSC 3-a (MRL8996). Biofilms were quantified using the XTT metabolic activity assay. Data represent means (+/– SDs) calculated from three separate experiments. Reprinted from Imamura, Y., Chandra, J., Mukherjee, P. K., et al. (2008). *Fusarium* and *Candida albicans* biofilms on soft contact lenses: Model development, influence of lens type, and susceptibility to lens care solutions. *Antimicrobial Agents and Chemotherapy* 52: 171–182.

Murine Model of *Aspergillus* Keratitis

Aspergillus species, the second most common cause of fungal keratitis after *Fusarium*, are also ubiquitous in the environment, and most people inhale hundreds of conidia daily. Although pulmonary aspergillosis occurs primarily in immunosuppressed individuals, this is not the case in keratitis, where the risk factors are similar to those of *Fusarium*, that is, the highest incidence is associated with agriculture and trauma. In addition, *Aspergillus* conidia are smaller than *Fusarium* conidia, can therefore penetrate deeper into the lungs, and likely also penetrate deeper into the corneal stroma. We generated a strain of *Aspergillus fumigatus* expressing a red fluorescent protein, and injected conidia into the corneal stroma of C57BL/6 mice. **Figure 6** shows that after 24 h, the cornea is opaque. However, **Figure 6(b)** also shows that the presence of corneal opacities coincides with the presence of *Aspergillus*. **Figure 6(c)** shows higher magnification of hyphae in the corneal stroma. Ongoing studies are examining the role of the host response and *Aspergillus* virulence factors in the pathogenesis of this disease.

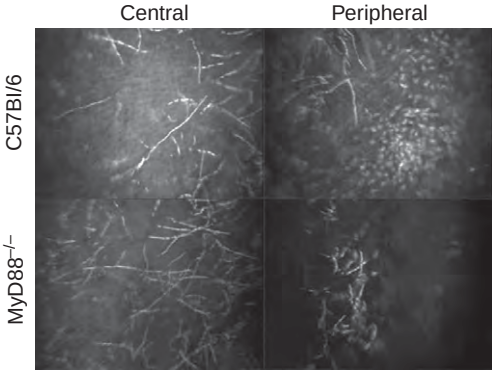

Figure 3 *In vivo* confocal microscopy of *Fusarium* keratitis in C57BL/6 and MyD88$^{-/-}$ corneas. C57BL/6 and MyD88$^{-/-}$ mice were injected intrastromally with 1 × 104 conidia from a clinical isolate of *F. oxysporum*. After 6 h, mice were examined by *in vivo* confocal microscopy (Confoscan). Representative images from the central and peripheral corneal stroma are shown. Note the presence of hyphae in the central corneal stroma of C57BL/6 and MyD88$^{-/-}$ mice (a, c); however, a cellular infiltrate is present in the peripheral cornea of C57BL/6, but not MyD88$^{-/-}$ mice (b, d). Reprinted from Tarabishy, A. B., Aldabagh, B., Sun, Y., et al. (2008). MyD88 regulation of *Fusarium* keratitis is dependent on TLR4 and IL-1R1 but not TLR2. *Journal of Immunology* 181: 593–600.

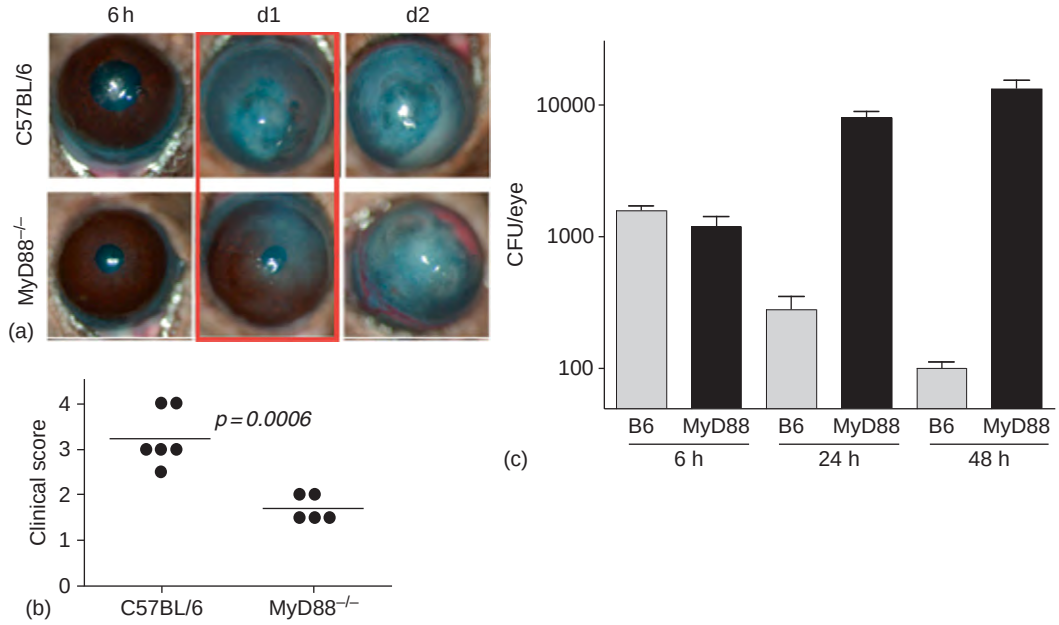

Figure 4 Fungal keratitis in C57BL/6 and MyD88$^{-/-}$ mice. Mice were injected intrastromally with 1 × 104 conidia from a clinical isolate of *F. oxysporum* as described above. Corneal opacification, CFU, and histology were examined by standard methods. (a, b) Corneal opacification in MyD88$^{-/-}$ mice was impaired at 24 h, but increased until 72 h after which time MyD88$^{-/-}$ corneas perforated, whereas C57BL/6 corneas eventually resolved. **(c)** CFU decreased in C57BL/6 mice over time, whereas *Fusarium* replicated in the corneas of MyD88$^{-/-}$ mice. Reprinted from Tarabishy, A. B., Aldabagh, B., Sun, Y., et al. (2008). MyD88 regulation of *Fusarium* keratitis is dependent on TLR4 and IL-1R1 but not TLR2. *Journal of Immunology* 181: 593–600.

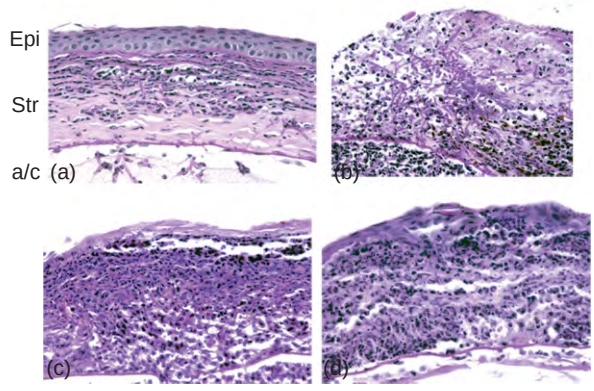

Figure 5 Impaired cellular infiltration in MyD88$^{-/-}$ mice (a, b) Histological analysis in MyD88$^{-/-}$ corneas after PAS staining shows *Fusarium* hyphae penetrating Descemet's membrane after 24 h, and growing in the stroma and anterior chamber after 48 h despite the presence of a cellular infiltrate. In contrast, there was an early and pronounced cellular infiltrate in C57BL/6 mice (c, d) comprised mostly of neutrophils. Reprinted from Tarabishy, A. B., Aldabagh, B., Sun, Y., et al. (2008). MyD88 regulation of *Fusarium* keratitis is dependent on TLR4 and IL-1R1 but not TLR2. *Journal of Immunology* 181: 593–600.

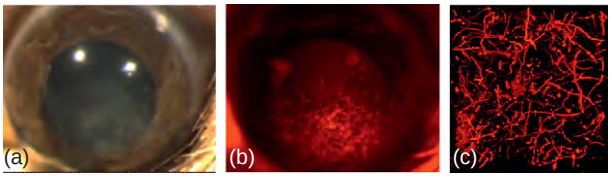

Figure 6 *Aspergillus fumigatus* in murine cornea. *Aspergillus fumigatus* was transfected with a plasmid expressing m-cherry. Conidia were injected into the corneal stroma of C57BL/6 mice, and after 24 h, corneas were examined by light (a) and fluorescence (b) microscopy. (c) Whole mount cornea examined by confocal microscopy.

Conclusions

The pathogenesis of fungal keratitis depends on the balance between the host response and expression of fungal virulence factors. Although some mediators of innate immunity and fungal virulence factors have been identified, it will require a combination of human and animal studies to determine the course of events leading to fungal killing and resolution of infection. Human disease correlates are particularly difficult to study; however, Bochud and co-workers showed that polymorphisms in TLR4 are associated with susceptibility to systemic aspergillosis; therefore, it is possible that TLR4 also mediates susceptibility to *Aspergillus* keratitis.

Pathogenesis of Uveitis in Humans

J V Forrester, University of Aberdeen, Aberdeen, UK

Glossary

Alarmins – The molecules that register danger and, thus, activate the adaptive immune system. These occur in the absence of infection but are capable of inducing inflammation.

Dendritic cells (DCs) – The professional antigen-presenting cells that process and present antigens to T cells.

Experimental autoimmune uveitis (EAU) – An animal model of posterior segment uveitis is elicited when rodents are immunized with interphotoreceptor binding peptide (IRBP) or retinal S-antigen (S-Ag) emulsified in complete Freund's adjuvant (CFA). The inflammation is usually progressive and destroys the retina.

Immune privilege – A condition in which immune responses are either blunted or deviated such that inflammation is reduced and sometimes completely silenced. This is present in the eye and brain and is believed to be an adaptation for controlling inflammation in organs with limited regenerative capabilities.

Pathogen-associated molecular patterns (PAMPs) – The molecular arrays that are present on various microorganisms and are recognized by elements of the innate and adaptive immune systems. These are believed to be important red flags for alerting the immune system, especially cells of the innate immune system, which act as first responders.

T regulatory cells (T regs) – The lymphocytes that maintain self-tolerance and suppress adaptive immune responses. They are believed to be important in preventing or dampening autoimmune responses.

Introduction

Uveitis is a misnomer. The anatomical term for the middle coat of the eye, the uvea, derives from the Latin word meaning grape and was applied to this layer of the eye wall by eighteenth-century anatomists due to the similarity of the intact globe to a large black grape when the outer scleral layer has been removed. The uvea is the lymphovascular layer of the eye and was originally considered to be the target site or locus of inflammation in uveitis. However, although many cases of inflammation could be directly attributed to an infectious agent, numerous studies over many years failed to identify any specific cause in a majority of cases. This led experimental pathologists to the idea of uveitis as an autoimmune condition, and indeed sympathetic ophthalmia, a condition in which the uninjured eye becomes inflamed after penetrating injury to the first eye, probably ranks as the first-described autoimmune disease. Sympathetic ophthalmia had been known from the time of Hippocrates, and was given its name by William McKenzie in 1854, but it was not until the young science of immunology had emerged that this condition was considered autoimmune, that is, a breakdown in tolerance to self-antigens, leading to a specific inflammatory disease.

Since sympathetic ophthalmia was clearly organ specific, and the uvea seemed to be the site of inflammation, it was inevitable that the uveal tract was considered to be the site where the specific self-antigen (autoantigen) was located. Experimental studies were embarked upon to prove this point. These were similar to experiments in other presumed autoimmune animal models of disease, such as encephalomyelitis, where antigenic extracts of brain and spinal cord material were shown to induce inflammation of the central nervous system (CNS) after intradermal inoculation into guinea pigs in an oily emulsion with adiuvant, usually extracts of mycobacteria (complete Freund's adiuvant (CFA)). However, repeated attempts to induce experimental uveitis using intradermal extracts of uveal tissue were not very effective or reproducible. In contrast, a single extract of retinal tissue produced a massive, aggressive, organ-specific ocular inflammation (panuveitis) and further experiments identified the retinal photoreceptor as the source of specific antigens which could cause uveitis/uveoretinitis. This produced a significant conceptual shift in the nature of uveitis as a disease, and has since broadened into considering inflammation of the uveal tract *per se* (uveitis) as one aspect of intraocular inflammation which is distinguishable from extraocular inflammation involving the conjunctiva, the eye lids, or the ocular adnexae. The importance of these experimental studies in shaping our ideas about human uveitis cannot be underestimated.

Currently, it is recognized that there are several retinal and other ocular autoantigens which can induce eye-specific inflammation and that the many clinical forms of human uveitis represent a spectrum of disease which can be

reproduced in different animal models using one or several retinal antigens, that is, there is a common pathway for the pathogenesis of many forms of intraocular inflammation and this includes infectious causes (**Figures 1(a) and 1(b)**). It is important, however, to note that certain pathogens and autoantigens commonly present with characteristic and recognizable clinical signs, which may allow a specific clinical diagnosis, for example, infective cytomegalovirus (CMV) retinitis and autoimmune Vogt–Koyanagi–Harada (VKH) disease, in which one of the autoantigens is a tyrosinase-related protein. Nevertheless, the underlying tissue-damaging processes in most forms of uveitis have many similarities. Interestingly, there is recent evidence that there may be immunological cross-reactivity between tyrosinase peptides and CMV envelope protein peptides.

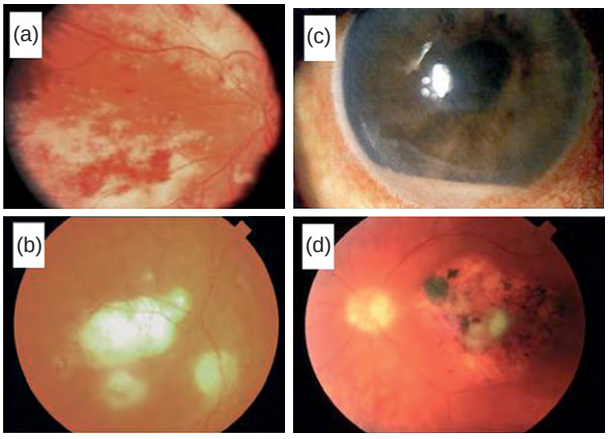

Figure 1 Photographs (a), (b), and (d), show posterior segment of the eye, and (c) shows the anterior segment of the eye of infective and noninfective human uveitis. (a) cytomegalovirus uveoretinitis; (b) toxoplasma chorioretintis; (c) and (d) Behcet's disease.

Causes of Human Uveitis

For centuries, ocular inflammation associated with infective and contagious diseases such as syphilis, rubella, and tuberculosis (TB) has been recognized. All known classes of microorganisms can cause uveitiic disease (**Figure 2**). Whether the ocular damage is caused directly by the infective agent or is the result of the host response to the infectious agent is often not clear, and is only resolved by recourse to a trial of specific therapy, for example, with an antiviral agent.

Infectious Uveitis

Viral disease

Many viruses can cause intraocular inflammation but most of these are of the herpes group, such as herpes simplex, herpes zoster, or CMV. Herpetic infections are contracted during early childhood and in most cases are subclinical. However, the virus remains latent in the ganglia of the nerves and may be reactivated during stress. Recent studies in herpes simplex have revealed that viral latency is achieved in part through virus-specific regulatory $CD8^+$ T cells residing in contact with the latently infected neural cell bodies. This may explain why viral reactivation with severe retinitis and encephalitis occurs in immunocompromised patients. In addition to herpetic disease, other viral diseases affecting the eye which can cause uveoretinitis and retinal vasculitis include

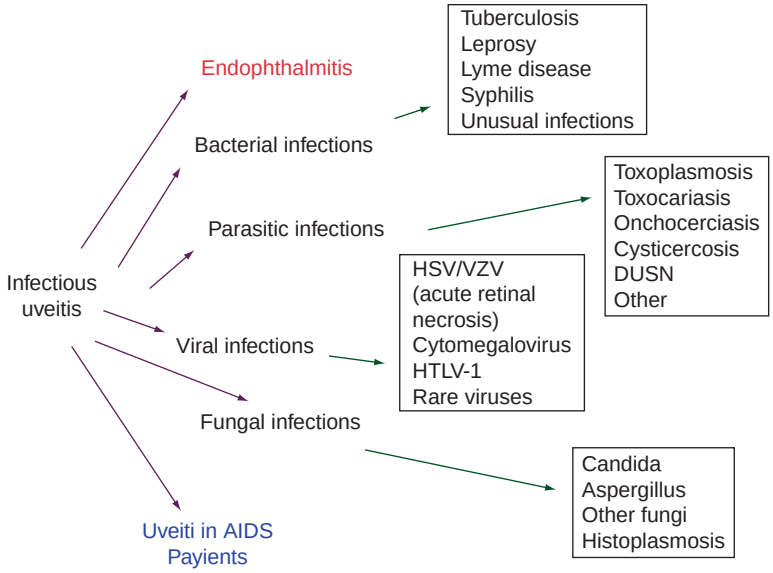

Figure 2 Infective causes of uveitis. HSV, herpes simplex virus; VZV; varicella zoster virus, HTLV-1, human T lymphotrophic virus-1; DUSN, diffuse unilateral subacute neuroretinitis (caused by parasitic worms).

ricekttsial disease and dengue virus, as well as West Nile fever, both of which are vector-borne diseases. The clinical manifestations are indistinguishable from idiopathic retinal vasculitis and frequently there is involvement of the macula in dengue fever while West Nile fever presents as a self-limiting multifocal choroiditis.

In the pathogenesis of viral disease, there is little doubt that replicating virus kills infected cells and in the case of herpes virus, this usually applies to epithelial or neuronal cells. In the eye, direct infection of the retinal nerves and/or the retinal pigment epithelium may explain the progressive clinical brush-fire signs typical of CMV retinitis and HSV-induced acute retinal necrosis, and progression in untreated acquired immune deficiency syndrome (AIDS) patients probably reflects this unchecked disease. However, in immunocompetent individuals with, for instance, HSV-associated recurrent anterior uveitis, or in treated AIDS patients with immune-recovery uveitis, the intraocular inflammation is probably not directly due to the virus but to the host-antiviral immune response.

Parasitic disease

The recognition that toxoplasmosis was a common cause of posterior uveitis, more common than TB, was due to the observations on excised eyes by Wilder Foerster, who demonstrated characteristic trophozoites in 41 adult eyes enucleated for pain and blindness. Despite this, congenital toxoplasmosis contracted *in utero* from maternal infection was considered the main type of ocular toxoplasmosis. It was not till the advent of AIDS that the extremely widespread subclinical infection with toxoplasmosis acquired in adulthood, mostly through ingestion of infected meat and detectable by rising frequency of antitoxoplasma antibodies in the general population, was widely appreciated although authors such as Rieger had suggested this. Pathogenetically, therefore, parasitic infection with toxoplasma organisms is the norm for many adults worldwide and a level of unconscious symbiosis is reached probably because this parasite is intracellular and has disabled macrophage-killing mechanisms while utilizing release of interferon gamma (IFNγ) to suppress CNS inflammation. Only in a few individuals does the organism die *in vivo* and this sets up an inflammatory reaction which is severe if it involves a critical tissue such as the macular area of the retina, or a vital CNS or liver component. As always, in patients who are immunocompromised, as in AIDS patients, the likelihood of this occurring is greatly increased since, although the immune system is evaded, it is not completely disabled and this delicate balance between infection and parasitization is disturbed in AIDS patients.

Other parasitic diseases, such as toxocara, loa loa, cysticercosis, and similar nematodes, can also damage the eye and may do so directly as extracellualr pathogens, as they track through the tissues leaving a pigmentary retinochoroiditis, or a vitreous abscess.

Fungal infections

Most fungal infections are quasi-commensal since they tend to colonize mucosal and skin surfaces. However, they can on occasion invade the tissues, and produce severe systemic infections. Certain fungal infections can directly damage ocular tissues such as the retina and vitreous if they gain access through the bloodstream to the eye, as in intravenous drug users who use infected needles and inject infected substances. In these cases, damage is usually due to the innate immune response induced in the tissues by the organism. For instance, *Candida albicans* generates a massive polymorphonuclear response with abscess formation and tissue damage due to the release of proteolytic enzymes. The pathogenesis of ocular disease in these cases is relatively clear.

More recently, subtle low-grade uveitic disease has been attributed to fungal infection. In the USA, certain forms of subretinal neovascularization with membrane formation have been attributed to low-grade inflammation caused by histoplasma. However, the evidence for histoplasma infection is minimal in these cases, since a similar if not identical clinical condition occurs in Europe and in nonendemic regions of the USA where histoplasma, a soil-residing organism, does not occur. More recently, evidence of antifungal immune reactivity to Candida antigens has been found in patients with certain forms of chronic, progressive posterior uveitis such as serpiginous choroiditis and the ill-defined condition, acute zonal occult outer retinopathy (AZOOR), and thus the possibility that low-grade chronic uveitis may represent damage due to a host-antifungal response from a persistent systemic source of infection requires further investigation.

Pathogenetically, chronic low-grade experimental autoimmune uveoretinitis can be associated with subretinal/intraretinal neovascularization in the late stages, and so a general pathological mechanism may explain this type of uveitic disease, which can produce devastating blindness.

Bacterial infections

Direct suppurative bacterial intraocular infection is not generally regarded as uveitis, but is considered a specific condition, that is, endophthalmitis. It is usually a consequence of direct intraocular inoculation of bacteria as a result of penetrating injury or surgery. However, some forms of postoperative infection can produce a grumbling low-grade inflammation, which is indistinguishable from chronic non-infectious uveitis and only resolve when the intraocular lens implant and the lens capsular bag containing the organism (e.g., propionbacterium) are removed.

Endogenous metastatic bacterial endophthalmitis can also occur usually as part of septicemia from a source of infection elsewhere such as in the kidney or gall bladder.

Bacterial infections may also underlie the pathogenesis of nonendophthalmitic uveitic disease. In patients with

various forms of posterior uveitis including multifocal choroiditis, retinal vasculitis, or panuveitis, infectious agents such as TB, syphilis, *Borrelia burgdorferi* (Lyme disease), and other micro-organisms are considered causative, particularly in endemic areas.

The relationship between active infection and tissue-destructive disease is complex: is loss of function and/or death due to the direct effects of the organism or due to the host defense response as it attempts to get rid of the organism? In this respect, TB presents a model example. Active TB is a global problem and it is estimated that one-third of the world's population is infected. However, the vast majority of patients (>90%) do not have symptoms, that is, the infection is latent. In some recent studies using a sensitive IFNγ-releasing assay, said to be specific for TB, some common and even obscure uveitic conditions have been attributed to tuberculosis. However, there is some concern over the high level of false positives using this assay.

The organism *Mycobacterium tuberculosis* (MTb) infects and resides in macrophages. Nonpathogenic forms of the bacterium kill the macrophage by apoptosis, a process which permits the apoptotic cell membrane to envelop the MTb and prevent its replication. The dead macrophage and its contents are phagocytosed, degraded, and removed by other macrophages. Pathogenic MTb evades this immune response by preventing the apoptotic process and induce a level of necrosis (central caseation) which permits MTb proliferation in the center of the immune granuloma, a structure now recognized to have a degree of immune privilege. A progressively stronger immunological reaction then develops with mounting tissue damage, while the surviving and proliferating MTb act as a sustained source of antigen. In patients with TB-associated disease, especially uveitic disease, it is unclear whether the uveitis is a direct result of infection of ocular tissues or whether it is, as for other infectious diseases, a host response to mycobacterial antigens, released from dead or dying bacteria. The adiuvant effect of mycobacteria is well known to immunologists and a chronic source of extraocular infection could provide a similar *in vivo* adiuvant effect in the presence of cross-reactive antigen. Alternatively, the protective effect of vaccination for MTb could actually generate IFNγ-producing $CD4^+$ Th1 cells which, while limiting bacterial growth, may have a deleterious effect on tissues. Evidence exists that the differential ability of pathogens to induce cytokine in antigen-presenting cells determines the outcome of the infection.

Noninfectious Uveitis

Associated with systemic disease

Several noninfectious conditions are associated with uveitis including sarcoidosis, tubulointerstitial nephritis, and HLA-B27-associated diseases such as ankylosing spondylitis, juvenile idiopathic arthritis, and inflammatory bowel disease. In some of these diseases, the condition is restricted to the anterior segment, while in others there is selective posterior-segment involvement. The etiology and pathogenesis of many of these conditions are obscure but they are commonly believed to be due to autoimmunity to one of more antigens, some of which are widely distributed such as collagen type II or connective tissue proteoglycans, while others are tissue restricted. Sarcoidosis is unusual in this respect in that it has many of the pathological features of TB without the central caseation in the granulomatous lesions. Accordingly, many believe that it has an atypical mycobacterial infectious origin.

As part of a characteristic syndrome

Behcet's disease

This condition also has many characteristics of an infectious disease without clear evidence of an infectious cause. Although described as an entity by Behcet and Adamatiades in the early part of the twentieth century, the condition has an ancient history, being first described by Hippocrates in his book Epidemion. Behcet's disease is common in the Middle East and Asia and has devastating effects on the eye and the CNS, leading to blindness in many cases, mostly due to an occlusive vasculitis. The ocular lesions are very similar to idiopathic retinal vasculitis. Immunologically, it has been difficult to identify any single autoantigen which may be involved and attention has been more recently directed toward a role for the innate immune system in this disease, as a form of auto-inflammatory disease. In particular, polymorphisms in the pathogen-recognition receptor, CARD15 have been described as well as involvement of the natural killer (NK) cell/dendritic cell (DC) cytokine interleukin 15 (IL15).

VKH disease

VKH disease, also known for many years, is a common cause of uveoretinitis in the Far East. Although thought to have a possible infectious etiology, autoimmunity to melanocytic antigens has been demonstrated, and experimentally, antigens to tyrosinase and to tyrosinase-related proteins can produce a similar disease in animals. Interestingly, IL23 and IL17 have been implicated in the pathogenesis of disease in humans.

Idiopathic

This last group of conditions probably comprises the most frequent set of conditions and includes idiopathic retinal vasculitis, multifocal choroiditis, intermediate uveitis, and its variants such as pars planitis, and several vague conditions known as the white-dot syndromes which have considerable clinical overlap. Included in this is sympathetic ophthalmia, probably the first uveitic condition as well

as the first autoimmune disease recognized. Considerable effort has been expended attempting to demonstrate autoimmunity to retinal antigens in many of these conditions and some good evidence has been generated. Despite the fact that several retinal antigens are now recognized as autoantigens, interphotoreceptor retinal-binding protein and its epitopes appear to be a dominant antigen in human disease. However, it is unlikely that a single antigen is the sole culprit particularly for chronic prolonged disease in which inter- and intramolecular epitope spreading are likely to generate reactivities to several potential uveitogenic peptides. The best evidence that idiopathic uveitis is immune mediated, if not directly autoantigenic, is the beneficial response to immunosuppressive agents, an observation that also applies to infectious uveitis, such as toxoplasmosis and tuberculosis, in which there is likely to be a significant and potentially tissue-damaging host immune response.

Classification of Human Uveitis in the Context of Pathological Signs

The bewildering variety of infectious and noninfectious conditions that can present as uveitis or intraocular inflammation has hindered the classification and delayed understanding of the pathological processes at play. Recently, a clinical classification of uveitis has been introduced by the standardization of uveitis nomenclature (SUN) group which has assisted in simplifying the clinical description of uveitis and this should be of considerable value in conducting studies of therapies which will be comparable between centers.

Thus, uveitis is categorized as anterior, intermediate, or posterior on an anatomical basis.

In addition, it is helpful when describing sight-threatening disease to restrict the description to a minimum number of signs which represent activity. Thus, anterior uveitis can be graded for severity on the level of cells and flare (protein) in the anterior chamber, while posterior uveitis can be graded on four basic signs: the level of haze in the vitreous cavity (due to vitreous cellular infiltrates), the number and size of chorioretinal infiltrates (microgranulomata), the degree of retinal vessel inflammation (retinal vasculitis), and the presence of edema (usually macular edema, and also optic nerve swelling and in severe cases, exudative retinal detachment). These signs roughly approximate to the classical signs of inflammation in any tissue and are helpful in correlating pathogenetic mechanisms in experimental and clinical disease.

Pathogenetic Mechanisms in Uveitic Disease

Inflammation is the response of the tissues, or the whole organism, to attack. Attack usually takes the form of invasion by foreign (nonself) microorganisms mediated by pathogen-associated molecular patterns (PAMPs), or can be due to various forms of trauma (danger-associated molecular patterns, DAMPs or alarmins). The organism can also respond to self-antigens if these are altered in any way or presented in a different format or context. Some believe that autoimmune disease is merely an extension of the organism's response to a danger signal represented by pathogenic microorganisms or altered self. Nonpathogenic (commensal) microorganisms and normal self-antigens do not constitute danger and no response occurs to them. This concept can be taken further into the organism by suggesting that some tissues, such as the skin and the lung, respond strongly to danger, and to a wider range of signals, than other tissues such as the brain and the eye. Thus, this provides a novel perspective on immune privilege of certain tissues, of which the eye is the paramount example.

From the above information on the many causes of uveitis in humans, uveitis can be considered the response of the intraocular compartment to a danger signal. This might be an infectious agent (*vide supra* toxoplasma) or it might be an immune-privileged photoreceptor antigen released from the eye after injury (*vide supra* sympathetic ophthalmia). In both cases, the antigen resides in the healthy tissues without causing inflammation, but when the circumstances or conditions change, inflammation ensues.

Thus, the antigen resides in the eye but the cells which induce the inflammation occur outside the eye. In addition, in the case of antigens, a specific (T-cell) response is required. How does this occur?

Tolerance and Its Dysregulation

The initial response to danger signals occurs through the innate immune system in which certain PAMPs are recognized by cells such as DCs and macrophages, NK cells, and gamma–delta T cells. PAMPs activate signal-transduction cascades and induce gene transcription in innate immune cells to generate proinflammatory cytokines. In addition, these cells process foreign antigens, which are then presented to T cells, activating them to enter clonal expansion, release cytokines, and express homing molecules for migration to the site of foreign antigen where they recruit further inflammatory cells, thus removing the antigen, downregulating the inflammation, and repairing the tissue. Self-antigens may also activate PAMPs through generation of DAMPs (alarmins) molecules, which register danger in the absence of infection and induce a similar inflammatory response in the appropriate conditions.

A potentially tissue-damaging response such as the above must be tightly regulated. Regulation of responses to self is mediated through tolerance. Tolerance is generated centrally by essentially deleting all potential self-reactive T-cell clones that might be generated by random

T-cell receptor recombinatorial mechanisms (a similar process occurs in B cells for immunoglobulin molecules), and in the periphery by anergy, deletion, and by generation of a special set of cells known as T regulatory cells (Tregs). Tolerance to nonpathogenic organisms, and even to some potentially pathogenic organisms, is also generated via peripheral mechanisms such as Tregs and by evolutionarily robust evasive tactics utilized by each type of microorganism. Thus, latency, for instance, in herpes viruses and in TB (it is estimated that less than 10% of individuals infected by TB have active disease), represents one form of immune evasion adopted by the microorganism. In a similar manner, the toxoplasma organism resides intact inside macrophages whose killing mechanisms have been disabled.

Self-Antigens versus Foreign Antigens

In inflammatory disease, this homeostatic balance is disturbed. In infectious disease, the organism responds by generating a powerful inflammatory response to get rid of the foreign antigen. In tissues such as the skin, repair of the tissue ensues but an adaptive T- and B-cell response is generated. In tissues such as the eye, the organism may not be able to invoke an immune response because of privilege but memory T cells are now present in the organism available for recall responses, should there be re-infection or even a nonspecific injury (DAMP) response which leads to a cross-reactive immune response. T-cell responses in particular are somewhat degenerate in that a single T cell can respond to a range of antigenic peptides at different levels. Thus, this supposedly tightly regulated adaptive immune response is leaky and cells activated by foreign antigens may have the potential to cross-react with self or other foreign antigens. Clinically, this bystander response is recognized by the increased risk of a recurrent attack of uveitis in patients who have an intercurrent unrelated infection.

Are Antigen-Specific Cells Required to Cause Damage?

As can be deduced from the above discussion, antigen specificity may not be exclusive and, indeed, since there are not only many self-antigens but also many antigens on a single microorganism, it is likely that immune-mediated damage will reflect responses to sets of antigens rather than a single antigen. Despite this, it is recognized that one or a restricted set of antigens in any condition is dominant. In contrast, cells recruited to the tissue to promote damage are relatively nonspecific, although they may be programmed for different activities. These include inflammatory macrophages and T/B cells brought in as part of the overall inflammatory response. For this reason, therapeutic approaches which target the cells causing the damage, such as macrophages and cytokine-producing cells, have proven to be effective in human uveitis, even where the specific causes are unknown.

Cells Regulating Disease

These concepts allow for new approaches to the control of human uveitis. As indicated above, cells regulating inflammation include Tregs which are probably important in downregulating or limiting inflammation. The most well-studied Treg population are the $CD4^+CD25^+$ T cells which occur naturally in the bloodstream at a level of around 3–8%. Two types of Tregs occur, natural Tregs and antigen-specific Tregs. Antigen-specific Tregs are the more suppressive cell type but they can be suppressive to a broad range of T-cell specificities.

Clinical studies of patients with autoimmune diseases, including VKH disease, have suggested that Treg populations are reduced and it has been hypothesized that this permits autoaggressive Tregs to act unhindered. Recent studies on patients with noninfectious uveitis have shown that Treg populations in the bloodstream are reduced, supporting this mechanism of pathogenesis. Experimental studies of autoimmune diabetes, as well as uveoretinitis, have also shown that vaccination with peptide-pulsed DCs suppresses inflammation by expanding Tregs. This approach could be considered for customized control of human uveitis.

Conclusion

In recent years, it has become clear that the classical division between infectious and noninfectious causes of immune-mediated diseases has become blurred at least in pathogenetic terms. On the one hand, there are many obviously infectious causes of sight-threatening uveitis, which respond well to specific antibiotic treatment, but many others in which the immune component (host response) may itself lead to severe tissue damage; this can be ameliorated by immunosuppressive treatments. On the other hand, well-defined autoimmune, noninfectious uveitis has been difficult to demonstrate in humans despite the well-described experimental models of autoimmune disease. Perhaps, there is a collaboration between the microbe and the host, the resultant of which can lead to many outcomes, including the most beneficial one to the host (i.e., clearance of the microbe), parasitism and latency, which are beneficial to the microbes (the most common outcome), or chronic disease in which active infection may be suspected but difficult to detect (e.g., sarcoidosis), but a dysregulated immune response sustains

a chronic, persistent response to sequestered (foreign or self) antigen. This unifying view of disease pathogenesis may help us to develop alternative approaches to their management.

Pathological Retinal Angiogenesis

A P Adamis, University of Illinois, Chicago, IL, USA

Glossary

Angiogenesis – The formation of new vessels from differentiated vasculature.
Chemoattractant – A chemical agent that induces cell migration (chemotaxis) toward the agent.
Embryogenesis – The phase of prenatal development involved in the establishment of the basic body form.
Hypoxia – A decrease below normal in the oxygen levels of a tissue.
Ischemia – Local loss of blood supply, with concomitant hypoxia, due to mechanical obstruction or degeneration of blood vessels.
Neovascularization – Proliferation of blood vessels in tissues not normally containing them or proliferation of blood vessels of a different kind than usual.
Uveitis – Inflammation of the uveal tract, which includes the iris, ciliary body, and choroid.
Vasculogenesis – Blood vessel formation occurring *de novo* from embryonic endothelial precursor cells (angioblasts).

Introduction

Research into the physiological development of the retinal vasculature and various ocular neovascular diseases has led to a deeper understanding of the molecular and cellular mechanisms underlying normal and pathological retinal vascularization. During embryogenesis, the developing retina is initially supplied by the hyaloid vasculature, which is then supplanted by a vascular plexus that originates at the optic nerve head and spreads peripherally. Subsequent remodeling and pruning leads to the formation of two additional parallel networks in the nerve fiber and inner plexiform layers, together with a circular avascular zone at the fovea.

Two basic mechanisms, vasculogenesis and angiogenesis, underlie the formation of new blood vessels; their relative contribution to the formation of the superficial retinal vasculature is a focus of some disagreement. Vasculogenesis, the differentiation of blood vessels from angioblasts, has been proposed as the mechanism for the formation of primary retinal vascular plexus, with deeper layers developing by angiogenesis; in contrast, it has been argued that all three vascular layers develop through angiogenesis, the formation of new vessels from differentiated vasculature. This process involves both sprouting from differentiated tip cells as well as intussusception, the splitting of existing vessels. The question as to the importance of vasculogenesis ultimately depends on the cellular identity of retinal precursors, and it is possible that some of the discrepancies may reflect species differences among mammals.

With respect to pathological retinal neovascularization, there is general agreement that angiogenesis is the driving mechanism. Many retinal neovascular conditions are associated with ischemia, with the resultant hypoxia leading to the upregulation of proangiogenic molecules. Depending on the particular disease, different pathophysiological mechanisms lead to a common endpoint of local ischemia and neovascularization. In central retinal vein occlusion, ischemia is a direct result of venous blockage. In proliferative diabetic retinopathy (PDR), the mechanism is more complex; the accumulation of polyols, reactive oxygen intermediates, and advanced glycation end products results in inflammation accompanied by retinal leukostasis leading to vascular injury, capillary blockage, and dropout. A third mechanism for ischemia-mediated neovascularization is seen in retinopathy of prematurity (ROP) in which premature birth interrupts the normal retinal vascular development; not only is postnatal tissue oxygen significantly higher than *in utero* but the effects are compounded by the use of oxygen therapy as well. Ultimately, these high oxygen levels lead to an increased rate of vascular pruning with ischemia-mediated increases in vascular endothelial growth factor (VEGF) levels and the resultant rebound aberrant neovascularization, which can be accompanied by retinal detachment. Finally, it should be noted that not all pathological retinal neovascularization is related to hypoxia since it is also observed in inflammatory conditions such as severe uveitis.

Promoters and Inhibitors of Angiogenesis

Over the past two decades, the identification and study of modes of action of proangiogenic and antiangiogenic factors have yielded an extensive list in both categories (see Table 1). While much of this work has been directed to developing treatments for cancer, considerable progress has also been made in elucidating the importance of these factors in ocular neovascular diseases. This article

Table 1 Proangiogenic and antiangiogenic factors

Proangiogenic and antiangiogenic factors	
Proangiogenic factors	*Antiangiogenic factors*
Angiogenin	Angioarrestin
Angiopoietin-1	Angiostatin (plasminogen fragment)
Complement factors C3 and C5	Antiangiogenic antithrombin III
Cryptic collagen IV fragment	Cartilage-derived inhibitor (CDI)
Developmentally regulated endothelial locus 1 (Del-1)	CD59 complement fragment
Ephrins/Ephs	Endostatin (collagen XVIII fragment)
Erythropoietin	Fibronectin fragment
Fibroblast growth factors; acidic (aFGF) and basic (bFGF)	Growth-related oncogene (Gro-β)
Follistatin	Heparinases
Granulocyte colony-stimulating factor (G-CSF)	Heparin hexasaccharide fragment
Hepatocyte growth factor (HGF)/ scatter factor (SF)	Human chorionic gonadotropin (hCG)
Interleukin-8 (IL-8)	Interferon α/β/γ
α5 integrins	Interferon-inducible protein (IP-10)
Leptin	Interleukin-12
Matrix metalloproteinases	Kringle 5 (plasminogen fragment)
Midkine	Metalloproteinase inhibitors (TIMPs)
Notch/D114	2-Methoxyestradiol
Pigment epithelium-derived growth factor	Pigment epithelium-derived growth factor
Placental growth factor	Placental ribonuclease inhibitor
Platelet-derived endothelial cell growth factor (PDECGF)	Plasminogen activator inhibitor
Platelet-derived growth factor-B (PDGF-B)	Platelet factor-4 (PF4)
Pleiotrophin (PTN)	Prolactin 16-kD fragment
Progranulin	Proliferin-related protein (PRP)
Proliferin	Retinoids
Transforming growth factor-α (TGF-α)	Slit/Robo4
Transforming growth factor-β (TGF-β)	Soluble VEGFR1
Tumor necrosis factor-α (TNF-α)	Tryptophanyl-tRNA synthase fragment
Vascular endothelial growth factor (VEGF)	VEGFxxxb
	Tetrahydrocortisol-S
	Thrombospondin-1 (TSP-1)
	Transforming growth factor-β (TGF-β)
	Vasculostatin
	Vasostatin (calreticulin fragment)

Table 2 Actions of VEGF in promoting angiogenesis

- Endothelial cell mitogen
- Endothelial cell survival factor
- Chemoattractant for bone marrow-derived endothelial cells
- Chemoattractant for monocyte lineage cells
- Inducer of synthesis of endothelial nitric oxide synthase and consequent elevation of nitric oxide, itself a promoter of angiogenesis
- Inducer of synthesis of enzymes promoting blood vessel extravasation
  - Matrix metalloproteinases
  - Plasminogen activator

examines the evidence for those molecules whose roles are best understood in the context of pathological retinal angiogenesis.

Promoters of Angiogenesis

Vascular endothelial growth factor

VEGF (also known as VEGF-A) is a 45-kDa homodimeric glycoprotein that is the most potent known promoter of angiogenesis. It exists in a variety of isoforms and acts as a ligand for two receptor tyrosine kinases: VEGF receptor-1 (VEGFR1) and VEGF receptor-2 (VEGFR2). As a key regulator of angiogenesis, VEGF has a variety of proangiogenic actions (**Table 2**). Given the importance of ischemia in many retinal neovascular diseases, it is of particular relevance that retinal expression of VEGF is upregulated by hypoxia. In addition, it is an extremely potent known promoter of vascular permeability, 50 000 times stronger than histamine, thereby contributing to the edema that is often a central factor in vision loss.

The importance of VEGF in pathological retinal neovascularization has been established from both clinical and preclinical studies. The clinical work is correlative, demonstrating that ocular VEGF levels are increased in diseases such as diabetic retinopathy (DR), diabetic macular edema (DME), ROP, neovascular glaucoma, and retinal vein occlusion and in choroidal neovascular membranes from eyes of patients with age-related macular degeneration (AMD). With respect to the preclinical work, elevations of VEGF, whether by laser-induced retinal vein occlusion, direct injection, or transgenic approaches, all have proved capable of inducing ocular neovascularization.

Moreover, VEGF elevation has also been shown to be necessary for the neovascular response since blocking VEGF signaling prevents blood vessel growth. The approaches employed in these experiments have included the use of anti-VEGF antibodies or fragments thereof, an anti-VEGF aptamer, VEGFR fusion proteins, a nonangiogenic isoform of VEGF, antisense oligonucleotides, and small interfering RNAs. This work already has resulted in the clinical approval of two agents for the treatment of

AMD, pegaptanib and ranibizumab. Additionally, bevacizumab, a monoclonal antibody related to ranibizumab, increasingly is being used off-label for the treatment of AMD and other ocular neovascular diseases while VEGF-Trap, a fusion protein combining components of both VEGFR1 and VEGFR2, currently is being examined in a phase 3 trial as a treatment for AMD.

Studies have further demonstrated that ocular neovascular diseases such as AMD and DR bear many hallmarks of an inflammatory process, with VEGF acting as a pro-inflammatory cytokine. Genetic studies have revealed that the risk of AMD is strongly correlated with polymorphisms of several components of the complement cascade. In addition, retinal leukostasis is believed to be important in the capillary dropout characteristic of DR, leading to the development of ischemia. Furthermore, while the molecular mechanisms involved in ischemia-mediated ocular neovascularization remain to be fully elucidated, the influx of inflammatory cells, including monocytes/macrophages (**Figure 1**) and neutrophils, is important for its development. Both of these cell types release VEGF. Since VEGF acts as a chemoattractant for macrophages while upregulating the expression of intercellular adhesion molecule-1 (ICAM-1), a molecule that promotes leukocyte adhesion, on influx of these inflammatory cells provides an inherent positive-feedback mechanism promoting neovascularization.

In detailed studies of VEGF action, the VEGF165 isoform proved to be especially active as an inflammatory cytokine, since it was highly expressed during ischemia-mediated neovascularization. VEGF165 was also more potent than VEGF121, another common isoform, both

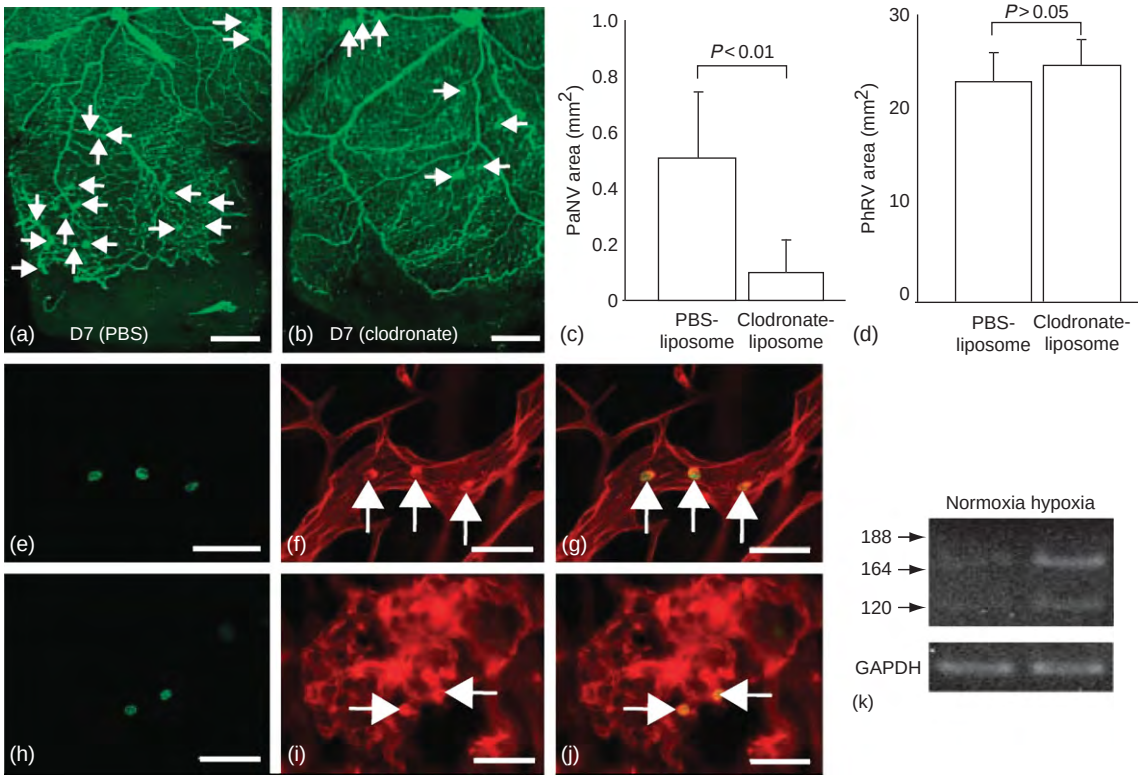

Figure 1 Monocytes contribute to pathological retinal neovascularization. In a ROP model, postnatal day zero (P0) rats were maintained for 10 days in 80% oxygen, interrupted daily by 30 min in room air followed by a progressive return to 80% oxygen. This treatment led to an avascular retina. On P10, corresponding to study day 0 (D0), retinal revascularization was induced by maintaining the rats in room air for an additional seven days (D7). (a–c) At D7, pathological neovascularization (PaNV; arrows in (a) and (b)) was significantly inhibited by treatment with clodronate liposomes compared to phosphate buffered saline (PBS) control liposomes ($n = 8$ for both treatments; mean ± standard deviation). (d) Physiological retinal vascular area (PhRV) was not significantly affected by treatment with clodronate liposomes ($P > 0.05$). (e–j) Influx of monocytes was observed just before and during pathological neovascularization (h–j). Monocytes were labeled with a fluorescein conjugated antibody to CD13 (e and h) while rhodamine-conjugated Concanavalin A was used to label the retinal vasculature and adherent leukocytes (f and i). As shown by superposition of these figures (panels (g) and (j)), the Concanavalin A and CD13 staining co-localized, indicating that the adherent leukocytes were monocytes. (k) In cultured peripheral blood monocytes obtained from retinopathologic rats at D7, exposure to hypoxia (1% oxygen) led to a marked increase in the expression of vascular endothelial growth factor mRNA compared to exposure to normoxia (21% oxygen). GAPDH; glyceraldehyde 3-phosphate dehydrogenase (used as a loading control). Scale bars: (a and b) 0.5 mm and (e–j) 50 μm. Originally published in *The Journal of Experimental Medicine.* doi:10.1084/jem.20022027.

as a macrophage chemoattractant and as a promoter of ICAM-1 upregulation.

Placental growth factor

Placental growth factor (PlGF) is a structurally related member of the same superfamily as VEGF, with all four PlGF isoforms acting as ligands for VEGFR1. PlGF has been implicated in a variety of physiological processes, including serving as a chemoattractant for monocytes and endothelial progenitor cells. Although ablation of the PlGF gene did not prevent embryonic angiogenesis, loss of PlGF led to impaired angiogenesis during conditions of ischemia and inflammation. In murine models, PlGF was found to be essential for the full expression of pathological neovascularization in laser-induced choroidal neovascularization (CNV) as well as for angiogenesis in tumors that were resistant to VEGFR inhibitors. Moreover, intravitreal injection of PlGF was shown to induce retinal edema in a rodent model, reflecting a disruptive effect on the retinal pigment epithelium. PlGF accordingly has attracted interest as a possible therapeutic target, and inhibition of its function is believed to contribute to the efficacy of VEGF-Trap, which, as discussed above, has been engineered to include the binding sites of both VEGFR1 and VEGFR2.

Platelet-derived growth factor

The platelet-derived growth factor (PDGF) family includes four members (PDGF-A through PDGF-D), with active forms being dimers and usually occurring in the homodimeric form. They serve as ligands for two receptor kinases, PDGFR-α and PDGFR-β. PDGF-B, acting through PDGFR-β, mediates most of the actions of PDGF in vascular development. Gene knock-out of either PDGF-B or PDGFR-β resulted in perinatal death owing to vascular deformities. In addition to promoting endothelial cell proliferation and capillary tube formation, PDGF-B signaling is especially important for the proliferation and recruitment of mural cells (pericytes and vascular smooth muscle cells) to the embryonic vasculature and for the maintenance of pericyte coverage (**Figure 2**). These actions are also essential for proper retinal vascular development. Endothelial cell-restricted ablation of PDGF-B produced defective pericyte coverage of retinal vessels and associated proliferative retinopathy; a similar phenotype resulted from the administration of an inhibitor to PDGFR signaling.

Investigations have demonstrated a complex interaction between PDGF and VEGF. During embryonic development, pericyte coverage was found to lag behind growth of retinal capillaries for several days, giving rise

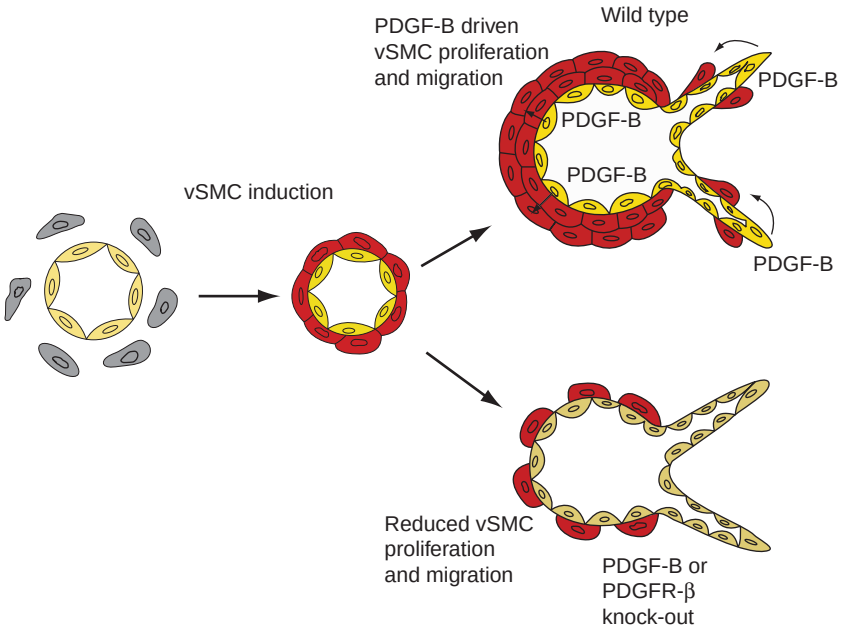

Figure 2 Platelet-Derived Growth Factor (PDGF)-B regulates the development of blood vessel walls. During blood vessel development, the nascent endothelial tube (yellow) is surrounded by undifferentiated mesenchymal cells (gray) that are induced to differentiate into vascular smooth muscle cells (vSMC) and to form a surrounding sheath (red). During further development of the vascular network, with concomitant growth and sprouting of blood vessels, PDGF-B derived from the endothelium further promotes vSMC proliferation and migration. These proliferative and migratory responses are reduced in mice in which PDGF-B or the corresponding receptor, PDGFR-β, have been genetically ablated, leading to defective coating of capillaries by pericytes as well as to vSMC hypoplasia in larger vessels. Reproduced with permission from Hellstrom, M., Kalen, M., Lindahl, P., Abramsson, A., and Betsholtz, C. (1999). Role of PDGF-B and PDGFR-beta in recruitment of vascular smooth muscle cells and pericytes during embryonic blood vessel formation in the mouse. *Development* 126: 3047–3055.

to an optimum window in which nascent blood vessels were especially vulnerable to VEGF depletion. Further investigations have revealed that the inhibition of both PDGF and VEGF signaling is quite effective in inhibiting ocular neovascularization. In experiments with three different murine models, VEGF inhibition was more effective for immature vessels while mature vessels were sensitive to PDGF-B. In every case, however, the most effective inhibition was achieved by interference with both signaling pathways (**Figure 3**).

Notch

The Notch family of cell surface proteins, consisting in mammals of four members, Notch1 through Notch4, is activated by ligands of the Jagged and Delta families and regulates pattern formation of numerous tissues, including those of the kidney, nervous system, and cardiovascular system. In its actions in the vascular system, the principal ligand for Notch is Dll4. Several recent studies have identified a key role for this signaling pathway as a negative regulator of retinal vessel patterning. Even heterozygous ablation of the dll4 gene led to dramatic increases in branching while other approaches to inhibiting the Notch pathway also caused excessive tip-cell (specialized endothelial cells which form the leading edge of vascular sprouts to initiate vessel branching) formation and endothelial cell proliferation. In a tumor model, blockade of the Notch pathway increased tumor vascularity but the vessels were nonproductive, resulting in decreased tumor growth. These findings are believed to reflect the importance of Dll4/Notch signaling in the negative regulation of VEGF-mediated angiogenic sprouting (**Figure 4**). Finally, the loss of Notch3 signaling mechanism has been found to interfere with mural cell differentiation, an action that may reflect Notch-mediated upregulation of PDGFR-β in vascular smooth muscle cells.

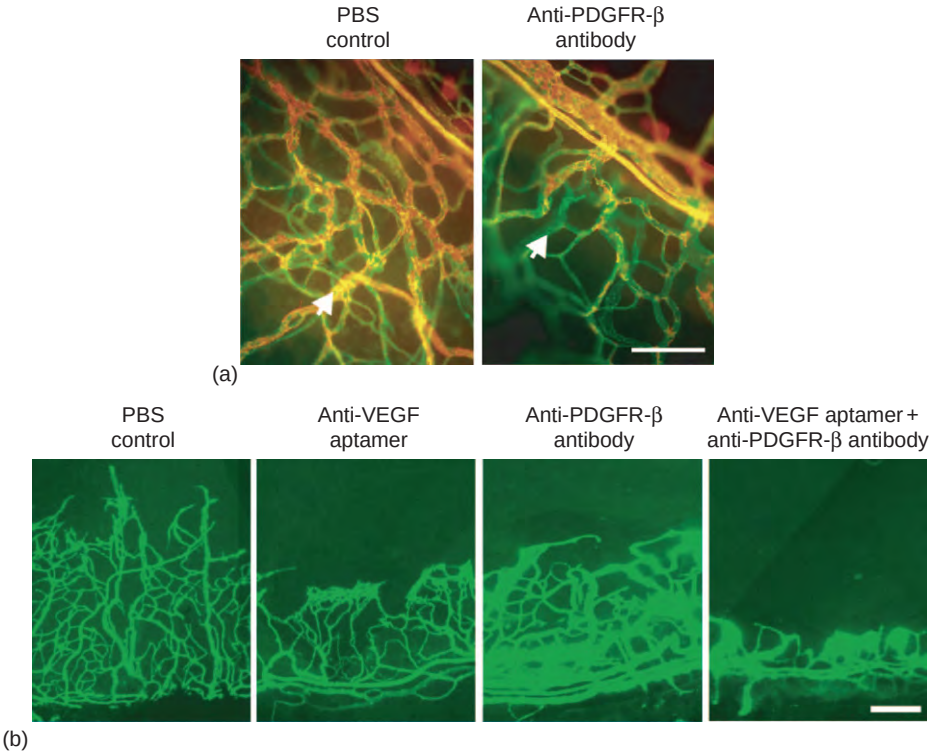

Figure 3 The role of platelet-derived growth factor (PDGF)-B in blood vessel growth and mural cell coverage in a corneal neovascularization model. (a) Endothelial cells were labeled by staining with lectin (green) and mural cells were stained with an antibody against smooth muscle actin (red). Starting at 10 days following corneal injury, mice received daily intraperitoneal injections of an anti-PDGFR-β antibody or phosphate-buffered saline (PBS) and were sacrificed at 20 days postinjury. Treatment with the anti-PDGFR-β antibody led to reduced mural cell coverage compared to controls (arrows). Scale bar = 20 μm. (b) Following induction of corneal injury, mice received daily intraperitoneal injections of one of the following: PBS; a polyethylene-glycolated antivascular endothelial growth factor (VEGF) aptamer; an anti-PDGFR-β antibody, or both the antiVEGF aptamer and the anti-PDGFR-β antibody. Neovasculature (green) was stained by fluorescein isothiocyanate–Concanavalin A. Neovascularization was significantly reduced by the antiVEGF aptamer compared with either PBS or the anti-PDGFR-β antibody ($P < 0.01$); inhibition of both VEGF and PDGF-B signaling led to a further significant reduction ($P < 0.05$), compared to inhibition of VEGF signaling alone. Scale bar = 100 μm. Adapted from Jo, N., Mailhos, C., Ju, M., et al. (2006). Inhibition of platelet-derived growth factor B signaling enhances the efficacy of anti-vascular endothelial growth factor therapy in multiple models of ocular neovascularization. *American Journal of Pathology* 168: 2036–2053. Copyright – The American Society for Investigative Pathology.

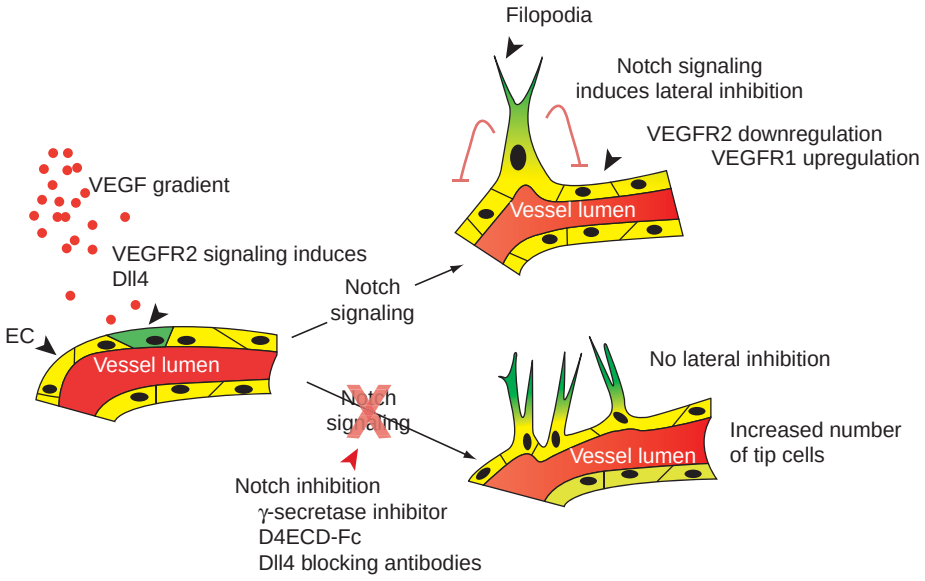

Figure 4 Role of Dll4/Notch in preventing tip-cell formation and branching. Schematic representation showing how Dll4/Notch signaling prevents excessive branching by inhibiting tip-cell phenotype. In response to a local gradient of vascular endothelial growth factor (VEGF), endothelial cells become tip cells and induce local Dll4 expression. This in turn activates Notch signaling in the neighboring cells and prevents these cells from becoming tip cells (lateral inhibition) through the induction of VEGFR1 and the downregulation of VEGFR2. Subsequently, these cells will become trunk/stalk cells and adopt the proliferative behavior necessary for vessel elongation. In the absence of Notch signaling, lateral inhibition is not induced and multiple branching occurs. Adapted from Sainson, R. C. and Harris, A. L. (2008). Regulation of angiogenesis by homotypic and heterotypic notch signalling in endothelial cells and pericytes: From basic research to potential therapies. *Angiogenesis* 11: 41–51, with permission from Springer.

Tumor necrosis factor-α

Tumor necrosis factor-α (TNF-α), a member of a large superfamily of cytokines and their receptors that are involved in regulating numerous physiological processes, is an important mediator of inflammation. Clinical studies have detected TNF-α in the fibrovascular membranes of patients with PDR and CNV. In two small case series, intravenous administration of infliximab, a monoclonal antibody directed against TNF-α, led to the regression of CNV in patients with AMD and to the alleviation of macular edema in patients with DME. In addition, a case report has described a similar regression of uveitis-induced neovascularization with this approach.

The mechanisms underlying the actions of TNF-α in ocular neovascularization have yet to be elucidated. TNF-α has been found to upregulate the synthesis of a number of genes that are important for angiogenesis, including VEGF, VEGFR2, angiopoietins 1 and 2 (Ang1 and Ang2), matrix metalloproteinases (MMPs) 2 and 9, PDGF-B, and the Notch ligand Jagged-1. The increase in Jagged-1 may account for the recent finding that TNF-α can induce the formation of tip cells.

Gene ablation studies in mice have been inconsistent, with some studies finding inhibition of retinal neovascularization in response to interference with TNF-α signaling, while others did not. Inhibition of laser-induced CNV by agents targeting TNF-α has been observed, though, both with intravitreal injection of infliximab and intraperitoneal administration of etanercept, a fusion protein containing the TNF-α receptor. Also, TNF-α signaling was determined to be important for ischemia-mediated neovascularization in the hind limbs of mice. Taken together, these data suggest that TNF-α may serve as a potential molecular target for controlling ocular neovascularization.

Ephrins and Ephs

Ephrins are a family of ligands that bind to the Eph receptor tyrosine kinases. The ephrins fall into two broad classes, the ephrinAs, which are attached to the cell membrane by a glycosylphosphatidyl anchor, and the ephrinBs, which span the cellular membrane and possess a cytoplasmic signaling domain (**Figure 5**). There is a corresponding division among the Eph kinases, which fall into A and B subclasses, with ephrinAs binding primarily to EphAs and ephrinBs to EphBs. Because of the tethered nature of the ephrins, ephrin–Eph signaling requires cell–cell contact and can proceed in either the forward or reverse direction. In addition to angiogenesis, ephrin–Eph interactions are required for the proper development of the nervous and cardiovascular systems as well as such processes as insulin secretion and trafficking of immune cells.

Evidence has been adduced supporting the roles of both major Eph/ephrin classes in angiogenesis, including retinal neovascularization. A soluble EphA-containing fusion protein significantly inhibited VEGF- or ephrinA1-induced

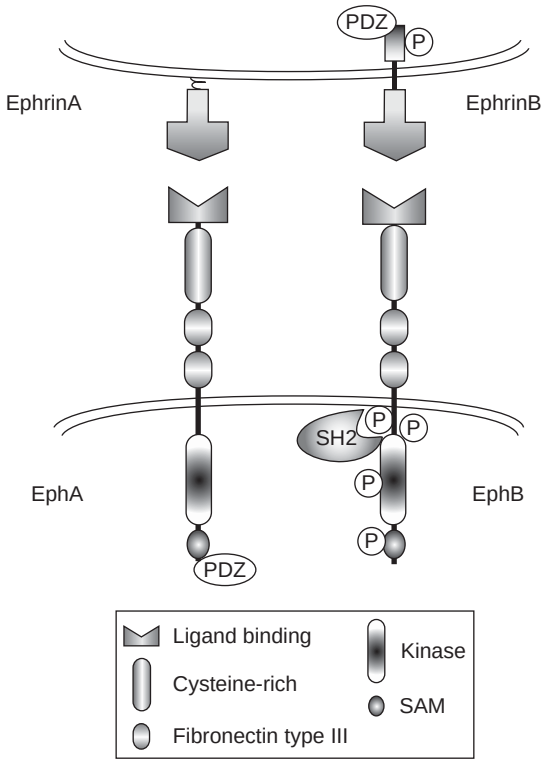

Figure 5 Ephrins and their Eph receptors. While both ephrins and Eph receptors are membrane-tethered proteins, ephrinBs traverse the membrane and possess a cytoplasmic signaling domain while ephrinAs do not. Ephrin–Eph binding results in receptor clustering followed by autophosphorylation of multiple tyrosine residues and docking of downstream effectors through *src*-homology domains. The presence of a sterile alpha motif (SAM) and a PDZ domain (shown here for the carboxy terminus of EphA but also present in EphB) promotes ligand-induced receptor clustering. Adapted from Dodelet, V. C. and Pasquale, E. B. (2000). Eph receptors and ephrin ligands: Embryogenesis to tumorigenesis. *Oncogene* 19: 5614–5619, with permission from Nature Publishing Group.

endothelial cell migration and assembly into capillary tubes *in vitro*, and when injected intravitreally the fusion protein also suppressed retinal neovascularization in a murine ROP model.

More extensive data are available implicating ephrinB/Eph signaling. In clinical studies, both EphB2 and EphB3 were found to be expressed in fibroproliferative membranes of patients with ischemic ocular neovascularization. Genetic ablation of either ephrinB2 or EphB4 led to homozygous embryonic lethality owing to aberrant development of the vasculature. Analysis of expression patterns suggested that ephrinB2 is expressed mainly on arteries and EphB4 on veins, and that these molecules act in defining arterial or venous identity.

Preclinical studies of the role of ephrinB/EphB in ocular neovascularization have not been consistent, however. In corneal models, neovascularization was promoted by ephrinB2, or fusion proteins containing it, and by an EphB1 fusion construct. In contrast, administration of soluble forms of EphB4 inhibited laser-induced CNV in rats as well as ischemia-induced retinal neovascularization in mice; the inhibition of retinal neovascularization also was seen when using soluble ephrinB2. Further work clearly is required if the ephrin/Eph systems can be considered as potential therapeutic targets.

Angiopoietins

Ang1 and Ang2 are members of a family of secreted ligands for Tie2, a receptor tyrosine kinase whose function is essential for vascular development and remodeling. Although Ang1 and Ang2 both activate Tie2, they usually act antagonistically. Similar lethal phenotypes involving gross vascular defects resulted from genetic ablation of Tie2 or Ang1 as well as from the overexpression of Ang2. While the effects of both Ang1 and Ang2 are complex, the overall action of Ang1 is to stabilize the quiescent vasculature while Ang2 is a destabilizing agent for the vascular endothelium (**Figure 6**).

Ang1, which is secreted by vascular smooth muscle cells, acts as a survival factor for endothelial cells *in vitro* and also can promote endothelial cell sprouting and tissue invasion of new blood vessels. In transgenic mice, co-expression of VEGF and Ang1 led to an additive effect on angiogenesis, but co-expression of Ang1 was found to suppress the leakiness of vessels induced by VEGF alone. Recently, this stabilizing effect has been shown to involve Ang1-mediated inhibition of the VEGF-induced internalization of vascular endothelial cadherin, a key component of adherent junctions. In addition, Ang1 inhibited other VEGF-mediated pro-inflammatory actions, including the upregulation of tissue factor, ICAM-1, and vascular cell adhesion molecule-1. Intravitreal injection of Ang1 also prevented many of the inflammatory changes characteristic of DR. In transgenic models, overexpression of Ang1 inhibited the development of laser-induced CNV and retinal neovascularization.

In contrast to the stabilizing effects of Ang1, Ang2 is primarily a destabilizing agent. In clinical studies, elevated levels of Ang2 and VEGF were detected in the vitreous of patients with DR as well as in choroidal neovascular membranes. Ang2 is synthesized by arterial smooth muscle cells and by endothelial cells where it is stored in Weibel-Palade bodies upon activation in response to stimuli such as thrombin or histamine, and sensitizes the endothelium to pro-inflammatory cytokines such as TNF-α. In addition to being upregulated by hypoxia and VEGF, Ang2 appears to act in concert with VEGF in many contexts, including enhancement of endothelial cell permeability. In several different rodent models, Ang2 was found to co-operate with VEGF in promoting neovascularization, but if VEGF levels were low, overexpression of Ang2 led to its regression.

Taken together, these findings suggest that Ang1 could have therapeutic potential as an antiangiogenic agent on

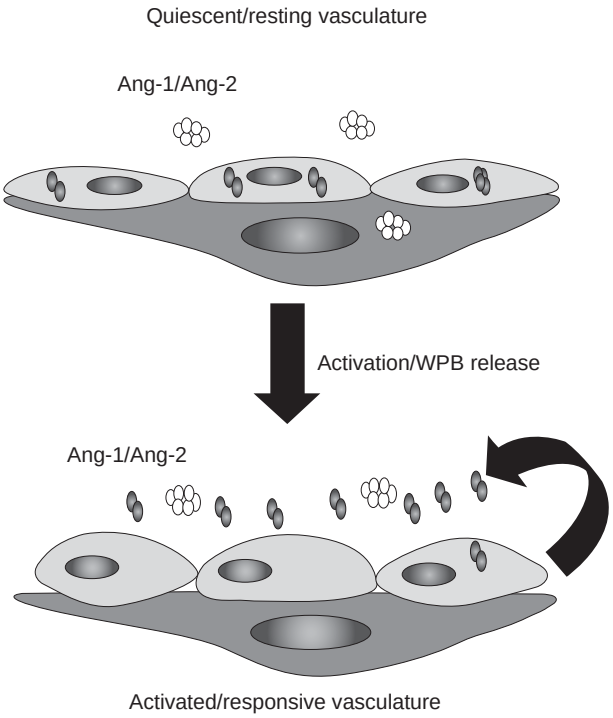

Figure 6 Regulation of vascular responsiveness by Ang1 and Ang2. Angiopoietin 1 (Ang1) (multimeric, white) is secreted constitutively at a low level by mural (periendothelial) cells, and acts on the quiescent endothelium to sustain a low-level activation of Tie2, thereby helping to maintain the luminal cell surface in an antithrombotic and antiadhesive state. Ang2 (dimeric, gray) is stored in Weibel-Palade bodies (WPB) in the endothelium and during endothelial cell activation is released from them, along with other stored factors, leading to the Ang1/Ang2 ratio being altered more in favor of Ang2. As a result, the endothelial cell layer becomes destabilized and more responsive to pro-inflammatory stimuli. Reproduced with permission from Pfaff, D., Fiedler, U., and Augustin, H. G. (2006). Emerging roles of the Angiopoietin–Tie and the ephrin–Eph systems as regulators of cell trafficking. *Journal of Leukocyte Biology* 80: 719–726.

its own. For Ang2, the situation is more complex, although it may have promise if administered together with a VEGF-suppressive agent.

Erythropoietin

While primarily identified as a promoter of erythropoiesis, erythropoietin also acts as a neuroprotective agent and as a promoter of angiogenesis. It plays an essential role in establishing the vascular network following vasculogenesis in that homozygous deletion of erythropoietin or its receptor leads to embryonic lethality with extensive vascular anomalies. In ischemic conditions, erythropoietin (which is itself upregulated by hypoxia) upregulates VEGF and VEGFR2 and promotes the recruitment of bone marrow-derived endothelial progenitor cells.

Correlative clinical findings implicate erythropoietin in ocular neovascular disease. Elevated ocular levels of erythropoietin were detected in patients with DME and PDR; in addition, treatment of premature infants with erythropoietin has been correlated with an increased risk of ROP. Preclinical studies are limited to one report in which intravitreal administration of a soluble erythropoietin receptor inhibited ischemia-induced neovascularization in a murine model. While not extensive, the available data suggest that further studies are warranted.

Integrins

Integrins comprise a large family of transmembrane cell surface receptors that transduce signals from ligands in the extracellular matrix to the cytoplasm. Each integrin is composed of one α and one β subunit; each subunit class contains many representatives, and more than 24 α–β combinations have been observed. The principal focus of integrin research has been their relevance to cancer, and in this context they play important roles in angiogenesis.

Studies with small molecule antagonists have identified a role for the $\alpha_5\beta_1$ integrin in murine models of ocular neovascularization. These inhibitors include JSM5562, which inhibited corneal neovascularization, and a related molecule, JSM6427, which inhibited laser-induced CNV and ischemia-induced retinal neovascularization. Studies indicated that $\alpha_5\beta_1$ contributed to an angiogenic pathway that was distinct from VEGF-mediated angiogenesis, suggesting that combinatorial approaches may offer the promise of even greater efficacy.

Matrix metalloproteinases

The MMPs comprise a large family of enzymes that degrade the extracellular matrix, facilitating the tissue penetration of nascent blood vessels. While the primary focus of their physiological impact has been in the context of cancer, they also have been shown to be involved in ocular neovascularization. MMP action has been implicated in the exposure of a cryptic epitope of collagen IV that promoted laser-induced CNV in a murine model. MMPs also generated soluble fragments of VEGF from matrix-bound forms; as MMP expression by cultured retinal pigment epithelium cells is upregulated by VEGF, this may provide for a positive feedback amplification of the angiogenic response.

Components of the complement cascade

In addition to the genetic studies implicating specific mutations in the complement system as risk factors for AMD (see above), both clinical and preclinical studies have directly implicated factors C3a and C5a in promoting ocular neovascularization. Both of these factors have been found in the drusen of patients with AMD as well as in the eyes of mice with laser-induced CNV; genetic ablation of their corresponding receptors reduced VEGF expression, leukocyte recruitment, and induction of CNV. Moreover, these

factors induced upregulation of VEGF expression when injected intravitreally in mice. Similar effects on CNV and VEGF expression were found in mice in which factor C3 was ablated. Finally, depletion of complement by administration of cobra venom factor has been shown to inhibit the development of the inflammation, which is often accompanied by neovascularization, in an animal model of uveitis. Taken together, these findings suggest that targeting certain components of the complement cascade could provide a therapeutic option for treating ocular neovascularization.

Inhibitors of Angiogenesis

Pigment epithelium-derived factor

Pigment epithelium-derived factor (PEDF) is a 50-kDa glycoprotein, originally found to be expressed in the retinal pigment epithelium that exhibits properties directly opposing VEGF: inhibition of VEGF signaling through VEGFR1, downregulation of VEGF expression in the context of ischemia, and inhibition of VEGF-induced increases in endothelial cell permeability. PEDF induces macrophage apoptosis, suggesting that it serves also as a modulator of inflammation. Systemic or intravitreal administration of PEDF, as well as its expression from a transgene, was found to inhibit ischemia-induced retinal neovascularization in mice. PEDF also induced apoptosis of cultured endothelial cells and suppression of VEGF-induced endothelial cell proliferation and migration. However, one study reported that the effects of PEDF were dose dependent, with both laser-induced CNV and endothelial cell differentiation *in vitro* being inhibited at low doses and promoted at high doses. Clinical data have been similarly inconsistent. While the expression of PEDF in Bruch's membrane was reduced in patients with AMD relative to controls, vitreous levels of PEDF were elevated in patients with PDR. The potential of PEDF as an antiangiogenic agent for ocular neovascularization thus remains to be established.

VEGFxxxb isoforms

VEGFxxxb denotes a parallel family of alternately spliced VEGF isoforms that are identical in length to the canonical VEGF family but differing in the last six amino acids. VEGFxxxb isoforms can bind VEGFR2 but have little or no ability to initiate downstream pathways. They therefore act as competitive inhibitors of VEGF. In clinical studies, VEGFxxxb was found to predominate in the vitreous of control eyes but to constitute only 12% in patients with PDR; similar downregulation of VEGFxxxb has been observed in several cancers. In preclinical studies, VEGFxxxb inhibited both corneal and retinal neovascularization. These findings suggest that downregulation of VEGFxxxb levels may contribute to pathological neovascularization and that members of this family may have potential as antiangiogenic therapies.

Soluble VEGF receptor 1

Soluble VEGFR1, also generated by alternative splicing, is a natural inhibitor that can bind VEGF but lacks the exons required for signaling. It is essential for maintaining the avascularity of the cornea. As an integral component of the engineered therapeutic agent VEGF-Trap (see above), the ligand-binding site currently is being evaluated in clinical trials as a VEGF-targeting agent.

Complementary regulatory protein CD59

In addition to containing components that promote pathological neovascularization, the complement cascade also includes regulatory components that are potential antiangiogenic agents. One such candidate protein is CD59, whose ablation facilitated the development of CNV in mice; in the converse experiment, laser-induced CNV was inhibited by intravitreal or intraperitoneal administration of a soluble fusion protein containing CD59.

Tryptophanyl-tRNA synthase fragment

Tryptophanyl-tRNA synthase fragment (T2-TrpRS), another naturally occurring molecule, was found to inhibit physiological retinal angiogenesis in mice as well as ischemia-induced preretinal neovascularization. Recently, it was shown that intravitreal injection of T2-TrpRS, together with an anti-VEGF aptamer, led to potent inhibition of ischemia-induced retinal neovascularization, suggesting yet another avenue for combinatorial therapy.

Slit/Roundabout4

Slit/Roundabout4 (Robo4) is a member of a family of transmembrane receptors for the Slit family of secreted ligands. While Slit/Robo signaling was initially shown to be important in neuronal patterning, it also has been implicated in angiogenesis. Recently, intravitreal injection of Slit2 was found to inhibit both ischemia-induced neovascularization and VEGF-retinal permeability; none of these effects were seen if Robo4 was genetically ablated. Slit2-mediated inhibition of VEGF-induced endothelial cell migration and tube formation also was dependent on the presence of Robo4. Taken together, these data suggest that Slit/Robo4 axis acts as a negative regulator of VEGF-induced proangiogenic signaling.

Other inhibitors

In addition to the inhibitors discussed herein, numerous other molecules have been identified that also possess antiangiogenic activity but whose involvement in ocular neovascularization is not as well characterized (**Table 1**).

New Directions in Antiangiogenic Therapy

While most research into pathological angiogenesis has been directed toward ablating the unwanted vasculature, recent studies into the control of malignant tumors suggest

that antiangiogenic therapy may act to normalize, rather than to destroy, the tumor vasculature. This normalization facilitated tumor penetration of chemotherapeutic agents and increased their efficiency. Similar concepts have emerged from studies of Dll4/Notch signaling where inhibition led to more profuse tumor vasculature but slower tumor growth. The molecular mechanisms underlying vascular normalization are yet to be determined. Inhibition of the regulator of G protein signaling 5 (RGS5), a protein found in pericytes, has been shown to promote vascular normalization in a mouse tumor model; this allowed the influx of immune cells into the tumor parenchyma and led to increased survival. Upregulation of RGS5 resulted in a significant reduction in the susceptibility of nascent vessels to regression by VEGF inhibition, suggesting that RGS5 contributes to pericyte-endothelial cell interactions and vascular maturation.

Normalization of the vasculature also has been proposed as a contributor to the utility of antiangiogenic therapy in pathological ocular neovascular diseases. Retinal neovascularization may reflect an adaptive response to hypoxia that has gone awry. It remains to be seen whether inducing regression or normalization of aberrant retinal vasculature will be the most effective in providing favorable visual outcomes.

Conclusions

The systematic study of the mechanisms underlying physiological and pathological angiogenesis has yielded a wealth of knowledge as to underlying molecular and cellular mechanisms involved in retinal neovascular diseases, including the actions of proangiogenic and antiangiogenic factors that modulate these processes. Drugs targeting VEGF have already proved their clinical utility. It is clear, moreover, that a variety of other agents offer promise, either alone or as adjunctive therapy with agents targeting VEGF, and that there is reason for optimism that the range of treatments for retinal neovascular diseases soon will be expanded.

Penetrating Keratoplasty

T H Flynn and D F P Larkin, Moorfields Eye Hospital, London, UK

Glossary

Afferent and efferent components of allogeneic response – Afferent arm of the immune response is the inductive stage in which antigens are presented to T lymphocytes in lymph nodes. Efferent arm of the allogeneic response is the stage in which T cells and antibodies are generated and are available to mediate graft rejection or protection from infectious agents.
Alloantigen – An antigen present in some, but not all, individuals of the same species.
Alloreactive – The reaction of lymphocytes or antibodies with alloantigens.
Anterior chamber-associated immune deviation – Systemic downregulation of antigen-specific cell-mediated immunity that is induced when antigens are introduced into the anterior chamber of the eye.
Delayed-type hypersensitivity – Immune response consisting mostly of T cells that develops 24–72 h after exposure to antigen.
Immune privilege – Condition in which immune responses are suppressed or downregulated.
Indirect and direct allorecognition – Two pathways whereby immune responses to histocompatibility antigens on a corneal allograft elicit an immune response and ultimately allograft rejection. Indirect pathway occurs when host-derived antigen presenting cells reprocess antigens from the allograft. Direct pathway involves direct stimulation of the host's T lymphocytes by major histocompatibility antigens expressed on the corneal allograft.

Penetrating Keratoplasty: Indications and Survival

Penetrating keratoplasty, or full thickness corneal transplantation, is the surgical procedure most commonly used in management of blinding corneal disease. Overall graft survival rates in corneal transplantation are similar to those in cadaveric renal transplantation: this indicates that the impact of corneal graft failure, due in most patients to allogeneic rejection, is significant, even if very few of the cornea patients receive oral immunosuppression as prophylaxis. In this way, corneal transplantation is one clinical circumstance in which immune homeostasis of the eye might seem undermined. However, in those patients in whom irreversible transplant rejection occurs, the selective targeting of immune-mediated injury to donor cells is a striking example of protection of host ocular tissue from bystander injury – afferent and efferent components of the allogeneic response in tandem maintaining immune homeostasis of the eye.

Large cohort outcome studies have identified a number of factors on multivariate analysis which, if present, have a statistically significant detrimental effect on corneal graft survival. These are a previous ipsilateral failed graft, ipsilateral ocular inflammation, vascularization of the recipient cornea, and the primary corneal diagnosis. In most patients, these factors increase risk of graft failure by immune rejection.

Corneal Immune Privilege

Apart from the specific diagnoses of keratoconus and Fuchs endothelial disease, few of the common indications for corneal transplantation can truly be considered low rejection risk. Nevertheless, it is clear that corneal transplants do enjoy comparative immune privilege. Early investigators attributed the immune privilege of the cornea entirely to its lack of vascularity, that is, sequestration of alloantigen from the immune response. There is no doubt that this is an important factor. Animal models and large human cohort studies have identified recipient corneal vascularization as the most significant factor conferring high rejection risk in multivariate analyses. In fact, the cornea is an immune-privileged tissue situated in and transplanted to an immune-privileged site.

Immune-Privileged Tissue

A number of factors are known to contribute to the relative immune privilege of the cornea as a tissue.

- On a gross level, the normal cornea is isolated from circulating immune cells due to (1) its avascular nature and (2) the blood–aqueous barrier.
- Until relatively recently, the cornea was thought to contain no passenger antigen-presenting cells (APCs). Recent work has established that it does, in fact, contain APCs but that they are immature and do not express major histocompatibility complex (MHC) class II in the normal setting. Subsequently, the normal cornea is

devoid of lymphatics to transport APCs. Experimental studies which increase the numbers of passenger APCs in the donor cornea have been shown to erode immune privilege and increase the direct component of allorecognition. Because in clinical transplantation normal avascular donor cornea is grafted, high rejection risk status is conferred by vascularization or inflammation of the residual host cornea.

- The stroma and endothelium have low immunogenicity.
- The endothelium, which is the most important target in rejection, expresses (i) low levels of MHC class I and II and (ii) high levels of Fas ligand which induces apoptosis in alloreactive T-lymphocyte cells and protects the graft.

Immune-Privileged Site

The cornea, or specifically its endothelium, constitutes the anterior boundary of the anterior chamber which has been shown to be an immune-privileged site by Medawar in one of the earliest studies of this concept. The aqueous humor in contact with the endothelial cells contains high levels of immunoregulatory proteins such as transforming growth factor beta (TGF-β). In addition, antigen placed in the anterior chamber of the eye alters the immune response (anterior chamber-associated immune deviation or ACAID) to subsequent exposure to the antigen even at a different site. Antigen from the anterior chamber leaves the eye via several pathways but at least some leaves via the conventional aqueous outflow pathway and travels to the spleen. There the interaction of antigen, natural killer (NK), T cells, B cells, and γδ T cells induces a type of operational tolerance.

Clinical Features of Corneal Graft Rejection

Selective rejection signs can be observed in the epithelium, stroma, and endothelium of donor cornea in the human. The corneal endothelial cell monolayer controls stromal hydration, which has an essential role in transparency and transmission of light (Figure 1). As (1) these cells do not have mitotic capability and (2) following uncomplicated corneal transplantation the endothelial cell monolayer density declines at an even faster rate than in health, rejection of the endothelial layer is a terminal threat to graft transparency unless reversed sufficiently early. Even if reversed by treatment, a proportion of endothelial cells is lost.

Patients with isolated epithelial rejection are often asymptomatic. In epithelial rejection, an elevated curvilinear opaque line is seen on the epithelium. However, epithelial rejection is direct evidence that the recipient has been sensitized to the graft and may progress to rejection of the deeper corneal layers. The clinical symptoms and signs of stromal rejection have two patterns. It more frequently manifests as subepithelial opacities. These infiltrates have a similar appearance to those seen in adenovirus viral keratitis but are seen only in the donor cornea. This type of stromal rejection is often asymptomatic, but like epithelial rejection it may precede the onset of a more severe and visually significant process. Rejection of the deeper stroma results in spreading graft opacification and decreased visual acuity.

Endothelial rejection usually presents with discomfort and decreased visual acuity. A line of leukocytes may, over a period of days, be seen migrating across the donor endothelium leaving edematous stroma in its wake (Figure 2). This line often spreads out like a wave from an area of deep vascularization to the graft host junction. Alternatively, a

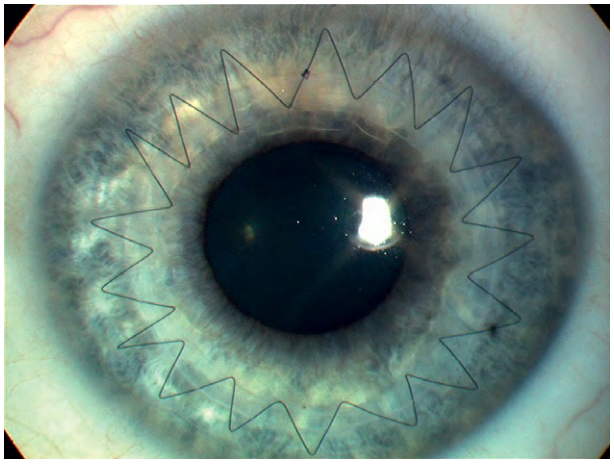

Figure 1 Transparent corneal transplant 8 months following surgery. The donor cornea is fully transparent, indicating normal endothelial function. Both recipient and donor cornea are avascular.

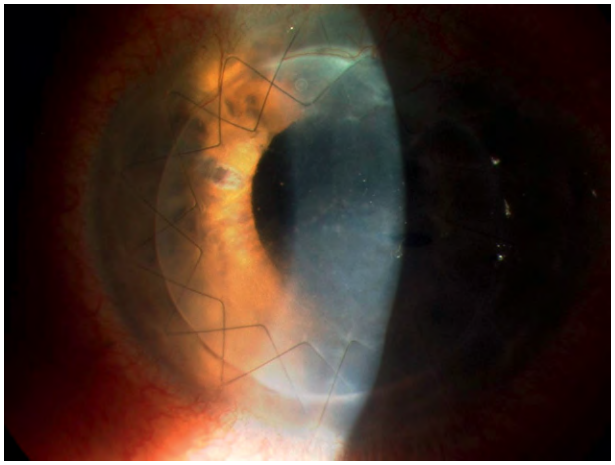

Figure 2 Endothelial rejection is indicated by the demarcated region of donor corneal opacification bordered by a horizontal linear opacity. Vascularization to the superior graft periphery can also be seen.

Table 1 Summary of cellular steps to corneal transplant destruction

	Direct pathway of antigen presentation	*Indirect pathway of antigen presentation*	*Low risk*	*High risk*
1	Egress of donor APCs	Host APCs infiltrate graft	Few recipient cornea APCs	More recipient cornea APCs
		Egress of host APCs bearing antigen	↓MHC II expression	↑MHC II expression
		Egress of host APC from anterior uvea bearing antigen shed from endothelium	Few lymphatics	Lymphatics *in situ*
			Indirect antigen presentation	Direct antigen presentation
			''Quiet'' eye	Inflamed eye
2	Direct priming of T lymphocytes (afferent allorecognition)	''Indirect'' priming of T lymphocytes (afferent allorecognition)	↓MHC II	↑MHC II
			↓Costimulatory molecules	↑Costimulatory molecules
			ACAID	Erosion of ACAID
3	Exposure of circulating primed lymphocytes and other leukocytes to graft	Exposure of circulating primed lymphocytes and other leukocytes to graft	Avascular cornea	Vascular cornea
			''Quiet'' eye	Inflamed eye
4	Recognition of alloantigen (efferent allorecognition)	Recognition of alloantigen (efferent allorecognition)	↓MHC expression	↑MHC expression
5	Recruitment of other effector cells	Recruitment of other effector cells		

APC – antigen presenting cell; MHC – major histocompatibility complex; ACAID – anterior chamber-associated immune deviation.

more diffuse corneal edema may be seen with diffuse keratitic precipitates of variable density. In all cases, there are visible cells in the anterior chamber and the signs of inflammation and of endothelial dysfunction are limited to the donor tissue, demonstrating specificity of the allogeneic response.

Pathogenesis of Rejection

Current understanding of the pathway to rejection of donor cornea following penetrating keratoplasty will be described in terms of the afferent component or sensitization, in which donor transplant antigens are recognized and processed, and the effector component. Components of the allogeneic response in low and high rejection risk corneal transplantation are summarized in Table 1.

Afferent Mechanisms and Components

Histocompatibility antigens

Otherwise known as transplantation antigens, these are proteins and peptides derived from donor cells; in most forms of transplantation, the most potent are class I and class II molecules of the MHC. Additional transplantation antigens termed minor histocompatibility antigens also induce allogeneic tissue rejection. The designation of major or minor refers to the relative importance of these antigens in vascularized organ transplants and may be quite inaccurate in corneal transplantation, in which, for example, minor H antigen appears to be relatively more important than MHC antigens.

Published evidence from several laboratories indicates that following transplantation recipient APCs enter the graft and endocytose exogenous alloantigen. APCs then migrate to the local lymph node where the alloantigen is presented on MHC class II molecules to naive CD4 cells and on MHC class I to naive CD8 cells. APC-associated antigen may be detected in the draining lymph node within hours of corneal transplantation. The exogenous antigen in question could be either a donor minor histocompatibility antigen or part of a donor major histocompatibility antigen. One self APC activates both CD4 and CD8 cells in what is known as the three-cell model of alloantigen presentation.

Direct and indirect alloantigen recognition

The type of antigen presentation by recipient APCs outlined above is termed indirect antigen presentation. Another form of antigen presentation, unique to the transplantation, is direct antigen presentation mediated by donor APCs transplanted within the graft (passenger leukocytes). According to the concept of self-restriction, alloantigen presented by these cells should not be recognized

by host T cells if the major histocompatibility antigens are not matched. In reality, the alloantigens are recognized by a significant number of host T cells. Some of these lymphocytes may recognize, and be primed, by the alloantigenic MHC molecule itself regardless of the peptide it bears. This method of antigen presentation is consistent with the three-cell model and in vascularized organ grafts directly primed T cells constitute ~90% of the alloreactive cells during acute graft rejection.

With its lack of mature resident APCs and lymphatics, the cornea would appear to be poorly equipped to facilitate antigen presentation via the direct route. This is confirmed by studies which show that the indirect route of antigen presentation plays a more prominent role in low-risk corneal transplantation. This lack of influence of the direct route may explain the following findings which are on first consideration counterintuitive:

- In human studies, MHC class I and particularly class II matching of corneal grafts has shown no convincing survival benefit.
- In animal studies, mismatches in minor rather than major histocompatiblity antigens have been shown to be equally or more important in influencing graft survival.

Further experimental evidence suggests that some of the factors which confer immune privilege do so by minimizing or preventing direct antigen presentation and that in erosion of immune privilege (i.e., in high-risk grafts) the direct route of antigen presentation becomes relatively more prominent. Nevertheless, the indirect route of antigen presentation is sufficient to induce sensitization.

T-lymphocyte activation

In the lymph node the MHC–peptide complex interacts with the T cell receptor (TCR), a complex cell surface receptor. The vigor of the T cell response following presentation of antigen is variable and dependent on the nature of the dendritic cell itself, the affinity of the clonotypic TCR for the MHC–peptide complex in question, the state of the T cell (naive, memory), soluble factors in the immediate microenvironment (cytokines and chemokines), and the interactions between accessory (adhesion and costimulatory) molecules.

Once a T cell is activated in the lymph node, there is rapid clonal expansion of alloantigen-specific T cells which enter the circulation. The lifespan of these cells is limited and it follows that there is a limited window of opportunity for these cells to bring about graft destruction in the absence of continuous antigenic stimulation. The rapid expansion of T cells is followed by contraction as many effector T cells undergo apoptosis. Memory (central and effector) cells make up part of the T cell repertoire thereafter.

Effector Mechanisms

Once primed in the regional lymph nodes, activated lymphocytes enter the peripheral circulation. The avascular nature of the cornea and the blood–aqueous barrier provide barriers to immune cell infiltration and endothelial cell destruction. In the case of vascularized corneas, immune cells have easier access to graft antigens/cells.

The nature of graft-infiltrating cells in corneal allograft rejection has been studied in human and animal pathological specimens. The cell types which appear in the highest numbers and with the greatest consistency are CD4+ and CD8+ lymphocytes of the adaptive immune system, and innate immunity component macrophages and NK cells. The presence of a cell in a tissue during rejection does not prove that the cell has an effector functional role: the important questions as to which cells cause endothelial cell destruction and by what mechanism(s) remain poorly understood. For instance, the mechanisms of allorecognition in the effector stage of graft rejection are unclear. A particular conundrum has been the question of how indirectly primed T cells (host MHC(+mH) molecules) can recognize antigen on donor cells (donor MHC(+mH) molecules). The discovery of a semidirect pathway of antigen presentation, whereby recipient APCs present whole donor MHC molecules as well as their own MHC molecules, provides a possible explanation for this but has not been demonstrated experimentally in corneal transplantation.

T lymphocytes

Because both CD4 and CD8 have been found in pathological specimens of rejected corneal grafts, much interest has fallen on the roles of these cells in corneal graft rejection. Several studies have demonstrated the presence of two distinct lymphocyte populations in response to a corneal allograft. One group appear to be CD4+ and are activated by indirect presentation of alloantigen. The other group are CD8+ cells with direct specificity for alloantigen. CD8+ cells act directly on target cells and are cytotoxic but it appears that CD8+ cells are less important in corneal graft rejection than in other organs. While CD4+ cells have the capacity using FasL to be directly cytotoxic, their primary modus operandi in corneal graft rejection appears to be via delayed-type hypersensitivity (DTH), by secreting cytokines and recruiting other cells such as macrophages. The evidence for role of CD4+ cells is supported by the finding that DTH responses rather than cytotoxic responses are found in rejectors of corneal grafts. We may conclude from findings in several laboratories that CD4+ cells play a more important role than CD8+ cells in graft rejection under most conditions but that either cell type may mediate rejection and that neither is essential for the process. However, there is considerable redundancy within the allogeneic response, with several lines of investigation supporting alternative cellular pathways for graft destruction.

Macrophages

The heavy mononuclear cell infiltrate in rejected grafts is in keeping with a DTH reaction. Depletion of corneal macrophages with clodronate liposomes prolongs corneal graft survival in rats, and macrophages have been shown to be necessary as APCs rather than as effector cells. However, cells of monocyte/macrophage lineage have been shown to be the dominant cell type in human aqueous humor during acute endothelial rejection. The function(s) of these cells in the effector arm of the rejection process remains unknown.

NK cells

NK cells of the innate immune system have been found in rejected corneal grafts and in the aqueous humor of experimental animals with corneal allograft rejection. These cells usually function in the elimination of virally infected cells. The default function of an NK cell is to kill any cell with which it comes in contact. Only the presence of self MHC class I on the cell inhibits this process. *In vitro* studies have demonstrated the capacity of NK cells to kill allogeneic corneal endothelial cells, so these cells are likely to be functionally active in the efferent arm of rejection.

Breakdown of immune privilege?

In a high rejection risk transplant there is a preexisting erosion of immune privilege at one or more of these steps mentioned in section "Immune-privileged Tissue". Low rejection risk grafts that reject later may be thought of as grafts that have acquired high rejection risk characteristics due to breakdown of immune privilege. In nonvascularized corneas, immune rejection occurring months or years after transplantation is often seen to be preceded by a local episode of alloantigen-independent inflammation (e.g., loosened transplant suture, bacterial suture-associated infection, and recurrent herpetic infection) which may lead to recruitment of immune-competent cells, angiogenesis, lymphangiogenesis, and upregulation of MHC molecules on the graft cells. Each step and the factors within it contributing to immune privilege are reasonably well understood but the extent to which one step inevitably follows the preceding one is less clear. We may ask of grafts which are not rejected, whether the recipient has not been sensitized due to the immune system not seeing the antigen (ignorance of the alloantigen), whether the immune system has seen the antigen but does not or cannot mount a response (tolerance of the antigen), or whether the immune system has seen the antigen and been sensitized but its effector cells cannot see the target antigen due to sequestration of the graft in its avascular bed.

While it is tempting to speculate that a single step exists, manipulation of which would induce tolerance or absolute immune privilege in all cases, it is far more likely that the relative contributions to immune privilege at each step is different for each person and for each graft and there is no factor contributing to immune privilege that cannot be overcome by one of the many redundant cellular pathways and mechanisms known to bring about rejection.

Treatment of Rejection

The mainstay of treatment for established rejection is intensive topical corticosteroid treatment. The most commonly used regimen is prednisolone acetate 1% or dexamethasone 0.1% hourly. This treatment effectively suppresses graft inflammation but once inflammation has been suppressed, the question of whether graft clarity will return depends on the extent to which the endothelium has been damaged. Topical corticosteroids influence effector cells such as T cells and macrophages in the cornea chiefly by inducing the expression of anti-inflammatory genes (Annexin-1, SLPI) and repressing the expression of proinflammatory genes (cytokines, chemokines, adhesion molecules, and MHC molecules). Inhibition of IL-2 receptor production inhibits T cell proliferation but this may not be an important effect of topical treatment as T cell proliferation occurs quite distal to the site of application in the regional lymph nodes. Corticosteroids also affect dendritic cell (DC) function and have been shown to alter cytokine production, to induce apoptosis in DCs and to delay DC maturation with resultant impairment of antigen presentation. Corticosteroids inhibit angiogenesis but this is unlikely to be relevant in setting of acute rejection. While some clinicians treat endothelial rejection with systemic as well as topical corticosteroid, a trial of intravenous methylprednisolone in addition to intensive topical treatment did not show an improvement in outcome compared with topical treatment alone.

Prevention of Rejection

The key to minimizing immune-mediated graft failure in patients is a dual strategy of (1) identifying pre- and post-transplant those at high risk of rejection, tailoring their management appropriately and (2) educating graft recipients as to the signs and symptoms of rejection. Preoperative risk factors for rejection include unmodifiable factors such as a previously rejected ipsilateral graft or previous herpetic keratitis and factors which are modifiable to a greater or lesser degree such as corneal vascularization or active external eye inflammation. All ocular inflammation should be brought under control where possible before elective corneal transplantation. A degree of regression of corneal vessels may be induced by topical steroid treatment particularly in an inflamed cornea. More established vessels may be difficult to treat. Of most concern are deep vessels and vessels close to the (projected) graft–host interface. Inhibition of formation

of lymphatic vessels from preexisting lymphatic vessels (lymphangiogenesis) in the host cornea has been shown to prevent or delay graft rejection by inhibiting APC egress and sensitization to alloantigen. Antivascular endothelial growth factor (anti-VEGF) treatment is a promising area for future investigation as it may help to mitigate both the afferent (lymphangiogensis) and efferent (angiogenesis) arms of the immune response to allogeneic cornea.

One rational approach to management of transplants at high rejection risk is the use of systemic immunosuppression with calcineurin inhibitors to prevent alloreactive T cell clonal expansion. Unfortunately, there is no robust evidence favoring any such regimes and complete absence of randomized trials. In grafts not at high risk of rejection, very long-term local immunosuppression with topical corticosteroid may be useful in preventing rejection but the benefit must be weighed against such risks as glaucoma, susceptibility to infection, and impaired corneal wound healing. In the postoperative period, patients presenting with alloantigen-independent ocular surface inflammation, such as suture loosening, should be treated promptly and aggressively.

Pericytes and Microvascular Remodeling: Regulation of Retinal Angiogenesis

I M Herman, Tufts University School of Medicine, Boston, MA, USA

Glossary

Cytoskeleton – The cellular organelle that constitutes the mechanically deformable, dynamic, and structurally rigid components that enable cell shape changes, cell cycle progression, and migration. Major components include the actin- and myosin-based system, the microtubule-based system, and the intermediate filament system.
Diabetic retinopathy – Pathologic disorder accompanying diabetes wherein unwanted cellular dystrophy and proliferation can give rise to vision loss. Components involved include, but are not restricted to, the retinal microvascular cells, including their associating extracellular matrix elements as well as neural retinal components. Proliferative diabetic retinopathy is heralded by ischemic insult, loss of vascular perfusion, fibrovascular lesion formation, microaneurysm formation, retinal detachment, and vision loss.
Pericyte – Discovered in the late 1800s by the French naturalist, Charles Rouget. Initially bearing the discoverer's namesake, Rouget cells were renamed during the early twentieth century by Nobel laureate, August Krogh, who confirmed and extended Rouget's original observations regarding the perivascular placement of these contractile cells. More recent work has revealed and significantly extended the regulatory roles that pericytes play in controlling capillary growth and contractile phenotype during development and disease.
Rho GEF – Rho guanine exchange factor(s) (GEF) are a class of small molecular weight protein components that specifically associate/bind to Rho GTPases enhancing the duty cycle of GTP hydrolysis, fostering the conversion of GTP to GDP, thus influencing the efficiency or activity of RhoGTPase function.
Rho GTPase – A member of the ras-related superfamily of guanine nucleotide-binding proteins that hydrolyzes guanosine triphosphate (GTP), converting it to the guanosine diphosphate (GDP)-bound form. Rho GTPase acts as a molecular switch within living cells. Upon GTP hydrolysis, Rho GTP is known to activate (phosphorylate) a number of key downstream effectors responsible for reversibly regulating cytoskeletal remodeling, mechanical tension, and cellular dynamics.
SMAD – A transforming growth factor (TGF)-β signal transducer that moves from cytoplasm to nucleus and regulates transcription.

Overview

Development of the adult retinal microcirculation is complex. As is the case in every human tissue bed or organ system, retinal microvascular morphogenesis is both tightly regulated and highly dependent upon the diverse signaling cascades that drive vascular cell proliferation and differentiation. Without question, retinal development is sustainable by the intimate relationship that exists between the neural and vascular retina where metabolites and available survival or growth factors help to shape microvascular remodeling during ocular angiogenesis, regardless of whether these adaptations are observed during development or in association with aging-related or chronic disease states such as diabetes. Indeed, as recent research findings and clinical studies suggest, nascent vessels are born, pruned, stabilized, and destabilized because of the regulatory roles that pericytes play in modulating retinal endothelial cell dynamics.

Retinal Microvascular Dynamics: Cell–Cell Interactions

During retinal microvascular development, there is considerable partnering between pericytes and nonvascular cells. For example, astrocytes transiently express vascular endothelial growth factor (VEGF) as they migrate across the retinal ganglion cell layer. Importantly, this transretinal migration precedes the formation of the superficial retinal microvessels and contributes to the formation of the deeper retinal microcirculation. As the glial cells migrate, VEGF gradients modify endothelial growth, cell–cell contacts, and subsequent structural alterations in basement membrane architecture. Just as these complex cell- and matrix-dependent remodeling events help to initiate and maintain the physiologic vasculature, neuronal and

vascular cell pathology contribute to a physiologic hypoxia. Thus, perictyes, astrocytes, and Müller cells are also contributory or are causally linked to the severe complications observed during diabetic retinopathy, age-related macular degeneration, or neovascular glaucoma, which contribute to the inception and etiology of pathologic angiogenesis. However, there are significant gaps in our understanding the angiogenic switch mechanisms responsible for inducing the recurrent rounds of pathologic angiogenesis observed during these chronic retinal diseased states. It seems likely that common molecular and cellular mechanisms deployed during developmental angiogenesis are recapitulated during the pathologic remodeling observed during diabetes, but we are uncertain whether hypoxic insult, microthrombus formation, or altered microvascular reactivity and permeability are responsible. What are the initiating signals that reactivate the previously quiescent adult retinal microvasculature? Are the initiating events plasma derived, linked with endothelial activation downstream of platelet derangements? Could platelet-driven or endothelial-initiated events signal through the associating pericytes to initiate incipient angiogenesis? Or, are there pericyte-driven, but endothelial-dependent signaling events responsible for initiating the loss or dedifferentiation presumed to take place during diabetes? Without question, early work indicated that pericyte loss and acellular capillaries might reflect an advanced state of microvascular remodeling marking the vascular proliferative disorders observed during diabetes; but, our unraveling the molecular and cellular mechanisms that govern the initiating events responsible for the switch from a growth-arrested endothelium to one that is actively proliferating and engaged in pathologic angiogenesis remains a topic of considerable scientific interest and clinical investigation. Dissection of these endothelial- and pericyte-associated signaling pathways, which govern the onset of vascular proliferative disorders, will help to enable new opportunities aimed at abrogating retinal pathology and the pathologic angiogenesis observed during diabetes or age-related macular degeneration.

Retinal Pericytes and Diabetes-Induced Vascular Proliferative Disorders

It has been long recognized that endothelial cells share and coproduce a common basement membrane through which direct contact with pericytes can be achieved. Ultrastructural evidence supports the notion that when pericytes emerge and associate with the developing capillary, there is a marked cessation of vessel growth. Interestingly, pericyte growth and recruitment is positively regulated by platelet-derived growth factor (PDGF)-B; endothelium-restricted ablation of PDGF-B generates viable mice with extensive inter- and intra-individual variations, including the density of pericytes throughout the central nervous system (CNS) and the retina. This strong inverse relationship between pericyte density and the range of retinal microvascular abnormalities observed in retinopathies suggests that aberrations in pericyte signal transduction or pericyte depletion serve as initiating events that lead to retinopathy. There is evidence using murine models and transgenesis approaches in support of this notion; and, *in vivo*, pericyte dropout has been observed during diabetes. But importantly, pericyte dedifferentiation and the phenotypic modulation that ensue are endothelial dependent, that is, controlled by endothelial-synthesized basement membrane components that are likely to regulate capillary growth state and tonus. Thus, the absence of pericytes and the retinal neovascularization observed during diabetic retinopathy has led investigators to postulate that pericytes suppress retinal capillary endothelial cell growth. Indeed, there seems to be a robust pericyte dependence on microvascular remodeling, either via matrix-initiated signals or via cell-dependent contacts. Yet, the upstream regulators that control the role pericyte stabilization of capillary quiescence or endothelial growth arrest are currently unknown and the subject of intensive investigation.

As mentioned, the molecular and cellular mechanisms by which pericytes suppress endothelial cell proliferation and stabilize the microvasculature have not been completely elucidated; but, *in vitro* experimentation using cocultures of pericytes with endothelial cells have recently revealed both transforming growth factor (TGF)-β1-dependent and, now, TGF-β1-independent processes. In turn, we suspect that these *in vitro* observations reflect local *in vivo* microenvironmental cues emanating downstream of platelet and endothelial activation. Indeed, during diabetes endothelial expression of vascular cell adhesion molecule (VCAM) is induced, neutrophil–endothelial interactions are fostered, and microthrombus formation ensues. However, the initiating events that specifically control microvascular remodeling and which are downstream of platelet activation during pathologic angiogenesis have not been fully characterized. In fact, recent work reveals that perturbation of Rho GTP signaling in retinal pericytes is sufficient to alter retinal capillary endothelial growth state, that is elevating pericyte Rho GTP levels reverses the TGF-b1-dominated, endothelial growth-arrested phenotype, even in spite of sustained cell–cell contacts. Quantitative analyses of the latent or activated TGF-β1 present within media conditioned by endothelial cells, alone, or in co-culture with wild-type or Rho GTP-overexpressing pericytes indicate that other pericyte-dependent signaling mechanisms, which are outside of the TGFβ family, might be causing the reversal of endothelial cell growth arrest observed.

Pericyte Rho GTP Signaling: A Role in Pathologic Angiogenesis?

Our recent work has revealed a pivotal role for Rho GTP signaling in controlling pericyte contractile phenoptype. Signaling through an isoactin-specific signaling cascade, these findings have simultaneously uncovered what may be a mechanically linked series of initiating events that function to activate capillary endothelial growth and angiogenesis during ocular vascular proliferative disorders. Indeed, altering pericyte Rho GTP status uncouples the TGFb- and cell-contact-mediated growth arrested state, which keeps endothelial cells restrained within Go, the resting phase of the growth cell cycle. These data also point to upstream signals and downstream effectors that are likely to be outside the signaling analogues of mothers against decapentaplegic (SMAD)- and vascular smooth muscle actin (VSMA)-regulated events that control pericyte cytoskeletal remodeling or endothelial growth. There are several likely candidates, which could foster these observable aberrations in pericyte-dependent, endothelial growth arrest. Soluble mediators originating in the blood, produced locally by the microvascular cells or elaborated by neighboring supporting cells, could play key roles in modulating pericyte–endothelial interactions during diabetes. For example, there are a multitude of platelet-derived bioactivities that might be locally released downstream of platelet–endothelial interactions, especially during diabetes when the endothelial cell surface is notably altered. In turn, endothelial-synthesized or pericyte-generated activities could also be strategic in the signal transduction cascades leading to this angiogenic switch (Figure 1). Indeed, just this past year, bioactive lipids, which are produced by blood platelets, for example, sphingosine-1 phosphate (S1P), have been reported to modulate angiogenesis. Genetic ablation of a key G-coupled receptor that mediates S1P signaling, S1PR-2, which is predominantly found on vascular smooth muscle cells, was also demonstrated to reduce ischemia-driven angiogenesis in the mouse retina. Perhaps, the convergence of the sphingosine and Rho GTP-dependent signaling pathways offers inroads into understanding the molecular signaling events responsible for regulating pathologic angiogenesis. Indeed, pharmacologic inhibitors of sphingosine kinase, which is required for S1P synthesis, have now been reported to reduce vascular leakage in diabetic retinopathy. In addition, Igarashi and colleagues have demonstrated that aortic endothelial cell S1P receptor expression is induced following VEGF stimulation. The latter occurs concomitantly with activation of endothelial nitric oxide synthase, suggesting that each of these independent events indicates a crosstalk between sphingolipid and endothelial growth factor receptor signaling. Despite these reports, the mechanisms regulating S1P function within the retinal microvasculature, physiologically and pathologically, have not been established. These findings, together with work ongoing in our laboratory, will likely prove pivotal in unveiling upstream signaling events determining the pericyte-dependent control of endothelial proliferation during pathologic angiogenesis. Anticipated outcomes of these experiments may help to lay the experimental infrastructure for innovative anti-angiogenic therapeutic approaches aimed at abrogating the unwanted angiogenesis accompanying diabetic retinopathy or age-related macular degeneration. Platelet–endothelial interactions during diabetes or subsequent platelet S1P release may contribute to elicit local endothelial activation and, possibly, microthrombus formation. This, in turn, could stimulate VCAM expression and downstream

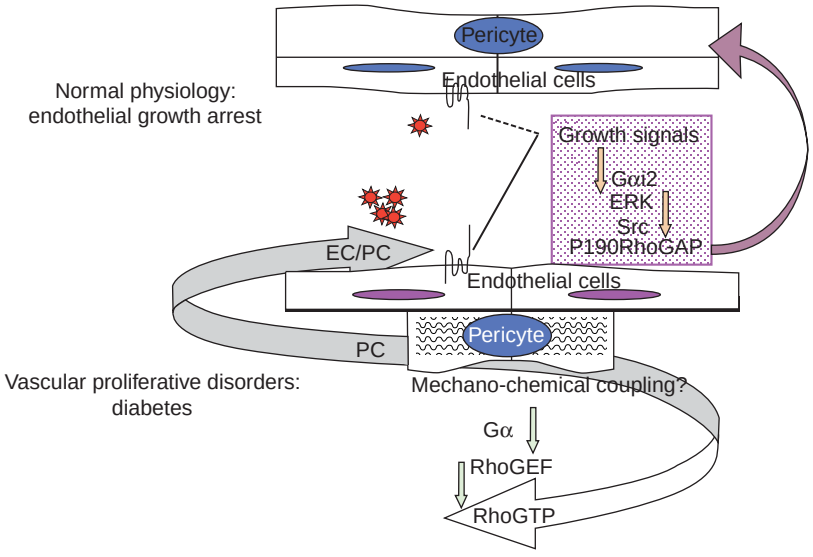

Figure 1 Mechanistic model depicting the putative up- and downstream regulatory roles for Rho GTP-dependent signaling in retinal pericytes and endothelial cells during proliferative diabetic retinopathy.

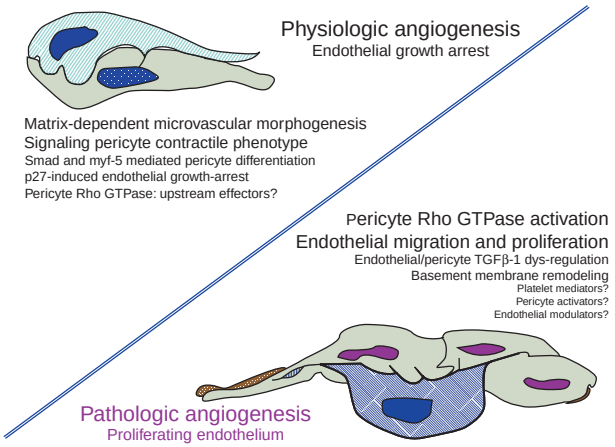

Figure 2 Model depicting the molecular and cellular events controlling the dynamic and reciprocal signaling pathways governing physiological and pathological angiogenesis.

Gq-S1PR signaling (**Figure 1**). While reasonably well worked out in smooth muscle cells, there is little information to suggest that such a signaling mechanism exists within the retinal microvasculature. Surely, diabetes-dependent perturbations in pericyte–endothelial interactions might arise downstream of platelet-dependent S1P release. As recently published findings suggest, more work will be required before we understand the mechanical and biochemical events that are up- or downstream of microvascular endothelial and pericyte Rho GTP-dependent signaling, which controls what we predict will be the angiogenic switch that is linked to the onset and severity of proliferative diabetic retinopathy (**Figure 2**).

Acknowledgments

Perimetry

D B Henson, University of Manchester, Manchester, UK

Glossary

Change probability – Change probability compares each test location with that of a baseline measure and establishes whether or not there has been any significant change. Results are presented in the form of a visual field plot where each location is classified according to a series of cut-off probability levels, for example, $p < 0.05$.

Kinetic perimetry – With the kinetic examination strategies, the perimetrist selects a stimulus of a given size and intensity and moves it from outside the visual field toward its center noting the position at which it first becomes visible.

Perimetry – Perimetry, or campimetry, is the technique used to measure the extent of the visual field or to assess the sensitivity of the visual system to stimuli presented within the visual field (IPS standards).

Standard achromatic perimetry (SAP) – SAP is the most widely used form of perimetry where a white stimulus is projected onto a white background, often called white-on-white perimetry.

Static threshold perimetry – In static threshold perimetry, an estimate of the patient's sensitivity is derived at a series of predetermined test locations.

Visual field – Tate and Lynn defined the visual field as "all the space that one eye can see at any given instant," it normally extends from the fixation axis: 60° up, 75° down, 100° temporally, and 60° nasally. The superior and nasal fields are limited by facial contours.

Perimetric Techniques

Kinetic Perimetry

With the kinetic examination strategies, the perimetrist selects a stimulus of a given size and intensity and moves it from outside the visual field toward its center noting the position at which it first becomes visible. This is repeated along a series of different meridians and the points at which the stimulus first became visible are then joined together by a line which is called an isopter. Scotomas within the area of an isopter are detected by continuing to move the stimulus toward the center of the visual field after it has first been detected. The patient is asked to report, if at any time, it disappears.

The perimetrist can repeat the whole process with stimuli of different sizes and/or intensities, in order to build up a map of the patient's visual field, such as that given in Figure 1. Kinetic examination strategies were very popular in the early days of perimetry. They have, however, been largely replaced by static techniques although they are still retained for specific cases such as small residual islands of vision and where patients have difficulty in performing automated perimetry.

Static Threshold Perimetry

In static threshold perimetry, an estimate of the patient's sensitivity is derived at a series of predetermined test locations. There are many different algorithms that can be used to establish the threshold and a great deal of effort has gone into deriving ones that minimize test time and error (difference between the true and the measured threshold).

The first widely used threshold algorithm (Full Threshold) was developed by Spahr and Bebie and their colleagues. It is a two-reversal staircase strategy in which the step size reduced from 4 to 2 dB after the first reversal.

This algorithm suffers from four major drawbacks:

1. long test time,
2. demanding and exhausting for the patient,
3. poor repeatability, and
4. a significant learning effect.

In an attempt to shorten test times, the fast threshold staircase algorithm was introduced, in which there was a single step size of 3 dB with only one reversal. While being faster, this algorithm is more variable than the Full Threshold algorithm and thus has not been widely adopted in clinical practice.

Tendency-orientated perimetry was similarly developed in order to reduce test times. The algorithm combines data from several neighboring locations and reduces test times by effectively reducing spatial resolution.

The Swedish interactive threshold algorithm (SITA) is currently one of the most widely used algorithms. It is considerably faster than the full threshold algorithm (approximately 5 min per eye for a normal field) with similar repeatability. This has been achieved by:

1. using maximum-likelihood procedures in combination with a 4–2 dB staircase algorithm;
2. removing the need for false-positive catch trials; and

3. speeding up the rate of stimulus presentation in patients who respond quickly. The SITA algorithm monitors the patient's response rate and adjusts the presentation rate accordingly.

The SITA algorithm is currently available in two forms, standard and fast. SITA Fast has more liberal terminating criteria to further reduce overall test times.

Static Suprathreshold Perimetry

In a suprathreshold examination, the stimuli are initially presented at an intensity that is calculated to be above the patient's threshold. If the stimuli are seen then it is assumed that no significant defect exists. This strategy has largely been developed as a screening procedure for conditions such as glaucoma.

There are many different types of suprathreshold tests and Table 1 highlights some of the major differences.

Selection of the test intensity is an important part of a suprathreshold test. If the intensity is set too high then the test will become insensitive to shallow defects. If the intensity is set too low then the test looses specificity. Most suprathreshold tests set the intensity at 5–6 dB above the threshold estimate.

Multiple stimulus tests are faster (approximately twice as fast in a person without a defect). The need to verbally respond to each presentation helps maintain patient attention, improves threshold estimates and reduces variability.

Test Targets

Most modern perimeters use stimuli whose sizes were defined by Goldmann (see Table 2).

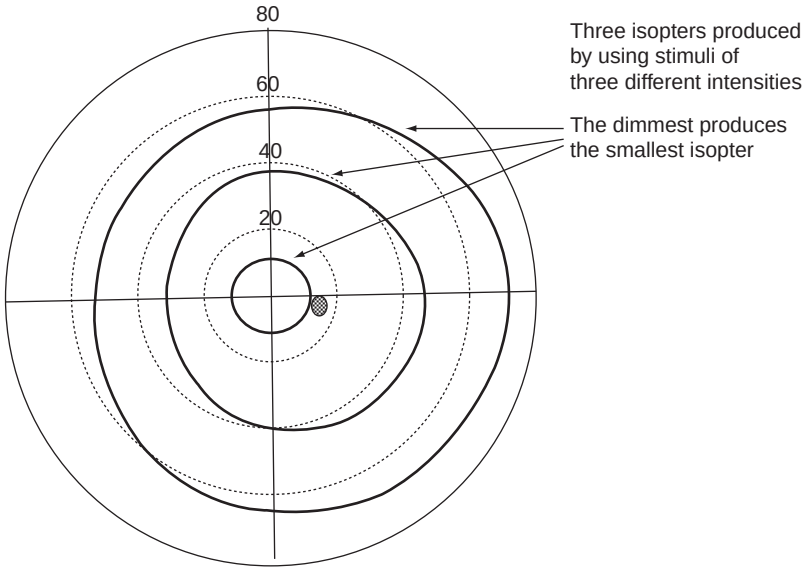

Figure 1 A map of a patient's visual field produced through kinetic perimetry using test stimuli of three different intensities. The dimmest test produces the smallest isopter.

Table 1 The different types of suprathreshold visual field test strategies

Test intensity	Fixed across the whole field	Used to test the visual field of drivers where the intensity is well above the estimated threshold
	Increases with eccentricity	Most common, with the increase matched to a database of threshold measures and age
Threshold setting	Age related	The test intensity is based upon the age of the patient.
	From measurement	The test intensity is based upon a series of threshold estimates at a few test locations, usually 4
Presentation	Single stimulus	Test locations are presented one at a time and the patient indicates when they see the stimulus by pressing a response button
	Multiple stimulus	Test locations are presented in patterns of 2–4 stimuli and the patient verbally reports the number seen
Algorithm	Standard	If stimulus is missed, it is presented a second time and only if missed twice is it marked as a miss. Pass criterion is one seen out of up to two presentations
	Multisampling	Pass criterion is raised, a typical one being three seen out of up to five presentations

Table 2 Goldmann stimulus sizes

Goldmann size	*Nominal size (mm^2)*	*Angular subtence (min of arc)*
0	0.0625	3.78
I	0.25	7.68
II	1.0	15.36
III	4.0	30.71
IV	16	61.3
V	64	122.56

Standard Achromatic Perimetry

Standard achromatic perimetry (SAP) is the most widely used form of perimetry where a white stimulus is projected onto a white background, often called white-on-white perimetry. It normally uses a size III or V Goldmann stimulus on a background luminance of 31.5 apostilbs (10 cd m^{-2}). The intensity of the stimuli is given in decibels of attenuation from a fixed value of 10 000 apostilbs (this can vary from instrument to instrument). Thus, 0 dB corresponds to 10 000 abs, 10 dB to 1000 abs, and 20 dB to 100 abs.

Short-Wavelength Automated Perimetry

Patients with glaucoma often have an associated color vision defect in which their sensitivity to blue light is reduced. This observation led researchers to question whether or not the blue sensitive mechanism was more susceptible to glaucomatous damage and whether or not a perimeter that specifically targeted the blue mechanism might not be more sensitive than those that use the conventional SAP stimuli.

A problem encountered when trying to test the blue mechanism is the relatively low sensitivity of blue cones. Even at short wavelengths (440 nm) the blue sensitive cones are only marginally more sensitive than the red and green cones. Selective damage to the blue cones would have relatively little effect upon sensitivity as the red and green cones would simply step in once the blue cone sensitivity dropped below that of the other receptors. To overcome this problem, the red and green cones are desensitized by adapting the eye to a yellow light. **Figure 2** shows the sensitivity of the three receptors after adaptation. The blue cones are exposed at 440 nm wavelength. The extent of exposure is important. If we consider that any damage to the blue cones mechanism is likely to lower its sensitivity we can see from **Figure 2** just how much loss can be tolerated before the red and green receptors again become the most sensitive (approximately 1.5 log units).

There have been a number of studies that have demonstrated that blue-yellow defects precede those for SAP, however, the test has not been widely adopted because:

1. blue-yellow perimetry is particularly sensitive to lens opacities;
2. short-wavelength automated perimetry is more variable than SAP;
3. patients find the test difficult; and
4. most patients seen in a glaucoma clinic either have no visual field loss or have defects that can be detected with SAP.

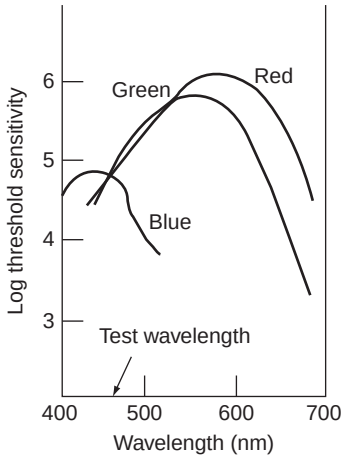

Figure 2 The log threshold sensitivity of the blue, green, and red cone systems after adaptation with a yellow light that desensitizes the red and green cones. Under these conditions the blue cones can be tested using 440 nm wavelength test light. Note that even after adaption, blue cones are approximately 1.5 log units less sensitive than green and red cones.

High-Pass Resolution Perimetry (Ring Perimetry)

High-pass resolution perimetry uses ring-shaped targets of varying size (see **Figure 3**). The luminance inside each ring target is the same as the background while the core of the ring is brighter and its inner and outer edges darker. The overall intensity profile of the ring is such that when it cannot be resolved it cannot be detected. Patients press a response key when they see the stimulus (presentation time 165 ms) and a repetitive bracketing strategy is used to establish the minimum resolvable ring size.

High-pass resolution perimetry has good sensitivity and specificity when compared to SAP. It has also been shown to have threshold variability that is independent of sensitivity and can detect progressive loss earlier than conventional perimetry. High-pass resolution perimetry is also fairly fast taking on average only 5.5 min to test 50 locations.

On the negative side, the technique is sensitive to blur, either refractive or due to media changes, unable to measure defect depth within small circumscribed lesions, and is unable to detect scotomata whose size is less than the local liminal test target. With the current monitor technology, there is also a relatively small dynamic range of stimuli which limits the test ability to monitor loss in patients with significant loss.

Figure 3 High-pass resolution perimetry uses ring-shaped targets of varying size. The luminance inside each ring target is the same as the background while the core of the ring is brighter and its inner and outer edges darker. The overall intensity profile of the ring is such that when it cannot be resolved it cannot be detected. Patients press a response key when they see the stimulus (presentation time 165 ms) and a repetitive bracketing strategy is used to establish the minimum resolvable ring size.

Frequency-Doubling Technology Perimeter

The frequency-doubling technology (FDT) perimeter is based upon an illusion known as frequency doubling, in which an alternating sinusoidal grating of low spatial frequency (<4 cpd) appears, at certain temporal frequencies (>15 Hz), to have twice as many lines. This illusion is believed to be mediated by the magnocellular (M-cell) pathway and in particular by the large fiber diameter *My* ganglion cells which constitute 1.5–2.5% of all retinal ganglion cells.

Recent investigations of ganglion cell fiber loss in glaucoma have led to the development of a number of theories. One theory is that there is selective loss of M-cell fibers during the early stages of this condition. Another is that there is selective loss of large diameter axons and a third is that mechanisms with little redundancy (sparse representation) are likely to show losses earlier than those with greater redundancy. As FDT is believed to be based upon large-diameter M-cell fibers, which are sparsely represented, a screening test based upon this illusion should, according to all these theories, be particularly sensitive to early glaucomatous loss. However, while FDT perimeter uses the appropriate spatial and temporal frequencies for the illusion, the task presented to the patient is one of contrast sensitivity, that is, the patient is being asked when he/she can detect the appearance of a target in the peripheral field not when he/she sees the frequency-doubling illusion.

The FDT perimeter uses 0.25 cpd stimulus that subtend 10° at a temporal frequency of 25 Hz. A modified binary search strategy is used to test 17 locations. Threshold and suprathreshold test strategies have good sensitivities and specificities and the instrument has many attractive characteristics for glaucoma screening. It is a small, self-contained, portable instrument that is not sensitive to background illumination levels. It does not require a corrective lens for refractive errors (results are reported to be independent of refractive error up to ±7.00 D) and it is relatively fast.

A second-generation FDT perimeter, Humphrey Matrix, was produced in 2005. This instrument uses a range of stimulus sizes (10°, 5°, and 2°), two spatial frequencies (0.25 and 0.5 cpd) and three temporal frequencies (25, 18, and 12 Hz) to give a wider range of test programs including those that mimic those widely used in SAP (24-2, 10-2). These modifications overcome the major drawback of poor spatial resolution in the earlier instrument.

Reliability Estimates

Most modern perimeters incorporate methods for estimating the reliability of the patient's responses. Widely used measures are fixation accuracy, false-positive response rate, and false-negative response rate. The relationship between these reliability measures and test–retest variability is, however, poor.

Fixation Accuracy

The simplest technique for monitoring fixation is observation by the perimetrist either with the aid of a telescope or camera. Such techniques are totally dependent upon the perimetrist's judgment and continued vigilance.

Some perimeters incorporate a fixation monitor that indicates when fixation has been lost. Most fixation monitors cannot differentiate between rotations of the eye, which occur when the patient looks away from the fixation target, and translations of the eye. A translation of the eye, such as a slight sideways movement of the head, does not necessarily mean that fixation has been lost or that the angular subtence of the perimetric stimuli has been changed by a significant amount. Automatic fixation monitors are also generally insensitive to small, but significant, fixation errors (e.g., 1°).

Most modern perimeters incorporate the Heijl–Krakau technique for sampling fixation. With this technique stimuli are occasionally presented in the region of the patient's blind spot. If fixation is maintained during these presentations the stimulus will not be seen. If, on the other hand, fixation is lost then the stimulus is likely to fall outside of the blind spot and elicit a response from the patient. A frequently quoted cut off for reliable fixation errors is less than 33% of presentations. There is no evidence on which to base this cut-off value and the relatively small number of trials (on average there are only 10–12 fixation trials in a perimetric test) mean that the precision of the estimated rate is very low. As the position of the blind spot varies from one individual to another it is necessary, at the onset of the examination, to have a little routine which establishes the blind spot's location. The accuracy of this routine is important as errors may later manifest themselves

as numerous fixation errors in a patient who has maintained good fixation.

The major advantages of the Heijl–Krakau technique are its simplicity and ease of implementation. Its disadvantages are:

1. It only samples fixation.
2. It increases the examination time.
3. It is unlikely to detect small fixation errors as the standard target subtends ≈0.5° and the blind spot an area of 5° × 7°.

At present, the best method is direct observation by the perimetrist. This technique is not only sensitive but also, via verbal feedback, can result in an improvement in the fixation accuracy for subsequent presentations.

False-Positive Responses

Single stimulus static test programs derive an estimate of the false-positive response rate with a number of catch trials (when the instrument goes through the motions of presenting a stimulus but does not actually present one). If the patient responds to one of these catch trials then this is classified as a false-positive response. In the SITA test algorithms this catch trial method has been replaced by one based upon response times (interval between the presentation of a stimulus and the patient pressing the response button). Olsson and colleagues were able to show a good relationship between the number of response times that fell outside a patient's normal response window and the false-positive response rate. They also demonstrated that estimates based upon response times were more repeatable than those based upon catch trials. An added advantage of using response times is that it reduces, slightly, the overall test time. Many patients do not give a single false-positive response during a visual field test and it is important to remember the false-positive response rate is a poor predictor of test–retest variability. A less than 33% false-positive rate is often used to differentiate reliable from unreliable results, again there is no evidence on which to base this cut-off value and the relatively small number trials means that the precision of the estimate is poor. More stringent cut-offs are often used in research studies.

False-Negative Responses

An estimate of the false-negative response rate is obtained by retesting a location with a stimulus whose intensity is above the already established threshold. If the patient fails to respond positively to this presentation then this is classified as a false-negative. False-negative responses are often found to increase with the extent of visual field damage and this is believed to be due to the relationship between variability and sensitivity. Most patients have a low false-positive rate and those with a rate above 33% are often classified as unreliable although more stringent cut-offs are often used in research trials. Again there is no evidence to support this cut-off value and the number of trials means that the precision of the estimate is poor.

Clearly, if the patient makes a high proportion of errors then his/her results must be viewed with a certain amount of suspicion. The judgment of an attending perimetrist is, however, often of greater value than these reliability estimates.

Analytical Techniques

Total Deviation and Pattern Deviation Plots

Total deviation and pattern deviation maps take the threshold data from a visual field examination and calculate, for each test location, whether or not the threshold values are significantly different from those of a normal eye of the same age. They rely upon the perimeter having a database of threshold values from normal eyes in order to perform these calculations. Pattern deviation values differ from total deviation values in that they have been adjusted for overall shifts in sensitivity. For example, we might get a patient whose overall sensitivity is below that of a normal patient of the same age. In this case, some locations may be highlighted as being abnormal on the total deviation map but not on the pattern deviation map. This adjustment is based upon the findings from some of the most sensitive test locations, that is, if these are above or below normal then all values are shifted down or up.

Total and pattern deviation probability maps use the distribution of total and pattern deviation values within a normal population, to calculate the probability of each threshold estimate coming from a normal eye. The results are expressed in the standard statistical way, that is, as being beyond the 5%, 2%, 1%, or 0.5% probability level.

Global Indices

Flammer and colleagues proposed that the visual field defects associated with glaucoma could be divided into three different categories: (1) those that cause an overall depression in the sensitivity of the eye, (2) those that cause local defects, and (3) those that cause an increase in the variability of results; and that each category could be represented by an index. They called these three indices mean defect, loss variation, and short-term fluctuation.

The concept of using three separate indices to represent a glaucomatous visual field has found very wide acceptance within the ophthalmological professions and most visual field instruments now incorporate a set of algorithms which compute these or very similar indices. The name given to these indices varies from one instrument to another, as does the form of calculation. In the

Humphrey instrument they are called mean deviation, pattern standard deviation, and short-term fluctuation and the values are weighted according to the normal variance seen at each location.

Mean defect (deviation) (MD) gives the average difference between the threshold values and those from an age-matched control. Loss variance is a measure of the spread of defect values which increases when there is a local defect. An alternative measure of spread is the standard deviation (SD). This statistic has the advantage of giving a measure of spread in decibels and is now used in preference to variance measures. In the Humphrey perimeter this is called pattern standard deviation (PSD) while in the Octopus it is called sLV, which stands for the square root of the loss variance, that is, the SD. Short-term fluctuation is a measure of variability in threshold estimates derived from repeat testing a subset of locations. However, a global estimate of variability is of limited value as it is now recognized that variability is dependent upon sensitivity and varies across the visual field.

MD and sLV or PSD can be plotted over time to aid the detection of progressive loss. They can also be plotted against each other to give a measure of the extent of loss, Brusini staging system. The sensitivity of MD to media opacities, such as cataract, has led to the development of a new global index for the Humphrey perimeter called the visual field index (VFI). This index gives a percentage measure of the residual field and uses pattern deviation values and a weighting system based upon cortical magnification to give a more representative measure of a patient's visual function.

The Glaucoma Hemifield Test (GHT) (Humphrey) and cluster analysis (Octopus) are additional indices designed to help detect rather than quantify glaucomatous visual field loss. They are designed to detect vertical asymmetry between the superior and inferior hemifields. The GHT looks at the asymmetry in pattern deviation probability values between five areas in the superior field and their mirror images in the inferior field, while the Octopus cluster analysis uses the defect values within each of five slightly different clusters within the superior and inferior visual field. Both use a database of normal values to establish whether or not a response is outside normal limits.

Linear Regression

Linear regression can be applied to a longitudinal series of:

1. global indices (MD, PSD, VFI),
2. clusters of test locations (Octopus cluster analysis), or
3. individual test locations (point-wise analysis).

The significance of any change over time and the gradient of the regression line can be used for predicting long-term outcomes.

The Progressor software package presents the findings from a point-wise regression analysis in a particularly novel way that retains the information on both the depth of the defect and the significance of any change while the Peridata software package (Peridata) color codes each test location according to the significance of any change. From these charts the clinician can ascertain whether or not any progressive changes are close to fixation or at the edge of the visual field, where they may have been influenced by artifacts such as a droopy upper lid.

The accuracy of a regression analysis and any predictions is dependent upon the number of examinations. Several research groups have concluded that we really need about five visual field results before we can reliably calculate the gradient of the regression line.

Change Probability

Change probability compares each test location with that of a baseline measure and establishes whether or not there has been any significant change. Results are presented in the form of a visual field plot where each location is classified according to a series of cut-off probability levels, for example, $p < 0.05$. The baseline value is often the average of two visual field results (to give a better estimate) that need not be the first ones recorded, that is, we can establish whether there has been any significant change from intermediate results.

Change probability analysis takes into account the relationship between variability and sensitivity. One of the criticisms of change probability is that it does not use the information obtained in intermediate examinations, that is, it only compares the current finding with the baseline value. The recently introduced Progression Analysis Probability plot for the Humphrey Visual Field Analyzer uses different symbols to code whether or not the change has occurred in just the current, last two, or last three examinations.

Pharmacological Vitreolysis

A Gandorfer, Augenklinik der Ludwig-Maximilians-Universität, München, Germany

Glossary

Internal limiting membrane (ILM) – The inner border of the retina composed of the basement membrane of retinal glial cells (Müller cells).
Microplasmin – The recombinant form of human plasminogen containing the catalytic domain of the enzyme.
Plasmin – A serine protease mediating fibrinolysis.
Posterior vitreous detachment (PVD) – Separation of the vitreous cortex from the retina either spontaneously or surgically/pharmacologically.
Synchisis – Liquefaction of the vitreous gel.
Syneresis – Separation of the vitreous from the retina.
Vitreoretinal interface – The functional complex between the retina and the vitreous, that is, between the internal limiting membrane of the retina and collagen fibers forming the vitreous cortex.
Vitreoschisis – Splitting of the vitreous cortex, leaving a layer of cortical vitreous behind at the retina, thereby resulting in an incomplete posterior vitreous detachment.
Vitreous liquefaction – Converting the gel-like status of the vitreous into a liquid status.

Introduction

Pharmacological vitreolysis is among the top five wish list of medical and surgical retina specialists. Separating the vitreous cortex completely from the retina by pharmacological means would be a major achievement compared to today's mechanical techniques of vitrectomy. As incomplete vitreoretinal separation and vitreoschisis play a central role in the progression of commonly and potentially blinding diseases such as diabetic retinopathy and maculopathy, proliferative vitreoretinopathy (PVR), and vitreomacular traction syndromes, induction of complete posterior vitreous detachment (PVD) by pharmacological means has a major impact on both surgical techniques and public health aspects.

Enzyme-assisted induction of PVD enables the surgeon to create a clean retinal surface which cannot be achieved by mechanical means currently. Moreover, complete vitreoretinal separation without directly approaching the retina and macula by bent needles or forceps would make surgery easier and safer. In children and young adults and in patients with firm vitreoretinal adhesion, complete separation of the vitreous from the retina would be possible. This would help to improve both the anatomical and functional outcome by eliminating remnants of vitreous which act as a scaffold and promoter of persistent and recurrent cellular proliferation. In progressively blinding diseases such as diabetic retinopathy, separating the vitreous from the retina before neovascular and fibrocellular proliferation grow into the vitreous cortex would prevent advanced stages of the disease. Finally, pharmacological vitrectomy holds the potential of improving retinal oxygen levels in hypoxic retinal diseases in a more applicable way compared with mechanical vitrectomy. This is of particular importance, given the increasing incidence of diabetic retinopathy in the world. The goal of enzymatic vitreous disruption is to manipulate the vitreous collagen pharmacologically, both centrally, achieving liquefaction, as well as along the vitreoretinal interface to induce PVD, and to create a cleavage plane more safely and cleaner than can be achieved by mechanical means.

The Role of the Vitreous in Disease

The vitreous, and in particular the vitreoretinal interface, plays an important role in the pathogenesis of many retinal disorders. An abnormal interface has been implicated in vitreomacular traction syndrome, macular holes, diabetic macular edema, proliferative diabetic retinopathy, retinal detachment, and PVR. A common finding in these entities is a vitreous which is firmly attached to the retina, thereby preventing complete PVD. Even in cases of vitreous liquefaction, the vitreous cortex remains attached to the retina, forming the so-called vitreoschisis, which acts as a scaffold for fibrocellular and fibrovascular proliferations. This may increase traction on the retina, leading to significant patient morbidity and surgical failure.

The Objectives of Pharmacological Vitreolysis

Vitrectomy is the treatment modality of choice in these patients, and complete removal of the cortical hyaloid is critical for success of the operation. However, mechanical separation of the vitreous from the retina is incomplete as cortical vitreous fibrils are left behind on the internal

limiting membrane (ILM) of the retina. Removal of the ILM creates a new vitreomacular interface by eliminating the vitreous cortex and proliferative tissue. ILM removal, however, requires direct manipulation of the macula which can potentially result in retinal damage, leading to functional defects, such as central or paracentral scotomata (an area of diminished vision within the visual field). Ultrastructural analysis of peeled ILM specimens has shown damage to Müller cells and avulsion of macular ganglion cells. Although ILM peeling appears safe in clinical terms, it may not be the best option in terms of safety and visual benefit.

Cleaving the vitreoretinal interface at the vitreal side of the ILM would be a logical approach to relieve traction as the ILM itself cannot exert traction. Traction is generated by contractile cells at the vitreoretinal interface. In most instances, these cells proliferate on a layer of vitreous cortex which remains attached at the ILM after incomplete PVD. From an ultrastructural point of view, separation of the cortical vitreous completely from the ILM would eliminate the cellular proliferations, thereby relieving the traction they generate.

Complete separation of the vitreous from the retina by enzymatic means would remove the pathologic tissue from the retina, and eliminate the scaffold for cellular reproliferation. Diabetic eyes, especially, are characterized by a firm vitreoretinal attachment and a thickened and taut vitreous cortex which frequently contains cellular proliferations. Given that some cells have been shown to produce vasoactive and vasoproliferative substances, such as vascular endothelial growth factor and others, complete removal of the vitreous cortex with embedded cells could lead back to a more physiological state of the vitreomacular interface in patients with diabetic macular edema.

Moreover, a clean ILM, without remnants of the cortical vitreous, would hypothetically prevent the growth of fibrovascular membranes out of the retina as these newly formed vessels commonly proliferate within and along the cortical hyaloid. Given that a complete PVD was achieved by a relatively atraumatic intravitreal injection and not by an operation such as vitrectomy, pharmacologic vitreolysis could be discussed in select cases as a prophylactic treatment regime to prevent proliferative diabetic retinopathy.

Another mechanism of action of enzymatically induced PVD and vitreous liquefaction is an alteration of molecular flux into the vitreous cavity, out of the vitreous cavity, and across the vitreoretinal interface. It has been known since the 1980s that oxygen levels within the vitreous cavity are higher in vitrectomized eyes compared to nonvitrectomized eyes. Recently, it has been demonstrated that the oxygen supply of the retina can be modified by a microplasmin-induced PVD and vitreous liquefaction. It is noteworthy that liquefaction alone did not have this effect. Obviously, the vitreous cortex acts as a barrier for molecules when crossing the vitreoretinal border, and this may not only be the case for oxygen, but also when other molecules are produced within the eye or even when they are injected intravitreally. A better oxygen supply of the retina addresses diseases with hypoxia such as diabetic retinopathy and retinal vein occlusion, both complicated by macular edema and neovascularization, and those in which anti-vascular endothelial growth factor (VEGF) treatment is performed in order to decrease intravitreal VEGF levels, such as age-related macular degeneration (AMD). Interestingly, eyes with wet AMD also show a significantly higher percentage of attached vitreous at the macula compared to dry AMD eyes as well as eyes without AMD. Separation of the posterior hyaloid from the retina and liquefaction alters the molecular flux across the vitreoretinal interface, and it might be expected that larger molecules are even more affected by the barrier function of the cortical vitreous than small molecules such as oxygen are.

The summary of potential objectives of pharmacologic vitreolysis (**Figure 1**) includes complete vitreoretinal separation, resulting in a clean ILM, less manipulation at the vitreoretinal interface compared to current vitrectomy techniques, a well-defined cleavage plane at the vitreal side of the ILM to remove fibrocellular traction, better oxygen supply of the retina due to an alteration of the molecular flux, and a less traumatic and potentially prophylactic treatment regime in select cases in the future.

Enzyme Candidates for Vitreous Disruption

Chondroitinase

A 240-kDa chondroitin sulfate proteoglycan is associated with the vitreoretinal interface (**Table 1**). The greatest immunoreactivity of this proteoglycan has been observed in regions of firm vitreoretinal adhesion, such as the vitreous base and the papillary margin, suggesting a major role in vitreoretinal adhesion. The enzyme chondroitinase cleaves this proteoglycan and has been studied as an adjunct in vitrectomy in two human donor eyes and in 57 cynomolgus monkeys. Intravitreal injection of the enzyme separated the vitreous from the retina without damaging the ILM. Three monkeys have been followed for 14–16 months after surgery without any adverse effects. Chondroitinase has also been utilized to detach epiretinal membranes in four monkeys, providing evidence that chondroitin sulfate proteoglycan participates in the adhesion of epiretinal membranes to the ILM. Unfortunately, no further preclinical or clinical results have been reported yet.

Hyaluronidase

Hyaluronan represents one of the two major macromolecules of the vitreous, and is supposed to maintain the three-dimensional structure of the vitreous gel by coating

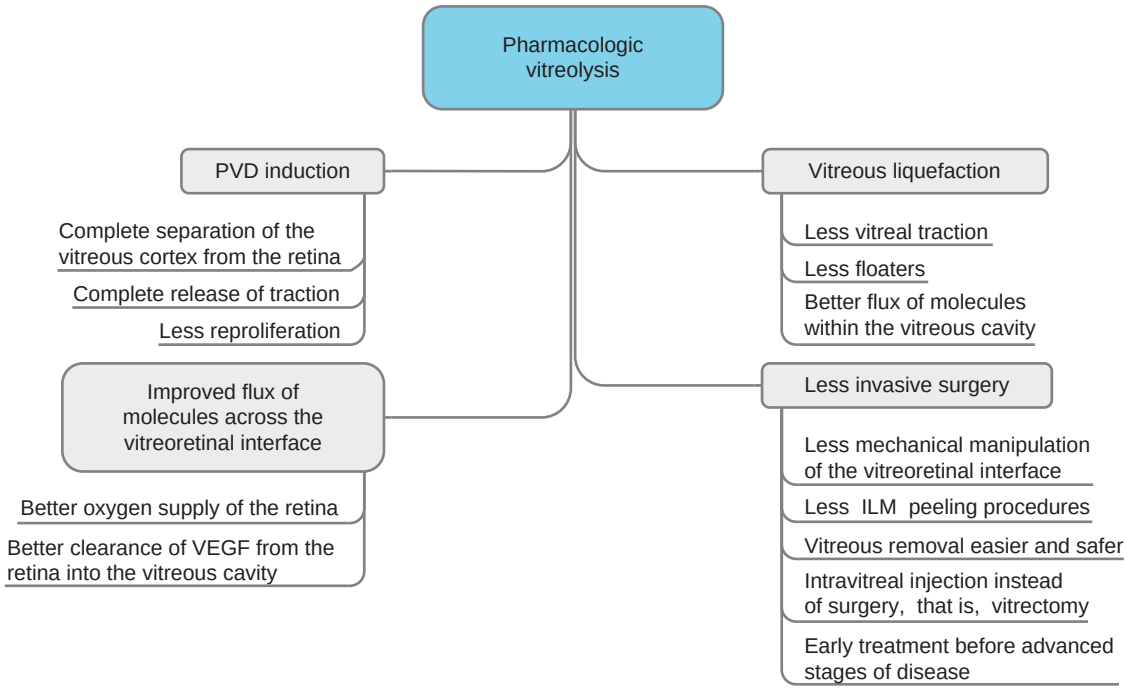

Figure 1 The objectives of pharmacologic vitreolysis.

Table 1 Enzyme candidates for enzymatic vitreous disruption

Enzyme	*Target*	*Effect*
Chondoitinase	Chondroitinsulfate at the vitreoretinal interface	PVD in animal models
Hyaluronidase	Hyaluronan	Liquefaction
Dispase	Type IV collagen	PVD, inner retinal damage
Plasmin/Microplasmin	Laminin and fibronectin at the vitreoretinal interface MMP-2 activation	PVD and liquefaction

PVD, posterior vitreous detachment; MMP, matrix metalloproteinase.

the collagen fibrils and by bridging them with interconnecting filaments. Hyaluronidase (Vitrase®) cleaves hyaluronan and has been suggested to liquify the vitreous.

A phase-III clinical trial has shown that 55 IU of highly purified ovine hyaluronidase (Vitrase®) helps to clear eyes with vitreous hemorrhage 1 month after intravitreal application. In a companion article on the safety results, no serious safety issues were reported. In particular, the incidence of retinal detachment was not statistically different between treated eyes and control groups. No assessment, however, was performed in terms of PVD induction, and previous experimental trials of hyaluronidase in rabbits failed to achieve PVD.

Dispase

Dispase, a neutral 41-kDa protease isolated from *Bacillus polymyxa*, selectively cleaves type IV collagen and fibronectin. The enzyme facilitated PVD in enucleated porcine and human eyes, and in pig eyes *in vivo*. However, partial digestion of the ILM was observed in postmortem eyes, exposing the mosaic pattern of Müller cell endfeet. In rabbit eyes *in vivo* and in human eyes 15 min before enucleation, intravitreal injection of dispase caused intraretinal hemorrhages and ILM disruption at bleeding sites. In this series, there was no effect of dispase on PVD induction.

As dispase acts on type IV collagen, forming the main structural protein of basement membranes including the ILM, changes of the inner retina following application of the enzyme are not surprising. The enzyme has been shown to effectively induce PVR in rabbits in a dose-dependent fashion, known as the dispase model of PVR; in addition, in case future studies are planned, there is a definite need to investigate the safety issues of the enzyme.

Plasmin and Microplasmin

Plasmin is a nonspecific serine protease mediating the fibrinolytic process. It also acts on a variety of glycoproteins including laminin and fibronectin, both of which are

present at the vitreoretinal interface. In 1993, PVD could be achieved in rabbit eyes by intravitreal injection of the enzyme followed by vitrectomy. In 1999, Hikichi and co-workers confirmed complete PVD after injection of 1 U plasmin and 0.5 ml SF_6 gas in the rabbit model, without evidence of retinal toxicity.

We investigated the effect of plasmin in porcine postmortem eyes and in human donor eyes. In porcine eyes, we observed a dose-dependent separation of the vitreous cortex from the ILM after intravitreal injection, without additional vitrectomy or gas injection. In scanning electron microscopy, a bare ILM was achieved by 1 U of porcine plasmin 60 min after injection, and with 2 U of plasmin 30 and 60 min after injection, respectively. In control fellow eyes which were injected with balanced salt solution (BSS), the cortical vitreous remained attached to the retina. In human donor eyes, 2 U of human plasmin from pooled plasma achieved complete PVD 30 min after injection, whereas the vitreoretinal surface of the fellow eyes was covered by collagen fibrils. In both studies, transmission electron microscopy revealed a clean and perfectly preserved ILM in plasmin-treated eyes, and no evidence of inner retinal damage. Li and colleagues confirmed these results, and reported a reduced immunoreactivity of the vitreoretinal interface for laminin and fibronectin following application of plasmin.

In an experimental setting simulating the application of plasmin as an adjunct to vitrectomy, we injected human donor eyes with 1 U of plasmin, followed by vitrectomy 30 min thereafter. All plasmin-treated eyes showed complete PVD, whereas the control eyes which were vitrectomized conventionally had various amounts of the cortical vitreous still present at the vitreoretinal interface.

Plasmin is not available for clinical application, and alternative strategies have been pursued to administer the enzyme in vitreoretinal surgery. Tissue plasminogen activator was injected into the vitreous in an attempt to generate plasmin by intravitreal activation of endogenous plasminogen. In an animal model in rabbit eyes, complete PVD was observed in all eyes treated with 25-μg tissue plasminogen activator. Breakdown of the blood–retinal barrier was necessary to allow plasminogen to enter the vitreous, and this was induced by cryocoagulation. In two clinical pilot studies, 25-μg tissue plasminogen activator was injected into the vitreous of patients with proliferative diabetic retinopathy 15 min before vitrectomy. The results of both studies, however, were contradictory in terms of PVD induction and clinical benefit. More recently, Peyman's group demonstrated PVD induction in rabbit eyes by an intravitreal administration of recombinant lysine-plasminogen and recombinant urokinase.

Autologous Plasmin

Autologous plasminogen purified from the patient's own plasma by affinity chromatography was converted to plasmin by streptokinase *in vitro*. A measure of 0.4 U of autologous plasmin enzyme (APE) was injected into the vitreous in patients with pediatric macular holes, diabetic retinopathy, and stage 3 idiopathic macular holes, followed by vitrectomy after 15 min. All APE-treated eyes achieved spontaneous or easy removal of the posterior hyaloids, including one eye that had vitreoschisis over areas of detached retina.

Microplasmin

Recombinant microplasmin (ThromboGenics Ltd., Leuven, Dublin, New York), a truncated molecule containing the catalytic domain of human plasmin, has been administered successfully into the vitreous of human and porcine postmortem eyes, and in rabbit and cat eyes *in vivo*. In all experimental settings, complete PVD was achieved in a dose-dependent fashion. No alteration of the inner retina was seen, and there was no change in antigenity of neurons and glial cells. Microplasmin was further tested in different animal models sponsored by the manufacturer, and a first clinical trial (the microplasmin in vitrectomy I (MIVI-I) trial) was designed then.

The MIVI-I trial investigated the effect of microplasmin given 1 h, 1 day, and 1 week before vitrectomy in patients with vitreomacular traction. The results of this trial have been published recently, and it can be said that the pharmacologic effect of microplasmin was promising and further trials are now underway to show the efficacy and safety of this recombinant enzyme in different clinical settings, such as vitreomacular traction syndromes, including macular holes, diabetic macular edema, and AMD.

Summary

There are at least four reasons to pursue enzymatic vitreous disruption. First, some retinal diseases that are currently treated by mechanical manipulation of the vitreoretinal interface could be managed more safely by pharmacologic technique. Second, enzymatic vitreous disruption may achieve better anatomic and, thus, potentially functional results by creating a cleaner cleavage plane between the vitreous and the retina than can currently be achieved by vitrectomy techniques. This is of particular importance in eyes with incomplete removal of the cortical vitreous from the retina, and those with vitreoschisis, such as diabetic eyes. Third, as incomplete PVD has been shown to be associated with the development of aggressive fibrovascular proliferation and macular edema, pharmacologic induction of complete PVD could prevent progression of diabetic retinopathy if given before advanced stages of diabetic eye disease. Fourth, cleaving the cortical hyaloid completely from the retina changes

the molecular flux across the vitreoretinal interface and improves the oxygen supply to the retina.

Plasmin holds the promise of inducing complete PVD without morphologic alteration of the retina. Several independent studies confirmed a dose-dependent and complete vitreoretinal separation, associated with perfect preservation of the ultrastructure of the ILM and the retina. In addition, a dose-dependent liquefaction of the vitreous induced by microplasmin has been demonstrated by dynamic light scattering in dissected porcine vitreous and in intact pig eyes. The combination of PVD induction and liquefaction in one molecule is one major advantage of plasmin and microplasmin compared with other enzymes tested, as liquefaction alone carries the risk of tractional retinal breaks. So far, the safety profile and the effects of microplasmin and plasmin are promising. Clinical trials will demonstrate whether practice can hold what theory has promised.

Pharmacology of Aqueous Humor Formation

C B Toris, Nebraska Medical Center, Omaha, NE, USA

Glossary

Aqueous flow – The flow rate of aqueous humor from the posterior chamber into the anterior chamber. It is measured by fluorophotometry and is considered to estimate aqueous humor production.
Aqueous humor production – The secretion rate of aqueous humor from the ciliary processes into the posterior chamber.
Fluorophotometry – The technique of measuring the amount of fluorescein in the cornea and anterior chamber. The disappearance rate of fluorescein over a period of a couple of hours is used in the calculation of aqueous flow.
Inflow – The flow of aqueous humor from the posterior to anterior chamber.
Outflow – The flow of aqueous humor out of the eye through the anterior chamber angle.

Physiology of Aqueous Humor Production

Aqueous humor performs several important functions in the eye (Figure 1). It is the source of nutrients for the avascular tissues of the anterior chamber, including the cornea and lens, and it removes their waste products. In addition, its controlled circulation around the anterior chamber and out through the anterior chamber angle is necessary for the maintenance of intraocular pressure (IOP).

The secretion of aqueous humor is a process requiring ultrafiltration and active transport. Ciliary processes are exquisitely designed for this purpose (Figure 1). They contain a stromal core with a rich supply of capillaries and two layers of epithelial cells positioned apex to apex. The innermost layer of nonpigmented ciliary epithelial cells is interconnected by tight junctions and the outer layer consists of pigmented ciliary epithelial cells interconnected by gap junctions. Plasma filtrate enters the interstitial spaces of the stromal core through capillary fenestrations (ultrafiltration). Plasma proteins are blocked from entering the posterior chamber by the tight junctions in the apical region of the intercellular spaces of the nonpigmented ciliary epithelium. This design creates a high protein concentration and high oncotic pressure in the tissue fluid and a reduction in the transcapillary difference in the oncotic pressure. Hydrostatic and oncotic pressure differences across the ciliary epithelium favor movement of water into the ciliary processes from the posterior chamber. Therefore, movement of fluid into the posterior chamber requires secretion. This is done by active transport of ions from the nonpigmented ciliary epithelium cells into the clefts between the cells. The major ions involved in this process are Na^+, HCO_3^-, and Cl^-. The osmotic pressure in the intercellular clefts increases as ions are pumped in. Water and its solutes follow and eventually move out of the clefts and into the posterior chamber. Enzymatic inhibitors of these transport processes significantly reduce aqueous flow.

In the healthy eye, the inflow and outflow of aqueous humor have a circadian rhythm which maintains a predictable pattern of IOP throughout a 24-h period. Chronic and extreme variations from this natural rhythm can cause serious sight-threatening conditions. At one extreme is the persistent elevation in IOP, which increases the risk of glaucoma; a well-documented means of treating glaucoma is to reduce IOP by slowing the production rate of aqueous humor. At the other extreme is chronically low IOP (hypotony), which increases the risk of sight-threatening conditions, including corneal changes, accelerated cataract formation, choroidal fluid, maculopathy, cystoid macular edema, or optic disk edema. Stimulating aqueous humor production and increasing IOP in a consistent and predictable manner should provide a means of treating the hypotony and its associated conditions. Dopaminergic drugs have been investigated for this purpose; however, increasing IOP in a safe and controlled manner remains an unmet need.

The circadian rhythm of aqueous humor production is thought to follow circadian changes in autonomic tone and circulating corticosteroids. Supporting this is the strong evidence that the ciliary processes are under autonomic control. Agonists that increase cyclic adenosine monophosphate (cAMP), such as beta-2 (β_2) adrenergic agonists, tend to increase aqueous humor production, while those that reduce cAMP, such as α_2 adrenergic agonists, tend to decrease it. During the day, when background autonomic tone is relatively high and aqueous humor is being produced at a relatively fast rate, α_2 adrenergic agonists and β-blockers effectively reduce aqueous flow and IOP. However, at night when adrenergic tone is relatively low and aqueous humor is being produced at about half its daytime rate, α_1 adrenergic agonists and β-blockers have little effect on aqueous flow and IOP.

Aqueous Flow Suppressants

Some aqueous flow suppressants, also known as inflow drugs, have been available for decades to treat glaucoma. These drugs are categorized as carbonic anhydrase inhibitors (CAIs), β-blockers, and sympathomimetics including α and mixed adrenergic receptor agonists. Clinically available inflow drugs are listed in Table 1.

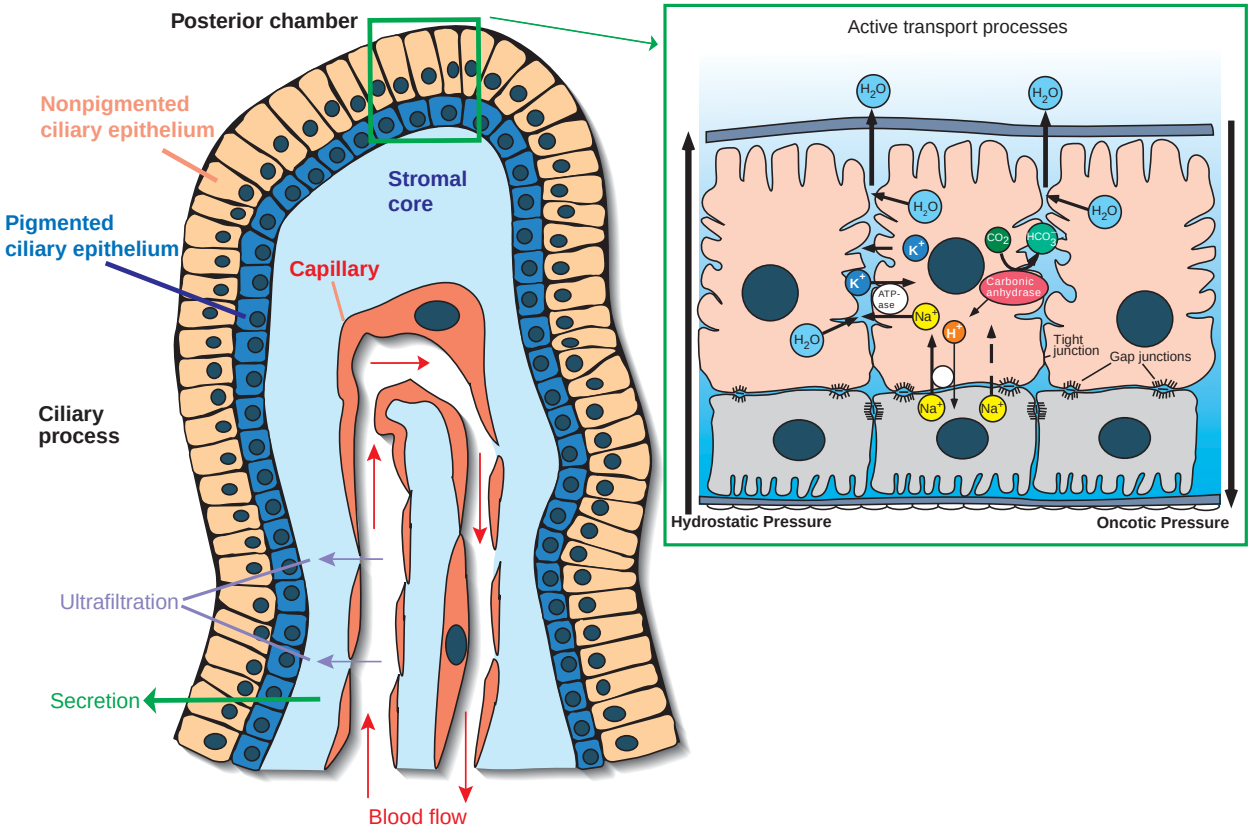

Figure 1 On the left is a ciliary process with a stromal core and capillary network surrounded by two epithelial layers, the nonpigmented and the pigmented ciliary epithelium. Plasma filtrate moves through the capillary fenestrations into the stroma by ultrafiltration and aqueous humor is secreted across the epithelial layers by an active transport process shown at the right.

Table 1 Clinically used drugs that reduce aqueous humor production

	Generic name	*Brand name*
β-blockers	Timolol maleate	Timoptic, Timoptic XE, Istalol
	Timolol hemihydrates	Betimol
	Levobunolol HCl	Betagan
	Carteolol HCl	Ocupress
	Metipranolol HCl	Optipranolol
	Betaxolol HCl	Betoptic
Carbonic anhydrase inhibitors	Dorzolamide HCl	Trusopt
	Brinzolamide HCl	Azopt
	Acetazolamide	Diamox
	Methazolamide	Neptazane
α_2-adrenergic agonists	Apraclonidine HCl	Iopidine
	Brimonidine tartrate	Alphagan
α- and β-adrenergic agonists[a]	Epinephrine HCl	Glaucon, Epifrin, Epinal, Epitrate, Eppy
	Dipivefrin, Dipivelol epinephrine	Propine
Combination drugs	Timolol + dorzolamide	Cosopt
	Timolol + brimonidine	Combigan

[a]Both increases and decreases in aqueous flow have been reported.

Carbonic Anhydrase Inhibitors

Bicarbonate ions are produced in the ciliary body by hydration of carbon dioxide under the control of carbonic anhydrase (**Figure 1**). Under normal conditions, bicarbonate is secreted into the posterior chamber, drawing water with it by osmosis. Inhibition of the carbonic anhydrase enzyme slows the rate of water movement into the posterior chamber, and aqueous production is reduced. If all else remain unchanged, this will decrease IOP.

When administered during the day, oral acetazolamide, a systemic CAI reduces aqueous flow quickly by approximately 30%. However, when administered at night, at a time when aqueous flow is normally low, its effectiveness is inconsistent. One clinical study of acetazolamide reported a decrease in aqueous flow at night, but another study found that it worked no better than placebo.

Systemic CAIs may cause some unpleasant and potentially serious side effects in some patients, which is why significant effort was invested in developing topical CAIs. These drugs, including brinzolamide and dorzolamide, can readily penetrate the cornea and have a very high affinity for ocular carbonic anhydrase. However, for several reasons they are only half as effective as acetazolamide at slowing the production rate of aqueous humor. To lower IOP, topical CAIs must penetrate the cornea and block 99% of the local carbonic anhydrase in ciliary processes. Systemic CAIs reach the ciliary processes through the vasculature, thus avoiding the corneal barriers. Additionally, systemic CAIs may produce extraocular effects that contribute to the IOP reduction. Due to its local delivery, extraocular effects of topical CAIs are expected to be minimal.

β-Adrenergic Antagonists (β-Blockers)

β-Blockers reduce aqueous flow by inhibiting sympathetic nerve activity in the ciliary processes. During the day, timolol suppresses aqueous flow by 28–50%. β-Blockers do not reduce IOP at night when autonomic tone is low because they cannot reduce aqueous flow further than the normally low nocturnal rate. There is additivity of the IOP and aqueous flow effect when β-blockers and CAIs are combined because of the different mechanisms by which these drugs reduce aqueous flow.

Adrenergic Agonists

Adrenergic agonists are drugs that stimulate α_1, α_2, and/or β-adrenergic receptors. Despite 50 years of study, there is no consensus as to the precise mechanism for the IOP reduction of some of these drugs. Although epinephrine, a mixed α_1, α_2, and β-adrenergic receptor agonist, is generally thought to stimulate aqueous production based on many clinical studies, some studies found no effect on or even a decrease in aqueous flow with epinephrine treatment. Epinephrine has complex and dynamic effects on the production and drainage of aqueous humor likely because of its differential activity at multiple receptors. The differing pharmacodynamic effects may depend on which receptor action predominates at the time of the measurement. Recently, more selective agonists at the $\alpha_2$receptor have been developed into efficacious IOP-lowering drugs. Two of these are apraclonidine and brimonidine.

Apraclonidine, an α_2-adrenergic agonist with some α_1-adrenergic activity, was developed initially for the topical treatment of ocular hypertension. Due to the high incidence of allergic reactions to this drug, apraclonidine is no longer routinely used for chronic treatment of ocular hypertension. It reportedly reduces IOP by reducing aqueous flow in addition to some possible effects on outflow.

Brimonidine is a more selective α_2 agonist than apraclonidine but some α_1 activity remains. Within an hour of topical administration, brimonidine reduces IOP by decreasing aqueous flow. In rabbits, one drop of brimonidine causes strong vasoconstriction in blood vessels of the uvea, reduced blood flow to the ciliary body, and insufficient delivery of oxygen and/or other essential energy sources to the ciliary processes. Without a substantial energy source, the production rate of aqueous humor slows. With continued use, the effect of brimonidine on aqueous flow fades and blood flow returns to its normal rate. While this is happening, an effect on outflow, specifically uveoscleral outflow, develops and IOP remains below pretreatment levels.

Although brimonidine and apraclonidine belong to the same class of drugs, their mechanisms of action are not identical. This may be related to the receptor selectivity of each drug. Possible receptors targeted differentially by these drugs include two imidazoline subtypes and four α_2 adrenergic subtypes. Additionally, two of the four known subtypes of α_1 agonists have been found in the anterior segment of the eye. The ocular hypotensive effect of brimonidine in the primate may be mediated through stimulation of an imidazoline receptor rather than an α_2 receptor. The effect of apraclonidine may be through stimulation of a combination of α_1 and α_2 receptors.

When β-blockers and α_2 agonists are combined, the IOP effect is additive despite the fact that both classes of drug reduce aqueous flow. Clearly, the aqueous flow reduction by the different classes of inflow drug is not mediated entirely by the same pathway.

Aqueous Humor Stimulants

At times, stimulation of aqueous flow is desirable, especially in the treatment of chronic hypotony. Currently, ibopamine is the only drug developed to treat hypotony. It is a prodrug of N-methyldopamine with α-adrenergic

properties that is hydrolyzed to epinine in the aqueous humor. It is believed that the D1-dopaminergic activity is responsible for the increase in aqueous humor production and adrenergic stimulation is responsible for its mydriatic effect. Efficacy of ibopamine has been disappointing leaving the need for an effective aqueous flow stimulant unfulfilled.

Prostaglandin $F_{2\alpha}$ analogs produce a small but significant increase in aqueous flow. This increase does not raise IOP because of concomitant increases in outflow facility and uveoscleral outflow. The outflow effects more than compensate for the inflow effect and IOP is substantially reduced. These drugs are used in the treatment of ocular hypertension and glaucoma. The small increase in aqueous flow by prostaglandin analogs is not considered to be clinically relevant.

Conclusions

A clearer understanding of the physiology of aqueous humor production has helped to clarify the mechanisms by which IOP is maintained and inflow drugs work. Several classes of inflow drugs are prescribed for glaucoma therapy, including β-blockers, CAIs, α_2 adrenergic agonists, and other sympathomimetics. Each class reduces aqueous flow by different mechanisms. β-Blockers block cAMP and reduce the autonomic tone needed to produce aqueous humor. CAIs block carbonic anhydrase which prevents the synthesis of bicarbonate, a key step in aqueous secretion. Sympathomimetics have mixed effects on aqueous production, depending on which receptor subtype is stimulated and to what degree.

Suppression of aqueous flow is not the preferred therapy for glaucoma because disturbing the production and flow of this essential fluid could potentially stress the eye in other ways. New classes of drugs under development for the treatment of elevated IOP are designed to target the outflow tissues rather than the inflow tissues because abnormalities in the outflow pathways are usually the source of the IOP elevation.

Pharmacology of the Aqueous Humor Outflow

K P B Cracknell and I Grierson, School of Clinical Sciences, Liverpool, UK

Glossary

Adrenergic agonists – These are compounds that mimic the peripheral effects of epinephrine (adrenaline).
Cholinergic agents – These are compounds that enhance the effects mediated by acetylcholine in the central and/or peripheral nervous system.
Miotics – Compounds that cause constriction of the pupil.
Parasypathomimetic agents – These are compounds that stimulate or mimic the parasympathetic nervous system.
Prostaglandin – Local hormone composed of lipids with 20 carbon atoms including a five-carbon ring.
Prostamide – A fatty acid amide compound similar to a prostaglandin, except that oxygen bonded to carbonyl group is replaced by a nitrogen-bearing substituent. This change significantly alters the electronic and stearic properties of the molecule.

Introduction

Much research has been carried out regarding direct medical means of enhancing ganglion cell survival in primary open angle glaucoma (POAG). However, the only therapeutic approach currently in use is the indirect neuroprotective route of lowering intraocular pressure (IOP). Antiglaucoma medications that lower IOP do so by several mechanisms that include (1) reducing the production rate of aqueous humor, (2) increasing drainage through the nonconventional or uveoscleral route, (3) enhancing drainage of aqueous humor through the conventional route via the trabecular meshwork and canal of Schlemm, and (4) combinations of the aforementioned (1), (2), and (3).

In POAG, there are a range of cellular and extracellular changes in the outflow system that contributes to a poorly understood functional failure of the tissues. However, it is this drainage failure that precipitates an IOP elevation. Of course, by no means do all glaucoma patients have elevated IOP but even the normal tension patients appear to benefit from medical reduction of their IOP. In theory, the physiologically most attractive pressure-lowering option has to be the enhancement of aqueous passage through the conventional drainage route, after all this is where there is pathology. In addition, the trabecular meshwork relies on the aqueous humor for its nutrition, well-being, and survival. There are several classes of antiglaucoma drugs that act on the outflow pathways and they include the miotics (pilocarpine), adrenergic stimulators (epinephrine or adrenalin), and a range of prostaglandins (PGs). A brief description of their mode of action on the various outflow routes is given in this article.

Drugs in Clinical Use That Act upon the Aqueous Humor Outflow Routes

Cholinergic Agents (Miotics)

The cholinergic parasympathomimetic agents that have been in use for the treatment of glaucoma include phospholine iodide, carbachol, and pilocarpine and among these pilocarpine has been by far the most widely used. They act either directly (pilocarpine), indirectly (phospholine iodide), or both (carbachol) on muscarinic receptors to increase the outflow of aqueous humor and effect pupil constriction. Miotics are not in widespread use as they once were, with phospholine iodide and carbachol hardly used in glaucoma treatment at all, and pilocarpine has assumed the status of being a second or even third option drug.

Pilocarpine is a plant alkaloid that is extracted from the leaves of the South American tree *Pilocarpus jaborandi*, and its chemical structure is shown in **Figure 1**. It was introduced in 1876, when it became one of the first commonly used medical treatments for glaucoma, and remarkably, it has remained an important antiglaucoma medication till date. An agent with such a long pedigree is undoubtedly good at what it is supposed to do, and it does lower IOP very effectively. Pilocarpine has systemic side effects, although not too many so it is preferred by the ophthalmologist but frequently loathed by the patient who has to come to terms with needing to take the drops several times a day, stinging on application, narrowed pupils, and blurred vision. Today, the cholinergic agent is applied more often in the form of a fixed combination, delivered by means of an ocusert, or given as a gel rather than as the more traditional stand alone eye drops.

Many years ago Ernst Barany and his team were able to show that pilocarpine induced contraction of the ciliary muscle. Principally, the longitudinal fibers pull the conventional outflow system and stretch the trabeculae, thus opening up the pathways for aqueous humor drainage

(see Figure 2). He surmised that pilocarpine might produce, as a result, a leaky endothelium in the wall of Schlemm's canal. Certainly they were able to infer from rather clever ciliary muscle disinsertion experiments that separating the muscle from the trabecular meshwork abolished the pilocarpine's IOP-lowering effect, as would be predicted if the drainage action of the miotic was primarily brought about by its action on the ciliary muscle. In this context, it is thought likely that all the cholinergic agents have a similar action on the ciliary muscle and presumably the outflow system. There is some morphological evidence to support this contention with at least the long-acting miotic, phospholine iodide.

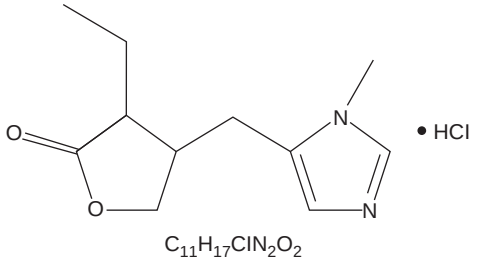

Figure 1 Chemical structure of pilocarpine.

The work on the pilocarpine action in monkeys was repeated by us and also in a number of humans showing essentially the same result. From histological sections, we measured the angle subtended by the cross-section of the sclera sulcus and the sclera spur which was around 15° of arch greater in the pilocarpine-treated group than in our untreated controls. Muscle contraction induced displacement of the spur in a trigger-like action thus pulling on the trabeculae and widening drainage pathways. As it is known that tendon-like structures (made up of extracellular matrix materials) extend from the sclera spur all the way up to Schlemm's canal, it is highly likely that it is altered and that turned out to be the case. We noted a significant distension of the inner wall of Schlemm's canal whose endothelium had an abundance of giant vacuoles and transcellular pores – so we had ultrastructural evidence that Barany's leaky endothelium proposal was essentially correct.

The predominant outflow action of pilocarpine is indirect but is there any evidence of a direct action within the outflow pathways themselves? On first examination, the absence of an IOP-lowering effect of any substance following ciliary muscle disinsertion argues against a direct action although these surgical manipulations tell us more about the relationship between the ciliary muscle and the

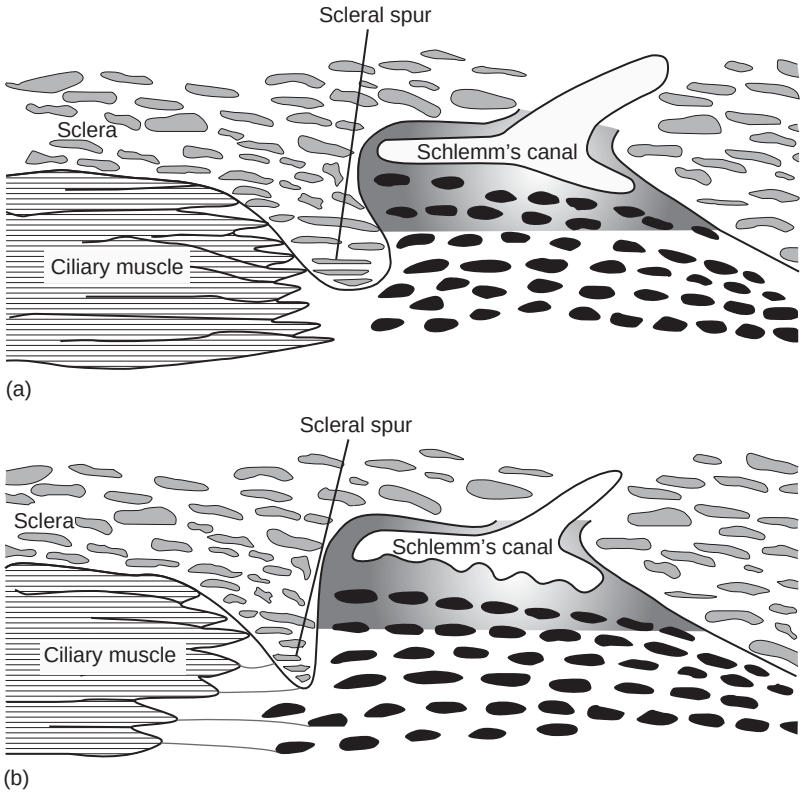

Figure 2 Schematic diagram illustrating the mode of action of pilocarpine: (a) the appearance of the ciliary muscle and trabecular meshwork in the normal meshwork; (b) following the application of pilocarpine the ciliary muscle is contracted, this contraction has pulled the scleral spur and opened up the spaces of the trabecular meshwork.

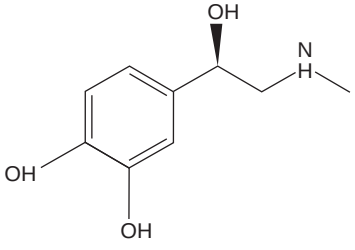
trabecular meshwork rather than what is going on in the meshwork tissue itself. As we now know, the trabecular meshwork is not a passive filter but has a cell population with characteristics in common with smooth muscle cells. Pharmacological examination of intact trabecular meshwork *in vitro* (which was isolated from the ciliary muscle) showed that pilocarpine contracted the cells in the mesh causing decreased outflow in these preparations. Thus, pilocarpine's overwhelming indirect action via the ciliary muscle opens up drainage through the outflow system despite a minor negative drainage effect caused by a local tightening effect.

Adrenergic Agonists

It is generally considered that the IOP lowering associated with adrenergic agonists such as epinephrine, diprivefrine (a prodrug-releasing epinephrine), and isoproterenol was primarily by a direct action on the conventional outflow system to produce a decrease in resistance. A less marked drainage increase through the uveoscleral outflow pathways is reported particularly in nonprimate animals. Evidence that epinephrine, for example, has more than a minor effect on aqueous production is controversial although that was the prevailing belief when epinephrine was first introduced as a potential antiglaucoma agent over 50 years ago. The outflow effect of adrenergic agonists is poorly understood but it does seem to be negated by the nonselective beta blocker timolol and also the effect is lost *ex vivo* by the eye being subjected to post-mortem delay. Epinephrine (adrenalin) has the chemical structure shown in **Figure 3**.

Cultured human trabecular meshwork cells and trabecular tissue *in vivo* contain $beta_2$-adrenergic receptors and epinephrine causes the intracellular accumulation and extracellular release of cyclic AMP from these cells. Both epinephrine and isoproterenol, using $beta_2$-adrenergic and possibly other (alpha) receptors, cause trabecular meshwork cells to become reduced in size with widening of their intercellular spaces. Such a direct drug action on cell morphology, presumably acting through the cell cytoskeleton, has functional consequences and epinephrine-induced inhibition of mitotic activity and phagocytosis in trabecular meshwork cells in tissue culture has been reported. What immediate benefit, if any, there are on the trabecular meshwork cells, caused by the functional and morphological changes which affect the increased outflow is not fully appreciated. In the longer term, the adrenergic agonist effect on trabecular meshwork cells might compromise tissue function and/or cell survival. The latter would be of particular concern given that excessive trabecular cell loss is part of the meshwork pathology in POAG.



$C_9H_{13}NO_3$

Figure 3 Chemical structure of epinephrine.

It is of some interest that both epinephrine and isoproterenol produce a size-reduction effect on Schlemm's canal endothelial cells in tissue culture similar to that described for trabecular meshwork cells. When the Schlemm's canal cells are established and subsequently organized into monolayers on Millipore filters then exposed to adrenergic agonists, these agents make the endothelial cell layers more permeable and so increase their hydraulic conductivity for at least a few hours. If such canal endothelial cell shrinkage takes place *in situ*, particularly in the inner wall endothelium of Schlemm's canal, then undoubtedly the resistance of the outflow system would decrease because of drug-induced widening of cell-to-cell spaces. Cyclic AMP is likely to have a second messenger role in this process because it has been shown that cyclic AMP analogs increase aqueous humor drainage and so implicate cyclic AMP in the mediation of the adrenergic agonist effect.

Increased permeability and aqueous flow through the canal endothelium is a hypothetical mechanism of action that is worthy of further testing. It is unfortunate that very little fundamental research has taken place to date on adrenergic agonist action within the outflow system and surrounding tissues. However, the role of epinephrine *per se* in glaucoma treatment is small because of patient tolerance to the adrenergic agonist and concern over local (stinging, orbital pain, and allergic blepharoconjunctivitis) or systemic (cardiac arrhythmias and systemic hypertension) side effects. The development of dipivefrin (a lipophilic prodrug formed by the addition of two pivalic acid groups to the epinephrine molecule) provided the much needed benefit of more efficient penetration into the eye at which point esterases removed the pivalic acid to release epinephrine. Unfortunately efficacy was not improved and the side-effect problem was not sufficiently dampened down.

PG Analogs

The relatively new groups of agents, the topical PG analogs, were designed specifically to maximize entry into the eye, exploit their IOP-lowering properties for the treatment of glaucoma and ocular hypertension, and minimize the tendency present in natural PGs to produce

red eye, irritation, and a foreign body sensation. The first two PG analogs that went into clinical use were unoprostone (Rescula) and latanoprost (Xalatan) and of the two, latanoprost was initially the more widely available. Thereafter, travoprost (Travatan) and bimatoprost (Lumigan) were licensed for glaucoma use while Tafluprost, the most recent PG, was in the process of seeking license approval (see **Table 1**).

It is not strictly the case that all the groups are true PGs as such. Bimatoprost is considered to be a prostamide because it is derived from anandamide which has both structural and pharmacological similarities to $PGF_{2\alpha}$ ethanolamide; it is accepted by some to be essentially different although the classification as a prostamide separate from the rest remains controversial. Despite the fact that bimatoprost's chemical structure is similar to the various $PGF_{2\alpha}$ analogs (see **Figure 4**), there are differences such as the fact that bimatoprost is poorly metabolized compared, for example, to latanoprost. As a group the PG analogs and the like, with perhaps the exception of unoprostone (Rescula), have remarkable IOP-lowering capabilities. This has led to their very rapid adoption as a first-line choice for glaucoma therapy.

The PGs have a poor ability to cross biological membranes, and as a consequence they require a carrier-mediated transport (i.e., receptor) to pass into cells. PGs interact with cells by attaching to specific receptor sites on the cell surface. The PGs are comprised of a family of five naturally occurring compounds. Each of the PGs has a particular affinity for a specific receptor site. However, naturally occurring PGs have a low selectivity for their specific PG receptor, and as a consequence they are found to be bound to a whole variety of receptor sites, whereas the synthetic PG analogs are much more selective. The naturally occurring $PGF_{2\alpha}$ has a binding affinity for the FP receptor, along with the EP_1, EP_2, and EP_3 receptor sites. All the $PGF_{2\alpha}$ analogs in use have a particular affinity to the FP receptor site but they are more selective agonists of this receptor with reduced affinity for the other receptors. However, the various analogs do have differing affinities for the other receptor subtypes, for example, latanoprost has a much reduced effect on the EP_2 receptor, and travoprost has a low affinity for all the EP receptors. It is indeed this selectivity which has improved the drug's therapeutic profiles. Certainly, the mechanism of action of the more conventional PG analogs seems to be that they function as FP receptor antagonists; although this may also, to some extent, be the case for bimatoprost, evidence for FP receptor antagonism as a major mechanism of its mode of action remains more controversial.

The mechanisms by which the PG analogs (including prostamides) in current clinical use produce their ocular hypotensive effects are not yet fully understood, but the FP receptor does seem to play an essential role for the majority of them. Studies examining FP receptor-deficient mice have shown that these animals at least do not exhibit any IOP-lowering action when exposed to latanoprost, travoprost, unoprostone, or even bimatoprost. Further research with receptor-deficient mice has shown that the IOP-lowering action of the newest analog, tafluprost, is also mediated through the prostanoid FP receptor. It has been demonstrated with reasonable clarity that the prostaniod IOP-lowering action does not appear to involve any marked alteration to the production rate of aqueous humor. On the contrary, early investigations of the drainage-improving action of latanoprost heavily implicated the uveoscleral drainage pathway as the major site of aqueous outflow increase producing the bulk of the IOP reduction. The conventional outflow pathway, via the trabecular meshwork and Schlemm's canal, is responsible for around 80% of the aqueous drainage in the normal eye, whereas the nonconventional or uveoscleral pathway (whereby aqueous passes through the adventitia of the ciliary muscle and across the sclera to reach the vortex vessels) accounts for most of the remainder. It was shown that latanoprost doubled uveoscleral drainage in human eyes and in some monkeys (where uveoscleral drainage is naturally high); outflow through this pathway increased from 30% to 60% in humans following latanoprost exposure. It has been the general belief that the other PG analogs also enhanced uveoscleral drainage, at least as part of their overall IOP-lowering action. There are three potential mechanisms proposed (relaxation of ciliary muscle, remodeling of the extracellular matrix, and vasodilatation causing tissue expansion), by which PGs could be increasing the uveoscleral outflow.

Vasodilation is strongly stimulated by the natural PGs; however, it has been demonstrated that the synthetic PGs (particularly latanoprost) do not significantly influence vasodilation. Hence, this mode of action seems to have been ruled out.

Table 1 Commercially available prostaglandin drugs and usage regimes

Drug	*Manufacturer*	*Dosage*	*Drug concentration*
Latanoprost Xalatan®	Pfizer	One drop once a day	0.005% solution
Unoprostone Rescula®	Novartis	One drop twice daily	0.15% solution
Travoprost Travatan®	Alcon	One drop once a day	0.004% solution
Bimatoprost Lumigan®	Allergan	One drop once a day	0.03% solution
Tafluprost	Santen	One drop once a day	0.005% solution

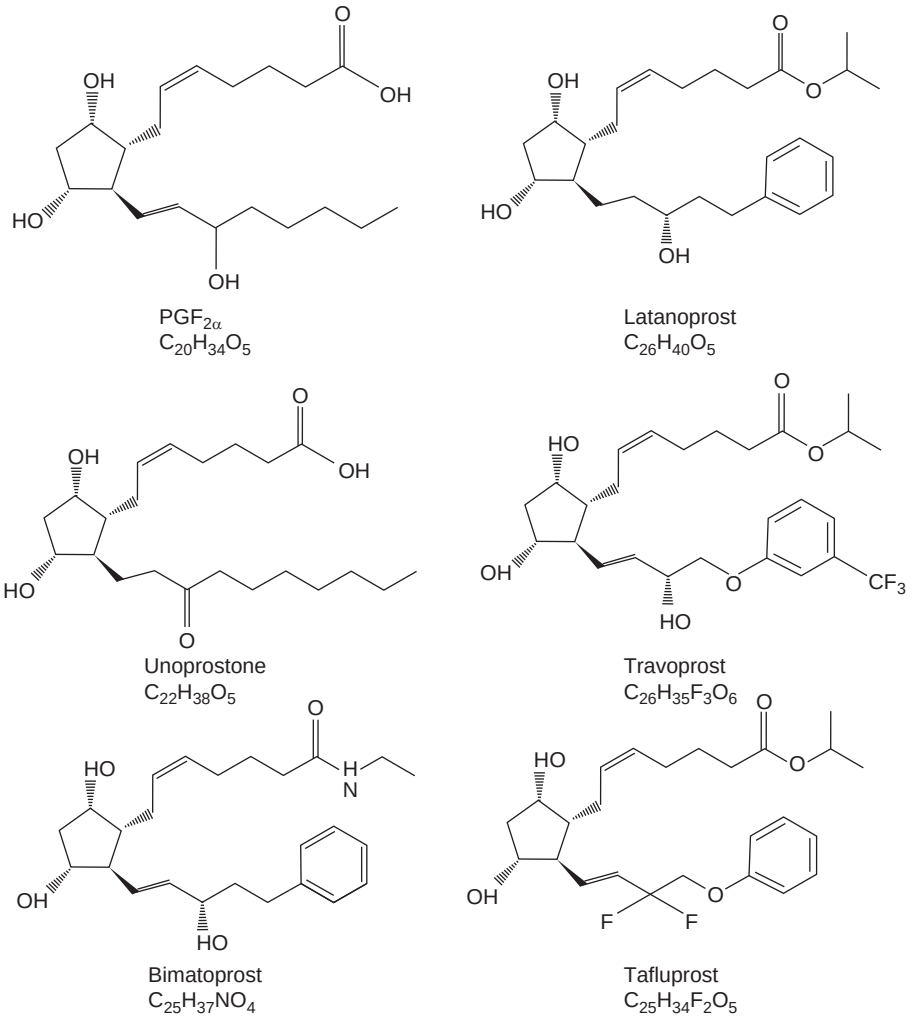


Figure 4 Chemical structures of the PGs in current use for the treatment of glaucoma.

For obvious reasons, attention has focused on PG-induced action on the uveoscleral drainage pathway where remodeling of the extracellular matrix between the muscle bundles of the ciliary body takes place. There appears to be an age-related decrease in the uveoscleral outflow both in humans and monkeys. This accompanies a morphological change seen in the aged ciliary muscle, of a buildup of extracellular material which reduces the spaces around the muscle bundles. In contrast, in aged monkey eyes treated with $PGF_{2\alpha}$ demonstrated a reduction in the extracellular matrix and an increase in interstitial spaces, mimicking the appearance of that seen in young eyes. The effects of PGs at the subcellular level in the ciliary muscle cells have been investigated and it was found that $PGF_{2\alpha}$ disrupted the turnover of some extracellular matrix components which presumably leads to a widening of the uveoscleral pathway. Latanoprost acid, in particular, has been shown to decrease some of the extracellular matrix components (specifically collagens I, III, and IV, laminin, fibronectin, and hyaluronan) in cultured human ciliary muscle cells. However, in monkeys 10 days of topical treatment with 3 μg latanoprost reduced the amount of collagens IV and VI in the ciliary body. In addition, the PG analogs remodel the extracellular matrix components of the intercellular environment of the ciliary tissue by synthesizing a range of matrix metalloproteinases and their inhibitors. Therefore, it is highly likely that all drugs in this class, to a lesser or greater extent, modulate the extracellular matrix materials that reside in the uveoscleral pathway to produce (at least part of) their aqueous outflow enhancing effect.

As far as relaxation of ciliary muscle *in vitro* is concerned, work using $PGF_{2\alpha}$ demonstrated a weak relaxation of monkey ciliary muscle strips. In monkeys, large doses of pilocarpine were found to partially inhibit the IOP-reduction effect produced by $PGF_{2\alpha}$. This IOP reduction is explained by the pilocarpine contraction of the ciliary muscle, from this it can be deduced that it is likely that some of the effect of $PGF_{2\alpha}$ is by causing a relaxation of the ciliary muscle.

Initial studies suggested that PGs had virtually no effect on the trabecular meshwork tissue or, for that matter, on drainage of aqueous humor through the conventional outflow pathway. However, there were some inconsistencies (true for most members of this class of drugs), and they may well relate to the difficulty of accurately measuring relatively small changes in conventional drainage facility, especially when uveoscleral drainage is enhanced. However, more recent work (e.g., that using organ cultured human anterior segments where a much clearer assessment of conventional drainage can be obtained) showed that PGs (specifically latanoprost) do reduce the resistance to aqueous outflow through this pressure-sensitive route. Matrix metalloproteinase analysis surprisingly did not show much change. Indeed, both organ and tissue culture models have been sufficiently robust to show a quite marked increase in outflow facility associated with the prostamide action of bimatoprost. In addition, much work has been done that indicates that unoprostone has an effect on trabecular meshwork cell contractility that may well promote conventional drainage. In general, it remains to be established whether or not extracellular matrix alteration, trabecular meshwork cell contractility, a combination of both, or even some other mechanism is behind the pressure-sensitive increase in outflow that seems to be produced by the PGs.

A combination of clinical, animal, and *in vitro* investigations provides evidence that underlines the fact that the PG analogs and their allies lower IOP by increasing the drainage of aqueous humor out of the eye. For most of these drugs, the important mechanism of action is on the uveoscleral drainage pathway but it is likely that they all produce some enhancement of conventional drainage. At least, for maybe unoprostone, the enhancement of conventional drainage may be of greater significance than for the others in this class of drugs.

The PGs are reported to be essentially free from major systemic side effects but they do have local side effects. The ocular side effects associated with these drugs are:

- conjunctival hyperaemia (5–15% with latanoprost to 35–50% with travoprost);
- ocular irritation (up to 15% of patients);
- burning sensation and dry eye (8% incidence);
- uveitis and cystoid macular edema are rare but severe events that occur in eyes that are susceptible due to other predisposing conditions such as diabetic retinopathy, and complicated cataract surgery;
- increased pigmentation of the iris (incidence highest with latanoprost); and
- increased growth of hair follicles.

The incidence of red eye, irritation, and a foreign body sensation with natural $PGF_{2\alpha}$ were high, and as a consequence much effort has been applied to attempts to subdue these side effects with the analogs. The efforts have significantly reduced the incidence although by no means have these side effects been entirely eliminated. Although it needs to be borne in mind that some drug preparations have a fairly high concentration of preservative which inevitably will contribute to the red eye.

The increased ocular pigmentation is a side effect that is specific to the PGs and as such has been the subject of much scrutiny. Eye-lid color change is uncommon with an incidence of only 1.5–2.9%. Eyelash darkening and thickening incidence has a wide variation in incidence between the different drugs (travoprost 0.7–76%, bimatoprost 3–36%, and latanoprost 0–25%). All of these color-change side effects are reversible upon the cessation of the PG drops.

Darkening of the iris is an irreversible change associated with PG use and has been investigated thoroughly in the case of latanoprost as this was the first drug to exhibit the effect. The findings to date suggest that there is no pathology associated with the darkening and that the color change is brought about by small but significant increase in the size of the individual melanin granules. It is considered at present that this side effect is purely cosmetic change with no significant pathological implications.

Photopic, Mesopic and Scotopic Vision and Changes in Visual Performance

J L Barbur, City University, London, UK
A Stockman, UCL Institute of Ophthalmology, London, UK

Glossary

Contrast sensitivity function (CSF) – The reciprocal of contrast threshold measured as a function of spatial frequency in a spatial CSF or as a function of temporal frequency in a temporal CSF.
Higher order aberrations (HOAs) – These aberrations in the eye describe imperfections in the optics that cannot, in general, be corrected for with conventional refraction (i.e., sphere and cylinder components).
Mesopic – The range of intermediate light levels between cone threshold and rod saturation where both rod and cone signals contribute to a visual response.
Photopic – The range of high light levels above rod saturation where vision is mediated by signals from cone photoreceptors.
Scotopic – The range of low light levels below cone threshold where visual responses rely entirely on rod signals.
Spectral luminous efficiency (SLE) – The SLE function represents an appropriate measure of detector spectral responsivity, which in the case of the human eye is used to convert radiant flux to an equivalent photometric flux.
Spectral power distribution (SPD) – This describes the wavelength distribution of radiant flux (power) emitted by a source or surface.
Spectral radiance – A quantity that describes the radiant flux (power) within a narrow wavelength interval emitted by a source or surface in a given direction per unit solid angle, per unit area of the source.
Spectral responsivity (SR) – The SR of a detector of radiation is a measure of the spectral sensitivity of the detector and represents the signal generated per unit incident radiant flux as a function of wavelength.

Introduction

Arguably, the most important feat of human vision is its ability to operate effectively over the enormous 10 000-million-fold range of illumination levels to which it can be exposed, from starlight to bright sunlight (see Figure 1). Moreover, it achieves this despite the limitations imposed by individual neurons in the visual system, many of which have dynamic ranges of no more than about 100-fold. Sensitivity regulation over such a massive range cannot be achieved without compromise. One compromise is to share the range between two different types of photoreceptors: the sensitive rods, functioning at lower scotopic levels of illumination, and the less-sensitive cones, functioning at higher photopic levels, the two working together at intermediate mesopic levels. Another important compromise is the trade-off between increased sensitivity at lower light levels, and improved temporal and spatial acuity at higher light levels. As the light level increases, high sensitivity is no longer needed and is traded for improvements in spatial and temporal acuity. These adjustments occur separately within the rod and the cone systems, but the rod system has a lower acuity and higher sensitivity compatible with its operation at lower light levels.

There are ~100 million rods, but only 5 million cones in the human retina. The 5 million cones are most densely packed in a small region of the retina at the center of our vision, where photopic vision is best. Cones are less sensitive to light but respond more quickly than rods. The cones and their postreceptoral pathways operate well at higher light levels in the upper mesopic and photopic range. Over most of this range, processes of light adaptation within the retina ensure that the operation of the cone photoreceptors adjusts to changes in light level to provide a useful dynamic range of about 100, which remains relatively independent of light level. When the light level is lower, the cone system increases its sensitivity by increasing the spatial and temporal extents over which light is summed, as a result of which spatial and temporal acuity is reduced. Even at very high light levels, bleaching of the light-sensitive pigment in the cone protects its output from saturating and thus failing to signal changes in light. By contrast, rods and their pathways operate well at lower light levels in the scotopic and lower mesopic ranges. The rods and rod pathways are optimized for these levels. The rods are more sensitive and much slower than the cones, so that they integrate light over time, and their postreceptoral pathways integrate light over space. Capable of single-photon detection at the lowest levels, the rod system ceases to operate effectively at the top of the mesopic range.

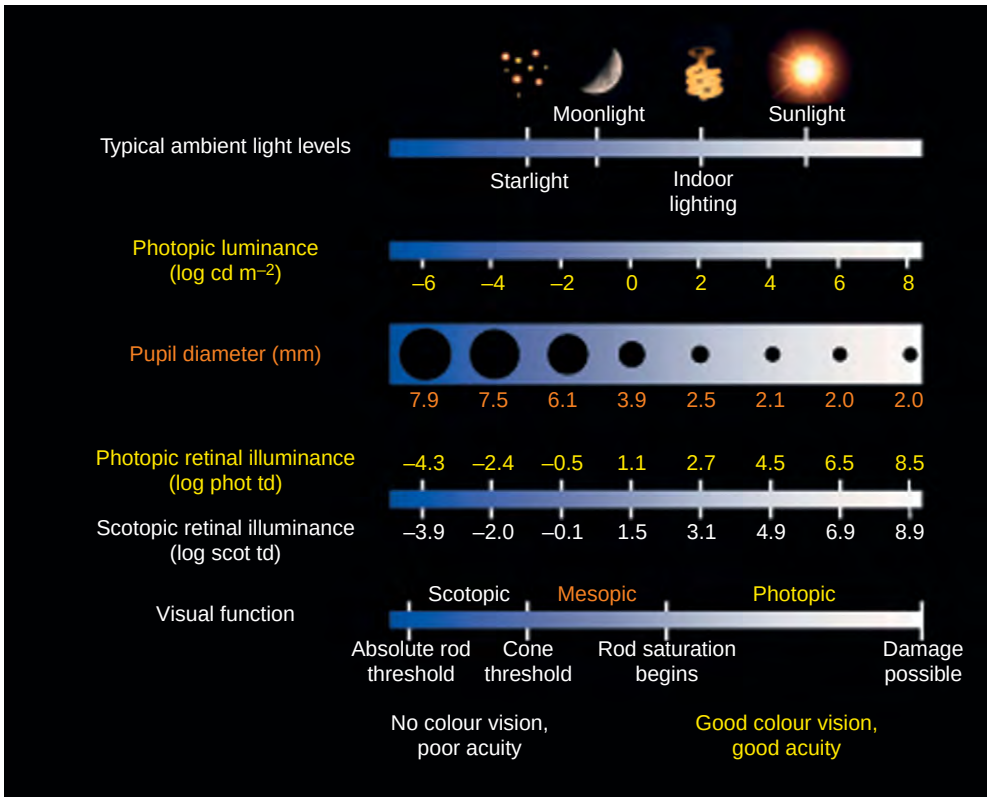

Figure 1 Illumination levels. Typical ambient light levels are compared with photopic luminance (log phot. cd m^{-2}), mean pupil diameter (mm), photopic and scotopic retinal illuminance (log photopic and scotopic trolands, respectively), and visual function. The scotopic, mesopic, and photopic regions are defined according to whether rods alone, rods and cones, or cones alone contribute to a visual response. The conversion from photopic to scotopic values assumes a white standard CIE D_{65} illumination. Based on **Figure 1** of Stockman, A. and Sharpe, L. T. (2006). Into the twilight zone: The complexities of mesopic vision and luminous efficiency. *Ophthalmic and Physiological Optics* 26: 225–239.

Mesopic vision describes the range of light levels over which signals from both rods and cones contribute to the visual response. This range extends just over a 1000-fold from cone threshold to rod saturation, and encompasses light levels that are often found in occupational environments. At mesopic levels, the spectral composition of the illuminant plays an important role in determining the relative strengths of rod and cone signals (see **Figure 2**). Marked changes in visual performance that vary over the visual field are observed as the level of illumination is lowered and/or the spectral composition of the illuminant is modified. The gradual increase in rod signals as the light level decreases causes changes in the overall spectral sensitivity of the eye that has consequences for the visual effectiveness of the illuminant spectral power distribution (SPD) (i.e., the intensity of the light as a function of wavelength). Mesopic luminous efficiency is inherently complex, and therefore difficult to standardize or model, because it depends on the outputs of both the rod and the cone photoreceptors. Not only are there differences in the photoreceptor spectral sensitivities, but there are also differences in the properties of the postreceptoral pathways through which the rod and cone signals are transmitted. The nature and balance of these pathways are constantly changing with changes in light level in the mesopic range.

Much effort has gone into establishing spectral responsivity functions that are appropriate for photopic, mesopic, and scotopic lighting conditions. This approach rests on the assumption that visual performance can be adequately predicted by weighting the intensity of the light reaching the eye (the radiant flux) with functions that reflect the spectral responsivity of the eye at high, intermediate, and low light levels. Some success has been achieved at low light levels in the scotopic range, but this success reflects the fact that the spectral responsivity is determined by a single photoreceptor type, the rods, which have a single type of photosensitive molecule. The approach has been less successful at photopic levels, where responsivity depends on up to three cone photoreceptors, and least successful at mesopic levels where it depends on different types of rod and cone photoreceptor systems with markedly different properties. In this article, we present data on

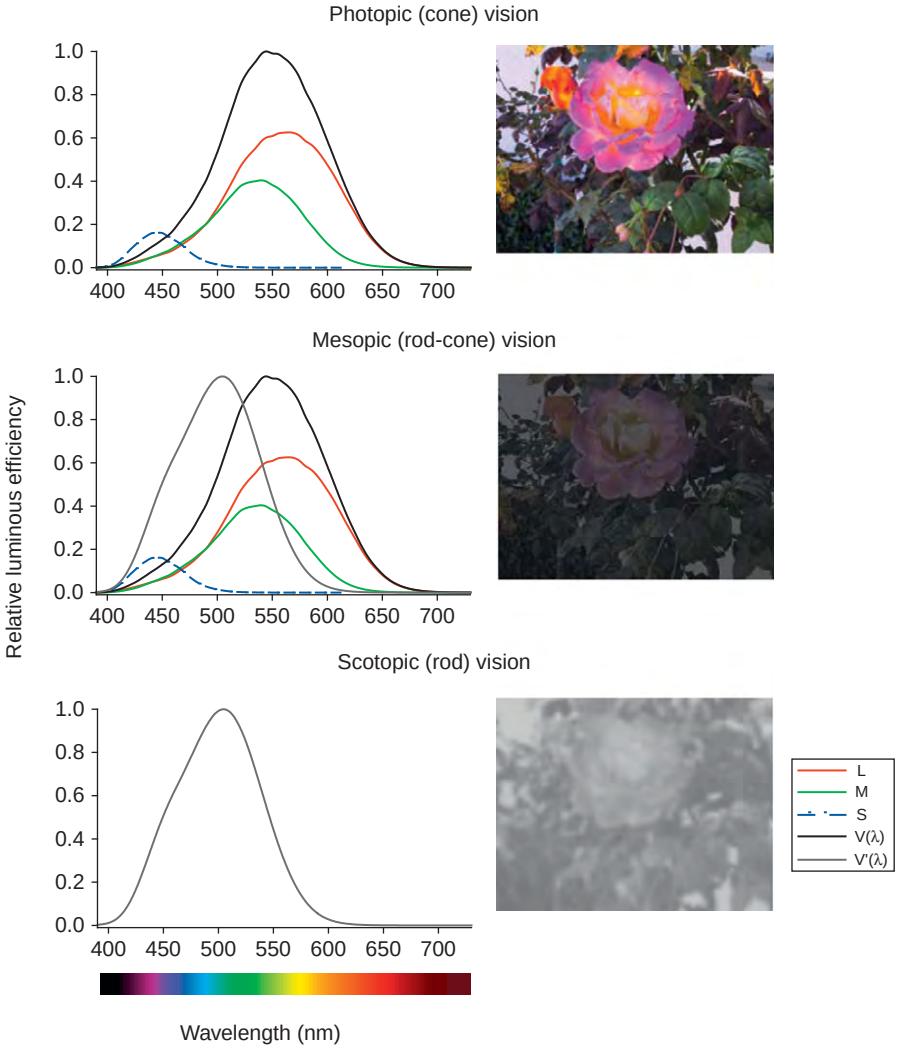

Figure 2 The useful range of light levels can be divided into three regions: the photopic range that yields best temporal and spatial contrast acuity and color discrimination, the mesopic range where color signals become less important, our temporal responses become more sluggish, and the world appears dark, and the scotopic range where the world appears brighter, but we can no longer discriminate color differences and can only see large, high-contrast objects. The spectral sensitivities of the photoreceptors are shown. The relative heights of the M- and L-cone spectral sensitivities reflect their assumed relative contributions to V(λ). The S-cone function is dashed to signify that its contribution to luminous efficiency is minimal. The photographs on the right illustrate how our vision changes as the eye adapts to mesopic and scotopic illumination.

how visual performance changes with light level. We argue that the changes in performance are much more profound than the changes in spectral sensitivity as captured by changes in luminous efficiency functions.

The Concept of Luminous Efficiency Function

The traditional development of photometry has been strongly influenced by radiometry and the properties of an ideal detector of radiation, which is assumed to exhibit response linearity and additivity and has a well-defined spectral responsivity (in the case of the eye at photopic levels, $V(\lambda)$). Let the radiant light fluxes Θ_1 and Θ_2, respectively, produce signals S_1 and S_2 when the detector is exposed to each flux separately. Response linearity means that when the detector is exposed to $\Theta_1 + \Theta_2$ together, the signal generated must equal $S_1 + S_2$, irrespective of the intensity and the spectral composition of Θ_1 and Θ_2. When this is the case, the spectral responsivity curve of the detector becomes a particularly useful quantity since it provides the means of computing the detector signal in response to any broadband, spectral distribution of light flux. This is achieved by simply integrating the radiant flux (weighted at each wavelength by the spectral luminous

efficiency function or $V(\lambda)$) over the spectral range for which $V(\lambda)$ and $\Theta(\lambda)$ are both nonzero to give:

$$\Theta_V \sim \int V(\lambda)\Theta(\lambda)d\lambda, \quad [1]$$

where Θ_V is usually described as the luminous flux. The simplicity of this approach continues to be important and relevant in the more applied areas of vision science, for example, in lighting engineering and photometry. Spectral luminous efficiency functions (i.e., curves that specify the spectral responsivity of the eye, and thus the effectiveness of lights) have been produced using a number of different experimental approaches for both photopic vision (when only cone photoreceptor signals are involved) and for scotopic vision (when vision relies entirely on rod signals). The response linearity of the eye is, however, very limited. Lights that are intense enough to adapt the visual response give rise to nonlinearities that break down the additivity required by eqn [1]. At photopic and mesopic levels, where up to four photoreceptors can contribute to the visual response, additivity is even more limited. As the wavelength or SPD of the illuminant changes, and the photoreceptors selectively adapt, so also do the relative contributions of the different photoreceptors to luminous efficiency. Mesopic and photopic luminous efficiency functions, in general, are not therefore fixed in spectral sensitivity.

Spectral luminous efficiency functions are currently used to provide a means of quantifying the total luminous flux associated with broad-band and narrow-band sources, and for computing the luminance contrast of an illuminated object with respect to that of the surrounding background. When the relative SPD of an object matches that of its surrounding background, the computed contrast is independent of the assumed spectral responsivity curve. However, for objects that differ in SPD from their surrounding background, the computed contrast is strongly dependent on the choice of spectral luminous efficiency function. Moreover, at photopic levels, perceived color differences can also contribute significantly to perceived object contrast, as a result of which any efforts to produce a single spectral luminous efficiency function to account for both the quantity of luminous flux and perceived contrast has severe limitations. In the mesopic range, when rod contrast signals also contribute to object conspicuity, prediction of effective contrast becomes even more challenging. The relative rod and cone contributions to luminous efficiency vary continuously with the illumination level, the spectral composition of the adapting background, the location of the stimulus in the visual field, and the temporal and spatial characteristics of the stimulus. A number of studies have attempted, with limited success, to model these complex interactions. Yet, any model based only on changes in spectral sensitivity is unlikely to capture the effects of the large number of parameters that have been shown experimentally to affect object appearance.

In the remainder of this article, we will be less concerned with the need to produce fixed spectral luminous efficiency functions appropriate for either the photopic or the mesopic range. Instead, we focus on describing how key aspects of visual performance change with ambient light level.

Quality of Vision and Light Level

Spatial Acuity, Spatial Contrast Sensitivity, and Light Level

An important aspect of visual performance is the ability to see fine spatial detail. A simple functional test is to measure the threshold luminance contrast (i.e., $\Delta L/L_b$, where ΔL represents the increment in stimulus luminance with respect to the surrounding background (L_b)) needed to resolve letters or some other visual stimuli when the angular subtense of stimulus elements is larger than the high-contrast resolution limit of the eye. The latter is often taken to be $1'$ of arc and corresponds to a letter size of $\sim 5'$ of arc. In order to avoid eye strain and to minimize the effects of microfluctuations of accommodation, a stimulus size three times the spatial resolution limit of the eye or larger is often employed in various occupational environments. For these reasons, the data shown in **Figure 3** were measured using a Landolt ring stimulus of $3'$ gap size. The orientation of the gap was restricted to four possible locations (i.e., top right, top left, bottom right, and bottom left) and the subject's task was to press one of four buttons to indicate the position of the gap. Two different groups of normal subjects (with high-contrast acuity of $1'$ of arc or better) were involved in this study. The photopic thresholds follow a tight distribution, while the mesopic thresholds are larger and exhibit significantly increased variability. Interestingly, about 50% of the 219 subjects examined under mesopic conditions exhibit thresholds that fall within the normal 2σ (σ: standard deviation) limits of the photopic range.

The results show no significant correlation with either age or the quality of the observer's optics (in terms of the mean-wavefront, higher order aberrations (HOAs)). **Figure 4** shows similar data as a function of retinal illuminance for a single subject measured at the fovea and $\pm 2.5^{\circ}$ away from fixation, along the horizontal meridian. In this experiment, the pupil size was measured every 20 ms and the luminance of the visual display was adjusted appropriately in order to maintain constant retinal illuminance. The results show a large $\sim$2.2-log unit increase in foveal contrast acuity thresholds over the 1000-fold change in retinal illuminance. Contrast acuity at low light levels in the mesopic range is extremely poor and below 0.6 photopic trolands (phot. td, a measure of photopic retinal illuminance) the periphery becomes more sensitive than the foveal region because of the distribution of rods and cones across the retina.

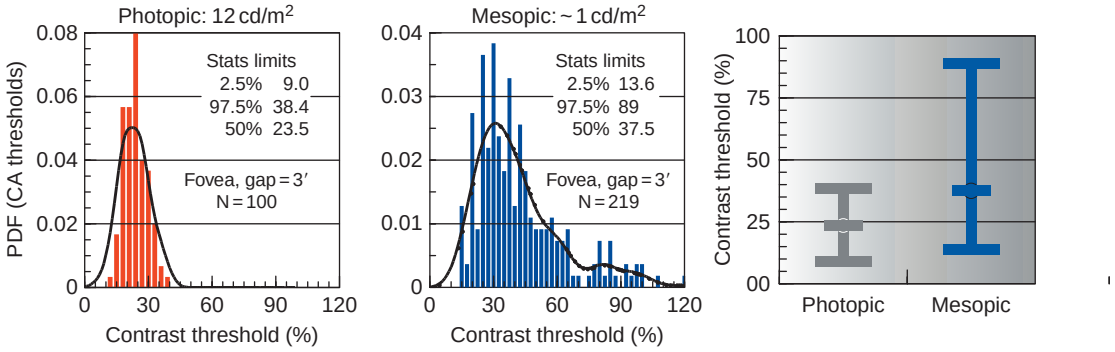

Figure 3 Low photopic and high mesopic measurements of contrast thresholds for gap orientation discrimination using Landolt ring stimuli of 3′ gap size. One hundred subjects participated in the photopic study and 219 subjects carried out the mesopic test. All subjects had normal Snellen acuity and the age distribution was as follows: photopic: mean = 23 years, standard deviation (sd) = ±7, mesopic: mean = 28 years, sd = ±14. The histogram shows the probability distribution function (PDF) of the contrast acuity (CA) thresholds measured as % luminance contrast (i.e., $\Delta L/L_b$, where ΔL represents the increment in stimulus luminance with respect to the surrounding background (L_b)). The statistical limits from each graph are shown as vertical bars to illustrate the overlap in photopic and mesopic thresholds.

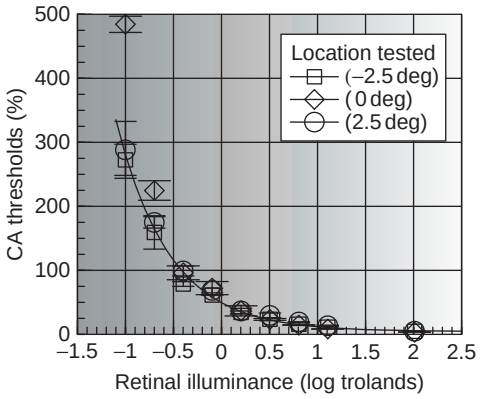

Figure 4 Contrast acuity thresholds ($\Delta L/L_b$) measured at the fovea and ±2.5° in the periphery, as a function of retinal illuminance, for a 3′-gap Landolt ring stimulus. Spectrally calibrated neutral density filters were employed to achieve the full range of retinal illuminance. Pupil size was monitored continuously and this measurement was used to adjust the luminance of the display to maintain constant retinal illuminance. The correlated color temperature of the background field was ~6500K (CIE (*x, y*) – chromaticity coordinates: 0.305, 0.323). The three stimulus locations were interleaved randomly and the subject's task was to report the orientation of the gap (i.e., top right, top left, bottom right, or bottom left) by pressing one of four buttons located at the corners of a square, each button corresponding with one of the gap locations.

Contrast acuity measurements, although functionally important, only partly characterize how the spatial properties of the visual system change with retinal illuminance. A more complete characterization is provided by the spatial contrast sensitivity function or CSF, which defines the sensitivity (i.e., the reciprocal of the contrast threshold) for the detection of sinusoidal gratings (smoothly changing black-and-white stripes) as a function of their spatial frequency (i.e., as they change from coarse to increasingly fine stripes). Loosely speaking, the contrast describes local, spatial differences between the object of interest (the stripes, in this case) and its background (the mean background level), and often correlates with subjective measures such as object conspicuity. In a typical CSF experiment, the observer is presented with sinusoidal gratings of a given spatial frequency, and is asked to vary its contrast to find the contrast at which the grating is just visible. This threshold measurement is then repeated at a series of spatial frequencies to build up a complete CSF. Several spatial CSFs measured by van Nes and Bouman as a function of retinal illuminance are shown in **Figure 5**. As the illumination level increases, the CSFs change in shape from being low-pass (i.e., falling monotonically with increasing spatial frequency) to being much broader, slightly band-pass functions (i.e., peaking in sensitivity at some intermediate frequency and falling off in sensitivity at lower and higher frequencies).

There are two notable features of the data in **Figure 5**. First, at low spatial frequencies, the contrast sensitivity becomes roughly constant above about 0.09 phot. td. Thus, the contrast sensitivity becomes independent of the illumination level at higher photopic levels. Second, at higher spatial frequencies, the highest spatial frequency that can just be seen, which corresponds to the spatial acuity measurements just discussed, improves markedly, increasing from 5 cycles per degree at 0.0009 phot. td to 55 cycles per degree at 5900 phot. td. These two features reflect, in part, the decrease in the spatial extent of visual integration with increasing light level.

In general, the visual system is good at spatial-contrast detection to the extent that, under optimal conditions, the threshold contrast can be as low at 0.2% (see **Figure 5**). By contrast, the visual system is poor at estimating the amount of total luminous flux, a task which is presumably

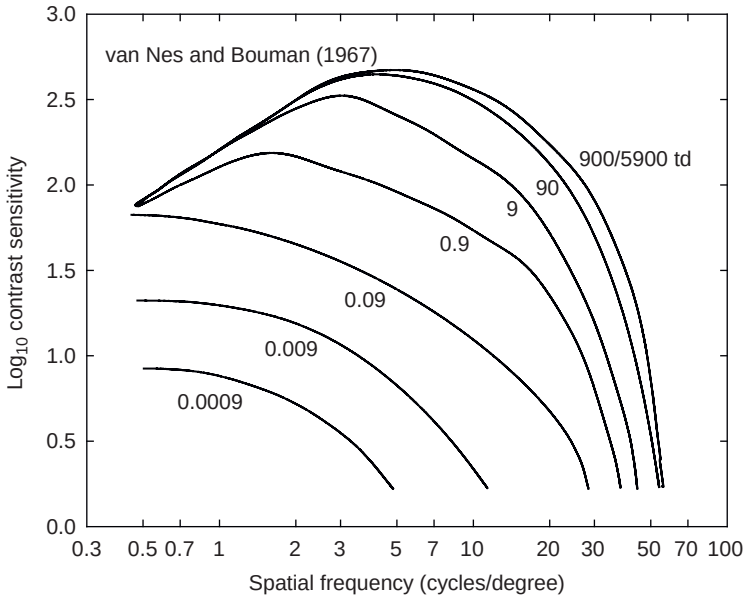

Figure 5 Spatial contrast sensitivity functions from 0.0009 to 5900 td measured by van Nes and Bouman (1967). The CSFs for 5900 td and 900 td are identical. A 2-mm diameter entrance pupil was used, so that these CSFs will be diffraction limited at highest illumination levels. Replotted from van Nes, F. L. and Bouman, M. A. (1967). Spatial modulation transfer in the human eye. *Journal of the Optical Society of America* 57: 401–406.

evolutionarily less important than the detection of faint edges and boundaries that reveal the presence of objects in the visual field.

Pupil Size, Higher order Aberrations, and Light Level

The size of the pupil affects retinal illuminance, depth of field, diffraction, and HOAs. In addition, it can also affect scattered light in the eye, when the light scattering is nonuniform over the pupil. The most important and best-studied afferent visual signal that drives the pupil is generated by changes in the ambient illumination, and this pathway is associated entirely with subcortical projections. Other pathways are also involved, but the corresponding pupil changes are more transient and smaller in amplitude. Aging affects steady-state pupil size, but in general the pupil varies from 2 mm in bright sunlight to over 8 mm in the dark (see **Figure 1**). The HOAs of the eye, mostly spherical aberration, increase rapidly with pupil diameter. Under natural conditions, this corresponds to either mesopic or scotopic vision. **Figure 6(a)** shows how the average wavefront aberration of the eye varies with pupil diameter. At low light levels, the pupil of the eye is large and consequently the quality of the retinal image is affected by increased aberrations and scattered light. When the light level is high, HOAs become very small and diffraction becomes more important and can often limit most the quality of the retinal image that can be achieved.

The potential of improving spatial vision by reducing HOAs using customized, wavefront-guided corneal refractive surgery has been of considerable interest. Since the size of the pupil significantly affects the aberrations in the eye (**Figure 6(a)**), any experimental assessment of the benefit of HOA correction must compare performance with and without correction using the natural pupil size. The visual benefit for contrast acuity that results from HOA correction is shown in **Figure 6(b)** for ambient light levels in the range 140–0.01 cd m^{-2}. Although HOA correction undoubtedly improves retinal image quality for large pupil sizes in mesopic and scotopic vision, the visual benefit for everyday visual performance as measured by contrast acuity is limited, largely as a result of the poor spatial resolution of mesopic and scotopic vision. The results of **Figure 6(b)** suggest that the spatial CSFs shown in **Figure 5** are well matched to the increases in the HOAs with increasing pupil size. As the light level decreases and the pupil size and HOAs increase, the retina is less able to resolve higher spatial frequencies, and thus the most deleterious effects of the increasing aberrations are invisible.

Flicker Perception

Similar to the changes in the spatial properties of the visual system that accompany light adaptation, the changes in its temporal properties can also be characterized by contrast sensitivity measurements. A temporal CSF defines the sensitivity for the detection of flicker as a function of temporal frequency. In a typical experiment, the observer is presented with a uniform disk that flickers sinusoidally

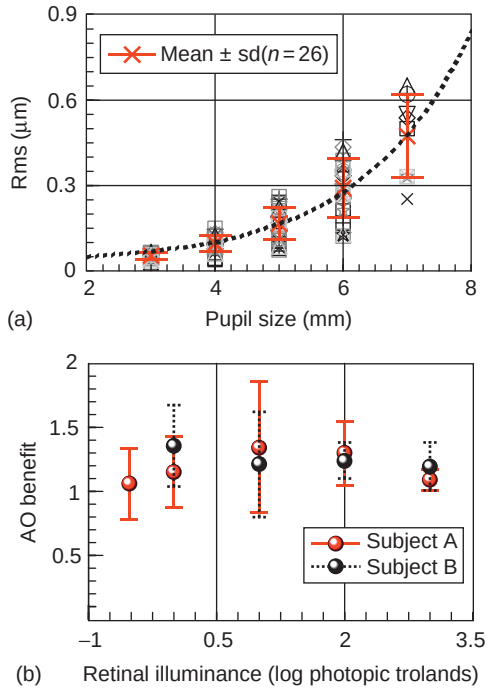

Figure 6 Mean root mean square (rms) wavefront aberration (a parameter that relates to the quality of the retinal image) was measured in 26 subjects and is plotted as a function of pupil diameter. The error bars show ±sd for this subject group. Section B plots the visual benefit (defined as the ratio of contrast sensitivities measured with and without correction of higher order aberrations in the eye), as a function of retinal illuminance. The visual benefit that follows correction of higher order aberrations is small when the retina is adapted to the corresponding ambient illumination. Supplementation with the carotenoids lutein or zeaxanthin improves human visual performance. *Ophthalmic and Physiological Optics* 26: 362–371; and Dalimier, E., Dainty, J. C., and Barbur, J. L. (2008). Effects of higher-order aberrations on contrast acuity as a function of light level. *Journal of Modern Optics* 55: 791–803.

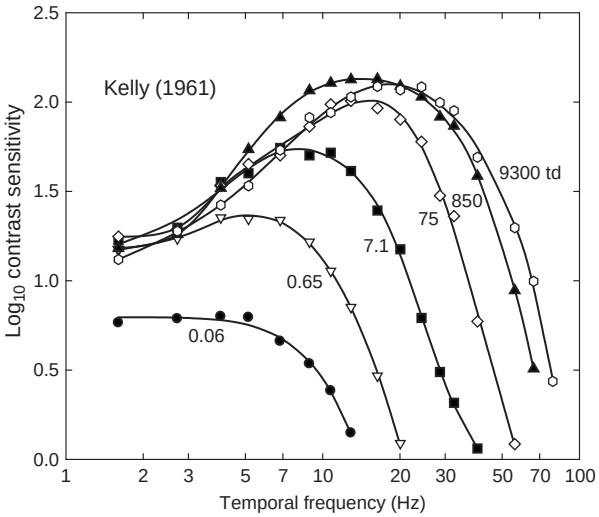

Figure 7 Temporal contrast sensitivity functions from 0.006 to 9300 td measured by Kelly (1962). Replotted from Kelly (1962). Visual responses to time-dependent stimuli I. Amplitude sensitivity measurements. *Journal of the Optical Society of America* 51: 422–429.

at some temporal frequency, and is then asked to adjust its flicker contrast (sometimes called ripple ratio or modulation) until the flicker is just visible. This threshold measurement is subsequently repeated at a series of temporal frequencies to build up a complete CSF. **Figure 7** shows temporal CSFs measured by Kelly as a function of retinal illuminance. These functions have several characteristics in common with the spatial CSFs shown in **Figure 5**. As the illumination level is increased, the temporal CSFs, like the spatial CSFs, change from being low-pass to slightly band-pass.

Other features are also shared between the spatial and temporal CSFs. First, at low temporal frequencies, like low spatial frequencies, the contrast sensitivity becomes roughly constant and therefore independent of light level – in this case, at 0.65 phot. td and above. Second, as the retinal illuminance is increased, the highest temporal frequency that can just be seen (i.e., the temporal acuity limit, which is also known as the critical fusion frequency) increases from about 13 Hz at 0.06 phot. td to 80 Hz at 9300 phot. td.

The changes in the shapes of the temporal CSFs and the reduction in integration time both reflect a speeding up of the visual response with light adaptation. This speeding up can be assessed more directly by measuring the differences in visual delay between the two eyes when they are in different states of adaptation. **Figure 8(a)** shows how the cone response speeds up as the retinal illuminance in one eye is increased (relative to the cone response in the other eye fixed at a retinal illuminance of 4.16 log phot. td). In terms of phase delay (where 360° is one cycle of flicker), the response speeds up, for example, at 10 Hz, by about 150° between 1.05 and 4.16 log phot. td. This is equal to 150/360 or 0.42 of a cycle, which, given that one 10-Hz cycle lasts 100 ms, represents a speeding up of roughly 42 ms. The visual response mediated by rods also speeds up over the scotopic range. **Figure 8(b)** shows the rod response in one eye with varying retinal illumination relative to the rod response in the other eye fixed at a retinal illuminance of 1.3 log scot. td. At 4 Hz, the response speeds up by 135° or 0.38 cycles between −3.3 and −0.8 log scot. td. This translates to a speeding up of roughly 94 ms. These results illustrate that changes in visual delay can be substantial. Visual performance, in terms of the speed of the visual response, improves markedly as the rod or the cone systems light adapt.

At mesopic levels, the situation is more complicated. Although the rod system is relatively light adapted and the cone system relatively unadapted at these levels, the rod system is still more sluggish than the cone system. These differences reflect intrinsic differences between the speeds of the responses of the rod and cone

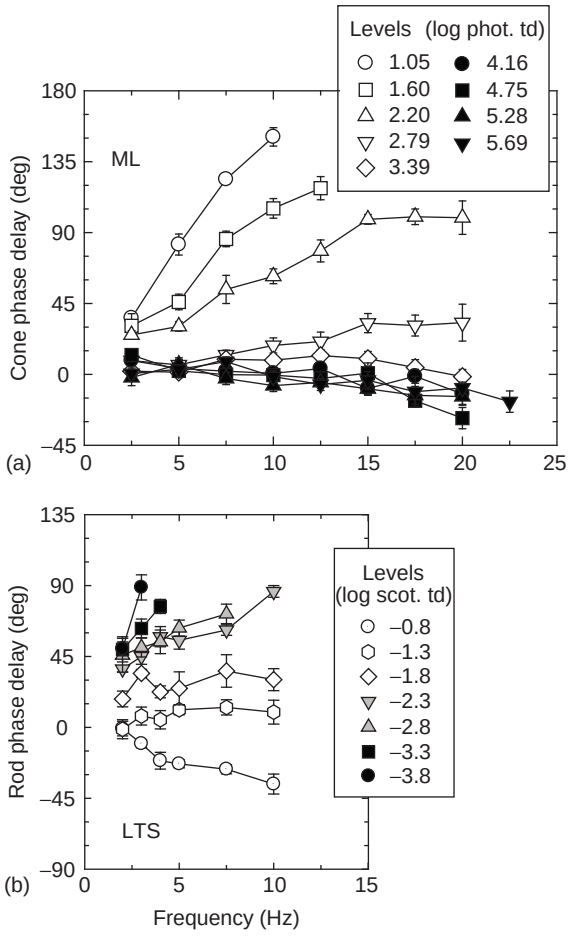

Figure 8 Binocular phase-delay measurements made between the two eyes in different states of adaptation. (a) M-cone phase delays in degrees between signals generated in the left eye and those generated in the right eye for observer ML. The adaptation level in the right eye was fixed at 4.16 log phot. td; that in the left eye was varied according to the key. Data replotted from Figure 5 of Stockman, A., Langendörfer, M., Smithson, H. E., and Sharpe, L. T. (2006). Human cone light adaptation: From behavioral measurements to molecular mechanisms. *Journal of Vision* 6: 1194–1213. (b) Rod phase delays degrees between signals generated in the left eye relative and those generated in the right eye for observer LTS. The adaptation level in the right eye was fixed at −1.30 log scot. td; that in the left eye was varied according to the key. Data replotted from Figure 9 of Stockman and Sharpe (2006). Into the twilight zone: The complexities of mesopic vision and luminous efficiency. *Ophthalmic and Physiological Optics* 26: 225–239.

photoreceptors, as well as differences between the rod and cone postreceptoral pathways. The situation is further complicated by an abrupt transition that occurs within the rod system at mesopic levels from a slow, sensitive postreceptoral pathway to a faster, more insensitive one. Due to the complex differences between the temporal properties of rod- and cone-mediated vision, mesopic measures of luminous efficiency and visual performance will be strongly dependent not only on the relative sensitivities of the rods and cones, but also on the temporal characteristics of the stimuli used to make those measurements. Thus, targets of different duration are likely to produce mesopic results with different rod to cone weightings.

Color Vision and Light Level

Color signals contribute significantly to the detection and appearance of objects, particularly when the photopic luminance contrast of the stimulus is low. In fact, in terms of cone-contrast signals under optimal conditions, the eye sees color better than it sees luminance. Other studies also show that even the pupil of the eye responds more vigorously to chromatic than to luminance signals when small stimuli are involved. Color can be perceived at or near the cone-detection threshold. For instance, the appearance of a spectrally green target is achromatic at scotopic levels, but takes on a clearly green tinge at mesopic levels. Color affects the conspicuity of stimuli. In general, the effective contrast of visual stimuli can be expressed as a complex function of photopic and scotopic luminance contrast with significant contributions from red/green and yellow/blue color signals in the photopic range. Importantly, chromatic signals also contribute to the perception of brightness (but not to luminance). In the mesopic range, cone signals become less effective, but the stronger rod signals do not appear to contribute significantly to color vision, particularly when threshold measurements are involved. When the stimulus is well above threshold, rod signals affect both the color appearance and the overall conspicuity of the stimulus.

Conclusions

The idea that the performance of the visual system can be usefully characterized over a 10 000-million-fold range of light levels by just three spectral luminous efficiency functions, corresponding to the scotopic, mesopic, and photopic ranges, is overly ambitious. Any model based solely on spectral sensitivity is unlikely to capture the effects of the large number of parameters that can influence object appearance. Here, we have focused on the way in which other key aspects of visual performance, such as spatial and temporal contrast sensitivity and acuity, visual delay, and color sensitivity, change with light level. We argue that only by linking such changes with changes in spectral luminous efficiency could we reasonably hope to predict visual performance, particularly at mesopic levels where the characteristics of the rod and cone systems are so different.

Photoreceptor Development: Early Steps/Fate

I Nasonkin, T Cogliati, and A Swaroop, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Glossary

Cell competence – In the context of retinal development, it refers to the characteristic ability of retinal progenitor cells (RPCs) to generate particular retinal cell types. It is determined by a combination of intrinsic and extrinsic factors.

Cell-fate determination – An early step (generally irreversible) in the developmental process leading to the acquisition of a differentiated cellular phenotype.

Cell-fate specification – Developmental process leading to the acquisition of a reversible cell fate, generally preceding determination.

Conditional knockout mouse – A genetically engineered mouse in which targeted deletion of gene(s) of interest can be temporally and/or spatially controlled.

Knockout mouse – A genetically engineered mouse carrying targeted deletion of one or more genes that is transmitted through the germ-line. Knockout mice in which gene function is completely ablated are referred to as *null* for that gene.

Phototaxis – Movement in response to light stimuli.

Precursor – For the purposes of this article, and in agreement with previously published material, the term precursor is used for a postmitotic cell committed to a specific cell fate but not having the differentiated cell function or phenotype. Other authors may use the term precursor interchangeably with the term progenitor.

Progenitor – For the purposes of this article and in agreement with previously presented material, a progenitor is a proliferating, undifferentiated, multipotent, yet developmentally restricted, cell that expresses a combination of genes biasing its fate toward one or multiple differentiated retinal phenotypes.

Rhabdomere – A visual pigment-containing organelle, characterized by numerous microvilli, normally found on the apical surface of photoreceptors, mostly in arthropods. Its counterpart in vertebrates is the outer segment of rods and cones.

Transgenic mouse – A mouse genetically engineered with random integration of one or more exogenous genes (transgenes) in its genome. Expression of the transgene can be cell/tissue specific and controlled over time.

Introduction

Rod and cone photoreceptors are highly specialized sensory neurons responsible for the detection of visual stimuli. They convert quanta of light into signals that are transmitted via interneurons (bipolar cells) to projection neurons (retinal ganglion cells (RGCs)) and then to the brain, where neuronal electrical stimuli are interpreted as visual sensation. In vertebrates, rod and cone photoreceptors are characterized by the expression of rhodopsin and cone opsins, respectively. Opsins belong to a family of membrane-bound guanine nucleotide binding protein-coupled receptors, which are covalently linked to a vitamin A-derived retinaldehyde chromophore and are responsible for initiating the phototransduction cascade.
