EDITORS BIOGRAPHIES

Darlene A. Dartt

Senior Scientist, the Harold F. Johnson Research Scholar, and Senior Scientist, Schepens Eye Research Institute; Associate Professor, Department of Ophthalmology, Harvard Medical School, Boston, MA, USA. At the Schepens Eye Research Institute Dr. Dartt served as the Acting Director of Research and the Director of Scientific Affairs for 10 years. She received her AB degree from Barnard College (Columbia University) in New York City and her PhD from the Department of Physiology at the University of Pennsylvania in Philadelphia. After postdoctoral fellowships at the University of Copenhagen, Denmark, and Tufts University School of Medicine in Boston, Dr. Dartt joined the Schepens Eye Research Institute in 1985. Her primary research interest is the neural regulation of tear production. Her research focuses on the signaling pathways used by nerves and growth factors in the lacrimal gland and conjunctival goblet cells to induce secretion and proliferation and how dysregulation of these pathways can lead to dry-eye syndromes in mouse models and humans, particularly after refractive surgery. She has been continuously funded by NIH since 1980 for this work. Dr. Dartt directs the Institute's Department of Defense Research Program; she also chaired four Military Vision Research Symposia. She served on and chaired the ARVO Cornea Program Planning Committee and served on the Members in Training Committee. She was a founding member, a member of the organizing committee, and more recently treasurer for the Tear Film and Ocular Surface Society. She has been on the organizing committee for the three Biennial Cornea Conferences in Boston, MA. She served as Vice President for North America for the International Society for Eye Research and a Councilor for the International Society for Contact Lens Wear. She is on the editorial board for *Investigative Ophthalmology and Visual Science, Experimental Eye Research*, and *The Ocular Surface*. She served on the review panel for Fight For Sight and has been an *ad hoc* member of numerous NEI and NIAMS study sections. She received the Lew R. Wasserman merit award by Research to Prevent Blindness and is a Gold Fellow of ARVO.

Joseph C. Besharse

Dr. Besharse is currently the Marvin Wagner Professor and Chair of the Department of Cell Biology, Neurobiology, and Anatomy at the Medical College of Wisconsin. He received his BA degree from Hendrix College (Conway, Arkansas) and MA and PhD degrees from Southern Illinois University. After a brief period on the faculty at Old Dominion University in Virginia, he moved to Columbia University as a Postdoctoral Fellow in Retinal Research. He was appointed to the faculty of Department of Cell Biology and Anatomy at Emory University School of Medicine in 1977, becoming full Professor in 1984. He assumed the position of Professor and Chair of Anatomy and Cell Biology at the University Kansas School of Medicine (Kansas City) in 1989 and moved on to his present position at Medical College of Wisconsin in 1997. Dr. Besharse's research has focused on membrane turnover, circadian clocks, and microtubule-based transport in photoreceptors, with special attention to fundamental pathways that are disrupted in photoreceptor degenerative diseases. His research has been continuously funded by the National Institutes of Health since 1978. In addition to his roles as Department Chair and a Principal Investigator, he directs an NIH funded training program in vision science. Dr. Besharse is a past member of the editorial boards of *Investigative Ophthalmology and Vision Science* and *Vision Neuroscience* and served as the Section Editor for the 'Retina' section of *Experimental Eye Research*. He has served as a trustee of the Association for Research in Vision and Ophthalmology, and has served two full terms as a member of two different NIH study sections. Among his awards are the Alcon Research Award for outstanding research in Vision Science (1993), the Alumni Achievement Award from Southern Illinois University (1998) and the Distinguished Service Award from the Association for Research in Vision and Ophthalmology (2005). He is a Gold Fellow of ARVO.

Reza Dana

In addition to his role as Senior Scientist and Co-Director of Research at the Schepens Eye Research Institute, Dr. Reza Dana holds the Claes H. Dohlman Chair in Ophthalmology at Harvard Medical School. He is Director of the Cornea and Refractive Surgery Service at the Massachusetts Eye and Ear, and serves as the Vice Chairman of the Harvard Department of Ophthalmology and Associate Chief of Ophthalmology for Academic Programs at Massachusetts Eye and Ear. After graduating *Summa Cum Laude* from St. Paul's School in New Hampshire, he completed his bachelor's (Phi Beta Kappa), graduate, and medical education at Johns Hopkins University. He performed his residency in

Ophthalmology at the Illinois Eye and Ear Infirmary in Chicago, followed by a clinical fellowship in cornea and external diseases at the Wills Eye Hospital in Philadelphia. Dr. Dana then completed additional fellowship training in immunology and uveitis at the Massachusetts Eye and Ear Infirmary, and in ocular and transplantation immunology at the Schepens Eye Research Institute. Dr. Dana also holds an MS degree in management from Harvard University. Reza has been a member of the full-time Harvard faculty since 1995. As a clinician-scientist, he has a particular interest in the molecular and cellular mechanisms of inflammation as they pertain to the ocular surface and anterior segment pathologies, including dry eye, allergy, wound healing responses, and transplant rejection.

PREFACE

Eye research has grown explosively over the years, and simultaneously with it individual scientists have become more specialized. Coupled with this dichotomy is the wide range of disciplines covered in eye research, from visual optics to butterfly vision and corneal structure to blood vessel growth. These variables necessitate a reference work that provides concise, easily understandable information on a wide range of subjects, and gives guidance on the most important articles to read from the literature. The *Encyclopedia of the Eye* was created to serve as such a reference work.

Each article in the encyclopedia contains text (easily understandable for scientists outside the field of the article), a number of multimedia and color figures that illustrate the most important points of the article, and a list of references to provide more in-depth information. Articles are primarily directed at scientists looking for an entry point into a field tangential to their specialty as well as at graduate students and postdoctoral fellows in eye research. The articles will be especially useful to scientists designing introductory or generalized courses that cover diverse fields of eye research. Scientists writing review articles or chapters will also find the encyclopedia articles especially useful as a starting point. The many introductory articles are written at a level that university undergraduates can understand, but include enough information to satisfy the more advanced needs of graduate students and postdoctoral fellows. The more in-depth articles on specialist research areas are ideal for postdoctoral fellows and experienced scientists. The plentiful multimedia figures will be especially helpful in understanding the more complicated points as well as illustrating basic processes and anatomy.

The format of the *Encyclopedia of the Eye* was selected by the editor-in-chief in collaboration with two senior editors, Drs. Reza Dana and Joseph C. Besharse. We covered the field of eye research with focus on specialties in ocular surface, immunology, clinical research, and retina. To choose the articles to be included in the encyclopedia, we selected 11 major areas of eye research that cover the entire field, with the exception of visual processing. The areas included the ocular surface, ocular immunology, vascular biology, orbit, aqueous humor, lens, vitreous, retina, visual optics, comparative eye research, and ocular development. Thus, the scope of the encyclopedia includes all fields of eye research, except visual processing. The latter area has been the focus of several recent major reference works. A prominent scientist in each area was chosen as a section editor. Each of the section editors in collaboration with the editor-in-chief and senior editors developed a list of articles to cover all important topics in the 11 major areas. The introductory articles and those with in-depth discussions of more focused specialized areas both are included in the encyclopedia. The section editors then selected an expert as the author for each article. Finished articles were reviewed by three individuals, the section editors, senior editors, and the editor-in-chief. Thus, the *Encyclopedia of the Eye* is a collaborative product of the most eminent scientists in eye research.

Eye research has become specialized and compartmentalized over the years and, to a large extent, has split among anatomical lines from the anterior to the posterior eye. For example, cornea research and retina research follow different paths and are based on different underlying concepts of cellular organization. The *Encyclopedia of the Eye* bridges this gap by including articles on all facets of eye research. In particular, we have included several topics usually not found in vision research reference works. These include orbit, vitreous, comparative eye research, and ocular development. These areas have unique specializations that are fascinating by themselves and highlight differences among well-known tissue or organism functions. Two articles in particular illustrate these points: one on the metabolism of intraocular muscles, which is unique to these nonfatiguing muscles; the other on color vision in butterflies, which allows butterflies to recognize each other.

Importantly, study of the eye and its various components involves pathways found in other tissues and provides insight into the function of the other tissues and organs. In addition, eye research has been a pacesetting discipline in many areas. Thus, the *Encyclopedia of the Eye* will provide knowledge and insight to scientists from wide-ranging disciplines, in addition to eye research itself. For example, eye research has provided seminal discoveries that impact other fields, such as gene therapy, genetics of human disease, angiogenesis, and retinal signaling pathways. Several unique areas of eye research

include the immune-privileged response of the eye, the prevention of blood vessel growth in the cornea and lens, and the role of a GTP-binding protein coupled cascade in retinal photoreceptor signaling. For all these reasons the *Encyclopedia of the Eye* will be valuable for nonvision biomedical scientists.

Articles are arranged in alphabetical order. The best way to find an article is to look at the subject index, as both introductory and more specialized articles are included in the encyclopedia. It could be advantageous to start with an introductory article to obtain knowledge about anatomy and the basic functions and then follow up with a more specialized, in-depth article. Furthermore, a subject could be included in an introductory, broader article and perhaps under a name that is not the reader's first guess.

An experienced, prompt, reliable, and thorough editorial staff is essential to the success of a major reference work. The outstanding contribution of the senior and section editors are appreciatively acknowledged by the editor-in-chief.

The editor-in-chief would like to gratefully acknowledge the scientific and editorial help of Ms. Robin Hodges. Ms. Hodges provided invaluable help in keeping track of all the articles in their various stages of the editorial process, contacting authors to keep them on schedule, and assisting the senior editors Drs. Reza Dana and Joseph C. Besharse. Without the expert help of Ms. Hodges, the *Encyclopedia of the Eye* would not be the outstanding new major reference work that it is. The editor-in-chief would also like to acknowledge the extremely helpful advice of Dr. Richard Masland, whose experienced suggestions were invaluable in setting up the editorial team as well as Dr. Joe G. Hollyfield for his helpful suggestions for section editors.

DARLENE A. DARTT
Editor-in-Chief

FOREWORD

This is a very long book – if indeed it should be denominated as a book – but it does not need a long Foreword. The editors, who are well chosen scholars of the eye, have assembled a remarkable series of over 200 articles, that cover a vast landscape on the biology of the eye, and do so with clarity and depth. They cover the eye from the front to the back – from the corneal tear film to the axons of the optic nerve.

The coverage is judicious. Each subject has an article that reviews its basic biology, these are accompanied by more specialized topics, commonly those relating to disease processes. Because disease processes are socially important, they deserve this emphasis – and it should be noted that they also have things to teach about the basic biology. The basic biology is presented in substantial depth, not only as a token gesture in the direction of the fundamentals. This kind of balance between basic biology and clinical subjects is rarely achieved, and the effect is that this is not only a Google-ready reference work but one that can be read serially, like a traditional expository volume.

The Introduction to another encyclopedia in this series makes reference to Wikipedia, the free form "Encyclopedia of Everything" created by a community of volunteer authors. The present encyclopedia has in common with Wikipedia great breadth, accessibility to rolling revision, and the fact that its authors are paid almost nothing. It is a credit to the editors, to the authors, and to our scientific community that so many talented people would devote their skill and effort primarily *pro bono* – for the common good.

And it is a very great "good." I hope and believe that this will become a standard, universal source for information about the eye. In this it also has a communality with Google and the Internet, but also a major difference: the information that appears in the Encyclopedia of the Eye is curated, by the editors and by the authentic experts whom they have chosen to write the articles. So I see this as an ongoing venture, a core resource that will roll forward with new authors and new editors as the science moves forward. It is an ambitious venture and I wish it all success.

A

Abnormal Eye Movements due to Disease of the Extraocular Muscles and Their Innervation

A Serra, University of Sassari, Sassari, Italy
R J Leigh, Case Western University, Cleveland, OH, USA

Glossary

Amblyopia – Lazy eye with poor vision because of misalignment of the eyes during development.
Chronic progressive ophthalmoplegia (CPEO) – This term describes a number of disorders affecting the extraocular muscles that lead to progressive limitation of eye motion.
Diplopia – Double vision.
Esotropia – Misalignment of the eyes, one of which turns in (toward the nose)–cross-eyed.
Exotropia – Misalignment of the eyes, one of which turns out (away from the nose)–wall-eyed.
Kearns–Sayre syndrome – One cause of CPEO (see above) that is inherited from the mother and affects other tissues, such as the heart.
Myasthenia gravis – A disorder causing muscle fatigue that is due to failure of the nerves to stimulate the muscles to contract.
Nystagmus – An oscillation of the eyes (shimmering or jumping eyes).
Optokinetic reflexes – Eye movements induced by moving a visual pattern in front of the eyes.
Ptosis – Droopy lids.
Saccades – Rapid eye movements that are used to move the point of visual fixation from one feature of interest to the next.
Smooth pursuit – Eye movements that smoothly follow a moving object, such as a bird in the sky.
Strabismus – Misalignment of the eyes; the eyes point in different directions.
Vestibulo-ocular reflexes – Eye movements induced by head movements, which stimulate the balance mechanism in the inner ear.

Introduction

In this article we apply current knowledge of the extraocular muscles (EOMs) and their brainstem innervation to develop working hypotheses to account for a range of abnormal eye movements. To be concise, we have mainly selected diseases with well-defined processes that affect specific sites, from muscle to premotor neurons in the brainstem (**Figures 1** and **2**). This bottom-up approach is somewhat reductionist and simplified, but we hope that it will provide insights for readers with a broad range of interests. For more comprehensive reviews, readers can turn to sources listed at the end of this article.

A prerequisite for understanding disordered ocular motility is that eye movements can be systemically examined (**Table 1**). Thus, restricting attention to the most evident disturbance (e.g., strabismus) will impoverish interpretation of the underlying disorder. Conversely, considering the properties of saccades, pursuit, vestibular, and vergence eye movements, as well as the presence of any visual deficits, will enrich the understanding of the pathogenesis of the disorder.

Effects of Disorders of the EOMs on Eye Movements

The EOMs (**Figure 1**, site 1) possess unique properties that make them resistant to some diseases and susceptible to others. Thus, on the one hand, the EOMs are spared in Duchenne muscular dystrophy, even when the disease is well advanced, a finding that has prompted much research. On the other hand, EOMs are rich in mitochondria, which is appropriate for the sustained contraction required for precise gaze control, but which makes them susceptible to mitochondrial disorders. Although such disorders

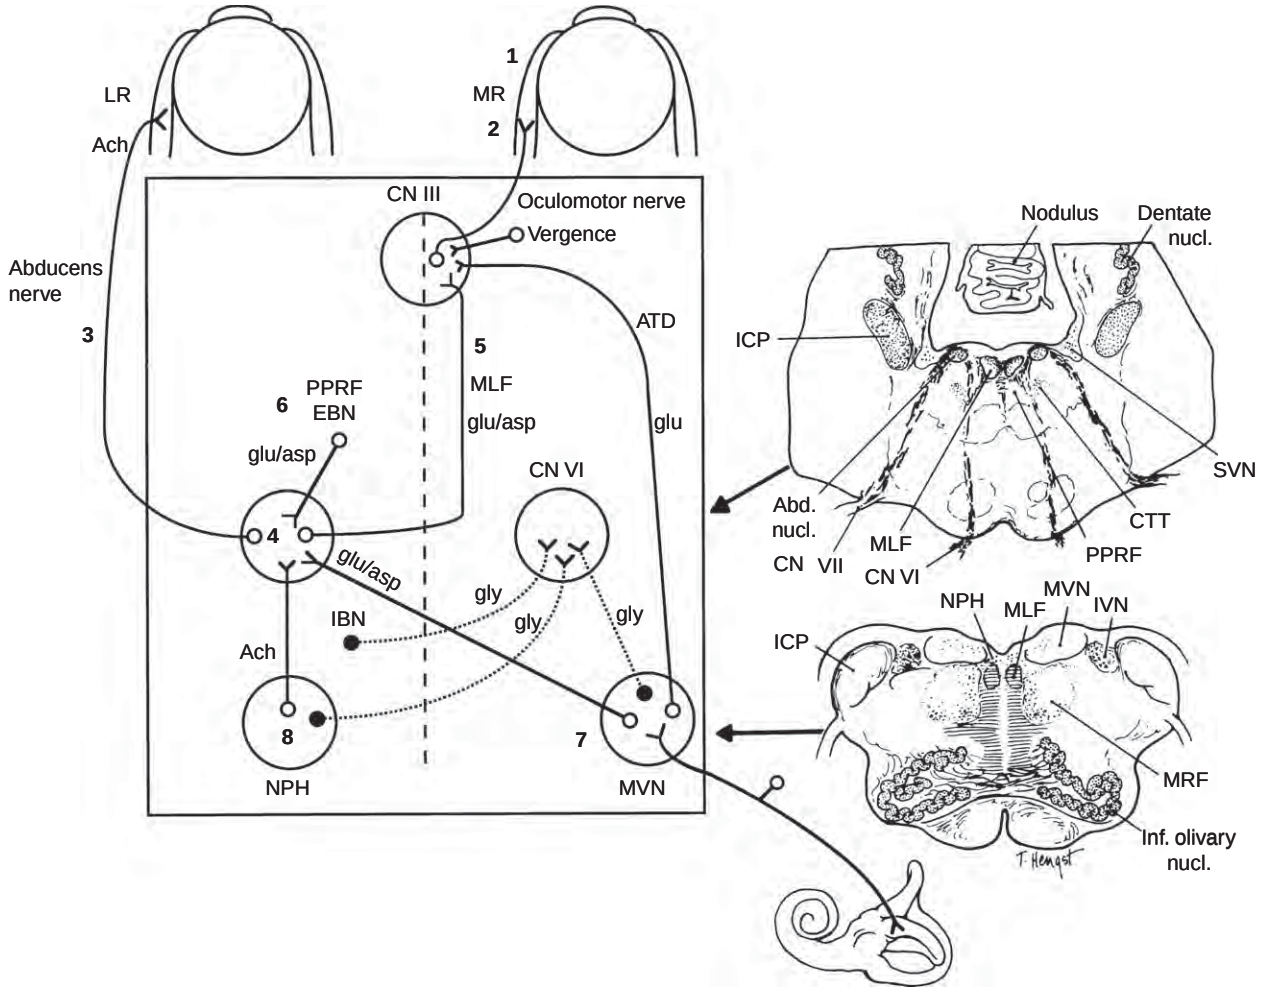

Figure 1 Anatomic scheme for the synthesis of signals for horizontal eye movements. The abducens nucleus (CN VI) contains abducens motoneurons that innervate the ipsilateral lateral rectus muscle (LR), and abducens internuclear neurons that send an ascending projection in the contralateral MLF to contact medial rectus (MR) motoneurons in the contralateral third nerve nucleus (CN III). From the horizontal semicircular canal, primary afferents on the vestibular nerve project mainly to the MVN, where they synapse and then send an excitatory connection to the contralateral abducens nucleus and an inhibitory projection to the ipsilateral abducens nucleus. Saccadic inputs reach the abducens nucleus from ipsilateral excitatory burst neurons (EBNs) and contralateral inhibitory burst neurons (IBNs). Eye position information (the output of the neural integrator) reaches the abducens nucleus from neurons within the nucleus prepositus hypoglossi (NPH) and adjacent MVN. The medial rectus motoneurons in CN III also receive a command for vergence eye movements. Putative neurotransmitters for each pathway are shown: Ach, acetylcholine; asp, aspartate; glu, glutamate; gly, glycine. The anatomic sections on the right correspond to the level of the arrowheads on the schematic on the left. Abd. nucl., abducens nucleus; CN III, oculomotor nerve; CN IV, trochlear nerve; CN VI, abducens nerve; CN VII, facial nerve; CTT, central tegmental tract; ICP, inferior cerebellar peduncle; IVN, inferior vestibular nucleus; Inf. olivary nucl., inferior olivary nucleus; MVN, medial vestibular nucleus; MRF, medullary reticular formation; SVN, superior vestibular nucleus. Numbers indicate lesion sites that are discussed in the text. Adapted from Leigh, R. J. and Zee, D. S. (2006). *The Neurology of Eye Movements*, 4th edn. New York: Oxford University Press.

may arise in childhood along with involvement of other tissues, such as heart muscle (Kearns–Sayre syndrome), these may present throughout adulthood with the syndrome of chronic progressive ophthalmoplegia (CPEO). Such individuals have ptosis and a limited range of eye movements. The complaint of diplopia is rare in CPEO, and although this had been ascribed to equal involvement of each of the eye muscles, another explanation seems more likely. Thus, slow progression of CPEO allows time for the visual system to adapt, and suppress images from one eye. Another interesting finding is that such patients may also make relatively quick eye movements (saccades or vestibular eye movements), despite a limited range of movement. This anomaly may be due to sparing of fast type myosin heavy chain (MyHC) EOM-specific global EOM fibers, which have fewer mitochondria.

Besides mitochondrial disorders, the EOM may be affected by other genetic diseases such as hereditary

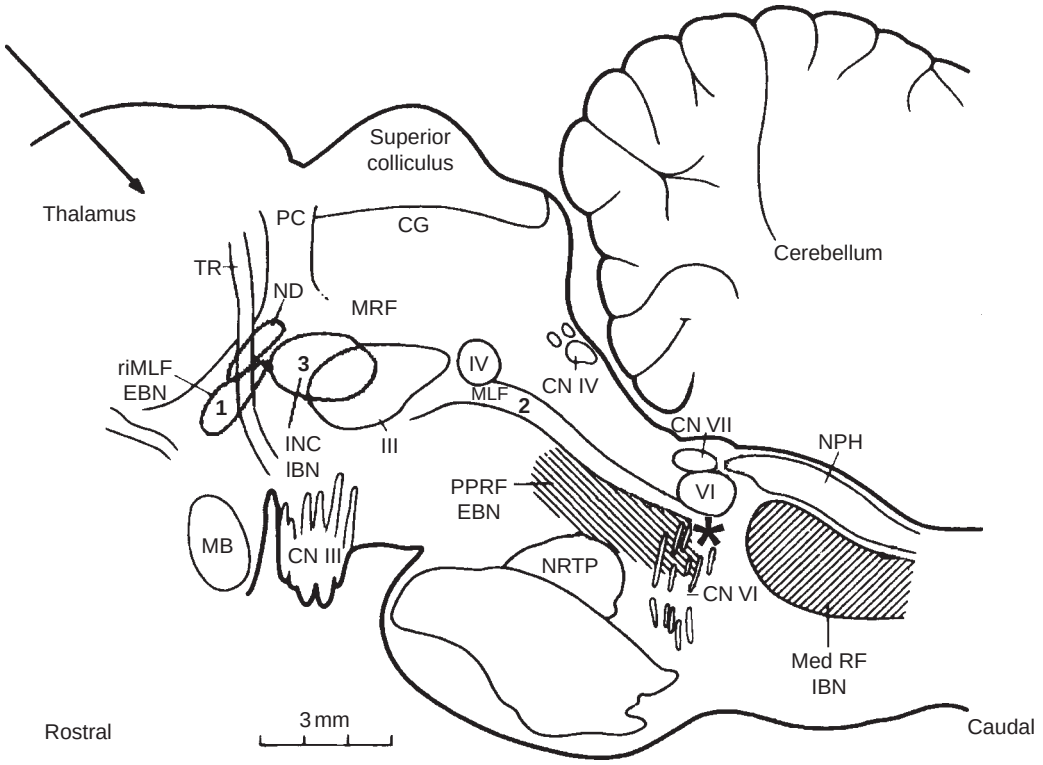

Figure 2 A sagittal section of the monkey brain stem showing the locations of premotor burst neurons: excitatory burst neurons for horizontal saccades lie in the paramedian pontine reticular formation (PPRF) and, for vertical and torsional saccades lie in the rostral interstitial nucleus of the medial longitudinal fasciculus (rostral iMLF). Burst neurons project to ocular motoneurons lying in the abducens nucleus (VI), the trochlear nucleus (IV) and the oculomotor nucleus (III). Omnipause neurons (indicated by an asterisk) lie in the midline raphe of the pons between the rootlets of the abducens nerve (CN VI) and gate the activity of burst neurons. CG, central gray; MB, mammillary body; MT, mammillothalamic tract; CN III, rootlets of the oculomotor nerve; CN IV, trochlear nerve; ND, nucleus of Darkschewitsch; NRTP, nucleus reticularis tegmenti pontis; PC, posterior commissure; NPH, nucleus prepositus hypoglossi; TR, tractus retroflexus. The arrow refers to the Horsley-Clarke plane of section. Numbers indicate lesion sites that are discussed in the text. Courtesy of Dr. Jean Büttner-Ennever).

disorders of myosin, or acquired disorders that present as a restrictive ophthalmopathy, such as thyroid disease. Thyroid ophthalmopathy, which has been attributed to accumulation of glycosaminoglycans in the orbit, often presents with vertical diplopia that is worse on wakening. Associated lid retraction and exophthalmia are common manifestations.

Effects of Disorders of the Neuromuscular Junction on Eye Movements

Eye movements are especially susceptible to a disease affecting the neuromuscular junction (**Figure 1**, site 2), classical myasthenia gravis, which is due to an abnormal immune attack on the postsynaptic acetylcholine receptor. In half of all patients with myasthenia gravis, diplopia or ptosis is the presenting complaint and, in about 80% of patients, movements of the eyes and lids are ultimately abnormal, with fluctuating weakness. Why are the EOMs so susceptible to diseases affecting the neuromuscular junction? One physiological reason arises from the demands made of eye movements to sustain the precise alignment of the eyes required for single binocular vision. It follows that fluctuating weakness due to myasthenia often causes ocular misalignment and diplopia. One morphological reason is that the postsynaptic junction of the EOM is poorly folded, thereby reducing the potential area for acetylcholine receptors. It follows that the EOM will be especially susceptible to loss of acetylcholine receptors. However, one subtype of EOM fibers, the MyHC EOM-positive myofibers (fast twitch/fatigable), which seems important for fast eye movements, does have substantial folding of its postjunctional membranes and, therefore, seems less susceptible to fatigue. Thus, it is interesting to note that patients with severe ocular myasthenia and little residual movement often retain the ability to make fast movements (quiver movements)-presumably due to preserved activity of their MyHC EOM-positive fast twitch myofibers.

Table 1 Functional classes of human eye movements

Class of eye movement	*Main function*
Vestibular	Holds images of the seen world steady on the retina during brief head rotations or translations
Visual fixation	Holds the image of a stationary object on the fovea by minimizing ocular drifts
Optokinetic	Holds images of the seen world steady on the retina during sustained head rotation
Smooth pursuit	Holds the image of a small moving target on the fovea; or holds the image of a small near target on the retina during linear self-motion; with optokinetic responses, aids gaze stabilization during sustained head rotation
Nystagmus quick phases	Reset the eyes during prolonged rotation and direct gaze toward the oncoming visual scene
Saccades	Bring images of objects of interest onto the fovea
Vergence	Moves the eyes in opposite directions so that images of a single object are placed or held simultaneously on the fovea of each eye

Adapted from Leigh, R. J. and Zee, D. S. (2006). *The Neurology of Eye Movements*, 4th edn. New York: Oxford University Press.

Why is diplopia a common complaint in ocular myasthenia but rare in CPEO? The view that the eyes move conjugately in CPEO but not in myasthenia is not supported by measurements of eye movements. A more cogent reason is that the weakness in ocular myasthenia is highly variable (hence the characteristic symptom of fatigue), whereas in CPEO it evolves slowly and steadily. Thus, in CPEO the visual system has time to adapt to the loss of binocular correspondence, whereas in ocular myasthenia visual inputs are continually varying. This is not to state that adaptation of eye movements does not occur in myasthenia: the converse is the case, and is often evident by the occurrence of abnormally large eye movements immediately following pharmacological reversal of the neuromuscular failure by intravenous injection of the acetylcholine esterase inhibitor, edrophonium.

Although ocular myasthenia is the most common disease to affect the EOM neuromuscular junction, other disorders that can impair eye movements include systemic botulism, neuromuscular blocking agents, and the Lambert-Eaton myasthenic syndrome (LEMS), which is due to the impaired release of acetylcholine secondary to autoimmune attack on presynaptic P/Q voltage-gated calcium channels. As opposed to myasthenia, in LEMS, repetitive saccades may change from hypometric (under-shooting) to hypermetric (over-shooting) as a consequence of the characteristic facilitation of muscle strength.

Effects of Disorders of the Oculomotor, Trochlear, and Abducens Nerves on Eye Movements

Palsies of the nerves innervating EOMs are common in clinical practice and cause diplopia and selective patterns of weakness of the muscles they supply. Such paralytic strabismus (misalignment of the visual axes) is greatest when the affected patient attempts to look in the direction of the weak muscle. Thus, in the case of left abducens palsy (**Figure 1**, site 3), the patient cannot abduct (turn out) the affected eye to the left. However, such weakness and the attendant diplopia is a stimulus to adapt the neural signals that move the eyes. Such adaptive changes are evident if the strong eye is covered and the weak eye forced to view the world. A similar situation occurs naturally if the weak eye is also the visually dominant eye. In either case, the level of innervation is increased in motoneurons supplying muscles that induce corresponding movements in each eye. Thus, in our example, the left lateral rectus, which turns the left eye out, and the right medial rectus, which turns the right eye in, would both receive increased innervation. One consequence of this adaptation is that movements of the weak eye may improve (unless paralysis is complete). A second consequence is that the strong eye, which also receives increased innervation, would, for example, make leftward saccades that overshoot the visual target. Such behavior is sustained for some time after adaptation even if the weak eye is covered and the strong eye views. This is a special example of plastic adaptation or motor learning, a property that depends heavily on the cerebellum, and which has been a subject of research interest for the past quarter-century. Because of the yoking mechanism by which eye movements are made conjugate in the brainstem circuitry (see the next section), there is a limitation to how much adaptive mechanisms can contribute to the recovery of the weakness due to nerve palsy. Nonetheless, such adaptive mechanisms undoubtedly contribute to the recovery from ocular motor nerve palsies. Paradoxically, in the case of trochlear nerve palsy, there is some recent evidence that such mechanisms may be maladaptive.

Effects of Disorders of the Brainstem Circuitry on Eye Movements

Horizontal Movements

The brainstem machinery whereby the eyes are coordinated to move together (conjugately) in the horizontal plane is summarized in **Figure 1**. The abducens nucleus, which lies in the pons, may be regarded as the horizontal gaze center (**Figure 1**, site 4). Thus, the abducens nucleus receives inputs for each functional class of eye

movements, including saccades, smooth pursuit, vestibular and optokinetic reflexes. It follows that each of these classes of conjugate eye movement (Table 1) may be independently affected by disease. The abducens nucleus contains two main groups of neurons: abducens motoneurons and abducens internuclear neurons. Axons of abducens motoneurons project in the sixth (abducens) cranial nerve to innervate the lateral rectus muscle. Axons of abducens internuclear neurons cross the midline and ascend in the contralateral medial longitudinal fasciculus (MLF, Figure 1, site 5) to contact medial rectus motoneurons in the oculomotor nucleus, which lies in the midbrain. Axons of medial rectus motoneurons project in the third (oculomotor) cranial nerve to innervate the medial rectus muscle.

It follows that lesions affecting the abducens nucleus (Figure 1, site 4) will impair movements of both eyes to the side of the lesion (horizontal gaze palsy). It also follows that lesions of the MLF (Figure 1, site 5) will impair the ability of the ipsilateral eye to adduct; this is called internuclear ophthalmoplegia (INO), because the coordination of the abducens motoneurons and oculomotor medial rectus motoneurons is disrupted. Multiple sclerosis (MS) is the most common etiology for an INO in young persons, especially when it is present bilaterally. Patients with INO due to demyelination of the MLF in MS show slowing or absent movements of the adducting eye because the MLF can no longer conduct high-frequency signals between the abducens and the oculomotor nuclei. However, vergence movements may be preserved either in abducens nucleus lesions or in INO, since vergence commands project directly to the oculomotor nucleus (Figure 1).

Horizontal saccades depend on premotor burst neurons, which lie in the paramedian pontine reticular formation (PPRF, Figure 1, site 6), and generate a high-frequency pulse of action potentials. Disorders affecting burst neurons of the PPRF selectively slow, or abolish, horizontal saccades. In contrast with abducens nucleus lesions, which cause complete horizontal gaze palsy, lesions of the PPRF usually spare ipsilateral smooth pursuit and vestibular eye movements.

The vestibulo-ocular reflex (VOR) for horizontal head rotations depends on vestibular afferents from the lateral semicircular canals, which relay their signal to the contralateral abducens nucleus via the medial vestibular nucleus (MVN, Figure 1, site 7). Wernicke's encephalopathy, a disorder due to thiamine deficiency that occurs in alcoholics, involves the vestibular nuclei and may impair the horizontal VOR.

The nucleus prepositus hypoglossi (NPH , Figure 1, site 8), the adjacent MVN, and the cerebellum play an important role in holding the eyes in an eccentric position (e.g., far right gaze) against the elastic pull of the orbital tissues. This function depends on mathematical integration of premotor (visual, vestibular, saccadic) signals by the NPH/MVN–cerebellar network. Impaired function of this network (leaky integration) due, for example, to intoxication with alcohol, causes the eyes to drift back to the center, leading to gaze-evoked nystagmus. It has also been postulated that the ocular motor neural integrator network may also become unstable causing either increasing velocity drifts away from center position or quasi-sinusoidal eye oscillations (acquired pendular nystagmus).

Vertical Movements

The coordination of eye movements in the vertical plane depends heavily upon neural circuits in the midbrain. However, there is no single vertical gaze center similar to the abducens nucleus for horizontal gaze. The oculomotor and trochlear nuclei (Figure 2) house motoneurons that innervate EOMs that rotate the eyes mainly vertically (superior and inferior rectus muscles) or mainly torsionally (around the line of sight-the superior and inferior oblique muscles). These motoneurons receive their saccadic input from the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF), which lies in the prerubral fields of the rostral midbrain. Bilateral lesions involving the riMLF (Figure 2, site 1) cause slow or absent vertical saccades, such as in progressive supranuclear palsy (PSP), a Parkinsonian disorder. Unilateral lesions of riMLF, such as in rostral brainstem strokes, cause loss of torsional rapid movements that rotate the top pole of the eye toward the side of the lesion.

The signals for vertical vestibular and pursuit eye movements ascend from the medulla and pons to the midbrain in the MLF and other pathways. Thus, bilateral MLF lesions (Figure 2, site 2), which occur in MS, cause impaired vertical pursuit and vestibular responses (as well as bilateral adduction failure during horizontal saccades, as described in the previous section). The interstitial nucleus of Cajal plays an important role in holding vertical eccentric gaze steady (e.g., far upward gaze); lesions here (Figure 2, site 3) cause gaze-evoked nystagmus on upward or downward gaze, postulated to be due to a leaky ocular motor integrator. The superior colliculus is a midbrain tectal structure that receives inputs from the cortical eye fields, and is important for triggering both horizontal and vertical saccades. Functional imaging studies in humans have demonstrated activation of the superior colliculus during generation of short-latency (express) saccades.

Neural circuits important for the generation of vergence eye movements are also located in the pretectum and midbrain, but pontine nuclei and their projections to the cerebellum also contribute. Thus, disturbances of vergence eye movements are encountered with lesions, such as strokes, throughout the brainstem. However, abducens nucleus lesions and INO (Figure 1, sites 4 and 5) usually spare vergence movements.

Congenital Misalignment of the Eyes (Infantile Strabismus) and Attendant Nystagmus

Ocular misalignment from infancy may be due to disorders of the orbital tissues, the innervation of EOM, or as a consequence of failure to develop binocular vision. The failure to develop binocular vision usually presents as the fusional maldevelopment nystagmus syndrome (FMNS), which includes amblyopia of one eye, strabismus (commonly esotropia and dissociated vertical deviation, with upward deviation of the covered eye) and latent nystagmus. Latent nystagmus is a jerk nystagmus comprising slow drifts of the eyes off target and a rapid resetting component that is absent when both eyes are viewing but appears when one eye is covered. The quick components of latent nystagmus beat away from the covered eye, and the nystagmus reverses direction upon covering of either eye. In most patients, the nystagmus is present (but low amplitude) when both eyes are uncovered, and is termed manifest latent nystagmus. Thus, although binocular viewing is possible, affected individuals almost invariably choose to fix with one eye and suppress the image from the other. Latent nystagmus can be induced experimentally in monkeys, either by depriving them of binocular vision early in life, or by surgically creating strabismus. In monkeys with latent nystagmus, the brainstem nucleus of the optic tract (NOT) shows abnormal electrophysiological properties. In normal monkeys, NOT neurons respond to visual stimuli presented to either eye. However, in monkeys with latent nystagmus, NOT neurons are driven mainly by the contralateral eye. Furthermore, inactivation of NOT with muscimol abolishes latent nystagmus in monkeys who have been deprived of binocular vision. Since the NOT projects to vestibular circuits concerned with gaze control during head rotations, one current view of the pathogenesis of latent nystagmus is that it represents the consequences of imbalance of visual inputs to the vestibular system, as if the subject was being rotated toward the side of the viewing eye.

Effect of Visual System Disorders on Eye Movements

Patients with a broad range of retinal disorders causing blindness is often a familial disorder. Both show continuous jerk nystagmus, with components in all three planes, which changes in direction over the course of seconds or minutes. The drifting null point, the eye position at which nystagmus changes direction, probably reflects an inability to calibrate the ocular motor system. Animals raised in a strobe illuminated environment, which deprives them of retinal image motion while still providing position cues, also develop spontaneous ocular oscillations. Gene therapy used to restore vision to dogs blind due to an inherited retinal disease resulted in a decrease in their associated nystagmus. Nystagmus is also a feature of albinism, which is associated with abnormal development of visual pathways and optic nerve hypoplasia.

Infantile Forms of Nystagmus in Individual with Normal Visual Systems

Infantile nystagmus syndrome (INS), or congenital nystagmus, may be present at birth but usually develops during infancy. The nystagmus is almost always conjugate and horizontal, even on up or down gaze, with a small torsional component. It is usually accentuated by the attempt to fix upon an object and by attention or anxiety. Up to 30% of patients with INS have strabismus but, even in individuals lacking strabismus, stereovision is usually degraded, partly due to retinal image motion. Head turns are common in INS and are used to bring the eye in the orbit close to the null point or zone, at which nystagmus is minimized. Some patients with INS also show head oscillations; such head movements could not act as an adaptive strategy to improve vision unless the VOR was negated. It seems possible that the head tremor and ocular oscillations in INS represent the output of a common neural mechanism. Measurements of nystagmus in INS demonstrate typical waveforms with increasing slow-phase velocity and the superimposed presence, during each cycle of oscillations (usually after a quick phase), of a brief period when the eye is still and is pointed at the object of regard. Such foveation periods are probably one reason why many individuals with INS have near-normal vision and why most do not complain of oscillopsia (illusory motion of the seen world), in spite of otherwise nearly continuous movement of their eyes.

INS, either with or without associated visual system abnormalities, is often a familial disorder. Both autosomal dominant and sex-linked recessive forms of inheritance have been reported. Although several hypotheses for the pathogenesis of INS have been offered, no animal models exist. At present, it seems possible that genetic studies will identify the underlying molecular mechanisms and point researchers to the neural disturbance causing INS.

Conclusions

Recent progress in understanding disorders of the EOMs and their innervation from the viewpoint of molecular biology and genetics is approaching the point where it can be combined with behavioral and electrophysiological studies. For example, recent evidence indicates that each functional class of eye movements (Table 1) is served by a separate population of ocular motoneurons

that receive specific premotor inputs. It follows that each functional class of eye movements may depend on distinct molecular mechanisms or morphological characteristics, from premotor neurons to EOM. Human diseases provide many opportunities to study behavioral effects of a disease when the disease process affects a specific site-such as the acetylcholine receptor in myasthenia gravis. In this way, insights from basic science have a growing impact on clinical ophthalmology and neurology, and vice versa.

Accommodation

A Glasser, University of Houston, Houston, TX, USA

Glossary

Accommodation – The dioptric increase in optical power of the eye to focus at near. In the young phakic eye, this occurs through an increase in the lens surface curvatures.
Depth of field – The range of movement of an object in object space over which there is no perceptible change in focus of the image.
Depth of focus – The range of movement of the image in image space over which there is no perceptible change in focus of the image.

Optics of the Eye

The cornea and lens constitute the primary optical refracting surfaces of the eye. These are optical interfaces at which light is refracted because they are curved surfaces at which there exists a refractive index interface or boundary between the medium preceding the optical surface and the optical surface itself. The anterior corneal surface is the primary refracting surface of the eye which constitutes approximately 75% of the total optical refracting power of the eye. The cornea constitutes such an important and powerful optical surface because there is a greater refractive index boundary between air and the cornea than exists elsewhere in the eye. The posterior corneal surface and the anterior and posterior lens surfaces constitute the other primary optical interfaces of the eye. In addition, the lens has a gradient refractive index with a greater refractive index at the center than at the surface. This gradient also imparts additional optical power to the lens, resulting in a lens with greater overall optical power than if the lens had a uniform refractive index equal to the highest refractive index value at the center of the gradient. Light entering the eye is refracted at these optical interfaces and the gradient refractive index of the lens and drawn to a focus toward the retina.

Optics of Accommodation

Accommodation is defined as a dioptric increase in optical power of the eye with an effort to focus at near. A dioptric change means a change in optical power expressed in units of diopters where diopters are inverse or reciprocal meters. An unaccommodated emmetropic eye will form an in-focus image on the retina for objects at optical infinity (**Figure 1**). For the purposes of subjectively determining the refractive state or refractive error of an eye clinically, an object at a distance of 6 m from the eye is sufficient to constitute optical infinity for the eye. The vergence of light rays entering an eye from an object 6 m in front of the eye is calculated as $1/-6\,\text{m} = -0.16$ D. The minus sign is used to denote an object distance in front of the eye or rays that are diverging from the object toward the eye. The vergence of light rays entering the eye from an object at infinity would be $1/\infty\,\text{m} = 0$ D. The difference in vergence between 0 D and –0.16 D is undetectable for the eye and can be considered as negligible. Therefore, an emmetropic eye focused on an object at 6 m can be considered to be unaccommodated or relaxed. If a near object is placed in front of the eye, say at a point 0.5 m in front of the eye, the near object will have a vergence of $1/-0.5\,\text{m} = -2.0$ D. In an unaccommodated, emmetropic eye, the more divergent light rays from this near object would not be refracted sufficiently by the cornea and the unaccommodated lens to form a focused image on the retina. The rays reaching the retina would form a blur circle on the retina rather than a point image as the rays would not have converged to a point focus by the time they reach the retina. If the unaccommodated eye is to achieve an in-focus image of the near object on the retina, the eye must accommodate to increase its optical power. An increase in optical power of the eye will increase the vergence of the rays after refraction by the lens so that the rays leaving the posterior lens surface will converge to a focus on the retina. In the accommodated eye, the near object will form an in-focus image on the retina.

The Accommodative Anatomy

The ciliary muscle is elongated, triangular in shape, and located beneath the anterior sclera just posterior to the limbus. The shortest side of the triangular region faces anterior-inward and it is to this region of the ciliary body that the base of the iris inserts. The elongated, superficial, external surface of the ciliary muscle extends from the scleral spur posteriorly, curved along the inner surface of the anterior sclera. The apex of the ciliary muscle is oriented inward in the eye toward the lens equator and is covered by the pars plicata region of the ciliary processes. The inner surface of the ciliary muscle extends from the

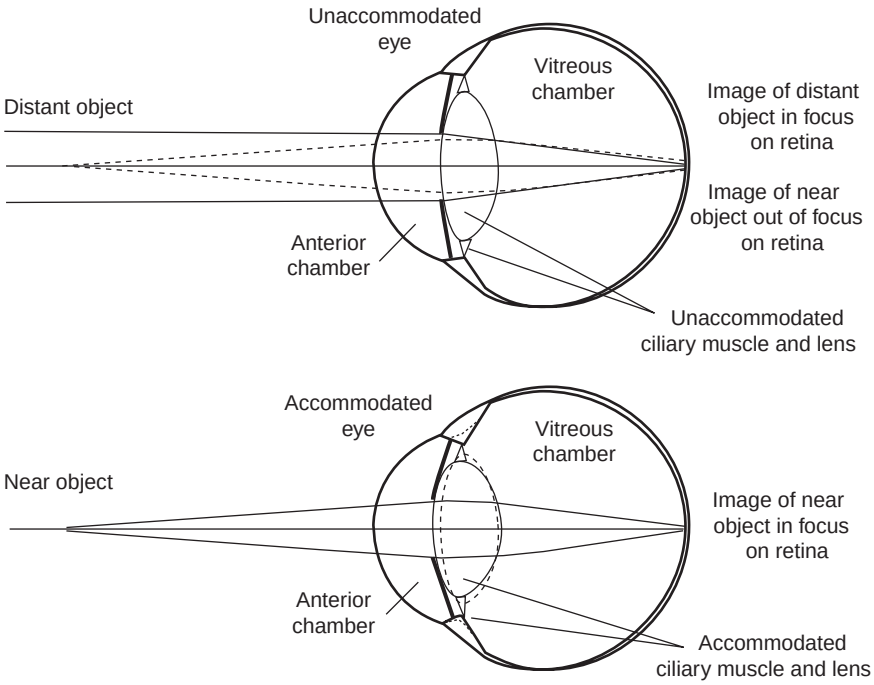

Figure 1 In an unaccommodated emmetropic eye, parallel rays from a distant object are refracted by the cornea and lens to form an in-focus image on the retina (upper diagram, solid rays). In the unaccommodated eyes, divergent rays from a near object would not be focused on the retina, resulting in an out-of-focus image on the retina (dashed rays). When the eye accommodated, the lens curvatures increase to increase the refraction of light such that the divergent rays from a near object are focused on the retina (lower diagram). Reproduced from Glasser, A. and Kaufman, P. L. (2002). Accommodation and presbyopia. In: Kaufman, P. L. and Alm, A. (eds.) *Adler's Physiology of the Eye: Clinical Applications,* 10th edn., pp. 197–233. St. Louis, MO: Mosby, with permission from Elsevier.

apex posteriorly toward the posterior insertion of the ciliary muscle and is covered by the pars plana region of the ciliary body. The ciliary muscle is composed of muscle fibers of three differing orientations. Most superficially, just beneath the sclera, are longitudinally oriented muscle fibers. These muscle fibers have their fixed origin at the scleral spur and their movable posterior insertion attached posteriorly to the choroid at the ora serrata of the retina. Deeper within the ciliary muscle and located more anteriorly toward the apex of the triangular-shaped region are the more radially oriented muscle fibers. Deeper still toward the apex of the triangular-shaped ciliary muscle are the circular muscle fibers. The muscle fibers are dually and reciprocally innervated by sympathetic and parasympathetic subdivisions of the autonomic nervous system. Although the muscle fiber orientations differ, the entire ciliary muscle contracts as a whole during accommodation. Contraction of the longitudinally oriented fibers acts principally to pull the posterior insertion of the ciliary muscle anteriorly; contraction of the radially oriented muscle fibers acts principally to consolidate and bulk up the apex of the triangularly shaped region; and contraction of the circularly oriented fibers acts principally to pull the apex of the triangle inward toward the lens equator. The pars plicate region of the ciliary body surrounding the anterior, inward-facing apical region of the ciliary muscle contains the dense vascular supply that provides oxygen and nutrients to the ciliary muscle. The ciliary muscle fibers have a greater abundance of mitochondria than any other muscle in the body, indicating the extraordinary high energy demands and requirements of this muscle. The lens is composed of transparent elongated lens fiber cells arranged in an onion-like shell structure. The central region of the lens, which is laid down earliest during embryological and postnatal development, is called the nucleus and, in the adult, is composed of anucleate lens fiber cells. Surrounding the nucleus is the developmentally younger lens cortex which is composed of the more recently differentiated lens fiber cells, some of which still contain nuclei. In the adult lens, the boundary between the nucleus and cortex is somewhat arbitrarily defined based on the appearance of optical zones of discontinuity due to refractive index boundaries visible from slit-lamp or Scheimpflug imaging. The lens is surrounded by a thin elastic membrane called the capsule. This is not of uniform thickness, but has an anterior midperipheral thickening ($\sim$10–15 μm) and thins toward the lens equator and around the lens posterior surface. The lens anterior surface is flatter than the posterior surface with radii of curvatures of approximately 10 mm and −6 mm, respectively. The lens axial thickness is approximately 4 mm and the lens equatorial diameter is approximately 10 mm. Dimensions of the lens change with age as the lens

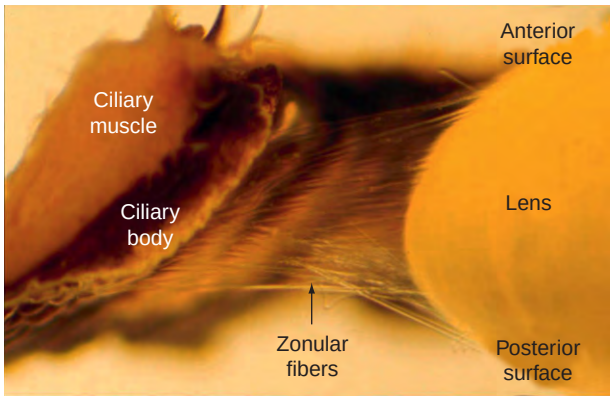

Figure 2 Photograph of a partially dissected human eye to show the accommodative structures. The cornea and sclera of the eye have been removed and the ciliary muscle and ciliary body have been cut through. The zonular fibers extend from all along the ciliary body across the circumlental space to insert into the capsule all around the lens equatorial region. Reproduced from Glasser, A. and Campbell, M. C. W. (1998). Presbyopia and the optical changes in the human crystalline lens with age. *Vision Research* 38: 209–229, with permission from Elsevier.

grows and also during accommodation, so these are approximate dimensions for an unaccommodated adult human lens. The lens is suspended by a fine meshwork of zonular fibers (**Figure 2**). These are fine elastic fibers and are inserted all around the lens equatorial region into the lens capsule, with no clear delineation into separate regional groups and with anterior–posterior crossing of zonular fibers visible. The zonular fibers extend from the lens equatorial region, through the valleys between the ciliary processes where they are anchored to the walls of the ciliary processes by a fine meshwork of anchoring fibers. The zonular fibers then continue their course posteriorly through the pars plicata region of the ciliary body forming a dense meshwork of fibers along the pars plana region of the ciliary body and finally insert into the ciliary epithelial tissue near the posterior insertion of the ciliary muscle.

The Accommodative Mechanism

The accommodative mechanism of the human eye has long been the subject of debate, but in recent years this debate has largely been quelled by numerous recent studies aimed at understanding why the eye gradually loses the ability to accommodate with increasing age in the condition called presbyopia. Early investigators studied the avian eye because of its relatively large size and ready availability in an effort to understand how the human eye accommodates. However, ultimately it has become clear that the accommodative mechanism in the avian eye differs between bird species and does not share much in common with the accommodative mechanism of the human eye. The varied accommodative mechanisms in birds led astray many early investigations into the accommodative mechanism. The relative inaccessibility of the structures involved in accommodation in the human eye also slowed progress in this area. Because of the similarity in anatomy and function between the eye of Old World monkeys and humans, much of our current understanding of the accommodative mechanism comes from studies on rhesus and cynomolgus monkeys, which share essentially the same accommodative mechanism as humans. Thanks to these studies, a consensus is developing regarding how the human eye accommodates.

The accommodative increase in optical power of the eye occurs through an increase in curvature of the anterior and posterior lens surfaces. In a young eye, the lens is relatively soft and pliable and is readily able to undergo a change in shape. When an object is moved toward the eye, the image on the retina becomes blurred. As the brain perceives that the near object is not in focus, it initiates a change in focus of the eyes. This begins with an increase in the frequency of the firing of the action potentials from the neurons in the midbrain Edinger–Westphal nucleus. Action potentials propagate down the preganglionic, parasympathetic long ciliary nerves to neurons in the ciliary ganglion. Postganglionic axons from the ciliary ganglion enter the globe via the short ciliary nerves, which enter the globe around the optic nerve, to innervate the ciliary muscle. The ciliary muscle contracts and the inner apex of the ciliary muscle moves toward the lens equator (**Figure 3**). The inward movement of the ciliary muscle and pars plicata of the ciliary body results in a release in the resting tension of the zonular fibers at the lens equator. When this zonular tension is released, the elastic capsule surrounding the lens molds the lens into a more spherical form. This causes a decrease in equatorial diameter of the lens (**Figure 4**), an increase in axial lens thickness, an increase in curvature of the anterior and posterior lens surfaces (**Figure 5**), a forward movement of the anterior lens surface, and a posterior movement of its posterior surface (**Figure 6**). These accommodative changes are qualitatively and quantitatively similar in humans and rhesus monkeys. The accommodative change in thickness of the lens is due to an increase in thickness of the lens nucleus without change in thickness of the anterior or posterior cortex. The anterior lens surface moves toward the cornea by about 75% of the increase in lens thickness and the posterior lens surface moves posteriorly toward the retina by about 25% of the increase in lens thickness. It is primarily the increase in the curvature of the anterior and posterior lens surfaces that results in the increase in optical power of the eye. These changes in the shape of the lens are linearly correlated with the increase in optical power of the eye during accommodation (**Figure 6**).

When an accommodative effort ceases, the ciliary muscle relaxes. In the young eye, the elastic posterior ciliary muscle, the elastic posterior tendons of the ciliary muscle and, possibly, the posterior zonular fibers pull the ciliary muscle back toward its unaccommodated state. As the

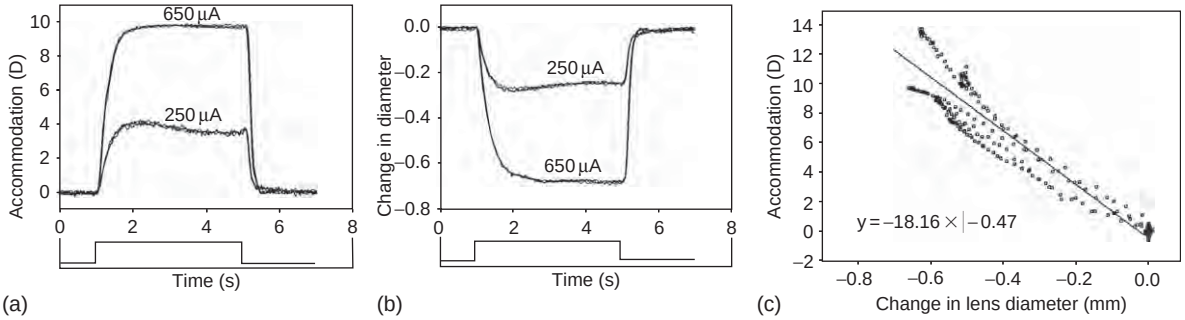

Figure 4 Graphs showing the decrease in lens diameter during centrally stimulated accommodation in iridectomized rhesus monkey eyes. (a) Accommodative refractive changes recorded dynamically with infrared photorefraction in response two different stimulus amplitudes (250 µA and 650 µA) delivered to the Edinger–Westphal nucleus of the brain. The lower graph represents the time course of the stimulus. Accommodative responses of about 4 D and 10 D, respectively, are produced. (b) Accommodative decreases in lens diameter recorded videographically, subsequent to the accommodative refractive changes, but using the same two different stimulus amplitudes. Decreases in lens diameter of about 250 and 650 µm, respectively, are produced. (c) Graph showing the correlation between accommodative refractive change and the accommodative decreases in lens diameter in the four eyes of two rhesus monkeys (with one experiment repeated in one eye). The data are from the accommodative phases only as seen in (a) and (b). Lens diameter decreases systematically with accommodation. Reproduced from Glasser, A., Wendt, M., and Ostrin, L. (2006). Accommodative changes in lens diameter in rhesus monkeys. *Investigative Ophthalmology and Visual Science* 47: 278–286, with permission from the Association for Research in Vision and Ophthalmology.

ciliary muscle is stretched posteriorly in the eye, the inner apex of the ciliary muscle and the ciliary body move outward at the lens equator. This causes an increase in tension on the zonular fibers at the lens equator, which pull the lens into its flattened, unaccommodated form via the elastic lens capsule. This results in a flattening of the anterior and posterior lens surface curvatures, a decrease in axial thickness of the lens and an increase in the equatorial diameter of the lens. The flattening of the lens results in a decrease in the optical power of the eye (**Figure 7**).

The most comprehensive, accurate, and widely known description of the mechanism of accommodation of the human eye was published by Helmholtz in 1855 (**Figure 8**). In actual fact, Antonie Cramer observed and published an earlier description of the changes in the curvature of the lens surface, quite possibly unbeknownst to Helmholtz. The accommodative mechanism, as is understood today, is often referred to as the Helmholtz accommodative mechanism. However, the mechanism originally described by Helmholtz was incomplete, due to limitations in early experimental methods. Subsequent investigators have added to the understanding of the accommodative mechanism. For example, although Helmholtz recognized that the lens undergoes an increase in thickness and a decrease in equatorial diameter during accommodation, he did not recognize how the lens changes its shape. Investigators prior to Helmholtz had suggested that the lens contained muscle fibers. In 1937, Fincham provided the first comprehensive description of the role of the capsule in accommodating the lens and, in 1979, Rohen offered a comprehensive description of the role of the zonular fibers. Only recently have studies identified limitations in

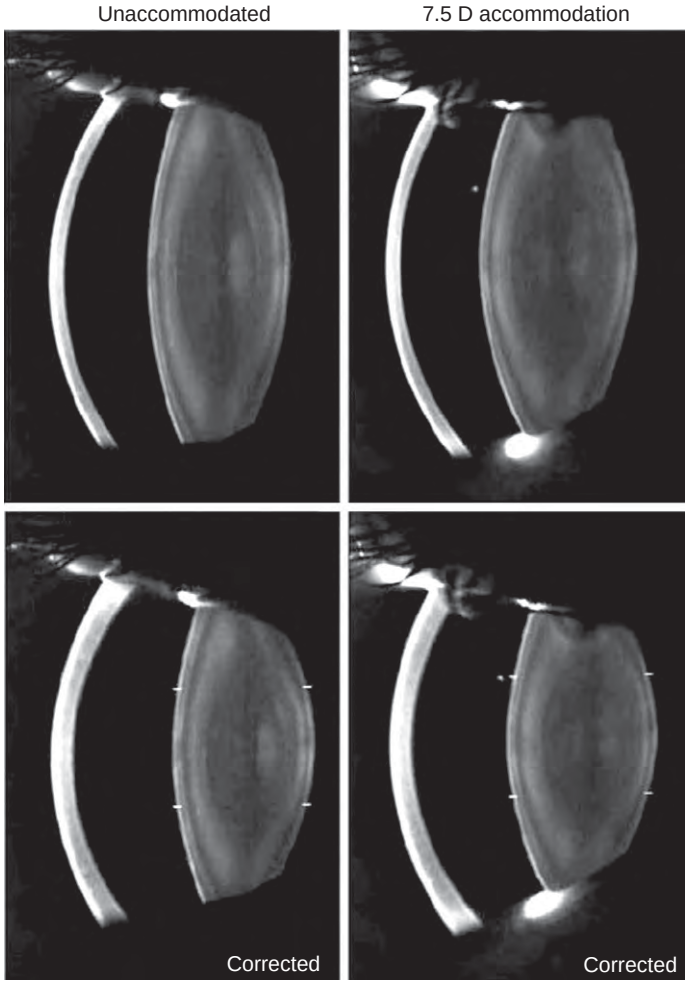

Figure 5 Scheimpflug images showing the accommodative change in the anterior chamber and lens from a 29-year-old human subject unaccommodated (left images) and accommodated to a 7.5-D accommodative stimulus (right images). The upper pair of images is uncorrected and the lower images have been corrected for the optical distortions through the preceding ocular media. As accommodation occurs, the lens surface curvatures become steeper, lens thickness increases, and anterior chamber decreases. Reproduced with permission from Dubbelman, M., van der Heijde, G. L., and Weeber, H. A. (2005). Change in shape of the aging human crystalline lens with accommodation. *Vision Research* 45: 117–132, with permission from Elsevier.

the mechanism described by Helmholtz. For example, Helmholtz and subsequent investigators believed that the posterior lens surface remains stationary during accommodation and undergoes little change in curvature. Recent studies however have documented a posterior movement of the posterior lens surface (see **Figure 6**) and an increase in curvature of the posterior lens surface during accommodation. Despite these modifications of the mechanism described by Helmholtz, the major tenets of the mechanism he described remain accurate and it is largely to his description that we owe our current understanding.

The Accommodative Triad

In a young individual, the effort to focus on a near object results in: (1) accommodation in both eyes, (2) constriction of the pupils, and (3) convergence of the eyes. These three events are together referred to as the accommodative triad. Accommodation, which is coupled in both eyes, increases the optical power of the eyes to allow focus on a near object. Convergence is required to achieve a single, fused image of the near object as viewed with both eyes. The pupil constriction increases the depth of field of the eye. As the pupil constricts, the cone of light converging toward the retina to form the image becomes narrower. A narrower cone of light means that there is a less perceptible change in focus of the image on the retina as the object is moved in object space. This represents an increased depth of focus of the eye and is closely related to the depth of field. The pupil constriction, therefore, further aids the actual accommodative optical change in power of the eye to allow near objects to be brought still closer to the eye without a perceptible change in focus. Convergence, pupil constriction, and

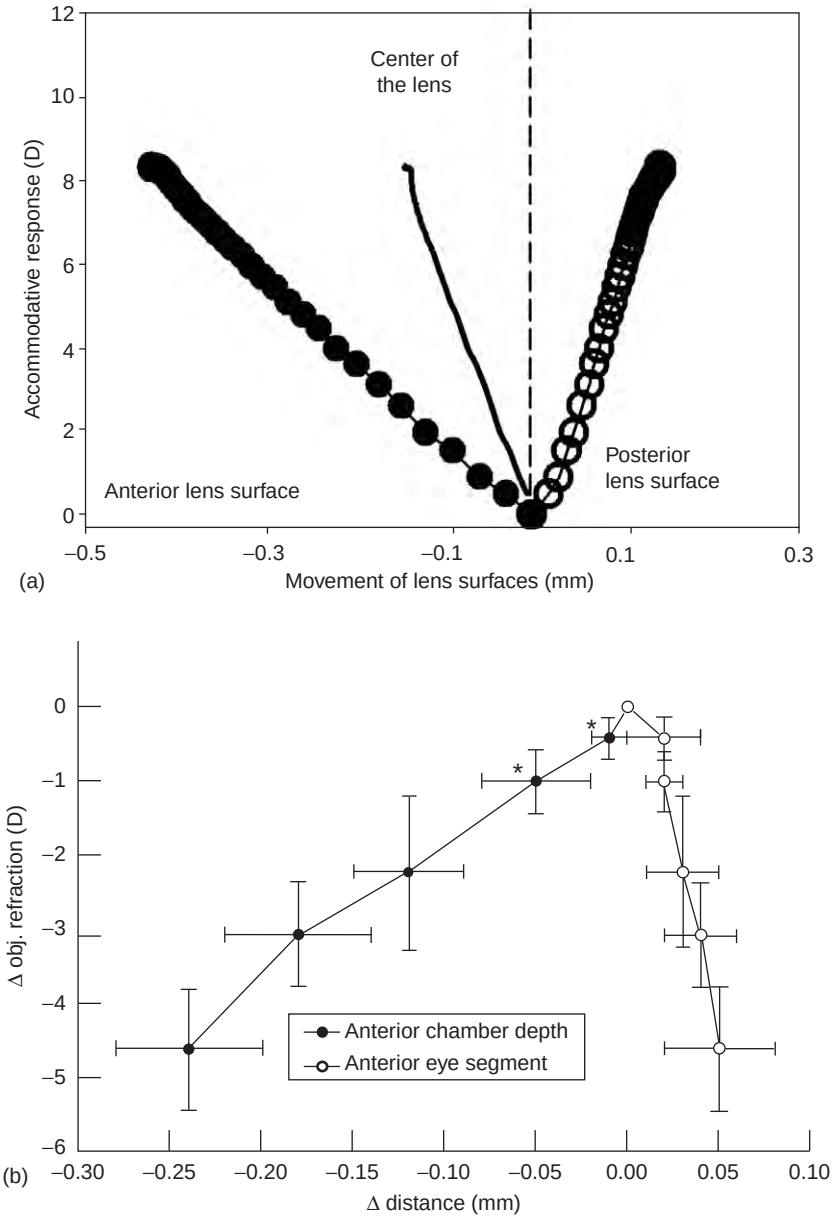

Figure 6 Axial accommodative biometric changes in the lens plotted as a function of the accommodative refractive changes in the eye in (a) an anesthetized rhesus monkey during Edinger–Westphal stimulated accommodation and (b) in 10 conscious human emmetropic subjects with a mean age of 23 years. Accommodation is represented as a positive number in (a) and as a negative number in (b). In both cases, the anterior lens surface moves toward the cornea (to the left in both graphs) and the posterior lens surface moves toward the retina (to the right in both graphs) relatively linearly with the accommodative refractive changes. The data from the monkey eye are both qualitatively and quantitatively similar to that from the human eyes. Reproduced from Vilupuru, A. S. and Glasser, A. (2005). The relationship between refractive and biometric changes during Edinger–Westphal stimulated accommodation in rhesus monkeys. *Experimental Eye Research* 80: 349–360, with permission from Elsevier and Bolz, M., Prinz, A., Drexler, W., and Findl, O. (2007). Linear relationship of refractive and biometric lenticular changes during accommodation in emmetropic and myopic eyes. *British Journal of Ophthalmology* 91: 360–365, with permission from BMJ Publishing Group Ltd.

accommodation are coupled in the brain. The act of initiating a convergence response to attain single binocular vision of a near object will also result in constriction of the pupils and accommodation. In the same way, accommodating to focus on a near object results in pupil constriction and a convergence response.

Changes in Optical Aberrations with Accommodation

The lens surfaces are aspheric and in conjunction with an aspheric cornea and the lens gradient refractive index; the eye is an imperfect optical system exhibiting optical

aberrations. Further, age-related changes in the lens and cornea result in age-related changes to the optical aberrations of the eye. The predominant aberration of the eye is spherical aberration. This is characterized by the light rays entering near the optical axis (paraxial rays) having a systematically different point of focus from the rays entering the eye at increasing distances from the optical axis. If the paraxial rays are focused to a point closer to the lens than the peripheral rays, this is called negative spherical aberration. The reverse situation, when the paraxial rays are focused further from the lens than the peripheral rays, is called positive spherical aberration. The young human lens has negative spherical aberration and with increasing age the spherical aberration becomes progressively more positive. After about 40 years of age, the human lens has predominantly positive spherical aberration. As the young eye accommodates, due to a combination of the changes in lens surface curvatures as well as a change in the form of the gradient refractive index of the lens, the lens and the eye undergo an increase in negative spherical aberration. This is due to a greater increase in optical power near the optical axis than toward the periphery of the lens. The pupil constriction that accompanies accommodation, in conjunction with the increase in negative spherical aberration of the eye, accentuates the overall increase in optical power of the eye by cutting off the more peripheral light rays that are focused further from the lens (**Figure 9**). Therefore, the pupil constriction is beneficial for increasing both the depth of field of the eye and in the overall optical power of the eye during accommodation.

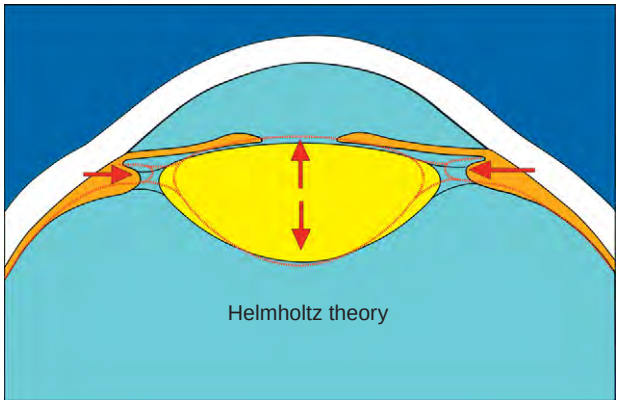

Figure 7 The accommodative changes in the ciliary body and the lens (red). The arrows depict the inward movement of the apex of the ciliary body (toward the axis of the eye) and the increase in lens thickness. Lens diameter decreases, the anterior lens surface moves anteriorly, the posterior lens surface moves posteriorly, and the anterior and posterior lens surface curvatures become steeper.

Other optical aberrations, such as astigmatism or coma, also aid in increasing the depth of field of the eye through degradation of the ocular image quality. In an eye with astigmatism or another optical aberration, the image formed on the retina is not ideal. For an eye with astigmatism, the image of a point object will appear as two orthogonal line foci separated by some distance (the interval of Sturm). The interval of Sturm is dependent on the magnitude of the astigmatism. As the object is moved in object space around the point of clearest vision in an unaccommodated eye with astigmatism, the image on the retina will transition gradually between one line foci and the orthogonal line foci. Therefore, although the appearance of the image on the retina will vary as the object is moved, there is no point of sharp image focus and hence no clear perception of a distinct change in image focus. As a consequence of the degraded image that is formed in an eye with astigmatism (or other optical

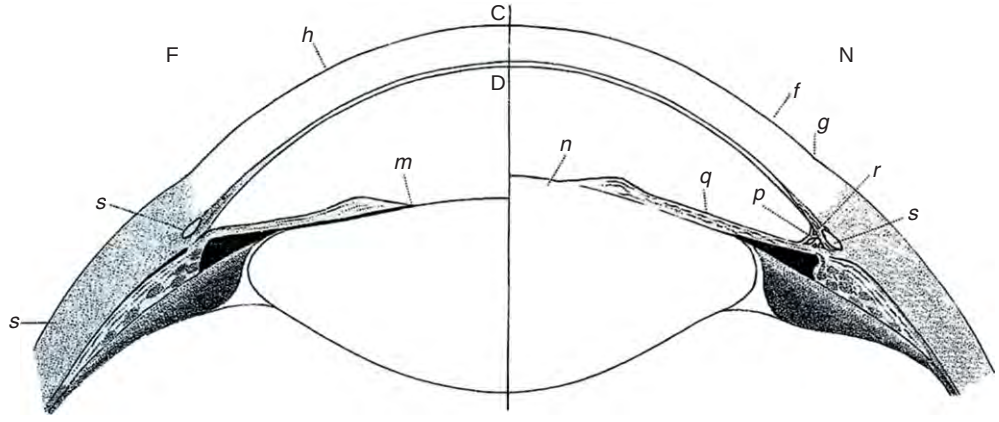

Figure 8 Helmholtz's diagram of the accommodative changes in the eye as he described it comparing the left unaccommodated side with the right accommodated side. Notice that there is no posterior movement of the posterior lens shown as is now known to occur. Reproduced from Helmholtz von, H. H. (1924). Mechanism of accommodation. In: Southall, J. P. C. (ed.) *Helmholtz's Treatise on Physiological Optics*, pp. 143–173. Baltimore, MD: The Optical Society of America. (Translated from the 3rd German edition, 1909.)

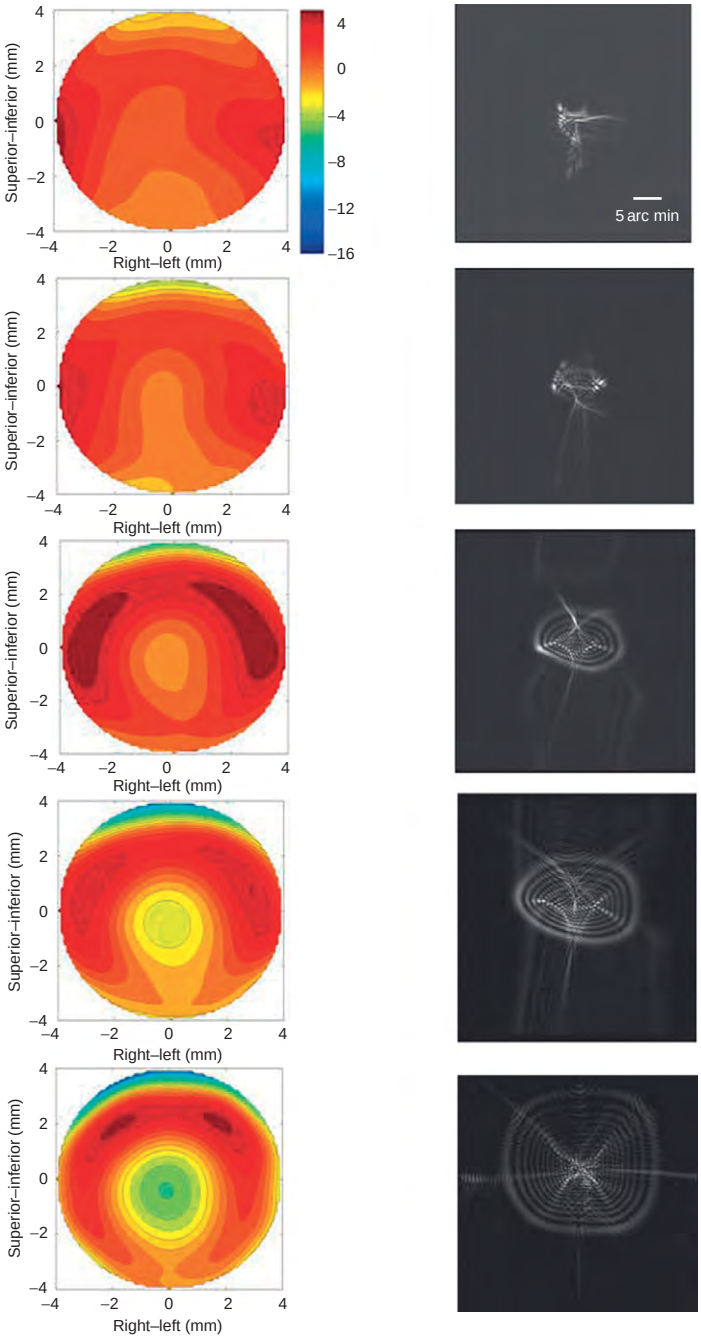

Figure 9 Measured wavefront maps with spherical defocus removed (left column) and calculated point spread function (PSF's) (right column) for 0 D, 1.41 D, 3.88 D, 5.93 D, and 10.91 D (top to bottom) of accommodation in the iridectomized of a rhesus monkey. There is a progressive increase in wavefront aberrations, especially near the center of the eye and a reduced image quality with accommodation. The false color scale is in microns and is the same for all wavefront maps. The predominant change in aberrations occurs in the central region with little change in the periphery which is normally obscured by the iris. The greatest change in optical power of the eye occurs at the center. Reproduced from Vilupuru, A. S., Roorda, A., and Glasser, A. (2004). Spatially variant changes in lens power during ocular accommodation in a rhesus monkey eye. *Journal of Vision* 4: 299–309, with permission from the Association for Research in Vision and Ophthalmology.

aberrations), the eye has an increased depth of field. Therefore, although the image quality is compromised by the optical aberrations, the object can be moved closer to the astigmatic eye without the subject reporting a perceptible change in image focus.

Measurement of Accommodation

Because of the many factors that affect the depth of field of the eye, such as ocular aberrations and small pupils, subjective measurement of near reading distance in a

distance-corrected eye, as is routinely performed clinically, is inappropriate for determining the true accommodative amplitude (the change in optical power of the eye during accommodation). Subjective push-up (or push-down) tests or subjective defocus tests, which rely on subjective blur cutoff criteria, inherently overestimate the true accommodative optical change in power of the eye, because they include the depth of field effects. The true accommodative optical change in power of the eye can only be measured with an objective optical instrument, such as autorefractors and wavefront aberrometers, which measures the refractive change in the eye with the effort to focus at near (**Figure 9**). To perform an objective measurement of accommodation, the refraction of the eye is first measured as the distance-corrected subject views a distant letter chart at 6 m. The subject is then presented with a near target at the closest near distance at which they can still maintain clear focus on the letters of a near letter chart and the refraction of the eye is again measured. The change in refraction between these two measurements represents the accommodative response amplitude. Subjective measurements of distance-corrected near reading distance overestimate the objectively measured accommodative amplitude by as much as 2–3 D in pre-presbyopic subjects (**Figure 10**). Subjective push-up tests suggest that accommodative amplitude is about 12–16 D at 10 years of age, which declines linearly to about 1 D by about age 55 years and remains at about 1 D thereafter. However, objective measurements in response to minus-lens-induced defocus show that there is an average of about 8 D of accommodative amplitude from age 5 to 25 years, which declines thereafter to essentially zero by age 55.

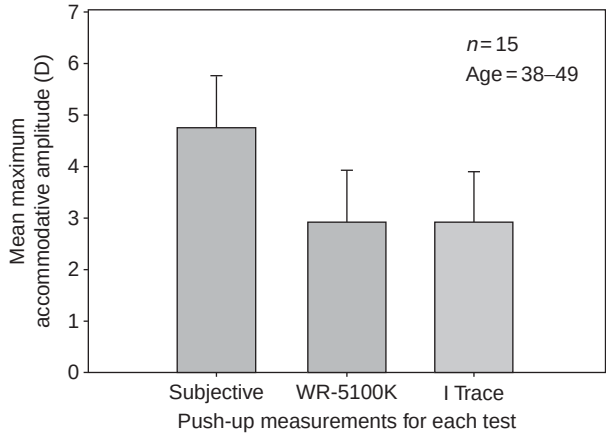

Figure 10 Comparison of the subjectively (subjective) and objectively (with a Grand-Seiko WR-5100K autorefractor or iTrace aberrometer) measured accommodative response amplitudes in pre-presbyopic subjects. Accommodation was stimulated with a real near-target progressively pushed-up toward the eyes. The subjective measurement of accommodation overestimates the objectively measured response amplitudes by between 1 and 3 D. Reproduced from Win-Hall, D. M. and Glasser, A. (2008). Objective accommodation measurements in prepresbyopic eyes using an autorefractor and an aberrometer. *Journal of Cataract and Refractive Surgery* 34: 774–784, with permission from Elsevier.

Stimulating Accommodation

Even when focused on a distant object, the young eye maintains a slight resting tonus of accommodation (sometimes referred to as the dark focus). This represents approximately 0.5–1 D of accommodation. Therefore, the normal resting refraction is slightly more myopic than the cycloplegic refraction, in which accommodation is completely paralyzed. The slight tonus of accommodation when focused for a distant object is called a lead of accommodation. To elicit an accommodative response, the eyes must be presented with an effective accommodative stimulus. This is best accomplished with a high-contrast stimulus that contains low-, mid-, and high-spatial-frequency visual cues. Letter charts or a Maltese cross represents visual targets often used to stimulate accommodation. There are several cues that can be effective for stimulating accommodation. Optical blur, proximity, and the requirement to converge to maintain single, binocular vision all offer cues that are important to facilitate an accommodative response. As a visual stimulus is moved progressively closer to the eyes, the target becomes blurred and this represents a cue to the eyes to start to elicit an accommodative response to attempt to maintain the target in clear focus. As the target is moved closer, the accommodative response falls behind the stimulus. This is called the lag of accommodation. As the target is moved toward the near point of the eyes, the eyes continue to accommodate within the amplitude of accommodation available. This is called the linear region of the accommodative stimulus/response curve. As the stimulus reaches the near point, the accommodative response reaches the maximum and asymptotes and the lag of accommodation becomes increasingly large as the stimulus is brought closer still. Since the eyes are no longer able to maintain clear focus on the stimulus, the accommodative response may begin to relax a little. To measure the maximum accommodative amplitude, the stimulus must be presented at the near point of the eyes and the refractive state of the eyes should then be measured objectively with an instrument such as an autorefractor or a wavefront aberrometer. The difference between this refraction measured when the eyes are focused on an object at the near point and the resting refraction when the eyes are focused on a distant target represents the objectively measured accommodative response amplitude.

Accommodative amplitude gradually declines with increasing age. This is the condition called presbyopia and ultimately results in a complete loss of accommodation.

Acuity

M D Crossland, UCL Institute of Ophthalmology/Moorfields Eye Hospital, London, UK

Glossary

Cycles per degree – The number of complete phases of a grating (e.g., the distance between the center of a white bar and the center of the next bright bar in a square-wave grating; or the distance between two adjacent areas of maximum brightness on a sine-wave grating) contained in 1° of visual angle.
Minimum angle of resolution – The size of the angle subtended at the eye of the smallest feature which can be reliably identified on an optotype.
Minute of arc – One-sixtieth of a degree.
Optotype – A letter, symbol, or other figure presented at a controlled size to measure vision.
Visual angle – The angle, which a viewed object subtends at the eye.

Detection and Resolution Acuity

Visual acuity can be defined in two broad ways. Detection acuity is measured by determining the size of the smallest object which can be reliably seen (is there a circle on the first or second screen?). Detection can be elicited reliably with targets, which subtend an angle at the eye as small as 1 s of arc (1/3600°). Even a small point of light will stimulate several photoreceptors due to the point-spread function of the eye: that is, the way in which light is diffracted through the eye's optics (**Figure 1(a)**).

Tests that require the identification of a target are a measurement of resolution acuity. These tests frequently involve identifying a letter or reporting an object's orientation (what direction is this letter C facing?). Acuity for these tests depends on the separation of the target features: if they are too close, the point-spread function from each element will overlap and they will not be identified (**Figure 1(b)**). The smallest separation of the elements required for identification of the target (**Figure 1(c)**) is known as the minimum angle of resolution (MAR). For an adult observer with good vision, a typical MAR for a centrally presented, high-contrast target can be as good as 30 s of arc (1/120°). **Figure 2** shows the feature critical for the MAR for some commonly used tests of visual acuity.

Measurement of Visual Acuity

Visual acuity tests have been used for millennia: the ancient Egyptians are reported to have used discrimination of the twin stars of Mizar and Alcor as a measurement of vision. The most familiar clinical test of visual acuity, the Snellen chart, was introduced in 1862, and is still widely used today.

Detection acuity is often measured psychophysically by means of a temporal two-alternative forced-choice experiment (did the light appear in the first or the second interval?). Detection acuity is rarely measured clinically.

In psychophysical experiments of the visual system, resolution acuity is commonly measured by asking observers to report the orientation of a grating with variable separation between each dark and light bar (**Figure 2(b)**). In clinical practice, gratings are rarely used, with the exception of forced-choice preferential looking tests in preverbal children. These tests consist of a uniform gray field with an isoluminant grating toward one side of the chart (**Figure 3(a)**). In a featureless room, the test is presented to the child and the clinician observes whether the child looks toward the grating. The finest grating toward which the child repeatedly looks is recorded as the visual acuity.

For cooperative patients, optotypes are more often used to measure clinical resolution acuity. The Landolt C (**Figure 2(c)**) is the standard to which letter visual acuity tests are compared. This target consists of a ring of fixed width with a gap, of height equal to the stroke width, at the top, left, right, or bottom of the circle. The observer is asked to report the position of this gap. The smallest gap whose position can be reliably reported is equivalent to the MAR.

The National Academy of Sciences standard for visual acuity measurement advocates the presentation of 10 optotypes, of equivalent difficulty to the Landolt C, at each acuity size. The horizontal spacing between each optotype should be at least one character width, and vertical spacing between lines should be 1–2 times the height of the larger optotypes. It suggests that the number of characters on each line should be equal, and that the size difference between consecutive lines is 0.1 log units: in other words, for each target size, the next line should be approximately 1.26 times smaller.

The Snellen chart (**Figure 3(b)**) does not meet these recommendations: the number of letters per line and step

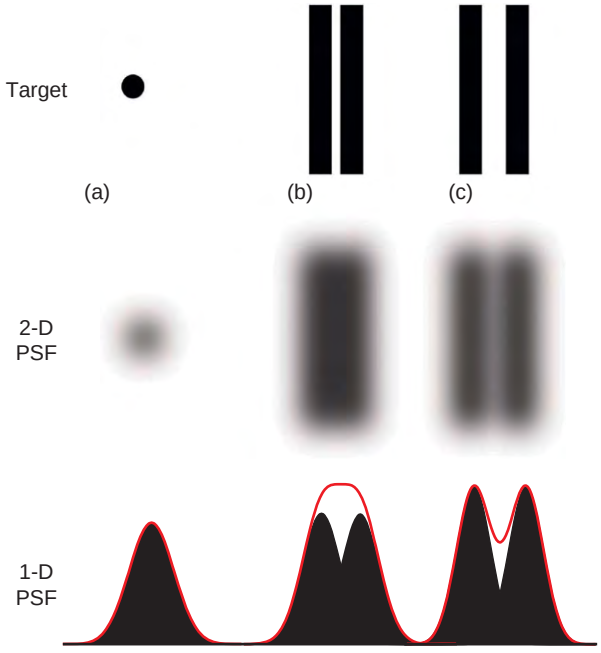

Figure 1 Schematic illustration of the point-spread function of three visual targets: (a) a point target; (b) two adjacent lines, too close to be resolved; and (c) two adjacent lines, with sufficient separation to be resolved. Middle row: two-dimensional representation of the target point-spread function; bottom row: one-dimensional representation of the point-spread function; and red line indicates the sum of energy incident on the retina. PSF, point-spread function.

size between the lines are variable, as is the horizontal and vertical spacing on the chart. There is also a marked difference in the legibility of different letters on the Snellen chart: a W, for example, has far less separation

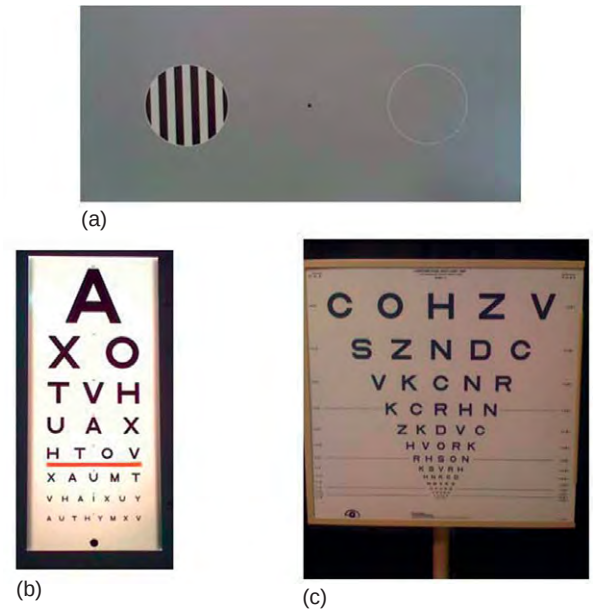

Figure 3 (a) A forced-choice preferential looking test consisting of a grating against an isoluminant background. Note the peephole in the center for the clinician to observe the child's visual behavior; (b) the Snellen chart; and (c) The ETDRS chart. ETDRS, Early treatment of diabetic retinopathy study.

between the elements of the letter and is more difficult to identify than a letter L. In the 1950s, Sloan suggested the use of 10 letters with a selection of vertical, horizontal, oblique, and round strokes which are each about as legible as a Landolt C. These Sloan letters are C, D, H, K, N, O, R, S, V, and Z. Each of the Sloan letters has a stroke width of the MAR and has a total height and width of five times the MAR.

The Bailey–Lovie chart, introduced before the recommendations of the National Academy of Sciences, conforms to most of these requirements, although it only has five letters per line. Further, the letters on the Bailey–Lovie chart are taller than they are wide: their height-to-width ratio is 5:4 and they are selected from the British Standards set of letters (D, E, F, H, N, P, U, V, R, and Z). The ETDRS chart (**Figure 3(c)**), developed for the early treatment of diabetic retinopathy study (ETDRS), is similar in design but does use the recommended 5×5 Sloan letters.

A criterion of 7/10 letters being read correctly for a line to be marked as seen was suggested by the National Academy of Sciences. This threshold reduces the chance of the line being scored correctly by chance (by a blind observer) to around 1 in 9 000 000. On a chart with five letters per line, recording a visual acuity where four of the five letters are read correctly equates to a chance success rate of 1 in 46 000. There is a theoretical advantage if the observer knows there are only 10 letters which can be presented on the chart: if an observer guesses from all 26 letters rather than the ten Sloan letters, the probability of the observer getting four out of five letters correct reduces to about 1 in 100 000.

Test–retest variability of the Snellen chart is around ±0.3 logMAR, while the ETDRS chart has far better repeatability (test–retest variability ~0.1–0.2 logMAR). Despite the many limitations of the Snellen chart, it is still widely used in clinical practice. While this is likely to be largely due to clinicians' familiarity with the Snellen chart, there is also a perception that Snellen acuity measurement is quicker than that on the Bailey–Lovie or ETDRS charts.

Various modified versions of the ETDRS chart exist: for example, a version with an altered letter set (A, B, E, H, N, O, P, T, X, and Y) has been developed for use by readers of most European languages, including those based on Cyrillic or Hellenic alphabets.

For observers unable to report letters on a sight chart, other frequently used optotypes include the tumbling E chart (formerly and less politically correctly known as the illiterate E chart), where a letter E is shown in each of four rotations; the HOTV chart, where only these four letters are used; symbols such as the Lea or Kay pictures; and simple shapes, such as the Cardiff card.

Reporting Visual Acuity

Clinicians have traditionally used Snellen fractions to record visual acuity, where the numerator is the test distance and the denominator the target size. The target size is expressed, counterintuitively, as the distance from which the target has an MAR of 1 min of arc. Therefore, a visual acuity of 6/6 indicates that from 6 m, letters with MAR 1-min arc are correctly identified, while a visual acuity of 3/36 indicates that from 3 m, the targets identified have a MAR of 1 min of arc when viewed from 36 m. The reciprocal of the Snellen fraction gives the visual acuity in MAR: so a visual acuity of 3/36 indicates a MAR of 12 min of arc.

In much of Europe, the Snellen fraction is reduced into a decimal fraction.

A further confusion with the Snellen system is that in countries not using the metric system, distances are expressed in feet rather than meters, with 20/20 being exactly equivalent to 6/6 but with a test distance of 20 ft rather than 6 m. Although Snellen recommended adoption of the metric system in 1875 and, in 1980, the US National Academy of Sciences favored adoption of a standard defined in meters, given the imminent adoption of the metric system, the feet system is still widely used in the USA, and among lay people in the UK.

The accepted standard for expressing visual acuity in clinical research, and increasingly in clinical practice, is to use the base 10 logarithm of the MAR (logMAR), such that 0.0 logMAR is equivalent to 6/6 or 20/20, and 1.0 logMAR is the same as 6/60 or 20/200. Table 1 gives approximately equivalent values in MAR, cycles per degree, Snellen fractions in meters and feet, decimal acuity, and logMAR for a range of visual acuities.

Optical and Neural Limits on Visual Acuity

Visual acuity is limited by many factors: the optics and refraction of the eye; the clarity of the optical media; the spacing and function of the retinal photoreceptors; the ratio of retinal ganglion cells to photoreceptors; and the resolution of the primary visual cortex and higher areas of visual processing.

Each diopter of myopia reduces visual acuity: a −1.00DS myope will typically have uncorrected visual acuity of around 0.5 logMAR (6/18; 20/60) and a two-diopter myope will have vision of around 0.8 logMAR on a distance test. Hypermetropia can often be relieved by accommodation in young people, but each diopter of hypermetropia

Table 1 Visual acuity conversion table[a]

MAR (min)	*Cycles/ degree*	*Snellen (metric)*	*Snellen (feet)*	*Decimal*	*Log MAR*
60	0.5	1/60	20/1200	0.017	1.8
20	1.5	3/60	20/400	0.05	1.3
10	3	6/60	20/200	0.1	1
6.3	4.7	6/36	20/120	0.17	0.8
4	7.5	6/24	20/80	0.25	0.6
3.2	9.4	6/18	20/60	0.33	0.5
2	15	6/12	20/40	0.5	0.3
1.6	18.8	6/9	20/30	0.67	0.2
1.3	23	6/7.5	20/25	0.8	0.1
1	30	6/6	20/20	1	0
0.83	36	6/5	20/17[b]	1.2	−0.1
0.67	44	6/4	20/13[b]	1.5	−0.2
0.5	60	6/3	20/10	2	−0.3
0.33	91	6/2	20/7	3	−0.4

[a]Each row contains approximately equivalent values of visual acuity. Log MAR values have been rounded to 1 decimal place.
[b]On US Snellen charts, these lines are 20/16 and 20/12 respectively.

beyond the accommodative ability of the eye will reduce visual acuity by a similar amount to an equivalent degree of myopia. Astigmatism, particularly where the meridia of astigmatism are oblique, will also reduce uncorrected vision significantly.

Other aberrations of the eye beyond defocus and astigmatism further limit visual acuity. Retinal image quality can be improved by viewing monochromatic stimuli (to reduce chromatic aberration) and by using a deformable mirror to correct coma, trefoil, and other higher-order aberrations of the eye. Under these ideal conditions, Williams and colleagues have shown that subjects are able to resolve gratings of up to 55 cycles per degree, equivalent to a visual acuity of approximately –0.30 logMAR (6/3; 20/10).

Assuming that an image is perfectly focused on the retina, the next limit on visual resolution is the spacing of the retinal photoreceptors. In order to detect a grating, alternate black and white bars must fall on adjacent photoreceptors. This theoretical limit of vision, known as the Nyquist limit, is equivalent to a grating with light to dark separation of $1/\sqrt{D}$, where D is the center-to-center separation of two photoreceptors. In the fovea, D is approximately 3 µm, equivalent to a visual angle of approximately 55 cycles per degree – almost identical to the value found by Williams. This confirms that in people with good vision, all of the limits on visual acuity are precortical. Amblyopia, where vision is reduced despite the absence of any eye disease, is dealt with elsewhere in the encyclopedia.

Visual Acuity across the Retina

Nonfoveal vision is limited by many elements. First, the eye's optics are not optimized for viewing off the visual axis, and peripheral vision is subject to greater aberration than central vision. Second, the size of photoreceptors increases and their density falls with increasing eccentricity. The number of photoreceptors per retinal ganglion cell also increases, from less than one photoreceptor per ganglion cell in the fovea to more than 20 photoreceptors per ganglion cell in the far periphery. The volume of visual cortex devoted to noncentral retina is also proportionally lower. It is unsurprising, therefore, that visual acuity falls quickly with increasing distance from the fovea (**Figure 4**). This is one reason for the severely reduced visual acuity of people with central vision loss from diseases such as age-related macular disease.

Visual Acuity over Life

Over the first year of life, visual acuity assessed by a preferential looking test appears to be reasonably stable

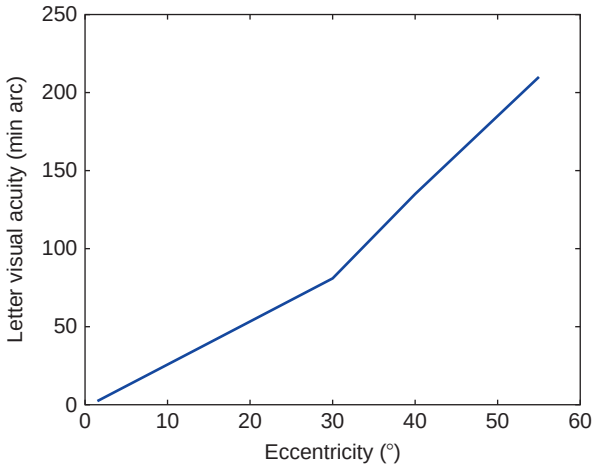

Figure 4 Letter visual acuity measured in peripheral vision as a function of degrees of eccentricity. Data from Anstis, S. M. (1974). Letter: A chart demonstrating variations in acuity with retinal position. *Vision Research* 14(7): 589–592.

at around 6 min of arc. Between a child's first and third birthday, visual acuity improves exponentially to reach 1 min of arc. A further small improvement in resolution ability to approximately 0.75 min of arc is achieved by age 5 years. In the absence of eye disease, this value remains relatively constant until the sixth decade. In a population-based study of nearly 5000 older adults, Klein found a decrease in visual acuity to a mean value of approximately 2 min of arc in those aged over 75 years. Of course, this reflects the age-related nature of many diseases which affect visual acuity, such as cataract, glaucoma, diabetic retinopathy, and age-related macular degeneration. **Figure 5** plots data from the studies of Mayer and Klein.

Visual Standards

In most countries, there is a visual-acuity requirement for car drivers. While the level and measurement technique varies between countries, the acuity limit is usually approximately 0.3 logMAR. Commercial airline pilots are required to have a binocular visual acuity of 0.0 logMAR.

Best corrected binocular visual acuity of 1.0 logMAR or poorer is used as a definition of low vision or partial sight in many countries, with acuity of worse than 1.3 logMAR being described as severe sight impairment.

Hyperacuity

Some visual tasks can be performed with a far greater degree of precision than would be suggested by the MAR. Alignment tasks such as Vernier discrimination (where the offset of one line with respect to another is detected, **Figure 6(a)**) can be performed with misalignment of less

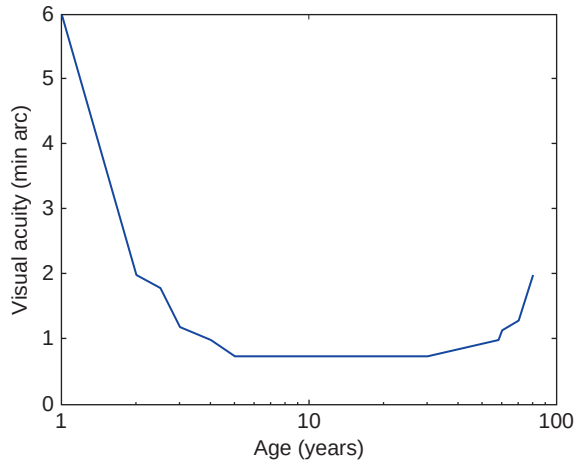

Figure 5 Variation in visual acuity over life. From Mayer, D. L. and Dobson, V. (1982). Visual acuity development in infants and young children, as assessed by operant preferential looking. Data from *Vision Research* 22(9): 1141–1151 and Klein, R., Klein, B. E., Linton, K. L., and De Mets, D. L. (1991). The beaver dam eye study: Visual acuity. *Ophthalmology* 98(8): 1310–1315.

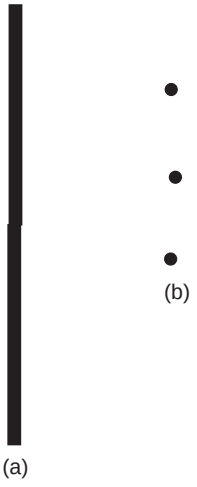

Figure 6 Examples of hyperacuity tasks. Misalignment of the lower element is easily visible. (a) Vernier alignment; (b) dot alignment: the offset of the middle dot with respect to the upper and lower dot is easily discerned.

than 5 s of arc – considerably less than the center-to-center spacing of a foveal photoreceptor. This is thought to be due to interpolation of the inputs of two or more adjacent neural elements.

Dynamic Visual Acuity

Throughout this article, visual acuity has been discussed for static targets. If the target is moved, central visual acuity decreases: the faster the target moves, the larger it must be for it to be seen. If a target moves with velocity of $40^\circ\ s^{-1}$, the MAR is increased to about 2 min of arc, while at $80^\circ\ s^{-1}$, acuity is about 3 min of arc.

In peripheral vision, slow image motion (less than $10^\circ\ s^{-1}$) slightly improves visual acuity for peripherally presented targets, perhaps because it breaks the phenomenon of Troxler fading.

Target motion at the retina can be induced by target movement, by eye motion, or by head motion. Many eye diseases, particularly those of the macula, are associated with poor fixation stability of the eye. This poor eye stability increases retinal image motion, and is significantly associated with poorer visual function. Small degrees of head motion do not significantly decrease visual acuity under normal conditions, but have a marked deleterious effect for subjects viewing through telescopic spectacles. Therefore, subjects with macular disease who have poor fixation stability and who view through telescopic low-vision aids have a marked impairment in their dynamic visual acuity.

Adaptive Immune System and the Eye: Mucosal Immunity

A K Mircheff, University of Southern California, Los Angeles, CA, USA

Glossary

CD80 and CD86 – B7 costimulatory ligands expressed by antigen presenting cells. They interact with coreceptors CD28 and CTLA4 on T cells and are necessary, but not sufficient for T-cell activation.

MHC class II (major histocompatibility complex class II molecules) – These molecules typically acquire autoantigen epitopes in endosomes and antigen processing compartments of antigen presenting cells and present them to antigen receptors of $CD4^+$ T cells.

TGF-β – Pleiotropic cytokine. One critical function in the mucosal immune system is to favor IgM-to-IgA isotype class switching; another is to promote differentiation of immature dendritic cells as regulatory antigen presenting cells. It may be mitogenic, antiproliferative, or pro-apoptotic, depending on target cell or synergistic interactions with other cytokines and growth factors.

The visual system interfaces with the external world at the epithelium of the corneal surface. The corneal epithelium is part of the convoluted yet topologically continuous surface that separates the body's *milieu intérieur* from the external world. Beyond the limbal and conjunctival epithelia, it ranges in one direction through the lacrimal excretory ducts and network of ducts to the acini of the lacrimal gland. In the other direction it ranges through the lacrimal drainage system to the oral and pharyngeal mucosae; through ducts to the acini of the salivary glands, through the airways to the alveoli of the lungs; through the mucosae of the esophagus, stomach, intestine, and colon; through ducts to the acini of the pancreas; and through ducts to the canaliculi of the liver. These moist tissues are linked topologically, via the epidermis, with the mucosal and glandular epithelia of the urinary tract, the reproductive tracts, and the mammary glands. They also are linked functionally, via the traffic of immune cells through the lymph vessels, secondary lymphoid organs, and vasculature, to comprise a physiological system, the mucosal immune system.

The metabolically active epithelial cells that comprise these surfaces perform diverse functions related to their roles in the visual, respiratory, gastrointestinal, liver, renal, and reproductive systems. However, they express several common functions. They either produce immense volumes of fluid, for example, saliva, gastric juice, bile, pancreatic juice, and occasionally diarrhea, or produce thin, largely aqueous, but physically and chemically complex, films as homeostatic *milieus extérieurs* for themselves. They also execute innate immune functions, and, at specialized inductive and effector sites, adaptive immune functions, which protect them, their underlying stromas, and the rest of the body from particulate irritants, noxious chemicals, and infectious microbes. The central principle of the adaptive immune strategy is to use noncomplement-fixing immunoglobulins (i.e., dimeric IgA and IgG1) to prevent infection while avoiding inflammatory processes that would damage host tissues and compromise their functions. As improved sanitary systems, antibiotics, and vaccines decrease morbidity and mortality due to infection, dysfunctions of mucosal immune system tissues that result in chronic inflammatory processes join other chronic inflammatory diseases among the main categories of afflictions that burden aging populations. The chronic inflammatory mucosal immune disorders of the visual system are subsumed under the prosaic rubric, dry eye disease. Other names have been suggested, including dysfunctional tear syndrome and lacrimal keratoconjunctivitis, or, as this author would prefer, dacryokeratoconjunctivitis.

Much of the current understanding of normal mucosal immune system physiology has come from studies of the gastrointestinal and respiratory systems. The gastrointestinal system must not only prevent infection by pathogens but it must also tolerate, and to a large extent, actively host, a rich flora of commensal microbes, which benefit the organism by processing or producing nutrients that would otherwise remain inaccessible or unavailable. When the mucosal immune barrier against infection fails, conventional innate and adaptive inflammatory mechanisms mount robust responses to rescue the host organism, but these responses typically induce diarrheal fluid loss, ulcerative damage to the mucosal and stromal tissues, and malabsorption of nutrients and electrolytes. The complex relationship the mucosal immune system maintains with its microbiota is paralleled by a nuanced relationship with the foods that the gastrointestinal system processes. Nutrient carbohydrates and proteins typically are digested to monosaccharides and amino acids before being absorbed across the intestinal epithelia. Nevertheless, antigen presenting cells continuously surveille the luminal contents, and both micropinocytosis and receptor-mediated transcytosis may transfer intact nutrient macromolecules across the epithelium. Clearly, it is in the organism's interest to avoid inflammatory responses against them.

While a smaller mass and less rich diversity of commensal and infectious microbial flora challenge the ocular surface tissues, the imperative to avoid inflammatory responses while preventing infection is no less urgent than it is in the gastrointestinal system. The executive decisions largely are made by antigen presenting cells, but these decisions are based on information conveyed by paracrine mediators that are produced by parenchymal cells and mesenchymal cells, as well as by neurotransmitters and neuropeptides.

Organized Inductive Sites

New generations of mucosal antigen presenting cells, T cells, and B cells are introduced to microbes and soluble molecules in organized signaling milieus that amplify B cells with high-affinity IgM and induce them to undergo somatic hypermutation and immunoglobulin isotype class switching while continuing to retain expression of the J chain. Some authors refer to the organized inductive sites generically as mucosa-associated lymphoid tissues (MALTs) and specifically as conjunctiva-associated lymphoid tissue (CALT), eye-associated lymphoid tissue (EALT), tonsils, adenoids, bronchus-associated lymphoid tissue (BALT), and Peyer's patches and gut-associated lymphoid tissue (GALT). Other authors include both the organized inductive sites and the less organized effector sites together as MALT.

Figure 1 illustrates stereotypical features of mucosal inductive site organization. The epithelial sheet that overlays an inductive site contains specialized cells with distinctive basal convolutions enfolding superficial dendritic cells. These so-called M cells phagocytose microbes and engulf soluble molecules at their apical surfaces, transcytose them to their basal surfaces, and release them to the underlying space. Dendritic cells in the immediate subepithelial areas again engulf the transcytosed microbes and soluble molecules, which then traffic to acidic endosomal compartments containing major histocompatibility complex class II (MHC class II) molecules and hydrolytic enzymes. Peptides that are exposed in superficial domains of the proteins being degraded have the greatest likelihood of entering the binding grooves of MHC class II molecules. Peptides that remain outside the binding grooves are exposed to further degradation. Peptide sequences that are protected from proteolysis become the dominant epitopes that the MHC class II molecules will present to $CD4^+$ T cells upon trafficking to the dendritic cells' surface membranes.

Whether or not a dendritic cell redistributes MHC class II molecules to its surface, upregulates expression of B7 costimulatory molecules, and migrates the short distance to the $CD4^+$ T-cell-rich zone may depend on signals received early in the encounter with the material it has internalized. The best understood of these signals are conveyed by lipopolysaccharides and double-stranded DNAs, which activate toll-like receptors (TLRs). The TLR activation induces a dendritic cell to downregulate chemokine receptors and homing receptors that favor retention in the subepithelial zone and to upregulate receptors that favor migration to the T-cell-rich zone. Typically, TLR activation also induces dendritic cells to upregulate surface expression of the costimulatory B7 ligands, CD80 and CD86, as they redistribute MHC class II molecule–epitope complexes to their surface membranes.

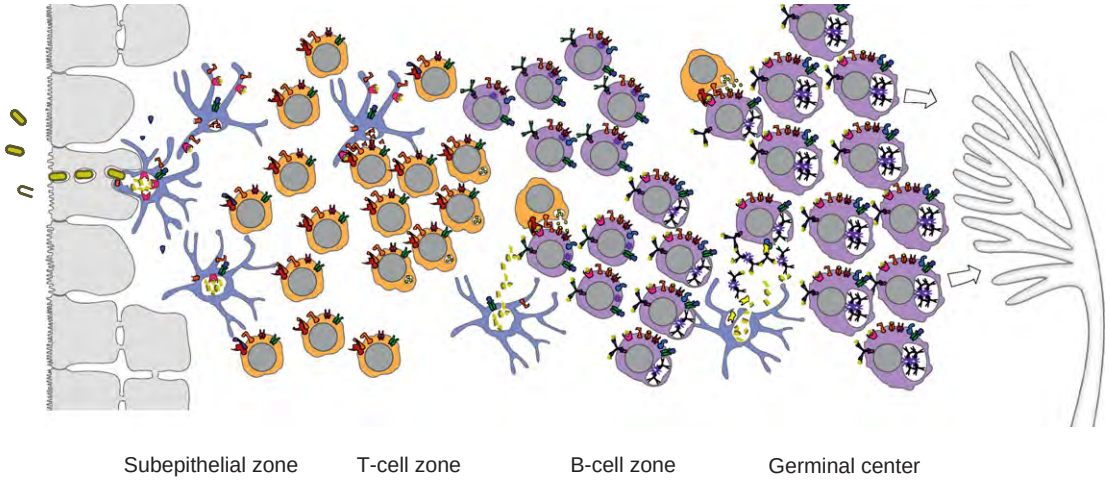

Figure 1 Stereotypical organization of mucosal immune inductive sites. After having taken up microbes or antigens transcytosed by M cells, dendritic cells may traffic directly to the B-cell zone, or they may migrate to the T-cell zone, where they activate antigen-specific $CD4^+$ cells to express T_H2 cytokines. B cells with antigen receptors of sufficient avidity internalize antigen, then use MHC class II molecules to present epitopes to activated T_H2 cells. Ongoing T_H2 activation promotes B-cell division and Ig hypermutation. In this signaling milieu, TGF-β induces IgM-to-IgA isotype class switching. In combination with B-cell growth factors, TGF-β in germinal centers promotes plasmablast proliferation and emigration via afferent lymph vessels.

While signals from engulfed microbes are decisive in determining whether the dendritic cell will undergo complete functional maturation and activation, the activated phenotype that the dendritic cell will assume is determined largely by paracrine mediators that are released by the overlaying epithelium and surrounding mesenchymal cells. The signaling mediators that are known to be predominant are transforming growth factor-beta (TGF-β) and interleukin (IL)-10, and they induce maturing dendritic cells to also express TGF-β and IL-10. An additional population of dendritic cells are distinguished by the absence of MHC class II molecule expression and expression of chemokine and homing signal receptors that lead them to bypass the T-cell-rich regions and enter B-cell-rich zones, where there they will release the material they had internalized.

Engagement of a naive $CD4^+$ T cell's antigen receptors by MHC class II molecule–epitope complexes generates the primary signal necessary, but not sufficient, for activation. Simultaneous engagement of CTLA-4 or CD28 at the T-cell surface by CD80 or CD86 at the dendritic cell surface provides the second signal essential for promoting T-cell activation and differentiation. However, the functional phenotype the activated $CD4^+$ T-cell expresses is determined by paracrine mediators in the immediate signaling milieu. These are secreted by dendritic cells, epithelial cells, and mesenchymal cells. They induce $CD4^+$ T cells to differentiate as T_H2 cells and to change their panel of chemokine receptors and homing receptors to favor migration from the T-cell-rich zones and into the B-cell-rich zone.

When molecules that dendritic cells have released encounter B cells with surface IgM antigen receptors that bind them with high enough affinity, they deliver a primary activation signal, which induces the B cell to endocytose the IgM–antigen complex to antigen-processing compartments and to begin expressing MHC class II molecules. Thus, $CD4^+$ T cells arriving from the interfollicular zone will be presented with dominant epitopes that maintain them in their activated state. They continue secreting the T_H2 cytokines needed to induce somatic hypermutation of B-cell immunoglobulin genes and promote selection of B-cell clones with increasing affinity for the determinant. The signaling milieus within some of the organized inductive sites, notably Peyer's patches, selectively induce IgM-to-IgA class switch recombination. The milieus in the inductive sites in the tonsils, adenoids, and airways may induce either IgM-to-IgA or IgM-to-IgG1 class switch recombination. In cases of IgA deficiency, the numbers of $IgG1^+$ cells and IgM cells may increase in compensation. Whether induced to express IgA or IgM, the activated B cells continue to express J chain. The IgA^+ B cells will express dimeric IgA (dIgA), while IgG1 B cells will express apparently irrelevant J chain.

The activated B-cell blasts amplify in germinal centers, and they alter their panel of chemokine receptors and homing receptors, so that they are induced to leave the inductive sites via lymph vessels, enter the circulation via the thoracic duct, and enter the mucosal immune effector sites. The IgA^+ B cells expressing CCR10, the receptor for CCL28, traffic to the lamina propria of the oral cavity, lower airways, and colon. The IgA^+ B cells expressing CCR9, the receptor for CCL25, traffic to the trachea, stomach, intestine, salivary glands, and mammary gland. The $IgG1^+$ B cells expressing CXCR4, the receptor for CXCL12, traffic to the bone marrow. In each setting, the plasmablasts will take residence and mature to become long-lived memory cells or plasmacytes.

Effector Sites

Specialized Niches

Stereotypical features of the mucosal immune effector site are illustrated in the upper panel of **Figure 2**. Like IgG^+ plasmablasts entering the bone marrow, the $dIgA^+$ plasmablasts that arrive in the mucosal effector sites receive signals that induce them to mature into plasmacytes. One of the critical mediators of maturation signaling at the mucosal effector sites is TGF-β. A mature plasmacyte's ongoing survival depends on the constant presence of additional signals to suppress the intrinsic apoptotic program. The candidate mediators of the survival signals include IL-6, B-cell activating factor (BAFF), a proliferation-inducing ligand (APRIL), and, perhaps, prolactin. In the rabbit lacrimal gland, which has been studied in some detail, epithelial expression of paracrine mediators is compartmentalized according to the epithelial histoarchitectural plan and vascular organization. Venules, the vascular elements that plasmablasts cross to enter the stromal space, tend to follow courses that parallel interlobular ducts. Epithelial cells of the interlobular ducts express TGF-β and prolactin at much higher levels than epithelial cells in the acini, and it appears they secrete these mediators both apically (i.e., into the fluid forming within the duct lumen) by way of their regulated exocrine secretory apparatus for proteins, and also basally, through either a constitutive paracrine secretory apparatus or a parallel paracrine apparatus that can be induced under certain circumstances. While TGF-β, as noted, induces $dIgA^+$ plasmablast-to-plasmacyte differentiation, it may not be conducive to the plasmacytes' ongoing survival. It appears that TGF-β signaling may be concentrated in the stromal spaces surrounding the venules and interlobular ducts. Preliminary findings in the author's laboratory suggest that transcripts for the extracellular matrix proteoglycan, decorin, are two orders of magnitude more abundant than TGF-β transcripts in lacrimal gland epithelial cells. Because decorin binds to the extracellular matrix and also binds the latent TGF-β, it may create a diffusion barrier that keeps latent TGF-β

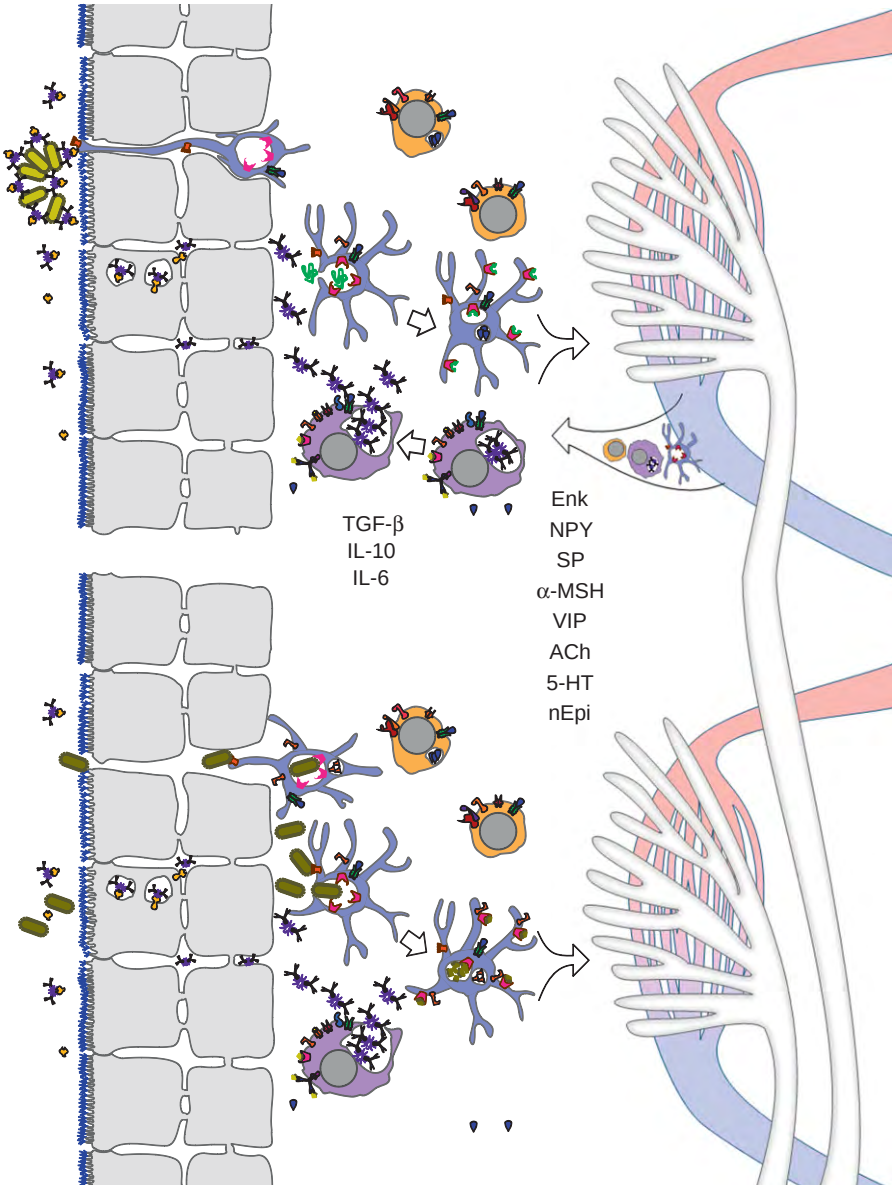

Figure 2 Normal (upper panel) and infected (lower panel) mucosal immune effector sites. IgA^+ J $chain^+$ plasmablasts, immature dendritic cells, and T cells enter the lamina propria of the conjunctiva and drainage system, stromal space of the lacrimal gland, and other effector sites from venules. Paracrine mediators induce plasmablasts to undergo terminal differentiation, then support their survival as plasmacytes. Of these mediators, TGF-β, IL-10, and IL-6 are provided, at least in part, by epithelial and stromal cells. Sensory, parasympathetic, and sympathetic nerve endings provide neurotransmitters and neuropeptides that may also influence plasmablasts, plasmacytes, dendritic cells, and lymphocytes. The normal signaling milieu induces dendritic cells that have taken up soluble proteins and cellular debris to mature as regulatory antigen presenting cells, which exit via afferent lymph vessels and induce regulatory T cells in the lymph nodes. The TLR activation by microbes that have evaded the immunospecific sIgA barrier induces dendritic cells to mature as immunoactivating antigen presenting cells that will elicit IgG responses in the lymph nodes.

concentrated in the periductal stroma. In contrast, prolactin may be free to equilibrate through the interstitial fluid, diffusing to plasmablasts throughout the gland's stromal spaces. Preliminary studies suggest that acinar epithelial cells may be able to express IL-6. In contrast, mRNAs for APRIL and BAFF appear substantially more abundant in whole gland extracts than in *ex vivo* acinar cells. If substantiated, this finding would imply that APRIL and BAFF are expressed by infiltrating lymphocytes, but it cannot exclude significant expression by ductal epithelial cells.

The information so far available about the cytophysiological mechanisms that secrete paracrine mediators to the stroma has come from immunohistochemical studies

of TGF-β, epidermal growth factor (EGF), fibroblast growth factor (FGF), and prolactin localizations in rabbit lacrimal gland and studies of the intracellular traffic of prolactin in *ex vivo* acinar cells from rabbit lacrimal gland. Under normal circumstances, the paracrine mediators are localized primarily in the apical cytoplasm, consistent with secretion into the duct lumen via the regulated exocrine secretory apparatus. Consistent with this inference, pilocarpine-induced lacrimal gland fluid contains high concentrations of TGF-β and prolactin. Two-color confocal immunofluorescence microscopy of the *ex vivo* model indicates that prolactin colocalizes with rab4, rab5, and rab11, which are effectors of traffic to and from endosomes, and electron microscopic-immunogold studies indicate that prolactin also is localized within mature secretory vesicles. These findings suggest that lacrimal epithelial cells may maintain two pools of the paracrine mediators they secrete: a large, often static, pool in the regulated exocrine secretory apparatus, and a small, but high throughput, pool in the paracrine apparatus.

Transfer of Immunoglobulins to the *Milieu Extérieur*

pIgR and dIgA

Several prominent aspects of lacrimal cytophysiology appear to reflect adaptations to the roles the epithelium plays in the mucosal immune system: maintaining the underlying stromal space as a niche for dIgA-secreting plasmacytes and then transferring dIgA from the stromal space to the fluid within the lumen of the acinus–duct system. The fundamental principles of the transcytotic mechanism for dIgA secretion were elucidated in studies of Madin-Darby canine kidney (MDCK) cells, derived from a canine kidney, which form continuous epithelial monolayers when cultured on microporous substrata. Renal tubular epithelial cells do not normally secrete IgA, but when MDCK cells are stably transduced to express the polymeric immunoglobulin receptor (pIgR), they gain the ability to internalize dIgA from their basal medium, which corresponds to the interstitial fluid, and secrete sIgA into their apical medium, which corresponds to the lumenal fluid of an exocrine gland or the surface fluid of a mucosal sheet. **Figure 3** illustrates the transcytotic apparatus as it is thought to function in conjunctival epithelial cells. The pIgR makes its way from the biosynthetic apparatus, that is, the endoplasmic reticulum and Golgi complex, through the trans-Golgi network (TGN) and endosomes, to the basal–lateral plasma membranes, hitchhiking in transport vesicles at each step. The pIgR may or may not bind the J chain and associated immunoglobulin while its ligand-binding domain is exposed at the basal–lateral membrane. In either case, it is internalized in an endocytotic transport vesicle that will traffic to the early endosome. Another transport vesicle will traffic pIgR and pIgR–dIgA complex to the recycling endosome, and yet another will traffic pIgR and pIgR–dIgA complex to the apical plasma membrane. Either during its transit through the recycling endosome, or upon arriving at the apical plasma membrane, the pIgR will encounter a protease that cleaves the extracytoplasmic, dIgA-binding domain, referred to as secretory component (SC), from the membrane-spanning domain. Thus, the cell releases both free SC and SC–dIgA complexes, that is, secretory IgA (sIgA), into the *milieu extérieur*. Consistent with the topological constraints that preclude traffic of transport vesicles between adjoining cells, expression of pIgR is concentrated in the apical-most layer of epithelial cells in the conjunctiva.

Acute Regulation of pIgR Traffic

The traffic of pIgR through lacrimal gland epithelial cells appears to be somewhat more complex than described in the MDCK cell paradigm. First, it appears that pIgR might cycle repeatedly to the basal–lateral plasma membrane from any compartment of the transcytotic apparatus, while free SC is preferentially trafficked from the recycling endosome to the apical plasma membrane. Second, some of the pIgR traffic from the TGN to the immature secretory vesicle, rather than to the transcytotic apparatus; SC derived from these pIgR remains in mature secretory vesicles until released into the lumen along with the classical secretory proteins. Interestingly, many of the classic lacrimal secretory proteins, such as β-hexosaminidase, lysozyme, and lactoperoxidase, are innate immune effector molecules. Free SC appears to perform important functions in the ocular surface fluid film, and the ability to sequester a portion of pIgR away from the transcytotic apparatus ensures that some free SCs always will be secreted, despite the large mass of dIgA that normally is present in the stromal space.

A considerable volume of membrane traffic flows through the lacrimal acinar cell's transcytotic apparatus. The micropinocytosis associated with endocytotic internalization of transport vesicles from the basal–lateral and apical surface membranes carries fluid phase markers into the cells, and such markers rapidly equilibrate throughout the aqueous phase within the lumena of the early endosome, recycling endosome, and TGN, as well as the late endosome, prelysosome, and lysosome. If *ex vivo* acinar cell models are acutely stimulated with the muscarinic acetylcholine receptor agonist, carbamylcholine (carbachol, CCh), they increase the rates at which they endocytose and exocytose fluid phase markers. If the CCh concentration is increased from 10 μM, which maximally accelerates fluid phase endocytosis but half-maximally accelerates protein secretion, to 100 μM, a concentration that maximally accelerates protein secretion, fluid phase endocytosis continues at the increased rate, but

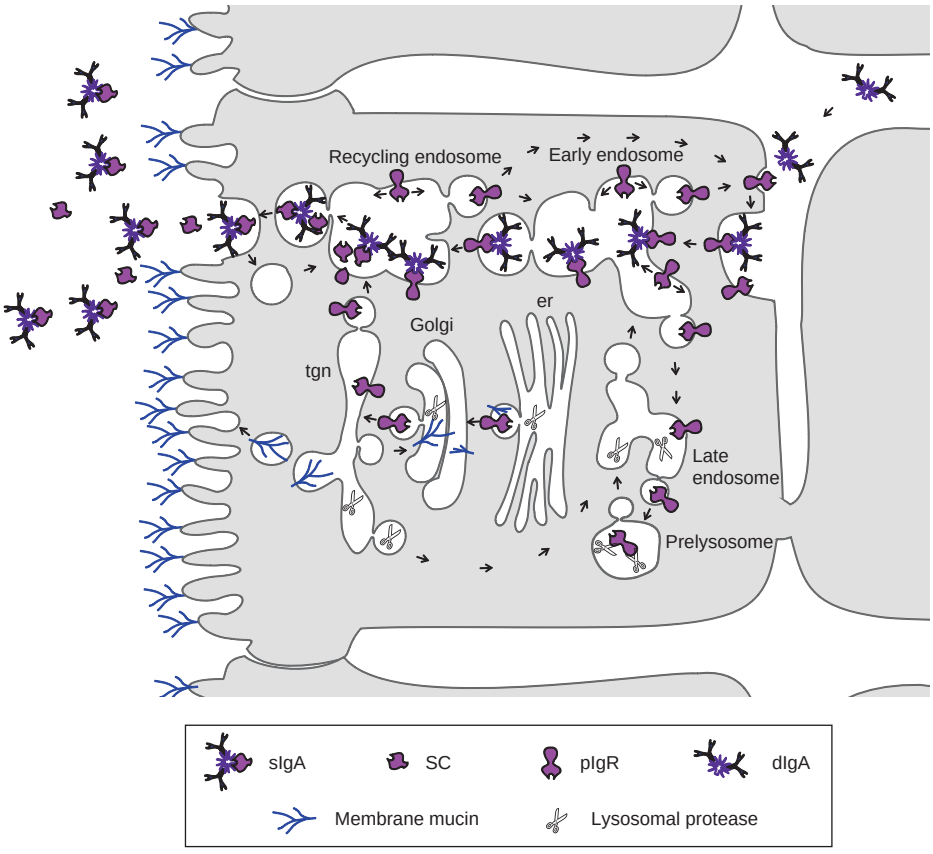

Figure 3 Transcytotic traffic of sIgA to the *milieu extérieur*. The apical-most layer of epithelial cells in stratified tissues, like the epithelial cells of lacrimal acini and ducts, express pIgR. At the basal–lateral surface membrane pIgR mediates endocytosis of dIgA, which it then chaperones through the early endosome and apical recycling endosome. Either within the apical recycling endosome or at the apical plasma membrane, the pIgR is cleaved by protease to release either free SC or dIgA–SC complex, that is, sIgA. In lacrimal gland epithelial cells, pIgR may cycle repeatedly through the TGN and transcytotic apparatus; it may enter immature secretory vesicles (not shown), where free SC is released and stored for subsequent secretion in response to secretagogue stimulation, or it may traffic through the late endosome, which is a gateway to the prelysosome and autophagic–lysosomal apparatus. The author proposes that the traffic of transport vesicles returning from the prelysosome and late endosome to the early endosome accounts for the constitutive release of an unusually heavy burden of autoantigens to the stromal space.

the volume of space that the fluid can reach decreases. If a marker is allowed to equilibrate through the fluid phases of the network of endomembrane compartments under resting conditions, subsequent acute stimulation with 100 μM CCh accelerates its release, but release then stops with a substantial portion of the marker remaining entrapped within the cell. These findings suggest that when the cell is maximally stimulated with CCh, it imposes a blockade of bidirectional traffic between proximal and distal compartments of the endocytotic pathway. Other studies indicate that the blockade affects traffic to the late endosome from both the early endosome and the TGN. A possible cytophysiological rationale for this phenomenon is suggested by preliminary studies of the kinetics of CCh-induced SC secretion. The CCh acutely induces a burst of secretory vesicle exocytosis, which releases SC along with the other secretory proteins. Secretory vesicle exocytosis is complete within 10 min. However, the cells continue to release SC at an increased rate for at least 60 min, while their total content of pIgR plus SC appears to remain unaltered. These phenomena suggest that the cell blockades traffic to the late endosome in order to divert an increased proportion of its newly synthesized pIgR from the degradative apparatus to the transcytotic apparatus.

A Mechanism That Constitutively Secretes Autoantigens to the Stroma

A consequence of the strategy of directing a large volume of transport vesicle traffic from the early endosome to the late endosome and prelysosome under nonstimulated conditions is that the reciprocal traffic of transport vesicles constitutively secretes lysosomal hydrolases and potential autoantigens that, in other cells, would remain in the autophagic–lysosomal apparatus and be degraded. Moreover, when traffic to the late endosome is blocked, the lysosomal hydrolases reflux into the compartments which remain accessible (i.e., the TGN), immature

secretory vesicle, early endosome, and recycling endosome. Of particular interest, at least some of the lysosomal proteases are catalytically active and may process other proteins that have accumulated with them in the same compartments. This phenomenon might lead to the degradation of dominant autoantigen epitopes and lead to the eventual presentation of epitopes that under normal circumstances are degraded.

FcγRn and IgG1

While the plasmacytes that produce dIgA reside in the stromal spaces of exocrine glands and the lamina propria of mucosal sheets, the plasmacytes that produce IgG1 typically reside in the bone marrow, and IgG1 must travel through the circulation to reach the epithelia that will secrete it. The same subcellular apparatus that transports SC and pIgR–dIgA complexes through epithelial cells likely also mediates the secretion of IgG1. However, IgG1 does not associate with J chain, and its traffic is mediated not by pIgR but by the neonatal Fcγ receptor, FcγRn. The association between IgG1 and FcγRn is regulated by pH, such that binding affinity is highest in relatively acidic endosomal compartments and lower at the pH of the interstitial fluid. In the tissues where it has been studied, the IgG1–FcγRn complex tends to bypass the late endosome in favor of the early endosome and recycling endosome. Because dissociation of IgG1 from FcγRn does not require proteolytic processing, FcγRn can mediate multiple cycles of IgG1 absorption as well as secretion. The FcγRn can also mediate absorption and secretion of IgG1-immune complexes, in some cases secreting opsonized microbes and immune complexes and in others absorbing them in a physical state that minimizes the risk of infection but perpetuates T-cell and B-cell responses. The extent to which FcγRn might be expressed in the lacrimal glands and drainage system has not been investigated; recently, however, it has been found to be present in epithelial cells of rat conjunctiva.

Mucosal Tolerance and Response to Infection

Commensal microbes in the gut are coated with sIgA, which normally prevents them from entering the epithelial lining. Notably, dendritic cells as well as dIgA-secreting plasmacytes populate the mucosal effector sites. They are present within the lamina propria and the epithelia and may extend processes that interdigitate between adjoining cells to surveille the *milieu extérieur*. As in the organized inductive sites, immature dendritic cells are endocytotically active, and under normal circumstances the material they internalize consists of soluble molecules and cellular debris. The robustness of the phenomenon of oral tolerance suggests that the TGF-β- and IL-10-rich milieu directs them to mature as regulatory antigen presenting cells, which, when they arrive in lymph nodes, induce food antigen- and, presumably, autoantigen-specific $CD4^+$ T cells to mature as T_H3 and T_R1 regulatory cells. The regulatory cells might function in both the effector sites and the lymph nodes to prevent inflammatory mediators or activated effect T cells from redirecting dendritic cells toward expression of immunoactivating phenotypes.

As illustrated in the lower panel of **Figure 2**, TLR on immature dendritic cells in the epithelium or lamina propria recognizes microbes that have evaded the immunospecific sIgA barrier, and TLR activation induces phagocytosis, redistribution of MHC class II molecules to the dendritic cell surface, and upregulation of surface CD80 and CD86. Certain microbes induce maturing dendritic cells to remain in the lamina propria and release antigen directly to B1 cells, stimulating activation independently of T-cell help. Typically, however, dendritic cells are activated to switch chemokine receptor and homing receptor expression to favor emigration via afferent lymph vessels. In the lymph nodes, they will induce activation of naive, antigen-specific $CD4^+$ T cells as T_H2 cells and generation of IgG-producing B cells.

Implications for Ocular Surface Pathophysiology

Contemporary paradigms hold that dry eye disease results from insufficiency of the ocular surface fluid film. Such might be the consequence of impaired lacrimal gland fluid production, excessive evaporation of water from the ocular surface fluid due to deficient production of lipids in the Meibomian glands, and excessive breakup of the fluid film due to deficiencies of the normally hydrophilic substratum provided by the apical surfaces of corneal and conjunctival epithelial cells. There is a general consensus that, whatever the etiology, the principal feature of pathophysiological state is inflammation of the ocular surface tissues. Inflammatory processes plausibly account for much of the cytopathology that occurs within the lacrimal gland and leads to quiescence of impairment of its exocrine functions. This seems to be the case, not only in Sjögren's syndrome, but also in graft-versus-host disease, sarcoidosis, Wegener's granulomatosis, and diffuse infiltrative lymphocytosis syndrome associated with HIV infection. A histopathological syndrome distinct from the familiar diagnoses and described primarily through postmortem studies is characterized by lymphocytic infiltration, acinar atrophy, ductal dilatation, and periductal fibrosis. Its underlying pathophysiological mechanisms have not been studied, although they appear not to involve production of autoantibodies.

The author suggests that these inflammatory processes normally are prevented by the same strategy that prevents immune responses to food antigens, soluble autoantigens, and cellular debris. There may be particular challenges to maintaining immunoregulation in the lacrimal glands, where vigorous traffic through the transcytotic apparatus releases an exceptionally heavy burden of potential autoantigens into the stromal space, and in the ocular surface tissues, where environmental stresses may induce release of inflammatory mediators that abrogate the local signaling milieu's ability to generate regulatory antigen presenting cells. Additional challenges may result from the epithelia's dependence on systemic hormones to maintain expression of the local signaling milieu.

Adaptive Immune System and the Eye: T Cell-Mediated Immunity

K C McKenna and R D Vicetti Miguel, University of Pittsburgh, Pittsburgh, PA, USA

Glossary

Antigen – A molecule recognized by receptors expressed by T cells (TCR) and B cells (immunoglobulin).
Complement – A system of serum proteins and cell surface proteins that combine to form the membrane attack complex that perforates cell membranes. Component proteins of the complement cascade have enzymatic activity and generate inflammatory mediators.
Cytokines – Soluble molecules that modulate immune responses.
Inflammation – The hallmark of an immune response characterized by edema, redness, and pain. Inflammatory mediators induce vasodilation of local vessels which are leaky and promote edema and facilitate immune cell infiltration. While inflammation controls infection, it can also cause tissue damage, as the effector function of the innate immune response is nonspecific.
Major histocompatibility complex (MHC) – Highly polymorphic molecule expressed on the cell surface that presents self and foreign peptides for T-cell recognition through the TCR.
Opsonization – The coating of cell surfaces with molecules that facilitate phagocytosis.
Phagocytosis – The process of pathogen engulfment through recognition of surface receptors.
Polymorphonuclear leukocytes (PMN) – Cells of the innate immune response characterized by a multilobed nucleus including neutrophils and eosinophils.
Signal transduction – The process by which signals received by the cell are converted into gene expression within the nucleus.

The human body and the microbes (bacteria, viruses, and parasites) that reside within it share the same simple mandate: to survive and to reproduce. The ground rules of the host are clear. The host–microbe relationship cannot cause damage that compromises the health of the host. When health is compromised, the host immune system eliminates or controls the growth of these unruly microbes, now termed pathogens. Immune responses in the eye are critical for protection from pathogens. For example, immune-suppressed HIV+ patients are more susceptible to ocular infection. However, ocular immune responses also pose a threat as inflammation can damage the delicate microanatomy of the eye and compromise vision. Examples of blinding inflammation include viral, bacterial, and parasitic keratitis, retinitis, bacterial endophthalmitis, and autoimmune uveitis, which are reviewed elsewhere in this encyclopedia. As an evolutionary adaptation to preserve vision, immune responses in the eye are normally tightly regulated to control pathogens while minimizing inflammation.

Innate and Adaptive Immunity

The two major arms of the immune system, innate and adaptive immunity, can be distinguished by the unique molecular structures they employ to recognize molecules expressed by pathogens or expressed by a host cell in response to a pathogen. The innate immune response utilizes a limited set of pathogen recognition receptors (PRRs) to detect pathogen-associated molecular patterns (PAMPs), which are conserved pathogen products. There are PRRs that recognize PAMPs expressed by all major classes of microbes for example: toll-like receptor (TLR) 4 recognizes lippopolysaccharide (LPS) of Gram-negative bacteria; TLR3 recognizes double-stranded RNA expressed by viruses; and TLR11 recognizes proteins expressed by parasites. PRRs can also recognize molecules associated with pathogen-induced cell death. For example, RAGE (receptor of advance glycation end products), TLR 2, 4, and 9 recognize nonoxidized high mobility group box 1 (HMGB1), which is released by normal cells upon necrotic but not apoptotic cell death. PRRs are expressed on epithelial cells at sites of microbial entry and on cells of the innate immune response which include: macrophages, dendritic cells (DC), and polymorphonuclear leukocytes (PMN).

Pathogen recognition by the adaptive immune response is not predetermined by a limited set of receptors. Rather, a random process of gene segment rearrangement by recombinase activation genes (Rag-1 and Rag-2) generates over a billion different receptors tailored to recognize essentially any molecule. Cells of the adaptive immune response include B cells, which express immunoglobulin (Ig) molecules and T cells that express T-cell receptors (TCRs). Individual B or T cells express receptors with a single specificity creating a repertoire of many B and T cells each with different specificities. B cells mediate humoral immunity through production of secreted Ig molecules (antibodies) which directly recognize

unique shapes, and conformations of pathogen-associated molecules including proteins, carbohydrates, lipids, nucleic acids, and simple chemical groups. Cellular immunity is mediated by T cells through TCR recognition of pathogen-associated proteins processed into peptides and presented on the cell surface by the major histocompatibility complex (MHC). These differences in antigen recognition specialize humoral immunity for defense against extracellular pathogens and cell-mediated immunity for defense against intracellular pathogens. The focus of this article is a general overview of T-cell-mediated immunity introducing how T-cell responses are regulated in the eye and conditions where ocular T-cell responses cause immunopathology.

Antigen Trafficking, Processing, and Presentation to T cells

The lymphatic system drains extracellular fluids through a network of collection channels and vessels that ultimately empty into the bloodstream through the thoracic duct. Interspersed between lymphatic vessels are lymph nodes that are filled with immune cells. This strategic placement of an immune organ within a drainage pathway allows the immune system to survey for foreign antigens contained within extracellular fluids from different regions of the body. For example, the eye is drained to cervical lymph nodes within the neck whereas the arms drain to axillary and brachial lymph nodes. Internal organs also have lymphatic drainage: lungs drain to mediastinal lymph nodes and intestine drains to mesenteric lymph nodes.

T cells, which have not encountered their antigen, are found in the lymph nodes, spleen, and blood but not in nonlymphoid tissues, such as the eye. Therefore, these naive T cells are not the first responders to an ocular pathogen. Rather, innate immunity is the first line of defense. Recognition of PAMPs through PRRs induces rapid expression of inflammatory cytokines (IL (interleukin)-1, IL-6, and tumor necrosis factor (TNF)) that increase the production of chemokines, such as IL-8 and acute phase proteins (e.g., C-reactive protein). Chemokines promote the migration of immune cells to the eye while acute phase proteins opsonize microbial surfaces where they activate complement and promote phagocytosis by macrophages and PMN. To control the pathogen, infiltrating PMN and macrophages produce reactive oxygen species, including superoxide which can be transformed into H_2O_2 by superoxide dismutase. H_2O_2 and chloride are substrates for myeloperoxidase which generates antimicrobial hypochlorous acid, the active ingredient of bleach. PMN and macrophages also release granules containing antimicrobial molecules and generate nitric oxide (NO) that reacts with superoxide to form the potent oxidant peroxynitrite. In addition to controlling the pathogen, DCs and macrophages which have internalized pathogens and/or pathogen products migrate to the lymph nodes through lymphatic vessels to activate pathogen-specific T cells.

Adaptive immune responses depend on innate immune responses, as T cells only recognize cell-associated antigens. Hence, antigens that flow freely into the lymph node or that are carried by DCs and macrophages from the pathogen site have to be processed and presented by antigen-presenting cells (APCs) for recognition by T cells. As a general rule, pathogen-expressed proteins from the extracellular milieu are digested by phagocytic APC and presented through MHC class II molecules for recognition by $CD4^+$ T cells, whereas intracellular pathogen-expressed proteins are processed and presented through MHC class I molecules for recognition by $CD8^+$ T cells (**Figure 1**). However, certain types of APC, for example CD8α+ CD11c+ DCs from mice, cross present extracellular proteins through MHC class I molecules.

T-cell activation

Very few T cells within the entire T-cell repertoire are specific for any one particular antigen. Therefore, to most effectively respond to a pathogen, these antigen-specific T cells undergo cell division to expand their numbers. This process of clonal expansion takes time, which explains why adaptive immune responses lag behind innate immune responses.

The activation of T cells to undergo proliferation results from several signals delivered from the APC. These signals initiate and sustain signal transduction cascades culminating in the transcription of genes necessary for T-cell proliferation, most importantly IL-2 (**Figure 2**). Transducing signals from the APC to T cells occurs by phosphorylation and dephosphorylation of intracellular substrates by kinases and phosphatases, respectively. Signal one is delivered by TCR engagement of MHC + peptide complexes, which results in a conformational change in the TCR that makes immunoreceptor tyrosine-based activation motifs (ITAMs) accessible on chains of the CD3 complex which is comprised of five distinct molecules (γ, δ, ε, ζ, and η). The CD3 complex is associated with the TCR and is necessary for signal transduction upon TCR engagement, as the TCR has a short cytoplasmic domain incapable of signaling. Upon TCR antigen recognition, CD3 ITAMS are phosphoylated by $p56^{lck}$, and $p59^{fyn}$ kinases, then bound by ZAP-70 ((CD3) zeta chain-associated protein of 70 kDa) kinase, which activates phospholipase Cγ1 (PLCγ1). PLCγ1 is an enzyme which catabolizes membrane-bound phosphatidlyinositol-1, 4-bisphosphate (PIP_2) into inositol-1,4,5-triphosphate (IP_3) and diacylglcerol (DAG). IP_3 induces an intracellular calcium increase which then activates the serine phosphatase calcineurin to dephosphorylate nuclear factor of activated T cells (NFAT). Dephosphorlated NFAT leaves the cytosol to enter the nucleus. DAG activates protein kinase C (PKC) initiating another cascade leading to degradation

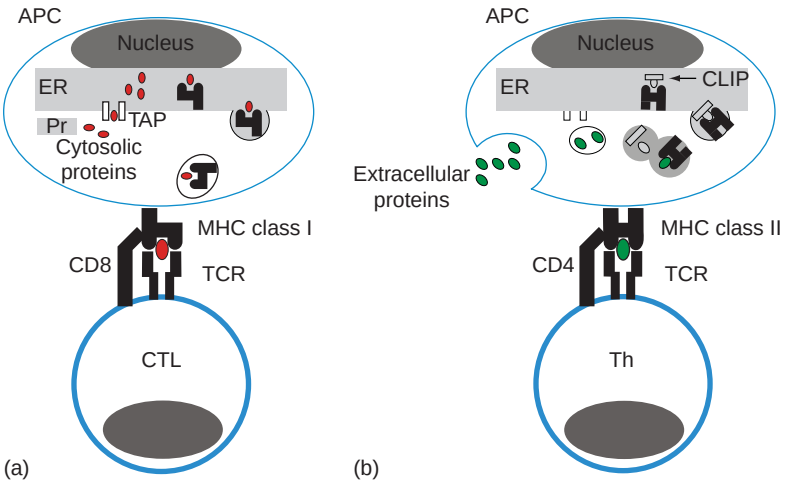

Figure 1 Antigen processing and presentation to T cells. (a) Proteins expressed within the cytosol are degraded into peptides by the proteasome (Pr), transported into the endoplasmic reticulum (ER) by the transporter associated with antigen processing (TAP) and then associate with newly formed MHC class I molecules which are transported to the cell surface for recognition by $CD8^+$ cytolytic T lymphocytes (CTL). (b) Extracellular proteins are degraded into peptides in endosomal vesicles that fuse with exocytic vesicles containing MHC class II molecules associated with the class II invariant chain peptide (CLIP). CLIP is then removed by the protein DM and replaced by peptides derived from extracellular proteins. MHC class II + peptide complexes are then transported to the cell surface for recognition by $CD4^+$ T helper (Th) cells.

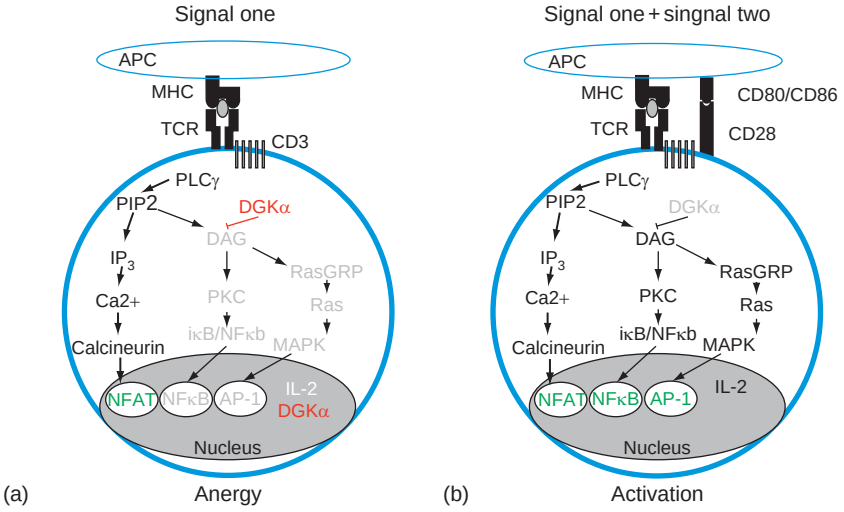

Figure 2 Signal transduction pathways of T-cell activation and anergy. (a) Engagement of TCR alone favors NFAT activation leading to inhibited IL-2 production and the induction of anergy-inducing genes. (b) Engagement of TCR along with co-stimulation provides balanced NFAT and NFκB activation and AP-1 formation leading to IL-2 production and repression of anergy-inducing genes. APC, antigen-presenting cell; MHC, major histocompatability complex; TCR, T-cell receptor; PLCγ, phospholipase Cγ; PIP_2, phosphatidylinositol-1,4 bisphosphate; IP_3, inositol 1,4,5-triphosphate; DGKα, diacylglycerol kinase alpha; DAG, diacylglycerol; PKC, protein kinase C; RasGRP, Ras guanyl releasing protein; MAPK, mitogen activated protein kinase; iκB, inhibitor of NFκB; NFκB, nuclear factor κB; NFAT, nuclear factor of activated T cells; AP-1, activator protein-1; IL-2, interleukin 2.

of the inhibitor of NFκB (i_kB) and subsequent translocation of NFκB from the cytosol to the nucleus. DAG also activates the Ras pathway, which through mitogen-activated protein kinase (MAPK) leads to formation and activation of the activator protein-1 (AP-1) molecule. NFAT, NFκB, and AP-1 are all transcription factors that cooperate to induce transcription of IL-2 and other T-cell activation genes. Signal one alone, however, is not sufficient to induce complete T-cell activation.

Signal two is delivered by invariant molecules expressed on the cell surface of APC that are upregulated after PRR engagement of PAMPs. The best characterized of these co-stimulatory molecules are CD80 (B7-1) and CD86 (B7-2), which bind to CD28 on T cells. CD28

engagement further activates the Ras/MAPK pathway to promote IL-2 production by making the IL-2 promoter accessible to transcription factors by chromatin remodeling, and by stabilizing IL-2 mRNA. Immediately, T-cell proliferation ensues.

The benefit of generating T cells with TCR capable of recognizing a tremendously diverse array of antigens carries the consequence that the same process generates TCR that recognize self molecules. While the most dangerous self-reactive T cells are deleted during T-cell development in the thymus by a process referred to as negative selection, many T cells with cross reactivity to both foreign and self-antigens escape negative selection. The requirement for two signals to induce T-cell activation may have developed to ensure that these cross-reactive T cells are activated only under appropriate circumstances; for example, when foreign antigen is encountered. During normal physiological conditions, APC that present self-antigens will not be activated by PAMPs to upregulate co-stimulatory molecules. Hence, signal one but not signal two will be delivered. Signaling through the TCR alone leads to long-lived T-cell unresponsiveness referred to as anergy, which is characterized by inhibited expression of IL-2. Therefore, anergy induction protects the body from the generation of autoimmunity while preserving the most extensive repertoire of TCR.

The current paradigm for anergy induction suggests that signal one induces NFAT activation with only partial AP-1 activation causing a signaling imbalance that leads to the expression of anergy-inducing genes, such as diacylglycerol kinase alpha (DGKα) (**Figure 2(a)**). DGKα phosphorylates DAG promoting its degradation and further decreasing activation of the Ras/MAPK and PKC pathways. Ultimately, the IL-2 promoter becomes inaccessible to transcription factors due to chromatin remodeling, and as a result, the cell becomes anergic. Anergy induction also involves T-cell expression of inhibitory co-stimulatory molecules, such as cytotoxic T-lymphocyte antigen 4 (CTLA-4), which antagonize activating co-stimulatory molecules.

T cell differentiation and effector function

Upon activation, T cells receive further instructions in the form of cytokines that promote differentiation that is best suited to respond to the offending pathogen. For example, $CD4^+$ T helper (Th) responses are directed toward at least four effector lineages: Th1, Th2, Th17, and adaptive T regulatory cells (Treg) by exposure to particular cytokines IL-12/ interferonγ (IFNγ), IL-4, transforming growth factor-β (TGF-β)/IL-6, or TGF-β, respectively (**Figure 3**). $CD8^+$ T cells differentiate into cytolytic T lymphocytes (CTLs) by exposure to IL-12 and express granzymes and perforin. $CD8^+$ T cells also produce cytokines and similar to Th cells are directed toward four effector lineages: Tc1, Tc2, Tc17, and Treg by exposure to IL-12/IFNγ, IL-4, TGF-β/IL-6, or TGF-β. PAMPs directly or indirectly induce the expression of these polarizing cytokines. For example, bacterial LPS and viral RNA induce DC expression of IL-12. The cellular source of IL-4 and TGF-β have not been defined. IL-6 is commonly expressed in inflammatory environments. These critical cytokines induce or repress the expression of key transcription factors. Th1 cells and CTL express T-bet while suppressing Gata-3 which is critical for Th2 development. Th17 cells do not express T-bet or Gata-3, but express retinoic acid-related orphan receptorγt (RORγt) which is fundamental for their development. Forkhead box P3 (FoxP3) is a signature transcription factor for Tregs. Each transcription factor promotes specific expression of subset-specific genes: Th1/Tc1 cells express IFNγ, Th2/Tc2 cells produce IL-4, 5, and 13, Th17/Tc17 cells produce IL-17, and Treg cells produce TGF-β.

The primary effector function of Th cells is to provide T cell help through co-stimulatory molecule expression and cytokine production, which orchestrates the immune response by inducing: T and B cell proliferation, Ig heavy chain class switching in B cells, and activation of innate cells. T follicular helper cells (Tfh) are another recently defined Th effector lineage characterized by expression of the chemokine receptor (CXCR5) and localization to B cell follicles within lymphoid tissues. Tfh cells promote B cell proliferation by production of IL-21. Activated B cells initially express IgM heavy chain molecules but upon engagement of Th cells through TCR and CD40L interactions, B cells change their Ig heavy chain isotype in response to Th expressed cytokines. For example, Th1-expressed IFNγ or Th2 expressed IL-4 promotes switching to IgG or IgE isotypes, respectively. Antibodies opsonize pathogen surfaces to: neutralize toxins, inhibit pathogen invasion by blocking cell surface receptors critical for binding host cells, and activate complement. In addition, antibody heavy chain isotypes are bound by Fc receptors expressed by innate cells to mediate antibody-dependent cellular cytotoxicity (ADCC). Antibody engagement of Fc receptors expressed by neutrophils (FcγRI), macrophages (FcγRI), NK cells (FcγRIII), and eosinophils (FcεR1), induces the release of lytic granules leading to targeted cell lysis. IgG molecules mediate ADCC through macrophages, neutrophils, and NK cells, whereas IgE molecules mediate ADCC through eosinophils.

Each Th lineage displays very different effector functions with clear protective and pathological consequences. Th1 cells mediate type IV delayed-type hypersensitivity responses (DTH) through production of IFNγ, which activates macrophages to increase their phagocytic activity and induce expression of TNF, NO, and reactive oxygen species. Hence, Th1 infiltration of the pathogen site amplifies inflammation initiated by PAMPs by further activation of macrophages. Th2 cells produce IL-4 and

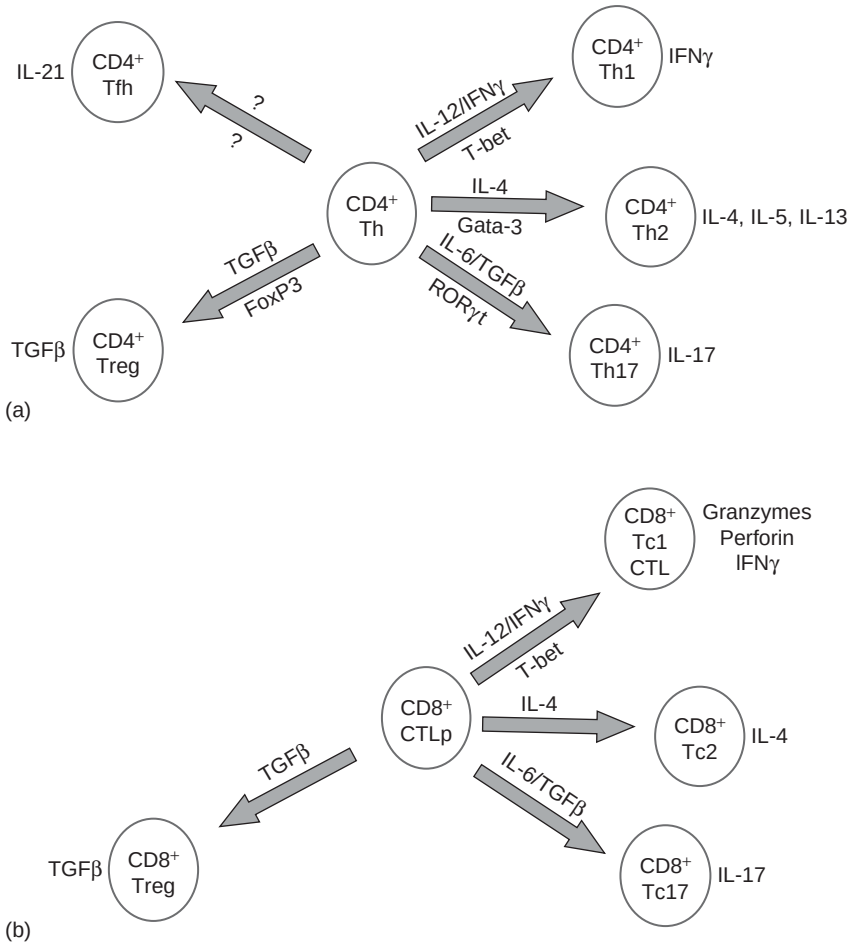

Figure 3 T-cell effector differentiation. $CD4^+$ Th cells (a) and $CD8^+$ T cells (b) differentiate into distinct subsets based on exposure to particular cytokines which induce unique transcription factor expression and cytokine expression. Th, T helper cell; Tfh, T follicular helper cells; Treg, regulatory T cells; TGFβ, transforming growth factor β; FoxP3, forkhead box P3; IL, interleukin; IFNγ, interferon gamma; RORγt, retinoic acid-related orphan receptor γt; CTLp, cytolytic T lymphocyte precursors.

IL-5, which control extracellular helminthic infections by activating eosinophils. The recently described Th17 subset produces IL-17 and has been implicated in the response against a wide variety of pathogens requiring a strong inflammatory response predominated by neutrophils. The nonspecific effector mechanisms elicited by macrophages, neutrophils, and eosinophils are associated with significant tissue damage. In contrast, Treg cells inhibit immune responses by expression of CTLA-4 and/or by the production of immunosuppressive cytokines such as TGF-β and IL-10, which inhibits T-cell proliferation and decreases co-stimulatory molecule and cytokine expression of APC. Tregs also suppress cytokine production and lytic activity of T cells, at sites of inflammation.

$CD4^+$ T helper cells are also critical for the generation of long-lived memory $CD8^+$ T cells that respond quickly and efficiently upon secondary exposure to antigen. $CD8^+$ T cells that expand in numbers to a pathogen in the absence of $CD4^+$ T cells rapidly undergo activation-induced cell death (apoptosis) through TRAIL/TRAIL receptor interactions upon secondary exposure to antigen. In addition, memory $CD8^+$ T cells generated in the presence of $CD4^+$ Th cells are not maintained if transferred to mice deficient in $CD4^+$ T cells, indicating that Th cells are somehow necessary to maintain long-lived memory $CD8^+$ T cells *in vivo*.

The primary effector function of $CD8^+$ T cells is control of intracellular pathogens. $CD8^+$ T cells differentiate into lytic effectors (CTL) which are characterized by expression of perforin and granzymes. CTL target infected cells by their expression of pathogen peptides presented on the cell surface by MHC class I molecules. Perforin molecules form pores in cell membranes which facilitate transfer of granzymes into the cytoplasm that activate caspases to induce apoptosis. Interestingly, granzyme B can also inhibit herpes simplex virus-1 (HSV-1) replication within latently infected neurons without

inducing apoptosis by caspase-mediated cleavage of viral proteins. Whether the neuron or the HSV-1 infection prevents apoptosis under this circumstance remains to be determined. $CD8^+$ CTL also produce IFNγ, which inactivates viral proteins and activates innate cells as previously mentioned.

Differentiation of T-cell effectors is coincident with the differentiation of long-lived memory T cells. Memory T cells are divided into central (Tc) and effector (Te) memory subpopulations based on their location and unique expression of cell surface molecules. Tc memory cells localize to lymph nodes and spleen through expression of the chemokine receptor7 (CCR7) and CD62L, whereas Te memory cells are present in nonlymphoid tissues and do not express these molecules. Several cell surface molecules have been useful in distinguishing naïve T cells from memory and effector T-cell populations. For example, naïve T cells express low levels of CD44 and killer cell lectin-like receptor G1 (KLRG1) and high levels of the IL-7 receptor (CD127). In contrast, both effector and memory T-cell populations express high levels of CD44. The retention or reexpression of CD127 along with low expression of KLRG1 distinguishes memory T cells from CD127 low KLRG1 hi T cell effectors.

The differentiation of effector and memory T cells from a single naïve T-cell precursor is an area of active research and several models are being tested. Lineage determination could involve dedifferentiation of effector cells. Another model suggests that the strength of signal delivered by APC to T cells may favor a particular lineage. For example, T effector generation may be favored when inflammation is high, whereas T memory generation may be favored when inflammation is low. Inverse regulation of T-bet and eomesodermin transcription factors by IL-12 expressed during inflammation may be critical for lineage determination. Alternatively, lineage commitment may be determined upon the first cell division by asymmetric distribution of critical lineage determining molecules to daughter cells.

T-cell immune responses in the eye

The eye was characterized as a site of immune privilege by the Nobel laureate Peter Medawar in 1948 based on the observation that foreign tissue transplanted in the anterior chamber persisted indefinitely whereas the same tissue transplanted in the skin was rapidly rejected by the host immune response. Based on the absence of demonstrable lymphatic drainage of the interior of the eye, Medawar concluded that ocular antigens were sequestered and the immune system was ignorant of their presence. However, subsequent investigations found that Medawar was incorrect. A reevaluation of ocular immune privilege almost 30 years later by Kaplan and Streilein indicated that soluble and cell-associated antigens injected into the anterior chamber escaped from the eye and induced systemic T-cell nonresponsiveness. Upon secondary exposure to the same antigen under immunogenic conditions, such as antigen administration with adjuvant, the magnitude of Th1 or Th2 type cell-mediated immune responses was markedly reduced in comparison to mice in which the first exposure to antigen was through a nonprivileged route (skin or conjunctiva of the eye). This phenomenon, termed anterior chamber-associated immune deviation (ACAID), is mediated by $CD4^+$ Tregs, which inhibit the induction of T-cell effector responses and $CD8^+$ Tregs, which inhibit the expression of T-cell effector responses specific for ocular antigens. ACAID may contribute to the tremendous success of corneal transplantation that does not routinely require donor/recipient MHC matching or systemic immunosuppression because mice that accept corneal allografts demonstrate reduced DTH responses to donor antigens.

Ocular immune privilege is also maintained by soluble molecules contained within the aqueous humor and by cell-associated molecules expressed on tissues lining the anterior chamber, which are immunosuppressive (**Table 1**). These molecules directly inhibit T-cell effector function, convert T effectors into Treg, or inhibit the activation of

Table 1 Immune suppressive factors that maintain ocular immune privilege

Factor	*Effect*
TGF-β (Transforming growth factor-beta)	Decreases expression of CD40 and production of IL-12 and increases production of TGF-β by antigen-presenting cells (APC) leading to generation of T-cell hyporesponsiveness and/or T regulatory cells (Treg) generation. Inhibits T-cell proliferation and T-cell effector function
αMSH (alpha-melanocyte stimulating hormone)	Conditions APC to generate $CD4^+$ Treg Converts $CD4^+$ Teffector into Treg Inhibits neutrophil function
VIP (vasoactive intestinal protein)	Inhibits T-cell proliferation
CGRP (calcitonin gene-related peptide)	Inhibits production of nitric oxide by macrophages
CD95 (FasL), TRAIL, and PD-L1	Induces apoptosis of effectors infiltrating the eye
Soluble FasL	Inhibits neutrophil function
CD86 (B7-2)	Expressed on pigmented cells of the eye Induces functional nonresponsiveness of T cells upon engagement of cytotoxic T-lymphocyte antigen 4 (CTLA-4)
MIF (macrophage migration inhibitory factor)	Inhibits natural killer (NK) cell activity

innate cells. These barriers to T-cell responses are thought to represent a necessary compromise to limit tissue damage during pathogen control. The inhibition of the adaptive immune response would suggest that the eye would be more susceptible to infection. However, this is not the case. Rather, the eye is more prone to immunopathology when T-cell responses break immune privilege to control an ocular pathogen.

Several ocular infections induce T-cell responses that promote immunopathology. Viral (HSV-1) and bacterial (*Pseudomonas aeruginosa*) infections of the cornea induce $CD4^+$ Th1 cells that infiltrate the cornea and orchestrate neutrophil infiltration leading to keratitis. Parasitic *Onchocerca volvulus* infections induce Th2 responses that contribute but are not alone sufficient to induce keratitis. Interestingly, endosymbiotic *Wolbachia* bacteria activate TLRs to induce infiltration of the cornea by neutrophils, which are the primary mediators of inflammation. Th17 and Th1 cells have been shown to contribute to immunopathology in experimental rodent models of uveitis. $CD4^+$ Th cells are also critical in the rejection of corneal allografts through induction of a classic DTH response in the cornea and mediate lacrimal keratoconjunctivitis in mice exposed to dessicating stress.

The factors that break immune privilege are not completely understood. However, changes in immunoregulatory elements due to inflammation must be involved. Interestingly, in animal studies, the type but not intensity of ocular inflammation has been shown to be critical in breaking immune privilege. For example, the induction of ACAID is preserved in mice with LPS-induced uveitis but not in mice with inflammatory pigmentary glaucoma, although neutrophil inflammation is more pronounced in uveitic mice. Differences in the duration of inflammation may distinguish whether privilege is broken, as LPS-induced uveitis resolves within days whereas glaucoma persists for months. Identification of the regulatory factors affected by pathogens that break immune privilege will be critical for our understanding of how T-cell responses to ocular antigens are modulated to promote the elimination of ocular pathogens while producing minimal tissue damage.

Glossary

Deformable mirror – A mirror equipped with an array of actuators on the back surface that can warp the mirror surface by small amounts into arbitrary shapes, allowing the correction of the eye's aberrations.

Diffraction-limited resolution – The resolution of an optical system that has no aberrations, the image quality of which is reduced only by the diffraction of the light in the pupil of the system.

Lipofuscin autofluorescence – Lipofuscin is composed of many molecules that are by-products of the visual or retinoid cycle. These accumulate in the retinal pigment epithelium with aging and can be visualized in the living eye because they fluoresce when exposed to short wavelength light.

Point-spread function (PSF) – The light distribution in the image plane of an optical system such as the eye, formed from light from a point source outside the eye, such as a very distant star.

Retinal densitometry – A method to measure the density of photopigment in the living eye.

Shack–Hartmann wavefront sensor – A device capable of measuring the optical defects of an optical system such as the human eye. The output of a wavefront sensor can be used to control the shape of a deformable mirror in an adaptive optics system.

Stiles and Crawford effect – The fact that the eye is far more sensitive to light entering through a point near the center of the pupil than the pupil margin even though the irradiance at the retina is very little dependent on entry point in the pupil. This effect is caused by the waveguide properties of cone photoreceptors, which are more sensitive to light falling on their optical axes (which point near the center of pupil) than obliquely incident light.

The Benefit of Adaptive Optics in Vision Science

The history of ophthalmoscopy after its invention by Helmholtz until today is marked by efforts to extract the most information possible from the light reflected from the retina. Over the last two decades, there has been a concerted effort to improve the resolution of the imaging process in all three spatial dimensions. The development of optical coherence tomography (OCT) improved the resolution in the axial dimension, and has allowed the routine imaging of individual layers of cells in the retina. More recently, the introduction of adaptive optics (AO) has improved the resolution of fundus cameras in both transverse dimensions. The transverse resolution of the conventional fundus camera is limited not by the camera itself but by the optics of the human eye. The sources of image blur in the eye's optics include diffraction, aberrations, and scatter. Diffraction is the image blur that results from the wave nature of light as it passes through the eye's pupil. Blurring by diffraction is not inevitable; there are exciting techniques on the horizon that may eventually overcome the fundamental resolution limit set by diffraction, but no one has yet demonstrated this in the eye. A hypothetical eye that suffered only from diffraction would allow a resolution no smaller than about 1.4 μm when imaging wavelengths of light in the middle of the visible spectrum (550 nm). This is smaller than the smallest cells in the retina, so that if one could make the natural human eye limited only by diffraction, cellular and even subcellular features that are invisible in conventional fundus imaging could be seen. As shown in **Figure 1** (upper panels), in a diffraction-limited eye, the larger the pupil, the smaller the image of a single point of light and therefore the better the resolution.

The monochromatic and chromatic aberrations of all eyes further blur the retinal image. The monochromatic aberrations of the human eye alone are greater than those of even a mediocre man-made optical system. As shown in **Figure 1** (lower panels), increasing the pupil reduces the effect of diffraction, but exacerbates the effect of aberrations, with the best trade-off between the two occurring for pupil sizes around 3 mm. Light scatter, the third cause of loss in retinal image quality, is relatively unimportant in young eyes but it can greatly reduce retinal image contrast in older eyes, especially those with cataract. Not only is the retinal image blurred by the optical factors mentioned above, it is also exceedingly dim. The amount of light that can be delivered to the retina is limited for safety reasons and the retinal reflectance is low: 10^{-3}–10^{-5} across the spectrum. This would be less of a problem if it were easy to integrate light over long exposures, but the eye is always moving; even an eye with excellent fixation moves about ~20 μm root mean square (rms) velocity. Eye motion artifacts are all the more troublesome in instruments with high magnification that are designed to look at cellular

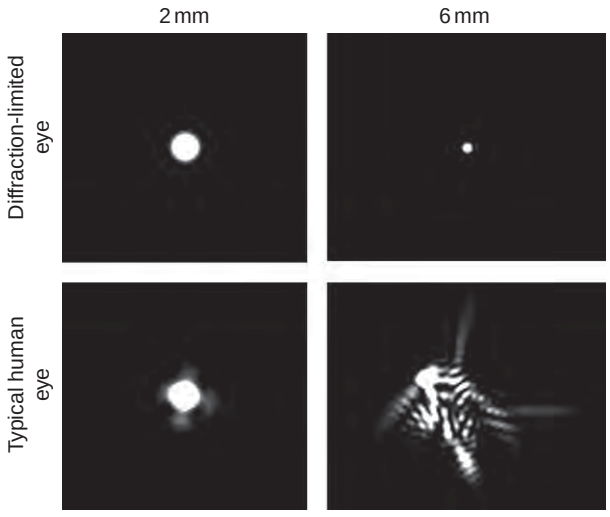

Figure 1 The point-spread function (PSF) for a diffraction-limited eye and a normal eye at two different pupil diameters. The PSF corresponds to the light distribution on the retina produced by a point source of light infinitely distant from the eye. For the hypothetical diffraction-limited eye, the PSF diameter decreases in inverse proportion to the pupil diameter such that large pupils produce the best image quality. However, in the typical human eye, aberrations increase with increasing pupil size, eliminating the benefit of escaping diffraction at the largest pupils. The goal of AO is to correct the aberrations to produce the PSF of a diffraction-limited eye with a large pupil. Adapted from Roorda, A. Garcia, C. A., Martin, J. A., et al. (2006). What can adaptive optics do for a scanning laser ophthalmoscope? *Bulletin de la Société Belge d'Ophthalmologie* 302: 231–244, Figure 1, with permission from Bulletin of the Belgian Societies of Ophthalmology (Copyright 2006).

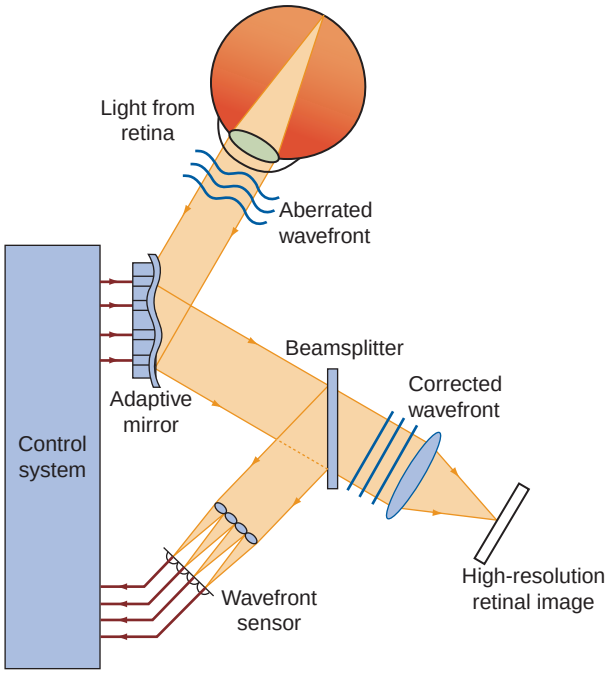

Figure 2 Principle of adaptive optics. The system contains two key parts: the wavefront sensor and wavefront corrector. The wavefront sensor, usually of the Shack–Hartmann type, measures the monochromatic aberration of the eye. It uses a 2-D array of lenslets conjugate with the eye's pupil to break the light from an infrared point source imaged on the retina into several hundred individual beams. Each beam is imaged on a CCD array. Its displacement on the CCD from where it would have landed had the eye been aberration-free indicates the slope of the wave aberration at that lenslet's location in the pupil. Information from all the lenslets is combined to compute the overall wave aberrations of the eye. These data are used to control a wavefront compensation device that corrects the wave aberration. The most commonly used device is a continuous surface deformable mirror. This mirror has a flexible surface overlying an array of actuators that can push or pull on the mirror surface locally. If the mirror surface is shaped so as to mimic the shape of the wave aberration but with half the amplitude of the wave aberration, the wavefront reflecting from the surface will be perfectly flat, and the monochromatic aberrations of the eye will have been corrected. Adapted from Carroll, J. Gray, D. C., Roorda, A., Williams, D. R. (2005). Recent advances in retinal imaging with adaptive optics. *Optics and Photonics News* 16: 36–42, Figure 1, with permission from Optical Society of America (Copyright 2005).

structures that are often far smaller than 20 μm. Despite all these formidable limitations, it is possible to design fundus cameras that address all of them with varying degrees of success, making microscopic resolution of the living retina possible as described below.

Correcting the Eye's Monochromatic Aberration

It is possible to overcome the eye's monochromatic aberrations with AO, a two-step process in which the eye's wave aberration is measured and corrected, usually in real time. **Figure 2** describes the principle of AO for imaging the eye. The monochromatic aberration of the eye is measured with a wavefront sensor. The measured aberration data are used to control a wavefront compensation device, usually a deformable mirror that corrects the wave aberration. Ideally, it would completely remove all the monochromatic aberrations, leaving diffraction and scatter as the only remaining sources of image blur. It usually takes several iterations of the measurement and correction loop to achieve the best correction, at which point it is possible to obtain a retinal image that is almost completely aberration free in eyes with normal amounts of aberrations. The rate of measurement and correction required to keep up with the temporal variations in the eye's wave aberration is relatively slow, at least compared with applications of AO in astronomy. Heidi Hofer has shown that measuring and correcting the wave aberration at 30 Hz or so is adequate to track the most important changes in the wave aberration, which are caused by microfluctuations in accommodation that have a temporal bandwidth of only a few Hertz. With complete wavefront correction, the point-spread function (PSF) is very

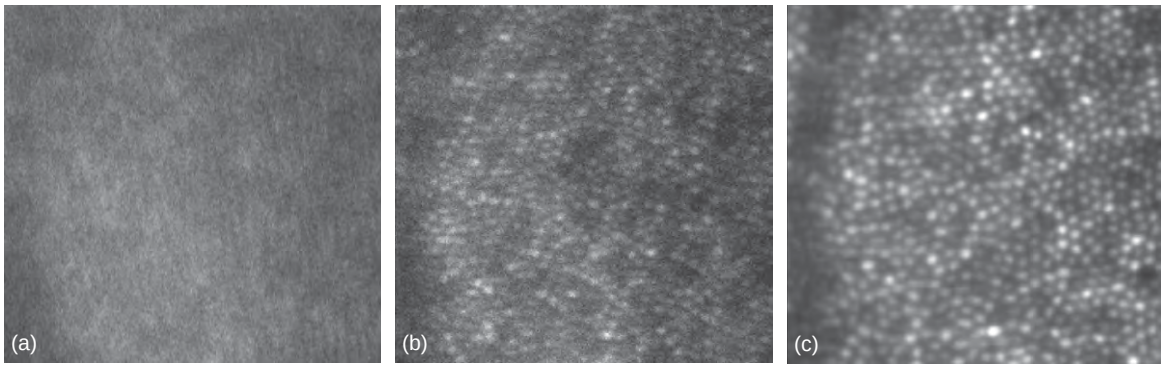

Figure 3 Adaptive optics and motion correction greatly improve the resolution of images of human cone mosaic. (a) Single frame of the reflectance image of the cone mosaic of a typical human eye at 1 degree of eccentricity imaged with all the aberrations of the eye, or (b) After the monochromatic aberrations of the eye were corrected with AO. (c) The summed frames of many images of the same cone mosaic with aberration and eye motion corrected with AO. The frames were registered before summing to correct for eye motion between frames, which increases the SNR over that obtained with single frames. The individual cones at this eccentricity are approximately 5 μm in diameter.

compact, approaching the light distribution produced by diffraction alone. Typically, one can achieve as much as an order of magnitude reduction in the rms wavefront error of a normal eye with this method. This provides a substantial improvement in image quality as shown in **Figure 3**.

Vision Correction with AO

One of the convenient features of AO correction is that the correction required to focus light onto the retina is the same as the correction required to image the retina at high resolution outside the eye. Many investigators have capitalized on the advantages of AO for vision correction as well as for retinal imaging. Correcting the higher order monochromatic aberrations (i.e., those other than defocus and astigmatism corrected by spectacles) produces a modest improvement in visual acuity and contrast sensitivity in the normal eye. The improvements can be dramatic in eyes with large amounts of higher-order aberrations such as those that suffer from keratoconus. The demonstration of these improvements in spatial vision with a deformable mirror has stimulated improvements in the control of laser ablation in refractive surgery as well as the fabrication of customized contact lenses that can correct higher-order aberrations. AO continues to be a valuable tool not only for correcting aberrations but also for generating specific patterns of aberrations so that their effects on vision can be studied conveniently. For example, it is possible to explore the design of contact lenses for presbyopes that increase the depth of field of the eye without the need to fabricate optical elements for each pattern one wishes to evaluate.

Retinal Imaging with AO

In retinal imaging, AO can be combined with almost any other imaging technology. David Williams' laboratory at the University of Rochester first demonstrated the value of a closed-loop AO system for retinal imaging, incorporating AO into a flood-illuminated system that acquired single snapshots of the retina with a resolution adequate to resolve cone photoreceptors near the fovea. Austin Roorda, then at the University of Houston, demonstrated that AO could also improve the resolution of the scanning laser ophthalmoscope (SLO). SLOs are potentially confocal devices and AO offers improvements in both axial and transverse resolutions. Moreover, AO improves the focus of the light on the confocal pinhole in front of detector, which increases the available signal. The AOSLO has a high lateral resolution of less than about 2 μm. The axial resolution of better than ~60 μm, though poor by OCT standards, is nonetheless adequate for some optical sectioning of the retina. AO has also improved the transverse resolution of OCT, allowing a resolution of less than 3 μm in all three spatial dimensions in the retina. AO systems can also be combined with other imaging modalities such as phase contrast microscopy, polarization imaging, or fluorescence microscopy.

Compensating for Eye Motion

In many cases, the signals acquired in a single video frame of an AOSLO are weak enough to warrant frame averaging to increase the signal-to-noise ratio (SNR) of the image (**Figure 4(a)**). Eye motion between frames, which is substantial in the high-magnification images of AO systems, must be corrected before frame averaging can be achieved. One correction method is to register successive frames with normalized cross-correlation, the benefit of which is shown in **Figure 3(c)**. However, it is not uncommon for single frames, such as the one shown in **Figure 4(a)**, to have inadequate SNR for this method. In the case, illustrated here of autofluorescence imaging by Jessica Morgan at the University of Rochester, there was typically less than

one photon for every 5 pixels in each frame. As shown in Figure 4(b), this problem can be solved by simultaneously recording infrared reflectance images of the cone mosaic at the same retinal location. Eye motion between frames can be reliably recovered from reflectance images of cone mosaic with an accuracy of one-fifth of the diameter of a foveal cone, and this information can be used to register the low SNR images as shown in Figure 4(b).

Eye movements can also produce warping artifacts within each frame. Austin Roorda and Scott Stevenson have developed methods in which the relative locations of local retinal features are compared across frames to compute and correct the eye movement warping within each frame as well as translation between frames. Figure 5 shows an AOSLO image motion before and after removing distortions from eye movements. Image motion after correction is reduced to a standard deviation of only 7 arcsec. David Arathorn at Montana State University, working in collaboration with Austin Roorda, has a fast software algorithm that can stabilize the retinal image in real time. This has very exciting applications for delivering light stimuli to single photoreceptors in both psychophysical and electrophysiological studies. Software registration approaches alone cannot address all the problems created by eye movements, particularly in AO instruments designed for routine clinical use where eye movements are much larger than the size of a single frame. In that case, successive frames do not share common features and cross-correlation cannot be

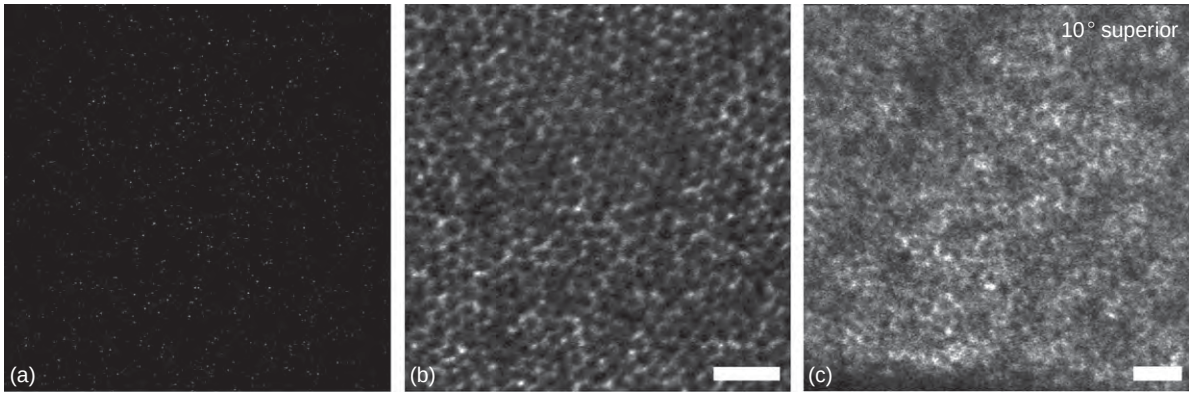

Figure 4 Dual registration improves the transverse resolution of autofluorescence images of the RPE mosaic. (a) Single frame of autofluorescence image of primate RPE mosaic. Because of the low SNR and photon density, the image does not have any apparent spatial structure. (b) 1000 frames of autofluorescence images of the same RPE mosaic shown in (a) summed with eye motion corrected using the dual-registration technique. The eye motion was calculated from reflectance images of the cone mosaic obtained simultaneously with the dim autofluorescence images, providing the translations necessary to register the autofluorescence images. The summed image reveals single cells in the RPE mosaic. (c) Autofluorescence image of human RPE mosaic at retinal eccentricity of 10 degrees. Bright regions in the images correspond to the accumulation of lipofuscin within the RPE cells. Dark regions correspond to the nuclei of RPE cells. Scale = 50 μm. Adapted from Morgan, J. I. Dubra, A., Wolfe, R., et al. (2009). In vivo autofluorescence imaging of the human and macaque retinal pigment epithelial cell mosaic. *Investigative Ophthalmology and Visual Science* 50: 1350–1359, Figure 5, with permission from Association for Research in Vision and Ophthalmology (Copyright 2009).

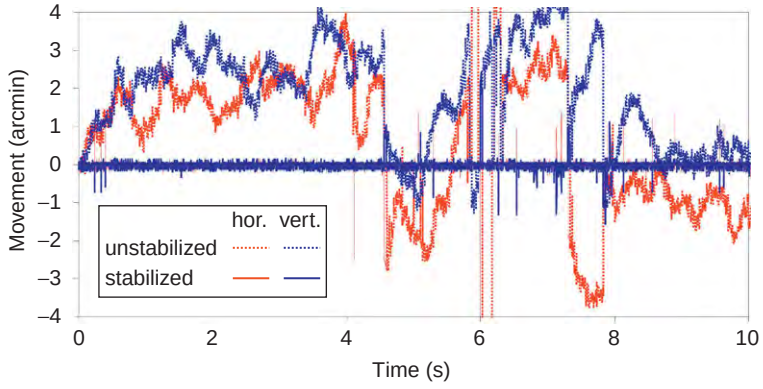

Figure 5 Eye motion in the AOSLO system before and after eye motion correction. Eye motion of a human subject within 10 s duration is captured at 480 Hz through AOSLO imaging (dotted red and blue lines: horizontal and vertical eye movements). After offline correction, the eye motion in the AOSLO images is reduced to flat lines (in red and blue: horizontal and vertical eye movement), with a standard deviation of 7 arcsec. This compares favorably with the most accurate methods to track the eye, having an accuracy that is roughly one-fourth of the diameter of the smallest foveal cones. Courtesy of A Roorda.

used. Dan Ferguson and Dan Hammer at Physical Sciences Incorporated have developed a hardware eye tracking system specifically for AO retinal imaging that complements the software approaches described above.

Imaging Cones

The ability to image cones at high resolution with AO opened a crucial window to examine both normal and abnormal processes in the retina. AO has made possible the first measurements of the antenna properties of single cones in the living human eye. Cone photoreceptors concentrate the image-forming light that passes through the pupil in the photopigment of the outer segment while simultaneously excluding stray light from sources that do not contribute to a sharp retinal image. This beneficial effect of the waveguide nature of cones gives rise to the psychophysical effect known as the Stiles and Crawford effect, in which the sensitivity of the eye declines dramatically for light beams that enter the margin instead of the center of the pupil. Austin Roorda and David Williams at the University of Rochester showed that nearby cones are remarkably well aligned with each other optically so that the angular tuning of a large group of cones is similar to the tuning function for a single cone.

Single cones imaged with AO in the living human eye show a striking variability in reflectance on a time scale of hours or days. The cause of this variability is unknown but could be related to the process of disc shedding in the cone outer segments. Don Miller at Indiana University has shown that, especially when the incoming light is highly coherent, there can be dramatic changes on very short time scales of 5–10 ms. These changes depend on the history of the cone's light exposure and provide an optical method to monitor to the response of cones to light. Kate Grieve and Austin Roorda have also reported increases in infrared reflectance following exposure to light that may provide an alternative method to monitor functional activity in single cones in the retina.

The Cone Mosaic and Color Vision

The first major scientific application of AO in the eye, undertaken at the University of Rochester, was to determine the organization of the human trichromatic cone mosaic. By combining AO retinal imaging with retinal densitometry, individual cones can be characterized by their sensitivity to long (L), middle (M), or short (S) wavelength light, according to the cone opsin it contains, as the example shown in **Figure 6**. Experiments using this method have shown that mosaic of L and M cones in the human are essentially randomly organized. It has been known for some time from indirect methods that the relative numbers of L and M cones varies greatly from eye to eye. AO revealed just how large this variation can be even across normal subjects where a variation in the order of 40-fold in L to M cone ratio has been observed. The human S cones are arranged randomly near the fovea but with slight tendency toward regular distribution, a tendency that is more pronounced in the macaque monkey.

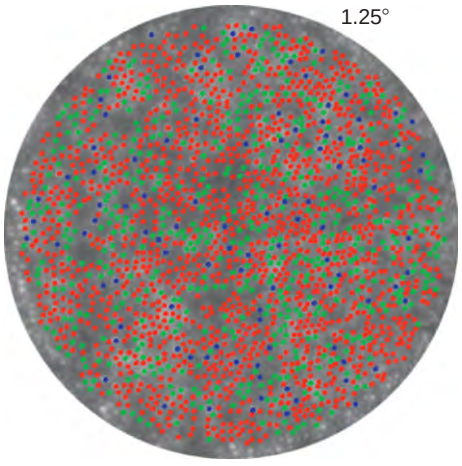

Figure 6 Cone mosaic of a human subject at a retinal eccentricity of 1.25 degree with normal color vision. Individual cones in each mosaic were categorized as L, M, or S cone types, using retinal densitometry, and false colored, respectively in red, green, and blue. Courtesy of O. Masuda.

The development of AO for the eye has also made it possible to study color vision in living human eyes in novel ways because it is now possible to deliver tiny flashes of light that are smaller than single cones. Heidi Hofer showed that near-threshold AO-delivered flashes of monochromatic light at a single wavelength produce a rich variety of color percepts. Indeed, for every subject she studied, the range of color experiences was too large to be explained by a simple model in which all cones of the same class produced the same color experience upon stimulation. David Brainard at the University of Pennsylvania has successfully described the range of color experiences in Heidi Hofer's data with a Bayesian model in which each cone feeds a specific circuit that provides the best estimate of the external stimulus given the local distribution of photon catches in the stimulated cone and its surrounding neighbors.

One of the most powerful applications of AO to date involves its use to characterize the topography of the cone mosaic in eyes in which the genotype is known. Until recently, it has been difficult to perform these studies with standard histological methods because of the difficulty in obtaining post-mortem tissue from eyes with specific and often rare genetic anomalies. Joe Carroll has shown that the cone mosaics of single gene dichromats appear completely normal despite the fact that they have two instead of the usual three cone photopigments (**Figure 7(b)**). On the contrary, dichromats with a specific polymorphism in one of the genes coding for a particular cone photopigment have a cone mosaic with numerous gaps corresponding to a spatially random loss of one class of cones (**Figure 7(c)**; also see **Figure 8** for another example).

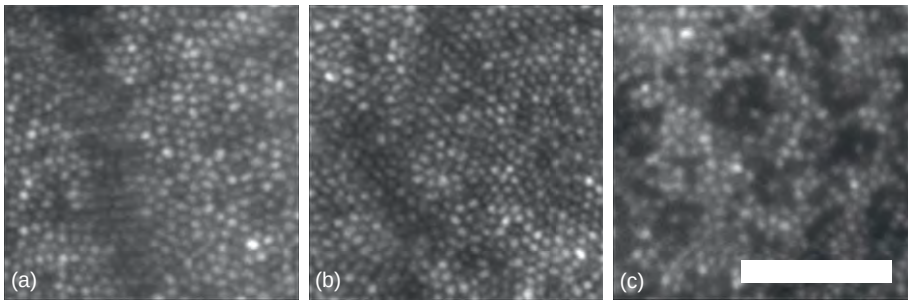

Figure 7 Pathological change of human cone mosaic in red or green dichromat. (a) Cone mosaic from a normal subject at approximately 1 degree of retinal eccentricity. (b) and (c) Cone mosaics at a similar eccentricity of two human subjects having red–green color-vision deficiency. In contrast to the normal cone mosaic in (a), the cone mosaic in (b) did not contain L cones, but appeared to have normal cone density. The cone mosaic in (c), did not contain M cones, and had reduced cone density with patches of functional loss of M cones. Scale = 50 μm for all panels. Reproduced from Carroll, J. Gray, D. C., Roorda, A., Williams, D. R. (2005). Recent advances in retinal imaging with adaptive optics. *Optics and Photonics News* 16: 36–42, Figure 3, with permission from Optical Society of America (Copyright 2005).

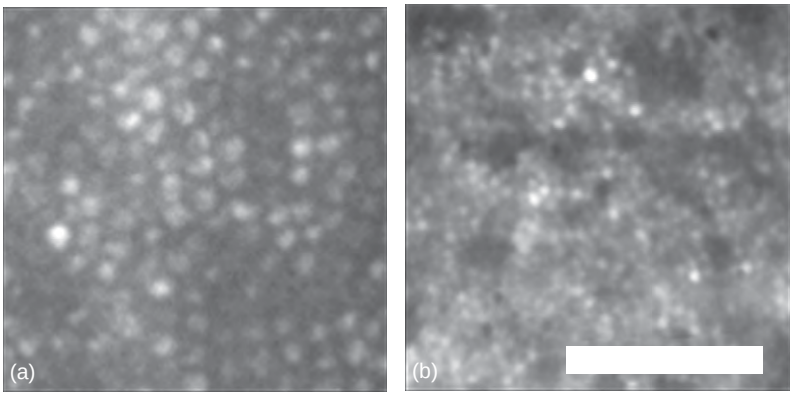

Figure 8 Pathological change of human cone mosaic in rod monochromat. (a) Cone mosaic from a normal subject at approximately 4 degrees of retinal eccentricity. (b) Possible rod mosaic of one subject who was a congenital achromat. The reason why the photoreceptors in (b) were believed to be rods is that their density and size match with the anatomical characteristic of the rod mosaic at this eccentricity, and differ greatly from the normal cones in (a). Scale = 50 μm for all panels. Reproduced from Carroll, J., Gray, D. C., Roorda, A., Williams, D. R. (2005). Recent advances in retinal imaging with adaptive optics. *Optics and Photonics News* 16: 36–42, Figure 3, with permission from Optical Society of America (Copyright 2005).

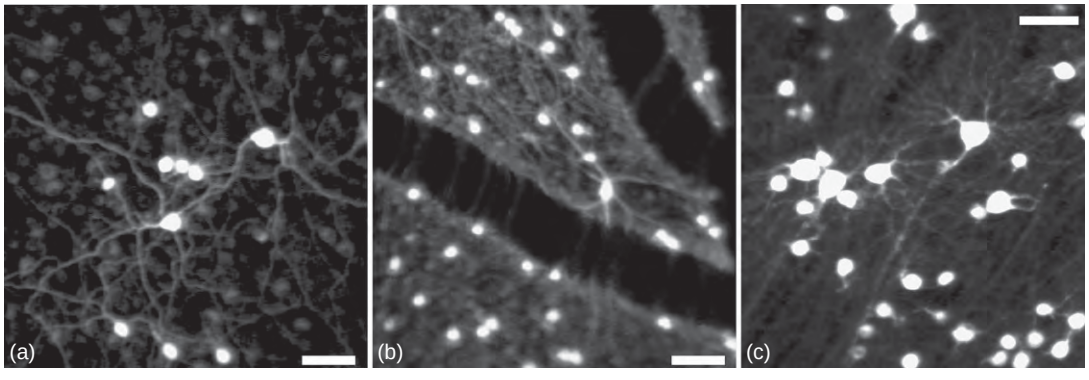

Figure 9 Fluorescence AOSLO images of primate retinal ganglion cells *in vivo.* (a–c) Fluorescence AOSLO imaging revealed the morphology of retinal ganglion cells labeled with fluorophore (rhodamine dextran) in living monkey eye. The transverse resolution of the images is fine enough to resolve the individual dendrites. The fluorophore was introduced into the ganglion cells through retrograde labeling through injections in the lateral geniculate nucleus (LGN). Scale = 50 μm for all panels. (a,c) Reproduced from Gray, D. C., Wolfe, R., Gee, B. P., et al. (2008). In vivo imaging of the fine structure of rhodamine-labeled macaque retinal ganglion cells. *Investigative Ophthalmology and Visual Science* 49: 467–473, Figures 1 and 5, with permission from Association for Research in Vision and Ophthalmology (Copyright 2008).

Imaging Retinal Pigment Epithelium

The retinal pigment epithelium (RPE) lies immediately behind the photoreceptors and plays several critical roles in maintaining their function. RPE cell damage is implicated in many retinal degenerative diseases such as age-related macular degeneration, retinitis pigmentosa, and Stargardt's disease. The ability to image these cells in the living retina and to track changes in them over time may prove valuable for understanding both normal RPE function and retinal disease. In AOSLO reflectance imaging, the more reflective photoreceptor mosaic normally obscures RPE cells. Occasionally, RPE cells can be seen in patients with retinal degenerative diseases, such as cone–rod dystrophy, where the overlying photoreceptors are absent. However, it has recently become possible to image the RPE mosaic in living human eyes in which the photoreceptor layer is intact, by taking advantage of the autofluorescence properties of lipofuscin in the RPE as shown in **Figure 4(c)**. Statistical characterization of the RPE mosaic, for example, packaging arrangement and cell density across eccentricity, in both normal subject and patients may eventually prove to be valuable for the clinical diagnosis of earlier stages of retinal degenerative disease. It may ultimately prove possible to use AO to image subcellular structures in RPE cells

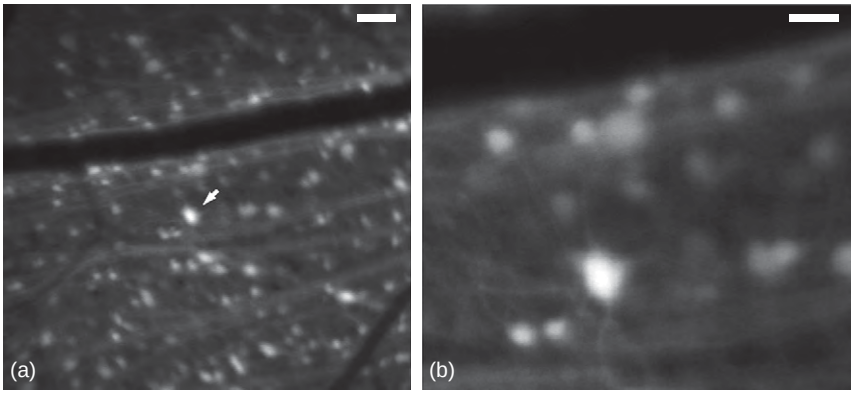

Figure 10 Fluorescence AOSLO images of rat retinal ganglion cells *in vivo.* (a) Fluorescence AOSLO image of rat retina with ganglion cell expressing EGFP. Scale = 50 μm. Image was taken at a large field of view (FOV). Gene encoding EGFP was delivered to ganglion cells through an AAV2 viral vector administrated intravitreally. The ganglion cell indicated by the white arrow was shown in (a) at higher magnification. Image at this view reveals the dendritic morphology of the cell. Such images could provide basis for morphological classification *in vivo*. Scale = 20 μm.

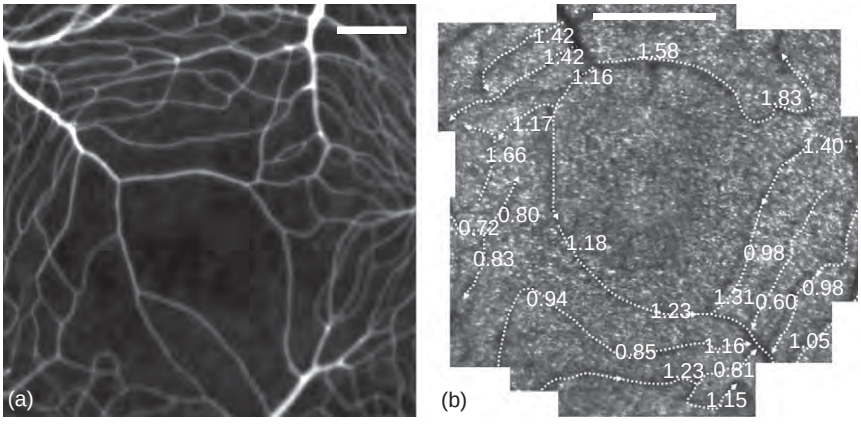

Figure 11 AOSLO images of retinal vasculature. (a) Retinal vasculature in the macular region in primate eye imaged by fluorescence AOSLO in combination with fluorescence angiography. Scale = 150 μm. (b) Direction of blood flow and leukocyte velocity within the capillaries of the macular region in human eye calculated from reflectance AOSLO images. Movement of discrete leukocytes was detected through an image-processing algorithm. The velocities of the leukocytes labeled on the images were in mm s^{-1}. Scale = 1 degree. and/or to monitor changes in RPE cells over time. Jessica Morgan has already shown that it is possible to use AO to track the time course of lipofuscin autofluoresence bleaching and RPE damage following exposure to bright light.

Imaging Retinal Ganglion Cells

The retinal image is conveyed to the brain through an array of 17 or more parallel ganglion cell pathways in the primate. We know remarkably little about the functional significance of many of these morphologically distinct ganglion cell classes. One of the major impediments to learning more about them is that the less numerous cells are difficult to target with a microelectrode that is capable of recording from only one single cell at a time. The development of optical methods to record from many ganglion cells simultaneously in the intact living eye could greatly accelerate our understanding of ganglion cell function. There are numerous technical hurdles to overcome before this is feasible, but AO retinal imaging has now solved an important one: it is now possible to image ganglion cells along with some of their subcellular structure *in vivo* in nonhuman primate retina. This capability may also eventually prove useful in the study of diseases such as glaucoma, in which blindness results from the death of ganglion cells. New ways to image ganglion cells at a microscopic spatial scale may lead to earlier diagnosis and delivery of therapy.

Dan Gray, working in the AO group at the University of Rochester, imaged the dendritic morphology of macaque ganglion cells retrogradely labeled with fluorescent dye (rhodamine dextran) *in vivo*, with a transverse resolution of 1.6 μm (characterized as full width at half maximum;

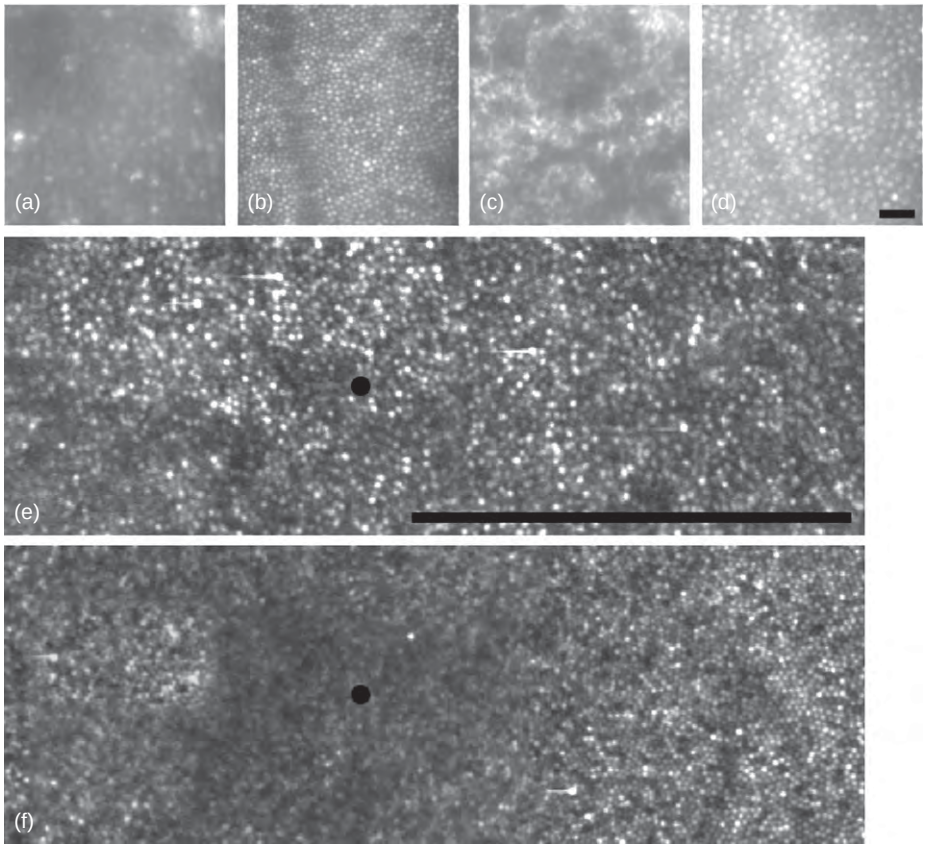

Figure 12 Structural change of cone mosaic of patients having retinal degenerative diseases. (a) and (c) Cone mosaics of a patient having cone–rod dystrophy compared, respectively with (b) and (d) cone mosaics of normal subjects at matched retinal eccentricity. For the patient, severe cone loss was apparent in (c), while in (a), cones still form a continuous mosaic, but the cone density is much decreased and cone size is much larger. Scale = 25 μm for panels (a–d). (e) and (f) Foveal cone mosaics of patients having disease caused by mitochondrial DNA (mtDNA) mutation. The two patients were affected by the disease at different severity. Cone mosaic of the less-affected patient in (f) showed normal cone spacing, while the cone mosaic of the more-affected patient in (e) showed increased cone size and cone spacing. The preferred fixation point of each subject is visualized as dark dots in (e) and (f). Scale = 1 degree for both panels. (a–d), Reproduced from Wolfing J.I., Chung, M., Carroll, J., et al. (2006). High-resolution retinal imaging of cone-rod dystrophy. *Ophthalmology* 113: 1014–1019, Figure 4, with permission from the American Academy of Ophthalmology, Elsevier Ltd (2006). (e,f) Adapted from Yoon, M.K., Roorda, A., Zhang Y., et al. (2009). Adaptive optics scanning laser ophthalmoscopy images in a family with the mitochondrial DNA T8993C mutation. *Investigative Ophthalmology and Visual Science* 50: 1838–1847, Figure 4, with permission from Association for Research in Vision and Ophthalmology (Copyright 2009).

Figure 9). Although in some cases, they were able to distinguish ganglion cell bodies at different depths in the retina, which is a valuable way to distinguish different classes, the depth resolution is modest, about 115 μm. Viral vector (e.g., AAV2)-mediated-gene delivery is another promising approach for delivering fluorophores (e.g., EGFP) to single cells. It requires a simpler intravitreal rather than an intracranial injection and can produce fluorescence that is essentially permanent in each cell that is transduced by the virus. Melissa Geng and Jason Porter at University of Rochester in collaboration with John Flannery at UC Berkeley combined this method with fluorescence AOSLO in the living rat eye (Figure 10). Another possibility is to use transgenics to create an animal whose cells express a fluorophore. Charles Lin and colleagues used this method to image microglia cells in living mouse eye. Work is underway to extend the viral vector method to nonhuman primate and to achieve expression of activity-dependent fluorophores such as G-CaMP (a green flurescent protein calcium probe) in single ganglion cells. These methods may ultimately allow AO retinal imaging to monitor the functional responses of ganglion cells.

Imaging Retinal Vasculature

Many retinal diseases, such as diabetic retinopathy or wet macular degeneration, have important effects on the retinal vascular structure and blood flow. AO combined with fluorescein angiography allows imaging of even the fine structure of the retinal capillary bed (Figure 11(a)). Austin Roorda, then at the University of Houston, showed that AO retinal imaging could image leukocyte motion in the smallest retinal capillaries without the need for fluorescein (Figure 11(b)). Steve Burns at University of Indiana has even succeeded in imaging the flow of erythrocytes by tracking movement of single erythrocytes in successive images of a single scan line superimposed on an oriented parallel to a small vessel.

Imaging Retinal Disease

The use of an AO to image retinal disease is one of the most exciting and also one of the most challenging applications. AO is at its best when the pupil is completely dilated and the ocular media are clear and scatter free. The challenge of imaging retinal disease lies in the fact that patients often have small pupils, poor fixation, and/or large amounts of light scatter. Despite these limitations, progress has been made in the deployment of AO in the clinical arena.

For many retinal degenerative diseases, the structural changes of the cone mosaic and the RPE mosaic of patients have been impressively documented *in vivo*. The diseases affecting cones include not only those relevant

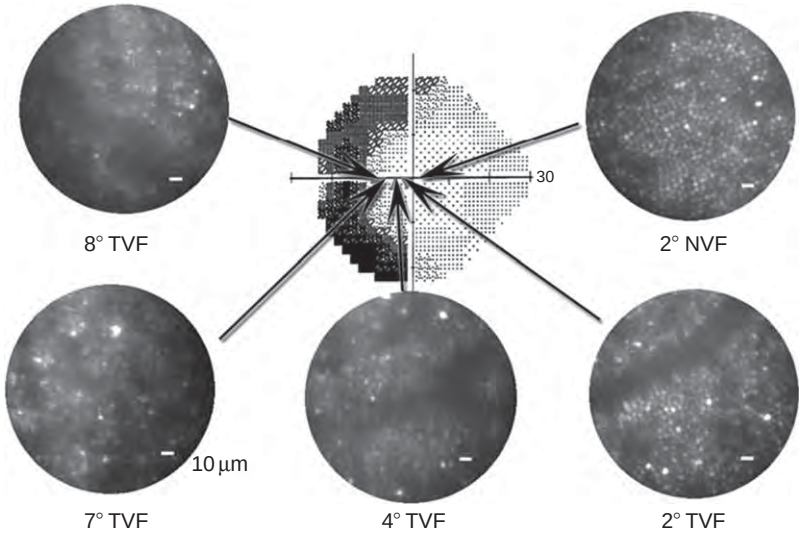

Figure 13 Correspondence between structural changes in the cone mosaic and functional measurement of visual sensitivity. Measured visual field sensitivity of a patient having rod–cone dystrophy is shown in the upper middle panel. The rest of the panels show the cone mosaics from retinal regions corresponding to locations in the visual field map. In those cone mosaic images, the darker regions indicate areas where cones are not reflecting light as in normal retina. From these images, it is not possible to determine if these dark regions represent loss of cones or structurally altered cones, hence became less effective in waveguiding and reflecting light. The extent of these dark regions strongly correlated with the level of visual sensitivity. The more extensive the dark regions (i.e., reduced cone density) were the lower the visual function (e.g., the comparison between the left and right panels). A strong positive relationship was found between the cone density and the level of visual sensitivity in patients with various types of retinal dystrophy. Adapted from Choi, S.S., Doble, N., Hardy, J.L., et al. (2006). In vivo imaging of the photoreceptor mosaic in retinal dystrophies and correlations with visual function. *Investigative Ophthalmology and Visual Science* 47: 2080–2092, Figure 5, with permission from Association for Research in Vision and Ophthalmology (Copyright 2006).

to color blindness mentioned previously, but also more common ones such as retinitis pigmentosa and photoreceptor dystrophy. As per the examples shown in **Figure 12**, cone loss can occur as a patchy, random dropout of cones that otherwise appear normal. In other cases, presumably when the mosaic has had the opportunity to remodel, the mosaic completely tiles the retina but the cones are larger and their density is reduced. Because the structure of the cone mosaic can be documented in living eyes, the specific structure in individual eyes can be correlated with the genotype of the patient, and also with functional measurements such as Humphrey visual field sensitivity, multifocal ERG, and contrast sensitivity (**Figure 13**).

Retinal degenerative diseases affect many other retinal structures, besides photoreceptors and RPE. As described in this article, AO imaging has enabled the accumulation of normative data of many retinal structures in both human and nonhuman primates, as well as data from animal disease models. These data will advance the clinical investigation of retinal degenerative disease. For example, the structure of lamina cribrosa was imaged in both normal primate eye and eye with experimentally induced glaucoma. Ultimately, AO imaging may play a role in the diagnosis of glaucoma and other retinal diseases in clinical practice.

Alternative Visual Cycles in Müller Cells

G H Travis, UCLA School of Medicine, Los Angeles, CA, USA

Glossary

Müller cell – A glial cell in the vertebrate retina that spans from the vitreal surface to the external limiting membrane, with apical processes that extend into the interphotoreceptor matrix. These cells perform multiple functions in the retina including the processing of visual retinoids.

Opsin visual pigment – A member of the G-protein-coupled receptor superfamily that functions as the light receptor in rods and cones. These pigments represent a complex between an opsin protein and a visual chromophore (see below).

Outer segment – An elongated light-sensitive structure attached to the connecting cilium of rod and cone photoreceptors. The rod outer segment in humans comprises a stack of approximately 1000 membranous disks. These disks are loaded with rhodopsin or cone opsin visual pigments.

Rpe65 – An abundant, membrane-associated protein in retinal pigment epithelium cells that functions as a retinoid isomerase. In particular, Rpe65 catalyzes the conversion of an all-*trans*-retinyl ester to 11-*cis*-retinol and a free fatty acid.

Visual chromophore – The light-absorbing molecular species in an opsin protein. The most common visual chromophore in vertebrates is 11-*cis*-retinaldehyde, which isomerizes to all-*trans*-retinaldehyde upon absorption of a photon.

Vision in vertebrates is provided by two types of photoreceptor cells, rods and cones. Rods mediate vision in dim light while cones mediate high-resolution color vision in bright light. Approximately 95% of photoreceptors in the human retina are rods. Nonetheless, cones are far more important for vision in humans. With the advent of artificial lighting, humans spend much of the time under conditions where the rod photoresponse is saturated and vision is mediated by cones. Both rods and cones contain a light-sensitive structure called the outer segment (OS) comprising a stack of densely packed membranous disks. These disks are packed with rhodopsin or cone-opsin visual pigment. The light-absorbing chromophore in most opsin pigments is 11-*cis*-retinaldehyde (11-*cis*-RAL). Absorption of a photon induces its isomerization to all-*trans*-retinaldehyde (all-*trans*-RAL), which activates the opsin pigment and stimulates the visual transduction cascade. After a brief period of activation, the pigment dissociates to yield free all-*trans*-RAL and apo-opsin, which is no longer light sensitive. The pigment is regenerated by recombination of apo-opsin with another 11-*cis*-RAL. To sustain light sensitivity, all-*trans*-RAL released by bleached opsin pigments is converted back to 11-*cis*-RAL by a multi-step enzyme pathway called the visual cycle (**Figure 1**).

Visual Cycle in Retinal Pigment Epithelium Cells

All but the first step of the visual cycle takes place within cells of the retinal pigment epithelium (RPE), an epithelial monolayer adjacent to photoreceptor OS. In brief, all-*trans*-RAL is reduced by all-*trans*-retinol dehydrogenase (all-*trans*-RDH) in rod and cone OS to all-*trans*-retinol (all-*trans*-ROL) or vitamin A. The all-*trans*-ROL is released by the OS into the extracellular space or interphotoreceptor matrix (IPM), where it is bound to interphotoreceptor retinoid-binding protein (IRBP). The all-*trans*-ROL is taken up by apical processes of RPE cells, where it binds to cellular retinol binding protein type-1 (CRBP1). Holo-CRBP1 is the substrate for lecithin:retinol acyl transferase (LRAT), which transfers a fatty acid from phosphatidylcholine in internal membranes to the all-*trans*-ROL. The resulting fatty-acyl ester of all-*trans*-ROL (all-*trans*-RE) is the substrate for Rpe65-isomerase. Rpe65 catalyzes hydrolysis of the carboxylate ester and utilizes the energy released for isomerization of all-*trans*-ROL to 11-*cis*-retinol (11-*cis*-ROL). The final catalytic step in the visual cycle is oxidation of 11-*cis*-ROL, by one of several 11-*cis*-ROL dehydrogenases (11-*cis*-RDH) to 11-*cis*-RAL. Both 11-*cis*-ROL and 11-*cis*-RAL are bound to cellular retinaldehyde binding protein (CRALBP) in the RPE. The 11-*cis*-RAL is released by the apical RPE to the IPM, where it binds IRBP. IRBP carries the 11-*cis*-RAL to the photoreceptor OS, where it is taken up and recombines with apo-opsin to reform a rhodopsin or cone-opsin pigment.

A Role for Müller Cells in Visual Pigment Regeneration

Evidence suggests that Müller glial cells in the retina also participate in the processing of visual retinoids. Müller cells span nearly the full thickness of the retina. The apical microvilli of Müller cells extend into the IPM and hence are well situated to exchange visual retinoids

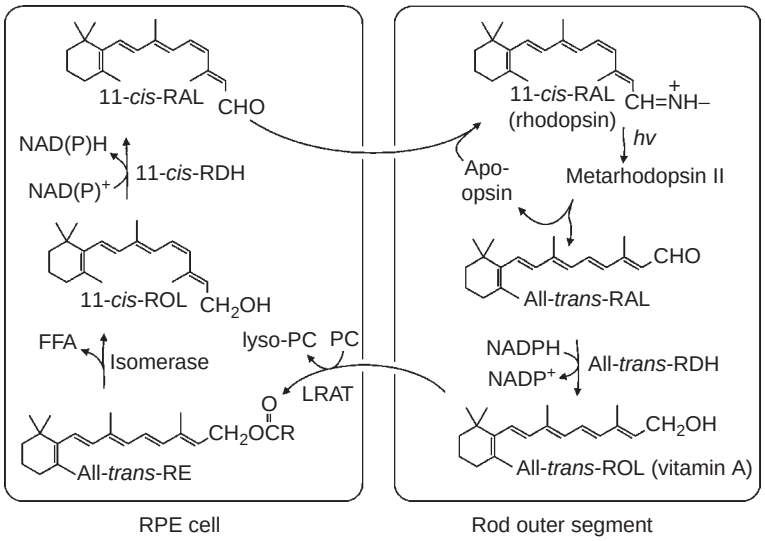

Figure 1 Visual cycle for rhodopsin regeneration. Absorption of a photon (*hv*) by a rhodopsin pigment molecule induces isomerization of 11-*cis*-RAL to all-*trans*-RAL, which converts the pigment to its active metarhodopsin II state. After deactivation, the pigment dissociates to yield apo-opsin and free all-*trans*-RAL. The all-*trans*-RAL is reduced to all-*trans*-ROL by one or more all-*trans*-RDHs that use NADPH as a co-factor. The all-*trans*-ROL is released by the OS to the IPM and is taken up by the apical RPE where it is esterified by LRAT to yield an all-*trans*-RE. The all-*trans*-RE is isomerized and hydrolyzed by Rpe65 to yield 11-*cis*-ROL. The 11-*cis*-ROL is oxidized by one or more 11-*cis*-RDHs to yield 11-*cis*-RAL chromophore. The 11-*cis*-RAL is released by the RPE into the IPM where it binds to IRBP. Finally, the 11-*cis*-RAL is delivered to the OS where it re-combines with apo-opsin to form a new visual pigment.

with rod and cone OS, similar to the apical microvilli of RPE cells. Importantly, Müller cells contain several proteins involved in the processing of visual retinoids. These include (1) CRALBP, (2) RPE-retinal guanine-nucleotide-binding protein (G-protein) coupled receptor (RGR-opsin), a non-photoreceptor opsin that effects light-dependent regulation of the visual cycle in RPE cells, (3) CRBP1, and (4) retinol dehydrogenases types 10 and 11. Müller cells neither express Rpe65 nor LRAT, which are both present in RPE cells. Therefore, Müller cells do not simply duplicate the function of RPE cells in the regeneration of visual chromophore.

A Second Source of Chromophore for Cones

Several lines of evidence suggest that an alternate source of chromophore precursor is available to cones but not rods. When frog retinas were separated from the RPE, cone opsins, but not rhodopsin, regenerated spontaneously after a photobleach. After photobleaching, isolated salamander cones recovered sensitivity with the addition of either 11-*cis*-ROL or 11-*cis*-RAL, while isolated rods only recovered sensitivity with the addition of 11-*cis*-RAL. Müller cells in primary culture were shown to take up all-*trans*-ROL and synthesize 11-*cis*-ROL, which they secreted into the medium. Salamander cones were shown to dark-adapt and regenerate visual chromophore in isolated retinas separate from the RPE. The intrinsic capacity of cones to recover sensitivity and regenerate visual chromophore in salamander retinas was lost after exposure to a selective Müller-cell toxin (α-aminoadipic acid), suggesting that Müller cells play a role in these processes.

Functional Differences between Rods and Cones

Although morphologically similar, rods and cones differ greatly in sensitivity, dynamic range, and speed of the photoresponse. Rods are single-photon detectors and show saturation of the photoresponse under relatively dim background illumination, producing 500 or more photoisomerizations per second. At saturation, all cyclic guanosine monophosphate (cGMP)-gated cation channels are closed and the rod no longer responds to light. Cones, on the other hand, are 100-fold less sensitive than rods but still exhibit a photoresponse to a light flash under bright background illuminations producing up to 10^6 photoisomerizations per second. The response kinetics of cones is also several-fold faster than rods. These disparities reflect differences in the properties of rhodopsin and the cone-opsin pigments. Rhodopsin is exceedingly quiet, with a spontaneous activation rate in the dark of one thermal isomerization every 2000 years. Cone opsins are much noisier than rhodopsin for two reasons. First, the spontaneous isomerization rate of cone opsin is 10 000-fold higher than of rhodopsin. Second, 11-*cis*-RAL spontaneously dissociates from cone-opsins. A dark-adapted

red cone contains approximately 10% apo-cone-opsin due to spontaneous dissociation of chromophore. In contrast, 11-*cis*-RAL combines almost irreversibly with apo-rhodopsin in rods. Apo-opsin, which results from dissociation of 11-*cis*-RAL, activates the transduction cascade, producing the phenomenon of dark light. These effects contribute to the noisy background of cones and explain their much lower sensitivity than rods.

Although the rod response is saturated in bright light, photon capture by rhodopsin continues unabated. Thus, in a rod-dominant retina under daylight conditions, the vast majority of photoisomerization events contributes nothing to useful vision. Under these circumstances, cones must compete with rods for the limited supply of 11-*cis*-RAL. The reversible binding of 11-*cis*-RAL to apo-cone-opsins and its irreversible binding to apo-rhodopsin confers a tendency of rods to steal chromophore from cones. This tendency aggravates the competition between rods and cones for limited chromophore.

An Alternate Retinoid Isomerase Activity in Cone-Dominant Retinas

Studies on the biochemistry of visual pigment regeneration in cone-dominant retinas suggest a mechanism whereby cones may escape competition from rods for visual chromophore. Experiments were performed on separated retinas and RPE from mice and cattle, as model rod-dominant species, and from chickens and ground squirrels, as model cone-dominant species. Measurement of endogenous retinoids showed that the rod-dominant species contain high levels of all-*trans*-retinyl esters (REs) in the RPE but no detectable REs in the retina. Cone-dominant species contain REs in both the RPE and retina, with predominantly 11-*cis*-REs in the retina. The activities of retinoid-processing enzymes were measured by incubating total homogenates or microsomes prepared from RPE or retinas with all-*trans*-ROL, then assaying for synthesis of new retinoids by high-performance liquid chromatography (HPLC). Incubation of RPE homogenates with all-*trans*-ROL resulted in rapid synthesis of all-*trans*-REs, due to the activity of LRAT. Only after accumulation of all-*trans*-REs was 11-*cis*-ROL synthesis detected, due to the activity of Rpe65. This profile of retinoid synthesis was observed with RPE homogenates from both rod- and cone-dominant species.

A strikingly different profile was observed when retina homogenates from cone-dominant chicken or ground squirrels were incubated with all-*trans*-ROL under similar conditions. Addition of all-*trans*-ROL resulted in rapid synthesis of 11-*cis*-REs and 11-*cis*-ROL, with negligible initial synthesis of all-*trans*-REs. Addition of palmitoyl coenzyme A (palm CoA) to the assay mixture increased synthesis of 11-*cis*-REs, again with minimal initial synthesis of all-*trans*-REs. Synthesis of 11-*cis*-ROL and 11-*cis*-REs from all-*trans*-ROL without prior formation of all-*trans*-REs suggests that the mechanism of retinoid isomerization is different in retina versus RPE. Instead of converting an all-*trans*-RE to 11-*cis*-ROL and a free fatty acid, as catalyzed by Rpe65 in RPE cells, cone-dominant retinas appear to catalyze the direct conversion of all-*trans*-ROL to 11-*cis*-ROL. This energetically unfavorable reaction appears to be driven by mass action through secondary esterification of the 11-*cis*-ROL product. Here, the energy of isomerization is indirectly supplied by hydrolysis of the thio-ester in palm CoA versus hydrolysis of the carboxyl ester in phosphatidylcholine, as catalyzed by Rpe65. The isomerase machinery in retinas may therefore involve two catalytic activities, as depicted in Figure 2. One is an isomerase that catalyzes the passive interconversion of all-*trans*-ROL and 11-*cis*-ROL. This enzyme has not yet been identified. The second is a palm-CoA-dependent RE synthase. Several proteins with acyl CoA:retinol acyltransferase (ARAT) activity have been described. At least one of these, diacylglycerol acyltransferase type-1 (DGAT1), is expressed in the retina.

11-*cis*-ROL Dehydrogenase Activity in Cones but Not in Rods

As discussed above, cones can regenerate visual pigments and restore light sensitivity with the addition of either 11-*cis*-RAL or 11-*cis*-ROL, while rods can only regenerate rhodopsin pigment and recover sensitivity with addition of 11-*cis*-RAL. Since 11-*cis*-RAL is the visual chromophore for both cone and rod pigments, these observations suggest that cones, but not rods, express an 11-*cis*-RDH activity that oxidizes 11-*cis*-ROL to 11-*cis*-RAL. Robust nicotinamide adenine dinucleotide phosphate (NADPH)-dependent 11-*cis*-RDH activity has been detected in cone

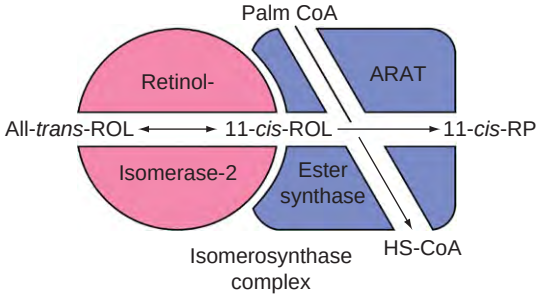

Figure 2 Proposed isomerase-2 complex in Müller cells. The isomerase in Müller cells appears to catalyze direct conversion of all-*trans*-ROL to 11-*cis*-ROL. This energetically unfavorable reaction appears to be driven by mass action through secondary esterification of 11-*cis*-ROL to an 11-*cis*-RE. This synthase uses palm CoA as an acyl donor, and hence is a type of ARAT. The isomerase-2/ARAT complex has been named isomerosynthase to denote its activities. Neither isomerase-2 nor its ARAT partner has been identified to date.

but not rod in photoreceptors. Reduction of all-*trans*-RAL to all-*trans*-ROL in bleached photoreceptors requires NADPH, and hence is an energy-consuming process. Oxidation of an 11-*cis*-ROL to 11-*cis*-RAL generates an NADPH reducing-equivalent. Since reduction of all-*trans*-RAL and oxidation of 11-*cis*-ROL occurs with 1:1 stoichiometry in a cone that is utilizing 11-*cis*-ROL as a chromophore precursor, the presence of reciprocal $NADP^+$/NADPH-specific dehydrogenases in cones affords a self-renewing supply of dinucleotide substrate at no energy cost to the cell. Eliminating the need for energy-dependent synthesis of NADPH may remove the metabolic bottleneck of all-*trans*-RAL-reduction in cones at high rates of photoisomerization.

An Alternate Visual Cycle that Mediates Pigment Regeneration in Cones

The observations outlined above can be explained by the hypothesized alternate visual cycle shown in Figure 3. According to this model, all-*trans*-ROL-isomerase (isomerase-2) and the 11-*cis*-ROL-specific ARAT are in Müller cells, which also express the 11-*cis*-ROL and 11-*cis*-RAL binding-protein, CRALBP. The major source of substrate for isomerase-2 is all-*trans*-ROL released by rods and cones during light exposure. Isomerization of all-*trans*-ROL to 11-*cis*-ROL and subsequent esterification of 11-*cis*-ROL to 11-*cis*-REs are probably limited by substrate availability. It has been shown that apo-CRALBP stimulates 11-*cis*-RE-hydrolase (11-*cis*-REH) in RPE cells. These observations suggest a regulatory mechanism for the proposed visual cycle: in the dark-adapted state, cones contain fully regenerated opsin pigment and hence do not use 11-*cis*-ROL. CRALBP is saturated with 11-*cis*-ROL and the level of 11-*cis*-REs are high in Müller cells. Both isomerase-2 and 11-*cis*-RE-synthase are inactive due to the absence of available substrate. With the onset of light and the bleaching of photopigments, cones begin to take up 11-*cis*-ROL. This results in desaturation of CRALBP, activation of 11-*cis*-REH, and mobilization of 11-*cis*-RE-stores in Müller cells. Rods and cones begin to release all-*trans*-ROL, which permits replenishment of 11-*cis*-REs through activation of isomerase-2 and 11-*cis*-RE-synthase. This pathway becomes progressively more active with increasing light intensity, availability of all-*trans*-ROL substrate, and consumption of the 11-*cis*-ROL product by cones.

A New Role for IRBP

IRBP is the major extracellular retinoid-binding protein in retinas. It has been suggested that the primary function of IRBP is to bind all-*trans*-ROL and 11-*cis*-RAL during translocation of these retinoids between OS and the RPE. However, loss of IRBP in $irbp^{-/-}$ mice has only a mild effect on rhodopsin regeneration. Might IRBP play another role? The endogenous ligands of IRBP have been studied.

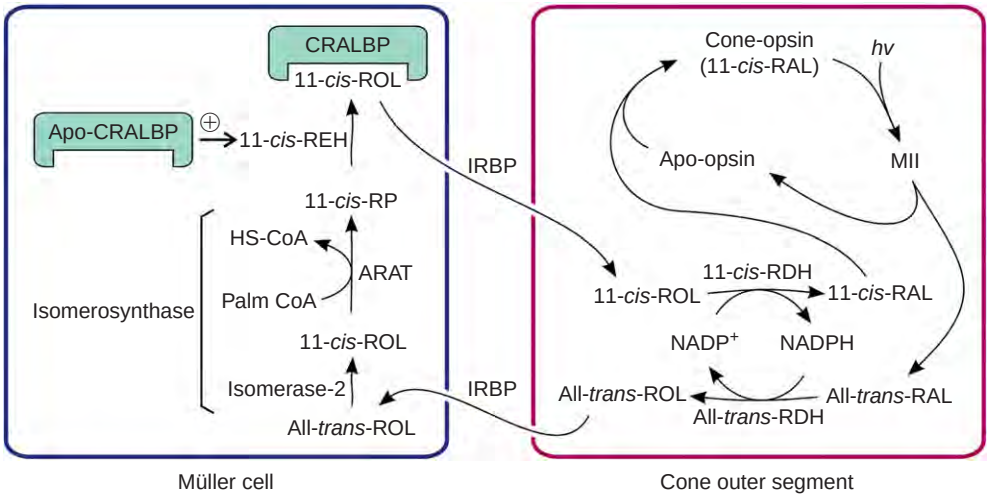

Figure 3 Proposed alternate visual cycle in Müller cells. Absorption of a photon (*hv*) induces 11-*cis* to all-*trans* isomerization of the retinaldehyde chromophore, resulting in activated opsin (MII) inside a cone outer segment. Decay of MII releases all-*trans*-RAL, which is reduced to all-*trans*-ROL by one or more NADPH-dependent all-*trans*-RDHs. The all-*trans*-ROL is released to the IPM where it binds IRBP and is carried to a Müller cell apical process. After uptake into the Müller cells, the all-*trans*-ROL is isomerized by isomerase-2 and esterified by ARAT to yield an 11-*cis*-RE (11-*cis*-RP). Müller cells also contain CRALBP, which binds 11-*cis*-ROL but not all-*trans*-retinol. 11-*cis*-REH is activated by apo-CRALBP to hydrolyze the 11-*cis*-RE, yielding 11-*cis*-ROL. Binding of 11-*cis*-ROL by CRALBP prevents its back-isomerization to all-*trans*-ROL. The 11-*cis*-ROL is released by CRALBP to IRBP in the IPM, where it is carried back to the cone OS. Within the cone, an $NADP^+$-dependent 11-*cis*-RDH oxidizes the 11-*cis*-ROL to 11-*cis*-RAL, which re-combines with apo-opsin to regenerate a new, light-sensitive cone pigment. The reciprocal reduction of all-*trans*-RAL and oxidation of 11-*cis*-ROL results in a self-renewing supply of NADP-co-factor at all rates of photoisomerization and no energy cost to the cell.

In light-adapted frog and bovine retinas, IRBP contains higher levels of 11-*cis*-ROL than 11-*cis*-RAL, in addition to all-*trans*-ROL. Moreover, IRBP immunoreactivity was found in association with cone but not rod OS. These observations suggest that the critical function of IRBP may not be exchange of all-*trans*-ROL and 11-*cis*-RAL between rods and RPE cells, as previously assumed, but rather exchange of all-*trans*-ROL and 11-*cis*-ROL between cones and Müller cells.

Alternate Visual Cycle in Rod-Dominant Species

Although clearly present in cone-dominant retinas, the evidence for an alternate visual cycle in Müller cells of rod-dominant species is less compelling. Endogenous 11-*cis*-REs and isomerase-2 catalytic activity were undetectable in homogenates from rod-dominant bovine and mouse retinas. The absence of 11-*cis*-retinoids in *rpe65*$^{-/-}$ mice has also been put forth as further evidence against the Müller-cell pathway in this species. However, this observation is difficult to interpret since *rpe65*$^{-/-}$ photoreceptors contain no visual chromophore, hence all-*trans*-ROL, the substrate for the alternative visual cycle, is not released following light exposure. The effective Michaelis constant (K_m) of all-*trans*-ROL for 11-*cis*-RE-synthesis by chicken retina homogenates is 13.5 μM. Thus, even in chickens, the alternate visual cycle is only active under conditions that yield high concentrations of all-*trans*-ROL. Recently, isolated mouse retinas were photobleached and analyzed physiologically for recovery of rod and cone light sensitivity. Cone sensitivity and the cone photoresponse recovered in these retinas despite the absence of RPE cells, while rod sensitivity and the rod response were dramatically attenuated. These physiological observations argue for existence of the alternate visual cycle in mouse retinas. The role of this pathway in rod-dominant retinas should be resolved upon identification of the proteins responsible for isomerase-2 activity, and measurement of their expression levels in rod- and cone-dominant retinas.

Amblyopia

D M Levi, University of California, Berkeley, Berkeley, CA, USA

Glossary

Anisometropia – A condition in which the two eyes have unequal refractive power so that the two eyes are in different states of myopia.
Astigmatism – An optical defect causing blurred images due to failure to focus a point object into a sharp image on the retina.
Sensitive period – An early developmental period that is particularly sensitive to development of amblyopia.
Snellen acuity – Clarity of vision as measured by eye care professionals using a chart called the Snellen chart.
Strabismus – Misregistration or misalignment of the images from the two eyes preventing the development of binocular vision.

What Is Amblyopia?

Amblyopia (from the Greek, *amblyos* – blunt; *opia* – vision) is a developmental abnormality that results from physiological alterations in the visual cortex and impairs form vision. Amblyopia is clinically important because, aside from refractive error, it is the most frequent cause of vision loss in infants and young children, occurring naturally in about 2–4% of the population; and it is of basic interest because it reflects the neural impairment which can occur when normal visual development is disrupted. The damage produced by amblyopia is generally expressed in the clinical setting as a loss of visual acuity in an apparently healthy eye, despite appropriate optical correction; however, there is a great deal of evidence showing that amblyopia results in a broad range of neural, perceptual, and clinical abnormalities. Currently, there is no positive diagnostic test for amblyopia. Instead, amblyopia is diagnosed by exclusion: in patients with conditions such as strabismus and anisometropia, a diagnosis of amblyopia is made through the exclusion of uncorrected refractive error and underlying ocular pathology. Amblyopic patients (especially those with strabismic amblyopia) often exhibit crowding problems, meaning they have better visual acuity when letters are presented in isolation than when they are presented in a line or a full chart. Clinically, crowding may be a useful sign to aid in the diagnosis of amblyopia.

Amblyopia Is a Significant Public Health Problem

Amblyopia can easily be reversed or eliminated when diagnosed and treated early in life. Thus, there is a premium on early detection of amblyopia and its risk factors. It has been estimated that perhaps as many as three-quarters of a million preschoolers are at risk for amblyopia in the United States, and roughly half of those may not be detected before school age. Moreover, detection is likely to be more delayed in low socioeconomic areas. Improved vision screening and access to treatment could, in principle, eliminate amblyopia as a public health issue.

Types of Amblyopia

Amblyopia comes in different sizes (degree of loss) and flavors (types). The presence of amblyopia is almost always associated with an early history of abnormal visual experience: binocular misregistration (i.e., strabismus – a turned eye), image degradation (high refractive error and astigmatism, anisometropia), or, less commonly, form deprivation (congenital cataract, ptosis). The severity of the amblyopia appears to be associated with the degree of imbalance between the two eyes (e.g., dense unilateral cataract results in severe loss), and to the age at which the amblyogenic factor occurred. Precisely how these factors interact is as yet unknown, but it is evident that different early visual experiences result in different functional losses in amblyopia, and a significant factor that distinguishes performance among amblyopes is the presence or absence of binocular function. Binocular function is much more likely to be damaged when amblyopia results from binocular misregistration (strabismus) than from image blur (anisometropia).

The Site(s) of Amblyopia

A longstanding question is the site of damage in amblyopia. Current opinion places the earliest functional physiological abnormalities in cortical area V1. Exhaustive anatomical and physiological experiments failed to find retinal alterations in monkeys reared with experimentally induced amblyopia. These same animals had marked

abnormalities in V1. Moreover, although human electroretinogram (ERG) studies are equivocal, after optimizing optical focus, fixation alignment, and fixation stability, Robert Hess and colleagues found no pattern ERG deficit in deep amblyopes, in a spatial frequency range where there were obvious psychophysical deficits for the same stimuli. Although it is possible that retrograde degeneration may affect the lateral geniculate nucleus (where there is some shrinkage of the cells in the parvocellular layers) and retina, it seems unlikely that these effects contribute significantly to the behavioral losses. In contrast, amblyopia results in profound alterations in V1 both in cats and monkeys. In monkeys, visual deprivation (via lid suture) leads to a massive loss of neurons in V1 that can be driven by the deprived eye. Experimentally induced blur during development leads to a selective loss of V1 neurons tuned to high spatial frequencies and the spatial tuning of neurons may be markedly different when tested through the two eyes. Experimentally induced strabismus disrupts the binocular connections of cortical neurons. It is difficult to draw distinctions based on the type of rearing from the physiology, because the effects of abnormal visual experience are complicated by the onset, duration, and depth of deprivation; however, there is evidence that the physiological deficits in amblyopia do not fully explain the behavioral losses (in the same monkeys), suggesting that there may be deficits downstream from V1.

The most dramatic changes in V1 involve alterations in binocularity. Specifically, neurons that appeared to be monocular often demonstrate clear binocular interactions during dichoptic stimulation. In strabismic (prism-reared) monkeys, there is marked binocular suppression during dichoptic stimulation suggesting that inhibitory connections are less susceptible to the effects of strabismus than excitatory connections. Interestingly, even very brief periods (just 3 days) of prism-induced strabismus at the height of the critical period (4 weeks in monkeys, which translates to about 4 months in humans) increased the prevalence of V1 neurons that exhibited binocular suppression without altering their sensitivity to interocular spatial phase disparity. This result suggests that the earliest change in V1 is increased binocular suppression and, importantly, that the suppression originates at a site downstream from where information from the two eyes is first combined.

Very much less is known about the physiological effects of amblyopia on visual areas downstream from V1. Brain-imaging studies using positron emission tomography and functional magnetic resonance imaging show a clear deficit in V1, and several studies have also found deficits in other areas (e.g., V2). However, it is difficult to discern whether these downstream losses are simply a pass-through effect from V1 or whether the V1 losses are amplified downstream. However, several imaging and psychophysical studies are consistent with the idea that the abnormalities in V1 are amplified in V2 and possibly beyond. These studies show losses in second-order detection global form and motion integration, symmetry detection, and counting.

Sensitive Periods for the Development of Amblyopia

Clinicians are well aware that amblyopia does not develop after 6–8 years of age, suggesting that there is a sensitive period for the development of amblyopia; however, in humans with naturally occurring amblyopia, the age of onset of the amblyogenic condition(s) is difficult to ascertain, and the effects of intervention combine to make it difficult to obtain a clear picture of the natural history of amblyopia development. Thus, much of our current understanding of the development of amblyopia accrues from animal studies, and from retrospective studies of clinical records. Technological improvements in infant testing have also provided more direct data on the development of naturally occurring amblyopia in humans and monkeys. All of these studies provide strong evidence for amblyopia induced by early deprivation.

While the upper limit for susceptibility of binocular interactions (binocular summation and stereopsis) is not yet certain, it appears to be later than that for acuity or contrast sensitivity in monkeys, and may extend to at least 7 or 8 years (and possibly more) in humans. Psychophysical studies of interocular transfer in humans with a history of strabismus provide an indirect estimate of the period of susceptibility of binocular connections. The results of both studies suggest that binocular connections are highly vulnerable during the first 18 months of life, and remain susceptible to the effects of strabismus until at least age 7 years.

Traditional Treatment of Amblyopia

For centuries, the primary treatment for amblyopia has consisted of patching or penalizing the fellow preferred eye, thus forcing the brain to use the weaker amblyopic eye. Typically, patients with mild to moderate amblyopia are prescribed complete occlusion for 2–6 waking hours per day, over several months to more than a year. Patients with moderate to severe amblyopia are often prescribed 6–10 h or more a day, and some clinicians recommend more aggressive full-time occlusion for severe amblyopia. As reported in a recent large-scale clinical study of children (3–8 years of age), the dose–response rate for occlusion is approximately 0.1 log unit (1 chart line) per 120 h of occlusion, and the treatment efficacy is 3–4 logMAR lines. The dose–response curve appears to plateau only after 100–400 h. The treatment outcome is dependent on

occlusion dose, the depth of amblyopia, binocular status, fixation pattern, the age at presentation, and patient compliance. Recent clinical studies suggest that atropine penalization may be just as effective as patching.

The notion that there is a sensitive period (or periods) for the development of amblyopia has often been taken to indicate that there is also a critical period for the treatment of amblyopia. This concept grew out of the work of Claude Worth in 1903. Worth suggested that the presence of a sensory obstacle (e.g., unilateral strabismus) arrested the development of visual acuity (amblyopia of arrest), so that the patient's acuity remained at the level achieved at the time of onset of strabismus. In this view, the depth of amblyopia is a direct function of the age of onset of the sensory obstacle. Worth further suggested that, if amblyopia of arrest were allowed to persist, amblyopia of extinction could occur as a result of binocular inhibition. In Worth's view, only this extra loss of sensory function (i.e., the amblyopia of extinction) could be recovered by treatment. Although this latter notion is open to question in the light of present knowledge, the ideas of Worth have had a powerful influence upon both clinicians and basic scientists. Many of our currently held concepts of amblyopia, such as plasticity, sensitive periods, and abnormal binocular interaction, were already described more than a century ago, and gained currency with the work of Hubel and Wiesel in 1970 and the many anatomical and physiological studies that followed. Consequently, while amblyopia can often be reversed when treated early, treatment is generally not undertaken in older children and adults. Below we consider both experimental and clinical evidence for plasticity in the adult visual system that calls into question the notion of a sensitive period for treatment.

Clinical Studies

It is often stated that humans with amblyopia cannot be treated beyond a certain age; however, a review of the literature suggests otherwise. Recent clinical trials suggest that in children, 2 h of patching per day may be just as effective as 6 h per day. Moreover, treatment may be just as effective in older (13–17 years) patients who have not been previously treated as in younger (7–12 years) children.

Plasticity in adults with amblyopia is also dramatically evident in the report of amblyopic patients whose visual acuity spontaneously improved in the wake of visual loss due to macular degeneration in the fellow eye. There are also reports suggesting that some adult amblyopes recover vision in their amblyopic eye following loss of vision in their fellow (nonamblyopic) eye. These studies are consistent with the notion that the connections from the amblyopic eye may be suppressed rather than destroyed. Loss of the fellow eye would allow these existing connections to be unmasked, as occurs in adult cats with retinal lesions (**Figure 1**).

Experimental Treatment of Amblyopia Beyond the Sensitive Period

Adults are capable of improving performance on sensory tasks through repeated practice or perceptual learning ('yes, you can teach old dogs new tricks!'), and this learning is considered to be a form of neural plasticity that also has consequences in the cortex. Specifically, in adults with normal vision, practice can improve performance on a variety of visual tasks, and this learning can be quite specific (to the trained task, orientation, eye, etc.). Interestingly, similar neural plasticity exists in the visual system of adults with naturally occurring amblyopia due to anisometropia and/or strabismus, suggesting that perceptual learning may be a useful approach for amblyopia treatment. Perceptual learning can improve visual functions in amblyopia on a wide range of tasks, including: Vernier acuity, positional acuity, contrast sensitivity, and letter identification. Practicing each of these tasks results in improved performance on the practiced task.

The specificity of perceptual learning noted above poses some interesting difficulties. If the improvement following practice was solely limited to the trained stimulus, condition and task, then the type of plasticity documented here would have very limited (if any) therapeutic value for amblyopia, since amblyopia is defined primarily on the basis of reduced Snellen acuity. Importantly, perceptual learning of many tasks (e.g., Vernier acuity, position discrimination, contrast sensitivity) appears to transfer, at least in part, to improvements in Snellen acuity, as does practicing contrast detection. In addition to visual acuity improvement, other degraded visual functions such as stereoacuity and visual counting improve as well.

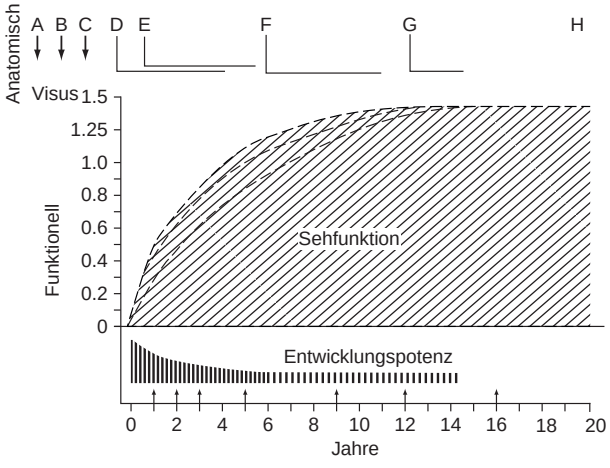

Figure 1 The postnatal development of visual function. Cartoon illustrating visual functions (*sehfunktion*) developing at somewhat different rates, while the developmental potential (*entwicklungspotenz*, in the lower panel) dissipates over the years (*Jahre*). Figure 2 Improvement in positional acuity (solid circles) and Snellen acuity (open circles) of a severe juvenile amblyope (observer AL, 8.8 years old, with unilateral strabismus). The triangle shows the improvement based on occlusion alone. The gray line shows the improvement based on occlusion alone (OT: occlusion therapy) in 2 amblyopes (aged 6–8) with acuities similar to that of AL. Replotted from Li et al., 2007; Stewart et al., 2004, 2005, 2007.

Perceptual Learning as a Clinical Tool for Treating Amblyopia

Occlusion therapy is the gold standard method for treating amblyopia. In all previous perceptual learning studies, the subjects are occluded while performing the visual task, so it is reasonable to ask whether active perceptual learning actually provides an added benefit over occlusion alone. Recent work suggests that occlusion plus perceptual learning may be more effective than occlusion alone (**Figure 2**). Combining occlusion with perceptual learning may be a useful method for obtaining the optimal treatment outcome in the shortest possible time. Eliminating or reducing the need to wear an eye patch in public would eliminate, or at the very least reduce, the emotional stress that often accompanies occlusion therapy.

Over the centuries, there have been numerous attempts to increase the effectiveness of treatment. These attempts have a long and chequered history, ranging from the sublime to the ridiculous, and include: subcutaneous injection of strychnine, electrical stimulation of the retina and optic nerve, flashing lights, red filters and rotating gratings, administration of Levodopa/Carbidopa and shocks to the brain via transcranial magnetic stimulation. Few were subjected to rigorous scrutiny, and those that were often failed to stand up to it. Thus, any promising new method should be examined critically and there is a clear need for careful controlled studies.

Anatomically Separate Rod and Cone Signaling Pathways

S Nusinowitz, UCLA School of Medicine, Los Angeles, CA, USA

Glossary

Neurotransmitter – A chemical substance that is released at synaptic connections that are used to relay, amplify, and modulate signals between cells and neurons.
Photopic vision – The scientific term for color vision mediated by multiple cone photoreceptor types in bright light. In the human retina, photopic vision is tri-chromatic.
Phototransduction – A process by which light is converted into electrical signals in rod and cone photoreceptor cells in the retina of the eye.
Retinal circuitry – It refers to the neuronal pathways in the retina that carry information from photoreceptor cells to ganglion cells.
Scotopic vision – Vision mediated by rod photoreceptors in dim light. Scotopic vision is color blind.
Spatio-temporal vision – A term commonly used to describe the spatial and temporal properties of human visual processing, and the neural mechanisms which underpin them.
Visual adaptation – A process by which vision adjusts to or gets used to a change in overall brightness, color, and other spatio-temporal properties, in order to maximize visual sensitivity.

Rod and Cone Photoreceptors

The process of vision is initiated by the absorption of light by a photoreceptor pigment molecule. The mammalian retina contains two classes of photoreceptors, referred to as rods and cones, each distinct in their structural morphology and in their behavior in response to light. Rod photoreceptors are highly sensitive to light and are capable of responding to a single photon. In contrast, cone photoreceptors are less sensitive to light, but are exquisitely tuned to mediate color and spatio-temporal vision. There are three types of cone photoreceptors in the human retina, each with different, but overlapping, spectral sensitivities, and the interaction of the output from these photoreceptor types mediates the ability to discriminate small color differences.

Based on studies of the evolution of visual pigments, it is hypothesized that rods evolved from cones. A single amino acid substitution has been shown to exchange the molecular properties of rod and cone visual pigments. This suggests that a single spontaneous amino acid substitution could have been one of the key steps in the divergence of rod- and cone-mediated vision. The first step in the formation of rods themselves may have been the spontaneous formation of disk membranes that were separated from the plasma membrane of the outer segment. This step is thought to have increased the light sensitivity of the photoresponse, a physiological property that is typical of rod photoreceptors. The post-receptoral retinal circuitry for rods is superimposed on pre-existing retinal circuitry mediating cone function. This feature of retinal circuitry predates the evolution of the rod photoreceptor itself and likely represents the pathway of a redundant cone photoreceptor that evolved into a rod. As described below, there are multiple sites in the retinal circuitry where rods have the opportunity to penetrate the cone system circuitry.

The absorption of a photon of light by a photoreceptor pigment molecule initiates a sequence of events referred to as the phototransduction cascade. Much of what we know about the specifics of the phototransduction cascade comes from the study of the rod photoresponse. In mammalian rods, the absorption of a photon of light by rhodopsin, the visual chromophore in rods, initiates a sequence of biochemical events that ultimately leads to a decrease in the intracellular level of cyclic guanosine 3,5′-monophosphate (cGMP) and the closure of the cGMP-gated ion channels in the outer segment. The resultant closure of the cGMP-gated channels in the outer-segment membrane decreases the circulating current by blocking inward current flow. This results in an hyperpolarization of the photoreceptor cell membrane and a decrease in the release of neurotransmitter at the photoreceptor synapse with second-order neurons. The biochemical steps in cone outer-segment phototransduction are thought to be similar to that which occurs in rods. In fact, there are corresponding components in rod and cone phototransduction at each step in the cascade, including rod and cone versions of visual pigment, tranducin, phosphodiesterase, arrestin, kinase, cGMP-gated channels, and Na^+/K^+, Ca^{2+} exchangers.

Cone Postreceptoral Circuitry

Consider first the retinal circuitry mediating cone function. Cone photoreceptor cells synapse with bipolar and horizontal cells in the outer plexiform layer of the retina

(see Figure 1). Cones release glutamate at a steady rate in darkness but this rate is slowed in a graded response that is correlated to the change in the outer-segment membrane potential after stimulation by light. The modulation of synaptic transmitter release drives signaling to second-order bipolar cells.

There are at least nine different types of cone bipolar cells in the mammalian retina that are distinguished on the basis of a number of features, including the number of cone photoreceptors contacting the bipolar cell, the spread of the dendritic terminals, and the stratification of their axon terminals in the inner plexiform layer. The precise function of each of these types of bipolar cells is not well understood but they are presumed to be tuned to process different aspects of the visual stimulus. Morphologically, bipolar cells can be subdivided into classes commonly referred to as diffuse and midget bipolar cells. Diffuse bipolar cells (of which there are at least six types) have broad dendritic spreads and make contact with 5–20 long (L-) and middle (M-) wavelength cones; the number of connections depends on where they are located in the retina. These cells are likely involved in tasks requiring broad spatial averaging and color processing but have poor spatial resolution. In contrast, midget bipolar cells have a narrow dendritic tree and can make contact with a single cone and with a single ganglion cell. This cone-mediated circuitry provides a mechanism for high spatial resolution of a scene and is thought to mediate an acuity channel. The midget bipolar cell also transmits color information by virtue of its one-on-one connections with L- and M-sensitive cones. In addition, bipolar cells that make specialized contacts with short (S-) wavelength sensitive cones have been described in the primate, rat, and mouse retina.

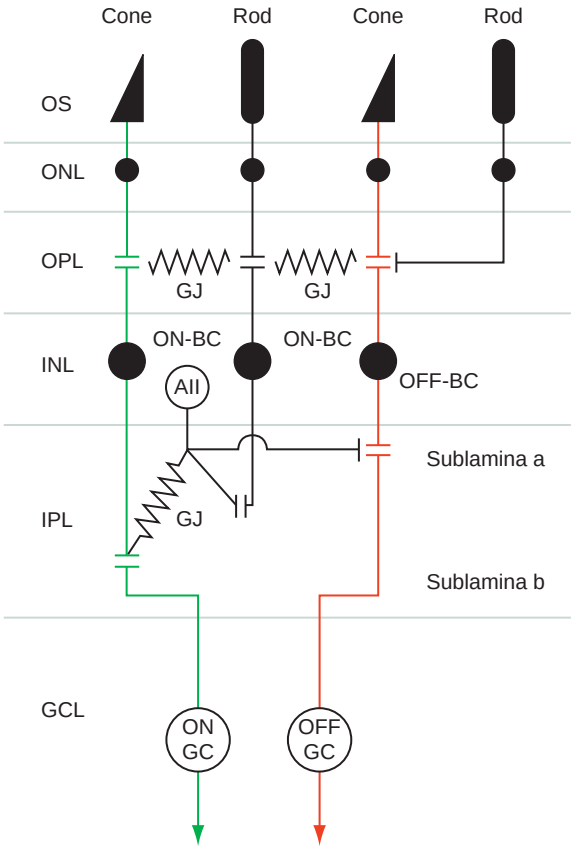

Figure 1 Cone signaling pathway in the mammalian retina. Cone photoreceptors respond to light with a graded hperpolarization and synapse with bipolar and horizontal (not shown) cells in the outer plexiform layer (OPL) of the retina. The release of glutamate at the synaptic terminal is modulated by the change in the outer-segment membrane potential. Cone signals are delivered to ON and OFF bipolar cells (BC) which carry signals to ON and OFF ganglion cells (GC) in the inner plexiform layer (green and red channels, respectively), thereby maintaining segregated cone pathways through the retina. ON and OFF bipolar cells provide excitatory and inhibitory inputs to amacrine cells and ganglion cells and respond with a graded depolarization (sign-inverting) or hyperpolarizing (sign-conserving) response, respectively. Cones communicate laterally with other cones (and rods) via electrical couplings called gap junctions (GJ). Lateral communication is also afforded by horizontal cells in the OPL and by amacrine cells in the IPL. Abbreviations: OS – outer segment, ONL – outer nuclear layer, OPL – outer plexiform layer, INL – inner nuclear layer, IPL – inner plexiform layer, GCL – ganglion cell layer, GJ – gap junction.

Functionally, there are two broad classes of bipolar cells in the mammalian retina mediating the cone signaling pathway. They are commonly referred to as ON and OFF bipolar cells, because of their expression of either excitatory glutamate receptors (mGluRs) or inhibitory glutamate receptors (iGluRs). ON cone bipolar cells make contact with photoreceptors through invaginations in the cone pedicle and are flanked by a pair of horizontal cell dendrites, an arrangement commonly referred to as a triad. The triads are apposed to a presynaptic ribbon, which is the release site for neurotransmitter mediating signal transfer to second-order neurons. There are typically about 25 invaginations in a cone pedicle, but as many as 50 invaginations have been reported. A recent study has identified the protein pikachurin, a previously unknown dystroglycan-binding protein, as critical for the apposition of photoreceptor and bipolar cells dendrites at the ribbon synapse. OFF bipolar cells make contact directly at the cone pedicle base where up to 500 contacts are made with postsynaptic cells.

ON bipolar cells that express mGluRs are depolarized (sign-inverting) by the light response in cone photoreceptor cells. Their dendritic processes terminate in sublamina B of the inner plexiform layer (see Figure 1). In contrast, OFF bipolar cells express iGluRs. In these cells glutamate expression is linked to Na^+ influx. OFF cone bipolar cells are hyperpolarized (sign-conserving) by the light response in cones and have processes that end in sublamina A of the inner plexiform layer. The two types of bipolar cells provide excitatory and inhibitory inputs to downstream cells

and tertiary neurons in response to light stimulation. In general, ON cone bipolar cells are excited by light that is brighter than its surround, whereas OFF cone bipolar cells are excited by light that is dimmer. This segregation of visual input is maintained in parallel signaling pathways to ON and OFF ganglion cells (see **Figure 1**).

Lateral Communication Networks

Signal transfer through the retinal layers, particularly for the rod system, depends on lateral communication between retinal cells. There are several cell types and neural connections within retinal layers that mediate lateral transfer of signal. The major cell types include amacrine and horizontal cells but lateral transfer is also accomplished by a class of low-resistance electrical gap junctions.

Gap Junctions

Low-resistance electrical gap junctions are ubiquitous in the mammalian retina. They enable the intercellular, bidirectional transport of ions, metabolites, and second-order messengers. These gap junctions are mediated by connexins of which several different types have been reported in the mammalian retina. The most abundant of these is neuronal Connexin36. Connexin36 is associated with processes in the outer and inner plexiform layers, consistent with expression in multiple cell types. In the outer plexiform layer, cone photoreceptors communicate laterally via Connexin36-mediated gap junctions between cone pedicles (see **Figure 1**). The gap junctions also permit signal transfer between cone pedicles and rod spherules. In the inner plexiform layer, the expression of Connexin36 co-localizes with the dendritic processes of AII-type amacrine cells. The latter gap junction mediates transfer of signal from AII amacrine cells to ON cone bipolar cells, a signaling pathway that is crucial for rod signals to infiltrate the cone postreceptoral signaling pathway. In addition, the gap junctions in the outer plexiform layer (between cone pedicles and rod spherules) allow rod signals to infiltrate the cone signaling pathway very early in visual processing. These pathways are described later in more detail.

Horizontal Cells

Horizontal cells are second-order, mainly inhibitory, neurons located in the outer plexiform layer. While these cells make synaptic connections with photoreceptors, they are also extensively coupled by either Connexin50 or Connexin57 gap junctions. Morphologically, three types of horizontal cells have been identified in the primate and human retina, referred to as HI, HII, and HIII. The HI-type horizontal cells have small dendritic fields (75–150 μm), but with long axons (300 μm) ending in a broad dendritic tree. HIII horizontal cells are similar to the HI horizontal cell but have larger dendritic trees at all retinal locations. In addition, HIII cells contact many more cones than HI. HII horizontal cells are more spidery and intricate in dendritic field characteristics than either of the other types. The three types of horizontal cells in the human retina demonstrate evidence of color-specific coding. HI horizontal cells contact primarily with green- and red-sensitive cones, with a smaller number of contacts with blue-sensitive cones. HII horizontal cells contact blue-sensitive cones primarily, and HIII horizontal cells contact only green- and red-sensitive cones.

Most, if not all, of the input to horizontal cells is derived from the response of cone photoreceptors to light and, depending on the type of horizontal cell, can make contact with many cones over broad retinal areas. In addition, because horizontal cells are extensively coupled via electrical gap junctions, their receptive fields can be much larger than their dendritic spreads. The connection to rod photoreceptors has traditionally been thought to occur at the axon terminal process, implying that signal transfer from cones to rods is unidirectional. However, rod inputs have been recorded in horizontal cell somata in the cat retina, presumed to be delivered via cone-rod gap junctions or direct dendritic connections. Like cone OFF bipolar cells, horizontal cells express iGluRs at their dendrites and are hyperpolarized in response to light.

In the primate retina, the transmitter release from cones that drives horizontal cells and bipolar cells is also regulated by feedback from horizontal cells. This feedback loop provides a mechanism for the inhibition of signals from adjacent cone photoreceptors. The precise mechanism by which horizontal cells produce this lateral inhibition is not well understood but may occur as a result of the modulated release of the inhibitory transmitter γ-aminobutyric acid (GABA) at the synaptic terminal of cones or via the modulation of the Ca^{2+} channels that regulate the release of glutamate. Regardless of the precise mechanism of lateral inhibition, the lateral interconnections provided by horizontal cells contribute to the formation of the antagonistic surrounds of bipolar cell receptive fields. The antagonistic center-surround interaction is thought to enhance the detection of edges but have also been implicated in the processing of color information where the center-surround configuration modulates antagonistic (or opponent) color information, and in illusory surface filling effects. In addition, the observation of rod and cone inputs at horizontal cell somata provides a mechanism for integrating light signals over broad retinal areas to ensure optimal retinal sensitivity over the entire intensity range.

Amacrine Cells

There are up to 30 types of amacrine cells located in the inner retina of the mammalian retina that have been

distinguished on the basis of morphological characteristics, physiological properties, and pharmacological criteria. While cells upstream from amacrine cells generate graded potentials in response to stimulation by light, the amacrine cell is the first site in the retina where action potentials are generated. Amacrine cells receive their input from bipolar cells, mediated by iGluRs at the synaptic terminals, and from ganglion cells and other types of amacrine cells. The main job of the amacrine cells is to provide a mechanism for transfer of signals from bipolar cells within and between sublamina of the inner plexiform layer, and with ganglion cells. However, amacrine cells, like horizontal cells, provide a mechanism for lateral signal communication between retinal cells, including providing a feedback loop to bipolar cells. They are assumed to play an important role in modulating activity in the antagonistic surrounds of ganglion cell receptive fields that shape higher visual functions, such as object segregation and spatio-temporal adaptation. The feedback from amacrine cells has also been implicated in switching the site of light adaptation between receptor and postreceptoral sites.

The extent of lateral transfer depends on the morphology of the amacrine cell. Wide-field amacrine cells transmit lateral information across a broad expanse of the inner plexiform layer and are present in many species, including the mouse, rat, cat, rabbit, salamander, and monkey. Small-field amacrine cells mediate local interactions between different sublaminae of the IPL. The best characterized of these is the AII amacrine cell which plays an important role in mediating signal transfer through the rod-mediated neural circuitry. Unlike cone bipolar cells, rod ON polar cells do not make direct contact with ON ganglion cells. Rather rod signals are transmitted to ON ganglion cells by AII electrical coupling (gap junctions) with ON cone bipolar cells and by synaptic connections with OFF-cone bipolar cells (see below). Another amacrine cell type, the A17 amacrine cell, has also been implicated in the rod-signaling pathway of the mammalian retina. Up to 11 other small-field amacrine cells have been identified in the cat, rabbit, and mouse, but their precise function is not well understood.

Ganglion Cells

Signals carried through the retinal layers converge on ganglion cells, the latter responsible for carrying information to higher-order visual centers. Up to 25 different types of ganglion cells have been identified in the mammalian retina, dependent on species. These retinal ganglion cells are broadly grouped into classes based on morphological characteristics and physiological properties. In the primate retina, for example, there are at least 18 different types of retinal ganglion cells that are classified morphologically into Pα (parasol), Pβ (midget), and Pγ types, and physiologically into two major types: parasol or magnocellular (M), and midget or parvocellular (P) cells. The parvocellular cells project exclusively to the parvocellular layers of the lateral geniculate nucleus (LGN) and play a key role in central acuity. Parasol ganglion cells are motion-sensitive cells and primarily project to the magnocellular layers of the LGN. Intrinsically photosensitive retinal ganglion cells (ipRGCs) containing melanopsin as the photosenstitive pigment have also been described recently. These neurons, which receive input from both rod and cone photoreceptors, have been implicated in nonimage-forming responses to environmental light such as the pupillary light reflex and circadian entrainment.

Multiple Rod Signaling Pathways

Cone photoreceptors synapse directly with both ON and OFF bipolar cells, which then transmit signals in parallel pathways to ON and OFF ganglion cells, respectively (**Figure 1**). In contrast, rod photoreceptors, which synapse with rod ON bipolar cells, do not make direct contact with ganglion cells, but rather transmit their signals to these cells through several alternate pathways. Consider first the evidence for multiple rod pathways. The alternative signaling pathways are described later and shown in **Figure 2**.

It is generally accepted that rod-mediated vision, like cone vision, involves multiple signaling pathways. The evidence in support of this hypothesis derives from early psychophysical experiments in humans in which critical fusion frequency (CFF; the intensity at which flicker can just be detected) was measured under conditions mediated by rods. These experiments revealed two distinct branches in the function that relates CFF and stimulus intensity. In the lower branch, over dim flash intensities, the CFF was no better than 15 Hz, and remained at this level over a broad range of stimulus intensities. However, at higher intensities, covering mesopic light levels, CFFs increased rapidly and could be as high as 28 Hz. The double-branched CFF versus intensity response function implied the existence of at least two signaling pathways mediating rod function in the mammalian retina. This hypothesis was supported by the observation that patients with achromatopsia, a retinal abnormality in which cone function is absent, also display the same response properties.

Additional support for at least dual rod signaling pathways comes from psychophysical measurements of rod flicker perception in humans. These experiments demonstrated that for 15 Hz flickering stimuli (the optimal stimulus presentation frequency for demonstrating the interaction), there is an intensity region, well above flicker detection threshold, where the perception of flicker is minimized or nulled. The perceptual nulling of flicker has been assumed to result from the mutual cancellation of signals originating from at least two signaling pathways

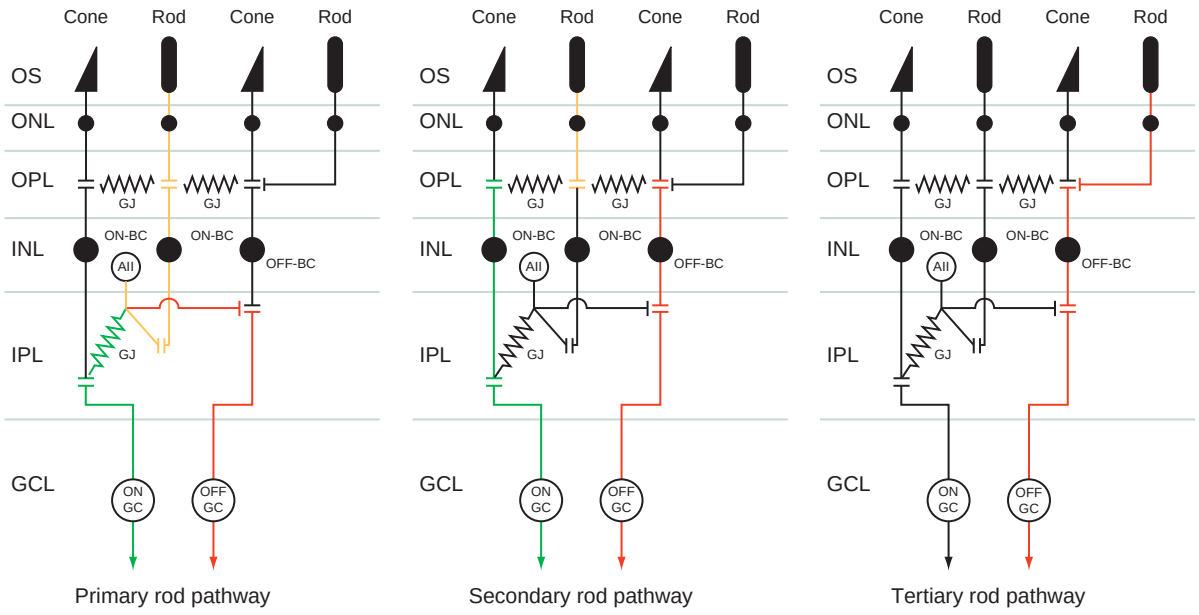

Figure 2 Rod signaling pathway in the mammalian retina. In the primary rod pathway (left panel), rod photoreceptors synapse with rod ON bipolar cells, which in turn make connections with amacrine AII cells in the inner plexiform layer (yellow pathway). Signals from the AII amacrine cells infiltrate the cone pathway by exciting ON cone bipolar cells via electrical gap junctions (green pathway) and via glycinergic (sign-inverting) synapses with OFF cone bipolar cells (red pathway). Rod signaling through the secondary rod pathway (middle panel) is mediated through rod-cone gap junctions between rod spherules and cone pedicles located in the outer plexiform layer. Through the rod-cone gap junction, rod signals have access to both ON and OFF cone bipolar cells and to ON and OFF ganglion cells (green and red pathways, respectively). A third pathway for rod signal transmission (right panel), in which rod photoreceptors bypass the rod ON bipolar cell and directly excite cone OFF bipolar cells, has also been hypothesized (red pathway). Abbreviations: OS – outer segment, ONL – outer nuclear layer, OPL – outer plexiform layer, INL – inner nuclear layer, IPL – inner plexiform layer, GCL – ganglion cell layer, GJ – gap junction.

having different speeds of signal transmission. The hypothesis argues that when signals are in phase, despite different speeds of transmission, they are mutually additive but, when out of phase, produce destructive interference, which contributes to the inhibition of signal strength and the flicker nulling perception. This mutual cancellation has also been demonstrated with the electroretinogram (ERG), which is a noninvasive measure of the massed response of the retina to light. It is assumed only to reflect activity of outer and middle retinal cells. As in the perceptual experiments described above, supportive evidence derives from a unique feature of the function that relates ERG signal amplitude and stimulus. A local response minimum is observed at an intensity that is well above ERG flicker detection threshold but still within the scotopic range of intensities and occurs at the same intensity where the perception of flicker in humans is also minimized.

Much of the electrophysiological evidence in support of the existence of multiple signaling pathways comes from experiments in which single unit extracellular recordings are made from ganglion cells in the mouse and rabbit retina. Using pharmacological agents to disrupt different cellular connections in the retinal circuitry, combined with animal models with known genetic defects affecting these connections, electrophysiological support for multiple rod pathways has come from what signals remain detectable at the ganglion cell level. On the basis of these types of experiments, rod photoreceptor signals are presumed to be transmitted to ganglion cells via three alternate pathways.

The anatomical substrates mediating rod postreceptoral signaling in the retina seem to be well established and are assumed to be conserved across mammalian species. They are illustrated in **Figure 2**. In the primary rod pathway (left panel), rod photoreceptors synapse with rod ON bipolar cells, via sign-inverting glutamatergic synapses. The output from the rod ON bipolar cell is then transmitted to AII amacrine cells in the inner plexiform layer via sign-conserving glutamatergic synapses. Signals from the AII amacrine cells then converge onto the cone pathway by exciting ON cone bipolar cells via electrical gap junctions and inhibit cone OFF bipolar cells via sign-inverting glycinergic synapses (see **Figure 2** for color coding).

Rod signaling through the secondary rod pathway (middle panel) converges onto the cone circuitry at an even earlier stage. The secondary rod pathway is mediated through rod-cone gap junctions that exist between rod spherules and cone pedicles located in the outer plexiform layer. Through the rod-cone gap junction, rod

photoreceptors can transmit signals directly to both ON and OFF cone bipolar cells and to ON and OFF ganglion cells. The circuitry for the primary and secondary rod pathways has been shown to exist in the cat, rabbit, primate, and more recently in the mouse.

A third pathway for rod signal transmission (right panel), in which rod photoreceptors bypass the rod ON bipolar cell and directly excite cone OFF bipolar cells, has also been hypothesized and supported by anatomical and physiological data. This alternative pathway has been demonstrated to exist using electrophysiological methods. In these experiments, a ganglion cell signal continues to be observed in animals without cones (thereby eliminating the rod–cone gap junction of the secondary pathway) and in which all signal transmission through the primary rod pathway is blocked with pharmacological agents.

Thus, the retinal circuitry comprising the rod system offers multiple signaling routes for carrying information from rod photoreceptors to inner retinal ganglion cells. While these signaling pathways provide the rod system with multiple opportunities for system redundancy, they also subserve specialized functions related to scotopic vision. It has been suggested that signal transfer from the primary to secondary rod signaling pathway affords the rod system the capability of enhanced temporal resolution at the expense of light sensitivity. However, further work is needed to better understand the precise role of each of the rod signaling pathways in the processing of visual information.

Concluding Statements

A major step in forming our perceptions of the visual world is accomplished in the retina, where information from rod and cone photoreceptors is filtered, processed, and channeled through multiple parallel signaling pathways. In addition to the different spectral sensitivities of rod and cone photoreceptors and the intensity range over which they operate, the different types of bipolar cells, amacrine cells, and horizontal cells are presumed to be tuned to capture or enhance specific attributes of a visual scene – color processing, brightness contrast, temporal processing, signal enhancement and integration, and adaptation mechanisms. Ultimately, these processed and filtered signals from the retina are transmitted to higher-order visual centers, such as the lateral geniculate nucleus and the primary visual cortex of the brain, where the information is optimized to form our perceptions of the visual environment.

Anatomy and Regulation of the Optical Nerve Blood Flow

R Ehrlich, A Harris, and A M Moss, Indiana University, Indianapolis, IN, USA

Glossary

Anastamosis – A network of streams that both branch out and reconnect forming a communication between two blood vessels or other tubular structures.
Autoregulation – The intrinsic ability of a system to maintain constant blood flow despite changes in perfusion pressure and local vascular parameters to maintain homeostasis.
Choriocapillaris – A layer of capillaries in the choroid immediately adjacent to Bruch's membrane.
Central retinal artery – A branch of the ophthalmic artery which pierces the optic nerve close to the globe, sending branches to the internal surface of the retina.
Extraocular muscles – A group of six muscles that control the movements of the eye, including the superior, inferior, lateral, and medial recti, and the superior and inferior obliques.
Fenestration – From the Latin word for window (fenestra), a fenestration is an opening in a wall or membrane.
Hemodynamics – The study of the forces generated by the heart and the flow of blood through the cardiovascular system.
Ophthalmic artery – A branch of the internal carotid artery which enters the orbit through the optic canal, along with the optic nerve, to supply structures in the orbit.
Poiseuille's law – A physical law that describes slow, viscous, incompressible flow through a circular cross section. It states that for a laminar, nonpulsatile fluid flow through a uniform straight tube, the vascular resistance is inversely proportional to the fourth power of the radius of a vessel, and is directly proportional to the blood viscosity and length of the vessel.
Retrobulbar vessels – Blood vessels behind the eye.

Introduction

A thorough understanding of vascular anatomy is critical to appreciate the physiology of the optic nerve head (ONH). The study of blood flow and the metabolism of the eye are also important in understanding the role of the circulatory system in various eye diseases. The arterial supply to the optic nerve has been widely investigated; however, the precise anatomy of the anterior optic nerve microvasculature remains difficult to ascertain. Detailed assessment of this anatomy is limited by its small vessel caliber, its complex three-dimensional structure, and the relative inaccessibility of the microvascular bed. Although the evaluation of ocular hemodynamics continues to improve with the development of new imaging technologies, current techniques for measuring optic nerve blood flow do not directly evaluate the optic nerve. We summarize the vascular anatomy of the ONH, retina, and choroid, the regulation of blood flow in the ONH, and several imaging techniques used to measure blood flow in the eye.

Anatomy of the Vascular Supply

The ophthalmic artery (OA), which is the first branch of the internal carotid artery, provides the vast majority of the ocular blood supply (**Figure 1**). The OA enters the orbit through the optic canal and, in most individuals, runs inferolaterally to the optic nerve. After coursing nasally and anteriorly, the OA runs superior to the optic nerve, where it gives off most of its major branches. These branches include vessels to each of the extraocular muscles, the central retinal artery (CRA), and the posterior ciliary arteries (PCAs) (**Figure 2**). There are usually two to three PCA trunks, each dividing into approximately 10–20 short PCAs before, or, occasionally after, penetrating the sclera. The short PCAs supply the posterior choriocapillaris, peripapillary choroid, and the majority of the anterior optic nerve. The medial and temporal long PCAs pierce the sclera about 3–4 mm nasally and temporally from the optic nerve (**Figure 2**). They then travel anteriorly within the suprachoroidal space, along the horizontal meridians of the globe. Typically, the long PCAs divide in the vicinity of the ora serrata to supply the iris, ciliary body, and the anterior region of the choroid.

The CRA branches directly from the OA to pierce the medial aspect of the optic nerve sheath approximately 10–15 mm behind the globe. The CRA courses adjacent to the central retinal vein (CRV) through the center of the optic nerve. It emerges from the optic nerve within the globe, where it branches into four major vessels: the arteriola nasalis retinae superior, arteriola nasalis retinae inferior, arteriola temporalis retinae superior, and arteriola temporalis retinae inferior.

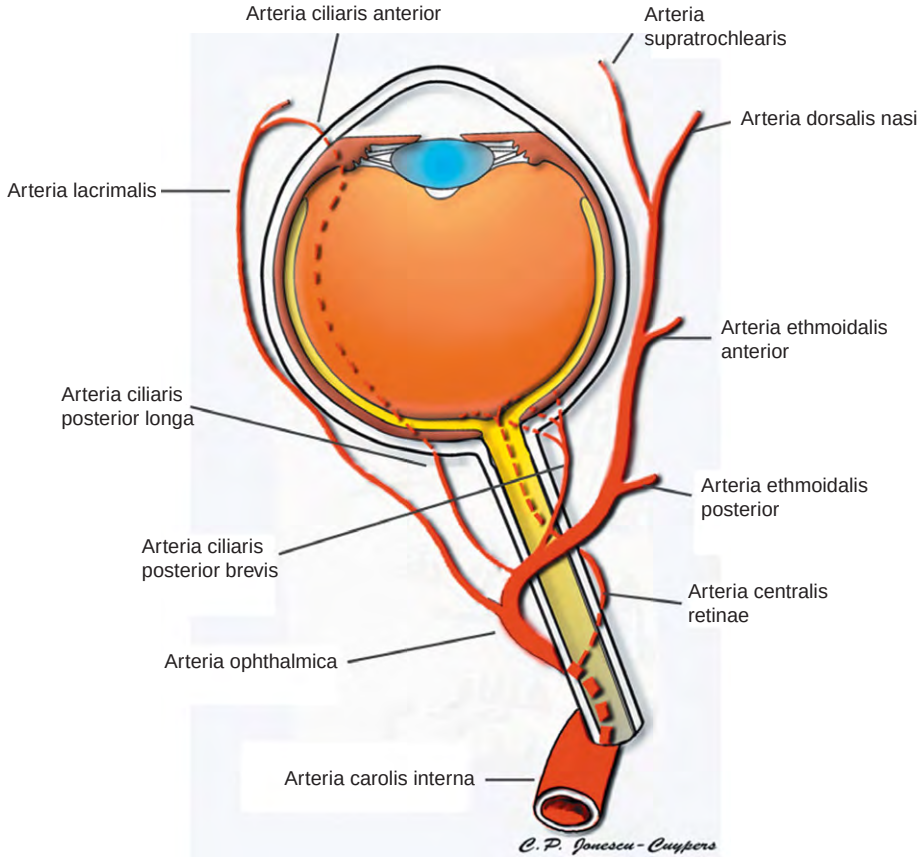

Figure 1 Schematic depicting the general vascular organization and the arterial feeds of the major and microciliary processes. The anterior and posterior arterioles that branch off the major arterial circle of the iris (MAC) supply the capillaries of the major and minor processes, respectively. Several smaller branches off the anterior arteriole feed into the marginal capillaries of the major process. Branches of the posterior arteriole feed the internal capillaries (ICs) of the major process. Blood supply to the capillaries of the minor processes is derived from more than one posterior arteriole. Anastomoses (green arrowheads) occur between the lateral branches, some marginal or central capillaries of the major processes and the basally located capillaries that extend posteriorly (white star). From Morrison, J. C. and van Buskirk, E. M. (1984). *American Journal of Ophthalmology* 97: 372–383 in Figure 11.25f in Bron, A. J., Tripathi, R. C., and Tripathi, B. J. (1997). The choroid and uveal vessels. In: *Wolff's Anatomy of the Eye and Orbit*, 8th edn., ch. 11. London: Chapman and Hall Medical.

The vasculature of the eye can be divided into two distinct systems: the retinal system and the uveal system. The retinal system provides blood flow to the inner two-thirds of the retina. The choroid and ciliary body are nourished by the uveal system. The retinal pigment epithelial layer, which is located between the retina and choroid, actively exchanges nutrients and metabolic waste products between the retina and the choroid. Thus, the outer layers of the retina receive their blood flow via the uveal system.

Retina

The retina receives its arterial blood supply from two distinct sources. The CRA provides blood flow to the inner two-thirds of the retina. The CRA branches on the surface of the optic disk, typically producing four main trunks which lie within the nerve fiber layer. Each trunk supplies its respective quadrant of the retina. The outer one-third of the retina, including the photoreceptors and bipolar cells, receives nourishment from the underlying choroid, specifically the choriocapillaris. Nutrients are actively transported between the choroid and retina via the retinal pigment epithelium. In approximately 30% of the people, a cilioretinal artery is present. Typically a branch of a ciliary artery, this vessel supplies a variably sized region of the retina temporal to the optic nerve. When present, the cilioretinal artery is an end artery, and therefore its territory receives no additional blood supply from any other vessels.

Retinal capillaries run parallel to the retinal nerve fiber layer, eventually coalescing into retinal veins, which empty into the CRV. The CRV exits the eye through the optic nerve, running parallel to the CRA. Once in the optic nerve, the CRV receives additional intraneural tributaries, and eventually empties into the superior ophthalmic vein. Although the CRV is normally the only outflow channel

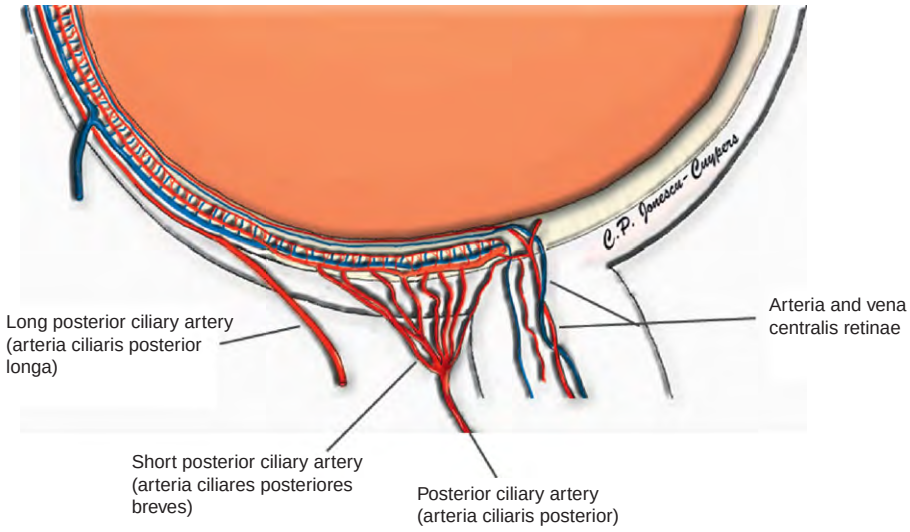

Figure 2 Drawing depicting the vascular territories of the ciliary processes. The first terroritory (outlined in the green box) includes the anterior arterioles, the lateral branches, and that feed the lateral branches, and the branches that drain into the basally located venules (white star). The second territory (indicated by the green arrows), includes the marginal capillaries and the capillary network (shown as short connections) that connect to these and the internal capillaries (IC) of the major process. The third territory (outlined in the purple box) includes the capillaries that branch off the posterior arterioles, and the vasculature of the minor processes. According to some authors the vessels in the posterior third of the major processes also fall within the third vascular territory. From Morrison, J. C. and van Buskirk, E. M. (1986). *Transactions of Ophthalmology Society* 105: 13 in Figure 10.28b in Bron, A. J., Tripathi, R. C., and Tripathi, B. J. (1997). The posterior chamber and ciliary body. In: *Wolff's Anatomy of the Eye and Orbit*, 8th edn., ch. 10. London: Chapman and Hall Medical.

for retinal circulation, potential anastamoses exist between the retinal and choroidal circulation. These alternate pathways are significant in the case of a CRV occlusion.

Choroid

The choroid supplies the outer retina with nutrients and maintains the temperature and volume of the eye. The choroidal circulation, which accounts for 85% of the total blood flow in the eye, is a high-flow system with relatively low oxygen content. The choroidal circulation is controlled mainly by sympathetic innervation and is considered not to be autoregulated. This lack of autoregulation makes the choroid more dependent on the ocular perfusion pressure.

The short PCAs supply the posterior choroid and the peripapillary region, while the anterior parts of the choroid are supplied by the long PCAs and the anterior ciliary artery. The anterior ciliary artery is a branch from the OA which accompanies the rectus muscle anteriorly to supply the iris and the anterior choriocapillaries.

The outer choroid, known as Haller's layer, is composed of large caliber, nonfenestrated, vessels. The inner choroid is referred to as Satler's layer, and is composed of significantly smaller vessels. The choriocapillaries of the innermost choroid are composed of richly anastomotic, fenestrated capillaries. The capillaries of the choriocapillaries are separate and distinct from the capillary bed of the anterior optic nerve.

Venous drainage from the choriocapillaries is primarily through the four vortex veins. Minor drainage also occurs through the ciliary body and the anterior ciliary vein. Venous anastomoses are frequent in the choroid. The vortex veins drain into the inferior and superior ophthalmic veins, which then exit the orbit through the superior and inferior orbital fissures, respectively.

Optic Nerve

The anterior optic nerve is divided into four anatomical regions: the superficial nerve fiber layer, the prelaminar layer, the laminar region, and the postlaminar region (**Figure 3**). The arterial supply to the ONH is derived from branches of the OA. The short PCAs penetrate the perineural sclera at the posterior aspect of the globe to supply the peripapillary choroid and anterior ONH. The circle of Zinn-Haller is a noncontinuous arterial circle surrounding the ONH within the perineural sclera. Formed by a network of small branches of the short PCAs, the circle of Zinn-Haller provides multiple perforating branches to various regions of the anterior optic nerve, peripapillary choroid, and pial arterial system. The capillaries of the anterior ONH are nonfenestrated, contain tight junctions, and form a rich anastomotic plexus. Some investigators surmise that the division of the short PCAs into branches

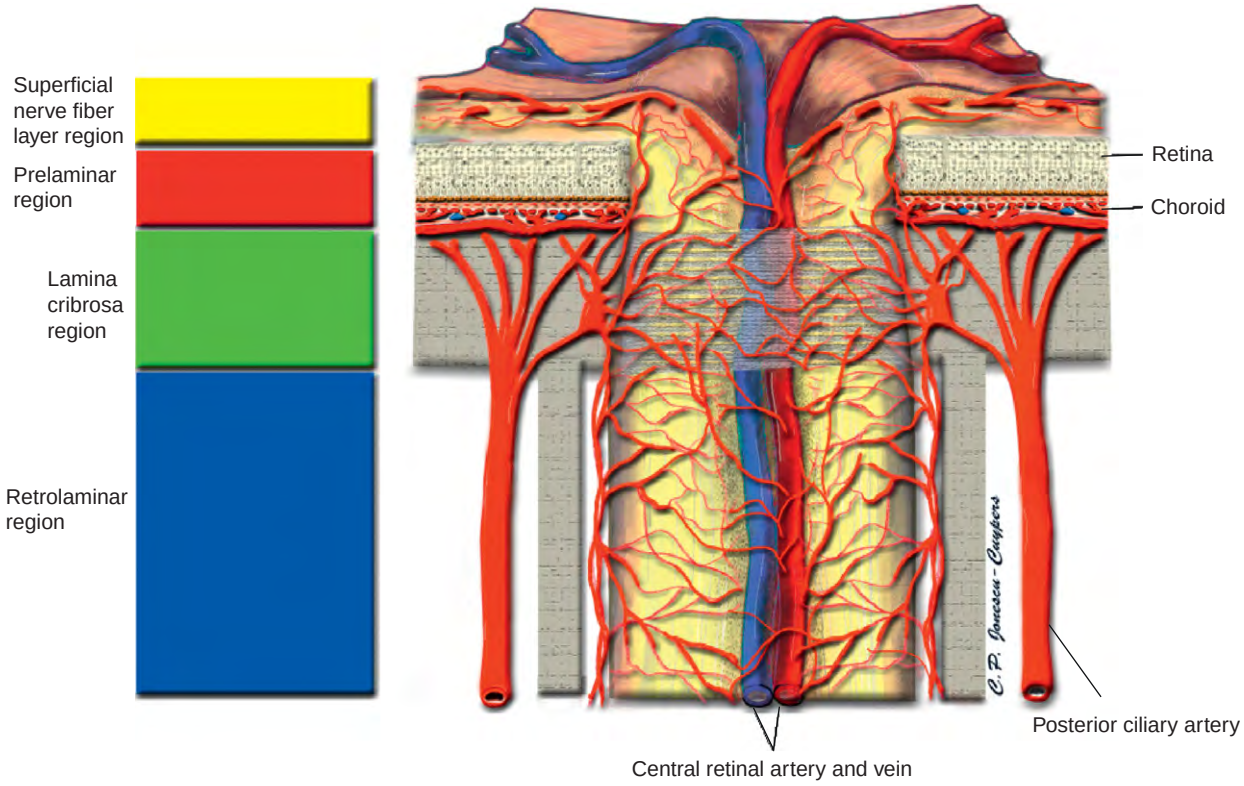

Figure 3 Left: anatomical regions of the optic nerve. Right: blood vessels of the anatomical regions of the optic nerve.

that supply the choroid and those supplying the ONH form the watershed zone near the ONH.

The superficial nerve fiber layer, which is continuous with the nerve fiber layer of the retina, receives its blood supply from recurrent arterioles arising from branches of the retinal arteries (**Figure 4**). These vessels, referred to as epipapillary vessels, originate in the peripapillary nerve fiber layer and run toward the center of the ONH. The temporal nerve fiber layer may receive additional arterial contribution from the cilioretinal artery when present.

Immediately posterior to the nerve fiber layer is the prelaminar region, which lies adjacent to the peripapillary choroid. In this region, ganglionic axons are grouped into bundles, surrounded by glial tissue septa, as they prepare for passage posteriorly through the lamina cribrosa. The prelaminar region is supplied primarily by branches of the short PCAs and, when present, by branches of the circle of Zinn-Haller (**Figure 5**). The amount of choroidal contribution may be difficult to determine, as there are branches from both the circle of Zinn-Haller and the short PCAs which course through the choroid and ultimately supply the optic nerve in this region. These vessels do not originate in the choroid, but merely pass through it. The choroid contributes little, if any, blood supply to this area of the ONH.

The laminar region is continuous with the sclera and is composed of fenestrated connective tissue lamellae which allow the passage of neural fibers through the sclera. This region, called the lamina cribrosa, receives its blood supply either from centripetal branches of the short PCAs or from branches of the circle of Zinn-Haller (**Figure 6**). These branches pierce the outer aspect of the lamina cribrosa before branching centrally to form an intraseptal capillary network throughout connective tissue. The larger peripapillary choroidal vessels occasionally contribute small arterioles to the lamina cribrosa region.

The retrolaminar region lies posterior to the lamina cribrosa, and is discernible by the beginning of the axonal myelination. Surrounded by the meninges of the central nervous system (CNS), the retrolaminar region is supplied primarily by branches of the pial arteries and the short PCAs (**Figure 7**). The pial system is an abundant anastomotic network fed by the OA, the circle of Zinn-Haller, and recurrent branches of the short PCAs. The pial branches are located within the pia matter and extend centripetally to perfuse the axons of the optic nerve. In addition, the CRA occasionally contributes small branches within the retrolaminar optic nerve.

Like that of the retina, the venous drainage from the ONH is through the CRV. In the superficial nerve fiber

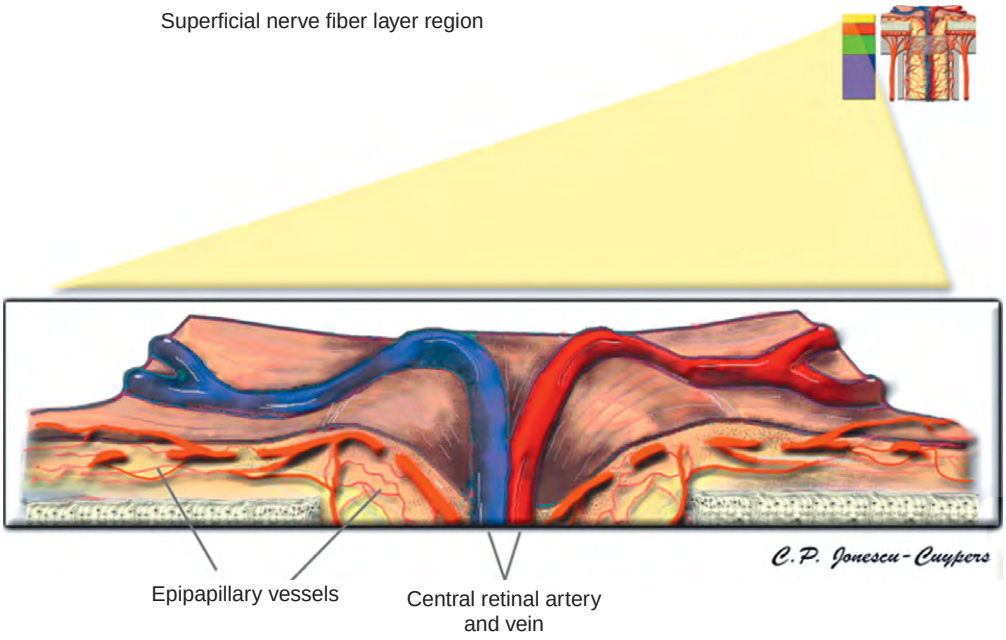

Figure 4 Schematic of the blood supply to the superficial nerve fiber layers.

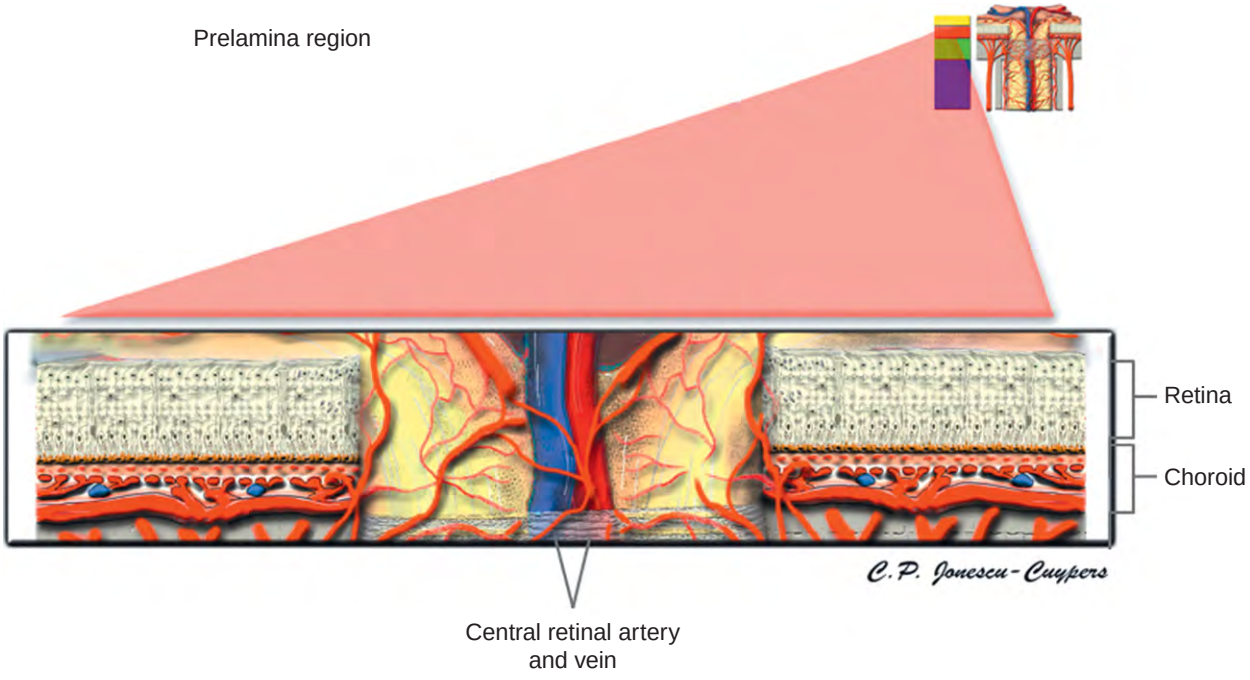

Figure 5 Schematic of the blood supply to the prelaminar region of the optic nerve.

layer, blood is drained by small, converging veins that empty into the CRV. In the other layers of the ONH, centripetal veins serve as tributaries, eventually emptying into the CRV. In the prelaminar region, there is also a noteworthy contribution from the peripapillary choroidal veins. Small portions of the peripheral region of the ONH may partially drain into the pial venous network, which ultimately joins together with the CRV as well.

Histology of Blood Vessels in the Optic Nerve

The anterior optic nerve is composed of nerve axons, neuroglia, blood vessels, and connective tissue. Large-caliber arteries of the optic nerve contain a muscularis layer, composed of multiple layers of smooth muscle, surrounded by the adventitia. The latter consists of

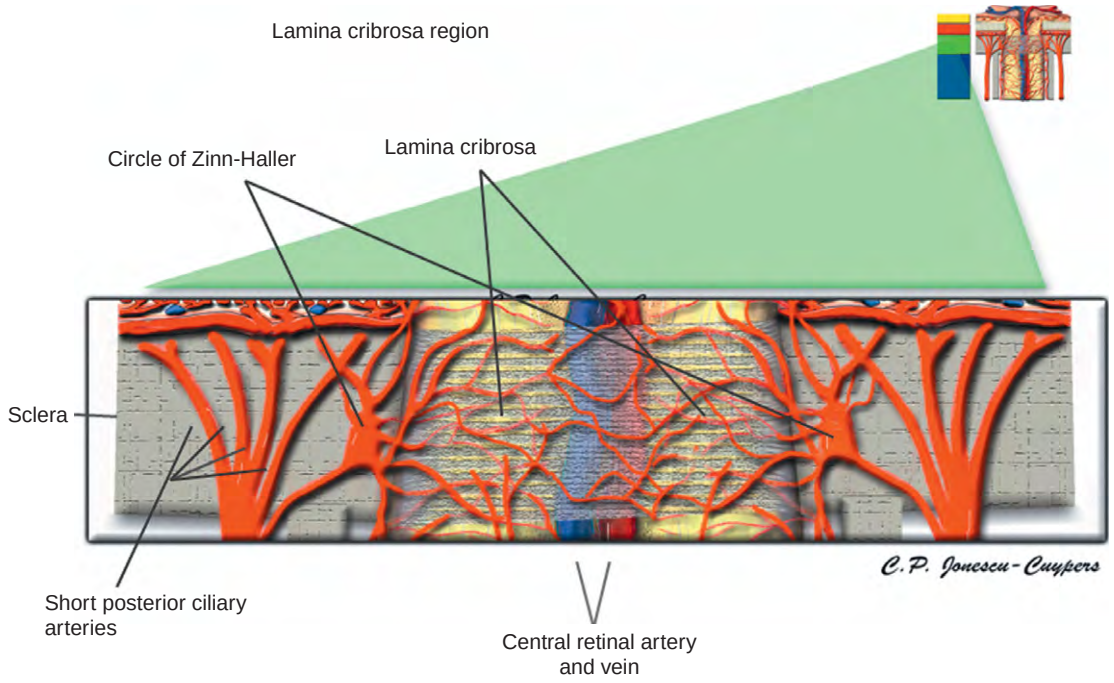

Figure 6 Schematic of the blood supply to the lamina cribrosa region.

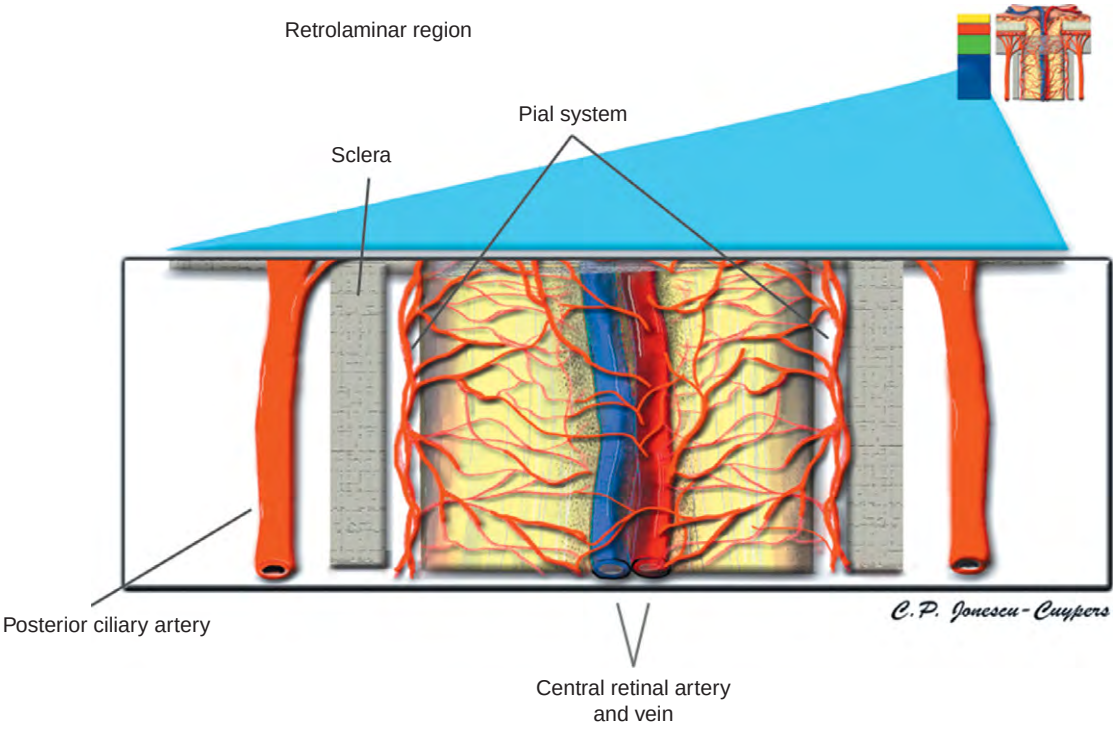

Figure 7 Schematic of the blood supply to the retrolaminar region of the optic nerve.

circumferential collagen fibers which blend with fibers from the perivascular space. On its luminal surface, the muscularis layer is separated from the endothelium by an inner elastic layer. The basement membrane lies between the endothelial cells and blends with the internal elastic lamina.

Arterioles of the optic nerve are much smaller in diameter, and have a single layer of smooth muscle.

They also possess minimal to no elastic lamina, but have a relatively dense reticular lining. The adventitia is continuous with collagen fibers of the intravascular space, and the endothelium is covered by a basement membrane.

Precapillaries and capillaries have a very thin wall and their basement membranes stain positively with the periodic acid-Schiff reaction. The endothelium, basement membrane, and mural cells of the venous structures are similar to that of the capillaries. The veins of the optic nerve are composed of an inner lining of endothelial cells, elastic fibers, thin adventitia, and intermittently, irregularly spaced, smooth muscle cells. When the venules enlarge, the basement membrane thickens accordingly.

Within the anterior ONH, the histology of the vasculature resembles that of the CNS, as the vessels contain a nonfenestrated endothelium with tight junctions. Capillaries predominate within the anterior ONH, and larger vessels are seldom visualized. Posteriorly, larger arterioles may be seen entering the lamina cribrosa. These capillaries and arterioles lack the internal elastic lamina and elastic tissue in the media that is characteristic of the larger vessels of the laminar and retrolaminar regions.

Regulation of Ocular Blood Flow

Autoregulation is the intrinsic ability of a system to maintain constant blood flow despite changes in perfusion pressure and local vascular parameters. The intrinsic control of blood flow involves chemical secretion by the cells in the immediate vicinity of the blood vessels. Within the eye, autoregulation is defined as local vascular constriction or dilation to alter vascular resistance, thereby maintaining a constant nutrient supply in response to perfusion pressure changes. Perfusion pressure is equal to the difference between the mean arterial pressure (MAP) and the venous pressure. The MAP is defined as the diastolic blood pressure plus one-third of the difference between systolic and diastolic blood pressure. Since the pressure in the central vein is normally slightly higher than the intraocular pressure (IOP), the IOP is used as an estimate of ocular venous pressure:

$$\text{Mean ocular perfusion pressure} = \frac{2}{3}\text{MAP} - \text{IOP}$$

$$\text{MAP} = \text{Diastolic BP} + \frac{1}{3}(\text{Systolic BP} - \text{Diastolic BP})$$

The maintenance of appropriate ocular blood flow is challenged by physiological changes in IOP, blood pressure, ocular perfusion pressure, and local tissue metabolic demands. As per Poiseuille's law, vascular resistance is inversely proportional to the fourth power of the radius of a vessel, and is directly proportional to the blood viscosity and length of the vessel. In the eye, vascular resistance is therefore dependent on the regulation of vessel diameter. In normal subjects, autoregulation is usually maintained until the IOP reaches approximately 40–45 mmHg. Failure of stable blood flow regulation may lead to ischemic damage of the optic nerve or retinal ganglion cells, which likely contributes to further impairment in vascular regulation. Several mechanisms, including neurogenic-, metabolic-, myogenic-, humoral-, and endothelial-mediated factors, have been demonstrated to play a role in the vascular regulation of ocular blood flow.

Fed primarily by the CRA, the retinal system is generally a low-flow, constant rate system that supplies a highly metabolically active tissue. Although it may only account for as little as 15% of the total ocular circulation, the retinal circulation is capable of providing relatively constant blood flow over a substantial range of IOPs. The retinal and anterior optic nerve head do not possess direct autonomic innervations. Although the retinal and optic nerve head have adrenergic and cholinergic receptors their role remains unclear. Consequently, retinal blood flow is locally autoregulated.

Several vasoactive molecules mediate retinal vascular autoregulation. Endothelial tone is determined by the balance between the vasoconstricting and vasodilating effects of secreted factors. Nitric oxide (NO) is produced by the oxidation of L-arginine by endothelial-derived nitric oxide synthase, which is present in both a constitutively active, membrane-bound form, and an inducible, cytosolic form. NO diffuses to nearby pericytes and smooth muscle, where it activates guanylyl cyclase, leading to the increase of cGMP and subsequent vasodilation. There are numerous stimuli for the production of NO, including increased shear force, bradykinins, insulin-like growth factor 1, acetycholine, and thrombin. Additionally, NO also inhibits platelet aggregation, platelet granule secretion, and leukocyte adhesion.

Vasoconstriction of the retinal microvasculature is stimulated by several vasoactive molecules. Endothelins, the most potent vasoconstricting agents known, are molecules that bind to receptors on pericytes and smooth muscle cells. A second vasoconstrictive substance is angiotensin II. Angiotensinogen is an inactive molecule that is constitutively produced by the liver. In response to physiologic stimuli, the kidneys release renin, which converts angiotensinogen into angiotensin I. Angiotensin converting enzyme (ACE), which is present on the surface of luminal endothelial cells, converts angiotensin I to angiotensin II, and also inactivates bradykinin. Once in its active form, angiotensin II moderates retinal vasoconstriction through the activation of smooth muscle cells and pericytes.

The choroidal vasculature is controlled extrinsically through hormonal influence and stimulation from the autonomic nervous system. It is characterized as a high-flow, variable-rate system which is tightly regulated by

the autonomic nervous system. The outer, larger vessels are composed of nonfenestrated endothelium, while the inner, smaller vessels form a richly anastomotic network of fenestrated capillaries. The vascular tone of the choroid is dominated by the sympathetic nervous system. Neurons course from the cranial cervical ganglion to the vascular bed, where vasoconstriction is mediated by the release of neuropeptide Y. The parasympathetic nervous system plays only a moderate and poorly defined role in the regulation of vascular tone. The presence of choroidal autoregulation is controversial and classically considered absent, though some autoregulatory response was reported during perfusion pressure changes.

Technology for Measuring Ocular Blood Flow

Color Doppler Imaging

Although originally developed for monitoring blood flow in the heart, carotid arteries, and peripheral vasculature, color doppler imaging (CDI) has proven to be useful in the study of retrobulbar vessels as well. By combining B-scan ultrasound images with velocity of measurements calculated from the Doppler shift of moving erythrocytes, CDI can be used to assess the velocity of blood flow through the retrobulbar vessels. The peak systolic velocity (PSV) and end diastolic velocity (EDV) can be measured and used to calculate the mean flow velocity (MFV). An index of resistance (RI) can be calculated as RI = (PSV – EDV)/PSV (Figure 8). Further research is necessary to determine the usefulness and application of the RI as it applies to the retrobulbar vasculature. Until recently, one critical limitation of this imaging technique had been that no quantitative information on vessel diameter was obtained, and therefore the calculation of total blood flow or flux was not possible. A recently developed analysis technique has made it possible to determine the diameter of the OA, allowing volumetric blood flow to be assessed. Further research is necessary to apply this technique to the assessment of blood flow through the other major vessels.

Angiography

Using sodium fluoroscein, angiography allows direct visualization of retinal blood flow. Most techniques measure the amount of time that it takes for the fluoroscein to pass through the retinal circulation. Using this technique, data can then be used to assess blood velocity through the retinal and optic disc circulation. Choroidal vessels are visualized in a similar fashion using indocyanine green, which is selected due to its increased binding to plasma proteins, preventing leakage from vessels to the surrounding tissue. Using videoangiography and scanning laser ophthalmoscopy, the arterio-venous passage time and retinal circulation time can be determined. This technology

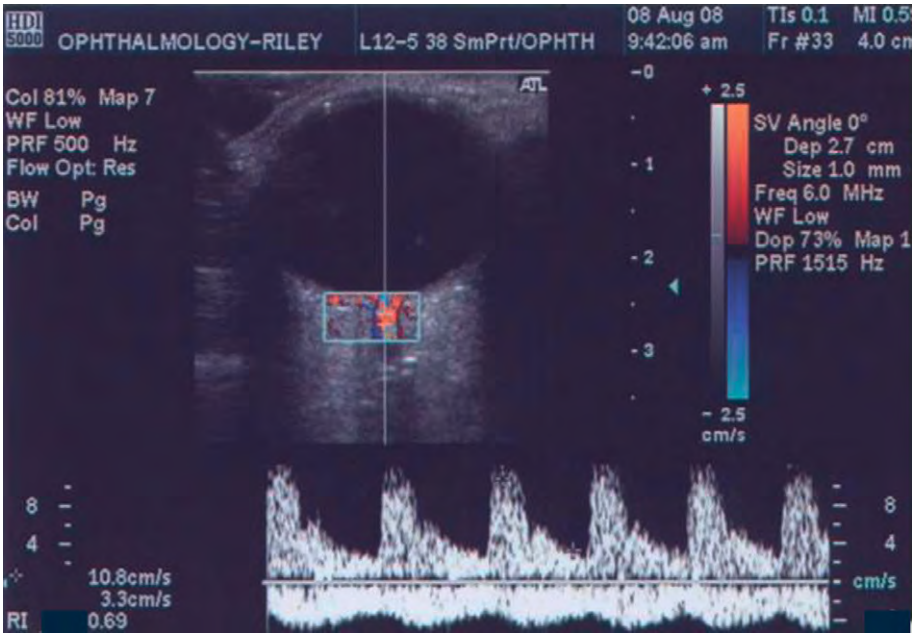

Figure 8 Color Doppler image of the central retinal artery and vein taken with a 7.5-MHz linear probe. The patient is placed comfortably in a half-supine position. An ultrasound probe is placed on closed eyelid and the optic nerve shadow of the optic nerve is identified. The vessels sampled include the ophthalmic artery, central retinal artery, and the nasal and temporal short posterior ciliary arteries. The Doppler-shifted spectrum (time–velocity curve) is displayed at the bottom of the image. Red and blue pixels represent blood movement toward and away from the transducer, respectively. The peak of the wave represents the peak systolic velocity (PSV) and the lower part of the wave the end diastolic velocity (EDV). The resistive index is calculated (PSV – EDV/PSV).

also has limitations, as it is based on the assumption that all of the blood of an area supplied by a specific artery is drained by a single corresponding vein.

Blue Field Entotpic Technique

The blue field entoptic phenomenon is produced by the different absorption of red and white blood cells when the retina is illuminated with blue light. Red blood cells absorb the short wavelength light, while passing white blood cells do not, thereby allowing the flux of the perimacular white blood cells to be estimated. This technique is limited by the assumption that leukocyte flux is proportional to retinal blood flow.

Laser Doppler Velocimetry

Laser Doppler velocimetry (LDV) is a technique that uses the optical Doppler shift of light to measure the blood flow velocities in retinal arterioles and venules. The Doppler shift of light is directly proportional to the blood velocity when the vessel is illuminated with a laser beam. The flow velocity in the vessel can be extrapolated from the range of frequency shifts of the power spectrum of the reflected laser light. The maximum frequency shift corresponds with the maximum velocity in the center of the vessel, assuming laminar flow.

Retinal Vessel Diameters

The aforementioned techniques can be utilized to provide information about ocular blood velocity, but lack the ability to calculate flux or flow rate. To determine blood flow, it is necessary to accurately measure the diameter of the vessel through which the blood is flowing. There are now commercially available systems that permit real-time assessment of retinal vessel diameter. The retinal vessel analyzer (RVA) is composed of a fundus camera and a sophisticated computer system which record vessel size in real time. One such system is the Canon Laser Doppler blood flowmeter, which combines the techniques of LDV and RVA. This approach is still limited to the study of larger vessels, and can only be performed on patients with clear ocular media.

Laser Speckle Technique

When the rough surface of the fundus is illuminated by coherent light, the backscatter of light produces a rapidly varying pattern. The rate of variation of this pattern produced by this laser speckle phenomenon can be measured to compute an estimate of the velocity of blood flowing through the retinal vessels. This laser speckle technique is limited by the fact that it provides only velocity information, as it cannot determine vessel diameter and therefore cannot be used to measure volumetric flow.

Laser Doppler Flowmetry

The scattering theory for light in tissue, formulated by Bonner and Nossal, assumes a randomization of light directions impinging on the erythrocytes. By directing a laser light on vascularized tissue that contains no large vessels, relative mean velocity of erythrocytes and blood volume can be calculated. Through two-dimensional mapping of the optical Doppler shift, blood flow to the juxtapapillary retina and ONH can be accurately evaluated. There is, however, significant variation in scattering of light between test subjects, likely a result of varying vascular densities and orientations. Thus, this technique can be used to compare changes in a given subject, but has less use in comparison of values between subjects.

Laser Doppler flowmetry can be combined with scanning laser tomography to provide a two-dimensional map of blood flow to the optic nerve and surrounding retina. The Heidelberg retina flowmeter (HRF) is one such commercially available system (**Figure 9**). This technique, however, is most sensitive to blood flow changes in the superficial layers of the ONH, and therefore provides only limited information about the deeper regions. This limits the ability to account for the retinal blood flow that is supplied by the choriocapillaris from the uveal system.

Pulsatile Ocular Blood Flow

Based on the changes in ocular volume and pressure during the cardiac cycle, it is possible to estimate pulsatile ocular blood flow. The pulse amplitude, which is the maximum IOP change during a cardiac cycle, is measured using a modified pneumotonometer. Alternatively, the

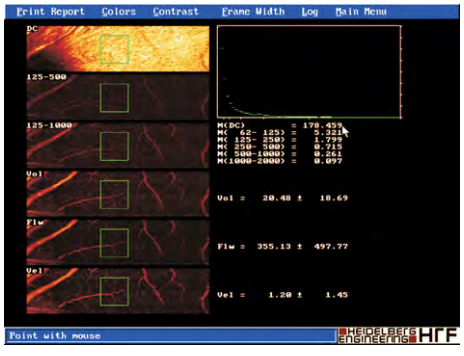

Figure 9 Confocal scanning laser Doppler flowmetry (Heidelberg retinal flowmeter) of optic nerve head and peripapillary retina. The patient is seated with the chin and forehead against the bar. The picture acquisition is performed without the need to dilate the patient's eye. The conventional 40 × 40 pixel measurement window collects flow values in arbitrary units from the entire retina except for large vessels.

ocular fundus pulsation amplitude can be determined by calculating the maximum change in distance between the retina and the cornea during a cardiac cycle. These two values have been shown to be useful in the calculation of pulsatile ocular blood flow, but lack information of the nonpulsatile component of ocular blood flow.

Optical Doppler Tomography

This technique combines the high-resolution cross-sectional imaging of optical coherence tomography with laser Doppler to measure velocity of blood flow in retinal arteries in real time.

Future Studies

Each of the previously discussed technologies quantifies some aspect of ocular blood flow. It is impossible, however, to interpret the impact of any single blood flow parameter measured within a single vascular bed on total retinal metabolism. The measurement of ocular blood flow is only a surrogate assessment of the metabolic status of the retina. Direct measurement of retinal tissue oxygenation would reveal the true impact of ischemia on retinal ganglion cell health and function.

New and emerging tools that assess metabolic parameters may help to reveal the relationship between reductions in ocular blood flow and tissue hypoxia. For example, Michelson and colleagues conducted a study in which they used imaging spectrometry to measure the oxygen saturation in retinal arterioles and venules in patients with glaucomatous optic neuropathy. In all examined eyes, the arteriolar oxygen saturation and the retinal arterio-venous differences in oxygenation were found to significantly correlate with the area of the patient's optic rim. Eyes with normal tension glaucoma, but not those with primary open angle glaucoma, showed significantly decreased arteriolar oxygen saturation. Although further advancements are still needed, these metabolic assessment tools may be very valuable in the evaluation of retinal hypoxia and in elucidating the effects of ocular ischemia. Obtaining accurate measurements of ocular tissue metabolism will greatly improve our understanding of disease pathophysiology, and will therefore lead to advancements in both diagnosis and treatment.

Angiogenesis in Inflammation

Z Szekanecz and L Módis, University of Debrecen Medical and Health Sciences Center, Debrecen, Hungary
A E Koch, University of Michigan Health System, Ann Arbor, MI, USA

Glossary

Angiogenesis – Physiological process involving the growth of new blood vessels from preexisting vessels.
Hypoxia inducible factors (HIFs) – Transcription factors that respond to decreases in oxygen.
Inflammation – A localized protective reaction of tissue to irritation, injury, or infection, characterized by pain, redness, swelling, and sometimes loss of function.
Neovascularization – Formation of functional microvascular networks with red blood cell perfusion.
Psoriatic arthritis – A form of rheumatoid arthritis usually affecting fingers and toes and associated with psoriasis.
Rheumatoid arthritis – A chronic autoimmune disease with inflammation of the joints and marked deformities.
Synovium – A thin layer of connective tissue with a free smooth surface that lines the capsule of a joint. Synovial fluid lubricates and facilitates movement of the joint.
Vascular endothelial growth factor – A signaling protein that regulates vasculogenesis.

Introduction

New capillary formation from preexisting blood vessels termed angiogenesis has been associated with inflammation and inflammatory diseases, as well as with malignancies. In inflammatory states, such as arthritis or psoriasis, the perpetuation of neovascularization increases the total endothelial surface and thus indirectly enhances leukocyte migration and accumulation into the involved tissue. There are numerous soluble and cell surface-bound mediators of angiogenesis, while angiostatic agents counterbalance neovascularization. The molecular mechanisms of angiogenesis and angiostasis, as well as angiogenesis in the eye are described in more detail elsewhere in this encyclopedia. Here we summarize the most relevant features of inflammation-related angiogenesis, as well as current therapeutic approaches to control angiogenesis in inflammatory states. Many of these therapeutic strategies have also been introduced to treat neovascular eye diseases. We have chosen rheumatoid arthritis (RA) as a prototype for inflammatory diseases, as the process of neovascularization, the most relevant angiogenic and angiostatic mediators and relevant anti-angiogenic therapies have been widely studied in context with inflammatory synovitis.

The Process and Models of Angiogenesis

In arthritis, there is excessive lymphocyte accumulation termed lymphoid neogenesis in the arthritic synovium. Inflammatory leukocytes migrate from the bloodstream through endothelia into the synovial tissue. Leukocyte adhesion to endothelium involves cell adhesion receptors, primarily integrins, selectins, and their respective ligands. Endothelial adhesion molecules, as well as several soluble mediators including growth factors, cytokines, chemokines, and others produced by synovial tissue macrophages and other cells may trigger synovial angiogenesis. First, these angiogenic mediators activate endothelial cells. Endothelium-derived proteolytic enzymes then digest the endothelial basement membrane and the perivascular extracellular matrix, thus enabling the proliferation and migration of endothelial cells into the interstitial tissue. The organization of these loose endothelial cells leads to the formation of primary and then further generation sprouts. Lumen formation within these endothelial sprouts leads to the genesis of capillary loops. Finally, new basement membrane is synthesized leading to new capillary formation.

There are several *in vitro* and *in vivo* models suitable to investigate the process of angiogenesis, the formation of new vessels on extracellular matrix substrata and to test anti-angiogenic compounds in preclinical studies. The corneal micropocket assay is the most relevant *in vivo* model of ocular angiogenesis. In this model, a micropocket is first prepared by cutting the cornea. The tested angiogenic compound is inserted into the pocket, and after 7–10 days vessel proliferation is induced toward the angiogenic compound (**Figure 1**).

Mediators of Angiogenesis

Numerous soluble and cell surface-bound mediators abundantly produced or expressed in inflammation exert angiogenic capacity (**Table 1**). There are endogenously

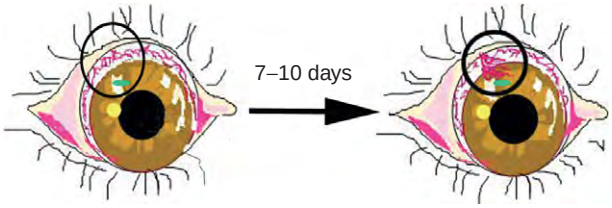

Figure 1 The rat corneal neovascularization model. The compound we wish to test for its angiogenic activity is inserted into the micropocket cut into the rat cornea. The degree of corneal neovascularization indicates the angiogenic activity of the compound.

Table 1 Some important mediators of inflammatory angiogenesis[a]

	Mediators
1. Growth factors	VEGF, aFGF, bFGF, HGF, HIF-1, HIF-2, PDGF, EGF, KGF, IGF-I, TGF-β
2. Cytokines	TNF-α, IL-1, IL-6, IL-8, IL-15, IL-17, IL-18, G-CSF, GM-CSF, oncostatin M, MIF
3. Chemokines/ receptors	IL-8/CXCL8, ENA-78/CXCL5, groα/CXCL1, CTAP-III/CXCL6, SDF-1/CXCL12, MCP-1/CCL2, fractalkine/CX3CL1 CXCR2, CXCR4, CCR2
4. Matrix molecules	Type 1 collagen, fibronectin, laminin, vitronectin, tenascin, proteoglycan
5. Cell adhesion molecules	β1 and β3 integrins, E-selectin, VCAM-1, ICAM-2, CD34, Lewis^y/H, MUC18, PECAM-1, endoglin, JAM-A, JAM-C
6. Proteolytic enzymes	MMPs, plasminogen activators
7. Others	Angiopoietin 1/Tie-2, angiotropin, pleiotrophin, angiogenin, survivin, COX/prostaglandin E2, PAF, nitric oxide (NO), endothelin-1, Serum amyloid A, histamine, substance P, adenosine, erythropoietin, prolactin, thrombin

[a]See text for abbreviations.

produced, natural inhibitors of neovascularization that try to counterbalance the effects of angiogenic agents; however, their amount and activity is usually insufficient to fully inhibit inflammatory angiogenesis so there is excess angiogenic over angiostatic capacity in inflammation, as well as in malignancies and other angiogenic diseases. Thus, anti-angiogenic therapies should be introduced by applying externally administered angiogenesis inhibitors in order to control pathological neovascularization in these disease states.

There are several angiogenic factors, including growth factors, cytokines, chemokines, extracellular matrix molecules, proteolytic enzymes, cellular adhesion molecules, and others implicated in inflammatory angiogenesis. In arthritis, these mediators are primarily released by macrophages and endothelial cells into the arthritic synovium. The most relevant molecules are listed in Table 1. Only angiogenic pathways also relevant for ocular neovascularization and anti-angiogenic treatment will be discussed in more detail.

There are numerous growth factors that are bound to heparin and heparan sulfate proteoglycans within the synovial matrix. Heparanase and plasmin produced during inflammation release these growth factors from the extracellular matrix. These growth factors include vascular endothelial growth factor (VEGF), basic (bFGF) and acidic fibroblast growth factors (aFGF), hypoxia-inducible factors 1 and 2 (HIF-1, HIF-2), as well as hepatocyte growth factor (HGF). In addition, some growth factors that do not bind to heparin, including platelet-derived growth factor (PDGF), epidermal growth factor (EGF), insulin-like growth factor-I (IGF-I), keratinocyte growth factor (KGF) and transforming growth factor-β (TGF-β) also promote neovascularization.

The hypoxia-HIF–VEGF-angiopoetin system is essentially involved in both inflammatory and ocular angiogenesis. In addition, as described later, VEGF is a primary target during angiogenesis. Hypoxia is a major feature of inflammation. In RA, there is intraarticular hypoxia, which induces branching of blood vessels. Hypoxia primarily acts by the stimulation of HIFs during angiogenesis and HIFs then stimulate the release of VEGF. (Hypoxia-induced neovascularization is discussed in more detail elsewhere in this encyclopedia.) As described recently, hypoxia may also act independently of HIFs by the peroxisome-proliferator-activated receptor-γ (PPARγ)/PPARγ coactivator 1α (PGC-1α) pathway. Upon ischemic injury, PGC-1α induces VEGF production and blood vessel reconstitution. Apart from PPARγ, activation of PPARβ/δ by specific ligands has also been recently implicated in VEGF production, inflammatory, and ocular angiogenesis.

Not only hypoxia and HIFs, but other proinflammatory mediators including tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), IL-6, IL-18, HGF, prostaglandins, and nitric oxide (NO) also promote VEGF release and capillary formation. VEGF stimulates angiogenesis, at least in part via cyclooxygenase-2 (COX-2) induction. VEGF also interacts with angiopoietin-1 (Ang1)/Tie-2, which promotes the stabilization of newly formed blood vessels. By contrast, Ang2, an antagonist of Ang1, inhibits vessel maturation. Survivin, an apoptosis inhibitor, has also been implicated in VEGF-induced angiogenesis. Thus, hypoxia, VEGF, HIF-1, HIF-2, Ang1, Tie2, and survivin are key players of inflammatory angiogenesis. Indeed, all these factors are abundantly expressed in the arthritic synovium. (More information on the molecular mechanisms of angiogenesis is available elsewhere in this encyclopedia.)

Pro-inflammatory cytokines may either directly induce neovascularization or may, as described above, act via VEGF-dependent pathways. The most relevant cytokines that have been implicated in arthritis-related

angiogenesis include TNF-α, IL-1, IL-6, IL-8, IL-15, IL-17, IL-18, oncostatin M, macrophage migration inhibitory factor (MIF), as well as granulocyte (G-CSF) and granulocyte-macrophage colony-stimulating factors (GM-CSF) (Table 1). As described above, TNF-α and IL-6 act via the induction of VEGF production. IL-17 exerts synergistic effects with TNF-α and thus stimulates the production of VEGF and other growth factors in synovitis. IL-18 also induces the production of VEGF, as well as that of angiogenic chemokines. Oncostatin M enhances adhesion molecule expression on RA synovial fibroblasts and vessels; it also stimulates endothelial cell migration and tubule formation. MIF is primarily produced by synovial macrophages and it acts via the release of VEGF and some angiogenic chemokines.

Some chemokines and chemokine receptors have also been implicated in inflammatory angiogenesis (Table 1). Chemokines are classified with respect to their chemical structure and the position of cysteine residues as CXC, CC, C, and CX_3C chemokines. In most angiogenic CXC chemokines the angiogenic capacity has been associated with the existence of glutamyl–leucyl–arginyl (ELR) amino acid motifs in their structure. The most relevant ELR^+ angiogenic CXC chemokines also abundantly produced in the inflamed synovium include IL-8/CXCL8, epithelial neutrophil activating protein-78 (ENA-78)/CXCL5, growth-related oncogene α (groα)/CXCL1, and connective tissue activating protein-III (CTAP-III)/CXCL6. Stromal cell-derived factor-1 (SDF-1)/CXCL12 is a key regulator of lymphoid neogenesis and the formation of lymphoid aggregates in the synovium. This chemokine lacks the ELR sequence; yet, it promotes neovascularization. Furthermore, hypoxia stimulates the release of SDF-1/CXCL12 in inflammatory synovitis. Among CC and CX_3C chemokines, MCP-1/CCL2 and fractalkine/CX3CL1 have been implicated in RA-associated angiogenesis. Among chemokine receptors, CXCR2 (the most important endothelial receptor for ELR^+ angiogenic CXC chemokines described above), CXCR4 (the receptor for SDF-1/CXCL12), and CCR2 (the receptor for MCP-1/CCL2) are all involved in chemokine-induced angiogenesis.

Inflammatory angiogenesis is associated with chemokine-driven recruitment of leukocytes through blood vessels into the synovium. This process involves cellular adhesion molecules, matrix macromolecules, as well as matrix-degrading proteolytic enzymes. Regarding adhesion molecules, most β_1 and β_3 integrins, E-selectin, selectin-related glycoconjugates including $Lewis^y$/H and MUC18, vascular cell adhesion molecule-1 (VCAM-1), intercellular adhesion molecule-2 (ICAM-2), platelet-endothelial cell adhesion molecule-1 (PECAM-1; CD31), endoglin (CD105), and junctional cell adhesion molecules A (JAM-A) and C (JAM-C) are expressed by endothelial cells and promote angiogenesis underlying inflammation. Among these adhesion receptors, the $\alpha_V\beta_3$ is of outstanding importance. This integrin mediates neovascularization, as well as osteoclast-mediated bone resorption and thus joint destruction in RA. During the process of angiogenesis, emigrating endothelial cells and soluble angiogenic mediators bind to extracellular matrix components. Thus, type I collagen, fibronectin, laminin, vitronectin, tenascin, and proteoglycans are also involved in neovascularization. Finally, matrix-degrading protease enzymes that digest the endothelial basement membrane and the interstitial matrix include various matrix metalloproteinases (MMPs) and plasminogen activators.

Other angiogenic mediators not mentioned above include endothelin 1 (ET-1), serum amyloid A (SAA), angiogenin, angiotropin, pleiotrophin, platelet-activating factor (PAF), substance P, histamine, erythropoietin, adenosine, prolactin, and thrombin. Among these mediators, ET-1 is released by endothelial as well as other cells. ET-1 stimulates VEGF production, endothelial proliferation, and angiogenesis. Abundant ET-1 production has been associated with RA, as well as scleroderma. SAA, an important acute-phase reactant in arthritis, stimulates endothelial proliferation, migration, and neovascularization.

Macrophages play a central role in angiogenesis related to arthritis and other types of inflammation. These cells express CXCR2 and CXCR4, which recognizes many angiogenic CXC chemokines described above. Macrophages also release numerous soluble angiogenic mediators, such as angiogenic CXC chemokines, TNF-α, IL-15, IL-18, VEGF, other growth factors, and MMPs. Finally, macrophages also secrete angiostatic factors such as CXCR3.

Angiogenesis Inhibition: Therapeutic Targeting of Angiogenesis in Inflammation

As a number of mediators are anti-inflammatory and also angiostatic, inflammation, and angiogenesis may be targeted simultaneously. Angiogenesis inhibitors relevant for inflammatory diseases, such as arthritis, are included in Table 2.

Naturally occurring endogenous angiogenesis inhibitors include interferons, IL-4, IL-13, CXC chemokines lacking the ELR motif including platelet factor 4 (PF4)/CXCL4, interferon-γ-inducible protein 10 (IP-10)/CXCL10 and monokine induced by interferon-γ (Mig)/CXCL9, thrombospondins, tissue inhibitors of MMPs, plasminogen activator inhibitors, and others. Theoretically all these inhibitors could be administered in high amounts in order to suppress neovascularization. Yet, only few compounds have been tested and found to be effective in animal models or humans (e.g., angiostatin, a fragment of plasminogen and endostatin, a fragment of

Table 2 Angiogenesis targeting strategies[a]

Endogenous inhibitors	• Angiostatin, endostatin
	• Thrombospondin 1 and 2
	• IL-4, IL-13
	• PF4/CXCL4
	• 2-Methoxyestradiol
Exogenous inhibitors	• VEGF inhibitors
	• HIF inhibitors
	• Ang1/Tie2 inhibitors
	• PPARγ, PPARβ/δ activators
	• Corticosteroids (triamcinolone)
	• Classical DMARDs
	• Biologics (infliximab, tocilizumab)
	• Thalidomide
	• Fumagillin analogues
	• Chemokine and chemokine receptor blockade (e.g., bicyclam)
	• $\alpha_v\beta_3$ integrin inhibitors (e.g., vitaxin)
	• Protease inhibitors
	• Endothelin-1 antagonists
	• Microtubule destabilizers (e.g., paclitaxel)

type XIII collagen block $\alpha_V\beta_3$ integrin-mediated angiogenesis). Endostatin also inhibits VEGF receptor 2 signaling. Both compounds successfully abrogated arthritis, as well as arthritis-associated neovascularization in various rodent models. Recently, new molecules related to angiostatin or endostatin have been developed and are being tested in angiogenesis and arthritis models. These compounds include protease-activated kringles 1–5 (K1–5), kallistatin, arresten, canstatin, and tumstatin. Regarding human studies, both angiostatin and endostatin have been introduced to clinical trials in cancer. Thrombospondin-1 (TSP1) and TSP2 that are angiostatic extracellular matrix components naturally produced by RA synovial macrophages and fibroblasts. Both TSP1- and TSP2-derived peptides suppress synovial inflammation and angiogenesis in rodent models. IL-4 and IL-13 gene transfer inhibited synovial inflammation and angiogenesis in rats. The angiostatic PF4/CXCL4 chemokine has also been tried in rodent models of arthritis. 2-Methoxyestradiol (2-ME), a natural metabolite of estrogen with low affinity for estrogen receptors, inhibited angiogenesis by disrupting microtubules and by suppressing HIF-1 activity. In recent preclinical studies, 2-ME suppressed VEGF and bFGF gene expression, as well as arthritis in the rats.

Exogenously administered agents are not naturally found in human tissues. These compounds include currently used anti-inflammatory drugs, biological monoclonal antibodies, receptor antagonists, and other small molecule inhibitors that interfere with the activity of VEGF, chemokines, adhesion receptors, and other angiogenic mediators. Some of these agents, primarily VEGF and VEGF receptor antagonists, have been introduced to the therapy of ocular vascular diseases, as well as arthritis.

Among currently used antirheumatic, anti-inflammatory drugs, corticosteroids, chloroquine, sulfasalazine, methotrexate, azathioprine, cyclophosphamide, leflunomide, thalidomide, minocycline, and some anti-TNF agents primarily infliximab also inhibit endothelial cell migration and synovial angiogenesis. Triamcinolone is not only effective in the treatment of inflammatory diseases, but it suppresses VEGF and endostatin production and it has been used to treat ocular neovascularization, such as AMD. Recently, the anti-IL-6 receptor antibody tocilizumab decreased serum levels of VEGF.

Certainly today targeting of VEGF and VEGF-induced angiogenesis, as well as the hypoxia-HIF-VEGF-Ang1-Tie2 system is in the focus of cancer, inflammation, as well as ocular angiogenesis research. There have been several attempts to target VEGF by using synthetic VEGF and VEGF receptor inhibitors, anti-VEGF antibodies, and inhibitors of VEGF and VEGF receptor signaling. The VEGF-Trap construct is a composite decoy receptor based on the fusion of type 1 and type 2 VEGF receptors with IgG1-Fc. These VEGF and VEGF receptor inhibitors have primarily been tried in colorectal, lung, renal, and liver cancers. Some of these agents have recently been introduced to suppress angiogenesis related to arthritis, as well as neovascular eye diseases. Bevacizumab is a full-length human monoclonal antibody to VEGF that has been approved for the treatment of various types of cancer. Later it has become the first biological agent to suppress AMD. The use of bevacizumab has been suggested in other vascular eye diseases including diabetic macular edema, pathological myopia, retinal angiomatous proliferation, branch retinal vein occlusion, neovascular glaucoma, and several other forms of ocular neovascularization including corneal neovascularization. Preclinical and clinical trials on bevacizumab in arthritis are underway. Ranibizumab (an antigen-binding anti-VEGF antibody fragment) and pegaptanib (an anti-VEGF pegylated aptamer) have been successfully used to treat AMD. A soluble VEGF receptor 1 chimeric protein dose-dependently inhibited the proliferation of synovial endothelial cells. Vatalanib, sunitinib malate, sorafenib, vandetanib, and AG013736 are small molecule inhibitors of VEGF receptor tyrosine kinases, which have been introduced to cancer studies. Among these compounds, vatalanib also inhibited knee arthritis in rabbits.

HIF-mediated neovascularization may also be targeted in various ways. For example, YC-1, a soluble guanylyl cyclase stimulator originally developed to treat hypertension and thrombosis, is also a HIF-1 inhibitor. Microtubule destabilizers, such as 2-ME mentioned above, as well as paclitaxel, an anti-cancer agent, also suppress HIF-1α activity. 2-ME elicited anti-inflammatory and angiostatic properties in animal models of arthritis, while paclitaxel was effective and safe in a phase I human RA trial. Regarding the Ang-Tie system, Tie2 inhibition by adenoviral gene therapy attenuated the incidence and severity of arthritis

in mice. The role of PPARγ and PPARβ/δ in conjunction with hypoxia HIF VEGF-mediated angiogenesis is described above. The PPARγ ligands, rosiglitazone and pioglitazone, inhibit VEGF- and bFGF-mediated angiogenesis. Pioglitazone suppressed psoriatic arthritis in a small clinical trial. Furthermore, the use of both PPARγ agonists has been suggested in the treatment of AMD, diabetic retinopathy, and other neovascular ocular disorders. GW501516, a PPARβ/δ ligand currently under development for the treatment of dyslipidemia, also blocked VEGF-dependent endothelial cell proliferation and angiogenesis.

The suppression of chemokine- and chemokine receptor-mediated neovascularization may also be feasible. For example, blockade of CXCR2 inhibits tumor-induced angiogenesis, while Mig/CXCL9 chemokine gene therapy enhances the angiostatic effects of cytotoxic agents in cancer trials. Bicyclam (previously AMD3100), a highly selective antagonist of SDF-1/CXCL4, also inhibits neovascularization in various models.

Vitaxin, a humanized antibody to the $\alpha_V\beta_3$ integrin, inhibited synovial angiogenesis and inflammation in animal models of arthritis; however, it showed very little efficacy in a phase II human RA trial. Some MMP inhibitors have been tried in angiogenesis models. ET-1 antagonists currently used in the treatment of primary and scleroderma-associated pulmonary hypertension may also exert anti-angiogenic effects.

Thalidomide, currently in use to treat multiple myeloma but also tried in lupus and RA, is a potent TNF-α antagonist and angiogenesis inhibitor. Thalidomide suppressed both synovitis and angiogenesis in human models; however, it showed little efficacy in human RA trials.

Fumagillin is a naturally occurring product of *Aspergillus fumigatus*. TNP-470 and PPI2458 are synthetic derivatives of fumagillin that inhibit the methionine aminopeptidase-2 enzyme involved in angiogenesis. These compounds also attenuate VEGF production and VEGF-induced capillary formation. In rodent models, TNP-470 prevented arthritis when administered before the onset of the disease, while PPI2458 also suppressed the development of arthritis and joint erosions.

Theoretically most angiogenic mediators described above could be targeted to treat inflammatory angiogenesis. Indeed, many of these agents have already been introduced to either preclinical or clinical therapeutic trials, first in cancer and later in inflammatory diseases. Numerous VEGF and VEGF receptor antagonists gave promising results in cancer, arthritis, as well as neovascular ocular disease trials. However, it remains to be seen whether angiostatic strategies using targets with multiple actions may be more effective on the long-term than specific targeting of one single angiogenic mediator.

Angiogenesis in Response to Hypoxia

Y Ozawa, K Tsubota, and H Okano, Keio University, Tokyo, Japan

Glossary

Erythropoietin (Epo) – Glycoprotein that controls angiogenesis as well as erythropoiesis.
Factor inhibiting HIF-1α (FIH-1) – Enzyme that hydroxylates and represses the transcription activity of HIF-1α.
Hypoxia-inducible factor-1α (HIF-1α) – A bHLH transcription factor regulated by hypoxia.
Oxygen partial pressure (pO_2) – Pressure of oxygen gas when it alone occupied the volume.
Proliferative diabetic retinopathy (PDR) – Most severe diabetes-induced retinopathy with pathological neovascularization.
Protein von Hippel-Lindau (pVHL) – E3-ubiquitin ligase that degrades ubiquitin-conjugated HIF-1α and a protein that determines the characteristic of von Hippel–Lindau syndrome.
Retinopathy of prematurity (ROP) – Disease that affects the newborn eye with disorganized growth of retinal vessels that may result in retinal detachment.
Vascular endothelial growth factor (VEGF) – Growth factor that controls angiogenesis and vascular permeability.

Introduction

Angiogenesis, the sprouting and branching of new blood vessels from the preexisting primitive network, involves several processes: endothelial cell proliferation and migration, degradation of the surrounding extracellular matrix (ECM) to allow migration, and vessel maturation by attracting pericytes and producing the basal lamina that surrounds the newly formed blood vessels. These processes are tightly regulated by the action of both stimulatory (angiogenic factors) and inhibitory (anti-angiogenic factors) molecules.

In the normal state, the action of angiogenic inhibitors dominates, and vessels are quiescent. However, under certain conditions that activate angiogenic factors, such as hypoxia or inflammation, the balance may shift in favor of angiogenesis. This mechanism contributes to the generation of new vessels not only during organogenesis, but also during the neovascularization associated with wound repair or pathological conditions in adults.

Pathological neovascularization is an important finding of vision-threatening diseases such as proliferative diabetic retinopathy (PDR) (Figure 1) and age-related macular disease (AMD). In PDR, vascular obliteration in the retina due to microangiopathy leads to extensive tissue hypoxia, which induces pathological angiogenesis; this angiogenesis leads to fibrovascular membrane formation, which causes severe vitreous hemorrhage, retinal detachment, and other detrimental conditions in the eye that result in vision loss. Worldwide, 194 million individuals have diabetes. Diabetic retinopathy is observed in 40% of individuals with diabetes, and over 8% of diabetic patients have vision loss from microvascular complications. In contrast, choroidal neovascularization in AMD is mainly caused by inflammatory reactions. More than 1.75 million people (1.5% of adults over 40) in the United States are estimated to have advanced AMD, which can induce registered legal blindness. The angiogenesis of both PDR and AMD is induced by the excessive expression of angiogenic factors and results in pathogenic conditions of the retina.

In this article, we focus on hypoxia-induced angiogenesis. We describe how angiogenic factors are regulated by hypoxia, and how they lead to pathological and physiological angiogenesis. The expression of two potent angiogenic factors, vascular endothelial growth factor (VEGF) and erythropoietin (Epo), is regulated by transcription factors called hypoxia-inducible factors (HIFs), and this regulation underlies most mechanisms that contribute to hypoxia-induced angiogenesis. Several pathways that regulate the HIFs under hypoxic conditions (and that, in turn, affect the levels of angiogenic factors regulated by the HIFs) are involved. Hence, hypoxia-induced angiogenesis is not mediated by a single pathway. The retina is a useful model system for studying angiogenesis in general, because it contains several thin vascular layers in which new vessels can be directly observed and quantified. This system has been used to elucidate the development of the vascular system and pathological neovascularization in the hypoxic retina. Here, we review the mechanisms of pathologic angiogenesis in the retina and describe supporting experimental data obtained from model animals in addition to human clinical data. We also discuss how hypoxia regulates vascular development in the retina.

Hypoxia and HIFs

One of the conditions regulating angiogenic factors is the local oxygen partial pressure (pO_2). While ambient air at sea level has a pO_2 of 149 mmHg (21% of the atmospheric

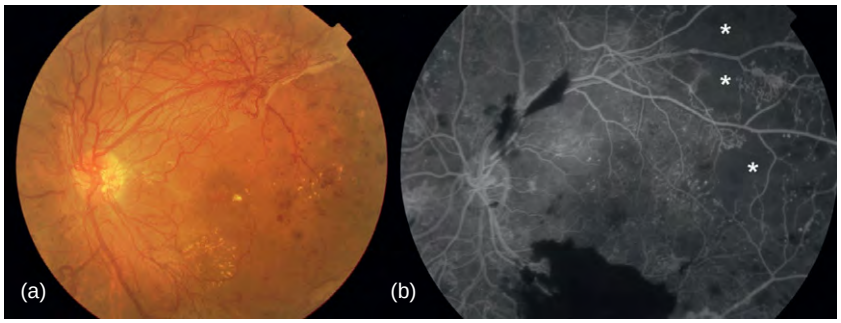

Figure 1 Fundus photograph of proliferative diabetic retinopathy. (a) Retinal neovascularization. (b) Fluorescent angiography shows areas of capillary nonperfusion in the retina (∗ in (b)).

pressure), the arterial oxygen content is as low as 75–100 mmHg (10–14%), and tissue pO_2 is lower still. For example, the pO_2 of resting skeletal muscle and ventricular myocardium is 30 mmHg (4%), which decreases to about 10 mmHg (1.4%) during contraction. Furthermore, the pO_2 in the inner segments of photoreceptor cells, where oxygen is supplied by diffusion from the choroidal vessels, decreases greatly during dark adaptation, to 5 mmHg (0.7%). In the dark, water and sodium flow passively into the photoreceptor cells from the surface membrane of their outer segment and are extruded by pumps in the inner segment. This dark current decreases during exposure to light, which promptly halts the pump action, thereby reducing the metabolism and oxygen uptake. Thus, oxygen consumption by photoreceptor cells is greater in darkness.

The condition of low pO_2 in normal tissue is called, physiological hypoxia. In a number of physiological and pathological processes, the tissue oxygen level may be further reduced due to poor circulation and/or rapid oxygen consumption. For example, in the diabetic retina, areas of capillary nonperfusion due to microangiopathy receive insufficient oxygen. During embryonic development, the rate of tissue expansion outpaces angiogenesis, creating an insufficient blood supply. Both of these situations lead to a very hypoxic environment in which various kinds of angiogenic factors can be simultaneously induced, to overcome the effects of insufficient blood flow.

Key molecules for promoting the expression of angiogenic factors are the HIFs. HIFs are heterodimers composed of an α subunit, HIF-1α (**Figure 2(a)**), HIF-2α (also known as HIF-1α-like factor; HLF), or HIF-3α, and a HIF-1β subunit. The subunits share a conserved domain structure, and, with the exception of HIF-1β, are upregulated by hypoxic conditions. The HIFα/HIF-1β heterodimeric complex forms a transcription factor that can bind to the HIF response element (HRE) (**Figure 2(b)**). In the HIF subunits, basic helix–loop–helix (bHLH) and PER-ARNT-SIM (PAS) motifs are required for dimerization, whereas a downstream basic region affords specific binding to the HRE sequence, 5′-RCGTG-3′. HIF-1α and HIF-2α activate the transcription of about 70 genes, including VEGF, Epo, and a VEGF receptor, VEGFR-1.

In the retina, HIF-1α is abundantly and broadly expressed during embryogenesis, when oxygen is supplied only by umbilical blood. Its expression is limited in the adult retina, but it can be induced again by hypoxic conditions. In contrast, HIF-2α is expressed generally in vascular endothelial cells.

HIF-1α is positively regulated by hypoxia through several pathways. A major pathway involves the stabilization of the protein by low levels of oxygen. In the presence of dioxygen, three oxygenases, prolyl hydroxylase domain proteins (PHD) 1-3, hydroxylate prolyl residues (proline residue 402 and/or 564) in human HIF-1α (**Figure 2(b)**). These residues are located in the N-terminal activation domain (TAD-N), within the oxygen-dependent degradation domain (ODDD) of HIF-1α. Hydroxylated HIF-1α is degraded by an E3-ubiquitin ligase, protein von Hippel–Lindau (pVHL), in a ubiquitin-proteasome-dependent pathway. However, under hypoxic conditions, PHD is inactivated and does not hydroxylate HIF-1α, and the degradation of HIF-1α by pVHL is, therefore, suppressed. HIF-2α also has an identical motif in the TAD-N, and HIF-3α has a partially identical one. The hydroxylation reaction by PHD requires Fe^{2+} and is inhibited by divalent cation chelators or cobalt chloride ($CoCL_2$). $CoCL_2$, which induces experimental neovascularization, promotes the induction of the angiogenic factor VEGF, and angiogenesis, by stabilizing HIFs. In addition, pVHL can degrade the RNA polymerase subunit, Rpb1, which may regulate the expression of HIFs both directly and indirectly.

Alternatively, factor inhibiting HIF-1α (FIH-1) represses the transcription activity of HIF-1α (**Figure 2(b)**). HIF-1α is hydroxylated by FIH-1 on asparagine residue 803, located in the C-terminal activation domain (TAD-C); this hydroxylation suppresses the binding of HIF-1α to its co-activators, p300/CBP. Thus, FIH-1 inhibits HIF-1α activity. This reaction is also dependent on Fe^{2+}, not only on oxygen. Moreover, PHD can bind to FIH-1, which together recruit histone deacetylase (HDAC) to repress the transcription of target genes.

Both of these HIF-1α regulatory pathways, that is, the PHD-pVHL-mediated protein degradation and the FIH-1-mediated inhibition of HIF-1α's function as a

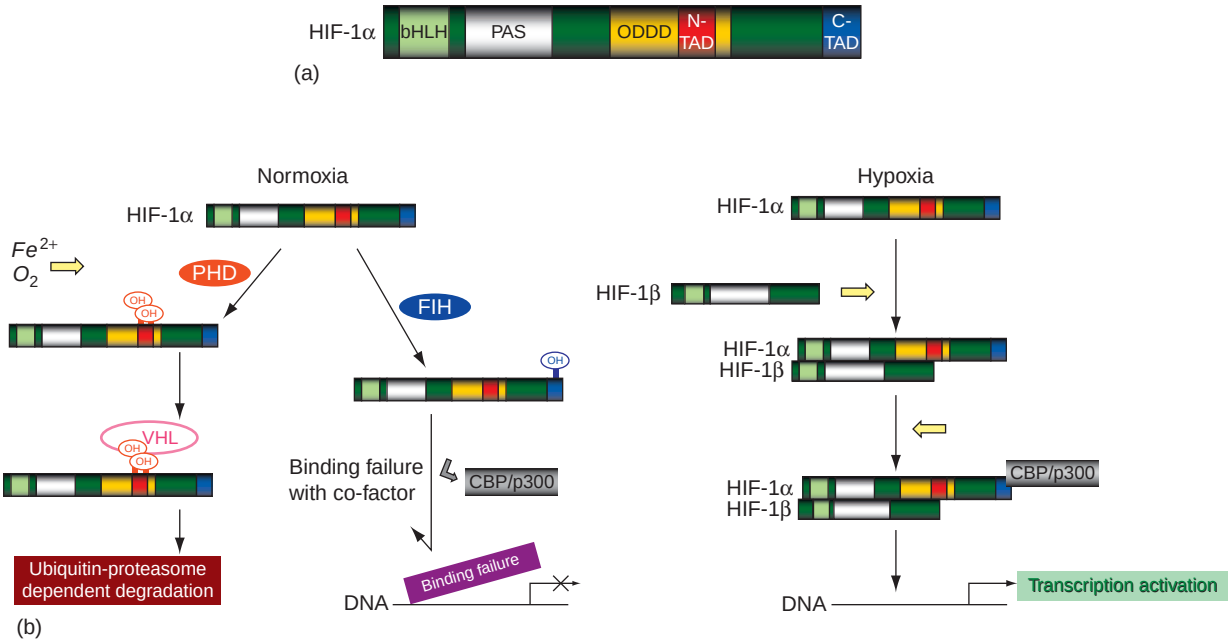

Figure 2 Regulatory systems of HIF-1α. (a) Structure of HIF-1α. (b) Molecular mechanism of HIF-1α regulation. PHD hydroxylates HIF-1α at N-TAD in the ODDD, leading to HIF-1α's ubiquitin-proteasome-dependent degradation by VHL protein. FIH-1 hydroxylates C-TAD, which inhibits HIF-1α transcriptional activity. The bHLH domain and PAS domain are required for HIF-1α dimerization to transactivate its target genes, binding with co-factors, CBP/p300. bHLH, basic helix loop helix; PAS, PER-ARNT-SIM; PHD, prolyl hydroxylase domain protein; N-TAD, N-activation domain; ODDD, oxygen-dependent degradation domain; VHL, von Hippel–Lindau; FIH-1, factor inhibiting HIF-1; C-TAD, C-activation domain.

transcriptional factor, are strictly pO_2 dependent. The K_m for O_2 in the PHD-pVHL-mediated reaction is 230–250 μM, and that in the FIH-1-mediated reaction is 90 μM. Therefore, a slight reduction in pO_2 is sufficient to inhibit the PHD-pVHL-mediated reaction, and if the hypoxia becomes more severe, the FIH-1-mediated reaction is inhibited, stabilizing HIF-1α function.

There are other pathways that regulate HIF-1α but are not dependent on pO_2. For example, the p42/p44 mitogen-activated protein kinase (MAPK) pathway suppresses the translocation of HIF-1α from the nucleus to the cytosol by phosphorylating HIF-1α serine residues 641 and 643. This mechanism prolongs HIF-1α's functioning as a transcription factor. A MAPK also phosphorylates a co-activator – p300 – to promote its interaction with HIF-1α. In addition, pVHL directly associates with and positively regulates the tumor suppressor p53 by inhibiting Mdm2-mediated ubiquitination, and p53 inhibits HIFs by directly binding to the ODDD of the HIF-1α subunit. p53 is induced to initiate apoptosis in response to DNA damage; thus, events following DNA damage may also regulate HIF activity.

Otherwise, HIF-1α regulation can also occur at the transcriptional level. The phosphatidylinositol 3 kinase (PI3K)/AKT signal-transduction pathway, which can be activated by insulin and by cytokines such as insulin-like growth factor (IGF)-1, promotes the transcription of HIF-1α gene.

HIFs and Angiogenic Factors

In this section, two major, potent angiogenic factors induced by hypoxia are discussed.

One of the most well-known angiogenic factors downstream of the HIFs is VEGF. VEGF (or VEGF-A) is a member of the platelet-derived growth factor (PDGF) family, molecules that function as dimeric glycoproteins. It also includes VEGF-B, VEGF-C, VEGF-D, and placental growth factor (PlGF). VEGF is a potent inducer of endothelial cell proliferation. In addition, it promotes the transcription of the *integrin V* gene. Since the selective display of integrin aVb3 and aVb5 on blood vessels guides endothelial cell migration, the induction of *integrin V* by VEGF promotes sprouting in angiogenesis.

Increased VEGF mRNA expression is reported in the human hypoxic retina in PDR. An increase in VEGF expression is strongly related to the transcriptional function of HIFs, and in addition, VEGF mRNA is stabilized by hypoxia posttranscriptionally. The hypoxia-induced RNA-stability factor, HuR protein, binds to an AU-rich element in the 3′-untranslated region (UTR) of VEGF mRNA, which extends the half-life of the VEGF mRNA 3–8 times. Moreover, HuR binds to and stabilizes HIF-1α mRNA, which also upregulates VEGF expression. Therefore, hypoxia induces VEGF through multiple pathways.

There are two homologous receptors for VEGF, VEGF receptor-1 (VEGFR-1/Flt-1) and VEGF receptor-2

(VEGFR-2/Flk-1/KDR), which are also targets of HIFs. VEGFR-1 is a target of both HIF-1α and HIF-2α, and VEGFR-2 is a target of HIF-2α. Although VEGFR-1 has a greater affinity for VEGF, VEGFR-2 induces tyrosine phosphorylation much more efficiently upon ligand binding, which, in endothelial cells, leads to mitogenesis, chemotaxis, and changes in cell morphology. The deletion of HIF-1α in endothelial cells disrupts an autocrine loop necessary for the hypoxic induction of VEGFR-2 by VEGF signaling through VEGFR-1. Disruption of the VEGF/VEGFR-1/VEGFR-2 autocrine signaling loop results in decreased endothelial cell proliferation and tube formation *in vitro*, and severely impairs tumor angiogenesis and tumor growth *in vivo*. Thus, the induction of VEGFR-2, not only of VEGFR-1, is also regulated by both HIF-1α, indirectly, and HIF-2α, directly. This positive feedback system promotes rapid and extensive angiogenesis under hypoxic conditions.

In the retina, VEGF is observed under normoxic conditions and is upregulated under hypoxic conditions in the inner nuclear layer cells, identified morphologically as Müller glial cells. VEGFR-1 is present in the retinal ganglion cells and retinal neural cells in the inner nuclear layer, and VEGFR-2 is mainly in the putative Müller glial cells and blood capillaries.

To date, six isoforms of human VEGF, which range in length from 121- to 206-amino acid residues (VEGF121–206), have been identified. Most VEGF-producing cells preferentially express VEGF121, VEGF165, and/or VEGF189. The splice variants differ in their ability to bind heparin and heparin sulfate, according to their size. The larger isoforms – VEGF189 and VEGF206 – have a high affinity for heparin and thus bind tightly to the cell surface and extracellular matrix (ECM). In contrast, the intermediate isoform, VEGF165, is moderately diffusible (up to half of it remains unbound), and the smallest isoform, VEGF121, is highly diffusible, due to a reduction in or lack of heparin-binding domains. The various isoforms of VEGF may play distinct roles during angiogenesis in the retina as well as during tumor proliferation. Diffusible VEGF165, secreted as a ~46-kDa homodimer, is the isoform responsible for inducing pathological angiogenesis. This function may partly be owing to the persistent potent downstream signaling that VEGF165 induces by binding to both VEGFR-2 and a co-receptor, one of the neuropilins (NRP1 or NRP2). The neuropilins enhance the binding of VEGF165 to VEGFR-2, and thus VEGF165's bioactivity.

Another angiogenic factor induced by hypoxia is Epo, a target of both HIF-1α and HIF-2α. Epo is a small, 30-kDa molecule that was originally reported as a regulator of erythropoiesis, but it also induces the proliferation and migration of endothelial cells. Epo mRNA is increased in the human retina with PDR where neovascularization is promoted. It is most abundant in the retinal ganglion cell and inner layers, and is expressed in vascular endothelial cells. In contrast, the Epo receptor mainly localizes to inner segments of photoreceptor cells and the region of synaptic complexes in the outer plexiform layer and, weakly, to the inner nuclear layer, as well as to the blood vessels.

HIFs and Ocular Angiogenesis

Hypoxia-induced angiogenesis is involved in diabetic retinopathy, and retinopathy of prematurity. In this section, human clinical data and experimental data that have helped to elucidate ocular angiogenesis are presented. Aiello and colleagues were the first to show, in 1994, that the VEGF is a mediating protein in retinal ischemia-induced intraocular neovascularization. The VEGF concentration was measured in ocular fluid obtained from 164 patients undergoing intraocular surgery. The 70 ocular fluid samples from patients with active PDR showed a higher VEGF concentration than the samples from patients with nonproliferative diabetic retinopathy (25 samples), quiescent PDR (41 samples), or nondiabetic patients (31 samples). The concentration of VEGF in the vitreous fluid was higher than in the aqueous fluid in 10 sample pairs obtained simultaneously from a single patient with active intraocular neovascularization. The persistently high level of VEGF in PDR has been confirmed by other research groups. In one study, the data were obtained from patients who had undergone vitrectomy for PDR. High levels of VEGF were found in the vitreous fluid collected at the time of fluid-air exchange during surgery, and several days after the primary operation.

The mechanism behind this hypoxia-induced VEGF expression in the diabetic retina has been little studied in animal models, because it is difficult to induce retinal vessel obliteration by artificial hyperglycemia. For example, in diabetic rats, acute intensive insulin therapy produces a transient worsening of the diabetic blood–retinal barrier breakdown via an HIF-1α-mediated increase in retinal VEGF expression; however, in this animal model, VEGF is induced by rapid insulin administration and not by hypoxia. Insulin-induced VEGF expression requires p38 MAPK and PI3K in this model, which may enhance HIF-1α stability and transcription. Another group showed that both a streptozotocin-induced mouse model of type 1 diabetes and the ob/ob mouse, a model of type 2 diabetes, show a high level of HIF-1α that leads to an increase in VEGF in the retina, but this effect is caused by insulin receptor substrate (IRS)-1 or 2 by binding to the insulin receptor.

There is an animal model of hypoxia-induced neovascularization associated with retinopathy of prematurity (ROP). This model is made by exposing young mice to a high pO_2 for several days to induce vessel obliteration, followed by normoxic conditions. The intra-retinal pO_2

declines just after the return to normoxic conditions – a relatively hypoxic state – but before the vessel occlusion is released, inducing HIF-1α expression in the inner nuclear layer. The HIF-1α expression profile coincides with VEGF expression, suggesting that VEGF may be a key molecule in ROP pathogenesis. However, Epo is also increased during ROP. Interestingly, Epo is not increased in HIF-2α-deficient mice following exposure to hyperoxia followed by normoxia, preventing ROP. In these mice, VEGF expression is unchanged. The article, therefore, showed that HIF-2α-induced Epo is required to induce ROP, which is compatible with the fact that HIF-2α has a higher affinity for the Epo than the VEGF promoter. It is also consistent with the finding that the HIF-1α expression in ROP models is only mildly and transiently increased, while the elevation of HIF-2α is large and rapid.

In contrast, ROP models in knockout mice of RTP801, a target of HIF-1α, show decreased levels of neovascularization. Moreover, a blockade of adenosine, which is synthesized by the HIF-1α-induced enzyme 5-nucelotidase (5 N), reduces neovascularization in ROP models, as shown by angiography. These data suggest the involvement of HIF-1α in ROP pathogenesis.

To complicate matters further, Epo is increased in the vitreous fluid of PDR patients independent of VEGF expression, suggesting that Epo is also a potent ischemia-induced angiogenic factor in the diabetic retina. These two separately proposed mechanisms of PDR and ROP generation – either by HIF-1α-induced VEGF or by HIF-2α-induced Epo – include the idea that several pathways are activated simultaneously in response to hypoxia. Further studies are required to elucidate how these multiple pathways are orchestrated to direct angiogenesis under various conditions.

The angiogenesis that occurs during development, following vasculogenesis, in which circulating or tissue-resident endothelial stem cells (angioblasts) proliferate and form the capillary plexus, may also be regulated by hypoxia. In the retina, vitreous vessels perfuse the retina during the embryonic stage; after birth they regress, and networks of vessels begin to form from the central to the peripheral retina. The pO_2 is low in the embryo, because the oxygen supply comes only from the umbilical flow, in which pO_2 is lower (up to 30 mmHg) than in the maternal venous blood flow. However, once that newborn is breathing on its own, the HIFs levels downregulate. Nonetheless, retinal vessel formation progresses in response to local gradient of pO_2 in the retina. Network of retinal astrocytes which guides vascular formation as templates during development is hypoxia sensitive. Retinal astrocytes proliferate under hypoxic condition and express HIF-1α and VEGF until they maturate to cease vascular induction in response to oxygen supply from newly formed vessels. Although oxygen may not be the only key molecule of vascular development, temporal and spatial regulation of HIFs and VEGF expression may be deeply involved in the retinal vascular development.

Recent studies have shown that anti-VEGF therapy reduces neovascularization in PDR, both in animal models and in human patients. However, as described above, VEGF is not the only regulator of angiogenesis; several other factors are also induced under hypoxic and pathologic conditions. It is not easy to completely regulate all of these factors therapeutically. Importantly, the HIF transcription factors can be regarded as master switches that regulate all oxygen-dependent retinal diseases. To date, several small-molecule inhibitors of HIF have been developed, and they are now being tested in clinical trials for the treatment of cancer-related disease. These HIF inhibitors may also be applicable to anti-angiogenic therapies for hypoxia-induced ocular diseases. Further studies are required to overcome the pathological angiogenesis.

Angiogenesis in the Eye

B Regenfuss and C Cursiefen, Friedrich-Alexander University Erlangen-Nuernberg, Erlangen, Germany

Glossary

Choroidal neovascularization – Formation of new blood vessels that are from the choroidal layer in the eye.
Hemangioblastoma – A benign tumor due to an abnormal growth of blood vessels.
Von Hippel–Lindau (VHL) disease – An inherited disorder involving the formation of tumors with abnormal growth of blood vessels.

Introduction: Angiogenesis in the Eye

The formation of new blood vessels can be achieved by two different mechanisms – angiogenesis and vasculogenesis. Both processes normally occur during embryonic development, whereas after birth most blood vessels remain in a quiescent state. Exceptions include physiological blood vessel growth in the adults during the hair cycle, during wound healing, and in the female reproductive system. Pathological blood vessel growth due to unregulated angiogenesis is associated with several disorders, including cancer, arthritis, and disorders such as corneal neovascularization, age-related macular degeneration (AMD), and diabetic retinopathy.

During embryonic development, the primary vascular plexus is established through a process called vasculogenesis. Vasculogenesis implies *de novo* blood vessel formation by differentiation of endothelial progenitor cells. From there on new blood vessels can be generated through angiogenesis, which means vessel growth is by sprouting from preexisting vasculature or by intussusception. During early development of the human fetal retina, both processes – vasculogenesis and angiogenesis – complement one another and contribute to meet the metabolic requirements of the developing retina. It has been suggested that vasculogenesis pioneers the establishment of a rudimentary vascular plexus, whereas angiogenesis provides further expansion of the vascular network and cares for increasing vessel density.

Steps of Angiogenesis

The formation of new blood vessels requires several steps comprising a degradation of the vascular basement membrane and remodeling of the extracellular matrix (ECM). Further on, endothelial cells need to proliferate and migrate in a defined manner, thereby invading the surrounding tissue and forming capillary-like tubes. Recent data suggest sprouting angiogenesis as a guided process with endothelial cells fulfilling specialized tasks.

Vessel vasodilatation and degradation of the ECM

One of the earliest steps in new blood vessel formation is vasodilatation, mainly effected by nitric oxide (NO), which itself can induce transcription of VEGF by endothelial cells. Vascular permeability factor (VPF) can increase vessel permeability and induce vascular leakage; thereby plasma proteins (such as fibrin/fibrinogen, and plasma-clotting proteins) can extravasate and form a fibrin gel, which serves as a temporary matrix for endothelial cell migration. To prevent excessive loss of plasma proteins, the organism has to provide mechanisms to regulate vascular permeability. Angiopoietin-1 (Ang1), a ligand for the endothelial receptor Tie-2 protects adult vessels from leakage. Ang1 and VEGF function together during vascular development and it is suggested that the coordinated action of Ang1 and VEGF contributes to vessel integrity in the adult.

For degrading the ECM, a prerequisite for endothelial cells to migrate, many proteolytic enzymes are necessary. Matrix metalloproteinases (MMPs) are thought to be primarily responsible for degrading ECM components and structures of the basement membrane. Their expression can be induced by growth factors, cytokines, interactions with the ECM, and is also regulated at the transcriptional and post-transcriptional levels. Both, MMP2 and MMP9 (gelatinase A and gelatinase B, respectively) can degrade collagen in the vascular basement membrane. The proteolytic activity of MMPs is controlled precisely and can be inhibited by endogenous factors such as tissue inhibitors of metalloproteinases (TIMPs). Besides their important role in degrading ECM components, MMPs are also involved in different pro- and antiangiogenic processes.

Endothelial cell proliferation, migration, and formation of tubular structures

After overcoming the ECM and loosening the endothelial cell–cell and cell–matrix adhesions, the endothelial cells proliferate and migrate to the chemotactic stimulus. Several factors, such as VEGF, basic fibroblast growth factor (bFGF), angiopoietins, and chemokines including monocyte chemotactic protein-1 (MCP-1) are involved in this process.

Endothelial cells that migrate to the ECM subsequently assemble as tubular structures whose diameter is regulated by several factors: for example, by different

isoforms of VEGF or through an interplay between VEGF and Ang1. Furthermore, endothelial cells can fuse with other existing vessels to form new ones and develop numerous cell–cell junctions. During further maturation of the vascular network, the endothelial cells differentiate to meet the local requirements due to specific tissues. To complete the maturation, a vascular basement membrane is deposited and periendothelial cells are recruited to stabilize the vessels by inhibiting endothelial cell proliferation and migration. The crucial role of pericytes and their interactions with endothelial cells becomes obvious, as intact pericyte–endothelial associations prevent vessels from regressing and aberrant remodeling. Additionally, activated transforming growth factor-β (TGF-β) produced in co-cultures of endothelial cells and pericytes inhibits further proliferation of endothelial cells and stabilizes the nascent vessels.

Corneal Angiogenesis

The cornea, the transparent window of the eye, normally is completely devoid of blood and lymph vessels, which is an indispensable prerequisite for good vision. Actively maintaining this avascularity, even under inflammatory or other pro-angiogenic conditions, is known as corneal angiogenic privilege. Deprivation of this privilege can lead to corneal neovascularization and to severe vision-threatening events. Therefore, angiogenic privilege is evolutionarily highly conserved and redundantly regulated by different molecular mechanisms, which are not completely elucidated to date. Corneal avascularity is already present during intrauterine development, at least from the gestational age of 17 weeks, suggesting that the cornea primarily is avascular and not as a result of regression of already existing vessels. An important mechanism for maintaining avascularity is the expression of vascular endothelial growth factor receptor-3 (VEGFR-3) on normal human corneal epithelial cells, where it can act as a decoy receptor to bind VEGF-C. VEGFR-3 is able to bind and neutralize pro-angiogenic molecules, thus inhibiting neovascularization in the limbus. Similarly, the soluble form of VEGFR-1 expressed in the cornea is believed to function as an endogenous VEGF-A trap, thereby inhibiting new vessel growth. As the angiogenic privilege is redundantly organized, a deficiency of a single antiangiogenic factor such as thrombospondin-1 (TSP-1) or TSP-2 does not result in a breakdown of the angiogenic privilege, at least during embryonic development. Nevertheless, the angiogenic privilege can be overcome and corneal neovascularization can occur (e.g., during severe inflammation). Neovascularization is induced by an imbalance of pro- and antiangiogenic molecules caused by upregulation of the pro-angiogenic factors and a downregulation of the antiangiogenic ones, thereby tilting the balance toward pro-angiogenic factors. Corneal neovascularization as a consequence of a temporary inflammatory stimulus (e.g., by placing sutures in the cornea of mice) seems to proceed in a defined manner. Initially, a parallel outgrowth of blood and lymphatic vessels occurs, both outgoing from the limbal vascular arcades. The outgrowth peaks around day 14 and is followed by vessel regression after removing the inflammatory stimulus, whereas lymphatic vessels regress earlier than blood vessels.

Angiogenic and Antiangiogenic Molecules

Several angiogenic and antiangiogenic molecules have been identified in the cornea over the years and are involved in corneal neovascularization. These include VEGFs, fibroblast growth factors (FGFs), MMPs, angiostatin, endostatin, TSPs, and pigment epithelium-derived factor (PEDF).

The VEGF growth factor family currently consists of five members: VEGF/VEGF-A, placental growth factor (PlGF), VEGF-B, VEGF-C, and VEGF-D, VEGF-A exists in five different isoforms, namely $VEGF_{115}$, $VEGF_{121}$, $VEGF_{165}$, $VEGF_{189}$, and $VEGF_{206}$ and are alternative splicing variants. VEGF-A can be released during hypoxia or inflammation and is upregulated in inflamed and vascularized human corneas. VEGF acts by binding to its cognate receptors VEGFR-1 and VEGFR-2 and stimulates endothelial cell proliferation and migration and also microvascular leakage, thereby promoting angiogenesis. Genetic polymorphism in the VEGF gene is implicated in eye diseases such as neovascular AMD and diabetic retinopathy. Furthermore, VEGF was suggested to induce not only hem-but also lymph-angiogenesis in an indirect manner through macrophage recruitment, which itself can release lymphangiogenic growth factors such as VEGF-C and VEGF-D.

VEGF-C and VEGF-D are the major lymphangiogenic growth factors with corresponding receptors VEGFR-2 and VEGFR-3, present on endothelial cells. VEGF-C plays a decisive role during lymphangiogenic development: homozygote as well as heterozygote VEGF-C-lacking mice were demonstrated to have severe defects in the formation of lymphatic vessels. Furthermore, VEGF-C is critically involved in corneal neovascularization and was also shown to promote angiogenesis *in vivo*. In its fully processed form, VEGF-C increases vascular permeability, migration, and proliferation of endothelial cells. *In vitro*, it stimulates migration of cultured endothelial cells.

bFGF/FGF-2 and acidic FGF (aFGF) belong to the FGF family. Their expression has been demonstrated immunohistochemically in the outer retina of rat and mouse. bFGF and aFGF seem to be involved in the development of choroidal neovascularization (CNV): both molecules are found to be expressed in retinal pigment epithelial cells from choroidal neovascular membranes from patients with AMD, but only little immunoreactivity for the growth factors was found in retinal pigment epithelial

cells from healthy eyes. As mice with a disruption of the bFGF-coding gene still can develop CNV, it is suggested that bFGF plays more of an indirect role in initiation of neovascularization and interacts with the signal transduction pathways of VEGF. Consistent with this fact, bFGF was found to be co-localized with VEGF in cells of epiretinal and choroidal neovascular membranes. To date, bFGF was analyzed in several corneal neovascularization models and was recently demonstrated to induce angiogenesis as well as lymphangiogenesis *in vivo* in a mouse corneal micropocket assay. Lymphangiogenesis was mediated by bFGF in an indirect way via VEGFR-3 and was suppressed after inhibition of VEGFR-3 signaling with antiVEGFR-3 antibodies.

Thrombospondins (TSPs) currently comprise a group of five multidomain extracellular glycoproteins that are involved in cell–cell or cell–matrix interactions. In this family, TSP-1, TSP-2, and TSP-5 are studied in detail, whereas only little is known about TSP-3 and TSP-4. TSP-1 was one of the first molecules shown to have an antiangiogenic activity. Its antiangiogenic activity was first observed in 1990. It was shown that a purified factor from baby hamster kidney (BHK) cells, similar to a fragment of the platelet and matrix protein thrombospondin, inhibited bFGF-induced corneal neovascularization. Since then, the impact of TSP-1 on angiogenesis has clearly been demonstrated in several *in vitro* and *in vivo* models. *In vitro* TSP-1 inhibits adhesion, proliferation, and tube formation of cultured endothelial cells and is implicated in inducing apoptosis in endothelial cells. *In vivo*, TSP-1 suppresses neovascularization in the chick chorioallantoic membrane (CAM) assay. TSP-2 is closely related to TSP-1 in its structure and amino acid identity and shows some similar properties, for example, an inhibitory effect on migration and proliferation on endothelial cells. Although TSP-1 and TSP-2 are the most similar in the TSP family and share such inhibitory functions, they differ significantly in promoter regulation and their expression patterns. In the eye, TSP-1 plays an important role in induction of immune deviation in the anterior chamber and thus contributes to the immune privilege of the eye. Furthermore, both TSP-1 and TSP-2 were shown to suppress corneal neovascularization in response to an inflammatory insult with a greater effect for TSP-1. In the case of developmental iris angiogenesis, a lack of TSP-1, TSP-2, or both leads to a significantly increased iris vessel density, with a more prominent role for TSP-2.

Diabetic Retinopathy and Retinal Angiogenesis

Diabetic retinopathy is one of the leading causes of blindness in Europe and North America. It is predominantly denoted to progressive vascular occlusion and increased vascular permeability and often leads to pathological neovascularization in the retina and the vitreous. Early stages of diabetic retinopathy are histologically characterized by the loss of pericytes from retinal capillaries and the formation of microaneurysm.

The mechanism of pericyte loss is still unclear but it might be caused by the accumulation of toxic products such as the sugar alcohol sorbitol and advanced glycation end products (the so-called AGEs) within the pericytes. An alternative hypothesis refers to an active elimination mechanism of the pericytes by upregulation of Ang-2 due to hyperglycemia. Recent data suggest that pericyte loss is due to pericyte migration, regulated by interactions of the Ang/Tie-2 system. The pericytes seem to control endothelial cell proliferation by releasing TGF-β. The pericyte drop-out leads to a disappearance of endothelial cells and subsequently to nonperfused acellular capillaries. Acellular capillaries characteristically can be found in histological sections of the ischemic retina.

Microaneurysms, one of the first clinical findings indicating a loss of pericytes, are mainly detected in hypoxic areas of occluded and unperfused capillaries (**Figure 1**). Hypoxia in diabetic retinopathy can occur due to several reasons including a thickening of the basement membrane, which impedes the diffusion of oxygen. Furthermore, the nonenzymatic glycosylation of membrane proteins of erythrocytes reduces cell plasticity and leads subsequently to an increased viscosity of the blood. Due to increased viscosity of the blood, the risk for thrombosis formation increases and can cause a lower perfusion and occlusion of the capillaries. Enduring retinal hypoxia can induce

Figure 1 Fluorescein angiography of diabetic retinopathy. Loss of pericytes leads to weak capillary walls and can result in microaneurysms, which are one of the first detectable signs in diabetic retinopathy (arrows).

neovascularization of the retina and the vitreous, whereas the extent of nonperfusion in the retina seems to be associated with the extent of neovascularization. Thus, VEGF plays a pivotal role in mediating the formation of the new blood vessels due to ischemia. *In vitro* studies have shown that VEGF mRNA is upregulated in cell cultures exposed to hypoxic conditions. Furthermore, VPF might be responsible for the fragility and increased permeability of the newly formed vessels. Due to the malformation of the proliferating vessels, their ingrowths can result in hemorrhage in the vitreous and thus leads to a compromised vision.

Central Retinal Vein Occlusion and Retinal Angiogenesis

Central retinal vein occlusion (CRVO), a common retinal vascular disorder, can be classified by means of the extent of retinal ischemia. According to the Central Vein Occlusion Study Group (CVOSG), it can be differentiated into the nonischemic and the ischemic CRVO, which are the milder and the more severe forms, respectively. Complications of the ischemic form are macular edema and neovascular glaucoma caused by iris neovascularization (Rubeosis iridis), which often results in vision loss. Due to an occlusion of the central retinal vein by a thrombus, the venous blood flow decreases and leads subsequently to an ischemic damage of circumjacent regions. It seems that VEGF is implicated in the pathophysiology of CRVOs. Several factors do support this hypothesis:

1. it was shown that cultured human retinal pigment epithelial cells synthesize and release VEGF;
2. hypoxia was shown to increase the level of VEGF mRNA in retinal cells;
3. furthermore, after induction of retinal ischemia in an animal model of retinal vein occlusion, upregulation of VEGF mRNA could only be found in the ischemic region; and
4. an upregulation of VEGF mRNA was also detected in the retinas of patients with CRVO.

Several studies have shown that excess VEGF application to tissues leads to the formation of leaky and hemorrhagic vessels, which can result in inflammatory responses with tissue swelling and edema. Capillary leakage induced by VEGF might be a pathogenic mechanism that contributes to the formation of macular edema in CRVO.

AMD and choroidal neovascularization

AMD is one of the main causes for vision disability among persons over 60 years of age. A metabolic disorder of the photoreceptors and the retinal pigment epithelial layer leads to the formation of yellow–white deposits (=drusen) that accumulate in the subretinal pigment epithelium of the eye (Figure 2). During late stages of the dry (nonexudative) form of AMD, a geographic atrophy can occur. In the case of the second form of AMD – wet (exudative) AMD – a detachment of the retinal pigment epithelium and CNV are significant. Clinically, visible signs during CNV are hemorrhage, retinal exudates, and serous or hemorrhagic pigment epithelial detachment. It is believed that the occurrence of pathological choroidal angiogenesis is due to the growth of new blood vessels from preexisting choroidal capillaries (angiogenesis) consequent to changes in Bruch's membrane. After rupturing the Bruch's membrane, choroidal vessels consequently grow in the subretinal or subpigmental epithelial space. Risk factors for the development of AMD include age, genetic dispositions, smoking, and other environmental factors.

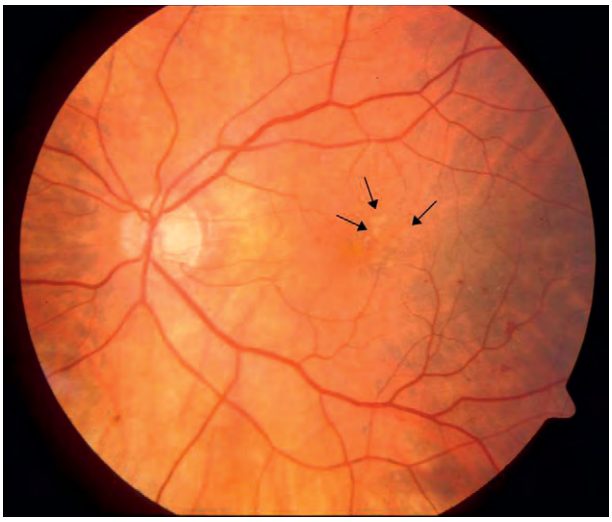

Figure 2 Central fundus photograph of AMD. Central fundus photograph with yellow–white deposits (=drusen, arrows) accumulating in the subretinal pigment epithelium due to a metabolic disorder of the photoreceptors and the retinal pigment epithelial layer.

Choroidal Neovascularization

Different factors seem to contribute to the pathogenesis of CNV, including hypoxia, inflammation, thickening of the Bruch's membrane, and angiogenic molecules, especially VEGF. As mentioned before, cultured human retinal pigment epithelial cells produce and secrete VEGF. Moreover, VEGF mRNA upregulation can be due to hypoxia.

Hypoxia can be induced in several ways. The eyes of pigeons show reduced thickness of the choroidea and decreased choroidal blood flow with increasing age.

Morphometric studies have revealed a thinning of the choroid in human eyes with increasing age. Another study showed a decrease in pulsatile ocular blood flow (a reliable parameter for evaluating chorioretinal circulation) occurring in aged human eyes. Furthermore, there is evidence that the choroidal blood flow in patients with AMD is modified. Due to the insufficient blood supply, a lower perfusion could result in hypoxia. Subsequently hypoxic conditions are known to upregulate VEGF mRNA, which can lead to a VEGF-induced choroidal angiogenesis. Lipid deposits within and around the Bruch's membrane and a thickening of the latter might also contribute to a disordered metabolism and reduced oxygen supply, which, in turn, can directly upregulate VEGF.

Chronic inflammatory processes, due to deposits in the Bruch's membrane, might also contribute to the development of AMD, which are associated with disorders of the complement regulatory system.

Besides VEGF, other molecules seem to be implicated in the pathogenesis of CNV during AMD. These include MMPs, especially MMP-2 and MMP-9, endostatin, PEDF, the angiopoietins, and NO. Nevertheless, the precise pathogenic mechanisms for the induction and the development of CNV are not completely elucidated to date.

Tumor Angiogenesis in the Eye

Since Judah Folkman first published his hypothesis in the early 1970s that tumor growth is depended on angiogenesis and the recruitment of capillary blood vessels, an extensive research has addressed this topic. A prerequisite for the development of new blood vessels is a shift of the balance between pro- and antiangiogenic molecules toward the pro-angiogenic ones (angiogenic switch). Thereafter, activated endothelial cells migrate to the tumor, proliferate, and form a new vessel network. Tumor neovascularization is a critical factor not only for tumor growth by supplying it with nutrients and oxygen, but also for tumor malignancy and metastasis, by providing an exit route for the tumor cells (**Figure 3**). Several pro-angiogenic molecules, including bFGF, PDGF, and VEGF, are produced by tumor cells. VEGF, a very potent inducer of neovascularization, is upregulated in many tumors and plays a pivotal role in tumor angiogenesis. Indeed, vascularization of microtumors in mice can be completely inhibited after treatment with a neutralizing antiVEGF antibody.

High levels of VEGF and VEGFR can be detected in the eyes of patients with retinoblastoma and choroidal melanoma. VEGF-targeted RNA-interference can suppress retinoblastoma growth and tumor angiogenesis.

The production of pro-angiogenic factors, like VEGF, by intraocular tumors is suggested to be a cause for breaking down the blood–retina barrier and subsequently for the formation of new vessels. VEGF also seems to be critically involved in the progression of tumors due to von Hippel–Lindau (VHL) disease, a hereditary cancer syndrome. Affected patients develop highly vascularized neoplasms called hemangioblastomas due to a germline mutation in the VHL tumor suppressor gene. An antiangiogenic therapy with VEGF-neutralizing antibodies or VEGFR inhibitors is an interesting tool for therapeutic treatments of ocular tumors.

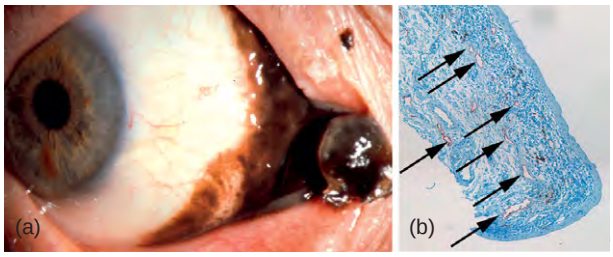

Figure 3 Malignant melanoma: (a) malignant melanoma of the conjunctiva; (b) immunohistochemistry shows various lymphatic tumor-associated lymphatic vessels (lymphatic vessels stained in red with LYVE-1 antibody, specific for lymphatic endothelium: arrows). Through these lymphatic vessels lymphatic metastasis in the regional lymph nodes can occur. Reproduced from Bock, F., König, Y., Dietrich, T., et al. (2007). Angiogenesis in Wound Healing

Z-J Liu and O C Velazquez, University of Miami, Miami, FL, USA

Glossary

Angiogenesis – A physiological process involving the growth of new blood vessels from preexisting vessels.
Endothelial cells – The type of cells forming the interior surface of blood vessels; they create an interface between circulating blood in the lumen and the rest of the vessel wall.
Endothelial progenitor cells – They are bone marrow stem cell-derived cells that have the ability to differentiate into endothelial cells. EPCs exist in bone marrow, peripheral blood, umbilical blood, and fetal liver.
Neovascularization – The formation of new blood vessels by either angiogenesis and/or vasculogenesis.
Vasculogenesis – Formation of vascular structures from angioblasts or circulating endothelial progenitor cells, which proliferate into *de novo* blood vessels.
Wound healing – Cutaneous wound healing is the body's natural process of regenerating dermal and epidermal tissue.

Introduction

Angiogenesis, a process of formation of new blood vessels, is essential for wound repair. Healing of any skin wound other than the most superficial cannot occur without angiogenesis. The new blood vessels provide nutrients and oxygen to support cell growth and tissue repair, promote granulation matrix formation, and facilitate the clearance of debris in injured tissue. Neovascularization is a complex multistep process including the creation of pro-angiogenic factors in the injured tissue which stimulate the local existing blood vessels, the release of proteases, such as matrix metalloproteinases (MMPs), from activated endothelial cells with subsequent degradation of the basement membrane surrounding the blood vessel, formation of tip cells and sprouting, migration of endothelial cells into the interstitial space, proliferation of endothelial cells, and remodeling into new blood vessels. Recently, it has been proven that endothelial progenitor cells (EPCs) are also involved and, in fact, play a critical role in neovascularization. EPCs, derived from bone marrow stem cells, can be released into circulation, recruited into wound lesion, and undergo *in situ* differentiation to become matured endothelial cells and contribute to neovascularization. The processes mentioned above are dynamic and tightly regulated in a spatial and temporal manner by cell–cell, cell–extracellular matrix (ECM), and cell–soluble factor interactions, leading finally to a functional vascular network formation. A better understanding of the underlying mechanisms in neovascularization will bring new insights into wound-related diseases and offer novel therapeutic options in the treatment of wounds, in particular, chronic and nonhealing wounds, and would thus have tremendous benefit to both individual patients and society.

Cellular and Molecular Basis of Wound Healing

The healing of a wound requires a well-orchestrated integration of the complex biological and molecular events of cell migration, proliferation, differentiation, and ECM deposition. Normal wound healing requires proper circulation, nutrition, immune status, and avoidance of negative mechanical forces. The process usually takes 3–14 days to complete and has three phases: inflammation, proliferation, and remodeling with wound contraction (**Figure 1**). During the inflammatory phase, neutrophils and macrophages appear in the wounded area to phagocytize bacteria and debris. A functioning immune system and adequate supply of growth factors are necessary in this phase of wound healing. In the proliferative phase, fibroblasts produce a collagen matrix, new blood vessels invade the forming granulation tissue, and epidermal cells migrate across the wound surface to close the breach. During the remodeling phase, fibroblasts reorganize the collagen matrix and ultimately assume a myofibroblast phenotype to effect connective tissue compaction and wound contraction. Wounds gain about 80% of their final strength in the first 3 weeks of normal wound healing through collagen deposition, remodeling, and wound contraction. Each phase has unique cellular and substance constituents without which it cannot progress normally. A large variety of factors may influence any part of wound healing, including local factors (growth factors, edema and ischemia, low oxygen tension, and infection), regional factors (arterial insufficiency, venous insufficiency, and neuropathy), systemic factors (inadequate perfusion and metabolic disease), and other miscellaneous factors, such as nutritional state, preexisting

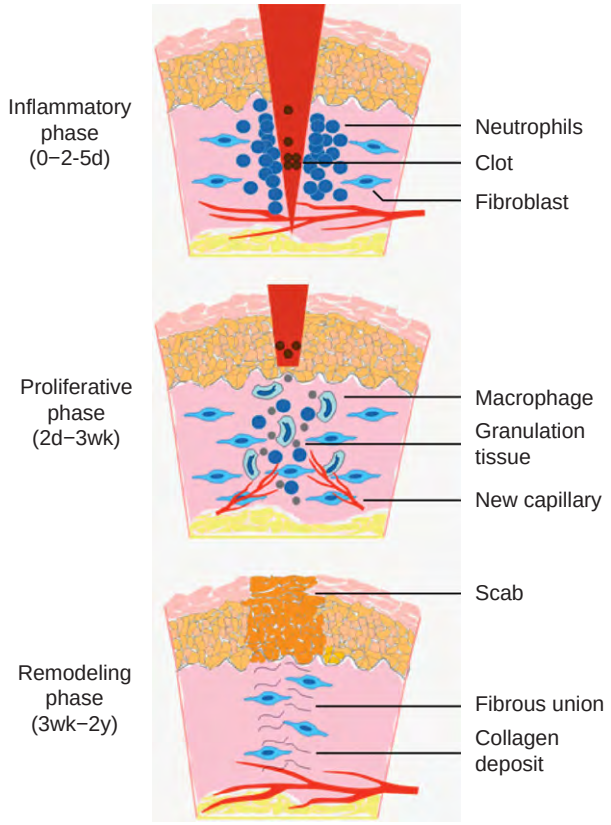

Figure 1 Schematic illustration of the three phases of acute wound healing. (1) Inflammatory phase: immediate to a few days. Immediately after the process of hemostasis, including vasoconstriction, platelet aggregation and thromboplastin production, injured tissue undergoes vasodilation and immune cells infiltrate and perform phagocytosis. (2) Proliferative phase: a few days to a few weeks. Fibroblasts lay a bed of collagen and fill the defect while new capillaries grow (granulation). Injured tissue undergoes contraction. Wound edges pull together to reduce the defect. Afterwards, epithelial cells migrate from the point of origin in all directions and cross the moist surface (epithelialization). (3) Remodeling phase: a few weeks to 2 years. During this phase, new collagen is formed and deposited, which increases tensile strength.

illnesses, exposure to radiation therapy, and smoking. When any of the components of the wound healing process is compromised, healing may be delayed. Chronic wounds are those that have failed to follow this sequence and do not achieve a sustained anatomic and functional result. Usually, a chronic wound requires a prolonged time (>8 weeks) to heal, or recurs, or even does not heal. The most prevalent forms of chronic wounds are leg ulcers caused by vascular insufficiency, and foot ulcerations associated with diabetic complications. It has been estimated that up to 2 million Americans have nonhealing lower extremity wounds. The economic costs associated with chronic wound are enormous and include hospital costs, disability, decreased productivity, and loss of independence.

Table 1 Pro-angiogenic and anti-angiogenic factors of angiogenesis

Pro-angiogenic factors	*Anti-angiogenic factors*
VEGF	Angiostatin
Angiopoietin	Anti-angiogenic anti-thrombin III
FGF	Endostatin (collagen XII fragment)
IL-8	Fibronectin fragment
PDGF-BB	Plasminogen activator inhibitor
Angiogenin	TSP-1
TGF-β	Retinoids

Abbreviations: VEGF, vascular endothelial growth factor; FGF, fibroblast growth factor; IL-8, interleukin-8; FGF, fibroblast growth factor; PDGF-BB, platelet-derived growth factor-BB; TGF, transforming growth factor; TSP-1, thrombospondin-1.

Molecular and Cellular Regulators of Wound Angiogenesis

Angiogenic Factors

Angiogenesis is tightly controlled by a variety of soluble factors and is determined by balance between pro-angiogenic and anti-angiogenic factors. In the physiological condition, the activity of inducers and inhibitors of angiogenesis maintains it in balance. When angiogenic factors are produced in excess of angiogenesis inhibitors, the balance is tipped in favor of blood vessel growth. When inhibitors are present in excess of stimulators, angiogenesis is stopped. Table 1 lists some most potent pro-angiogenic and anti-angiogenic factors.

Injury is the initiating factor with bleeding and microvascular damage. The clotting cascade is activated and injured vessels contract keeping blood loss to a minimum. Inflammatory cells are recruited rapidly, releasing vasoactive compounds that contribute to the leak of plasma and proteins into the wound allowing further effector cells to enter. Leukocytes secrete interleukin (IL)-8 and macrophage chemoattractant protein (MCP)-1. Platelets and monocytes can both release vascular endothelial growth factor (VEGF) when activated. Platelets also release platelet-derived growth factor (PDGF)-BB and transforming growth factor (TGF)-β (promoting angiogenesis and attracting macrophages), while monocytes release TGF-β and basic fibroblast growth factor (FGF). All these factors contribute to angiogenesis in healing wounds.

The angiogenic factors bind to specific receptors located on the endothelial cells of nearby preexisting blood vessels. Once angiogenic factors bind to their receptors, the endothelial cells become activated. Signals are sent from the cell's surface to the nucleus. The endothelial cell's machinery begins to produce new molecules including enzymes.

One of the most specific and critical regulators of angiogenesis is VEGF, which regulates endothelial

proliferation, permeability, and survival. VEGF family includes six members: VEGF-A (VEGF), -B, -C, -D, -E, and placenta growth factor (PLGF). VEGF stimulates vascular endothelial cells through VEGF receptors (VEGFRs). VEGFRs include VEGFR-1 (Flt-1), VEGFR-2 (KDR/Flk-1), and VEGFR-3 (Flt-4). VEGF associates VEGFR-1 and VEGFR-2, whereas VEGF-C and -D bind to VEGFR-2 and VEGFR-3, and primarily affect lymphangiogenesis. VEGF is a unique potent angiogenic factor that stimulates capillary formation *in vivo* and has direct mitogenic actions to endothelial cells. Human VEGF has at least four structurally related isoforms, $VEGF_{121}$, $VEGF_{165}$, $VEGF_{189}$, and $VEGF_{206}$. Of these, $VEGF_{165}$ has the most potent biological activity and is the most abundant subtype *in vivo*. VEGF is secreted by many cell types, and its expression is regulated by a number of growth factors and cytokines. For example, interleukin 1-β, PDGF-BB, and TGF-β stimulate VEGF production by smooth muscle cells.

It is known that VEGF acts on its receptor VEGFR-2, which stimulates increased intracellular calcium through phospholipase C activation and production of diacylglycerol and inositoltrisphosphate. This increase in intracellular calcium can then activate nitric oxygen synthase (NOS) through a calcium/calmodulin-dependent process, and the NO diffuses across the endothelial cell wall into the smooth muscle cells of the arterioles to result in muscle relaxation and vasodilatation. This results in increase in blood flow in injured tissues. This increase in blood flow is likely to have a significant effect on oxygen and glucose delivery and of course removal of CO_2, H^+, and lactate.

When sufficient neovascularization has occurred, angiogenic factors are downregulated or the local concentration of inhibitors increases. As a result, the endothelial cells become quiescent, and the vessels remain or regress if no longer needed.

Extracellular Matrix

The angiogenic response in the microvasculature is associated with changes in cellular adhesive interactions between adjacent endothelial cells, stromal cells, and surrounding ECM. In the process of active neovascularization, activated endothelial cells reorganize their cytoskeleton, express cell surface adhesion molecules such as integrins and selectins, secrete proteolytic enzymes, and remodel their adjacent ECM. The ECM is a complex mixture of matrix molecules, including the glycoproteins, fibronectin (FN), collagens, laminins, and proteoglycans. The ECM not only provides scaffolds for cellular support, but also participates in regulating wound angiogenesis by direct transduction of signals pivotal for cellular processes primarily via integrin interactions in concert with growth factor activation.

The interactions of endothelial cells with ECM involve diverse ECM molecules, which differ to some degree among vessels and certainly differ depending on the state of the vessel (quiescent, injured, or angiogenic). In resting vessels, endothelial cells are in contact with a basement membrane, which they share with pericytes in the case of small vessels. Vascular basement membranes contain laminins (predominantly laminin-8/laminin411 and laminin-10/laminin511), type IV collagens, perlecan, nidogens, collagen XVIII, and von Willebrand factor (vWF). The endothelial cells and pericytes in mature, quiescent vessels are nonproliferative and stably attached to the basement membrane. During vascular remodeling and angiogenesis, the quiescent endothelial layer becomes activated and endothelial cells breach the basement membrane and migrate into surrounding tissue containing different complements of ECM proteins, which can include collagens and FNs in interstitial ECM or fibrinogen and FNs in provisional matrices generated after vascular injury and during wound healing. Other ECM proteins encountered by endothelial cells and pericytes include vitronectin, thrombospondins, and tenascins. The effects of ECM on vascular cells therefore differ greatly, depending on the state of the vessel and, very probably, to a lesser degree among different vessels. It is evident that the switch from quiescence (adherent to laminins and probably other basement membrane proteins, stably assembled into tubes) to the angiogenic state (migratory, invasive, tube remodeling, and formation) involves marked changes in the cell–ECM interactions. It is also evident that different sorts of angiogenesis probably involve different forms of ECM and therefore different cell–ECM interactions.

Each of the many ECM proteins of vascular basement membranes or in the ECM during angiogenic sprouting has cell surface receptors, predominantly of the integrin family, although other ECM receptors (e.g., dystroglycan, GPIb, GPVI, and DDR collagen receptors) are also known. Integrins are a family of heterodimeric transmembrane proteins comprising at least 16 α and 8 β subunits in mammals. Different combinations of single α and β subunits dimerize to form approximately 24 different receptors with distinct and often overlapping specificity for ECM proteins. Integrins are widely recognized as important molecules for the transduction of positional cues from the ECM to the intracellular signaling machinery. For example, integrin ligation induces a wide range of intracellular signaling events, including the activation of Ras, mitogen-actived protein (MAP) kinase, focal adhesion kinase (FAK), Src, Rac/Rho/cdc42 GTPases, protein kinase C (PKC), and PI3K (phosphatidylinositol 3-kinase). In addition, integrin ligation increases intracellular pH and calcium levels, inositol lipid synthesis, cyclin synthesis, and the expression of immediate early genes and promotes cell survival.

On the other hand, MMPs play important roles in degradation and remodeling of ECM, permitting

endothelial cell migration during angiogenesis. For example, MMP2 is constitutively secreted as an inactive zymogen that is activated upon need by a complex of proteins on the surface of invading cells. The activation complex consists of tissue inhibitor of matrix metalloproteinase-2 (TIMP-2), membrane type I MMP (MT1-MMP), and integrin $\alpha V\beta 3$. Cells that express integrin $\alpha V\beta 3$ on their surface are able to bind active MMP2 (aMMP2) via the c-terminal hemopexin domain, and form an invasive front that enables migration. Eventually, the binding of aMMP2 to integrin $\alpha V\beta 3$ causes autocatalytic maturation that results in degradation of aMMP2 and the generation of PEX2, the 29–32 kDa hemopexin-like fragment. PEX2 is able to bind integrin $\alpha V\beta 3$ independently and compete with MMP2, preventing cell surface activation and thereby disrupting angiogenesis.

Pericytes and Stromal Cells in Angiogenesis

In addition to soluble factors and ECM, pericytes and surrounding stromal cells are critical in regulating neovascularization as well. Generally speaking, endothelial cells make up the blood vessel framework, but their assembly and stabilization are dictated by external signals from surrounding cells.

Pericytes are vascular mural cells which are embedded in the basement membrane of microvessels and play multiple roles in angiogenesis and maintenance of blood vessel morphology and stability. The relationship between endothelium and pericyte is for each to provide the other with growth factors and cell contacts that promote mutual proliferation and survival. At growing capillary tips, sprouting endothelium degrades the basement membrane, and releases PDGF-BB. PDGF-BB ligand is tethered to cell surfaces and matrix proteins, creating a polarized concentration gradient attracting $PDGFR\beta^+$ cells to vascular endothelium. Pericytes, in turn, release VEGF, which acts as a chemotactic agent and survival factor for proliferating endothelium. Pericytes are derived by differentiation of local mesenchymal cells and myofibroblasts, as well as by proliferation of existing pericytes. A proportion of pericytes is also derived by migration from the bone marrow.

Vasculature in skin granulation tissue is physically supported by connective tissue elements elaborated by resident fibroblasts. These fibroblasts provide a unique microenvironment that facilitates and sustains the microvasculature. Fibroblasts and their activated counterpart, the myofibroblast, play a pivotal role in regulating neovascularization in the process of wound healing by secreting various soluble factors, synthesis of ECM and direct cell–cell interaction. Fibroblasts, once activated, undergo a change in phenotype from their normal relatively quiescent state in which they are involved in slow turnover of the ECM, to a proliferative and contractile phenotype termed myofibroblasts. Myofibroblasts actively produce growth factors and ECM, and display an elongated spindle shape, and express contractile α-smooth muscle actin (α-SMA) and vimentin. Myofibroblasts can either arise from the local, resident fibroblasts or from circulating mesenchymal precursors/stem cells. It has been reported that fibroblasts located at chronic wound sites have been shown to be physiologically different from adjacent fibroblasts in nonaffected sites. Therefore, modulating the function of fibroblasts in wound tissue (in particular in chronic wound tissue) can be an alternative approach for the treatment of chronic, nonhealing wound.

Neovascularization and EPC

Until recently, neovascularization was thought to arise solely from preexisting vessels (angiogenesis). However, recent studies have proven that EPC can contribute to neovascularization (vasculogenesis) as well. In 1997, Asahara and colleagues first identified circulating EPCs contributing to neovascularization. Since then, increased evidence has suggested that bone marrow-derived EPCs can functionally contribute to neovascularization during wound healing, limb ischemia, postmyocardial infarction, endothelialization of vascular grafts, atherosclerosis, retinal and lymphoid organ neovascularization, vascularization during neonatal growth, and tumor growth. It has been estimated that EPCs contribute up to 25% of endothelial cells in newly formed vessels in animal models.

Although there have been conflicting reports regarding the importance of EPCs in neovascularization, a substantial amount of study in both animals and humans has provided strong evidence for the role of EPCs in neovascularization. Particularly, a very recent study showed that notwithstanding low numbers of EPC, recruitment of these EPCs is pivotal for the progression of avascular micrometastatic tumors to lethal macrometastatic ones. The lack of consensus may be due in part to heterogeneous phenotypic definitions of EPCs. In this aspect, two recent reports have shown that the subpopulations of EPCs with distinct phenotypes give rise to different outcomes, indicating an importance in defining the correct EPCs for such studies. Overall, however, these researchers clearly demonstrated a significant contribution of EPCs to neovascularization. Other factors, such as types of ischemic models or tumors (in which the profiles of chemoattractant factors may vary), time frame of the experiment, and method of *in situ* endothelial cell identification, may also contribute to some of the reported discrepancy. In general, it is now well accepted that at the site of tissue vascularization, endothelial cells originate from both adjacent preexisting blood vessels and recruitment of EPCs.

EPCs exist in peripheral blood, umbilical blood, bone marrow, and fetal liver. Multiple markers have been used

for characterization of EPCs and matured endothelial cells. Platelet endothelial cell adhesion molecule-1 (PECAM-1/CD31), VEGFR-2, von Willebrand factor (vWF), and vascular endothelial cadherin (VE-cadherin) are commonly used for the identification of endothelial cells. The ability to take up Dil-labeled acetylated low-density lipoprotein (Dil-Ac-LDL) has been used as a marker for the identification of endothelial precursors. CD34 is a marker for both endothelial and hematopoietic progenitor cells. In humans, EPCs (but not mature endothelial cells) express AC133 (CD133), a stem cell marker with as-yet unrecognized functions. Purified populations of $CD133^{+}VEGFR\text{-}2^{+}$ EPCs proliferate *in vitro* in an anchorage-independent manner and can be induced to differentiate into mature adherent $CD133^{-}VEGFR\text{-}2^{+}$ endothelial cells. Expression of various markers is a dynamic process. It is likely that different markers are present on EPCs and matured endothelial cells at various points along their differentiation cascade from immature progenitors to mature endothelial cells. Expression of CD133 will be turned off with the maturation of endothelial cells. Until now, the corresponding marker for CD133 in murine EPCs has not yet been substantiated. Murine EPCs are characterized as $Sca\text{-}1^{+}/c\text{-}Kit^{+}/Lin^{-}/VEGFR\text{-}2^{+}/CXCR4^{+}/Tie2^{+}$. With maturation, expression of stem cell marker Sca-1 and hematopoietic marker c-Kit will be turned off.

Interestingly, EPCs are not a single type of cell population and display tremendous heterogeneity in terms of phenotype and angiogenic potential. EPCs can be classified into two subpopulations: early EPCs and late EPCs. Early EPCs display spindle shape and show peak growth at 2–3 weeks and die at 4 weeks, whereas late EPCs have cobblestone shape and appear late at 2–3 weeks, show exponential growth at 4–8 weeks, and can live up to 12 weeks. Late EPCs are different from early EPCs in the expression of VE-cadherin, VEGFR-1, VEGFR-2, and CD45. Late EPCs produce more NO, incorporate more readily into human umbilical vein endothelial cells monolayer, and form capillary tubes better than early EPCs. Early EPCs secrete angiogenic cytokines (VEGF, IL-8) more so than late EPCs during culture *in vitro*. Both types of EPCs show comparable *in vivo* vasculogenic capacity. In addition, it has been reported that early EPCs can cause the disorganization of preexisting vessels, whereas late EPCs likely constitute and orchestrate vascular tube formation.

EPCs are embedded in a microenvironment (niche) of bone marrow and can be mobilized to the circulation (**Figure 2**). Under normal conditions, the number of circulating EPCs is relatively small but is increased in response to trauma or ischemia, which mobilizes these cells from the bone marrow and allows them to proliferate. The recruitment of EPCs from the bone marrow and circulation to homing sites of neovascularization is subject to regulation by many factors, including chemokines and growth factors. The precise mechanism of EPC mobilization is not entirely elucidated and is still under investigation. Many chemokines and cytokines trigger stem/progenitor cell release by induction of MMP-9 in bone marrow and NO-mediated signaling pathways have been previously proposed to be essential for EPC mobilization. Using VEGF as a proximal stimulus, Aicher and colleagues demonstrated that endothelial NOS (eNOS) becomes activated in bone marrow stroma, NO then S-nitrosylates by paracrine mechanisms and activates MMP-9, which releases the stem cell active cytokine, soluble Kit ligand. This agent shifts endothelial progenitor and hematopoietic stem cells from a quiescent to the proliferative niche and stimulates rapid stem cell mobilization to the peripheral blood. We have recently demonstrated that hyperoxia, induced by a clinically relevant hypoerbaric oxygen therapy (HBO) therapy protocol, can significantly enhance the mobilization of EPC from the bone marrow into peripheral blood. It has been shown that in the setting of trauma and ischemia, systemic VEGF levels rise following a time course that mirrors the rise in circulating bone marrow-derived EPC. In addition to the direct integration into vessel lumen and the contribution to neovascularization, recent studies have suggested that EPCs may promote local neovascularization by secreting angiogenic growth factors in a paracrine manner. In addition to VEGF, granulocyte colony-stimulating factor (G-CSF) and stromal cell-derived factor (SDF)-1α have been demonstrated to be able to enhance EPC mobilization. SDF-1α can promote EPC homing as well. Transplantation of EPCs into ischemic tissues may emerge as a promising approach in the therapy of diseases associated with blood vessel disorders.

Therapeutic Angiogenesis in Chronic Wound Healing

Chronic wounds continue to be a major clinical problem and novel therapeutic approaches are needed. Recent advances in the field of angiogenesis have led to very promising breakthroughs in the treatment of diabetic and other types of chronic wounds. The understanding of the crucial role of growth factors in wound healing has already led to the development and regulatory approval of topically applied growth factors, particularly PDGF-BB. Greater efficiency of delivery of growth factors by gene therapy or by cell therapy is now possible and being tested.

In addition to the use of growth factors, there has also been considerable interest in the application of ECM proteins to accelerate healing of diabetic foot ulcers, including collagen and hyaluronic acid.

Cell-based therapy is a promising therapeutic option for treating patients with diabetic, nonhealing wounds.

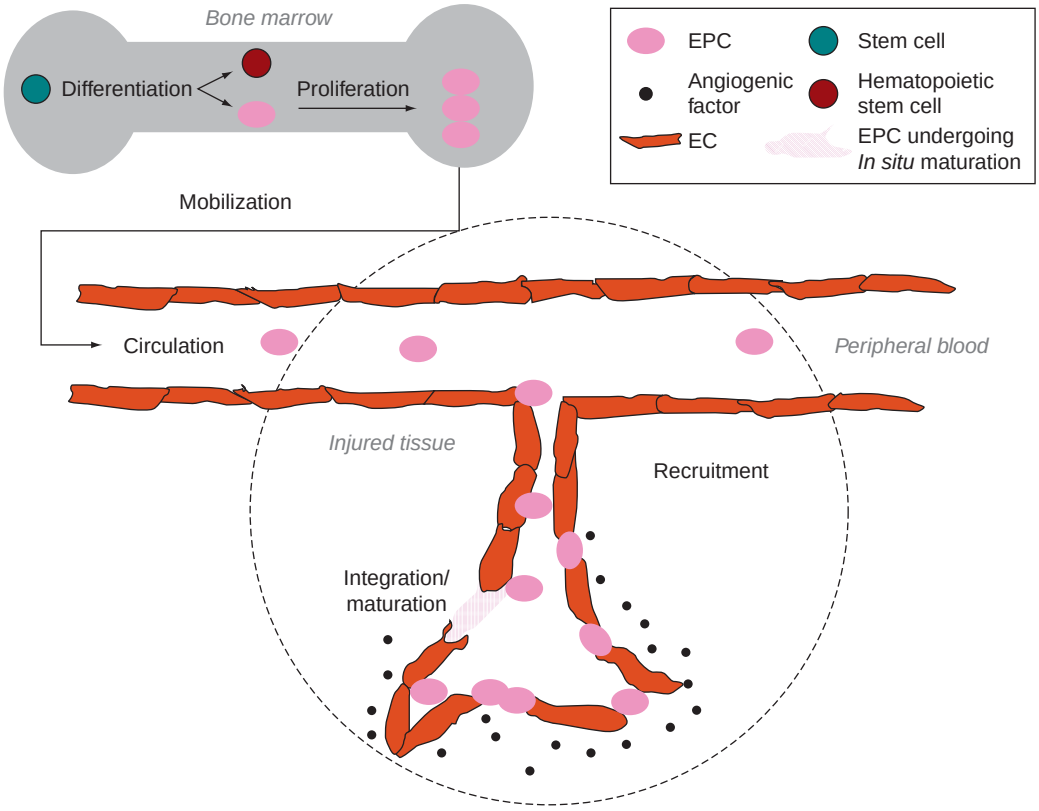

Figure 2 Overview of differentiation, mobilization, recruitment, and *in situ* maturation of endothelial progenitor cells (EPCs). Contribution of bone marrow-derived EPCs to wound healing involves multiple critical events. Bone marrow-derived EPCs are released from their niche into the circulation (mobilization). The circulating EPCs are recruited (homing) to injured tissue and contribute to neovascularization and wound healing (integration/*in situ* maturation). In addition, EPCs may contribute to neovascularization by secretion of soluble factors.

There is great interest in delivery of stem or progenitor cells, either applied topically or recruited from the circulation. Bone marrow is an enriched pool of stem and progenitor cells. Some preliminary work suggests that topically applied autologous bone marrow cells can heal human chronic wounds that are recalcitrant to other treatments, including growth factors and bioengineered skin. Of various different types of stem or progenitor cells, EPC is one type of cells which has been moved from experimental models to the clinic trials. EPC has thus far been tested in patients with acute and chronic ischemic disease and outcomes are very encouraging. A few properties, such as its endogenous, BM-derived character, ability to home to sites of pathological entities, and relative stability in terms of lineage specification in culture which allows genetic and epigenetic manipulation, make EPC a unique cell source and ideal candidate to be widely tested to formulate cell-based therapy for ischemic disorders, including chronic wound. The efficiency of cell therapy to augment recovery after ischemia depends on not only the sufficient amount of circulating EPCs, but also efficient recruitment of the cells to the target tissue. This is not surprising as the contribution of EPC to neovascularization is a coordinated sequence of multistep process, including mobilization, homing, *in situ* differentiation, and maturation, and each step is controlled by a specific mechanism(s). More important, some of these mechanisms are impaired with diabetes. Thus, a combination of therapeutic approaches which target individual steps, correct diabetes-inherited EPC deficits, and can synergize with each other's action, is likely to lead to a more successful treatment outcome for diabetic wounds.

Based on the importance of stromal cells in modulating neovascularization, targeting fibroblasts is a promising therapeutic option. Delivery of fibroblasts in an absorbable mesh, or in type 1 collagen, has been tested and the outcome is encouraging.

Advances in the treatment of chronic wounds, particularly diabetic wounds, are promising. In the future, we will probably see combination therapies of growth factors, ECM and EPC and/or stromal cells. It is believed that a better understanding the molecular and cellular etiologies of chronic, nonhealing wounds will eventually result in the development of clinically efficient and feasible therapies to prevent wound progression, eliminate amputations and promote rapid healing in patients with chronic, nonhealing wound.

Animal Models of Glaucoma

S I Tomarev, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Ltd.

Glossary

BAC – Bacterial artificial chromosome. It is a DNA construct based on a functional fertility plasmid, used for cloning in bacteria. The bacterial artificial chromosome's usual insert size is 150–350 kbp.
BAX – Proapoptotic BCL2-associated X protein. BCL2 is an integral outer mitochondrial membrane protein that blocks the apoptotic death of some cells.
Retrobulbar space – The area located behind the globe of the eye.
Synechia – An eye condition where the iris adheres to either the cornea (anterior *synechia*) or the lens (posterior *synechia*).
Tonometry – The procedure to determine the intraocular pressure.
TUNEL – Terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate nick end labeling for detection of DNA fragmentation resulting from apoptotic programmed cell death.

Glaucoma is a complex disease, the initiation and progression of which involves interactions between different parts of the eye and brain. It is difficult to perform experiments directed toward elucidating pathogenic molecular mechanisms and potential treatments for glaucoma in human subjects and, as a rule, only postmortem material can be used for biochemical analysis. Experiments in cell culture or organ culture systems may only partially reproduce the complexity of the natural ocular environment. It is now well recognized that animal models may provide a very useful tool for understanding the underlying molecular mechanisms involved in glaucoma and for identifying new genetic components of the disease, including both causative and modifier genes. In addition, appropriate animal models are used to develop and test new regiments of glaucoma treatment as a prerequisite for clinical trials in humans. A number of animal models of glaucoma have been developed over the years. Since elevated intraocular pressure (IOP) is the most important risk factor in glaucoma, most of the animal models of glaucoma are based on elevation of IOP by surgical procedures or by genetic manipulations. Several models used to study death of the retinal ganglion cells (RGCs) include optic nerve crush or transaction, intravitreal injection of excitory amino acids (glutamate and *N*-methyl-D-aspartic acid (NMDA)), or retinal ischemia. Although these are not true glaucoma models, they allow the comparison of processes leading to RGC death induced by different initial insults. Such comparative analysis may lead to the identification of changes that are specific to glaucoma versus changes that are involved in more general RGC dysfunction. While none of the existing animal models is perfect, some of the existing models have been successfully used to uncover important features of glaucoma pathology in humans. Several factors should be considered in selecting a particular animal model of glaucoma for experimentation: (1) the similarity of the model visual system to the human eye; (2) the similarity in the time course of pathological changes in the model and human eyes; (3) ability to apply genetic manipulations; (4) training necessary to produce affected animals; (5) the size of the eye; (6) availability and difficulties of methods of analysis; (7) availability of animals; and (8) cost. This article briefly describes available animal models of glaucoma with emphasis on the strengths and weaknesses of each model.

Mammalian Models

Primate Models of Glaucoma

Monkey and human eyes are very similar both anatomically and functionally, making monkey models very attractive to study different eye pathologies including glaucoma. IOP in monkeys is measured using the same equipment that is used to measure IOP in humans. Moreover, tonometry and visual-field analysis can be performed in conscious, trained monkeys. This is an important factor since it is well documented that general anesthesia that is necessary to measure IOP in most other animal models results in rapid ocular hypotension. The main disadvantage of monkey models is that experiments with monkeys are expensive and require a highly skilled team of investigators. Moreover, large numbers of animals are required to assess effects of elevated IOP on the optic nerve head (ONH) and retina because of genetic variations between animals.

Several approaches have been used to develop pressure-induced glaucoma models in nonhuman primates. The most common method of IOP elevation in the monkey was originally developed more than 30 years ago and involves circumferential laser photocoagulation treatment of the trabecular meshwork. Several laser sessions are normally required to produce a sustained elevation of IOP. In the treated eyes, IOP rises several days after the laser treatment, normally to between 25 and 60 mmHg, and may last for more than a year. Other methods that have

been used to produce elevated IOP elevation in monkeys are less consistent than laser coagulation. They include injection of ghost red cells, latex microspheres, cross-linked polyacrylamide gels, or enzymes into the anterior chamber or application of topical steroids. A non-IOP-related monkey model of glaucoma involves the delivery of endothelin-1 to the retrobulbar space through osmotic pump for 6–12 months; this induces ischemia and leads to the preferential loss of large RGC axons. Ischemia-induced focal axonal loss is similar to human glaucoma and this model may reproduce some aspects of normal tension glaucoma.

A number of important observations have been made using the monkey photocoagulation model. Apoptosis as the primary mechanism of glaucomatous RGC death was first demonstrated in this model before later being confirmed in other models and in human glaucoma. Multifocal electroretinogram (ERG) techniques were used in monkeys to demonstrate that not only RGCs but also cells in the inner and outer nuclear layers are damaged in advanced glaucoma. The monkey glaucoma model has been successfully used to study changes in retinal gene expression patterns after the induction of ocular hypertension. It is also being used to efficiently test new drugs and techniques to reduce IOP. For instance, recombinant adenoviral delivery of the human $p21^{WAF\text{-}1/cip\text{-}1}$ gene to cause cell cycle arrest before filtration surgery in ocular hypertensive monkey eyes has shown a beneficial effect in long-term control of IOP.

Rodent Models of Glaucoma

Several rodent models of glaucoma have been developed over the last 20 years and new models are at different stages of development in several laboratories. These models have proven useful because the drainage structures of the rodent eye are similar to those in humans. Their utility was enhanced further by the development of new methods to measure IOP and analyze glaucomatous changes in these small eyes. Rodent models, and especially mouse models, are relatively cheap and allow extensive genetic manipulations. Rodent models are preferred when a significant number of animals are required to conduct genetic screens or to test different drugs and agents for neuroprotective or IOP-lowering effects. One of the main disadvantages of rodent models is that there are anatomical differences between rodent and human eyes, including the arterial blood supply to the ONH and the absence of a well-developed, collagenous lamina cribrosa. These variations, as well as differences in general physiology, may explain why expression of certain genes in mouse and human eyes (e.g., mutated myocilin) have differential effects.

Rat Models

Rats are easy to handle. The relatively large size of their eyes allows multiple noninvasive IOP measurements in awake trained animals with commercially available equipment. The TonoPen was the instrument of choice for IOP measurements for many years but has recently been superseded by an induction/impact tonometer, marketed as the TonoLab rebound tonometer. This instrument is easy to operate and can be used in both rats and mice.

Several rat models of pressure-induced glaucoma have been developed over the last 15 years. IOP elevation in the rat eye may be achieved by injection of hypertonic saline solution into the episcleral vein that leads to sclerosis of the aqueous humor outflow pathway. Sustained IOP elevation occurs 7–10 days after injection in most but not all rats. The saline injection generally produces a range of IOP elevation in different animals from a very minimal rise to twofold increase over IOP in control eyes, which can remain elevated for up to several months. Cauterization of two or more of the four large episcleral veins is another method of IOP elevation. In this model, IOP elevation occurs very quickly and there are some indications that this procedure impedes blood outflow from the globe and leads to ischemia. Reports indicate that IOP elevation may last from several weeks to several months without requiring retreatment. IOP increase can be also achieved by laser photocoagulation of the trabecular meshwork with or without injection of Indian ink into anterior chamber. Intracameral injection of hyaluronic acid or latex microspheres is another method of IOP elevation in rats. However, the repeated weekly injections required by this method may produce undesirable effects and are labor consuming. Topical application of dexamethasone for 4 weeks may also be used to induce ocular hypertension. These methods of chronic IOP elevation in rats are accompanied by death of the RGCs by apoptosis, optic nerve degeneration, and ONH remodeling similar to those observed in glaucoma in humans. Acute ocular hypertension, on the other hand, may be produced in rats by cannulation of the anterior chamber with a needle attached to a saline reservoir. Although such treatment leads to retinal ischemic injury, it has been suggested that this model mimics acute angle-closure glaucoma in humans.

A mutant rat strain with a unilateral or bilateral globe enlargement and IOPs that range from 25 to 45 mmHg have been described. In this strain, cupping of the ONH as well as reduction in the number of RGCs progress with age. Unfortunately, this strain was obtained from the Royal College of Surgeons colony that has a mutation in the receptor tyrosine kinase gene, leading to degeneration of the photoreceptors. This drastically limits the utility of this strain to study phenomena that are specific to glaucoma and not confounded by other neurodegenerative processes.

Rat models of glaucoma have been used to study effects of elevated IOP on the ERG, changes in the gene expression patterns in the retina, RGCs and optic nerve, and

changes in the protein spectrum of the retina. Rat models also are often used to study neuroprotection. For instance, the hypertonic saline model was used to demonstrate for the first time that agents targeting multiple phases of the amyloid-β pathway provide a therapeutic avenue in glaucoma management.

Mouse Models

Mouse models of glaucoma recently have become very popular. Although most mouse models of glaucoma are based on the elevation of IOP, information about IOP is essential even for the models that do not include experimental IOP manipulation. The mouse eye is much smaller than the human eye, and devices designed for tonometry in humans do not produce reliable data in the mouse. Thus, new methods to measure IOP in mice have been developed and, as a result, the development and acceptance of mouse models of glaucoma have been accelerated. Currently, several invasive and noninvasive methods of IOP measurements in mice exist. The oldest method remains as one of the most reliable and accurate methods and does not depend upon the mechanical properties of the cornea. It involves the insertion of a glass microneedle connected to a pressure transducer into anterior chamber of the eye. However, this procedure cannot be performed too frequently in the same eye, as adequate time is required for corneal wound healing. In addition, cannulation tonometry is technically difficult and training is required to develop sufficient expertise to obtain reliable IOP readings. Cannulation tonometry was used to demonstrate that common mouse strains exhibit different average IOPs in the range between 10 and 20 mmHg. Other methods of IOP measurements in mice were later developed including noninvasive techniques (TonoLab tonometer). Noninvasive techniques allow multiple IOP measurements within short periods of time without extensive training.

Pressure-induced mouse models

Surgical approaches similar to those that were used to produce elevated IOP in rats have also been developed in mice. Significant elevation of IOP in the C57BL/6J mouse eye is accomplished by combined injection of indocyanine green dye into the anterior chamber and diode laser treatment of the trabecular meshwork and episcleral vein region. IOP in operated eyes is significantly elevated 10 days after the surgery but returns back to normal 60 days after the procedure. Histological analysis of the treated eyes 65 days after the surgery revealed development of anterior synechia, loss of RGCs, thinning of all retinal layers, and damage to the optic nerve structures without evidence of prominent cupping. A reduction in the function of all retinal layers, as assessed by ERG studies, indicates that this model produces more dramatic changes in the retina compared to glaucoma in humans. Elevation of IOP may also be induced by argon laser photocoagulation of the episcleral and limbal veins in C57BL/6J mouse eyes or by cauterization of three episcleral veins in CD1 mouse eyes. In one study, mean IOP in the eyes that underwent laser treatment was about 1.5 times higher than in control eyes for 4 weeks. RGC loss was $22.4 \pm 7.5\%$ at 4 weeks after treatment with the majority of terminal deoxynucleotidyl transferase mediated deoxyuridine triphosphate (dUTP) nick end labeling (TUNEL)-positive apoptotic cells detected in the peripheral areas of the retina. Episcleral vein cauterization produced a maximum IOP elevation within 2–9 days after the procedure, which decreased progressively after that to baseline values in the following 24–33 days. This was associated with a 20% decline in the number of RGCs 2 weeks after the surgery.

The DBA/2J strain has become a popular mouse model of secondary-angle-closure glaucoma and is one of the best-characterized mouse models of glaucoma in general. DBA/2J mice have mutations in two genes, *Tyrp1* and *Gpnmb*, which lead to pigment dispersion, iris transillumination, iris atrophy, and anterior synechia. IOP is elevated in most mice by the age of 9 months. IOP elevation was accompanied by the death of the RGCs, optic nerve atrophy, and optic nerve cupping. Although no group of the RGCs appears especially vulnerable or resistant to degeneration, fan-shaped sectors of cell death and survival radiating from the ONH have been detected. It has been suggested that axon damage at the ONH might be a primary lesion in this model. Several important observations have been made using DBA/2J model. It was shown that proapoptotic protein BAX is required for RGC death but not for RGC axon degeneration in this model of glaucoma, suggesting that BAX may be a candidate human glaucoma susceptibility gene. Unexpectedly, high dose of γ-irradiation accompanied with syngenic bone marrow transfer protected RGCs in DBA/2J. Similar to the results obtained with rat and monkey models, genes involved in the glial activation and immune response are activated in DBA/2J retina as shown by array hybridization. Complement component C1q is upregulated in the retina in several animal models of glaucoma and human glaucoma with timing, suggesting that complement activation plays a significant role in glaucoma pathogenesis. Recent data suggest that complement proteins opsonize central nervous system synapses during a distinct window of postnatal development and that the complement proteins C1q and C3 are required for synapse elimination in the developing retinogeniculate pathway. In DBA/2J mice, C1q relocalizes to adult retinal synapses at an early stage of glaucoma prior to obvious neurodegeneration. These data indicate that C1q in adult glaucomatous retina marks synapses for elimination at early stages of disease, suggesting that the complement cascade mediates synapse loss in glaucoma.

Another DBA/2 substrain, DBA/2NNia, also develops elevated IOP and demonstrates RGC loss and optic nerve degeneration when aged. However, depletion of cells in the inner and outer nuclear layers and significant damage of the photoreceptor cells in 15-month-old mice have also been observed.

Transgenic and knock-out approaches have been used to prospectively develop several mouse models of glaucoma. The main advantage of these approaches is that animals within a particular line produce more uniform responses in terms of IOP elevation and damage to the retina and optic nerve as compared to surgically induced models. A large number of animals may be obtained and no training is needed to produce affected mice. Several lines of transgenic mice have been developed that contain BAC DNAs with a Tyr423His point mutation in the mouse or Tyr437His point mutation in the human *MYOCILIN* (*MYOC*) genes. Tyr437His mutation in the *MYOC* gene leads to severe glaucoma cases in humans, and mouse Tyr423His mutation corresponds to this human mutation. However, expression of mutated mouse or human myocilin in the eye-drainage structures of mice leads to moderate (about 2 mmHg at daytime and 4 mmHg at nighttime) elevation of IOP which is much less dramatic than IOP elevation in humans carrying the same mutation in the *MYOC* gene. Since these mice demonstrate progressive degenerative changes in the peripheral RGC layer and optic nerve with normal organization of the drainage structures, it has been suggested that these mice represent a mouse model of primary open-angle glaucoma. Another model of primary open-angle glaucoma was developed by the expression of a mutated gene for the α1 subunit of collagen type I. This mutation blocks the cleavage of collagen by matrix metalloproteinase-1. Transgenic mice expressing mutated collagen demonstrate elevated IOP which increases to a maximum of 4.8 mmHg greater than controls at 36 weeks.

A transgenic model of acute angle-closure glaucoma was developed by expression of calcitonin-receptor-like receptor under the control of a smooth muscle α-actin promoter. Overexpression of this receptor in the papillary sphincter muscle results in enhanced adrenomedullin-induced sphincter muscle relaxation that leads to abrupt transient rises in IOP in some mice up to a mean level of about 50 mmHg between 30 and 70 days of age. Although the aberrant ocular functions of adrenomedullin and calcitonin-gene-related peptide have not been associated with the pathogenesis of human acute glaucoma, it has been suggested that adrenomedullin and its receptor in the iris sphincter may present novel targets for the treatment of angle-closure glaucoma.

Normal-tension mouse models

Mice deficient in the glutamate transporters GLAST or EAAC1 show RGC death and typical glaucomatous damage of the optic nerve without elevation of IOP. It has been shown that the glutathione levels are decreased in Müller cells of GLAST-deficient mice, while administration of glutamate receptor blocker prevents loss of RGCs. RGCs are more sensitive to oxidative stress in EAAC1-deficient mice. These mice represent a model of normal tension glaucoma and are currently being used to develop therapies directed at IOP-independent mechanisms of RGC loss.

Developmental mouse models

Defects in genes involved in the development of the anterior eye segment may lead to relatively rare developmental glaucomas, which account for less than 1% of all human glaucoma cases. Several genes have been implicated in congenital glaucoma and anterior segment dysgenesis. They include *CYP1B1, FOXC1, FOXC2, PITX2, LMX1b*, and *PAX6*. Although *Cyp1b1* knock-out mice do not develop elevated IOP, they have ocular abnormalities similar to defects in humans with primary congenital glaucoma: small or absent Schlemm's canal, defects in the trabecular meshwork, and attachment of the iris to the trabecular meshwork and peripheral cornea. $Foxc1^{-/-}$ mice die at birth, while $Foxc1^{+/-}$ animals are viable but have defects in the eye-drainage structures in the absence of IOP changes. Similar eye defects are observed in $Foxc2^{+/-}$ mice. It has been suggested that $Foxc1^{+/-}$ and $Foxc2^{+/-}$ mice are useful models for studying anterior segment development and its anomalies, and they may allow identification of genes that interact with *Foxc1* and *Foxc2* to produce a phenotype with elevated IOP and glaucoma.

Transgenic mice overexpressing the ocular development-associated gene (ODAG) in photoreceptors under the control of mouse Crx promoter exhibit gradual protrusion of the eyeballs with dramatically increased IOP that is not attributable to mechanical block of the aqueous humor outflow. These transgenic mice demonstrate optic nerve atrophy and impaired retinal development. All retinal layers of these transgenic mice are affected, thereby differentiating this model from a typical glaucomatous retina where morphological changes are detected only in the RGC layer.

Other Mammalian Models

Several other mammalian models of glaucoma have been developed. Pig eyes are relatively large and, although the drainage outflow system of the pig eye is slightly different from that of the human eye, the porcine retina is more similar to the human retina than that of other large mammals (i.e., dog, goat, and cow). Cauterization of three porcine episcleral veins leads to a 1.3-fold elevation of IOP that is apparent 3 weeks after the surgery and persists for at least 21 weeks. It has been shown that endothelium leukocyte adhesion molecule 1 (ELAM-1), a molecular marker

for human glaucoma, is also elevated in the trabecular meshwork of pigs with elevated IOP.

Rabbits are a standard ophthalmic animal model for glaucoma filtration surgery and are often used for the development of new devices (e.g., drainage implants and degradable biopolymers) and medical therapies including gene therapy. At the same time, due to the unique anatomy of the rabbit eye, laser-induced elevation of IOP, like that in the monkey eye, is difficult to achieve. Alternatively, application of glucocorticoids has been successfully used to induce ocular hypertension in rabbit model. In addition, a line of rabbits with congenital glaucoma has been developed. Thick subcanalicular tissues and the deposition of extracellular matrix in the trabecular meshwork appear to contribute to the ocular hypertension exhibited by this model.

Several purebred dogs develop glaucoma with high frequency. Among North American breeds, the highest prevalence of primary glaucoma is observed in the American cocker spaniel (5.52%), basset hound (5.44%), and chow chow (4.70%), exceeding that in humans. Lens displacement resulting in secondary glaucoma is common in terrier breeds. The high prevalence of the glaucomas in these canine breeds suggests a genetic basis of pathophysiology.

It has been reported that topical application of corticosteroid induces reproducible elevation of IOP in the cow. The large amount of tissues available from the cow eye makes this model useful for biochemical studies.

Nonmammalian Models

Zebrafish

The zebrafish is an excellent model system to study complex diseases as it allows one to combine forward and reverse genetic approaches. The general organization of the zebrafish eye is similar to the human eye, although the fine details of individual ocular structures are rather different. In particular, there are significant differences in the organization of the iridocorneal angle between zebrafish and mammals. They include the trabecular meshwork and lack of iris muscles as well as ciliary folds in zebrafish as compared to mammals. Even with these limitations in mind, zebrafish have been used as a model organism for glaucoma studies. An accurate method exists to measure IOP in zebrafish which is based on servo-null electrophysiology. Using this method, baseline IOP differences have been demonstrated in genetically distinct zebrafish strains. Among tested strains, the long fin strain (LF) had the highest IOP (20.5 ± 1.2 mm Hg) while the Oregon AB strain (AB) has the lowest IOP (10.8 ± 0.3 mm Hg). At the same time, these differences in IOP do not lead to detectable defects of the retina or in visual function. Zebrafish have also been used to determine the function of several genes (*foxc1*, *lmx1b*, *wdr36*, *olfactomedin 1*, and *olfactomedin 2*) implicated in glaucoma. It has been shown that wdr36 functions in ribosomal RNA processing and interacts with the p53 stress-response pathway, while olfactomedin 1 is essential for optic nerve growth and targeting of the optic tectum. Thus, zebrafish system may be very useful to complement studies with other model organisms, but by itself should be used with caution to study glaucoma.

Other Nonmammalian Models

Open-angle glaucoma characterized by elevated IOP can be induced in domestic chickens or in Japanese quails when they are reared under continuous light. Besides, an unknown autosomal dominant mutation in a Slate line of domestic turkeys has been identified that leads to secondary angle-closure glaucoma. Although these models might be useful to study certain aspects of glaucoma in humans, one should remember that structural and physiological differences between human and bird eyes complicate direct comparison.

Drosophila eyes have been suggested as a useful system for the discovery of genes that are associated with glaucoma. However, the general organization of human and *Drosophila* eyes are very different and data obtained with *Drosophila* may not always be relevant to glaucoma in humans.

Conclusion

Animal models have already provided interesting new information about potential mechanisms of glaucoma in humans. However, even in monkey models which most closely mimic the human form of the disease, the time course of changes in the glaucomatous eyes may be significantly accelerated as compared with human glaucomatous eyes. Indeed, all of the previously discussed systems are, after all, just models of human glaucoma. Reactions to the same insult (IOP, expression of the same mutated protein, etc.) may be somewhat different between various animal models and humans. Results obtained with these models should not automatically be applied to human condition and should be confirmed by testing in human subjects when possible. Nevertheless, information on molecular mechanisms of glaucoma obtained using animal models might be extremely valuable to develop new therapeutic approaches for glaucoma treatment and prevention in humans.

Anti-Angiogenic Properties of Vitreous

G A Lutty, Johns Hopkins Hospital, Baltimore, MD, USA

Glossary

Angiogenic factor – A factor that stimulates the growth of new blood vessels.
Anti-angiogenic factor – A factor that inhibits the growth of new blood vessels.
Hyalocytes – The monocytic cells that reside in vitreous through life and have been called the dendritic cell of vitreous. These cells are capable of producing many of the angiogenic and anti-angiogenic factors found in vitreous.
Hyaloid vasculature – This occupies the vitreous during fetal life and then regresses to become a vestige called Cloquet's canal. This vasculature has its origins in the central retinal artery and is composed of the hyaloid artery, the vasa hyaloidea propria, which nourishes retina before it is vascularized, and the tunica vasculosa lentis, which nourishes the lens during development.
Hyaluronic acid – A nonsulfated glycosaminoglycan that is a major component of vitreous and other extracellular matrices throughout the body.
Pigment-epithelium-derived factor (PEDF) – A monomeric peptide that is a member of the serpin serine protease inhibitor family that is neurotrophic as well as anti-angiogenic.
Sea fan neovascular formations – The extraretinal neovascularization formations found in patients with sickle cell disease.
Thrombospondin-1 (TSP-1) – A 450-kDa multifunctional extracellular matrix glycoprotein produced by many cells including smooth muscle, endothelial, and retinal pigment epithelial cells in the eye. The major source of this anti-angiogenic protein is platelet granules.
Transforming growth factor beta (TGF-β) – A ubiquitous dimeric polypeptide growth factor found in vitreous. It is produced by most cells in a large latent form and affects the differentiation, proliferation, and migration of many cell types, including inhibition of endothelial cell proliferation and migration.
Vascular endothelial growth factor (VEGF) – The major hypoxia-inducible, secreted angiogenic factor in the body. It also increases vascular permeability, is an endothelial cell survival factor, and is thought to be a major contributing factor in ischemic retinopathies and age-related macular degeneration.
Vitreous humor – The transparent gel of extracellular matrix material that fills the chamber of the eye between lens and retina. It is vascularized during development but avascular in normal adult mammals.

Vitreous

Vitreous humor is the transparent gel between the crystalline lens and the retina. It serves as a stabilizer and shock absorber for any movement or mechanical impact reaching retina and lens. The adult vitreous body is 80% of the volume of the human eye. Ninety-eight percent of vitreous is water and the major extracellular matrix (ECM) macromolecules are collagen type II and hyaluronic acid. Though seeming to be a simple transparent viscoelastic matrix, it is physically and biochemically partitioned and a complex mixture of macromolecules. It contains at least 121 distinct proteins, 38 of the proteins were known in 2003, and the protein concentration ranges from 0.45 to 1.1 mg ml^{-1}. In youth, vitreous is normally a gel but liquification or syneresis occurs with age, 50% being liquid by age 80 in humans. The concept that vitreous had anti-angiogenic properties arose from the fact that, in normal adult life, this gel is avascular even though it is surrounded by vasculatures of the retina and ciliary processes.

Development of Vitreous

The first evidence of vitreous in human development is during the third-to-fourth week gestation (WG) when neural ectoderm becomes separated from the surface ectoderm. The PAS-positive and Alcian-blue-positive material that bridges this space is the initial vitreous. Between 4 and 5 WG, mesodermal cells enter the vitreous space within the concave optic vesicle with the optic fissure fusing at 5 WG. The mesodermal cells will become the hyaloid vascular system, which includes the vasa hyaloidea propria (VHP), posterior tunica vasculosa lentis (TVL), and the hyaloid artery (**Figure 1**). The mesodermal cells may also become hyalocytes, which are of monocytic origin. We have recently demonstrated that the vascular development in vitreous occurs by hemo-vasculogenesis, development of blood vessels and blood cells from a common precursor,

Figure 1 Scanning electron microscope image of a 3-day-old mouse eye from which a temporal cap was removed. In the vitreous cavity, the artifactually broken hyaloid artery is present (arrow) supplying blood to the tunica vasculosa lentis on the posterior surface of the lens (L). The hyaloid artery also supplies the vasa hyaloidea propria (arrowhead), which has pulled away from retina (R) in processing. The round cells on the abluminal surface of the fetal vasculature are hyalocytes and macrophages. From Steve Wajer.

the hemangioblasts. This suggests that some of the mesodermal cells that enter vitreous are hemangioblasts, which will differentiate into the fetal vasculature and perhaps into the hyalocytes. Balazs and associates hypothesized that the monocytic cell that resides in vitreous through life, the hyalocyte, differentiated from the mesodermal cells as well. This cellular vitreous is termed the primary vitreous. The secondary vitreous forms by 12 WG between the VHP and the surface of the retina. It is virtually acellular and the major ECM molecules are collagen type II and hyaluronic acid.

The VHP will nourish inner retina until a retinal vasculature forms, while the posterior TVL will nourish the developing lens. The hyaloid vasculature reaches prominence at 9 WG and will regress thereafter. The VHP in human regresses first and then the posterior TVL. By 23 WG, flow ceases in the hyaloid artery. Adult vitreous is avascular and all that remains of the fetal vasculature of vitreous will be Cloquet's canal, a vestige of the hyaloid artery. Richard Lang and associates have demonstrated that macrophages mediate the regression of these transient vasculatures in vitreous and the anterior pupillary membrane through macrophage wingless-type MMTV integration site family, member 7B (WNT7B). The macrophage-induced apoptosis of select endothelial cells in turn causes obstruction of flow and widespread endothelial cell apoptosis. In human vitreous, apoptosis begins around 13–15 WG followed by necrosis. Other work suggests that hyalocytes (positive for major histocompatibility complex class I (MHC-1), MHC-II, cluster of differentiation 45 (CD45), and calcitonin-gene-related peptide-positive cells) are of two forms: dendritic, which associate with the regressing vasculature, and round in the secondary vitreous.

Switch from Pro-Angiogenic to Anti-Angiogenic in Development

The hyaloid vascular system regresses during the third trimester in human and postnatally in rodents with the vitreous remaining avascular for life in normal subjects. Judah Folkman and Arnall Patz noted a striking correlation between cartilage and vitreous: both tissues were vascularized during development and avascular during adult life. Folkman's lab had demonstrated that adult cartilage inhibited the growth of blood vessels induced by tumors and surmised that an anti-angiogenic agent was produced in adult cartilage. When tumor was implanted in vitreous, it only grew and became vascularized if it touched retina. An extract of vitreous in a slow-release polymer was then placed in corneal micropockets with tumor, and corneal neovascularization in response to the tumor was inhibited. Using the chick chorioallantoic membrane (CAM) assay, our lab demonstrated that bovine vitreous extract could inhibit retinal-derived growth-factor-induced angiogenesis. Furthermore, the major glycosaminoglycans (GAGs) in vitreous were not responsible for this inhibition of angiogenesis on the CAM assay. Our lab and others then demonstrated that the anti-angiogenic activity was heat stable and specifically inhibited endothelial cells *in vitro*. When the inhibitory effect of fetal bovine vitreous compared to adult was assessed during the author's dissertation studies, it was found that fetal vitreous stimulated endothelial cell proliferation, while adult vitreous inhibited; fetal vitreous that was heat treated inhibited endothelial cell proliferation (**Figure 2**). This suggested that while the hyaloid vasculature was present, the vitreous was pro-angiogenic but anti-angiogenic in adult life. Heat treatment also enhanced the inhibitory activity of adult bovine vitreous. This experiment also suggested that either the angiogenic factor(s) was heat labile or the inhibitor was heat activated. It was subsequently demonstrated in the author's dissertation that adult human, dog, rabbit, sheep, and chicken vitreous inhibited endothelial cell proliferation, and heat treatment enhanced the activity. The purification process demonstrated that the anti-angiogenic activity had many characteristics in common with transforming growth factor beta (TGF-β): binds to glass and most filters, heat stable and activated, acid stable and activated, activity lost under reducing conditions, inhibits mink lung epithelial cell proliferation, elutes from C-18 columns in 40% acetonitrile, and active form elutes in 8 M urea from molecular sieve columns with an apparent molecular weight of 25 kDa. The inhibitory activity from vitreous was then neutralized with antibodies against TGF-β. It was then demonstrated that the predominant species in vitreous was TGF-β2 but TGF-β1 was also present.

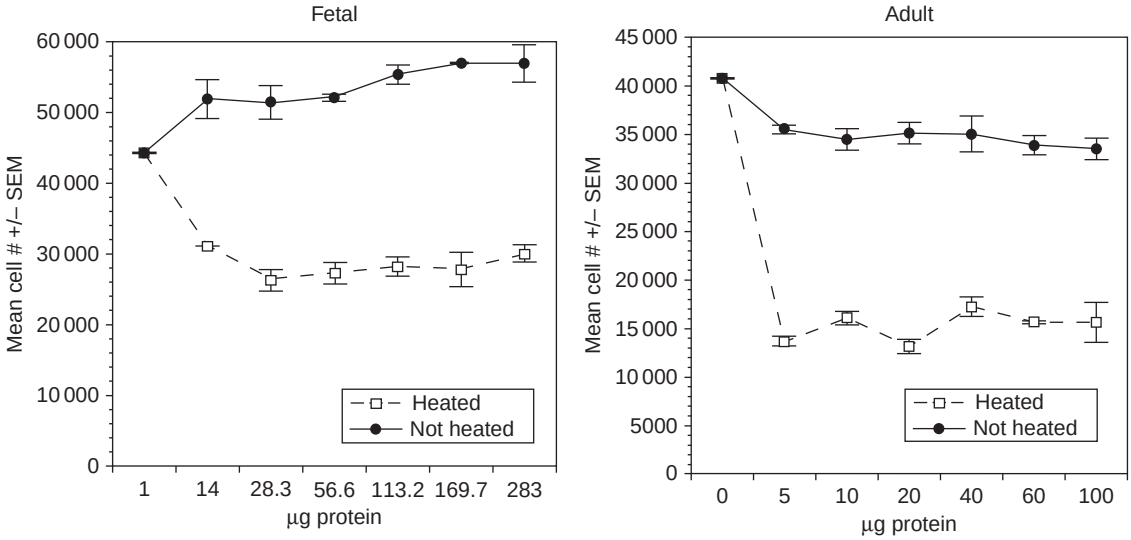

Figure 2 Effect of fetal (a) and adult (b) bovine vitreous on the proliferation of fetal bovine aortic endothelial cells. (a) Fetal vitreous stimulated proliferation (closed circles), but after heat treatment (95 °C for 10 min) inhibited proliferation (open squares). (b) Adult vitreous inhibited proliferation whether heated (open squares) or nonheated (closed circles).

Transforming Growth Factor Beta

TGF-β is a family member of dimeric polypeptide growth factors that includes bone morphogenic proteins (BMPs) and activins. Virtually every cell in the body, including epithelial, endothelial, hematopoietic, neuronal, and connective tissues, produces TGF-β and makes receptors for TGF-β. There are three isoforms in mammals: TGF-β 1, 2, and 3. They are synthesized as large precursor molecules, cleaved before the precursor is secreted, and most TGF-β is stored in ECM. The active form is a disulfide-linked dimer and the three isoforms share receptors. TGF-βs inhibit the proliferation of most epithelial, endothelial, and hematopoietic cells *in vitro*. TGF-β inhibits microvascular and macrovascular endothelial cell proliferation and migration. Ironically, early studies demonstrated that it was angiogenic *in vivo*, which was subsequently demonstrated to be due to an indirect effect of stimulating macrophage migration and then production of angiogenic cytokines by recruited macrophages. When TGF-β2 is knocked out in mice, the hyaloid vasculature does not regress and ocular pathology resembling persistent fetal vasculature results. The source of TGF-βs in vitreous may be hyalocytes or the pericytes of the fetal vasculature because pericytes are known to produce TGF-βs. Hyalocytes appear to produce and process TGF-β1 because both antiprepro-β1 and antisecreted-β1 localization were associated with them (**Figure 3**). Hyalocytes *in vitro* produce TGF-β2. They have a battery of acid hydrolases, which could be responsible for activating latent TGF-β. As the sole cellular occupant of normal adult vitreous, they then may control the rate of TGF-β activation in vitreous. It is noteworthy that hyalocytes also had immunoreactivity for TGF-β 2 and β3 (**Figure 3**); this was the only cell type in the posterior human eye that had immunoreactivity for all four forms of TGF-β evaluated: secreted TGF-β1, prepro-TGF-β1, TGF-β2, and TGF-β3. Ciliary epithelial cells as well as ciliary body stromal cells may also be a source of TGF-β1 and TGF-β2 in vitreous. When panretinal photocoagulation was performed in rats, the levels of both TGF-β1 and TGF-β2 were significantly elevated in vitreous. Therefore, the successful treatment of diabetic retinopathy with panretinal photocoagulation may be due to increased TGF-β production in the eye and its accumulation in the vitreous.

Pigment Epithelium-Derived Factor

In addition to TGF-β, there are many other substances in vitreous that have anti-angiogenic activity. PEDF is a 49.5-kDa monomeric protein, which is a member of the serine protease inhibitor (serpin) family. This was first purified from the conditioned medium of human retinal pigment epithelial (RPE) cells. It binds to many matrix components in vitreous, including collagen and hyaluronic acid. It is a neurotrophic factor that induces neurite outgrowth and promotes neurite survival. PEDF is a potent anti-angiogenic factor, inhibiting endothelial cell migration and proliferation and neovascularization in oxygen-induced retinopathy (OIR). There are high levels of PEDF in human vitreous. Some investigators found that PEDF levels were higher in patients with proliferative diabetic retinopathy (PDR) than in control subjects, while others claim that there is lower PEDF in PDR vitreous than in control subjects. Using immunohistochemistry,

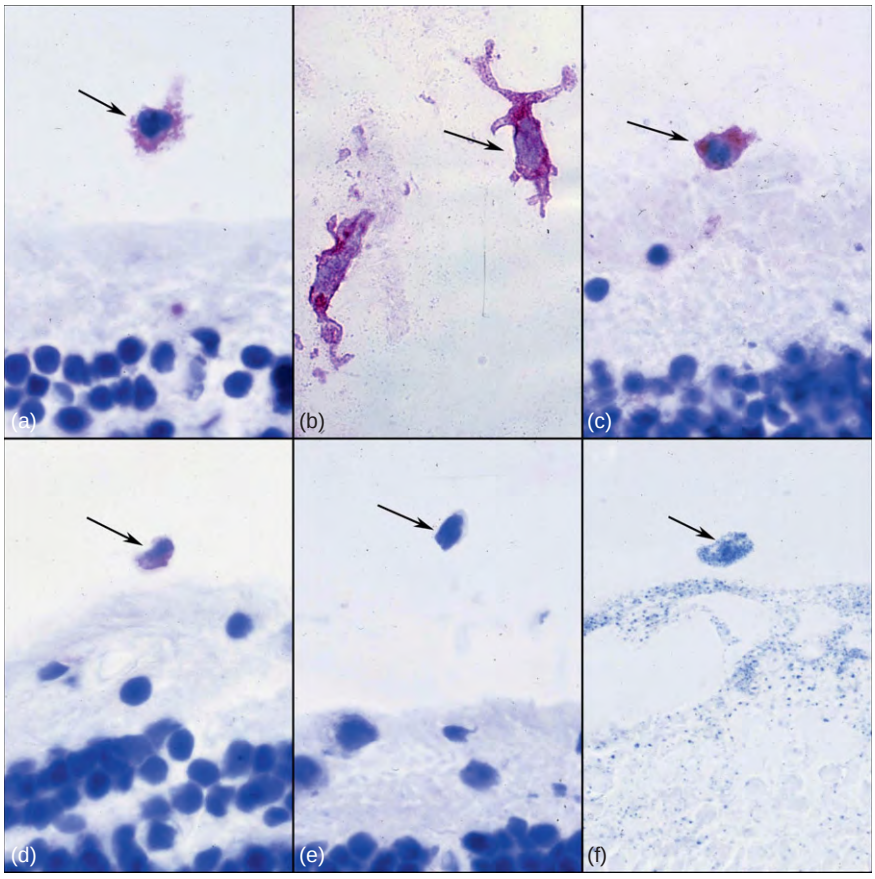

Figure 3 TGF-β isoforms expression in hyalocytes in human vitreous of a 71-year-old male subject who died of respiratory failure. (a) Antibody against prepro-TGF-β1 binds to a hyalocyte in cortical vitreous near the vitreoretinal interface. (b) Anti-secreted TGF-β1 immunoreactivity is prominent in amoeboid-shaped hyalocytes. (c) Anti-TGF-β2 labels a hyalocyte resting on the internal limiting membrane of retina. (d) Antibody to TGF-β3 labels a hyalocyte near the vitreoretinal interface. (e) There is no background labeling when a nonimmune IgG was used instead of anti-TGF-β antibodies. (f) Nonspecific esterase enzyme histochemistry labels a hyalocyte because they are of monocyte origin (arrow indicates hyalocytes in all; AEC immunoreaction product with hematoxylin counterstain).

we found high levels of PEDF in the vitreous of normal as well as sickle retinopathy subjects. During mouse development, levels of PEDF in vitreous change: at midgestation it was expressed in ciliary body and choroid; near term it was expressed in ganglion cell layer where levels remained high through 2 weeks postnatal; and then the levels decreased but persisted at low levels into adulthood. It is interesting that penetrating ocular wounds, such intravitreal injection, increases PEDF messenger RNA (mRNA) in retina and PEDF protein levels in vitreous. The injury and subsequent upregulation of PEDF in vitreous in those studies resulted in less intravitreal neovascularization in the rodent OIR model. Therefore, it would not be surprising if an injury like photocoagulation results in elevated levels of PEDF in human vitreous.

Endostatin

Endostatin, another endogenous inhibitor of angiogenesis, along with fragments of it were recently isolated from vitreous. Mouse endostatin consists of 184 amino acids at the noncollagenous carboxyl terminus of collagen XVIII (coll XVIII), and is released from coll XVIII through proteolytic cleavage. The production and liberation of endostatin is still poorly understood, but it has been found to be expressed in some differentiated tissues (e.g., kidney and liver) and freely circulating in serum. Endostatin blocks mitogen-activated protein kinase (MAPK) activation in endothelial cells. It specifically inhibits endothelial cell proliferation and migration *in vitro* and potently inhibits angiogenesis *in vivo*. Endostatin is currently being aggressively pursued as a candidate for cancer therapy in humans.

Coll XVIII, the source of endostatin, is widely expressed in mice and humans. In mouse, coll XVIII has been demonstrated prominently in all ocular basement membranes except Descemet's membrane. It is associated with collagen fibrils in vitreous that are connected to the internal limiting membrane. Intracellular endostatin was found in lens epithelium and nonpigmented epithelium of the ciliary body. It has been suggested that there is a ring

of extracellular endostatin around vitreous and the anterior chamber that might physiologically prevent neovascularization. Coll XVIII knock-out mice have delayed regression of the hyaloid vasculature and VHP. Novel mutations in coll XVIII have been associated with Knobloch syndrome and patients with this syndrome, who had no measurable endostatin in their serum, had persistent fetal blood vessels in the vitreous similar to the endostatin knock-out mouse.

Thrombospondin-1

TSP-1 was found in vitreous of normal rat and man. TSP-1 is a 450-kDa multifunctional ECM glycoprotein produced by endothelial cells, monocytes/macrophages, smooth muscle cells, platelets, and RPE cells. Since the major source of TSP-1 is platelet granules, one might assume that increased vascular permeability, as in diabetes, might result in greater levels in vitreous. However, TSP-1 was absent in vitreous of diabetic rats and endothelial cell production of TSP-1 was reduced in the presence of high glucose. As an anti-angiogenic factor, TSP-1 inhibits endothelial cell proliferation and migration, induces endothelial cell apoptosis, and it activates transforming growth factor. In the rat eye, TSP-1 inhibits corneal angiogenesis induced by pro-angiogenic factors: basic fibroblast growth factor and vascular endothelial growth factor (VEGF). Moreover, TSP-1 knock-out mice show more intense neovascularization than wild-type mouse in the cornea and have delayed regression of preretinal neovascularization in retinal angiogenesis models.

Other Anti-Angiogenic Factors in Vitreous

There have been reports on several other anti-angiogenic factors in vitreous that are less well known. Opticin was actually purified initially from bovine vitreous. This 90-kDa dimeric leucine-rich repeat ECM protein is O-linked glycosylated and binds hetereotypic collagen fibrils of vitreous. This protein binds growth hormone in vitreous and retina. Opticin-null mice showed increased neovascularization compared to wild-type mice after exposure to hyperoxia in the murine OIR model, whereas when recombinant opticin was injected into the vitreous there was decreased neovascularization compared to controls. The soluble form of VEGF receptor-1 (sflt-1) has been identified in vitreous. This form of VEGF receptor is thought to be one of the molecules responsible for the avascularity of normal cornea. Chondromodulin has also been found in vitreous. This 25 kDa endogenous anti-angiogenic factor was isolated from cartilage originally and, like TGF-βs, is made initially as a precursor form. mRNA for chondromodulin was found in ciliary body, ganglion, and RPE cells.

Two multifunctional cytokines with anti-angiogenic properties, interleukins (IL) 12 and 13, have been identified in vitreous by multiplex bead analysis. IL12 inhibits the proliferation of endothelial cells and corneal neovascularization induced by basic fibroblast growth factor or tumor. This was accomplished by inducing interferon gamma. IL12 inhibits tumor-induced neovascularization, which was the rationale for its evaluation as a cancer therapy. IL12 also inhibits choroidal neovascularization. IL13 inhibits endothelial cell migration and tube formation *in vitro* as well as the aortic ring assay. IL13 inhibits neovascularization in arthritic joints by upregulating endostatin. Its anti-angiogenic effect is through activation of janus kinase 2 (JAK2) and subsequent activation of signal transducer and activator of transcription 6 (STAT6).

Angiogenic Factors in Vitreous

Although normal adult vitreous is anti-angiogenic, vitreous can be angiogenic in disease states. Most angiogenic factors present in vitreous have been found in diseased states, especially in ischemic retinopathies. We found in our early studies that diabetic vitreous was angiogenic and that an 18-kDa, heat-labile molecule that eluted from heparin-Sepharose at 1.2 M NaCl could be isolated from diabetic vitreous. It was similar to the mitogen in brain extracts, which was subsequently identified as fibroblast growth factor (FGF). The angiogenic factor(s) could either be produced by cells in retina, usually in response to hypoxia, or they may leak from retinal blood vessels in diseases such as diabetes. More recently, the exact identity of these angiogenic factors has been determined.

VEGF was found in vitreous and it was significantly elevated in the vitreous of diabetic subjects and patients with iris neovascularization and central vein occlusion. It was assumed that ischemic retina had produced this heparin-binding growth factor and that it had diffused into vitreous. Soon thereafter, this was demonstrated experimentally when all branch retinal veins in monkey retina were occluded and increased levels of VEGF in aqueous humor and iris neovascularization were observed.

Another hypoxia-inducible, secreted angiogenic factor found in vitreous is erythropoietin (EPO). This increases with age in human vitreous between 12 and 24 WG, a period when the retinal vasculature is forming and the hyaloid system is regressing. This increase in EPO in vitreous was not paralleled by an increase in serum levels so it was assumed that it was produced locally. It is curious that the levels were still elevated at 24 WG when a significant retinal vasculature is present and retina should be less hypoxic. Increased levels of both VEGF and EPO were found in the vitreous of patients with diabetic retinopathy compared to no diabetic subjects. EPO levels in

vitreous are also higher than normal in subjects with diabetic macular edema.

Hepatocyte growth factor (HGF) or scatter factor has also been identified in human vitreous. HGF levels were higher in subjects with PDR and iris neovascularization than in normal subjects. Increased levels were also found in vitreous from subjects with proliferative vitreoretinopathy (PVR) and the level increased with severity of the disease. This is logical because HGF stimulates the proliferation of both endothelial and epithelial cells, cells present in PVR membranes. Insulin-like growth factor-1 (IGF-1), but not-2, is elevated in the vitreous of diabetic subjects compared to normal subjects and the level correlates with serum levels in the subjects, suggesting that serum was the source of vitreal IGF-1. Interestingly, IGF-binding proteins are also present in vitreous but there is no correlation of levels between vitreous and serum. Stromal-derived factor-1 (SDF-1), another hypoxia-inducible molecule, is elevated in vitreous of PDR and non-PDR and in subjects with diabetic macular edema. SDF-1 stimulates migration of endothelial cells and endothelial cell progenitors, but not their proliferation. Osteopontin has diverse functions, including angiogenesis, and increased levels of this factor were found in vitreous of diabetic subjects. Finally, fractalkine was found to be elevated in diabetic subjects compared to normal subjects.

Balance between Anti-Angiogenic and Angiogenic Factors

Although many angiogenic and anti-angiogenic proteins are found in human vitreous, we found that the net effect of normal human vitreous was anti-angiogenic (inhibits the proliferation of endothelial cells), while pathological diabetic vitreous is angiogenic most of the time, even after heat activation. From the previous section, it is apparent that there are many angiogenic factors normally in vitreous at very low levels or not present normally, but they are elevated in disease states such as diabetes. Conversely, there are many anti-angiogenic factors normally in vitreous and they may decline in disease states. Therefore, it is probable that the balance between pro- and anti-angiogenic factors determines if neovascularization forms in vitreous or whether the fetal vasculature in vitreous is viable or not.

Such a balance has been demonstrated between VEGF and PEDF levels in vitreous: levels of PEDF were significantly lower in PDR subjects compared to macular hole (MH) patients used as control; conversely, VEGF levels were significantly higher in PDR subjects compared to MH subjects. Vitreous PEDF levels were lower in PVR subjects than MH patients and higher in retinal detachment subjects, while VEGF vitreous levels were significantly higher with PVR than MH or retinal detachment subjects. When the vitreous of subjects with diabetic macular edema was analyzed, lower PEDF levels were observed with VEGF levels elevated compared to non-diabetic subjects and diabetic subjects without retinopathy. VEGF, of course, is not only angiogenic but increases vascular permeability as well. When we investigated PEDF and VEGF immunohistochemically in sickle cell retinopathy patients, we found that PEDF was not lower but VEGF levels were higher in sea fan neovascular formations and vitreous surrounding them, tipping the balance toward angiogenesis (**Figure 4**). Interestingly, infarcted sea fan formations had high PEDF and no VEGF immunoreactivity.

A balance has also been investigated between VEGF and endostatin. Endostatin levels in vitreous have been correlated with severity of DR: in PDR, VEGF was high and endostatin low, while VEGF was low and endostatin high in diabetics with quiescent DR. Levels of VEGF and endostatin in vitreous were predictive of outcome of DR: VEGF was higher and endostatin lower in a group of diabetics whose retinopathy progressed over the next 6 months, while endostatin was high and VEGF low in group whose retinopathy regressed.

Conclusions

Avascularity of vitreous is imperative for a transparent visual path. After macrophage-induced death of the fetal vasculature in vitreous, it will remain avascular and contain high levels of anti-angiogenic factors through normal adult life. The most prominent anti-angiogenic molecules in vitreous are either bound to matrix (PEDF, TGF-β) or are matrix proteins (endostatin, TSP-1), so their presence and accumulation in vitreous is logical since vitreous is a gelatinous matrix. Metabolic exchange from vitreous and equilibration may be so slow that clearance from vitreous is slowed and matrix-bound substances may accumulate with age. It is interesting that hyalocytes, the only resident cell of vitreous, produce some of the anti-angiogenic substances as well as the matrix components of vitreous. Basic FGF, which is found in vitreous and binds to heparan sulfate, makes hyalocytes morphologically round and stimulates their proliferation while TGF-β, which also binds GAGs, makes hyalocytes more amoeboid, inhibits their proliferation, and stimulates their production of GAGs. Therefore, the level and type of angiogenic and anti-angiogenic factor affects not only the anti-angiogenic properties of vitreous, but also the endogenous vitreous cells. The two types of hyalocytes that have been documented may actually be the same monocytic cell type exposed to different angiogenic and anti-angiogenic factors. It is apparent now that there are both angiogenic and anti-angiogenic factors in vitreous normally. The actual balance between them must be quite complex because there are many angiogenic and anti-angiogenic molecules found in vitreous that will determine the net effect of vitreous on

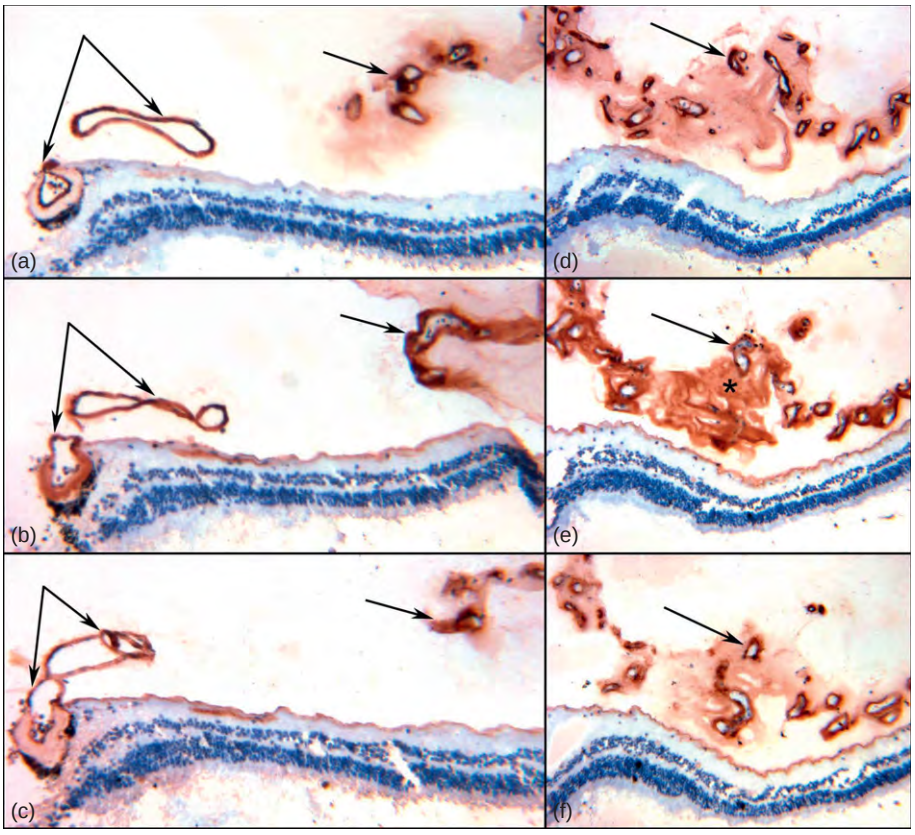

Figure 4 Localization of PEDF and VEGF in proliferative sickle cell retinopathy. A feeder vessel (a–c) and adjacent sea fan neovascularization formation (d–f) in a 58-year-old female SC subject. Heparan sulfate proteoglycan (HSPG) is prominent in vascular basement membranes in retina and the feeder vessel for the sea fan ((a); double arrow) and the sea fan blood vessels (arrow) and condensed vitreous around the vessels (d). PEDF is present in the wall of retinal blood vessels and the feeder vessel as well as condensed vitreous (b) and the sea fan, its matrix (*), and condensed vitreous associated with the membrane (e). VEGF localization is almost identical to HSPG in retinal blood vessels (c) and preretinal sea fan formation (f). (AEC immunoreaction product and hematoxylin counterstain in all.) Reproduced from Lutty, G. A. et al. (2003). *Experimental Eye Research* 77: 433–445.

angiogenesis and may even be predictive of disease progression. Undoubtedly, there is a dynamic balance between these two groups of factors that determines whether vitreous is avascular or not, which is apparent in animals with anti-angiogenic genes knocked out that have a persistent fetal vasculature and have more intravitreal neovascularization in the OIR model.

Acknowledgments

The studies mentioned in this article from the Lutty lab were funded by the Juvenile Diabetes Foundation International, Research to Prevent Blindness, the Helena Rubinstein Foundation, the Altsheler-Durell Foundation, and NIH grants EY09357 (GL), HL45922 (GL), and EY01765 (Wilmer). The author greatly appreciates Scott McLeod's creation of the figures and Steve Wajer for Figure 1, and Arnall Patz, M.D., for his guidance and support during these studies.

Antigen-Presenting Cells in the Eye and Ocular Surface

P Hamrah and R Dana, Harvard Medical School, Boston, MA, USA

Glossary

ACAID (anterior chamber-associated immune deviation) – Systemic inhibition of delayed-type hypersensitivity reactions to antigens which have previously been placed into the anterior chamber of the eye.
APC (antigen-presenting cell) – A cell that displays foreign antigen complex with major histocompatibility complex on its surface.
CX3CR1 – CX3CR1 (Fractalkine receptor) is important for homing of Langerhans-like dendritic cells to the corneal epithelium.
DC (dendritic cell) – Professional antigen-presenting cells.
DC-LAMP/CD208 – A member of the lysosome-associated membrane glycoprotein (LAMP) family, specifically expressed by mature dendritic cells.
DC-SIGN/CD209 – A type 2 transmembrane protein that also contains a mannose-binding (C-type lectin) domain, expressed on dendritic cells.
EAU (experimental autoimmune uveitis) – A disease of the neural retina induced by immunization with retinal antigens.
F4/80 – Antibody that recognizes both dendritic cells and macrophages.
GFP (green fluorescent protein) – Originally isolated from the jellyfish *Aequorea victoria* that fluoresces green when exposed to blue light. The GFP gene is frequently used as a reporter of expression. Animals have been created that express GFP as a proof-of-concept that a gene can be expressed throughout a given organism.
LCs (Langerhans cells) – Dendritic cells that typically reside in the epithelium or epidermis.
MHC class II (major histocompatibility complex class II) – These are necessary to present antigen to T cells.

Introduction

Antigen-presenting cells (APCs) serve as the immune sentinels to the foreign world and can be subdivided into professional and nonprofessional APCs. In the eye, professional APCs, such as dendritic cells (DCs), epithelial Langerhans cells (LCs), macrophages, and B cells, are derived from hematopoietic stem and progenitor cells in the bone marrow (BM), forming an integral part of the immune system. Nonprofessional APCs are found among nonlymphoid cells (e.g., vascular endothelial cells, corneal endothelial cells, and keratocytes) and have a low T-cell stimulatory capacity. However, they can gain requisite signals for T-cell priming under certain circumstances (e.g., inflammation).

DCs are specialized APCs that play a dual role in inducing adaptive immune responses to foreign antigens and in maintaining T-cell tolerance to self. DCs can also play an important role in innate immunity due to their capacity to respond acutely to inflammatory insults or danger signals in peripheral tissues. DCs consist of several distinct populations that can be differentiated by surface and intracellular phenotypic markers, immunological function, and anatomic location. In mice, DCs variously express the CD11c integrin and MHC class-II (MHC-II) molecules, and are further phenotypically distinguished by their differential expression of CD8α, CD4, and CD11b, as well as a growing list of other new markers. Irrespective of their phenotype and immunological role, DCs exert their activity in the eye remote from their place of origin, where they utilize their advanced migratory skills for navigation.

DC progenitors are not restricted to the BM and can be found in multiple locations. These progenitors can differentiate into DCs upon challenge in peripheral tissues. Fully differentiated DCs are found in healthy tissues as immunologically immature cells, being able to sample foreign antigens, but not able to prime naive T cells. Immature DCs express negligible amounts of MHC-II on their surface, and lack the requisite accessory (costimulatory) signals for T-cell activation, such as CD40, CD80 (B7-1), and CD86 (B7-2). In their immature state, they remain alert until signals in the extracellular milieu through inflammatory mediators (derived from microbes or distressed bystander cells) induce a rapid change in function, also known as activation or maturation. Maturation induces redistribution of MHC molecules from the intracellular endocytic compartments of DCs to the cell surface, allowing for T-cell stimulation.

Macrophages reside in virtually every tissue, are an integral part of the innate immune response, and synthesize and secrete a variety of powerful biological molecules. They develop from myeloid progenitor cells, enter the bloodstream as monocytes, and migrate into tissues as macrophages. Monocytes are circulating precursors for

tissue DCs and macrophages, being able to maintain or replenish populations in the peripheral tissues during homeostasis. Macrophages express low levels of MHC-II and costimulatory molecules that enable them to act as APCs, even though much less efficient than DCs. Macrophages are generally poorly responsive to activation signals, and also play a role in other processes, including immune regulation and suppression, tissue reorganization, angiogenesis, and lymphangiogenesis. APCs, including macrophages and DCs, are found in a variety of ocular tissues, including the cornea, conjunctiva, iris, ciliary body, sclera, retina, and choroid.

Antigen-Presenting Cells of the Ocular Surface

The immune-mediated responses of the ocular surface are influenced by its unique anatomy and physiology. The ocular surface consists of three distinct anatomical regions: the cornea, the limbus, and the conjunctiva that function both independently and in concert as specific barriers against microbial, immunogenic, and traumatic insults. Although the conjunctiva and cornea are anatomically proximate and are bathed in the same tear film, their immune responses are distinctly different from each other. Two populations of BM-derived cells, (1) macrophages or monocytes and (2) DCs/ LCs, form the main APC arm of the ocular surface immune response (Figure 1).

Corneal APCs

Epithelial Langerhans cells

During homeostasis, peripheral resident LCs, a subset of DCs, are the only cells that constitutively express MHC-II in the corneal epithelium (Table 1). While a large number of LCs are MHC-II^{+} in the periphery, a large population of MHC-II-negative immature LCs are present both in the periphery and the center of the epithelium, with the center being exclusively negative for MHC-II and costimulatory markers. These immature LCs are capable of expressing MHC-II and costimulatory markers during inflammation and migrate to draining lymph nodes (LNs) to present antigen. Phenotypically, both the peripheral and central murine LCs are CD11c^{+}CD11b^{-}, with the density of these cells decreasing from the limbus toward the center. These LCs have a classic dendritic morphology with long processes interdigitating among the corneal epithelial cells. In mice lacking the chemokine receptor CX3CR1, homing of immature LCs to the epithelium is markedly impaired.

APCs can be observed in living healthy corneas by modern *in vivo* confocal microscopy. Similar to rodents, the density of APCs declines from the limbus to the

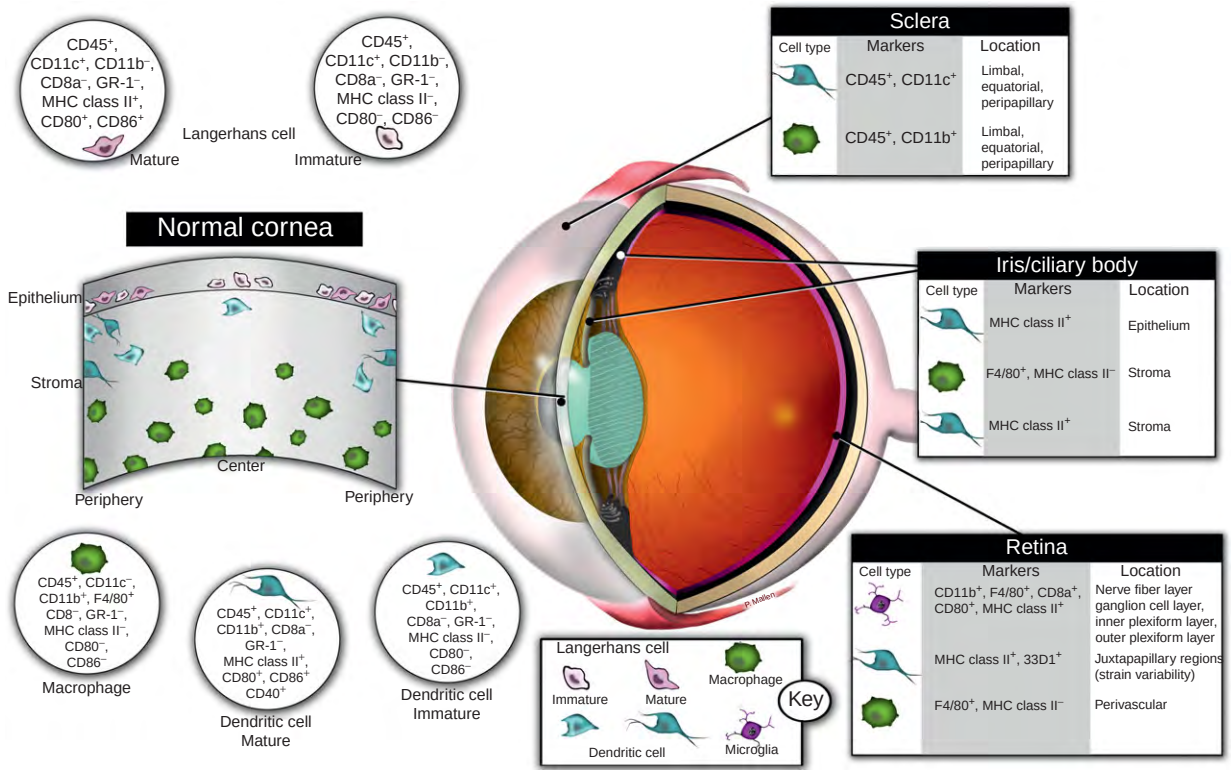

Figure 1 Schematic of antigen-presenting cells of various tissues in the eye.

Table 1 Antigen-presenting cell markers in *normal* corneal tissue

Tissue/cell type	*Markers*	*Location*
Corneal epithelium (Mouse)		
Langerhans cells (mature/immature)	$CD45^+$, $CD11c^+$, $CD11b^-$, $CD8a^-$ GR-1^-, MHC class $II^{+/-}$, $CD80^{+/-}$ $CD86^{+/-}$	Periphery
Langerhans cells (immature)	$CD45^+$, $CD11c^+$, $CD11b^-$, $CD8a^-$ GR-1^-, MHC class II^-, $CD80^-$, $CD86^-$	Center/periphery
Corneal epithelium (Human)		
Langerhans cells	$CD45^+$, $CD11c^+$, $CD207^+$, $CD1a^+$, HLA-DR^+, $CD11b^-$, DC-$SIGN^-$, DC-$LAMP^-$	Periphery
Langerhans cells	$CD45^+$, $CD11c^+$, $CD207^-$, $CD1a^-$, HLA-DR^-, $CD11b^-$, DC-$SIGN^-$, DC-$LAMP^-$	Center/periphery
Corneal stroma (Mouse)		
Dendritic cells (mature/immature)	$CD45^+$, $CD11c^+$, $CD11b^+$, $CD8a^-$ GR-1^-, MHC class $II^{+/-}$, $CD80^{+/-}$, $CD86^{+/-}$, $CD40^{+/-}$	Periphery
Dendritic cells (Immature)	$CD45^+$, $CD11c^+$, $CD11b^+$, $CD8a^-$ GR-1^-, MHC class II^-, $CD80^-$, $CD86^-$	Center/periphery
Macrophages	$CD45^+$, $CD11c^-$, $CD11b^+$, F4/80^+ $CD8^-$, GR-1^-, MHC class II^-, $CD80^-$, $CD86^-$	Center/periphery
Corneal stroma (Human)		
Dendritic cells	$CD45^+$, mostly $CD11c^+$, $CD11b^+$, HLA-DR^+, $CD207^-$, $CD1a^-$, DC-$SIGN^-$, few DC-$LAMP^+$	Periphery/few central
Dendritic cells	$CD45^+$, DC-$SIGN^-$, DC-$LAMP^-$ mostly $CD11c^+$, $CD11b^+$, HLA-DR^-, $CD207^-$, $CD1a^-$	Central/periphery
Macrophages	$CD45^+$, $CD11b^+$, $CD11c^-$, HLA-DR^-, $CD207^-$, $CD1a^-$, DC-$SIGN^-$, DC-$LAMP^-$	Periphery/few central

center in the healthy human cornea. In the corneal limbal epithelium, DCs are present in almost every healthy subject, while in the central cornea only some 20–30% of healthy controls show APCs. LCs are located at a depth of 35–60 μm, mostly at the level of basal epithelial cells and the subbasal nerve plexus. Phenotypically, peripheral LCs in freshly cultured human corneas are Langerin $(CD207)^+$/$CD1a^+$/$CD11c^+$/HLA-DR^+, with no Langerin expression on central LCs. The expression of high levels of CD1a and Langerin on peripheral LCs suggests a unique role of these cells in initiating immune responses to microbial pathogens.

Stromal APCs

Resident DCs reside in the periphery and center of the anterior corneal stroma. Phenotypically, these DCs are $CD11c^+CD11b^+CD8a^-$ demonstrating their monocytic lineage, although a small number of plasmocytoid DCs have been described. Peripheral stromal DCs are MHC-II^+ and positive for the costimulatory markers CD80, CD86, and CD40. The stromal center, however, contains exclusively MHC-$II^-CD80^-CD86^-$ DCs, similar to those of the highly immature LCs in the epithelium. The density of murine stromal DCs decreases from the limbus toward the center of the cornea. A population of undifferentiated monocytic precursor cells distinct from DC and macrophage populations also resides in the corneal stroma. Thus, in contrast to other organs, where terminally differentiated populations of resident DCs and/or macrophages outnumber colonizing precursors, large numbers of DCs within the cornea remain in a relatively undifferentiated state. The absence of MHC-II molecules in the normal cornea might actively maintain tolerance to foreign antigens, as antigen presentation to T cells by immature DCs can lead to anergy of T cells and subsequent tolerance, protecting the cornea from immune-mediated damage, when the insults are minor.

Resident $CD11c^-CD11b^+$ corneal macrophages are present in the posterior stroma of the normal mouse and human cornea, and are distinct from the DCs described in the anterior stroma. They are located in the peripheral, paracentral, and central regions. These resident stromal macrophages likely provide a critical first line of defense against pathogens that breach the epithelial barrier of the cornea by producing antimicrobial substances, as well as other inflammatory cytokines and chemokines to attract and activate additional macrophages, neutrophils, and DCs.

In freshly cultured human corneas, DCs express DC-SIGN and are detected mainly peripherally and in the anterior stroma, having only variable CD11c expression. Most of these cells are HLA-DR^-, with few mature DCs expressing DC-LAMP/HLA-DR or costimulatory markers. These DCs can be found in the cornea even after long-term culture. DC-$LAMP^+$ mature DCs are only partially DC-$SIGN^+$, implying that the peripheral stroma harbors two sets of rare mature DCs, those that coexpress DC-SIGN (mostly $CD11c^-$) and those that do not coexpress DC-SIGN ($CD11c^+$).

Studies in BM chimera mice have demonstrated a turnover rate for BM-derived cells in the stroma at around 24% at 2 weeks. Replenishment occurs initially in the peripheral cornea and the anterior stroma. By 8 weeks, turnover reaches 75%, reaching a plateau between 2 and 6 months. Close to one-third of migrating cells into the central and peripheral cornea are DCs.

Corneal APCs in Inflammation

Microbial products stimulate the immune system by interacting with toll-like receptors (TLRs) on APCs and other cells. The interaction between TLRs and their ligands activates APCs toward maturity. In addition, the release of proinflammatory cytokines, including interleukin (IL)-1β, GM-CSF, tumor necrosis factor (TNF)-α, and lipopolysaccharides (LPS), or heat-shock proteins from dying cells, creates a microenvironment that activates immature DCs. DCs themselves are also important producers of these proinflammatory cytokines, which act in an autocrine fashion to promote DC activation and maturation. Resident immature epithelial LCs and stromal DCs in the central cornea can significantly upregulate maturation markers, including MHC-II and costimulatory markers, within 24 h after induction of inflammation (Table 2).

In addition to the resident APC population, APCs are also recruited into the cornea from the limbal areas through upregulation of IL-1 and TNF-α during inflammation (Figure 2). In general, the migration of APCs to peripheral tissues requires the concerted activity of cell adhesion molecules and chemotactic factors. Cell adhesion molecules regulate both cell–cell and cell–matrix interactions, while chemokines provide directionality to local and infiltrating APCs. Suppression of these cytokines leads to downmodulation of APC migration into the cornea. IL-1 and TNF-α can act in concert to recruit APCs from the limbus into the cornea by mediating the expression of cell adhesion molecules and chemokines. Recruitment of macrophages into the cornea plays a crucial role in inducing inflammatory neovascularization by supplying or amplifying signals essential for pathological hemangiogenesis. Macrophages, but not DCs, physically

Table 2 Antigen-presenting cell markers in *inflamed* corneal tissue

Tissue/cell type	*Markers*	*Location*
Corneal epithelium (mouse)		
Langerhans cells (mature/immature)	$CD45^+$, $CD11c^+$, $CD11b^-$, $CD8a^-$ GR-1^-, MHC class $II^{+/-}$, $CD80^{+/-}$, $CD86^{+/-}$	Periphery/center
Corneal stroma (mouse)		
Dendritic cells (Mature/immature)	$CD45^+$, $CD11c^+$, $CD11b^+$, $CD8a^-$ GR-1^-, MHC class $II^{+/-}$, $CD80^{+/-}$, $CD86^{+/-}$, $CD40^{+/-}$	Periphery/center
Macrophages	$CD45^+$, $CD11c^-$, $CD11b^+$, F4/80^+ $CD8^-$, GR-1^-, MHC class II^-, $CD80^-$, $CD86^-$	Periphery/center

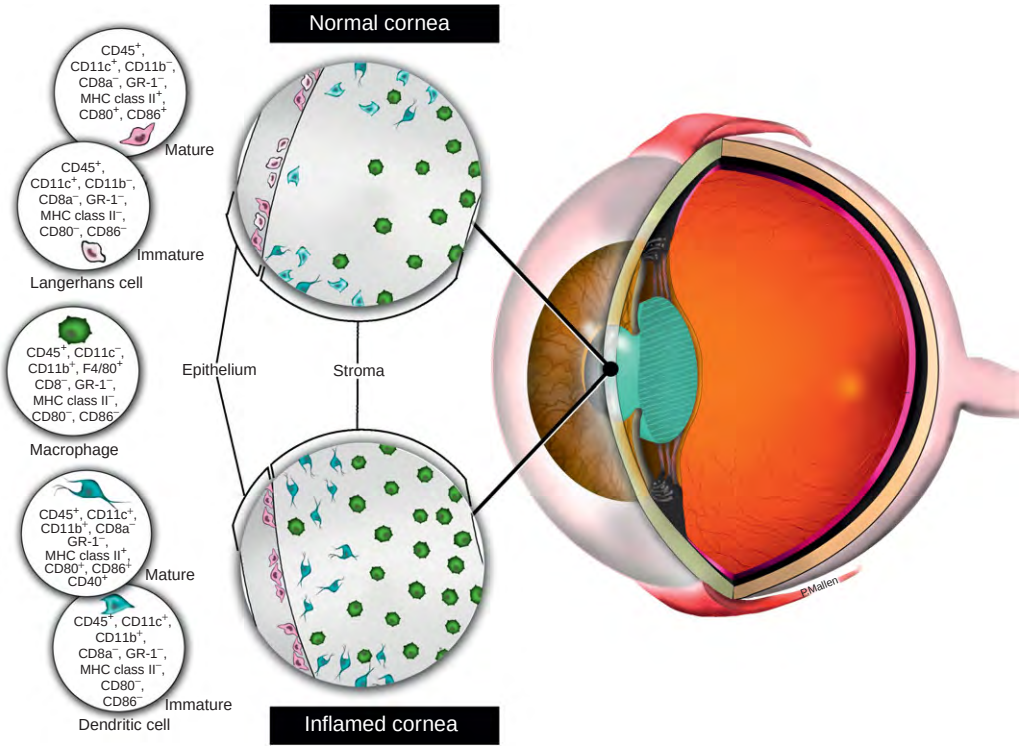

Figure 2 Schematic of the effect of inflammation on corneal antigen-presenting cells.

contribute to lymphangiogenesis under pathological conditions and express lymphatic endothelial markers such as LYVE-1 and Prox-1 under inflamed conditions. Macrophages are capable of forming tube-like structures that express LYVE-1 and podoplanin, and are actively involved in lymphangiogenesis.

The Function of APCs in Corneal Transplantation

The process of corneal transplant rejection includes an induction phase, called the afferent arm, and an expression phase, called the efferent arm. In the afferent arm the host becomes sensitized to the donor antigens by means of APCs , presenting antigens to T cells. This process can take place through two different pathways. The direct pathway, involving donor APCs that sensitize the host directly and the indirect pathway, involving host APCs that move toward the graft, take up donor antigens, and then present these antigens to T cells in draining LNs. While both direct and indirect alloreactive T cells can mediate graft rejection, host sensitization to donor antigens of corneal grafts occurs through both pathways of sensitization, especially in high-risk corneal grafting, where transplantation occurs in an inflamed bed. CD40 is a critical costimulatory molecule expressed by many APCs (including corneal DCs and LCs), whose ligation by CD154 leads to overexpression of other costimulatory molecules, and IL-12 – critical factors in priming a T-cell response. Blocking the interaction of CD40 with CD40 ligand/CD154 can block both the direct and indirect pathways of allosensitization, by preventing T-cell priming, but without promoting active tolerance.

Disruption of the eye–LN axis in the setting of corneal transplantation has been shown to lead to both complete prevention of host allosensitization and the indefinite survival of corneal grafts, demonstrating the functional relevance of corneal APC trafficking to draining LNs. Both donor and host-derived corneal APCs are capable of migrating efficiently to host LNs within 24 h after corneal transplantation. Since the cornea is alymphatic, this is achieved through sprouting of new lymphatic vessels into the cornea upon inflammation, and through migration of APCs toward the lymphatic-rich limbus and conjunctiva. Signaling through vascular endothelial growth factor receptor-3 (VEGFR-3) is critical for DC access to lymphatics, and selective blockade of this pathway can impair DC flow to LNs and the induction of alloimmunity, leading to reduction in the rate of graft rejection. On the one hand, migration of DC to LNs is facilitated by the interaction of the chemokine receptor CCR7 on their surface, with CCL21 secreted by the lymphatic vessels. On the other, CCR1 and CCR5 have been shown to be responsible for the recruitment of immature DCs in inflamed tissues, through their ligands CCL4, CCL5, and CCL7, with only stromal DCs expressing CCR1. Blockade of CCR1 leads to significant reduction in the rate of graft rejection, indicating the important role of stromal DCs in the alloimmune response. Interestingly, depletion of donor APCs before transplantation, however, does not have a significant effect on promoting graft survival, even in the high-risk setting, suggesting that these cells, other than promoting immunization, may also be relevant in the induction of maintenance of tolerance.

The Function of APCs in Microbial Keratitis

Herpetic stromal keratitis (HSK) is an inflammatory disorder induced by herpes simplex virus (HSV)-1 infection and is characterized by T-cell-dependent destruction of corneal tissues. The number of MHC-II$^+$ LCs present in the central areas of the cornea has been shown to correlate with the degree of corneal damage. Virally induced migration or maturation of LCs in the cornea precedes the development of HSK. Induction of LC migration into the central cornea before HSV-1 infection results in an accelerated and enhanced delayed-type hypersensitivity (DTH) response to HSV-1 antigens, and in an increased severity of HSK. Contrary, depletion of DCs reduces the incidence and severity of HSK, suggesting a role for DCs in the induction of a T-cell response. These findings have led to the conclusion that HSV-1 infection results in *de novo* migration of LCs from the limbus, which in turn might play a role in the immunopathology of HSK though presentation of antigens to T cells in the infected cornea.

Pseudomonas aeruginosa is an opportunistic pathogen associated with sight-threatening keratitis, whose outcome is largely determined by the host inflammatory response. Specific susceptible mouse strains challenged with *P. aeruginosa* undergo corneal perforation, while other strains are resistant. While induction of LCs into the central cornea of already susceptible strains before infection does not alter the outcome of disease, induction of LCs into the central cornea of resistant strains converts these to a susceptible phenotype. LCs in these mice express the costimulatory molecule B7-1, enhancing their capacity to present antigen to T cells. Further, macrophages control resistance to *P. aeruginosa* corneal infection through regulation of neutrophil number and apoptosis, bacterial killing and balancing pro- and anti-inflammatory cytokine levels.

Conjunctival APCs

In the naive conjunctiva, predominantly MHC-II$^+$ DCs are consistently detected from birth in the subepithelial layer and substantia propria. There are species and strain-specific differences in the numbers of these cells, with 200–400 LCs mm^{-2} in humans as compared to 100–150 LCs mm^{-2} in mice, with rat and guinea pig numbers intermediate between these two. Further, the

number of LCs is not static and increases with age. Moreover, a significant variability in LC density is also found in different regions of the conjunctiva. The largest number of epithelial LCs is found in the palpebral and inferior fornical region, followed by the medial and inferior epibulbar conjunctiva. DCs of the substantia propria are distributed most densely in the superior and medial epibulbar conjunctiva. This variability within the conjunctiva is interesting, and may be related to exogenous antigenic challenge secondary to the direction of normal tear drainage or to microenvironmental differences within the conjunctiva. Finally, macrophages have a density of 6.5 cells/mm^2 in the tarsal epithelium and 32.2 cells/mm^2 in the tarsal substantia propria, with similar numbers in the bulbar conjunctiva.

Role of APCs in Allergic Eye Disease

Allergic eye disease is a spectrum of diseases that share a common initiating mechanism and pattern of inflammation. While B cells and T cells are the mediators of the allergic immune response, DCs are the actual initiators and modulators of this response. Mast cells mediate the effector phase of the allergic response, whereas DCs are critical in determining the nature of the allergic response. During the sensitization phase, allergens encounter DCs on the ocular surface. Following allergen challenge, there is a marked influx of conventional DCs and plasmocytoid DCs into the subepithelial layer and throughout the substantia propria. DCs then process and present the allergen to T cells in association with the MHC-II. These T cells are then polarized in favor of the development of allergen sensitivity.

APCs of the Uvea

The uveal tract, the vascularized middle layer of the eye, consists of the iris, ciliary body, and choroid. It contains rich networks of F4/80$^+$ APCs that reside and traffic through the eye (**Figure 1** and **Table 3**). These populations include large numbers of macrophages and to a lesser extent, immature DCs, maintaining local immunological homeostasis, and play a role in inflammatory processes and immune-mediated diseases. Dendritiform and pleiomorphic macrophages are distributed in a regular array within the rat iris and ciliary body stroma (600–700 cells/mm^2). The iris contains a network of MHC-II$^+$ DC (400–600 cells/mm^2) within the iris stroma and ciliary epithelium, with few DCs in the uveal tract expressing costimulatory molecules. BM chimera studies demonstrate replenishment of BM-derived cells starting at 2 weeks, with almost complete turnover by 8 weeks in the iris stroma and posterior iris surface. Replenishment rates in the uveal tract are similar in the choroid, iris, and ciliary body stroma, although DCs in the ciliary epithelium replenish at a slightly slower rate starting at 4 weeks.

Table 3 Antigen-presenting cells of the *normal* uvea

Tissue/cell type	*Markers*
Iris/ciliary body stroma	
Macrophages	F4/80$^+$, MHC class II$^-$
Dendritic cells	MHC class II$^+$
Ciliary body epithelium	
Dendritic cells	MHC class II$^+$

Intraocular DCs, after contact with aqueous humor of the anterior chamber, migrate through the trabecular meshwork to the spleen. Additionally, they begin to secret IL-10 and transforming growth factor (TGF)-β in an autocrine fashion, thereby creating a microenvironment that is rich in tolerance-inducing mediators. These DCs promote the effective suppression of T-cell-dependent inflammatory reactions in the lymphoid organs, inducing sufficient levels of tolerance. DCs in the tissues lining the anterior chamber represent a rich network of APCs and are the most likely candidates for transmitting antigen-specific signals from the anterior chamber *in vivo* and in experimental models such as anterior chamber-associated immune deviation (ACAID).

Anterior Chamber-Associated Immune Deviation

The eye receives immune protection against pathogens, while avoiding inflammatory and immunological damage. The selective inability to develop delayed-hypersensitivity responses following antigen invasion into the anterior segment of the eye is highly dependent on DCs, which form the basis of an extraordinary phenomenon called ACAID. The immune response begins with intraocular capture of antigen by specialized ocular F4/80$^+$ APCs in the iris/ciliary body. ACAID-inducing APCs create a microenvironment rich in TGF-β and IL-10, but deficient in IL-12, thus failing to upregulate CD40. These APCs then migrate through the trabecular meshwork and the venous circulation, preferentially to the marginal zone of the spleen, where they become part of an intricate and highly specific cluster of immune cells. The end result is the emergence of a population of antigen-specific T-regulatory lymphocytes that return to the eye and suppress DTH response. A similar process has been described in the vitreous and other posterior compartments of the eye.

Role of APCs in Age-Related Macular Degeneration

AMD is the most common cause of legal blindness in elderly individuals of industrialized countries. The presence of complement factor proteins in drusen in AMD eyes and single nucleotide polymorphisms (SNPs) for complement factor regulatory genes in individuals with AMD implicate inflammation as an important component

in this disease. Choroidal macrophages are proposed as key players in the removal of age-related accumulation of extracellular debris at the choroidal–retinal interface. Observation of aging mice deficient in CCR2 or CCL-2 indicates that defective clearance or scavenging mechanism by resident choroidal macrophages may, in part, be responsible for the presence of drusen deposits at the choroidal–retinal interface. In addition to the potential role of choroidal macrophages, the discovery of age-dependent accumulation of subretinal microglia has recently implicated this population of cells as potential initiators of neovascularization and photoreceptor damage.

Role of APCs in EAU

Resident APCs of the normal human uvea are endowed with the complete LPS receptor complex and are strategically positioned in perivascular and subepithelial locations for surveying blood-borne or intraocular LPS. LPS may act as an adjuvant by activating APC maturation in the presence of the putative uveitogenic self-antigens and thus mediate the breakdown of peripheral tolerance resulting in the induction of an autoimmune response. APCs that capture self-antigens, present them to autoreactive T cells and induce T-cell tolerance by deletion or anergy, as these APCs are relatively immature. TLRs, however, can convert tolerogenic signals to activating signals by promoting APC maturation.

DCs and macrophages act as local APCs in the induction of uveoretinitis. Specifically, MHC-II$^+$ DCs appear at the time of disease onset and continue to be recruited during the inflammatory process, indicating their role in initiation if EAU. MHC-II$^-$ macrophages expressing antigens, however, are prominent during the peak phase of tissue damage in the retina and choroid. Depletion of these cells causes a delay in the onset and a reduction in the severity of EAU.

APCs of the Retina

The presence of the blood–retinal barrier and a predominantly immunosuppressive intraocular environment contribute to the suppression of local immune responses to retinal antigens. Nevertheless, retinal inflammation is not uncommon. Retinal antigen-specific T cells must encounter cognate antigen on APCs within the retina to initiate retinal inflammation. Several distinct populations of myeloid-derived cells reside in the retina, namely, the more prevalent retinal microglia (CD11b$^+$F4/80$^+$CD8a$^+$ CD80$^+$MHC-II$^+$), as well as perivascular macrophages (**Figure 1** and **Table 4**). Perivascular macrophages have poor antigen-presenting capability and are not thought to be absolutely essential for disease induction. Further, a population of BM-derived MHC-II$^+$ 33D1$^+$ DCs has been identified in mice, of which small numbers reside in the peripheral margin and juxtapapillary regions. Of note, the distribution and phenotype of these DCs within the retinas differs between mouse strains exhibiting different disease susceptibility. In EAU-resistant mice, DCs are MHC-II (low/–). Conversely, DCs are MHC-II$^+$ in EAU-susceptible mice.

Table 4 Antigen-presenting cells of the *normal* retina

Cell type	*Markers*	*Location*
Retinal microglia	CD11b$^+$, F4/80$^+$, CD8a$^+$, CD80$^+$, MHC class II$^+$	Nerve fiber layer ganglion cell layer, inner plexiform layer, outer plexiform layer
Dendritic cells	MHC class II$^+$, 33D1$^+$	Peripheral margin and juxtapapillary regions (strain variability)
Macrophages	F4/80$^+$, MHC class II$^-$	Perivascular

Microglia reside in the nerve fiber/ganglion cell layer, inner plexiform layer, and outer plexiform layer of the retina. Resting microglia play various roles in host defense, immunoregulation, and tissue repair and rapidly increase in numbers in response to various insults in the retina. Retinal microglia respond to photoreceptor light-induced injury or degeneration by migration from the inner retinal layers toward the photoreceptor layer and subretinal space, where they phagocytose photoreceptor debris and remain for prolonged periods. Resident host microglia residing in the inner retina are the principal source of the phagocytic microglia that accumulate in the photoreceptor layer and subretinal space during aging or retinal degeneration.

BM chimera studies demonstrate reconstitution of myeloid cells in the retina beginning at 4 weeks. Migrating cells are evident at the juxtapapillary margin and migrating deeper into the retinal layers, and almost completely replenish between 2 and 6 months, depending on the strain. Turnover of microglia within the retinal microenvironment occurs at a much slower rate than other peripheral tissue macrophages. When photoreceptor degeneration is induced, large numbers of microglia/macrophages are observed in the injured retina, starting at 12 h after injury, and peaking at 24 h. In addition, the number of MHC-II$^+$ cells in the retina increases greatly after retinal injury. In response to retinal damage, numerous BM-derived cells migrate to the retina from the ciliary body, optic nerve, and retinal vessels and differentiate into microglia. The higher rate of immunologic activation and the increased specificity to the damaged site appear to be the characteristic features of BM-derived microglia.

APCs of the Sclera

BM-derived cells have been described in the sclera. In BM chimeras, BM-derived cells replenish the sclera

Table 5 Antigen-presenting cells of the *normal* sclera

Cell type	*Markers*	*Location*
Dendritic cells	$CD45^+$, $CD11c^+$	Limbal, equatorial, peripapillary
Macrophages	$CD45^+$, $CD11b^+$	Limbal, equatorial, peripapillary

through limbal vessels and optic nerve vessels, migrating into the equatorial zone. These cells are $CD11c^+$ or $CD11b^+$ DCs and macrophages are found among the scleral fibroblasts (**Figure 1** and **Table 5**). During EAU, significant infiltration of these BM-derived cells takes place into the sclera, contributing to the ocular immune response.

Conclusions

The integrity of the visual system in the face of ever-changing immune challenges is vital. The unique immune homeostasis and immunological status of the eye and ocular surface is fascinating and continuously evolving. It is compelling that most of the APCs described herein were only discovered less than 10 years ago, emphasizing how much still has to be learned about APCs and their function in the eye. The constitutive presence of APCs in the ocular tissues has significant implications for a variety of infectious, autoimmune, and inflammatory responses in the eye. Since the presence of resident ocular APCs was largely unknown until very recently, many paradigms have already been shifted and many more will need to be rethought in the future. Understanding the mechanisms that lead to APC maturation, activation, and trafficking may well lead to novel approaches in the induction of tolerance, autoimmunity, and vaccine therapy.

Glossary

Bioengineered corneas – Are natural-based substitutes for human donor tissue that are designed to replace part or the full thickness of damaged or diseased corneas.
Collagen – The most common naturally occurring structural protein found in all multi-cellular animals and accounts for approximately 30% of all body proteins.
Interpenetrating polymeric networks (IPNs) – Polymeric structures comprising two or more networks that are interconnected on a molecular scale through chemical (covalent) and physical bonds.
Keratoprosthesis – A type of artificial cornea that is designed to be implanted in a patient who has severe bilateral corneal disease for which a corneal transplant is not an option.
Lenticles – A tiny disk slipped into the pocket of the patient's own cornea between corneal epithelium and Bowman's membrane for vision correction.
Penetrating keratoplasty – A surgical procedure where a damaged or diseased cornea is replaced by donated corneal tissue which has been removed from a recently deceased individual having no known diseases which might affect the viability of the donated tissue.
Photorefractive keratectomy (PRK), laser-assisted sub-epithelial keratectomy (LASEK), or laser-assisted *in situ* keratomileusis (LASIK) – Laser eye-surgery procedures for correcting a person's vision can reduce the need for glasses or contact lenses.

The Need for Artificial Corneas

The terms artificial corneas (ACs) or bioengineered corneas are widely used to describe corneal scaffolds that are designed to restore vision. These scaffolds are used as substitutes to human donor corneas, and can replace part or the full thickness of damaged or diseased corneas. Corneal scaffolds can range from solely synthetic ocular prostheses through to tissue-engineered hydrogels that allow some regeneration of the host tissues. In addition, bioengineered lenticles may be implanted into the cornea to improve vision. This is achieved by altering the refractive properties of the eye, which is an alternative procedure to laser-assisted *in-situ* keratomileusis (LASIK), laser-assisted sub-epithelial keratectomy (LASEK), and photorefractive keratectomy (PRK).

Compromising the transparency of the cornea interferes with its function. Once optical clarity is compromised, due to disease or damage, vision loss occurs and can result in corneal blindness (**Figure 1**). According to the World Health Organization (WHO), there are approximately 37 million people worldwide who possess bilateral blindness, as well as at least 124 million people who have impaired vision in both eyes. Corneal ulceration and ocular trauma are reported to be the major causes of corneal blindness, accounting for 1.5–2 million new cases annually. At present, transplantation of matched human donor tissue is the only widely acceptable treatment.

Corneas are the most successful organ transplants – with an 86% graft-survival rate at the 1-year postoperative follow-up, 73% after a 5-year period, 62% after 10 years, and 55% at 15 years. The success of the transplantation is dependent upon the availability of good-quality donor tissue, as well as the patient's condition. Inactive central scars or keratoconus are amenable to transplantation; however, alkali burns or neurotrophic scars that are secondary to Herpes zoster ophthalmicus have a poor prognosis. The cornea donor pool is in limited supply due to a longer life expectancy, combined with the aging population within North America. Demand for corneas is expected to increase, but a shortage in supply will most likely be experienced. The shortage is expected to be compounded by the increasing incidence of infectious diseases (HIV, hepatitis, Creutzfeldt–Jakob disease, etc.), as well as the growing popularity of refractive surgery. Surgically treated corneas are thinned, rendering them unacceptable as donor tissue. As alternatives to donor tissues, bioengineered corneas are designed to replace some or all of a damaged or diseased cornea. They range from prosthetic devices that solely address replacement of the cornea's function, to tissue-engineered hydrogels that permit regeneration of host tissues. This article focuses on the efforts employed to build an *in vitro* model of the visual system.

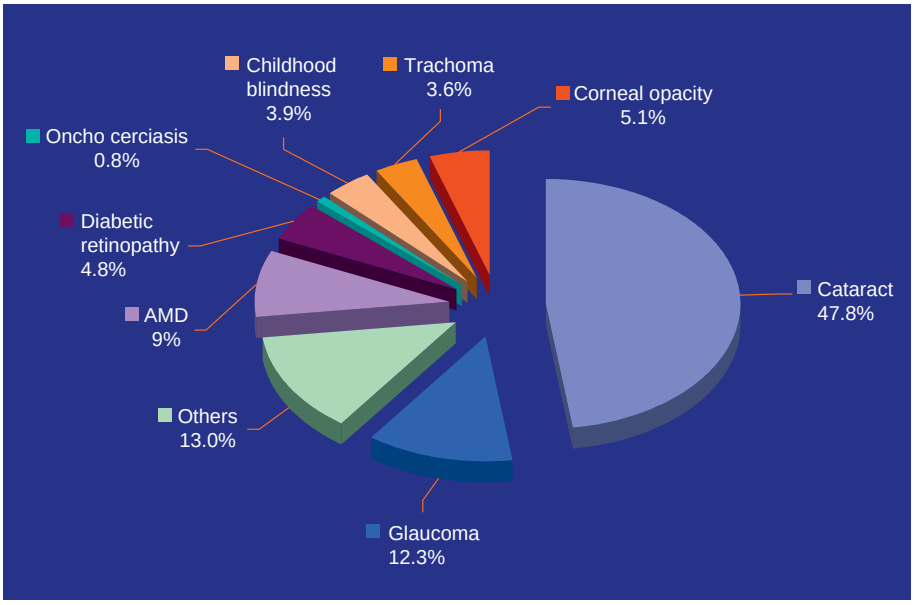

Figure 1 Global causes of blindness as a percentage of total blindness in the year 2002. Trachoma and corneal opacity are cornea-related diseases comprising about 10% of the total causes of blindness. Adapted with permission from **Fig. 1** in Resnikoff, S., Pascolini, D., Etya'ale, D., et al. (2004) Global data on visual impairment in the year 2002. *Bulletin of the World Health Organization* 82: 844–851, with permission from WHO Press.

In particular, we examine the development of novel biomaterials that serve as the building blocks for the fabrication of scaffolds in engineered tissues.

Desired Characteristics for an Implantable AC

In order to be clinically applicable, fabricated corneal substitutes need to replicate the functions of the human cornea. The human cornea forms a transparent window through which light is transmitted to the retina, enabling one to see. A unique property of the cornea is its optical clarity, which accounts for over 70% of the light that is transmitted to the retina for vision. Corneal clarity is now believed to result from a combination of refractive-index matching, and the presence of structural components that are well below the wavelength of visible light.

As alternatives to donor tissues, ACs are designed to replace some or all of a damaged or diseased cornea. They range from prosthetic devices that solely address replacement of the cornea's function, to tissue-engineered hydrogels that permit regeneration of host tissues. In instances where corneal stem cells have been depleted by injury or disease, tissue-engineered lamellar implants reconstructed with stem cells have been transplanted. *In situ* methods using ultraviolet A (UVA) cross-linking have also been developed to strengthen weakened corneas. In addition to the clinical need, bioengineered corneas are also rapidly gaining importance in the area of *in vitro* toxicology. In Europe, there is currently a ban on consumer product testing in animals (European Union Directive 76/768/EEC) that is expected to expand worldwide. Complex, fully innervated, physiologically active, three-dimensional (3D) organotypic corneal models are currently being developed and tested.

ACs must meet certain requirements, without exception, to be successful. To properly integrate into host tissue, AC must be biocompatible and noncytotoxic. A watertight junction with the host tissue is essential for preventing infection and epithelial down-growth. Epithelial cell growth must be supported over the anterior surface, allowing a wettable, self-renewing layer that promotes a healthy tear-film formation. Nerve innervations must be supported for high touch sensitivity. Penetration and proliferation of host fibroblast cells must be promoted for tissue regeneration. Optical transparency >80% and light scatter of <5% should be exhibited, as well as a suitable morphology and curvature to obtain the appropriate refractive index. In addition, flexibility and sufficient tensile strength is required to allow surgical manipulation and fixation, as well as to protect the eye. The AC should exhibit sufficient swelling in aqueous solutions similar to that of native cornea, but at the same time be permeable to oxygen, nutrients such as glucose, and serum albumin – which is a major water-soluble protein in the human cornea. Lastly, the AC must be inexpensive and easy to fabricate.

Artificial or bioengineered corneas developed to date range from prostheses – known as keratoprosthesis (KPro) – to naturally fabricated cell-based tissue equivalents, to bioengineered scaffolds that serve as templates for regeneration of host tissues.

Synthetic Artificial Corneas or Keratoprosthesis

Research into the development of an AC has existed for more than 200 years, with the original glass and quartz optics being put forward, in 1789, by Guillaume Pellier de Quengsy. Since then, there have been numerous attempts at developing ACs. Currently, four generations of KPros have been defined, according to the KPro Study group. KPros are synthetic implants designed to replace the central portion of an opaque cornea. First-generation KPros are comprised of monoblocks, or one-piece prostheses that are made from plastics such as poly methyl methacrylate (PMMA). An example of a second-generation KPros is the osteo-odonto keratoprosthesis (OOKP). This prosthesis, developed by Strampelli in 1964, consists of autologous tissue derived from tooth and bone, which surrounds a central PMMA optic. An osteodental skirt is preimplanted into the buccal mucosa, allowing colonization of fibroblasts to support its integration as an ocular implant. Third-generation KPros include a range of devices with plastic optics and metal parts that aid in anchoring the device to host tissues. Donor-tissue attachment can also be achieved through skirts, allowing for host integration. Fourth-generation KPros utilize the optic-skirt model, in which a solid optical core is surrounded by a porous skirt. This encourages biointegration with the adjacent host tissues to circumvent implant extrusion. Rigid synthetic polymers, such as PMMA, were used in the early attempts to develop artificial corneal transplants. While PMMA still remains a popular material, poly(2-hydroxyethyl methacrylate) (PHEMA) has been used more frequently in various types of KPros. In this article, we provide a synopsis of several examples of KPros that have either been tested clinically, or are currently in clinical use.

KPros currently in clinical use include the following: the OCULAID® KPro, Dohlman KPro, AlphaCor™ Kpro, OOKP KPro, BioKPro III, Seoul-type KPro, and Pintucci KPro. **Figure 2(a)** and **2(b)** represents the OCULAID® KPro, composed of an anti-conical shaped shaft that can be fixed into the host cornea or sclera. It creates a valve on the cornea to ensure a watertight environment. The pressure in the eye pushes the corneal rim around the 3-mm top of the KPro, while the steel-suture fixation on the sclera is designed to prevent extrusion. The Dohlman AC is a collar-button-design KPro, composed of PMMA. It consists of a central optical stem that penetrates the full thickness of the cornea. This stem is sandwiched between two plates and sutured into place similar to a penetrating keratoplasty (PKP) graft (**Figure 2(c)**).

The AlphaCor™ Kpro is one of the best-known keratoprosthetic devices fabricated as a one-piece device that comprises a transparent core and an opaque porous skirt. The implant is a 7-mm-diameter, one-piece, nonrigid synthetic cornea (**Figure 2(d)**). Composed of a transparent central optic core of PHEMA gel, the KPro is designed to allow the passage of light into the posterior of the eye. The outer porous skirt – an opaque, high-water PHEMA – is designed to allow cell infiltration from the host, which anchors the prosthesis into place. This device gained the Food and Drug Administration (FDA)-approval in 2002 for use in patients with scarred, vascularized, or diseased corneal tissues who are either ineligible for conventional donor-tissue transplants or have had multiple previous graft failures. Early results suggest that the AlphaCor™ Kpro, previously known as the Chirila KPro, is clinically safe. Associated complications include the formation of retroprosthetic membranes, corneal melt, retained lenticular material, optic depositions, and rare cases of device extrusion. Contraindications include abnormal tear film, as well as uncontrollable high intraocular pressure. Topical administration of medroxyprogesterone has been shown to limit corneal melting of the device. However, this KPro has been effectively used to restore a degree of vision in patients considered untreatable by conventional corneal transplantation.

The OOKP, described above, consists of autologous tissue derived from tooth, which surrounds a central PMMA optic. This KPro is one of the most successful, as it has a low extrusion rate due to the excellent integration of the skirt material with the host tissue. Associated complications with the OOKP include retroprosthetic membrane formation, glaucoma and decentration of the central optic, due to absorption of the osteodental skirt.

The BioKPro III, designed by the Legeais group, was recently clinically evaluated at the Moorfields Eye Hospital, London, UK. The BioKpro III consists of a central 5-mm-diameter, 500-mm-thick silicone optic, and a surrounding opaque skirt made of porous fluorocarbon. The device was implanted into seven patients with severe corneal scarring, and monitoring occurred between 18 and 48 months. The results showed that the KPro failed in six patients, due to extrusion occurring between 2 and 28 months postoperatively. One patient, who had a thermal burn, retained the KPro and reported an improvement in vision. However, this patient also reported mucous accumulation on the optic.

The Seoul-type KPro (S-KPro) consists of three sections: a long cylindrical optic surrounded by a mushroom-shaped anterior flange, a skirt for corneal fixation, and haptics for scleral fixation. The 4-mm diameter optic is made of PMMA; the anterior flange is composed of fluorinated silicone approximately 0.2-mm thick and 6 mm in diameter; while the skirt is fabricated from expanded polytetrafluoroethylene (e-PTFE). Preliminary results from the first human trial indicate that complications including retinal detachment, formation of a retroprosthetic membrane, and extrusion have been identified.

The Pintucci KPro consists of a 3-mm thick and 5-mm long optical cylinder made of PMMA. A woven, 0.7-mm

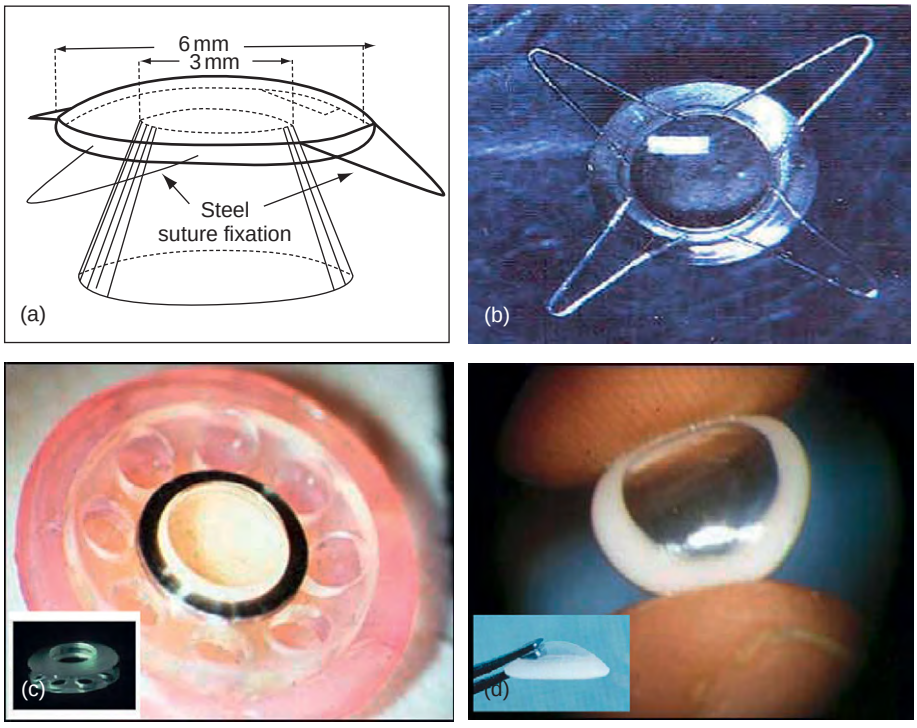

Figure 2 A glance at some of the keratoprostheses used in human clinical trials: (a) and (b) OCULAID® KPro, (c) Dohlman or Boston KPro, and (d) AlphaCor™ Kpro. thick and 10-mm circular Dacron membrane is added to the KPro for tissue integration. Like the OOKP, this device is preimplanted into the patient for colonization of the skirt. Thirty-one patients have received implants from 1997 to 2004, by means of clinical trials. Results indicated that no infections or retroprosthetic membranes were reported. Seventy-seven percent of implanted eyes improved enough to enable the patients to function independently. However, approximately 40% of implanted eyes had complications, although only a few cases were vision threatening.

Recent developments in the design of KPros include a KPro developed by Storsberg and colleagues in Germany; the Stanford KPro; and recent work by Sheardown and colleagues on the coverage of KPros by extracellular matrix (ECM) proteins for enhanced epithelialization. The German KPro adheres to the eye without sutures, reducing inflammation and infection. Sheardown and colleagues have covalently attached cell-adhesion peptides to poly(dimethyl siloxane) (PDMS) surfaces. This surface modification has been effective, leading to a synergistic effect on corneal epithelial cell attachment when compared to single peptides only. The Stanford KPro has also been designed using a polymer network hydrogel, comprised of poly(ethylene glycol) and poly(acrylic acid) (PEG/PAA). When implanted in rabbit corneas, this hydrogel was retained and tolerated well in nine out of 10 cases for a 2-week period.

To date, however, no KPro meets the previously defined standards for a successful corneal implant. As such, no particular KPro is in widespread use to date, although recent versions appear to be promising.

Self-Assembled Corneal Equivalents

There have been various attempts at developing a natural-based self-assembled corneal equivalent. These range from the use of purely biological materials synthesized by cells in culture, to the use of noncorneal tissues as substitutes. Most bioengineering approaches to the restoration and repair of damaged tissue require scaffold materials upon which cells can attach, proliferate, and differentiate. Such scaffolds can be made using a self-assembly approach in which chemicals are used to stimulate the secretion of collagen, and other ECM molecules by fibroblast cells. Resulting sheets of scaffolds are stacked together to form a stroma, allowed to further integrate *in vitro*, and then epithelial cells are seeded on top of the stack. These constructs mimic corneal morphology, and the cells express appropriate tissue-specific markers. The main drawback is the time needed to produce enough self-assembled scaffolding for transplantation.

A cornea equivalent, composed of a 3D, bovine, dermal collagen matrix has been developed by Minami and

colleagues for *in vitro* studies. Zieske and colleagues also developed an *in vitro* cornea – fabricated using primary rabbit stromal cells. Funderburgh and colleagues have used keratocytes of the corneal stroma to produce a transparent ECM that may be useful in cell-based corneal therapy or for the development of bioengineered corneas. Funderburgh and colleagues also determined there is a population of cells present in adult mammalian corneal stroma having the ability to divide extensively, generating differentiated keratocytes. Previously, the authors reconstructed a human cornea using immortalized human corneal cell lines. Each cell line was subjected to electrophysiological, biochemical, and morphological tests. This was carried out to determine the phenotype, which was compared to postmortem human corneal cells, before being used in the 3D reconstruction. Collagen–chondroitin sulfate was the base scaffold in which keratocytes were integrated, before epithelial and endothelial cells were layered above or below. Two weeks following construction, the resulting corneal equivalent was found to behave similarly to a normal cornea, with respect to morphology, transparency, ion and fluid transport, and gene expression following injury. Although this human corneal equivalent shared functional properties with the natural cornea, it was not designed to meet the mechanical characteristics needed for transplantation. However, these studies represent an important future directive toward the development of bioengineered corneal implants. Reconstructed corneal equivalents presently have use in the biomedical world, as they are used as replacements for animals in toxicology testing and pharmacological studies.

Bioengineered ACs that Address Regeneration

To overcome the challenges of biocompatibility, inflammatory responses, and rejection, there have been attempts to promote varying degrees of corneal tissue regeneration through implants of bioengineered corneal ECM substitutes. In general, these matrix-mimetic materials range from simple cross-linked ECM macromolecules, such as collagen, to hybrids of ECM macromolecules and synthetic polymeric components. Prior to the assembly of these ECM mimetics for implantation, a bioactive scaffold material with accurate chemical/physical properties must be designed. It must be able to form robust scaffolds, promote cell differentiation/integration, and promote tissue formation in a uniform manner that is repeatable and reliable.

Polymeric blends of collagen have been previously used to emulate the collagen–glycosaminoglycans scaffolding of the ECM. Various tissue-engineering applications have utilized this technology, for example, as a scaffold for artificial liver, skin scaffolds with nerves and dermal models, membranes for controlled drug release, and as an *in vitro* model to test antineoplastic agents. Many efforts have been made to stabilize collagen, and its blends, by chemical cross-linking methods. These methods can be divided into two categories: bifunctional and amide-type. Several bi-functional reagents such as glutaraldehyde (GTA), polyethylene glycol diacrylate (PEGDA), and hexamethylene diisocyanate (HDC) have been used to bridge amine groups of lysine or hydroxylysine residues of collagen polypeptide chains. A major handicap of these cross-linking agents is the potential toxic effect of residual molecules and/or compounds released when the biomaterial is exposed to biological environments (i.e., during *in vivo* degradation).

Amide-type cross-linkers such as carbodiimide, especially 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC), and *N*-hydroxysuccinimide (NHS) offer the main advantage of lower toxicity and better compatibility over GTA and HDC. However, collagen scaffolds stabilized by carbodiimide are not strong, yet are elastic enough for PKP transplantation. This is due to limited zero-length cross-links; in addition, there are reaction sites on collagen molecules that are not linkable by carbodiimide. It is reported that EDC and NHS (EDC/NHS) can link carboxylic acid and amino groups located within 1 nm from each other. Therefore, functional groups that are located on adjacent collagen microfibrils are too far apart to be bridged by carbodiimide. With systems such as EDC/NHS, the increase in tensile strength, especially when induced by the increasing of a cross-linking agent, is associated with the decrease in elasticity and toughness. This compromise in integrity may be due to restraints placed on the mobility of the polymer network, a decrease in scaffold porosity, and/or a diffusion of reactive residues and byproducts out of the scaffolds.

Despite the drawbacks, cross-linking agents have been used effectively to fabricate collagen based matrices. The application of these matrices has been mainly diagnostic; where the tissue is made and used *in vitro* for testing drug metabolism, uptake, and toxicity.

The authors have previously reported collagen-based materials, ranging from corneal scaffolds based on the copolymer poly(*N*-isopropylacrylamide-co-acrylicacid-co-acryloxylsuccinimide), to a simple EDC/NHS cross-linked collagen scaffold. These scaffolds allow regeneration of corneal cells and nerves, when implanted as lamellar grafts. However, these materials still lack the optimal toughness and elasticity required to withstand PKP surgical procedures, as well as normal day-to-day mechanical stresses.

In our most recent ongoing clinical study, we reported corneal regeneration following the implantation of a bioengineered corneal substitute, based on recombinant collagen. Visual acuity, ocular surface quality, and corneal sensitivity are continuously improving in the first recipients of the implants. **Figure 3** shows slit-lamp and optical coherence tomography (OCT) photographs of the operated cornea immediately following lamellar keratoplasty and at 9 months post operation. Such substitutes

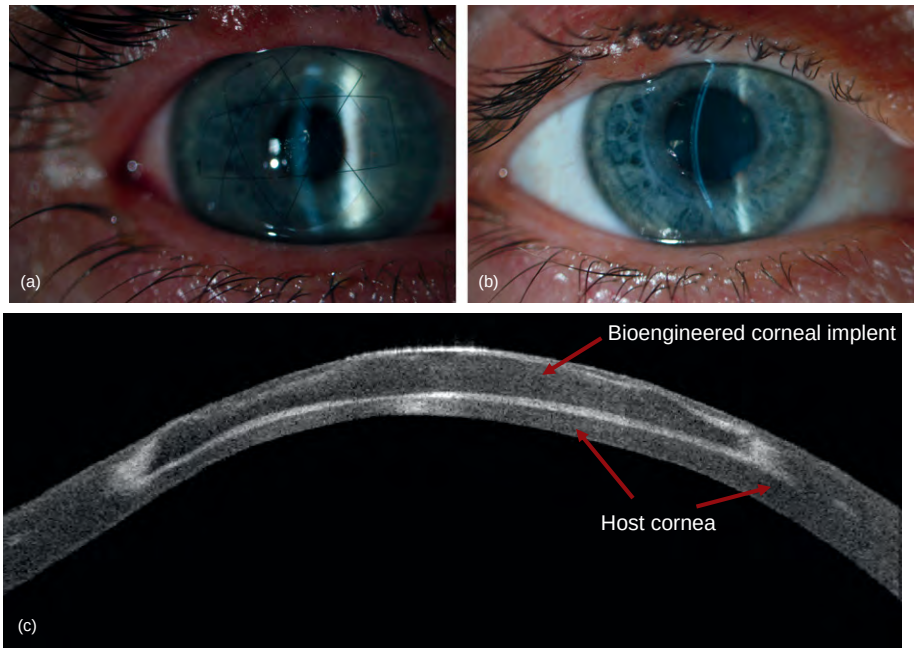

Figure 3 Operated cornea of a 37-year-old man following implantation of a bioengineered artificial cornea, which is transparent with a smooth corneal surface and is well accepted by the patient's eye: (a) slit-lamp photograph of the implanted cornea right after lamellar keratoplasty (LKP) anchored with three overlying 10-0 nylon sutures. may find use as temporary or emergency corneal replacements, where human tissue is unavailable.

In several attempts to enhance mechanical properties of corneal substitutes, hybrid interpenetrating polymeric networks (IPNs) have been developed as ACs. Synthetic-based IPNs have been widely explored and used; however, bioengineered IPNs have not been investigated and examined for corneal applications until recently. Efforts were made by the authors to develop a bioengineered IPN as an AC. The goal was to develop an IPN scaffold that combines the bioactive features of biopolymers with the physical characteristics of synthetic polymers. Composite IPN structures – comprised of two or more interconnected networks on a molecular scale through chemical (covalent) and physical bonds – were developed.

The scaffold material used bio-functional polymers that naturally occur in the native tissue (e.g., collagen) as the core material. As an alternative, tissue-mimetic polymers such as chitosan, 2-methacryloyloxy ethyl phosphorylocholine (MPC) or chondroitin sulfate were used as bio-interactive components; with poly (ethylene glycol) dibutyraldehyde (PEG-DBA) or poly(ethylene glycol) diacrylate (PEG-DA) being used as a synthetic long-range cross-linker. Bio-inert short-range cross-linkers, including EDC and NHS, were also used in conjunction with long-range cross-linkers. This composition allowed the formation of hybrid IPNs that are mimetic of the natural cornea. The IPN scaffolds demonstrated significantly enhanced mechanical strength and elasticity compared to their non-IPN counterpart. In addition, they demonstrated excellent optical properties, optimum mechanical properties and suturability, and good diffusivity to glucose and albumin. The IPNs had excellent biocompatibility, and were further tested by being implanted into pig corneas. Over the 12-month monitoring period, it was demonstrated that there was seamless host–graft integration with successful regeneration of host corneal epithelium, stroma, and nerves. Figure 4 depicts an IPN-bioengineered AC compared to an eye-bank human donor cornea.

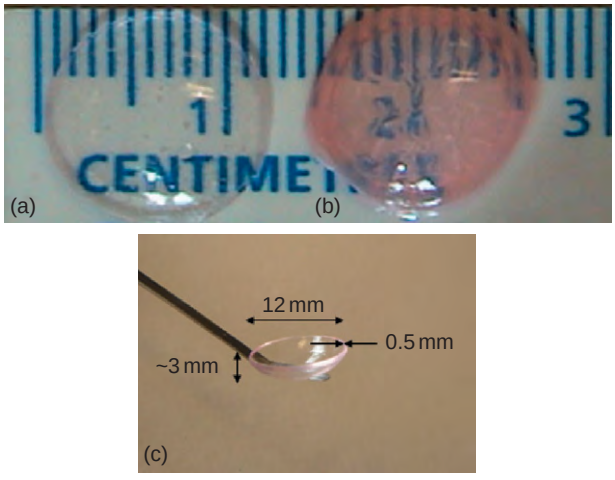

Figure 4 Corneal implants: (a) bioengineered artificial cornea (IPN), (b) eye-bank human donor cornea, and (c) dimensions of a typical bioengineered artificial cornea.

Future Directions

In the cornea, regeneration of the host cornea could overcome the rejection problems and other postoperative complications from donor-tissue transplantation and KPros. In addition, corneal implants that allow nerve- and host-tissue regeneration could also circumvent problems after surgery, found both in human donor tissue and in synthetic KPros. At the current pace of product development and testing, viable alternatives to donor corneas for transplantation are not far off. Processing procedures can affect both the native material properties and the subsequent clinical utility of scaffolds intended for certain tissue-engineering applications. Irrespective of the method, the AC must be engineered to mimic morphological, physiological, and biochemical properties of the natural tissue as closely as possible.

Astigmatism

M J Cox, University of Bradford, Bradford, UK

Glossary

Against-the-rule – Ocular astigmatism in which the meridian with greater optical power in the eye is horizontal.
Astigmat – An individual with ocular astigmatism.
Axis meridian – The meridian of a cylindrical surface that is flat and consequently has no optical power.
Emmetropization – The active process of reduction in refractive error toward an ideally focused system that occurs in the human eye during the first 2 years of development.
High-order wave front aberrations – Wave front aberrations that are expressed using cubic, or higher, powers of the light ray's distance from the pupil center to predict the amount of aberration.
Meridional amblyopia – A lack of contrast sensitivity to high and medium spatial frequency contours oriented along a particular meridian without any refractive error or ocular pathological process affecting the visual function.
Paraxial optics – Image forming through an optical system where only rays traveling close to the optical axis of the system and/or at small angles to this axis are considered.
Penetrating keratoplasty – A surgical procedure to remove corneal material and replace it with material from a donor cornea.
Stokes lens – A lens constructed from two symmetrically counter-rotating cylindrical lenses of equal absolute power but opposite sign. These combine to make a continuously variable power crossed-cylinder lens.
Wave front aberrations – Deviations of a wave front of light propagating through an optical system from a perfect spherical wave front.
With-the-rule – Ocular astigmatism in which the meridian with greater optical power in the eye is vertical.

The Definition and Etymology of Astigmatism

The earliest forms of correction for visual loss caused by refractive errors in the eye used spherical spectacle lenses. These are rotationally symmetrical about the optical axis and, considering paraxial optics, produce a point image from a point object on the axis of the lens. This type of image forming is known as stigmatic, from the Greek stigma, meaning a branding mark. Astigmatism describes an optical system where any nonpoint image is formed from a point object. In practice, astigmatism commonly refers to the simplest extension of stigmatic image formation, namely where the optical system forms two perpendicular line images from an axial point object, each at a different distance along the optical axis.

In an astigmatic optical system the power varies as a function of the meridian, with a maximum and minimum power in meridians that are perpendicular. This variation in power approximates very well to a sinusoidal function, as seen in the formula

$$F_\theta = F_{\text{Sph}} + \frac{F_{\text{Cyl}}}{2} + \frac{F_{\text{Cyl}}}{2}\cos[2(\theta - \alpha)] \qquad [1]$$

where F_θ is the power in the meridian at $\theta°$, measuring angles anticlockwise from the horizontal, F_{Sph} is the power in the meridian of minimum power, F_{Cyl} is the difference in power between the meridians of maximum and minimum power, and α is the angle of the meridian of maximum power.

The double angle $[2(\theta - \alpha)]$ in eqn [1] demonstrates that the power varies through a complete cycle as we rotate the meridian 180° around the optical axis.

Newton is said to be the first to describe the variation in optical power with meridian and the consequent formation of line foci, but did so in the rather specialized form of oblique astigmatism. It was left to Thomas Young to first describe and measure ocular astigmatism, a finding which was a by-product of his attempts to measure his own refractive error as a starting point for investigating accommodative mechanisms in the human eye. He found his own astigmatism to be around 1.75 D and even had additional evidence to suggest that its source was a tilt in his crystalline lens. Airy was the first individual to measure and correct his ocular astigmatism. Wollaston, Ostwalt, and Tscherning discovered means by which spectacle lenses could be manufactured to minimize lens-induced oblique astigmatism.

The above discussion concerns regular astigmatism, where two perpendicular axes of symmetry exist within the optical system and the relationship between power and the angle of the meridian is known. In irregular astigmatism this symmetry does not exist over the aperture through which light travels to form an image. Locally, over much smaller apertures, such symmetry may be present, but for

the purposes of image formation by the optical system or eye it is absent. This results in objects that do not form line images but rather two elongated spreads of light, even at best focus. Furthermore, these two elongated images are not oriented perpendicularly. All eyes contain some degree of irregular astigmatism but this is rarely visually limiting except in pathological processes where the irregular astigmatism is large. Examples of such pathology include keratoconus; lenticonus; corneal scarring, inflammation, dystrophy, and degeneration; pterygium; mechanical effects on the cornea from neighboring structures such as the lids or sclera or following the use of rigid contact lenses; lens dislocation; localized lens index changes; and polycoria and ectopic pupils. In ocularly healthy individuals with unusually large pupils and statistically higher levels of irregular astigmatism, visual function can be affected in low and medium light levels.

Ocular Astigmatism: Prevalence and Age-Related Changes

Ocular astigmatism is important for two main reasons. First, it prevents optimal retinal image formation and leads to a loss of contrast in the retinal image. It can be argued that it is more debilitating than either myopia or hypermetropia as, unlike myopia, there is no object distance at which a clear retinal image can be formed and unlike hypermetropia, it is not possible to overcome the refractive defect by using one's accommodation. Second, if the high levels of astigmatism that are naturally present during early infancy do not reduce during the process of emmetropization, then permanent meridional amblyopia can occur leading to lack of visual sensitivity to small oriented details in later years, even when the astigmatism has been refractively corrected. In addition, some suggest that visual blur during early life may help to drive the development of myopia in later years. Uncorrected ocular astigmatism may be one such cause of visual blur, and an association between ocular astigmatism and myopia development has been found.

Almost all neonates have significant amounts of astigmatism caused by an unusually steep cornea in one meridian, although the angle of this meridian with higher power is not consistent across the population. Early development reduces this cornea-generated astigmatism such that by 4–6 years of age only around one-twentieth of the population has ocular astigmatism in excess of 1 D and in the great majority of young astigmats, the meridian with the greatest power is vertical (or within 15° of vertical, the so called with-the-rule astigmatism). In later childhood (5–17 years of age) the proportion of individuals with at least 1 D of astigmatism increases up to around a quarter, with a higher risk for Asians and Hispanics (around a third), and a lower risk for African-Americans (around a fifth).

In adults, about two-thirds of the population have measureable astigmatism (> 0.25 D), but the majority of this is at low levels (<1 D). Estimates suggest that the prevalence of higher amounts of ocular astigmatism (>1 D) in adults ranges from about 10–20%, dropping to only 0.5% for astigmatism in excess of 4 D. A general trend can also be found in the adult population concerning the angle of the meridian of greatest power. In younger adults (<40 years of age) this is predominantly with-the-rule. In older adults it is predominantly against-the-rule. This change is believed to be due to the changes in the effects of the upper and lower lids on the cornea as the lids age and the tension generated by the lids on the cornea reduces. The lids squeeze on the upper and lower cornea in youth, flattening the cornea directly underneath them but steepening the corneal cap in the vertical meridian. The mechanical effects of the collagen structure within the cornea cause a consequent flattening of the cornea in the horizontal meridian. With aging, the cornea steepens overall, but the steepening in the vertical meridian is offset by the reduction in lid tension, leaving a steeper corneal curvature in the horizontal meridian and a consequent change from with-the-rule to against-the-rule ocular astigmatism.

The Origin of Ocular Astigmatism

The cornea is the major refracting surface in the eye and the ocular astigmatism is best correlated with the astigmatism generated by the cornea. Both the anterior and posterior surfaces of the cornea generate astigmatism and show similar changes in curvature as a function of meridian. Due to the aqueous humor immediately behind the cornea, the refractive power of the posterior surface is only about one-tenth of the anterior surface power and of opposite sign. Keratometers, when used to predict the refractive power of the cornea from anterior corneal curvature measurements in a meridian, account for this by adjusting the value used for the refractive index of the cornea. The physiological value of the corneal refractive index is believed to be close to 1.38, but the majority of keratometers (and their keratographic successors) utilize a value of 1.3375.

With the exception of corneal astigmatism associated with syndromic conditions, there is a complex pattern of heredity associated with corneal astigmatism in the general population, with some evidence of autosomal dominant inheritance patterns, but it seems likely that polygenic inheritance with variable penetrance exists. Unidentified environmental factors are also believed to influence the corneal astigmatism.

There is good evidence to suggest that the corneal shape, and hence the corneally generated ocular astigmatism, is influenced by lid position, tension, and shape.

Performing a task that alters the usual lid position, for instance prolonged reading, produces measureable but temporary changes in the corneal shape and astigmatism. Extra-ocular muscles may also influence the corneal shape, certainly showing effects following changes as dramatic as those induced by strabismus surgery where the extra-ocular muscles are recessed or resected.

Corneal astigmatism is also associated with some well-described syndromes, such as Down's syndrome and Treacher Collins syndrome (also known as Treacher Collins–Franceschetti syndrome or mandibulofacial dysostosis). Changes in the orientation of the palpebral aperture correlate with the axis of the astigmatism, the most powerful corneal meridian lying perpendicular to the axis connecting the inner and outer canthus.

In addition to ocular astigmatism being generated by the cornea, it is also influenced by the shape and position of the anterior and posterior surfaces of the crystalline lens, as well as the refractive index distribution of the crystalline lens. Accurate *in vivo* measurements of the shape of the anterior and posterior surfaces of the crystalline lens are difficult to make. Consequently, it is not known how great a contribution crystalline lens surface shape makes to ocular astigmatism, as opposed to the effect of surface position and refractive index changes. What is known is that the internal astigmatism, that is, that generated by the crystalline lens, partially compensates for the corneal astigmatism and it is believed that some active feedback process is responsible for this compensation. Decentration and tilt of the optical axis of the crystalline lens with respect to that of the cornea will also induce astigmatism. The average internal astigmatism is 0.5 D against-the-rule and this does not appear to alter significantly with age. This is too great to be explained by crystalline lens tilt alone, as the required tilt is 4–5 times the average tilt found for the crystalline lens.

Refractive index changes in the cortex of the crystalline lens, commonly associated with age-related cortical cataract, are also able to induce internal astigmatism, with the axis of the astigmatism believed to be associated with the long axis of the cortical opacity. Other pathological conditions that lead to abnormally large displacement of the crystalline lens also induce astigmatism, including sectoral weakness in the zonular supports of the crystalline lens in conditions such as Marfan's syndrome and homocystinuria, following blunt trauma, and associated with hypermature cataract. Lenticonus is a condition that results in conically shaped lens surfaces inducing large amounts of both regular and irregular astigmatism.

Image Formation and Refractive Specification in Astigmatism

The basic image-forming process that occurs in astigmatic imaging can be seen in Figure 1.

Standard Notation for Specifying Astigmatic Refraction

Here, the front surface of the lens is a cylindrical surface. Note the straight line section of the lens front surface in the XX′ meridian compared to the curved section in the YY′ meridian. This cylindrical surface is created by rotating a line about an axis. The orientation of this axis defines the axis meridian of the cylindrical surface. The distance of the line from the axis defines the radius of curvature, and hence power of the surface. The back surface of the lens is a spherical surface, and the lens is described as a sphero-cylindrical lens. Although used at one time in the production of spectacle lenses, such lens designs are now very uncommon and nearly all spectacle lenses used to correct

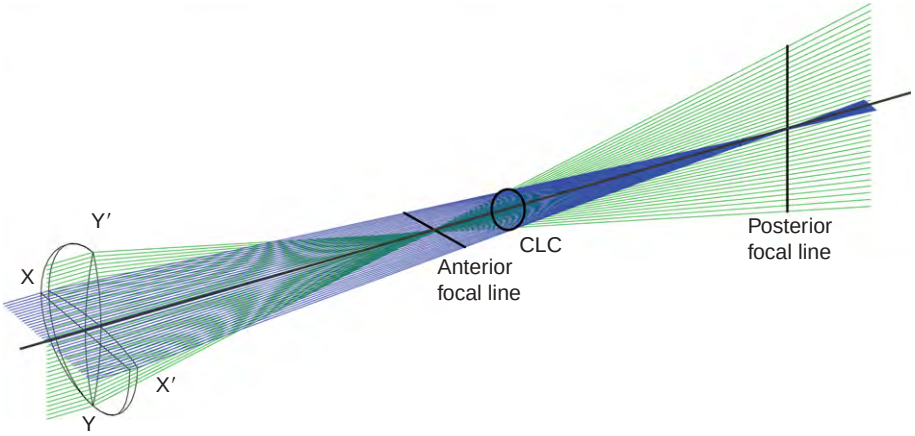

Figure 1 Image formation from a distant axial point object through a sphero-cylindrical lens. Blue rays are traveling in the horizontal meridian. Green rays are traveling in the vertical meridian. The front surface of the lens is cylindrical with a horizontal axis meridian, XX′. The bold lines show, from front to back, the anterior focal line, the circle of least confusion (CLC), and the posterior focal line.

astigmatism use a toric back surface, which is defined using two perpendicular radii of curvature.

The front surface power in the axis meridian is 0, while in the perpendicular meridian (the power meridian) it is F_{Cyl}. The angle of the axis meridian is measured from the perspective of looking at a person with astigmatism. An angle of 0° is represented by 180° but the degree sign is omitted. If the power of the spherical back surface in this lens was F_{Sph}, then we would denote the lens power as

$$F_{Sph}\text{DS}/F_{Cyl}\text{DC} \times 180$$

where DS is dioptres of spherical power. DC is dioptres of cylindrical power. F_{Cyl} is the difference in power between the meridians of maximum (F_{max}) and minimum (F_{min}) absolute power and is a signed value. Conversion between positive cylinder and negative cylinder notation is a straightforward process of

$$F_{Sph'} = F_{Sph} + F_{Cyl} \quad [2]$$

$$F_{Cyl'} = -F_{Cyl} \quad [3]$$

$$\text{Axis}' = (\text{Axis} + 90) \bmod 180 \quad [4]$$

A third much less commonly used notation is crossed-cylinder notation where the F_{max} and F_{min} meridians are considered as two separate cylindrical lenses. If F_{max} is +2.00 DC × 180 and F_{min} is +1.00 DC × 90 then the crossed-cylinder specification for the lens is

$$+1.00\ \text{DC} \times 90/+2.00\ \text{DC} \times 180$$

Ocular Image Formation in Astigmatism

The eye that suffers from astigmatism can usually be successfully studied by considering it to have a single toric corneal refracting surface with perpendicular meridians of maximum and minimum power. The image forming is very similar to that shown in **Figure 1**, where the more powerful meridian is vertical, denoting an eye having with-the-rule astigmatism. This astigmatic image pencil is known as the conoid of Stürm. Rays from a distant axial point that fan out in the vertical meridian (shown in green) are brought to a focus closer to the lens than the rays that fan out in the horizontal meridian (shown in blue). Hence, in the focal plane of the vertical meridian there is horizontal defocus and a horizontal line image is formed. In the focal plane of the horizontal meridian there is a vertical line image. Dioptrically (but not geometrically) equidistant between these two line images, the defocus in the horizontal and vertical (and all other) meridians is equal and the defocused image has its smallest spread, the circle of least confusion (CLC). At other image planes in the light pencil, the image is a horizontal ellipse if measured anterior to the CLC and a vertical ellipse if measured posterior to the CLC.

Paraxial optics can be used to determine the size and position of these astigmatic focal images. For a distant object (vergence of 0 D) and a pupil diameter d, the length of the anterior focal line is

$$\frac{dF_{Cyl}}{F_{max}} \quad [5]$$

The length of the posterior focal line is

$$\frac{dF_{Cyl}}{F_{min}} \quad [6]$$

The diameter of the CLC is

$$\frac{dF_{Cyl}}{F_{max} + F_{min}} \quad [7]$$

Given that F_{Cyl} found in human eyes is <1 D in around 80% of the cases, and the average value for F_{max} is around 60 D it is evident that eqns [5] and [6] will produce very similar results that are about twice the value of the result from eqn [7]. Thus, the focal lines give around twice as large an extent of blur as the CLC. This is helpful in explaining some of the effects of ocular astigmatism on human visual performance.

Classification of Ocular Astigmatism

Ocular astigmatism is divided into five categories depending upon where the retina lies with respect to the conoid of Stürm:

- The anterior focal line lies behind the retina – compound hypermetropic astigmatism;
- The anterior focal line lies on the retina – simple hypermetropic astigmatism;
- The anterior and posterior focal lines lie on either side of the retina – mixed astigmatism;
- The posterior focal line lies on the retina – simple myopic astigmatism;
- The posterior focal line lies in front of the retina – compound myopic astigmatism.

Most individuals with astigmatism have one or other form of compound astigmatism.

Astigmatic Blurring and Visual Perception

Unless the CLC is coincident with the retina, as is only possible in mixed astigmatism or hypermetropic astigmatism when accommodation is used, the retinal blur patches in an uncorrected astigmat will be oriented. In myopic astigmatism the long axis of the blur patch will typically be oriented along the more powerful corneal meridian, and in hypermetropic astigmatism along the

less powerful corneal meridian. Contours and edges in a scene that are parallel to the long axis of the blur patch will appear relatively clear, while those perpendicular to this axis will appear to be most blurred. As most scenes contain more contrast energy for horizontal and vertical orientations than for oblique orientations, there is often useful nonblurred information available to the viewer who has with-the-rule or against-the-rule astigmatism compared to a viewer with obliquely oriented astigmatism. This can be measured with visual acuity results, where with-the-rule and against-the-rule astigmatism produce a smaller loss of visual acuity than astigmatism along an oblique axis. In addition, as the line spacing in printed text is larger than the letter spacing, horizontal blurring is worse for reading than vertical blurring. An astigmat will benefit when reading printed text if he/she accommodates to a position where the vertical focal line is on the retina. For a with-the-rule astigmat, this would typically mean more accommodation is required to bring the vertical focal line (which is more posterior) onto the retina, compared with the accommodation required by an against-the-rule astigmat, for whom the vertical focal line is more anterior. If moderate to large amounts on myopia are present in addition, then the text would be best held at a distance that places the vertical focal line on the retina.

Figures 2 and **3** demonstrate the effects of astigmatic blur, compared to spherical blur, for Snellen letters and oriented contours (**Figure 2**) and an interior scene (**Figure 3**) when there is simple myopic astigmatism (or equivalent spherical error) present in with-the-rule (axis 180°), against-the-rule (axis 90°) and oblique (axis 135°) meridians. The images are taken from the viewer's perspective and the level of blur chosen is that of a narrow failure to pass the European vision standard for driving.

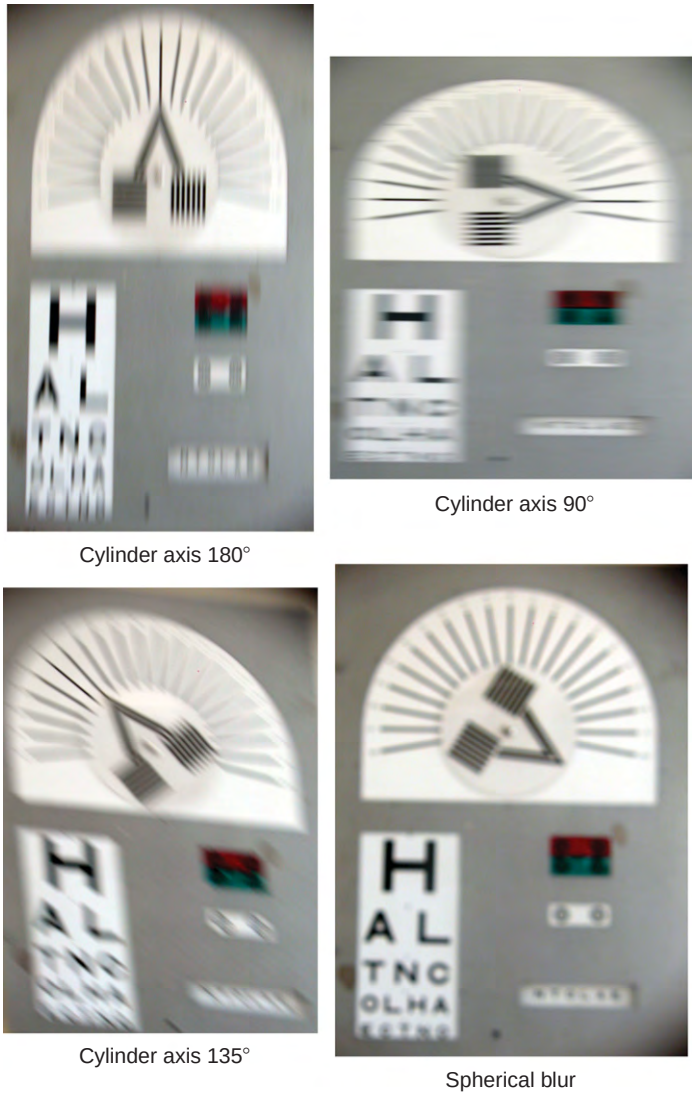

Figure 2 The effects of astigmatic blur, compared to spherical blur, for Snellen letters and oriented contours. Simple myopic astigmatism (or equivalent spherical error) is present in the following meridians: with-the-rule (axis 180°), upper left panel; against-the-rule (axis 90°), upper right panel; and oblique (axis 135°), lower left panel. The level of blur is that of a narrow failure to pass the European vision standard for driving.

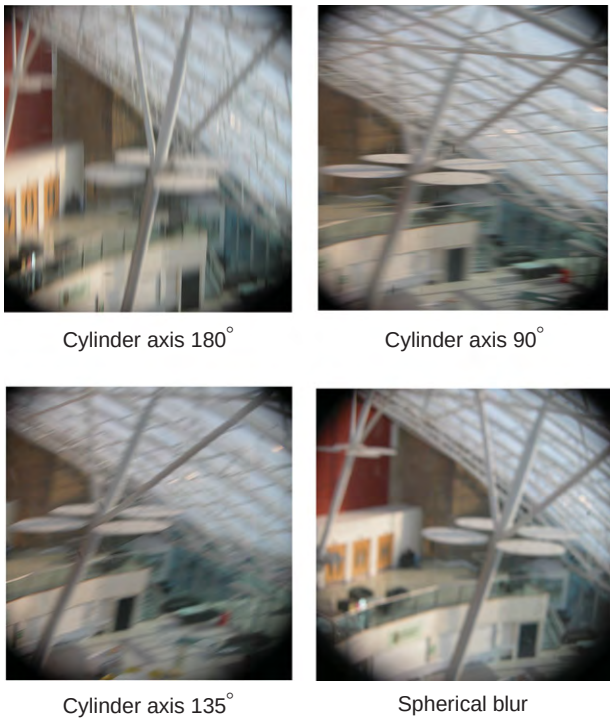

Figure 3 The effects of astigmatic blur, compared to spherical blur, for an interior scene. Simple myopic astigmatism (or equivalent spherical error) is present in the following meridians: with-the-rule (axis 180°), upper left panel; against-the-rule (axis 90°), upper right panel; and oblique (axis 135°), lower left panel. The level of blur is that of a narrow failure to pass the European vision standard for driving.

The induced spherical error is half that of the induced cylindrical error such that the diameters of the blur circle for the spherical lens and the CLC for the cylindrical lens would be matched.

Oblique Astigmatism

Even in an optical system that is rotationally symmetrical, the formation of images from off-axis object points will result in astigmatism, known as oblique astigmatism. This should not be confused with conventional astigmatism along an oblique axis meridian, which is due to different radii of curvature of the refracting surface in different meridians. In the eye, oblique astigmatism is important because the fovea is offset from the best approximation to an optical axis that the eye has, so that the objects that form an image on the fovea are nearly always slightly offset from this optical axis. It is also the dominant form of aberration in image formation for the peripheral retina.

Figure 4 shows the image-forming properties in oblique astigmatism. Rays in the tangential plane, the one containing the optical axis and the chief ray, form a line image oriented in the sagittal plane. Rays in the sagittal plane (the plane containing the chief ray that is perpendicular to the tangential plane) form a line image oriented in the tangential plane. In this biconvex lens, the tangential images form nearer the lens than the sagittal images, but for any given lens power the relative locations of the tangential and sagittal images depend upon the relative powers of the two surfaces of the lens, assuming that there is an aperture stop behind the refracting surface as is the case in the eye or when a spectacle lens is used in front of an eye. The distance from the tangential image to the image position found in a system free from oblique astigmatism is always three times the equivalent distance for the sagittal image. Circumferential image contours are formed clearly in the tangential image plane. In the sagittal image plane, radial image contours are formed clearly.

Any ocular astigmatism caused by oblique astigmatism at the fovea can be corrected with the usual refractive techniques and the oblique astigmatism that is present in the periphery of the visual field is unimportant in normal visual function as the retinal ganglion cell mosaic limits the visual resolving power of the eye to a greater extent than the optics. It is argued that ocular oblique astigmatism acts as a useful high spatial frequency filter to prevent aliasing and the consequent perception of reverse motion in the peripheral visual field.

Oblique astigmatism in refractive correction using spectacles is important. As the eye rotates to view different objects in the field of interest it will make different angles with the optical axis of any spectacle lens, and this will then cause different amounts of oblique astigmatism to be generated by the lens.

Ocular Astigmatism During Near Work

In addition to the nature of the visual task typically being different for near work compared to distance viewing, occasionally the ocular astigmatism itself, or its correction, can change. The power and/or axis of the ocular astigmatism at near compared to distance viewing may be affected by the following factors:

- when the eyes converge and depress for near work they tend to excyclotort;
- the suspensory ligaments of the crystalline lens may not be uniform, causing induced astigmatic changes in the lens during accommodation;
- the ciliary muscle fibers themselves may not exert uniform force on the crystalline lens;
- the crystalline lens may not be homogenously plastic, inducing irregular shape changes during accommodation;
- the pupil or lens may displace with respect to the corneal axis during accommodation inducing some change in the oblique astigmatism.

The power of the astigmatic correction using spectacles can change due to near vision effectivity when the astigmatic or spherical refractive error is large.

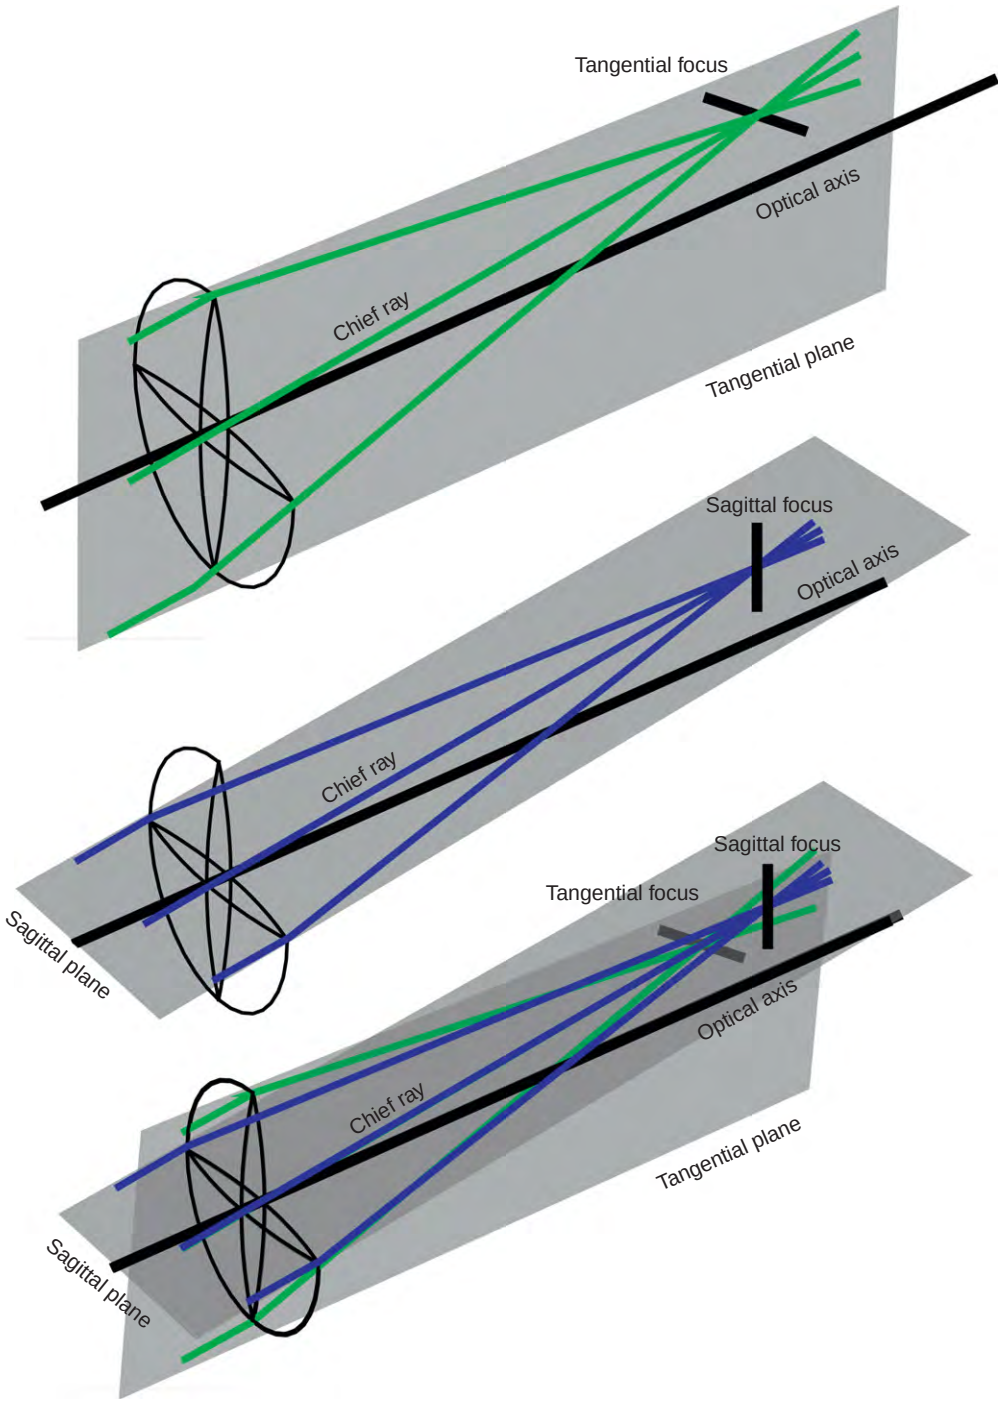

Figure 4 The image-forming properties for a biconvex spherical lens demonstrating oblique astigmatism for imaging a distant off-axis object point. Rays (green) in the tangential plane, upper panel, the one containing the optical axis and the chief ray, form a tangential focus, which is a line image oriented in the sagittal plane. Rays (blue) in the sagittal plane, middle panel, a plane perpendicular to the tangential plane that also contains the chief ray, form a sagittal focus, which is a line image oriented in the tangential plane. The lower panel demonstrates the relative position of these light rays and the induced astigmatism.

Specialized Notations for Specifying Astigmatic Refraction

In addition to the standard sphero-cylindrical notation used to specify astigmatic refractive errors, more specialized notations have been developed. The chief limitation of the standard notation happens when more than one refractive error needs to be considered, for instance when trying to determine population descriptive

statistics for refractive errors, assessing change in refractive error, or when trying to determine the effects of a refractive error when used in conjunction with other optical equipment or other induced refractive errors. Two main alternative forms of notation have been suggested: power vector notation and matrix notation.

Power vector notation resolves the optical power of any sphero-cylindrical lens into three components, a spherical component M, and two crossed-cylinder components, $\mathcal{J}_0$ and $\mathcal{J}_{45}$, with their axes at either 90°/180° or 45°/135°, respectively. Equal values of the components in this notation will lead to equal retinal blur circle sizes. Equations for computing the M, $\mathcal{J}_0$, $\mathcal{J}_{45}$ values from the conventional $F_{\text{Sph}}/F_{\text{Cyl}} \times \theta$ are given below:

$$M = F_{\text{Sph}} + \frac{F_{\text{Cyl}}}{2} \quad [8]$$

$$\mathcal{J}_\theta = -\frac{F_{\text{Cyl}}}{2}\cos(2\theta) \quad [9]$$

$$\mathcal{J}_{45} = -\frac{F_{\text{Cyl}}}{2}\sin(2\theta) \quad [10]$$

While this notation is useful for adding, subtracting, and multiplying by a scalar when dealing with thin sphero-cylindrical lenses, it is much less convenient to use when multiplying lens powers (as required when computing the powers of multiple lens systems or dealing with thick lens systems) or computing the prismatic effects of lens systems.

The alternative matrix representation of lens power is more general and can be used in the above-mentioned instances. A 2 × 2 matrix,

$$F = \begin{pmatrix} f_{11} & f_{12} \\ f_{21} & f_{22} \end{pmatrix}$$

is defined in thin lenses such that

$$f_{11} = F_{\text{Sph}} + F_{\text{Cyl}}\sin^2(\theta) = M + \mathcal{J}_\theta \quad [11]$$

$$f_{12} = f_{21} = -\frac{F_{\text{Cyl}}}{2}\sin(2\theta) = \mathcal{J}_{45}\sqrt{2} \quad [12]$$

$$f_{22} = F_{\text{Sph}} + F_{\text{Cyl}}\cos^2(\theta) = M - \mathcal{J}_\theta \quad [13]$$

It is interesting to note the simple transformations between these two systems in thin lenses and their relationship to the Zernike basis function representation of wave front aberrations now commonly used when considering irregular astigmatic refractive error. The Zernike astigmatism coefficients C_2^{-2} and C_2^{+2} are exactly $\frac{-r^2}{2\sqrt{6}}$ times the value of $\mathcal{J}_{45}$ and $\mathcal{J}_\theta$, respectively, given a pupil radius r, and using normalized variance terms. This has implications when measuring and correcting ocular astigmatism.

The Measurement of Ocular Astigmatism

Various techniques are employed to measure the extent of ocular astigmatism. The majority are based upon locating the meridians of maximum and minimum power and then minimizing the size of the retinal blur ellipses along those meridians. This may be done objectively or subjectively. Alternatively, different components of the astigmatic power may be measured and the final astigmatic refraction inferred from them.

Subjective methods include the Stenopaeic slit, Jackson's crossed-cylinder, fan and block, and Stokes lens techniques. Objective methods include retinoscopy, automated refraction, keratometry, and wave front analysis. It is the latter two that have benefited from the greatest development effort in the last few years.

Keratometry

In this method, the image magnification produced by using the anterior corneal surface as a convex mirror is measured along the meridians of maximum and minimum curvature. The sagittal radius of curvature is inferred from this magnification and the corneal astigmatism is inferred from the sagittal curvature the corneal refractive index and the presumed corneal back surface curvature. The ocular astigmatism is then inferred by assuming a fixed value for the internal astigmatism.

An extension to the principle of the keratometer is the corneal topographer that uses either reflected light from the cornea to measure the local curvature, or light (or even sound) scattered from the cornea – tear-film or cornea – aqueous interfaces to measure the local surface heights. It is possible to computer the local curvature from the local surface heights and vice versa. Unlike keratometers, such instruments clearly demonstrate the conicoidal nature of the cornea over most of its surface excluding the limbal region. Estimates of ocular astigmatism can be made by finding the best fitting overall match to the power map provided by the instrument. They also detect and measure irregular astigmatism much more accurately than keratometers. **Figure 5** shows a corneal keratometric power map and surface height map from the right eye of an individual with approximately 4.50 D of regular with-the-rule ocular astigmatism. The symmetric bow tie pattern in the curvature map is a typical finding in these types of representations of corneal power in astigmatism and the corneal axis of astigmatism can be clearly identified from both maps.

Wave Front Analysis

Most of the methods of refractive measurement estimate the refractive power of the eye along one meridian at a

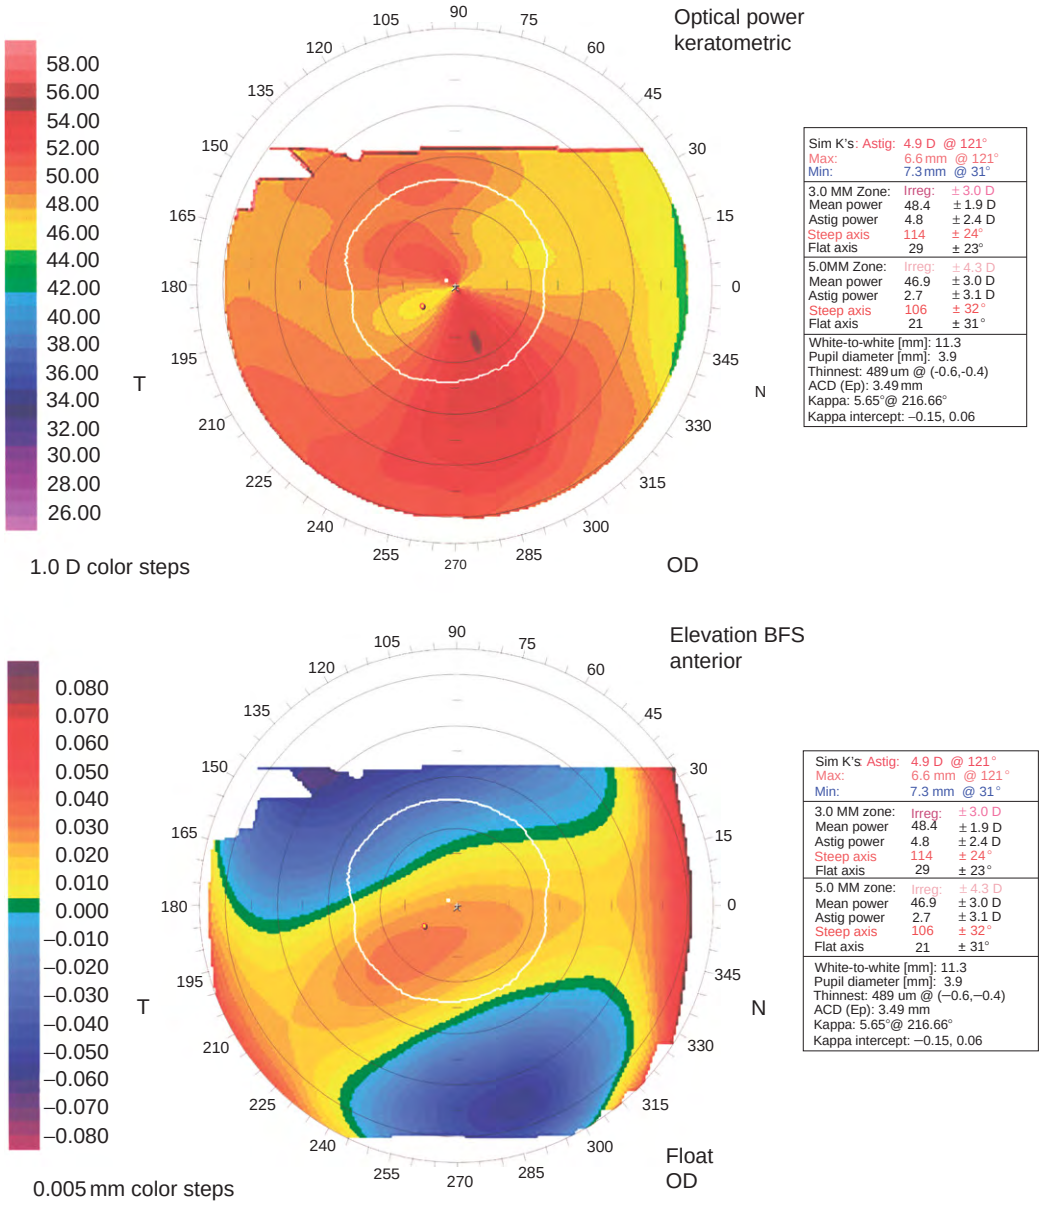

Figure 5 A corneal keratometric power map (upper image) and surface height map (lower image) from the right eye of an individual with approximately 4.50 D of regular with-the-rule ocular astigmatism. Color coding is for D in the upper map and millimeters in the lower one.

time. In these cases the refractive power in that meridian is a best fit to the combination of low-order refractive errors, high-order wave front aberration, and light scatter in the eye to produce the best perceived retinal image by viewing or varying light rays in only that meridian. If scatter or high-order aberrations are large (as in irregular astigmatism) then maximum and minimum power meridians may not be perpendicular giving a problem (albeit soluble) when attempting to arrive at a sphero-cylindrical refractive error. In addition, because change is restricted to one meridian at a time, and the imaging effects from the two meridians tested may interact, it is far from guaranteed that an optimum solution will be found. Furthermore, intermediate meridians will also influence image quality and these are not assessed.

The Stokes lens subjective method circumvents these problems to some extent by estimating along two perpendicular meridians at the same time. Corneal topography assessments can theoretically reduce the problem significantly by estimating ocular astigmatism from combining many individual samples of corneal power across the whole pupil area. Wave front analysis, where the refractive power of the eye is also sampled across multiple small apertures across the pupil, also estimates ocular astigmatism from this array of samples and is typically represented using Zernike polynomials. The Zernike terms are

orthogonal to each other and therefore theoretically do not influence one another over a circular pupil. By considering the measurement or expression of ocular astigmatism using this basis, as opposed to along meridians of maximum and minimum power, it is possible to arrive at an astigmatic correction that is optimized for reducing the wave front aberration given a limitation of being able to use only sphero-cylindrical refractive correction such as can be worked onto spectacle lenses, contact lenses, and intraocular lenses. The spherical element of the correction is not well predicted using an equivalent method, however, due to the extra importance of central versus peripheral pupil rays in the wave front. Techniques that can use asymmetrical surfaces, such as laser refractive corneal ablation, directly make use of the additional higher-order terms of the Zernike expression of the optical defect to provide further optimization of the refractive correction. However, neither corneal topography nor wave front analysis can account for the effects of ocular scatter.

The Correction of Ocular Astigmatism

Spectacles

Spectacles are the most common form of correction for ocular astigmatism. Except in unusual circumstances these lenses are successful in providing optimal visual function. In a limited number of individuals with unusually high irregular astigmatism and/or under conditions where the eye's pupil is very large, the other nonrotationally symmetric optical aberrations such as coma, trefoil, tetrafoil, and secondary astigmatism can reduce the visual performance significantly despite the correction of regular astigmatism.

Spectacle correction of high levels of regular astigmatism also produces spatial distortions due to the different levels of relative spectacle magnification in the different meridians. These make it difficult to binocularly fuse objects that are viewed through the more peripheral parts of the lenses. Patients corrected in this way will often learn to limit this effect by substituting head movement for eye movements when viewing outside a limited area from the optical center of the lens. Misperceived orientations of features and contours in the field of view also occur in high levels of regular astigmatism. Perceptual adaptation takes place over about a 2-week period to ameliorate this effect. Changing the power of the lenses significantly can, however, lead to a return of the perceptual problems.

Tscherning offered a solution to the problem of spectacle lens-induced oblique astigmatism by deriving the necessary lens forms (distribution of lens power between the front and back surfaces) to eliminate oblique astigmatism from spectacle lenses with a given refractive index and for use viewing objects at a given distance. These lens forms are known as punctal (or point focal) lenses. It is more common today to use minimum tangential error, where the tangential image plane is designed to be of a specified power that is independent of the angle of viewing. While this leaves a small residual astigmatic error, it reduces the spherical power error found in punctal lens designs where power changes as a function of viewing angle.

Spectacle lenses with an aspheric surface can also be used to reduce or eliminate oblique astigmatism with the additional benefit of a flatter front surface that makes the lens look less bulbous and also allows the lens to be thinner and hence lighter. The disadvantage is that aspheric lenses must be centered on the visual axis correctly or they induce, rather than reduce oblique astigmatism and other nonrotationally symmetric aberrations. Progressive addition lenses (PALs, also known as varifocals), with their aspheric surface induce astigmatism in a similar way as they can be centered for only two zones in the lens.

Contact Lenses

Contact lens correction of astigmatism can be with rigid or soft lenses. Spherical rigid contact lenses can eliminate the majority of regular or irregular corneal astigmatism. Ensuring the correct fitting of the rigid contact lens limits the amount of correction that can be provided with this method and bitoric lenses, with front and back toric surfaces, are needed for high degrees of astigmatism. Toric front surface rigid contact lenses can be used in cases of internal astigmatism that require correction. Most soft contact lenses flex sufficiently to align to the shape of the anterior corneal surface and so do not correct corneal astigmatism through a tear lens in the same way that rigid lenses do. Front surface toric soft contact lenses are required for the proper correction of ocular astigmatism.

In either rigid or soft contact lens correction of ocular astigmatism, many of the optical problems associated with spectacle correction are relieved. Meridional image magnification, near vision effectivity, and differential prismatic effects are all greatly reduced in contact lens correction. One of the principal difficulties in using contact lenses to correct astigmatism is in maintaining a stable rotational alignment between the contact lens and the cornea.

Surgery

Surgical control or correction of ocular astigmatism usually relies upon altering the shape of the cornea. This is most commonly done by making circumferential incisions in the corneal periphery. This reduces the tensile forces across the corneal stroma in that location, steepening the cornea locally, but flattening it across the pupil in the meridian which intersects with the incision. It is common because cataract surgery is common and most cataract surgery uses a corneal incision, the incision usually being

made in the steepest corneal meridian to reduce postoperative astigmatism. Penetrating keratoplasty is sometimes needed in severe cases of irregular corneal astigmatism. In this case, the resulting corneal shape can be altered by increasing or decreasing the tensile forces created by sutures. It is even possible to remove corneal material in one meridian, a wedge resection, to stretch the cornea, and change its shape. For healthy eyes, laser refractive surgery and conductive keratoplasty are the two techniques commonly used to treat ocular astigmatism. Toric intraocular lens implants also exist that can be used to correct ocular astigmatism and these may be used following cataract surgery or clear lens extraction.

Not Correcting Ocular Astigmatism

It is not always desirable or necessary to correct ocular astigmatism in adults. The most useful property of astigmatism is that, if one is accepting limited amounts of blur, it creates depth of focus in the eye. As mentioned earlier, for near tasks blur along a vertical meridian can usually be tolerated more readily than horizontal blur. An individual with against-the-rule simple myopic astigmatism will have vertical blur conjugate with a near distance equivalent to the amount of astigmatism and horizontal blur conjugate with distance vision. As long as this patient can tolerate the distance blur, they will have functional vision at both distance and near without accommodative effort. Such a situation would be useful for later presbyopes and pseudophakes and free the individual from needing any form of optical correction.

In addition, in some instances where individuals have very different ocular astigmatism in each eye the fusion difficulties that occur with spectacle correction make binocular vision impossible. If contact lenses cannot be tolerated and surgery is not an option, then there may be no alternative than to significantly undercorrect the astigmatism in the nondominant eye and allow visual suppression of the resulting blurred image to occur.

Finally, it is sometimes the case that an individual with high levels of ocular astigmatism has a measureable change in that astigmatism but is not complaining of any significant visual difficulties. One would be very cautious about changing any refractive correction in this individual as the perceptual adaptation to the meridional magnification differences would be affected by doing so and the person may end up feeling that he/she see worse rather than better. The same is true when large changes to the ocular astigmatism are found that do cause symptoms. Adapting to large changes in the correction can be intolerable for some people.

Summary

Although ocular astigmatism is very common, affecting two out of every three adults, visually disabling ocular astigmatism is much less common, affecting only one in five. Correcting this astigmatism is straightforward in the great majority of cases, although the measurement and correction of both irregular astigmatism and high degrees of regular astigmatism remain challenging. Astigmatism induced when looking obliquely through spectacles is well controlled by using the appropriate lens design and contact lens and surgical correction of astigmatism is successful in many instances, even though the uptake of these latter forms of refractive correction is still low. Measuring and correcting irregular astigmatism has improved with the use of more accurate assessment of the corneal surface and with wave front aberrometry to sample the local refractive powers across a fine array of pupil locations. Optimally correcting irregular astigmatism with custom contact lenses and surgical refractive correction is proving to be challenging but successful trials have been performed.

Avascularity of the Cornea

R J C Albuquerque and J Ambati, University of Kentucky, Lexington, KY, USA

Glossary

Alloimmunity – A condition in which the body gains immunity, from another individual of the same species, against its own cells.
Aniridia – Congenital disorder characterized by the abnormal deficient development of the iris and associated with corneal angiogenesis and poor vision.
Atopic keratoconjunctivitis (AKC) – Allergic conjunctivitis where the conjunctiva is red and swollen. Untreated, AKC can progress to ulceration, scarring, cataracts, keratoconus, and corneal vascularization.
Hemangiogenesis – It pertains to the specific growth of blood vessels.
Limbus – The edge of the cornea where it joins the conjunctiva and the sclera.
Lymphangiogenesis – It pertains to the specific growth of lymphatic vessels.
Neovascularization – Formation of new blood and lymphatic vessels.
Perforating keratoplasty – Corneal transplant with replacement of all layers of the cornea, but retaining the peripheral cornea.

Light, the substrate of vision, is required to transverse the full diameter of the eye globe and reach retinal photoreceptors giving rise to the intricate biophysical phenomenon of sight. The cornea, interfacing the outer world and the intra-ocular tissues, serves as an entry window through which light comes into the eye. Avascularity and optical transparency are directly related and a requirement for optimal vision. The absence of vessels in the cornea is also one of the pillars of corneal immune privilege, an important physiological phenomenon that is associated with the maintenance of corneal clarity and responsible for the high success rate of corneal transplants. The growth of blood and lymphatic vessels into the normally avascular cornea (neovascularization) is considered pathological as it impairs the passage of light resulting in severely deteriorated vision or complete corneal blindness, which together afflict over 200 million people worldwide.

The absence of vascular structures in the cornea has been known for over 1000 years. But only recently, advances in molecular biology have led to improved understanding of the homeostatic mechanisms underlying such phenomenon. The absence of vasculature (blood and lymphatic vessels) in the cornea is remarkably intriguing given the highly vascularized nature of the neighboring tissues such as the ocular conjunctiva. The abrupt and precise delineation of the limbal vasculature (**Figure 1**) suggests that corneal avascularity is an active process in which endogenous pro- and anti-angiogenic mechanisms are in harmony and that these molecular modulators of angiogenesis are differently expressed in these interfaces between the cornea and its neighboring tissues preventing the blood and lymphatic vessels from invading the avascular cornea.

Corneal Histology

Histologically, the cornea is comprised of five layers (**Figure 2**). The epithelial layer coats its outermost surface and is composed of a thin nonkeratinized squamous stratified epithelium (only a few cells thick). Unlike the stratified squamous epithelium of the epidermis, that contains indented dermal papillae, the corneal epithelium lays flat on a thick basement membrane called Bowman's membrane. The subjacent layer of the cornea, its stroma or substantia propria, is formed by tightly packed collagen fibers that are uniquely organized in a parallel fashion affording the cornea its crystal clear disposition. The corneal stroma is devoid of blood and lymphatic vessels and is populated by fibroblasts. In addition to fibroblasts, the substantia propria is also endowed with a heterogeneous population of cells including bone-marrow-derived cells, and antigen presenting dendritic cells, most of which, under normal physiological conditions, are still immature and remain quiescent. Descement's membrane, a thick lamina propria, separates the corneal stroma from its innermost cellular layer: the corneal endothelium, which consists of a single layer of low cuboidal cells. The corneal endothelium is critical for water homeostasis as it actively transports excess fluid from the corneal stroma into the anterior chamber. This peculiar histological organization of the cornea with a thin epithelium layer and an active endothelium allows oxygen from the room-air and nutrients from the aqueous humor to diffuse through its full thickness. Because the loss of avascularity in the cornea results in impaired light transmission and poor vision, these unique histological features evolved over time and bestowed the cornea with the ability to remain viable and clear in the absence of a direct blood supply.

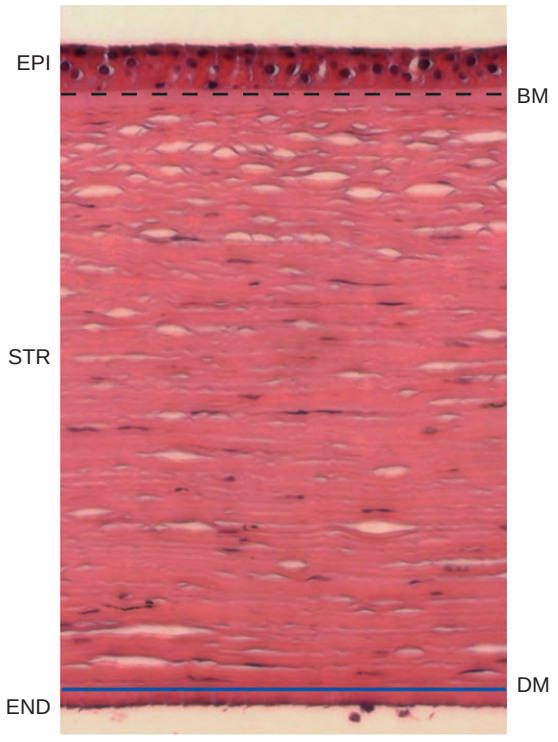

Figure 2 Photomicrograph of the human cornea stained with H&E showing its histological layers. The epithelial layer (EPI) overlaying Bowman's membrane (dotted line). The corneal stroma (STR) displaying its tightly packed parallel collagen fibers. Descement's membrane (DM) interfacing the substantia propria and the corneal endothelium (END).

Corneal Avascularity and Optical Clarity

The visual impairment associated with the loss of corneal avascularity is not only related to the physical obliteration caused by the opaque vessels within the visual field. Corneal neovascularization also reduces visual acuity because the infiltrating vasculature disrupts the tightly packed collagen bundles eliciting opacities, especially in areas surrounding the newly formed vessels. Vascular leakage and edema, usually associated with inflammatory neovascularization, overwhelms the endothelium drainage capacity, creates fluid accumulation, disrupts corneal clarity, and perturbs light transmission. Additionally, the neovascular corneas may also have diminished transparency due to lipid deposits. This is observed in vascularized corneas following corneal herpetic infections. Altogether, these observations speak of the tight correlation that exists between corneal avascularity, corneal transparency, and optimal optical performance.

Endogenous Anti-Angiogenic Mechanisms

The molecular homeostatic mechanisms supporting the lack of vessels in the cornea were unknown until recently. Long ago, it was postulated that corneal avascularity was a passive process. It was thought that the cornea was avascular simply because pro-angiogenic forces were not present. It is quite intriguing, however, that the avascular cornea is surrounded by extremely vascularized tissues, such as the ocular conjunctiva and iris. Because pro-angiogenic factors are a requirement for endothelial cell survival one may postulate that the cornea must be armed with angiostatic capabilities in order to counteract the constant angiogenic stimuli that derives from the adjacent vascular beds. This alternate hypothesis has challenged the previous beliefs, became accepted as a working hypothesis, and still stands as a paradigm of modern vascular biology. Currently, it is well known that corneal avascularity is an extremely active phenomenon, requiring an exact balance between pro- and anti-angiogenic forces, and not the mere absence of pro-angiogenic stimulation.

Extrinsic and intrinsic mechanisms have been proposed to underlie the absence of blood and lymphatic vessels in the cornea. The aqueous humor, fluid that circulates through the anterior chamber of the eye, has been regarded as a major extrinsic inhibitor of corneal angiogenesis. It contains several soluble angiostatic molecules including heparan sulfate proteoglycans. Because vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF), the foremost studied angiogenic factors, bind to

these glycoproteins with relative high affinity, it has been proposed that the aqueous humor sequesters VEGF and bFGF from the cornea into the anterior chamber. However, it is important to bear in mind that not all isoforms of VEGF, like VEGF121, shown to be expressed in the cornea, bind heparan sulphate. This suggests that additional mechanisms are in place to secure corneal avascularity. In reality, it has long been suggested that corneal avascularity is a phenomenon supported by a redundant system. Additional factors contributing to corneal avascularity include the intrinsic synthesis of angiostatic molecules. It has been shown that the cornea expresses several of these anti-angiogenic factors, like angiostatin, endostatin, thrombospondins (TSPs), interleukin-1 receptor antagonist, pigmented epithelium-derived factor (PEDF), non vascular VEGF receptor-3 and soluble VEGF receptor-1.

The current paradigm of intrinsic angiostatic mechanisms in the cornea derived from the clinical observation that corneal epithelial dysfunction was often associated with neovascularization. This suggested that the anti-angiogenic powers of the cornea resided primarily in its epithelial layer. In fact, most of the anti-antiangiogenic factors identified in the cornea have been localized primarily to the corneal epithelium.

Angiostatin, a by-product of plasminogen, was first isolated in 1994. Its angiostatic effect was initially demonstrated in a cancerous tumor growth and metastasis model. Mechanistically, angiostatin is thought to inhibit ATP synthase activity, block endothelial cell migration and proliferation and also cause vascular endothelial cell apoptosis. Angiostatin has been detected in healthy human corneal extracts and it has been shown that human corneal epithelium in culture is capable of converting exogenous plasminogen into its angiostatic by-product. Angiostatin has also been implicated in the maintenance of angiogenic privilege in the normal cornea and after wound healing.

Endostatin was first described in 1997. It is a proteolytic fragment of the caroboxyterminus of collagen XVIII. It has been portrayed as a potent inhibitor of angiogenesis and tumor growth. Collagen XVIII is a component of the basement membrane ubiquitously expressed and it also has been shown to exist in ocular tissues. Immunohistochemical studies have localized collagen XVIII and endostatin to the corneal epithelium, principally in the basal epithelium. Endostatin has been shown to block VEGF-induced phosphorylation of VEGFR-2 and inhibit endothelial cell proliferation and migration. The synthesis of endostatin in the cornea is upregulated during injury and has been shown to inhibit injury-induced corneal neovascularization. Although endostatin has been shown in the uninflammed cornea, mice deficient in collagen XVIII have normal avascular corneas, suggesting that endostatin is only one of many factors contributing to the maintenance of corneal avascularity.

TSP-1 and -2 are potent anti-angiogenesis protein. TSP-1 directly inhibits the migration and survival of endothelial cells by activation transforming growth factor-beta (TGF-β). TSP-2 inhibits vascular endothelial cell proliferation independently of TGF-β activation. Both molecules have been detected in the mouse and human corneas under normal physiological conditions. Exogenous administration of TSP-1 and/or -2 have been associated with diminished suture-induced corneal angiogenesis. However, the systemic ablation of TSP-1 and -2 was not associated with spontaneous angiogenesis in the cornea, suggesting that alternate redundant angiostatic mechanisms are operative in the cornea.

Interleukin (IL)-1 receptor antagonist, a key modulator of IL-1 activity, was shown to be expressed in the normal human cornea. It was localized to the corneal epithelium and some stromal fibroblasts. In a mouse model of suture-induced corneal neovascularization IL-1 receptor antagonist was shown to have anti-angiogenic properties and its exogenous administration was also associated with diminished infiltration of inflammatory cells into the cornea. IL-1 receptor antagonist deficiency in mice had no bearing in corneal avascularity, once again implying that corneal avascularity is secured by a multifactorial and redundant system.

VEGFR-3, normally expressed in lymphatic endothelial cells (LECs), corneal dendritic cells, and macrophages, was shown to be ectopically expressed in corneal epithelial cells of human and mice. These ectopic receptors have been shown to work as an inhibitor of injury-induced corneal angiogenesis in mice.

Since its discovery in 1993, soluble VEGFR-1 (sVEGFR-1) has been extensively studied as a powerful inhibitor of VEGF-induced angiogenesis. It has been implicated in several pathological states, including pre-eclampsia, sepsis, arthritis, and cancer. Interestingly, VEGF, a powerful driver of angiogenesis, is expressed in the normal avascular cornea. Recently, it has been shown that sVEGFR-1 is co-expressed by the corneal epithelium serving as a VEGF manacle. Because the systemic ablation of VEGFR-1 gene is not compatible with survival, corneal specific deletion of VEGFR-1 was employed in mice and led to spontaneous corneal neovascularization. sVEGFR-1 is considered to be singularly essential for maintaining corneal avascularity of the uninjured cornea. The expression of sVEGFR-1 in the cornea was also shown to be conserved among mammals, including humans. One exception is the Manatee, whose cornea is spontaneously vascularized and lacks sVEGFR-1 expression. A similar splice variant of VEGFR-2, sVEGFR-2, was recently identified and described as the first specific endogenous inhibitor of lymphangiogenesis. In the cornea, sVEGFR-2 was shown to be singularly essential to maintaining the cornea devoid of lymphatic vessels, as its genetic deletion cause spontaneous invasion of lymphatic, but not blood vessels into the cornea.

Loss of Corneal Avascularity

Corneal neovascularization occurs when the precise equilibrium between pro- and anti-angiogenic forces is disrupted. The loss of corneal avascularity is pathological. Several ocular disorders are hallmarked by corneal neovascularization. These neovascular disorders of the cornea range from benign contact lens-associated neovascularization to congenital and hard to manage ocular anomalies such as aniridia.

Extended contact lens wear may induce neovascularization because the associated hypoxia triggers a steep rise in VEGF expression, overwhelming the natural anti-angiogenic barriers. Other corneal disorders are coupled with pathological angiogenesis because of direct damage to the corneal epithelium. Corneal trauma, such as corneal abrasions or chemical (alkali) burn of the ocular surface, infections (herpetic keratitis), immune diseases such as atopic keratoconjuctivitis or rheumatoid arthritis, limbal cell deficiency, or congenital anomalies such as aniridia are all associated with the loss of avascularity. These clinical entities commonly require surgical management, like refractive surgery or perforating keratoplasty, both of which are negatively impacted by the preexistence of vessels in the cornea. This represents a significant clinical predicament and speaks of the critical nature of unveiling molecular targets that may be manipulated to treat the aberrant and disordered growth of vessels into the cornea.

Immune Privilege of the Avascular Cornea

The absence of blood and lymphatic vessels in the cornea is known to play a critical role in maintaining its immune privilege, but other immune-protective mechanisms have been described. One such mechanism is referred to as anterior chamber-associated immune deviation (ACAID). ACAID is regarded as the ability of antigen-presenting cells (APCs) and antigens from anterior chamber-associated tissues (i.e., cornea) to directly enter the blood circulation through the trabecular meshwork homing to the spleen where immune tolerance is induced. Additionally, tissues from the anterior segment of the eye have been reported to express Fas-ligand which induces apoptosis in activated immune cells (Fas-receptor positive), thus protecting the cornea from damage by stimulated lymphocytes. These mechanisms are thought to collectively downregulate inflammation in the cornea, thereby preserving corneal clarity which is essential for optimal vision. Corneal avascularity is therefore one factor of several redundant active mechanisms aimed at preserving corneal transparency and optical light transmission.

Corneal Transplant and Avascularity

In 1905, ophthalmologist Edward Zim performed the first corneal transplant in a human subject. Since then, corneal transplants have become the most common type of solid tissue transplantation in the world. Nearly 46 000 corneal transplants are preformed yearly in the US. In addition to being the most prevalent, corneal allograft transplantation, it is also the most successful intervention among other commonly transplanted organs. However, the long-term outcome of this intervention is greatly influenced by pre-operative risk factors, with corneal neovascularization (high-risk group) being an important negative predictor of corneal allograft survival. While graft survival is approximately 90% in the low-risk group (no pre-operative inflammation or neovascularization), these numbers are drastically reduced to roughly 35% in the high-risk group. Recent studies targeting corneal angiogenesis with VEGF-A binding molecules (VEGF-trap®) demonstrated that allograft survival is inversely related to the amount of neovascularization in the murine corneal transplantation model corroborating the aforementioned epidemiological observations. The loss of corneal avascularity is therefore a significant clinical quandary.

The surgical procedures used in corneal allograft transplantation require delicate techniques to prevent adverse inflammatory reactions which may compromise outcome. The corneal graft is attached to the recipient's ocular surface with the placement of small sutures. Paradoxically, in a vastly employed injury model of corneal angiogenesis, similar intrastromal sutures are used as a method of eliciting blood and lymphatic vessel growth. Because suture placement is a requirement for corneal transplantation as well as a pro-angiogenic stimulus, it is critical to understand the molecular underpinnings related to the growth of blood and lymphatic vessels into the cornea, so potential molecular targets could be identified and manipulated to promote corneal avascularity, optimal optical performance, and prevent corneal blindness.

Corneal Alymphaticity and Allograft Rejection

Because the growth of blood and lymphatic vessels into the cornea are intimately intertwined, the individual contribution of each of these vasculatures to the fate of corneal allografts is not clearly understood. However, recent evidence suggests that the growth of lymphatic vessels into the cornea may be more tightly associated with loss of corneal immune privilege and critical for corneal allograft rejection than corneal hemangiogenesis.

Substantial progress in the study of corneal lymphangiogenesis has taken place since the discovery of VEGFR-3

and its ligands VEGF-C and –D. The identification of specific cellular makers preferentially expressed by LECs, such as LYVE-1, Prox1, and Podoplanin, has also propelled great advances to the field of lymphangiogenesis.

Corneal lymphangiogenesis generally occurs after corneal injury and inflammation, which in turn is associated with increased levels of VEGF-C. The newly formed corneal lymphatic vessels give rise to an afferent route through which corneal transudate and APCs are carried from the interstitial space into the lymphatic system and later back into the blood circulation. This drainage pathway becomes extremely deleterious in the context of corneal transplantation. Under these circumstances, the alternative route bypassing the standard outflow pathway (i.e., trabecular meshwork in the anterior chamber) allows for antigens from the donor cornea to escape through the lymphatic system and into the draining lymph node where a graft rejection reaction is initiated. The significance of this alternate drainage pathway to corneal alloimmunity and graft rejection has been portrayed in studies demonstrating that removal of cervical lymph nodes significantly increases the transplant survival rates in the low-(noninflamed, nonvascularized) and high-risk (neovascularized) groups. Together, these observations suggest that improved molecular understanding of corneal lymphangiogenesis, as well as the identification of endogenous compounds with the ability to uncouple lymphangiogenesis from hemangiogenesis would shed light into our current understanding of allograft rejection and potentially unveil therapeutic targets to enhance the survival of corneal allograft.

The Avascular Cornea as an Angiogenesis Study Platform

The avascular disposition and its ready accessibility have made the cornea an important platform for the study of angiogenesis allowing scientists to test the pro-and/or anti-angiogenic effects of several compounds *in vivo*. Numerous assays have been developed to study angiogenesis modulation utilizing the cornea. Direct intra-stromal injection of angiogenesis compounds have been performed in the mouse, rat and rabbit cornea. Models in which a transient chemical (alkali), physical (scraping), or thermal (cautherization) injury are incurred to the cornea to provoke an angiogenic response have been widely used. Prolonged injury of the cornea has been achieved with intra-stromal suture placement. The insertion of a small pellet containing pro-angiogenic molecules has also been described and termed corneal micropocket assay. The cornea stroma has even been utilized for the implantation of tumor cells. The reliability of these models and the easy visualization of corneal vessels have placed the cornea in the forefront of discovery and *in vivo* testing of drugs for the treatment of disorders hallmarked by aberrant angiogenesis, particularly cancer. The ability of analyzing these molecules *in vivo* provides valuable insight regarding the angio-modulatory effects of such compounds.

Conclusions

Avascularity of the cornea is intimately related to optical transparency and optimal vision. Hence, the loss of corneal avascularity is pathological and often results in impaired vision or corneal blindness. A precise balance between pro- and anti-angiogenic factors is essential to maintain the avascular disposition of the cornea. Even though it is well known that corneal immune privilege is a function of a constellation of factors, the absence of blood and lymphatic vessels in the cornea has proven to be one of its most important underlying mechanisms. A more precise understanding regarding the individual contribution of blood and lymphatic vessel growth to corneal alloimmunity is needed. The cornea, given its avascular nature and accessibility, is an ideal the platform for the *in vivo* testing of angiogenesis modulators.

Binocular Vergence Eye Movements and the Near Response

C M Schor, University of California at Berkeley, Berkeley, CA, USA

Glossary

Cyclo-vergence – The torsional rotations of the two eyes in opposite directions.
Horopter – The locus of points in space imaged on corresponding regions of the two retinae that results in identical visual directions (singleness).
Retinal disparity – The perspective differences between the two retinal images.
Torsion – The ocular rotation of the eye about the visual axis.
Vergence – The rotations of the eyes in opposite directions (horizontal, vertical, and torsional).

Vertebrates are equipped with two eyes that are either widely separated in the head to provide panoramic vision, or they are narrowly separated to provide stereoscopic depth perception but with a reduced extent of the binocular visual field. Panoramic vision provides a useful field of view for herbivores that graze throughout the day, and stereopsis provides a useful range finder for predators and hunter-gatherers. Stereopsis is stimulated by perspective differences between the two eye's retinal images that result from the small 6-cm separation between viewpoints of the two eyes.

Stereopsis is stimulated by horizontal disparities that result from the horizontal misalignment of the two retinal images from corresponding or homologous regions of the two eyes retinae. When objects in space are imaged on these corresponding points, they appear in identical visual directions, that is, single vision, and the surface in space where points are imaged on corresponding retinal points is referred to as the horopter. For the purpose of single vision, correspondence is between small areas (Panum's fusional area) that result in a singleness horopter surface in space that is approximately 0.5° thick and it passes through the point of binocular convergence. Figure 1 also describes the backward pitch of the horopter surface that results from a 2° shear between the corresponding vertical meridians of the two retinae. Only this small region of space described by the horopter surface appears single and all objects in front and behind the horopter appear double when one image is not suppressed.

Stereopsis is supported by two classes of eye movements that obtain and maintain registration or alignment of the two retinal images on corresponding retinal regions of the two eyes to produce single binocular vision. The two eyes rotate in a yoked fashion (versions) to maintain binocular image registration while the eyes change direction of gaze, and they rotate in opposite directions (vergence) to establish binocular registration. Misalignment of the two eyes with the viewing geometry of a given target produces a misalignment with corresponding points, referred to as binocular parallax or absolute disparity, and these absolute disparities stimulate vergence eye movements.

For the purpose of binocular eye alignment, absolute disparity can be described with three degrees of freedom, including horizontal, vertical, and cyclo-components. 'Cyclo' describes the twist of the eye about its visual axis. Binocular alignment minimizes all three components of disparity at the fovea with vergence control, and any residual disparities in the periphery are used to interpret relative depth and surface orientation. All three components of disparity are necessary to interpret space, because, by themselves, horizontal, vertical, and cyclo disparities are ambiguous. The same horizontal disparity can correspond to many different depth intervals that depend on distance and direction (azimuth) of targets relative to the observer. Similarly, many different slant angles correspond to the same cyclo and shear disparities. These disparities are disambiguated with information about distance and direction (azimuth) of objects relative to the head. This information can be obtained from extra-retinal information from the sense of eye position or from retinal information from vertical disparity.

Horizontal disparity is the primary stimulus for horizontal vergence (convergence). Disparities are defined with reference to the horopter, which passes through the

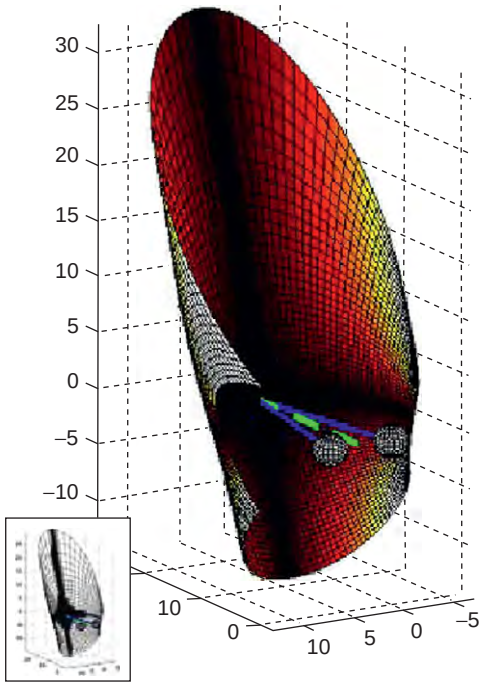

Figure 1 The horopter with a vertical shear deviation from a pattern of identical corresponding points. Gaze is straight ahead at a vergence of 10°.
The horopter with gaze straight ahead at a vergence angle of 20°.

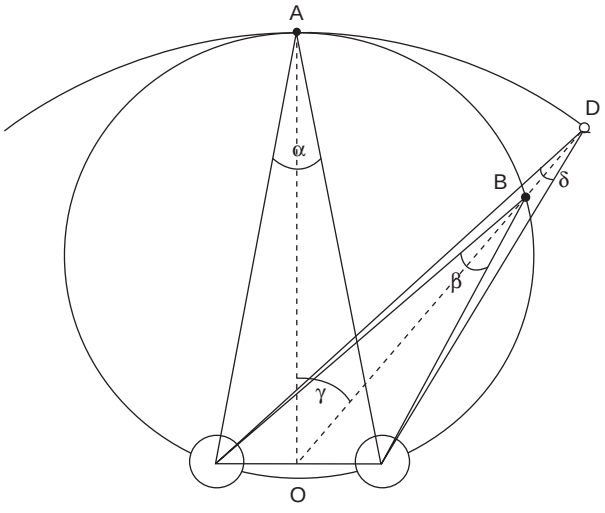

Figure 2 Plan view of iso-vergence circle (large complete circle), iso-accommodation circle (shown as an arc) and various azimuth angles. The two small circles represent the right and the left eye. The point A represents the spatial location that corresponds to matched stimuli for accommodation and convergence. ‡ = convergence angle at point A (angle made by the intersection of two lines of sight), β = convergence angle at point B, and $* = \beta$ along the iso-vergence circle, γ = lateral gaze angle. Note that at point D on the iso-accommodation circle, the convergence stimulus (δ) is lower than β at point B.

point of binocular convergence. Note that the distance corresponding to a fixed angle of convergence varies with gaze azimuth along an isovergence circle that passes through the two eyes centers of rotation. (**Figure 2**). The

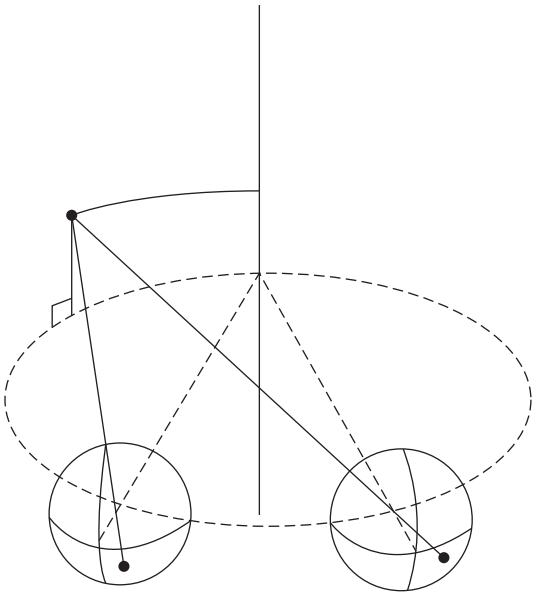

Figure 3 Optical geometry producing vertical disparity of points presented in tertiary directions at finite viewing distances.

iso-accommodation circle is also shown, which has a center at the point midway between the two eyes. Differences between these two circles are discussed below. If we assume that the nodal point of the eye is very close to the centers of rotation, then the horopter surface contains the isovergence circle. Targets lying in the horopter surface all subtend zero disparity, and targets lying at distances closer or farther than the horopter subtend crossed and uncrossed disparities respectively, which in turn stimulate convergence and divergence of the eyes.

Vertical disparity is subtended by all near targets lying in tertiary directions above and below the visual plane. These disparities arise from the difference in distance of the target from the entrance pupils of the two eyes (**Figure 3**). Normally binocular fixation of targets at near distances in a tertiary position requires that the abducting eye move up more than the adducting eye (Fick coordinates). This vertical vergence occurs automatically with gaze shifts, even when one eye is occluded.

Uniform cyclo-disparities along both horizontal and vertical meridians result from vergence errors. The uniform cyclo-disparities produced by ocular cyclo-torsion can be distinguished from nonuniform cyclo-disparities produced by slanted surfaces, which do not produce cyclo-disparity between horizontal lines imaged on the two foveas.

A Coarse-to-Fine Strategy for Vergence

Voluntary binocular gaze shifts respond to both perceived spatial location and retinal disparity. When the gaze shifts are between targets separated widely in depth, retinal disparity is too large to provide useful visual feedback and the primary cue for gaze is perceived spatial location.

As the voluntary response to perceived location proceeds, retinal-image disparity and blur are reduced into the effective stimulus-operating range of a fine adjustment or foveal-maintenance mechanism that utilizes visual feedback from retinal cues, including binocular disparity and blur. These perceptual and retinal classes of stimuli are used to control the vergence response in a coarse-to-fine strategy and their goal is to optimize stereopsis by minimizing horizontal, vertical, and cyclo-components of retinal-image disparity at the fovea.

Cross-Coupling of Voluntary and Involuntary Motor Responses and the Near Response

While all three vergence components respond to retinal cues of horizontal, vertical, and cyclo-disparity, only horizontal vergence responds voluntarily to perceptual cues. Vertical vergence and cyclo-vergence are only under involuntary control, and they do not respond directly to perceived target location. The two involuntary components of the vergence are cross-coupled with voluntary version and horizontal vergence eye movements. Involuntary components of vergence are guided by the attentionally driven voluntary components of version and convergence that change direction and distance of gaze in response to perceived space. The cross-coupled vergence responses reduce all three components of retinal-image disparity into the effective stimulus-operating range of all three components of vergence. Couplings that link involuntary components of vergence with convergence are collectively referred to as the near response.

Ideal Cross-Links for Three-Dimensional Viewing Geometry

Cross-links between voluntary and involuntary components of the near response are based upon predictable relationships between version and vergence components of eye position that reduce retinal-image disparity to zero. Horizontal, vertical, and cyclo-disparities are determined by target location and the coordinate systems that control horizontal and vertical eye position. These predictable relationships allow the cross-coupled involuntary responses to be scaled with version and horizontal vergence components of the voluntary response. Scale factors are used to describe the couplings quantitatively.

Horizontal Vergence Coupling

Coupling interactions have been described for all three components of vergence. The horizontal component of vergence, which is under voluntary control, can be guided by voluntary accommodation under conditions where an occluder, such as the nose, blocks one eye's view of a target. The linkage between accommodation and convergence is possible because both respond to optical–geometric properties of a common viewing distance. The linkage between horizontal convergence (C) with the accommodation response (A) to blur is described by the accommodative vergence ratio (K_c).

$$C = K_c \times A \quad [1]$$

Ideally, the K_c would be 1.0 for symmetrical convergence expressed in meter angles and accommodation in diopters. Empirical measures demonstrate a normal $K_c = 0.66$ MA/D. Accommodation (A) can also follow convergence responses (C) to disparity with a different empirical scalar value (K_a) of 1.0.

$$A = K_a \times C \quad [2]$$

The ideal K_c and K_a change with gaze azimuth. Ideal K_c is lower and ideal K_a is higher for targets viewed in eccentric horizontal gaze than in symmetrical convergence because constant stimuli for accommodation and convergence lie on different circles. **Figure 2** illustrates the iso-vergence circle and iso-accommodation circles that intersect one another in the midsagittal plane, but differ elsewhere. Empirical measures of K_c follow these changes in the ideal K_c with azimuth. The empirical K_c becomes reduced and a bias of K_a increases with increasing horizontal eccentric gaze in asymmetric convergence. The low empirical value of K_c is also a compromise of several different gaze azimuths.

Vertical Vergence Coupling

Binocular vertical alignment of foveal images is controlled by vertical vergence. In a Fick coordinate system that is often used to describe vertical disparity, the amplitude of vertical vergence is scaled proportionally with the vertical image size ratios of the two ocular images of a target viewed in a tertiary direction. In this application, vertical vergence is quantified as the ratio of vertical positions of the left and right eyes (V_l/V_r) that is necessary for bifoveal fixation of elevated targets in tertiary directions of gaze. In symmetrical convergence, the ratio equals 1.0 and in asymmetric convergence it depends upon both, convergence (C) and horizontal gaze eccentricity (H). Convergence is positive following a sign convention where left and down are positive values, and where convergence equals R–L eye position. In left-gaze, the ratio of left over right eye position is described by (in Fick coordinates)

$$V_l/V_r = K_v \tan^{-1}[\cos(H_l - C/2)]/\tan^{-1}[\cos(H_r + C/2)] \quad [3]$$

where H_l and H_r represent the azimuth of the left and right eye relative to primary position and V_l and V_r represent the elevation of the left and right eye in Fick coordinates. Empirical measures demonstrate a normal scalar value of

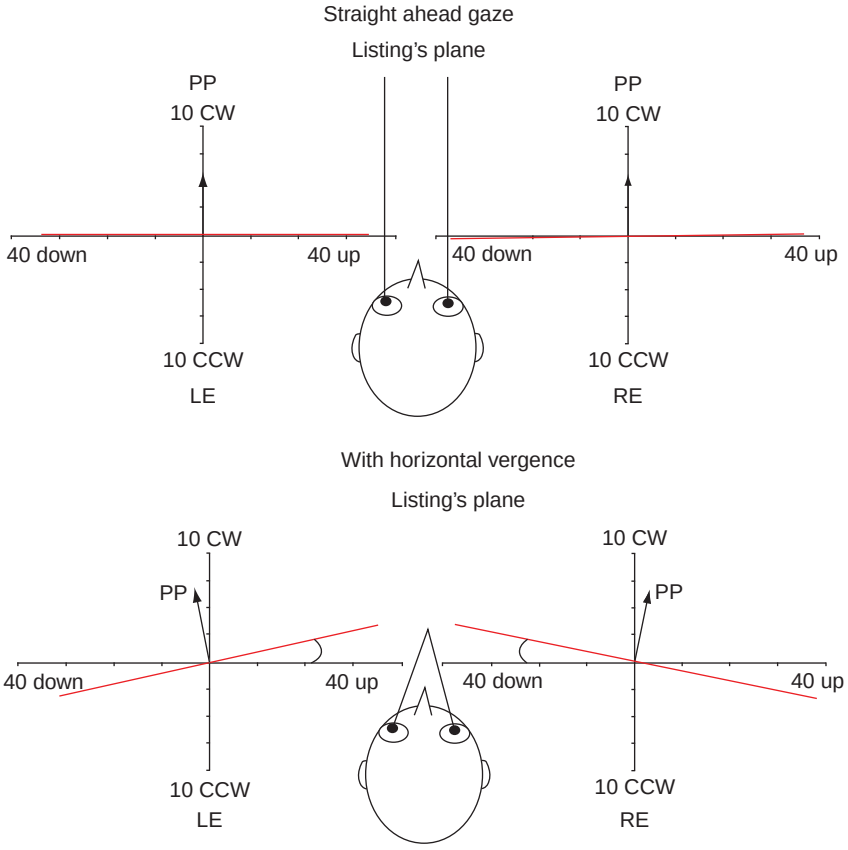

Figure 4 Changes in the divergence between Listing's planes with gaze at infinity (upper panel) and during convergence (lower panel). Primary position (PP) is orthogonal to Listing's plane. During distance viewing, the primary positions are nearly parallel, and during near viewing they diverge by approximately the angle of convergence.

$K_v = 1.0$. Note that when vertical vergence is described in a Helmholtz coordinate system,

$$V_l / V_r = K_v \qquad [4]$$

and K_v is independent of convergence or gaze angle. $K_v = 1.0$ for both the Fick or Helmholtz coordinate systems.

Cyclo-Vergence Coupling

Nearly 150 years ago, Donders recognized that the torsional orientation of the eye in any given direction of gaze was independent of the path the eye took to reach that position. This was noteworthy because spherical rotations of physical objects such as satellites are normally noncommutative, that is, the twist about the primary depth axis does depend on the path taken to reach a tertiary direction. The amount of ocular torsion was described by Listing as though the eye had rotated from a primary position about an axis that was in a common plane with other axes describing ocular torsion in other directions of gaze (**Figure 4** showing Listing's plane from old **figure 5**). Helmholtz referred to this as Listing's plane. Listing's law describes a coupling between cyclo-torsion and versional eye position that makes spherical rotations of the eye commutative.

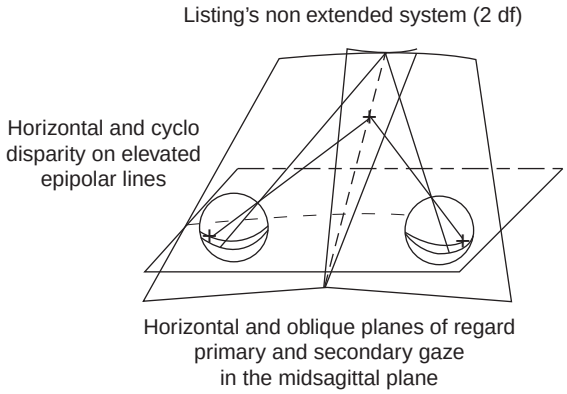

Figure 5 Torsional orientation of epipolar planes passing through the foveas with gaze horizontal and elevated gaze when Listing's law is not extended. The projections of the corresponding epipolar meridians (planes of regard) are extorted such that the horopter collapses to a single point where the visual axes intersect. Pure horizontal disparities (no vertical or cyclo-disparity) only exist along the line at the intersection of the planes of regard.

The orientation of Listing's planes changes with convergence. Hering first observed a binocular coupling between horizontal vergence, eye elevation, and cyclovergence. He observed that in upward gaze, the eyes

were intorted and in downward gaze, they were extorted relative to the orientations predicted by the orientation of Listing's planes located in the facial plane. In a Fick coordinate system, incyclo-vergence forms an A pattern between the vertical meridians of the retinae and excyclo-vergence forms a V pattern. This coupling between cyclo-vergence and eye elevation during convergence is part of the near response.

During convergence, ocular torsion is still described as commutative, as though the eyes had rotated about axes in two fixed planes, one for each eye, from their respective primary positions. However, the orientation of the planes is different from the orientation of the classical Listing's plane that lies in the facial plane when the eyes view distant targets. During near fixation, ocular torsion has a different pattern in which the eyes incyclo-verge in upward gaze and excyclo-verge in downward gaze. These changes follow Listing's law for Listing's planes that are diverged for the right and left eye by approximately the amount that the eyes have converged (**Figure 4**). The benefit of this change in cyclo-vergence with vertical gaze and convergence is described below.

Coupling between cyclo-vergence with vertical gaze and convergence is optimized to match viewing geometry. During symmetrical convergence, the torsional alignment of the horizontal meridians of the retinae is controlled by cyclo-vergence (T) that is scaled proportionally by K_t with combinations of convergence (C) and vertical eye position (V). Following a right-hand-rule sign convention, left, down, and clockwise ocular rotations are positive and convergence equals R–L eye position. Eye position is described in Helmholtz coordinates so that foveal alignment is achieved by equal elevation of the two eyes. The cyclo-vergence necessary for coplanar alignment of the planes of regard is described by

$$T = K_t \times 2\left(\tan^{-1}[\tan\ C/2 \times \tan\ V/2]\right) \quad [5]$$

When expressed in radians,

$$T = K_t \times V \times C/2 \quad [6]$$

The coupling between the diverged orientation of Listing's planes and convergence can be described by the scalar K_t as a ratio of the change in divergence difference between the two eyes' Listing's planes (ΔY) over the change in convergence (ΔC).

$$K_t = \Delta Y/\Delta C \quad [7]$$

Effects of Listing's Law and Coupling with Convergence on Stereoscopic Depth Perception

The change in orientation of Listing's planes with convergence makes it possible to have good stereoscopic depth for targets lying in the visual plane by twisting the horizontal meridians of the retinae of the two eyes so that they are coplanar and all targets along the visual plane can be imaged on corresponding points without any vertical disparity. The change in orientation of Listing's planes also makes it possible to have good stereopsis with gaze elevated, even in tertiary directions of gaze.

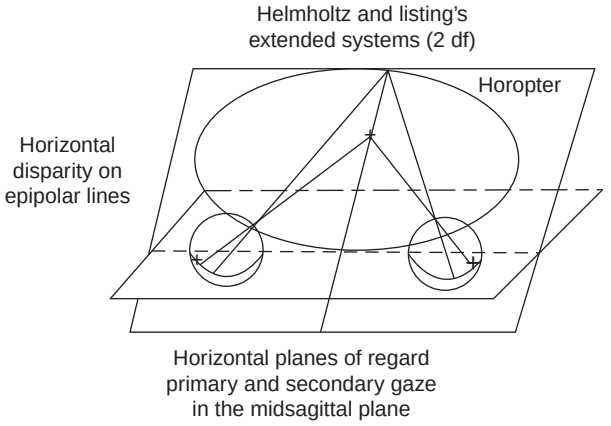

Figure 6 Coplanar orientation of epipolar lines and planes of regard passing through the foveas with horizontal and elevated gaze when Listing's law is extended. The longitudinal horopter exists in elevated gaze and any point in the elevated visual plane subtends pure horizontal disparity on epipolar meridians.

Figures 5 and **6** illustrate the torsional orientation of the two horizontal retinal meridians during two near-fixation conditions in symmetrical convergence. They illustrate variations of cyclo-torsion for the classical Listing's coordinate system and the extended Listing's coordinate system. Both fixation conditions are illustrated for symmetrical convergence. Either the eyes have zero elevation or gaze is elevated in the midsagittal plane. The arcs across the two retinae represent sections of great circles that pass through the horizontal meridians of the retinae and the foveas. The arcs describe epipolar meridians of the eye with gaze elevated. The planes in the figures describe projections of the horizontal meridians of the retinae through the entrance pupils (planes of regard) when gaze is elevated. The locus of points where the two planes of regard intersect represent points in space that subtend pure horizontal disparity without any vertical or cyclo-components.

During convergence, the only targets that can be viewed without retinal image cyclo-disparity must lie in the horizontal plane that passes through the nodal points of the two eyes and intersects the two foveas (i.e., the visual plane). When the eyes are converged in the zero-elevation position, all points lying in the visual plane will subtend pure horizontal disparities because the visual plane contains both planes of regard (i.e., it intersects both horizontal retinal meridians). If the orientation of the Listing's planes did not change during convergence (**Figure 5**), then when gaze was elevated, the planes of regard would become extorted. Images of most objects lying in the inclined

visual plane would be off the horopter and they would subtend complex combinations of horizontal, vertical, and incyclo-disparities. The torted planes of regard would not be coplanar, and they would only intersect along a line in the midsagittal plane. Only points on the line of intersection would be imaged with pure horizontal disparities and the fixation point would be the only point on the line of intersection that could be imaged on the horopter.

Figure 6 demonstrates how the oculomotor system remedies this situation and still obeys Listing's law during symmetrical convergence. In a binocular extension of Listing's law, cyclo-vergence intorts the eyes with gaze elevation and extorts the eyes with gaze depression to keep the horizontal meridians coplanar in symmetrical convergence. When gaze is elevated, an incyclo-rotation of the planes of regard makes them coplanar so that it is possible to image real targets on the longitudinal horopter. All targets in the inclined visual plane, whether they are nearer or farther from the fixation point, will be imaged on corresponding epipolar meridians of the eye with pure horizontal disparities. These gaze-dependent changes in cyclo-vergence are consistent with an outward or divergence of Listing's planes. Stereoscopic depth perception would be compromised if this torsional compensation did not occur. Interestingly, these same yaw rotations of Listing's planes preserve stereopsis in tertiary directions of gaze by keeping the horizontal meridians of the two retinae coplanar in gaze directions composed of combined elevation and azimuth.

Figure 1 describes the backward pitch of the horopter surface that results from a 2° shear disparity between the vertical meridians of the two retinae. When the eyes rotate downward to fixate in the ground plane, the horopter pitches back into the ground plane so that objects at all distances along the ground plane appear single. When the eyes fixate different viewing distances along the ground, changes in eye elevation cause changes in cyclo-vergence, predicted by Listing's law, that keep the horopter in the ground plane. The benefit of this is to have single vision over a large range of distances within the ground plane while converged in that plane at a single distance.

Biological Properties of the Trabecular Meshwork Cells

J Z Gasiorowski, University of Chicago, Chicago, IL, USA
P Russell, University of California at Davis, Davis, CA, USA

Glossary

Anisotropic substrates – Surfaces that have a regular pattern. Although cells typically grow on native basement membranes with isotropic surfaces, investigation of cellular responses to repeating biophysical cues are often useful as initial studies.
Biophysical cues – The signals that a cell obtains as a result of external characteristics upon which it is located. Biophysical cues involve both topographic features as well as the rigidity of the substratum.
Cell culture – The maintaining of cells generally from vertebrate species *in vitro*. Cells directly from donor tissue (primary) or from immortalized or transformed lines are supplied with a culture medium that provides nutrients necessary for survival and proliferation.
Oxidative stress – The damage to a cell as a result of exposure to an oxidative environment. In general, an oxidative environment contains reactive oxygen species, such as hydrogen peroxide or oxygen radicals.
Phagocytosis – A process in which the cell actively takes up material from the extracellular environment. Phagocytosis results in the expenditure of energy by the cell to engulf extracellular components. The process is usually performed by the cell to reconstruct the external environment or structures, or to remove noxious components.
Topography – The three-dimensional features of a surface. In the discussed biological context, this refers to the physical shapes and features of a native or fabricated extracellular matrix.

Introduction

In order to understand the relationship between the trabecular meshwork and glaucoma, one must appreciate the level of anatomical and physiological complexity in the eye, beginning with the aqueous humor. Aqueous humor is produced by the ciliary body of the eye and flows from the posterior chamber around the lens into the anterior chamber through the pupil. The fluid exits the eye by going through either the trabecular meshwork (TM), known as the conventional outflow pathway, or through the uveal–sclera pathway, the unconventional pathway. In humans, the majority of aqueous humor leaves the eye through the TM. The TM consists of cells and matrix and is believed to be the tissue that regulates intraocular pressure (IOP). To date, the exact mechanism by which IOP is regulated has not been elucidated. While a TM has been found in all animals studied from fish to humans, there is a wide variety of anatomical features in this tissue from one species to another. In the humans, the cell-covered trabeculae (beams) are present in the uveal and corneoscleral parts of the meshwork. In the outer part of the meshwork is the juxtacanalicular tissue (JCT) or cribiform region consisting of TM cells on an extracellular matrix (ECM) connecting with the inner-wall cells of Schlemm's canal. Curiously, the human TM has anatomical differences with other primates but has similarities to the mouse and the rat.

Even with humans, there are documented differences in the TM from one eye to the other in the same individual. Notable differences have been found in the cellularity (nuclei of TM cells per solid tissue area) as well as in the variation in cell number with deviations as high as 39%. In primary open-angle glaucoma (POAG), the cellularity difference between paired eyes was reported to be even higher. Even with these variations, the study of the human trabecular meshwork (HTM) and HTM cells is essential in understanding glaucoma.

Glaucoma is found in a number of species, but the anatomical differences between species make the study of the disease very complicated. Because of these differences, the study of glaucoma, particularly as it is influenced by changes in the regulation of outflow in humans, lacks adequate animal models. Currently, the progression of glaucoma in humans is studied by either *ex vivo* organ culture of human, primate, and other species TM or the tissue culture of HTM cells. Since organ culture of TM is complex and somewhat difficult, hypotheses are generally tested with cultured HTM cells first and then validated with organ culture.

Cell Culture

TM can be dissected from whole donor eyes or from unused corneal buttons. Cells from TM are generally separated from the tissue by enzyme digestion and placed

in tissue culture. HTM cells in culture will send out long processes to other cells; and after proliferation, a somewhat cobblestone appearance of cells can be observed. The cells can be passaged but will undergo senescence after an estimated seven passages. If cells are obtained from very young donors, the passage number can be increased before the cells become unusable. In general, work with HTM cells is often limited to five or six passages with the maximum passage level studied annotated in the report. The best way to test hypotheses about the glaucoma is to study normal and glaucomatous HTM cells in the same experiment. Unfortunately, the culture of glaucomatous HTM cells has proven very challenging. Although there have been some laboratories that are successful in their culture, most investigators have found that cells from glaucomatous donors are difficult to passage, and therefore, the number of cells obtained is insufficient for most experiments. The reason for the obstacles in culturing glaucomatous HTM cells is not yet understood. To circumvent this problem, different techniques are used to stimulate normal HTM cells to express glaucoma-like phenotypes.

HTM Cell Characteristics

Of all the proteins that have been identified in HTM cells, myocilin is perhaps the most characteristic. Myocilin was initially known as trabecular-meshwork-inducible glucocorticoid response protein (TIGR). After HTM cells are treated with dexamethasone for a period of time, myocilin is upregulated. This induction appears to be specific for HTM cells even though myocilin has been located in other cells in the eye, and can be used to determine if dissected, cultured cells are indeed HTM cells. Myocilin is one of the families of olfactomedin proteins and has the characteristics of a matricellular protein. Another protein that has been reported in cells in the JCT region of the TM is αB-crystallin. This protein, initially described in the lens of the eye, is actually found throughout the body. It is one of the small heat-shock proteins that can be induced with transforming growth factor-β (TGF-β), heat shock, and oxidative stress. This protein has been reported to be upregulated in glaucoma. The protein αB-crystallin has been shown to be present in normal TM only in the JCT region, suggesting that there may be more than one cell type present in the TM. Other proteins identified in the TM include: the alpha-2 adrenergic receptor, aquaporin-1, as well as acetylated and acetoacetylated low-density lipoproteins; however, these proteins are not specific to the TM and thus are not good markers for HTM cells. Therefore, it can be helpful to also use behaviors, such as phagocytosis, to help define cell types.

HTM Cell Phagocytosis

One characteristic of HTM cells is their pronounced capacity for phagocytosis. Pigment granules are phagocytized with aging, resulting in the TM looking pigmented when viewed in the dissected eye. Excessive amounts of pigment can overwhelm phagocytosis of the TM and this causes pigment dispersion glaucoma. An obvious reason that HTM cells engage in phagocytosis would be to maintain the pores and openings in the outflow pathway so that aqueous humor can readily flow through to Schlemm's canal. Maintaining homeostatic phagocytosis rates is important because a decline in phagocytosis can cause complications as well. The glaucoma that can follow glucocorticoid treatment results in part from the steroid-mediated decrease in phagocytosis by HTM cells. This decrease leads to the increased deposition of ECM material in the TM, which causes an increase in IOP. With phagocytosis, there is a loss of extracellular fibronectin and laminin, again indicative of a role for phagocytosis in ECM remodeling. Thus, besides removal of miscellaneous material that might be washed into the TM by aqueous humor, maintenance of the TM matrix would be another function for the phagocytosis observed. A number of studies have attempted to analyze TM phagocytosis using a variety of particles, such as latex beads, zymosan particles, and *Staphylococcus aureus* bioparticles. These studies have been conducted *in vivo*, in organ-cultured TM, as well as with HTM cells *in vitro*. In one study using cats, one eye was challenged with particles *in vivo*, while the fellow eye in organ culture was similarly challenged. More cells *in vivo* were engaged in phagocytosis, suggesting activation was occurring that was not present in organ culture. There is an indication that an inflammatory pathway might be responsible for this activation, since gamma-interferon has been shown to inhibit phagocytosis. This effect is thought to be related to the alteration of actin filaments in the cell that form the radial spoke-like arrangements during the process of phagocytosis. Conversely, platelet-derived growth factor was shown to enhance phagocytosis by limiting stress-fiber formation in TM cells.

Glaucoma Models

As stated previously, the use of cultured HTM cells allows investigators to test hypotheses about the initiation and progression of glaucoma. HTM cells *in vitro* do not always have the same characteristics that these cells have *in vivo*. It has been reported that gene expression and protein synthesis are often altered when cells are placed in tissue culture. Different culturing methods, described later in this article, discuss some specific steps that can be

taken to coerce the HTM cells into producing a protein expression profile that more closely mimics the whole TM. While cultured cells offer challenges, not the least of which is the short, productive life span, at least four different models that use external stimuli have been used to study glaucoma progression *in vitro*. It is important to note that all of these models possess limitations.

Glucocorticoid Treatment

One of the earliest *in vitro* models for glaucoma and the one that remains widely used today is the addition of glucocorticoids to the culture medium. This class of compounds produces a variety of effects depending on the presence of receptors and the transduction cascades they induce. Clinically, glucocorticoids can increase IOP in certain individuals; a discovery that stimulated the modeling of glaucoma in HTM cells with the glucocorticoid most typically used, dexamethasone. After several days of drug delivery, myocilin will increase in cultured HTM cells, which mimics the myocilin increase seen in the aqueous humor of glaucomatous individuals. Other hallmarks of glaucoma are also present in HTM cells treated with dexamethasone. Notably, a specific type of cross-linked actin network is formed with drug treatment. The HTM cells create dense actin networks, become less pliable, and are more likely to inhibit outflow. Furthermore, when HTM cells are subjected to 50-mmHg pressure, there is an upregulation of matrix metalloproteinase (MMP)-3. The increase in MMP-3 appears to be a response by the cells to elevated pressure and may help in degrading or remodeling the ECM to allow increased outflow. This upregulation of MMP-3, however, is blocked by dexamethasone, which can also downregulate MMP-2 and MMP-14. With dexamethasone treatment, there is also a decrease in the amount of endothelin-1 receptor B. Under normal conditions, the B receptor binds endothelin-1 and causes a release of nitric oxide, resulting in vasodilation. By decreasing the expression of the B receptor, nitric oxide levels will drop. The ligand will then bind the endothelin-1 receptor A, which starts a vasoconstrictive signaling cascade, leading to less outflow and increased IOP.

Transforming Growth Factor-β

Another model system for studying glaucoma is dependent on treatment of cultured cells with TGF-β, which is a superfamily of signaling proteins that includes the bone morphogenetic proteins (BMP). TGF-β2, which can exist in either an active or latent form, has been found in the aqueous humor of glaucoma patients at high levels. Thrombospondin-1, a TGF-β activator, is upregulated in glaucomatous HTM and may influence the signaling cascade. Thus, there is reason to hypothesize that the increased expression of TGF-β may lead to the progression of glaucoma. In cultured cells, TGF-β2, at levels reported in aqueous humor, will increase the expression of tissue transglutaminase, an enzyme that can cross-link ECM proteins; it will also upregulate fibronectin production. Both of these increases have the potential to modify ECM and reduce the facility of outflow. There is a balance between the TGF-β's and the BMPs, with the BMPs appearing to counter the effects of TGF-β in the TM and HTM cells under normal conditions. BMP2 is present in the TM, but appears to be downregulated when HTM cells are cultured. The effects of TGF-β on fibronectin expression can be blocked by co-treatment with BMP4, and BMP7 can similarly negate the effect of TGF-β on the expression of collagens IV and VI. In addition, several reports on specific proteins or results from gene array studies indicate increased TGF-β2 can initiate changes in expression of ECM components that could impede outflow. With glaucoma, there is increased expression of not only TGF-β2, but also gremlin, a protein that inhibits the action of the BMPs. Altogether, these data suggest that the important and delicate balance between these members of the TGF-β superfamily is disrupted with disease and needs to be studied further.

Oxidative Stress

There is evidence for increased oxidative modification of both DNA and lipids with glaucoma. With exposure to 40% oxygen for 10 days, HTM cells lose proteasome activity and have increased cell death. The inhibition of proteasome activity could contribute to decreased facility of outflow by preventing the degradation of both intra- and intercellular debris. Continuous exposure of HTM cells to oxidative stress results in the generation of reactive oxygen species, which stimulate nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) and subsequent production of interleukins (ILs), particularly IL-1. A positive-feedback loop is generated between the activated NF-κB and IL-1, which may be a cellular response to lower IOP. Higher levels of NF-κB and IL-1 have been reported after phacoemulsification of the lens during cataract surgery. A lower IOP is typically observed after this surgery. This would support the hypothesis that this signaling pathway is an attempt by the TM to increase outflow in response to oxidative challenge. Curiously, when IL-1 is administered to rat eyes, aqueous humor flow is decreased. The relationship of the effects of oxidative stress both on the HTM cells and on the inflammatory signaling pathway is not clear at this point, but there is evidence that oxidative stress may play a key role in the progression of glaucoma.

Mechanical Stretch

The TM is subjected to mechanical stretch as a result of accommodation, contraction of the ciliary muscle, and elevated IOP in many cases of POAG. Mechanical stretching of HTM cells has revealed major changes in messenger RNA (mRNA) and protein expression patterns. A gene array study found that mechanical stretch resulted in a downregulation of 29 genes and an upregulation of over 100 genes. Tenacin C, fibronectin, TGF-β, and some collagens were among the many genes upregulated between 1.5- and 3.7-fold. Mechanical stretch also increases the expression of MMP-2 and MMP-14 through the intracellular signaling molecule mammalian target of rapamycin (mTOR). The upregulation of these two MMPs can modulate the remodeling of the ECM. In addition to regulating transcription of genes, mechanical stretch influences the alternative splicing of several mRNAs, including tenacin C, collagen XII, and CD44. The relative amounts of these variants change the composition and functionality of the meshwork ECM. Stretching also controls fibronectin splicing, and variants of this protein could influence outflow as a result of providing different binding domains within the ECM. Overall, mechanical stretch alters the ECM of the TM in many ways, all of which have downstream implications on outflow dynamics.

Biophysical Cues

While biochemical cues have been used to study HTM cells, the mechanical stretch model listed above illustrates the importance of also studying biophysical cues that the cells receive. *In vivo*, cells do not sense the hard, flat surfaces that are typically used to culture cells *in vitro*. Rather, the cells are provided with thousands of biophysical cues through cell-to-cell contact or cell-to-ECM attachment. All basement membranes that have been studied have a rich three-dimensional topography consisting of pores, bumps, and ridges. One can easily see that HTM cells are influenced by substrates that have the biomimetic topographic features in the nano- to micron-scale range. In **Figure 1**, HTM cells were plated onto anisotropic substrates consisting of repeating 600-nm grooves and 600-nm ridges (lower right-hand side) as well as a flat surface that was chemically identical (top and left side). The HTM cells orient parallel to the grooves and ridges and are dramatically elongated on these biomimetic substrates compared to the cells on the flat surfaces. In addition to the orientation and alignment differences, the actin cytoskeleton has been shown to align with the patterned substrate (**Figure 2**). Not surprisingly, gene expression is also dramatically altered with biophysical cues in the nano to micron size. Myocilin expression is upregulated on topography, independent of any dexamethasone

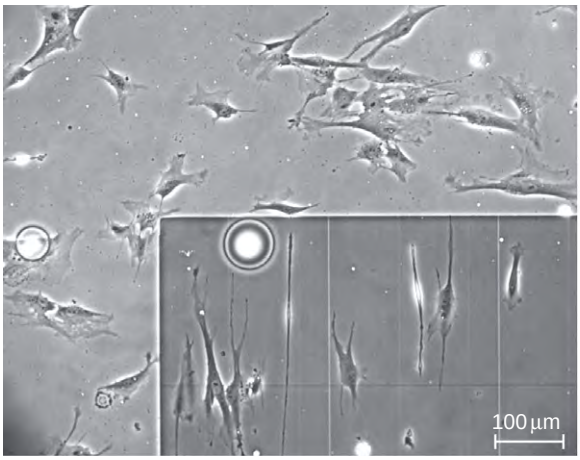

Figure 1 Human trabecular meshwork cells sensing biophysical cues from nanopatterned substrate. Human trabecular meshwork cells growing on a flat surface (top and left) and on a chemically identical nanopatterned substrate (bottom and right). The nanopatterned surface has parallel sets of grooves and ridges each of which are 600 nm in width. The direction of the grooves and ridges is marked. The cells orient parallel to the direction of the biomimetic pattern and become elongated. Cells will also migrate in the direction of these patterned surfaces.

stimulation. A 12-h time lapse of the HTM cells plated on the anisotropic surface and contiguous flat surface shows the random movement of the HTM cells on the flat surface. Cells on the 600-nm grooves and ridges can be seen to migrate along an axis parallel to the patterned substrate. Thus, biophysical cues present in basement membranes can influence basic cellular functions and gene expression. By culturing cells on flat plastic or glass, cells do not experience these cues and this may be the reason why cell-specific proteins or properties often appear to be downregulated when cells are first placed in tissue culture.

In addition to the topography, cells also sense a less rigid, more compliant substrate *in vivo*. Compliance also modulates HTM cell behavior. HTM cells plated onto polyacrylamide surfaces spread less and at a slower rate than cells plated onto stiff tissue culture plastic. The actin cytoskeleton has fewer stress fibers and focal adhesion kinase is minimally phosphorylated on the soft gels. Similar to the topographically patterned surfaces, myocilin expression is upregulated on the more compliant gels. These data, combined with the data reported on the biomimetically patterned surfaces, show the importance of biophysical cues on cells and the necessity to incorporate these features when growing cells *in vitro*.

Summary

The biological properties of HTM cells are varied and complex. While certain characteristics are known, the

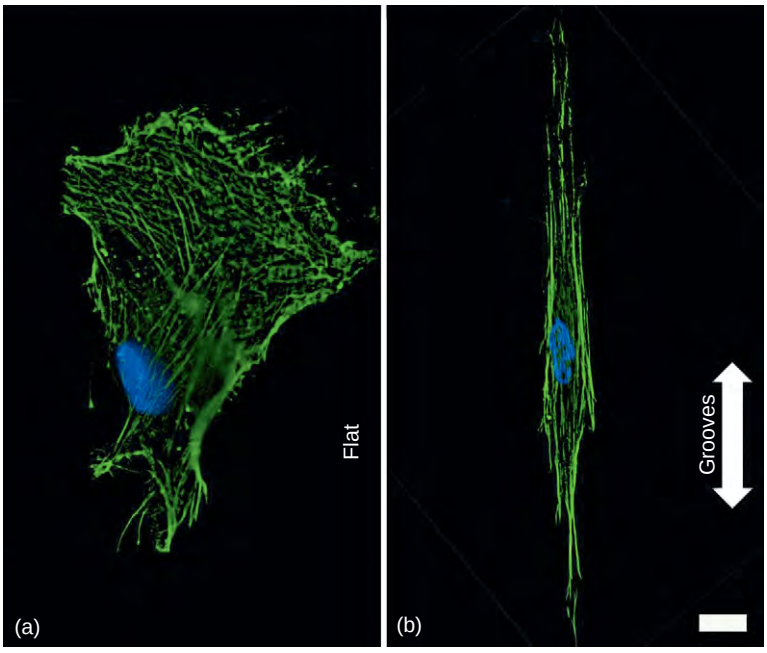

Figure 2 HTM cells orient and elongate with topographic cues. HTM cells were plated onto (a) a flat surface or (b) an anisotropically patterned surface with a repeating pattern of grooves and ridges. Both surfaces were chemically identical. The actin cytoskeleton (green) and nuclei (blue) of the HTM cells were stained 24 h after plating. HTM cells on the flat surface were spread out with actin stress fibers oriented in all directions, while the HTM cells plated on the topographic surface strongly aligned and elongated with the groove and ridge pattern. Scale = 10 μm.

complicated interaction of biochemical and biophysical cues that the HTM cells sense, particularly during the progression of glaucoma, requires additional research. The currently used models have limitations, but with the incorporation of biochemical and biophysical cues, a more accurate representation of HTM cell behavior can be realized. Eventually, a better comprehension of HTM cell properties will aid the development of new treatments for glaucoma.

Biomechanics of Aqueous Humor Outflow Resistance*

M Johnson, Northwestern University, Evanston, IL, USA
E R Tamm, University of Regensburg, Regensburg, Germany

Glossary

Conventional aqueous outflow pathway – Comprised of the trabecular meshwork, the juxtacanalicular connective tissue, the endothelial lining of Schlemm's canal, Schlemm's canal itself, the collecting channels, and aqueous veins.
Flow resistance – The flow resistance ($R=\Delta P/Q$) of a tissue is the ratio between the pressure drop across that tissue (ΔP) and the flow rate generated by that pressure drop (Q).
Giant vacuoles – The outpouchings of the inner-wall endothelium of Schlemm's canal into its lumen. They are caused by the pressure drop across inner-wall endothelial cells.
Hydraulic conductivity (L_p) – A measure of the ease with which a fluid passes through a tissue: $L_p=Q/A/\Delta P$ where A is the cross-sectional area of the tissue facing flow.
Inner-wall region – Comprised of the inner-wall endothelium of Schlemm's canal, its basement membrane, and the adjacent juxtacanalicular tissue.
Laser trabeculoplasty – The surgical treatment of glaucoma, in which a laser beam is focused on the trabecular meshwork making tiny, evenly spaced burns.

More than 135 years ago, in 1873, Leber recognized that the elevated pressure characteristic of primary open-angle glaucoma arises due to an increased resistance to the outflow of aqueous humor out of the eye. However, a conclusive determination of where in the outflow pathways this elevated outflow resistance is generated has been elusive. Surprisingly, the locus of aqueous humor outflow resistance in the normal eye has also not been unequivocally determined.

In 1921, Seidel, using light microscopy, stated "that the inner wall of Schlemm's canal stand in open communication with the anterior chamber, and that the aqueous humor directly washes around the inner wall endothelium of Schlemm's canal and is only separated from the lumen of Schlemm's canal by a thin, outer membrane." Our view is little different today. The locus of outflow resistance, both in the normal eye and the glaucomatous eye, is thought to arise either in the endothelial lining of Schlemm's canal, or very near to this location. In this article, current viewpoints on where that flow resistance might be generated are reviewed.

There are a number of excellent review articles (see the section titled 'Further reading') that describe the detailed morphology and physiology of the aqueous outflow pathway. Here, we first review the evidence leading to the conclusion that the region surrounding the inner-wall endothelium of Schlemm's canal generates the bulk of aqueous outflow resistance. We then turn our attention to the aspect of the outflow nearest to the endothelial lining of Schlemm's canal, and examine the transport characteristics of those structures.

The bulk of the aqueous humor flows out of the anterior chamber of the eye through the conventional aqueous outflow pathway comprised of the trabecular meshwork (TM), the juxtacanalicular connective tissue, the endothelial lining of Schlemm's canal, Schlemm's canal itself, the collecting channels, and aqueous veins, and, then finally, drains into the episcleral venous system, rejoining the venous system. A second unconventional outflow pathway exists, but carries less than 10% of the total flow in the adult human eye, and thus does not significantly contribute to the dynamics of aqueous humor outflow in the normal eye. This pathway is important, however, for the understanding of the mechanism of action of prostaglandins in the treatment of glaucoma.

Regions of Low Outflow Resistance

In this section, those aspects of the conventional aqueous humor outflow pathway that are generally agreed to have small or negligible outflow resistance are examined. These include the TM, Schlemm's canal, and the collector channels and aqueous veins.

The TM is made up of the uveal meshwork, corneoscleral meshwork, and the juxtacanalicular connective tissue (JCT). The former two regions are highly porous structures with numerous openings that range in size from 25 to 75 μm in the proximal regions of the uveal meshwork to 2–15 μm in the deeper aspects of the corneoscleral meshwork. In 1958, McEwen used Poiseuille's law to show that a single pore that is 100 μm long (the thickness of the TM) and 20 μm in diameter could carry the entire aqueous humor flow with a pressure drop of 5 mmHg, and thus concluded that there was negligible flow resistance in

*Adapted from Johnson, M. (2006). What controls aqueous humour outflow resistance? *Experimental Eye Research* 82: 545–557.

this region. In 1963, Grant provided experimental support for this conclusion by cutting through the proximal aspects of the meshwork of enucleated human eyes and found no effect on outflow resistance. The JCT is discussed in the next section.

Schlemm's canal and its endothelium, shown in Figure 1, exist between the JCT and the sclera.

While the canal is open at low intraocular pressures (IOPs), Johnstone and Grant, in 1973, showed that the TM expands and Schlemm's canal collapses as the IOP is increased. While the size of the canal at low IOP is much too large to generate a significant outflow resistance, the collapse of Schlemm's canal at higher IOP has led some to speculate that this might be a cause of primary open-angle glaucoma. However, in 1983, Johnson and Kamm pointed out that outflow resistance, when measured at high IOP in nonglaucomatous human eyes, is not nearly as high as that of a glaucomatous eye. Collapse of the canal would make a glaucomatous condition worse, but it could not cause the glaucoma.

After traveling circumferentially in Schlemm's canal, the aqueous humor enters one of approximately 30 collecting channels that connect Schlemm's canal with the aqueous veins. The collector channels and aqueous veins have diameters that are tens of microns across. The use of Poiseuille's law leads to the conclusion that these vessels should have negligible flow resistance.

The experimental support for this conclusion is mixed. In 1992, Mäpea and Bill measured pressures in Schlemm's canal of primate eyes and found that the pressure there was little different from episcleral venous pressure. This is in agreement with the theoretical calculations. However, a 360° trabeculotomy, which would be expected to eliminate all flow resistance proximal to the collector channels and aqueous veins, leaves substantial flow resistance remaining. These disparate experimental results regarding the flow resistance of the collector channels and aqueous veins have not been reconciled, perhaps due to the fact that while a significant fraction of normal aqueous humor outflow resistance may be generated by the collector channels and/or aqueous veins, these vessels do not appear to be responsible for the elevated outflow resistance characteristic of the glaucomatous eye. Several observations lead to this conclusion. First, trabeculotomy was shown to eliminate nearly all elevated glaucomatous flow resistance in eight glaucomatous eyes. This result indicates that in primary open-angle glaucoma, the outflow obstruction is proximal to the collector channels and aqueous veins. Further support for this conclusion can be found in the success of laser trabeculoplasty (LTP) in reducing outflow resistance in glaucomatous eyes. While it is not known precisely where in the outflow pathway LTP acts, recent evidence suggests that the site of action is in the TM, and it seems very unlikely that LTP has a significant effect on the outflow resistance of the collector channels and/or aqueous veins.

The conventional wisdom now is that little, if any, significant flow resistance in the normal eye is found in the uveal meshwork, corneoscleral meshwork, Schlemm's canal, or the collector channels and aqueous veins. Furthermore, while some increased resistance might be found in these structures in the glaucomatous eye, they are not responsible for the bulk of the elevated outflow resistance characteristic of the glaucomatous eye. All evidences indicate that the bulk of normal aqueous humor outflow resistance resides in the region surrounding the inner wall of Schlemm's canal, and this is also the region where the elevated flow resistance characteristic of primary open-angle glaucoma likely arises.

The Inner-Wall Region of Schlemm's Canal

We use the term inner-wall region to refer to the inner-wall endothelium of Schlemm's canal, its basement membrane, and the adjacent JCT. Figure 2 shows a

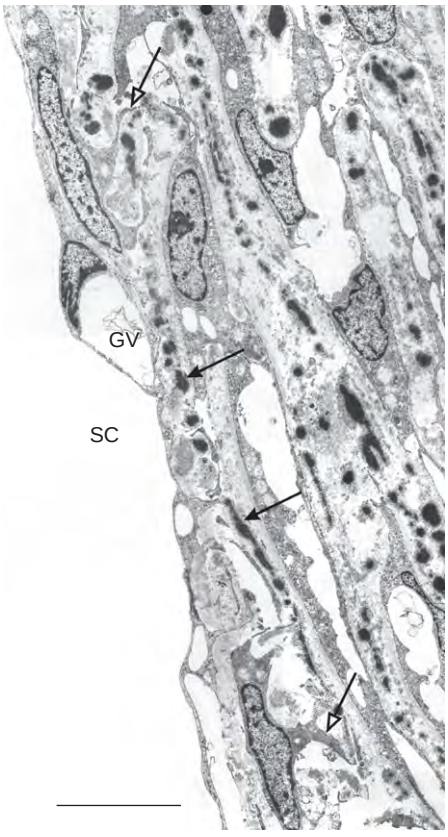

Figure 2 Electron micrograph of the inner-wall region including juxtacanalicular tissue and Schlemm's canal (SC) endothelium. transmission electron micrograph (TEM) of the tissues that neighbors Schlemm's canal on its upstream side.

The endothelial lining of the inner wall of Schlemm's canal is typical in some ways of other vascular linings. The cells have their long axis parallel to the canal (in the direction of flow through the canal) with a length of 40–100 μm and a width of 5–15 μm. They are attached to one another with tight junctions.

This endothelium has several unique characteristics. First, structures known as giant vacuoles are seen in this layer (**Figure 3**). While they appear to be intracellular structures, giant vacuoles are really outpouchings of the endothelium into Schlemm's canal, caused by the pressure drop across inner-wall endothelial cells. In 1978, Grierson and Lee showed that these structures were invaginations into the canal with most having a large opening on the meshwork side of the vacuole and a smaller percentage (20–30%) also having a distal opening, a pore (**Figure 3**). Thus, some of the vacuoles are transcellular channels.

The distal openings, or pores, in these vacuoles are a second feature of the inner-wall endothelium that is relatively unique (**Figure 3**). Majority of these pores are transcellular, although a fraction of these pores are located at the border of two cells (border pores), and thus not transcellular but paracellular. These transcellular pores do not connect the extracellular fluid with the cytoplasm of the cell. Instead, they pass from the basal side of the cell to the apical side at a location on the cell surface where the cell membranes from the inner and outer surfaces of

the cell have come together and fused. The pore is thus membrane-lined on its surface. These pores usually form on giant vacuoles, since it is this region in which the cell is greatly attenuated and the cytoplasm becomes thin.

Fusion of the inner and outer cell membranes and the formation of transcellular pores are not entirely unique to these cells. Pores associated with giant vacuoles are also found on the arachnoid villi in the drainage pathway for the cerebrospinal fluid. When cell thickness is reduced below a critical measure, vascular endothelium can form transcellular pores involved in transport processes.

The inner-wall endothelium of Schlemm's canal is supported by a discontinuous basement membrane. This makes Schlemm's canal a somewhat unique vessel having a continuous endothelium with tight junctions between neighboring cells, supported by a discontinuous basement membrane. Blood vessel endothelia have a continuous endothelium with a continuous basement membrane, while lymphatics have a discontinuous endothelium with a discontinuous basement membrane.

The region immediately underlying the inner wall and basement membrane and extending to the last trabecular beam is the JCT. It has many large, apparently empty spaces and is typically 2–15 μm thick.

The Generation of Flow Resistance in the Inner-Wall Region of Schlemm's Canal

While there is agreement among most investigators that the bulk of aqueous humor outflow resistance is generated in the immediate vicinity of the inner-wall endothelium of Schlemm's canal, the precise location and the mechanism by which this dissipation occurs is still a topic of active debate and research.

The JCT

With its tortuous submicron-sized flow pathways, the JCT is a natural location to investigate as to its role in generating outflow resistance. Surprisingly, morphometric analyses combined with theoretical calculations have indicated that, unless these apparently open spaces are actually filled with an extracellular matrix gel, they would generate an insignificant fraction of the total outflow resistance.

This conclusion follows from porous media theory an approach that has been used to characterize flow resistance of other connective tissues. Several different parameters can be used to characterize the fluid transport capacity of a tissue. The flow resistance ($R = \Delta P/Q$) of a tissue is the ratio between the pressure drop across that tissue (ΔP) and the flow rate generated by that pressure drop (Q); the inverse of this quantity is known as the total hydraulic conductance of this tissue. The conductance per unit surface area is known as the hydraulic conductivity (L_p), while the conductance of the tissue normalized for surface area, tissue length in the flow wise direction (L), and fluid viscosity (μ) is known as the specific hydraulic conductivity (K).

Darcy's law relates the flow resistance (R) of a tissue to the specific hydraulic conductivity (K) of that tissue,

$$R = \frac{\Delta P}{Q} = \frac{\mu L}{KA} \quad [1]$$

and the specific hydraulic conductivity is related to the hydraulic conductivity as:

$$K = L_p \mu L \quad [2]$$

Typical values of K and L_p for a variety of tissues are found in **Tables 1** and **2**.

The K value that characterizes the flow resistance of a tissue can be measured experimentally by determining the other parameters in eqn [1], all of which are easy to determine or estimate for aqueous humor outflow with the exception of the length (L) over which the pressure drop occurs. However, since the bulk of the pressure drop occurs somewhere in or near the inner wall of Schlemm's canal, it can be concluded that this length is less than roughly 10 μm, or so, an estimate supported by experimental studies. Using

a flow rate through the aqueous outflow pathway of 2 µl min^{-1} passing through a cross-sectional area of between 0.054 and 0.13 cm^2 (canal width of 150–350 µm; canal length around the eye of 3.6 cm), and a pressure drop of 5 mmHg, it can then determined that K of the resistance-causing region in the aqueous outflow pathway must be less than 65×10^{-14} cm^2. Unless the length over with the pressure drop occurs (L) is much lesser than 10 µm, the specific hydraulic conductivity of the connective tissue elements in the outflow pathway is greater than that of any other connective tissue with the exception of the vitreous humor (**Table 1**).

K can also be estimated from photomicrographs showing the ultrastructure of a tissue. This can potentially allow an evaluation of which structures in the aqueous outflow pathway are generating the measured outflow resistance. Carmen–Kozeny theory relates the structure of a porous medium to K as:

$$K = \frac{\varepsilon\, D_h^2}{80} \qquad [3]$$

where D_h is the hydraulic diameter of the open spaces available for flow and ε is the porosity, or fraction of open space of the medium (note that at porosities higher than roughly 0.8, this equation becomes inaccurate). Using Carmen–Kozeny theory combined with conventional TEM, it was found (in immersion-fixed eyes) that the porosity of the JCT was approximately 0.15–0.25, D_h was approximately 1–1.5 µm, and, most importantly, K of the JCT was calculated to be approximately 2000–10 000 10^{-14} cm^2 based on the photomicrographs. This is, at least, 30 times greater than K based upon measured properties of the outflow system.

In 1986, Ethier and coworkers concluded that the JCT, as visualized using conventional TEM, could not generate a significant fraction of outflow resistance. Other investigators have confirmed this conclusion, including studies in which the eyes were fixed by perfusion. It thus followed that either this region was filled with an extracellular matrix gel that was poorly visualized using

conventional TEM techniques, or, that this region was not the primary site of outflow resistance. The age-related accumulation of plaque-like material in this region that is reported to be enhanced in glaucomatous eyes would have no influence on this conclusion.

More recently, in 2002, Gong and coworkers used quick-freeze/deep-etch (QFDE) methodology to examine the apparent open spaces seen in the JCT region in greater detail. QFDE is a morphological technique that preserves the cellular and extracellular ultrastructure in exquisite detail and allows visualization of structures poorly preserved or not seen at all using conventional TEM tissue preparation techniques. A more elaborate and extensive extracellular matrix was seen in the JCT using QFDE as compared to conventional methods of preparation for TEM (**Figure 4**); however, micron-sized open spaces were still seen in this region, casting doubt on whether a significant fraction of outflow resistance could be generated in this region. An important caveat pointed out by the Gong group regarding their studies was that it was not clear whether or not QFDE can visualize the glycosaminoglycans (GAGs) in their uncollapsed state, and this leaves uncertain the question of generation of appreciable flow resistance in the JCT region.

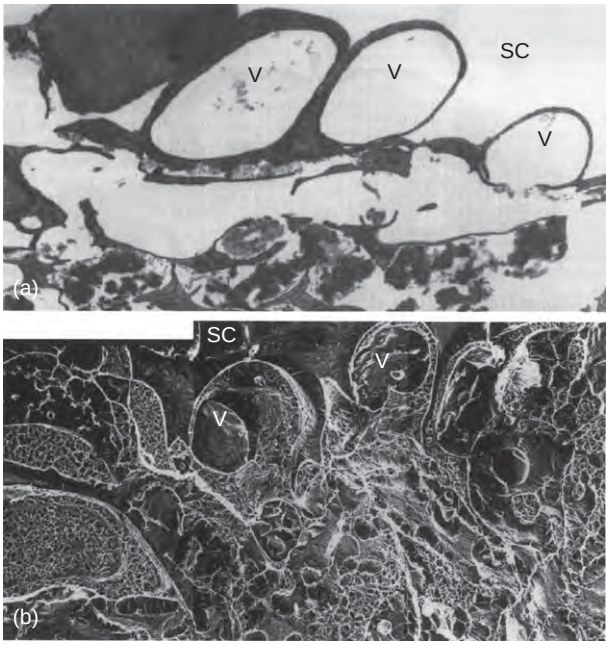

Figure 4 Enucleated human eye fixed by perfusion at 15 mmHg: (5A) vacuoles (V) in the inner wall of Schlemm's canal (SC) in tissue prepared for TEM using conventional methods; notice the large open space in the region of the JCT immediately under these vacuoles; (4B) the same region as seen in tissue prepared using QFDE; notice that while open spaces still exist under the vacuoles, a more complex and extensive extracellular matrix is seen. Magnification ×4860. Adapted from Gong, H., Ruberti, J., Overby, D., Johnson, M., and Freddo, T. F. (2002). A new view of the human trabecular meshwork using quick-freeze, deep-etch electron microscopy. *Experimental Eye Research* 75: 347–358, with permission from Elsevier.

The role that GAGs and other extracellular matrix elements found in the JCT might play in generating outflow resistance is unclear. While it has been shown that enzymes that degrade macromolecules (GAGases) increase outflow facility in a number of species (e.g., cow, guinea pig, dog, and rabbit), the evidence regarding primates is conflicting, and there has been no confirmed data yet showing that GAGases decrease outflow resistance in human eyes. Matrix metalloproteinases (MMPs) have been shown to reversibly increase outflow facility in perfused human anterior segment organ culture, and this is a strong indicator that the extracellular matrix may generate significant aqueous outflow resistance.

Perhaps the strongest experimental evidence implicating the JCT as a major site of outflow resistance is the 1992 study by Maepea and Bill in which they used micropipettes and localized the pressure drop to occurring somewhere between 7 and 14 μm from the inner wall of Schlemm's canal (i.e., in the JCT). While this result is frequently cited in the literature, it is not widely appreciated that this measurement was made with micropipettes whose tip sizes were as large as the measurement zone. When this reservation is combined with the fact that the inner wall of Schlemm's canal distends several to many microns during the process of penetration by the micropressure probe (unpublished work by Dr. Milko Iliev in collaboration with Dr. Johnson's laboratory), it leads to the conclusion that the bulk of the aqueous humor pressure drop occurs near the inner wall of Schlemm's canal (within 5–10 μm), but that no further quantitative conclusions are possible.

The basement membrane

The basement membrane of the inner wall of Schlemm's canal is another possible location for generation of outflow resistance. **Table 1** shows that the specific hydraulic conductivities of basement membranes (top four tissues in table) are among the lowest of connective tissues.

However, basement membranes tend to be quite thin and this limits the flow resistance they can generate (see eqn [1]). **Table 2** shows the hydraulic conductivity of a variety of physiological membranes, including cells membranes, epithelia, and basement membranes. The large variation in L_p of basement membranes is due not only to variation in the specific hydraulic conductivity of these tissues, but also to significant differences in their thicknesses (ranging from 0.15 μm for Bruch's membrane to 7 μm for Descemet's membrane).

It is interesting to compare the values seen in this table with the estimated value of the hydraulic conductivity of the outflow pathway. From the definition of hydraulic conductivity (or by combining eqns [1] and [2]), $L_p = Q/A/\Delta P$. Using the values characterizing the aqueous

outflow pathway presented above, we can estimate that L_p for the aqueous humor outflow pathway is between 4000 $\times 10^{-11}$ and 9000 $\times 10^{-11}$ cm^2 s g^{-1}. Note that this is not a theoretical calculation but an estimate based on measured quantities.

Table 2 shows that several basement membranes, in particular those of the renal system, have hydraulic conductivities similar to that of the aqueous outflow pathway. This suggests that the basement membrane of the inner-wall endothelium of Schlemm's canal might be an important contributor to aqueous humor outflow resistance.

However, as noted above, this basement membrane is discontinuous (Figure 3), as recently confirmed in 2002 by Gong and coworkers. If there are breaks in the basement membrane, it is difficult to see how a significant flow resistance could be generated by this tissue.

The inner-wall endothelium of Schlemm's canal

The inner-wall endothelium of Schlemm's canal has been an attractive candidate for the generation of outflow resistance since the time that light microscopes and later electron microscopes were focused on the inner-wall endothelium. Comparison of the hydraulic conductivity of this tissue (4000–9000 $\times 10^{-11}$ cm^2 s g^{-1}) with that of other endothelia and epithelia as seen in Table 2, leads one to conclude that this vessel lining must have one of the highest hydraulic conductivities in the body. Compared to other tissues in Table 2, it is clear that only fenestrated endothelia (and some basement membranes) have such high hydraulic conductivities.

While the inner-wall endothelium is not fenestrated, this endothelium is unique in that it contains micron-sized pores. It is interesting that even early investigators (e.g., Seidel) had concluded that such pores existed, long before they were first seen by electron microscopy. This conclusion was based on early filtration studies that examined the sizes of microparticulates that would pass through the outflow pathway. It was found in these studies that a filtration barrier existed for particles larger than roughly 0.5 µm or so, and thus it was concluded that pores nearly 1 µm in size must exist. More recent studies have confirmed this conclusion using microparticles and latex microspheres.

While there is some debate concerning the existence of these pores (which is discussed below), no group has offered an alternate explanation for the extraordinarily high hydraulic conductivity of the aqueous outflow pathway. Nor has any alternate explanation been offered for the relatively easy passage of microparticles 200–500 nm in diameter through the outflow pathway, except through these large pores. Since there are tight junctions (Figure 3) between the inner-wall cells (presumably to prevent blood reflux into the eye that can occur during periods of transient increases in ocular venous pressure), there are no other structures apparent in this endothelium that could explain the high hydraulic conductivity of this tissue or its filtration characteristics.

The flow resistance generated by these pores was first considered by Bill and Svedbergh in 1972. In an exhaustive study using scanning electron microscopy, they characterized the size distribution of these pores, and then used hydrodynamic theory to calculate for hydraulic conductivity of these pores. Using Sampson's law, that gives the hydraulic conductivity for a single pore of diameter d,

$$L_p = \frac{d}{6\pi\mu} \qquad [4]$$

they found that the inner-wall endothelium could present, at most, 10% of the outflow resistance. That is, the hydraulic conductivity of the pores in the inner-wall endothelium is, at least, 10-fold higher than the measured hydraulic conductivity of the outflow pathway. This conclusion has been confirmed in a number of studies.

These results would appear to rule out the inner-wall endothelium as a major site of outflow resistance. However, a number of experimental findings are at variance with this conclusion. In particular, when chelating agents (ethylenediaminetetraacetic acid (EDTA) and ethylene glycol tetraacetic acid (EGTA)) or a proteolytic enzyme (α-chymotrypsin) were perfused through the outflow pathway of live primates, it was found that ruptures of the inner-wall endothelium were produced by these agents that decreased outflow resistance more than could be explained by the calculated flow resistance of the inner-wall pores. A hydrodynamic interaction (the funneling effect) between the inner-wall pores and the JCT, which lies immediately below these pores, has been proposed as an explanation of the findings (see Figure 5).

In this scenario, the pores and vacuoles themselves contribute negligible flow resistance, but since they force aqueous humor to funnel through those regions of the JCT nearest the pores and vacuoles, the vacuole size

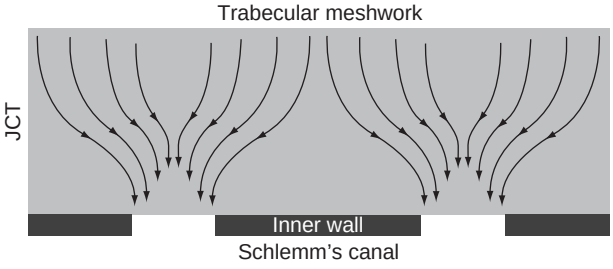

Figure 5 Schematic of the funneling of aqueous humor through the JCT, toward a vacuole and pore that allows this fluid to pass through the inner-wall endothelium. Adapted from Overby, D., Gong, H., Qiu, G., Freddo, T. F., and Johnson, M. (2002). The mechanism of increasing outflow facility during washout in the bovine eye. *Investigative Ophthalmology and Visual Science* 43: 3455–3464. ©The Association for Research in Vision and Ophthalmology.

and pore density can have a significant effect on the effective hydraulic conductivity (L_p) of the JCT:

$$L_p = \frac{2KnD}{\mu} \quad [5]$$

Here, K is the specific hydraulic conductivity of the JCT region, n is the number of pores per unit area in the inner wall, D is the diameter of the vacuoles in the inner wall, and μ is the viscosity of the aqueous humor.

The funneling model suggests that while the bulk of outflow resistance is actually generated in the JCT or basement membrane, its magnitude is modulated by the pores and vacuoles of the inner-wall endothelium of Schlemm's canal. This model explains many of the characteristics of the outflow pathways discussed above. However, two recent studies failed to find a correlation between outflow facility and inner-wall pore density as would be expected if eqn [5] describes the hydraulic conductivity of the outflow pathway. Furthermore, these studies found that at least some inner-wall pores may be artifacts of the fixation process.

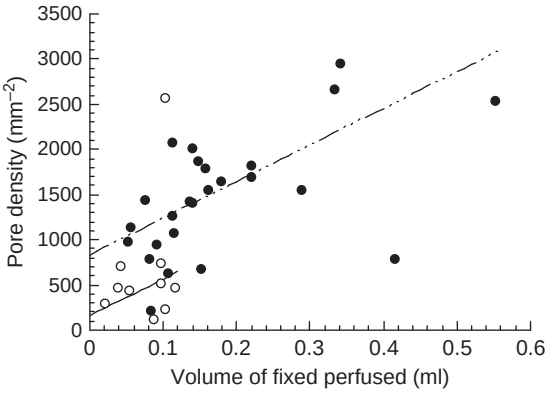

Figure 6 Pore density as a function of volume of fixative perfused through the outflow pathway of normal eyes (filled symbols) and eyes with POAG (open). Lines are best fit with outliers excluded. Pores as possible fixation artifacts and the possible importance of flow through inner-wall cell junctions or through water channels

The micron-sized pores that pass through the endothelial cells of the inner-wall endothelium of Schlemm's canal are relatively unique to these cells and to the cells of the arachnoid villi, a tissue of the cerebrospinal fluid pathway. This unique character has led some investigators to doubt that these are physiologic structures, but instead consider them to be artifacts of the tissue-preparation process. The possibility that pores form during tissue preparation for electron microscopy was supported in recent studies that showed that during tissue fixation under flow conditions, the inner-wall endothelium pore density increased as a function of the volume of fixative perfused through the outflow pathway (see **Figure 6**).

It has been postulated by several investigators that instead of passing through the pores in the inner-wall endothelium, a significant fraction of the aqueous humor passes through gaps between the tight-junction strands of these cells. In 2001, Ethier and Chan found that cationized ferritin perfused into enucleated human eyes acted to decreased outflow facility and was seen accumulating in junctions between inner-wall endothelial cells. While Ethier and Chan argue that the decreased outflow facility caused by cationized ferritin was due to pore blocking that was also seen to occur in this study, others have interpreted their results as consistent with a significant flow through the junctional complexes.

There are a several reasons why this hypothesis is untenable. Two strong arguments against this possibility were suggested above, namely that the uniquely high hydraulic conductivity of the aqueous outflow pathway is inconsistent with flow through junctions, and that the relatively free passage of microspheres 200–500 nm in diameter through the outflow pathway would be precluded if transport was primarily through cell junctions. It is well known in the vascular system that macromolecules larger than roughly 10–20 nm are largely excluded from passing through cell junctions, for either fenestrated or nonfenestrated vessels.

In 1981, Raviola and Raviola examined the tight junctions of the inner-wall endothelium and calculated the flow that would be expected through these junctions. The gaps they found available for transport around the tight-junctional strands were nanometers in size, and they concluded that any flow that might occur through these spaces would be negligible. In 1997, Ye and coworkers used freeze-fracture techniques to examine these junctions in eyes fixed under flow conditions and did not report significant differences from the dimensions reported by Raviola and Raviola. The notion that microparticles that are roughly 0.5 μm in size could relatively easily pass through such openings seems improbable, at best.

The study of Ye and coworkers did find that the tight junctions of the inner-wall cells simplified with increasing IOP. They speculated that the junctional simplification that occurred with increasing perfusion pressure might lead to formation of pores at locations of focal separation in the tight junctions. While they did not find a statistically significant relationship between junctional complexity and outflow facility in this small series of eyes, they did find a trend in that direction, consistent with their hypothesis.

Thus, while there are a number of strong arguments against the possibility of transport of a significant quantity of aqueous humor across the inner wall of Schlemm's canal passing directly through cell junctions, simplification of these junctions might be involved in the process of pores formation. In particular, paracellular flow through border pores could be consistent with the 1991 findings of Epstein and Rohen of dilations of this paracellular space.

It has also been suggested that a fraction of outflow might pass through water channels (aquaporins) in the cell membrane of the inner-wall cells. Red blood cells and renal proximal tubules are cell types expressing high levels of aquaporin 1. The hydraulic conductivities of the water channels in these cell membranes have been measured, as have those of cells in which aquaporins are overexpressed (see **Table 2**). All of these values are more than 1000 times smaller than the hydraulic conductivity of aqueous outflow pathway. It goes without saying that water channels also cannot explain the relatively free passage of 0.5-μm-sized particles through the outflow pathway.

The only pathway that appears consistent with the available physiologic evidence is through the inner-wall pores whose existence was already postulated more than 80 years ago by Seidel in 1921, and that now are easily seen using scanning electron microscopy of this tissue. Importantly, the size of these pores is consistent with the predictions of Seidel. Whether this transport is primarily through border pores or is also through the transcellular pores remains to be determined.

The question remains as to why the number of these pores increases during the fixation process, as shown in **Figure 6**. A further finding of the studies was that the number density of pores in the inner-wall endothelium decreases as a function of postmortem time, something not expected of an artifact. Instead, it may be that fixation under flow conditions generates stresses in the inner wall due both to pressure-induced stretching of the inner wall of Schlemm's canal and also to shrinkage of the tissue following fixation. Pressure-induced stress is likely what causes the formation of these pores under physiologic conditions. Then, fixative-induced pore formation might be an artifact associated with a physiological process, namely stress on the inner-wall endothelium.

In this scenario, the y-intercepts of the lines seen on **Figure 6** would then represent the true physiological pore density of normal and glaucomatous eyes, respectively. Importantly, **Figure 6** shows this density to be greatly reduced in glaucomatous eyes. Through their importance to funneling (eqn [5]), a decrease of inner-wall pores would be expected to decrease the hydraulic conductivity of the outflow pathway and thereby increase IOP.

This decrease pore density in the inner-wall endothelium of Schlemm's canal may then represent the cause of the elevated pressure characteristic of glaucoma. Future work may then indicate why this pore density is decreased.

Biomechanics of the Optic Nerve Head*

J C Downs, M D Roberts, and C F Burgoyne, Devers Eye Institute, Portland, OR, USA

Glossary

Anisotropic materials – These materials exhibit higher or lower stiffness properties along different directions. For instance, concrete may be isotropic by itself, but the introduction of rebar during fabrication would produce an anisotropic material with higher resistance to tension along the direction of the rebar.

Elastic materials – These materials exhibit no time-dependent stress–strain behavior.

Isotropic materials – These materials exhibit identical resistance to load in all directions.

Linear materials – These materials exhibit a stress–strain relationship in which stress is directly proportional to strain by a constant factor known as the Young's modulus.

Material properties – These describe the ability of a tissue to resist deformation under applied load and therefore relate stress to strain (i.e., load to deformation). Material properties can be thought of as the stiffness or compliance of a particular tissue or material that is intrinsic to the material itself. These properties are often described in terms of their material symmetry (isotropic or anisotropic), the nature of the relationship between load and deformation (linear or nonlinear), and the time dependence of their response to loading (elastic or viscoelastic).

Mechanical failure – It occurs at even higher strain, typically follows yield, and generally manifests in soft tissues as catastrophic rupture or pulling apart.

Mechanical yield – It occurs when a material is strained beyond its elastic limit, and is therefore unable to return to its undeformed shape. A material or tissue that has yielded in response to high strains is permanently damaged and deformed and is usually less resistant to further loading (hypercompliance).

Nonlinear materials – These materials have a varying proportionality between stress and strain that is generally dependent on the level of strain, and hence do not have a unique or constant Young's modulus. Connective tissues such as the sclera and lamina cribrosa generally get stiffer as they are stretched.

Strain – It is a measure of the local deformation in a material or tissue induced by an applied stress, and is usually expressed as the percentage change in length of the original geometry (e.g., a wire that was originally 10 mm long that has been stretched an additional 1 mm, exhibits 10% strain). It is important to recognize that strain, unlike stress, may be observed and measured and it is strain, not stress, which causes damage to tissues.

Stress – It is a measure of the load applied to, transmitted through, or carried by a material or tissue, and can be defined as the amount of force applied to a tissue divided by the cross-sectional area over which it acts (e.g., pressure is a stress and can be expressed in pounds per square inch (psi)).

Structural stiffness – It is a composite measure of the entire structure's resistance to deformation that incorporates both the material properties and geometry of a complex load bearing system. In the posterior pole, both the geometry and material properties of the sclera and lamina cribrosa contribute to their structural stiffness, and hence determine the ability of the optic nerve head (ONH) and peripapillary sclera to withstand strain when exposed to intraocular pressure (IOP). As such, individual ONH biomechanics is governed by the geometry (size and shape of the scleral canal, scleral thickness, regional laminar density, and beam orientation) and the material properties (stiffness) of the lamina cribrosa and sclera. Hence, two eyes exposed to identical IOPs may exhibit very different strain fields due to differences in their structural stiffness.

Viscoelastic materials – These materials exhibit a stress–strain response that is time dependent, that is, they have higher resistance when loaded quickly than when loaded slowly (similar to the behavior of a hydraulic shock absorber).

The Optic Nerve Head as a Biomechanical Structure

The optic nerve head (ONH) is of particular interest from a biomechanical perspective because it is a weak spot within an otherwise strong corneo-scleral envelope. While there are likely to be important pathophysiologies within the lateral geniculate and visual cortex as well as evidence both for and against direct, intraocular pressure (IOP)-induced damage to the retinal photoreceptors, most evidence suggests that the lamina cribrosa is the principal site of retinal ganglion cell (RGC) axonal insult in glaucoma.

The lamina cribrosa provides structural and functional support to the RGC axons as they pass from the relatively high-pressure environment in the eye to a low-pressure region in the retrobulbar cerebrospinal space. To protect the RGCs in this unique anatomic region, the lamina cribrosa in higher primates has developed into a complex structure composed of a three-dimensional (3D) network of flexible beams of connective tissue (**Figure 1**). The ONH is nourished by the short posterior ciliary arteries, which penetrate the immediate peripapillary sclera to feed capillaries contained within the laminar beams. This intra-scleral and intra-laminar vasculature is unique in that it is encased in load-bearing connective tissue, either within the scleral wall adjacent to the lamina cribrosa, or within the laminar beams themselves (**Figure 1**). Glaucoma is a multifactorial disease, and we believe that biomechanics not only determines the mechanical environment in the ONH, but also mediates IOP-related reductions in blood flow and cellular responses through various pathways (**Figure 2**).

Consideration of the anatomy of the lamina cribrosa and peripapillary sclera suggests that the classic mechanical and vascular mechanisms of glaucomatous injury are inseparably intertwined (**Figures 1 and 2**). For example, prior to structural damage, purely IOP-related stress could detrimentally affect the blood supply to the laminar segments of the axons through deformation of the capillary-containing connective tissue structures. Also, IOP-related remodeling of the extracellular matrix (ECM) of the laminar beams could limit the diffusion of nutrients to RGC axons in the ONH. Reciprocally, primary insufficiency in the blood supply to the laminar region could

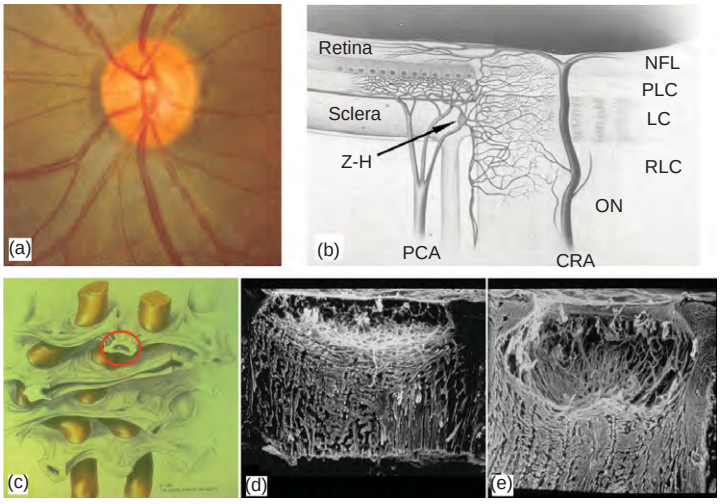

Figure 1 The optic nerve head (ONH) is a three-dimensional (3D) structure comprised of multiple interactive tissue systems that exist on different scales. This complexity has been a formidable deterrent to characterizing its mechanical environment. (a) While clinicians are familiar with the clinically visible surface of the optic nerve head (referred to as the optic disc), in fact the ONH is a dynamic, 3D structure in which the retinal ganglion cell (RGC) axons in bundles surrounded by glial columns, pass through the connective tissue beams of the lamina cribrosa. The blood supply for the connective tissues of the lamina cribrosa (b) derives from the posterior ciliary arteries and the circle of Zinn-Haller (Z-H), and capillaries inside the laminar beams supply the axons in the laminar region. The relationship of the axon bundles to the laminar beams and their contained capillaries is shown in schematic form in (c). Individual beams of the lamina cribrosa are lined by astrocytes. Together this system provides structural and metabolic support for the adjacent axon bundles. Within the lamina, the RGC axons have no direct blood supply, and axonal nutrition requires diffusion of nutrients from the laminar capillaries, across the endothelial and pericyte basement membranes, through the extracellular matrix (ECM) of the laminar beam, across the basement membranes of the astrocytes and through their processes to the adjacent axons. Chronic age-related changes in the endothelial cell and astrocyte basement membranes, as well as intraocular pressure (IOP)-induced changes in the laminar ECM and astrocyte basement membranes may diminish nutrient diffusion to the axons in the presence of a stable level of laminar capillary volume flow. In advanced glaucoma, the connective tissues of the normal lamina cribrosa (shown in (d) in a sagittal view of a trypsin-digested ONH; vitreous above, orbital optic nerve below), remodel and restructure into a cupped and excavated configuration (e). (b) reprinted with permission from Cioffi GA; (c) reprinted with permission from Quigley HA; (d, e) Courtesy of Harry A. Quigley, MD.

induce cell-mediated connective tissue changes that would serve to weaken the laminar beams, making them more prone to failure under previously safe levels of IOP-related mechanical stress.

To incorporate these concepts into a global conceptual framework, we have previously proposed that the ONH is a biomechanical structure. This paradigm assumes that IOP-related stress (force/cross-sectional area) and strain (local deformation of the tissues) are central determinants of both the physiology and pathophysiology of the ONH tissues and their blood supply (**Figure 2**) at all levels of IOP. These stresses and strains are complex and can be separated into three components that act simultaneously: tension, compression, and shear (**Figure 3**). The distributions of stress, strain, and deformation are determined by the complex material properties and geometries of the sclera and lamina cribrosa (**Figures 4** and **5**). IOP-related stress and strain induce changes in the tissues that include not only alterations to the load-bearing connective tissues of the lamina cribrosa and the peripapillary sclera, but also the cellular components of these tissues, including astrocytes, glial cells, endothelial cells, and pericytes, along with their basement membranes and the RGC axons in the ONH. Experienced over a lifetime at physiologic levels, they underlie normal ONH aging. However, acute or chronic exposure to pathophysiologic levels results in glaucomatous damage.

Although clinical IOP-lowering remains the only proven method for preventing the onset and progression of glaucoma, the role of IOP in the development and progression of the disease remains controversial. This largely arises from the clinical observation that significant numbers of patients with normal IOPs develop glaucoma (e.g., normotensive glaucoma), while other individuals with elevated IOP show no signs of the disease. While there is a wide spectrum of individual susceptibility to IOP-related glaucomatous vision loss, the biomechanical effects of IOP on the tissues of the ONH likely play a

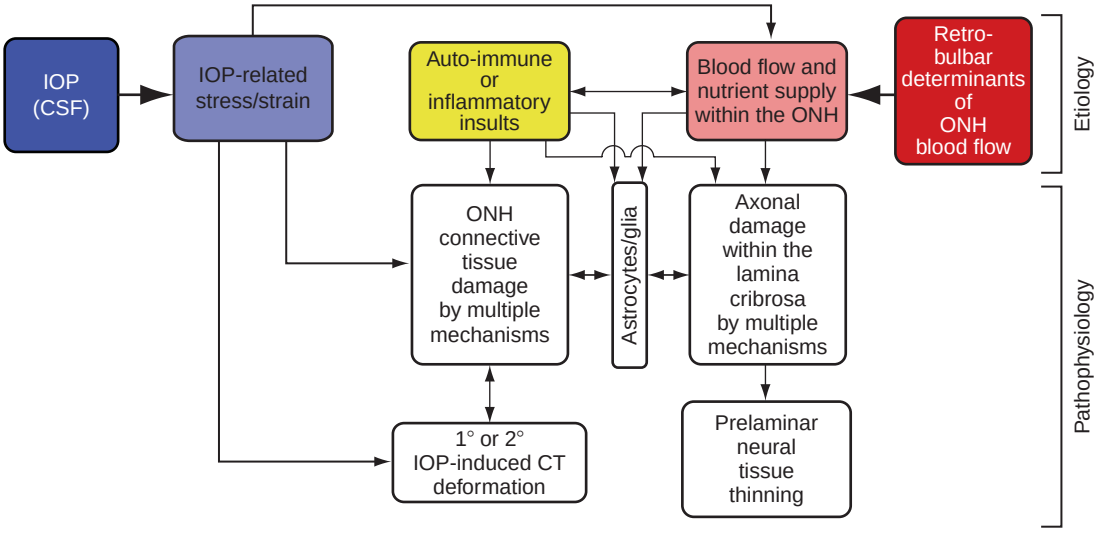

Figure 2 IOP-related stress and strain are a constant presence within the ONH at all levels of IOP. In a biomechanical paradigm, IOP-related strain influences the ONH connective tissues and the volume flow of blood (primarily), and the delivery of nutrients (secondarily) through chronic alterations in connective tissue stiffness and diffusion properties (explained in **Figure 1**). Non-IOP-related effects such as autoimmune or inflammatory insults (yellow) and retrobulbar determinants of ocular blood flow (red) can primarily damage the ONH connective tissues and/or axons, leaving them vulnerable to secondary damage by IOP-related mechanisms at normal or elevated levels of IOP. Based in part on Fig. 5, Burgoyne, C. F. and Downs, J. C. (2008). Premise and prediction – how optic nerve head biomechanics underlies the susceptibility and clinical behavior of the aged optic nerve head. *Journal of Glaucoma* 17(8): 318–328.

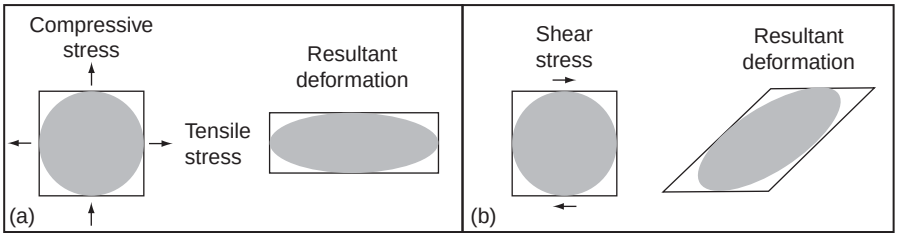

Figure 3 Normal and shear components of stress and strain. (a) The normal tensile and compressive stresses acting on a small square in the manner shown will act to elongate the region in one direction and compress it in the other. (b) The shear stresses acting on a similar region will act to distort the shape of the region.

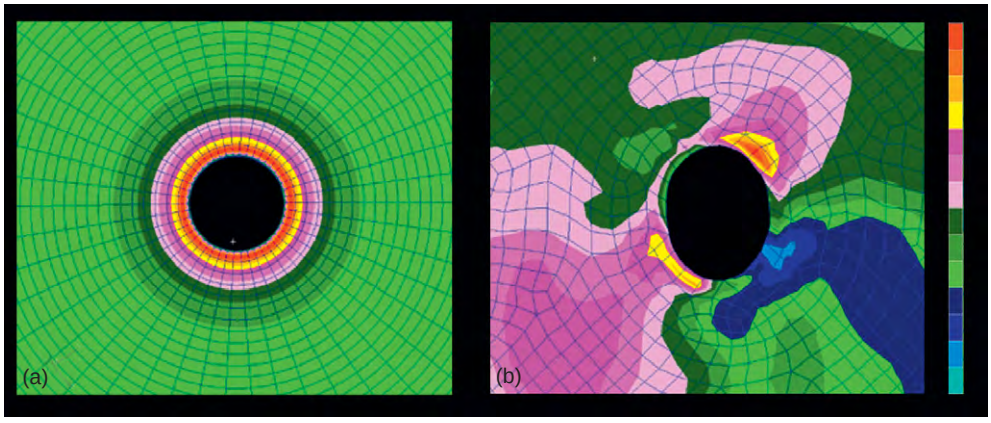

Figure 4 The material properties of the peripapillary sclera are influenced by nonlinearity and collagen fiber orientation (anisotropy). Separate from its thickness, the behavior of the sclera is governed by its material properties, which in turn are influenced by nonlinearity and fiber orientation. (a) Nonlinearity is an engineering term for tissues or structures whose material properties are altered by loading. Panel (a) demonstrates that the sclera becomes stiffer as it is loaded uniaxially (in one direction). In the case of the sclera, this is likely due to the fact collagen fibers embedded within the surrounding ground matrix start out crimped and progressively straighten as the load is increased. This conformational change in the fibrils accounts for the transition from an initially compliant, nonlinear response to a stiffened linear response as IOP increases. (b) Apart from nonlinearity, collagen fiber orientation (anisotropy) within the sclera strongly influences its mechanical behavior. Fiber orientation can be totally random (isotropic – not shown) or have a principal direction (anisotropic – three idealized cases shown). Finite element (FE) models of an idealized posterior pole with principal collagen fiber orientation in the circumferential, helicoidal, and longitudinal directions are shown. As the displacement plots show, the underlying fiber orientation can have profound effects on the deformation that occurs for a given IOP. Note that the displacement scale is exaggerated for illustrative purposes. Courtesy of Michael Girard.

central role in the development and progression of the disease at all IOPs. The individual susceptibility of a particular patient's ONH to IOP insult is likely a function of the biomechanical response of the constituent tissues and the resulting mechanical, ischemic, and cellular events driven by that response. Hence eyes with a particular combination of tissue geometry and stiffness may be susceptible to damage at normal IOP, while others may have a combination of ONH tissue geometry and stiffness that can withstand even high levels of IOP.

In this article, we focus on ocular biomechanics along two main themes: What is known about how mechanical forces and the resulting deformations are distributed in the posterior pole and ONH (biomechanics) and what is known about how the living system responds to those deformations (mechanobiology).

Mechanical Environment of the ONH and Peripapillary Sclera

Overview of the Mechanical Environment of the ONH and Peripapillary Sclera

From an engineering perspective, the eye is a vessel with inflow and outflow facilities that regulate its internal pressure. IOP imposes a pressure load normal to the inner surface of the eye wall, generating an in-wall circumferential stress known as the hoop stress (**Figure 6**). This IOP-generated stress is primarily borne by the stiff, collagenous sclera, while the more compliant retina and nerve fiber tissues bear little of the in-wall stress load and are therefore exposed primarily to the compressive stress of IOP. IOP is borne in the ONH by the fenestrated connective tissues of the lamina cribrosa, which span the scleral canal opening and tether into the stiff outer ring of circumferential collagen and elastin fibers in the peripapillary sclera (like a trampoline). While Laplace's law is useful to describe the pressure–deformation relationship in a spherical vessel of uniform thickness, it is inadequate for describing the eye's response to variations in IOP (**Figure 7**). There are several characteristics of the ocular load-bearing tissues that complicate the study of the mechanical environment to which the ONH and its resident cell populations are exposed.

First, the 3D connective tissue geometry of the eye is complex and difficult to measure. For instance, the thickness of monkey sclera can vary as much as fourfold from the equator to the peripapillary region and the 3D morphology of lamina cribrosa is more regionally complex and individualized than is generally appreciated. Second, the cornea, sclera and lamina cribrosa have extremely complex ECM microstructures with highly anisotropic collagen and elastin fibril orientations. As a result, the experimental characterization and theoretical/mathematical description of their constituent material properties are complex and difficult to obtain. Third, the cells that maintain the ocular connective tissues are biologically active. As such, the geometry and material properties of the sclera and lamina cribrosa change in response to both physiologic (age) and pathologic (IOP-related damage)

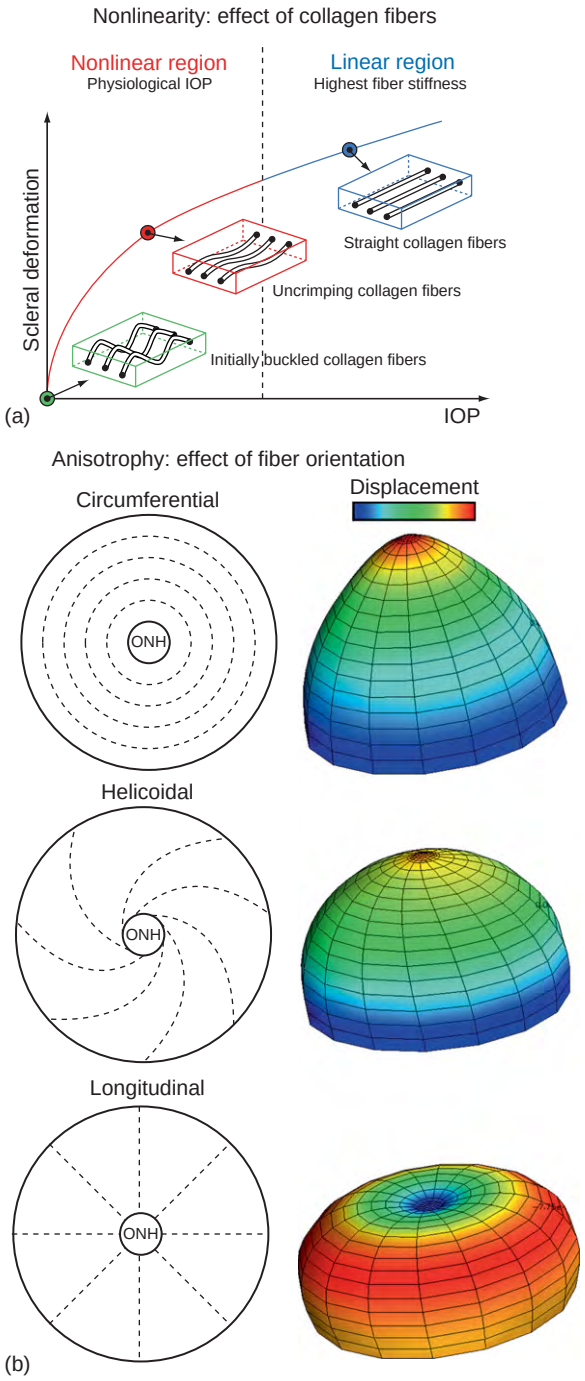

Figure 5 The thickness of the peripapillary sclera, and the size and shape of the scleral canal influence the magnitude and distribution of IOP-related stress within the peripapillary sclera. Stress plots within 3D biomechanical models of the posterior sclera and ONH demonstrate that stress concentrates around a defect (scleral canal) in a pressure vessel (eye) and varies according to the geometry of the peripapillary sclera and scleral canal. The idealized model in (a) shows the stress concentration around a circular canal in a perfectly spherical pressure vessel with uniform wall thickness (the ONH has been removed from these images for visualization purposes). The model in (b) shows the IOP-related stress concentration around an anatomically shaped scleral canal with realistic variation in peripapillary scleral thickness. In this case, the highest stresses (red) occur where the sclera is thinnest and the lowest stresses (blue) occur where the sclera is thickest, and also tend to concentrate around areas of the scleral canal with the smallest radius of curvature. The response of the sclera to this load is determined by its structural stiffness, which is the combination of geometry (how much tissue is bearing the load) and material properties (how rigid or compliant is the tissue).

factors. Fourth, the eye is exposed to ever changing loading conditions because IOP undergoes acute, short-term and long-term fluctuations ranging from blinks and eye rubs to circadian rhythms.

Finally, IOP-related stress generates strain patterns in the ONH and peripapillary sclera that are not only dependent on differing connective tissue geometries and material properties but are also influenced by complex loading conditions. The important factors contributing to this biomechanical component include the alignment and density of collagen fibrils in each tissue (stiffness and anisotropy), the rate of change in IOP (via tissue viscoelasticity), and the level of IOP-related strain at the time of altered loading (via tissue nonlinearity). In broad terms, the ONH connective tissues should be stiffer when there is already considerable strain present and/or if the IOP load is applied quickly. Conversely, the ONH should be more compliant in response to slow changes in IOP and/or at low levels of strain.

Mechanical Response of the ONH to Acutely Elevated IOP

It is important to note that the ONH responds to IOP elevations as a structural system, so the acute mechanical response of the lamina cribrosa is confounded with the responses of the peripapillary sclera, prelaminar neural tissues, and retrolaminar optic nerve. Also, because the lamina lies buried underneath the prelaminar neural tissues and the structural responses of these two tissue types to acute IOP elevations are quite different, acute laminar deformation cannot be directly measured or inferred by imaging the surface topography of the ONH. A final confounding effect is the cerebrospinal fluid pressure, which, along with IOP, determines the translaminar pressure gradient that must be borne by the lamina cribrosa.

Intuitively, it may seem that for a given acute increase in IOP, the lamina cribrosa should deform posteriorly and there have been several experimental studies designed to measure acute IOP-related laminar deformation. Yan and co-workers found that increasing IOP from 5 to 50 mmHg for 24 h produced an average posterior deformation of the central lamina of 79 μm in human donor eyes. Levy and Crapps reported a 12 μm average posterior movement of the central lamina with acute IOP elevations from 10 to 25 mmHg for shorter time periods in human eyes.

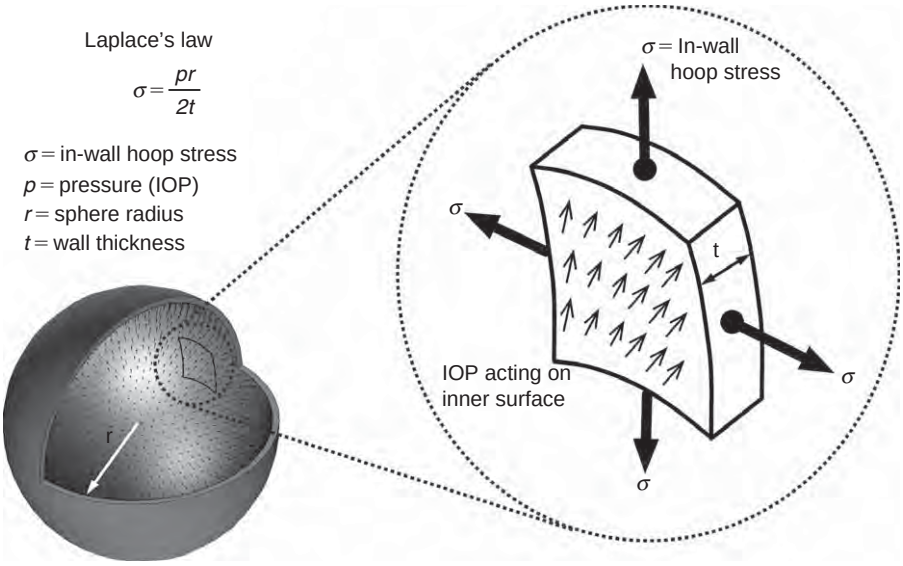

Figure 6 In-wall stress engendered by IOP loading. In an idealized spherical shell, the majority of the stress generated by IOP is transferred into a hoop stress borne within the thickness of the wall. Laplace's law, which relates the in-wall hoop stress to the internal pressure, is only applicable to spherical pressure vessels with isotropic material properties and uniform wall thickness, and can only be used to calculate very rough estimates of hoop stress in actual eyes. In pressure vessel geometries like the eye, with variable wall thickness, aspherical shape, and anisotropic material properties, the hoop stress may vary substantially by location.

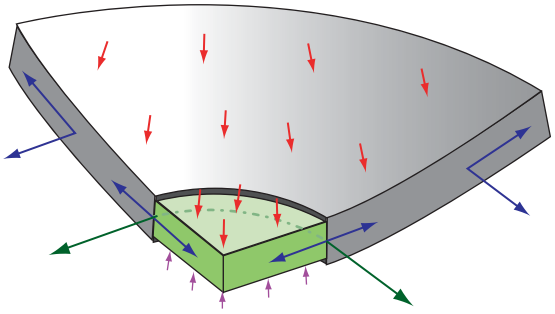

Figure 7 Stress, relative to IOP (red arrows) in the lamina cribrosa (light green) and peripapillary sclera (grey) engendered by IOP loading. Cut-away diagram of IOP-induced stress in an idealized spherical scleral shell with a circular scleral canal spanned by a more compliant lamina cribrosa. In this case, the majority of the stress generated by IOP (red arrows) is transferred into a hoop stress borne within the thickness of the sclera and lamina (blue arrows) that is concentrated circumferentially around the scleral canal (green arrows). Note that the difference between IOP (red arrows) and the retrolaminar cerebrospinal fluid pressure (pink arrows) is the translaminar pressure gradient that generates both a net posterior force on the surface of the lamina and a hydrostatic pressure gradient within the neural and connective tissues of the pre-laminar and laminar regions. Most importantly, note that the in-plane hoop stress transferred to the lamina from the sclera is much larger than stress induced by the translaminar pressure gradient.

More recently, Bellezza and colleagues reported a small but significant posterior laminar deformation of 10–23 μm (95% confidence interval (CI)) in a histologic evaluation of monkey eyes perfusion fixed with one eye at 10 mmHg and the contralateral eye at 30 or 45 mmHg for 15 min prior to death. However, these deformations, while statistically significant, did not substantially exceed the 95% CI for intra-animal physiologic differences (1–17 μm) between normal eyes bilaterally immersion fixed at an IOP of 0 mmHg.

The previous studies were performed using 2D measurements of laminar compliance within actual histologic sections. Angled sectioning, section warping, and the lack of a stable measurement reference plane can influence the accuracy of this technique. To overcome these problems, Downs, Yang and co-workers developed a technique for 3D delineation and measurement of ONH structures within high-resolution, digital 3D reconstructions (**Figure 8**). While our initial reports have concentrated on monkeys with early experimental glaucoma in one eye, preliminary data from a larger group of bilaterally normal monkeys perfusion fixed with both eyes at an IOP of 10 mmHg ($n = 5$), one eye at 10 mmHg, the other at 30 mmHg ($n = 3$), and one eye at 10 mmHg, the other at an IOP of 45 mmHg ($n = 3$) suggest that while acute IOP elevation causes expansion of the scleral canal, in most monkey eyes there is no net posterior laminar deformation from the plane of the sclera. Thus, our current understanding of the aggregate response of the young adult monkey ONH to acute IOP elevation is that expansion of the scleral canal tightens the lamina within the plane of the sclera, making it more resistant to posterior deformation out of that plane (**Figure 9**). These data are preliminary and our interpretation may change with further study.

It is important to note that the lack of laminar deformation in these eyes does not mean that the lamina is not

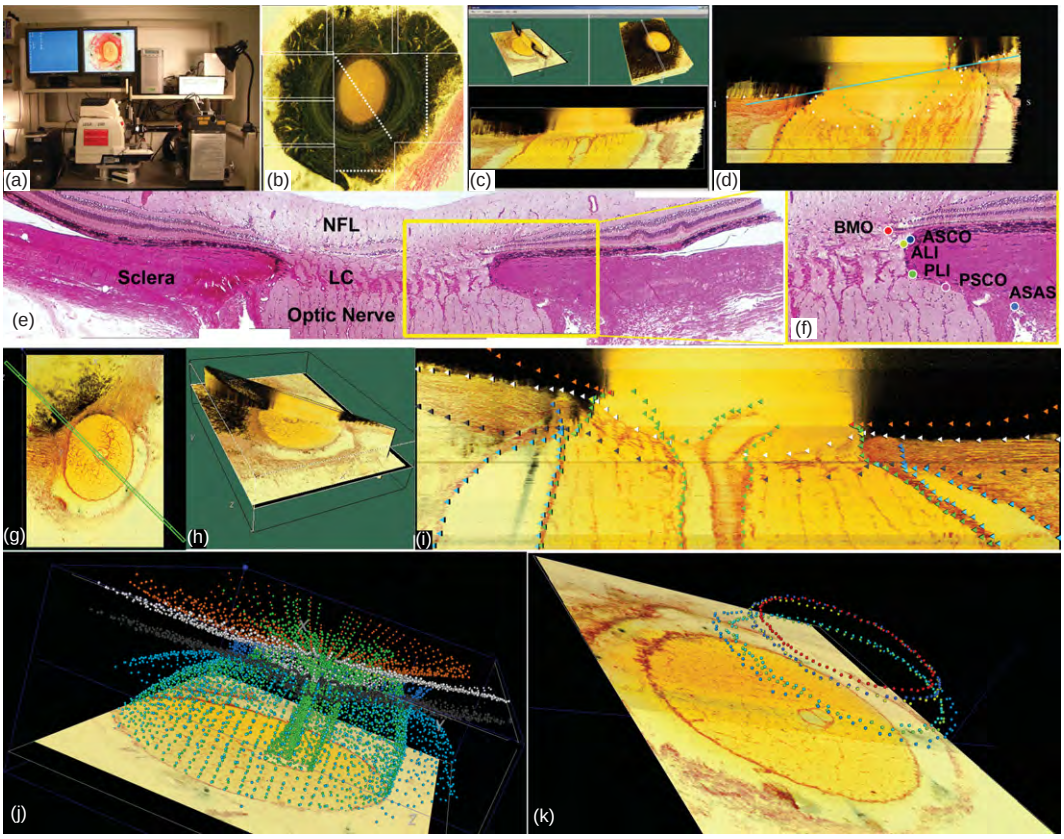

Figure 8 3D delineation of ONH and peripapillary scleral landmark points within digital 3D ONH reconstructions. (a) Photograph of our microtome-based 3D reconstruction device allows for serial sectioning and high-resolution image capture of the stained block face of embedded ONH specimens. (b) Images are acquired in a mosaic, then stitched into a composite of the entire 6-mm-diameter specimen, and stacked into a digital 3D reconstruction of the connective tissues of the ONH with 1.5 x 1.5 x 1.5 μm voxel resolution (c). Once loaded into custom software, the reconstruction can be digitally sectioned and landmarks delineated. In this view (d) our measurement reference plane, Bruch's membrane opening (BMO), is marked and shown with a light blue line. (e) Central horizontal histologic section through a representative normal monkey eye showing the ONH anatomy. (f) Magnified view of the nasal side of the neural canal showing the following landmark points: BMO (red), the anterior scleral canal opening (ASCO, dark blue), the anterior laminar insertion point (ALI, yellow), the posterior laminar insertion point (PLI, green), the posterior scleral canal opening (PSCO, pink), the anterior-most aspect of the subarachnoid space (ASAS, light blue). (g, h) With the 3D digital ONH reconstruction, a total of 40 radial, sagittal slices (each 7 voxels thick) are served to the delineator at 4.5° intervals. (i) A representative digital sagittal slice, showing the marks for seven landmark surfaces and six landmark point pairs. These features are interactively delineated within the 3D volume by viewing the position of a marking cursor displayed simultaneously within the sagittal (g) and transverse section images (h). (j) Representative 3D point cloud showing all delineated points for a normal monkey ONH in relation to the last section image of the reconstruction. (k) A subset of the 3D point cloud showing the neural canal landmarks depicted in (f).

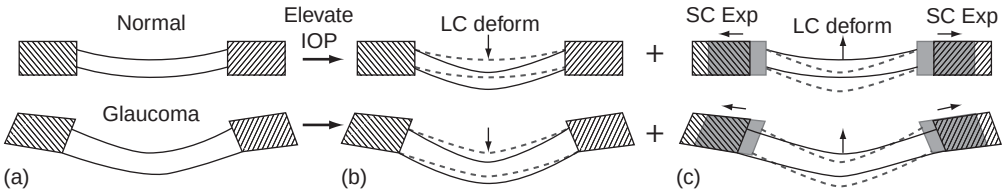

Figure 9 There are two components of acute IOP-induced ONH deformation in normal and early glaucoma eyes. (a) Sagittal section diagram of the ONH, showing the peripapillary sclera (hatched) and the lamina cribrosa for normal (upper) and early glaucoma (lower) eyes. Note that the early glaucoma eye has undergone permanent changes in ONH geometry including thickening of the lamina, posterior deformation of the lamina and peripapillary sclera, and posterior scleral canal expansion. Upon acute IOP elevation we believe two phenomena occur simultaneously and with interaction: the lamina displaces posteriorly due to the direct action of IOP (b), but much of this posterior laminar displacement is counteracted as the lamina is pulled taut by simultaneous scleral canal expansion (c). It is important to note that even though the net result of these IOP-related deformations is a small amount of posterior displacement of the lamina, substantial levels of IOP-related strain are induced in both the peripapillary sclera and lamina in this scenario.

strained. In this scenario, the expansion of the canal stretches the lamina cribrosa within the plane of the sclera generating substantial strain within the laminar beams. Estimation of laminar beam strain within these same 3D reconstructions is one of the outputs of finite element (FE) modeling, an engineering technique that is discussed in the section entitled 'Other acute, IOP-related changes in the ONH'.

The Contribution of the Sclera to ONH Biomechanics

The data described above, as well as the closed form analyses and computational models described in the next section suggest that the sclera plays an important role in ONH biomechanics. The peripapillary sclera provides the boundary conditions for the ONH. By this we mean that the peripapillary sclera is the tissue through which load and deformation are transmitted to the ONH, and that the structural stiffness of the peripapillary sclera, therefore, influences how the lamina deforms (**Figure 9**). This can be understood from the discussion above in which a compliant sclera allows the scleral canal to expand following an acute IOP elevation, tightening the laminar beams within the canal and thereby increasing laminar resistance to posterior deformation. In contrast, a rigid sclera allows less expansion of the canal or none at all, forcing the structural stiffness of the lamina alone to bear the IOP-related stress. Hence, characterization of both components of scleral structural stiffness (geometry and material properties) is essential to understanding the effects of IOP on the ONH.

Characterization of scleral geometry

Maps of the thickness variation for the posterior pole of human and monkey eyes show extreme spatial variation in scleral thickness, with very thin regions near the equator (as low as 300 μm in the human and 111 μm in the monkey). In both species the peripapillary sclera is notably thicker (1000 μm in the human and 415 μm in the monkey). Interestingly, this thick ring of peripapillary sclera is absent in the nasal quadrant of monkey eyes due to the oblique nasal insertion of the optic nerve through the scleral canal. Such variation in peripapillary scleral thickness as occurring naturally or in pathologic conditions such as myopia, may be important in assessing individual susceptibility to glaucomatous damage.

Characterization of scleral material properties

Several researchers have characterized scleral material properties in various species. Most recently, Downs and co-workers used a strain-rate controlled, servo-hydraulic materials testing system to determine the viscoelastic material properties of normal rabbit and monkey peripapillary sclera. They found that the material properties of peripapillary sclera are highly time dependent (viscoelastic), but reported no significant differences in material properties by quadrant.

However, uniaxial testing of scleral strips is limited in its ability to describe the nonlinear and anisotropic responses of the sclera (**Figure 5**), leading Girard and colleagues to develop a new 3D approach. Using a customized scleral shell pressurization apparatus, precise IOP control, and laser-based electronic speckle pattern interferometry, they measure the 3D deformation of the entire posterior scleral shell in response to small, stepped increases in IOP (from 5 to 45 mmHg). Results suggest that the monkey posterior sclera is highly nonlinear (it gets stiffer as IOP increases) and anisotropic (the underlying collagen fibril distribution is nonuniform and changes throughout the scleral shell, which affects directional stiffness) (**Figure 10**). By using an FE model backfitting method (see the following section), they have calculated the nonlinear, hyperelastic, anisotropic material properties for the entire posterior scleral shell of normal monkeys, and characterized changes in these properties due to age and stage of glaucomatous damage.

Engineering Models of Stress and Strain in the ONH and Peripapillary Sclera

Closed form solutions

Attempts to mathematically model the mechanical environment of the ONH generally fall into two broad categories – closed form solutions and numerical solutions. In closed form solutions, engineering principles are used to derive equations that can be analyzed to understand the effects of selected biological parameters. Examples of closed form approaches include work by Donqui, Edwards, and Good, and a hybrid cellular solid approach by Sander. The appeal of closed form solutions is that general conclusions may be drawn from a model cast in terms of a limited number of geometric and material parameters that are felt to be of interest or might be clinically measurable. However, closed form solutions may be of limited utility because of the complexity of the ONH and peripapillary scleral tissues (e.g., the nonuniform and asymmetric geometry and material properties). The most sophisticated of these studies suggest that the structural stiffness of the sclera is the most important determinant of macro-level ONH biomechanics.

Numerical solutions – FE analysis

To overcome the inherent limitations of closed form solutions, researchers often utilize numerical methods to study more complex biological systems. One of the most powerful of these is FE analysis. In FE analysis, complex load-bearing structures are broken into small, regularly shaped elements (**Figure 4**). Stress and strain within each element is calculated and then superposed to predict the mechanical response of the entire structure.

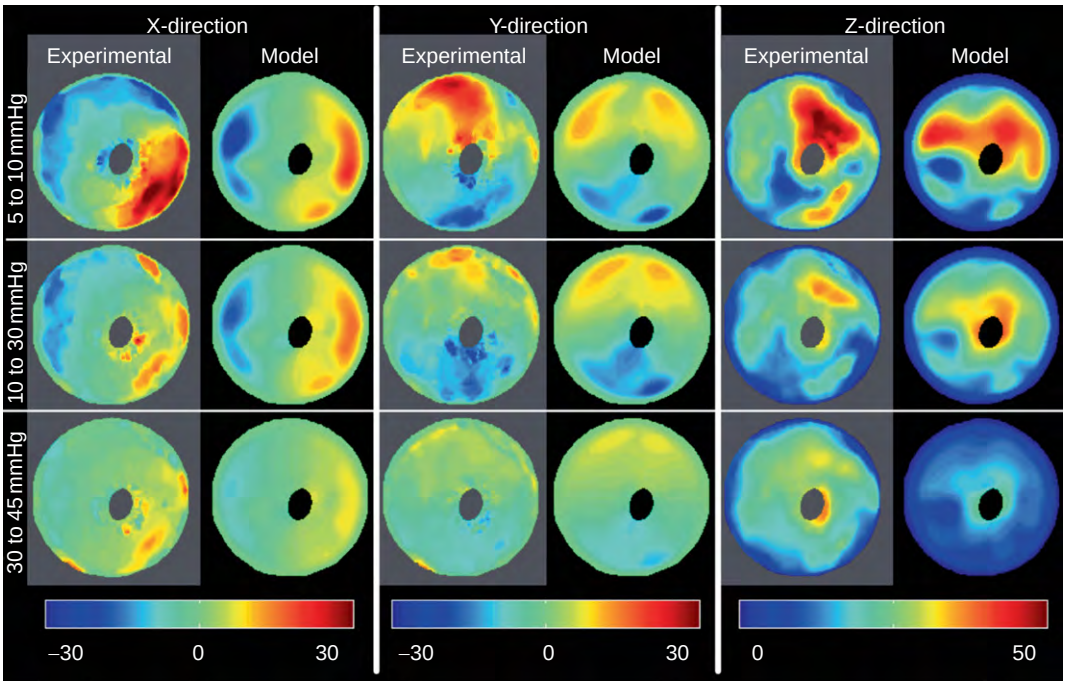

Figure 10 Experimental results and finite element (FE) model predictions of the nonlinear, anisotropic displacement behavior of an individual monkey posterior scleral shell as IOP increases from 5 to 10 mmHg (top row), 10 to 30 mmHg (middle row), and 30 to 45 mmHg (bottom row). Experimental (gray background) and predicted (model, black background) displacements for the X-direction (left-to-right), Y-direction (top-to-bottom), and Z-direction (in-and-out) are mapped onto the outer surface of the scleral shell of a right eye (for each map superior top, inferior bottom, temporal left and nasal right). The inhomogeneity of the experimental displacement patterns are indicative of underlying tissue anisotropy, and the much greater displacements seen in the 5–10 mmHg IOP elevation as compared to the 30–45 mmHg IOP elevation reflect the highly nonlinear behavior (i.e., the sclera is stiffer and therefore more resistant to deformation at higher levels of strain). Figure, including experimental and modeling results, courtesy of Michael Girard.

The power of FE analysis lies in its ability to model structures with highly complex geometries using material properties with varying levels of complexity as warranted (e.g., inhomogeneous, anisotropic, nonlinear, or viscoelastic material descriptions). The three components necessary as input for FE models are: the 3D geometry of the tissue structure to be modeled, the material properties of the different tissues in the model, and appropriate loading and boundary conditions. These requirements have spurred the development of methodologies to isolate and describe the 3D geometry of the ONH and peripapillary sclera (**Figure 8**) and experimentally characterize their constituent material properties (**Figure 10**).

There are two basic approaches to FE modeling of the ONH: parametric and individual specific. Parametric modeling involves computing stress and strain in average, idealized geometries that do not conform to any individual's particular anatomy. Within these models, parameters such as peripapillary scleral thickness and laminar stiffness can be varied independently to gauge the parameter's effects on ONH biomechanics as a whole. This is a similar approach to analytical modeling, but the analyzed geometries are much more fidelic and the results more relevant and intuitive. Although parametric FE models are by nature simplified in their geometries and there are limited cases that can be modeled, these investigations yield interesting insight into the contributions of individual anatomical elements and tissue material properties to overall ONH biomechanics.

Bellezza and colleagues used parametric FE modeling to study the mechanical environment of an idealized 3D model of the posterior pole. In this study, the effects of the size and shape (aspect ratio) of an elliptical scleral canal within a spherical scleral shell of uniform thickness were studied. Idealized beamlike structures spanning the ONH were also incorporated into the model to simulate the lamina cribrosa. This study illustrated that IOP-related stress concentrations within the load-bearing connective tissues of the ONH is substantial, even at low levels of IOP. Specifically, models with larger scleral canal diameters, more elliptical canals, and thinner sclera all showed increased stresses in the ONH and peripapillary sclera for a given level of IOP. In the peripapillary sclera and ONH, stresses were as much as one and two orders of magnitude greater than IOP, respectively. While the model used in this study was idealized in terms of its material properties and geometry, it served to reinforce the concept of the peripapillary sclera and ONH as a high stress environment even at normal levels of IOP.

Sigal and co-workers used idealized axisymmetric FE models to pursue a more complex parametric analysis of the factors that influence the biomechanical environment within the ONH (**Figure 11**). In these studies, various geometric and material details of a generic model were parametrized and independently varied to assess their impact on a host of outcome measures such as strain in the lamina cribrosa and prelaminar neural tissue (**Figure 11**). This work identified the five most important determinants of ONH biomechanics (in rank order) as: the stiffness of the sclera, the size of the eye, IOP, the stiffness of the lamina cribrosa, and the thickness of the sclera. The finding that scleral stiffness plays a key role in ONH biomechanics is especially interesting, and was also found to be important in the analytical models of Sander and co-workers. Parametric studies such as these are important because they can be used to identify important biomechanical factors that warrant more in-depth study, thus narrowing and focusing future experimental and modeling efforts.

To address the limitations of idealized geometric and material property descriptions inherent in parametric FE models, individual-specific FE models can be created from the reconstructed geometries of particular eyes. At present, individual-specific modeling is based on high-resolution 3D reconstructions of monkey and human cadaver eyes (**Figure 8**), with a long-term goal to build models based on clinical imaging of living eyes so as to use them in the assignment of target IOP. This is especially important given that the 3D geometry of the scleral canal and peripapillary sclera largely determines the stress and strain transmitted to the contained ONH (**Figure 7** notes specifically how the 3D geometry of the scleral canal and peripapillary sclera alter the stress environment). Anatomically accurate 3D models are necessary to capture the biomechanics of anisotropic scleral material properties (varying collagen fibril orientation), and scleral canals that are noncircular and have varying optic nerve insertion angles (i.e., the optic nerve inserts from the nasal side resulting in a thinner peripapillary sclera in that quadrant). When modeling an ONH with anatomic fidelity, the tissue geometries can be constructed either by serial histologic methods or by 3D imaging, and material properties are generally determined through direct mechanical testing (**Figure 10**). Unfortunately, imaging of the lamina *in vivo* is not yet possible at the resolutions required for modeling, and no technology exists for experimental biomechanical testing of laminar beams. As a result, ONH FE models are typically constructed from eyes that are perfusion or immersion fixed at a selected IOP, and then undergo *ex vivo* 3D reconstruction of their connective tissues.

Bellezza and co-workers developed a histologic technique to 3D reconstruct the trabeculated structure of the lamina cribrosa from individual monkey eyes that have been perfusion fixed at varying levels of IOP (**Figure 8**). The resulting 3D data sets form the geometries of individual-specific FE models of the ONH at the macro- and micro-scale. Roberts, Downs, and co-workers have developed macro-scale continuum FE models of the posterior pole and ONH connective tissues from individual monkey eyes (**Figure 12**). In these models, the laminar microarchitecture is modeled using a continuum approach, with anisotropic material properties assigned to each FE in the ONH based on the connective tissue volume fraction and the predominant beam orientation of the contained laminar microarchitecture (**Figure 13**). Regional variations in connective tissue volume fraction and predominant

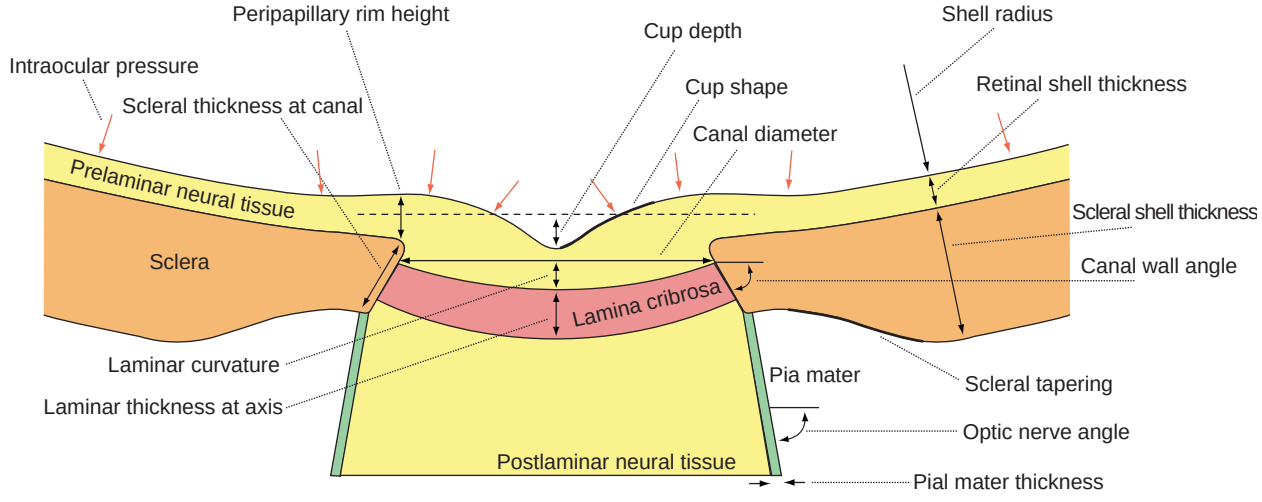

Figure 11 Parametric models can be used to study the influence of geometric and material property factors. To model the ONH, Sigal and colleagues created an idealized, axisymmetric (symmetric about the anterior-to-posterior axis) reference geometry and varied geometric and material property factors to assess their influence on various outcome measures of stress and strain within the model. This type of parametric sensitivity analysis is useful for identifying the tissues and anatomic structures that may be most important in the mechanical response of the ONH. Such information can serve to focus future biomechanics research and clinical device development efforts on the tissues and structures determined to be most important in ONH biomechanics. Figure courtesy of Ian Sigal.

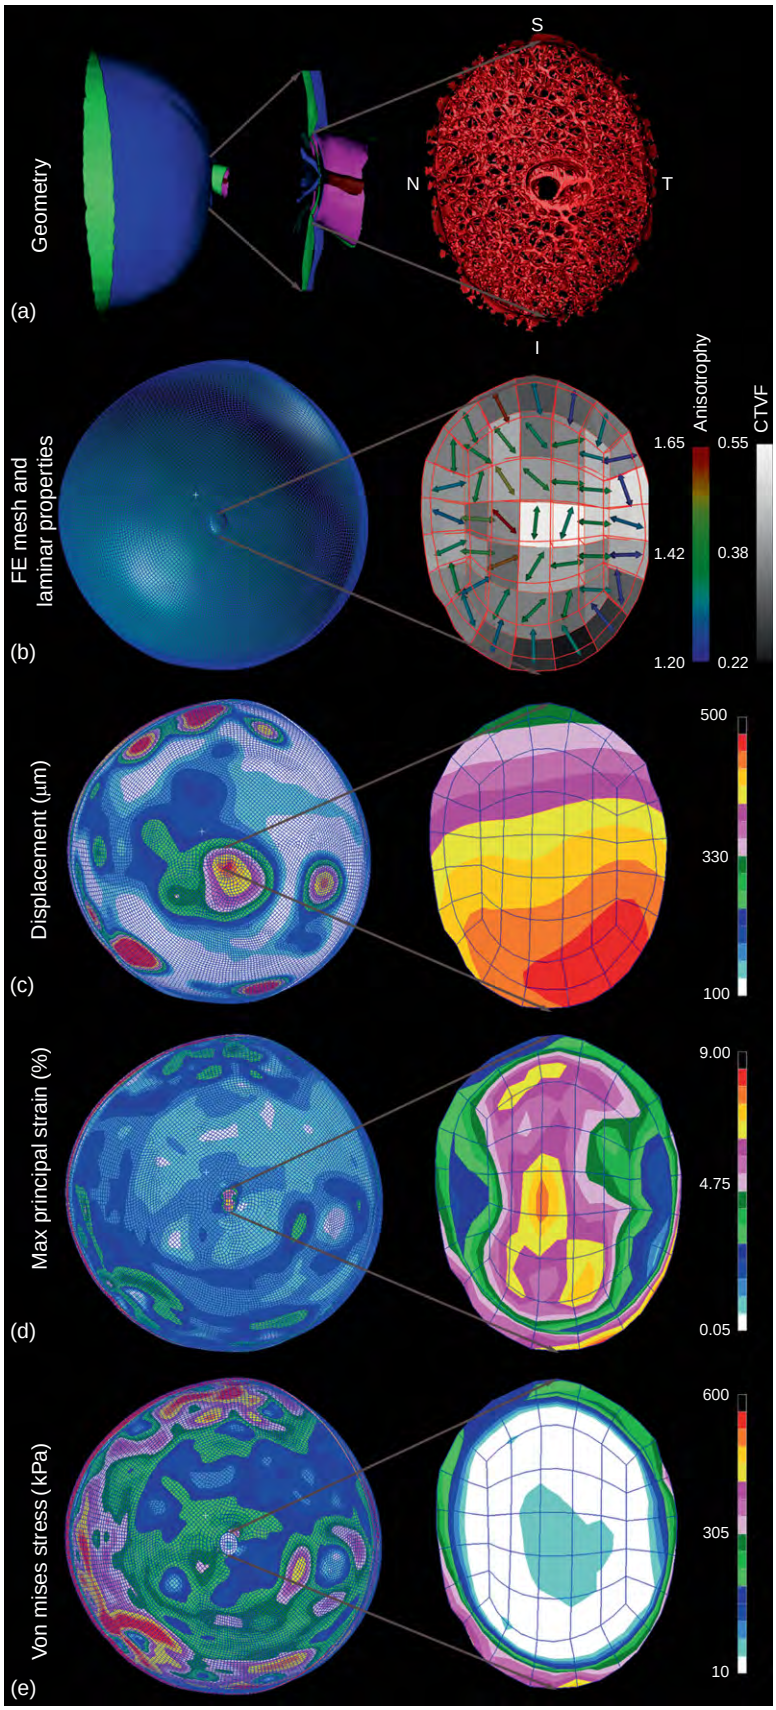

Figure 12 Construction and results from a macro-scale continuum FE model of the posterior scleral shell and ONH of a normal monkey eye. (a) To construct the model geometry, the 3D-delineated lamina cribrosa and surrounding peripapillary sclera (see **Figure 8**) of an individual eye are incorporated into a generic anatomic scleral shell with regional thickness variations mapped from previous

orientation are translated into variations in local oriented stiffness so that regions of higher and lower porosity reflect greater and lesser compliance, respectively. The inclusion of regional laminar material properties (connective tissue volume fraction and beam orientation) into FE models has a pronounced effect on the ONH's response to IOP (Figure 14). This indicates that the regional variations in laminar geometry and structural stiffness must be represented in models to fully capture the biomechanical behavior of the ONH and suggests that the lamina is biologically optimized to withstand IOP-induced deformation.

Downs and colleagues have also used the 3D reconstruction and continuum modeling approaches to characterize and explore laminar beam biomechanics. This micro-scale modeling approach utilizes a substructuring technique based on parent macro-scale FE models to calculate the IOP-related stress and strain fields in laminar beams (Figure 15). This technique reveals a complexity of IOP-related strains and stresses within the lamina cribrosa microarchitecture that is not available through macro-scale FE modeling. There have been several interesting preliminary results from this work. First, stress and strain in the laminar microarchitecture are likely higher than predicted by macro-scale models of the ONH. Second, even at normal levels of IOP, the micro-FE models predict that while the majority of laminar beams are within physiologic strain ranges, there are individual laminar beams with levels of IOP-related strain that are likely pathologic. Third, mean strain within the laminar beams of different

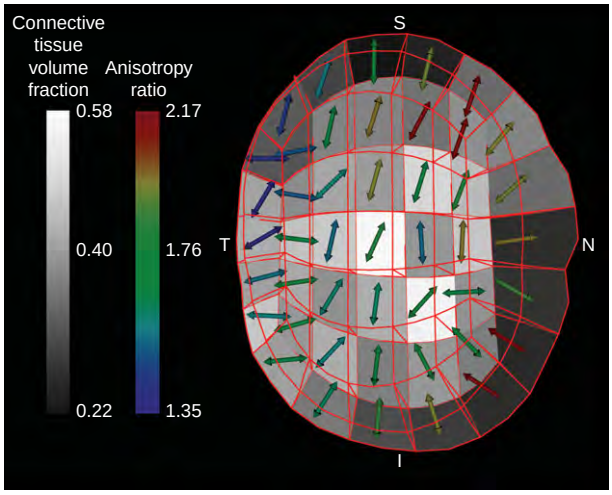

Figure 13 Regional differences in laminar microarchitecture in a normal monkey eye. Characterization of the laminar microarchitecture utilizes the element boundaries of a continuum finite mesh to partition the lamina cribrosa connective tissue into 45 subregions. The connective tissue volume fraction (CTVF) for each region is expressed as a percentage and mapped to a grayscale value in the background. The arrows indicate the predominant orientation of the laminar beams in each region, with higher values (color-coded) indicating regions in which the beams are more highly oriented. Note that in the peripheral regions of the lamina, the beams are tethered radially into the scleral canal wall.

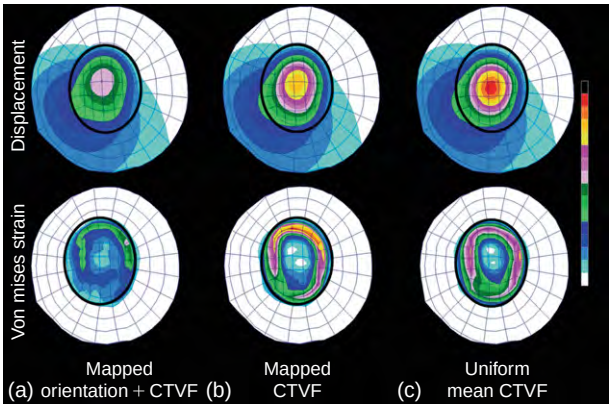

Figure 14 Incorporation of laminar beam orientation and connective tissue volume fraction into the material description of the lamina cribrosa affects the predictions of finite element (FE) models. Internal (vitreous) surface views of the displacement and strain in the ONH (within the heavy black outline) and peripapillary sclera in continuum models of the same eye following acute IOP elevation. In column (a), the stiffness of each laminar element is determined from both the predominant laminar beam orientation and connective tissue volume fraction (CTVF) of the contained lamina. In column (b) the orientation information (i.e., using an isotropic material stiffness), but retaining mapped CTVF produces a substantial increase in the displacement of the lamina with markedly higher strains. In column (c) all elements in the lamina are assigned the same isotropic material stiffness based on an average CTVF (with no beam orientation information). This model has slightly more central laminar displacement than case (b), but actually has lower strain in the superior lamina cribrosa owing to the fact that the superior elements in case (b) had lower CTVFs in that region (i.e., below the mean CTVF). These results suggest that representing regional laminar microarchitecture in FE models is essential to accurately predict ONH biomechanical behavior.

histologic measurements. The segmented 3D reconstruction of the laminar connective tissue (shown) is represented in each model. (b) A continuum FE mesh of the posterior pole is generated from the geometry. The sclera in this model is assigned uniform isotropic material properties based on previous experimental testing. The continuum elements representing the porous load-bearing laminar architecture are assigned anisotropic material properties that reflect the microstructure of the lamina enclosed by each laminar FE. This material property description is defined using a combination of the connective tissue volume fraction (CTVF) and the predominant laminar beam orientation. A visualization of the CTVF and predominant beam orientation are presented. Note that in this visualization, an anisotropy value of 1 would represent an isotropic material with no predominant orientation while larger values imply oriented laminar beams that impart higher stiffness in the direction of the plotted arrow. (c, d, e) FE results showing predicted displacement, strain, and stress distributions due to an increase in IOP from 10 to 45 mmHg. Note that in this eye, the model predicts that the ONH tilts inferiorly, the strains are highest along the superior–inferior axis of the ONH, and that the sclera bears most of the IOP-related stress.

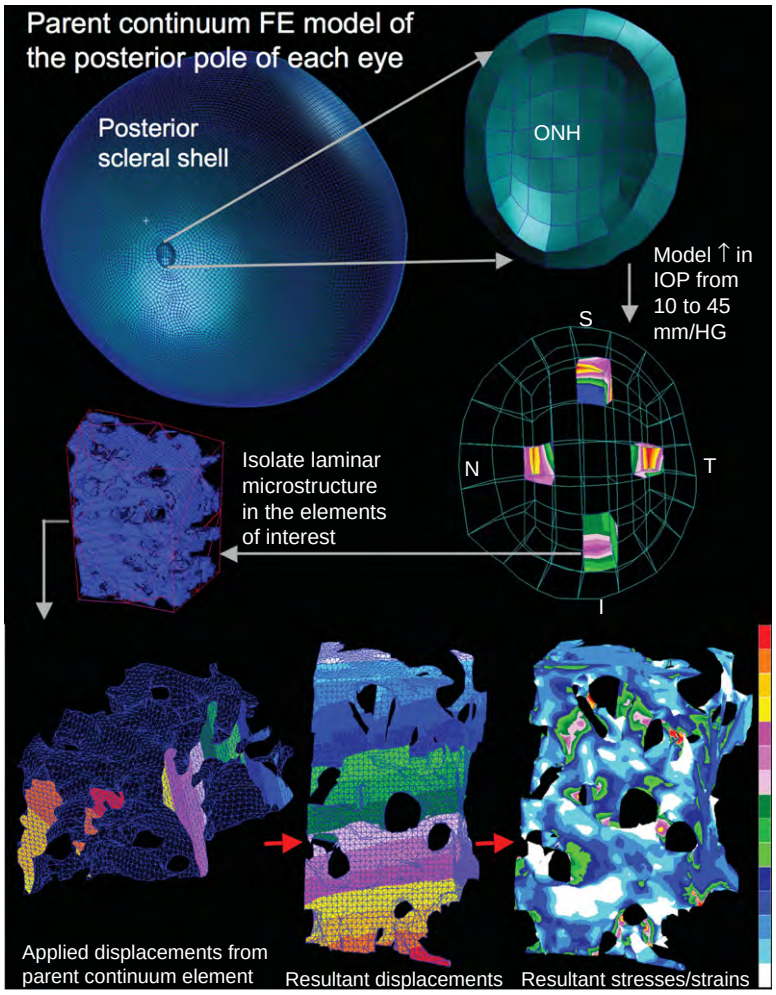

Figure 15 Construction and analysis of micro-FE models of the laminar microarchitecture of a monkey eye. The complexity of the stresses and strains at the laminar beam level is not captured in the macro-scale continuum FE models because the details of the microstructure are homogenized into a bulk material description. To address this limitation, a substructuring technique has been developed to characterize the beam-level strain environment within ONH models. The displacement field calculated from a continuum model is used along with individual element boundaries to define input loading conditions for micro-scale FE models of subregions of the 3D reconstructed lamina cribrosa. These micro-FE models illustrate that the stress and strain borne by the individual laminar beams are highly variable and complex. Modeling of individual beam mechanics will be necessary to predict the yield and failure of individual beams, model changes in blood flow in the laminar capillaries, and determine the strains to which laminar astrocyte basement membrane are subjected.

monkeys varies greatly, and is generally dependent on the 3D geometry of each eye's ONH connective tissues. Finally, strain is not equally distributed though the ONH, and are concentrated in regions with less dense laminar beams. This work, while still in its early stages, holds the possibility of testing hypotheses about failure mechanisms and cellular responses at the level of the laminar beams.

Other Acute, IOP-Related Changes in the ONH

ONH, retinal, and choroidal blood flow are all affected in different ways by acute IOP elevations. Previous studies using microspheres have suggested that volume flow within the prelaminar and anterior laminar capillary beds is preferentially diminished once ocular perfusion pressure (defined as the systolic arterial blood pressure plus one-third of the difference between systolic and diastolic pressures minus IOP) is less than 30 mmHg.

While a direct link to mechanical strain has not been established, axonal transport is compromised in the lamina cribrosa at physiologic levels of IOP and is further impaired following acute IOP elevations. Several hypotheses regarding this behavior emerge when considering ONH biomechanics. First, as the pores in the lamina cribrosa change conformation due to IOP-related mechanical strain, the path of the axons through those pores may be disrupted, thereby directly impeding axoplasmic

transport. Second, it may be that the IOP-related reduction in blood flow in the laminar region impairs the mitochondrial metabolism that drives axoplasmic transport. Finally, axoplasmic transport could be sensitive to the magnitude of the translaminar pressure gradient, and as that hydrostatic pressure gradient gets larger with increasing IOP (or lower cerebrospinal fluid pressure), the mechanisms driving that transport are unable to overcome the resistance of the pressure gradient (**Figure 7**).

In summary, while connective tissue dynamics should, by themselves, directly and indirectly influence astrocyte and glial metabolism and axonal transport, glaucomatous damage within the ONH may not necessarily occur at locations with the highest levels of IOP-related connective tissue strain, but rather at those locations where the translaminar tissue pressure gradient is greatest and/or where the axons, blood supply, and astrocytes and glia have been made most vulnerable. Further studies are necessary to elucidate the link(s) between IOP, mechanical strain, blood flow, astrocyte and glial cell homeostasis, and axoplasmic transport in the ONH, in both the physiologic and diseased states.

Restructuring and Remodeling of the ONH

Normal Aging

The ONH connective tissues are exposed to substantial levels of IOP-related stress and strain at normal levels of IOP (**Figure7**). We believe that physiologic levels of stress and strain experienced over a lifetime induce a broad spectrum of changes in both the connective tissues and vasculature that are central to normal aging. Thus, the restructuring and remodeling of glaucomatous damage (described in the following sections) should be understood to occur in the setting of the physiologic restructuring and remodeling inherent in normal aging.

Age-related alterations of the laminar ECM have been reported to include increased collagen deposition, thickening of astrocyte basement membranes, and increased rigidity of the lamina and sclera. Girard and colleagues have recently shown that the sclera in old monkeys is approximately twice as stiff than sclera from young monkeys at all IOPs. The aged ONH is thus more likely to have stiff connective tissues. Age-related hardening of the laminar ECM not only stiffens the connective tissues, it should also diminish nutrient diffusion from the laminar capillaries through the laminar ECM, across the astrocyte basement membranes, and into the adjacent axons (**Figure 1**). Thus, in addition to the effects of age-related decreases in the volume flow within the laminar capillaries, axonal nutrition in the aged eye may be further impaired as a result of diminished nutrient diffusion from the laminar capillaries to the center of the axon bundles.

Alterations in Connective Tissue Architecture, Cellular Activity, Axoplasmic Transport, and Blood Flow in Early Glaucoma

Pathophysiologic stress and strain induce pathologic changes in cell synthesis and tissue microarchitecture that exceed the effects of aging and underlie the two governing pathophysiologies in glaucoma: (1) mechanical yield and/or failure of the load-bearing connective tissues of the ONH (**Figures 2** and **16**) and (2) progressive damage to the adjacent axons by a variety of mechanisms (**Figure 2**).

Early glaucomatous damage has not been rigorously studied in humans because human cadaver eyes with well-characterized early damage are rare. In monkeys, following moderate experimental IOP elevations, we have described the following changes in ONH and peripapillary scleral connective tissue architecture and material properties at the onset of confocal scanning laser tomography-detected ONH surface change (clinical cupping): (1) enlargement and elongation of the neural canal (**Figure 17**); (2) posterior deformation and thickening of the lamina cribrosa accompanied by mild posterior deformation of the scleral flange and peripapillary sclera (**Figure 18**); (3) hypercompliance of the lamina in some cases; and (4) alteration in the viscoelastic material properties of the peripapillary sclera. These findings are accompanied by prelaminar neural tissue thickening and are summarized in **Figure 19**.

Roberts and coworkers have shown that in the monkey model of early experimental glaucoma, the volume of the laminar connective tissues is approximately 80% larger in the glaucoma eyes compared to their contralateral controls. The most surprising result of that work is the nature of that addition of laminar volume. Their results suggest that the connective tissues in glaucomatous eyes remodel in a way that the immediate retrolaminar septa add connective tissue and are recruited into the 3D load-bearing structure of the lamina.

The increase in laminar thickness in these early glaucoma monkey eyes is likely a combination of axonal swelling, tissue edema, gliosis, connective tissue remodeling, and new connective tissue synthesis. Preliminary quantification of the amount of connective tissue within our 3D reconstructions of the lamina suggests an increase in connective tissue volume of 50–100% in early glaucoma (**Figure 20**). These data strongly support the notion that connective tissue remodeling, and new connective tissue synthesis, are present at this early stage of the neuropathy.

Alterations in cellular activity, axoplasmic transport and blood flow in early glaucoma have not been rigorously studied. However, in a recent study in rat eyes (which has a very minimal lamina cribrosa), Johnson and colleagues used genomic techniques to characterize the alterations in the genome of ONH tissues following 5 weeks exposure to experimental elevated IOP. Within

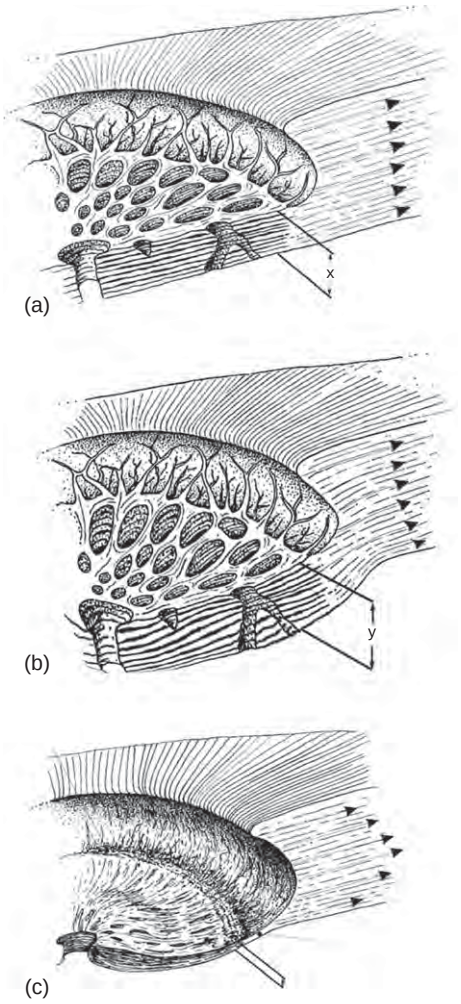

Figure 16 Progression of connective tissue morphology from normal health to early glaucoma to end-stage glaucoma. (a) Diagram of normal ONH connective tissue showing the thickness of the lamina cribrosa (x) and the in-wall hoop stress generated by IOP in the peripapillary sclera. (b) In early experimental glaucoma, our data to date suggests that rather than catastrophic failure of the laminar beams, there is permanent posterior deformation and thickening (y) of the lamina which occurs in the setting of permanent expansion of the posterior scleral canal. These changes indicate that a combination of mechanical yield and subsequent remodeling of the connective tissues occur very early in glaucoma that is not yet accompanied by physical disruption of the beams or frank excavation. (c) As the disease progresses to end-stage damage, we believe that the anterior laminar beams eventually fail, the lamina compresses (z) and scars, the laminar insertion into the sclera displaces posteriorly, and the scleral canal enlarges to the typical cupped and excavated morphology. Very little is known about the biomechanics, cellular processes, and remodeling that drives the morphological progression from the earliest detectable stage of glaucoma to end-stage damage, but it is likely that these processes continue to be driven by the distribution of IOP-related stress and strain within the connective tissues either primarily or through their effects on the capillaries contained within the laminar beams and the adjacent astrocytes. Modified from Burgoyne, C. F. and Downs, J. C. (2008). Premise and prediction – how optic nerve head biomechanics underlies the susceptibility and clinical behavior of the aged optic nerve head. *Journal of Glaucoma* 17(8): 318–328.

the large group of animals studied, a subset of eyes had an early focal stage of orbital optic nerve axon loss. Within these animals, expression of genes governing initiation of cell division was maximally elevated (compared to later stages of damage) as well as the genes for several ECM components including fibulin 2, tenascin C, and the matrix metalloproteinase inhibitor TIMP-1. While gene expression for transforming growth factor (TGFβ1) increased linearly with severity of damage in all studied eyes, gene expression for TGFβ2 was lowest in the focally damaged eyes suggesting differential expression of TGFβ isoforms at this early stage of the neuropathy. Similar to TGFβ2, gene expression for the principal water channel protein in astrocytes, aquaporin-4, demonstrated the largest degree of downregulation in focal damage. Most importantly, Johnson and co-workers characterized gene expression patterns in a group of 2-week optic nerve transection eyes and found a pattern of expression similar to the most severely damaged high IOP eyes, suggesting that the changes in gene expression in the focal group were likely IOP-related, not simply a reflection of early axonal loss.

Alterations in Connective Tissue Architecture, Cellular Activity, Axoplasmic Transport, and Blood Flow in Later Stages of Glaucomatous Damage

The classic descriptions of profound laminar deformation, excavation of the scleral canal beneath the optic disk margin, compression, and increased rigidity of the lamina are largely based upon human and monkey eyes with moderate, severe, and end-stage glaucomatous damage. Because these studies describe a broad range of damage that has occurred in response to an IOP insult that is uncharacterized in magnitude and duration, a common description of events has yet to emerge. However, astrocyte basement membrane disruption and thickening as well as damage to elastin, physical disruption of the laminar beams, and remodeling of the ECM are consistent phenomenon within these reports. It is assumed that IOP-induced alterations in the synthetic activities of the cells associated with these tissues underlie these changes.

Within the more severely damaged eyes in Johnson's study (above), expression of genes governing initiation of cell division was also elevated (compared to normals) but to a lesser degree than in eyes with focal damage. Genes associated with activation of microglia, immune response, ribosomes, and lysosomes were all linearly elevated in the more severely damaged eyes. Genes for the ECM components including fibulin 2, tenascin C, and the matrix metalloproteinase inhibitor TIMP-1 were elevated nonlinearly (most elevated in early damage, elevated less in more severe), whereas genes for periostin, collagen IV,

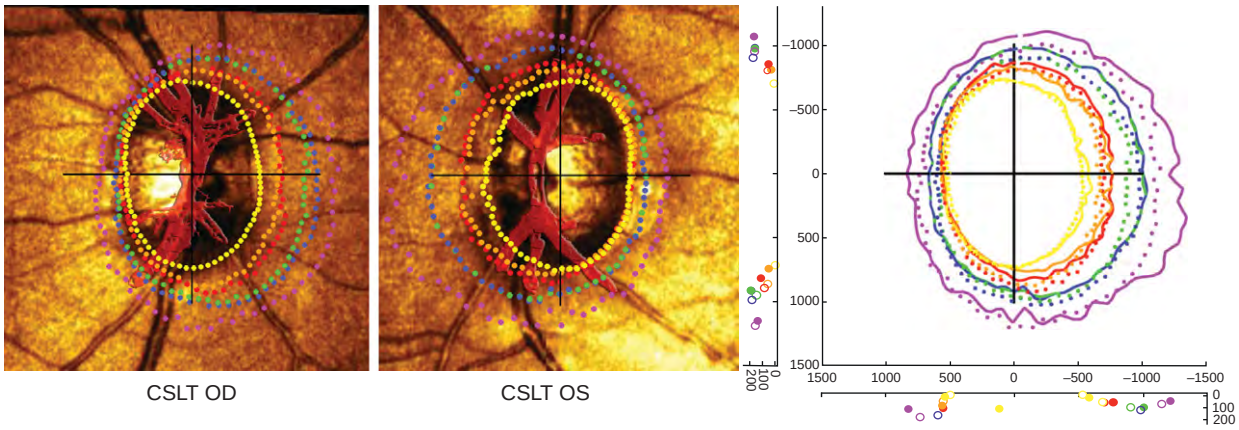

Figure 17 (left and middle) Our method of 3D reconstruction and delineation (**Figure 8**) includes the central retinal vessels, which allows clinical alignment of the delineated point clouds to clinical images and demonstrates the anatomic expansion of the neural canal under the clinically visible disc margin. Here just the Neural Canal landmark points are three-dimensionally overlaid onto Heidelberg Retinal Tomograph images of the normal (OD, left) and early experimental glaucoma (OS, middle) eye of a monkey. Note that the clinically visible disk margin in these eyes has been histomorphometrically determined to be BMO (yellow dots) in both eyes. Note also that the neural canal is not the size of the clinical visible disk margin, but rather it enlarges dramatically as it passes through the sclera. Because the data are digital, the left eye data can be converted to right eye orientation and overlaid onto the right eye data as shown in (right). Here the early glaucoma (solid line) and normal (dotted line) eye data can be directly compared. Note that expansion of the neural canal is present at the onset of early glaucomatous damage in the monkey eye and is greatest in the posterior aspects of the canal.

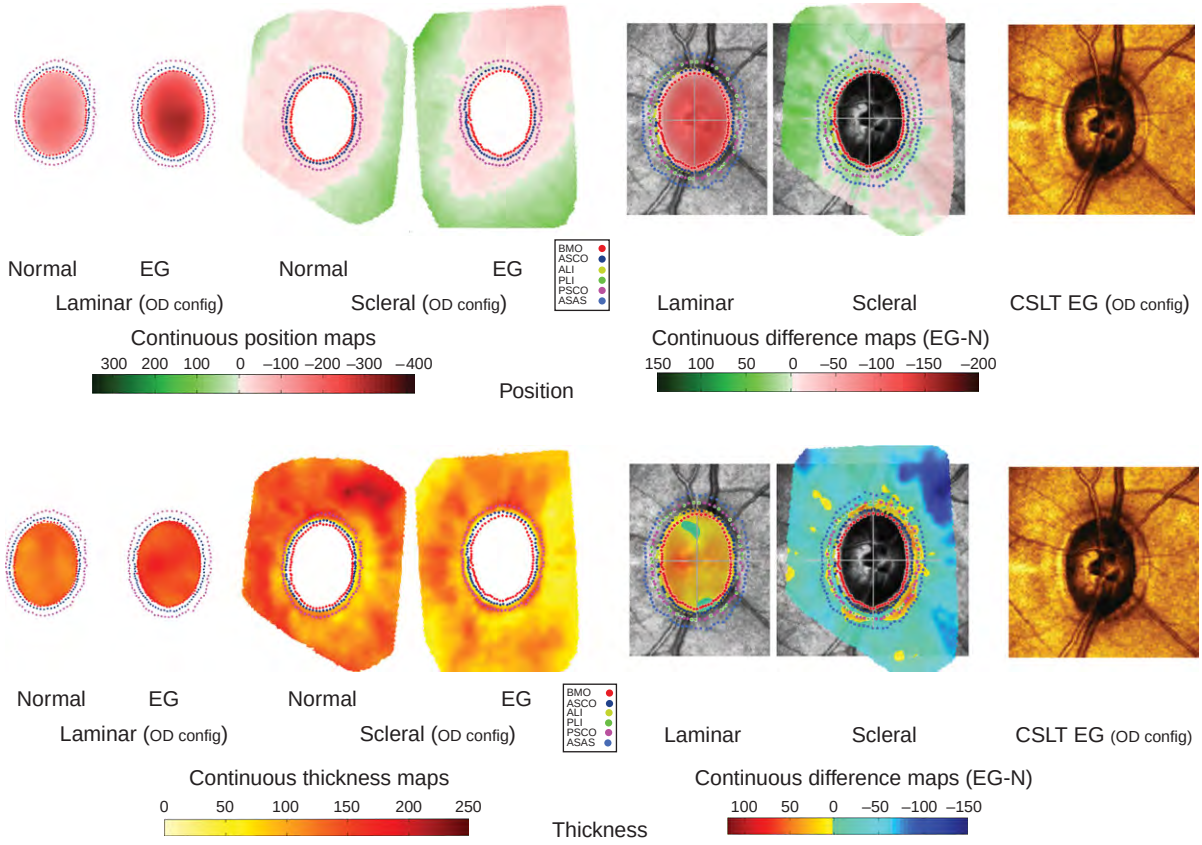

Figure 18 3D histomorphometric maps of laminar and peripapillary scleral position and thickness demonstrate profound permanent posterior deformation of the lamina cribrosa and peripapillary sclera and thickening of the lamina cribrosa in the early glaucoma eye of one monkey. Laminar and peripapillary scleral position (above) and thickness (below) are co-localized with the neural canal landmark points for both the normal and early glaucoma eyes of one monkey (left four columns). Early glaucoma eye difference maps for each parameter are shown in the first two columns to the right, followed by a Confocal Scanning Laser Tomograph image of the early glaucoma eye prior to sacrifice for orientation. These maps are typical for early glaucomatous changes in the monkey eye and demonstrate the permanent posterior deformation of the lamina and immediate peripapillary sclera, as well as the marked thickening of the lamina in the glaucoma eye compared to its contralateral control.

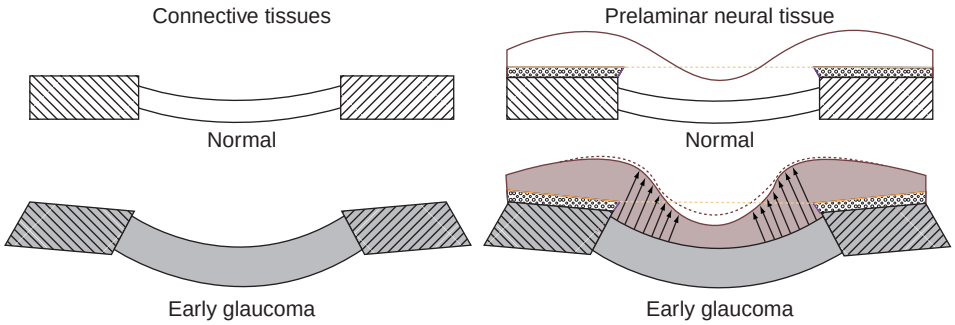

Figure 19 Remodeling and restructuring of the ONH in early experimental glaucoma. Sagittal section diagrams of the ONH, showing the peripapillary sclera (hatched) and the lamina cribrosa for normal and early glaucoma eyes. (left) The early glaucoma eye has undergone permanent changes in ONH geometry, including thickening of the lamina, posterior deformation of the lamina and peripapillary sclera, and posterior scleral canal expansion. (Right) Recent work has also shown that although the cup deepens relative to Bruch's membrane opening (dotted orange line) as can be detected by longitudinal confocal scanning laser tomography imaging (orange line) in early glaucoma, the prelaminar neural tissues (gray) are actually thickened rather than thinned. Reprinted with permission from Hongli Yang.

and collagen VI were elevated linearly. Differential gene expression for TGFβ1 and TGFβ2, as well as nonlinear expression of aquaporin are described above.

Axoplasmic transport alterations at the lamina cribrosa and a complicated array of ONH, retinal and choroidal blood flow alterations have been described following chronic IOP elevation in monkey and human eyes. However, direct observation of ONH blood flow at the level of the peripapillary sclera and lamina cribrosa capillaries is not yet possible either experimentally or clinically. We thus lack the ability to study primary interactions between IOP and non-IOP-induced alterations in ONH blood flow, ONH connective tissue integrity, ONH glial cell activity, and RGC axonal transport within individual human and animal eyes.

Integrins are mechanotransduction proteins that span the laminar astrocyte and capillary endothelial cell basement membranes to bind to ligands in the ECM and interact with the cell cytoskeleton. Morrison has described the location and alteration of integrin subunits in normal and glaucomatous human and monkey eyes and proposed them as an important link between laminar deformation and damage, laminar connective tissue remodeling, and laminar astrocyte mediated axonal insult in glaucoma.

Biomechanical Manipulation of ONH and Peripapillary Scleral Cells in Culture

Laminar astrocytes have been shown to respond to changes in hydrostatic or barometric pressure. However, the uncertain role of hypoxia and lack of astrocyte basement membrane deformation in the barometric pressure model has led to genomic and biochemical characterization of ONH astrocytes exposed to controlled levels of strain. At present, these strain-based techniques are in their infancy and a consistent stimulation cycle and pattern of gene and protein expression has yet to emerge. Eventually, strain predictions from FE models and data on IOP fluctuation from telemetric IOP monitoring studies will allow these experiments to more closely model physiologic/pathophysiologic conditions in the normal and glaucomatous human and animal eye.

Future Directions

Clinical Implications

There are currently no science-based tools to predict at what level of IOP an individual ONH will be damaged. As described herein, FE modeling is a computational tool for predicting how a biological tissue of complicated geometry and material properties will behave under varying levels of load. The goal of basic research FE modeling in monkey and human cadaver eyes is to learn what aspects of ONH neural, vascular, and connective tissue architecture are most important to the ability of a given ONH to maintain structural integrity, nutritional and oxygen supply, and axoplasmic transport at physiologic and nonphysiologic levels of IOP. In the future, clinical imaging of the ONH will seek to capture the architecture of these structures so as to allow clinically derived biomechanical models of individual patient ONHs to make predictions regarding physiologic and pathophysiologic levels of IOP. Eventually knowing the relationship between IOP, mechanical strain, systemic blood pressure, and the resultant astrocyte and axonal mitochondrial oxygen levels will drive the clinical assessment of safe target IOP. Clinical characterization of the actual IOP insult through telemetric IOP monitoring will eventually allow better-controlled studies of ONH directed neuroprotection. Finally, these FE modeling-driven targets for deep (subsurface) ONH imaging will likely allow early detection of lamina cribrosa deformation and thickening. Once clinically

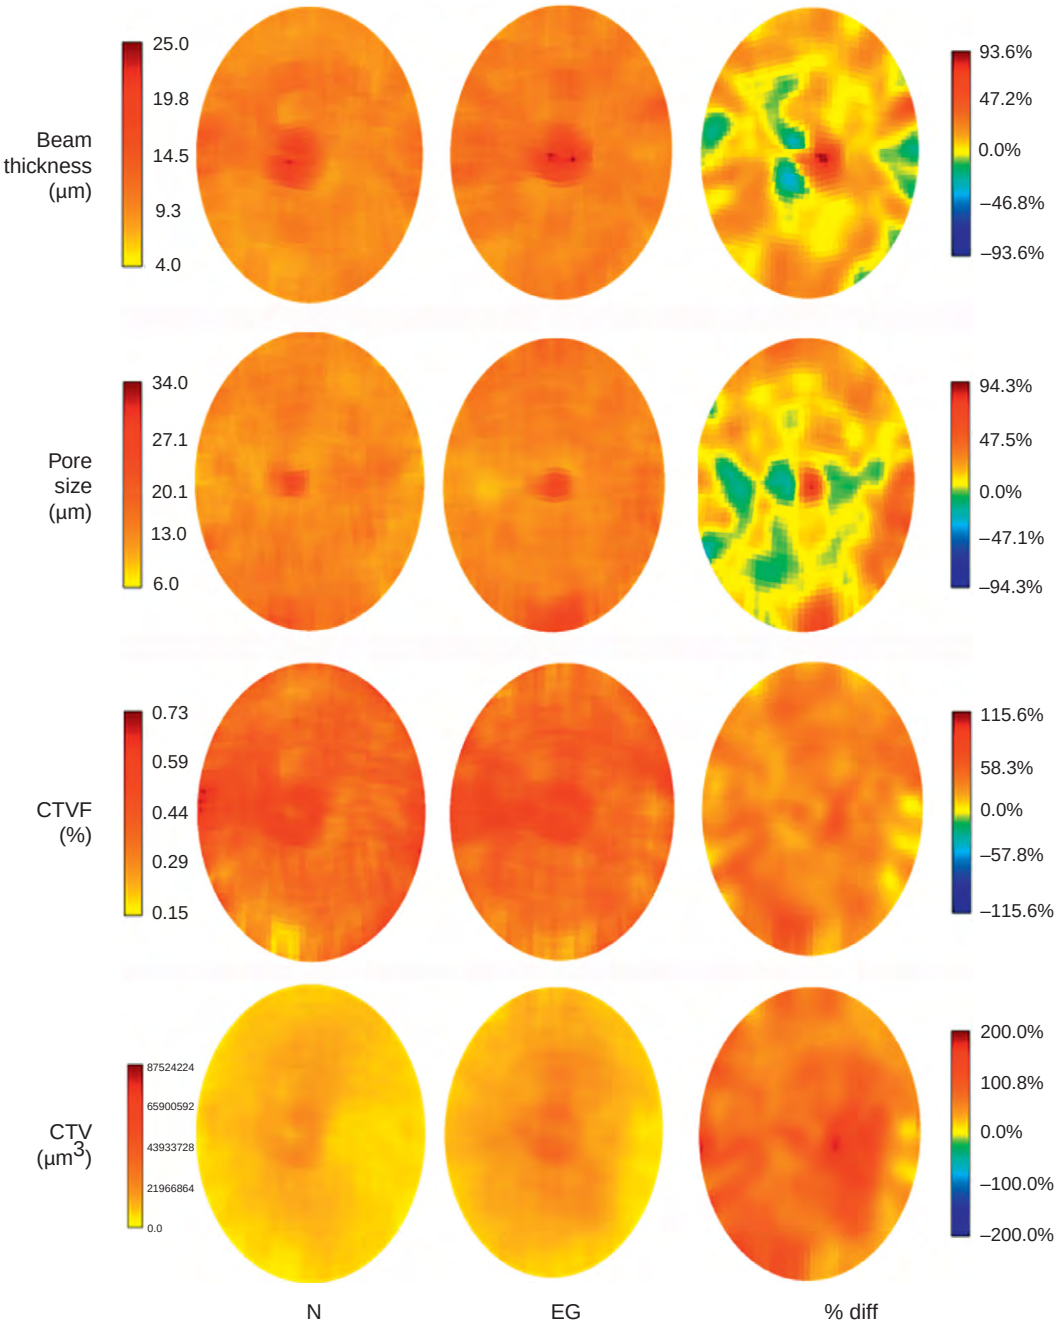

Figure 20 3D histomorphometric maps of laminar microarchitecture in paired and normal and early glaucoma eyes for three monkeys (left and center). Maps of laminar beam thickness, pore size, connective tissue volume fraction (CTVF), and connective tissue volume (CTV) for contralateral normal and early glaucoma eyes of a monkey derived from the same 3D reconstruction technique described in Figure 8. (Right) The differences between the normal and early glaucoma eyes for each parameter are mapped as a percentage. Note that CTVF is ratio of laminar connective tissue volume to total tissue volume in each regional sample. In early glaucoma, the CTVF and total laminar connective tissue volume increase significantly in all regions, and laminar beam thickness and pore size increase in most regions but decrease in others. These results together indicate that the increase in laminar thickness described in Figure 18 in early experimental glaucoma, is due not just to axonal swelling or tissue edema, but also contains a very substantial component of laminar connective tissue synthesis.

detectable, early stabilization, and perhaps reversal, of these laminar changes will become a new end point for target IOP lowering in most ocular hypertensive and all progressing eyes.

Basic Research Directions

From an engineering standpoint, large challenges remain to achieve basic and clinical knowledge regarding: (1) the mechanisms and distributions of IOP-related yield and

failure in the laminar beams and peripapillary sclera; (2) the mechanobiology of the astrocytes, scleral fibroblasts, and lamina cribrosa, and glial cells; (3) the mechanobiology of axoplasmic flow and within the lamina cribrosa; (4) the fluid dynamics governing the volume flow of blood within the laminar capillaries and scleral and laminar branches of the posterior ciliary arteries; and (5) nutrient diffusion to the astrocytes in young and aged eyes. We predict that knowledge gained from these studies will importantly contribute to new therapeutic interventions aimed at the ONH and peripapillary sclera of glaucomatous eyes.

Blinking Mechanisms

C W McMonnies, University of New South Wales, Kensington, NSW, Australia

Glossary

Blepharospasm – The eye closure due to an uncontrolled contraction of the orbicularis muscle.
Goblet cell – A mucus-secreting epithelial cell found in the conjunctiva.
Levator palpebrae superioris – An eye opening muscle of the upper lid.
Meibomian glands – The specialist sebaceous glands opening onto the lid margin, and producing an oily sebum that reduces tear evaporation.
Orbicularis muscle – An eye-closing sphincter-like sheet of muscle of the lids that encircles the palpebral fissure.
Punctate keratopathy – The fine gray-white microdot opacities of the corneal epithelium that may require disclosure with sodium fluorescein stain and ultraviolet light examination.
Tear meniscus: lacrimal rivus – The concave strip of tears at the junction of the lid margin and ocular surface.

A blink is a brief eye closure, normally involving contraction of the palpebral portion of the orbicularis muscle in the closing phase, and the levator palpebral superioris in the opening phase. Most blinks are regular and spontaneous, occurring without any apparent external stimulation. However, spontaneous blinks may be spontaneous only in the sense that the stimulus is not readily apparent. For example, any sensation of tear evaporation from the corneal surface, or the associated loss of temperature, may be a stimulus for apparently spontaneous blinks. Strong, reflex, and most voluntary blinks involve the additional contraction of the orbital portion of the orbicularis muscle. The average time for a blink is about 0.25 s, with the closure phase about twice as fast as the opening phase. Blink velocity varies between individuals and for the same individual, depending on the type of blink. Reflex blinks take less time with, again, closure being much faster than opening. Reflex blinks may occur defensively when the eyes are exposed to real or perceived risk of injury. Strong lights, the sudden approach of an object toward the eyes, and loud noises are common stimuli for reflex blinks. For example, reflex blinks are a response to the irritation caused by a foreign body and, together with reflex lacrimation, will help to displace the irritant particles toward the nasal canthus. Blepharospasm involves strong eye closure, with the action of the orbicularis muscle being supplemented by the muscles of the eyebrow. Blepharospasm can accompany anterior segment diseases, especially those involving the cornea and pain sensations. Repetitive nonrhythmic involuntary blinks can occur as a tic or as a compulsive behavior in an obsessive compulsive disorder. A similar involuntary series of blinks can become an affectation that, for example, accompanies an attentive listening pose, or as part of an assumed pose of concern. High-speed recordings of the blink mechanism were developed by Marshal Doane, PhD, Schepens Eye Research Institute, Boston, MA. They show how the upper lid action is like a windshield wiper. However, the lower lid can be seen to make a horizontal movement of 2–5 mm toward the nose. In the case of a complete blink, and full contact of the lid margins, the lower lid tends to carry the top lid nasally. Doane's recordings show that there is no Bell's phenomenon (upward eye rotation) with normal blinks, only with forced blinks.

Inter- and Intrasubject Variations in Blink Rate

A review of studies that examined blink rates in human subjects indicated a range of mean blink rates between 10 and 22 blinks per minute. Apart from differences in the criteria used to select subjects for inclusion in these studies, the disparities between them demonstrate how blink rate is also dependent on varying experimental conditions for measurement. The nature of the visual task involved is a major factor. For example, blink rate during computer use was found to be four blinks per minute, only 20% of the rate recorded for the same subjects during a period of general conversation. Another group was found to record an average of eight blinks per minute while reading and 21 blinks per minute while engaged in general conversation. Blink rate has been found to reduce significantly as task difficulty increased from watching a film, to reading, and to counting the number of times the letter a appeared in a sample of reading material. These results are consistent with the finding that there is a tendency for nonblink periods to be sustained, until difficult target recognition tasks are completed. The results support the presence of a mechanism for inhibiting spontaneous blinks. The precentral gyrus appears to be responsible for both voluntary and inhibited blinking, but the parietal area appears to be exclusively related to blink inhibition. However, apart

from intrasubject blink rate variation, according to visual task demands, for example, there is also a large range of intersubject blink rate variation. For the same experimental conditions of watching an educational film, the blink rate for 20 subjects varied between 6 and 30 blinks per minute. Ambient humidity, air quality, presence of draughts, visual fatigue, general fatigue, interest in the film's subject matter, and many other factors, may contribute to variations in blink rate.

Benefits of Complete Blinks

The blinking mechanism makes a crucial contribution to the health of the ocular surface and to many eye and vision functions. Mechanical protection is provided for the delicate eye tissues, for example, when the lids close rapidly and repeatedly in response to a gust of wind and dust foreign bodies. Blinking is also a protective mechanism for the cornea and conjunctiva, by serving to maintain a tear layer over the ocular surface. The tear layer is necessary for epithelial health and optical performance. Complete blinks help to maintain a clean and wet anterior surface. These blinks cause debris to be swept into the inferior marginal tear strip, allowing a cleaner tear layer to be distributed as the upper lid ascends. Complete blinks maximize the extent of distribution of tarsal goblet cell mucin. The normal apposition of the lids during a complete blink is a means of promoting lipid secretion from meibomian glands. Forceful blinking can significantly increase lipid-layer thickness, provided the meibomian glands have adequate reservoirs of secretion, and the gland orifices are not blocked with clusters of keratotic cells. The lipid layer is spread across the cornea by the upper lid and incomplete blinking, or a reduced blink rate, may be associated with poor maintenance of lipid-layer integrity. For example, during prolonged reading, when blink rate is significantly reduced, the lipid layer can disappear and then reappear with conscious blinking. Apart from a critical multifaceted role in maintaining tear function and ocular surface health, efficient complete blinks also contribute to the comfort and vision performance of contact lenses.

Consequences of Incomplete Blinking

For a sample of normal subjects, under experimental conditions of watching an educational film, incomplete blinks were found, on average, to represent 10% of the total number. In another group of normal subjects, the rate of incomplete blinking for an unspecified vision task was 20% of the total. Apart from variations in experimental methods and sampling, the frequency of incomplete blinks will depend on the criteria for distinguishing between normal and incomplete blinks. For example, high-speed records of blinking performance indicate that most blinks are not fully complete, in the sense of full apposition of top and bottom lid margins at the point of maximum closure. However, the distinction between incomplete, partial, and twitch blinks does not appear to have been specified. Incomplete blinks appear to have occurred immediately prior to the photographs shown in **Figures 1(a)–1(c)** and **2(b)**. However, as is the case for overall blink rate, incomplete blink rates may vary widely between individuals. Incomplete blink rates may also vary for the same individual according to the ambient conditions and the state of fatigue and/or mental alertness, for instance, as well as the difficulty of the vision task involved. An incomplete blink may be the result of partial or unsuccessful inhibition of a spontaneous blink. Thus, visually and/or intellectually demanding tasks may be associated with higher-than-normal rates of incomplete blinking as well as reduced rates of all types of blinking. Fluorophotometry assessment shows that, following complete closure with a normal blink, tear layer thickness reduces over the inferior cornea. This phenomenon appears to be due to the spreading of tears as the top lid rises.

Evaporation can also substantially reduce tear film thickness, especially over the exposed (inferior) cornea. (**Figures 1(a)–1(b)** and **2(b)**). Evaporation is associated with long interblink intervals as well as incomplete blinking. Significant tear evaporation and breakup problems appear to be more likely to occur in regions of a deficient lipid layer. Close apposition of the lid margins during a complete blink may involve the combination of the tear meniscus of the upper and lower lids, providing a larger volume of tears for distribution over the cornea by the ascending upper lid. In contrast, an incomplete blink is only able to redistribute the tears of the upper lid tear meniscus and the superior cornea during the upper lid ascending phase. The bands of thinned tear layer, evident in **Figures 1(a)–1(b)** and **2(b)**, appear to have been created as the upper lid tear meniscus reforms during an incomplete blink. Assuming that the concave tear meniscus at the margin of the upper lid is deformed by any tears collected and pushed downward during the blink descending phase, reformation of the concave meniscus appears to draw fluid upward as the blink ascending phase commences. Thus, tear thinning inferiorly may sometimes be a consequence of an incomplete blink sequence. Loss of tear layer thickness inferiorly, possibly to critical levels, also appears to be at least partly due to longer evaporative interblink periods for the inferior cornea which are associated with an incomplete blink. In the case of a blink rate of $12\,\text{min}^{-1}$, (average interblink interval of 5 s) an incomplete blink creates an interblink interval of approximately 10 s for the corneal, conjunctival, and/or contact lens surface areas, which are exposed by the lack of

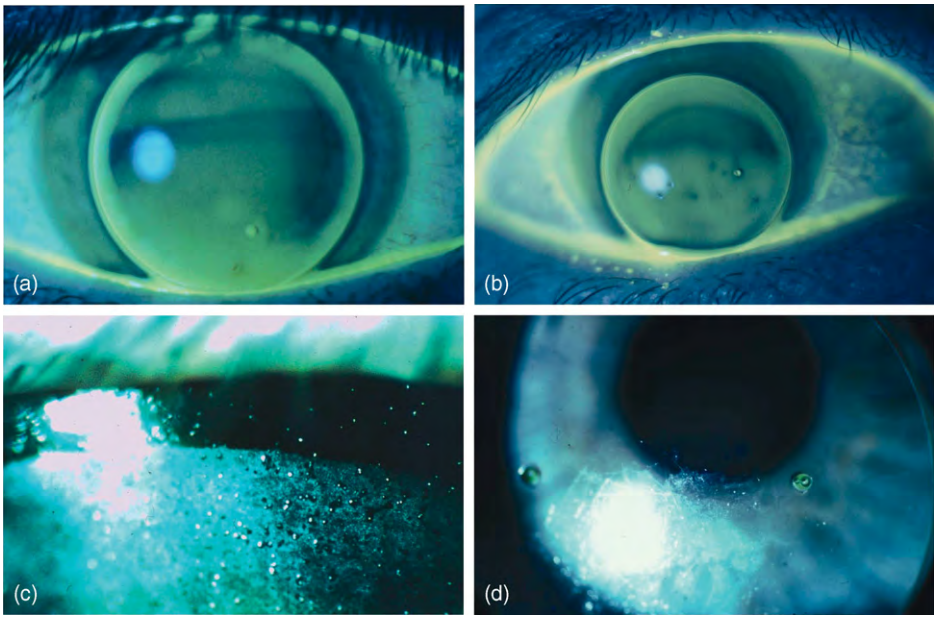

Figure 1 Reading clockwise from top left: (a) Top left: The band of thinned tear layer provides evidence of an incomplete blink prior to this photograph. (b) Top right: Downward lens displacement and tear breakup on the inferior lens surface following an incomplete blink. (c) Bottom right: An incomplete twitch blink appears to have occurred prior to this photograph of a rapidly drying lens surface.(d) Bottom left: Deposits that are restricted to the inferior contact lens surface on nonrotating (e.g., prism ballast) lenses appear to be due to incomplete blink habits. Reproduced from McMonnies, C. W. (2007). Incomplete blinking: Exposure keratopathy, lid wiper epitheliopathy, dry eye, refractive surgery, and dry contact lenses. *Contact Lens and Anterior Eye* 30: 37–51, with permission from the British Contact Lens Association.

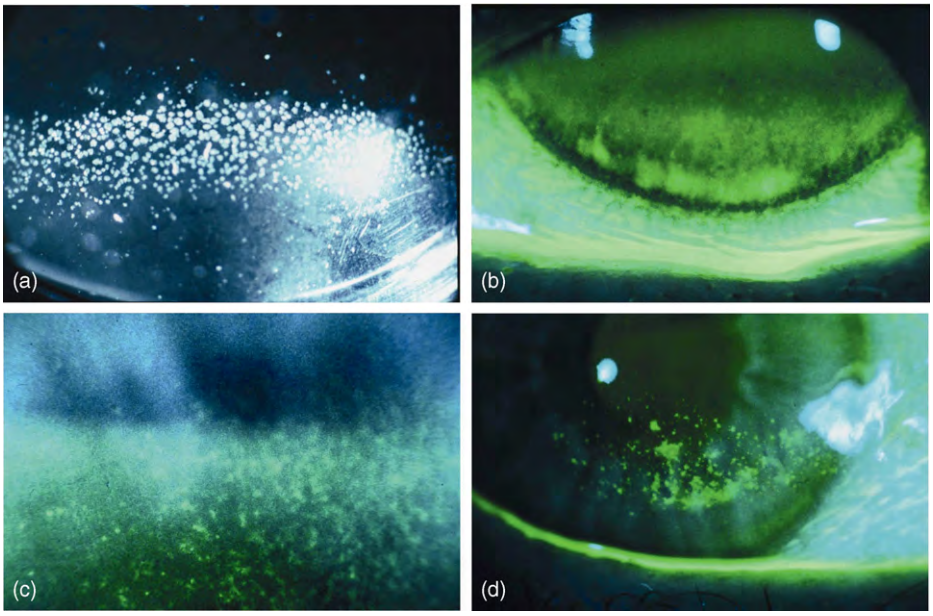

Figure 2 Reading clockwise from top left: (a) Top left: For a nonrotating (e.g., prism ballast) lens designs, a horizontal band of mid-peripheral deposits suggests that incomplete blinking, and associated tear thinning and evaporation, can play a crucial role in deposit precipitation. (b) Top right: The band of thinner tears immediately above the stained exposure keratopathy appears to define the limit of downward excursion of the top lid for the blink immediately prior to this photograph. The keratopathy below the thinned tear layer suggests that this type of incomplete blink is common. (c) Bottom right: Punctate inferior corneal epithelial keratopathy that developed with soft lens wear without symptoms and appears to indicate a high rate of incomplete blinking in association with intensive (proof) reading. (d) Bottom left: A causal role for incomplete blinking is suggested by exposure keratopathy that occurs following a laser-assisted keratomileusis procedure, especially when the keratopathy involves the normally innervated region outside the flap. Reproduced from McMonnies, C. W. (2007). Incomplete blinking: Exposure keratopathy, lid wiper epitheliopathy, dry eye, refractive surgery, and dry contact lenses. *Contact Lens and Anterior Eye* 30: 37–51, with permission from the British Contact Lens Association.

completeness. When the blink rate is reduced to 8 min^{-1} while reading, for example, the average interblink interval is 7.5 s and an incomplete blink increases the interblink interval for the exposed cornea, conjunctiva, or contact lens surface to approximately 15 s. However, when the blink rate is only 4 min^{-1} (e.g., during computer use), and the average interblink interval is 15 s, an incomplete blink creates an interblink interval of approximately 30 s for the exposed cornea, conjunctiva, or contact lens surface.

It is a well-known clinical phenomenon that desiccation occurs in the exposed cornea (**Figures 2(b)–2(d)**) in consistent partial blinkers. For example, incomplete blinking for subjects with superficial inferior punctate keratopathy was found to represent 90% of the total number of blinks. This finding raises the question as to what extent do incomplete blinking habits contribute to the development of inferior punctate keratopathy, and to what extent are they also partly a consequence of the epitheliopathy, and any associated symptoms. If symptoms of inferior punctate keratopathy irritation occur with blinking, blinking may be inhibited and/or the rate of incomplete blinks may increase. However, when the superior cornea is normal, and inferior punctate keratopathy is symptomless (**Figures 2(c)** and **2(d)**), the incomplete blinking rate, which appears to have contributed to the development of the keratopathy, does not appear to have been provoked by irritation. For example, **Figure 2(c)** shows inferior punctate keratopathy that developed without symptoms under a soft contact lens in association with a period of intensive proofreading.

To the extent that lipid secretion depends on lid margin contact, incomplete blinking appears likely to contribute to lipid-layer deficiencies. Incomplete blinking will not express the meibomian glands or reform those portions of the lipid layer that are not wiped by the blinks; the tear layer over the unwiped areas of cornea will continue to thin until re-wiped by a subsequent complete blink.

The classical view of tear film structure is that of an aqueous layer sandwiched between a very thin layer of mucus bound to the corneal epithelium, and a lipid layer. A review of the mucous contribution to tear film structure indicated that the classical aqueous layer is really an aqueous/mucous gel. The concentration of the mucous component reduces toward the lipid layer, from a maximum at the epithelial surface. Apart from the possibility of deficient meibomian gland secretion, and inadequate lipid spreading, incomplete blinking results in reduced opportunities for the tarsal goblet cells to contribute to the integrity of the mucin layer of the exposed cornea. In **Figure 2(b)**, the bottom of the zone of thinner tears, immediately above the stained exposure keratopathy, appears to have been the limit of downward excursion of the top lid for the blink immediately prior to this photograph. The relative normality of the epithelium (freedom from staining), in the zone above the exposure keratopathy, raises the possibility that tear thinning alone may not be a sufficient basis for keratopathy to develop. For example, reduced delivery of tarsal goblet cell mucin to the exposed area may be a more important factor for the development of keratopathy than a thinned tear layer.

Conjunctival stain is increased in symptomatic patients with both sodium fluorescein and lissamine green stains being discriminating factors for symptomatic noncontact lens wearers. However, only lissamine green staining could discriminate symptomatic from asymptomatic soft lens wearers. These findings suggest that the exposed conjunctiva may also be disadvantaged by incomplete blinking. It is assumed that deposits are more easily precipitated on a contact lens anterior surface when the pre-lens tear layer thins or evaporates, and leads to a concentration of tear constituents. In the case of nonrotating lens designs (e.g., prism ballast toric lenses), a horizontal band of deposits (**Figure 2(a)**) suggests that incomplete blinking can play a crucial role in deposition. It appears that incomplete blinks may thin the tear layer in the region of the deposit as well as allow the tear film over that area to evaporate, per medium of longer interblink intervals. It is presumed that regular surface re-wetting inhibits deposition over the superior portion of the lens in **Figure 2(a)**. The lower lid margin tear meniscus appears to have kept the lower region free of significant deposits by preventing tear layer thinning and evaporation (**Figure 2(a)**). Similar deposits appear unlikely to be as evident for the same patient wearing a lens design that is free to rotate and assume different meridional positions on the eye from day to day. In this case the deposits could be precipitated, but because they are distributed over 360° of the lens mid-periphery, the band of deposit would not develop, and the patient's incomplete blinking habits may not be as apparent. Incomplete blinking is frequently observed during a biomicroscopy examination (**Figures 1(a)–1(c)**) with patients having to be instructed to blink completely, in order that a clearer view of the cornea through a contact lens can be achieved.

Lid Wiper Epitheliopathy Mechanisms and Symptoms

A comparison of sodium fluorescein and rose Bengal staining of the marginal conjunctiva of the upper lid, that wipes the ocular and/or contact lens surface during a blink (lid wiper), was made between symptomatic dry eye patients and asymptomatic controls. Patients with dry eye symptoms (without corneal stain) were found to have lid wiper stain in 76% of cases, compared with 12% for the asymptomatic controls. Inadequate lubrication at the lid wiper–ocular surface interface with a concomitant increase in the frictional coefficient, and an increase in the potential damage to either, or both of these ocular surfaces, appears to be applicable in the case of lid

wiper epitheliopathy. Exposure keratopathy may result in increased friction between an abnormal epithelium of the lid wiper and the desiccated inferior cornea (**Figures 2(b)** and **2(d)**). This frictional increase may be greatest for the complete blink that follows an incomplete blink, because the tear layer over the desiccated exposed cornea may be thinnest, and its lubricant properties most deficient, at the end of the prolonged interblink interval that is associated with an incomplete blink. Consequently, the risk of mechanical trauma to the lid wiper epithelium appears to be significantly higher following an incomplete blink.

Lid wiper epitheliopathy may be difficult to treat and improved blink efficiency, which is achieved through a reduction in the rate of incomplete blinking, may be an important component of management. Lid wiper epitheliopathy was evident for 74% of ocular irritation symptomatic contact lens wearers, and 16% of an asymptomatic contact-lens-wearing control group. The prime sensory mechanism for lens awareness, or discomfort associated with an undamaged and well-fitted soft lens, appears to be the blink-related action of the lid wiper over the contact lens surface. The contrast in lubrication for the rewet and dry contact lens surface areas shown in **Figure 1(c)**), and the deposits in **Figure 2(a)**, indicates how lid wiper sensation and trauma may be associated with dry and/or harsh surfaces. Lack of wetness of the soft lens front surface (**Figure 1(c)**), and associated symptoms of dryness, may be an important factor in increasing or decreasing the overall blink rate, as well as the incomplete blink rate. For example, contact lens discomfort has been reported to have the effect of reducing the completeness and rate of blinking, so that awareness of lens dryness (and associated discomfort), that is detected by the lid wiper during a blink, may be a stimulus to reduced blink rate and/or incomplete blinks. Alternatively, awareness of lens dryness may be a stimulus to reflex tearing and blinking. However, the high frequency of dryness symptoms in soft contact lens wear suggests that awareness of a dry lens that is detected by the lid wiper, and any associated increased reflex aqueous production and blinking, is not usually an adequate stimulus for the significant relief of dryness symptoms.

Reflex tear production may be poorly sustained over long periods of dryness symptoms. In addition, any reflex tears may be diluted with respect to lipids and dissolved protein, for example, and their lubricant performance may be reduced accordingly. An association between lid wiper epitheliopathy, and symptoms, suggests the possibility of a lowered threshold for lid wiper sensation in dry eye and dry contact lens conditions. Loss of superficial epithelium from a traumatized lid wiper may expose nerve endings and increase sensitivity. Conversely, the occasional observation that some patients are able to wear contact lenses that are very soiled and/or unwet, without apparent discomfort, suggests that such patients have high thresholds for lid wiper sensation. It is possible that the lid wiper in these cases has become toughened, and desensitized, through the development of an increased epithelial thickness, including an increased density of keratinized cells.

Indications for Blink Efficiency Exercises

Exposure keratopathy may be successfully managed if efficient (complete) blinking habits can be developed, or restored, to help reestablish healthy corneal, conjunctival, and lid wiper epithelia. Improved regularity of complete blinks may contribute to reduced tear thinning and evaporation rates by improving mucin, lipid, and aqueous distribution. Accordingly, there may be the possibility of avoiding tissue changes and symptoms that result from tear evaporation and hyperosmolarity, as well as drying that increases friction between lid wiper and the ocular surface. Similarly, improved blink efficiency may help to maintain a wet and clean contact lens surface, with a concomitant reduction in friction-related trauma to the lid wiper, and any associated symptoms. Blink efficiency exercises should not be introduced into patient care without consideration of other aspects of dry eye and dry contact lens management. For example, patients with exposure keratopathy in association with incomplete blinking can benefit from tear substitutes in addition to improved blink efficiency. However, signs of exposure keratopathy may not be accompanied by symptoms. For example, post-laser-assisted *in situ* keratomileusis (LASIK) exposure keratopathy may be symptomless (**Figure 2(d)**). In addition, the keratopathy shown in **Figure 2(c)**, developed during soft lens wear and periods of intensive proofreading, in the absence of any symptoms. Nevertheless, these types of findings are an indication for blink efficiency exercises and tear substitutes, as well as representing a contraindication to extended contact lens wear, in particular, if they cannot be managed successfully.

The findings that chronic dry eye conditions increased the risk for refractive regression after LASIK, and that ocular surface management minimized the impact of LASIK on goblet cell density reduction and dry eye symptoms, suggest the possibility that blink efficiency exercises may also have a beneficial role for refractive surgery outcomes (even when symptoms are absent). Wound healing and refractive outcomes may be enhanced. Given prophylactically, ocular surface management that includes blink efficiency exercises may also serve to allow some patients to present for surgery with an improved prognosis for optimum refractive outcomes. Indications for blink efficiency exercises based on signs without symptoms may be more difficult to manage if patient

motivation to follow remedial recommendations is lacking. Conversely, the presence of symptoms may provide the basis for increased patient compliance with remedial blink efficiency instructions.

Post-LASIK symptoms are often reported in the absence of exposure keratopathy. Similarly, contact lens wear is often associated with symptoms without signs of exposure keratopathy. In some post-LASIK cases, and for some contact lens wearers, exposure keratopathy and/or lid wiper epitheliopathy may repair overnight and then return during the day following exposure to provocative conditions. For example, these provocative conditions may involve incomplete blinking that is associated with central heating, air-conditioning, computer use, reading, and other visually demanding tasks. An assessment in the early part of the day may not detect exposure keratopathy and/or lid wiper epitheliopathy, or may underestimate the significance of these findings. Similarly, contact lens soiling and unwetting that increases during the day may not be apparent at an assessment during the early part of the day.

Lubricant Therapy: Incomplete Blink Habit Reversal; Optimizing Lid Wiper and Corneal Therapy

Lubricant drops can be rapidly diluted and eliminated from the ocular surface by reflex blinking and lacrimation that follow drop instillation. Exposure keratopathy may respond more favorably from increased blink rate and completeness during the short period of presumed maximum therapeutic potential, immediately after drop instillation. The same principles apply to the use of contact lens rewetting drops. At this critical opportunity, full complete blink exercises ensure the therapeutic drop components are distributed over the exposed ocular or contact lens surface. The emphasis during blink efficiency exercises is for voluntary blinking that is complete, relaxed, and rapid as well as natural in appearance. According to the principles of behavior modification and habit reversal, patient education is a key element of these forms of therapy. Motivation to improve blink efficiency depends on an awareness of the significance of the problems associated with incomplete blinking. Explaining the links between incomplete blinks, the drying of the inferior corneal and/or contact lens surfaces, and symptoms, is greatly facilitated by the use of clinical photographs (**Figures 1(a)–1(d)** and **2(c)**). These are included in the consulting room (take-home) Blink Instruction Guide (BIG). The provision of take-home written instructions, which include these clinical photographs, is intended to assist the development and maintenance of patient motivation required to achieve optimum results. Often drop instillation is inconvenient, but blink efficiency exercises can nevertheless be beneficial at these times. As indicated in the BIG instructions, in order that conscious (practice-session-related) efficient blinks to become spontaneous, practice sessions need to be frequent. The goal for patients should be to perform the exercises frequently enough in order that improved blink completeness habits are generalized across all conditions of spontaneous blinking. A patient who can understand how complete blinks are critical to the maintenance of a wet corneal or contact lens surface is in a position to appreciate negative reinforcement that derives from symptoms of dryness, as well as positive reinforcement from a symptom-free period following blink completeness practice. Symptoms of dryness may serve as a prompt for performing blink efficiency exercises. However, symptom prevention, by performing the exercises routinely, and prior to the onset of symptoms is preferred.

Conclusions

An efficient blink mechanism is critical to ocular surface health and satisfactory contact lens performance. Inefficient blinking may be associated with, for example, low blink rates and/or incomplete blinking. Corneal surgery outcomes may also depend, in part, on blink efficiency. The consequences of inefficient blinking may be complicated by, for example, exposure to air conditioning, central heating, and demanding visual tasks. Any form of dry eye disease may be exacerbated by inefficient blinking. Consequently, improved blink efficiency may contribute to the amelioration of any dry eye condition.

Blood–Retinal Barrier

J Cunha-Vaz, AIBILI, Coimbra, Portugal

Glossary

iBRB – The inner blood–retinal barrier is a situation of restricted permeability established at the level of the retinal vessels, between the blood and retinal tissue, by the tight junctions (zonula occludents) between neighboring retinal endothelial vessels and the retinal endothelial cells themselves.
oBRB – The outer blood–retinal barrier is a situation of restricted permeability established at the level of the retinal pigment epithelium, the blood, and the retinal tissue, by the tight junctions (zonula occludents) between neighboring retinal pigment epithelial cells and the retinal pigment epithelial cells themselves.
Retinal leakage analyzer – A method developed to perform localized measurements of blood–retinal barrier fluorescein leakage using a confocal scanning laser ophthalmoscope modified to obtain fluorescence measurements in the vitreous.
Tight junctions – Tight junctions are specialized junctions uniting neighboring cells by fusion of the outer leaflets of their cell membranes (zonulae occludentes) thus obliterating the intercellular space fusion and restricting paracellular diffusion.
Uveitis – Uveitis is inflammation of the uvea, which is the vascular layer of the eye sandwiched between the retina and the sclera. The uvea extends toward the front of the eye and consists of the iris, choroid layer, and ciliary body.
Vitreous fluorometry – A method developed to measure the fluorescence resulting from the presence of fluorescein in the vitreous after intravenous administration. It is a direct indicator of the permeability of the blood–retinal barrier to fluorescein.

The entire eye must function as the organ for vision and is organized with two major goals: normal function of the visual cell and the need to maintain ideal optical conditions for the light to access the visual cells, located in the back of the eye.

The blood–ocular barriers play a fundamental role in the preservation and maintenance of the appropriate environment for optimal visual cell function (Figure 1).

The blood–ocular barriers include two main barrier systems: the blood–aqueous barrier and the blood–retinal barrier (BRB) (Figure 2), which are fundamental to keep the eye as a privileged site in the body by regulating the contents of its inner fluids and preserving the internal ocular tissues from variations which occur constantly in the whole circulation. The blood–ocular barriers must not only provide a suitable, highly regulated, chemical environment for the avascular transparent tissues of the eye, but also serve as a drainage route for the waste products of the metabolic activity of the ocular tissues.

One of these barriers, the BRB, similar to the blood–brain barrier (BBB), is particularly tight and restrictive and is a physiologic barrier that regulates ion, protein, and water flux into and out of the retina.

It is also important to realize that once inside these barriers there are no major diffusional barriers between the extracellular fluid of the retina and adjacent vitreous; nor does the vitreous body itself significantly hinder the diffusional exchanges between the posterior chamber and the retinal extracellular fluid. This means that the functions of both barriers, blood–aqueous barrier and BRB, influence each other and must work in equilibrium.

Blood–Retinal Barrier

The presence of an intact BRB is essential for the structural and functional integrity of the retina and in clinical conditions where BRB breakdown occurs vision may be seriously affected.

The BRB consists of inner and outer components (inner BRB (iBRB) and outer BRB (oBRB)) and plays by itself a fundamental role in of the microenvironment of the retina and retinal neurons.

The BRB regulates fluids and molecular movement between the ocular vascular beds and retinal tissues and prevents leakage into the retina of macromolecules and other potentially harmful agents (Figure 3).

The iBRB is established by the tight junctions (TJs) (zonulae occludentes) between neighboring retinal endothelial cells. These specialized TJs restrict the diffusional permeability of the retinal endothelial layer to values in the order of $0.14 \times 10^{-5}\,\mathrm{cm\,s^{-1}}$ for sodium fluorescein. The retinal endothelial layer functions as an epithelium and in this way is directly associated with its differentiation and with the polarization of the BRB function. This continuous endothelial cell layer, which forms the main structure of the iBRB rests on a basal lamina that is covered by the processes of astrocytes and Müller cells. Pericytes are also present, encased in the basal lamina, in

close contact with the endothelial cells but do not form a continuous layer and, therefore, do not contribute to the diffusional barrier. Astrocytes, Müller cells, and pericytes are considered to influence the activity of the retinal endothelial cells and of the iBRB by transmitting to endothelial cells regulatory signals indicating the changes in the microenvironment of the retinal neuronal circuitry.

The oBRB is established by the TJs (zonulae occludentes) between neighboring retinal pigment epithelial (RPE) cells. The RPE is composed of a single layer of RPE cells that are joined laterally toward their apices by TJs between adjacent lateral cell walls. The RPE resting upon the underlying Bruch's membrane separates the neural retina from the fenestrated choriocapillaries and plays a fundamental role in regulating access of nutrients from the blood to the photoreceptors as well as eliminating waste products and maintaining retinal adhesion. The metabolic relationship of the RPE apical villi and the photoreceptors is considered to be critical for the maintenance of visual function.

In both, iBRB and oBRB, the cell TJs restrict paracellular movement of fluids and molecules between blood and retina, and the endothelial cells and RPE cells actively regulate inward and outward movements. As a result, the levels in the blood plasma of aminoacids or fatty acids fluctuate over a wide range while their concentrations in the retina remain relatively stable.

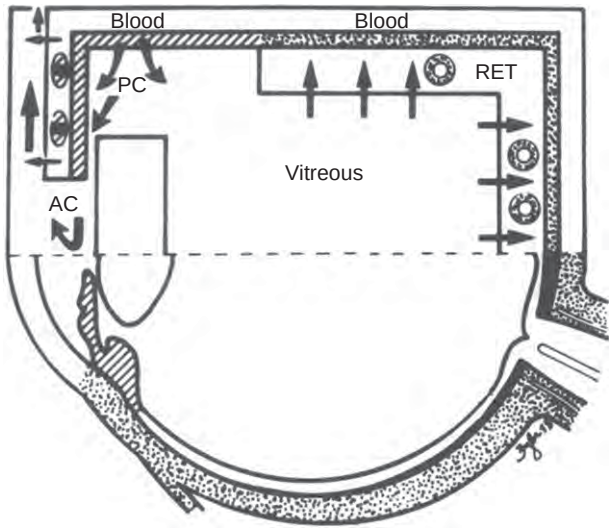

Figure 1 Schematic drawing of the blood–ocular barriers and main fluid movements. RET, retina; PC, posterior chamber; AC, anterior chamber.

Inner Blood–Retinal Barrier

Retinal endothelial cells

The endothelial cells of retinal capillaries are not fenestrated and have a paucity of vesicles. The function of these endothelial vesicles has been described as endocytosis or transcytosis that are receptor mediated. Pinocytotic residues are selectively decreased in the BRB endothelial cells. Receptor-facilitated transport mechanisms are used to move materials across the BRB (**Figure 4**). Channel-facilitated transport using transmembrane proteins is another mechanism for diffusion of specific substrates across the BRB. The glucose transporter Glut 1 is a good example, supplying the neuronal tissue with necessary glucose. Disruption of the iBRB in pathological conditions

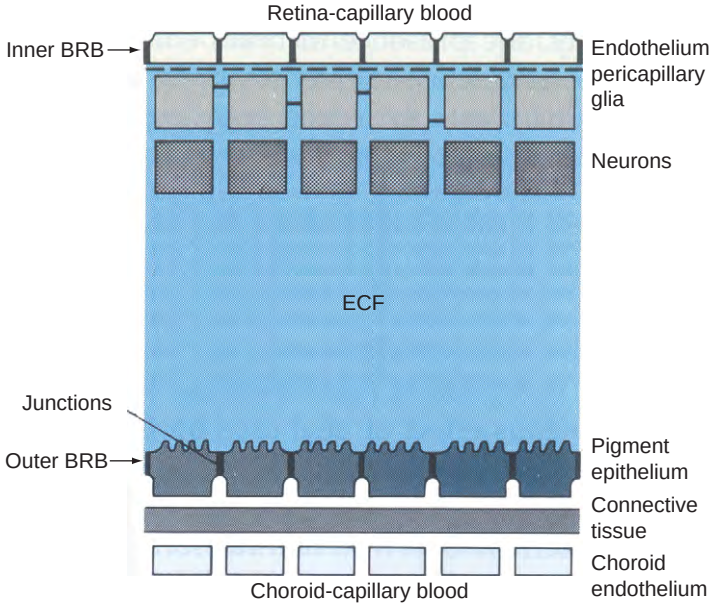

Figure 2 Schematic presentation of the inner and outer blood–retinal barriers (BRBs) and their relative location. ECF, extracellular fluid.

is associated with increased vesicle formation and disrupted endothelial membranes. These alterations may develop before opening of the TJs is detected on ultrastructural examination.

Retinal endothelial TJs

TJs or zonula accludentes of the retinal vascular endothelium are formed by fusion of the outer leaflets of adjacent endothelial cell membranes and were described for the first time in the retinal vessels in 1966.

The TJ obliterates the interendothelial space and confers highly selective barrier properties to the capillaries. Diffusion of molecules from the lumen to the tissue is significantly restricted by TJ.

These endothelial junctions have, like in the brain capillaries, extremely high electrical resistance, 1000–3000 ohm cm^2.

The TJ complex contains at least 40 proteins composing transmembrane and internal adapter proteins that regulated paracellular flux. Transmembrane proteins that make up the TJ are occludins, claudins, and junctional adhesion molecules (JAMs). Occludin is a 65-kDa protein and its changes correlate with permeability changes making it a likely candidate in regulating the opening and closing of the TJ. Claudins regulate small charged molecules and ion permeability. JAM is part of a family of proteins and is associated with adhesion molecules.

Numerous adapter proteins localize just below the membrane and act as TJ organizers and cytoskeleton anchors.

It is important to realize that TJs are dynamic structures that can be regulated by signal transduction through cyclic AMP levels, tyrosine kinases, etc.

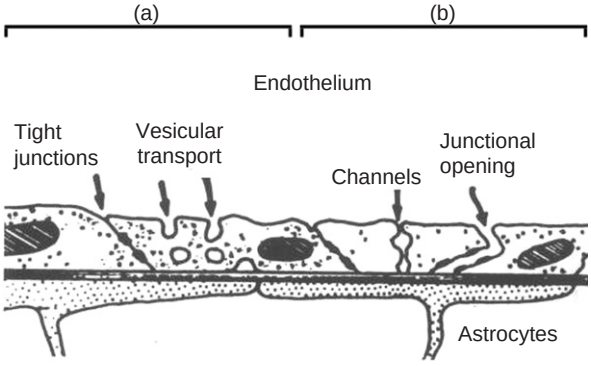

Figure 3 Pathways for solute movements across the inner blood–retinal barrier (retinal endothelial cells): (a) normal; (b) mechanisms of breakdown of iBRB.

Müller cells, astrocytes, and pericytes

A close spatial relationship exists between Müller cells and blood vessels in the retina suggesting a critical role for these cells in the formation and maintenance of the BRB, regulating the functions of barrier cells in the uptake of nutrients and in the disposal of metabolites under normal conditions. Barrier function is also impaired by matrix metaloproteinases (MMPs) from Müller cells as these MMPs lead to proteolytic degradation of the TJ protein occludin.

Astrocytes originate from the optic nerve and migrate to the retinal nerve fiber layer during retinal vascular development. They are associated closely with the retinal vessels and help to maintain their integrity. Astrocytes are known to increase the barrier properties of the retinal endothelium by enhancing the expression of TJ protein Z0.1 and may moderate TJ integrity. Astrocytes are considered to play an important regulatory role in the function of the BRB.

Finally, the pericytes have been shown to play a role in regulating vascular tone, secrete extracellular material, and being phagocytic. Pericytes are considered to play an accessory role in maintaining the integrity of the iBRB by inducing mRNA and protein expression of occludin and other protein junctions. There is evidence that pericytes interact with the endothelial cells contributing to their modulation.

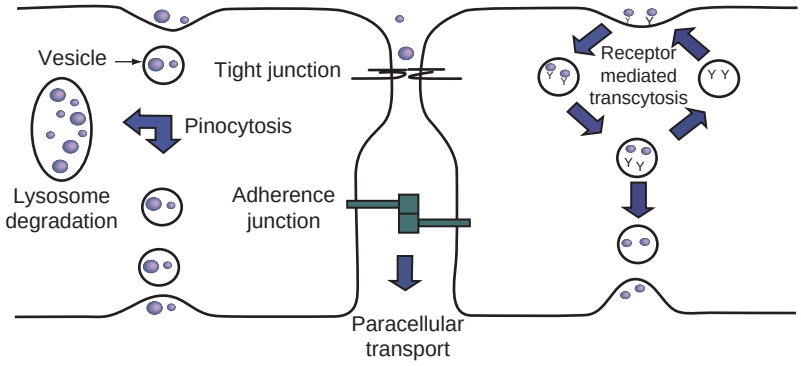

Figure 4 Transport mechanisms across retinal vascular endothelial cells. Modified from Philips, B. E. and Antonetti, D. A. (2007). Blood–retinal barrier. In: Joussen, A. M., Gardner, T. W., Kirchoff, B., and Ryan, S. J. (eds.) *Retinal Vascular Disease*, pp. 139–153. Berlin: Springer.

Outer Blood–Retinal Barrier

RPE cells

The RPE cells transport water from the subretinal space or apical side to the blood or basolateral side. Therefore, the RPE has the structural properties of an ion-transporting epithelium.

RPE cells regulate water content and lactic acid removal generated by the characteristic high metabolic rates in the retina. RPE cells transport water out of the retina and into the choroidal capillary plexus. The force generated by this water flux produces an adhesion force and helps to maintain retinal attachment. Water transport is linked with ion transport, organic anion transport, and other drainage mechanisms.

This outward molecular movement is largely dependent on active ionic transport associated with a relevant high oncotic pressure in the choroid.

RPE cells also have a fundamental role by transporting glucose and retinol, in the appropriate direction, from blood to the photoreceptors.

RPE tight junctions

Paracellular movement of larger molecules is restricted by the TJ between neighboring RPE cells. The paracellular resistance is 10 times higher than the transcellular resistance, classifying the RPE as a tight epithelium. Occludin, claudins, and adapter proteins have been detected at the RPE TJ as in TJ elsewhere. The TJs of the RPE are anchored to the actin cytoskeleton of RPE cells, interact with signaling molecules, and are important for the establishment of cell polarity.

In addition to TJ between RPE cells, the polarized distribution of RPE membrane proteins contributes to the function of the oBRB.

The outer retinal layers are nourished from the blood circulation through the fenestrated capillaries of the choriocapillaris and to subserve this function there is a necessity of a large baso-apical molecular movement from choroid to retina. Waste products of retinal metabolism are transported to the choroid through the oBRB.

Polarity of the outer and inner barriers: TJ modulation

Establishment of cell polarity is a characteristic of a tissue barrier. The endothelial cells of the retinal vessels and RPE develop distinct apical versus basal membrane surfaces. This cell polarity is associated with organization of the cytoskeleton, apical/basal cell membrane proteins, and organization of the junctional complexes between neighboring cells.

It is these TJ protein complexes that allow the establishment of the polarities of the BRB, restricting paracellular diffusion of blood–barrier compounds into the neuronal tissues.

Understanding the normal function of these TJs and the pathological changes that are induced by their alteration resulting in increased permeability is necessary to understand disease progression in retinal diseases such as diabetic retinopathy (iBRB primarily affected) and wet age-related macular degeneration (oBRB primarily affected).

Understanding the role of relevant proteins such as occludins, claudins, and JAMs in BRB physiology and in retinal pathology will certainly contribute to improved management of retinal disease.

Other factors regulating the molecular movement in the eye

Molecular movement from the retinal and choroidal vascular systems into, out, and across them is complex and limited by a variety of other ocular structures. There is a continuous molecular movement of small molecules (mainly water) from the vitreous cavity into the inner retina and through RPE to the choroid.

The major proportion of aqueous humor secreted by the ciliary body from its rich vascular supply provides a bulk flow of fluid through the anterior chamber of the eye but a smaller proportion enters the vitreous cavity where it is largely cleared across the retina and RPE to the choroidal circulation.

Molecular movement from vitreous to choroid is slowed by the cortical vitreous with its high concentration of hyaluronic acid stabilized in a relatively dense type II collagen matrix and the internal limiting membrane (ILM) of the retina. The ILM offers resistance to the diffusion of macromolecules of 148 kDa but allows the passage of smaller molecules. Movement through the retina of molecules that have crossed the iBRB into the retina is largely through the extracellular tissue spaces. Similary, Bruch's membrane that separates the basal RPE from the fenestrated capillaries appears, in health, to offer little resistance to molecular movement.

The presence of fenestrations in the choriocapillaris allows the passage of even large molecules such as albumin into the extravascular spaces of the choroid. The choriocapillaris, therefore, contributes little to the oBRB.

Molecular movement across the oBRB is, however, probably influenced by the very high rate of blood flow in the choroid. A possible explanation for the high blood flow in the choroid is that there is a need not only to supply oxygen and metabolites to the energy demanding retina and RPE, but also for the rapid removal of waste products of the retinal metabolism into the blood circulation.

Finally, the ciliary body may have a relevant regulatory role in the overall maintenance of the retinal

microenvironment. The large surface covered by the ciliary processes, their location where the aqueous and vitreous meet, and the multiple transport functions of the ciliary epithelium are all factors suggesting an important role for the ciliary body in the regulation of the inner ocular fluids.

The microenvironment of the retina, which closely resembles brain extracellular fluid and is in equilibrium with the vitreous is, therefore, maintained by a variety of facilitated and active transport processes which are located mainly in the iBRB and oBRB with the retinal endothelial cells and RPE playing fundamental roles.

The Blood–Retinal Barrier and Ocular Immune Privilege

The immune response has developed and evolved to protect the organism from invasion and damage by a wide range of pathogens. With time, the immune system has developed destructive responses that are specific for pathogens as well as tissues. Such tissue injury might, however, have a devastating effect on the function of an organ such as the eye that needs to maintain optical stability.

The existence of ocular immune privilege is dependent upon multiple factors such as immunomodulatory factors and ligands, regulation of the complement system within the eye, tolerance promoting antigen-presenting cells (APCs), unconventional drainage pathways, and, with particular relevance, the existence of the blood–ocular barriers.

The blood–ocular barriers provide a relative sequestration of the anterior chamber, vitreous, and neurosensory retina from the immune system and create the necessary environment for the existence of ocular immune privilege. The evolution of immune privilege as a protective mechanism for preserving the function of vital and delicate organs such as the eye has resulted in a complex system with multiple regulatory safeguards for the control of both innate and adaptative immurity. The consequences of inadvertent bystander tissue destruction by antigen-monspecific inflammation can be so catastrophic to the organ or host that a finely tuned regulatory system is needed to ensure the integrity of the ocular tissues and maintain optical relationships.

There are also several lines of evidence that points to immunosuppressive functions in the BRB cells, RPE, and retinal endothelial cells. These immunosuppressive effects are apparently due to the secretion of a variety of soluble factors, such as cytokines and growth factors.

Clinical evaluation of the blood–retinal barrier

Fluorescein angiography, an examination procedure performed routinely in the ophthalmologist's office, permits a dynamic evaluation of local circulatory disturbances and identifies the sites of BRB breakdown (**Figure 5**). It is, however, only semi-quantitative and its reproducibility depends on the variable quality of the angiograms.

Vitreous fluorometry was developed as a method capable of quantification of both inward and outward

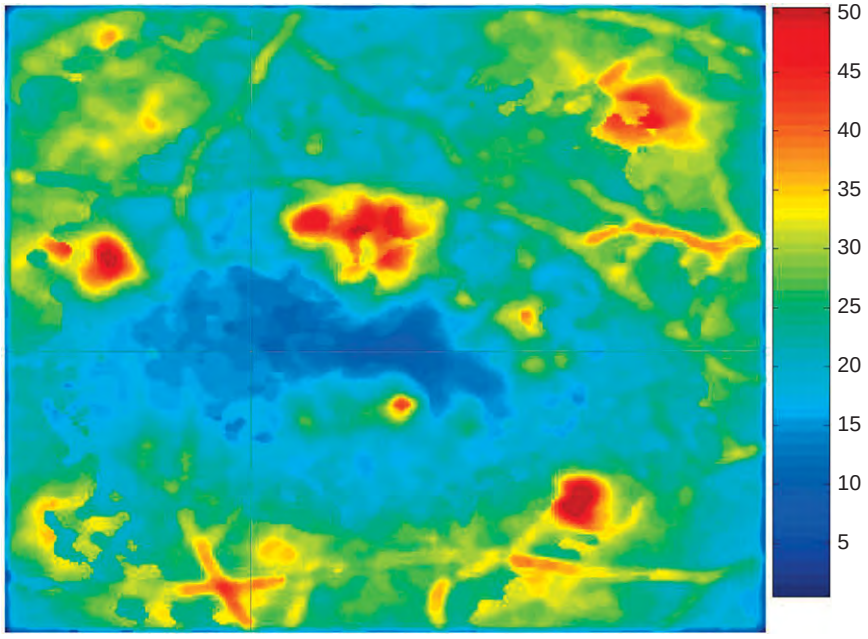

Figure 5 Sites of fluorescein leakage into the vitreous identified by the retinal leakage analyzer in an eye with nonproliferative retinopathy of a patient with diabetes type 2. Blue indicates minimal leakage; red indicates maximum leakage.

movements of fluorescein across the BRB system in the clinical setting. Protocols were devised, tested, and dedicated instrumentation developed.

With the development of vitreous fluorometry methodologies, a large number of clinical and experimental studies demonstrated convincingly the major role played by alterations of BRB in posterior segment disease.

In clinical situations, alterations of the BRB have been measured in pathologies of the RPE, aged-related macular degeneration, and macular edema, as well as in hypertension and diabetes. The clinical use of vitreous fluorometry, however, has declined because it offers only an overall measurement over the posterior role and because at the time of its development there were no drugs available for stabilizing the BRB. Nowadays, vitreous fluorometry is mostly used in experimental research and in drug development.

More recently, retinal leakage mapping has been introduced to identify the sites of BRB breakdown. Further developments of this methodology based on confocal scanning laser ophthalmology (SLO-Retinal Leakage Analyzer) associated with improved optical coherence tomography imaging are expected to contribute to earlier diagnosis of BRB alterations in retinal disease as well as improved testing of the effect of new drugs that are now becoming available for treatment of retinal disease.

Blood–retinal barrier and macular edema

Macular edema is the result of an accumulation of fluid in the retinal layers around the fovea, contributing to vision loss by altering the functional cell relationship in the retina and promoting an inflammatory reparative response.

Macular edema is only a nonspecific sign of ocular disease and not a specific entity. It should be viewed as a special and clinically relevant type of macular response to an altered retinal environment, in most cases associated with an alteration of the BRB. It occurs in a wide variety of ocular situations such as uveitis, trauma, intraocular surgery, vascular retinopathies, hereditary dystrophies, diabetes, age-related macular degeneration, etc.

The increase in water content of the retinal tissue that characterizes macular edema may be initially intracellular or extracelullar. In the first case, also called cytotoxic edema, there is an alteration of the cellular ionic distribution.

In the second case, more frequent and clinically more relevant, the extracellular accumulation of fluid is directly associated with an alteration of the BRB. In this later situation, the protective effect of the BRB is lost and the Starling law applies. When there is breakdown of the BRB, any changes in the equilibrium between hydrostatic and oncotic pressure gradients across the BRB contribute to further water movements and progression of the macular edema.

It is also of great relevance to keep in mind that the BRB cells, retinal endothelial cells, and retinal pigment epithelial cells, are both the target and producer of ecosanoids, growth factors, and cytokines. Breakdown of the BRB leading to situations of macular edema may be mediated by locally released cytokines and induction of an inflammatory reparative response creating the conditions for further release of cytokines, growth factors, etc.

Macular edema is also one of the most serious consequences of inflammation in the retinal tissue. Inflammatory cells can alter the permeability of the TJs that maintain the iBRB and oBRB. Cell migration may occur primarily through splitting the junctional complex or through the formation of channels or pores across the junctional complex.

Macular edema has particular relevance for its frequency in diabetic retinopathy. Leukocyte adhesion to retinal vessels and breakdown of the BRB appear to be mediated by nitric oxide (NO). NO upregulates intercellular adhesion molecule-1 (ICAM-1) and promotes the downregulation of TJ protein expression.

Relevance of BRB to Treatment of Retinal Diseases

When administered systemically, drugs must pass the BRB to reach therapeutic levels in the retina. Drug entrance into the retina depends on a number of factors, including the plasma concentration profile of the drug, the volume of its distribution, plasma protein binding, and the relative permeability of the BRB. To obtain therapeutic concentrations within the retina, new strategies must be considered such as delivery of nanoparticles, chemical modification of drugs to enhance BRB transport, coupling of drugs to vectors, etc.

The BRB must be considered as a dynamic interface that has the physiological function of specific and selective membrane transport from blood to retina and active efflux from retina to blood for many compounds, as well as degradative enzymatic activities.

From the viewpoint of drug delivery, designing drugs (including peptides) with greater lipophilicity to enhance BRB permeability seems to be an easy approach. However, such a strategy would not only increase the permeation into tissues other than the retina, but also decrease the bioavailability due to the hepatic first pass metabolism in the case of oral administration. Accordingly, for the development of retina-specific drug delivery systems for neuroactive drugs the most effective approach is to utilize the specific transport mechanisms active at the BRB. That would mean designing drugs that mimic the substrates to be taken by particular transporters or receptors existing in the BRB.

Eye drops are generally considered to be of limited benefit in the treatment of posterior segment diseases. Newer pro-drug formulations that achieve high concentrations of the drug in the posterior segment may have a

role in the future. Meanwhile, periocular injection is one modality that has offered mixed results.

Finally, the last years have seen a generalized and surprising safe utilization of intravitreal injections, a form of administration that circumvents the BRB. Steroids and a variety of anti-VEGF drugs have been administered through intravitreal injections to a large number of patients without significant side effects and demonstrating good acceptance by the patients. Intravitreal injections can achieve high drug concentrations in the vitreous and retina preserving the BRB function and its crucial protective function. At present the major challenge appears to be the need to decrease the number of intravitreal injections which in the case of anti-VEGF treatments are given every 6 weeks to maintain efficacy. The search for safe slow-delivery devices or implantable biomaterials is ongoing but the invasive approach to treat retinal diseases appears to be the only effective way of reaching rapidly therapeutic levels in the retina in the presence of a functioning BRB.

Breakdown of the Blood–Retinal Barrier

S A Vinores, Johns Hopkins University School of Medicine, Baltimore, MD, USA

Glossary

Fenestrations – Spaces between vascular endothelial cells that allow free fluid exchange between vessel and tissue. Fenestrations are characteristic of vessels found in tissues that do not have a blood–tissue barrier.

Leukostasis – The adhesion of leukocytes to the vascular endothelium as part of an inflammatory reaction.

Macular edema – Fluid accumulation, due to blood–retinal barrier (BRB) breakdown, in the area of the human or primate retina of highest visual acuity.

Tight junctions – Also referred to as zonula occludens, tight junctions are complex arrangements of microfilaments and other proteins that connect retinal vascular endothelial (RVE) or retinal pigment epithelial (RPE) cells and restrict the flow between them. Tight junctions are an integral component of the blood–retinal, blood–brain, or blood–nerve barrier.

Vesicular transport – The nonspecific transcellular transport of fluid and high-molecular-weight molecules from the luminal to the abluminal surface of the vascular endothelium by means of pinocytotic vesicles.

Uveitis – An inflammation of the uvea, or the middle layer of the eye. The uvea consists of three structures: the iris, the ciliary body, and the choroid.

Introduction

The blood–retinal barrier (BRB), which is analogous to the blood–brain barrier, maintains homeostasis in the retina by restricting the entry of blood-borne proteins from the retina and by maintaining strict ionic and metabolic gradients. When this barrier breaks down, excess fluid accumulates in the retina and this can result in macular edema, which is associated with ischemic retinopathies, including diabetic retinopathy (DR) and retinopathy of prematurity (ROP), ocular inflammatory diseases, retinal degenerative diseases, and a variety of other ocular disorders, or following ocular surgery. BRB breakdown can occur at the inner BRB, which is established at the retinal vasculature, at the outer BRB, which consists of the retinal pigment epithelial (RPE) cells, or at both sites. The BRB is established by the formation of tight junctions between the retinal vascular endothelial (RVE) cells and the RPE cells and a paucity of endocytic vesicles within these cells. The establishment and maintenance of the BRB is regulated by the perivascular astrocytes and pericytes, but the mechanism for this regulation is not entirely clear. Some studies have shown that cell to cell contact is necessary to establish and maintain the BRB, while others provide evidence that a soluble mediator is sufficient. BRB breakdown can result from a disruption of the tight junctions, which are composed of a complex network of junctional proteins, an upregulation of vesicular transport across the RVE or RPE, or by degenerative changes to the barrier-forming cells or to the regulatory cells, the pericytes and glia. In some cases, BRB breakdown is related to identifiable structural defects, such as loss of pericytes, astrocytes, or RPE cells or changes to the vascular endothelial cells, as would be caused by microaneurysm formation. In other cases, where retinal vascular leakage is diffuse, such as in uveitis, or when the leakage is remote from a lesion, such as a surgical wound or tumor, it is clear that diffusible factors are involved. Blood–tissue barriers exist only in the retina, brain, and nerve. Vascular endothelial cells in the choroid and in other tissues are fenestrated (**Figure 1(a)**), allowing large molecular weight molecules to freely pass from the blood to the tissue, and thus do not have a barrier function.

Tight Junctions

Tight junctions or zonula occludens consist of complex arrangements of over 40 proteins in the peripheral cytoplasm and apical plasma membrane that connect RVE or RPE cells and restrict flow between them (**Figure 1(b)**). Occludin and the claudins (over 24 isoforms), which form the junctional strands and are believed to constitute the backbone of the tight junction, span the plasma membrane and bind junctional proteins in adjacent cells. Zonula occludens proteins 1, 2, and 3 (ZO-1, -2, and -3) are intracellular proteins that associate with the cytoplasmic surface of the tight junctions and organize the complex. The binding of ZO-1 to occludin establishes the tight junction. Other integral components of the junctional complex are the junctional adhesion molecules, tricellulin, cingulin, 7H6, and symplekin. A breach of the tight junctions (**Figure 1(c)**) can result from an alteration in the content of the junctional proteins, their redistribution, or their

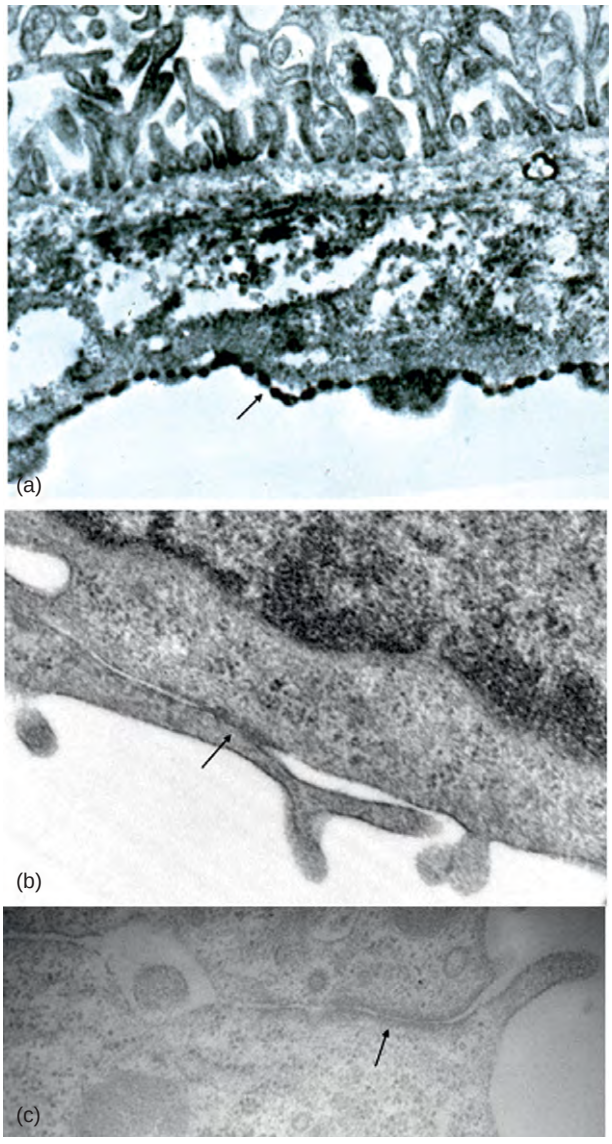

Figure 1 (a) Choroidal vessels are fenestrated (arrow) and, therefore, do not form a blood–tissue barrier. (b) A morphologically closed tight junction (arrow) in a normal retinal vessel. Note close apposition of vascular endothelial cells and an intact junctional complex. (c) A morphologically open tight junction (arrow) in a retinal vessel. The space between the vascular endothelial cells allows vascular leakage through the junction.

phosphorylation. Occludin content at the tight junction is higher in cells that have a tighter barrier and decreased occludin correlates with increased BRB permeability, but occludin knockout mice appear to form functional tight junctions, so the association is complex and not simply regulated by occludin. Increased occludin phosphorylation is also associated with increased BRB permeability. Altered expression of claudins can lead to changes in selectivity of the junctions and claudin-5 appears to be particularly important for maintenance of a functional tight junction.

Adenosine, prostaglandin E1 (PGE1), interleukin-1β (IL-1β), tumor necrosis factor-α (TNFα), and vascular endothelial growth factor (VEGF) appear to be capable of causing a morphological and functional opening of the RVE tight junctions. A significant number of interendothelial cell tight junctions appeared open along their entire length within 6 h of intravitreal injection of each agent into rabbits with TNFα showing the greatest effect (35.6% of the interendothelial cell junctions appeared open, morphologically). The effect of PGE1 on tight junctions appeared to be transient, that of VEGF and IL-1β were partially reversible by 24 h, and the effect of the adenosine agonist, *N*-ethylcarboxamidoadenosine was not reversible by 48 h. The demonstration of immunoreactive albumin, which would normally be confined to the lumens of vessels with a blood–tissue barrier, along the entire length of these junctions, from the luminal to the abluminal surface, suggests that they are also functionally open (**Figure 2(c)**).

Vesicular Transport

Since the tight junctions restrict the flow of molecules across the BRB, a series of pumps, channels, and transporter molecules are necessary to transport specific essential molecules from the blood to the retina. The nonspecific transport of high molecular weight molecules and fluids across the RVE by way of pinocytotic vesicles (**Figure 2(a)**) or caveolae is referred to as vesicular transport (**Figure 2(b)**) and serves as a transcellular means of BRB breakdown. This mechanism appears to be the predominant means for BRB compromise associated with VEGF-A-induced hyperpermeability in monkeys and in DR in humans, rats, and rabbits.

In addition to causing the opening of interendothelial cell tight junctions in the retina, adenosine, PGE1, IL-1β, TNFα, and VEGF also promote the formation of pinocytotic vesicles in RVE cells and the distribution of albumin-containing intraendothelial vesicles across the entire RVE cell and at both the luminal and abluminal surfaces suggests that active vesicular transport is occurring. Although infrequently seen, the vesiculo-vacuolar organelle, which is associated with VEGF in the vascular endothelium of tumors, was also evident in the RVE of VEGF-treated rabbits, but not monkeys, and is likely to play a role in VEGF-mediated vascular permeability. The effect of these mediators on the outer BRB is less clear.

Role of Inflammation

Inflammation has been associated with BRB breakdown in DR, choroidal neovascularization (CNV) associated with age-related macular degeneration, aging, ocular

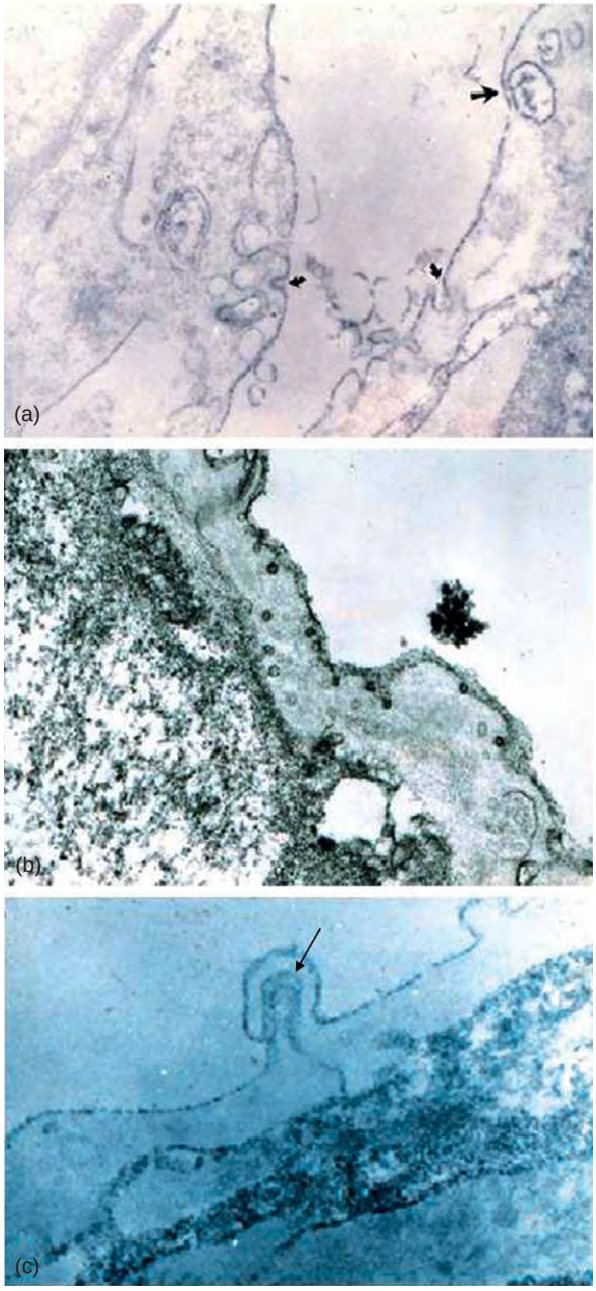

Figure 2 (a) Immunocytochemical staining for endogenous albumin shows the formation of pinocytotic vesicles (arrows) on the luminal surface of vascular endothelial cells in a 7 month galactosemic rat. Immunoreactive albumin is contained within the formed vesicles (top right). (b) Immunocytochemical staining for albumin demonstrates albumin filled vesicles throughout the cytoplasm of the vascular endothelial cells of a rabbit. The presence of these vesicles and the positive staining for albumin in the extracellular matrix (left) suggests that vesicles are actively transporting serum proteins across the endothelium and extruding their contents at the abluminal surface as a means of transcellular BRB breakdown. (c) Immunocytochemical staining for albumin along the entire length of the interendothelial cell junction (arrow) and in the basal lamina indicates that there is vascular leakage through the junction.

inflammatory disease, and the administration of pro-inflammatory molecules. The increased adhesion of leukocytes to endothelial cells in the retina is associated with increased expression of intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1), CD18, and other adhesion molecules, which are upregulated by VEGF and other pro-inflammatory molecules in DR and other ocular disorders, and appear to be regulated, at least in part, by protein kinase C (PKC). Diabetic CD18 and ICAM-1 knockout mice have significantly fewer adherent leukocytes than diabetic mice with normal CD18 and ICAM-1 and the decreased leukostasis is associated with fewer damaged endothelial cells and reduced BRB breakdown, supporting the role of adhesion molecules in increased inflammation and the correlation of an inflammatory response with endothelial cell damage and permeability. It is not clear whether the same molecules that facilitate leukostasis also mediate BRB breakdown or if this is attributable to molecules secreted by the recruited leukocytes, or both, but there appears to be a direct correlation between increased leukostasis and vascular permeability in the retina and pro-inflammatory molecules, such as TNFα and IL-1β, are among the most potent inducers of BRB breakdown. Leukocyte adhesion to the diabetic vascular endothelium can promote endothelial apoptosis and inhibition of leukocyte adhesion to the retinal vessels can not only prevent endothelial degeneration, but also reduce the diabetes-associated loss of pericytes, which support the vascular endothelium and help to confer BRB integrity. Inflammation can also alter the distribution of astrocytes and their ensheathment of retinal vessels, leading to alterations in BRB integrity. Leukocytes have also been shown to cause a downregulation and redistribution of tight junctional proteins, which leads to a disruption of tight junctions and a transient breakdown of the BRB during retinal inflammation.

Molecular Mechanisms

The induction of BRB breakdown is a complex process that is mediated, not by a single factor, but by the interaction of multiple factors operating through different receptors and signaling pathways. The list of molecules that have been identified as playing a role in BRB breakdown, which is by no means all-inclusive, includes VEGF, hypoxia-indicible factors-1 and -2 (HIF-1 and -2), placental growth factor (PlGF), TNFα, IL-1β, platelet-activating factor, adenosine, histamine, prostaglandins (PGE1, PGE2, and PGF2α), platelet-derived growth factors A and B (PDGF-A and -B), insulin-like growth factor-1 (IGF-1), ICAM-1, VCAM-1, P-selectin, and E-selectin. The key will be to determine what the initiating event is and which events are parts of the

resulting cascade. By targeting the appropriate molecules, subsequent events leading to BRB failure may be blocked.

The various isoforms of VEGF and PlGF are members of the VEGF family. VEGF-A, a potent inducer of vascular permeability, binds to both VEGF type-1 (fms-like tyrosine kinase-1 or Flt-1) and type-2 (kinase insert domain-containing receptor, referred to as KDR in humans or Flk-1 in other species) receptors (VEGFR1 and VEGFR2), whereas PlGF binds only to VEGFR1, so comparing their activities may be a means of dissecting the respective roles of the VEGF receptor isoforms, since both receptors have been implicated in BRB breakdown. VEGFR1-mediated signaling appears to operate primarily through p38 MAPK (mitogen-activated protein kinase), while VEGFR2 signaling may be mediated through RAS, phosphoinositide 3-kinases (PI3K)/Akt, or phospholipase C (PLC)γ, but the interaction of VEGFR1 and VEGFR2 is complex and much remains to be learned about this interaction. Both receptors are associated with vascular permeability and angiogenesis, but in some circumstances, VEGFR1 can act as a negative regulator for VEGFR2.

VEGF is a key molecule in promoting increased retinal vascular permeability. This activity may be mediated, at least in part, by an upregulation of ICAM-1, E-selectin, and P-selectin as a means of facilitating its pro-inflammatory activity. VEGF-induced permeability showed a biphasic pattern with a rapid and transient phase followed by a delayed and sustained phase, the latter of which was blocked by antibodies to urokinase plasminogen activator or its receptor. VEGF receptor kinase inhibitors can suppress VEGF-mediated BRB breakdown, but this strategy shows that TNFα, IL-1β, and IGF-1 do not induce BRB leakage through an induction of VEGF, indicating that these mediators operate through distinct pathways that may also be targeted. Endothelial nitric oxide synthase activation and NO formation also appear to be implicated in VEGF-mediated vascular permeability, probably through activation of the serine/threonine protein kinase AKT/PKB, which can lead to an increase in nitric oxide production and ICAM-1 upregulation. Deletion of the hypoxia response element of the *Vegf* promoter also suppresses BRB breakdown in oxygen-induced ischemic retinopathy, demonstrating that HIF-induced VEGF is critical in this process.

TNFα and IL-1β are upregulated in DR and other ischemic retinopathies, as well as ocular inflammatory disease, and both molecules are associated with increased leukostasis and BRB breakdown. IL-1β has been shown to accelerate apoptosis of retinal capillary endothelial cells through activation of nuclear factor kappa light-chain enhancer of activated B cells and this is exacerbated in high glucose. IL-1β can also stimulate the production of reactive oxygen species, which in turn can induce the release of additional cytokines. Aspirin and etanercept are inhibitors of TNFα and each can reduce ICAM-1 levels, diabetes-related leukostasis, and BRB breakdown in diabetic rats without altering VEGF levels, showing that TNFα is involved in this process and that it operates through a distinct pathway from VEGF.

These data show that there are a number of potential target molecules for inhibitors to suppress BRB breakdown. The challenge will be to identify the best target or targets and develop the most effective therapeutic strategy.

Assessing BRB Breakdown

A variety of methods exist for the quantitative and qualitative assessment of the BRB, but each method has its particular limitations and sensitivity, so the choice of methods will largely depend on whether quantitative or qualitative data are desired and on the nature of the tissue being evaluated, whether it be fixed tissue, patients in a clinical setting, or experimental animal models. Since no single method can provide a quantitative assessment with precise localization of the site of BRB breakdown, multiple approaches may be necessary to provide an overall perspective. In addition, some methods can produce precise data in experimental models or on tissue specimens, but are not appropriate for use in the clinic.

To identify and compare factors that cause BRB breakdown and to evaluate the efficacy of new treatments designed to prevent or reduce macular edema, a reliable quantitative assay for assessing BRB function is essential. The most widely used protocols for the quantitative assessment of BRB breakdown utilize Evans blue or 3H-mannitol as tracers. With the Evans blue assay, the extracted dye is quantified in the retina following intravenous injection of the dye and subsequent perfusion with saline. A spectrophotometer, set at 620 nm, is used to quantify the leakage of dye into the retina. With the 3H-mannitol assay, a scintillation counter is used to determine the CPM/mg tissue, 1 h after an intraperitoneal injection of the tracer, and the data are expressed as a ratio of retina/lung or retina/kidney. Since the lung and kidney do not have a blood–tissue barrier, the ratio corrects for any variation in the amount of isotope injected or absorbed. These methods have been used to assess the BRB in several models of ocular disease and to determine the effect of various factors, agents, and genetic manipulations on the integrity of the BRB. Thus, these methods have been useful in identifying factors that initiate BRB compromise and for determining the relative efficacy of various agents at preventing or reducing BRB failure. Both methods produce highly reproducible results in an experimental setting, with the 3H-mannitol assay possibly being somewhat more sensitive due to the lower molecular weight of mannitol than Evans blue dye, but neither is applicable to the clinic. Vitreous fluorophotometry (VFP) is a more appropriate means of assessing BRB failure in

a clinical setting. Although these methods can provide a quantitative assessment of the BRB, they cannot localize the site of leakage or provide any insight into the mechanism, so alternative techniques are required to provide this information.

Fluorescein angiography has been used extensively in the clinic to visualize BRB breakdown, but it does not allow resolution at the cellular level. Magnetic resonance imaging (MRI) enhanced by the paramagnetic contrast agent gandoliniumdiethylene-triaminetetraacetic acid has been used to localize and quantify BRB breakdown in living animals. MRI is not subject to the optical limitations of VFP and allows the investigator to distinguish between inner and outer BRB failure in the rabbit. Its resolution is not as great as that resulting from microscopic evaluation of fixed tissue, but MRI allows *in vivo* analysis, thus enabling the investigator to monitor progressive changes in BRB integrity within the same animal. The use of exogenous tracer substances can provide a higher resolution, but several limitations are associated with their use. The use of tracers is impractical for clinical studies, the introduction of exogenous material may alter BRB integrity, and retrospective studies cannot be done on archival tissues. The immunolocalization of endogenous albumin (**Figure 3**) or IgG can circumvent most of these limitations and offers the following advantages for BRB assessment. The technique can be used with fixed surgical, autopsy, or archival specimens, no exogenous substance is introduced, and it can be used at the light and electron microscopic (EM) levels. Although, by nature, this is not a quantitative method, it can show the location and extent of BRB breakdown and, if used at the EM level, it can demonstrate the means by which serum proteins are extravasated from the retinal vessels or may transverse the RPE layer. This technique has been used to assess the BRB in a variety of human and experimental ocular disorders, including DR, retinitis pigmentosa, vascular occlusive disease, neoplastic disease, ocular inflammation or infection, and other diseases that develop macular edema, but for which pathological defects do not reveal a cause for BRB breakdown. EM immunocytochemical staining for albumin reveals that BRB breakdown can occur by the opening of tight junctions between RVE or RPE cells (**Figure 2(c)**), by an upregulation of trans-endothelial vesicular transport (**Figures 2(a)** and **2(b)**), or by increased surface membrane permeability of RVE or RPE cells resulting from degenerative changes associated with the disease process. It has also provided insights into how various factors, such as VEGF, TNFα, IL-1β, prostaglandins, adenosine, and others promote BRB breakdown. VEGF transiently opens some tight junctions and some leakage through the interendothelial cell tight junctions is induced by VEGF, but electron microscopy has revealed that the predominant mechanism for VEGF-A-induced hyperpermeability of the RVE in monkeys and diabetes-related BRB breakdown in humans, rabbits, and rats is an upregulation of pinocytotic vesicular transport.

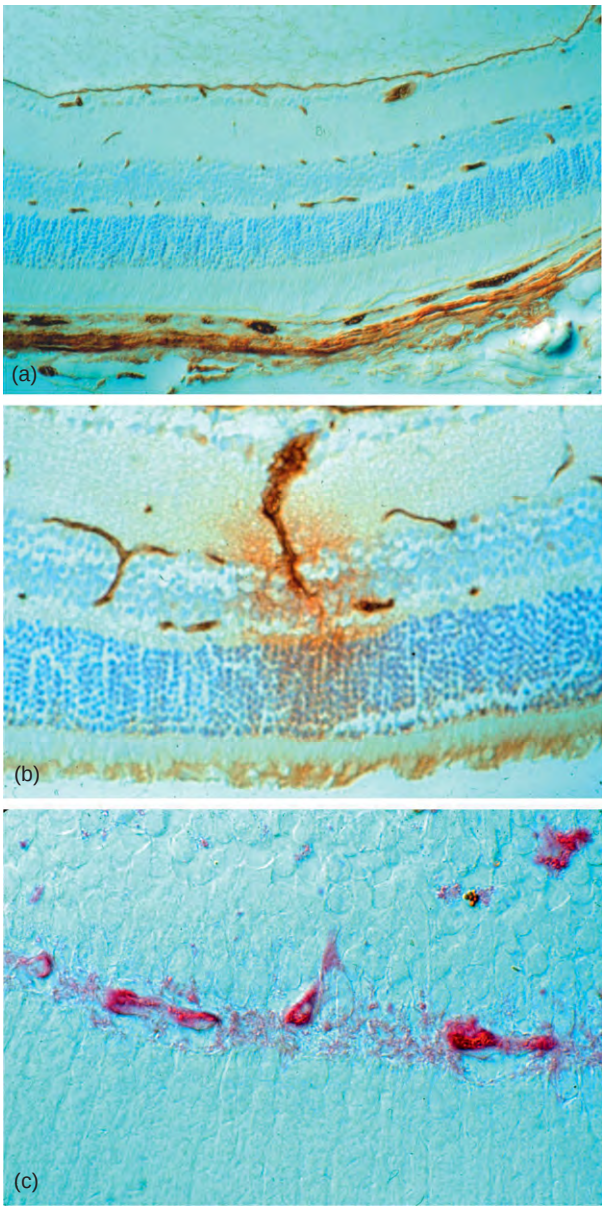

Figure 3 (a) In a normal mouse, immunohistochemical staining for albumin shows that, within the retina, albumin is confined to the vessels, indicating an intact BRB, but diffuse staining is demonstrated in the choroid (bottom) due to the fenestrated vessels and the absence of a blood–tissue barrier. (b) In a mouse infected with coronavirus, vascular leakage is demonstrated from a retinal vessel by immunohistochemical staining for albumin. (c) Immunohistochemical staining (red) shows that albumin has leaked from retinal vessels in a VEGF transgenic mouse. Vinores, S. A., et al. (2001). Blood–retinal barrier breakdown in experimental coronavirus retinopathy: Association with viral antigen, inflammation, and VEGF in sensitive and resistant strains. *Journal of Neuroimmunology* 119: 175–182, with permission from Elsevier.

Inhibiting BRB Breakdown

A variety of therapeutic approaches have shown success at inhibiting BRB breakdown, but generally not preventing it. Most of the agents currently in clinical trials target inflammatory processes or VEGF. Antibodies to key molecules, such as VEGF, PlGF, or TNFα, have been effective at suppressing BRB breakdown, as have inhibitors of these molecules. Drugs that block histamine receptors also reduce retinal vascular leakage in diabetic rats and humans. Bevacizumab (avastin), an anti-VEGF IgG1 antibody, Ranibizumab (lucentis), the Fab fragment of a humanized anti-VEGF antibody, Pegaptanib sodium (macugen), a VEGF aptamer, and VEGF trap, in which the binding domains of VEGFR1 and VEGFR2 are combined with the Fc portion of IgG to neutralize all VEGF family members, have all shown varying degrees of success in clinical trials for reducing macular edema by targeting VEGF. Corticosteroids inhibit BRB breakdown, but it is not clear whether this activity is mediated by their anti-inflammatory effect, which occurs, at least in part, through a downregulation of ICAM-1, their inhibition of VEGF expression, their induction of occludin and ZO-1 expression, their reversal of occludin phosphorylation, or a combination of these activities. Even though steroids may improve visual acuity, they carry a high risk of cataracts and glaucoma. The involvement of PKC in vascular permeability has been established and a PKC activator can promote BRB breakdown. PKC inhibitors can reduce retinal vascular permeability, particularly that mediated by VEGF or prostaglandins, but generalized inhibition of PKC is likely to have serious systemic consequences. A PKCβ inhibitor (LY333531) was also effective at suppressing retinal vascular permeability and may have fewer complications.

Prospects for the Future

As more studies are conducted, the complexity of BRB breakdown leading to macular edema becomes increasingly apparent. This process is not attributable to a single factor or event, but the interaction of an undetermined number of initiating events that generates a cascade of subsequent events, ultimately leading to BRB failure. Since this is a multifactorial process, a multifaceted or pleiotropic approach that restores the homeostatic balance is more likely to suppress BRB breakdown than targeting a single pathway with an inhibitor. That would explain why the currently used monotherapies may lead to a reduction of macular edema and improved visual acuity, but generally not a total resolution of the disorder. To develop more effective therapeutic strategies, a better understanding of the basic mechanisms in the pathogenesis of BRB breakdown is imperative. In addition, the frequent injections, high cost, and the occasional side effects associated with current therapeutic approaches emphasize the need for more effective treatment that is less invasive, less costly, and has little or no side effects.

Conclusions

BRB breakdown, leading to macular edema, occurs in a number of ocular disorders and can be due to structural changes or soluble mediators. Alteration in the content, distribution, or phosphorylation of junctional proteins can result in vascular leakage through the tight junctions. BRB breakdown can also result from an upregulation of transendothelial vesicular transport, which has been shown to be a major contributor to BRB failure caused by several mediators and in ocular disease models. Many of the same mediators can simultaneously promote opening of the tight junctions and upregulation of vesicular transport. Degenerative or structural changes to the RPE or RVE cells or to the pericytes and perivascular astrocytes that regulate the inner BRB can also lead to BRB breakdown. Inflammation promotes BRB breakdown, so the use of anti-inflammatory agents may be beneficial. BRB breakdown is not due to a single factor, but is a complex process involving multiple factors, receptors, and signaling pathways. Information on the molecular mechanisms is being revealed, but much remains to be learned. The complexity of the pathogenesis of BRB breakdown makes it likely that the greatest chance for success in preventing macular edema would be in targeting multiple molecules or pathways and a sensitive method for assessing the integrity of the BRB is necessary to monitor the efficacy of different therapeutic strategies.

Breakdown of the Retinal Pigmented Epithelium Blood–Retinal Barrier

M E Hartnett, Department of Ophthalmology, University of North Carolina, Chapel Hill, NC, USA

Glossary

Adherens junction – Cell–cell junction having transmembrane proteins called cadherins that connect to cadherins of epithelial cells through extracellular domains and to anchor proteins, known as catenins, through intracellular tails. Anchor proteins also bind to a continuous belt of actin filaments along cytoplasmic side of the cell plasma membrane, ultimately holding neighboring cells together.
Focal adhesions – Cell–matrix junctions having transmembrane proteins called integrins that connect cells to extracellular matrix and also to the actin cytoskeleton. Transmembrane proteins can trigger signaling within and between adjacent cells.
Inner blood-retinal barrier – It regulates the transport of fluid, ions, and metabolites between the neurosensory retina and the retinal vasculature.
Na,K,ATPase – Enzyme providing active transport mechanism in the retinal pigment epithelial and other cells. By catalyzing an ATP-dependent transport of three Na^+ ions out and two K^+ ions into the cell, a transmembrane sodium gradient is created (necessary for other Na^+ coupled transport systems) and an osmotic gradient (drives water toward the choroidal or basal side of the RPE and away from the subretinal space).
Outer blood-retinal barrier – It regulates the transport of fluid, ions, and metabolites between the neurosensory retina and the choroidal vasculature.
Tight junction – A cell–cell adhesion usually at the apical lateral aspects of polarized endothelia but can be present in other cells consisting of a number of proteins, including ZO-1, -2, -3, transmembrane protein, occludin, and claudins. The tight junction regulates paracellular permeability between adjacent cells and protein and lipid movement between apical and basal compartments of the cell.

Introduction

The retinal pigment epithelium (RPE) forms the outer blood-retinal barrier (BRB), which regulates the transport of fluid, ions, and metabolites between the neurosensory retina and the choroidal vasculature. The inner BRB is formed by retinal endothelial cells (RECs), which regulate the transport of fluid, ions, and metabolites between the neurosensory retina and the retinal vasculature. Together, the RPE and RECs collectively form the BRB that serves to exclude blood-borne substances from the neurosensory retina and regulates the ionic and metabolic gradients required for normal retinal function. The RPE barrier structures and functions will be broadly described below and for further detail, the reader is directed to other articles in this encyclopedia.

RPE Barrier Structure

The RPE is a polarized monolayer located deep to the neurosensory retina with its apical processes adjacent to the photoreceptors and its basal aspect on Bruch's membrane, a semipermeable collagen and elastin sandwich that separates the choroid from the RPE and neurosensory retina (**Figure 1**). The RPE helps to maintain the outer BRB through tight junctions that are located at the apical–lateral junctions of adjacent cells. Much of what is known about tight junctions was learned from studies of epithelial cells other than the RPE.

Tight junction-associated proteins include ZO-1, -2, -3, and several transmembrane proteins, including junction adhesion molecules and occludin, which bind ZO-1 and -2 that then bind the cytoskeleton. Occludin also has extracellular domains, which bind to those of adjacent cells to form the tight junctions. Claudin proteins are also important in this structure and have tissue and regional specificity. There are a number of other proteins that are important in the development and function of the tight junction.

Besides tight junctions, there are other points of contact between cells or cells and extracellular matrix. Adherens junctions have transmembrane proteins called cadherins that connect to cadherins of adjacent RPE cells through their extracellular domains and to anchor proteins, known as catenins, through intracellular tails. The anchor proteins also bind to a continuous belt of actin filaments along the cytoplasmic side of the cell plasma membrane. The resulting structure holds neighboring cells together. Focal adhesions have transmembrane proteins called integrins that connect cells to extracellular matrix and also to the actin cytoskeleton. Besides providing structure and connections, transmembrane proteins can trigger signaling pathways within and between adjacent cells.

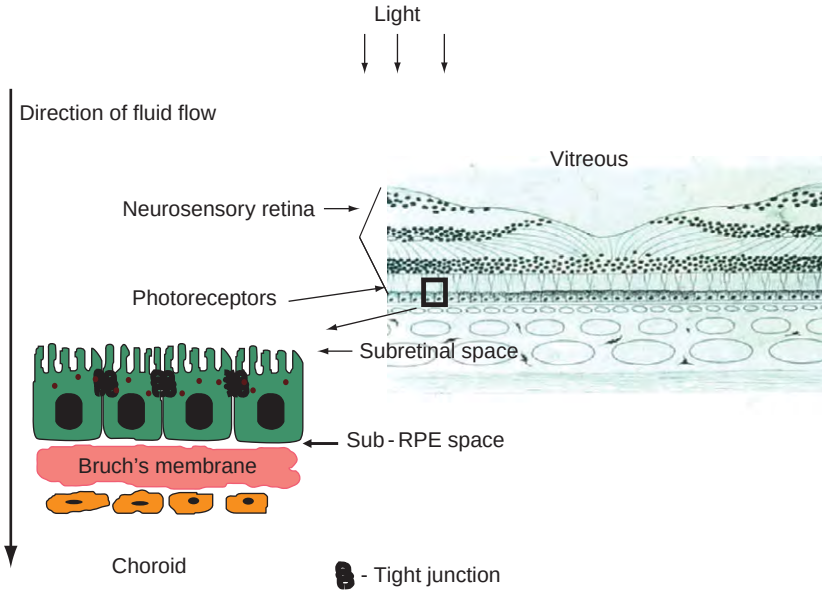

Figure 1 Artist diagram of RPE monolayer with tight junctions at the apical lateral junctions (see inset of RPE/Bruch's membrane/choroid in lower left corner) and in relation to the layers within the macula (shown as a diagram of cross-section of macula on right) and eye. Light is shown coming from above. Overall direction of fluid through the eye is represented by arrow on left.

In addition, a number of active processes regulate the flow of ions, glucose, and amino acids across the RPE. For example, ion fluxes and signaling processes are synchronized between cells through gap junctions, such as connexin 43.

RPE Barrier Functions

The RPE tight junctions regulate the passage of molecules across the paracellular pathway and this regulation depends on the selectivity and permeability of the tight junctions. The transcellular pathway requires pumps, such as Na,K-ATPase, channels, transporters, and metabolic modification to regulate transport across the cells of the monolayer. Breakdown of the RPE barrier may include disruption of the tight junction structure with reduced barrier properties of the RPE. To measure RPE barrier function in a living human, RPE barrier dysfunction is determined clinically by leakage of sodium fluorescein across the RPE seen on stereoscopic images of fluorescein angiograms following an intravenous injection of sodium fluorescein into the bloodstream. However, the distinction between dysfunction of the inner from the outer BRB is difficult in human diseases. This may be because broad BRB breakdown occurs from similar pathophysiologic mechanisms or because of limited resolution in optical imaging. Therefore, techniques are used *in vitro* to study the RPE barrier properties or *in vivo* to selectively poison the RPE and measure fluorescein leakage into the vitreous or eye in animal models (see below). When considering diseases associated with RPE barrier breakdown, it is useful first to understand the fluid flow and forces within the eye.

Transport and Fluid Flow within the RPE and Eye

The vitreous gel is within the eye adjacent to the inner retina, the ciliary body, zonule, and posterior lens capsule. The neurosensory retina includes retinal layers extending from the inner limiting membrane adjacent to the vitreous to the photoreceptors above the RPE. The subretinal space is the potential space between the photoreceptor outer segments and the apical processes of the RPE. The sub-RPE space is a potential space beneath the RPE basal infoldings and Bruch's membrane. The choroid is deep to Bruch's membrane (**Figure 1**). Historically, fluid tends to accumulate more easily in the subretinal than the sub-RPE spaces.

Passive and active transport mechanisms within the RPE and ocular forces within the eye are important when considering the pathophysiology of disease (**Figure 1**). These mechanisms serve to maintain a directional flow from inside the eye, that is, vitreous, to the choroid. Passive transport mechanisms include intraocular pressure and the osmotic pressure from the choroid. However, studies have shown that the RPE reduces directional fluid movement from the subretinal space to the choroid. When the RPE barrier is damaged in animal models (such as through chemicals like sodium iodate), fluid egress from the subretinal space to the choroid is faster than in conditions in

which the RPE has not been damaged. Therefore, in conditions in which there is increased fluid in the subretinal space and presumed RPE BRB breakdown, there is believed to be another pathophysiologic abnormality, such as increased perfusion pressure from the choroid from a vascular tumor, choroidal neovascular membrane, or hyperpermeable choroidal vessels, or reduced ability to accommodate extra fluid, such as with choroidal ischemia or inflammation.

RPE Na,K-ATPase pump

Since the RPE restricts fluid movement from within the eye toward the choroid, it is believed that one or more active transport mechanism is necessary to prevent fluid from accumulating in the subretinal space. The Na, K-ATPase pump is an important active transport mechanism in the RPE. This enzyme is located at the apical surface of the RPE and it is believed that the asymmetric positioning of this enzyme with other transporters, such as chloride channels, is important in creating directional fluid flow. The enzyme catalyzes an adenosine triphosphate (ATP)-dependent transport of three Na+ ions out and two K+ ions into the cell. This transmembrane sodium gradient is necessary for functions of other Na^+ coupled transport systems and creates an osmotic gradient, which helps drive water toward the choroidal or basal side of the RPE and away from the subretinal space. It has been shown *in vitro* using human RPE grown in polarized monolayers that Na,K-ATPase function is necessary for the structural integrity of tight junctions and their function. Inhibition of Na,K-ATPase using a K^+ free media or with ouabain led to increased ionic and nonionic permeability in association with a reduction in the number of contact points in the tight junctions as seen by transmission electron microscopy. Thus, Na,K-ATPase function is necessary to reduce paracellular permeability.

Methods to Assess RPE Barrier Structure and Function

Tight Junction Structure

ZO-1 staining is useful to define the hexagonal architecture of the RPE monolayer *in vitro*, but does not indicate that paracellular permeability is reduced and the barrier is tight. RPE is cultured in specific media to attain tight properties, and the tightness of the monolayer often correlates with the duration in culture and the immunolocalization of occludin to the cell junctions (Figure 2). However, lack of occludin can be associated with a functional tight junction and from this it has been shown that other proteins, including the claudins, are important. Therefore, ZO-1, occludin, and claudins, as well as other proteins, are important in the RPE tight junction function, and the reader is directed to other articles of this encyclopedia.

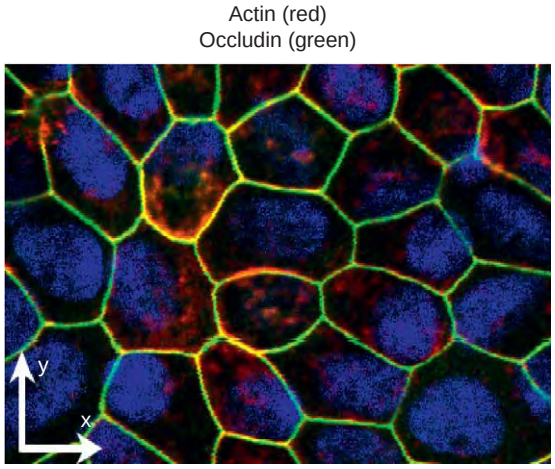

Figure 2 Immunolocalization of occludin (green), actin (red), and Hoechst nuclear stain (blue) in human fetal RPE cultured for >1 month.

When viewed with electron microscopy, it is noted that functional tight junctions have multiple contact points between cells, and that when functional assays show reduced tightness of the barrier, the number of contact points was reduced. The protein components of the tight junction and phosphorylation or activation of certain component, such as occludin, can be determined by immunoprecipitation and/or Western blot analysis.

Barrier Function

Electrophysiologic methods are used to measure barrier function. Transepithial electrical potential (TEP) measures the ion gradient across the monolayer generated by energy-driven ion pumps that regulate passage across the cells. Transepithelial electrical resistance (TER) measures resistance of substances through the paracellular space mainly through the fine structure of the tight junction structure. Permeability to nonionic compounds such as inulin or mannitol can be measured.

Assays That Measure Barrier Properties of RPE

In vitro. Measures of barrier function can vary depending on the RPE cell type, the components making up the media, and the duration of time in culture. Although a TER of 100 Ω cm^2 is sufficient to exclude movement from the apical and basal compartments of a monolayer of RPE, many investigators strive to obtain culture conditions in which the RPE monolayer develops a TER of 500 Ω cm^2. However, in RPE-choroid explants, a TER of 200 Ω cm^2 has been reported. Therefore, it remains unclear whether a higher TER than that *in vivo* indicates a physiologic condition or one in which the structure of the tight junction is

altered by an abnormal microenvironment. It is important in studies that compare the effects of agents on a barrier properties that the cell culture conditions be standardized and replicable.

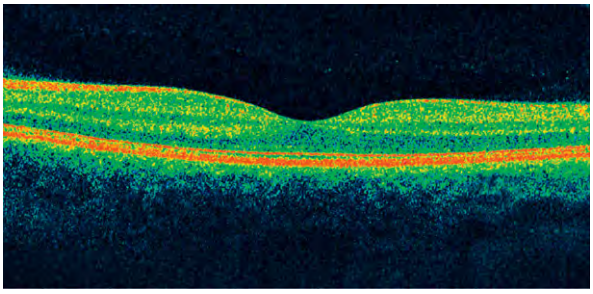
Ex vivo. Explants of the RPE and choroid have been used in modified Ussing chambers to study the movement of compounds and to determine the barrier properties.

In vivo. Assessing the BRB function is performed with several assays that measure the amount of a substance leaked into the retina. In animal studies, quantitative assays include comparing blood concentration of Evans' blue dye to that measured within the retina after administration of a known concentration, or measuring the extravasation of albumin or inulin into the retina. In addition, qualitative and semi-quantitative assessment (i.e., measuring the area of fluorescein leakage) of fluorescein angiograms can be performed. However, it is difficult to distinguish leakage from the inner versus the outer BRB using these methods.

Clinical assays. Since direct measure of specific functions of the outer BRB is not possible in humans *in vivo*, *in vitro* testing and fluorescein angiography or vitreous fluorophotometry are performed. Vitreous fluorophotometry measures fluorescein leakage into the vitreous by measuring fluorescence.

Fluorescein angiography. When sodium fluorescein (376 Da) dye is activated with blue light (490 nm), it emits fluorescence in the green wavelength (520–530 nm). In a fluorescein angiogram, the dye is injected as a bolus (usually 500 mg/5 mL over 7 s) into the antecubital vein, and images of the fundus are obtained digitally or on film over time. At ~10 s following injection, a choroidal flush from filling of the choroid that is partly blocked by the RPE melanin occurs. Nearly simultaneously, filling of the retinal arterioles occurs. Subsequently, the veins fill (**Figure 3(a)**). Areas of abnormal hyperfluorescence can occur from loss of the RPE melanin or cell (known as window defects because of permitted fluorescence from the underlying choroidal vasculature) or from filling of abnormal vessels or pooling or leakage into spaces where fluid is not naturally present. Hypofluorescence can occur from blockage by pigment or blood, or from nonperfusion within any of the vascular structures in the eye (choroid, retinal vasculature, vessels of the optic nerve). Stereoangiography is helpful to determine the relative position within the retina where abnormal fluorescence was seen. Currently, clinicians gain additional data from optical coherence tomography (OCT).

OCT. Light is directed through a dilated pupil and reflects off different optical interfaces corresponding to layers within the retina (**Figure 3(b)**). Disorganization of the retinal architecture, invasion of tissue, and fluid-like cysts can occur within layers and be used in conjunction with the fluorescein angiogram to diagnose and manage several diseases (see below). Spectral domain OCT has provided better image quality than time domain OCT.

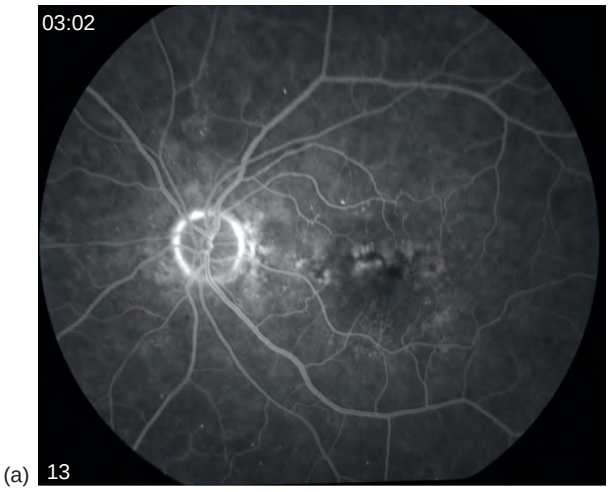


(b)

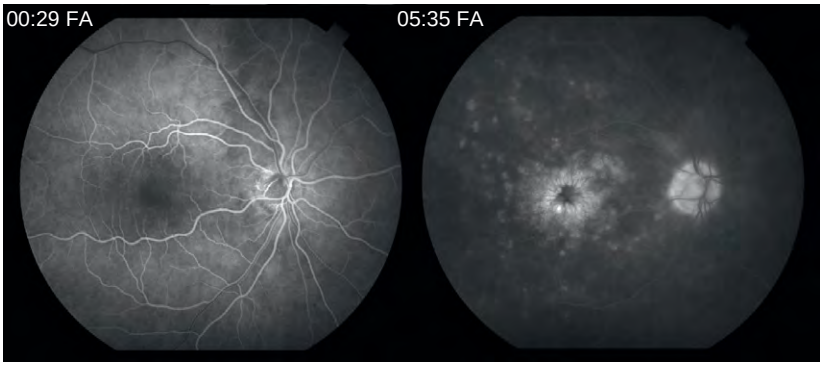
Figure 3 (a) Normal mid-phase fluorescein angiogram showing optic nerve at left (slightly out of focus) and filling of retinal arterioles and veins. (b) Spectral domain optical coherence tomogram (OCT) of adult macula showing reflective layers of retina (red – highly reflective) and natural foveal depression.

Clinical Conditions Associated with Breakdown of the RPE Barrier

Dysfunction of the BRB is believed to disrupt the normal health and function of the neurosensory retina in several diseases and lead to reduced visual function. RPE barrier dysfunction is diagnosed usually by the presence of hyperfluorescence in the deeper retina, unlike in normal, as determined by fluorescein angiography (cf. **Figures 3(a)** and **4(a)**). Occasionally, vitreous fluorophotometery is used, but this method does not distinguish leakage from the inner or outer BRB. Leakage of fluorescein from the RPE can appear as mild hyperfluorescence and staining, but may lead to intraretinal edema, seen as cystoid macular edema, shown by hyperfluorescence in early frames at the level of the RPE with petalloid hyperfluorescent within the retina in late frames (**Figure 4(b)**). However, most causes of CME are believed to involve several factors including leakage from the inner BRB and Müeller cell dysfunction.



(a)



(b) Early frame FA Late frame FA

Figure 4 (a) Deep hyperfluorescence in macula of left eye seen on recirculation phase of fluorescein angiogram demonstrating subtle leakage at the level of the RPE barrier. (b) Early angiogram shows minimal hyperfluorescence surrounding the avascular zone of the macula, but in the recirculation frame of the angiogram, hyperfluorescence takes on a petalloid appearance in a patient with cystoid macular edema.

Inflammation/Infection

Inflammation reduces the BRB function and affects both the inner BRB of the RECs and the outer BRB of the RPE. Clinically, any disease that has an infectious or inflammatory component can compromise the BRB. Viral infections (such as human immunodeficiency virus (HIV), cytomegalovirus (CMV), Herpes) and bacteria (such as *Bacillus cereus*) have been shown to disrupt the tight junctions of the RPE *in vitro*. Factors such as tumor necrosis factor (TNF)-α, interleukins (IL)-6, -8, -1 disrupt tight junction barrier functions *in vitro* or *in vivo*. The RPE has been shown to have chemokine receptors, such as CXCR4, which can be activated by its ligand, stromal-derived factor (SDF-1), to release chemokines such as monocyte chemotactic protein-1 (MCP-1) and IL-8. Chemokines, like MCP-1, can attract leukocytes. Contact of RPE with monocytes results in additional secretion of IL-8 and MCP-1 through several pathways involving mitogen-activated protein kinases. Such pathways may amplify the effects of inflammation on BRB breakdown. As a model of human uveitis, experimental autoimmune uveoretinitis (EAU) is induced in animals by immunization with different proteins. For example, EAU can be induced in Lewis rats by immunization with S-antigen or in mice using peptides to interphotoreceptor retinoid-binding protein. A number of events occur in the EAU model and one is the movement of leukocytes into the retina. It has been shown that transient loss of ZO-1 occurs in RPE from IL-1 and MCP-1. (Transient loss of occludin-1 in RECs within venules was believed to play a role in permitting leukocyte diapedesis in the EAU model.) Inflammation in conditions such as Vogt Kayanagi Harada's disease, or choroidal inflammatory conditions can reduce RPE barrier function in humans.

Age-Related Macular Degeneration

Age-related macular degeneration (AMD) is a leading cause of nonreversible blindness worldwide. Clinical

evidence of RPE BRB dysruption is seen in fluorescein angiograms showing hyperfluorescence from the choroidal vascular normally blocked by healthy RPE, but where loss of melanin or RPE cells has occurred, as in atrophic AMD (**Figure 5**). Hyperfluorescence can also occur from leaky blood vessels that appear to disrupt the RPE barrier and lead to fluid accumulation in neovascular AMD (**Figure 6**). OCT provides additional evidence in neovascular AMD as to the location of the fluid: beneath the RPE (sub-RPE), above it (subretinal), or within the retina itself (intraretinal) (**Figure 7**). Neovascular AMD occurs in about 10% of AMD cases but accounts for 90% of severe vision loss.

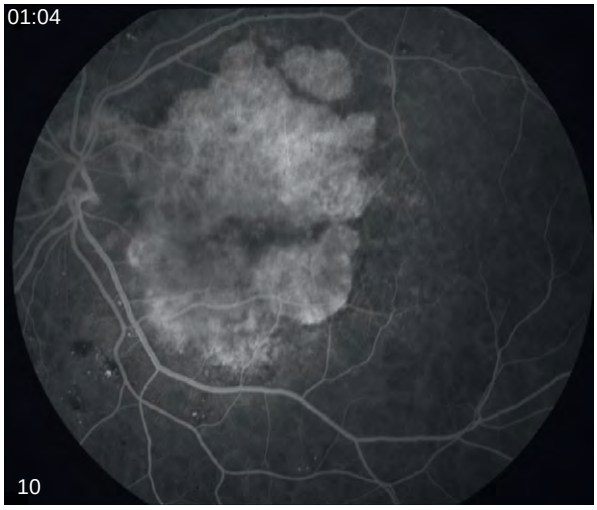


Figure 5 Presence of hyperfluorescence in late frame of fluorescein angiogram because of loss of RPE melanin, which naturally blocks fluorescence of underlying choroid.

Most of the neovascular AMD begins as ill-defined hyperfluorescence and late leakage noted on fluorescein angiography and had been initially called occult choroidal neovascularization (CNV). Later, occult CNV was characterized histopathologically as type 1 CNV, indicating that CNV remained beneath the RPE (**Figure 6**). This is in contrast to classic or well-defined CNV, characterized histopathologically as type II CNV in which the CNV has entered the neurosensory retinal space (compare **Figures 6 and 8**). (This distinction is useful as a model but in reality is not so clear-cut, since clinically there are often mixed types.) However, studies have provided support that when vision declines from neovascular AMD, more than half of the time it is from the transition from occult to classic CNV. This prompts the hypothesis that contact of the ECs with the RPE or its matrix can trigger signaling pathways leading to the release of angiogenic or chemotactic growth factors and the migration of choroidal ECs and movement of fluid into the neurosensory retina. These events would appear to involve a breakdown in the RPE BRB properties. Many stimuli that are believed to be involved in the pathophysiology of AMD also reduce BRB properties as determined in *in vitro* assays described earlier. These include, for example, oxidative stress (can disorganize tight junction proteins including occludin), inflammation (can reduce TER and disrupt tight junctions), activation of complement factors (RPE possess complement 5a receptors and can be stimulated by complement 5a to release several cytokines which can then regulate leukocyte function during inflammation), and contact of RPE or its extracellular matrix with endothelial cells (reduce TER and increase permeability of RPE through release of soluble forms of vascular

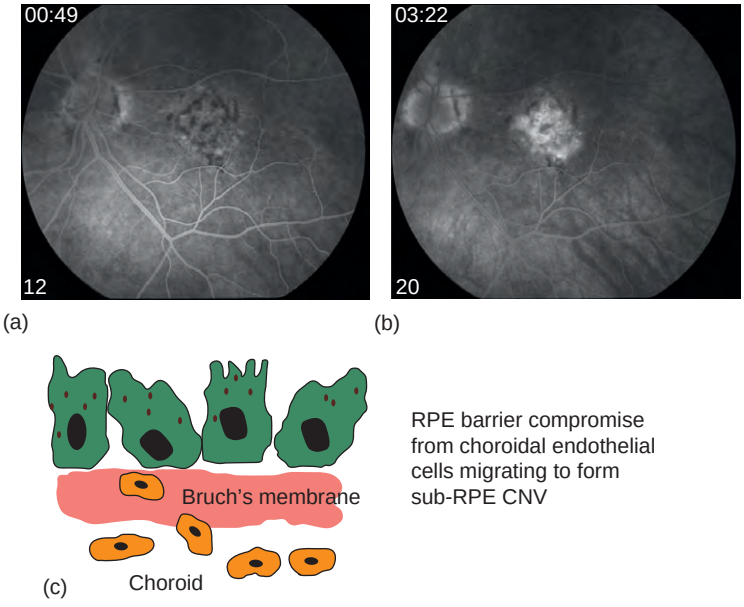

Figure 6 (a) Ill-defined hyperfluorescence in early frame with (b) leakage in late frame of fluorescein angiogram secondary to RPE barrier disruption from occult or type 1 choroidal neovascularization beneath the RPE depicted in (c).

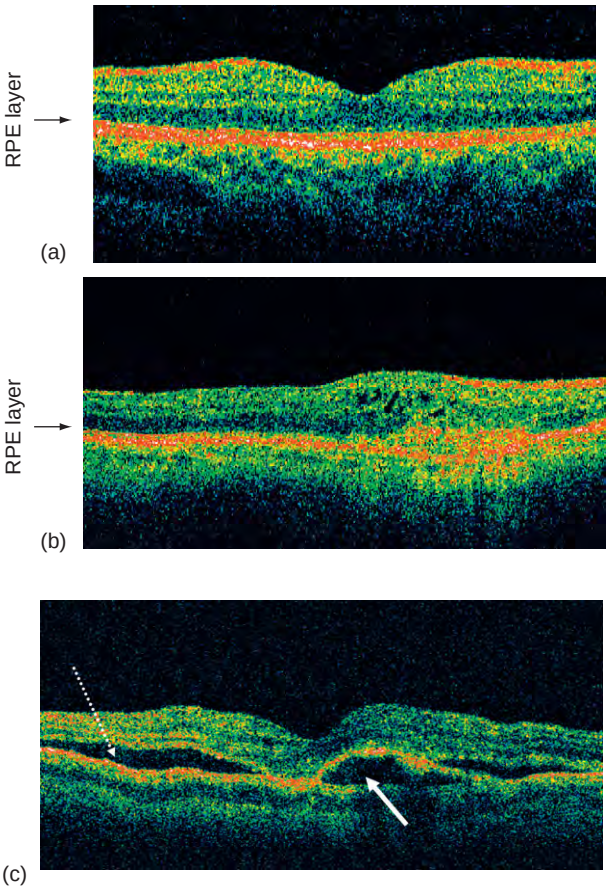

Figure 7 (a) Time domain optical coherence tomogram from patient with normal macula showing good definition of macular layers and normal foveal contour. (b) Optical coherence tomogram from patient with neurosensory retinal choroidal neovascularization, showing disruption of ordered architecture of the retinal layers, increased hyperreflectance (red) in layer near RPE/Bruch's membrane and intraretinal cysts, indicating intraretinal fluid (arrowhead). (c) Optical coherence tomogram showing subretinal fluid (dotted arrow – beneath the photoreceptors and above the RPE) and sub-RPE fluid (solid arrow – beneath the RPE and above Bruch's membrane).

endothelial growth factor (VEGF)). All these stimuli can lead to increased secretion of VEGF, which also increases permeability of blood vessels and RPE and choroidal endothelial migration, proliferation, and chemotaxis, all processes believed important in the development of neurosensory retinal choroidal neovascularization. Furthermore, RPE can release other cytokines that recruit leukocytes, including macrophages that can then release VEGF, or that interact with other processes important in the pathogenesis of AMD.

Diabetes Mellitus

In diabetic retinopathy, the inner BRB is impaired and is most easily appreciated clinically on fluorescein angiography, as leakage from microaneurysms, dilated capillaries, intraretinal microvascular abnormalities, and neovascularization that grows above the inner limiting membrane into the vitreous (**Figure 9**). However, fluorescein staining at the level of the RPE is seen on fluorescein angiograms of patients with diabetes. Also, hyperglycemia has been shown to impair the function of tight junctions of the RPE *in vitro*. Diabetic retinopathy also impairs vision through the development of macular edema, which occurs when there is fluid and solutes that leak from the vasculature into the neurosensory retina (**Figure 10**). It can occur through a breakdown of the inner and potentially outer BRBs. Besides the finding that hyperglycemia can reduce TER in cultured RPE, animal models of diabetic retinopathy have found that there is reduced Na,K-ATPase activity in the RPE. So, once retinal blood vessels leak fluid, lipids, and protein into the neurosensory retina, mechanisms to transport fluid and compounds out of the retina also appear to be impaired in the diabetic state.

Inflammation has been shown to play a role in the pathophysiology of diabetic retinopathy. In animal models, leukostasis or adherence of white blood cells to retinal capillaries has been found and postulated to be a mechanism of later capillary nonperfusion and endothelial damage, which precede the development of proliferative diabetic retinopathy and macular edema. Furthermore, diabetes can also cause a choroidal vasculopathy associated with leukostasis, which may cause choroidal ischemia and later angiogenesis both of which can interfere with intrinsic ocular flow from the vitreous toward the choroid.

Proliferative Vitreoretinopathy

Proliferative vitreoretinopathy (PVR) occurs when cellular contractile membranes develop on the surface of the retina and contract it and pull open breaks in the retina, which can lead to complex retinal detachments. It is the most common cause of failed retinal detachment repair. Vitreous fluorophotometry readings in animal models of PVR show a breakdown in the BRB associated with released cells into the vitreous cavity. It is believed that RPE cells, serum, and other factors have access to the vitreous cavity and are responsible for further breakdown of the BRB and growth of preretinal membranes.

The treatment for PVR, currently, is surgical, requiring vitrectomy and stripping of the membranes from the retina, and then methods to reattach the retina and create a permanent chorioretinal adhesion. However, ongoing research may provide medical means to prevent the formation of preretinal membranes.

Drug Toxicity

Several drugs, including thioridazine (Mellaril), thorazine, hydroxychloroquine, and chloroquine, have been shown to cause vision loss and toxicity with pigmentary changes. The exact effects on the RPE and BRB are unclear.

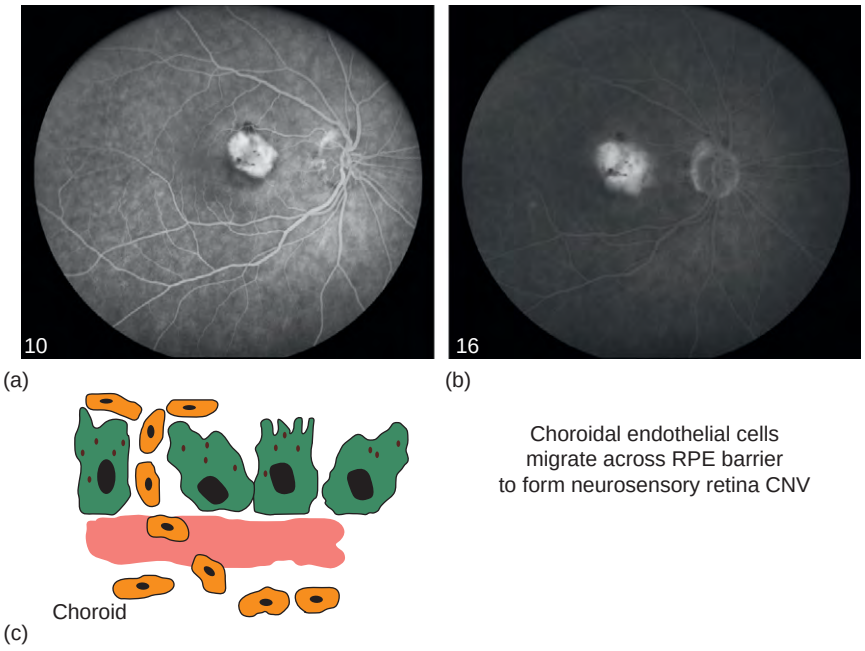

Figure 8 (a) Well-defined hyperfluorescence in early frame with (b) leakage in late frame of fluorescein angiogram from type II choroidal neovascularization (CNV) that has entered the neurosensory retina (depicted in (c)).

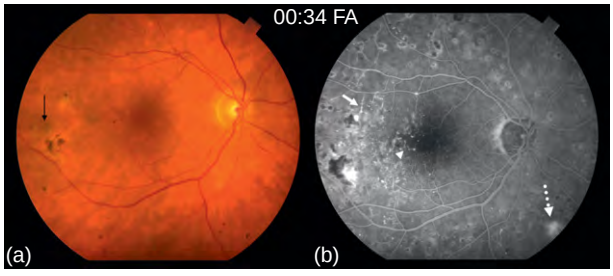

Figure 9 (a) Color images of right eye of patient with diabetic retinopathy previously treated with laser (examples of pigmented laser spots shown by arrows). (b) Fluorescein angiogram of same eye showing intraretinal microvascular abnormalities (arrow) and areas of avascular retina with dilated capillaries, an irregular foveal avascular zone, and microaneurysms (arrowhead). Dotted arrow shows area of hyperfluorescence from leaking neovascularization likely growing above the inner limiting membrane.

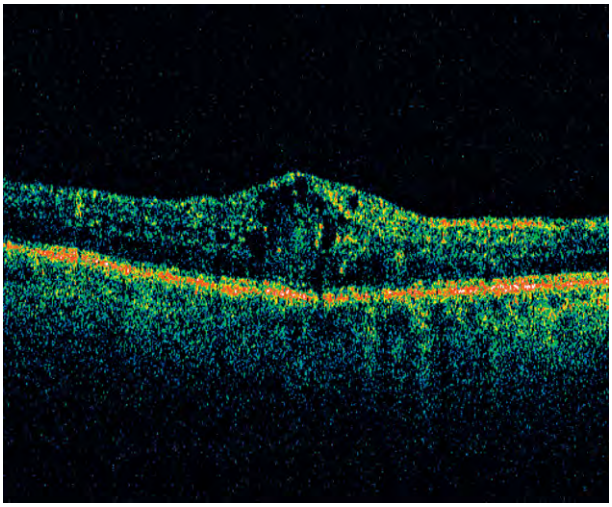

Figure 10 Example of intraretinal edema in a time domain optical coherence tomogram from a patient with diabetic macular edema. Note that the RPE reflective layer is intact in contrast to **Figure 7(b)** in which invasion of cells into the neurosensory retina has occurred in neovascular AMD.

Central Serous Retinopathy

Central serous retinopathy (CSR) is a clinical disease often occurring in young to middle-aged individuals, although it can also manifest or recur and become chronic in later life. Symptoms include reduced vision or inability to focus, and clinical examination shows the presence of a neurosensory retinal detachment within the macula. Fluorescein angiography shows focal areas of RPE leaks (**Figure 11**) or diffuse RPE disturbances. In chronic CSR, RPE decompensation occurs (**Figure 12**) and can lead to chronic subretinal leakage and accumulation of subretinal and intraretinal fluid. Although cases of CSR usually resolve without permanent vision loss, recurrent or chronic CSR can lead to permanent loss of visual acuity. Even when a sole leak appears to be present, CSR is believed to be associated with broad RPE dysfunction, because if only one area of dysfunction were present, the Na,K-ATPases of surrounding healthy RPE would pump out fluid from the subretinal space.

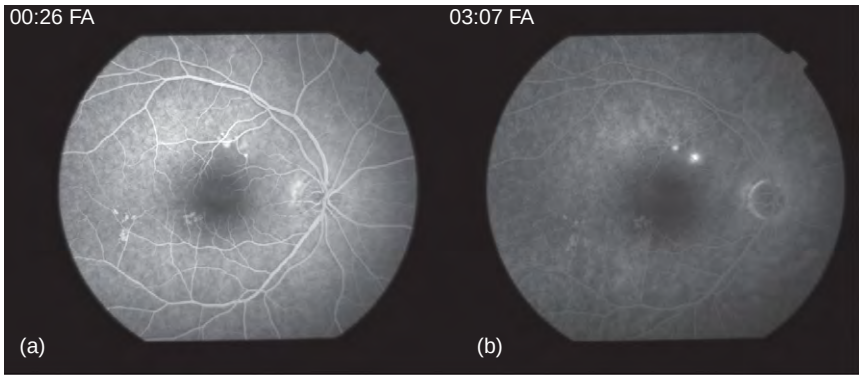

Figure 11 (a) Early hyperfluorescence at level of RPE in fluorescein angiogram from central serous retinopathy in 40-year-old male. (b) Late pooling of dye into the neurosensory retina from a leak in the RPE.

Figure 12 RPE decompensation showing broad area of hyperfluorescence in fluorescein angiogram from chronic long-standing central serous retinopathy in 60 year old male.

Angiograms using indocyanine green dye, which permits visualization of the choroidal vasculature, show that areas of choroidal hypoperfusion and later choroidal hyperpermeability are present in CSR. Although one might suspect inflammation to be a cause of the hyperpermeability, treatment with steroids can severely worsen CSR and should be avoided. Corticosteroids can affect the expression of adrenergic receptor genes and it is thought that this contributes to the overall effect of catecholamines on CSR. Some have postulated that the pathology may involve the adrenocorticotrophic hormone. Another unusual aspect of CSR is that treatment of a sole RPE leak on fluorescein angiography can hasten resolution of the serous detachment, even though it is believed that broad RPE dysfunction is present. Besides corticosteroids, hypertension also increases the risk.

CSR has long been believed to be associated with breakdown in the BRB particularly of the RPE. The cause remains unknown but it is associated with increased stress and a type A personality and is believed to be related to elevated cortisol and epinephrine, which affect the autoregulation of the choroidal circulation. In early studies, adult Japanese monkeys that received multiple daily (>30) injections of intravenous adrenalin developed serous retinal detachments and leaking RPE spots by fluorescein angiography similar in appearance to that seen in CSR. An intramuscular injection of prednisolone led to the same findings on fluorescein angiography but required fewer doses of adrenalin.

Retinitis Pigmentosa

Evidence of abnormalities in the localization of ZO-1, beta-catenin, and other associated adherens proteins in the $rho^{-/-}$ mouse, a model of autosomal dominant retinitis pigmentosa, provides support for tight junction and adherens junction-associated protein modifications in retinitis pigmentosa. Furthermore, in retinitis pigmentosa, there is cystoid macular edema often associated with hyperfluorescence of the RPE cells on fluorescein angiography, suggesting a breakdown of the RPE barrier. Toxins such as sodium iodate selectively poison the RPE and have been used to test the role of the RPE BRB in animal models in which fluid had been injected into the subretinal space or for studies in PVR. Although the toxin is selective for RPE, it poisons the RPE and therefore affects all functions of the RPE, not just the tight junctions.

Urethrane was used to test the BRB in earlier studies and was reported to lead to inhibition of intervesicular transport across endothelia and loss of RPE.

Growth Factors

Besides the role of VEGF in reducing RPE barrier properties, other growth factors play a role. Insulin-like growth factor-1 (IGF-1) can induce VEGF-related RPE barrier breakdown. Also, hepatocyte growth factor (HGF) can lead to disassembly of tight and adherens junctions in

association with reduced barrier properties. HGF has also been shown to be increased in human PVR.

Studies to Increase the Function of the BRB

Carbonic anhydrase inhibitors lead to acidification of the subretinal space, which, in turn, leads to an increase in chloride ion transport into the choroid, thus eliminating water from the subretinal space and retina and increasing the adhesiveness of the RPE. Carbonic anhydrase inhibitors have been associated with improved BRB function, based on reduced fluorescein leakage into the retina, in small clinical studies. However, larger clinical trials have shown a smaller benefit.

Glossary

Basement membrane – Basement membranes are sheets of extracellular matrix that provide support and anchorage for epithelial and endothelial cells. Typical extracellular matrix components that are found in basement membranes include collagen IV, collagen XVIII, agrin, perlecan, laminin, and nidogen.
Heparin sepharose – This is a media used in chromatography that consists of beads coated with heparin. It is used to isolate heparin-binding molecules.
***In situ* hybridization** – A technique used to detect RNA or DNA. In this case, it is used to localize messenger RNA (mRNA) in tissue sections using labeled complementary RNA as a probe.
Nonpigmented ciliary epithelium – This is a monolayer of cells that is an anterior extension of neuroretina and lines the inner surface of the ciliary body. Underlying this layer is another monolayer of cells called the pigmented ciliary epithelium that is an anterior extension of the retinal pigment epithelium.
Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE)/mass spectrometry – This is a technique, sometimes referred to as proteomics, for identifying multiple proteins in a sample. The proteins are separated by electrophoresis (in this case using sodium dodecyl sulfate-polyacrylamide gel electrophoresis). The individual proteins are then identified by tryptic digestion, measuring the mass of the resultant peptides by mass spectrometry and then interrogating databases to match to the distinctive peptide fingerprint of the protein.

The Composition of the Vitreous Body Extracellular Matrix

The vitreous body (VB) is a fibrillar meshwork of extracellular matrix (ECM) that fills the vitreous cavity of the eye (Figure 1(a)). Immunocytochemistry and western blot analysis revealed that major protein constituents of the VB include collagens II, V/XI, IX, and XVIII, and the noncollagenous components fibrillin, fibronectin, opticin, and tenascin (Figure 1(b)). Among the protein components, collagens and fibrillin establish the loose ECM meshwork that is responsible for the gelatinous nature of the VB, while the glycosaminoglycans of the chick vitreal chondroitin sulfate proteoglycans bind the large quantities of water, the most prominent component of the vitreous. The high concentration of water in VB is essential for providing the large volume of the VB and the intraocular pressure that is necessary for eye expansion during development and the close apposition of the retina to the pigment epithelium.

A sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE)/mass spectrometry analysis of embryonic chick VB extended the list of ECM proteins to about 40. The analysis not only confirmed the presence of the proteins already detected by western blotting, but also added vitronectin, FREM2, chondromodulin, fibulin, lumican, reelin, mimecan, and several basement membrane proteins that are found in the inner limiting membrane of the retina and lens capsule as an additional set of VB components (Table 1). Hyaluronic acid, a linear, high-molecular-weight carbohydrate polymer, is also found as a major VB constituent of mammalian eyes. Hyaluronic acid is not a major constituent of the vitreous in all species, since little is found in the avian eye. The constituents of the vitreous also include a variety of secretory proteins that are typically found in serum or other tissues fluids, such as albumin, transferrin, crystallins, apolipoproteins, immune globulins, $\alpha 2$ macroglobulin, and vitellogenins; they are not considered ECM proteins that do not contribute to the fibrillar matrix of the vitreous.

Collagen II establishes together with collagens V/XI and IX the dominant fibrillar network of the VB ECM that is responsible for the gel-like nature of vitreous. Many of the other ECM proteins, such as fibronectin, tenascin, and opticin are noncovalently associated with these collagen fibrils. Linear polymers of fibrillin establish

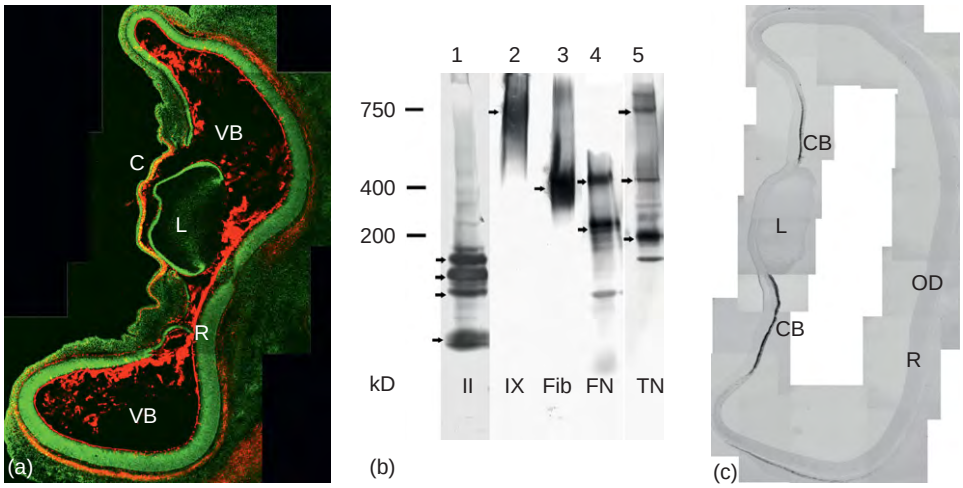

Figure 1 Localization, western blot analysis, and *in situ* hybridization of major VB proteins in the embryonic chick eye. Immunocytochemistry using an antibody to collagen II (a) shows the VB as a loose meshwork of ECM fibrils (red) that fills the entire lumen of the posterior eye. Particular high concentrations of collagen II are found in the cortical vitreous along the surface of the retina (R). Sytox-Green was used as a nuclear counter-stain (green). Collagen II is also found in the stroma of the cornea (C). Western blot analysis (B) of embryonic chick vitreous showed the multiple protein bands of collagen II (II), fibronectin (FN), and tenascin (TN). Fibrillin (Fib) and collagen IX (IX) appeared as long smears due to their extensive glycosylation. Specific bands are indicated by arrows. *In situ* hybridization (C) shows the high concentration of collagen IX mRNA in the ciliary body (CB), the main site of protein synthesis for the interior of the eye. The retina (R) and optic disk (OD) were not labeled, and thus, do not contribute in the synthesis of this protein.

a second ECM network that is ultrastructurally different from the collagen II fibrils. The water-binding and space-filling components of the VB are the highly charged glycosaminoglycans that exist either by themselves (i.e., hyaluronic acid) or are covalently connected to the core proteins of collagen IX and versican, the two chondroitin sulfate proteoglycans that have been detected in VB. The gelatinous nature and the very high water content of the vitreous are responsible for the transparency of the VB and allow passage of light to the retina. The high water concentration of the VB gel also buffers the interior of the eye, presses the retina against the pigment epithelium, and creates the intraocular pressure that promotes the expansion of the eye during ocular development.

Synthesis of VB Proteins in the Eye and Assembly of the VB Gel

Based on its localization next to the retina, most textbooks state that the VB proteins are synthesized by the retinal glial cells and (or) by the hyalocytes, the few macrophage-like cells that are found in the VB. However, the ECM of the VB is assembled from secreted proteins, and the sites of synthesis of these proteins cannot be predicted by location based on immunocytochemistry. A straightforward technique for the detection of the site of synthesis of VB proteins is the localization of their messenger RNA (mRNA) expression sites in the eye by means of *in situ* hybridization, reverse transcription polymerase chain reaction (RT-PCR), or Northern blotting. *In situ* hybridization is currently the method of choice to localize mRNA expression and to pinpoint the sites of synthesis of VB ECM proteins in the eye; particularly since Northern blotting and RT-PCR require microdissection of defined parts of the eye that is inherently prone to contamination from adjacent tissues. Several *in situ* hybridization studies have shown that the dominant site of mRNA expression for VB ECM proteins is the nonpigmented epithelium of the ciliary body, the nonneuronal epithelium that is an anterior extension of the retina located adjacent to the lens (**Figure 1(c)**). The retina contributes to VB protein synthesis to a minor degree: collagen II, for example, has been shown to originate in early embryonic development from the retina, and collagen IX apha1 mRNA has been detected in the retina as well. But even for these proteins, the dominant production site is the ciliary body, and the retina is only a secondary site of synthesis. Other minor sites of VB protein synthesis during eye development are the optic disk and the hyaloids blood vessels.

Independent support for the ciliary body as the dominant site of VB protein synthesis comes from mutant mice with targeted deletions of nectin 1 and 3. Both proteins are cell adhesion proteins that are essential for the morphogenesis of the ciliary body. Deletion of either of the proteins, or the expression of dominant negative constructs, results in an aborted development of the ciliary body and the absence of the VB.

Several of the serum-typical proteins, such as transferrin and α2-macroglobulin that have been detected in the

The list of proteins was established from samples of E9 chick VB resolved by SDS-PAGE and analyzed by mass spectrometry. The proteins are listed in alphabetical order. The most abundant ECM protein in vitreous is collagen II. Proteins indicated by x were also detected by western blotting and (or) by immunocytochemistry. The proteins indicated in gray were detected after subfractionation of the vitreous by affinity chromatography using heparin sepharose. The sites of synthesis in the eye for each of the proteins, as determined by *in situ* hybridization, are listed in the last column. CB: ciliary body; BV: blood vessels; OD: optic disk; ?: unknown. Minor sites of synthesis are listed in a smaller font size. Note, that with few exceptions, most vitreous ECM proteins are synthesized by the ciliary epithelium, the dominant production site for ECM proteins of the interior of the eye. The IPI numbers refer to the International Protein Index.

vitreous, are also synthesized by the ciliary body. Thus, the current data indicate that the ciliary body is the dominant site of protein synthesis for the interior of the eye.

In vitro experiments, trying to recreate ECM fibril assembly of hyaline cartilage, have shown that mixtures of collagen II, IX, and V/XI, when incubated at physiological temperatures and at defined molar ratios, form long and uniform fibrils with a diameter of 20 nm. Since the VB shares many of its ECM proteins with cartilage, it is conceivable that a similar self-assembly of a fibrillar collagen network occurs in the vitreous chamber of the eye. What has not been established, though, is whether the self-assembled collagen II/IX and V/XI fibrils formed *in vitro* establish a transparent ECM gel with the same biomechanical stability as the vitreous gel. Further, *in vivo* experiments showed that a one-time liquefaction of the vitreous gel is irreversible, as the VB does not reconstitute to a gel even after collagen II and many of the remaining VB ECM proteins have reached normal concentrations again. It appears that a high concentration of collagen II alone may not be sufficient for the VB gel to assemble. Targeted gene deletion in mice has shown that collagen V/XI initiates collagen I fibrillogenesis; therefore, it is possible that collagen V/XI is required for the initiation of the collagen fibrillar network of the VB. It is worth noting that the mouse is not an optimum model system for studying VB assembly, since the vitreous cavity is very small and VB samples difficult to obtain.

The Turnover of VB Proteins

Western blotting showed that the monomeric ECM proteins in the VB are very abundant in the embryonic but almost undetectable in the adult eye. A time-course study in

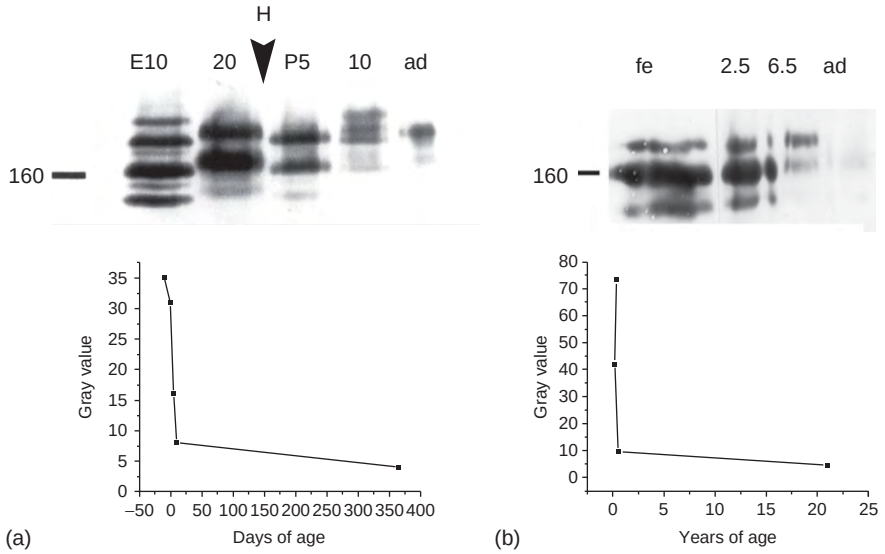

Figure 2 Time course of monomeric collagen II concentration in chick (a) and human (b) VB. The chick VB samples (a) were taken from E10, E20, posthatched (P) 5, P10, and adult chicken. The gray values of the bands was measured by densitometry and plotted against age showing the high concentration of collagen II in embryonic stages of development, and its rapid decline after hatching. The human VB samples (b) were from 20-week fetuses, from 2.5, 6.5 month, and adult humans. The gray values of the collagen II bands blotted against age shows the high concentration of collagen in fetal VB, its rapid decline postnatally and the very low abundance in the adult VB.

chick and human demonstrated a dramatic age-dependent decline in the abundance of the major ECM proteins from VB. In chick, the decline occurred in late embryonic stages, and the concentration of the VB ECM proteins reached very low levels already 10 days after hatching (**Figure 2(a)**). In human, the decline occurs in the first few months after birth, and plotting the data shows that monomeric collagen II is almost undetectable by the second year of life (**Figure 2(b)**).

The presence of monomeric VB ECM proteins during embryogenesis is indicative for active VB *de novo* assembly: for example, chick eyes grow between E2 and E20 by a factor of 20, and the high abundance of VB protein monomers at that stage of development allows for an instant assembly of new VB ECM during the rapid eye growth. The low abundance of monomeric VB proteins in the adult eye indicates a major reduction in the rate of *de novo* synthesis and reflects a slow turnover of the VB.

Quantification of mRNA expression for VB proteins in mouse eyes by Northern blotting at different stages of development confirmed the western blotting data: the mRNA concentrations for collagen II and IX peaked at mid-embryogenesis and then steeply declined postnatally approaching the detection limit. Thus, both western blotting and mRNA expression levels are consistent with the notion that the *de novo* synthesis of VB proteins is dramatically tuned down at early postnatal stages of development and remains at a low level throughout adult life. The data are consistent with the fact that the VB gel undergoes an age-dependent liquefaction and does not regenerate after vitrectomy. Further, immunostaining has shown that the density of collagen IX on the surface of the collagen II fibrils decreases with age, most likely due to protein degradation and insufficient *de novo* synthesis. Not all proteins in VB decrease in concentration over time: transferrin, a non-ECM protein that is synthesized by the ciliary body, remains steady from embryogenesis to old age. A similar steady expression was detected for fibronectin and α2-macroglobulin, the latter even increasing in concentration from embryonic to adult stages. It appears that the downregulation of VB protein expression is prominently targeted to ECM proteins with long half-lives.

It is tempting to speculate that the very long half-life of many of the ECM proteins in the body requires a major downregulation of protein synthesis. Several studies have shown that collagens in articular cartilage have half-lives of up to 100 years, and the half-life of collagen IX in human VB has been estimated to be 11 years. A continued high rate of synthesis of the very slowly metabolized ECM proteins in the eye would probably lead to an over-concentration of the proteins in the vitreous chamber resulting in an opaque vitreous that would interfere with vision.

It if of note that *de novo* synthesis of collagen II has been demonstrated in human eyes after vitrectomy; yet, the concentration was below the detection level of immunocytochemistry and western blotting. Other authors have also suggested that the vitreous is undergoing a constant renewal in the adult.

Acknowledgments

We would like to thank Robert Johnson from the Brain and Tissue Bank for Developmental Disorders (University of Maryland, Baltimore, MD) and Janice Anderson from the Center for Organ Recovery and Education (CORE) of Pittsburgh for providing the fetal and adult human eye samples and the National Science Foundation for support of the project (IBN# 0240774).

Central Retinal Vein Occlusion

S S Hayreh, University of Iowa, Iowa City, IA, USA

Glossary

Demographic – The statistical study of a population, including geographical distribution, sex and age composition, and birth and death rates.
Electroretinography – The recording of the changes in electric potential in the retina by stimulating it by light.
Fluorescein fundus angiography – The visualization of blood vessels in the interior of the eye following intravenous injection of fluorescein.
Glaucoma – An eye disease caused by an increase in eye pressure, which causes changes in the optic nerve and loss of vision.
Hematological – Dealing with the blood and blood-forming tissues.
Histopathological – Dealing with the minute structure of diseased tissues.
Lamina cribrosa – The perforated portion of the back part of the white of the eye (sclera) through which nerve fibers from the retina exit.
Multifactorial – Related to, or arising through the action of many factors.
Neovascularization – The formation of abnormal new blood vessels.
Ophthalmoscopy – The examination of the interior of the eye with the instrument called ophthalmoscope.
Panretinal photocoagulation – The application of an intense beam of laser light to the entire retina.
Pathogenesis – The mechanisms of development of a disease.
Perimeter – An apparatus used to test the visual field.

Retinal vein occlusion is the most common retinal vascular occlusive disorder. In general, there is a tendency to regards this as one disease; that is not only incorrect but also causes much confusion. From the point of view of pathogenesis, clinical picture, prognosis, and management, retinal vein occlusion in fact consists of six distinct clinical entities that are categorized as follows:

1. Central retinal vein occlusion (CRVO), which comprises
   a. nonischemic CRVO, and
   b. ischemic CRVO.
2. Hemi-central retinal vein occlusion (HCRVO), which comprises
   a. nonischemic HCRVO, and
   b. ischemic HCRVO.
3. Branch retinal vein occlusion, which includes
   a. major BRVO, and
   b. macular BRVO.

It is beyond the scope of this article to discuss all the six types of retinal vein occlusion; hence, we restrict our discussion only to CRVO. Over the last 150 years, a large volume of literature has accumulated on the subject of CRVO. The objective of this article is to provide a brief review of the current state of our knowledge on the subject.

Pathogenesis

A good understanding of the pathogenesis of a disease is fundamental to a full grasp of the clinical features of the disease and its logical management. There is almost a universal tendency to blame one or two factors as causative factor(s) in the development of CRVO, but association does not necessarily mean there is a cause-and-effect relationship. Available evidence strongly suggests that the pathogenesis of CRVO, like many other ocular vascular occlusive disorders, is a multifactorial process. It seems that some risk factors predispose an individual or an eye to CRVO (predisposing risk factors), while others act as the final insult and produce clinically evident disease (precipitating risk factor(s)). Only when an eye and an individual have the critical number of risk factors required for the development of CRVO, does the CRVO develop. This must explain why bilateral CRVO is rare. Once this basic concept of multifactorial causation is understood, one can attach appropriate significance to the various risk factors. The various risk factors for CRVO may be divided into the following three categories:

Local. Two local factors are particularly important:

1. The central retinal vein and central retinal artery lie in the center of the optic nerve, surrounded by a fibrous tissue envelope (**Figure 1**). In elderly persons, sclerotic changes in the central retinal artery and the fibrous tissue envelope compress the thin-walled central retinal vein, resulting in narrowing of its lumen. This produces circulatory stasis. According to Virchow's triad, slowing down of the blood stream causes stagnation thrombosis.

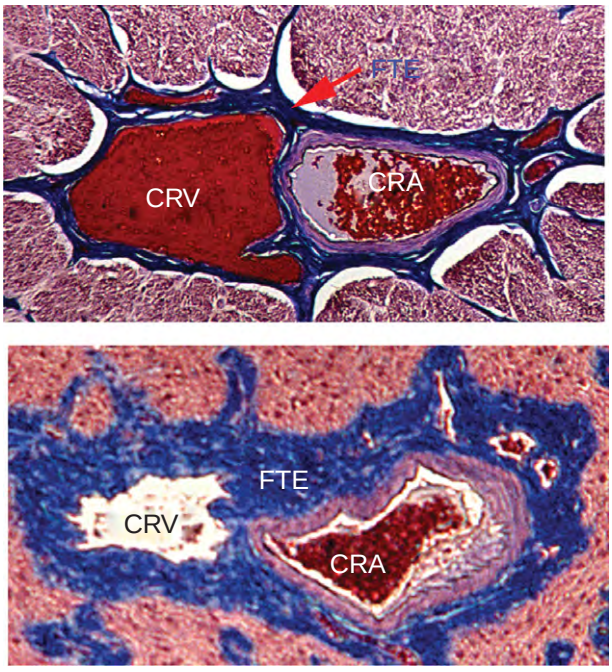

Figure 1 Histological sections (Masson's trichrome staining) showing the central retinal vessels and surrounding fibrous tissue envelope, as seen in a transverse section of the central part of the retrolaminar region of the optic nerve, in a normal rhesus monkey (above) and in a rhesus monkey with experimental arterial hypertension, atheroselerosis, and glaucoma (below). CRA, Central retinal artery; CRV, central retinal vein; FTE, fibrous tissue envelope.

2. It is well established that CRVO is significantly more common in patients with raised intraocular pressure (IOP) and glaucoma.

Systemic. A significant association of CRVO has been reported with arterial hypertension, diabetes mellitus, cardiovascular disease, atherosclerosis, and thyroid disease.

Hematological. The literature is full of reports of hematological abnormalities in CRVO. The author recently critically reviewed the literature dealing with these and found no definite pattern – often the negative findings outweighed the positive ones. The idea of hematologic factors playing a role in CRVO is essentially based on the assumption that those hematological disorders, which play a role in development of systemic venous thrombosis (e.g., deep vein thrombosis), must also do so in CRVO. All the available evidence, however, indicates that the hematologic risk factor responsible for major systemic venous thrombosis occurs only sporadically in CRVO. Furthermore, CRVO is extremely rare in patients with systemic venous thrombosis. Moreover, the presence of a particular hematologic disorder in a patient does not necessarily mean it has a cause-and-effect relationship with CRVO. In view of this, there is no particular reason for conducting a detailed hematological investigation in all patients with CRVO.

Site of Occlusion in CRVO

Based on histopathological studies, there is a widespread misconception that the site of occlusion in CRVO is invariably at the lamina cribrosa. However, all the available anatomical, experimental, and clinical evidence (particularly fluorescein fundus angiography) shows that the actual site of occlusion in the central retinal vein is typically in the optic nerve, at a variable distance posterior to the lamina cribrosa, and not at the lamina cribrosa (Figure 2). The farther back the site of occlusion, the more collaterals are available, and the less severe is the retinal venous stasis. Thus, in nonischemic CRVO the site of occlusion most likely is farther back in the optic nerve, whereas in ischemic CRVO it is closer to the lamina cribrosa.

Demographic Characteristics

CRVO is more common in middle-aged and elderly persons, and patients with ischemic CRVO tend to be older than those with nonischemic CRVO. Contrary to the prevalent impression, CRVO is not at all rare in young persons, and the incidence in persons under the age of 45 years has been reported as high as 18%. Thus, no age is immune. In our series of 620 consecutive CRVO cases, 81% were nonischemic and 19% ischemic CRVO. The Kaplan–Meier estimate of the cumulative proportion of eyes that developed nonischemic CRVO in the fellow eye is about 6% within 1 year and 7% within 5 years from onset in the first eye; for ischemic CRVO it is 5.6% at 2.8 years.

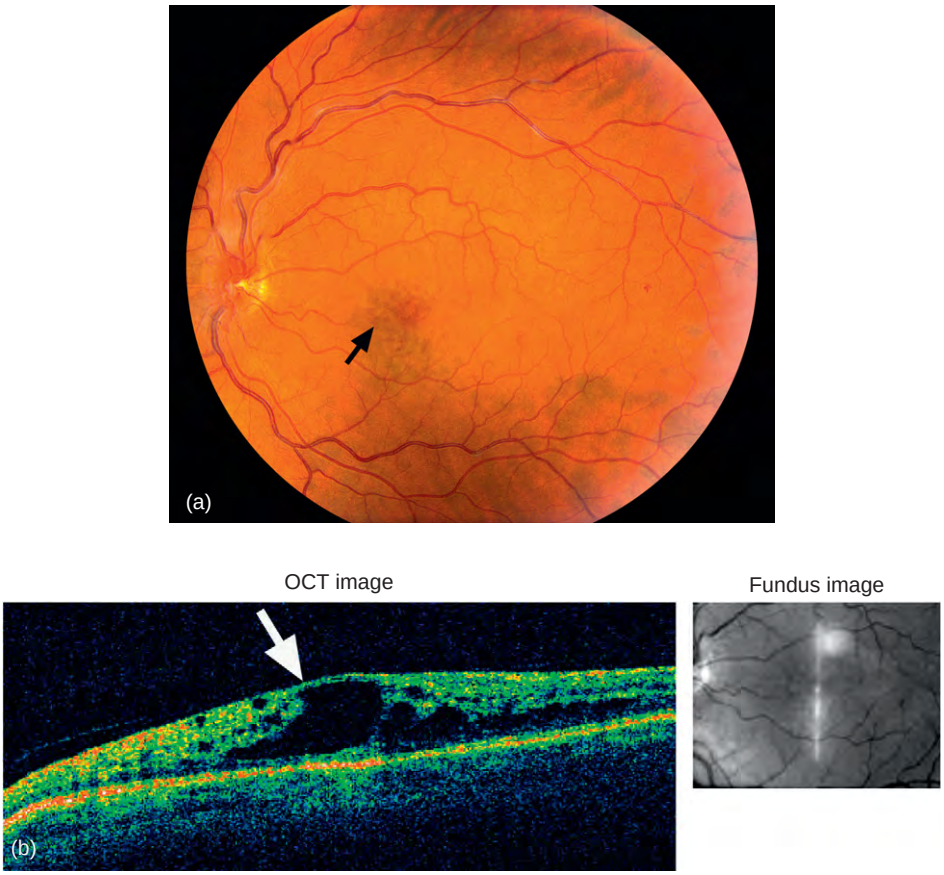

Figure 3 Fundus photograph (a) and OCT (b) of a nonischemic CRVO eye with resolution of retinopathy, except for the cystoid macular edema (arrow).

Clinical Features

With regard to symptoms, patients with nonischemic CRVO may have no symptoms and it may be detected as an incidental finding on a routine ophthalmic examination. Retinal venous stasis with mild retinal hemorrhages *per se* is asymptomatic. Occasionally there may be a history of episodes of transient visual blurring before constant visual deterioration. Almost invariably, it becomes symptomatic only when there is involvement of the foveal region by development of macular edema (**Figures 3** and **4**) and rarely by hemorrhages. Therefore, the most common complaint is gradual development of central visual blurring, usually more marked on waking up in the morning, improving to a variable extent after a few hours or in the afternoon. In ischemic CRVO, on the other hand, there is always marked deterioration of vision.

While the diagnosis of CRVO is not difficult because of its classical clinical features (**Figures 5** and **6**), the main problem is differentiation of nonischemic from ischemic CRVO, which is crucial for the correct management of CRVO. This is because nonischemic CRVO is a comparatively benign condition, with permanent central

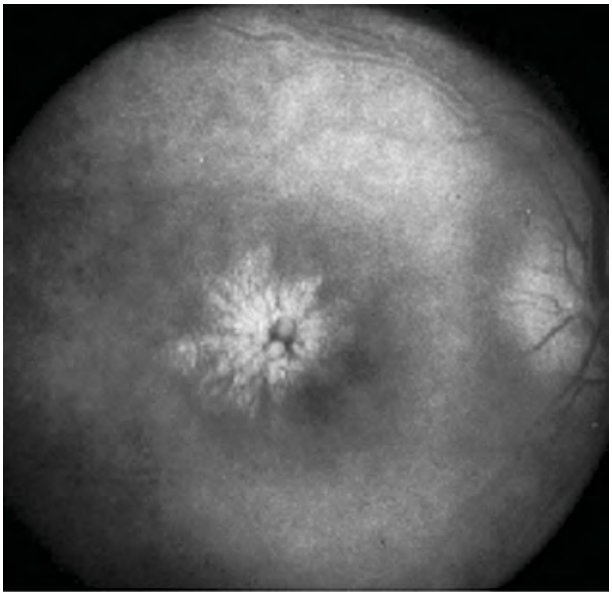

Figure 4 Late phase of fluorescein fundus angiogram of an eye with nonischemic CRVO showing classical petaloid pattern of cystoid macular edema.

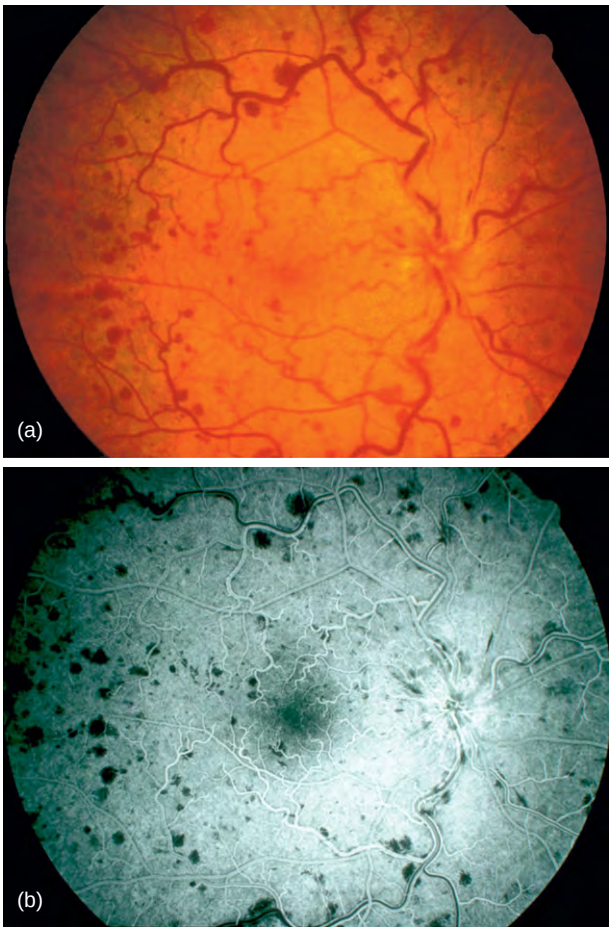

Figure 5 Fundus photograph (a) and fluorescein fundus angiogram showing intact retinal capillary network (b) of an eye with nonischemic CRVO. Reproduced from Hayreh, S. S. (1994). *Indian Journal Ophthalmology* 42: 109–132.

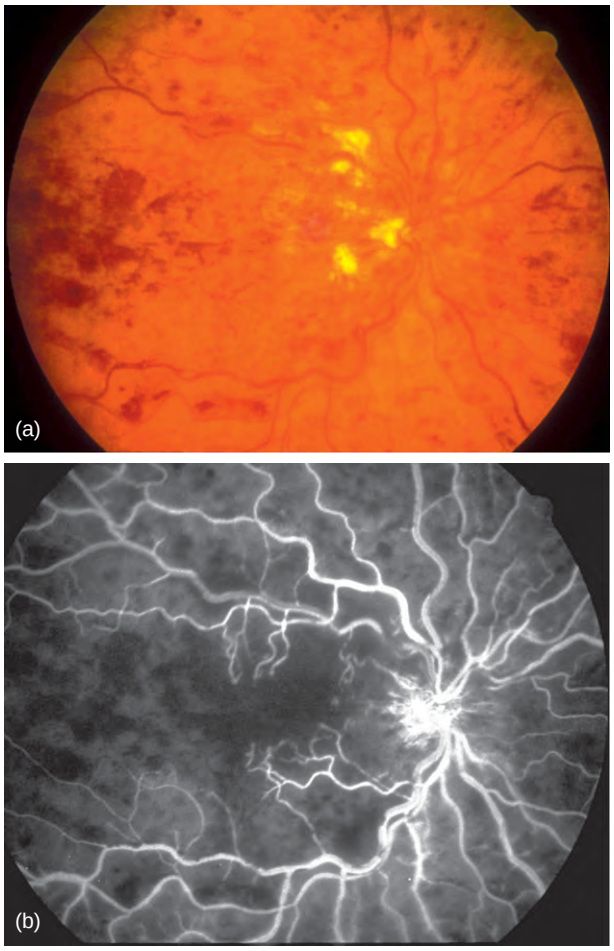

Figure 6 Fundus photograph (a) and fluorescein fundus angiogram showing complete nonperfusion of retinal capillary network (b) of an eye with ischemic CRVO. Reproduced from Hayreh et al. (1983). Ocular neovascularization with retinal vascular occlusion III. Incidence of ocular neovascularization with retinal vein occlusion. *Ophthalmology* 90: 488–506.

scotoma as the major complication in some eyes, but no ocular neovascularization (NV). In sharp contrast to this, ischemic CRVO is a blinding disease, with high risk of development of anterior segment NV, particularly neovascular glaucoma, which often results in blindness or even loss of the eye. Thus, the two types of CRVO can be compared to benign and malignant tumors.

Differentiation of Ischemic from Nonischemic CRVO

Ophthalmologists have almost universally used ophthalmoscopic and fluorescein angiographic appearances to evaluate and manage CRVO and to differentiate ischemic from nonischemic CRVO. However, these two morphological tests have much lower sensitivity and specificity to differentiate the two types of CRVO compared to the four functional tests – visual acuity, peripheral visual fields plotted with a Goldmann perimeter, relative afferent pupillary defect, and electroretinography. Table 1 gives sensitivity and specificity of various functional tests to differentiate ischemic from nonischemic CRVO.

On fluorescein fundus angiography, to differentiate ischemic from nonischemic CRVO, the presence of a 10 disk area or more retinal capillary obliteration has been regarded as the gold standard in practically all the reported studies, but there are several serious problems with this criterion, including the following:

1. During the early, acute stages of CRVO, to provide reliable information on retinal capillary obliteration, angiography has many serious limitations, including extensive retinal hemorrhages, poor-quality angiograms, inability to perform angiography for a variety of reasons, the time lag of several weeks after the onset of CRVO before retinal capillary obliteration is visible, and other limitations. A study showed that fluorescein angiography provided reliable information at best in only

50–60% of cases during the early, acute phase, which is clinically unsatisfactory for early management.
2. Most importantly, a criterion of a 10 disk area or more of retinal capillary obliteration has been widely advocated as the definitive yardstick for diagnosis of ischemic CRVO. However, this is an invalid criterion to differentiate nonischemic from ischemic CRVO. A multicenter study showed that eyes with <30 disk diameters of nonperfusion and no other risk factor are at low risk for iris/angle NV (i.e., ischemic CRVO), 'whereas eyes with 75 disk diameters or more are at highest risk'.

As regards ophthalmoscopy, there is a marked overlap between the two types of CRVO and virtually a continuous evolution of ophthalmoscopic lesions (i.e., retinal hemorrhages, venous dilatation, and cotton-wool spots, etc.; **Figures 5(a)** and **6(a)**), which makes it hard to use this to differentiate the two types of CRVO.

A study showed that to differentiate the two types of CRVO, the overall order of reliability of various tests is as follows:

1. *Relative afferent pupillary defect*. In unilateral CRVO, when the fellow eye is normal.
2. *Electroretinography*. This is the next best test and it can be done even when the fellow eye is not normal, as in bilateral CRVO.
3. *Relative afferent pupillary defect combined with electroretinography*. This proved to be the most reliable (in 97%).
4. *Peripheral visual fields plotted with a Goldmann perimeter*. This is next in order and better than visual acuity. Since central scotoma is present in all CRVO eyes, that does not help in differentiation.
5. *Visual acuity*. This is also helpful in many cases.
6. *Fluorescein angiography*. This proved to be much worse than any of the functional tests in early stages.
7. *Ophthalmoscopy*. This is the least reliable and most misleading parameter of all.

Table 1 Sensitive and specify of various functions tests to differentiate ischemic from nonischemic CRVO

Functional test		*Sensitivity*	*Specificity*
Visual acuity	20/400 or less	91%	88%
Peripheral visual fields	No I-2e	97%	73%
	Defective V-4e	100%	100%
Relative afferent pupillary defect	≥0.9 log units	80%	97%
Electroretinography	b-wave amplitude <60%	80%	80%

From Hayreh, S. S., Klugman, M. R., Beri, M., Kimura, A. E., and Podhajsky, P. (1990). Differentiation of ischemic from non-ischemic central retinal vein occlusion during the early acute phase. *Graefe's Archive for Clinical and Experimental Ophthalmology* 228: 201–217.

Thus, we can conclude that no single test has 100% sensitivity and specificity to differentiate the two types of CRVO during the early, acute phase, such that no single test can be considered a gold standard; however, combined information from all the six tests is almost always reliable. The four functional tests overall are much superior to the two morphologic tests.

Course of CRVO

Both types of CRVO run a self-limited course, taking from a few weeks to many years for the retinopathy to resolve. In the meantime, some of these eyes can develop various complications, including those discussed below.

Complications

The main complications of the two types of CRVO are as follows:

1. *Macular edema*. This is the most common complication in both types of CRVO (**Figures 3** and **4**). However, it does not affect eyes with mild nonischemic CRVO. Chronic macular edema later on may produce cystoid macular degeneration (**Figure 3(a)**), macular pigmentary degeneration (very much resembling age-related macular degeneration; **Figure 7**), and/or epiretinal membrane – all resulting in central scotoma.
2. *Ocular NV*. This is the most dreaded complication of CRVO and a complication of ischemic CRVO alone. It is extremely important to note that ocular NV is almost never seen in nonischemic CRVO, unless it is associated with diabetic retinopathy or ocular ischemia.

The cumulative probability of developing various types of ocular NV in ischemic CRVO is shown

Figure 7 Fundus photograph of an eye with resolved nonischemic CRVO, showing macular pigmentary degeneration and retinociliary collaterals on the optic disk, as the permanent, residual changes.

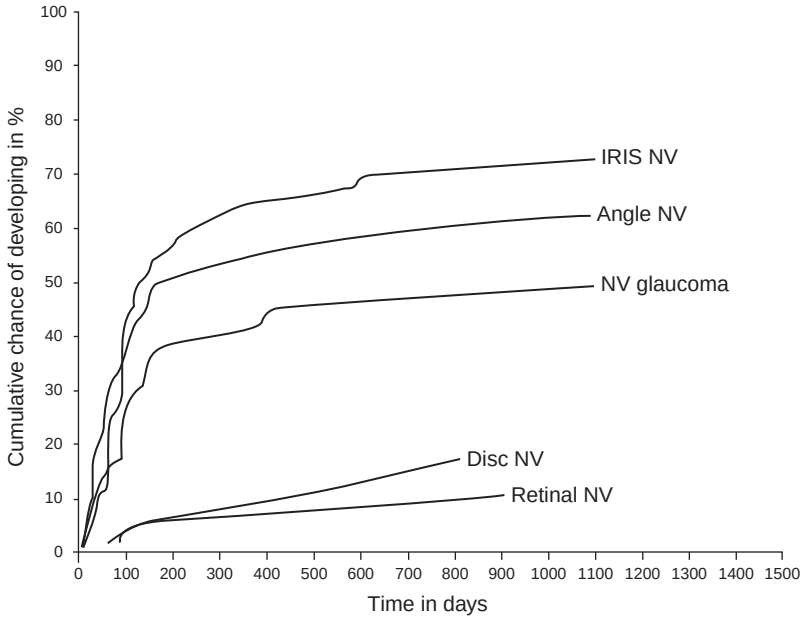

Figure 8 A graphic representation of cumulative chances (in %) of developing various types of ocular neovascularization in ischemic CRVO in relation to time from onset of the disease (in days).

graphically in Figure 8, which provides five very important pieces of information for management of CRVO:

a. Not every eye fulfilling the criteria given above for ischemic CRVO develops ocular NV.
b. When ocular NV does develop, the most common site is the anterior segment, much less frequently the posterior segment.
c. The greatest risk of developing anterior segment NV is during the first 7–8 months, after which the risk falls dramatically, to minimal. The old concept of 100-day glaucoma has no validity.
d. The maximum risk of developing neovascular glaucoma is about 50% – not 100%, as often stated.
e. About one-third of eyes with iris NV and about one-quarter of eyes with both iris and angle NV, contrary to the prevalent impression, never progress to develop neovascular glaucoma.

In order to place the overall incidence of ocular NV, particularly of neovascular glaucoma in CRVO, in true perspective, it is essential to point out two important facts:

i. ischemic CRVO constitutes only one-fifth of all CRVO cases (see above);
ii. neovascular glaucoma, the most dreaded complication of CRVO, is seen at the maximum in about 50% of ischemic CRVO cases only.

This means that the overall incidence of neovascular glaucoma in all CRVO cases is no more than 10% at the most – a key fact in any consideration of the management of CRVO.

3. *Vitreous hemorrhage.* In CRVO, this may be either secondary to retinal/optic disk NV or due to rupture of the retinal blood through the internal limiting membrane, particularly in eyes with many subinternal limiting membrane hemorrhages (Figures 9–11). Therefore, it is important to be aware that the presence of vitreous hemorrhages in CRVO does not always mean that there is retinal/disk NV.

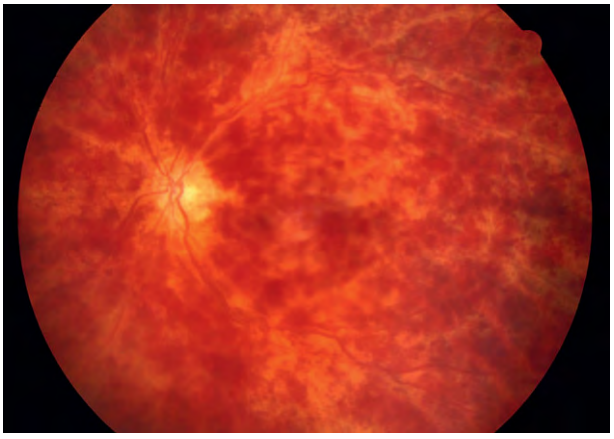

Figure 9 Fundus photograph of an eye with nonischemic CRVO in a patient on aspirin, showing extensive retinal hemorrhages.

4. *Cilioretinal artery occlusion.* The major cause of serious visual loss in nonischemic CRVO is the development of associated transient occlusion of a cilioretinal artery due to hemodynamic block and not due to any thrombosis in the artery (Figures 12 and 13). This is particularly so when the artery supplies a large sector of the retina (Figure 13) or supplies the entire maculopapillar bundle (resulting in a large absolute centrocecal defect).

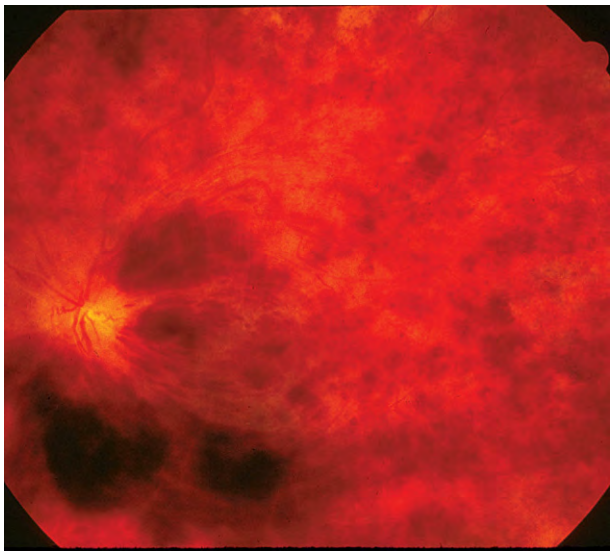

Figure 10 Fundus photograph of an eye with nonischemic CRVO in a patient on anticoagulant therapy, showing extensive retinal hemorrhages. Reproduced from Hayreh, S. S. (2006). *Retina* 26: S51–S62, with permission from Wolters Kluwer.

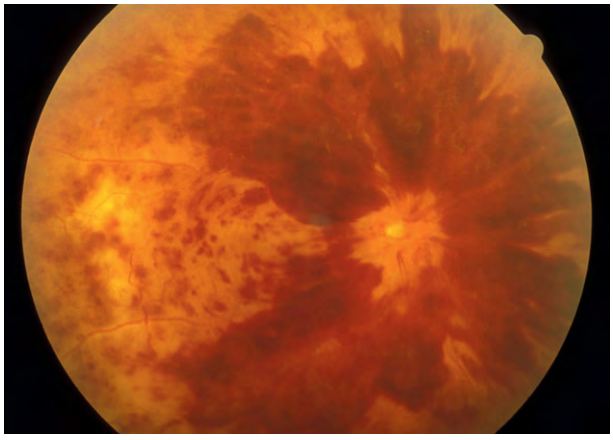

Figure 11 Fundus photograph of an eye with ischemic CRVO in a patient on anticoagulant therapy, showing extensive preretinal hemorrhages.

5. *Conversion of nonischemic CRVO to ischemic CRVO.* Figure 14, based on study of 620 consecutive CRVO eyes, shows Kaplan–Meier survival curves for cumulative probability of conversion of nonischemic CRVO to the ischemic type. This change can happen either overnight or gradually.

Management of CRVO

In the management of CRVO, the first, most crucial step is to determine whether one is dealing with nonischemic or ischemic CRVO because of their very different nature, prognosis, visual outcome, and management. Lack of such differentiation has resulted in major controversies on CRVO.

Figure 12 Fundus photograph of an eye with nonischemic CRVO and retinal infarct in a narrow strip below the foveola due to associated cilioretinal artery occlusion. Reproduced from Hayreh, S. S., Fraterrigo, L., and Jonas, J. (2008). Central retinal vein occlusion associated with cilioretinal artery occlusion. *Retina* 28: 581–594, with permission from Wolters Kluwer.

Over the years, many treatments have been advocated enthusiastically and success claimed. A review of the treatment options, which have been championed from time to time, reveals that they vary from the logical to the totally absurd. The most important consideration when evaluating any proposed therapy for any disease is

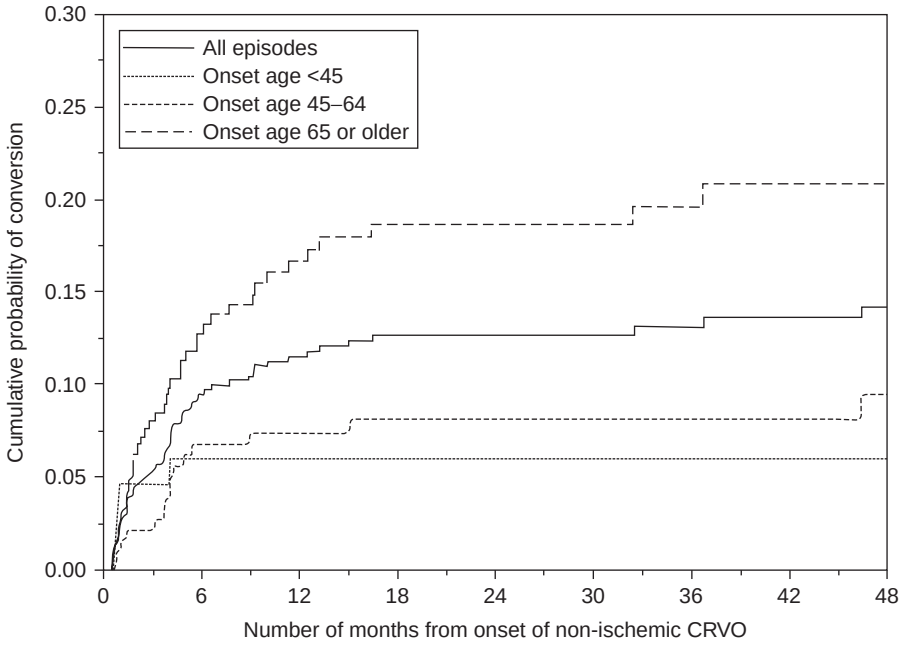

Figure 14 Kaplan–Meier survival curve for cumulative probability of conversion of nonischemic central retinal vein occlusion to ischemic type. Vertical axis gives cumulative probability of the conversion. Horizontal axis gives number of months from onset of nonischemic central retinal vein occlusion. Reproduced from Hayreh, S. S., et al. (1994). *American Journal of Ophthalmology* 117: 429–441.

to determine whether it is based on incontrovertible scientific facts and rationale. Treatments without such a logical foundation prove not only useless but also sometimes harmful. Most of the reported studies have been based on retrospective collection of information or on limited personal experience and, therefore, have a variety of limitations which make it hard to evaluate the claimed benefits; the limitations include lumping together of central and branch retinal vein occlusion, no differentiation of ischemic and nonischemic CRVO or use of invalid criteria to do so, therapies having no scientific validity, flawed study designs, and personal biases. All the proposed therapies must then be carefully scrutinized.

The main treatments advocated for CRVO can be divided into three categories, namely medical, surgical, and panretinal photocoagulation (PRP), which are discussed below.

Medical Treatments

These include anticoagulants, aspirin or other antiplatelet agents, ocular hypotensive therapy, hemodilution, systemic or intravitreal corticosteroids, intravitreal anti-VEGF (VEGF, vascular endothelial growth factor) drugs, systemic acetazolamide, and antihypertensive therapy. Of these, either aspirin or anticoagulants have been most widely used, based on the impression that a treatment which is beneficial for systemic venous thrombosis is also good for CRVO; however, the two conditions are totally different etiologically and pathogenetically. Neither anticoagulants nor aspirin has any scientific rationale in the management of CRVO. They increase retinal hemorrhages (**Figures 9–11, and 15**), thereby adversely influencing the visual outcome. Moreover, patients already on those drugs for other reasons do develop CRVO, indicating that they do not prevent an eye from developing CRVO. The so-called blood-and-thunder or tomato-ketchup fundus appearance described in CRVO is usually an iatrogenic phenomenon resulting from the use of aspirin or anticoagulants; it is not usually seen in regular CRVO. There is no scientific rationale for the commonly used ocular hypotensive therapy in CRVO eyes with normal IOP; however, if the fellow uninvolved eye has ocular hypertension or glaucoma (which is common), that eye must be treated to reduce the chances of its developing CRVO – thus, it is mostly the wrong eye (i.e., with CRVO) which is being treated. Recently, intravitreal corticosteroids and intravitreal anti-VEGF drugs have been widely advocated, primarily to manage macular edema; however, it is important to stress that the treatment with these agents is simply helping to reduce or eliminate macular edema transiently to prevent long-term permanent macular changes (**Figures 3 and 7**); it is not a cure for the CRVO, which has to take its own natural course. Moreover, both drugs require repeated intravitreal injections to maintain effectiveness and can have some side effects. As regards the rest of treatment modalities, there is not much scientifically valid evidence of beneficial effects.

Surgical or Invasive Treatments

These include (1) surgical decompression of the central retinal vein, (2) fibrinolytic therapy, and (3) laser-induced

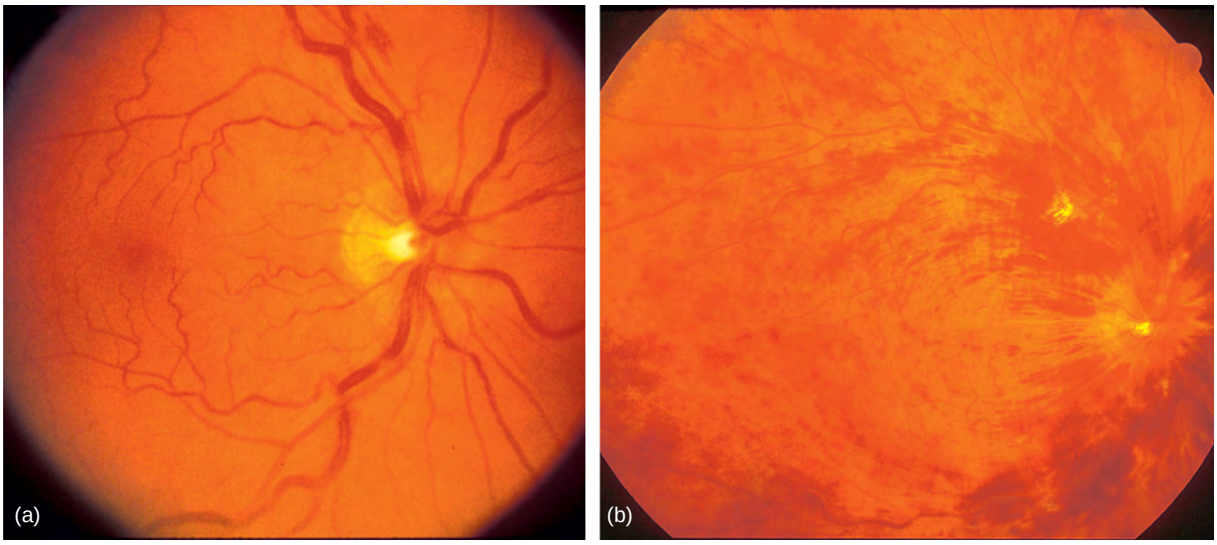

Figure 15 Fundus photographs of a 36-year-old man, who had nonischemic CRVO. When first seen by his ophthalmologist, he had a visual acuity of 20/20 and the fundus showed some peripheral retinal hemorrhages and a rare one posteriorly (a). The ophthalmologist started him on aspirin, and at next visit he had extensive hemorrhages all over (b). On follow-up, his visual acuity progressively deteriorated to finally 20/200. Reproduced from Hayreh, S. S. (2006). *Retina* 26: S51–S62, with permission from Wolters Kluwer.

chorioretinal venous anastomosis for treatment of nonischemic CRVO, which are detailed below:

1. *Surgical decompression of central retinal vein.* It has been claimed that a procedure called radial optic neurotomy, in which a radial cut in the optic nerve head, from the vitreous side, extending all the way down to the lamina cribrosa and adjacent sclera, is beneficial. This procedure not only has no scientific rationale but also can actually be deleterious – it involves cutting thousands of optic nerve fibers, which results in visual loss in the distribution of the cut nerve fibers.
2. *Fibrinolytic therapy.* Currently, the most widely promoted procedure of this type is vitrectomy with branch retinal vein cannulation and infusion of tissue plasminogen activator (t-PA). This procedure lacks scientific rationale and can be associated with complications; beneficial claims made for it seem unwarranted.
3. *Laser-induced chorioretinal venous anastomosis for treatment of nonischemic CRVO.* This procedure has many immediate and late complications, which heavily outweigh any dubious benefits. Therefore, it is not a safe and effective mode of treatment for a condition which has a fairly good outcome if simply left alone (see below).

Panretinal Photocoagulation

Currently, PRP is almost universally considered the treatment of choice in CRVO to prevent development of ocular NV, and macular grid photocoagulation for the management of macular edema. The rationale for usefulness of PRP in CRVO is based primarily on its beneficial effect seen in proliferative diabetic retinopathy.

1. *Macular grid photocoagulation for macular edema.* A multicenter clinical trial showed no difference between treated and untreated eyes in visual acuity at any point during the follow-up period. This indicated that there is no role for this treatment in CRVO.
2. *PRP for prevention of ocular NV.* The theoretical justification for PRP in ischemic CRVO is to prevent development of ocular NV and associated blinding complications of neovascular glaucoma and/or vitreous hemorrhage. As discussed above, ocular NV and neovascular glaucoma are seen only in ischemic CRVO. Since nonischemic CRVO does not develop these complications, there is absolutely no indication or justification for PRP in nonischemic CRVO.

Two large prospective studies have been conducted to evaluate the role of PRP in ischemic CRVO. The first study, based on 123 eyes with ischemic CRVO (47 had PRP and 76 no PRP), showed no statistically significant difference between the two groups in the incidence of development of angle NV, neovascular glaucoma, retinal and/or optic disk NV, or vitreous hemorrhage, or in visual acuity. What it did show was that the PRP group suffered a statistically significant ($p \leq 0.03$) greater loss of peripheral visual fields than the nonlaser group (**Figure 16**).

The second study investigated the role of PRP in ischemic CRVO by a multicenter clinical trial in 181 eyes (90 had immediate prophylactic PRP, and 91 no PRP). The purpose of that study was twofold – first to determine whether prophylactic PRP prevents development of iris and angle NV, and second whether PRP prevents progression of iris/angle NV to neovascular glaucoma. In answer to the first question, the study

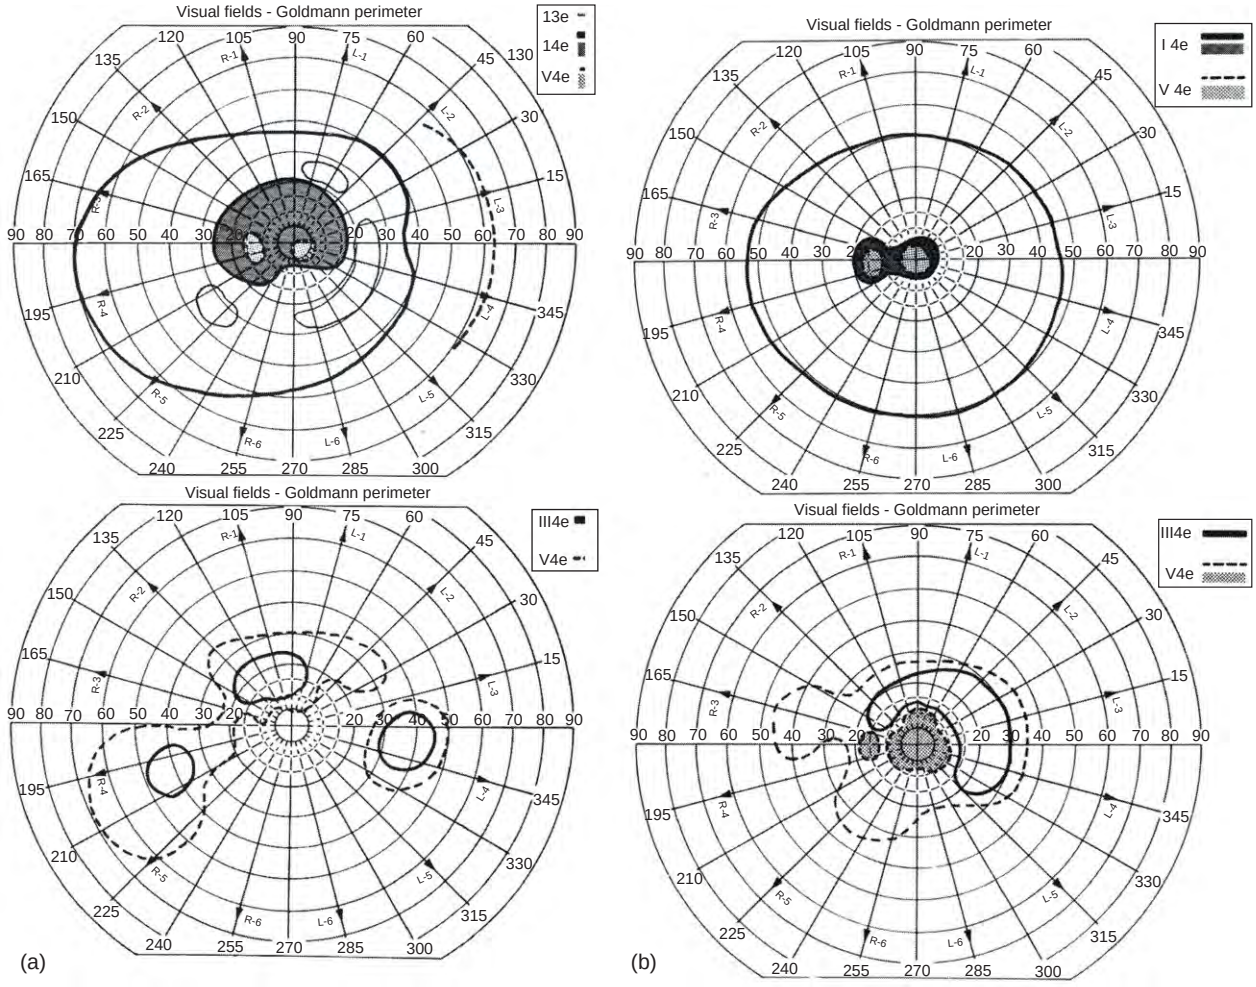

Figure 16 Visual fields, plotted with a Goldmann perimeter, of two left eyes (a, b) with ischemic CRVO, before (top) and after (bottom) panretinal photocoagulation. In both eyes, before photocoagulation (top) the peripheral fields were normal with I4e and V4e isopters, but after photocoagulation (bottom) the peripheral fields developed marked constriction and deterioration. Reproduced from Hayreh, S. S., Klugman, M. R., Beri, M., Kimura, A. E., and Podhajsky, P. (1990). Differentiation of ischemic from non-ischemic central retinal vein occlusion during the early acute phase. *Graefe's Archive for Clinical and Experimental Ophthalmology* 228: 201–217.

reported that "prophylactic PRP does not totally prevent" development of iris/angle NV; its recommendation was not to do that. As for the second aspect of the study, the authors recommended "careful observation with frequent follow-up examinations in the early months (including undilated slit-lamp examination of the iris and gonioscopy) and prompt PRP of eyes in which 2'clock iris/angle neovascularization develops." The most important feature of any study is its design, because that can determine its conclusions and their validity. This multicenter study unfortunately had flaws in its study design, which raised serious issues about the validity of its conclusions. There were three major flaws with the design of this study;

1. there was poor differentiation of ischemic and nonischemic CRVO, so that their treated and untreated groups had mixtures of both types of CRVO, instead of only ischemic CRVO (PRP is indicated only for ischemic CRVO);
2. all eyes that developed 2'clock iris/angle NV were treated so that there was no control group to determine whether there was any difference in progression of iris/angle NV to neovascular glaucoma in treated versus the untreated eyes; and
3. no visual fields were plotted to evaluate the side effects and complications of PRP in CRVO.

The first study, as mentioned above, showed that following PRP, the large central scotoma combined with severe loss of peripheral visual fields might virtually blind the eye (**Figure 16**). It is unfortunate, that this multicenter study, in spite of all these serious flaws, has become the gold standard for treatment of CRVO.

In conclusion, as is quite evident from the brief discussion above, there is no scientifically valid proof so far that

PRP is safe and effective in prevention or management of neovascular glaucoma in ischemic CRVO.

Primary Factor Responsible for Blindness in Ischemic CRVO with Neovascular Glaucoma

The most important consideration in the management of neovascular glaucoma seen in ischemic CRVO is high IOP, which is the primary factor causing marked loss of vision or even blindness in the vast majority of these eyes, by producing glaucomatous optic neuropathy and anterior segment changes. Therefore, if neovascular glaucoma develops (the maximum risk of that is 50%; Figure 8) and the IOP is controlled satisfactorily by any means, the eye can maintain a reasonably good peripheral visual field once the retinopathy burns itself out in due course; the peripheral visual field constitutes a very important component of our visual function, because our navigational capacity depends essentially on that. As the retinopathy regresses, the stimulus for NV diminishes, resulting in spontaneous regression of NV – a fact too often overlooked.

Overall Conclusions About Advocated Treatments for CRVO

It is well known that 'a disease which has no treatment has many treatments' – each advocated enthusiastically for a while and then found to be not only no better than the natural history of the disease or sometimes actually harmful. CRVO has become a graveyard of such therapies, but, given that they were not backed by sound science, it is not surprising that there is so far no treatment for CRVO that has stood the test of time for safety, efficacy. and long-term beneficial and curative effect. It is unfortunate when enthusiastic claims made for different modes of treatment give desperate patients false hope, cost them so much, not only in money but also in trouble, unnecessary pain and disappointment, and, sometimes, do them more harm than good. Currently, these desperate patients shop for treatment via the Internet and are often misled because not all the information on the Internet is peer reviewed. In this review, we have challenged some of the conventional wisdom in the management of CRVO – that is never popular. To advocate watchful waiting rather than action is even more unpopular. We can only hope that science, logic, and common sense will prevail in the end.

Natural History of Visual Outcome in CRVO

The outcome of all advocated treatments has to be compared with the natural history of a disease, so that natural recovery is not attributed to the beneficial effect of a mode of treatment. Recently, the natural history of visual outcome was reported in a prospective study of 214 untreated consecutive patients with nonischemic CRVO – in 155 of them the retinopathy and macular edema had resolved completely during follow-up and 59 eyes still had macular edema at the last visit. This study was based on evaluation of both visual acuity and visual fields plotted with a Goldmann perimeter – visual acuity provides information about the function of the fovea only and not of the entire retina, while visual fields provide information about the function of the entire retina involved by CRVO. Table 2 gives the findings on visual acuity and permanent central scotoma in all the 214 eyes as well as in 155 eyes with completely resolved retinopathy. Peripheral visual fields were perfectly normal in both the groups all along. Among the 59 eyes that still had macular edema, resolution of macular edema would improve the visual acuity and central visual fields in due course. Thus, the natural history of visual outcome in nonischemic CRVO is much better than the results of any of the treatments advocated so far. By contrast, in ischemic CRVO, during the initial stages, the ganglion cells in the macular retina are irreversibly damaged by ischemia → a permanent central scotoma → little chance of improvement of visual acuity. Almost all eyes with ischemic CRVO initially have normal peripheral visual fields.

Table 2 Visual acuity in 214 eyes with nonischemic CRVO – in 155 of them retinopathy had resolved completely and 59 eyes still had macular edema

	All eyes (214 eyes)	*Resolved eyes (155 eyes)*
Visual acuity		
20/20–20/25	50%	65%
20/30–20/40	14%	12%
20/50–20/70	11%	7%
20/80–20/100	4%	3%
20/200	12%	6%
20/400–CF[a]	10%	7%
Central scotoma		
None	56%	68%
Small size	34%	26%
Moderate size	5%	3%
Large size	1%	1%

[a]Mainly due to cataract, age-related macular degeneration, etc. but not due to CRVO.
From *Retina* 2007 27: 514–517.

Investigations of CRVO Patients

Finally, a commonly asked question is: What systemic and hematologic investigations need to be done in patients with CRVO? A voluminous and confusing literature exists on systemic and hematologic disorders in CRVO. Our study of 612 patients with CRVO showed that, apart from a routine medical evaluation, the vast majority of

patients with CRVO need not undergo an extensive and expensive workup for systemic diseases. As regards hematological evaluation, there is no good reason why all patients with CRVO should be subjected to the costly, exhaustive special hematologic and hypercoagulability investigations usually done in patients with spontaneous major systemic venous thrombosis – unless, of course, there is some clear indication. The routine, inexpensive hematologic evaluation is the one required by CRVO patients.

Chick Metabolism in the Chick Retina

P M Iuvone, Emory University School of Medicine, Atlanta, GA, USA

Glossary

Basic helix–loop–helix-Per-ARNT-Sim (bHLH-PAS) domain transcription factors – A family of transcription factors that heterodimerize and bind to E box enhancer elements in gene promoters. The family includes the clock gene products CLOCK, neuronal PAS domain protein 2 (NPAS2), and brain and muscle aryl hydrocarbon receptor nuclear translocator 1 (BMAL1), as well as the arylhydrocarbon nuclear receptor and the hypoxia-inducible factors.

Circadian rhythms – Changes in biological processes that occur on a daily basis; they are driven by autonomous circadian clocks; these rhythms provide selective advantage to organisms by allowing them to anticipate temporal changes in their environment.

Clock-controlled genes – Genes that are regulated by circadian oscillators via clock gene transcription factors; the proteins encoded by clock-controlled genes are rhythmically expressed and generate rhythms of physiology.

Clock genes – Genes that encode proteins that form the molecular basis of circadian oscillators; most clock gene proteins are transcription factors.

Scotopic vision – Vision in dim light that is mediated by rod photoreceptors and rod bipolar cell pathways.

Zeitgeber time – Time of day relative to the light–dark cycle; light onset corresponds to ZT0.

Introduction

The chick retina has been used extensively to study ocular circadian rhythms. It displays particularly robust rhythms of clock gene expression, clock-controlled gene expression, and several biochemical and physiological clock outputs. In addition, embryonic chick retinal cells can be cultured, and they maintain light responsiveness and circadian rhythm generation *in vitro*. These cell cultures facilitate pharmacological and molecular studies of clock signaling pathways.

Clock Gene Expression

The current model for the molecular basis of circadian clocks involves transcriptional–translational feedback loops that are comprised of highly conserved clock genes and the proteins that they encode (**Figure 1**). The clock gene proteins are characterized as positive and negative elements, based on their transcriptional activity. The positive elements include basic helix–loop–helix–PAS-domain (bHLH-PAS) transcription factors that heterodimerize and bind to circadian E box enhancer elements in promoters of other clock genes and clock-controlled genes. These positive elements include brain and muscle aryl hydrocarbon receptor nuclear translocator 1 (BMAL1; also called ARNTL, MOP3) and CLOCK. The BMAL1 heterodimerizes with CLOCK and the dimerized transcription factors stimulate the transcription of the genes encoding the negative elements, the cryptochromes (CRY1 and CRY2) and periods (PER1, PER2, and PER3). The CRY and PER proteins are imported into the nucleus and inhibit transactivation of their own promoters by BMAL1:CLOCK. In some clocks, neuronal PAS domain protein 2 (NPAS2, also called MOP4) can substitute for CLOCK and form active heterodimers with BMAL1. A second feedback loop involves E-box-mediated transcriptional activation of the orphan retinoic-acid-related receptor family genes, *Rev-erbα* and *Rora*; the protein products of these genes contribute to the rhythmic regulation of *Bmal1* gene transcription. These feedback loops, coupled with a variety of post translational modifications, generate daily rhythms of gene expression that ultimately generate physiological circadian rhythms.

Most of the clock gene transcripts identified in mammalian circadian clocks have been identified in the chick retina and in cultured chick photoreceptors, and the regulation of their expression has been analyzed (**Figures 2 and 3**). Of the genes encoding the positive elements of the oscillator, *Bmal1* and *Npas2* transcripts show robust daily rhythms under light–dark cycles or in constant (24 h day^{-1}) darkness (**Figure 2**). These circadian rhythms peak near the time of subjective dusk (~ZT12) *in vivo* and *in vitro*. In contrast, *Clock* mRNA appears to be constitutively expressed in dark–dark (DD). Transcripts encoding the negative elements, the cryptochrome and period proteins, also show rhythmic expression (**Figure 3(a)** and **3(b)**). The *Cry1* mRNA peaks in the middle of the day (~ZT8) *in vivo* and in photoreceptor cultures. *In vivo*, the most robust rhythms of *Cry1* mRNA expression are observed in the ganglion cell and photoreceptor cell layers. The *Cry2* mRNA is also expressed in retina, but analyses of whole retina mRNA suggest that it is not rhythmically expressed. The *Per2* mRNA expression is maximal in the early morning, while *Per3* transcript level appears maximal late in the night.

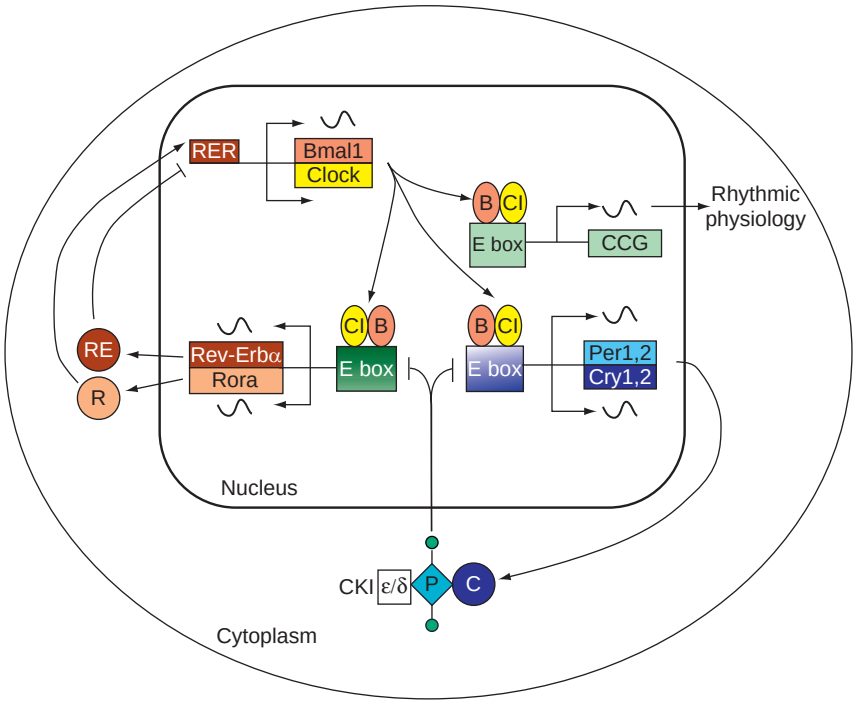

Figure 1 Circadian clockwork mechanism. Circadian clocks in a wide range of organisms are composed of two interdependent transcription–translation feedback loops that drive the periodic rhythms in the mRNA and protein levels of the clock components. In mammalian SCN, the first loop involves two bHLH-PAS-containing transcription factors, CLOCK (Cl) and BMAL1 (B). These transcription factors heterodimerize and activate the rhythmic transcription of three *period* genes (*Per1-Per3*, with *Per1* and *Per2* being critical to the circadian clock) and two *cryptochrome* genes (*Cry1* and *Cry2*). The PER (P) and CRY (C) proteins complex with casein kinase 1 δ and ε (CKIδ/ε), which phosphorylates PER. The resulting complex inhibits CLOCK/BMAL1-mediated transcription of *period* and *cryptochrome* genes, thus providing the negative feedback loop. The second loop involves CLOCK/BMAL1 driven rhythmic transcription of *Rev-erbα* and *Rora*, members of the retinoic acid-related orphan nuclear receptor family. The phase of *Rora* expression closely resembles those of *Per1* and *Per2*, and is opposite in phase with *Rev-erbα*. The resultant REV-ERBα and RORa proteins (RE and R, respectively) compete for the same promoter element, RRE (Rev-erb/Ror element) and drive the rhythm in *Bmal1* transcription. CLOCK/BMAL1 heterodimers also bind to circadian E-boxes in clock-controlled genes (CCGs), providing an output from the clock that drives rhythmic physiology. Adapted from Iuvone, P. M., Tosini, G., Pozdeyev, N., et al. (2005). Circadian clocks, clock networks, arylalkylamine N-acetyltransferase, and melatonin in the retina. *Progress in Retinal and Eye Research* 24: 433–456, with permission from Elsevier.

Thus far, *Per1* has not been identified in the chick retina, and the gene may be missing from the chicken genome. In addition to oscillating in a clock-dependent manner, *Per2* and *Cry1* are rapidly induced by light exposure (**Figure 3(c)** and **3(d)**). It is generally thought that this induction is a mechanism for circadian clock entrainment by light.

The rhythmic and light-regulated expression of circadian clock genes in the chick retina, particularly in cultured retinal cells, provides conclusive evidence that the retina contains autonomous circadian oscillators that can function independently of oscillators in the brain and pineal gland. Nevertheless, in the intact organism, retinal, pineal, and brain clocks are thought to interact to regulate physiology.

Circadian Regulation of Cyclic AMP in Retina

Cyclic AMP is a ubiquitous second messenger molecule that regulates multiple aspects of cellular metabolism and function. Effects of cyclic AMP are mediated by activation of cyclic AMP-dependent protein kinase (PKA), which phosphorylates proteins to regulate their function or activity. In so doing, cyclic AMP regulates intermediary metabolism, neurotransmission, and gene expression. Cyclic AMP can also affect cellular function by regulating cyclic nucleotide-gated channels or activating Epac, a cyclic AMP-dependent Rap GTP exchange factor. The Rap is a guanine nucleotide-binding protein of the Ras family.

In chick photoreceptor cell cultures, cyclic AMP levels are regulated by light and circadian clocks. Photoreceptor cyclic AMP levels are high in darkness and reduced by light exposure. Thus, when cells are exposed to a daily light–dark cycle, cyclic AMP fluctuates as a daily rhythm with high levels at night in darkness and low levels during the daytime in light (**Figure 4**). Exposure to light at night rapidly reduces cyclic AMP. The daily rhythm of cyclic AMP persists, albeit with reduced amplitude, when cells are transferred from a light–dark cycle to constant darkness. Thus, the combined effects of illumination and

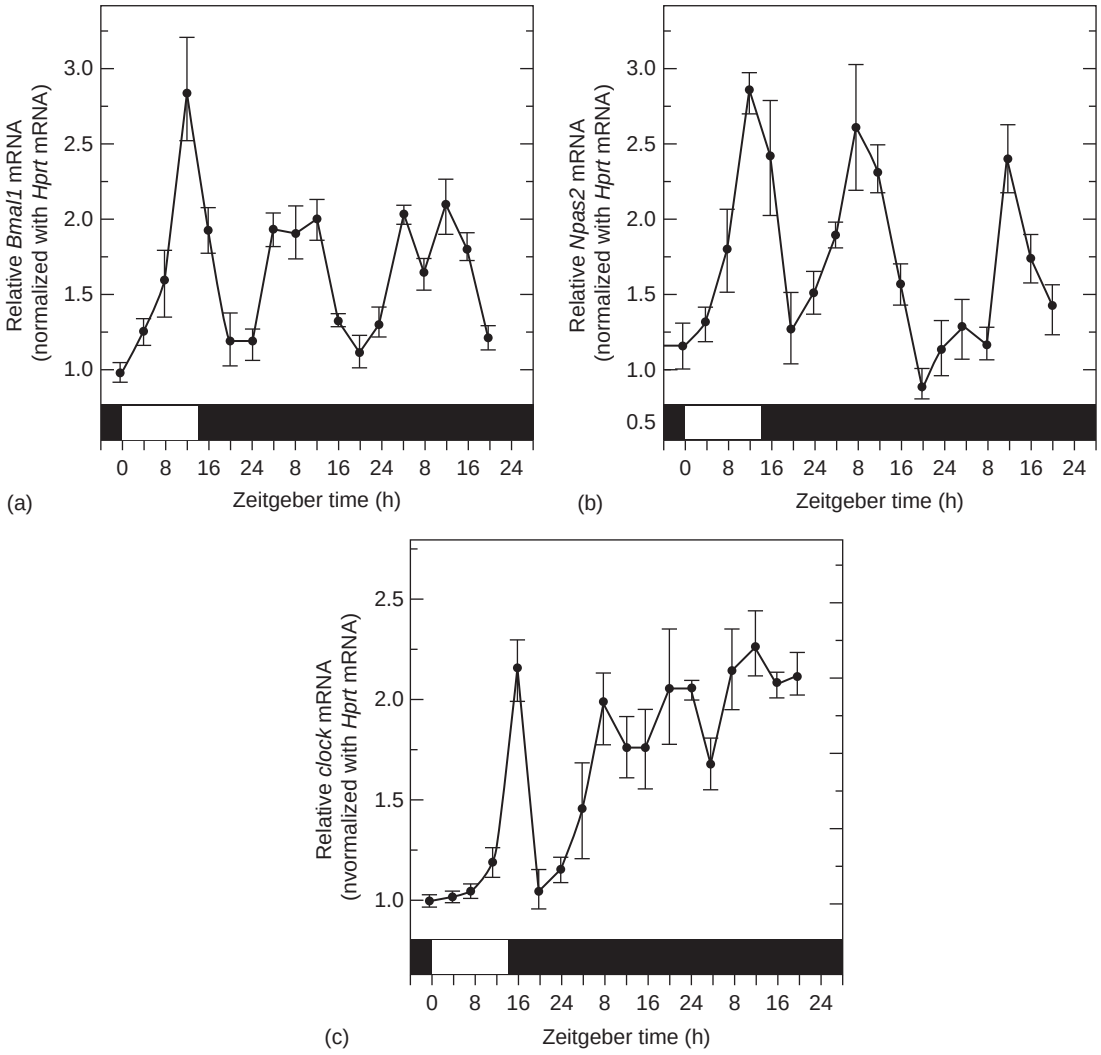

Figure 2 Temporal expression of positive modulators of the circadian clockwork system. Relative mRNA levels of *Bmal1* (a) and *Npas2* (b) in photoreceptor-enriched retinal cell cultures collected at the indicated Zeitgeber times (ZT) in light–dark (LD) and dark–dark (DD). Each data point represents clock gene transcripts normalized to hypoxanthine-guanine phosphoribosyl transferase (*Hprt*) mRNA and expressed relative to the lowest values in LD. The open horizontal bar at the X-axis represents times of light exposure; the black bars represent times of darkness. Analysis of variance (ANOVA) indicated significant rhythms of *Bmal1* and *Npas2* transcripts in LD and DD, with highest levels in the late day and early night. (c) *Clock* mRNA showed significantly higher values during the night (ZT 16) than during the day in LD; transcript levels increased on the first day of DD but there were no significant rhythms on DD1 or DD2. Reproduced from Chaurasia, S. S., Pozdeyev, N., Haque, R., et al. (2006). Circadian clockwork machinery in neural retina: Evidence for the presence of functional clock components in photoreceptor-enriched chick retinal cell cultures. *Molecular Vision* 12: 215–223, Copyright Molecular Vision 2006.

circadian influences interact to generate the daily rhythm of cyclic AMP.

The regulation of cyclic AMP formation in chick photoreceptor cells is Ca^{2+}-dependent, at least in part. Depolarization of the plasma membrane with high concentrations of extracellular K^+ stimulates cyclic AMP formation. This effect requires Ca^{2+} influx through L-type voltage-gated Ca^{2+} channels. The plasma membrane of photoreceptors is partially depolarized in darkness and is hyperpolarized by light. Thus, the dark–light difference in cyclic AMP formation in photoreceptors is likely due to high Ca^{2+} conductance in darkness and decreased Ca^{2+}conductance following light exposure, due to closure of the voltage-gated channels. Accordingly, the circadian fluctuation in cyclic AMP levels is eliminated by nitrendipine, an L-type Ca^{2+} channel blocker.

Cyclic AMP is synthesized from ATP by adenylyl cyclase. There are 10 isoforms of adenylyl cyclase that are regulated by multiple mechanisms. The findings described above indicate that photoreceptor cyclic AMP levels may be regulated by a Ca^{2+}/calmodulin-stimulated cyclase. The type 1 and type 8 adenylyl cyclases are both stimulated by Ca^{2+}/calmodulin and are both expressed in the chick retina. There is a circadian rhythm in the expression of

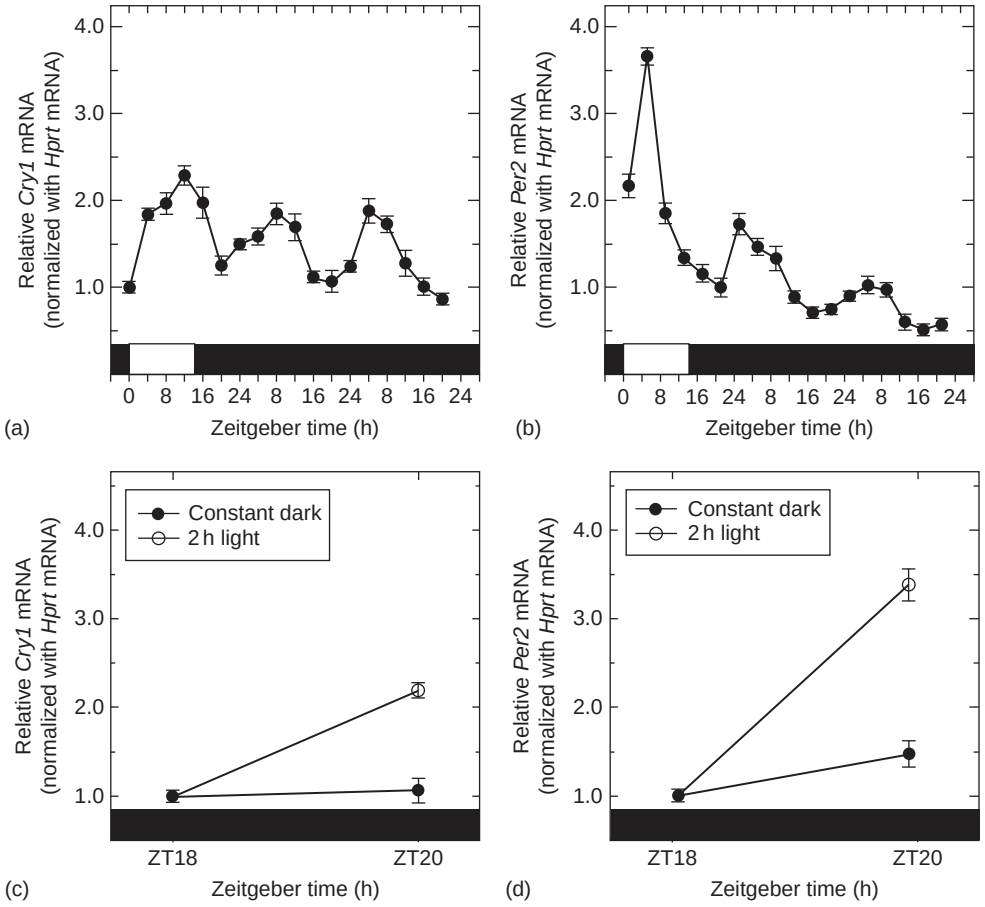

Figure 3 Temporal expression of negative modulators of the circadian clockwork system. Circadian profiles of *Cry1* (a) and *Per2* (b) transcripts in the photoreceptor-enriched retinal cell cultures collected at the indicated Zeitgeber time (ZT) in light–dark (LD) and dark–dark (DD). Each data point represents clock gene transcripts normalized to *Hprt* mRNA, expressed relative to the lowest values in LD. Acute light exposure at night induces *Cry1* (c) and *Per2* (d) mRNA expression. On day 9 *in vitro* (DIV9) cells were kept in constant darkness until ZT 18, when one group of cells was collected. Another group of cells remained in darkness for an additional 2 h (solid symbol), while a third group of cells was exposed to light for 2 h prior to cell harvesting (open symbol). Exposure to light significantly increased *Cry1*and *Per2* transcript levels. Reproduced from Chaurasia, S. S., Pozdeyev, N., Haque, R., et al. (2006). Circadian clockwork machinery in neural retina: Evidence for the presence of functional clock components in photoreceptor-enriched chick retinal cell cultures. *Molecular Vision* 12: 215–223, Copyright Molecular Vision 2006.

Adcy1, the transcript that encodes the type 1 adenylyl cyclase, in photoreceptor cell cultures and in the chick retina *in vivo*. In addition, there is a circadian rhythm in Ca^{2+}/calmodulin-stimulated adenylyl cyclase activity in membranes prepared from photoreceptor cell cultures, with high activity at night. Thus, the circadian regulation of cyclic AMP is due to clock-controlled expression of Ca^{2+}/calmodulin-stimulated adenylyl cyclase. The mammalian *Adcy1* gene contains an E-box in its promoter that can be activated by BMAL1:CLOCK heterodimers, and a similar mechanism may contribute to the circadian regulation of *Adcy1* expression in chick photoreceptor cells. However, this hypothesis has not yet been tested directly in the chick. The circadian rhythm of cyclic AMP formation may also be influenced by the clock-controlled expression and activity of the L-type Ca^{2+} channels in photoreceptors.

Circadian Regulation of Melatonin Biosynthesis

Melatonin is a neurohormone that is synthesized in the retinal photoreceptor cells and in the pineal gland. Melatonin synthesis in retinas of most vertebrate species, including chicken, is regulated in a circadian fashion, with high levels at night in darkness. Melatonin functions in the retina to optimize nighttime visual function. Like cyclic AMP formation, melatonin levels are regulated by both illumination and circadian clocks.

The key regulatory enzyme in melatonin biosynthesis is arylalkylamine N-acetyltransferase (AANAT). In chicken retina, AANAT activity undergoes a robust circadian rhythm with peak activity at night (**Figure 5**). Exposure to light at night causes a rapid decline in AANAT activity

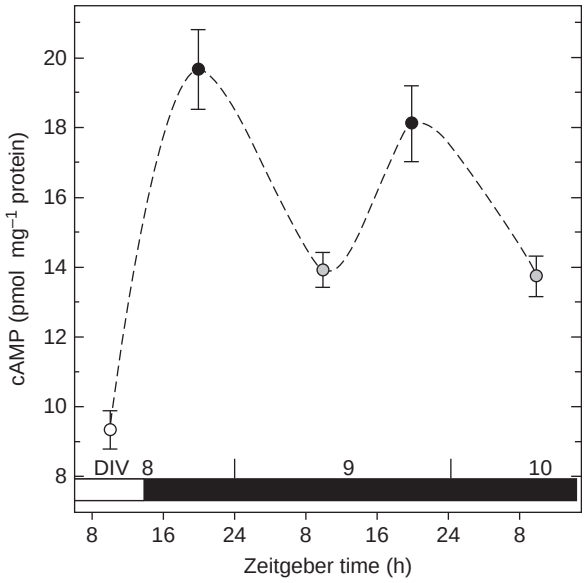

Figure 4 Circadian fluctuation of intracellular cAMP level. Cells were prepared from embryonic neural retinas and incubated for 8 days under LD. Illumination was switched from LD to DD before expected onset of light at the beginning of day 9 *in vitro* (DIV 9). White symbols represent cAMP level at Zeitgeber time (ZT) 10 in light; black symbols represent ZT 20 in darkness; gray symbols represent subjective day, ZT 10, in darkness. The horizontal white and black bars above the *x*-axis represent times of light and darkness, respectively. Level of cAMP was significantly higher at night than during the day in LD on DIV 8 and this fluctuation persisted in DD on DIV 9 and DIV 10. Reproduced from Ivanova, T. N. and Iuvone, P. M. (2003). Circadian rhythm and photic control of cAMP level in chick retinal cell cultures: A mechanism for coupling the circadian oscillator to the melatonin-synthesizing enzyme, arylalkylamine N-acetyltransferase, in photoreceptor cells. *Brain Research* 991: 96–103, with permission from Elsevier.

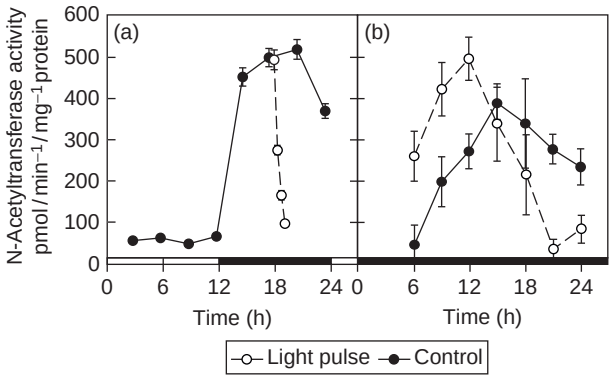

Figure 5 Daily rhythm of retinal AANAT activity: effects of light. (a) AANAT activity fluctuates during the 12 h light–12 h dark cycle (filled circles). Unexpected light exposure at night (open circles) rapidly inhibits activity. (b) AANAT activity in constant (24 h day^{-1}) darkness. The activity rhythm persists on the second day of constant darkness (filled circles). The rhythm is phase advanced by a 6 h light pulse from 18 to 24 h 2 days prior to sampling in constant darkness (open circles). Filled bars on the *x*-axis represent darkness; open bars represent light. Activity was measured in retinal homogenates of 2-week old chickens. Reproduced from Iuvone, P. M. and Alonso-Gómez, A. L. (1998). Melatonin in the vertebrate retina. In: Christen Y., Doly, M., and Droy-Lefaix, M. -T. (eds.) *Retine, Luminiere, et Radiations,* vol. 9, pp. 49–62. Paris: Irvinn; and Iuvone, P. M., Tosini, G., Pozdeyev, N., et al. (2005). Circadian clocks, clock networks, arylalkylamine N-acetyltransferase, and melatonin in the retina. *Progress in Retinal and Eye Research* 24: 433–456, with permission from Elsevier.

($t^{1/2} \approx 20$ min), to insure that significant melatonin synthesis occurs in darkness only. Chicken AANAT activity is regulated by transcriptional and post-translational mechanisms (**Figure 6**). The retina displays daily rhythms of *Aanat* mRNA and AANAT protein in chickens exposed to a light–dark cycle or constant darkness. Levels of transcript, protein, enzyme activity, and melatonin all peak at night. The proximal promoter of the chicken *Aanat* gene contains a circadian E-box that can be activated by either BMAL1:CLOCK or BMAL1:NPAS2 heterodimers, and it is generally thought that this directly couples the circadian clock to the rhythmic expression of *Aanat*. In addition, the chicken *Aanat* 5′-flanking region contains cyclic AMP response elements. Thus, the circadian rhythm of cyclic AMP may also contribute to the rhythm of *Aanat* mRNA.

The AANAT protein is regulated by PKA-dependent phosphorylation and proteasomal degradation (**Figure 6**). The AANAT contains two consensus PKA phosphorylation sites. When cyclic AMP levels are high at night, AANAT is phosphorylated. Phospho-AANAT binds to 14-3-3 proteins, which are ubiquitous signaling proteins involved in multiple cellular functions. The interaction of 14-3-3 with AANAT increases the affinity of the enzyme for its substrate, increasing catalytic activity. Exposure to light at night causes a very rapid decrease in AANAT activity and protein level ($t^{1/2} \approx 20$ min) without any initial change of *Aanat* mRNA (**Figure 6**). The decrease of AANAT is accompanied by a similarly rapid decline in melatonin levels, insuring that melatonin only functions in darkness. The decrease of protein and activity results from the light-induced decrease of cyclic AMP levels, resulting in dephosphorylation of AANAT, unbinding of 14-3-3, and rapid proteolytic degradation of the enzyme. The degradation can be blocked by proteasome inhibitors, indicating that this is a proteasome-dependent event.

During the daytime, multiple mechanisms cooperate to keep melatonin biosynthesis at a minimum (**Figure 6**). Low levels of cyclic AMP appear to play key roles in these mechanisms. The *Aanat* transcript levels are low, presumably due to reduced cyclic AMP-directed transcriptional activation and suppression by Cry1 of E-box-mediated transactivation (**Figure 6**). In addition, the low levels of cyclic AMP during the daytime, especially in light, favor the dephosphorylated state of the AANAT protein, resulting in its rapid degradation by proteasomes.

The majority of AANAT in the chick retina is expressed at night in photoreceptor cells. However, there is some

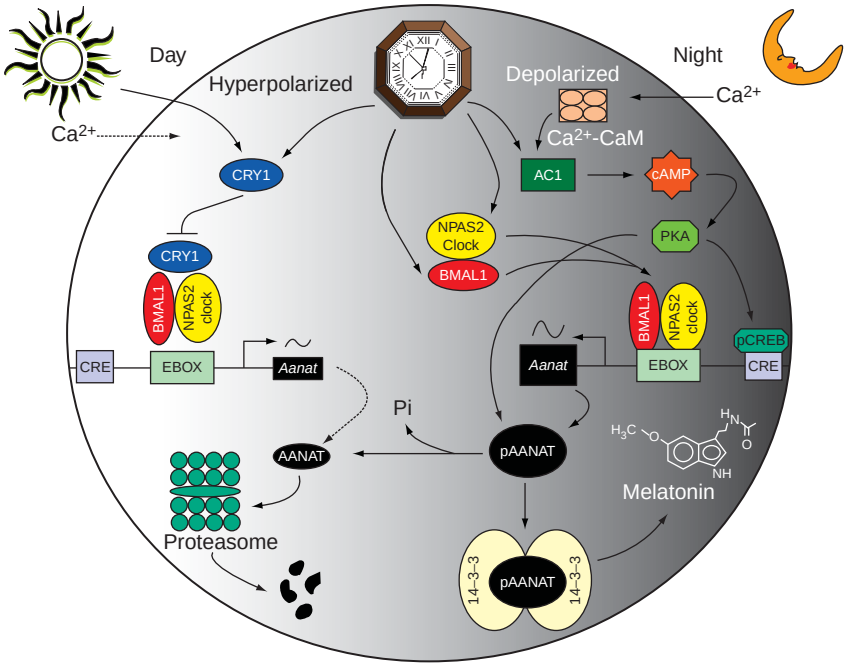

Figure 6 Model for circadian clock- and light-regulated melatonin biosynthesis in photoreceptor cells (see text for detailed description of the model). The left side of the figure depicts processes occurring in light while the right side shows processes occurring at night in darkness. Abbreviations: AANAT, arylalkylamine N-acetyltransferase; AC1, type 1 Ca^{2+}/calmodulin-stimulated adenylyl cyclase; CaM, calmodulin; cAMP, cyclic adenosine 3′,5′-monophosphate; CRE, cAMP-responsive element; pAANAT, phosphorylated AANAT; pCREB, phosphorylated cAMP response element-binding protein; PKA, cAMP-dependent protein kinase, with permission from Elsevier.

evidence that small amounts of AANAT may be expressed in ganglion cells during the daytime. The role of ganglion cell-derived AANAT is not known.

Other Rhythms of Gene Expression and Metabolism in the Chick Retina

Circadian clocks regulate phospholipid metabolism in the chick retina. Daily rhythms of phospholipid labeling with either ^{32}P or [^{3}H]glycerol have been observed in chicks kept on a light–dark cycle or in constant darkness. The ^{32}P labeling of total phospholipids in photoreceptors and ganglion cells peaks in the late night. The major phospholipid labeled under these conditions is phosphotidylinositol. In contrast, labeling with [^{3}H]glycerol peaks midday, with phosphatidylcholine as the major labeled species.

Melanopsin (Opn4) is a photopigment first discovered in *Xenopus* melanocytes, where it mediates photic regulation of melanin pigment aggregation. Subsequent cloning of orthologous melanopsin genes revealed that it is expressed in mammalian retina exclusively in a small subset of ganglion cells that are intrinsically photosensitive. These ganglion cells project to the suprachiasmatic nucleus (SCN) of the hypothalamus, the inferior olivary nucleus, and other brain regions involved in nonimage forming vision. The intrinsically photosensitive ganglion cells mediate the pupillary light reflex and photic entrainment of the circadian oscillator in the SCN.

In contrast to mammals, chickens express two melanopsin genes, designated *Opn4x* and *Opn4m* because of their sequence homology to the *Xenopus* and mammalian melanopsin genes, respectively. The *Opn4x* and *Opn4m* transcripts are more widely distributed than their mammalian counterpart. Chicken melanopsin transcripts are found in a subpopulation of cells in the ganglion cell layer, and also in photoreceptors, retinal pigment epithelium (RPE) cells, inner nuclear layer (INL) cells, the pineal gland, and areas of the brain known to contain deep brain photoreceptors. The *Opn4x* is rhythmically expressed in the chicken retina in light–dark cycles and in constant darkness. Patterns of rhythmicity differ among retinal layers; *Opn4x* peaks in the morning in RPE and INL cells, but at night in photoreceptors. Similar to the retinal photoreceptors, *Opn4x* also peaks at night in chicken pinealocytes, which are directly photosensitive and contain a circadian clock that is entrained by light. The regulation and localization of *Opn4* is consistent with the hypothesis that this novel photopigment plays a role in circadian regulation in the retina and pineal gland.

Iodopsin is the photopigment of red-sensitive cone photoreceptors of avian species. Iodopsin mRNA levels fluctuate as a circadian rhythm in retinal photoreceptors *in vivo* and *in vitro*, in cultured photoreceptors, and in

retinal explants. The rate of transcription of the iodopsin gene peaks late in the subjective day in constant darkness, ~3 h before the beginning of the subjective night, and mRNA levels peak early in the subjective night. The functional significance of the circadian rhythm of iodopsin mRNA is yet to be determined.

Ion channels in chicken cone photoreceptors are also subject to circadian regulation. There is a circadian rhythm in the affinity of the cone cyclic nucleotide-gated channel for cGMP, with highest affinity during the subjective night. In addition, L-type Ca^{2+} channels are regulated in a circadian fashion. The Ca^{2+} currents and immunoreactivity for α1C and α1D calcium channel subunits are greater at night than during the day. There is also a rhythm of α1D mRNA level. More details on rhythms of ion channels can be found elsewhere in this encyclopedia.

Conclusion

The chick retina is a remarkably rhythmic tissue, with robust circadian control of gene expression, metabolism, physiology, and melatonin synthesis. Most attention has been paid thus far to photoreceptor rhythms, but inner retinal neurons also express clock genes and are likely to be subject to circadian control. The ability to generate retinal cell cultures, which maintain their circadian properties and can be manipulated pharmacologically and genetically, suggests that the chick retina will continue to be a valuable model system for exploring the circadian organization of the retina.

Acknowledgments

The author is grateful to the past and present members of his laboratory, especially Rashidul Haque, Nikita Pozdeyev, Shyam Chaurasia, and Tamara Ivanova, and to David Klein and the members of his laboratory, who contributed greatly to the body of knowledge contained within this article. The author also thanks Gianluca Tosini for his collaborative contributions and for critical comments and suggestions on the article. Research in the author's laboratory is funded by the National Institutes of Health EY004864 and EY06360, and by Research to Prevent Blindness.

Choroidal Neovascularization

M R Kesen and S W Cousins, Duke Eye Center, Durham, NC, USA

Glossary

Age-related macular degeneration (AMD) – An eye disease with its onset usually after age 60 that progressively destroys the macula, the central portion of the retina.
Angiomatous – Relating to a tumor consisting of a mass of blood vessels.
Brusch's membrane – The inner layer of the choroid, separating it from the pigmentary layer of the retina.
Choriocapillaris – The capillaries forming the inner vascular layer of the choroid.
Choriocapillaris pillars – Lateral walls of the choriocapillaris.
Choroid – The layer of the eye containing blood vessels that furnish nourishment to the other parts of the eye, especially the retina.
Leukostasis – Increased blood viscosity and tendency to clotting.
Subretinal space – An area below the retina.
Telangiectatic – Small dilated blood vessels.

Choroidal Neovascularization

Choroidal neovascularization (CNV) is the growth of pathologic new blood vessels originating from the choriocapillaris invading into the subretinal pigment epithelium (subRPE) and/or the subretinal space. In the early stages of CNV formation, these vessels are capillary-like, lacking the structural integrity of mature vessels causing them to leak plasma or blood. Components of CNV often mature into more organized vessels with features of arteries and veins, and CNV can ultimately evolve into fibrovascular scar tissue.

CNV is known to occur in many ophthalmic diseases. However, it is the most important sequella of age-related macular degeneration (AMD), causing the neovascular form of AMD (NVAMD). In developed countries, NVAMD is the leading cause of blindness in people older than 50 years of age.

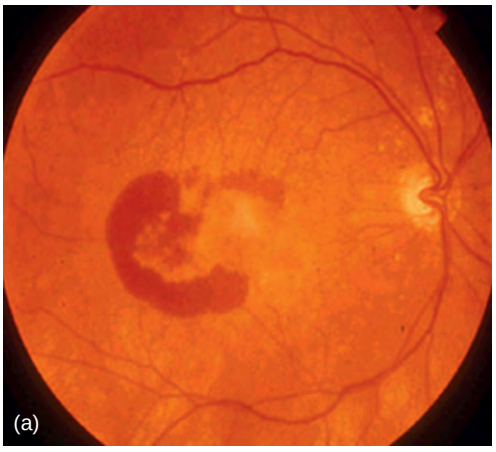
Clinical Detection of CNV

Clinically, CNV is detected in patients who complain of blurred and distorted vision, often caused by leakage of plasma from the CNV into or under the overlying neurosensory retina. Because of the optical clarity of the ocular media, the retina can be directly observed by clinicians. Upon examination, eyes with CNV exhibit evidence of leakage such as retinal edema, subretinal fluid, or hemorrhage (**Figure 1(a)** and **1(b)**). If they are not leaking, CNV can sometimes be observed as circular gray or reddish structures under the retina (**Figure 2(a)**). However, in most cases, nonleaking CNV is not directly visible. In some cases, untreated CNV evolves into fibrovascular membranes, called disciform scars.

Clinical imaging technologies have greatly contributed to our understanding of CNV pathobiology and are utilized to enhance detection of CNV. Fluorescein angiography (intravenous injection of a fluorescent dye which can be photographed as it transits through the retina and CNV) is the standard diagnostic technology to confirm the presence of CNV. In classic CNV, fluorescein angiography often reveals CNV to manifest well-defined margins with homogeneous leakage of dye (**Figure 2(b)**). Yet, most cases of CNV are occult, demonstrating less well-defined margins with irregular leakage. Originally, an association was assumed between the fluorescein angiographic appearance and the anatomic location or the growth pattern of CNV. It was presumed that classic CNV was located subretinally, external to the retinal pigment epithelium (RPE) and occult CNV was located external to the RPE within Bruchs membrane. However, data from the Submacular Surgery Trials (SST) research group indicated a lack of correlation between fluorescein angiography pattern and anatomic localization of the CNV.

In the past decade, newer imaging technologies have revealed that the morphologic manifestation of pathologic new vessels in NVAMD (and presumably other diseases with CNV) is much more diverse than traditionally described using fluorescein angiography. Another angiographic imaging technology employs indocyanine green (ICG) dye, allowing visualization of the morphology and the flow of the choroidal vasculature. Dynamic (or video) ICG angiography demonstrates that most CNV is a complex of three components, including an intrachoroidal feeder artery, a subretinal or subRPE capillary network, and an intrachoroidal draining vein (**Figure 2(c)**).

By ICG angiography, CNV appears to manifest a spectrum of morphology ranging from capillary pattern to branching arteriolar pattern. Capillary pattern CNVs are composed mostly of capillaries with minimal arterioles and short, small-caliber feeder arteries. Branching arteriolar pattern CNVs are composed of long, large-caliber



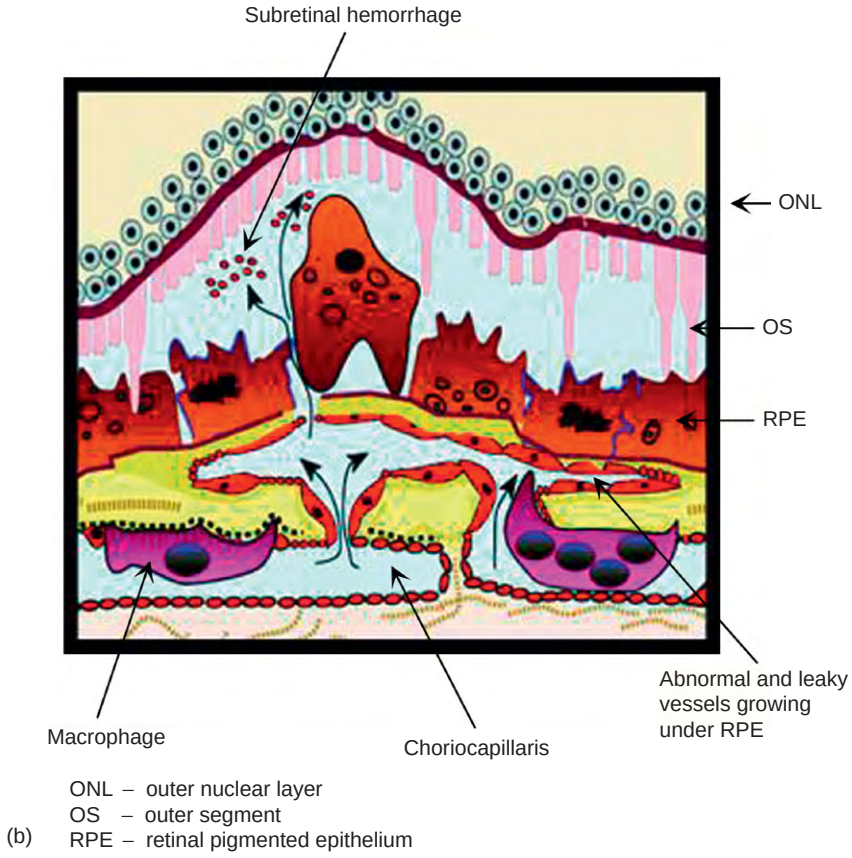


Figure 1 (a) The color fundus photograph demonstrates subfoveal choroidal neovascular membrane with surrounding subretinal hemorrhage. (b) Schematic diagram demonstrates the choroidal neovascular membrane located beneath the retinal pigment epithelium causing leakage of fluid or blood. Arrow indicate direction of fluid and blood leakage.

feeder arteries, many branching arterioles, and minimal capillary morphology (**Figure 3(a)–3(d)**). Mixed pattern CNV demonstrates feature of both extremes. Presumably, all CNVs initially begin as capillary pattern, then progress through a process of remodeling whereby small capillaries obtain a sheath of pericytes which stabilize the incipient new vessel. In some cases, the new vessels become surrounded by vascular smooth muscle and collagen, thus becoming arteriolarized. Hypothetically, the variability among CNV morphology is due to differences in the degree and extent of remodeling. One emerging hypothesis is that capillary-dominated CNVs are exquisitely responsive to anti-vascular endothelial growth factor (anti-VEGF) treatment, whereas branching arteriolar CNV with large feeder vessels are less responsive or even resistant to anti-VEGF therapy.

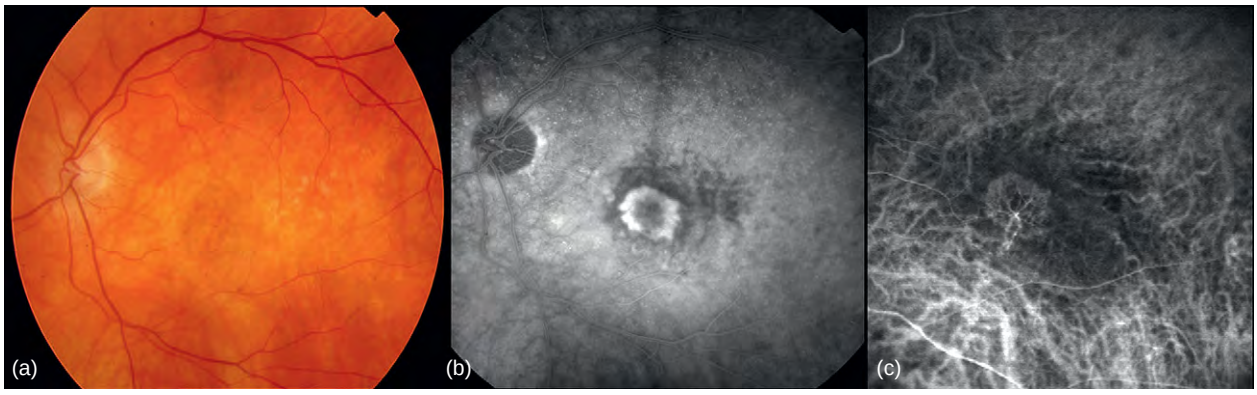

Figure 2 (a) The color fundus photograph demonstrates subtle gray discoloration of the retina due to underlying choroidal neovascular membrane. (b) Late phase fluorescein angiogram shows area of hyperfluorescence corresponding to classic choroidal neovascular membrane with progressive leakage of dye resulting in blurring of the margins. (c) Dynamic indocyanine green angiogram reveals branching vascular network composed of afferent arteriole, capillaries, and draining venule.

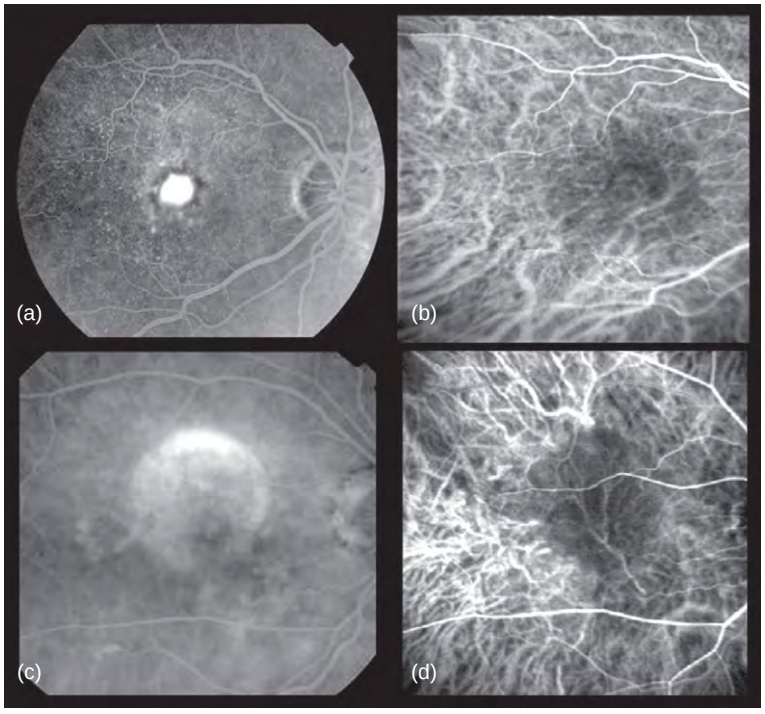

Figure 3 (a) Late arteriovenous phase angiogram shows bright hyperfluorescence corresponding to choroidal neovascular membrane. (b) Dynamic indocyanine angiogram reveals neovascular membrane composed of capillaries with minimal branching arterioles or venules. (c) Venous phase angiogram shows a well-demarcated area of hyperfluorescence corresponding to pigment epithelium detachment with pooling of dye. (d) Dynamic indocyanine angiogram reveals long, large-caliber choroidal feeder vessel perfusing many branching arterioles extending into the pigment epithelium detachment. Minimal capillary structure is observed.

Another imaging technology, called optical coherence tomography (OCT), is a high-resolution, cross-sectional imaging technique that enables visualization of tissue structures up to 2 mm below the surface of the retina. The projected light is reflected back from intraocular structures based upon their distance, thickness, and reflectivity. OCT has become the most commonly used imaging modality in diagnosis and management of patients with AMD since it can demonstrate retinal edema, subretinal fluid, pigment epithelial detachments, and, in some cases, the CNV itself (**Figure 4**). Being the preferred technique to assess treatment response, OCT plays a critical role in guiding the management of patients with AMD.

Histopathology of CNV

Histopathology of CNV has been performed by two types of analyses: evaluation of postmortem specimens within

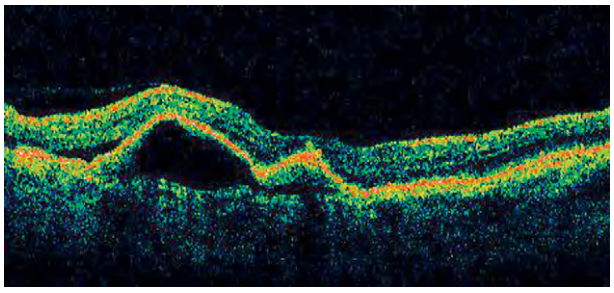

Figure 4 Optical coherence tomography (OCT) image demonstrates pigment epithelial detachments with overlying subretinal fluid.

intact eyes or after removal of CNV as part of a surgical procedure. Postmortem analysis demonstrates that CNV exhibits a wide morphological spectrum. Some cases demonstrate that endothelial-lined capillary tubes are within Bruch's membrane or under the retina. Most cases show that CNV demonstrates more complex morphology, with additional cellular components including RPE cells, pericytes, myofibroblasts, and inflammatory cells. Many cases also demonstrate extensive extracellular matrix deposition and fibrosis. Unfortunately, minimal information is available for the histopathology of the initial stages of CNV formation.

Analysis of the choroid in postmortem specimens has also revealed significant changes, including loss of choriocapillaris surface area, changes in large vascular architecture, increased extracellular matrix, and thickening of the choriocapillaris pillars. Additionally, intrachoroidal vascular changes with polypoidal-like outpouchings of some of the choroidal vessels have been observed.

Analyses of surgically excised CNV during submacular surgery have allowed examination of CNV at an earlier stage in the course of the disease than in postmortem eyes. Histopathology of many early CNV is dominated by macrophage infiltration in addition to the other cellular components (endothelial-lined channels, pericytes, RPE cells) and extracellular matrix. Some examples of surgically excised CNV demonstrate more fibrosis and myofibroblasts with minimal inflammation. In general, Grossniklaus and colleagues have suggested that CNVs in postmortem eyes appear to be more fibrotic than surgically excised CNV, implying that cellular morphology evolves from inflammatory active to inflammatory inactive stages.

Animal Models of CNV

No ideal animal exists for CNV or NVAMD. In current experimental models, CNV is induced by disruption of the Bruch's membrane/RPE complex using laser (argon, krypton, diode), by injections of growth factors, and by genetic manipulations (transgenic or gene transfer) to overexpress angiogenic growth factors. At present, the few models of spontaneous CNV in animals are not reproducible enough to lend themselves to robust scientific analysis.

Laser-induced CNV

Placement of a small laser injury to the outer retina and choroid reliably induces CNV in rodents and subhuman primates. Some believe that a physical hole in Bruch's membrane is necessary. Others believe that thermal injury to the choroid and Bruch's membrane without physical disruption is adequate to trigger CNV, and the model represents a response to injury. Nevertheless, laser injury does not mimic the (unknown) natural stimulus for spontaneous neovascularization in humans. In spite of the artificial trigger, the model does accurately mimic many of the subsequent mechanisms for neovascularization and has predicted therapeutic response to drugs that have been validated in human studies.

The model is triggered by local inflammation at the laser site. Within 3–5 days, authentic pathologic neovascularization occurs. The initial lesion appears to be an invasion of fibrocytes and endothelial cells. Macrophages are prominent at all stages of development. Within a week of development, cell types within the growing vessels include endothelial cells, mesenchymal subtypes (pericytes, myofibroblasts, and smooth muscle cells), macrophages, RPE cells, CD34 cells, and bone-marrow-derived progenitor cells. Numerous growth factors are expressed within the growing CNV, including angiogenic factors, inflammatory cytokines, integrins, and connective tissue growth factor. Among agents that prevent the development of CNV include VEGF inhibitors, anti-inflammatory agents, and integrin antagonists. Recently, agents that block platelet-derived growth factor (PDGF) – important growth factor for mesencyhmal cells – have shown to cause regression of established laser-induced CNV.

Growth factor models

Overexpression of angiogenic growth factors in the outer retina can also induce CNV, but the interpretation of the pathobiology is surprisingly complex. A detailed review is beyond the scope of this article. Briefly, subretinal injection using adenoviral vector containing VEGF-164 causing RPE transduction and overexpression of VEGF induces robust CNV in rodents. Interestingly, transgenic overexpression of VEGF using choroid- or photoreceptor-specific promoters failed to induce CNV without additional injury by subretinal injection, suggesting another stimulus (inflammation or injury) is necessary to trigger CNV. Subretinal injection of pellets or spheres impregnated with basic fibroblast growth factor or other angiogenic factors could also induce CNV in rabbits and primates.

Pathobiology of CNV

Several theories regarding the pathogenesis of CNV have been proposed including RPE dysfunction, changes in choroid, changes in Bruch's membrane, oxidative stress, genetics, ocular perfusion abnormalities, inflammation, and ischemia.

Angiogenesis

Angiogenesis is the growth of new blood vessels originating from preexisting network of blood vessels. Angiogenesis plays a major role in normal vascular development and in wound healing (during which new vessels form, then regress). Angiogenesis has been proven to contribute significantly to the formation of pathologic new vessels in CNV and NVAMD.

Vascular endothelial growth factor

It is now well established that VEGF plays a key role as a stimulator in the neovascular forms of AMD. VEGF, a homodimeric glycoprotein of approximately 45 kDa, is a very potent vascular endothelial cell mitogen that stimulates proliferation, migration, and proteolytic activity of endothelial cells. VEGF is also a potent mediator of increased vascular permeability. Its additional functions include retinal leukostasis and neuroprotection. Three receptor tyrosine kinases have been identified for VEGF: VEGF receptor 1 (VEGFR1) has both positive and negative angiogenic effects; VEGFR2 is the primary mediator of the mitogenic, angiogenic, and vascular permeability effects of VEGF-A, and VEGFR3 mediates the angiogenic effects on lymphatic vessels.

The VEGF gene family is comprised of VEGF-A, -B, -C, -D, and placental growth factor (PlGF). VEGF-A has the strongest association with angiogenesis and is the target of most current anti-VEGF treatments. Nine major VEGF-A isoforms with varying heparin-binding capabilities and tissue distribution have been identified to date: 121, 145, 148, 162, 165, 165b, 183, 189, and 206. These isoforms are produced by alternative exon splicing of the VEGF-A gene. VEGF-165 has been shown to be the most abundant isoform and has a vital role in angiogenesis.

VEGF is essential for normal and abnormal angiogenesis. Deficiency of VEGF expression in the RPE results in the absence of choroid. VEGF is induced by hypoxia in RPE cells and is secreted from the basal side of these cells toward the choroid. High levels of VEGF receptors KDR and flt-4 are found on the choriocapillaris endothelium facing the RPE layer.

The strong evidence supporting its critical role in CNV has made VEGF an optimal target for the treatment of NVAMD. Ranibizumab, a humanized antibody fragment against all isoforms of VEGF, has been developed and proven to be efficacious. Data from two pivotal phase III clinical trials – MARINA (Minimally Classic/Occult Trial of the Anti-VEGF Antibody Ranibizumab in the Treatment of Neovascular AMD) and ANCHOR (Anti-VEGF Antibody for the Treatment of Predominantly Classic CNV in AMD) – led to the approval of Food and Drug Administration (FDA) of Ranibizumab in June 2006 for the treatment of all forms of NVAMD.

Other angiogenic factors

Although VEGF has the primary role in the development of CNV, it likely does so in concert with other growth factors including transforming growth factor-β (TGF-β), aFGF, and bFGF. Other cytokines including the integrins, angiopoetins, and matrix metalloproteinase (MMP) inhibitors may also play an important role. Activation of endothelial cells from the subjacent choriocapillaris results in the production of various degradatory enzymes, such as MMP-2 and -9, allowing them to invade Bruch's membrane and the subretinal space. Both MMP-2 and -9 are activated by VEGF and facilitate the spread of proliferating endothelial cells by digesting the extracellular matrix.

Natural inhibitors of angiogenesis

Endogenous inhibitors include endostatin, and pigment epithelium-derived factor (PEDF), both of which were demonstrated to be significantly reduced in Bruch's membrane in eyes with AMD. Thrombospondin 1, a 450-kDa glycoprotein, contributes to the regulation by functioning both as a stimulator and an inhibitor with its ability to bind to different matrix proteins and cell-surface receptors.

Inflammation Inflammation is typically divided into antigen-specific immunity (T cells, B cells, and antibody-mediated reactions) and innate immunity (neutrophils, macrophages, and amplification cascades, such as cytokines and complement). Although a role for specific immunity has not been excluded, a major role for innate immunity is emerging in the pathogenesis of CNV. Space does not permit a thorough review, but brief mention will be made of two key inflammatory components: monocytes/macrophages and complement.

Monocytes and macrophages Monocytes (the circulating cells) and macrophages (tissue infiltrating equivalent) represent 5% of the circulating white blood cell population. Macrophages are recruited into tissues for the purposes of scavenging, repair, and defense. In the process, they can impart either beneficial effects (like removing deposits and repairing extracellular matrices) or harmful ones (like bystander damage to healthy tissue or neovascularization). As mentioned above, macrophages are numerous in many examples of human CNV. In most experimental models of CNV, macrophages are positive regulators of increased severity of pathologic neovascularization, although some

investigators have identified an anti-angiogenic subtype of macrophages. Macrophages can be induced to synthesize and release pro-angiogenic factors, including VEGF, PDGF, tumor necrosis factor-alpha, prostaglandin E2, and others. Conversely, VEGF is a moderately potent chemotactic factor to recruit and stimulate macrophages into tissues. In addition to their role in angiogenesis, macrophages may contribute to bystander damage in the retina. Numerous macrophage-like cells can be observed in the neurosensory retina overlying CNV in animal models and in human specimens. Presumably, these cells may be releasing factors that promote neuronal injury and decreased vision. Patients with circulating monocytes in the blood that express high levels of pro-angiogenic factor mRNA are more likely to have CNV. Macrophages are attractive targets for therapy. Antimacrophage drugs that are under investigation include those that block macrophage-derived pro-angiogenic cytokines, block cell adhesion molecules (especially integrin alpha 5, beta 1, necessary for monocytes to adhere to vessel surfaces and enter into tissues), block cyclo-oxygenase and block macrophage retention within the CNV or retina.

Complement Complement is a series of over 30 proteins, produced by the liver and secreted into the blood, that serve as an amplification cascade for host defense. Complement activation is triggered by one of three distinct processes (immune complexes, lectin pathway, or alternative pathway) to activate a sequential cascade of interrelated proenzyme intermediates, whose main goal is to produce three types of effector molecules: C3b (coats structures to promote phagocytosis), anaphylatoxins (C3a, C5a, promotes chemotaxis of macrophages and neutrophils), and membrane attack complex (creates pores in cell membranes promoting activation or death). Recently, genetic variations in various complement molecules have been associated with AMD, especially polymorphism in CFH (a negative regulator of activation of the alternative pathway). C3, C3b, and other complement fragments have been demonstrated in specimens of human CNV. In experimental CNV, genetic knock-out or drug inhibition of complement, C3aR, and C5aR significantly diminish CNV formation. It is assumed that C5a may directly activate endothelial cells, or may serve to recruit macrophages into CNV to potentiate neovascularization. Accordingly, complement inhibitors are in clinical trial for the treatment of CNV, including inhibitors of C3, C5, and C5aR.

Vasculogenesis Postnatal or adult vasculogenesis is the contribution of circulating bone-marrow-derived vascular progenitor cells to the repair of normal vessels or the formation of pathologic new vessels. Adult animals maintain a reservoir of stem cells in the bone marrow that may enter the circulation, become recruited into tissues, and differentiate into mature cell types that contribute to healthy repair in regenerating organs. A subset of these marrow cells has been shown to exist in humans and animals that specifically contribute to vascular repair, including both endothelial cells and mesenchymal subtypes (pericytes, myofibroblasts, vascular smooth muscle). Although this field is in its infancy, postnatal vasculogenesis has been shown to contribute to both endothelial and mesenchymal subsets in experimental CNV in several animal models. These cells can be positive or negative regulators of CNV severity, depending on prior environmental exposure of the bone marrow stem cells. Vascular progenitor cells can be identified in the blood of patients with AMD, and certain subsets may identify those with more severe pathology or worse therapeutic outcomes. If confirmed, identification of these cells may be useful as a biomarker for worse outcome and blocking their recruitment may be a therapeutic target.

Therapy of CNV

Prior to 1970, no effective therapy for CNV was available. Upon the recognition of the vascular character of CNV, thermal laser ablation of the CNV lesion as defined by the area of classic leakage on fluorescein angiography was introduced as therapy. The effectiveness of thermal laser as superior to the natural history was validated by several randomized controlled trials, and laser remained the standard of care until the twenty-first century. Photodynamic therapy (PDT) with the photosensitizing agent verteporfin was introduced in early 2000. After intravenous infusion of verteporfin, low energy red-laser light directed at the CNV was used to photoactivate verteporfin into a thrombotic agent, which caused occlusion of the CNV. PDT with verteporfin was proven superior for the treatment of classic CNV, but remained controversial for other subtypes.

Upon the realization that VEGF was the major factor driving angiogenesis and vascular permeability, several companies developed inhibitors of VEGF that could be administered by direct injection into the vitreous cavity of the eye. The first of these to become approved and clinically available was pegaptanib, a synthetic RNA aptamer which specifically bound extracellular VEGF-165 isoform. Although superior to PDT and standard of care, the therapeutic effect on vision and leakage control was modest. Subsequently, two pan-VEGF (i.e., blocking all isoforms) antibody-based inhibitors were introduced. Bevacizumab, a full-length antibody, was developed for intravenous inhibition of VEGF in cancer treatment. Ranibizumab, closely related to the Fab fragment of bevacizumab, was developed for intraocular injection. In 2005, ranibizumab's effectiveness was validated in two landmark clinical trials which showed that monthly injections resulted in outstanding leakage control, stabilization of CNV growth, and improved vision in 30–40% of patients with classic or occult CNV. However, effectivity

requires once a month injection for at least 2 years, and less frequent regimens have not produced the same magnitude of positive outcomes. Subsequently, intravitreal injection of the full-length antibody, bevacizumab, has also been adopted by clinicians but without validation by a randomized controlled trial.

Other interesting agents are currently in clinical trial. Several target VEGF, including VEGF trap (a fusion protein between Fc heavy chain and VEGF receptor that blocks extracellular VEGF), bevasirinib (RNA interference, selectively targeting VEGF mRNA), and several small molecule drugs that inhibit VEGF receptor signaling (the so-called receptor tyrosine kinase inhibitors). Drugs targeting other molecular targets are also in trial, including inibitors of complement, integrins, and PDGF.

Variants of Pathologic Neovascularization in NVAMD

Over the past decade, the spectrum of neovascular AMD has been expanded beyond classic and occult CNV. Identification of additional variants, especially polypoidal choroidal vasculopathy (PCV) and retinal angiomatous proliferation (RAP), has suggested that the pathobiology and treatment of neovascular AMD is a more complex than suggested by the previous review.

Polypoidal choroidal vasculopathy

PCV is a form of intrachoroidal neovascularization that accounts for up to 50% of NVAMD in Asians and may be underdiagnosed in Caucasians. PCV is characterized by large-caliber feeder vessels perfusing intrachoroidal branching arteriolar networks which terminate in one or more intrachoroidal polypoidal structures rather than typical subretinal capillaries of CNV (**Figure 5(a)–5(d)**). Clinical features include orange–red subretinal nodules corresponding to dilated, polyp-like lesions associated with hemorrhagic or serous pigment epithelial detachments, retinal edema, or subretinal hemorrhage. PCV most commonly occurs in the peripapillary and macular regions. ICG angiography is required for diagnosis and visualization of PCV.

The pathobiology of PCV is debated, especially whether it is a distinct disorder from CNV or a disease of similar biology but with different vascular morphology. Anectdotal cases illustrate examples of eyes with PCV

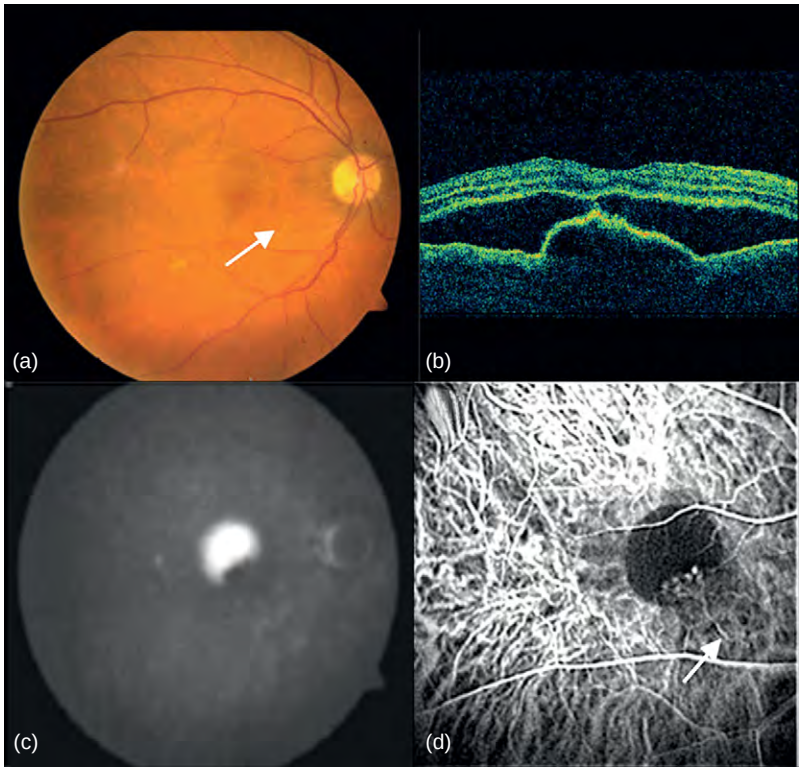

Figure 5 (a) A color fundus photograph shows pigment epithelial detachment and faintly visible feeder vessel extending into the detachment as pointed by the arrow. (b) Optical coherence tomography image shows pigment epithelial detachment with overlying subretinal fluid. (c) Late venous phase fluorescein angiogram shows an area of hyperfluorescence due to pooling of dye into the pigment epithelial detachment. The angiogram fails to show any details of the choroidal neovascular membrane. (d) Dynamic ICG angiogram demonstrates a long afferent arteriole perfusing terminal polypoidal structures consistent with classification as polypoidal choroidal vasculopathy as indicated by the arrow.

that later develop CNV, and vice versa. Histopathology demonstrates thin-walled, saccular polypoidal vessels that were initially regarded as being of venular origin. However, some excised specimens demonstrate the presence of both large choroidal arterioles and venules. Light microscopy demonstrated disruption of inner elastic layer and arteriolosclerotic changes of the blood vessels, and in some cases, the branching arterioles are associated with pericyte-like cells.

The natural history and treatment of PCV is not well established. Anecdotal reports suggest that about half of cases demonstrate deterioration of vision in spite of treatment and that anti-VEGF therapy is less effective than for traditional CNV. The efficacy and safety of PDT seems promising in small studies, but this treatment combined with anti-VEGF therapy must be investigated in future randomized clinical trials.

Retinal angiomatous proliferation

RAP is another recently recognized but common variant of NVAMD that is characterized by the formation of pathologic new vessels within the retina that secondarily invade into the subretinal space or into the choroid. The incidence of RAP variant of NVAMD is unknown, since it requires the use of ICG angiography for definitive diagnosis. Anecdotal reports suggest that at least 15% of the newly diagnosed patients with NVAMD manifest RAP. This variant may be less common in Asians.

High speed ICG angiography offers best visualization of the RAP lesion, particularly for localizing the retinal feeding arterioles and draining venules (**Figure 6(a)–6(e)**). Clinically, stage I RAP lesions present with intraretinal neovascularization with telangiectatic retinal capillaries and small angiomatous structures perfused by the retinal circulation. Stage II RAP lesions extend the new vessel complex into the subretinal space to form subretinal neovascularization often associated with a serous PED. Most stage II RAP lesions are also perfused by retinal arterioles and drained by retinal venules. In these cases, focal closure of the retinal feeding arteriole by thermal laser leads to loss of flow into the RAP lesion and disappearance of hemorrhage, retinal edema, and PED. In stage III RAP,

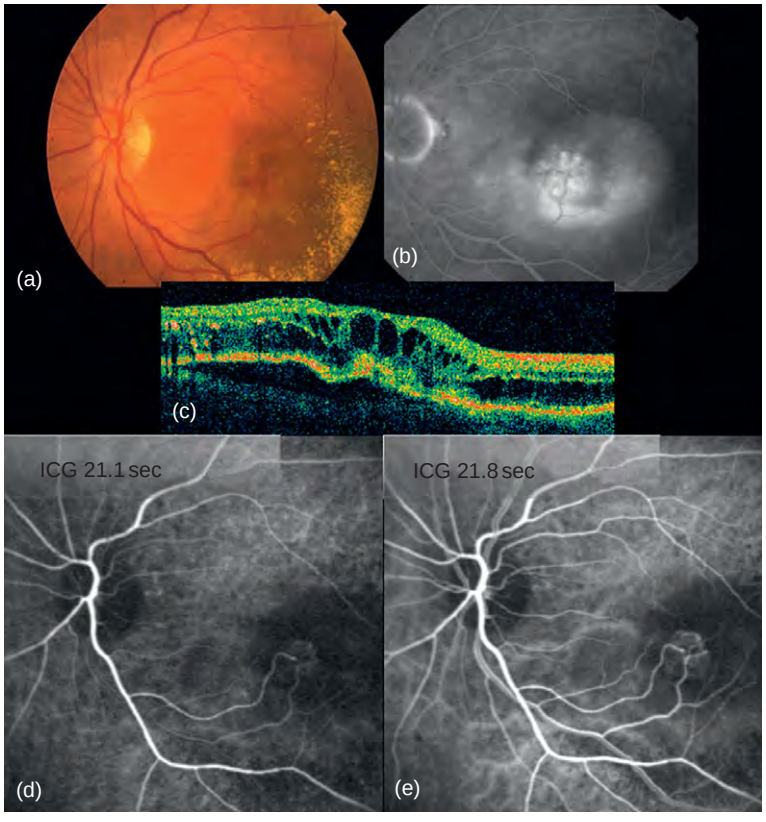

Figure 6 (a) A color fundus photograph shows pigment epithelial detachment associated with intraretinal hemorrhages and extensive exudates temporal to the detachment. (b) Late arteriovenous phase angiogram demonstrates an area of hyperfluorescence corresponding to the pigment epithelial detachment, however, fails to reveal details of the choroidal neovascular membrane to allow for proper classification. (c) Optical coherence tomography image demonstrates serous pigment epithelial detachment with cystic thickening of the overlying retina. Areas of intraretinal hemorrhage appear as hyperreflective spots. (d, e) Dynamic angiogram clearly demonstrates the details of the subretinal neovascular membrane including the afferent arteriole derived from the retinal artery, capillary network, and the draining venule merging with the retinal vein, consistent with classification of the lesion as stage II RAP lesion.

retinal–choroidal anastomosis (RCA) is formed through a break in RPE, often associated with an underlying choroidal neovascular membrane with both choroidal and retinal perfusion. Late stage III RAP lesions develop large fibrotic scars. The transition between purely retinal perfusion (stage I–II RAP) into choroidal perfusion (early stage III RAP) can be difficult to determine clinically.

As with PCV, the pathobiology of RAP is unknown. The histopathological findings in stage II cases demonstrate intraretinal neovascularization without any evidence of CNV. Stage III cases demonstrate both CNV and chorio–retinal anastomosis. RAP responds well to anti-VEGF therapy, suggesting that the underlying pathobiology is strongly mediated by VEGF. Identification of the cellular source of VEGF in RAP (i.e., retinal, RPE, or choroidal) to explain the origination of new vessel growth in the retina as differentiated from choroidal origin in typical CNV remains speculative.

Prior to the advent of anti-VEGF therapy, many treatments for RAP were tried, however, with variable results. Fortunately, anti-VEGF agents effectively control leakage, but rapid recurrences necessitate frequent injections. Focal thermal laser treatment of the afferent arteriole and extrafoveal angioma has been demonstrated to be effective as salvage therapy for recurrences. Advanced forms of the disease involving a vascularized RPE detachment and RCA are unlikely to respond well to any form of current treatment.

Future Directions

Our knowledge base regarding the pathobiology of CNV is expanding as new generation imaging modalities become available and provide us with further anatomical details allowing recognition of the variety in morphology of these lesions. A vast amount of research is focused on learning various aspects of AMD. Although we have come a long way in understanding and treating AMD, considerable amount of work remains to fully understand the pathogenesis, recognize different types, and tailor the therapy based upon special characteristics of each of these lesions to optimize the prognosis in these patients. Areas that especially require additional study include the role of VEGF isoform contribution to healthy choroid and CNV, role of complement and macrophage inflammation, role of endothelial and mesenchymal subtypes in vasculogenesis, predictive biomarker development, and clarification of pathobiology of NVAMD variants, especially PCV and RAP. Combination of comparison of imaging technologies, genotyping studies, and biomarker studies in the context of therapeutic trials will clarify some of these issues.

Chromatic Function of the Cone

D H Foster, University of Manchester, Manchester, UK

Glossary

CIE, Commission Internationale de l'Eclairage – The CIE is an independent, nonprofit organization responsible for the international coordination of lighting-related technical standards, including colorimetry standards.
Color-matching functions – Functions of wavelength λ that describe the amounts of three fixed primary lights which, when mixed, match a monochromatic light of wavelength λ of constant radiant power. The amounts may be negative. The color-matching functions obtained with any two different sets of primaries are related by a linear transformation. Particular sets of color-matching functions have been standardized by the CIE.
Fundamental spectral sensitivities – The color-matching functions corresponding to the spectral sensitivities of the three cone types, measured at the cornea. The spectral sensitivities may be normalized so that the maximum is unity or according to the nominal population densities of the cone types.
Heterochromatic flicker photometry – The adjustment of the radiant power of one of two spatially coextensive lights presented in alternating sequence at a temporal frequency such that there is a unique value of the radiant power where the sensation of flicker is minimum; that is, with a higher or lower radiant power, the sensation of flicker becomes greater.
Luminous efficiency function V_λ – The inverse of the radiant power of a monochromatic stimulus of wavelength λ that produces a luminous sensation equivalent to that of a monochromatic stimulus of fixed wavelength λ_0. The units and λ_0 may be chosen so that the maximum of this function is unity. It is also known as the relative luminous efficiency or relative luminosity function.
Optical density – Absorbance; see spectral absorbance.
Radiant power and quantum units – Radiant power is measured in watts but it is sometimes more appropriate to measure it in quanta s^{-1}. Sensitivities may be expressed as the logarithm to the base 10 of the reciprocal of the radiant power required to reach a criterion level of performance.
Spectral absorbance $A(\lambda)$ – Logarithm to the base 10 of the reciprocal of the spectral transmittance, $\tau(\lambda)$; that is, $A(\lambda) = -\log_{10} \tau(\lambda)$. It depends on the path length. If l is the path length and $a(\lambda)$ is the spectral absorptivity, then, for a homogeneous isotropic absorbing medium, $A(\lambda) = la(\lambda)$ (Lambert's law).
Spectral absorptance $\alpha(\lambda)$ – Ratio of the spectral radiant flux absorbed by a layer to the spectral radiant flux entering the layer. If $\tau(\lambda)$ is the spectral transmittance, then $\alpha(\lambda) = 1-\tau(\lambda)$. The value of $\alpha(\lambda)$ depends on the length or thickness of the layer. For a homogeneous isotropic absorbing medium, $\alpha(\lambda) = 1-\tau(\lambda) = 1-10^{-la(\lambda)}$, where l is the path length and $a(\lambda)$ is the spectral absorptivity. Changes in the concentration of a photopigment have the same effect as changes in path length.
Spectral absorptivity $a(\lambda)$ – Spectral absorbance of a layer of unit thickness. Absorptivity is a characteristic of the medium, that is, the photopigment. Its numerical value depends on the unit of length.
Spectral sensitivity – The inverse of the radiant power of a monochromatic stimulus of wavelength λ that produces a criterion response equal to that of a monochromatic stimulus of fixed wavelength λ_0. The units and λ_0 may be chosen so that the maximum of this function is unity. In specifications by the CIE, the lower limit of the wavelength range is generally 360–400 nm and the upper limit is generally 760–830 nm, but smaller ranges may be used. The spectral sensitivity of a cone is essentially the normalized spectral absorptance of its photopigment (discounting any geometrical factors, e.g., cone waveguide properties).
Spectral transmittance $\tau(\lambda)$ – Ratio of the spectral radiant flux leaving a layer to the spectral radiant flux entering the layer. The value of $\tau(\lambda)$ depends on the path length.
Unique hues – Hues that are judged to be unmixed. They form mutually exclusive pairs, so that no light can appear to contain both red and green or both blue and yellow.
Wavenumber – The reciprocal of wavelength, usually in cm^{-1}.

Introduction

Normal human color vision is governed by three types of retinal cone photoreceptors sensitive to light over

different, but overlapping, regions of the spectrum and conventionally designated long-, medium-, and short-wavelength-sensitive (L, M, and S). Because the intensity and spectral properties of light cannot be distinguished once it has been absorbed (the principle of univariance), chromatic information is obtained by comparing the outputs of these different cone types. Signals from L, M, and S cones converge via excitatory and inhibitory pathways onto subsets of anatomically distinct ganglion-cell populations, which then project to the lateral geniculate nucleus, and thence to the higher cortical areas. The aim of this article is to provide an overview of how the cones contribute to chromatic function and how that contribution is modified by prereceptoral filtering and postreceptoral processing within the eye.

Photopigments and Phototransduction

The photopigment in the outer segment of the cone consists of two covalently linked parts, a protein called opsin and a chromophore based on retinal, an aldehyde of vitamin A. It is the latter that provides light sensitivity by isomerizing from 11-*cis* to all-*trans* forms. This leads to the activation of a guanine nucleotide-binding protein (G-protein), transducin, and a cascade of molecular events that result in a change in the rate of neurotransmitter release from the receptor to other neurons in the retina. In the course of the cascade, the signal provided by photon absorption is greatly amplified.

The wavelength λ_{max} of maximum absorption of the pigment (see the section entitled 'Cone Spectral Sensitivities') depends on the particular amino acid sequence of the opsin and its relationship to the chromophore. The L and M pigments are members of an ancestral medium/long-wavelength-sensitive class of vertebrate pigments. These two pigments have a high degree of homology, and the majority of the difference in λ_{max} arises at just a few amino acid sites. A common polymorphism of the L and M pigments, in which alanine is substituted for serine at codon 180, can create shifts in λ_{max} of several nanometers.

The S pigment is a member of a distinct ancestral ultravoilet (UV)-sensitive class of vertebrate pigments. Its spectral tuning is different from that of the L and M pigments, and the shift in λ_{max} from UV to the violet of normal human S cones arises from amino acid replacements at multiple tuning sites.

Fundamental Spectral Sensitivities

The spectral sensitivities of the cones, *in vivo*, have been estimated by many different methods. Historically, the most important method is based on psychophysical color-matching, in which a mixture of three fixed primary lights is matched against a monochromatic light of variable wavelength and constant radiant power. These data form the basis of the system of colorimetry standardized by the Commission Internationale de l'Eclairage (CIE). In the normal trichromatic eye, such color-matching functions yield a family of spectral sensitivities that are a linear transformation of the unknown cone spectral sensitivities. This transformation is not unique in that it varies with the choice of primaries, but data obtained from dichromatic and sometimes monochromatic observers, who have, respectively, only two and one of the three normal cone types, provide good estimates of these so-called fundamental spectral sensitivities.

Figure 1 shows one set of normalized L-, M-, and S-cone fundamental spectra, with wavelengths λ_{max} of maximum sensitivity of *c.* 570, 543, and 442 nm. These estimates represent corneal cone spectral sensitivities, as color matching necessarily involves the spectral transmission properties of the ocular media (see the section entitled 'Prereceptoral Attenuation'). Several such sets of fundamentals have been derived, based on different sets of color-matching functions and different assumptions about cone sensitivity and prereceptoral absorption.

Other psychophysical methods of estimation involve selectively chromatically adapting the three cone types by a background light and measuring the spectral sensitivity of the most sensitive color mechanism at or near its threshold level of response, a technique associated primarily with W. S. Stiles (see the subsection entitled 'Isolating Cone Responses: Selective Chromatic Adaptation'). Psychophysical methods have the advantage that sensitivity can be determined over a range of two to five decades

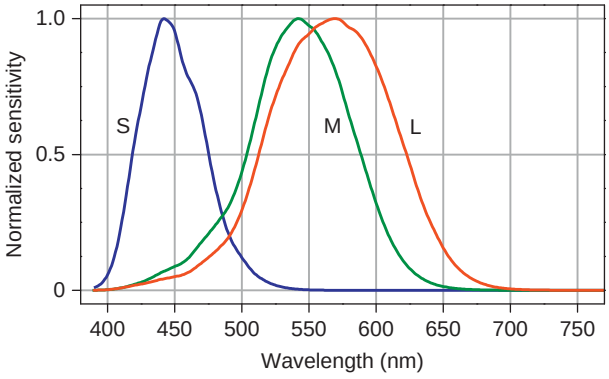

Figure 1 Fundamental spectral sensitivities of the long-, medium-, and short-wavelength-sensitive (L, M, and S) cones. Data are normalized to a maximum of unity on a radiance scale and are based on the 2° data of Table 2 of Stockman, A. and Sharpe, L. T. (2000). The spectral sensitivities of the middle- and long-wavelength-sensitive cones derived from measurements in observers of known genotype. *Vision Research* 40: 1711–1737; modified from the mean 10° color-matching functions of Stiles, W. S. and Burch, J. M. (1959). N.P.L. colour-matching investigation: Final Report (1958). *Optica Acta* 6: 1–26.

(i.e. 2–5 log units), although with normal trichromats, chromatic adaptation cannot generally isolate the response of a single cone type throughout the spectrum.

Nonpsychophysical but noninvasive methods of *in vivo* estimation include retinal densitometry (i.e., fundus spectral reflectometry) and electroretinography. In retinal densitometry, differences in reflectance of the fundus are measured, at various wavelengths, before and after selectively bleaching the cone pigments. The method is limited by its low signal-to-noise ratio and the need to distinguish between signals from L and M cones. It is also difficult to obtain signals reliably from S cones. In electroretinography, the summed electrical response of the retina to a flickering light is measured with a corneal electrode. This method provides a much larger dynamic range, of several log units, along with a good signal-to-noise ratio, but, as with retinal densitometry, signals from L and M cones need to be separated. Both techniques are best applied to well-characterized dichromats.

Prereceptoral Attenuation

The spectrum of the incident light reaching the cones is modified by two prereceptoral filters. The first is the lens (and cornea). In the young eye, the lens appears colorless, but, with increasing age, it becomes yellow, partly as a result of light scatter and absorption, which produce large transmission losses at short wavelengths (**Figure 2**). Even within the same age group, however, the size of the loss at 400 nm may vary over 1 log unit. Another important factor in the changing appearance of the lens is the accumulation of a particular fluorogen, which leads to increased lens fluorescence.

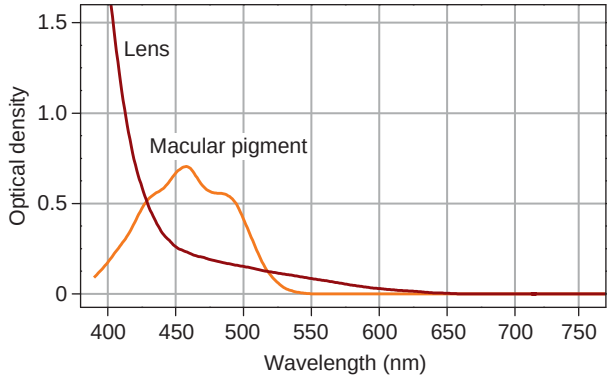

Figure 2 Variation of the optical density of the lens and of the macular pigment with wavelength. Data are from Table 2 of Stockman, A. and Sharpe, L. T. (2000). The spectral sensitivities of the middle- and long-wavelength-sensitive cones derived from measurements in observers of known genotype. *Vision Research* 40: 1711–1737; based on van Norren, D. and Vos, J. J. (1974). Spectral transmission of human ocular media. *Vision Research* 14: 1237–1244; and on Bone, R. A., Landrum, J. T., and Cains, A. (1992). Optical density spectra of the macular pigment *in vivo* and *in vitro*. *Vision Research* 32: 105–110. Plotted values are means over observers. Macular-pigment densities have been doubled for clarity.

The second prereceptoral filter is a nonphotosensitive yellow pigment, usually referred to as the macular pigment. Its maximum absorption is at *c.* 460 nm (**Figure 2**). It is a carotenoid consisting of two xanthophylls, lutein and zeaxanthin, whose densities decline with increasing eccentricity, with zeaxanthin concentrated only in the fovea.

The optical density of macular pigment can be quantified, *in vivo*, by heterochromatic flicker photometry and by Raman spectroscopy, in which argon laser light is used to excite the xanthophylls. Values of the optical density at the fovea vary markedly across individuals, from >1.0 to almost zero, with a mean of *c.* 0.6. Some of the hypothesized benefits of the macular pigment include protection from the damaging effects of short-wavelength light, reducing the effects of longitudinal chromatic aberration and glare, and protection against reactive oxygen species.

In addition to the lens and macular pigment, there is another important factor modifying the effective spectral sensitivity of the cones, namely, self-screening by the photopigment, which acts to broaden its absorption spectrum. If at wavelength λ the spectral absorptivity is $a(\lambda)$ and the path length is l, then the spectral absorptance $\alpha(\lambda)$ is given by $1-10^{-la(\lambda)}$. Therefore, increasing l (or equivalently the concentration of the pigment) has a proportionally larger effect at values of λ where $\alpha(\lambda)$ is small than at values where it is large.

Cone Spectral Sensitivities

Estimates of cone spectral sensitivities can be obtained from corneal spectral sensitivities, that is, the fundamental spectra of **Figure 1**, by eliminating the estimated effects of prereceptoral losses (see the section entitled 'Prereceptoral Attenuation'). **Figure 3** shows the results. The normalized L-, M-, and S-cone spectral sensitivities have wavelengths λ_{max} of maximum sensitivity of *c.* 559, 530, and 421 nm, respectively. Comparing these spectra with corneal spectra (**Figure 1**) reveals the influence of prereceptoral filtering in shifting λ_{max} toward longer wavelengths, especially for S cones, where the increase in λ_{max} is *c.* 20 nm.

In vitro methods of estimating cone spectral sensitivities include recording from single cone outer segments with a suction microelectrode, direct microspectrophotometry of intact receptor outer segments, and differential spectrophotometry of recombinant cone pigments produced in tissue-culture cells. Microelectrode recordings take advantage of the amplification of the signal provided by the phototransduction cascade and so can provide sensitivities over 5–6 log units, but spectrophotometry, as with *in vivo* reflectance measurements, is limited by

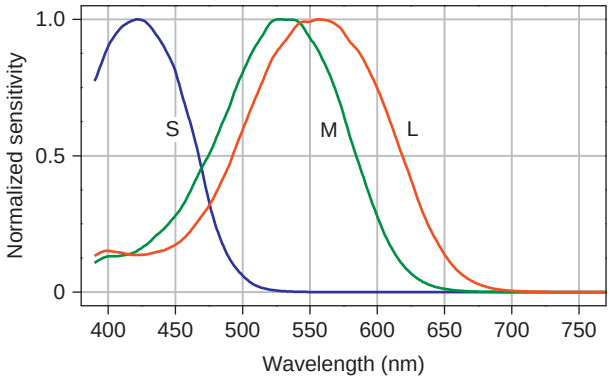

Figure 3 Spectral sensitivities of the long-, medium-, and short-wavelength-sensitive (L, M, and S) cones derived from mean L-, M-, and S-cone fundamental spectra (Figure 1). Data are normalized to a maximum of unity on a radiance scale and are based on Table 2 of Stockman, A. and Sharpe, L. T. (2000). The spectral sensitivities of the middle- and long-wavelength-sensitive cones derived from measurements in observers of known genotype. *Vision Research* 40: 1711–1737.

its low signal-to-noise ratio, providing sensitivities over only 1 or 1–2 log units. All *in vitro* methods are constrained by the nonphysiological nature of the illumination (and sometimes by the method of specimen preparation and recording). Notwithstanding the differences in experimental methodology and analysis, there is broad agreement in the values of λ_{max} (Table 1).

Template for Cone Spectral Sensitivity

The response of a cone is determined by the number of photons it absorbs: the spectral sensitivity describes the probability of that absorption at each frequency ν, which is invariant of the medium, unlike wavelength λ. The main absorption band of mammalian visual pigments is the α band (the β and other bands at progressively shorter wavelengths have less influence because of absorption in the ocular media). Despite the differences in λ_{max} of the L, M, and S pigments, plotting cone spectral sensitivity or spectral absorbance against the normalized frequency, that is, ν/ν_{max}, where ν_{max} is the frequency of maximum sensitivity, yields closely similar dependencies, as illustrated by the data in Figure 4 for suction microelectrode recordings from monkey cones (symbols).

These dependencies may be fitted empirically by a polynomial or other smooth function of normalized frequency (Figure 4, curve). This function may then be used as a template or nomogram and applied to sample data that are noisy or of limited range, allowing, for example, more accurate estimates of λ_{max}, as was done with the entries in Table 1. Templates are best obtained separately for sensitivities on logarithmic and linear ordinates, for the weighting of the fits is different and the templates are therefore not exact logarithmic transforms of each other (the data in Table 1 were based on both kinds of templates).

Table 1 Estimated wavelengths λ_{max} of maximum sensitivity of long-, medium-, and short-wavelength-sensitive cones and cone pigments from *in vivo* and *in vitro* measurements in humans and primates

Method	λ_{max} *(nm)*		
	L	*M*	*S*
Psychophysics[a]	559	530	421
Suction microelectrode recording from primate cones[b]	561	531	430

Cone Gains and von Kries Scaling

The chromatic function of the cones is determined by not only their spectral sensitivities but also their relative gains. The effect of the spectrum of the prevailing light on those gains is summarized by the coefficient rule of von Kries, which refers to the idea that the sensitivity of each cone type depends only on activity in that cone type. Thus, if the radiant power in the light is biased toward long wavelengths, then the gain of the L cones is reduced in proportion to that bias. In fact, the evidence from microelectrode recordings in the retina of primates suggests that although substantial and independent chromatic adaptation does takes place among the three cone types, it is not complete. Adaptation also takes place at postreceptoral levels (see the section entitled 'Postreceptoral Spectra'). Even so, to a first-order approximation, von Kries scaling achieves a normalization of cone responses over a wide range of illumination conditions before bleaching dominates.

Isolating Cone Responses

The experimental investigation of chromatic function sometimes requires the selective stimulation of a particular cone type. There are two general methods for achieving this *in vivo*: one employs selective adaptation either by

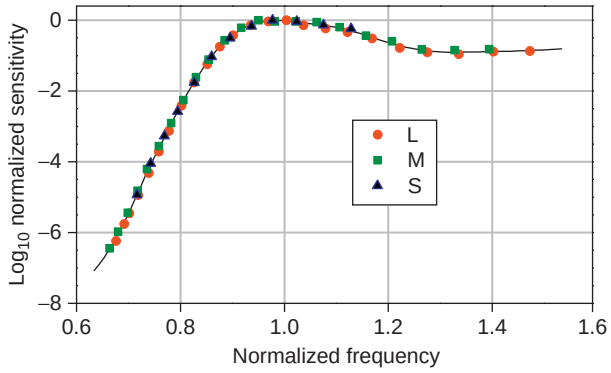

Figure 4 Spectral sensitivities of long-, medium-, and short-wavelength-sensitive (L, M, and S) monkey cones measured by suction microelectrode. Log mean absorbance, normalized to a maximum of zero (i.e., unity on a linear scale), is plotted against normalized frequency ν/ν_{max} for each cone type. Data are from Table 1 of Baylor, D. A., Nunn, B. J., and Schnapf, J. L. (1987). Spectral sensitivity of cones of the monkey *Macaca fascicularis*. *Journal of Physiology – London* 390: 145–160. The smooth curve is a locally weighted polynomial regression.

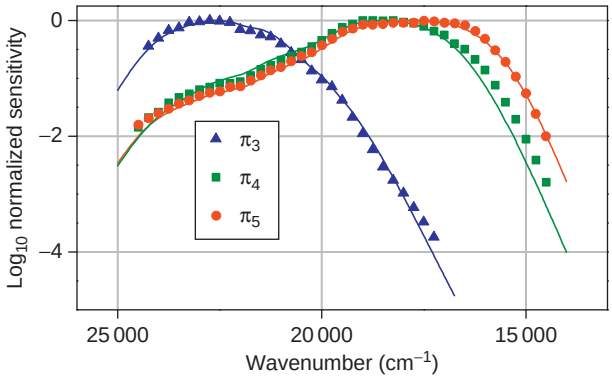

Figure 5 Stiles' background-field spectral sensitivities of the mechanisms π_3, π_4, and π_5 (symbols). Log mean sensitivity, normalized to a maximum of zero on a log quantum scale (i.e., unity on a linear scale), is plotted against wavenumber (proportional to frequency). The corresponding mean S-, M-, and L-cone fundamental spectral sensitivities, in the same units, are also shown (curves). Data are based on Table 2 (7.4.3) of Wyszecki, G. and Stiles, W. S. (1982). Color science: Concepts and methods, quantitative data and formulae. New York: John Wiley & Sons and on Table 2 of Stockman, A. and Sharpe, L. T. (2000). The spectral sensitivities of the middle- and long-wavelength-sensitive cones derived from measurements in observers of known genotype. *Vision Research* 40: 1711–1737.

a steady or temporally modulated background field so that only the chosen cone type mediates detection; the other constrains changes in the stimulus so that they are invisible to all but the chosen cone type.

Selective Chromatic Adaptation

The two-color threshold method of Stiles is based on the properties of the increment-threshold function. The minimum detectable radiance (the increment threshold) of a small test flash of wavelength λ is measured as a function of the radiance of a large steady background field of wavelength μ. The resulting monotonically increasing, threshold-versus-radiance (t.v.r.) curve may have more than one branch, but, over a limited range, each branch typically retains its shape while undergoing a vertical displacement with a change in λ (yielding a test spectral sensitivity) or a horizontal displacement with a change in μ (yielding a background-field spectral sensitivity). Provided certain assumptions hold, the test spectral sensitivity should coincide with the background-field spectral sensitivity, where both are defined. The assumptions are that the mechanisms underlying the t.v.r. curves – Stiles' π mechanisms – act independently of each other; that the observed t.v.r. curve depends only on the smallest increment threshold of the mechanisms available; and that each mechanism has a well-defined spectral sensitivity.

Figure 5 shows background-field spectral sensitivities for three mechanisms, π_3, π_4, and π_5 (symbols) superimposed on the corresponding S-, M-, and L-cone fundamental spectra (curves) (see the section entitled 'Fundamental Spectral Sensitivities').

The π mechanisms cannot represent individual cone activity, for there are too many of them: three S mechanisms (π_1, π_2, and π_3), two M mechanisms (π_4 and π_4'), and two L mechanisms (π_5 and π_5'), depending on the conditions of measurement. In addition to their multiplicity, there is evidence of nonadditivity, that is, the effect of a background field consisting of two monochromatic lights is different from the sum of the effects of the two lights alone. Yet, as Figure 5 shows, π_3, π_4, and π_5 approach quite closely the corresponding cone fundamentals.

The mechanisms defined by the t.v.r. curves depend, of course, on where in the visual pathway the threshold for detection is determined. With an appropriate choice of the spatial and temporal properties of the test flash and the background field, it is possible to obtain both test and background-field spectra that appear to mainly represent not cone responses but opponent combinations of cone responses (see the subsection entitled 'Postreceptoral Spectra: Cone Opponency').

Silent Substitution

The principle of silent substitution is illustrated in Figure 6. At a particular criterion response level, here 0.9 of maximum (other levels might be chosen), there are two wavelengths, 543 nm and 594 nm, at which the L-cone sensitivities are equal (red crosses). The alternation of two monochromatic, equal-radiance lights at these two wavelengths is therefore invisible to L cones but visible to M cones, for the M-cone sensitivity at 543 nm is more

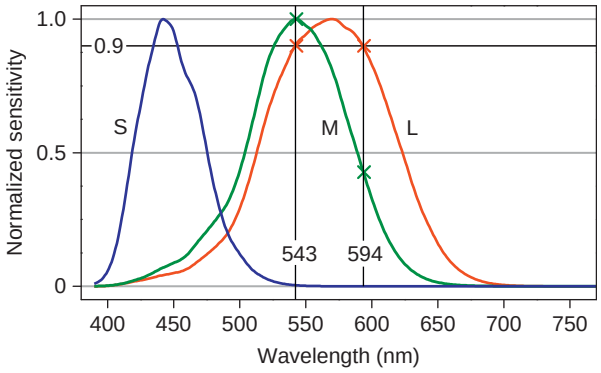

Figure 6 Silent substitution. Responses at 543 and 594 nm are the same for L cones (red crosses) but different for M cones (green crosses). Data are normalized cone fundamental spectra (Fig. 1).

than twice that at 594 nm (green crosses). At these two wavelengths, the S-cone sensitivity is vanishingly small and can be ignored. The same technique may be applied to M and S cones.

Unlike selective chromatic adaptation, the isolation achieved by silent substitution is a second-order one: it is not the stimulus but its alternation that is silent. Nevertheless, the method may be used to determine the spectral sensitivity of the isolated cone class (here the M cones); and even when the spectral sensitivity of the silenced class (the L cones) is known only approximately, it may still, in principle, be applied in an iterative way.

Rod Intrusion

The rod photoreceptors of the retina are not normally associated with chromatic function. But with large stimulus fields of low-to-moderate luminance, color vision can be influenced by rod activity, which biases the apparent hue and diminishes the saturation of extrafoveal stimuli. Even for foveal stimuli of just 1° visual angle, some rod involvement may be detected. Under daylight conditions, however, rod intrusion in color matches is small and is likely to be negligible above 100 cd m^{-2}.

Spatial Densities

The numbers of the three cone types are neither constant over individuals nor uniform across the retina. These variations have different implications for chromatic and luminance function.

Individual Variations

The relative frequencies of the different cone types, as proportions of the total number of cones, have been estimated across individuals by indirect psychophysical methods and by more direct methods, both *in vivo* and *in vitro*. The most important psychophysical method models the photopic luminous efficiency function obtained by heterochromatic flicker photometry as a linear sum of signals from L and M cones, under the working assumptions that the contribution of each is weighted by its numerosity and that the spectral sensitivity of each is known. Direct *in vivo* methods include retinal densitometry, electroretinographic flicker photometry, and high-resolution adaptive-optics imaging combined with retinal densitometry. Results from flicker photometry correlate with those from electroretinographic methods. *In vitro* methods include microspectrophometry with single cones, immunocytochemical labeling of small retinal patches, and analysis of L and M opsin messenger RNA in homogenized retinal patches.

It is clear that the relative frequency of S cones is fairly constant over individuals, *c.* 5–6% for a patch of retina at 1° eccentricity. For L and M cones, it is their ratio that is normally specified, and, although a working value of 1.5:1 or 2:1 is often assumed in modeling their contributions to the luminous efficiency function, the actual ratio varies greatly from individual to individual, from *c.* 0.7:1 to 12:1, by direct measurement, and over a somewhat larger range by indirect measurement. This variation may reflect the different evolutionary and developmental histories of the S-cone and L- and M-cone pathways.

Retinal Distributions

That the three cone types have different distributions across the retina has been long known from psychophysical measurements of, for example, increment threshold and grating acuity with cone-specific stimuli. These findings have been confirmed and extended by some of the techniques mentioned in the preceding subsection.

The spatial density of L and M cones is greatest in the central fovea and it declines steadily with increasing retinal eccentricity. By contrast, the spatial density of S cones is zero in the central *c.* 20 arcmin of the fovea (0.1 mm); it increases to a maximum at *c.* 1° eccentricity, and then declines again. Because the decrease in S-cone density is less rapid than that of the other cone types, the relative frequency of S cones, as a proportion of the total number of cones at each eccentricity, increases slowly with eccentricity and levels off at *c.* 5° or a little more.

In the fovea, there seems to be little evidence for other than a random distribution of S cones and L and M cones, although occasional departures in the direction of a more regular S-cone distribution and some clumping of L and M cones have been observed. In the periphery, there are more systematic departures from randomness in the distributions of both S cones and L and M cones. The purpose of the cone-rich rim of the ora serrata is unknown.

Eccentricity and Chromatic Function

The absence of S cones in the center of the fovea accounts for the perceptual phenomenon of small-field tritanopia: for sufficiently small fields, color vision is dichromatic, so that just two fixed primary lights are needed to match an arbitrary test light (see the section entitled 'Fundamental Spectral Sensitivities'). The size of the tritanopic zone varies across individuals, and it may be absent in some.

The consequences of individual variation in L:M cone ratios are largely confined to luminance function. For chromatic function, the variation may be counterbalanced by changes in gain associated with excitatory and inhibitory inputs. In judgments of a perceptually unique yellow, in which the wavelength of a monochromatic light is adjusted so that it appears neither red nor green and which might be expected to reveal an imbalance between L and M cone inputs, the variation in the selected wavelength seems not to be attributable to ratio differences. One factor contributing to the stability of unique hues may be a form of chromatic adaptation to the spectrum of the environment.

For the individual eye, there are marked variations in chromatic function with retinal eccentricity. Thus, in general terms, color-matching performance with a small field, of the order of 1° extent, diminishes with increasing distance from the fovea, tending to dichromacy at 25–30° and to monochromacy at 40–50°. More specific changes are revealed by psychophysical measurements of hue and saturation and of chromatic contrast sensitivity with eccentricity. The latter is quantified by the detectability of a stimulus modulated along a red–green or blue–yellow color axis, defined with respect to stimuli specific for L, M, or S cones (i.e., an L vs. M axis and an S vs. L + M axis). The size of the stimulus is usually increased with eccentricity for optimum response. For red–green modulation, contrast sensitivity is high at the fovea and then declines rapidly with eccentricity, falling to zero at 25–30°, whereas for blue–yellow modulation, contrast sensitivity is much flatter and declines only slowly with eccentricity, and at a rate similar to that for luminance modulation. Since luminance contrast sensitivity is determined by the same cone signals as red–green contrast sensitivity, the decline in the latter with eccentricity is presumably due to changes in chromatic coding rather than in L and M cone densities (see the subsection entitled 'Postreceptoral Spectra: Cone Opponency').

Postreceptoral Spectra

Cone Opponency

Spectral sensitivity at postreceptoral levels is modified by antagonistic interactions between signals from the different cone types. This cone opponency – also occasionally called color opponency – is not the same as the red–green and blue–yellow color opponency identified in some perceptual experiments where the poles of the reference axes correspond to the unique hues, red, green, blue, and yellow.

The detailed organization of cone opponency has been difficult to characterize unambiguously, and retinal connectivity is not as specific as has sometimes been assumed. Thus, there is anatomical evidence of random, nonselective connectivity of L and M cones to ganglion-cell receptive fields, and physiological evidence of both randomness and selectivity. Nevertheless, because the response of a ganglion cell is determined by a weighted sum of its excitatory and inhibitory inputs, the nature of the connectivity has less effect on the spectral characteristics of cone-opponent responses than the weights associated with the inputs. Figure 7 shows theoretical cone-opponent spectra (curves) from simple linear combinations of cone signals of the form $S - k(M + L)$ in the left panel, $M - kL$ in the middle panel, and $L - kM$ in the right panel, where the amount of inhibition is indicated by the weight constant k (the assumption of linearity is not essential).

With $k = 0.4$, the wavelength λ_{max} of maximum sensitivity for the $L - kM$ spectrum shifts from 570 to 589 nm, a difference of 19 nm, whereas for the $M - kL$ spectrum, λ_{max} shifts from 543 to 539 nm, that is, just 4 nm, and for the $S - k(M + L)$ spectrum, there is no shift at all. With larger k, both $L - kM$ and $M - kL$ spectra become more narrowed. Combined with a shift in λ_{max}, the effect is sometimes described as spectral sharpening.

These changes in spectral shape are similar to those observed in microelectrode recordings in primate retina and psychophysically in both test and background-field spectral sensitivities (see the subsection entitled 'Isolating Cone Responses: Selective Chromatic Adaptation') obtained under conditions designed to isolate cone-opponent activity. Examples of background-field cone-opponent spectra are also shown in Figure 7 (symbols). Notice that the asymmetries in the shifts of λ_{max} do not themselves require asymmetric weighting of cone signals nor do they imply asymmetric $L - kM$ and $M - kL$ responses.

As already observed (see the subsection entitled 'Spatial Densities: Eccentricity and Chromatic Function'), red–green and blue–yellow contrast sensitivity varies with retinal eccentricity, but there is evidence that the opponent weights revealed in those measurements remain constant with retinal location up to *c.* 10° eccentricity. Beyond that, differences emerge in the L versus M and M versus L responses.

It is at present unclear how these kinds of cone-opponent activity relate to the perceptual color opponency of unique hues.

Advantages of Cone Opponency

Along with providing information about the spectral content of a stimulus, cone opponency has two other

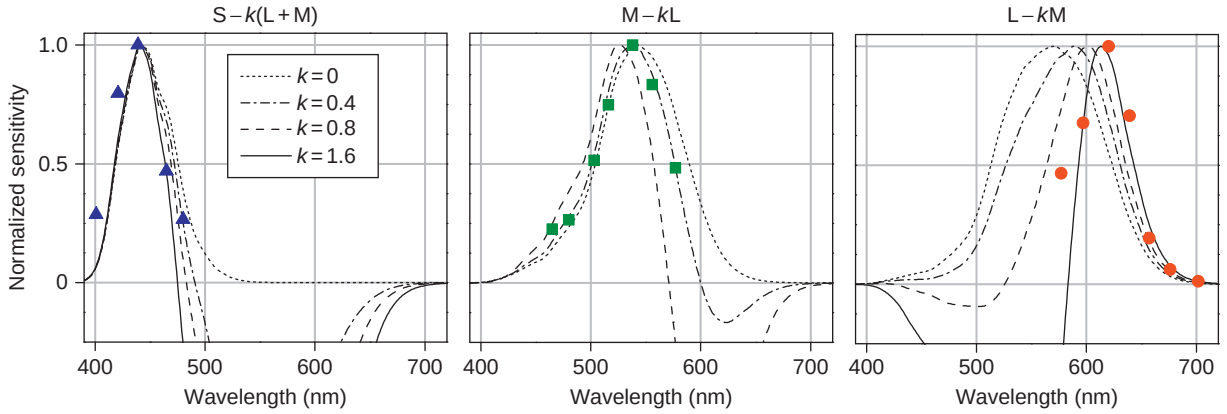

Figure 7 Theoretical and observed cone-opponent spectral sensitivities. Each set of curves represents spectra of the form S − *k*(M + L) (left panel), M − *k*L (middle panel), and L − *k*M (right panel), normalized to a maximum of unity on a radiance scale, with values of the weight constant *k* indicated (for *k* = 1.6, the function M − *k*L is mainly negative). Normalized L-, M-, and S-cone fundamental spectra were taken from Table 2 of Stockman, A. and Sharpe, L. T. (2000). The spectral sensitivities of the middle- and long-wavelength-sensitive cones derived from measurements in observers of known genotype. *Vision Research* 40: 1711–1737. The symbols show psychophysical background-field spectra obtained under conditions intended to isolate cone-opponent function, and are means calculated from Figure 1(a)–(c) of Foster, D. H. and Snelgar, R. S. (1983). Test and field spectral sensitivities of colour mechanisms obtained on small white backgrounds: Action of unitary opponent-colour processes? *Vision Research* 23: 787–797.

advantages. First, it reduces information redundancy. Because of the close overlap in the L- and M-cone spectral sensitivities, their responses are highly correlated. But spectrally sharpened L − *k*M and M − *k*L combinations provide greater independence and more efficient coding for neural transmission. Second, with chromatic adaptation at a cone-opponent level and not just at a receptoral level (see the subsection entitled 'Cone Spectral Sensitivities: Cone Gains and von Kries Scaling'), it is possible to compensate more completely for any bias in the spectrum of the prevailing light. This may be achieved by von Kries scaling, but of cone-opponent responses rather than cone responses.

Ciliary Blood Flow and its Role for Aqueous Humor Formation

J W Kiel, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA
H A Reitsamer, Paracelsus Medical University, Salzburg, Austria

Glossary

Diffusion – The movement of molecules down a concentration gradient.
Hydrostatic pressure – The pressure (force per unit area) in a liquid.
Oncotic pressure – The hydrostatic pressure needed to stop the movement of water due to a protein concentration gradient.
Osmosis – The movement of water down its concentration gradient. For example, water will move across a semipermeable membrane from a compartment with a low sodium concentration (high water concentration) to a compartment with a high sodium concentration (low water concentration).
Osmotic pressure – The hydrostatic pressure needed to stop the movement of water due to a solute concentration gradient.
Pseudofacility – The decrease in aqueous production that can occur when intraocular pressure is elevated during tonography and can cause falsely high measurements of outflow facility.
Starling equilibrium – The sum of hydrostatic and oncotic pressures across a vessel wall.
Ultrafiltration – The passive movement of fluid out of a blood vessel due to a net positive gradient of hydrostatic and oncotic pressures across the vessel wall.

Introduction

Aqueous humor is the clear liquid in the posterior and anterior chambers of the eye. It is produced by the ciliary processes, flows through the posterior chamber, then between the iris and lens through the pupil into the anterior chamber, and then leaves the eye through the trabecular and uveoscleral outflow pathways. The flow of aqueous humor serves two vital functions – it is the surrogate vascular system for the cornea and lens, delivering nutrients and removing metabolic waste for these avascular tissues, and it generates the intraocular pressure (IOP), which maintains the shape of the eye and sets the venous pressure for the intraocular circulations.

Figure 1 shows a schematic overview of aqueous production. Aqueous humor is formed in the ciliary processes in the pars plicata region of the anterior uvea by the translocation of fluid and solute across the pigmented epithelial (PE) and nonpigmented epithelial (NPE) layers, the epithelial bilayer that comprises the primary blood–aqueous barrier. Aqueous production occurs in three steps: (1) convective delivery of the aqueous components and metabolic fuels through the ciliary circulation, (2) ultrafiltration and diffusion from the capillaries into the stroma driven by the oncotic pressure, hydrostatic pressure, and concentration gradients, and (3) ionic transport into the basolateral spaces between the NPE cells, followed by water movement down the resultant osmotic gradient into the posterior chamber. Once formed, the aqueous composition is modified as it travels through the posterior and anterior chambers by metabolic exchange with the tissues it contacts – the lens, iris, and cornea.

Ciliary Circulation

The circulation of the ciliary processes is derived from branches off the major arterial circle of the iris, which is fed by the long posterior ciliary arteries and anastomotic connections from the anterior ciliary arteries. In humans, the vasculature of the ciliary processes divides into three zones. The first zone is at the anterior base of the processes and consists of arterioles and capillaries that drain into a venular system separate from the other zones. This zone is the boundary between the nonfenestrated capillaries of the iris and the fenestrated capillaries of the ciliary processes. The fenestrations in the ciliary capillaries permit passage of protein into the stroma which establishes an oncotic pressure that is important in aqueous production. The second zone also originates at the anterior base but extends more anteriorly into the processes and then drains into marginal venules running along the inner edge of the processes that coalesce into a venous segment that travels posteriorly into the pars plana and the vortex veins. The third zone supplies the posterior portion of the major processes and the minor processes.

Because of its inaccessible location and complexity, our knowledge of ciliary hemodynamics is somewhat limited. However, the plasma clearance of ascorbate is high in the ciliary processes, and the typical values for the aqueous-to-plasma ascorbate ratio (26.5) and aqueous production (2.75 $\mu l\,min^{-1}$) in humans provide a rough estimate of ciliary plasma flow at 73 $\mu l\,min^{-1}$, or a blood flow of 133 $\mu l\,min^{-1}$ assuming a normal hematocrit. Microsphere measurements in anesthetized monkeys indicate a slightly lower ciliary

blood flow at 89 µl min^{-1}. Direct measurements of ciliary arterial pressure have not been made, but a reasonable estimate for arterial pressure just outside the eye is 67 mmHg for humans in an upright position with a normal mean arterial pressure (MAP) of 100 mmHg. Episcleral venous pressure is approximately 9 mmHg in humans. However, the venous pressure inside the eye is set by the IOP, and in animals it is 1–2 mmHg higher than the IOP. Capillary pressure is similarly IOP dependent, and approximately 8 mmHg higher than the IOP in the rabbit choriocapillaris. Assuming that ciliary hemodynamics are similar in humans, the ciliary capillary and venous pressures should be approximately 23 and 17 mmHg, respectively, at a normal IOP of 15 mmHg.

Ultrafiltration

The permeability of the ciliary capillaries permits the passage of water, ions, and relatively large molecules into the stroma. The larger molecules move by diffusion down their respective concentration gradients, while the movement of water and dissolved solutes occurs by ultrafiltration, which is driven by the hydrostatic and oncotic pressure gradients across the capillary wall as defined by the Starling equation:

$$\text{Flux} = Kf[(P_c - P_t) - \sigma(\pi_p - \pi_t)] \quad [1]$$

Here, the flux is the fluid movement, Kf is the capillary filtration coefficient, P_c and P_t are the capillary and tissue hydrostatic pressures, σ is the protein reflection coefficient (an index of protein permeability), and π_p and π_t are the plasma and tissue oncotic pressures.

The dynamics of the Starling equilibrium in the ciliary processes are poorly understood. However, values for some of the Starling variables are known, and reasonable estimates can be deduced for the others. At steady state, the flux out of the capillaries must equal the rate of fluid movement into the posterior chamber plus any fluid exiting the ciliary processes through the supraciliary space. Thus, the normal rate of aqueous formation in humans of 2.75 µl min^{-1} provides an estimate of the minimum rate of ultrafiltration. The normal value for π_p is 20 mmHg. In rabbits, the stromal protein concentration is approximately 75% of that in plasma. Assuming that the same ratio holds for humans, the estimated π_t is 17 mmHg. Based on the net filtration of albumin and gamma globulin, σ is approximately 0.96. A reasonable estimate for P_t is 15 mmHg, since P_t should equal or slightly exceed the IOP.

The more difficult Starling variables to estimate are P_c and Kf. As mentioned earlier, P_c in the choriocapillaris is approximately 8 mmHg higher than the IOP, suggesting a ciliary P_c estimate of 23 mmHg at a normal IOP. The ciliary capillary Kf is unknown, but if the values for the other variables are correct, the graphic analysis in **Figure 2** (left) indicates that the Kf would need to be at least 0.48 µl min^{-1}mmHg^{-1} to provide a flux of 2.75 µl min^{-1}. The Kf for the whole eye is 0.3 µl min^{-1} mmHg^{-1}. Alternatively, lower Kf values would provide sufficient ultrafiltration if P_c were higher than 23 mmHg.

The role of ultrafiltration in aqueous formation is permissive rather than active; aqueous could not be formed if the fluid were not provided. However, although arguments to the contrary have been made, ultrafiltration appears to contribute little to the movement of fluid from the stroma into the posterior chamber. This is clear from the analysis of the capillary-to-aqueous Starling forces shown in **Figure 2** (right). For this analysis, the aqueous oncotic pressure is zero and σ is 1 since the ciliary nonpigmented epithelium is normally impermeable to protein. Consequently, the P_c would have to exceed 35 mmHg to generate a net movement of fluid from capillary to aqueous by ultrafiltration. Since P_c is likely less than 35 mmHg, the Starling forces favor reabsorption of fluid from the aqueous back into the ciliary processes.

The analysis in **Figure 2** is useful for estimating the minimal values of Kf and P_c consistent with normal steady-state ocular conditions. However, because the analysis holds the other variables constant, it fails to accurately predict the flux behavior in response to a change in Kf or P_c. Specifically, if P_c increases so that ultrafiltration exceeds

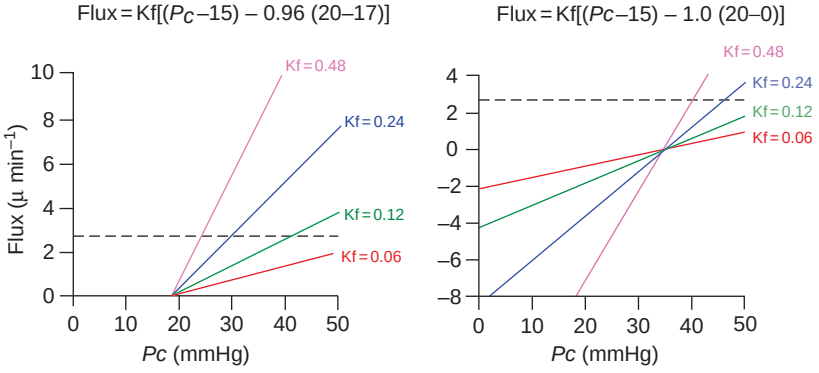

Figure 2 Graphic analysis of the Starling forces for fluid movement from capillary to stroma (left) and from capillary to aqueous (right). Adapted from Kiel, J. W. (1998). Physiology of the intraocular pressure. In: Feher, J. (ed) *Pathophysiology of the Eye 4 Glaucoma*. Budapest: Academiai Kiado.

aqueous formation, the fluid volume in the stroma increases, thereby raising P_t and lowering π_t until the flux re-equilibrates with aqueous formation.

Conversely, if P_c decreases so that ultrafiltration falls below aqueous production, the loss of stromal fluid volume decreases P_t and raises π_t until ultrafiltration and aqueous formation are again equal. It should be noted that the equilibrium of the Starling forces obscures the true value of Kf, which may be much higher than the minimum value needed to support a particular rate of aqueous formation, and that a higher Kf would also tend to preserve ultrafiltration if P_c falls. Nonetheless, if P_c falls below some critical level, aqueous production will become limited by the reduced rate of ultrafiltration. Autoregulation of ciliary blood flow may help maintain P_c during moderate reductions in MAP, but further reductions in MAP will cause P_c to fall. In monkeys, aqueous production starts to decline when the MAP falls below 70–90 mmHg.

In contrast to the effects of arterial pressure on the Starling forces, the effect of IOP is more difficult to assess. IOP elevation reduces aqueous formation by approximately 0.02–0.06 $\mu l\ min^{-1}\ mmHg^{-1}$, and this effect has been attributed to the Starling equilibrium, that is, raising the IOP increases P_t, which reduces the hydrostatic pressure gradient for ultrafiltration from the capillaries. A problem with this explanation is that raising the IOP should cause a similar increase in P_c due to the Starling resistor effect on the intraocular veins. If the hyrdostatic gradient is not altered appreciably, it seems unlikely that the reduction in aqueous production is due to a change in capillary ultrafiltration. Alternative explanations include increased fluid loss through the supraciliary space and sclera, or blood-flow-dependent changes in epithelial metabolism. Regardless of the underlying mechanism, an IOP-dependent decrease in aqueous formation (also known as pseudofacility) is a potential source of error in tonographic measurements of outflow facility.

Active Secretion

The transciliary Starling gradients and the significant plasma-to-aqueous concentration differences for certain solutes and macromolecules indicate the presence of a permeability barrier within the ciliary epithelia, and that a mechanism other than ultrafiltration is responsible for the majority of the fluid entry into the posterior chamber. The available evidence indicates that the majority of the barrier arises from the tight junctions between adjacent NPE cells, and that active secretion of Na^+ and other ions into the basolateral spaces between NPE cells establishes the osmotic gradient responsible for fluid movement across the barrier.

The ciliary epithelia consist of an outer layer of PE cells and an inner layer of NPE cells. The PE and NPE cells are arranged apex to apex, a unique organization caused by the embryonic invagination of the optic cup. The PE is the anterior continuation of the retinal pigment epithelium and its basal surface is separated from the stroma by a basement membrane contiguous with Bruch's membrane. The NPE is the anterior continuation of the retina and its basal surface is separated from the posterior chamber by an extension of the retinal internal limiting membrane.

The proximity of the layers and the complex array of intercellular connections within and between layers suggest that the bilayer behaves as a syncytium, although it is as yet poorly understood. The numerous gap junctions may provide sites of rapid intercellular communication. In addition, the channels seen in electron micrographs of PE and NPE apical surfaces provide another potential route of communication. Moreover, electrical coupling between the PE and NPE has also been reported.

The PE basement membrane and the gap junctions between PE cells do not impede the movement of protein or tracers, such as horseradish peroxidase, rather it is the tight junctions at the apical surface of adjacent NPE cells that constitutes the transciliary barrier. The other component of the blood–aqueous barrier is the absence of fenestrations and the low permeability of the iris capillaries, the other potential site for appreciable blood–aqueous exchange.

The barrier formed by the NPE cells and their tight junctions has a low hydraulic conductivity (i.e., 0.0071 $\mu l\ min^{-1}\ mmHg^{-1}$ from stroma to aqueous) that must be overcome for fluid to reach the posterior chamber. This is thought to occur by means of a standing osmotic gradient established in the lateral intercellular channels beyond the NPE tight junctions. The osmotic gradient is generated by the active transport of solute into the intercellular channels, with the highest solute transport occurring nearest to the tight junctions. This results in fluid flux from the NPE cells and across the tight junctions so that the fluid leaving the channels and entering the posterior chamber is either isoosmotic or slightly hyperosmotic relative to plasma.

Na^+ is one of the principal ions responsible for generating the osmotic gradient in the intercellular channels, and the basolateral membrane adjacent to the tight junctions has a high concentration of the membrane-bound sodium–potassium–adenosine triphosphate (Na/K-ATP) ase enzyme complex needed to provide the transport. The operation of the Na/K-ATPase requires the expenditure of metabolic energy and, as would be expected, perturbations that disrupt ATP production or utilization also decrease aqueous formation. The PE and NPE cells appear similar in their aerobic and anaerobic ability, but the NPE cells are more active with a higher rate of oxygen consumption. Although both cell types can increase their glycolytic activity if oxygen or substrate is unavailable, glycolysis alone cannot fully support normal rates of Na^+ transport.

Another significant contributor to the fluid flux into the intercellular channels is HCO_3^- and the enzyme carbonic anhydrase. The enzyme is present in high concentration in the basolateral membrane and in the cytosol, and

acetazolamide and other carbonic anhydrase inhibitors significantly inhibit aqueous formation. In addition to the Na/K ATPase and carbonic anhydrase contributions to aqueous formation, a variety of other transport systems have been identified as shown in **Figure 1**. Also shown are corresponding transport systems present in the PE basal membrane. In both locations, some of these may be important in aqueous formation, while others may not, and continued research is needed to clarify their separate roles.

The orchestration of the various transport systems is modulated by the neurohumoral milieu of the ciliary process and the receptor distributions in the different cell types. One primary common pathway in this complex regulatory system is the adenylate cyclase receptor complex generating the intracellular second messenger, cyclic adenosine monophosphate (cAMP), since changes in aqueous formation are typically associated with changes in cAMP. Growing evidence indicates that nitric oxide and cyclic guanosine monophosphate (cGMP) may also play a regulatory role. Another regulatory candidate is the phosphoinositidase receptor complex. When activated, this system hydrolyzes phosphatidylinositol 4,5 P2 to yield the second messengers, inositol 1,4,5 trisphosphate (Ins1,4,5P3) and diacylglycerol (DAG). Ins1,4,5P3 mobilizes intracellular Ca^{2+} by stimulating release of internal Ca^{2+} stores and promoting extracellular Ca^{2+} entry. DAG activates protein kinase C. The phosphoinositidase system has been identified in both PE and NPE cell types, both of which undergo spontaneous and agonist-evoked changes in intracellular Ca^{2+}.

Relationship between Ciliary Blood Flow and Aqueous Production

From the preceding section it is evident that aqueous formation is dependent on ciliary blood flow; however, it should be noted that ciliary blood flow and aqueous production are difficult to measure, and little was known about the relationship between them until recently. The information in the following section is based on ciliary blood flow measurements by fiber-optic-based laser Doppler flowmetry (LDF) that gives readings in arbitrary perfusion units (PUs), and fluorophotometry that uses the rate of disappearance from the cornea and anterior chamber of fluorescein applied to the cornea to calculate the rate of aqueous flow through the anterior chamber.

To determine the relationship between ciliary blood flow and aqueous production, it is necessary to vary ciliary blood flow and measure the resulting effect on aqueous flow. Ideally, only ciliary blood flow should be varied (i.e., neurohumoral input to the eye, the ocular perfusion pressure, and blood flow through the other ocular circulations should all be constant), but this is impossible. Instead, ciliary blood flow has been varied by mechanically holding blood pressure at different levels (80, 70, 55, and 40 mmHg) in anesthetized rabbits. The results of the initial study are shown in **Figure 3** (left); the relationship between ciliary blood flow and aqueous flow based on additional experiments are also shown (right).

The graphs in **Figure 3** show that when ciliary blood flow is increased above its normal level, aqueous flow is relatively unchanged. This is also true for reductions in ciliary blood flow of ≈25%, but further reductions cause proportional decreases in aqueous flow. In other words, there is a critical level of ciliary blood flow below which aqueous flow is blood flow dependent; above that critical level, aqueous flow is independent of ciliary blood flow. A similar relationship occurs in the gastric mucosa, where acid secretion is blood flow independent until mucosal blood flow is reduced below a critical level, whereupon it becomes blood flow dependent. In addition, secretory stimulants in the stomach shift the relationship upward, whereas secretory inhibitors shift the relationship downward. Ciliary secretion behaves similarly, giving rise to the following hypotheses: (1) aqueous production requires an

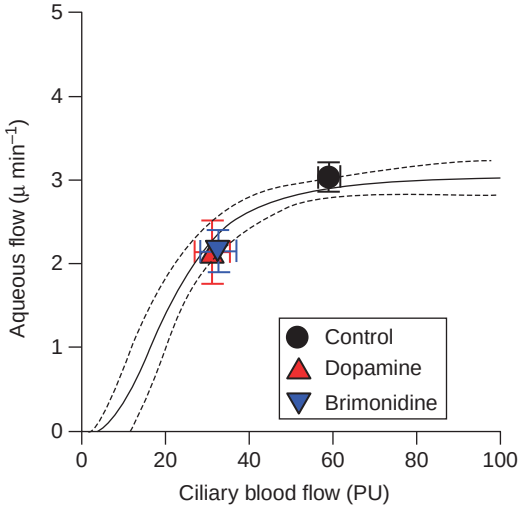

Figure 6 Vasoconstrictors decrease ciliary blood flow below the critical point and decrease aqueous flow indirectly. Data from Reitsamer, H. A. and Kiel, J. W. (2002). Effects of dopamine on ciliary blood flow, aqueous production, and intraocular pressure in rabbits. *Investigative Ophthalmology and Visual Science* 43: 2697–2703; and Reitsamer, H. A. adequate supply of oxygen and nutrients delivered by the ciliary circulation, (2) the neurohumoral milieu of the ciliary processes determines the level of secretory stimulation so that the rate of aqueous production at a given ciliary blood flow can be stimulated or inhibited pharmacologically, and (3) the autoregulatory mechanisms governing ciliary blood flow are modulated by endogenous neurohumoral factors and that ciliary autoregulation can be overridden by the administration of exogenous vasoactive compounds or large changes in perfusion pressure.

These hypotheses are illustrated in **Figure 4**. The figure has three curves generated by a mathematical model with aqueous production plotted as a function of ciliary blood flow: a control curve for a normal level of secretory stimulation (Ctrl), a curve for a state of heightened secretory stimulation (Stim), and a curve for an inhibited secretory state (Inhib). Point #1 on the control curve occurs at a normal ciliary blood flow (150 $\mu l\,min^{-1}$) and aqueous production (2.75 $\mu l\,min^{-1}$). A drug that acts directly on the active secretion by the epithelial cells (e.g., by changing intracellular cAMP) can decrease (point #2) or increase (point #3) production without changing ciliary blood flow. In this scenario, imposing large changes in perfusion pressure sufficient to overcome ciliary autoregulation will define the stimulated and inhibited curves. Alternatively, a drug that causes ciliary vasoconstriction (point #4) or vasodilation (point #5) without altering the stimulus for secretion can nonetheless decrease or slightly increase production. In this case, imposing large changes in perfusion pressure will generate the normal curve and reveal that the drug had no direct effect on secretion. A third scenario is that ciliary autoregulation is linked to metabolism so that a drug that stimulates secretion will cause a concomitant vasodilation (point #6), while a drug that inhibits secretion will cause a vasoconstriction (point #7). In this case, varying the perfusion pressure will reveal that the system has shifted to a new level of secretory stimulation rather than the effect being due simply to a change in blood flow. Some drugs will affect both secretion and vascular tone, and in this case varying the perfusion pressure will help to discern the relative contributions to the overall effect on production.

Figure 5 shows results in the rabbit similar to the model predictions. Eliminating neural circulatory control by ganglionic blockade with hexamethonium permits a wider range of ciliary blood flow with perfusion pressure manipulation, but does not alter the relation between ciliary blood flow and aqueous flow. (Note that aqueous

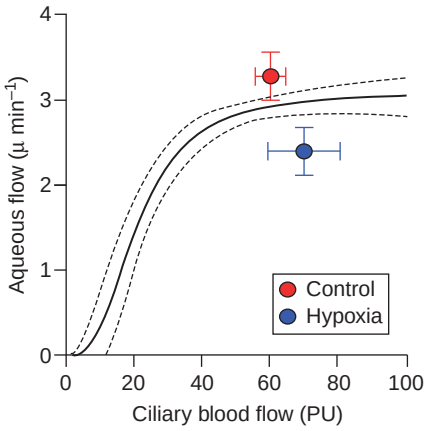

Figure 8 Effect of hypoxia on ciliary blood flow and aqueous flow. Lowering the percent saturation of hemoglobin with oxygen from 95% to 75% decreases aqueous flow without changing ciliary blood flow or the delivery of other nutrients and washout of metabolites. Adapted from Reitsamer, H. A. and Kiel, J. W. (2008). Effects of circulatory events on aqueous humor inflow and intraocular pressure. In: Civan, M. M. (ed) *The Eye's Aqueous Humor: From Secretion to Glaucoma*, pp. 273–300, San Diego: Academic Press.

flow is normal in Horner's patients, adrenalectomized patients, and atropine-administered primates.) Consistent with the model prediction, stimulating aqueous production with a subpressor dose of isoproterenol (0.02 μg min^{-1} kg^{-1}, intravenous (i.v.) infusion) shifts the relationship upward, while inhibiting aqueous production with topical dorzolamide (2%, 50 μl) shifts the relationship downward. The latter findings indicate that isoproterenol and dorzolamide exert direct effects of the ciliary epithelium. By contrast, ciliary vasoconstrictors, such as dopamine (300 μg kg^{-1} min^{-1}, iv) or brimonidine (0.15%, topical), decrease aqueous flow to the same extent as mechanically decreasing ciliary blood flow, indicating their effect on aqueous production is indirect (Figure 6).

A key question for the role of ciliary blood flow in aqueous production is what is provided by the ciliary blood flow. It provides oxygen and nutrients to the ciliary epithelia and removes metabolic waste. It is unclear which of these is critical; however, oxygen is a reasonable candidate because the ionic transport systems responsible for the osmotic gradient that produces aqueous utilize oxidative metabolism for energy and they largely stop functioning when insufficient oxygen is provided, despite the availability of other substrates. If ciliary blood flow is raised above the critical level, oxygen extraction decreases and the excess simply passes through in the venous effluent. However, if blood flow is reduced below the critical level, even maximum oxygen extraction cannot provide sufficient high-energy substrates (e.g., ATP) to drive ionic transport, and therefore aqueous production decreases. In support of oxygen as the critical factor, the change in the partial pressure of oxygen (PO_2) adjacent to the ciliary body in the rabbit decreases with ciliary blood flow in response to topical brimonidine (Figure 7). The decrease in PO_2 indicates increased oxygen extraction rather than the decreased oxygen consumption that would be consistent with secretory inhibition.

Additional evidence that oxygen is the critical factor delivered in ciliary blood flow is shown in Figure 8. In this experiment, anesthetized rabbits (n = 12) were respired with a mixture of room air and nitrogen sufficient to lower their percent hemoglobin saturation with oxygen to 75%. Ciliary blood flow increased slightly but not significantly, yet aqueous flow decreased by 22%. In this situation, the delivery of other nutrients and removal of metabolic waste remained constant and only oxygen delivery was reduced. Thus, it appears that oxygen is indeed a critical factor delivered in ciliary blood flow.

Circadian Photoreception

I Provencio, University of Virginia, Charlottesville, VA, USA

Glossary

Circadian rhythm – An endogenously generated biological rhythm with a period of about 24 h.
ipRGC – The term stands for intrinsically photosensitive retinal ganglion cell, which is a small subset of retinal ganglion cells that are rendered light sensitive because they express melanopsin, implicated in nonvisual photoresponses.
Melanopsin – The opsin-based photopigment of intrinsically photosensitive RGCs.
Nonvisual photoresponses – Physiological or behavioral responses to light that do not require the formation of images. Circadian photoentrainment is an example of a nonvisual photoresponse.
Photoentrainment – The synchronization of circadian rhythms to the daily light:dark cycle.

Introduction

Circadian rhythms are biological rhythms that exhibit a period of about 24 h (Latin, *circa* around + *dies* day). They persist in an environment devoid of time cues (*Zeitgebers*; German, *Zeit* time + *Geber* giver). This persistence of rhythmicity in constant conditions indicates the presence of an internal circadian clock. Circadian clocks are ubiquitous, existing in organisms ranging from cyanobacteria to humans. In metazoans, many tissues are capable of autonomous circadian rhythmicity, however, the phases of such rhythms tend to be orchestrated by a master pacemaker. In mammals, this master circadian pacemaker resides in the hypothalamic suprachiasmatic nuclei (SCN), two bilateral structures that straddle the midline immediately dorsal to the optic chiasm and are separated from each other by the third ventricle. The SCN coordinate the phases of multiple oscillators located in peripheral tissues, including heart, liver, and lung. The intergeniculate leaflet (IGL) of the lateral geniculate complex is also considered a component of the circadian system and receives input from both of the eyes. The IGL has been proposed to function in assessing ambient illumination levels.

While the periods of circadian rhythms are about 24 h, rarely are they exactly 24 h. Similar to a timepiece that runs too slowly or too quickly, the utility of a circadian clock is dependent on occasional resetting of its phase. The primary resetting agent for most circadian systems is light. Daily fluctuation in ambient irradiance resulting from the Earth's rotation about its axis is the most predictable diurnally variable feature of the environment. Organisms have evolved photoreceptive mechanisms to communicate this most reliable of *Zeitgebers*, the day:night cycle, to the circadian machinery so that circadian phase can be synchronized (entrained) with the astronomical day.

The SCN receives retinal input via the retinohypothalamic tract which is comprised of the myelinated axons of retinal ganglion cells (RGCs) (**Figure 1**). The response of the SCN to phase-shifting stimuli varies throughout the course of the circadian day and is phase-dependent (**Figure 2**). For photic stimuli, illumination during an animal's early subjective night results in a phase delay of the circadian clock as measured through the recording of circadian locomotor activity rhythms. By contrast, light pulses administered during the late subjective night cause activity rhythms to be phase advanced. Illumination during the subjective day has a negligible effect on circadian phase. In addition to this phase dependence, the magnitude of the light-induced phase shifts also varies as a function of the duration, intensity, and wavelength composition (color) of the light pulse. Conclusive identification of the photoreceptors that mediate circadian phase shifting has been wrought with problems but significant strides have been made recently.

Nonvisual Photoreception

Nonmammalian vertebrates possess numerous extraocular photoreceptors, some of which are necessary to shift the phase of the circadian system, so it is in proper phase alignment with the day:night cycle. Amphibians, for example, have photoreceptors in the pineal gland, the frontal organ, paraventricular zones of the brain, iris, and skin, in addition to the classical rod and cone photoreceptors of the retina. By contrast, all mammalian photoreception is restricted to the eyes.

One notable exception was a report in humans claiming that blue-light illumination of the popliteal region behind the knee caused shifts in the phase of salivary melatonin and temperature rhythms. This surprising result, which suggested the presence of extraocular photoreception in the mammals, inspired others to investigate the possibility of extraocular photoreception in other animal models. One group found no effect of direct sunlight on bilaterally

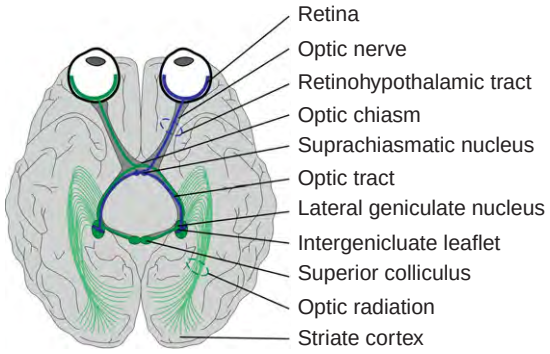

Figure 1 Retinal projections to the visual and circadian systems. Projections to the visual system are shown in green and those to the circadian system are shown in blue.

enucleated golden hamsters whose backs were shaved to maximize skin exposure. In these animals, locomotor circadian rhythms and levels of pineal melatonin were unperturbed by sunlight exposure during the animals' subjective night. Intact control animals, however, showed dramatic phase shifts in activity rhythms and suppression of pineal melatonin levels. Several other groups using human subjects failed to replicate the initial observation in humans indicating that some uncontrolled, nonphotic aspect of the experimental paradigm in the original study caused the observed effects on the circadian system. It is now widely accepted that the anatomical site of mammalian photoreception is exclusively ocular.

Physiological responses to light may be classified as visual or nonvisual. The responses that require the construction of images are considered visual, while those responses that simply require detection of changes in irradiance, such as circadian photoentrainment, may be considered nonvisual. The mammalian retina, the primary focus of this article, subserves both visual and nonvisual photoreception.

Due to the anatomical accessibility of the eye and the profound quality-of-life deficits experienced by the blind, the retina has been one of the most intensely studied tissues. Additionally, the laminar organization of the retina has made it an exquisite model for understanding basic concepts of development and neural communication. Retinal cytoarchitecture has been extensively described for more than 150 years. In fact, the rod and cone cells were postulated to be the light-sensing elements of the retina, as early as the mid-1850s by the German anatomist and physiologist Heinrich Müller.

In view of this long history of study, it was reasonable to suspect that rods and cones mediated both visual and nonvisual photoreception because no other classes of photoreceptors were known to exist in the mammalian eye. However, several lines of evidence suggested the existence of a class of ocular photoreceptor that was neither rod nor cone. In 1927, Clyde Keeler recognized that blind mice lacking photoreceptor cells continued to exhibit a pupillary light reflex, although this response was slower and less sensitive than that of fully sighted mice. Seventy-four years later, it was confirmed that the pupillary light reflex does indeed persist in blind mice and is maximally sensitive to blue wavelengths. Phase shifting of the circadian clock in response to light pulses is also maintained in mice homozygous for the retinal degeneration 1 allele ($Pde6b^{rd1/rd1}$), resulting in the loss of rods and cones. Similar to the pupillary response, light-induced circadian phase shifting in these visually blind mice exhibits a peak spectral sensitivity in the blue wavelengths. Finally, elevated nighttime levels of serum melatonin can be acutely suppressed by blue light presented to the eyes.

All of these blue-sensitive responses exhibit a peak spectral sensitivity in the 460–480 nm wavelength range, a domain of the electromagnetic spectrum that does not coincide with the peak sensitivity of known rod and cone photopigments of the human or murine retina. Since photoreceptors are defined by their photopigments, which in turn dictate their spectral sensitivity, a common strategy for identifying new photoreceptors is to identify new photopigments which should eventually point to the identification of a new photoreceptor class. The accumulating evidence for novel photoreceptors that mediate nonvisual responses to light led to the discovery of many new opsin-based photopigments. First among these was pinopsin, which was originally identified in the pineal gland of chicken and whose function remains unknown, but most likely plays a role in the photoregulation of melatonin synthesis. Very ancient opsin (VA-opsin), parapinopsin, and parietopsin were subsequently identified in the eye, parapineal, and parietal eye, respectively, of nonmammalian vertebrates. Based on an inspection of completed genomes, it is unlikely that mammalian homologs of these opsins exist.

However, within the last decade new opsins were indeed revealed in the mammals, none of which were localized to rods or cones. Peropsin and retinal G-protein-coupled receptor (RGR) opsin are expressed in the retinal pigment epithelium and are likely to function as accessory photoisomerases which use photic energy to convert all-*trans*-retinoids to their respective 11-*cis* isomers. 11-*cis*-Retinal is the requisite chromophore of all vertebrate signaling opsins. Encephalopsin was originally identified only in the brain and spinal cord of mouse, sites not known to be inherently photoreceptive. A subsequent study claimed the presence of encephalopsin message in the eye, however, the role of encephalopsin in the central nervous system remains unknown. Opn5 is another opsin predicted to exist within the mammalian eye based on the presence of messenger ribonucleic acid (mRNA), although a translated gene product remains to be discovered (**Table 1**).

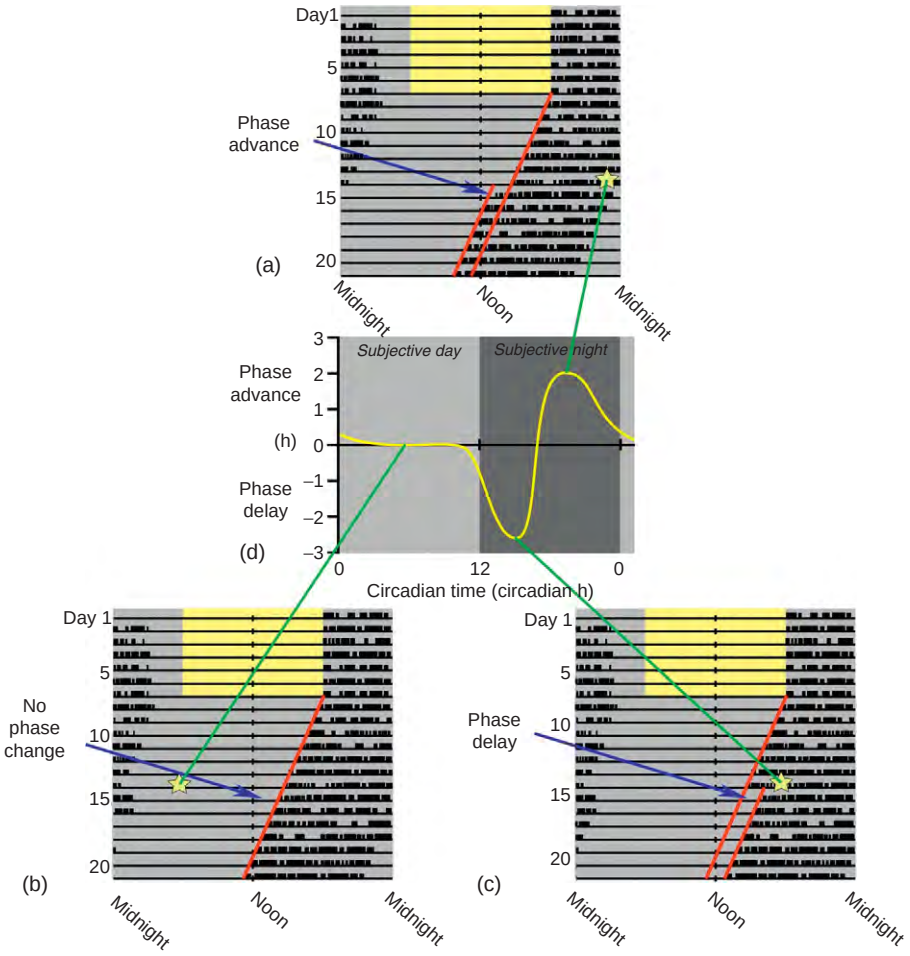

Figure 2 Phase response curve. Actograms (a, b, c) of daily activity obtained in running wheel cages containing a single mouse. Each horizontal line represents one day. Line thickenings indicate bouts of activity. Animals are maintained in a 12-h light:12-h dark cycle for the first week (gray background, dark; yellow background, light) and then maintained in constant darkness for the remainder of the experiment (gray background). After approximately 1 week in constant darkness, a standardized light pulse is administered (star symbol) and the phase shift of the onsets of activity on the days following the pulse are determined. The magnitude and direction (delay or advance) of the phase shift in response to a standardized light pulse varies as a function of the circadian phase of the circadian cycle during which the pulse is given. This relationship can be plotted as a phase:response curve (d). In general, light exposure during the early subjective night elicits phase delays, while illumination during the late subjective night causes phase advances. Pulses administered during the subjective day do not shift the clock.

Melanopsin and the Mammalian ipRGC

Among the nonvisual opsins, melanopsin has been the most extensively studied photopigment. It is expressed in a small subset of RGCs that project to sites in the brain not involved in the formation of images. Originally cloned from the photosensitive dermal melanophores of *Xenopus laevis*, homologs were subsequently identified in chicken and other nonmammalian vertebrates. A second melanopsin gene was recognized in the chicken genome and is also present in other vertebrate classes. However, based on chromosome synteny, it is clear that one of these two genes has been lost in mammals.

In the nonmammalian vertebrates, melanopsin is expressed in the retina and extraretinal tissues, including the iris, brain, pineal, and skin. Many of these sites had been shown previously to be inherently light sensitive, although the photopigments mediating the sensitivity were unidentified. Unlike the broad anatomical distribution observed in nonmammalian vertebrates, in mammals, melanopsin expression is restricted to less than 2% of the RGCs. Notably, extraretinal expression has not been observed in any mammal.

Pituitary adenylyl cyclase-activating peptide and glutamate are coexpressed within the melanopsin-containing cells. Melanopsin is what confers photosensitivity upon these intrinsically photosensitive retinal ganglion cells (ipRGCs). Loss of melanopsin renders these cells nonresponsive to light.

Murine ipRGCs elaborate two or three primary dendrites which bifurcate within 50 μm of the perikaryon. The

Table 1 Nonvisual opsins of mammals

Encephalopsin/ panopsin	*opn3*	Brain, testis	Unknown

dendrites ramify within the S1 (OFF layer) or S5 (ON layer) sublaminae of the inner plexiform layer. A small fraction of ipRGCs may have dendrites arborizing in both S1 and S5. Dendrites are studded with varicosities giving a rosary bead appearance. Melanopsin protein is found throughout the plasma membrane of the cell body, the segment of the axon contained within the eye, and the dendritic arbor. Arbors are sparse, regularly tiled across the retina with substantial overlap, and rather large, having mean field diameters of around 450 μm in mice and 600 μm in rats. The receptive field of ipRGCs corresponds to the dimension of the dendritic field, indicating that the entire arbor is capable of initiating phototransduction. Membrane density of melanopsin is about 10 000-fold lower than that of rods and cones. This is largely attributable to the lack of a specialized light harvesting organelle in ipRGCs comparable to the photopigment-dense outer segments of rods and cones. This relative paucity of photopigment in ipRGCs results in a very low photon-capture efficiency, thereby rendering this system effective only in very bright irradiances. Nevertheless, ipRGCs, similar to rods, can signal the absorption of single photons. The spectral sensitivity of dark-adapted melanopsin peaks in the blue wavelengths and coincides with the action spectra of many of the nonvisual responses previously described, including circadian photoentrainment and the pupillary light reflex of visually blind mice that lack rods and cones.

A comparison of the melanopsin peptide sequence against known opsins indicates that it more closely resembles the rhabdomeric opsins of invertebrates rather than the ciliary opsins of vertebrates. Not surprisingly, melanopsin employs a phototransduction cascade more similar to that of insect rhabdomeres rather than vertebrate outer segments. Illuminated amphibian melanophores darken and exhibit a light-stimulated increase in inositol trisphosphate and protein kinase C (PKC)-dependent phosphorylation. Presumably, these effects are mediated by a melanopsin-initiated cascade because overexpression of melanopsin hypersensitizes melanophores to light. Inhibition of phospholipase C (PLC), PKC, or chelation of intracellular calcium blocks melanophore darkening suggesting that this light-initiated response must activate a phosphoinositide signaling cascade. Heterologous expression of melanopsin in HEK293 cells renders them light sensitive and leads to a light-dependent increase in intracellular calcium and depolarization of membrane potential. Depolarization can be blocked by pharmacologic inhibitors of the $G\alpha_{(q/11)}$ subunit of guanine nucleotide-binding protein or PLC. These lines of evidence again suggest that light-activated melanopsin triggers a phosphoinositide signaling cascade similar to that of rhabdomeric photoreceptors. These same transduction components are found within ipRGCs and are critical for eliciting photoresponses. Furthermore, responses to light can be elicited in excised, inside-out patches of ipRGC membrane indicating that the critical signaling molecules are closely associated or are within the plasma membrane. A hallmark of rhabdomeric opsins is the formation of a stable red-shifted metastate in response to illumination. Whether melanopsin forms such a state remains equivocal, although some dark-adapted responses to blue light appear to be primed by preexposure to red light, which presumably photoconverts a red-sensitive metastate back to the blue-sensitive dark-adapted state. The general similarity to rhabdomeric signaling indicates that ipRGCs and invertebrate photoreceptors may have shared a common evolutionary ancestor.

ipRGCs project to central sites not associated with vision but implicated in regulating different forms of nonvisual photophysiology. For example, the SCN of the hypothalamus, the site of the primary circadian pacemaker, receives a robust input from ipRGCs. By contrast, the classical, nonphotosensitive RGCs provide minimal innervation to the SCN. Photoreceptor-mediated effects on the circadian axis occur exclusively through ipRGCs, suggesting that classical retinal rod and cone circuits impinge upon ipRGCs at the inner plexiform layer. Other principle central targets of ipRGCs include the IGL, the olivary pretectal nucleus, and the lateral habenula. The subparaventricular zone, the ventrolateral preoptic nucleus, and the ventral lateral geniculate nucleus are secondary, less intensely innervated targets.

Functions of ipRGCs

The role of ipRGCs in mediating nonvisual responses to light has been largely elucidated through the use of genetic mouse models. Mice null for melanopsin exhibit rather modest phenotypes. The magnitude of light-induced phase shifts of circadian locomotor activity rhythms is attenuated in melanopsin knock-out mice to about 40% of that observed in wild-type sibling controls (**Figure 3(a)**). The lengthening of circadian period observed in wild-type

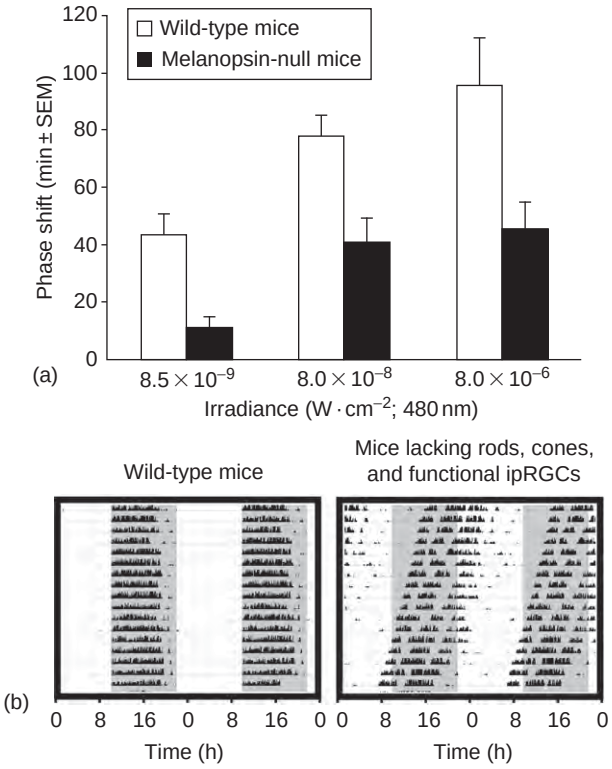

Figure 3 Circadian responses to light in retinal mutants. (a) Irradiance-dependent circadian phase shifting in wild-type and melanopsin-null mice. Mice lacking melanopsin were deficient in light-induced circadian phase shifting at all irradiances tested. (b) Melanopsin-null mice also lacking rods and cones fail to show synchronization (entrainment) of circadian locomotor activity to the light:dark cycle; white is the time that lights are on. Actograms are double plotted (i.e., horizontal lines correspond to 48 h) and darkness is indicated by a gray background. By contrast, the wild-type mouse is well entrained.

mice that are maintained in constant light is also diminished in melanopsin knockout mice. However, entrainment to standard light:dark cycles appears to be unaffected in mice lacking melanopsin. Other nonvisual responses such as the pupillary light response, the acute inhibition of activity by light (masking), and the suppression of the melatonin biosynthetic pathway are unaffected in melanopsin knockout mice. Interestingly, many of these same responses show no deficits in murine genetic models lacking rods and cones. Combined, these results suggest some level of redundancy between the rod/cone system and ipRGCs. To test this possibility, melanopsin-null mice have been crossed with mice either lacking functional rods and cones or lacking rods and cones all together. These animals exhibit no responses to light (**Figure 3(b)**). Essentially, they behave as though they have been bilaterally enucleated.

Many of the retinorecipient structures such as the SCN that mediate nonvisual responses to light receive negligible, if any, input from rod and cone pathways. However, melanopsin-knockout mice with light-insensitive ipRGCs continue to exhibit some degree of light-driven nonvisual responses. This raises the possibility that in addition to their inherent photoreceptive capacity, ipRGCs may also serve to convey light signals initially detected by rods and/or cones to brain sites such as the SCN. Indeed, specific ablation of ipRGCs mimics the previously mentioned results obtained in animals lacking functional rods, cones, and ipRGCs. These results indicate that ipRGCs, while intrinsically light sensitive, also transmit information generated by the classical photoreceptors.

Apart from its role in entraining circadian rhythms, the eye is a circadian oscillator itself. This was first demonstrated in the isolated eyes of gastropods, which show a circadian rhythm in the firing frequency of compound action potentials. Shedding of disks from the distal tips of rods is also circadian and persists in isolated amphibian and mammalian eyes whose optic nerves have been severed. Teleost eyes exhibit circadian rhythms in retinomotor movements of photoreceptors and the migration of melanosomes within cells of the retinal pigment epithelium. Syntheses of melatonin and dopamine are perhaps the best-studied circadian outputs of the eye. These amines are synthesized in antiphase; melatonin levels peak in the night and dopamine levels peak during the day. This phase relationship is maintained in constant darkness indicating that these rhythms are indeed circadian. However, in the absence of melatonin, dopamine is only acutely synthesized in response to light and is no longer produced in a circadian fashion.

Determining which ocular cell types harbor the circadian clock has proved to be difficult. Isolated amphibian eyecups continue to produce melatonin rhythmically, even when the vast majority of inner retinal neurons are lesioned. These findings suggest that the photoreceptors contain a competent clock and the biosynthetic machinery to make melatonin. Additionally, action spectral analyses in the amphibian retina implicate the principal green-sensitive rods as critical to the acute light-mediated regulation of ocular melatonin synthesis. Whether these cells are the actual site of the amphibian retinal clock remains to be determined.

The mammalian eye also contains a circadian clock. Cultured hamster retinas maintained in constant darkness produce melatonin rhythmically with a period near 24 h. Retinas from *tau* hamsters whose period of locomotor rhythms are significantly shorter than those of wild-types also exhibit rhythms in retinal melatonin with periods that parallel the shortened activity cycles. Importantly, these rhythms can be reset by pulses of light demonstrating that similar to the amphibian eye, the mammalian eye is an autonomous circadian system with a circadian pacemaker that drives a measurable output, which can be reset if it comes out of phase with the light:dark cycle.

In summary, the mammalian eye has a dual function. Similar to the ear which supplies auditory and vestibular

input to the brain, the eye provides visual input for the formation and interpretation of images and nonvisual input for the regulation of a myriad of light-regulated physiology such as the entrainment of circadian rhythms. The primary central circadian pacemaker within the SCN is entrained by light, the most reliable of external, daily time cues. The photoreceptors mediating photoentrainment include the classical photoreceptors (rods and/or cones), known primarily for their role in vision, and unique RGCs, which are inherently light sensitive because they express the photopigment melanopsin. The relative insensitivity of ipRGCs suggests that the classical photoreceptors mediate photoentrainment at low light levels, while ipRGCs are responsible for entraining the SCN at higher irradiances. However, even at low light levels, photoreceptive signals transmitted through rod or cone pathways reach sites of the brain involved in nonvisual photoresponses via the ipRGCs.

The presence of an ocular photoreceptive system that is anatomically distinct from the rods and cones raises the possibility that individuals suffering from blindness due to photoreceptor loss may retain a full healthy complement of ipRGCs. Some blind individuals do indeed lack cognitive vision but maintain an ability to regulate pineal melatonin and remain synchronized to the prevailing day:night cycle. The high incidence of ocular infection in the blind drives many clinicians to replace the eyes with prosthetics. Care should be taken to consider the anatomical source of blindness. Those suffering from photoreceptor-derived or cortical blindness may develop circadian-based maladies upon removal of the eyes, thereby exacerbating an already diminished quality of life.

Circadian Regulation of Ion Channels in Photoreceptors

G Y-P Ko, K Jian, L Shi, and M L Ko, Texas A&M University, College Station, TX, USA

Glossary

Circadian oscillator – A system that generates self-sustained oscillations or rhythms of about 24 h. Current models include self-sustained transcription and translation feedback loops that operate at the cellular level to provide outputs that are circadian in nature.

Cyclic GMP-gated cation channels (CNGCs) – The nonselective cation channels that are activated through direct binding of cyclic nucleotides onto the channel proteins. In general, cyclic-nucleotide gated channels are heterotetrameric complexes consisting of two or three different subunits (α, β, and γ), with important channel properties determined by the subunit composition.

ENSLI amacrine cells – A class of retinal amacrine cells that release the peptide, somatostatin. These cells get their name because they are immunoreactive for enkephalin, neurotensin, and somatostatin (ENSI, enkephalin-, neurotensin-, and somatostatin-like immunoreactive).

L-type voltage-gated calcium channels (L-VGCCs) – The membrane channels that mediate a voltage-dependent and depolarization-induced calcium influx. They regulate diverse biological processes such as contraction, secretion, neurotransmission, differentiation, and gene expression in many different cell types. The L-VGCCs are composed of a pore-forming α1-subunit and the auxiliary β-, $\alpha 2\delta$-, and γ-subunits. They can be blocked by divalent cations (e.g., cobalt) and organic L-VGCC antagonists, including dihydropyridines, phenylalkylamines, and benzothiazepines.

Retinoschisis – An X-linked retinal dystrophy that features disorganization of retinal cell layers, disruption of the synaptic structures and neurotransmission between photoreceptors and bipolar cells, and progressive degeneration of rod and cone photoreceptor cells. Retinoschisis results from mutations in retinoschisin.

Circadian Oscillators Regulate the Functions of the Visual System

Circadian oscillators are biological clocks that exist in almost all living organisms on the earth from bacteria to humans, with persistent rhythmic periods close to 24 h (*circa dian*) even in the absence of external timing cues. The circadian oscillators coordinate rhythmic changes in biochemistry, physiology, and behavior of living organisms, so that organisms can be synchronized with the 24-h oscillations of the external environment. The molecular nature of circadian oscillators varies from species to species. A generalized model for the generation of circadian rhythm involves the transcription, translation, and feedback of clock genes and their own transcriptional products. It is composed of two interlocking transcription–translation feedback loops as well as post-translational modulations. Collectively, these components comprise the core oscillator or the circadian oscillator. Visual systems have to detect images despite large daily changes in ambient illumination between day and night, and intrinsic circadian oscillators in the retina provide such a mechanism for visual systems to initiate more sustained adaptive changes throughout the course of the day. The retina is a heterogeneous tissue with multiple cell types organized in several cell layers. Early studies of circadian regulation in *Xenopus* and chicken retinas indicated that retinal circadian clocks are mainly located in the photoreceptors. Later research revealed that there are multiple oscillators present in various retinal cells in a species-dependent manner. The overall circadian regulation of the retina relies on the synaptic circuitry and feedback modulation among different retinal oscillators, so that the retina is able to anticipate and adapt to sustained daily illumination changes as well as acute light/dark adaptation.

Circadian Regulation of Photoreceptors

The circadian oscillators in photoreceptors are endogenous and able to function independently in the absence of other retinal inputs. These photoreceptor oscillators lead to morphological, physiological, biochemical, and molecular changes that ultimately regulate photoreceptor function and physiology in a circadian fashion. In vertebrate rod photoreceptors, outer segment shedding and renewal is a continuous process, but its rate is under circadian control. In some teleosts and anurans, the

inner segments of rod and cone photoreceptors undergo contraction and elongation (i.e., retinomotor movement) in response to changes in ambient illumination as well as in the circadian cycles. While cones remain in a contracted state during the day, rods contract at night. Photoreceptors form specialized ribbon synapses with secondary neurons such as horizontal or bipolar cells. The numbers and ultrastructures of synaptic ribbons in both photoreceptors and bipolar cells undertake changes in relation to the time of day and light intensities. In avians, amphibians, reptiles, and other lower vertebrate species, melatonin is synthesized and secreted from photoreceptors at night, while its synthesis is inhibited by light. The transcription of arylalkylamine N-acetyltransferase (AANAT), the melatonin synthesis enzyme, is under circadian control. While the synthesis and release of dopamine from retinal amacrine cells shows light-driven and circadian fluctuations, the circadian nature of dopamine is dependent on the melatonin rhythm. In addition to the circadian oscillator genes, several photoreceptor-specific genes, ion channels, and enzyme activities are also under circadian control that ultimately contribute to the circadian regulation of photoreceptor physiology and function.

Ion Channels in Photoreceptors

Ion channels are macromolecular pores that allow charged ions to move across cell membranes and contribute to the excitability of neurons and muscles. Electrical signals are generated and modulated as different types of channels open and close in response to neurotransmitters, hormones, membrane potential changes, mechanical forces, and other agents. There are two major classes of ion channels: voltage-gated and ligand-gated ion channels. Voltage-gated ion channels open or close their pores in response to membrane potential changes. Ligand-gated ion channels gate ion movements and generate electrical signals in response to specific chemicals such as neurotransmitters or cyclic nucleotides. Vertebrate photoreceptors are highly polarized, so the distribution of ion channels on the plasma membrane is spatially compartmentalized. The outer segment membrane contains cyclic guanosine monophosphate (cGMP)-gated ion channels that are closed by light, whereas the inner segment and the synaptic terminal are furnished with at least six different ion channels. These six ion channels include:

1. hyperpolarization-activated and cyclic-nucleotide-modulated cation channels;
2. L-type voltage-gated calcium channels (L-VGCCs);
3. calcium-activated potassium (K_{Ca}) channels;
4. noninactivating voltage-gated potassium channels;
5. calcium-activated chloride channels; and
6. cGMP-gated ion channels.

Thus far, cGMP-gated ion channels and L-VGCCs have been studied the most rigorously, especially with regard to their gating properties and physiological functions in photoreceptors. Both ion channels are under circadian control. In the following sections, the circadian regulation of cGMP-gated ion channels and L-VGCCs are reviewed in detail.

Circadian Regulation of cGMP-gated Cation Channels

Cyclic GMP-gated cation channels (CNGCs) are nonselective cation channels that belong to the family of cyclic-nucleotide-gated channels. In general, cyclic-nucleotide-gated channels are heterotetrameric complexes consisting of two or three different subunits (α, β, and γ), with important channel properties determined by the subunit composition. Activation of these channels is through direct binding of cyclic nucleotides onto the channel proteins. The CNGCs of rods and cones have structurally similar but distinct α- and β-subunits. Rods contain CNGCα1-subunits that are more sensitive to calcium-induced inhibitions, while cones contain CNGCα3-subunits that are not as sensitive to calcium. In the vertebrate retina, phototransduction is mediated by a G-protein-coupled cascade that results in changes in the gating of CNGCs in the outer segments of rods and cones. Light initiates a fall in intracellular cGMP as the end point of a G-protein-mediated phototransduction cascade, resulting in closure of CNGCs, reduced cation influx, and membrane hyperpolarization. In the dark, the intracellular cGMP concentration is relatively high. This causes tonic activation of these channels and a steady transmembrane influx of sodium (Na^+) and calcium (Ca^{2+}) ions. Therefore, CNGCs carry the photoreceptor dark current and serve essential roles in the light-dependent changes in photoreceptor membrane potential and subsequent neural processing.

In chick cone photoreceptors, the apparent affinity of CNGCs for their activating ligand is under circadian regulation. There is roughly a twofold change in the apparent affinity of CNGCs for cGMP throughout the course of a day, with the affinity substantially higher at night than during the day even in constant darkness. Such changes in channel affinities can be expected to occur especially at the lower range of cGMP concentrations ($\leq$7 μM in the dark) that are within the photoreceptor physiological range. Other biophysical features of the gating of CNGCs, such as unitary conductance, numbers of cGMP-binding sites on the channels, density of channels in the plasma membrane, and the maximum current amplitudes do not vary as a function of the time of day.

The ion channel gating properties of photoreceptor CNGCs can be modulated by multiple processes, including direct phosphorylation or dephosphorylation of the

channel subunits and the binding of Ca^{2+}/calmodulin or related molecules. Dephosphorylation of CNGCs on serine/threonine residues or tyrosine residues causes an increase in the apparent affinity of CNGCs for their activating ligand. Binding of Ca^{2+}/calmodulin or phosphorylation of CNGCs causes these channels to shift to a lower affinity state for cGMP. The clock regulation of cone CNGCs entails a post-translational modification of the channel molecules. More specifically, it is the circadian rhythmicity of tyrosine phosphorylation that underlies the circadian modulation of cone CNGC affinity to its ligand. Inhibition of tyrosine kinases during the day increases the apparent affinity of CNGCs for cGMP, whereas inhibition of tyrosine phosphatases at night produces the opposite effect. While the protein expression and phosphorylation of the channel pore-forming CNGCα3-subunits remain constant throughout the course of the day, tyrosine phosphorylation of an auxiliary subunit (probably the β-subunit, ~85 kDa) displays a circadian rhythm. During the daytime, tyrosine phosphorylation on this 85-kDa protein is twice as high as at night. Therefore, circadian rhythmicity of tyrosine phosphorylation on the 85-kDa auxiliary subunit of cone CNGCs provides one of the final steps in the circadian regulation of CNGCs.

The CNGCs in photoreceptors are essential components of visual phototransduction cascades. As such, it is possible that they also play a role in the light entrainment of the circadian oscillators in photoreceptors. As the gating of CNGCs is under circadian control in cone photoreceptors, these channels represent a potential example of an entity that is both an input to and an output from the circadian oscillator. Roenneberg and Merrow have presented models of circadian oscillator systems in which pathways that lead to entrainment of the core oscillators (i.e., the circadian inputs) can themselves be regulated by the oscillators (i.e., they are also components of circadian outputs). One feature of these models is that they contain additional feedback loops that can markedly enhance the stability of the overall oscillator system. Therefore, the circadian regulation of CNGCs in retinal photoreceptors represents an adaptation to enhance the stability of the circadian oscillators in photoreceptors.

Signaling Pathways Leading to the Circadian Regulation of CNGCs

Even though the connection from the molecular oscillator to the regulation of CNGC affinity rhythm is still not completely understood, the small guanosine triphosphate (GTP)ase Ras and mitogen-activated protein kinase (MAPK) signaling pathway and calcium-calmodulin kinase II (CaMKII) are involved as circadian outputs to regulate CNGC rhythms. The activities of Ras and MAPK are themselves under circadian control and oscillate concurrently with the CNGC affinity rhythm. The activity of CaMKII also displays a circadian rhythm, but it runs antiphase to the MAPK rhythm, and CaMKII is a downstream target of MAPK. Perturbation of the activities of Ras, MAPK, or CaMKII causes phase-dependent changes in the gating properties of CNGCs. Furthermore, this Ras–MAPK–CaMKII pathway serves as part of a common circadian output pathway to regulate other molecules in photoreceptors (see **Figure 1**). However, neither MAPK nor CaMKII directly phosphorylates CNGCs in a circadian fashion. It is their downstream targets leading to tyrosine phosphorylation on the auxiliary subunit of CNGCs that ultimately govern the circadian regulation of CNGC gating properties.

The expression and activation of adenylate cyclase in the retina are under circadian control, and the cyclic adenosine monophosphate (cAMP) content in retinal photoreceptors is maximal at night. In avian retinas, this cAMP rhythm not only drives the rhythm of melatonin synthesis and secretion, but it also serves as part of the circadian output and leads to MAPK activation and modulation of the CNGC affinity rhythm. Besides serving as a circadian output to regulate ion channels, cAMP can stimulate retinomotor movements. In *Xenopus* retina, cAMP signaling resets circadian oscillators within photoreceptors. Hence, the second messenger, cAMP, may well serve as part of both input and output pathways in photoreceptors.

Circadian Phase-Dependent Modulation of Cone CNGCs by Dopamine

While circadian rhythms can occur in retinal photoreceptors cultured in the absence of other functional cell types, multiple cell types contribute to the overall circadian control of the intact retina. In avian retina, melatonin inhibits the release of dopamine from a subpopulation of amacrine cells. Consequently, retinal melatonin and dopamine are in antiphasic circadian cycles. As a result, dopamine functions as a feedback signal from the inner retina that refines and modulates circadian control mechanisms within the photoreceptors. Dopamine evokes a phase-dependent modulation of CNGC affinity rhythm in chick cone photoreceptors that is through the activation of the D2 family of dopamine receptors. Exposure to dopamine or D2 agonists causes a significant decrease in the apparent affinity of CNGCs at night but has no effect on CNGCs during the day. It is well established that D2 receptors are pertussis-toxin-sensitive G-protein-coupled receptors that mediate inhibition of adenylate cyclase and cause a decrease of cAMP formation in the retina. However, the phase-dependent modulation of

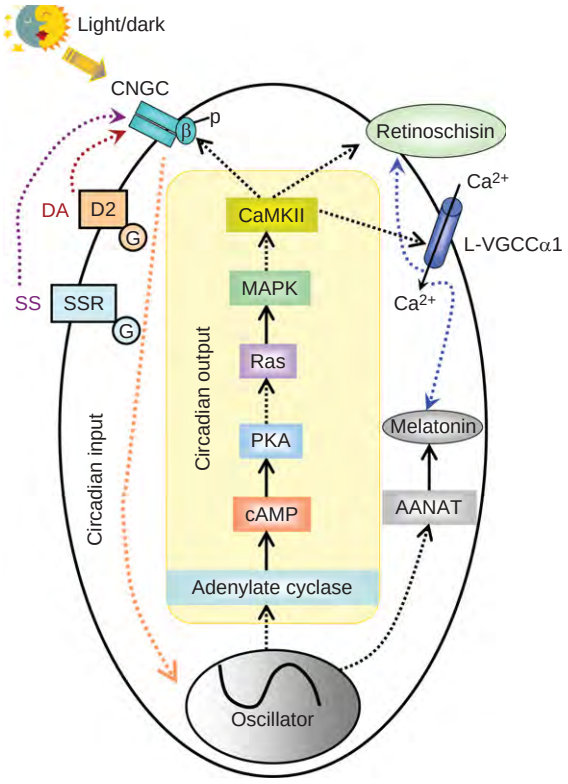

Figure 1 This model illustrates the circadian rhythm in retina cone photoreceptors. Light and dark (day and night) signals from the environment enter the photoreceptor through cGMP-gated cation channels, since cGMP-gated cation channels are essential in phototransduction for light detection. The light/dark signals through the circadian input pathway entrain the photoreceptor core oscillator that cause the photoreceptor to be in sync with the environment. From the core oscillator through the circadian output, the activities of different molecules, including cGMP-gated ion channels, L-type voltage-gated ion channels, and retinoschisin are under circadian regulation. This circadian output is composed of a series of signaling pathways. The circadian regulation of CNGCs in retinal photoreceptors represents an adaptation to enhance the stability of retinal circadian oscillators. It demonstrates a model that Roenneberg and Merrow have presented, in which the elements that lead to entrainment of the core oscillators (e.g., cGMP-gated cation channels) can themselves be regulated by the oscillators. One feature of this model is that it contains additional feedback loops that can markedly enhance the stability of the overall oscillator system at the cellular level (photoreceptors only) and maybe at the retinal network level (the retinal oscillators). The circadian phase-dependent regulation of cGMP-gated cation channels by dopamine and somatostatin is represented by brown and purple dotted arrows, respectively. The black dotted arrows indicate that there are multiple steps currently not known, while the solid arrows represent known signaling. Blue dotted arrows represent that the secretion of melatonin and retinoschisin is under the control of L-type voltage-gated calcium channels. AANAT, arylalkylamine N-acetyltransferase; Ca^{2+}, calcium ion; CaMKII, calcium-calmodulin kinase II; CNGC, cGMP-gated cation channel; DA, dopamine; D2, dopamine D2 receptor; G, G protein; L-VGCCα1, L-type voltage-gated calcium channel α1-subunit; SS, somatostatin; SSR, somatostatin receptor.

CNGCs in cone photoreceptors by dopamine does not involve pertussis-toxin-sensitive G protein or cAMP signaling, since exposure to cAMP or pertussis toxin does not reverse the phase-dependent modulation of dopamine on CNGCs. This circadian modulation of cone CNGCs by dopamine is partially through the MAPK–CaMKII signaling pathway.

Modulation of Cone CNGCs by Somatostatin

Somatostatin is released from a class of amacrine cells that are immunoreactive for enkephalin, neurotensin, and somatostatin, and thus are called ENSLI (enkephalin-, neurotensin-, and somatostatin-like immunoreactive) amacrine cells. There are two forms of somatostatin: somatostatin-14 (SS-14) with 14 amino acids and somatostatin-28 (SS-28) with 28 amino acids, and both forms are released from ENSLI cells. The release of somatostatin from the ENSLI cells is under circadian control, which is high at night and low during the day in mammalian retinas, and this rhythm is concurrent with the activities of these cells with a high sustained rate of activity in the dark and a low sustained rate of activity in the light. The five somatostatin receptors (referred to as Sst1–Sst5) are guanine nucleotide binding protein (G-protein)-coupled receptors. While all five subtypes of somatostatin receptors are expressed in mammalian retina, only Sst2–Sst5 are present in the chick retina. Both SS-14 and SS-28 modulate cone CNGC sensitivity to cGMP that depend on circadian phase and immediate history of illumination. Both SS-14 and SS-28 decrease CNGC sensitivity to cGMP at night, which are similar to the action of dopamine via the D2 receptor and resistant to pertussis toxin. In addition, SS-28, but not SS-14, evokes a transient increase in CNGC affinity to cGMP only during the early part of the day in cone photoreceptors that have been exposed to light for 1–2 h. This transient effect by SS-28 is mediated by pertussis-toxin-sensitive G-protein-coupled receptors and activation of phospholipase C and protein kinase C signaling cascades. Therefore, somatostatin modulation of retinal cones may serve to reinforce circadian processes intrinsic to the photoreceptors, and may also contribute to more rapid adaptive responses to changes in ambient illumination.

Circadian Regulation of L-VGCCs

L-VGCCs mediate a voltage-dependent and depolarization-induced calcium influx and regulate diverse biological processes, such as contraction, secretion, neurotransmission, differentiation, and gene expression in many different cell types. The L-VGCCs are composed of a pore-forming α1-subunit and the auxiliary β-, $\alpha 2\delta$-, and γ-subunits, and

they can be blocked by divalent cations (e.g., cobalt) and organic L-VGCC antagonists, including dihydropyridines, phenylalkylamines, and benzothiazepines. The α1-subunit serves as a voltage sensor to detect voltage changes across the plasma membrane, and it also controls the pore size to allow selective divalent cations to pass through. Mammalian α1-subunits are encoded by at least 10 distinct genes, and α1C, α1D, and α1F (also known as $Ca_v1.2$, $Ca_v1.3$, and $Ca_v1.4$, respectively) are expressed in the retina photoreceptors. Photoreceptors are nonspiking neurons, and they release glutamate continuously in the dark as a result of depolarization-evoked activation of L-VGCCs.

Circadian regulation of L-VGCCs has been observed in goldfish retinal bipolar cells, chick cone photoreceptors, and other nonretinal neurons. In both retinal cases, the average maximum current amplitudes of L-VGCCs are significantly larger at midnight than at midday. The activation voltages that elicit L-VGCC currents (i.e., current–voltage relationship) and the channel gating kinetics do not change throughout the course of a day. In chick retinas, the main factor contributing to the circadian regulation of L-VGCC current amplitudes is the expression of functional L-VGCCα1-subunits, and both messenger RNA (mRNA) levels and protein expression of VGCCα1D are rhythmic. The Ras–MAPK–CaMKII signaling pathway (**Figure 1**) serves as part of the circadian output to regulate L-VGCCs as well as CNGCs as described above. However, the varying maximum amplitudes of the L-VGCC currents is in stark contrast to the CNGC maximum currents, which remain constant throughout the day, and which instead exhibit changes in gating properties.

One major functional significance of the L-VGCC rhythm is the circadian control of melatonin release. In nonmammalian vertebrates, melatonin is synthesized and secreted from retinal photoreceptors and is under circadian control. Inhibition of L-VGCCs with dihydropyridines blocks the synthesis and release of melatonin. Another physiological aspect of the L-VGCC rhythm is the circadian control of retinoschisin secretion. Retinoschisin is a 224-amino-acid protein secreted mainly by retinal photoreceptors and bipolar cells. Retinoschisin is distributed throughout the retina but is mainly concentrated around outer and inner segments of photoreceptors and both retinal plexiform layers. Mutations in the retinoschisin gene (*RS1*) cause X-linked retinoschisis, a retinal dystrophy that features disorganization of retinal cell layers, disruption of the synaptic structures and neurotransmission between photoreceptors and bipolar cells, and progressive degeneration of rod and cone photoreceptor cells. Hence, retinoschisin is believed to play an important role in the development and maintenance of retinal cytoarchitecture. In chick retinas, the mRNA level and protein expression of retinoschisin are under circadian control, and the secretion of retinoschisin is higher at night than during the day. Inhibition of L-VGCCs with dihydropyridines dampens the circadian rhythm of retinoschisin secretion where only nighttime secretion is affected. Therefore, the circadian control of L-VGCCs has a profound impact in regulation of photoreceptor physiology and synaptic transmission.

Circadian Regulation of Other Photoreceptor Ion Channels: Potassium Channels (K^+ Channels)

Potassium (K^+) channels are the most diverse ion channels with more than 100 genes of the pore-forming α-subunits identified to date. They can dampen membrane excitability and set the resting membrane potentials in neurons. According to their genetic homology and functional characteristics, there are four major families of K^+ channels: voltage-gated K^+ channels, Ca^{2+}-activated K^+ channels, inward rectifier K^+ channels, and leak K^+ channels. In photoreceptors, the dark inward current through CNGCs in the outer segment is balanced by a K^+ outward current in the inner segment, and this K^+ outward current is mainly carried out by the voltage-gated K^+ channels. The major subtypes of voltage-gated K^+ channels present in photoreceptors are delayed-rectifier K^+ channels (Kv1.2, 1.3, and 2.1) and A-type transient K^+ channels (Kv4.2). The Ca^{2+}-activated K^+ channels and outward-rectifying noninactivating K^+ channels (Kv10.2; *eag*2) are also found in photoreceptors.

Thus far, the reports on circadian regulation of K^+ channels have been limited to invertebrate studies. In *Aplysia* retinal pacemaker neurons (not photoreceptors), there is a robust circadian rhythm of potassium currents carried by voltage-gated K^+ channels (I_{KV}), while A-type K^+ currents and Ca^{2+}-activated K^+ currents remain constant throughout the day. When I_{KV} peaks during the late night (predawn), the compound action potential firing frequencies reaches its nadir. The circadian rhythm of I_{KV} contributes to the circadian control of the frequency of compound action potentials in pacemaker neurons. The basal retinal neurons in the eye of the mollusk *Bulla gouldiana* express a circadian rhythm in optic nerve impulses. It is the circadian regulation of I_{KV}, but not other outward K^+ channels, that drive the daily fluctuations in membrane conductance and membrane potential of these neurons.

Conclusion

The circadian oscillators in the retina play important roles in the regulation of retinal physiology and function, including sensitivity to light, neurotransmitter release, gene expression, morphological changes at the synaptic terminals, metabolism (as pH changes), and rod–cone dominance. The photoreceptor components of

electroretinograms (ERGs), the electrophysiological recordings of retinal physiology, recorded from humans as well as animals, show daily rhythms. The circadian oscillators in photoreceptors are endogenous, and they can function independently without other retinal inputs. These circadian oscillators regulate retinomotor movement, outer segment disk shedding and membrane renewal, morphological changes at synaptic ribbons, gene expression, a delayed rectifier potassium current, the affinity of cGMP-gated ion channels, the L-type voltage-gated Ca^{2+} channel currents, and the activities of MAPK and CaMKII, among other photoreceptor activities. Photoreceptors are more sensitive to intense light damage during the subjective night than during the subjective day, even in animals that have been maintained in constant darkness for several days after circadian light–dark cycle entrainment. Several retinal degenerative diseases are associated with dampened or abnormal circadian rhythms in ERGs. In the Royal College of Surgeons rats, the first known animal model with inherited retinal degeneration, the diurnal changes in the c-wave of the ERGs are dampened prior to the beginning of retinal degeneration from postnatal day 17 to 24. Mutations in human cone–rod homeobox (CRX) are associated with retinal diseases, including cone–rod dystrophy-2, retinitis pigmentosa, and Leber congenital amaurosis, which all lead to blindness. In a mouse model of CRX mutation, the circadian rhythmicity of the ERG is abolished, and the mutant mice are not able to be entrained by light–dark cycles. The synthesis and release of dopamine from retinal amacrine cells is also under circadian control, and disruption of the circadian rhythmicity of dopamine synthesis causes a glaucoma-like disorder in quails. Fain and Lisman have proposed that circadian oscillators may provide a common pathway mediating several forms of retinal degeneration. Therefore, dysfunctions of circadian oscillators in the retina contribute to some forms of retinal degeneration, which in many instances may lead to blindness.

Circadian Rhythms in the Fly's Visual System

E Pyza, Jagiellonian University, Kraków, Poland

Glossary

Circadian clock – A cell-autonomous, cyclical autoregulatory molecular mechanism, involving genes – clock genes and their proteins that generate circadian molecular oscillations.
Clock genes – The cyclically, with a cycle about a day, expressed genes engaged in molecular mechanism of circadian clock.
Cryptochrome – A blue-light absorbing protein, which contains a flavin-binding domain and functions as a circadian photoreceptor and an element of the molecular clock in the central and peripheral clocks of *Drosophila*, respectively. In the mammalian circadian clock, cryptochromes are the core clock elements.
Electroretinogram – A record of electric activity of cells, measured by inserting an electrode into the eye.
Entrainment – The synchronization of circadian oscillations of the clock to the external daily changes of day and night or to other cyclically changing environmental cues.
Green fluorescent protein (GFP) – A green-light-emitting protein originally found in *Aquorea victoria* and used, after insertion of its gene in transgenic animals, as a reporter of selected proteins and cell types.
Pigment-dispersing hormones – A family of peptides that regulates migration of pigment granules in the crustaceans' eye and in chromatofores of their body surface and also plays the role of neurotransmitters in circadian systems of crustaceans and insects. In insects, these peptides are called pigment-dispersing factors.
Rhabdomere – A light-absorbing part of the compound eye photoreceptor.
Subjective day – A part of the circadian cycle under constant darkness (DD) or in continuous light (LL) in which previously, in the day/night cycle (LD), was the day.
Subjective night – A part of the circadian cycle under constant darkness (DD) or in continuous light (LL) in which previously, in the day/night cycle (LD), was the night.
Zeitgeber time – A time of the 24-h day/night cycle in the environment measured in hours. Usually ZT0 means the beginning of the day.

The Fly's Visual System

The visual system is a major sensory system for flies and includes the large compound eyes, the ocelli – simple eyes located on the vertex of the head and the optic lobes of the brain. The compound eyes are image-forming eyes, while the ocelli play a role in orientation. In addition to the photoreceptors in the compound eyes and ocelli, light stimuli can be received by extraocular photoreceptors and deep brain photoreceptors.

The most external layer of the compound eye is the retina, which overlies three optic neuropils of the optic lobe: lamina, medulla, and lobula (**Figures 1(a)** and **1(b)**). In flies, the lobula is divided into the lobula and the lobula plate. The retina of the compound eye is composed of many single units called ommatidia whose number depends on the size of the eye. In the housefly *Musca domestica*, the compound eye is composed of 3000 ommatidia, while the fruit fly, *Drosophila melanogaster*, has about 800 ommatidia in each eye. Each ommatidium is composed of eight photoreceptors and six of them, R1–R6, terminate in the first optic neuropil or lamina. The other two photoreceptors, R7 and R8, have axons that bypass the lamina and terminate in the medulla. The light-sensitive pigment in the R1–R6 is the blue-sensitive rhodopsin Rh1, while the visual pigments in R7 and R8 are ultraviolet (UV)-sensitive: Rh3, Rh4, or Rh5.

The lamina also has a modular structure and is composed of cylindrical modules called cartridges (**Figures 1(c)**, **1(d)** and **2**). Each cartridge contains 12 cell types and is surrounded by three epithelial glial cells. Elements of the cartridge include the terminals of photoreceptors R1–R6, the axons and dendrites of the lamina monopolar cells L1–L5, amacrine cell processes, processes of cells located in the medulla, and processes of tangential neurons with cell bodies located in other parts of the brain. The structure and synaptic contacts of the medulla have not been as extensively studied as in the lamina; however,

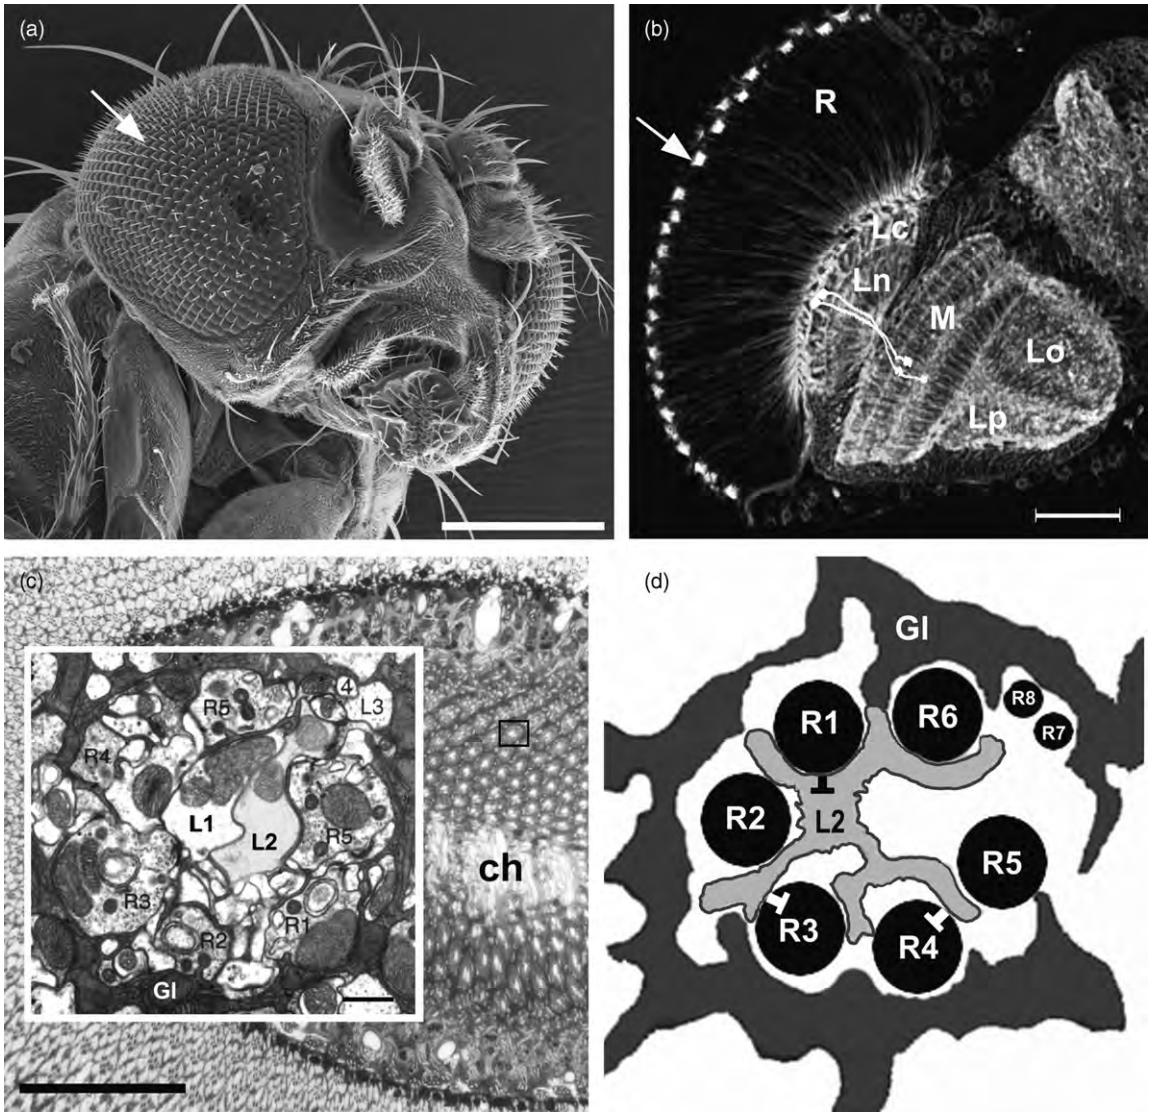

Figure 1 The visual system of *Drosophila melanogaster*. (a) Scanning electron micrograph of the head and compound eye of *Drosophila* viewed from the right side. The fly's compound eye is composed of hexagonally arranged units/facets called ommatidia. Arrow denotes the surface of the compound eye. Scale bar = 200 μm. (b) The structure of the compound eye and optic lobe in horizontal section as revealed by immunostaining with an antibody against α-tubulin. The ommatidial array of photoreceptors in the retina (R) innervates the first of a series of neuropils, the lamina (Ln), where the first-order interneurons, L1 and L2 monopolar cells (marked in white) have their cell bodies and axons. L1 and L2 axons terminate in the second optic neuropil or medulla (M). Lc, lamina cortex; Ln, lamina neuropil; M, medulla; Lo, lobula; Lp, lobula plate. Arrow indicates the surface of the eye. Scale bar = 50 μm. (c) The structure of the lamina in cross section. The lamina is composed of cylindrical modules called cartridges (the region enclosed in a small box), which comprise the same cell types and constitute synaptic units of this neuropil. ch, chiasma. Scale bar = 20 μm. Inset: EM micrograph showing the magnification of a single cartridge with the profiles of L1 and L2 monopolar cells at its axis and the surrounding photoreceptors (R1–R6) and glial cells (Gl). L3: monopolar cell L3; 4: monopolar cell L4. Scale bar = 1 μm. (d) Schematic representation of the lamina cartridge in cross section with the positions of photoreceptors axons (R1–R-8), and the axon of L2 monopolar cell (L2), as well as presynaptic elements (T-bars) of synaptic contacts that are formed between these cell types; tetrad synapses (white T-bars) and feedback synapses (black T-bar). Gl, epithelial glia that surround each cartridge. Reproduced from Pyza, E. and Górska-Andrzejak, J. (2008). the medulla is known to consist of columns each of which contains 35 cells. The lobula and the lobula plate are centers for processing motion information, and they contain, among others, 10 individually identifiable vertical system neurons that respond to visual wide-field motions of arbitrary patterns.

The function of the retina is to receive photic and visual information, transduce this information into receptor

potentials, then transmit the information to the lamina by regulating the release of the neurotransmitter histamine at synaptic contacts called tetrad synapses. At these tetrad synapses, photoreceptors R1–R6 contact two large monopolar cells (LMCs), L1 and L2, the major output neurons of lamellar cartridges, and two other postsynaptic elements which may include processes of amacrine cells, epithelial glial cells, and L3 monopolar cell (**Figure 2**). L2 also forms feedback synapses back onto the photoreceptor terminals.

The Fly's Circadian System

Circadian rhythms are self-sustaining oscillations with a period of about 24 h that are maintained in constant conditions, such as constant darkness (DD). These rhythms are not only entrained to the external day/night cycle primarily by light, but they also can be entrained by other environmental cues. The eyes of flies and of other insect species provide light input to the circadian system which controls circadian rhythms in behavior and in physiological and biochemical processes, including those within the visual system. The circadian system in flies is composed of a central clock (pacemaker) located in the brain as well as peripheral clocks located in many tissues throughout the body. All circadian rhythms in the body are synchronized to each other and maintain the organism's homeostasis in time. As will be described in greater detail below, the circadian system controls structural changes within the lamina of the visual system and the numbers of specific synapse, and these changes are correlated with the animal's locomotor activity rhythm.

In *D. melanogaster*, clock genes are expressed in approximately 100 neurons in the brain belonging to seven groups on each side of the brain: small and large ventral

lateral neurons (s-LN_vs and l-LN_vs), dorsal lateral neurons (LN_ds), lateral posterior neurons (LPNs), and three groups of dorsal neurons (DN_1, DN_2, and DN_3). These cell groups constitute the main circadian pacemaker. Four of five s-LN_vs and four l-LN_vs express the neuropeptide pigment-dispersing factor (PDF), the only output neurotransmitter of the circadian system known so far. Peripheral clocks, distributed throughout the animal, generate circadian rhythms in peripheral organs, including antennae, Malpighian tubules, testes, and the retina photoreceptor cells. In contrast to the pacemaker neurons, in which the circadian oscillations of clock gene expression are self-sustained for many days in DD, oscillations in the peripheral clocks decline after several cycles in DD. Thus, the molecular mechanisms underlying central and peripheral clocks may be different.

Circadian clocks are cell autonomous, and a cell is said to contain a circadian clock if it expresses clock genes, those that show circadian expression and control the expression of a large population of other genes (so-called clock-controlled genes). In clock cells, clock genes and their proteins form transcriptional/translational negative- and positive-feedback loops that are the molecular basis of circadian clocks. Much of our understanding of molecular clocks comes from studies of *D. melanogaster*, and our ideas about how these molecular clocks are regulated and entrained continue to be refined. A basic model is presented below and in **Figure 3**.

In central pacemaker clock cells, two cyclically expressed core clock genes are *period* (*per*) and *timeless* (*tim*). When their proteins PERIOD (PER) and TIMELESS (TIM) accumulate in cytoplasm, they form heterodimers and enter the nucleus. In the nucleus, they bind to heterodimers of the transcription factors CLOCK(CLK)/CYCLE(CYC) encoded by *Clock* (*Clk*) and *cycle* (*cyc*) genes, respectively, and PER, and possibly TIM, repress their own transcription. This is the negative-feedback loop of the molecular clock. CLK/CYC also control the cyclical expression of two other core clock genes, *vrille* (*vri*) and *Par domain protein* 1ε (*Pdp*1ε) and their protein products, VRI and Pdp1ε, respectively, regulate the transcription of *clk*. VRI represses the transcription of *Clk* while Pdp1ε enhances it. The increase in *clk* transcription is a positive-feedback loop of the molecular clock. The level of PER and the transition of PER and TIM from the cytoplasm to the nucleus is controlled by phosphorylation so that the transcriptional feedback occurs at a particular time of the day.

Light entrainment of the molecular clock in central pacemaker neurons depends on an intracellular blue-light-photosensitive protein CRYPTOCHROME (CRY). CRY is involved in the light-dependent degradation of TIM. When the light is on, TIM does not accumulate in the cytoplasm, the negative-feedback loop that represses *per* and *tim* transcription is delayed and, as a result, the phase of the clock will be delayed. However, if TIM is degraded, while it is in the nucleus, the repression of CLK/CYC will be removed early, the transcription of *per* and *tim* will be advanced and the phase of the clock will be advanced.

The molecular mechanism in the peripheral clocks is also based on *per* and *tim* cyclical expression; however, in peripheral clocks, CRY may be a central element of the molecular mechanism in addition to its role as a circadian photoreceptor involved in the light entrainment of the molecular clock. It has been suggested that in peripheral clocks of *D. melanogaster*, CRY is a transcriptional repressor playing a role similar to that of CRY proteins (mCRY1 and mCRY2) in mammalian molecular clocks.

Similar circadian systems – consisting of many circadian clocks that are based on a transcriptional/translational feedback loop model – are probably present in other insect species. However, some aspects of the molecular mechanism of the clock may differ in even closely related dipteran species. For example, in *Lucilia cuprina*, the PER expression pattern is similar to that of *D. melanogaster*, but in the housefly, *M. domestica*, PER isolated from the whole head does not cycle.

As was described above, light is the major environmental cue that entrains the central pacemaker to the day/night cycle. The light input to the central pacemaker is complex, and the fly's compound eyes are not the only source. Ocelli photoreceptors, the extraocular photoreceptors known as the Hofbauer–Buchner (H–B) eyelet, and the intracellular blue-light-photosensitive protein CRYPTOCHROME (CRY), which is present in most cells harboring molecular circadian clocks, also provide light input. The H–B eyelet consists of four photoreceptors located between the retina and medulla. These photoreceptors contact the small LN_vs pacemaker neurons and synchronize the molecular rhythms in these neurons. The small LN_vs, in turn, synchronize the animal's behavioral rhythms by the rhythmic release of PDF. Since the pacemaker comprises several groups of neurons, each group may be important for producing circadian rhythms in different cells, tissues, and systems, and receive light inputs from different photoreceptors.

The visual system receives circadian input from pacemakers; however, it is still unknown which group or groups of pacemaker neurons send the circadian input to the visual system. In addition, the visual system possesses peripheral clocks in the retina photoreceptor cells.

Circadian Rhythms in the Retina of the Compound Eye

Most arthropods, including insects, show daily changes in the structure of photoreceptors manifested by changes in the size of the rhabdomere, the photosensitive part of photoreceptors. Moreover, daily changes in screening pigment movements have been documented in many

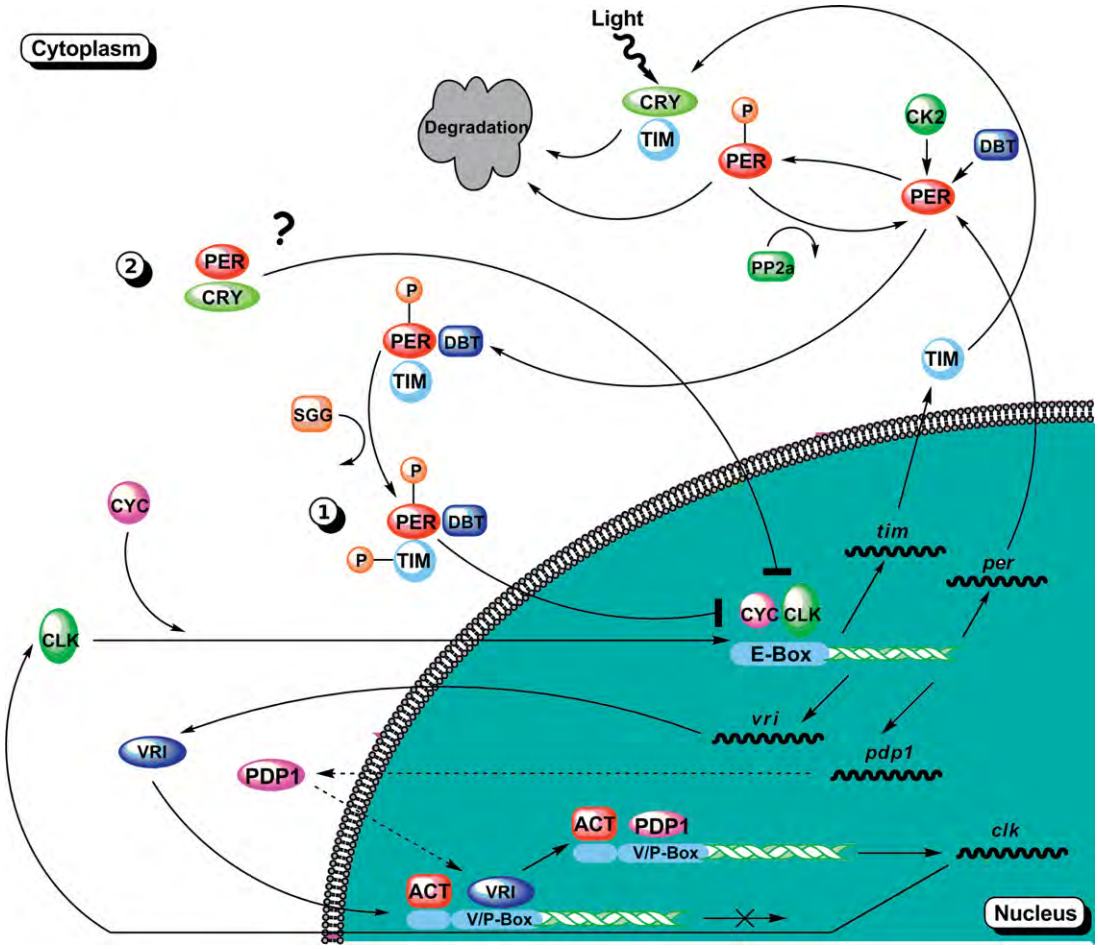

Figure 3 Molecular mechanisms of circadian clocks in *Drosophila*. 1. Current model of the circadian clock operating in the pacemaker neurons in the brain. In this model *period* (*per*) and *timeless* (*tim*) clock genes are cyclically expressed at the end of day and at the beginning of night. Later during the night, PER and TIM proteins accumulate in the cytoplasm and PER is phosphorylated by DOUBLETIME (DBT) and possibly by casein kinase CK2. The phosphorylation leads to PER degradation if TIM does not bind to PER forming PER/TIM heterodimers. PER is also stabilized by PP2a, which dephosphorylates PER. In the heterodimers PER/TIM, TIM is phosphorylated by SHAGGY (SGG) and PER is bound to DBT which enables PER and TIM to be transported to the nucleus. In the nucleus, PER and, possibly, also TIM inhibit transcription factors CYCLE (CYC) and CLOCK (CLK), which as heterodimers repress transcription of *per* and *tim*. Repression of *per* and *tim* transcription by their own proteins constitutes a negative-feedback loop of the molecular clock. CYC/CLK heterodimers also control cyclical expression of *vrille* (*vri*) and *pdp*1ε which proteins affect transcription of *clk* by competing for binding to *clk* promotor. PDP1ε stimulates, while VRI inhibits *clk* expression. The increase in *clk* transcription is a positive loop of the molecular clock. Transcription of *clk* can also be activated by a clock-independent activator, ACT. In this model, CRYPTOCHROM (CRY) protein is a clock photoreceptor. During the day, CRY is activated by light and binds TIM leading to TIM degradation. After TIM degradation PER cannot form heterodimers with TIM in the cytoplasm and be transported to the nucleus. In result, the clock is delayed in phase. When light stimulates the degradation of TIM while TIM is in the nucleus, the repression of *per* and *tim* transcription by PER/TIM is removed and the molecular clock advances in phase. 2. A possible mechanism of circadian clock functioning in peripheral clocks and in a clock controlling circadian rhythms in the visual system. In this model, PER forms heterodimers with CRY which are transported to the nucleus where CRY represses the transcription of *per* and *tim*.

insect and crustaceans species. The most pronounced structural changes in photoreceptors, regulated by a circadian clock, have been described in the horseshoe crab *Limulus polyphemus*. In contrast to crustaceans, locusts, praying mantis, and mosquitoes, the cross-sectional area of rhabdomeres in the retina photoreceptors of flies shows no (*L. cuprina*) or only little (*D. melanogaster*) change during the day and night cycle.

However, in many species, including flies, diurnal rhythms have been detected in the amplitude of the electrical activity of the eye recorded with the electroretinogram (ERG). The ERG originates from both the retina and the lamina L1 and L2 monopolar cells and measures changes in eye sensitivity. In *D. melanogaster*, cyclical changes are observed in both the amplitude of the ERG and the level of visual pigment in photoreceptors as measured by microspectrophotometry. When *D. melanogaster* is maintained under normal LD conditions, the ERG-measured sensitivity and the concentration of visual pigment in photoreceptors are highest during the night. Then about 8 h before

lights-on, the sensitivity begins to decline and, about 2 h after lights-on, the level of visual pigment in the eye starts to decrease. The sensitivity and the level of visual pigment continue to decrease until 4 h after the onset of the light. In white-eye *D. melanogaster* mutants, the level of visual pigment recovers 2–4 h later. The observations that changes in ERG sensitivity and visual pigment levels anticipate changes in illumination, and that these cyclic changes are maintained in DD conditions indicate both processes are under circadian control.

In the blowfly *Calliphora vicina*, a diurnal insect, three ERG components have been studied under LD and DD conditions; one component called the sustained negative potential originates at least partly from the retina photoreceptors, and two others, ON and OFF transients, originate from the lamina monopolar cells. The lamina transients exhibit circadian oscillations and increase during the subjective night in DD. The negative potential that originates from the retina changes in antiphase with the transients and becomes smaller during the subjective night, indicating that the retina and the lamina components of ERG seem to be regulated by two different circadian clocks. In the cockroach *Leucophaea maderae*, a nocturnal insect, the opposite changes to those recorded in the blowfly have been observed, and the negative potential of ERG in this species exhibits the highest amplitude during the subjective night. The changes in the ERG observed in these two different species indicate that the photoreceptor activity is correlated with the animal's pattern of locomotor activity. This activity is higher during the day than at night in diurnal insects and higher at night in nocturnal insects.

In addition to regulating the content of visual pigment in insect photoreceptors, circadian clocks may regulate phototransduction by controlling the expression of some genes such as the one that encodes a transient receptor potential channel involved in this process.

Much evidence indicates that retinal photoreceptors are themselves peripheral clocks. They show daily changes in the abundance of the clock protein PER that are maintained in DD conditions and they express other clock genes, including *cry*. As in the pacemaker neurons in the brain, the abundance of PER in the photoreceptors is highest at the end of the night. In photoreceptors, however, PER decays faster during the day than in the *per*-expressing neurons in the brain. The rhythmic changes in PER immunostaining in the photoreceptors are also affected by *per* mutations. For example, in flies expressing the per^{s} mutation, in which the period of circadian locomotor activity is shorter (19 h) than 24 h, PER in photoreceptors appears earlier than in wild-type flies. Evidence that the circadian clocks in retinal photoreceptors are cell autonomous comes from experiments that used transgenic *D. melanogaster* in which PER was expressed only in photoreceptors. In these animals, cyclic PER expression was observed in photoreceptors in DD condition, even though no PER expression was detected elsewhere in the animal and the animals were otherwise arrhythmic. Although the retinal photoreceptors possess autonomous circadian clocks, it is unknown to what extent these clocks control the rhythms observed in photoreceptors. Again, it is unknown if the clocks in the fly's retina impact the rhythms in cells that are postsynaptic to the photoreceptors.

Circadian Rhythms in the First Visual Neuropil (Lamina)

Although structural changes in the photoreceptor cell bodies of flies are not dramatic, striking circadian rhythms have been detected in the lamina of the fly's visual system. Here, the number of synaptic contacts, the morphology of two visual interneurons, and the number of some organelles in the photoreceptor terminals change during the LD and DD conditions. These rhythms are examples of plasticity in the nervous system regulated by a circadian clock, and they may serve to gate the flow of information through the visual system to correlate with the animal's locomotor activity.

Since clock gene expression has not been detected in the lamina neurons, circadian rhythms observed in the lamina must be driven by circadian pacemaker neurons located in the brain and/or clocks present in the retina photoreceptors. These rhythms may also be maintained by clock-gene-expressing glial cells distributed between neurons and other glial cells in the optic neuropils.

Circadian Plasticity of Synaptic Contacts

In the lamina of the housefly *M. domestica*, cyclic changes have been found in the frequency of two types of synaptic contacts: tetrad presynaptic profiles or the so-called T-bars, and feedback synapses (**Figure 1(d)**). In the housefly, which is a diurnal species, the number of tetrad presynaptic profiles is highest at the beginning of the day when the flies also show the highest locomotor activity. In contrast to the tetrads, the number of feedback synapses peak at the beginning of the night. The oscillations in the number of feedback synapses are maintained in DD and are not affected by light. Therefore, they are clearly controlled by circadian clocks. By contrast, the number of tetrad synapses does not significantly change in DD, but increases after a 1-h light pulse presented during the subjective day or subjective night in DD. This could be interpreted to mean that the number of tetrad synapses is controlled by light, not by circadian clocks. However, studies with *D. melanogaster* suggest that circadian clocks are important regulators of the number of tetrad synapses.

In *D. melanogaster*, daily oscillations have been found in the abundance of a scaffolding protein of the T-bar ribbon in presynaptic tetrad synapses, the BRP protein encoded by the *Bruchpilot* gene (**Figure 2**). As in the housefly, the number of presynaptic sites immunoreactive to BRP and the abundance of the protein in the lamina are highest at the beginning of the day. This rhythm was not detected in DD, but it was also absent in cyclic light in the arrhythmic *per* null mutant. Taken together, these observations indicate that although the daily rhythm in the formation of T-bar presynaptic tetrads depends on light, signals from circadian clocks are also required.

Circadian Plasticity of Second-Order Neurons and Glial Cells

The daily oscillations in the frequency of photoreceptor tetrad synapses are correlated with morphological changes in the L1 and L2 monopolar cells of the lamina. In the housefly, both cells swell at the beginning of the day and shrink during the night, and this rhythm is maintained in DD and also in LL, a condition that disrupts circadian rhythms in behavior, causing animals to become arrhythmic. Examination of the morphology of the entire L2 cells in transgenic *D. melanogaster*, in which green fluorescent protein (GFP) was expressed specifically in L2 cells (**Figures 2(b) and 2(e)**), has shown that circadian changes occur in the girth of axons and in the length of dendrites extending from these axons (**Figure 4**). The daily pattern of morphological changes of the L2 is slightly different in males than in females. Circadian changes also occur in the size of L2 nuclei but not in their cell bodies (**Figure 4**).

Changes in the size of monopolar cell axons are correlated with the pattern of the locomotor activity of fly species. In typically diurnal species such as *M. domestica* and *C. vicina*, L1 and L2 monopolar cell axons are largest at the beginning of the day when flies show highest locomotor activity. The sizes of these axons can be further increased, by 20–30%, when insects are additionally stimulated to fly intensively. In *D. melanogaster* the daily pattern of changes in sizes of L1 and L2 axons is different. Under LD, *D. melanogaster* has two peaks in locomotor activity, one in the morning and a second one in the evening, and in this species, the L1 and L2 cell axons enlarge twice during the day, in the morning and in the evening. Changes in size of L1 and L2 monopolar cell axons are offset by changes in size of the surrounding epithelial glial cells, which shrink during the day and swell during the night. Changes in the girth of L1 and L2 interneuron axons seem to be correlated with the perimeter of their dendritic trees. Studies of transgenic

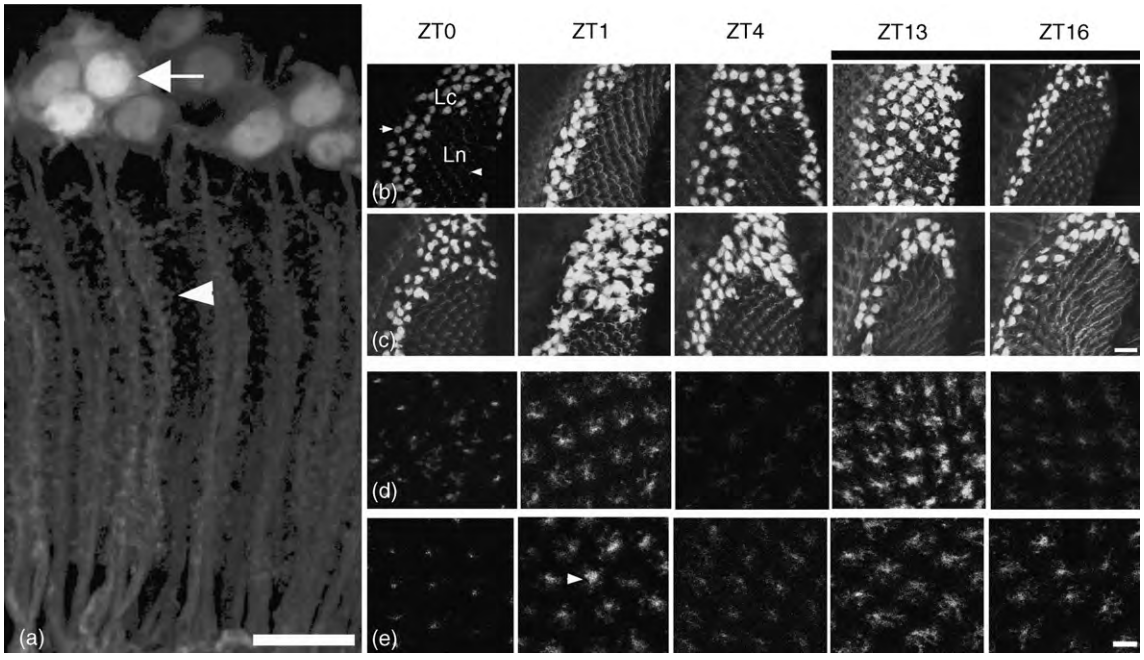

Figure 4 Daily changes in morphology of L2 monopolar cell in the lamina of transgenic *D. melanogaster* expressing GFP in the L2 cells (21D-GAL4/UAS-S65T-GFP). (a) Confocal image showing the structure of L2 monopolar cells in the lamina. GFP expression labels nuclei of the somata (arrow) in the lamina cortex, as well as axons and dendrites (arrowhead) in the neuropil. Scale bar = 10 μm. (b, c) Daily changes (ZT0-ZT16, ZT0: the beginning of the day. ZT 13: the beginning of the night, dark bar) in the size of L2 cell nuclei in males (b) and females (c). The cross-sectional area of the nuclei appears to be largest 1 h after lights-on (ZT1, females) and 4 h after lights-on (ZT4, males) and smallest in the middle of the night (ZT16, females and males). Scale bar = 20 μm. (d, e) Differences in morphology of the dendritic tree of L2 in males (d) and females (e). The cross-sectional area of L2 monopolar cell axons is larger at ZT1 and ZT13 than in other time points in both males and females. Scale bar = 5 μm. Reproduced from Pyza, E. and Górska-Andrzejak, J. (2008). External and internal inputs affecting plasticity of dendrites and axons of the fly's neurons. *Acta Neurobiologiae Experimentalis* 68: 322–333.

D. melanogaster, in which GFP is expressed specifically in L2 monopolar cells, revealed that the L2 dendrites postsynaptic to tetrad synapses are longest at the beginning of the day. This rhythm is absent in arrhythmic *per* null mutant flies (per^0), and its pattern is changed from wild-type in mutant flies harboring a mutation in the CRY protein (cry^b). These findings indicate that circadian plasticity of the L2 cells depends on cyclical expression of *per* and involves *cry* in maintaining the phase of the rhythm.

In contrast to L1 and L2 monopolar cells, photoreceptor terminals in the lamina do not change their girth. It is unknown, however, if other monopolar cells in the lamina show similar morphological circadian changes.

Circadian Rhythms in Organelles inside Photoreceptor Terminals

Although photoreceptor terminals in the lamina do not show circadian changes in their size, circadian structural changes have been detected in some organelles inside the terminals. For example, in the housefly, there is a vertical migration of pigment granules into and out of photoreceptor terminals. Radial movements of screening pigment within the cell bodies of photoreceptors R1–R6 are well documented. These movements are driven by light. Pigment granules move horizontally toward the rhabdomeres during light adaptation and away from the rhabdomeres during dark adaptation providing an important pupillary mechanism. However, the vertical migration of pigment granules in the housefly photoreceptors appears regulated by a circadian clock. Fewer pigment granules are present in photoreceptor terminals during the day compared to the night. This rhythm is maintained in DD, thereby indicating its endogenous, circadian regulation. These vertical movements of pigment granules may play a role in light adaptation providing more pigment granules to the photoreceptor cell bodies during the day.

Other organelles in the housefly photoreceptor cell terminals are formed from the invaginations of neighboring cells in the lamina: from other photoreceptor terminals and glial cells. Among these two types of invaginations, only the number of inter-receptor invaginations changes during the subjective day and subjective night in DD, and the number is greatest at the end of the subjective night. These organelles are rare in the photoreceptor terminals in flies reared in LD conditions, but increase in dark-reared flies. Their functions remain to be discovered.

Neurotransmitter Regulation of Circadian Rhythms in the Visual System

The lamina is invaded by several sets of wide-field tangential neurons with processes directed at right angles to the lamellar cartridges; thus, they are appropriately suited for the global regulation of visual processing. In the housefly's lamina, the most numerous of these processes are immunoreactive for serotonin (5-hydroxytryptamine, 5-HT). They originate from two giant ventral protocerebral neurons called LBO5-HT that project ipsi- and contralaterally to the optic lobes. Another group of processes is immunoreactive for PDF and originates from the LNvs. Still other processes are immunoreactive for the neuropeptide Phe-Met-Arg-Phe-NH_2 (FMRFamide). The neurotransmitter chemistry of remaining processes remains to be identified.

Processes of LBO5-HT neurons are also present in the lamina of *D. melanogaster*, but in this species, processes of other wide-field neurons, including PDH-immunoreactive processes, arborize in the distal medulla and only a few reach the lamina. Since the paracrine release of both biogenic amines and neuropeptides has been reported, neuromodulators released in the medulla may reach targets in the lamina of the fruit fly through volume transmission.

Among neurotransmitters detected in the lamina and the medulla, 5-HT has been found to influence both photoreceptors and L1 and L2 monopolar cells. 5HT modulates potassium channels in the photoreceptors of *D. melanogaster*, and in photoreceptors of locust, a diurnal modulation of potassium channel function can be mimicked by application of 5-HT. In the lamina of the housefly, 5-HT has robust effects on the structure of L1 and L2 cells, but the effects are not the same on both cells. Injections of 5-HT into the housefly's medulla increase the diameter of L1 but not L2 monopolar cell axons. However, when 5-HT and other biogenic amines are depleted from the lamina by injecting the drug reserpine, there is a decrease in the girth of the L2 axon but not in the axon of the L1 cell. This suggests that 5-HT influences the diameter of both L1 and L2 axons, but that the effects observed depend on its concentration.

Injections of other neurotransmitters into the medulla also affect L1 and L2 axon sizes, but their effects are less significant than that of 5-HT. PDF injections induce a small increase of both cells, while FMRFamide had the opposite effect. PDF applications also have an effect on the screening pigment granules in the photoreceptor terminals. Injections of histamine, a neurotransmitter released from photoreceptor terminals, increase the size of L1 but not L2 processes, while injections of either glutamate or gamma aminobutyric acid (GABA) decrease L1 and L2 axons. The effects of glutamate and GABA mimic the changes in L1 and L2 processes seen during the night under LD conditions and during the subjective night in flies held in constant darkness. Glutamate is a transmitter candidate for the L1 and L2 cells and amacrine cells of the lamina, and GABA is detected in cells that project from the medulla into the lamina. GABA injections also decreased the number of feedback synapses from L2 onto photoreceptors.

Larval Visual System

Circadian rhythms in the visual system exist not only in adult flies but also in larvae. The larval visual system, Bolwig's organ (BO) is located on both sides of the head and consists of 12 photoreceptors expressing either Rh-5 or Rh-6. All these photoreceptors project to the LNs of the larval circadian system, which includes four neurons on each side of the fruit fly's larval brain. The BO photoreceptors do not express clock genes, so they are not circadian oscillators like the retina photoreceptors; instead, the BO photoreceptors receive circadian information from the LNs as do other target neurons. The circadian input from the LNs seems to control sensitivity of the larval visual system since the *per* and *tim* null mutants are relatively insensitive to light, while mutations in the positive clock elements, *Clk* and *cyc*, increase the light sensitivity of larvae. In *D. melanogaster* larvae, the circadian clock regulates the light-avoidance behavior and visual sensitivity. Both are high at the end of the subjective night and low at the end of subjective day in DD conditions.

The BO photoreceptors survive metamorphosis, and in the adult fly, Rh6-expressing photoreceptors correspond to the extraocular photoreceptors of the H–B eyelet. In larvae and in adults these structures play an active, if subsidiary, role in the entrainment of circadian rhythms. In larvae, light is transmitted from the BO to the LNs where light-induced degradation of TIM is essential for the larval circadian clock entrainment. Moreover, when BO is eliminated, the LN dendrite structure is altered indicating direct interactions between the larval visual system and the larval circadian system. The larval optic nerve is also required for the development of a serotonergic arborization originating in the central brain and for the development of the dendritic tree of the circadian pacemaker neurons – the small LN_vs. The larval optic nerve and adult extraocular photoreceptors sequentially associate with the small LN_vs during *D. melanogaster* brain development.

Circadian Circuits in the Fly's Visual System

In flies, circadian rhythms in the visual system are correlated to the circadian rhythm in locomotor activity. This indicates that circadian oscillators, both central and peripheral, must communicate with each other, but the underlying circuitry is largely unknown. The circadian rhythms in the retina seem to depend mostly on the peripheral clocks inside the photoreceptors, although pacemaker neurons could impact rhythms in the retina by controlling the number of feedback synapses from L2 onto photoreceptor terminals. As it was described above, these synapses show robust circadian changes. However, it is unclear if the rhythms in the lamina, and probably in the other optic neuropils, are regulated only by the LNs or by both the photoreceptor's clocks and the LNs. It is also unknown if the dorsal neurons, DN_1–DN_3, have any effects on the circadian rhythms in the visual system.

In the housefly, severing the optic lobe from the rest of the brain abolishes circadian changes in the sizes of the L1 and L2 monopolar cell axons. This suggests that circadian information is transmitted to lamina monopolar cells from central pacemaker neurons by neurotransmitters. So far, the only neurotransmitter identified in the pacemaker neurons is PDF, which is present in the LNvs of *D. melanogaster* and in a similar set of neurons in *M. domestica*. In the housefly, this peptide is cyclically released from PDF varicosities in a paracrine fashion. In this species, the circadian changes of PDF varicosity sizes have been observed in LD and DD, and the daily release of PDF from the dense-core vesicles of PDF-immunoreactive processes have been detected. If PDF, which has been detected in dense arborizations in the medulla of all fly species studied and clearly in the lamina of larger flies, transmits circadian information from the LNvs, then PDF receptors should be present in neurons in this part of the visual system. However, PDF receptors have not been detected in the distal part of the medulla or in the lamina, but in the proximal medulla and in the lobula. In *D. melanogaster*, however, the processes of PDF-immunoreactive l-LN_vs terminate in the distal medulla next to *per*-expressing glial cells, which may intermediate between the pacemaker neurons and neurons in the lamina cartridges showing circadian plasticity. Thus, glial cells in the optic lobe might be the third player in the regulation of circadian rhythms in the visual system. In the lamina, the epithelial glial cells change their sizes, decreasing during the day and increasing during the night, completely opposite to the neurons. Disrupting glial metabolism and closing gap-junction channels in the lamina have an effect on L1 and L2 monopolar cell sizes and their circadian morphological plasticity.

The Role of Circadian Clocks in the Visual System

The autonomous circadian oscillators located in retina photoreceptors, and clocks in the pacemaker neurons and in glial cells of the optic lobe, provide a circadian gating of visual information. This gating changes during the day and night and differs between diurnal and nocturnal animals. The activity of the visual system is the highest during the day in diurnal species and during the night in nocturnal species. Furthermore, this pattern correlates with the pattern of locomotor activity in each species. Because of the circadian gating of visual information, light stimuli received during the night in diurnal species

do not disrupt its daily rhythm of activity and the daily pattern of animal behavior, but light stimuli can shift the phase of these rhythms. On the other hand, stressful conditions in the environment and a temporary increase in locomotor activity can result in an increase of the flow of information through the visual system, but only when this stimulation is correlated with the active period of the daily rest (sleep)/activity rhythm. Locomotor stimulation, however, may also shift the phase of the rhythm.

In addition to the gating visual information, the circadian system allows an organism to predict daily changes in the environment, and to prepare the visual and other sensory systems for a proper reception of sensory stimuli and efficient transmission of sensory information. The circadian clocks in the photoreceptors control the reception of light stimuli, while the transmission of sensory information is controlled by clocks in several types of cells, including the retina photoreceptors, the pacemaker neurons, and glial cells. These properties of the circadian and visual systems are typical not only for flies but also for other animals.

Color Blindness: Acquired

D M Tait and J Carroll, Medical College of Wisconsin, Milwaukee, WI, USA

Glossary

Blue–yellow (tritan) defect – A color-vision deficiency in which colors along the blue–yellow axis are difficult to distinguish from one another and sensitivity to blue light is decreased. This is typically caused by a defect in the short-wavelength-sensitive cone photoreceptor pathway. The word tritanopia derives from the Greek *tritos*, meaning third, alluding to the defect being associated with the third of the three primary colors (blue) + *anopia*, meaning blindness.

Deuteranopia – A type of red–green defect in which the middle-wavelength-sensitive photopigment is nonfunctional, leading to decreased hue discrimination and a tendency to confuse reds and greens. Derives from the Greek *deuteros*, meaning second, alluding to the defect being associated with the second of the three primary colors (green) and *anopia*, meaning blindness.

Monochromacy – A complete lack of ability to distinguish colors.

Photopigment – A light-sensitive protein in the photoreceptors (rods and cones) that undergoes a conformational change when absorbing light and initiates the process of visual transduction.

Protanopia – A type of red–green defect in which the long-wavelength-sensitive photopigment is nonfunctional, leading to a loss of sensitivity to red light and a tendency to confuse reds and greens. Derives from the Greek *protos*, meaning first, alluding to the defect being associated with the first of the three primary colors (red) and *anopia*, meaning blindness.

Trichromacy – The fundamental ability to see in full color, based on the possession of three types of cone photoreceptor. The formal proposal of this theory to explain human color vision is credited to Thomas Young.

Introduction

"He *knew* the colors of everything, with an extraordinary exactness (he could give not only the names but the numbers of colors as these were listed in a Pantone chart of hues he had used for many years). He could identify the green of Van Gogh's billiard table in this way unhesitatingly. He knew all the colors in his favorite paintings, but could no longer see them, either when he looked or in his mind's eye. Perhaps he knew them, now, only by verbal memory." Oliver W. Sacks describes the 'Case of the colorblind painter' in his book *An Anthropologist on Mars* where after a car accident a painter tragically lost all ability to experience color.

While many color-vision deficiencies are inherited and present from birth (congenital), they may also be acquired, as in the case of the colorblind painter described above. Acquired defects, as the name implies, indicate a disruption in color discrimination as a consequence of a traumatic event, such as exposure to toxins, a cortical injury, or the defect may accompany an ocular disease. In most cases, the color-vision defect can be thought of as secondary because the causative event often has more serious consequences for the individual.

Classifying Acquired Color Blindness

Normal color vision relies on the presence of three spectrally distinct cone photoreceptor types in the retina, where the spectral sensitivity of the cone cell is determined by the photopigment it contains (short-, middle-, or long-wavelength sensitive; S, M, or L, respectively). Inherited disruptions in color discrimination are normally classified according to which of the cone photopigment classes is functionally disrupted or absent altogether. A defect in the S photopigment produces a tritan defect, corresponding to a loss along the blue–yellow axis, whereas defects in the M and L pigments produce a deutan or protan defect, respectively, though both correspond to a loss along the red–green axis of color vision. Consequently, in inherited defects there is a 1:1 relationship between the affected cone type and the perceptual deficit. However, acquired defects are far more complex and thus must be categorized not by the type of photoreceptor affected, but rather as a variable loss along a particular color axis: blue–yellow axis, red–green axis, or a nonspecific loss of color vision. The dimensionality of these losses can be appreciated by looking at **Figure 1** which illustrates the red–green and blue–yellow axes of color vision.

In addition to classifying the perceptual problems associated with acquired defects, they can be categorized based on the mechanism of the defect: absorption, alteration, and reduction. Absorption defects affect the absorption of a

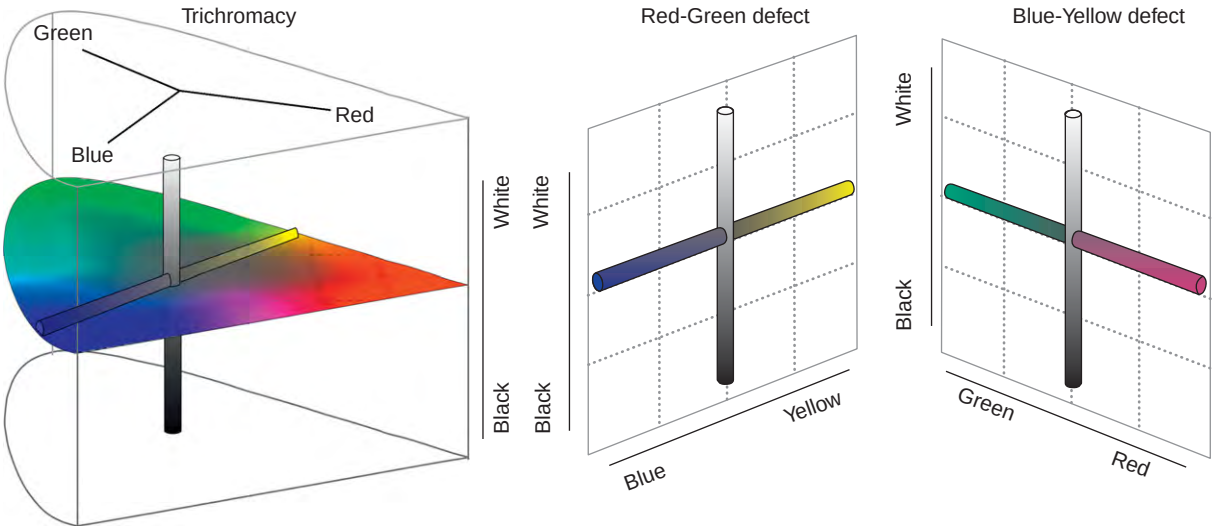

Figure 1 The geometric reduction of color discrimination that accompanies color-vision defects. Possession of three types of cone photopigment makes trichromatic color vision possible. In this case, there is good color discrimination along three distinct axes (black–white, red–green, and blue–yellow) and each discriminable hue (of which there are over 2 million) has a unique combination of activity along each of these axes (left). Acquired color-vision defects can typically be characterized by a loss along the blue–yellow or red–green axis. In red–green defects (middle), color vision is reduced to only the black–white and blue–yellow axes, reducing the dimensionality of color vision (c. 10 000 discriminable hues). Blue–yellow defects (right) show the same reduction in dimensionality. However, the residual color discrimination exists along the red–green and black–white axes. Modified from Neitz, J., Carroll, J., and Neitz, M. (2001). Color vision: Almost reason enough for having eyes. *Optics and Photonics News*, January 2001, pp. 26–33.

particular hue due to deposits affecting the lens or cornea. For example, the normal aging process introduces a yellowing of the lens of the eye, causing a selective absorption defect in discrimination in the blue–yellow axis of color vision. An alteration defect is one that shifts normal color perception and normally reflects a destruction of the macular cones. A reduction defect occurs typically as a result of diseases of the optic nerve and causes perceptive reduction of saturation within colors along the red–green axis as well as a more mild blue–yellow reduction.

Discriminating Acquired from Inherited Color Blindness

There are a number of key differences between inherited and acquired defects. Acquired defects are often difficult to classify because combined, and sometimes subtle, defects often occur. While congenital color-vision deficiencies are typically stable throughout life and both eyes are equally affected, acquired deficits may change in severity over time, and they are more likely to be asymmetric. Furthermore, acquired defects are predominantly tritan, have an equal incidence in males and females, and are typically accompanied by a reduction in visual acuity. Erroneously, color-vision defects are often thought of as being exclusively inherited. However, acquired defects are even more common, with 5% of the population being affected. Table 1 provides a complete comparison of acquired and inherited defects.

Table 1 General differences between acquired and inherited color-vision defects

Acquired color-vision defects	*Inherited color-vision defects*
Acquired after birth	Present at birth
May progress with age	Stable throughout life span
Combined defects may occur making diagnosis difficult	Precise diagnosis of a given type (protan, deutan, tritan)
Monocular deficiencies can occur	Both eyes are equally affected
Visual acuity is often reduced	Visual acuity is unaffected (except in achromatopsia and blue-cone monochromacy)
Predominantly tritan deficiencies	Predominantly red–green deficiencies
Equal incidence in males and females	Higher incidence in males
Frequency (1 in 20 individuals)	Frequency (1 in 12 males affected with red–green defect)

Clinically, there are a number of tests used to diagnose color-vision defects (acquired or inherited). While genetic tests are obviously the definitive approach for characterizing inherited disorders, the diagnosis of acquired color-vision defects relies on the patients' performance on psychophysical tests of color vision. Perhaps the most

widely used are pseudoisochromatic plate tests. These plates contain a field of dots that vary in luminance, and embedded within the dots is a number or other shapes differing in chromaticity from the background. For normal trichromats, this shape will be distinguishable from the background. However, depending on the design of the plate, the shape may blend into the background or a different shape may appear altogether for the color-deficient observer. Different plates are used to test for defects along the primary color axes (red–green and blue–yellow). Another type of test is an arrangement test in which the patient orders materials in a specific hue or saturation order. The stimulus is prearranged in a random order and subjects are instructed to arrange the stimuli according to color. Correct arrangement of the various color samples requires not only normal color vision, but also good discriminative ability. Finally, the gold standard in assessing color vision is color matching. By asking the patient to match either a monochromatic yellow test light to a mixture of red and green primaries (Rayleigh match) or a cyan/yellow test mixture to a blue/green primary mixture (Moreland match), one can detect even the most mild red/green or blue/yellow defect, respectively.

Conditions Resulting in an Acquired Color-Vision Defect

Ocular Diseases

The most common acquired color-vision deficiencies arise from various diseases which can impact the eye in a number of ways. Such diseases include progressive cone dystrophies, retinal pigment epithelium (RPE) dystrophies, ocular media opacities, and impairments that affect the retinal neurons (ganglion cells). As a group, these deficiencies can be characterized by an abnormal cone electroretinogram (ERG), reduced visual acuity, central visual-field loss, and/or light sensitivity (photophobia). The age of onset, severity of color-vision defect, and rate of progression can vary widely among different diseases. A few of the most common diseases are discussed below. As an aside, the color-vision defect is often the least of these patients' worries; nonetheless, it is affiliated with the disease (which itself may be an inherited condition) and can sometimes contribute to the diagnosis.

Age-related macular degeneration

Age-related macular degeneration (AMD) is the leading cause of blindness in the developed world. As such, it also represents the most prevalent form of acquired color-vision deficiency. Although this disease has two forms (wet and dry), both involve a degeneration of the photoreceptors in the central retina (macula). It is in this area where acuity and color vision are at their best, so it comes as no surprise that individuals with AMD suffer deficits in both. In the slower-progressing dry form of AMD, yellow deposits called drusen develop underneath the macula. As these drusen negatively affect the health of the RPE, which is required for normal function of the photoreceptors, a loss of vision slowly results. In the fast-progressing wet AMD, tiny blood vessels begin to grow behind the retina toward the macula. Bleeding, leaking, and scarring occur from these fragile blood vessels, eventually causing irreversible damage to the retina and rapid vision loss. Color vision becomes progressively distorted as the disease progresses and more photoreceptors are functionally compromised, but this does not usually contribute to the differential diagnosis.

Glaucoma

The term glaucoma represents a group of diseases of the optic nerve characterized by a loss of retinal ganglion cells with a corresponding loss of some or most of the fibers of the optic nerve. In this disease, constriction of the visual field occurs slowly over time, and may not be recognized until the impairment is quite severe, with as many as 60% of the retinal ganglion cells degenerating before a perceptual consequence is detected. Worldwide, glaucoma is the second leading cause of blindness, and interestingly the deterioration in color vision of these patients has been proposed as a predictor of significant visual-field loss. Field loss arises from diffuse changes in the neural retina, supporting the idea that acquired color deficiency in glaucoma is caused by damage to the neural pathway rather than the retinal photoreceptors. Despite these patients having a normal S-cone ERG, acquired tritanopia (with severity paralleling the visual-field loss) is often found. This tritan deficiency is consistent with other optic nerve diseases, which suggests that the S-cones themselves remain intact, but that postreceptoral mechanisms involved in the transmission of blue–yellow color discrimination must be selectively disrupted.

Retinitis pigmentosa

Retinitis pigmentosa (RP) is a hereditary retinal dystrophy in which abnormalities of the rods, or the RPE of the retina, lead to progressive visual loss. Affected individuals first experience night blindness and defective dark adaptation, followed by reduction in peripheral vision (tunnel vision), and often a loss of central vision late in the course of the disease. There is good evidence that the progressive degeneration of the rods leads to the secondary loss of cones, likely as a result of reduced rod-derived cone viability factors. Disruptions in color discrimination can occur as the cones degenerate, and these individuals can exhibit a severe tritan defect or occasionally pseudoprotanomaly (a mild red–green defect). Most RP sufferers eventually go blind, therefore again the color-vision defect is of relatively minor importance to the individual.

Cataract

An age-related cataract is an impairment of the crystalline lens of the eye in which the lens hardens, becomes opaque, and yellows. A normal lens selectively absorbs short-wavelength light, however, both normal aging and the development of cataracts enhance this effect and causes problems discriminating in the blue–green portion of the spectrum. This condition is known as xanthopsia and refers to an abundance of yellow which dominates the visual scene. Patients who have cataract surgery in which their natural lens is removed and replaced with a clear plastic lens often experience cyanopsia – or a blue-dominated visual scene. This cyanopsia results because the brain compensates the perceptual yellow tint caused by the cataract by adding a blue tint to the visual scene, and when the yellow lens is removed it takes the brain time to renormalize to the new chromatic input. The mild-blue perception after cataract removal may persist for weeks or even months but normal color vision gradually returns, highlighting the significant chromatic plasticity of the adult visual system.

Diabetic retinopathy

Diabetic retinopathy is an ocular manifestation of the systemic disease, diabetes, occurring when the disease is left untreated. Elevated blood sugar levels present in diabetics can induce changes in the retinal blood vessels severe enough to impact patients' vision. The swelling and growth of new vessels in the eye can cause these vessels to bleed, cloud vision, and destroy the retina by failing to supply adequate oxygen and meet the metabolic needs of the photoreceptors. Visual disturbances begin with a blur, but the pattern of vision loss in these patients is often diffuse, irregular, and achromatic, reducing visual perception to shades of gray interrupted by large blank patches.

Optic neuritis

Optic neuritis is an inflammation of the optic nerve which can cause partial or complete vision loss. These patients report sensitivity to light (photophobia), pain with eye movements, and a degradation of color vision. Direct axonal damage may also play a role in nerve destruction in many cases. The loss of color vision starts as an abnormal dimming, and apparent increased noise in the visual images, which then progresses to a general dimming or loss of color discrimination and blurring across the entire visual field. In many cases, only one eye is affected and patients are not aware of the loss of color vision until the doctor asks them to close or cover the healthy eye. Typically, these defects are similar to a deutan defect (a form of red–green defect), but with additional reduction in sensitivity to the shorter wavelengths. Nearly half of all patients with multiple sclerosis (MS) will develop an episode of optic neuritis, and up to one-third of the time optic neuritis is the presenting sign of MS. This stems from inflammation of the optic nerve, as a result of the degeneration of the myelin sheath surrounding it. MS patients may suffer periodic attacks of optic neuritis, which increase in severity, leading to a permanent loss of color vision.

Cortical Defects

Another way in which one can acquire a color-vision deficiency is through a cortical insult. Cortical defects result from a head injury, stroke, or neurodegenerative disease. Unlike other forms of acquired color-vision deficiencies, those arising from cortical defects are often unilateral, impacting one-half of the brain, and in turn only one part of the visual field, although full-field defects can occur. Injuries impacting color vision typically result from damage to either V2 (prestriate cortex), or V4 – the areas of the brain responsible for processing color information; however, uncertainty remains about precisely which cortical loci (if any) are responsible. As cortical damage is rarely localized to a small section of the brain, there are often other behavioral deficits resulting from the injury, making it difficult to interpret individual cases and generalize about an individual's symptoms.

Cerebral achromatopsia

One famous case of cerebral achromatopsia is that of the colorblind painter discussed in the introduction of this article. It is presumed that the painter's acquired monochromacy was due to cortical injury caused either by damage to the visual cerebral cortex during an automobile accident, or by a stroke affecting one of the visual areas. As V2 and V4 are among the most metabolically active areas of the cerebral cortex, they are among the first to suffer from the effects of reduced oxygen delivery, and may therefore be affected in the case of a stroke. In this case, color disturbances occur very rapidly and may precede other symptoms. The resulting loss of color vision may occur as a total loss (complete achromatopsia), or as a partial loss affecting only one-half of the visual field (hemiachromatopsia). Unlike degenerative disorders with the same perceptual appearance, in central achromatopsia, the retina is not damaged so acuity typically remains unchanged. This finding illustrates how different cortical areas can serve discrete aspects of vision.

Neurodegenerative diseases

Parkinson's disease (PD) is a disease that impairs cognitive, motor, and sensory function through the progressive loss of dopaminergic neurons, and a few studies have reported abnormal color vision in these patients. Dopamine

deficiency is believed to alter retinal visual processing primarily by changing the receptive field properties of ganglion cells. The S-cone photoreceptors are sparse in the retina and are believed to have elevated susceptibility to retinal damage caused by progressive loss of the dopaminergic cells in the retina. This is certainly the case in retinal detachments where S-cone defects predominate. Consequently, those who have cited color-discrimination problems in patients with PD identified a tritan axis of confusion. There is debate on this, however, because most standard methods of testing color vision require the patient to make motor movements, which can provide an additional disadvantage and confounding variable for PD patients.

Another neurodegenerative disease, Alzheimer's disease, also has implications for color vision. The cortical atrophy which causes the hallmark dementia associated with this disease causes not only degeneration of the visual areas of the brain (gray matter), but may also induce optic nerve degeneration. As the disease progresses, patients' vision tends to decline from a mild tritan color-vision deficiency into complete achromatopsia.

Toxin-Induced Defects

In addition to the internal defects that cause color-vision abnormalities, there are numerous environmental factors that can alter color perception. Multiple therapeutic drugs have been reported to produce color-vision deficiencies in patients. While most of these occurrences have been documented as a result of toxic levels of the prescribed drugs, some can occur even at recommended dosages, though most side effects are transient. Many studies have found altered color perception in workers occupationally exposed to chemicals as well. A possible mechanism for these toxin-induced defects may be related to the direct effect of the chemicals on cone function, and/or an interference with neurotransmitter signaling.

Digitalis

The digitalis family of drugs (digoxin and digitoxin) is typically prescribed to control congestive heart failure as well as certain cardiac arrhythmias. Several retinal cells (i.e., photoreceptors, Müller's cells, and retinal pigment epithelial cells) express digitalis-sensitive isoforms of sodium–potassium adenosine triphosphate (ATP)ase, and inhibition of these pumps by digitalis is associated with alterations in electrical-response properties of the retina. Clinical ERG and *in vitro* cell studies have shown that toxic levels of digoxin lead to rod and cone dysfunction, with cones being affected to a greater extent. Patients experiencing disturbances of color vision while taking these drugs usually exhibit a red–green defect in which objects are covered with a reddish haze and sometimes exhibit symptoms similar to optic neuritis. Fortunately, color vision tends to recover after the drug is withdrawn. It has been speculated that the prevalent use of yellow in Vincent Van Gogh's work may be due to the use of digitalis, used at the time for its euphoric effects and as a treatment for epilepsy.

PDE5 inhibitors

Phosphodiesterase (PDE) inhibitors, including Viagra (sildenafil), Levitra (vardenafil), and Cialis (tadalafil), are used to treat erectile dysfunction by selectively inhibiting cyclic guanosine monophosphate (cGMP)-phosphodiesterase type 5 (PDE5), present in all vascular tissue, which leads to vasodilation. It also exerts an inhibitory action against PDE6, the phosphodiesterase isoform present in rod and cone photoreceptors, though the inhibition efficacy is only about 1/10 of that for PDE5. PDE6 is a key player in the phototransduction cascade, catalyzing the hydrolysis of cGMP in response to absorption of light by the photopigment molecule. This results in a reduction in cGMP, which results in a closing of the cyclic-nucleotide-gated ion channels and thus a hyperpolarization of the cell. As such, PDE5 inhibitors can interfere with this process and lead to transient changes in rod and cone outer segment function, and the retinal effects may include impaired blue–green color discrimination and decreased rod- and cone-driven ERG amplitudes. At high doses of PDE5 inhibitors, patients have reported a blue tinge to vision, increased apparent brightness of lights, and blurred vision, although some studies report no effects on vision. Color-vision disruptions that were experienced were transient, and no consistent pattern has emerged to suggest any long-term effect of PDE5 inhibitors on the retina or other ocular structures.

Chloroquine

This drug is used in the treatment and prevention of malaria and more recently has gained use as an immune system suppressant prescribed in autoimmune disorders such as rheumatoid arthritis and lupus erythematosus. The color-vision impairment from chloroquine is a consequence of the fact that it is a melanotropic compound with an affinity for pigmented, melanin-containing structures; this naturally results in accumulation of the drug in the highly pigmented RPE. Both the dose and duration of chloroquine treatment impact the level of toxicity because the compound remains in the retina for several years, even after treatment has been discontinued. A tritan defect is most common, but as toxicity increases, a protan-like red–green defect can also manifest. Unfortunately, this is one of the few cases in which withdrawal of the drug is typically insufficient to prevent further damage.

Ethambutol

Ethambutol is a drug prescribed in combination as a treatment for tuberculosis. It has been found to induce a secondary color-discrimination disturbance which shifts the threshold for wavelength discrimination without a change

in absolute sensitivity, resulting in color-discrimination errors along the red–green axis. There is evidence that it may disrupt the morphology of the cone pedicle – disturbing the transmission of signals from the cone photoreceptors to their postreceptoral contacts (horizontal and bipolar cells). This disturbance is most profound for low-intensity stimuli. These effects can occur after either a lengthy therapy at a low dosage, or a short therapy at high doses. The color defect is similar to a deutan-like red–green defect, but with a reduction in sensitivity to the shorter wavelengths as well. Unlike many other acquired defects, in this case, impairments in color discrimination can be useful for detection of toxicity, thus color vision should be monitored in patients undergoing regular treatment for tuberculosis. Generally, color vision improves gradually after withdrawal of the drug; yet, in some cases color vision is permanently impaired.

Vitamin A deficiency

Common in developing countries, and associated with alcoholism and metabolic storage diseases in developed countries, vitamin A deficiency is a very preventable cause of acquired color-vision deficiency. This essential vitamin is required for regeneration of the visual pigments of both rods and cones in the retina. A deficit in vitamin A initially causes night blindness and, if left untreated, will contribute to complete blindness by making the cornea very dry and damaging the retina and cornea. In the more mild forms, tritan deficiencies occur, and transition to a general loss of hue discrimination. Approximately 400 000 children in developing countries go blind each year due to a deficiency in vitamin A. If reached before the onset of blindness, recovery can be shown following oral or injectable doses of the vitamin.

Exposure to metals and chemicals

Multiple studies have examined the color perception in groups of workers exposed to high levels of metallic mercury. Surprisingly, a dose-related loss of color vision is demonstrated even at presumed safe levels of mercury exposure. Although the mechanism of mercury's impact on the visual system is not fully understood, it seems to be localized to the retina because traces of mercury have been reported in the optic nerve, RPE, inner plexiform layer, vessel walls, and ganglion cells. Color-vision deficiencies revolve mainly around the blue–yellow axis, but may show some nonspecific losses. As with most of the other toxins, this effect seems to be reversible if individuals are removed from toxic exposure.

An additional collection of chemicals used in plastic, rubber, and viscose rayon manufacturing plants, rotogravure printing industries, as well as dry-cleaning facilities have similarly been implicated in reversible color-vision deficiencies. These chemicals include styrene, perchloroethylene (PCE), toluene, carbon disulfide, and n-hexane.

Conclusion

The range of acquired color-vision deficiencies is broad in both type and severity; some affect ocular structure directly while others perturb the neural pathways responsible for color vision, some are preventable and/or reversible while others are merely an indicator of a more serious condition. Despite their diverse etiology and manifestation, these defects can have a significant impact on the individual, for unlike those born with a color-vision deficiency, acquired sufferers know, and in most cases can remember, what they are lacking perceptually. Returning to the case of the colorblind painter gives those of us who are color normal a small taste of the devastating psychological effect of an acquired color-vision deficiency: "The wrongness of everything was disturbing, even disgusting, and applied to every circumstance of daily life."

Color Blindness: Inherited

J Carroll and D M Tait, Medical College of Wisconsin, Milwaukee, WI, USA

Glossary

Blue–yellow defect – A color-vision deficiency in which blue and yellow are difficult to distinguish from one another. In inherited defects, this is typically caused by a defect in the short-wavelength-sensitive photoreceptor.
Dichromacy – A color-vision deficiency in which only two primaries are required to perfectly match a monochromatic light. In this deficiency, one of the three types of photopigments is functionally absent so color vision is reduced to only two dimensions.
Monochromacy – A complete lack of ability to distinguish colors caused by defects in the morphology or function of the cones.
Photopigment – A light-sensitive protein in the photoreceptors (rods and cones) that undergoes a conformational change when absorbing light and initiates the process of visual transduction.
Red–green defect – A color-vision deficiency in which red and green are difficult to distinguish from one another. There are two inherited forms of this defect: Deutan, which is caused by a defect in the medium-wavelength-sensitive photoreceptor, and protan, which is caused by a defect in the long-wavelength-sensitive photoreceptor.
Trichromacy – The fundamental ability to see in full color, based on the ability to match a monochromatic light by using a mixture of any three primaries. This ability requires the possession of three distinct classes of photoreceptors.

Introduction

Beyond the occasional spousal argument over the color of a shirt or tie, a significant number of people are born with a defect in their ability to perceive and discriminate colors. While the existence of deficiencies in color discrimination had been appreciated for some time, it was the famous chemist John Dalton who gave the most well-known analytical description of the condition in 1798. This was due to the fact that he himself suffered from a color-vision defect: "Reflecting on these facts, I was led to conjecture that one of the humors of my eye must be a transparent, but colored, medium, so constituted as to absorb red and green rays principally, because I obtain no proper ideas of these in the solar spectrum; and to transmit blue and other colours more perfectly." While Dalton did not accurately identify the biological basis of his color-vision deficiency, he articulately described it, and thus the term Daltonism is now synonymous with color-vision deficiencies.

Photoreceptor Basis of Human Color Vision

Humans with normal color vision can discriminate some 2 million hues. The retinal substrate for this exquisite color vision is the cone photoreceptor mosaic. While the highly sensitive rods outnumber cones nearly 20:1 and subserve vision at low (scotopic) light levels, it is the cones that underlie the majority of our visual experience at high light levels (photopic), including high spatial acuity and color vision.

There are three subclasses of cone photoreceptor, each having a distinct spectral sensitivity (**Figure 1**). The spectral sensitivity of the photopigment simply reflects the probability of it absorbing a photon of light, and is determined by the particular photopigment present in the cone cell. Photopigments (and their associated cones) are classified according to the region of the visible spectrum they are most sensitive to – either short-, middle- or long-wavelength sensitive (abbreviated S, M, and L). All humans with normal color vision have the same S-cone pigment, with peak absorption around 417 nm. The M-cone pigment varies slightly among individuals, with an average peak of about 530 nm. There is widespread variation in the peak sensitivity of the L-cone pigment among humans with normal color vision, though there are two main variants that peak at 555 and 559 nm, respectively. Trichromatic color vision is afforded by the presence of one cone type from each of these three spectral classes, and these cone types appear to be randomly arranged within the cone mosaic (**Figure 1**). While the human retina contains nearly 100 million photoreceptors, only about 5 million of them are cones, and of the cones, about 95% are of the L/M type. If the function of one or more of the cone classes is disrupted or absent, the result is a compromised ability to make chromatic discriminations, that is, a color-vision deficiency.

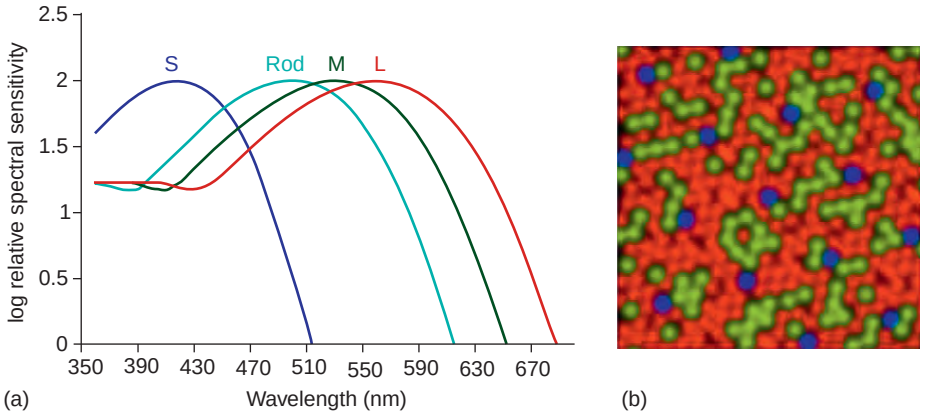

Figure 1 Photopigment basis for trichromatic color vision. (a) Photopigment absorption spectra. The human photopigments have different, but overlapping, spectral sensitivities. The cone photopigments, which dominate our photopic (daytime) vision, are named based on the region of maximal absorption in the visible spectrum – short-(S), middle-(M), or long-wavelength sensitive (L). Rods serve scotopic vision and are maximally sensitive at about 500 nm. (b) Simulation of the organization of the L (red), M (green), and S (blue) cones within the cone photoreceptor mosaic. Note the relative paucity of S cones in the mosaic, and the random arrangement of the L and M cones, with L cones outnumbering M cones by about 2:1 in individuals with normal color vision, though this is variable.

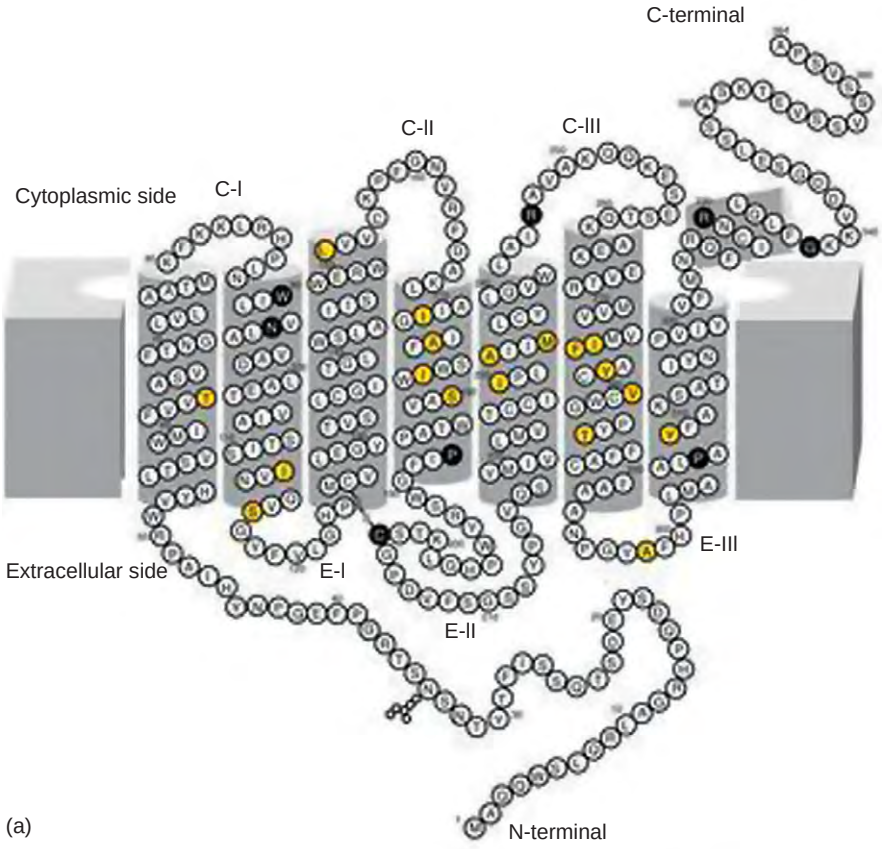
Genetic Basis of Human Color Vision

All inherited color-vision defects are associated with disruptions in the expression of normal cone photopigments. Human photopigments differ only in their opsin (protein) component, though they share the same chromophore, 11-*cis*-retinal. At the protein level the L and M pigments are about 96% homologous, though they show only 43% identity with the S pigment, while human rhodopsin (the opsin found in rods) is about 41% homologous with any of the cone opsins. Each of the human cone opsins is encoded by a different gene. The gene encoding rhodopsin is 5.0-kb long and found on chromosome 3, while the gene encoding the S opsin is located on chromosome 7 and is 3.2-kb long. The rhodopsin and S-opsin genes each have four introns and five exons, and as a result of their autosomal location, humans normally have two copies of each of these genes. In contrast, the L/M gene(s) are located on the X chromosome. While most mammals have only a single L/M gene on the X chromosome, most Old World primates (including humans) possess both L and M genes. In primates that have both the L and M genes on a single X chromosome, they are located in a tandem array near the end of the long arm of the X chromosome (Xq28), and a locus-control region (LCR) enables exclusive expression of one gene from the array in a given cone photoreceptor cell.

The location of the L/M gene array and their high homology allow for frequent unequal homologous crossovers (intermixing of the genes). During meiosis, this can occur between the genes (intergenic crossover) or within the genes (intragenic crossover) between two parental X chromosomes. Such recombination events are responsible for the observed variation in L/M gene number on the X chromosome (humans with normal color vision can have between two and nine genes in this array). In addition, genes with hybrid L and M sequences are produced from intragenic crossover events. These hybrid genes encode photopigments that have spectral sensitivities intermediate of the normal L- and normal M-cone photopigments. The combined variability in gene number and gene sequence means that in a group of 100 males, the probability that any two will have identical L/M arrays is less than 2%. Interestingly, there is no normal variation in the S-pigment gene.

As mentioned previously, there is a great deal of variability in the L and M photopigments. In fact, of the 364 amino acids there are 18 residues where differences have been identified between and among the L and M photopigments (positions 65, 111, 116, 153, 171, 174, 178, 180, 230, 233, 236, 274, 275, 277, 279, 285, 298, and 309; see **Figure 2(a)**). Positions 274, 275, 277, 279, 285, 298, and 309 co-segregate and can be used to identify a pigment as either L or M. This is because these amino acids, in particular the substitutions at positions 277 and 285, are responsible for generating the majority of the spectral separation between the L and M pigment classes. L genes specify tyrosine and threonine at positions 277 and 285, respectively, whereas M genes specify phenylalanine and alanine at these same positions, resulting in a shift in peak sensitivity toward shorter wavelengths of approximately 24 nm. Substitutions at the other amino acid positions can produce more subtle spectral shifts, driving the spectral variations within the L and M classes. The most common, a serine/alanine dimorphism at position 180, shifts the maximum absorption (λ_{max}) by about 3–7 nm, though the amino acid identity at other polymorphic positions can influence the magnitude of this shift.

This genetic variation can have a measurable impact on color vision. For example, among normal trichromats, the



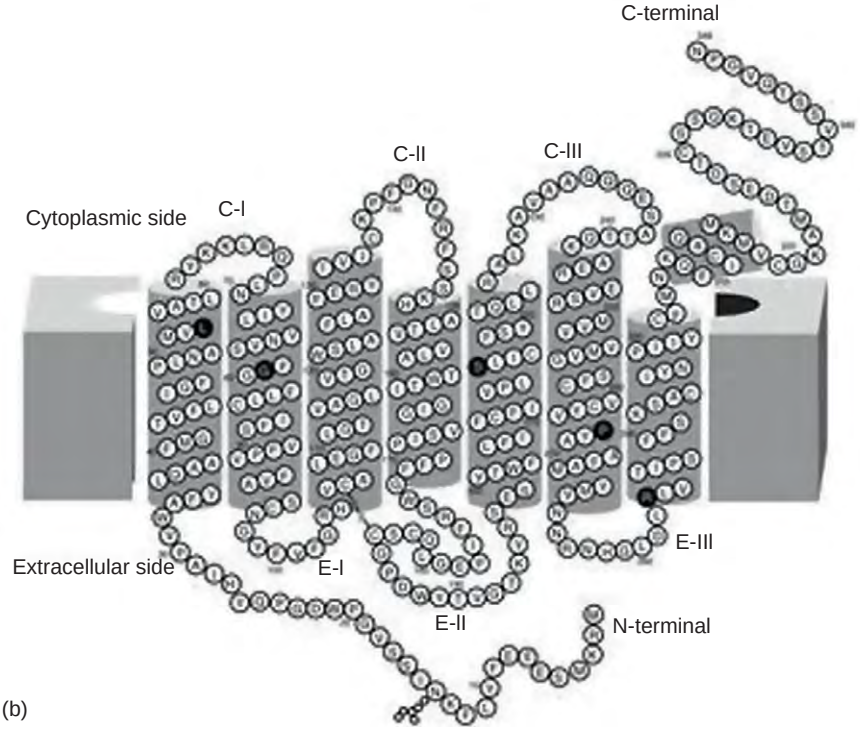


Figure 2 Two-dimensional models of the human cone opsins. (a) L/M opsin. Each circle represents a single amino acid, with mutations associated with the loss of L- or M-pigment function shown as filled black circles. Filled yellow circles represent the dimorphic sites that can differ between the L and M pigments. A number of these sites have been shown to be involved in the spectral tuning of the pigments (see text). The amino acid identities at all 18 dimorphic sites are those of the presumed primordial L opsin. (b) S opsin. Each circle represents a single amino acid. The five mutation sites associated with inherited tritan color-vision deficiency are indicated by black circles.

variation in spectral sensitivity within the L and M pigment classes can be readily observed on color-matching performance. In the Rayleigh match, an individual is asked to determine the mixture of a red and green primary needed to exactly match a monochromatic yellow light. Variability in color-matching behavior had long been recognized, but only in the last 20 years has it been directly linked to the variability in the L and M photopigments, and thus the L/M gene array.

Red–Green Color-Vision Deficiencies

Besides inducing subtle alterations in performance on laboratory color-vision tests, the genetic mechanisms that give rise to variability in the L/M-gene array can induce significant defects in color discrimination. Disruptions in normal L/M-photopigment expression result in an inherited form of color-vision deficiency that affects the red–green (L/M cone) system. Among individuals of Western European ancestry, about 8% of males have a red–green color-vision defect. The incidence is significantly lower among Africans and Asians, as well as smaller isolated populations such as Fijian Islanders and the Inuit. These defects are associated with the L/M array on the X chromosome and are inherited as X-linked recessive traits, so the incidence in females is much lower (approximately 0.4%). Nonetheless, approximately 15% of females are heterozygous carriers of a red–green color-vision defect. It has been suggested that there may be a heterozygous advantage for female carriers, as given the variability with the L and M spectral classes, these women can have four spectrally distinct cone types, providing the photoreceptor basis for tetrachromatic color vision.

The genetic causes of inherited red–green color-vision deficiency fall into two main categories. The most common cause is a rearrangement of the L/M genes resulting either in the deletion of all but one L or M pigment gene, or in the production of a gene array in which the first two genes encode a pigment of the same spectral class (i.e., L/L or M/M). Even though the L/M array can contain more than two genes, it is believed that only the first two genes in the array are expressed. The second general cause involves the introduction of a mutation in either the first or the second gene in the array, rendering the expressed pigment nonfunctional. The most prevalent inactivating mutation, accounting for nearly 10% of red–green dichromacy, results in the substitution of arginine for cysteine at position 203 (C203R) in the L/M opsin molecule. Mutating the corresponding cysteine residue in human rhodopsin (position 187) causes autosomal dominant retinitis pigmentosa (RP). This cysteine residue forms an essential disulfide bond and is highly conserved among all G-protein-coupled receptors. Mutant photopigments do not fold properly, and are retained in the endoplasmic reticulum and not targeted to the cone outer segment membrane. As such, L/M cones expressing this mutant pigment are nonfunctional, and individuals harboring this mutation base their color vision on an S cone and a single L- or M-cone type (rendering them dichromatic).

In the case where the first two genes encode pigments from the same spectral class, they can have either the same spectral sensitivity or slightly different spectral sensitivity (owing to the fact that there is variation within the L and M pigment classes). If the first two genes encode pigments with identical spectral sensitivities, the individual again bases their color vision on an S cone and a single L- or M-cone type and will be dichromatic. However, if the first two genes encode pigments with different spectral sensitivities (though from the same spectral class, L or M), the individual is technically trichromatic, in that they have three different cone types. However, since the spectral separation between their two types of L (or M) pigment is not as great as the separation between L and M, their discrimination is not normal. Thus, these individuals are known as anomalous trichromats. The standard L and M photopigments differ in their peak spectral sensitivity by nearly 30 nm. In anomalous trichromats with multiple L (or M) pigments, the λ_{max} may be separated by as few as 2 nm or as many as 10–12 nm, where the degree of spectral separation depends on the identity of the amino acids at sites 65, 111, 116, 153, 171, 174, 178, 180, 230, 233, and 236 within the L/M pigment (**Figure 2(a)**). In general, the further apart the pigments, the better the discrimination; in some cases, the deficiency is so mild that the individual is unaware of it until genetic and/or behavioral testing. Likewise, as the λ_{max} of the pigments gets closer together, the discrimination worsens, with the most severe individuals behaving nearly like dichromats.

The red/green defects can be separated based on the (1) dimensionality of the residual color vision (dichromat or anomalous trichromat) and (2) spectral subtype of the remaining cone (protan or deutan). **Figure 3** shows the different spectral sensitivity curves that underlie the different forms of red/green color-vision deficiency.

Individuals with an absence of L-cone function are said to have a protan defect. Protanopes are dichromats who possess an S pigment and an M pigment. Protanomalous trichromats possess a normal S pigment and two spectrally distinct M pigments. Perceptually, the absence of a cone type can have differing effects. Individuals with a protan defect are less sensitive to light in the long-wavelength (red) portion of the spectrum. Therefore, the brightness of red, orange, and yellow are reduced compared with a normal observer. Furthermore, they may have problems in distinguishing red from green, as well as difficulties differentiating a red hue from black.

Individuals with an absence of M-cone function are said to have a deutan defect. A deuteranope possesses an

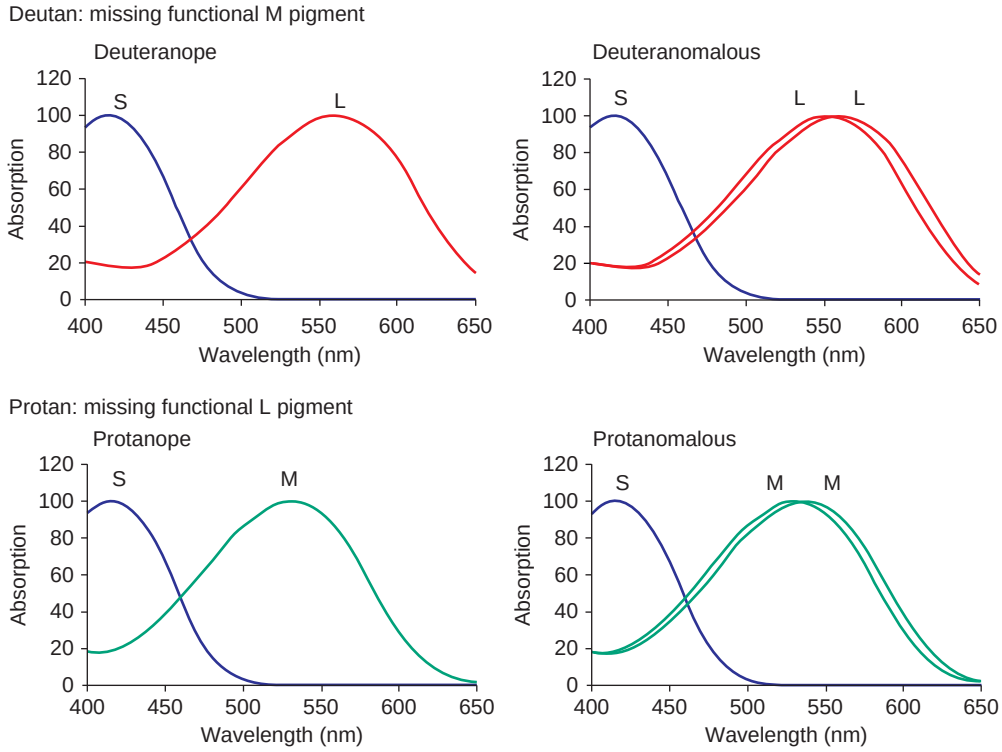

Figure 3 Photopigments underlying defective red–green color vision. Red–green color-deficient individuals are missing either all members of the M class or all members of the L class of pigment. Dichromats have only one pigment in the L/M region of the spectrum, whereas trichromats have two pigments in the L/M region of the spectrum. The degree of color-vision deficiency in persons with anomalous trichromacy depends on the magnitude of the spectral difference between their pigment subtypes. Deuteranopes and deuteranomalous trichromats have no functional M pigment, though deuteranomals have two slightly different L pigments. Likewise, protanopes and protanomalous trichromats have no functional L pigment, though protanomals have two slightly different M pigments.

S pigment and an L pigment, whereas deuteranomalous trichromats possess an S pigment and two spectrally distinct L pigments. Deuteranomalous defects are by far the most prevalent of any of the congenital color-vision defects, affecting nearly 5% of men. Individuals with deutan defects exhibit a reduction of sensitivity to colors in the green region of the spectrum, though the decrease in sensitivity is less pronounced than the long-wavelength depression in protans due to the manner in which the spectral sensitivities overlap (**Figure 1**). Deutans suffer similar hue-discrimination problems as the protans, but without the long-wavelength dimming. These discrimination errors are exploited in the design of color-vision tests; however, the real-world consequences of having certain red–green deficiency can be minimal. The perceptual consequences of having various color-vision defects are simulated in **Figure 4**. Interestingly, there is evidence that individuals with red–green defects may actually have an advantage when viewing camouflage, which is designed to blend into the environment, but this is done assuming a trichromatic visual system.

While the red–green color-vision defects can be behaviorally classified according to the cone subtype that is nonfunctional, the structural basis of the defects has been unclear. Recent work using high-resolution, *in vivo* imaging of the human retina has shown that while conceptually one can think of a deutan retina containing only S and L cones, and a protan retina containing only S and M cones, the residual cone mosaic in red–green-deficient individuals can vary dramatically, depending on the genetic cause of the defect. Shown in **Figure 5** are images of the cone mosaic from a normal trichromat and an individual with a red–green defect caused by an inactivating mutation in his M gene. Each circle is a single cone photoreceptor, and the dark spaces in the red–green-deficient retina represent cones that have degenerated or that are morphologically compromised. Thus, some individuals will have normal numbers of cones (though only two, instead of three types), while some will be structurally missing an entire cone class. The impact on vision in general is not yet known, and the genetic heterogeneity within the red–green defects remains to be reconciled with the mosaic phenotype.

Tritan Color-Vision Deficiencies

Tritan defects are an inherited autosomal dominant abnormality of S-cone function. These defects occur in

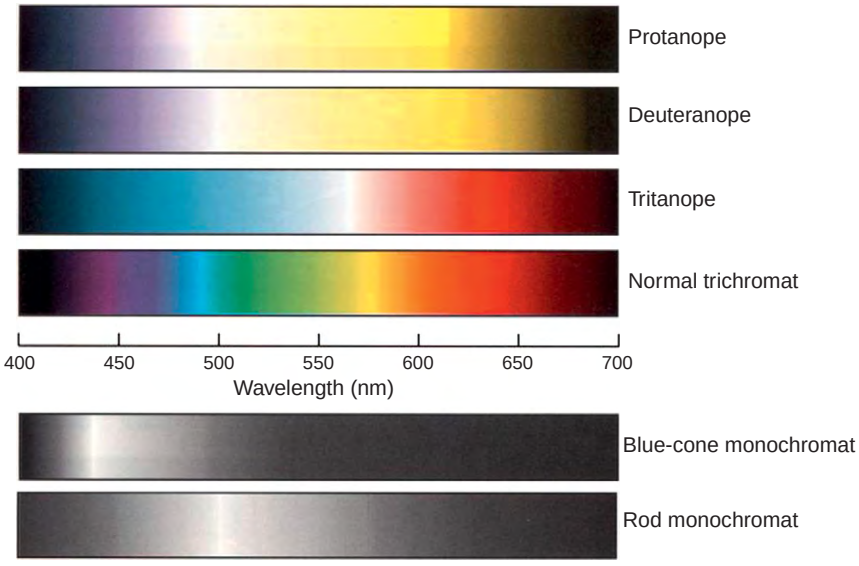

Figure 4 Perceptual consequences of inherited color-vision defects. Shown is a computer simulation of the color spectrum as it would appear to a protanope, deuteranope, tritanope, and normal trichromat. Each color-vision deficiency shows greatly reduced chromatic discrimination compared to that of a normal trichromat. The bottom two panels reveal the perceptual consequences of monochromacy on the appearance of the spectrum for a blue-cone monochromat and rod monochromat. Reproduced from Gegenfurtner, K. R. and Sharpe, L. T. (1999). *Color Vision: From Genes to Perception*. New York: Cambridge University Press, with permission of Cambridge University Press.

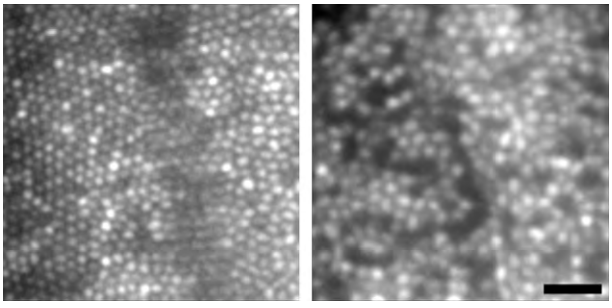

Figure 5 High-resolution images of the living retina obtained with adaptive optics. On the left is a retinal image from a patient with normal vision, at an eccentricity of approximately 1° temporal to fixation. Each circular structure is an individual cone photoreceptor. On the right is an image from a patient who is red–green color blind. Visible are numerous holes where cones have either died or degenerated, due to a mutation in one of the genes responsible for normal color vision. Despite the loss of nearly 33% of his functioning cones, this person has normal visual acuity. Scale bar = 20 μm.

both males and females with equal frequency and are believed to be rare, affecting as few as 1 in 10 000 people. As the S-pigment gene is on chromosome 7 and humans are diploid, each S-cone photoreceptor expresses the S-cone pigment genes from both copies of chromosome 7. Consequently, a defect in one S-pigment gene can be sufficient to cause tritanopia, just as a mutation in one rhodopsin gene is sufficient to cause RP, a retinal degeneration that involves the degeneration of the rod photoreceptors. Unlike the red–green defects, there is no genetic/pigment basis for a tritanomalous defect, as there is no spectral variation among functional S-cone pigments.

This disorder exhibits incomplete penetrance, meaning that individuals with the same underlying mutation manifest different degrees of color-vision impairment, even within a sibship. Mutations in the S-cone-opsin gene, which encodes the protein component of the S-cone photopigment, have been identified and they give rise to five different single amino acid substitutions that have only been found in affected individuals but not in unaffected control subjects (**Figure 2(b)**). Each substitution occurs at an amino acid position that lies in one of the transmembrane alpha helices, and is predicted to interfere with folding, processing, or stability of the encoded opsin. For example, one of the identified mutations corresponds to an amino acid position at which a substitution in the rod pigment, rhodopsin, causes autosomal dominant RP.

A fundamental difference between S cones and L/M cones is the potential for dominant negative interactions between normal and mutant opsins. This is because each S cone expresses both autosomal copies of the S-opsin gene, whereas L and M cones each only express one gene from the L/M array on the X chromosome. Rod photoreceptors also express a rhodopsin gene from two autosomes, and for rhodopsin mutations underlying autosomal dominant RP, dominant negative interactions lead to the death of the photoreceptors and ultimately the degeneration of the retina. Curiously, tritan defects have not been reported to cause progressive retinal degeneration and are only slightly

more rare than adRP; however, it has been suggested that the relative paucity of S cones compared to rods in the normal retina may be responsible for the absence of more general retinal degeneration. Nevertheless, the structural homology between the S-cone opsin and rhodopsin, taken together with the similar molecular mechanisms underlying the defects, suggest that S cones themselves degenerate in autosomal dominant tritan defects.

Blue-Cone Monochromacy

Blue-cone monochromacy (BCM) is a condition where both L- and M-cone function is absent. This disorder affects approximately 1 in 100 000 individuals. Since L and M cones comprise about 95% of the total cone population, these individuals have a rather severe visual impairment, including photophobia (light sensitivity), poor acuity, minimally detectable electroretinogram (ERG) responses, and diminished color discrimination. Any residual color vision in these individuals must be based solely on the S cones and rods. This means that under most conditions, they are monochromatic, though under mesopic (dim light; between photopic and scotopic levels) conditions they may gain some additional discrimination capacity.

As with the red–green defects, there are two main genetic causes of BCM, sometimes referred to as one-step or two-step mutations, though both lead to the absence of functional L and M cones. One-step mutations involve a deletion of essential *cis*-regulatory DNA elements needed for normal expression of the pigment genes. Two-step mutations involve a deletion of all but one of the X-chromosome visual pigment genes. This would normally confer red–green dichromacy (see above), but the one remaining gene contains a missense mutation. Due to the X-linked nature of the condition, female carriers are spared from a full manifestation of the associated defects, but they can show abnormal cone function on the ERG. One-step and two-step conditions may have important phenotypic differences in terms of the architecture of the cone mosaic in carriers. For the one-step mutations, the absence of an essential enhancer means that the cone photoreceptors cannot transcribe an opsin gene from the affected X chromosome. In contrast, for the two-step condition, there is a completely functional gene but the encoded opsin has a deleterious amino acid substitution, and the photoreceptor is expected to produce the mutant opsin. Depending on the nature of the mutation, it may either reduce or abolish proper folding of the encoded protein, or the gene may be transcribed but the message may be immediately targeted for degradation, and these may in turn ultimately affect the viability of the cone or its neighboring cells. While both conditions will likely compromise the viability of the cone, they may do so over different timescales.

Achromatopsia

Complete achromatopsia (i.e., rod monochromacy) is a congenital vision disorder in which all cone function is absent or severely diminished. It is typically characterized by an absolute lack of color discrimination, photophobia, reduced acuity, visual nystagmus, and a nondetectable cone ERG. Previously, exploration of this disease was limited to findings from histological and anatomical review and there was a debate surrounding whether the cones were absent, malformed, or merely minimally present. Recent work using *in vivo* cellular imaging, together with improved measures of cone function, suggest that not all achromats have the same cellular deficit, though in all cases their perception is dominated by the rod system and vision at normal light levels can be difficult if not impossible.

Rod monochromacy affects up to 1 in 30 000 people, and results from mutations in one of two components of the cone phototransduction cascade – transducin or the cyclic-nucleotide-gated (CNG) channel. Mutations in CNG alpha 3 (CNGA3) and CNG beta 3 (CNGB3), which encode the α- and β-subunit of the CNG channel, respectively, are by far the most common genetic cause of rod monochromacy, accounting for about 60–80% of the cases. A relatively small number of patients (~5%) have a mutation in the GNAT2 gene, which encodes the α-subunit of the cone G-protein transducin. The current theory is that the genetic heterogeneity underlies the observed phenotypic variability in patients with this disease, and this likely explains the previous discrepancies in histological reports. However, a systematic linkage of genotype and phenotype has not been done. Recently, a gene therapy approach has been used to restore cone function in dog and mouse models of the disease; however, one would predict that the degree of remaining cone structure would be a predictor of whether a particular human achromat could benefit from similar therapeutic intervention.

Conclusion

Inherited color-vision deficiencies range from mild difficulties discerning pale hues from gray to quite severe issues differentiating even the most saturated hues, and while most of these deficiencies are often categorized by the general misnomer color blindness, the defects are in fact quite different from one another and rarely indicate a condition in which the patient is truly blind to color. There is enormous genetic variation in all inherited color-vision defects, and it is becoming clear that this variation has consequences for the visual system that reach far beyond subtle differences in color perception/discrimination.

Concept of Angiogenic Privilege

B Regenfuss and C Cursiefen, Friedrich-Alexander University Erlangen-Nuernberg, Erlangen, Germany

Glossary

Angioblast – Mesenchymal tissue that differentiates into blood cells and vascular endothelium.
Angiogenesis – Formation of new blood vessels by outgrowth from preexisting vessels.
Intussusception – Formation of new blood vessels by splitting of existing vasculature.
Keratoplasty – Corneal transplantation.
Vasculogenesis – *De novo* blood-vessel formation from endothelial progenitor cells.

Introduction: Angiogenesis and Lymphangiogenesis

(Hem)angiogenesis describes the process of new blood-vessel formation by outgrowth from preexisting vessels. Accordingly, lymphangiogenesis means the formation of lymphatic vessels from preexisting ones. Both processes are precisely regulated and play an essential role in physiological and pathophysiological events in the organism.

In the context of the eye, pathological new blood and lymphatic vessels are associated with numerous disorders reducing visual acuity.

New blood-vessel formation in the organism is achieved either by angiogenesis or by vasculogenesis. Both processes can be distinguished from each other and strongly differ in the way the vessels arise. Vasculogenesis occurs mainly during embryogenesis and implies *de novo* blood-vessel formation by endothelial progenitor cells. During embryonic development, angioblasts, a subset of mesodermal cells, differentiate into endothelial cells and form the early vascular plexus. After establishing the primary vascular plexus, new blood vessels can be generated through angiogenesis that means by sprouting from preexisting blood vessels or by intussusception (nonsprouting angiogenesis). Angiogenesis and vasculogenesis normally occur during embryonic development. For the vascularization of the central nervous system (CNS) and the kidneys, angiogenesis seems to be the more important process. Following birth, most blood vessels remain in a quiescent state except for the once in the hair cycle, in the female reproductive system and during wound healing. In the case of unregulated angiogenesis, however, neovascularization can occur in the adult organism and usually is associated with diseases such as arthritis, tumors, or corneal and retinal disorders.

During early development of the retina, which is embryologically derived from the diencephalon, vasculogenesis and angiogenesis take place. In 1970, Ashton first described the mechanism of vasculogenesis for blood vessel formation in the retina of the human embryo. He proposed that primitive mesenchymal cells, after invading the retina, differentiate into endothelial cells, thereby, forming a capillary network. Nowadays there is evidence that vasculogenesis and angiogenesis both are responsible for the vascular development of the human fetal retina. Hughes and colleagues suggest a mechanism where vasculogenesis pioneers the establishment of a rudimentary vascular plexus, whereas angiogenesis provides further expansion of the vascular network and cares for increasing vessel density. Considering the fact that the retina is a highly metabolic active tissue both mechanisms complement one another and contribute to meet the metabolic requirements of the developing retina. The developed retina is a highly vascularized tissue that shows a dual blood supply. The inner layer of the retina is supported by the centralis retinae artery, originating from the arteria ophthalmica. The outer layer – especially the receptors – receive blood from the arteriae chorioideae.

In general, the eye is an efficiently vascularized organ and shows a significantly higher blood circulation compared to other organs with the same volume; however, there are exceptions at the anterior pole of the eye being completely devoid of blood and lymph vessels. Whereas posterior structures like the retina, as mentioned earlier, show a strongly branched blood-vessel network, the sclera is relatively low vascularized and the adjacent cornea and the vitreous even are devoid of blood and lymphatic vessels. Keeping up corneal avascularity comprises an active process and needs the balance between angiogenic and anti-angiogenic factors. In this process, the cornea maintains the transparency even under inflammatory or other pro-angiogenic conditions by different molecular mechanisms which are not completely elucidated to date. This ability is called the corneal angiogenic privilege.

Corneal Angiogenic Privilege

Corneal Avascularity

The corneal angiogenic privilege normally prevents the ingrowths of new vessels in the cornea even under

inflammatory or angiogenic conditions, thus maintaining corneal transparency and preventing loss of vision. A study with corneas from stillborn patients showed that this privilege is already present during intrauterine development at least from gestational age of 17 weeks. Contrary to the conjunctiva, in which blood and lymphatic vessels are detectable, no vessels are found in the cornea. This leads to the presumption that due to an early expression of anti-angiogenic and anti-lymphangiogenic factors, the cornea is primarily devoid of blood and lymphatic vessels and not as a result of regression of already existing vessels. The occurrence of neovascularization by angiogenic activity is initiated by a disbalance of angiogenic and anti-angiogenic factors caused by upregulating angiogenic molecules as well as by downregulating angiogenesis-inhibiting molecules. Interestingly, homozygote TSP-1 or TSP-2-knockout mice and even TSP-1/2-knockout mice showed no spontaneous corneal angiogenesis. The deficiency of an important anti-angiogenic factor like TSP-1 or TSP-2 does not result in a breakdown of the angiogenic privilege. This leads to the conclusion that at least during embryonic development the angiogenic privilege seems to be redundantly regulated by several anti-angiogenic factors. However, secondary to severe inflammation and several other diseases the angiogenic privilege can be overcome and an initial parallel outgrowth of blood and lymphatic vessels occurs.

Several factors comprising angiogenic and anti-angiogenic molecules, the cornea itself, and adjacent structures like the limbus are known to be involved in affecting the angiogenic privilege (see **Figure 1**). Deprivation of the angiogenic privilege can lead to corneal neovascularization and, in consequence, loss of vision.

Angiogenic and Anti-Angiogenic Molecules Involved in Corneal Neovascularization

Numerous angiogenic and anti-angiogenic molecules have been identified in the cornea over the last years. Angiogenic molecules include vascular endothelial growth factors (VEGFs), basic fibroblast growth factors (bFGFs), and matrix metalloproteinases (MMPs). Angiostatin, endostatin, thrombospondins, and pigment epithelium-derived factor (PEDF) are some of the anti-angiogenic molecules detected in the cornea.

The regulation of angiogenesis is due to the interaction of pro-angiogenic molecules and angiogenesis inhibitors, where tilting the balance toward pro-angiogenic factors can lead to neovascularization. Lymphangiogenesis seems to proceed in a similar way as angiogenesis, and can be activated in the adult during inflammation, immune responses, or malignant processes.

Stimuli like hypoxia, for example, in the context of wound healing, can also trigger the induction of hemangiogenesis via hypoxia-inducible transcription factor (HIF), a key transcriptional regulator for VEGF-A. In contrast, lymphangiogenic VEGF-C cannot be upregulated by hypoxia but only by proinflammatory cytokines.

Vascular endothelial growth factors

The VEGF growth factor family currently consists of five members, VEGF/VEGF-A, PIGF, VEGF-B, VEGF-C, and VEGF-D. The growth factors are recognized by different VEGF receptors, namely VEGFR-1, VEGFR-2, and VEGFR-3. VEGF-A originally isolated from a human histiocytic lymphoma cell line U937 is secreted

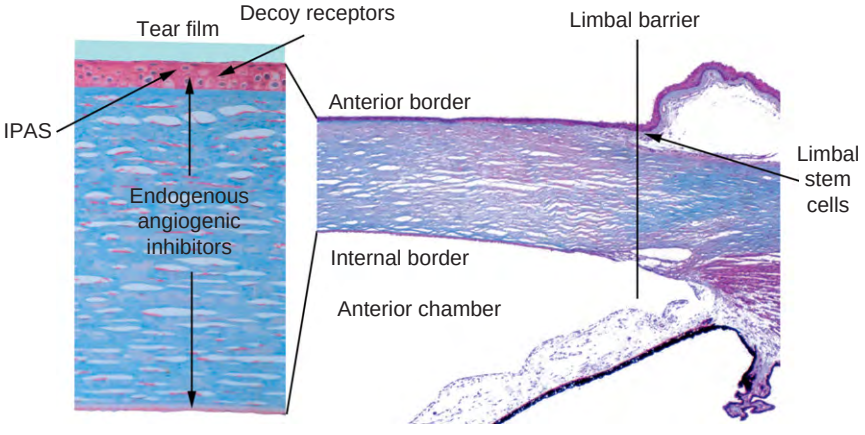

Figure 1 Several strategies are used by the normal cornea to maintain corneal avascularity (corneal angiogenic privilege): The cornea possesses several defense lines against invading vessels: an anterior border at the epithelial basement membrane, an internal border at Descemet's membrane, and the limbal barrier beneath the limbal epithelial stem cell niche. Several mechanisms contribute to maintain the angiogenic privilege of the cornea: (a) endogenous inhibitors of angiogenesis, (b) decoy receptors neutralizing angiogenic growth factors, (c) anti-angiogenic stem cells, and (d) anti-hypoxia-driven-angiogenesis agents. © M. Vogler.

in five different isoforms, generated by alternative splicing: $VEGF_{115}$, $VEGF_{121}$, $VEGF_{165}$, $VEGF_{189}$, and $VEGF_{206}$.

Vascular endothelial growth factor

VEGF-A shows numerous activities such as inducing endothelial cell proliferation and migration, proteolytic activity, and stimulating microvascular leakage – all of them promoting angiogenesis. VEGF-A mediates its function through receptors VEGFR-1 and VEGFR-2. Additionally, VEGF-A was reported to promote angiogenesis via an indirect pathway by upregulating NRP1, a neuronal receptor that has recently been shown to act as an isoform-specific receptor for $VEGF_{165}$.

VEGF-A can be released during hypoxia, in inflammatory situations, and during glucose deficiency. It was shown that the expression of VEGF-A is upregulated in inflamed and vascularized human corneas. In conclusion, VEGF-A seems to play an important role in inducing wound and inflammation-related corneal neovascularization. This was confirmed by the fact that corneal neovascularization could be suppressed after implantation of VEGF-A neutralizing antibodies in the corneal stroma of rats and rabbits. Whereas early data proposed that VEGF stimulates selectively hemangiogenesis but not lymhangiogenesis, recent data also suggest an (indirect) lymphangiogenic role: endogenous VEGF can promote lymphangiogenesisvia the recruitment of bone marrow-derived macrophages, releasing lymphangiogenic growth factors such as VEGF-C and -D. This broadens the impact of VEGF-A, not only for pathological hemangiogenesis, but also for lymphangiogenesis – at least in context of inflammation-induced neovascularization. A specific role for VEGF-A in the regulation of lymphangiogenesis was also described for primary tumors. The tumors were shown to overexpress VEGF-A, thereby inducing sentinel lymph node lymphangiogenesis. In a mouse model of delayed-type hypersensitivity (DTH), lymphangiogenesis was promoted by VEGF-A that was produced in the inflamed tissue.

In addition, genetic variety, that is, single-nucleotide polymorphisms in the gene coding for VEGF-A, is associated with eye diseases like neovascular age-related macular degeneration and diabetic retinopathy.

VEGF-C and VEGF-D

VEGF-C and VEGF-D are the main growth factors for lymphangiogenesis and both mediate their function by binding to receptors VEGFR-2 and VEGFR-3, present on endothelial cells. VEGF-C stimulates migration of cultured endothelial cells *in vitro* and increases – in its fully processed form – vascular permeability, migration, and proliferation of endothelial cells. Recently, the decisive role for VEGF-C during lymphangiogenic development was demonstrated in a study where homozygote as well as heterozygote VEGF-C-lacking mice were shown to have severe defects in the formation of lymphatic vessels. A study undertaken to analyze VEGF-C and its role in corneal neovascularization suggests VEGF-C to induce corneal lymphangiogenesis by binding to its cognate receptor VEGFR3 on lymphatic vessels in the conjunctiva. Inflammatory cells invading the cornea were identified as the main source of VEGF-C that was strongly upregulated 3 days following the injury. Besides its role as classic lymphangiogenic growth factor, VEGF-C was reported to induce angiogenesis *in vivo*. VEGF-D also can act as a potent angiogenic factor, controlled by the nuclear oncogene c-fos and thus playing an important role in tumor invasion and tumor cell growth.

Basic fibroblast growth factor

Another important pro-angiogenic molecule – the basic fibroblast growth factor (bFGF/ FGF-2) – belongs to the FGF family. bFGF and acidic FGF (aFGF) expression has been demonstrated immunohistochemically in the outer retina of rat and mouse. bFGF was analyzed in several corneal neovascularization models and was recently demonstrated to induce angiogenesis as well as lymphangiogenesis *in vivo* in a mouse model corneal micropocket assay. Lymphangiogenesis was mediated by bFGF in an indirect way via VEGFR3 and was suppressed after inhibition of VEGFR3 signaling with anti-VEGFR3 antibodies.

Both factors, bFGF and aFGF, were detectable in retinal pigment epithelial cells from choroidal neovascular membranes from human subjects with age-related macular degeneration (AMD), whereas there was only little immunoreactivity for the growth factors in retinal pigmented epithelial (RPE) cells from healthy eyes. This suggests an important role for aFGF and bFGF in the development of choroidal neovascularization. bFGF might play an indirect role in initiation of neovascularization and interacts with the VEGF signal-transduction pathways. This is supported by the fact that bFGF was found to be colocalized with VEGF in cells of epiretinal and choroidal neovascular membranes, suggesting that more than one growth factor may contribute to pathological angiogenesis. In favor for that theory is that mice with a disruption of the bFGF-coding gene can still develop choroidal neovascularization.

Recently, bFGF was thought to take a role in progression and survival of retinoblastoma, a tumor producing significant amounts of bFGF. The differential production and response to isoforms of bFGF reveal bFGF as a growth factor influencing pathogenesis and chemoresistence of retinoblastoma.

Inhibitory PAS (Per/Arnt/Sim) domain protein

As mentioned earlier, the upregulation of angiogenic molecules like VEGF-A and angiopoietin-4 (Ang-4)

during hypoxia is mediated by hypoxia-inducible transcription factor-1 (HIF-1) and can induce an angiogenic response. Interestingly, hypoxic conditions in the cornea appearing, for example, during overnight closure of the eye, do not induce corneal neovascularization, indicating the presence of factors suppressing hypoxia-induced angiogenesis. However, prolonged contact lens use has been associated with corneal angiogenesis and hypoxia has been implicated in this process. IPAS, a basic helix–loop–helix (bHLH)/PAS protein, expressed in mouse corneal epithelium, was suggested as a negative regulator of HIF-mediated control of gene expression: only low levels of IPAS mRNA were detectable in primary cultures of mouse corneal cells under normoxic conditions, whereas under hypoxic conditions IPAS mRNA expression was upregulated. Following transfection of primary corneal cells with an IPAS antisense vector, VEGF mRNA expression – under normoxic and hypoxic conditions – was upregulated. Furthermore, *in vivo* experiments with mouse corneas containing pellets with IPAS antisense oligonucleotides showed a significantly induced neovascularization compared to the eyes treated with the IPAS sense oligonucleotide.

Cornea and Corneal Epithelium

Consistent with the assumption of a redundantly organized angiogenic privilege, numerous endogenous anti-angiogenic factors in the cornea are described to be implicated in the regulation of angiogenesis.

Years ago, the corneal epithelium itself was found to have angiogenic activity. In 1978, Eliason reported data from an *in vivo* system suggesting corneal epithelium as a source for an unknown vasostimulating substance. *In vitro* experiments from Eliason and Elliott also showed a stimulating effect of corneal epithelial homogenate and epithelial-conditioned medium on the proliferation of cultured rabbit vascular endothelial cells. Recent research attributes corneal epithelium an anti-angiogenic function: an intact corneal epithelium can suppress inflammation and corneal neovascularization in the graft following orthotopic transplantation in mice. Secondly, mice with de-epithelialized corneas have significantly increased recruitment of CD45+ inflammatory cells and an increased neovascular response compared to mice with an intact epithelium. One potent mechanism for an anti-angiogenic function of corneal epithelium is the ectopic constitutive expression of VEGFR-3 on normal human corneal epithelial cells. VEGFR-3 can act as a decoy receptor to bind VEGF-C, thus functioning as a sink for the angiogenic molecules and inhibiting inflammation induced corneal hemangiogenesis and lymphangiogenesis. A similar task fulfils the soluble form of VEGFR-1 – expressed in the cornea – where it can neutralize VEGF-A.

Limbal Barrier Function

The border between sclera/conjunctiva and the transparent cornea, the limbus, is of great importance for angiogenesis: the loops and arcades of conjunctival capillaries as well as the lymphatic capillaries end in the limbal region. Corneal neovascularization, however, arises in the limbal area from preexisting pericorneal vessels (hemangiogenesis as well as lymphangiogenesis).

Stem cells, required for corneal epithelial cell proliferation and differentiation, are located in the basal epithelium at the corneoscleral limbus. They were described to act as a barrier between conjunctival and corneal epithelium and as important for corneal wound healing. In normal situations, the limbal stem cells prevent conjunctival epithelial cells from migrating to the ocular surface thereby inhibiting corneal neovascularization. This limbal-barrier concept may contribute to the maintenance of the angiogenic privilege. The theory is supported by the observation of conjunctivalization of the corneal surface with subsequent vascularization in situations of loss or malfunction of the stem cells.

Angiogenic Privilege and Immune Privilege

Ingrowth of blood and lymphatic vessels into the cornea is incompatible with good vision. Visual acuity is impaired not only by vascularization itself, but also by secondary changes such as lipid keratopathy, corneal edema, or bleeding into the cornea, thereby reducing corneal clarity and transparency. As mentioned earlier, actively maintaining the avascularity even under inflammatory or other angiogenic conditions is ensured by the angiogenic privilege. It contributes, at least partly, to the occurrence of the prolonged graft survival of corneal allografts, called the immune privilege of the eye. The phenomenon of the immune-privileged site was first proposed by Medawar, in 1948, and has built a foundation for numerous research. Nowadays, ocular immune privilege is commonly seen as the fact that vulnerable organs or tissues are protected from pathogens without an immunogenic inflammation that would permanently damage those tissues and/or would lead to a loss of specialized functions.

An immune response after transplantation in so-called low-risk eyes can only be noticed in around 10%, although under normal circumstances there is no HLA matching and only a topical, but no systemic, immunosuppression. In contrast, immune reactions in high-risk eyes with preceding corneal inflammation or neovascularization occur in over 50%. The pathologically vascularized recipient bed prior to corneal transplantation (i.e., penetrating keratoplasty), therefore, lowers the outcome of corneal transplantation and is an important risk factor for subsequent immune reactions.

Immune responses are primarily mediated by corneal lymphatic vessels which form the afferent arc of the immune response. Via the lymphatic vessels invading antigen-presenting cells (APCs; dendritic cells from the graft or host) and antigenic material from the graft can be transported via conjunctival lymph vessels to the regional lymph nodes. The draining cervical lymph nodes were shown to be critically involved in promoting alloimmunity and allograft rejection. Following surgical removal of the cervical lymph nodes and following orthotopic corneal transplantation of fully mismatched high-risk allografts, over 90% of the hosts accepted the allograft.

The importance of the lymphatic vessels, being the afferent arc of the immune response, offers new therapeutic opportunities for improving graft survival. Interfering with this pathway might restore the immune privileged status of the eye and ensures prolonged graft survival in low- and high-risk eyes. Early studies have shown that induction of donor-specific anterior chamber-associated immune deviation (ACAID) – manifestation of the ocular immune-privilege induced prolonged graft survival in high-risk eyes of C57BL/6 mice. Recently, it was shown that Integrin a5-blockade could significantly block the outgrowth of lymphatic vessels in the cornea. The angiostatic drug bevacizumab, a recombinant humanized monoclonal antibody against VEGF-A, inhibits corneal hemangiogenesis and lymphangiogenesis *in vitro* and *in vivo*. Furthermore, inhibition of corneal hemangiogenesis and lymphangiogenesis by a molecular VEGF-A trap leads to improved long-term graft survival. In addition to the inhibition of inflammatory lymphangiogenesis, alternative strategies like induction of regression of established lymphatic vessels in prevascularized corneas and influencing the recruitment of APCs could be possible methods for corneal anti-lymphangiogenic treatment. Recently, it was shown that even hemangiogenesis and lymphangiogenesis occurring following transplantation increase the risk for graft rejection after high-risk corneal transplantation.

Cone Photoreceptor Cells: Soma and Synapse

R G Smith, University of Pennsylvania, Philadelphia, PA, USA

Glossary

Cascade – A sequence of biochemical reactions that process a neural signal.
Connexin – A molecule comprising a gap junction that sits in a neuron's membrane and can join with a connexin from another neuron to create a large nonspecific pore that conducts ions and small molecules.
Ephaptic – Electrical conduction across a synapse between neurons without the mediation of a neurotransmitter.
Henle fiber – The long axon of a foveal cone that extends laterally to terminate outside of the fovea.
Invagination – A permanent infolding of a cell's external membrane, associated in photoreceptors with their synaptic ribbons, and containing fine dendritic processes of bipolar and horizontal cells.
Invert – In a postsynaptic cascade, to convert a rising signal into a falling signal.
Low-pass filter – A filter that removes high frequencies and passes low frequencies.
Mesopic – The 3-log unit range of background illuminance in which rod and cone signals temporally sum in cones and the cone bipolar pathway.
Microtubule – A small tubule composed of the protein tubulin, often found as arrays in neural axons, involved in transport of cellular components.
Pedicle – The cone terminal, with a foot-like flat base, which contains synaptic ribbons.
Ribbon – A presynaptic structure that collects vesicles of neurotransmitter for release.
Telodendria – Fine axonal processes extending laterally from the base of the cone terminal, which contact neighboring rod and cone terminals.
Triad – A synapse in the cone terminal that contacts dendritic processes of two horizontal cells and a bipolar cell.

Introduction

The cone photoreceptor is responsible for vision in daylight and provides color vision for most vertebrates. The cone is specialized to compress the large range of environmental illumination into a neural signal that can be processed by bipolar and ganglion cells in the retina and passed to the brain. The cone soma and synapse support this compression by several mechanisms located in its biophysical properties and at its ribbon synapse. In addition, cones perform spatial filtering because their terminals are electrically coupled to their neighbors and to the surrounding rods through gap junctions.

Structure

Morphology and Topology

The cone is a specialized neuron consisting of an outer segment, inner segment and soma, axon, and axon terminal (Figure 1). The biochemical pathways responsible for transducing light into an electrical signal are contained in the outer segment. The electrical signal passes to the inner segment where it is processed by voltage-gated channels. The inner segment is contiguous with the soma but they lie in distinct retinal layers separated by the external limiting membrane. The cone soma lies in the upper row of the outer nuclear layer. For most mammalian cones, the soma is larger in diameter (~5 μm) than the outer segment. It contains the nucleus which holds the cell's DNA, necessary for development and to maintain the cell's biochemical machinery. Many mammalian species have ~20-fold more rods than cones, so the remainder of the outer nuclear layer consists of several layers of rod somas. Cones of most species (and outside the fovea in primate) are spaced semirandomly with a nearest-neighbor distance that varies from ~5 μm in central retina or the visual streak (e.g., cat, rabbit, and guinea pig) to ~15 μm in peripheral retina, and are surrounded by rods.

Axon and Terminal

The cone axon carries the electrical signal from the soma to the axon terminal. The axon varies in length depending on the species and eccentricity (distance from central retina) of the photoreceptor. In foveal cones near the center of the primate eye, cone axons extend up to 400–600 μm laterally to allow the outer segments to be packed tightly together in the foveal pit and the axon terminals to be given adequate space outside the fovea to make their synaptic connections with other neurons. These long axons are termed Henle fibers, and the layer containing the horizontally projecting axon fibers is termed Henle's layer. In other mammals, the cone axon

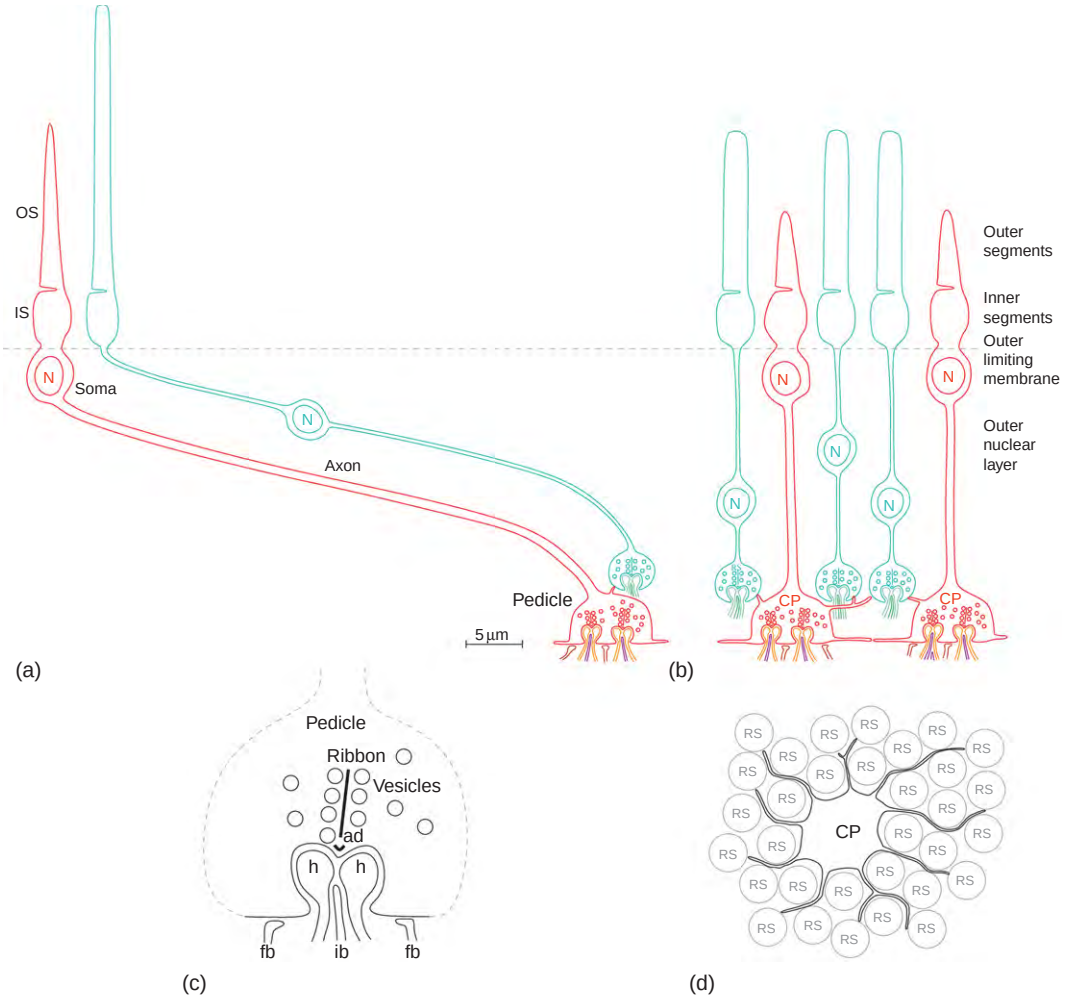

Figure 1 Morphology and topology of the cone. (a) Primate cone with its outer segment in parafovea, showing the lateral extension of the axon which allows the axon terminal sufficient space to make its synaptic connections. A few rods (gray) exist in the parafovea and their axons also extend laterally. Primate foveal cones extend farther, up to 600 µm. (b) In most mammals and in distal primate retina, cones extend vertically interspersed between rods (gray). The cone pedicles are interconnected by gap junctions between basal processes. (c) The cone ribbon synapse sits at the apex of an invagination into the basal surface of the cone pedicle. Attached to the ribbon are two rows of vesicles that contain glutamate. The vesicles are released at the active zone near the arciform density (ad). Two horizontal cell processes (h) and one or more invaginating ON bipolar cell dendrites (ib) extend into the pedicle to receive glutamate from vesicles released from the ribbon. Flat OFF bipolar cell dendrites (fb) contact the cone pedicle outside the invagination, and are thought to receive glutamate that diffuses from several nearby ribbons. (d) Tangential view of a cone pedicle (CP) surrounded by rod spherules (RS, gray). Telodendria extend from each cone pedicle to contact all the surrounding rods and cones with gap junctions.

extends vertically: in cat, the cone axon typically extends ~50 µm in the outer nuclear layer traversing 6–10 layers of rod somas, and in guinea pig, the axon is shorter, typically 10–25 µm. Typically, cone axons are 1–2 µm in diameter, interspersed between rod somas (35 µm dia.) and rod axons (0.4 µm dia.). The fourfold greater diameter of cone axons suggests a functional interpretation, because space in the outer nuclear layer is limited. One possibility is that the faster cone response might require a larger diameter in a long axon to transmit the cone's higher frequency response. This was tested with a computational model, and a thin diameter in a long axon was found sufficient, also consistent with the maintenance of the difference in diameter between cone and rod axons even where they are shorter. Another possibility is related to the axon terminal: the cone terminal has ~20-fold more synaptic contacts than the rod, and its cross-sectional area is ~16-fold greater. Both rod and cone axons are filled with microtubules, which are essential for transporting synaptic proteins from the nucleus, so the larger diameter of the cone axon may be a consequence of its need to perform more synaptic maintenance. The cone axon terminal is typically ~5 µm in diameter, and is flat on its basal surface (toward the ganglion cells); hence, it looks

like a foot and is commonly called a pedicle. The pedicles of adjacent cones align to form a flat plane which lies near the upper edge of the outer plexiform layer.

Synapse

The cone makes chemical synaptic contacts onto ~10 types of bipolar cell and two types of horizontal cell (HA and HB in cat and rabbit; H1and H2 in primate) at its axon terminal. The synapse releases glutamate via packets of membrane called synaptic vesicles, which are small (~30–50 nm) organelles created by endocytosis from the cell's external membrane. The vesicles diffuse freely around the cytoplasm while they are being filled with glutamate by transporters. The presynaptic machinery in the terminal contains several dense structures known as ribbons because in cross section they are thin and extend vertically away from the cell's membrane. The active zone, where vesicles are released from the ribbon onto the external membrane, is defined by a trough-shaped band called the arciform density, which contains structural proteins for anchoring the ribbon to the cell membrane and the calcium channels responsible for triggering release. The ribbon allows high continuous release rates, for it collects several rows of vesicles and tethers them for release, to provide a larger readily releasable pool. The mechanism for vesicle release is complex, containing several dozen proteins, and its details are not yet understood, but it is initiated by calcium ions binding to a receptor protein which causes a vesicle to fuse with the external membrane and release its contents into extracellular space. To fuse with the external membrane, the vesicle must be docked near membrane calcium channels at the base of the ribbon. However, there is some evidence for compound fusion, where vesicles fuse with and release into nearby docked vesicles. After release, the vesicle membrane is recycled with a specialized mechanism involving the protein clathrin which coats an invaginating bit of external membrane with a buckyball-type structure and pinches it off as a cytoplasmic vesicle.

Invagination and Triad

The cone's ribbon synapse is located at the apex of an extension of extracellular space into the bottom surface of the cone terminal, called an invagination, where fine processes of horizontal and bipolar cells extend to form postsynaptic specializations. Each invagination holds two horizontal cell dendritic processes which emanate from different horizontal cells, and one fine dendritic process of an ON bipolar cell. The horizontal cell processes swell up inside the invagination on either side of the bipolar dendrite. Together, the ribbon and postsynaptic processes are called 'a triad'. The function of the invagination is unknown but it has been suggested to limit diffusion of the neurotransmitter released by the cone or by horizontal cells for negative feedback. The cone terminal contains 20–50 ribbons, each in a separate invagination, so there are several dozen triads. Off-bipolar cells also contact the cone terminal. Some with alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors invaginate the cone near the ON bipolar process, and others with kainate receptors contact the base of the pedicle at the so-called flat or basal contacts which lack associated presynaptic vesicles. The flat contacts are located in the space between the invaginations, allowing them to sense the release from several ribbons.

Biophysical Properties

The inner segment and axon terminal of photoreceptors contain several membrane-bound ion channels, including K_v, K_{Cn}, BK, and L-type Ca^{2+}. The K_v channels of the inner segment are activated by depolarization, providing an outward current to balance the inward dark current through the light-modulated cyclic guanosine monophosphate (cGMP)-gated channels of the outer segment. These K^+ channels provide an adaptational influence, opposing the dark signal, and indirectly opposing the light signal by deactivating with hyperpolarization. The K_{Cn} channels, underlying the I_h current, provide a delayed depolarization when activated by hyperpolarization, and calcium-activated potassium channels (BK) help to maintain the resting potential near −40 mV. These are adaptational effects that tend to limit the hyperpolarization from bright light and depolarization in the dark. The cone terminal's L-type Ca^{2+} channels ($Ca_v1.4$) uniquely include alpha 1D subunits and may have special gating properties. In addition, the terminal contains a calcium-activated chloride current ($I_{Cl(Ca)}$) and calcium-induced calcium release (CICR). Calcium is highly regulated in the terminal, with internal buffering and plasma membrane transporters (protein misfolding cyclic amplifications (PMCAs)), because calcium is the trigger for vesicle release. Calcium is highly compartmentalized at the terminal because calcium in the outer and inner segments and soma performs other cellular functions. In the terminal, ryanodine receptors and IP_3 receptors modulate calcium release from internal stores. Voltage-gated sodium channels have been identified in primate cones, possibly to help amplify the cone signal along its axon. The cone terminal contains several transporters with special functions. A proton pump in the vesicles acidifies them so that protons are released along with the glutamate. The protons bind to the local calcium channels to block calcium entry, and thus regulate release. Several transporter proteins carry glutamate, including at least two isoforms that are inserted into the membrane of vesicles to load them with glutamate. A glutamate transporter sitting in the external membrane of the pedicle is important for uptake

of glutamate from the extracellular space. The light response of postsynaptic cells depends on a reduction in glutamate, but when the transporter is blocked pharmacologically the postsynaptic light response is greatly reduced. This implies that the triad synapse is protected to some extent against diffusion by the cone pedicle's invagination.

Gap Junctions

Cone axon terminals are coupled by gap junctions which carry electrical signals and small molecules directly from each cone to its neighbors. Each gap junction comprises connexin molecules which can form a conductive pore when they are aligned in the membrane of both coupled neurons. The gap junctions are located on telodendria which are basal processes that emanate from the cone terminals to make contact with the neighbors. The cone gap junctions are punctate, that is, they comprise just a few connexin molecules. The connexin has been identified as Cx36. In addition, a cone's telodendria contact all the surrounding rods with punctate gap junctions. The cone side of the rod-cone gap junction also comprises Cx36, but the identity of the rod-specific connexin molecule is not known. In foveal cones, because their terminals are all located outside the fovea, some of the telodendria extend several hundred micrometers around the perimeter of the fovea to make contact with the neighboring cones, whose axons have extended in the opposite direction from central fovea.

Morphological Implications of Spectral Sensitivity

The cones of most vertebrates exist in several types that differ in their spectral sensitivity. Until recently, it was difficult to distinguish cone spectral type based on morphology, but antibodies are now available to specifically stain the outer segments by spectral type. Direct imaging is now able to routinely determine the spectral type. The inner segments of birds and some species of reptiles and mammals contain oil droplets which filter out some wavelengths, to narrow the outer segment's sensitivity and improve the ability for color discrimination. The primate S-cone, sensitive to short wavelengths, is smaller and its terminal makes fewer contacts, so it is distinguishable from middle (M)- and long (L)-wavelength-sensitive cones. In addition, the M- and L-type cones can be distinguished by the number and location of their synaptic connections with bipolar cells. The M- and L-cones are electrically coupled by gap junctions, which blur their spectral sensitivity. The coupling is a reasonable compromise because the coupling increases their contrast sensitivity and the spectral blurring effect is moderate due to the similarity of the M- and L-type spectral sensitivities. The M- and L-type cones are located randomly in bunches of similar type, which along with the indiscriminate coupling may improve contrast sensitivity without causing much blurring of color. The S-type cone is not coupled strongly to its M- and L-type neighbors, apparently because its spectral sensitivity is farther from the M- and L-type curves.

Function

Adaptation and Predictive Coding

The role of the cone photoreceptor in daylight is crucial because it is the first step in the visual pathway. The cone's task is to transduce and relay information in the visual environment relevant to an organism's survival. A major problem faced by the cone is that daylight varies over 5 log units, but a synaptic signal is only able to vary only over 1–2 log units. The problem is one of dynamic range and also of noise because dynamic range limits the maximum signal, and noise limits the minimum discriminable signal. The amount of information available is related to the maximum signal divided by the minimum, that is, the number of distinguishable levels. Since cone transduction is noisy and the ribbon synapse is also noisy, to maximize the amount of information the cone must remove all irrelevant information and selectively transmit the most important signal components with high sensitivity. One way the cone deals with this problem is by removing information about the background level by adaptation. This is accomplished first in the outer segment. In addition, the cone has several more adaptational mechanisms: modulation of the light-evoked signal by voltage-gated channels in the inner segment and terminal, gain reduction at the ribbon synapse, and regulation of its neurotransmitter release by negative feedback. To preserve information about fine temporal detail, the adaptational mechanisms must be slow, and to preserve spatial detail, the adaptational mechanisms must be wide. The theory for such adaptational mechanisms is called predictive coding, in which a temporally slow or spatially wide average signal is subtracted from a photoreceptor. Thus, the cone ribbon synapse carries a signal that is optimally adapted in time and also in space.

Synaptic Transfer Function

Upon depolarization, the ribbon synapse releases glutamate with a nonlinear transfer function, which is controlled by the voltage sensitivity of the L-type calcium channel. The mechanism for release is linearly modulated by calcium because glutamate release is proportional to the terminal's local calcium concentration. Release is maximal in the dark when the cone is depolarized, and minimal in bright light when the cone is hyperpolarized

(Figure 2). Due to the nonlinear release function, the synaptic gain for small light increments is also maximal in the dark, and minimal in the light. Thus, the synaptic gain is adaptive, that is, it tends to oppose the light-evoked signal and reduce contrast gain in bright light. Negative feedback tends to oppose this effect, that is, it reduces the change in synaptic gain due to a change in background level. Glutamate released by the cone binds to the postsynaptic metabotropic glutamate receptor 6 (mGluR6) receptor to activate a second-messenger cascade which inverts and low-pass filters the signal in the bipolar cell. Glutamate also diffuses out of the invagination to bind to kainate receptors at the tips of off-bipolar cells.

Rate of Vesicle Release

A major source of noise for the cone signal is the random release of vesicles by the ribbon. Although the details of the release mechanism are not known, it is thought to be stochastic (noisy), similar to a modulated Poisson distribution, for which the standard deviation is equal to the square root of the mean. There is also some evidence for more regular release. Protons released along with the vesicle's packet of glutamate bind to the local calcium channels which may generate a short refractory period, allowing release to be more regular. The cone synapse is thought to release vesicles at 100–200 s^{-1} per active zone in the dark, but in bright sunlight the rate is reduced to $<10\,s^{-1}$ per active zone. The ability of a ribbon synapse to transmit information about contrast, even with a high release rate, is extremely limited: at a Poisson rate of 200 ves s^{-1}, contrast threshold for a 100 ms response would be ~0.2. Therefore to increase sensitivity, several ribbons transmit the same cone signal in parallel. With 20 ribbons, the total release rate is $\sim 2000\,s^{-1}$, for which the contrast threshold would be 0.07. Each bipolar cell contacts several (4–8) ribbons per cone, and bipolar cells (except foveal midget bipolars) normally contact several (4–6) cones, so a bipolar cell integrates signals from one to several dozen cone ribbons.

Electrical Coupling

The gap junctions between cone terminals function as a spatial filter, averaging cone signals to remove noise, and removing high spatial frequencies. The effect is to enlarge the cone receptive field beyond the effect of optical blur. Adjacent L- and M-cones in primate are electrically coupled by gap junctions, which blur to some extent their ability to support color discrimination, implying that their action to reduce noise provides a benefit to luminance contrast discrimination. S-cones are uncoupled to the other types, probably because their spectral sensitivity is so different that it would suffer out of proportion to the potential increase in contrast sensitivity. Cone coupling is paradoxical to some extent because in a linear system which collects cone signals, for example, convergence to a large ganglion cell's dendritic tree, gap junctions would

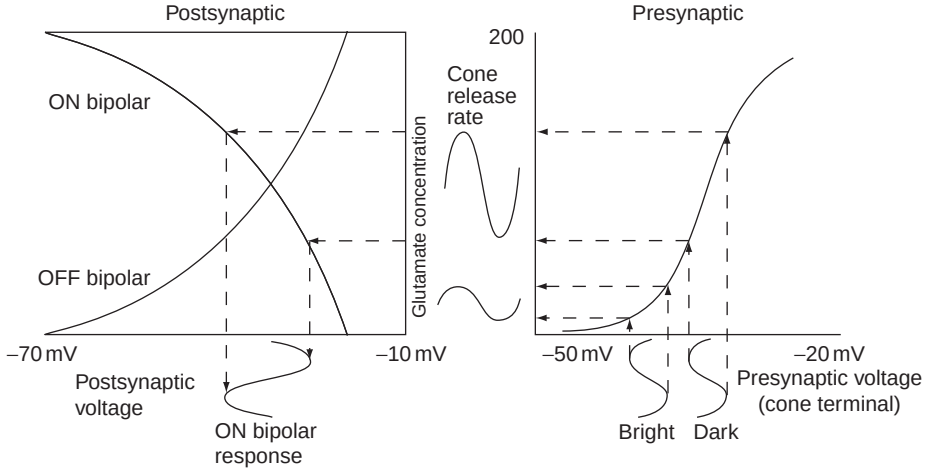

Figure 2 Transfer function of cone ribbon synapse. At right, presynaptic ribbon release function, showing two signals in the cone terminal, one more hyperpolarized (bright), and the other more depolarized (dark). The brighter signal releases less glutamate and has lower release gain because the release function is nonlinear. The fraction of modulated release is higher for the hyperpolarized (bright) signal than for the depolarized (dark) signal because the maintained release rate is lower in bright light. However, the system must compromise to set a relatively high release rate. At left, the postsynaptic transfer function from glutamate binding to voltage in the ON bipolar response is inverted. For the relatively high release of the dark signal, the ON and OFF bipolar responses are similar in amplitude and degree of saturation. The presynaptic release rate must be maintained relatively high to keep the postsynaptic signals symmetrical; if the release rate were lower, the OFF bipolar signal would decrease and the ON bipolar signal would saturate. Negative feedback maintains the cone ribbons' relatively high maintained release rate to optimize the signal/noise ratio in both ON and OFF bipolar cells.

provide no benefit. However, the cones apparently benefit from the reduction of noise before their signal passes through the ribbon synapse which is to some extent nonlinear. The gap junctions coupling a cone to its neighboring rods allow rod signals at mesopic backgrounds, where a rod temporally sums several photon signals, to pass to cones to be transmitted through the cone pathway to ganglion cells. Since cones are 30–100-fold less sensitive than rods, this rod–cone coupling represents a form of adaptation for the cone pathway.

Negative Feedback

Adaptation from spatially pooled horizontal cell feedback at the cone triad is important for retinal signal processing. Glutamate released by the cone ribbon synapse binds to AMPA receptors on the horizontal cell dendrite to depolarize it, and in turn the horizontal cell provides negative feedback to control the release of glutamate by the cone. The negative feedback contributes to an antagonistic surround in bipolar cells and in all other postsynaptic neurons. In some species (e.g., turtles, fish, and putatively in some mammals), horizontal cells receive spectrally specific signals from cones and therefore their negative feedback contributes to cone color opponency. The mechanism for the negative feedback from horizontal cells is not known but several candidates are currently being studied. Horizontal cells synthesize γ-aminobutyric acid (GABA) and release it through a transporter working in reverse, and in some species (e.g., turtle, fish, salamander, and frog), GABAergic feedback has been found in the cone terminal. Horizontal cells also generate a feed-forward surround signal in both on- and off-bipolar cells, which have $GABA_A$ receptors in their dendrites. The effect is to generate a stronger surround signal in the bipolar cell, allowing it to more tightly control its release of neurotransmitter. However, standard GABA-receptor blockers do not affect the surround in most species. Some evidence suggests that feedback may be provided through release of protons in the invagination, because when pH buffers, such as 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) are applied via the perfusion bath *in vitro*, they block horizontal cell feedback proportionate to their buffering capacity. A third possibility is that the feedback is ephaptic (electrical). The pH and ephaptic theories describe a feedback signal that directly modulates the cone terminal's calcium current. One benefit of all these putative feedback mechanisms is their freedom from noise that would occur with vesicular release. Feedback is necessary to control neurotransmitter release, but it has one problem, that if too strong it can cause instability from delays in the feedback loop. Oscillations can be evoked by flashed full-field stimuli with a dark mask over the horizontal cell recording site. The dark depolarizes the cone, increasing gain in the feedback loop, which tends to generate oscillations. Other adaptational mechanisms such as K^+ channels can generate similar resonances related to the delay in their response.

Theory of Ephaptic Feedback

The proposed ephaptic feedback modulates the cone pedicle's calcium channels by controlling the polarization of the external surface of the membrane inside the invagination. When a horizontal cell is hyperpolarized by a remote light (i.e., without modulating local glutamate release), the current that flows from extracellular space into its dendritic tips is increased. The increase in current causes a voltage drop inside the invagination, which shifts the voltage at the external membrane surface more negative. As both surfaces of the membrane have been shifted negative, the calcium channel senses a depolarization (lack of polarization) and thus opens further, which opposes the original light signal. The opposite effect occurs when a cone terminal is hyperpolarized by light but the horizontal cell is not. Light reduces glutamate release, which closes the horizontal cell's glutamate-gated (AMPA) channels, decreasing the current flow into the dendritic tip, which shifts the external cone membrane more positive, causing the calcium channel to sense a greater hyperpolarization, which comprises net positive feedback. However, the horizontal cell dendritic tips contain hemichannel gap junctions (connexins) which are not gated by glutamate but shunt the glutamate-gated channels. Their effect is to reduce positive feedback and to enhance negative feedback. One potential problem for the theory is that the hemichannels reduce the light response, and because their conductance is less than the AMPA receptor channels one imagines they should not cause a robust effect. However, the theory is supported by strong evidence, for example, the hemichannels can be blocked by carbenoxolone which reduces the negative feedback, and the same result occurs in knockout animals in which the hemichannels are removed. The relative magnitude of the positive and negative ephaptic feedback effects depend on several factors, including the conductances and the location of the underlying channels. The amount of voltage drop at the external membrane surface depends on the geometry of the current path through extracellular space in the invagination. A robust feedback signal, for example, the typical 5–10 mV shift seen in the calcium current in the cone pedicle, would require a relatively high resistance, and therefore the mechanism is currently controversial. Although the ephaptic theory has not generally been accepted by the field, it can explain

some of the phenomena given as evidence for pH feedback. HEPES buffer is known to acidify neurons, and hemichannels are known to be modulated by internal pH, which is consistent with the well-known effect of HEPES to block the cone surround. An advantage of ephaptic feedback is its short delay, reducing the tendency for instability. A further merit to the ephaptic theory is that it provides a functional role for the invagination, to generate the extracellular voltage shift. Putatively, then, the invagination creates a specialized local environment for the triad synapse, to limit chemical and/or electrical diffusion.

Bandpass Adaptation Filter

The cone terminal comprises a spatiotemporal filter consisting of a low-pass filter from electrical coupling between cones, and a high-pass filter from horizontal cell negative feedback. The signal in horizontal cells is low pass in space because they are large and well coupled: their receptive fields can be ~10-fold larger than their dendritic field. The feedback signal in some species has two components, the faster (pH or ephaptic) modulation of the calcium current, and a slower GABAergic component. Therefore, the horizontal cell signal, when it modulates the cone synaptic release, can be characterized as a subtraction of a low-pass filter, effectively making the cone synapse a high-pass filter. The overall effect of electrical coupling and negative feedback is to generate a band-pass filter at the cone terminal. The filter removes spatial and temporal frequencies that transmit less information, improving the performance of the visual pathway which utilizes noisy synapses for transmission.

Conclusion

The cone photoreceptor plays a crucial role in vertebrate vision because it is responsible for transducing fast changes in contrast while ignoring the background light level. To improve its sensitivity over 5 log units of background illumination, the cone contains several mechanisms for adaptation, originating in the transduction cascade, in its biophysical properties, and in the ribbon synapse. The ribbon is part of a complex local circuit called the triad that combines adaptation with spatial filtering. The triad maximizes the amount of information that can be transmitted through noisy synapses over a wide range of environmental light levels.

Congenital Cranial Dysinnervation Disorders

T M Bosley, D T Oystreck and K K Abu-Amero, Ophthalmology Department, King Saud University, Riyadh, Saudi Arabia

Glossary

ABDS (Athabascan brainstem dysgenesis syndrome) – A syndrome found in American Indians that is also caused by homozygous *HOXA1* mutations, but usually with more severe symptoms than BSAS, including primary hypoventilation in childhood, cerebral cortical ischemic injury, and mental retardation.

BSAS (Bosley–Salih–Alorainy syndrome) – An autosomal recessive syndrome including variable bilateral DRS type 3 (sometimes with complete horizontal gaze restriction bilaterally), deafness due to absence of the hearing apparatus in the petrous bones, cerebrovascular and cardiac malformations, and autism, caused by homozygous mutations in *HOXA1*.

CFEOM (congenital fibrosis of the extraocular muscles) – A group of congenital, nonprogressive strabismus disorders that may be sporadic, familial, or teratogenic.

CFEOM1 – An autosomal dominant congenital bilateral ptosis with globes infraducted bilaterally and unable to elevate even to primary gaze; in general, ocular motility is restricted bilaterally in an asymmetric fashion in all directions; sometimes associated with DRS; caused by heterozygous mutations in *KIF21A*.

CFEOM2 – An autosomal recessive congenital bilateral ptosis with a large exotropia and complete inability to adduct, elevate, or depress either globe, often with partial restriction of abduction bilaterally as well; associated with unreactive pupils; caused by homozygous mutations in *PHOX2A*.

CFEOM3 – An autosomal recessive congenital bilateral ptosis and asymmetrically restricted ocular motility similar to CFEOM1, but in general less severe so that globes can be elevated to primary position; associated with heterozygous mutations in *KIF21A*, a locus at 16q24.2–q24.3, and other heterozygous mutations.

DRRS (Duane radial ray syndrome) – Also known as Okihiro syndrome, this is an autosomal dominant syndrome marked by DRS together with forearm and hand anomalies and variable expression of cardiac, renal, hearing, and vertebral anomalies; caused by heterozygous mutations in *SALL4*.

DRS (Duane retraction syndrome) – A congenital horizontal ocular motility disturbance, usually unilateral but occasionally bilateral, defined largely by the presence of retraction of the globe and narrowing of the palpebral fissure on adduction; usually described as types 1, 2, and 3; most often sporadic but familial in 5–10%.

HGPPS (Horizontal gaze palsy and progressive scoliosis) – An autosomal recessive disorder marked by congenital absent or almost absent horizontal gaze (not caused by DRS) and severe, progressive scoliosis typically beginning in early childhood; caused by homozygous mutations in *ROBO3*.

Moebius syndrome – A congenital neurologic disorder marked by unilateral or bilateral facial weakness, often with horizontal ocular motility restriction, usually in abduction.

Introduction

Early Concepts and Nomenclature

The concept of congenital fibrosis of the extraocular muscles (CFEOM) was created to include strabismus disorders that were congenital and nonprogressive with active limitation and/or passive restriction of globe movement. These disorders were commonly associated with fibrous changes in extraocular muscles that were obvious to ophthalmologic surgeons trying to correct the strabismus that was frequently associated. The most common CFEOM pattern was a horizontal retraction syndrome (now typically called Duane retraction syndrome (DRS)) involving the medial and/or lateral recti muscles. Pediatric ophthalmologists knew for years that extraocular muscles of patients with DRS were frequently tight and fibrotic, sometimes with posterior insertions into the globe or anomalous fibrous bands to the globe and other orbital structures. These observations led to the concept that many individuals with congenital ocular motility disorders suffered from an abnormality in the development of extraocular muscles. Thus, the original CFEOM concept focused on abnormal muscle development.

Many CFEOM problems seemed sporadic, but others were clearly familial. CFEOM was initially categorized into

five groups based on the putative muscles involved: (1) typical and atypical horizontal retraction syndrome (presumably involving medial and/or lateral recti, now commonly called DRS), (2) strabismus fixus (involving medial and/or lateral recti), (3) vertical retraction syndromes (involving superior and/or inferior recti), (4) superior oblique tendon sheath syndromes (possibly involving inferior and superior oblique muscles, now commonly called Brown syndrome), and (5) general fibrosis syndromes (involving three or more of the extraocular muscles). Defined broadly, the concept of the congenital fibrosis syndromes includes CFEOM, Duane syndrome, Moebius syndrome, and certain other sporadic and hereditary disorders of ocular motility.

It is now well recognized that some of these syndromes affect muscles and somatic structures not directly related to vision. Perhaps the best recognized of these is the Moebius syndrome, which has been defined in a variety of ways, but which is now typically recognized as the association of unilateral or bilateral facial weakness with horizontal gaze restriction, commonly with at least an abduction defect.

In addition, it became clear after hundreds of publications, that other, less common, sometimes familial, congenital ocular motility disturbances also existed. These were particularly vexing problems, clinically because of technical difficulties dealing with ptosis and fibrotic muscles, and theoretically because of enormous variability from patient to patient. At times, CFEOM was also found in association with deformities of the limbs (including limb hypoplasia, polydactyly, hypoplastic or absent radius and thumb, and other anomalies), skull hypoplasia and asymmetry, cleft palate, Klippel–Feil anomaly, scoliosis, spina bifida, and anomalies of the vertebra, ribs, and scapulae. Associations were also described with nystagmus, ptosis, microphthalmos, colobomas, iris heterochromia, congenital cataracts, congenital ear anomalies, and sensorineural deafness. Clearly, this was a complex field, and initially, only descriptive, phenotypic reports were possible.

Information regarding the possible etiology of a number of CFEOM disorders gradually became available shortly after the concept was initially proposed. In 1932, Phillips first reported the absence at autopsy of the sixth cranial nerves on both sides in a child operated for DRS. Since then, at least four additional autopsy reports have described the absence of the sixth cranial nerves in patients with DRS. Electrical studies of extraocular muscles documented anomalous firing of the lateral recti on attempted adduction, and DRS also occurs in the setting of other conditions with anomalous axonal guidance. Brainstem abnormalities have been found at autopsy in a number of patients with Moebius syndrome. These and many other reports began to point toward a possible neurologic etiology of at least some patients previously described as having CFEOM.

The concept of congenital fibrosis of extraocular muscles has a 50-year history and has become well entrenched in ophthalmologic textbooks. During this time, hundreds of reports described unusual congenital abnormalities of ocular motility, the lids, and the face, occasionally also associated with other dysmorphic changes of the skull and body. Through this time, the suspicion lingered that these congenital strabismus syndromes might in some way contain clues regarding the much more common comitant esotropia and exotropia. These comitant ocular motility abnormalities are commonly not present at birth, but appear within the first months of life. They are not associated with fibrosis of the extraocular muscles, and surgical correction (when necessary) is more easily performed. More importantly, they are much more common, occurring in as many as 1–5% of Americans and Europeans. The hope still persists that understanding the uncommon occurrence of congenital noncomitant strabismus may tell us something important about the development of the human ocular motility apparatus and ways to avoid or more easily ameliorate the visual and cosmetic effects that occur when that developmental process goes awry.

The Concept of Congenital Cranial Dysinnervation Disorders

In October 2002, a multidisciplinary group of clinicians and scientists met in Naarden, The Netherlands, under the auspices of the European Neuromuscular Center (ENMC). The meeting was extraordinarily timely because the power of modern genetics was just beginning to yield important results with regard to some variants of CFEOM. At that time, the responsible genes had been identified for CFEOM type 2 (*PHOX2A*) and DRS with radial ray anomalies (*SALL4*), and considerable clinical and radiological data had been obtained regarding other CFEOM syndromes. In every case, the available clinical, radiologic, and genetic data pointed toward a neurogenic etiology rather than a myopathic one. Therefore, the ENMC group suggested that the term congenital fibrosis of the extraocular muscles was likely inaccurate because it specifically identified the extraocular muscles as the unifying cause of these ocular motility abnormalities. They proposed the alternative concept of congenital cranial dysinnervation disorders (CCDDs) to focus attention on abnormalities of innervation of extraocular and facial muscles together with dysinnervation by nearby nerves when the correct nerve failed to innervate a developing muscle or muscle group. The subsequent years have seen a rapid elaboration of knowledge regarding the genetic etiology of a number of syndromes included under the concept of CCDDs (**Table 1**). However, the conceptual grouping remains large, and there are likely many additional genetic and teratogenic syndromes that are yet to be identified and characterized.

Current Genetically Defined CCDDs

Congenital Fibrosis of the Extraocular Muscles Type 1 (CFEOM1; MIM #135700)

This is the most common of the genetic CFEOM phenotypes. It is defined by the presence of congenital bilateral ptosis and bilateral, frequently asymmetric, ocular motility limitation. By the current definition of the syndrome, the globes bilaterally must be infraducted and unable to reach primary position. Upgaze is severely restricted, while horizontal and downgaze is variably restricted (Figure 1). These patients commonly have positive forced ductions and misdirected eye movements such as synergistic convergence on attempted upgaze, but they are rarely noted to have retraction of the globe unless DRS coexists. Neuropathology has suggested a defect of at least the superior division of the oculomotor nerve.

Detailed orbital magnetic resonance imaging (MRI) neuroimaging in CFEOM1 patients showed profound atrophy of the levator and superior rectus muscles, and all the remaining extraocular muscles had reduced size of varying degrees. The orbital motor nerves were absent, hypoplastic, or misdirected in most patients. Intracranial imaging revealed hypoplastic oculomotor and abducens nerves in appropriately imaged subjects. Optic nerve size was reduced 30–40% in cross section, but no patient reported a visual problem or had an afferent pupillary defect.

CFEOM1 is an autosomal-dominant syndrome present worldwide that is caused by heterozygous mutations in *KIF21A*. The *KIF21A* gene encodes a kinesin microtubule-associated motor protein that is associated with anterograde organelle transport in neuronal cells. The corresponding protein is neuronally expressed and is important in axonal maintenance. All mutations detected thus far in this gene are located in the stalk domain of the *KIF21A* protein, which links the active motor domain to the tail domain. These mutations may affect some of the structural components of the protein and thus limit its function.

Congenital Fibrosis of the Extraocular Muscles Type 2 (CFEOM2; MIM #602078)

Patients with CFEOM2 have bilateral ptosis and a large angle exotropia with severely limited horizontal and vertical eye movements. The disorder looks like bilateral oculomotor nerve palsies with no adduction, elevation, or depression on both sides and with incomplete abduction (Figure 2). Pupils are variable in size and shape and unreactive to light even though they react correctly to pupillary pharmacologic agents. High-resolution MRI documented absence of the oculomotor nerves bilaterally in all appropriately studied patients, but the remainder of the brain appeared grossly normal.

CFEOM2 is an autosomal-recessive genetic disorder caused by homozygous mutations in the gene *PHOX2A*. *PHOX2A* is a homeodomain transcription factor that regulates the expression of tyrosine hydroxylase and

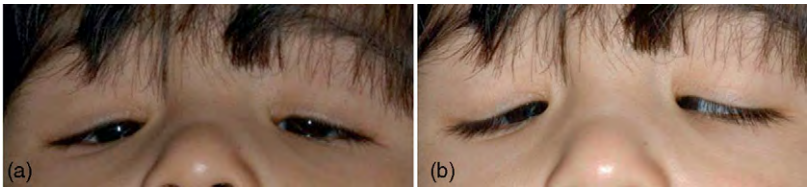

Figure 1 CFEOM1 phenotype. (a) bilateral ptosis with a characteristic chin-up head posture. Eyes are straight in downgaze but both globes are fixed in an infraducted position and are unable to elevate to midline; (b) attempted upgaze results in marked bilateral adduction.

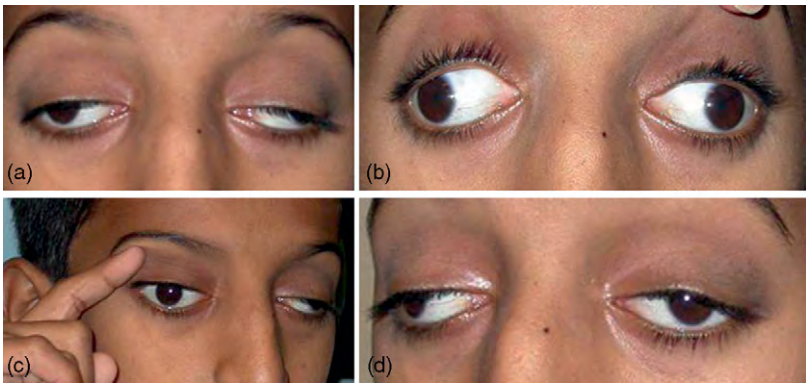

Figure 2 CFEOM2 phenotype. (a) primary position showing bilateral ptosis with brow effort trying to clear visual axis; (b) primary position with lids held showing both globes fixed in abducted positions with neither eye able to fixate in a straight ahead position. Anomalous horizontal head position is adopted to fixate with either eye. (c) the right eye is fixed in abduction requiring a marked head turn to the left. Brow effort cannot clear the right visual axis, requiring manual lid elevation to see. Chin elevation to avoid ptosis cannot be utilized because of the absence of downgaze; and (d) marked head turn to the right to fixate with left eye where adequate lid elevation from brow effort is achieved.

dopamine β-hydroxylase, two catecholaminergic biosynthetic enzymes essential for the differentiation and maintenance of the noradrenergic neurotransmitter phenotype. The encoded protein plays a central role in the development of the autonomic nervous system and has also been shown to regulate transcription of the α3 nicotinic acetylcholine receptor gene. *PHOX2A* is mainly expressed in the nervous system and specifically in the developing oculomotor and trochlear nerve nuclei, supporting the hypothesis that CFEOM2 results from maldevelopment of the oculomotor and trochlear nerves.

Congenital Fibrosis of the Extraocular Muscles Type 3 (CEOM3; MIM #600638)

This is another CCDD in which patients have bilateral ptosis and bilateral, typically asymmetric, restriction of ocular motility in all directions of both eyes (OU). This congenital ocular motility syndrome looks very similar to CFEOM1, although generally without the complete restriction of upgaze that is a diagnostic feature of CFEOM1 (**Figures 3** and **4**).

Inheritance is autosomal dominant with incomplete penetrance and variable expressivity. This phenotype may be caused by mutations in several different genes, including *KIF21A* at times. CFEOM3 has been mapped to 16q24.2–q24.3 in several pedigrees, and analysis of chromosomal translocation t(2;13)(q37.3;q12.11) detected in a three-generation family with clinical features typical of CFEOM3 has helped in mapping a fourth locus. It seems quite possible that each of the genes involved in this syndrome may have a role similar to *KIF21A* in directing growing cranial nerves to a correct termination in the extraocular muscles.

Horizontal Gaze Palsy and Progressive Scoliosis (HGPPS; MIM #607313)

This disorder was first described in English literature by Dretakis because he recognized the severe associated scoliosis. Neurologically, the syndrome is marked by complete or almost complete bilateral horizontal gaze restriction with full vertical gaze (**Figure 5**), variable convergence, variable congenital nystagmus, rare and mild vertical oculomotor imbalance, and normal lids except for asynchronous blinking. These patients are generally intellectually normal. Neuroimaging revealed intact abducens nerves bilaterally but deep anterior and posterior clefts in the medulla and low pons, a large fourth ventricle (**Figure 6**), and no evidence of corticospinal tract or superior cerebellar peduncle decussation.

HGPPS is an autosomal recessive syndrome caused by homozygous mutations in *ROBO3*. *ROBO3* mutations likely disturb brainstem morphogenesis by failing to promote decussation of long motor and sensory tracts in the pons and medulla. Impaired decussation of pontine horizontal gaze pathways in the pontine paramedian reticular formation could explain the absence of horizontal eye movements and, to some extent, the small size of the pons on neuroimaging. Mutation of the *ROBO3* gene may disturb decussation in the spinal cord as well as the brainstem (as happens in the mouse), even though the human spinal cord appears normal on neuroimaging, preventing equalization of tone in the paraspinous muscles on the two sides of the spine. Such a tone asymmetry might well lead to scoliosis over time as the spine is bent and twisted by the action of asymmetric forces. Most of the mutations in *ROBO3* are homozygous mutations reported in consanguineous families, but some are compound heterozygous mutations found in nonconsanguineous families.

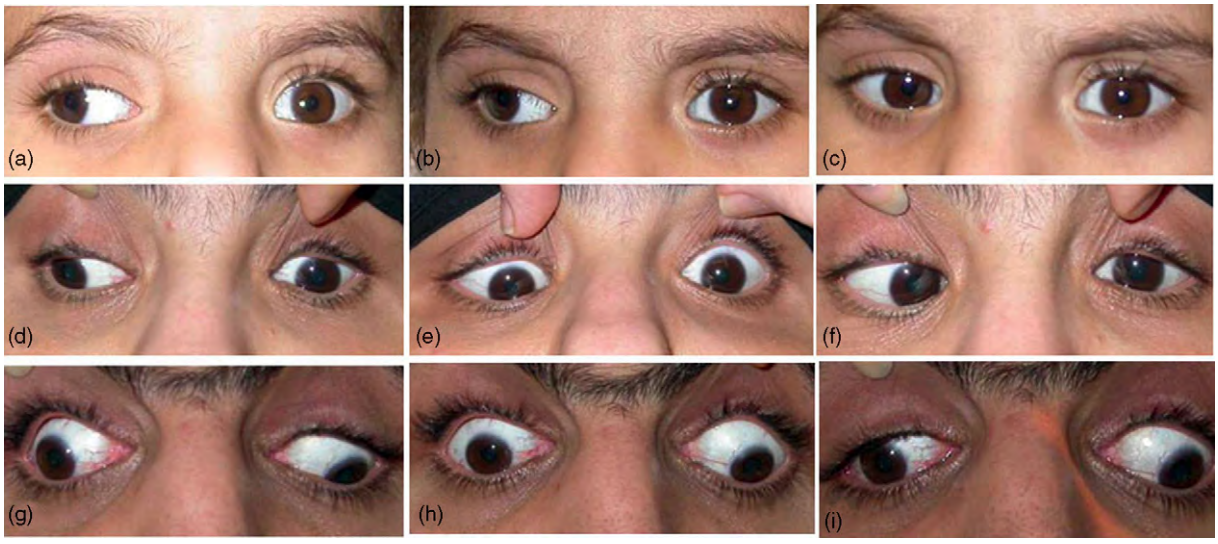

Figure 3 Phenotypic heterogeneity in CFEOM3 – horizontal eye movements. Images (b), (e), and (h) are in primary position, while images (a), (d), and (g) are right gaze, and images (c), (f), and (i) are left gaze. Example subject 1 (images (a), (b), and (c)) has unilateral absence of horizontal movement in the left eye. Interestingly, the preferred eye in primary position is the left eye, resulting in a marked secondary exotropia of the right eye. Example subject 2 (images (d), (e), and (f)) also has a unilateral absence of horizontal eye movements in the left eye together with bilaterally infraducted globes and an esotropia. There is globe retraction on the left with attempted right gaze. Example subject 3 (images (g), (h), and (i)) is the brother of subject 2. He also has bilaterally infraducted globes, but has a marked exotropia and complete absence of adduction. He retains some abduction of each eye and develops synergistic divergence of the left eye during attempted right gaze (g).

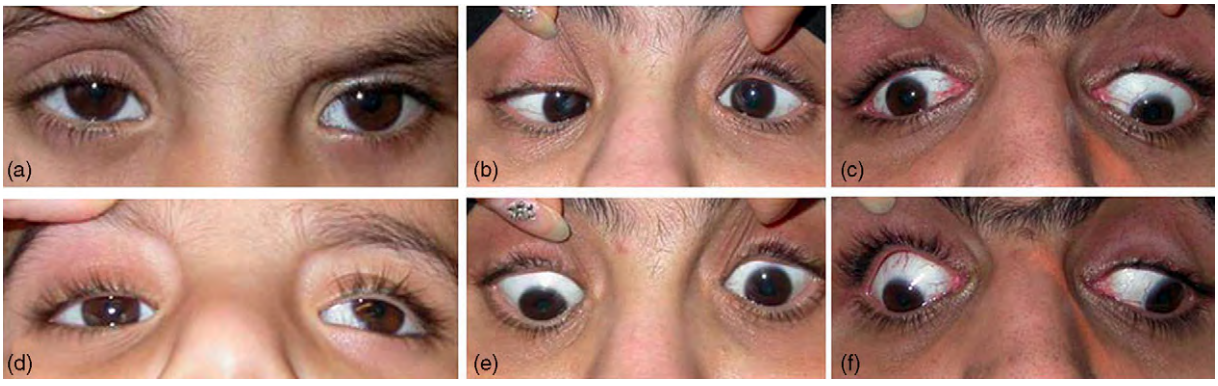

Figure 4 Phenotypic heterogeneity in CFEOM3 – vertical eye movements. Images (a), (b), and (c) are of upgaze, and images (d), (e), and (f) are of downgaze in the same three subjects seen in **Figure 3**. Example subject 1 (images (a) and (d)) has unilateral absence of vertical movement in the left eye. Example subject 2 (images (b) and (e)) has bilateral absence of upgaze with synergistic convergence during attempted movement. Only slight downward movement could be achieved in each eye from the already infraducted position of the eyes. In example subject 3 (images (c) and (f)), elevation is absent bilaterally, and he lacks the synergistic convergence movement evident in his sister. However, right globe retraction is present during attempted downgaze.

The *HOXA1* Spectrum (BSAS and ABDS; MIM #601536)

In 2003, several consanguineous families in Saudi Arabia were found to have a previously unreported syndrome consisting most notably of deafness, bilateral DRS type 3 (**Figure 7**), and cerebrovascular malformations without other obvious central nervous system abnormalities. Careful neuroimaging revealed absence of the abducens nerve bilaterally and almost completely absent development of the hearing and vestibular apparatus in the petrous bone. Several of the patients were autistic. This disorder was termed the Bosley–Salih–Alorainy syndrome (BSAS) after the clinicians who initially recognized the syndrome.

Genome wide screen revealed homozygous mutations in *HOXA1* that presumably cause an early and profound disturbance of brainstem development, probably including loss of rhombomere 5 similar to that found in the knockout mouse model. The Athabascan brainstem dysgenesis syndrome (ABDS) in Native Americans had similar characteristics, and after the gene responsible for BSAS

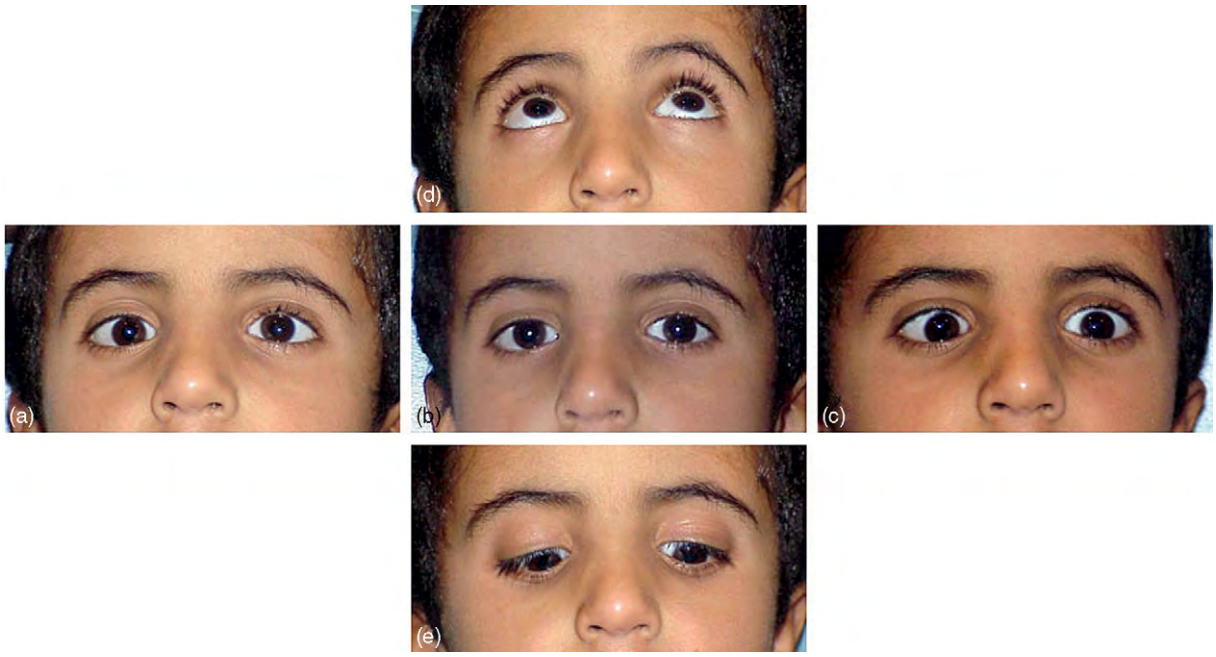

Figure 5 Ocular motility in HGPPS. Image (b) is primary gaze. Images (a) and (c) show that attempted right and left gaze, respectively, are severely limited. Images (d) and (e) show that upgaze and downgaze, respectively, are full.

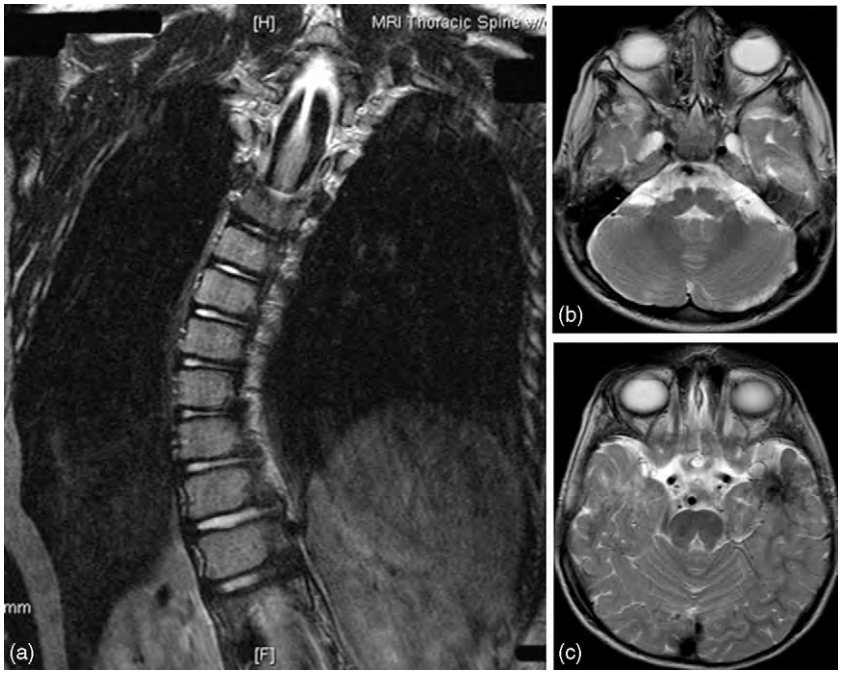

Figure 6 MRI in HGPPS. Image (a) is a coronal image through the thoracic spine showing severe scoliosis concave right. Image (b) is a transverse image through the medulla, where the brainstem is small and indented by both an anterior and posterior cleft. The fourth ventricle is large. Image (c) is a transverse image through the pons, where the brainstem is smaller than normal with a deep posterior cleft.

was identified, ABDS also was found to be due to homozygous mutations in *HOXA1*.

The Saudi population and the Native American population quite likely provide substantially different genetic substrates on which *HOXA1* mutations act, and these genetic differences alone may explain the fact that ABDS tends to be clinically more severe than BSAS. However, it is also noteworthy that Native Americans often exhibit symptoms

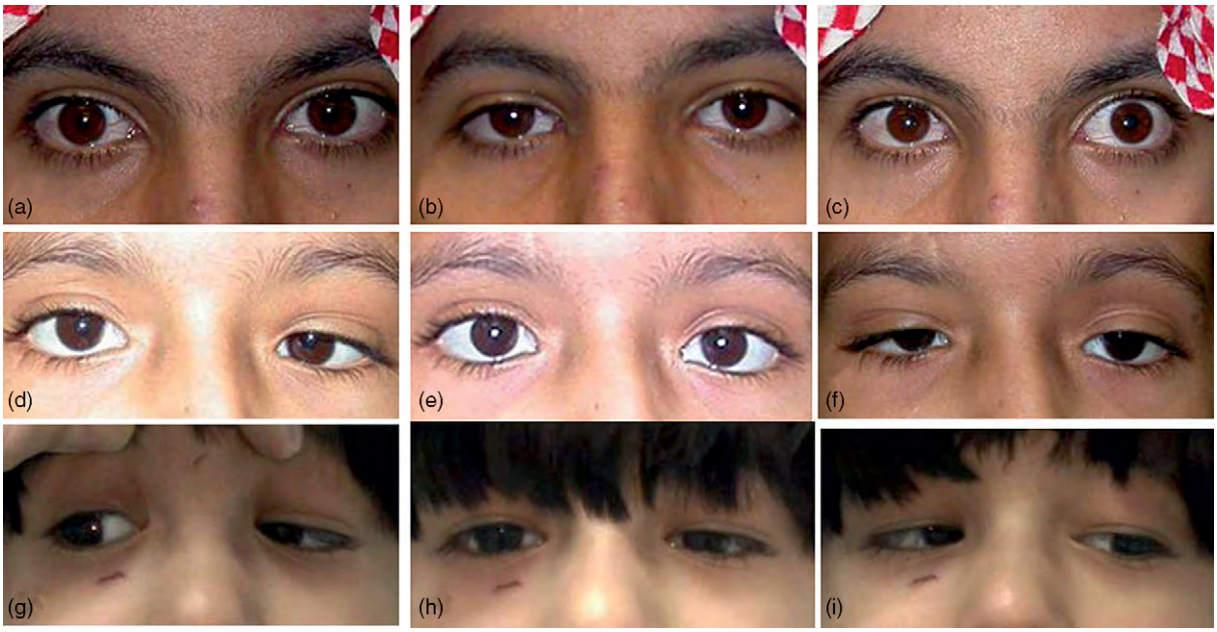

Figure 7 Ocular motility in the *HOXA1* spectrum. Images (a), (b), and (c) are from example subject 1, while images (d), (e), and (f) are from example subject 2, and images (g), (h), and (i) are from example subject 3. Images (b), (e), and (h) are in primary gaze; images (a), (d), and (g) are right gaze; and images (c), (f), and (i) are left gaze. Example subject 1 has very little horizontal movement and this could be termed horizontal gaze palsy. Example subject 2 has classic bilateral DRS type 3 with no abduction in both eyes (OU), restricted adduction OU, and retraction of the adducting globe, associated with narrowing of the palpebral fissures. Example subject 3 has full ocular motility OU despite having homozygous *HOXA1* mutations. Vertical gaze was full in all three. These three patients illustrate the variability of ocular motility in the *HOXA1* spectrum.

of primary hypoventilation during infancy and cortical ischemic injury when older, possibly because they are frequently born at a considerably higher altitude than Saudi patients. The current suggestion is that there exists a *HOXA1* spectrum of disorders that is made up of BSAS and ABDS and consists of variable horizontal gaze restriction (usually due to bilateral DRS type 3), deafness, cerebrovascular and cardiovascular maldevelopment, and cognitive disturbances ranging from autism to diffuse cortical ischemic injury.

Duane Retraction Syndrome (DRS)

DRS is the most common of all CCDD ocular motility patterns. It is characterized most commonly by limited or absent abduction and full adduction marked by retraction of the globe and narrowing of the palpebral fissure. This ocular motility pattern is called DRS type 1 and is generally sporadic, unilateral, and more common in females than in males. DRS type 2 consists of full abduction with limited adduction, also with globe retraction and narrowing of the palpebral fissure on adduction. DRS type 3 is similar to DRS type 1 except that adduction (as well as abduction) is limited to some extent (Figure 8).

Up to 10% of cases may be familial, including obvious autosomal-dominant inheritance in some families. At times, DRS may be found in other congenital ocular motility syndromes like Moebius syndrome, CFEOM1, and the *HOXA1* spectrum, and on occasion it may be associated with other developmental problems.

Recent neuroimaging studies provide evidence supporting abducens nerve abnormalities and anomalous innervation in DRS. DRS can be differentiated by MRI from congenital abducens nerve palsy because lateral rectus atrophy is found in chronic cases of abducens nerve palsy but not in DRS. The lateral rectus in DRS may be spared denervation atrophy as a result of anomalous innervation from branches of the oculomotor nerve. Several imaging studies in sporadic DRS involving types 1, 2, and 3 have reported either absence or hypoplasia of the abducens nerve.

Monogenetic autosomal-dominant syndromes in which DRS is prominent include Duane-radial ray syndrome (DRRS) and familial dominant DRS (DURS2-DRS).

Duane-Radial Ray Syndrome (DRRS or Okihiro syndrome; MIM #607323)

This syndrome is characterized by DRS with forearm and/or hand anomalies and variable expression of cardiac, renal, hearing, and vertebral anomalies. This genetic syndrome also includes absent or small abducens nerves with normal-appearing oculomotor and optic nerves. DRRS is caused by mutations in the *SALL4* gene, which is thought to be involved in the patterning of several embryonic structures such as limbs, abducens nerve, and heart.

Figure 8 Ocular motility variants in DRS. Images (a), (b), and (c) are from example subject 1, while images (d), (e), and (f) are from example subject 2, and images (g), (h), and (i) are from example subject 3. Images (b), (e), and (h) are in primary gaze; images (a), (d), and (g) are right gaze; and images (c), (f), and (i) are left gaze. Example subject 1 has DRS type 1 OD with an upshoot of that eye together with globe retraction and fissure narrowing on adduction. Example subject 2 has bilateral DRS type 1 with retraction of the adducting globe bilaterally together with narrowing of the palpebral fissure. Example subject 3 had a left DRS type 3 with limitation of both right and left gaze with the left eye together with globe retraction and narrowed palpebral fissure on adduction.

Duane Retraction Syndrome (DURS2-DRS; MIM #604356)

Individuals with DURS2-DRS can have isolated unilateral Duane syndrome but more commonly have bilateral involvement and associated vertical movement anomalies. Neuroimaging studies have demonstrated absent or hypoplastic abducens nerves and, in some cases, hypoplastic oculomotor nerves or muscles innervated by the oculomotor nerve. The causative gene has recently been identified as *CHN1*, which is thought to participate in ocular motor axon path finding, particularly involving the abducens nerve and to a certain extent the oculomotor nerve.

Discussion

The CCDDs provide an excellent example of the power of current genetic techniques to advance our understanding of certain complex clinical disorders. This heterogeneous amalgam of congenital ocular motility disorders coalesced 50 years ago around the concept of undefined abnormalities in the development of extraocular muscles. Subsequent anatomic, neuroradiologic, and genetic information has largely left in place the clinical grouping, but replaced the central concept with one of developmental abnormalities in ocular motility mechanisms in the brainstem, peripheral cranial nerves, and orbit that are neurogenic in origin. This group of disorders proved very difficult to classify by clinical criteria alone, but much more progress has been made since it has become possible to study groups of genetically homogenous individuals.

There appear to be at least three pathways by which congenital abnormalities in the human ocular motility system occur in these patients with genetically defined disorders (Table 1). The first involves the failure of cranial nerve nuclei to develop normally. Perhaps the best current example of this mechanism is the *HOXA1* clinical spectrum in which abducens nerve nuclei fail to develop as part of the loss of rhombomere 5 during development in the absence of a normal *HOX* cascade. The second mechanism involves genetic defects that lead to abnormal axonal transport of molecules necessary for normal guidance of developing peripheral neurons to the correct extraocular muscles and possibly for the normal functional development of these muscles. The best current example of this mechanism is CFEOM1 with mutations in *KIF21A* causing abnormalities in axonal transport and leading to loss of ocular motor axons and possibly abnormal termination of all peripheral nerves within the orbits. CFEOM3 is a clinically similar disorder but genetically heterogeneous, implying that other genes may play similar roles in orbital innervation. The third mechanism occurs with abnormalities in the development of upper motor neurons in the brainstem, sometimes with associated lower motor neuron abnormalities as well. The best-understood current example of this mechanism would

be individuals with HGPPS who have mutations in *ROBO3* resulting in the loss of decussation of a number of developing brainstem neural pathways, including those in the pontine paramedian reticular formation responsible for horizontal gaze.

Today, we can finally define at least some CCDD syndromes by the responsible gene as we build a montage of genes acting during development of the brainstem and orbits (**Table 1**). We now have some idea about what can go wrong in the setting of certain specific mutations, and by inductive reasoning, what role these genes play in the development of the normal human efferent visual system. Curiously, an intensive evaluation of the CCDD group has not yet yielded any implication that genes responsible for the development of the extraocular muscles themselves are involved. Rather, anatomic abnormalities in extraocular muscles noted in this group of disorders seem to be secondary to denervation and dysinnervation. Further study, of course, may change this situation.

Thus far, we have no complete explanation for the variability within each genetically defined disorder. At times, it is clear that individuals with identical mutations of the same gene nevertheless have a somewhat different phenotype, as described with mutations of *KIF21A*, *ROBO3*, and *HOXA1*. It is now clear that a single genetic abnormality can result in a fairly broad range of phenotypic presentations. For example, *KIF21A* mutations can cause CFEOM1 or CFEOM3, both of which may present with variable, bilateral ocular motility restriction and may occur with or without DRS. Likewise, *HOXA1* mutations cause deafness in most, but not all, affected individuals, autism in some, and a range of cardiovascular and cerebrovascular malformations in all individuals who have been studied appropriately.

It also seems clear now, even within this limited set of genetic syndromes, that different mutated genes can result, at least in part, in the same phenotype. DRS, for example, occurs with heterozygous mutations of *KIF21A* and *SALL4* and homozygous mutations of *HOXA1*. The cause of DRS is relatively well understood in each setting. *HOXA1* mutations probably result in the loss of rhombomere 5, including the absence of abducens nucleus development. In contrast, *KIF21A* mutations cause abnormalities in directing the abducens nerve successfully to the ipsilateral lateral rectus muscle. The diagnostic feature of globe retraction on attempted adduction is probably the result of lateral rectus denervation by the abducens nerve and dysinnervation by a nearby branch of the oculomotor nerve.

Some variants of DRS are associated with somatic mutations involving the face, neck, ears, and extremities. Such an association is understandable in the setting of *HOXA1* mutations, given that *HOXA1* is the first gene in the *HOX* cascade that is responsible for the development of orientation and certain major anatomic features of the early fetus. In fact, it is somewhat surprising that *HOXA1* mutations result in such a relatively benign syndrome given the role of *HOXA1* at the beginning of the *HOX* cascade. However, consanguineous families with *HOXA1* homozygous mutations have a greater than normal spontaneous abortion rate, implying that the result of these mutations may not always be benign.

The role of *HOXA1* is complex because it seems that this gene is not expressed in the petrous bone, and yet the petrous bone fails to elaborate the bony hearing and vestibular structures in most individuals with homozygous *HOXA1* mutations. It seems likely that abnormal development of the petrous bone results from the absence of appropriate developmental signals from abnormal neuroectoderm and brainstem nearby. The cause of cerebrovascular and cardiovascular abnormalities in patients with *HOXA1* mutations seems somewhat more straightforward because *HOXA1* may actually be active in the early development of the vascular system. The *HOXA1* clinical spectrum resembles early thalidomide poisoning, bringing up the possibility that thalidomide interferes with the early *HOX* cascade. Thus, genetic knowledge of these uncommon congenital ocular motility syndromes can increase our understanding of teratogenic phenomena as well.

HGPPS brings up further considerations regarding development during childhood. The ocular motility abnormalities of HGPPS are congenital. However, the severe scoliosis associated with the syndrome is not present at birth; rather, it begins in early childhood and progresses rapidly. *ROBO3* activity has not been documented to date in the developing spine. A direct effect of this gene's activity remains possible, but an alternative explanation is that the tone of the powerful paraspinous muscles is asymmetric in affected individuals because the absence of *ROBO3* prevents decussation of fibers in the brainstem and/or spinal cord important for equalization of paraspinous muscle tone. The action of gravity across the spine would conceivably result in accelerating scoliosis once a mild bend or torque occurs in the spine. Whatever the actual mechanism, it is possible that better understanding of the scoliosis that occurs with *ROBO3* mutations will aid in understanding other early scoliosis syndromes and even the fairly common sporadic scoliosis in pubescent females.

Patients with homozygous *ROBO3* mutations lack decussation of the major corticospinal tracts and medial lemniscus sensory tracts, an unanticipated and truly profound neuroanatomic abnormality. Curiously, these individuals in general are intellectually normal, implying that these major motor and sensory tracts find the correct termination, permitting grossly normal cortical activity despite being in the wrong hemisphere. The implication of this observation is that these developing fiber tracts respond to direction signals sequentially, with a response (or lack of it) to one signal potentially having little or no effect on the response to the next signal.

It is obvious that development of the human brainstem and development of the human efferent visual system do

not depend exclusively on the few genes identified in the CCDD syndromes discussed here. It is quite likely, therefore, that more autosomal dominant and recessive clinical syndromes are yet to be identified under the CCDD rubric. Indeed, there have been many reports over the last 50 years of unusual congenital ocular motility syndromes that were clearly familial, and some of these are surely genetic in origin. The power of current genetics may finally permit us to identify the responsible genes.

Conjunctiva Immune Surveillance

E Knop, Charité – Universitätsmedizin Berlin, Berlin, Germany
N Knop, Hannover Medical School, Hannover, Germany

Glossary

Conjunctiva-associated lymphoid tissue (CALT) – It is the physiological protective mucosal immune tissue of the conjunctiva. It consists of lymphoid cells and accessory cells inside the mucosal tissue and can be divided into the epithelial and underlying connective tissue (lamina propria) compartments. It is arranged as a diffuse lymphoid effector tissue along the whole extension of the conjunctiva and has interspersed organized lymphoid follicles for afferent antigen uptake and effector cell generation.

Dendric cells (DCs) – They are a special class of professional antigen-presenting cells (**APC**, together with macrophages and B-cells). They take up external antigens, degrade them into small fragments (epitopes), present them on MHC-class-II to T-helper cells, and hence, induce immune reactions. Depending on their maturation status which is influenced by the presence of inflammatory signals, they modulate between the inductions of tolerance versus inflammation. They also link the unspecific innate to the induced specific immune system and are hence key modulators of the immune reaction.

Eye-associated lymphoid tissue (EALT) – This tissue summarizes all the lymphoid tissues of the extended mucosal ocular surface, that is, of ocular surface proper (conjunctiva and cornea) along with its mucosal adnexa (the lacrimal-drainage-associated lymphoid tissue, LDALT, and the lymphoid cells inside the lacrimal gland). EALT is in line with the mucosal immune system in other parts of the body (e.g., gut-associated lymphoid tissue (GALT) in the gut and bronchus-associated lymphoid tissue (BALT) in the airways).

High endothelial venules (HEVs) – Specialized postcapillary venules that have an endothelium of bright roundish cells compared to the ordinary flat dense ones. They are located in lymphoid tissues and have tissue-specific adhesion molecules (vascular addressins) on the cell surface that specifically interact with homing receptors on circulating lymphocytes in order to maintain a regulated immigration of lymphocytes into the tissue.

Human leukocyte antigen (HLA) – A system of the major histocompatibility complex (⇒ MHC) in humans. It contains of a number of genes and their respective encoded proteins (that can act as antigens). The term HLA is frequently used to describe immunological self and nonself in the context of transplant rejection.

Intercellular adhesion molecule 1 (ICAM-1) – An adhesion molecule (CD54 according to the immunological cluster of differentiation, CD, nomenclature) mainly on vascular endothelial cells which is upregulated in inflammation and promotes the increased immigration of leukocytes, that carry corresponding integrin receptors, into the tissue.

Membraneous cells (M-cells) – Also called microfolded cells, they are a special type of cells in the modified epithelium overlying organized lymphoid follicles, the so-called follicle-associated epithelium (FAE). Their name refers to the fact that they have a different, usually smooth, surface ultrastructure compared to the ordinary epithelial cells. They form cellular pockets populated by groups of leukocytes which are separated from the lumen by a thin luminal cytoplasmic sheet. M-cells actively transcytose luminal antigens for uptake by the leukocytes and their subsequent presentation to and activation of T- and B-cells in order to generate antigen-specific effector cells.

Major histocompatibility complex (MHC) – It is differentiated mainly into class-I and class-II. Their encoded proteins on the surface of cells perform the presentation of protein antigen fragments (epitopes) to immune cells. MHC-class-I is found on all nucleated cells and presents antigens produced inside the cell (either own or viral proteins after infection) to cytotoxic CD8 lymphocytes and natural killer cells. MHC-class-II, in contrast, occurs physiologically only on specialized antigen-presenting cells and presents foreign antigens to the CD4 receptor of T-helper cells. In inflammation, it can be upregulated by other cells.

Lipopolysaccharide (LPS) – A component of the outer cell membrane of the wall of Gram-negative bacteria that acts as an endotoxine. The presence of LPS, that is detected for example, by toll-like receptors, signals the pathogenic nature of antigens to the immune system and elicits a strong inflammatory reaction.

Tolerance – Immune tolerance is a status in which the immune system is in a state of nonreactivity to an antigen in order to prevent inflammatory tissue-destructive reactions. Tolerance is actively generated and directed not only against the bodies' own cellular self-antigens but also against nonpathogenic external antigens. If tolerance fails, autoimmunological disease or allergy may occur. Tolerance is the default mode of the mucosal immune system, including CALT and EALT, in order to preserve tissue integrity.

Conjunctival Morphology and Function Are Closely Interacting for Immune Surveillance

Epithelial Defense Mechanisms

Epithelial morphology and function

The conjunctiva is a moist mucous organ that consists of a surface epithelium and an underlying loose connective tissue (lamina propria), separated by the epithelial basement membrane. The epithelium of the human conjunctiva has, in contrast to small rodents (e.g., rat and mouse), a stratified nonsquamous morphology and consists of two to three cell layers of cubical cells in most parts. It becomes multilayered and assumes prismatic morphology at the fornix whereas it tends to become squamous toward the limbus (**Figure 1(a)** and **1(b)**). Interspersed mucus-secreting goblet cells occur inside the epithelium as single cells or in small groups as well as intraepithelial lymphocytes (IELs) that reside mainly in the basal layers (**Figure 2(b)** and **Figure 3(a)**) as well as dendritic cells (DCs), that have long narrow extensions, for uptake of antigens from the surface. The conjunctival epithelial surface is covered by small cytoplasmic protrusions (microvilli and microplicae) with a well-developed surface coat of filamentous projections (glycocalyx) that form a meshwork (**Figure 1(c)** and **Figure 2(a)**).

Epithelial Immune Surveillance Takes Care of Environmental Antigens

Physical and physicochemical barriers keep antigens outside

The structure of the conjunctival epithelium already contributes to basic protective mechanisms which can be considered as part of the innate defense. Epithelial cells are mechanically connected by desmosomes and have an apical belt of intercellular junctions including tight junctions that seal the intercellular space and limit the passive para-cellular leakage of antigens in and out of the tissue (**Figure 2(a)**). This physical cellular barrier is supplemented by the physicochemical barrier of the epithelial mucins, that consist of cell membrane-spanning mucins (glycocalyx) produced by the ordinary epithelial cells and of soluble mucins secreted by the goblet cells which mix with the aqueous phase. Together they form a layer in the range of few micrometers thickness, that is, a sticky gel to which microbes adhere and can hence be cleared by the constant renewal of the preocular tear film. Soluble protective factors, including secretory immunoglobin A (SIgA), are fixed to the mucin layer in order to make it an almost impenetrable and lethal barrier to antigens and in particular to microbes.

Figure 1 Structure of the human conjunctival epithelium. (a) The epithelium of the human conjunctiva is stratified cuboidal in most regions and assumes more layers with prismatic surface cells toward the fornix. Interspersed goblet cells (BZ) release mucus (M) tufts onto the surface. (b) Goblet cells contain densely packed mucin granules and a flat or triangular nucleus. They may be slightly inclined if located in the relatively flat bulbar epithelium close to the limbus. The surface of the conjunctival epithelial cells shows numerous microprotrusions that result in a rough surface in low-magnification transmission electron microscopy. (c) In higher enlargement, microvilli (MV) and microplicae (MP) are seen which have a dense glycocalyx of fine molecular antennae (arrows) that project into the lumen and form a meshwork, as better seen in cross section (inset, ×2). Reproduced from Knop, E. and Brewitt, H. (1992). *Morphology of the Conjunctival Epithelium in Spectacle and Contact Lens Wearers – A Light and Electron Microscopic Study*. Contactologia, Stuttgart: Enke Verlag.

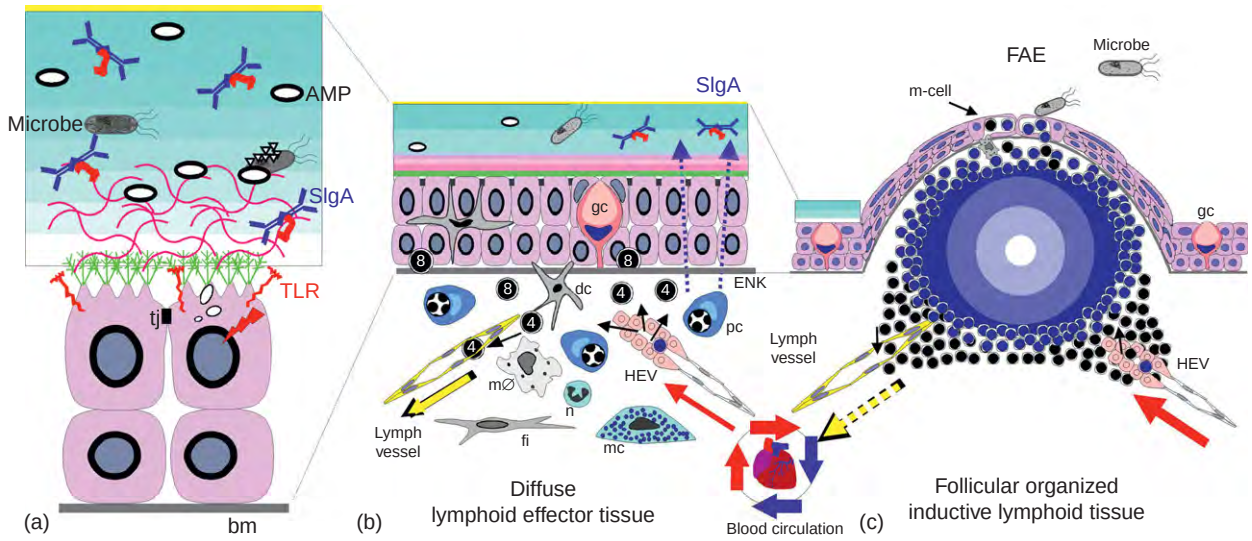

Figure 2 Defense systems of the human conjunctiva. (a) The conjunctival epithelium has an array of defense systems consisting of the integrity of the surface epithelial cells (provided with pattern recognition receptors, TLR) that are sealed by apical tight junctions (tj), of the attached mucin layer that is enforced by adhering antimicrobial proteins and peptides (AMPs) including specific secretory IgA (SIgA) and of the overlying tear film (shaded blue) that contains similar protective molecules and provides a washing effect. (b) A diffuse effector tissue is formed by lymphoid cells of the specific adaptive immune system and by innate cells such as macrophages (mø), mast cells (mc), neutrophilic granulocytes (n), and dendritic cells (dc). They functionally interact with stromal fibrocytes (fi). Lymphoid cells consist of $CD4^+$ and $CD8^+$ T-cells (black circles) that constitute intraepithelial and lamina propria lymphocytes. Differentiated B-cells (plasma cells (pc), large blue) produce dimeric IgA, which is transported through the epithelium as SIgA. (c) Interspersed solitary lymphoid follicles consist of B-cells (small blue circles), frequently have a bright germinal center due to cell proliferation, have an apical follicle-associated epithelium (FAE) with M-cells for antigen transport but without goblet cells (gc) and have para-follicular T-cell (small black circles) zones with lymph vessels (yellow) and high endothelial venules (HEVs); small arrows indicate the direction of cell migration. The mechanisms for conjunctival immune surveillance are explained topographically in this figure from the epithelium (a) over the diffusely interspersed effector cells (b) toward the organized lymphoid follicles that generate the effector cells (c). Functionally, it is reverse because the effector cells generated in lymphoid follicles after antigen uptake and presentation recirculate via the blood circulation (symbol of heart and blood flow between (c) and (b)) to and migrate into the diffuse effector sites to exert their protective function by cell contact or by soluble mediators. The drawing is not to scale.

The mechanical washing effect of the tear film wipes away antigens and detritus

The tear film is an important functional component of the ocular surface mucosal protection system. Apart from providing the necessary moisture, the constant flow of tears over the ocular surface and in particular, over the cornea, together with the wiping effect of the lid margin with every blink, provides a constant mechanical washing. This discharges antigens and removes dust and cell detritus. Other parts of the ocular surface along the retropalpebral tear film are not so rapidly cleared so that antigens can stay in longer contact with the epithelium. Therefore, the tear film contains a large number of antimicrobial factors that contribute more specifically to the innate immune defense.

Epithelial innate immune defense factors

The innate immune system uses pattern-related receptors (PRRs) that mainly detect conserved pathogen-associated molecular patterns (PAMPs) but also host antigens from destroyed cells. It reacts via effectors, which consist of soluble antimicrobial proteins and peptides (AMPs) which bind to the microbial cell wall in order to destroy it or which interfere with the microbial metabolism. The innate immune system also employs production of soluble mediators, such as inflammatory cytokines and chemotactic cytokines (chemokines) that functionally couple the innate and adaptive immune answer.

PRRs on epithelial cells provide an external alarm system

As soon as microbial antigens have breached the physicochemical barrier, they get in touch with epithelial PRRs (**Figure 2(a)**, the most prominent of which is presently the diverse family of toll-like receptors (TLRs). Binding of their ligands causes activation of the host cell via a MyD88-dependent signaling pathway that activates a nuclear transcription factor, nuclear factor kappa B (NFκB), and results in production of inflammatory cytokines such as interleukin 6 (IL-6), interferon gamma (IFN-γ), or tumor necrosis factor alpha (TNF-α). Subsequently, these induce the production of chemokines, adhesion molecules, and inducible AMP. Altogether this represents an inflammatory cascade with activation, first

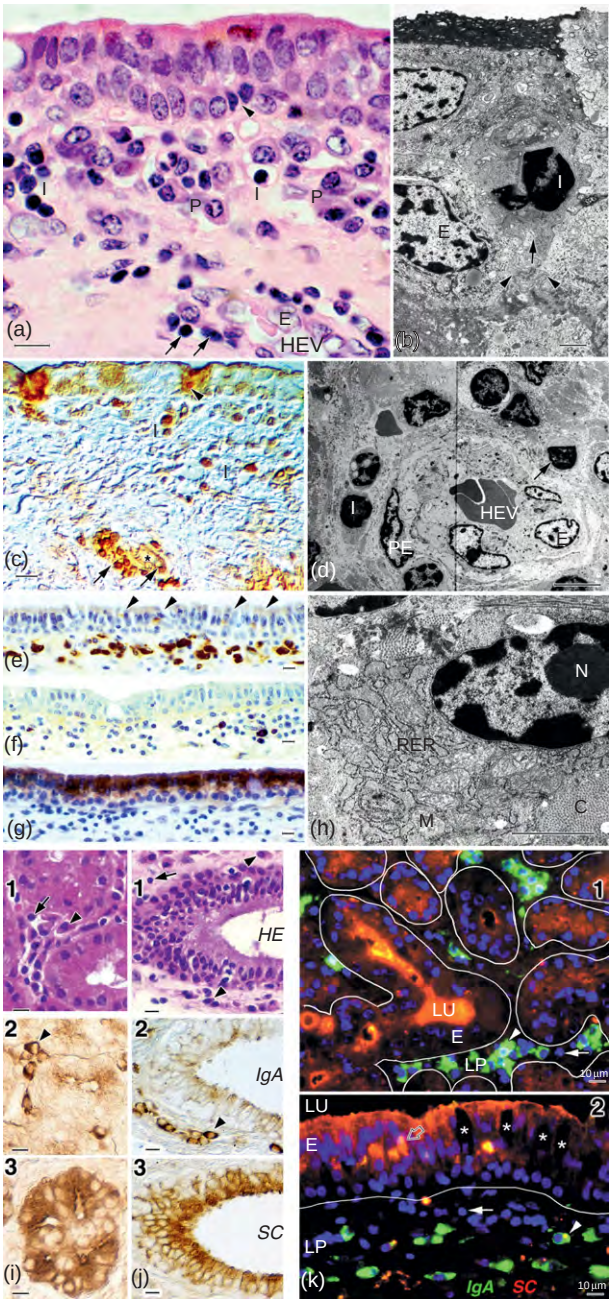

Figure 3 Characteristics of diffuse CALT. (a) Tarso-orbital conjunctiva. Plasma cells (P) and lymphocytes (l) form a diffuse lymphoid cell layer in the lamina propria covered by an epithelium with intraepithelial lymphocytes (arrowhead). A high endothelial venule (HEV) underneath has typical roundish endothelial cells (E) and contains lymphocytes within and around the wall (arrows). (b) TEM shows an intraepithelial lymphocyte (l) between epithelial cells (E) on the basement membrane (arrowheads). (c) Immunostaining indicates T-cells inside the epithelium (arrowhead), in the lymphoid layer (l) and around or in the wall (arrows) of a HEV (asterisk). (d) Ultrastructurally, a HEV shows large bright endothelial cells (E), a contractile pericyte layer (PE), and adjacent (l) or intramural (arrow) lymphocytes. (e) The vast majority of plasma cells in the lymphoid layer are IgA positive as also deposits in the epithelium (arrowheads), while IgM (f) is rare. (g) The epithelium is positive for the transporter SC. (h) A plasma cell lying in the loose collageneous (C) tissue has extended rough endoplasmic reticulum (RER), mitochondria (M), large nucleolus (N), and radial heterochromatin; (b, d, h: bar = 1 µm; a, c, e–g: bar = 10 µm). (i (1–3)) Lacrimal gland, LG, with lymphocytes (arrow), and plasma cells (arrowead) between the roundish acini. (2) IgA is found strongly in plasma cells and as weaker patchy staining in acinar epithelial cells, which more strongly express SC (3). (j (1–3)) Excretory lacrimal ducts that connect the LG to the conjunctiva have similar characteristics but in the epithelium IgA (2) and SC (3) are mainly expressed in the luminal layer (j) the duct has two cell layers but appears wider to the left due to oblique plane of section. (k (1,2)) Multiple-fluorescent staining for IgA (green), SC (red), and cell nuclei (blue) shows that the components of the secretory immune system are similarly arranged in the LG (1) and the conjunctiva (2, here orbital zone); bm level indicated by fine lines. IgA-positive plasma cells are diffusely interspersed in the LP of both tissues; in the LG frequently in groups. Epithelium (E) shows strong staining for SC;

of the epithelial cells and later also of lamina propria leukocytes and vascular endothelial cells. It induces leukocyte recruitment into the epithelium and their immigration from the blood stream into the tissue.

The normal conjunctival epithelium expresses a number of different TLRs, similar to the cornea. TLR1, 2, 3, 5, and 6 were found in all conjunctival and limbal epithelial cell samples, TLR4 and 9 only inconstantly, but not TLR7, 8, and 10. TLR2 may only occur upon stimulation by IFN-γ and bacterial cell wall extract, for example, in patients with ocular allergy. This results in upregulation of inflammatory markers, such as the intercellular adhesion molecule 1 (ICAM-1), human leukocyte antigen (HLA), TNF-α, and IL-8, in a dose-dependent manner. Bacterial-specific TLRs are of interest in ocular allergy because colonization by bacteria is common there. The activation of TLRs represents an important co-factor in ocular allergy and their blockade can significantly inhibit release of inflammatory mediators which may turn out as a promising new therapy option for ocular allergy.

The conjunctival epithelium secretes diverse AMPs

The spectrum of epithelial derived AMPs is distinct for cornea and conjunctiva but overlapping. Conjunctival epithelium produces not only the human β-defensins (hBD)-1,2,3 and further AMPs such as liver-expressed antimicrobial peptides (LEAPs) 1 and 2 and cathelicidin (LL-37) but also macrophage inflammatory protein 3alpha (MIP-3α) and thymosin beta 4 (Tβ-4). Some of the AMPs are constitutively produced, whereas others are inducible. hBD-2 is induced by inflammatory cytokines in ocular surface inflammation and by presence of bacterial LPS, while hBD3 is induced by infection and LL-37 by epithelial wounding. Conjunctival AMPs such as LL-37 are active against bacterial (*Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Staphylococcus epidermidis*) and viral (Herpes simplex virus 1, adenovirus) infection. They can act as multifunctional factors in wound healing and signaling pathways. Interestingly, the antimicrobial activity of some of these AMPs (e.g., hBD-1, hBD-2, and Tbeta-4) is almost completely inhibited in the presence of tear fluid. This may indicate that not all epithelial AMPs are produced in order to act as tear film factors but rather play a major role for local protection inside the conjunctival epithelium itself. Apart from AMPs, there is a plethora of other protective proteins. AMPs continue downstream in the lacrimal drainage system.

Conventional antibacterial factors are surprisingly versatile defense tools

Even the 'old fashioned' established antimicrobial proteins in the tear film, such as lysozyme and lactoferrin, have surprising newly detected functions. Apart from being bactericidal, either by lysis of components in the Gram-positive bacterial cell wall (lysozyme) or by interfering with their iron metabolism (lactoferrin), they are also antifungal and antiviral. Through the absorption of the strongly inflammatory bacterial endotoxin lipopolysaccharide (LPS), which is a surface molecule on Gram-negative bacteria, they also act anti-inflammatory. They have further anti-inflammatory functions by their influence on antigen-presenting cells (APCs) and hence appear as key elements in host defense that link innate and adaptive immunity.

Conjunctival Lamina Propria: Morphology and Function of the Diffuse Mucosal Immune System

Diffusely arranged lymphoid and innate cells contribute to conjunctival immune surveillance

The lamina propria contains bone-marrow-derived cells and vessels of different types. Apart from capillaries and lymph vessels, specialized high endothelial venules (HEVs) occur. Vessels serve for the supply with nutrition and discharge of metabolites, for hormonal regulation of the tissue, and also for the migration of immune cells. Lymphocytes, together with accessory leukocyte populations (macrophages, granulocytes, mast cells, and DCs), form a diffuse lymphoid tissue (**Figure 3(a)**) which is regarded mainly as an effector site of CALT although antigen uptake via DCs can also occur here to a certain extent. The diffuse lymphoid tissue is located in the vast majority of the surface, except for the solitary lymphoid follicles. The thickness of this cell layer depends on the location along the conjunctiva, shows a certain topographical variation, and is frequently only one to two cells wide, which may be a reason why these cells have often been overlooked in the past. It also shows a certain interindividual variation that may depend on the immune status of the person. IEL also functionally belong to the diffuse effector cells (**Figure 3(b)**).

Different subtypes of lymphocytes occur in the conjunctiva

Diffuse conjunctival lymphocytes are mainly $CD3^+$ T-cells (**Figure 3(c)**) (whereas $CD20^+$ B-cells are largely restricted to the solitary lymphoid follicles). They are activated ($CD45Ro^+$, $CD25^+$) and express the human

goblet cells (asterisks) are negative for SC. Mixed color indicating both proteins (=SIgA) is seen in the tubuloacinar lumina (LU) of the LG and frequently delineates the luminal cell surface. Local production of secretory IgA in the eye-associated lymphoid tissue (EALT) of the normal human ocular surface. *Investigative Ophthalmology and Visual Science* 49: 2322–2329.

mucosa lymphocyte antigen (HML-1, integrin αEβ7) which substantiates the integration of CALT into the mucosal immune system. In the epithelium $CD8^+$, cytotoxic/suppressor cells prevail that have been proposed to act mainly in the suppressor mode and may hence provide a component of the immune tolerance at the ocular surface. Lamina propria lymphocytes, in contrast, consist of equal or prevailing amounts of $CD4^+$ T-helper (Th) cells compared to $CD8^+$ T-cells. All known types of T-cells exist in CALT and their immune regulation is considered below (see the section titled 'Mechanisms of conjunctival immune regulation'). Plasma cells (see the section titled 'The conjunctiva contributes actively to the secretory immune system') account for about 20% of the conjunctival leukocytes in histology but their absolute number is in the range (2/3) of those in the lacrimal gland that was long regarded as the sole source of tear film SIgA. Conjunctival lymphocytes are even more abundant. This supports the concept that the conjunctiva considerably contributes to its own specific defense and it very well supports the recognition of a diffuse CALT along the whole extension of the human conjunctiva in tissue whole mounts.

The conjunctiva contributes actively to the secretory immune system

Specific soluble antigen-receptors (immunoglobulins, Ig) produced by local mucosal differentiated B-lymphocytes (plasma cells) and transported through the overlying epithelium constitute the secretory immune system. This is a major mucosal defense mechanism and is also present in the conjunctiva. Mucosal Ig mainly consist of polymeric (p)IgA that also forms the predominant Ig in the tear film, besides small amounts of the other polymeric Ig (IgM) and trace amounts of IgG. During eye closure, overnight IgA is the predominant protein in the closed eye tear film, but only recently the components of the conjunctival secretory immune system could be consistently verified by immunohistochemistry and polymerase-chain reaction.

Local conjunctival plasma cells produce mainly the anti-inflammatory IgA

The vast majority of conjunctival plasma cells produce IgA and hence stain positive for it in immunohistochemistry (**Figure 3(e)**). IgM, which performs the initial acute secretory immune answer, is rarely observed (**Figure 3(f)**) and hence indicates that the physiological conjunctival diffuse lymphoid cells do not reflect any kind of reaction to an acute insult. The epithelial transporter molecule for both of them (pIgR, represented by its extracellular domain secretory component, SC) is strongly expressed throughout the human conjunctival epithelium (**Figure 3(g)**). After transport, SC remains linked to pIgA which together constitute secretory IgA (SIgA). Conjunctival plasma cells show a typical ultrastructure in transmission electron microscopy (**Figure 3(h)**).

IgA-positive plasma cells in the lamina propria and SC in the overlying epithelium are continuously expressed from the lacrimal gland (**Figure 3(i)** 1–3) along its excretory ducts (**Figure 3(j)** 1–3) into the conjunctiva and further within the lacrimal drainage system. In multifluorescent immune staining, the secretory immune system of the lacrimal gland and the conjunctiva show the same characteristics (**Figure 3(k)** 1,2).

SIgA performs diverse protective and antiinflammatory functions at the ocular surface

SIgA is deposited onto the epithelial surface and into the tear film (**Figure 2(a)**). It contributes to the binding of specific antigens and to their immobilization and discharge. It binds to the surface of microbes and viruses and thereby limits their binding to and entrance into the tissue. It binds and thereby neutralizes bacterial toxins such as LPS. SIgA antibodies occur naturally to the physiological commensal ocular flora and are induced by the presence of pathological microbes, such as *Acanthamoeba* and *Pseudomonas*.

IgA does not only exert immune functions at the luminal ocular surface but also locally inside the tissue. IgA has a low complement-binding activity and hence acts in an antiinflammatory fashion. Bound antigens are opsonized to phagocytes which facilitates microbe uptake and destruction. IgA can bind to pathogens that have already penetrated into the tissue including intracellular viral particles. During the vectorial transport of pIgA toward the lumen, the bound pathogens are cleared from the tissue. IgA-bound antigens have an antiinflammatory effect on signaling networks and immune regulation inside the tissue by induction of the tolerogenic cytokines TGF-β and IL-10 and by limiting the activation of DC.

Lamina Propria Leukocytes Provide Immediate Innate Response against Invading Pathogens and can Orchestrate an Inflammatory Reaction

Apart from the lymphocytes, various other types of bone-marrow-derived leukocytes exist in the diffuse conjunctival effector tissue that are all not purely pathogenic, but exert important protective immune functions. Macrophages are reportedly frequent in immunohistochemistry but less obvious in conventional histology (**Figure 3(a)**). Phagocytes, such as macrophages, granulocytes, and DCs, can engulf and devour the invader but in addition, they act in different ways. Macrophages mainly destroy pathogens by internal digestion but are also capable to present epitopes of the pathogen on the MHC-class-II molecule (MHC-II) to $CD4^+$ T helper-cells for their subsequent activation. DCs digest pathogens mainly for this purpose. Granulocytes, also known as polymorphonuclear (PMN) cells, are usually the first cells that arrive at the site of acute defense reactions.

Protective functions of conjunctival lamina propria leukocytes

Neutrophile granulocytes are regularly observed in the normal human conjunctiva. They account for about 5% of the leukocytes and occur massively in the closed-eye tear film. In addition to their phagocytic capacity, they secrete several soluble factors such as antimicrobial proteins (e.g., lactoferrin, alpha-defensins, and cathelicidin) for immediate destruction of microbes. Furthermore, they secrete proteases (e.g., cathepsins, gelatinase, and neutrophile elastase) that lead to digestion of the extracellular matrix in order to provide space for accommodating the plethora of cells necessary to mount an effective inflammatory response. Eosinophile granulocytes are reportedly not observed in a normal conjunctiva but immigrate in parasitic infection. They produce chemokines and cytokines (e.g., RANTES [CCL5], TGF-β, TNF-α) for the activation and recruitment of other leukocytes including T-cells, as found in ocular allergy. Mast cells, apart from their potential physiological function, are mainly known for their inflammatory activity during IgE-mediated allergic disease where they release a variety of vasoactive mediators (e.g., histamine and heparin) and Th1 and Th2 cytokines (IL-4, IL-5, IL-6, and TNF-α) that can orchestrate an inflammatory response.

HEVs Provide the Regulated Immigration of Bone-Marrow-Derived Cells into the Tissue

The bone-marrow-derived cells that populate the conjunctiva all arrive here via the blood stream. Most of them stay here but lymphocytes, after being primed, and DCs, after antigen uptake, can also leave the tissue again via lymphatics. Although lymphocytes can emigrate through ordinary capillaries and venules, they do so with higher efficiency through conjunctival HEV via their tissue-specific adhesion molecules (lymphocyte homing molecules) that interact with vascular endothelial addressins. HEVs occur particularly in the para-follicular T-cell areas of lymphoid follicles (**Figure 2(c)**) but they are also found in the diffuse lymphoid effector tissue of the conjunctiva. Emigrated T-cells are frequently observed around HEV (**Figures 3(c)** and **3(d)**). Conjunctival HEVs are a normal component of the lymphoid tissue and they have a characteristic ultrastructure similar to that in other mucosal organs.

Conjunctival Lymphoid Follicles Have a Typical Morphology and Function

Solitary organized lymphoid follicles are interspersed into the diffuse effector tissue along the conjunctiva. They are relatively flat due to the limited space in the narrow conjunctival lamina propria but still show typical follicular characteristics. They consist of accumulations of B-cells (**Figure 4(a)**). The overlying epithelium changes its morphology toward the apex into a follicle-associated epithelium (FAE) by losing the goblet cells, by assuming a flat cell shape (**Figures 4(a)–4(c)**), and by a rarefied expression of SC (**Figure 4(c)**). Groups of lymphocytes, including $CD20^+$ B-cells (**Figure 4(a)**) and $CD3^+$ T-cells, occur inside the epithelium and are separated from the lumen just by a very narrow epithelial lining. Altogether, this is a conspicuous sign for the presence of specialized M-cells that form intraepithelial pockets populated by lymphoid cells. M-cells serve for the uptake and transport of luminal antigens toward the lymphoid cells in the pocket that can detect the antigen and present it to naive lymphocytes. The typical morphology of conjunctival M-cells and their antigen transport have been verified in a number of animal species, including guinea pig, turkey, chicken, rabbit, dog, and monkey. It has been shown that CALT is able, for example, to induce a tolerance against retinal antigens upon their topical conjunctival instillation.

The number of lymphoid follicles in elderly humans is relatively low (about 10 follicles per eye) with an average diameter of about 0.25 mm. Their small size again offers an explanation for the fact that CALT has frequently been overlooked in the past. They are more frequent in the upper conjunctiva than in the lower one (**Figure 5(a)**) and show a bilateral symmetry. In younger individuals, however, lymphoid follicles are more frequent and before puberty they occur in every person. Therefore, CALT follicles show a similar involution with age as observed for other locations of the mucosal immune system in general. Mucosal lymphoid B-cell follicles and their associated para-follicular T-cell zones (**Figure 2(c)**) serve for the generation of B- and T-effector lymphocytes, respectively (**Figure 7**).

The Topographical Distribution of CALT is in the Right Place to Assist Corneal Immune Surveillance

If the distribution of CALT is used to draw a topographical map (**Figure 5(b)**), it corresponds to the position of the cornea during eye closure. CALT in the tarso-orbital regions of the palpebral conjunctiva is then in the right position to support the immune protection of the cornea, which itself is largely devoid of lymphoid cells and other leukocytes. CALT may act during blinking as an immunological windscreen wiper and during sleep as an immunological cushion that covers the cornea (**Figure 5(c)**).

CALT can provide the cornea with innate and specific antibacterial peptides and proteins including SIgA that are not produced there. This concerns the usual daytime setting when the conjunctiva regularly glides over the cornea and wipes it clean. Even more so, CALT may be

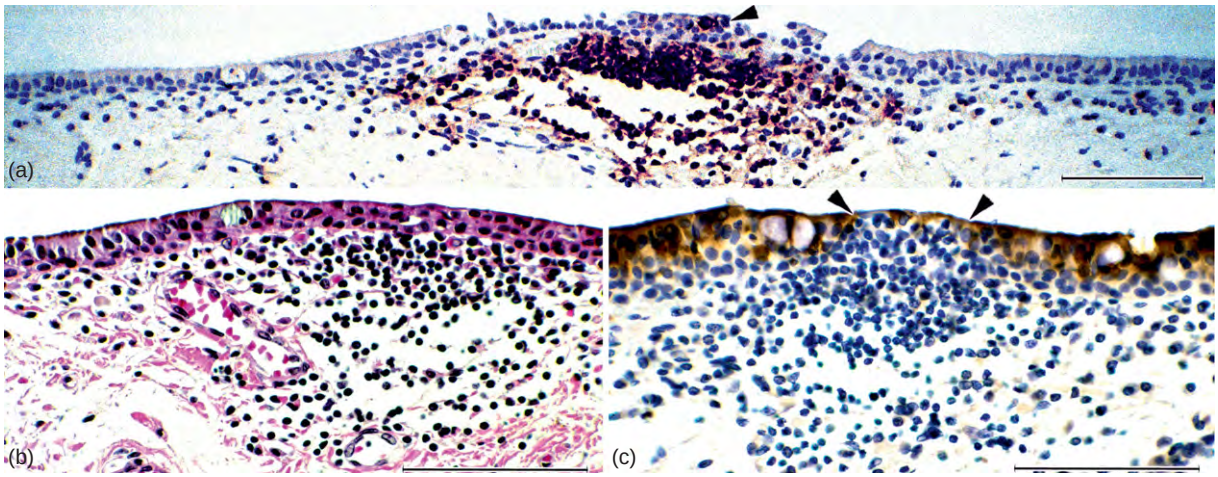

Figure 4 Characteristics of follicular CALT. (a) Even smaller lenticular lymphocyte accumulations are primarily composed of B-cells in immunostaining (brown dots). Over the apex, the overlying epithelium becomes flatter ((b), this follicle is not exactly met at the apex) and changes into a follicle-associated epithelium (FAE, between arrowheads in (c)), where goblet cells are absent, immunostaining for secretory component is rarefied (c) and numerous intraepithelial lymphocytes (IEL) are present in groups, suspicious for M-cells. The IEL are arranged in groups, including B-cells (arrowhead in (a)). Immunostaining for $CD20^+$ B-cells (a) and the IgA-transporter SC (c) of a small, almost flat, follicular accumulation that appears homogeneous, apart from disintegration at the location of the former germinal center, in HE staining (b); size bar in all figures = 100 μm. From Knop, N. and Knop, E. (2000). Conjunctiva-associated lymphoid tissue in the human eye. *Investigative Ophthalmology and Visual Science* 41: 1270–1279.

relevant during nighttime when the eye is closed. Then, an upregulated level of proinflammatory factors from PMN cells is obtained as a temporary approach in order to dampen the growth of the entrapped microorganisms that enjoy a comfortable environment without disturbance. Due to the intimate contact, CALT can also detect corneal antigens and generate respective effectors.

CALT is a Part of the Complete Eye-Associated Lymphoid Tissue

The conjunctival mucosa is, at the temporal and nasal side (**Figure 6**), anatomically continuous, through the lacrimal excretory ducts, with the lacrimal gland and through the lacrimal canaliculi with the lacrimal drainage system, respectively.

The histology clearly shows that a continuous mucosal immune system is also present from the periacinar tissue of the lacrimal gland throughout the conjunctiva into the lacrimal drainage system, that is, along the extended ocular surface. Together, this constitutes an eye-associated lymphoid tissue (EALT) and CALT is the regional part of it at the ocular surface proper (**Figure 6**).

EALT is an undividable anatomical and functional unit and its different parts support each other in function. EALT is in line with the other parts of the mucosal immune system of the body, such as gut-associated lymphoid tissue (GALT) in the gut or bronchus-associated lymphoid tissue (BALT) in the bronchi. Therefore, primed effector cells from EALT can be distributed by the regulated recirculation of lymphocytes (**Figure 2(b)** and **(c)**) within the mucosal immune system in order to repopulate the ocular surface mucosal tissues and other mucosa-associated lymphoid tissue (MALT) locations and in return, EALT can also share effector cells from other organs.

Mechanisms of Conjunctival Immune regulation

CALT Is Physiologically Biased to Tolerogenic, Anti-Inflammatory Responses

The mucosal immune regulation including CALT is maintained via the mode of antigen presentation by APC, on their MHC-class-II, to the T-cell-receptor (TCR) of naïve $CD4^+$ T-cells (To) and influenced by additional signals such as co-stimulatory molecules and the prevailing cytokine milieu within the tissue. This leads to the generation of different types of $CD4^+$ Th cells which produce characteristic cytokine patterns and have different functions (**Figure 7**). Due to the prevalence of nonpathogenic antigens and the delicate tissue construction, CALT is biased toward anti-inflammatory immune answers. Tolerance is also necessary in order to avoid autoimmune reactions against own tissue constituents by self-reactive T-cells.

Normally, CALT favors Th2 cells under the influence of cytokines such as IL-4. These interact with B-cells and produce cytokines (e.g., IL-4, IL-5, and IL-13) that promote B-cell Ig iso-type class switch to IgA and their differentiation into IgA-secreting plasma cell precursors

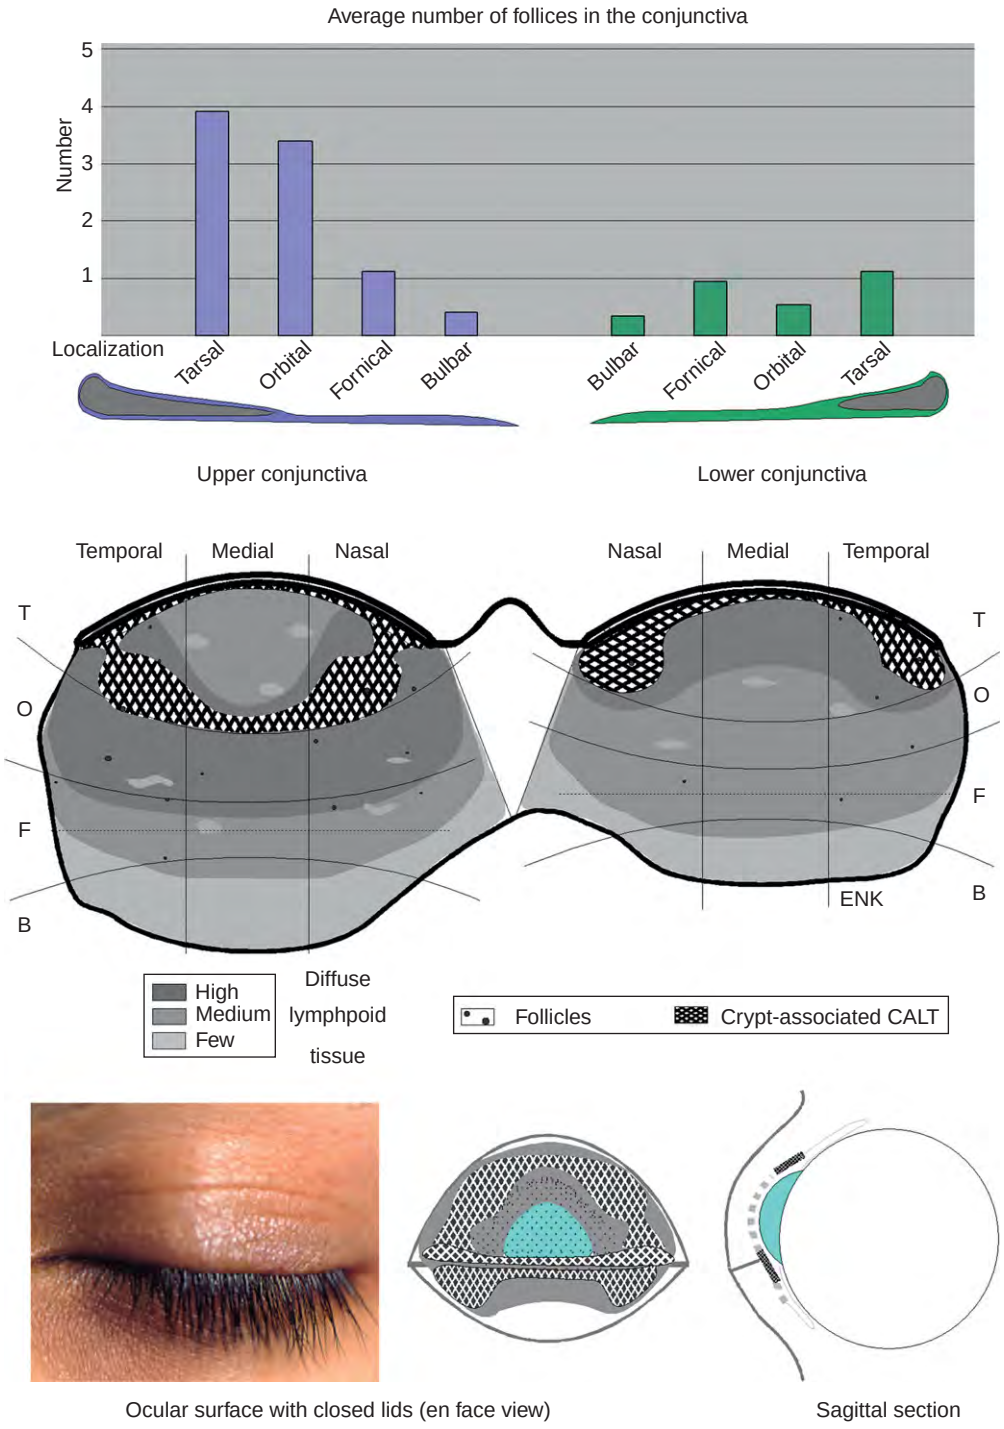

Figure 5 Topography of CALT – in the right position to assist corneal immune protection. (a) Morphometrical analysis of lymphoid follicles in the different zones (tarsal, orbital, fornical, bulbar) of upper (left) and lower (right) human conjunctiva, in a flat preparation of a tissue whole mount, shows a main expression in the tarso-orbital zones. More follicles are present in the upper lid and the average total number of CALT follicles in an elderly population is about 10 follicles per eye. (b) The topographical distribution of lymphoid follicles is the same as that of the diffuse lymphoid effector tissue in which they are interspersed, as seen in a topographical map of CALT in a complete flat whole mount of a human conjunctiva with the lid margin to the top and the nasal zone in the middle. The map differentiates the previously mentioned zones (T, O, F, B) as well as temporal, medial, and nasal locations. Increasing density of diffuse lymphoid cells is indicated as increased shades of gray. Hatched lines indicate the location of conjunctival crypts of Stieda that are associated with CALT. (c) If the topographical distribution of CALT is projected onto the bulbar surface in a closed lid situation, it is obvious that CALT covers the cornea as seen in frontal en face view (middle) and sagittal section (right). The central portion is covered by the tarsal crypts of Henle (open circles in middle figure) that are associated with CALT but not indicated in the topographical map in (b). From Knop, E. and Knop, N. (2003) *Eye-Associated Lymphoid Tissue* (*EALT*) *is Continuously Spread Throughout the Ocular Surface from the Lacrimal Gland to the Lacrimal Drainage System*. Der Ophthalmologe, Heidelberg: Springer.

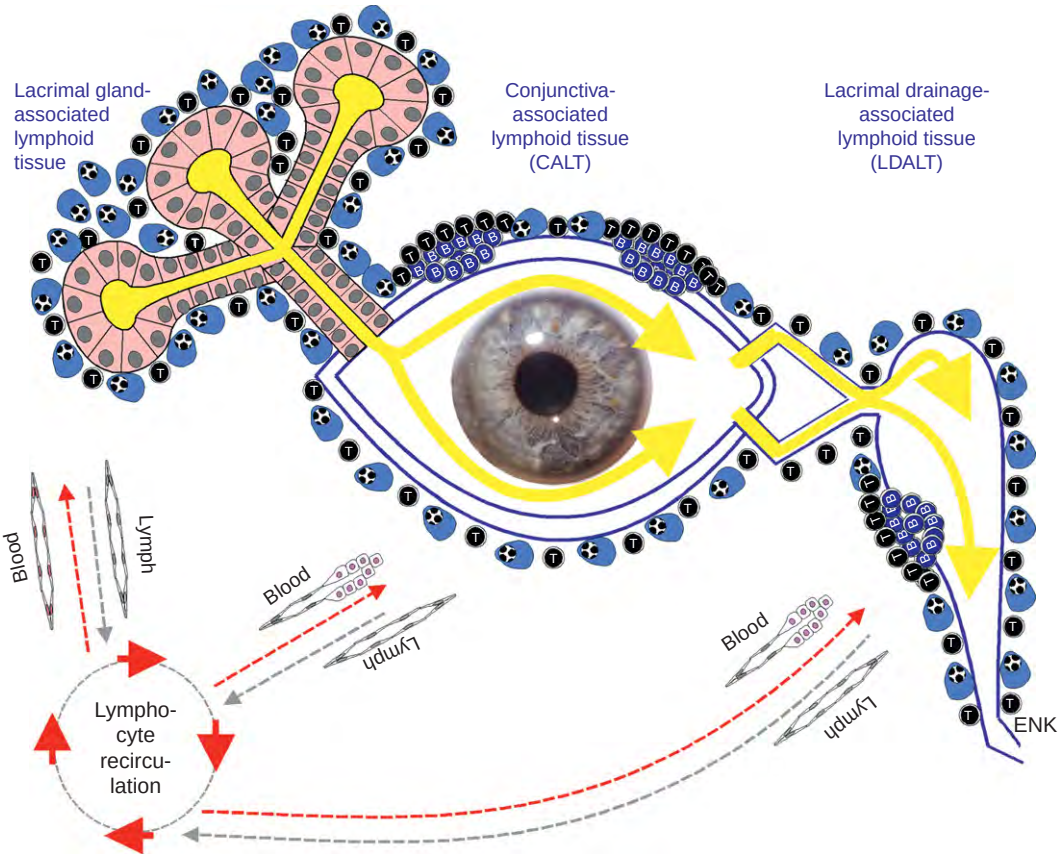

Figure 6 Eye-associated lymphoid tissue (EALT). Eye-associated lymphoid tissue integrates the continuous mucosal immune system of the conjunctiva (CALT) and its mucosal adnexa, composed of the lacrimal gland and lacrimal drainage system, which together form the extended functional ocular surface. The ocular tissues belong together embryologically and functionally. They are connected by the flow of tears (yellow arrows) which lets them share protective immune factors as well as antigens and they are furthermore connected by the regulated recirculation of lymphoid cells in the body via efferent lymph vessels and blood vessels. Lymphoid cells enter the tissues via blood vessels, including high endothelial venules (represented by roundish endothelial cells), and leave them via lymphatics. EALT is continuous throughout these organs in the form of a diffuse lymphoid effector tissue composed of T-lymphocytes (represented by black cells in the drawing) and plasma cells (represented by large blue cells) together with accessory leukocytes (not indicated here, compare **Figure 2(b)**). Inductive sites, in the form of lymphoid follicles, composed of B-cells (small blue cells) with adjacent para-follicular T-cell areas (compare **Figure 2(c)**), are present in CALT and LDALT. They serve for the uptake and presentation of antigens and for the subsequent generation of respective effector cells specific for the ocular surface relevant antigens. Not only the effector cells generated in EALT, but also those from other mucosal sites, can, after recirculation in the lymph and blood system, populate the diffuse lymphoid effector tissue that is present along the whole extended ocular surface including the large mucosa-associated gland (lacrimal gland). Adapted from Knop, E. and Knop, N. (2007). Anatomy and immunology of the ocular surface. In: Niederkorn, J. Y. and Kaplan, H. J. (eds.) *Immune Response and the Eye. Chemical Immunology and Allergy*. Basel: Karger Verlag.

and mature plasma cells as observed in the conjunctiva. Under the influence of mainly IL-6, the well-known inflammatory Th1 cells are formed that produce inflammatory cytokines such as IFN-γ and TNF-α which have the physiological function to activate cells, in particular phagocytes, to destroy intracellular pathogens. If inflammatory cytokines and other danger signals, such as bacterial LPS or components of dead cells occur in the tissue, they can bind to TLRs and mediate the secretion of excess inflammatory cytokines that skew CALT toward inflammatory immune answers. The antagonistic action of Th1 and Th2 cells led to the construction of the Th1–Th2 paradigm for explanation of immune regulation and phenomena at the ocular surface. In recent years, however, other anti-inflammatory (regulatory T-cells, Treg) and inflammatory (Th17 cells) were also observed which indicated that immune regulation is more complex (**Figure 7**) and needs further investigation.

Deregulation of EALT Is a Central Component of Inflammatory Ocular Surface Disease

Various stress mechanisms, for example, mechanical alteration, hyperosmolar tears or exposure to inflammatory cytokines can pathologically activate the ocular surface epithelium that responds by secretion of (further) inflammatory cytokines and proteases (such as matrix-metalloproteinase, MMP) and upregulates surface

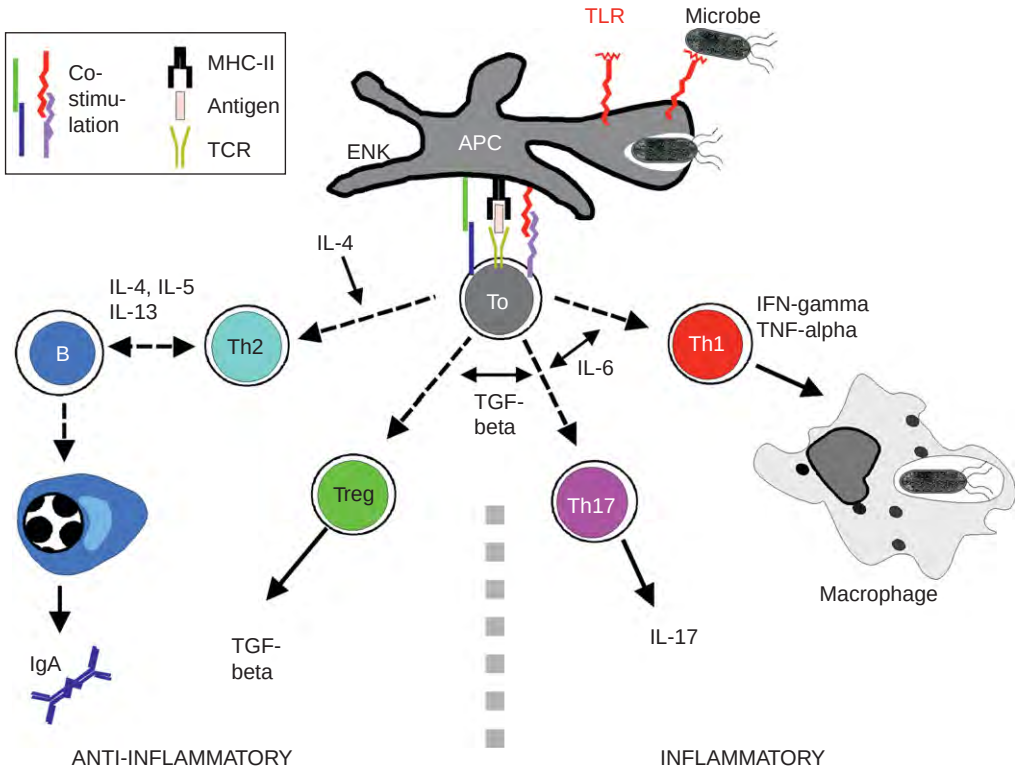

Figure 7 Generation of T- and B-effector cells in CALT. Immune regulation in CALT is governed via the presentation of antigens by antigen-presenting cells (APC) on their MHC-class-II (MHC-II) to the T-cell-receptor (TCR) of naive $CD4^+$ T-cells (To), and assisted and modulated by co-stimulatory molecules. This is influenced (indicated by uninterrupted arrows) by cytokines (interleukins, IL) and by microbial antigens that are recognized, for example, by TLR. This leads to the generation (interrupted arrows) of different types of $CD4^+$ T-helper cells (Th) that produce characteristic cytokine patterns and perform different functions. CALT is naturally biased toward anti-inflammatory immune answers. It favors the generation of Th2 that promote B-cells to differentiate into IgA secreting plasma cells. It also favors Treg that produce anti-inflammatory TGF-beta. Binding of microbial antigens to TLR and presence of IL-6 represents danger signals to the immune system and induces inflammatory immune answers via Th17 and Th1, the latter of which normally assist phagocytic cells to clear intracellular pathogens.

markers, such as ICAM-1 and MHC-class-II. This promotes an inflammatory process and through MCH-class-II the epithelial cells acquire the potential for presentation of antigens, including self-antigens, to resident conjunctival T-cells (**Figure 8(a)**) that can induce a loss of natural conjunctival immune tolerance.

Similar events are also shown for the acinar epithelial cells in inflammatory disease of the lacrimal gland where diverse perturbations result in altered intracellular protein traffic, alter the lacrimal acinar cell autoantigenic spectra, and upregulate MHC-class-II. This results in a loss of tolerance to own cell constituents, such as the M3 receptor with a subsequent autoimmune process. This again indicates that the natural tolerogenic bias can be lost in inflammatory disease and may be the underlying reason for a self-perpetuating inflammatory process at the ocular surface and its associated gland.

In fact, in inflammatory ocular surface diseases such as dry eye disease, autoreactive T-cells are generated that are specific to ocular surface tissue. They can be transferred and lead to destruction of the same ocular tissues in a naive recipient that has never experienced the pathological condition. Respective Tregs can prevent the tissue destruction and offer therapeutic potentials.

In addition, wounding can allow the entry of nonpathogenic antigens into the tissue and their presentation to T- and B-cells, as observed in ocular allergy. Downstream effects are the activation of conjunctival vascular endothelial cells that upregulate adhesion molecules (such as ICAM-1, VCAM-1, or E-selectin) with subsequent recruitment of further leukocytes from the vascular compartment and the activation of bystander cells including stromal fibroblasts. They contribute to the accumulation of MMPs that lead to tissue degradation. Altogether, this constitutes an immune-mediated conjunctival inflammatory process (**Figure 8(a)**), that can be compared with events in other mucosal organs, for example, in inflammatory bowel disease, and is based on a deregulation of the physiologically protective CALT and perpetuated by several vicious circles.

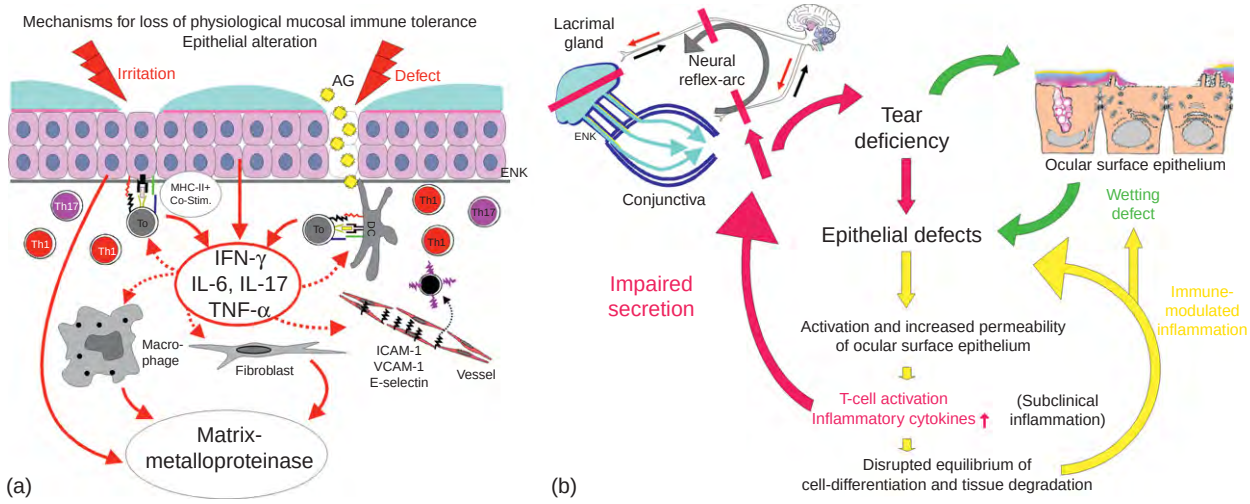

Figure 8 Deregulation of CALT determines immune-mediated inflammatory ocular surface disease. (a) Compromised integrity leads to loss of mucosal immunological tolerance and to immune-mediated inflammation. Irritation of the surface epithelium, for example, by tear film (light blue) defects, its infection or its wounding results in activation of the epithelial cells. These may respond by secretion of inflammatory cytokines and proteases (such as matrix-metalloproteinase, MMP) and by expression of the antigen-presenting molecule MHC-class-II (MHC-II) resulting in potential presentation of self-antigens to resident conjunctival T-cells. Wounding with physical defects can, in addition, allow the entry of nonpathogenic antigens into the tissue and their presentation in the context of inflammatory cytokines as observed in ocular allergy. As described for immune-regulation (**Figure 7**) this represents danger signals that contribute to a further accumulation of inflammatory cytokines in the tissue and to the generation of inflammatory, potentially autoreactive, types of T-cells. All of which is shown in inflammatory ocular surface disease. Downstream effects are the activation of vascular endothelial cells that upregulate adhesion molecules with subsequent recruitment of further leukocytes from the vascular compartment and the activation of bystander cells, including stromal cells (fibroblasts). They contribute to the accumulation of MMPs that lead to tissue degradation which all together constitutes an immune-mediated conjunctival mucosal inflammatory process that is based on a deregulation of the physiologically protective CALT. (b) Immune-mediated inflammation is a core mechanism that results in several vicious circles in the pathogenesis and propagation of ocular surface disease. An immune-mediated inflammation represents an important common factor in the vicious circles of ocular surface disease, including the dry eye syndrome and ocular allergy, which is first subclinical but tends to amplify if it is not limited. Tear film deficiency results in epithelial defects and these in turn are an important primary factor for onset of an immune-mediated inflammatory conjunctival process that tends to self-propagation via several vicious circles. These include disturbance of afferent innervation resulting in impaired secretion with further tear film deficiency and increase of epithelial damage and in impairment of mature ocular surface differentiation (leading to squamous metaplasia) that results in wetting defects and amplification of epithelial destruction. Conjunctival Goblet Cells

R R Hodges and D A Dartt, Schepens Eye Research Institute, Boston, MA, USA

Glossary

Dry eye – A multifactorial disorder of the tear film characterized by either decreased tear production or increased tear evaporation.
Glycosylation – The process by which a carbohydrate is added to protein.
Goblet cells – Specialized epithelial cells that secrete mucins.
Mucins – Large, highly glycosylated proteins.
Signal transduction – The process by which a cell converts a signal or stimulus from outside the cell into a functional change.

Goblet cells are columnar epithelial cells that synthesize and secrete mucins, for example, the gel-forming mucin MUC5AC. These cells were originally termed goblet cells because of their distinctive goblet-like shape (Figure 1). The basal portion is narrow and shaped like the stem of a goblet containing the nucleus and organelles, while the apical portion of the cell is shaped like a cup due to the presence of numerous secretory granules. Goblet cells are found in all wet-surfaced epithelia such as the respiratory, gastrointestinal, and reproductive tracts, and the conjunctiva and are surrounded by stratified squamous epithelial cells. Goblet cells of the respiratory, gastrointestinal, and reproductive tracts have been extensively studied with regard to secretion and proliferation in healthy and diseased states. Conjunctival goblet cells have not been studied as extensively, but much information is available. The purpose of this article is to examine the current knowledge of conjunctival goblet cells.

Goblet Cell Development

In humans, conjunctival goblet cells begin to appear in the eighth to ninth week of gestation in the region of the lid margin. By the 11th to 12th week, mature goblet cells can be seen containing secretory granules in the palpebral conjunctiva. Goblet cells appear in the bulbar conjunctiva around the 20th week. In the developing chick, goblet cells appear 2 days after hatching in the fornix and 3 days after hatching in the palpebral and bulbar conjunctivae. In rats, messenger ribonucleic acid (mRNA) expression for the conjunctival goblet cell-specific mucin, MUC5AC, first appears 1 day after birth, before eyelid opening. This expression was detected in cells in the fornix region. By day 13 (before eyelid opening), a few round-shaped cells in the fornix expressed cytokeratin 7 (a cytokeratin expressed in goblet cells of adult rats) and were positive for alcian blue/periodic acid Schiff's (AB/PAS) reagent, a stain that that binds to sialomucins synthesized and secreted by the goblet cells. These cells also bind Ulex europaeus agglutinin I (UEA-I), which is a lectin that binds specific glycoprotein moieties present in adult goblet cells of the rat. In humans, the lectin Helix pomatia agglutinin (HPA) specifically binds to the goblet cell secretory products. On day 17, single and small clusters of these cells were seen distributed in the fornix and palpebral regions. Goblet cell clusters were seen by day 60. In addition to the appearance of the secretory product, by day 17, immunofluorescence microscopy showed nerves surrounding the basolateral portion of goblet cell clusters and the muscarinic receptor subtypes M_2 and M_3 and β_1- and β_2-adrenergic receptors were located on the goblet cells. The presence of nerves and neurotransmitter receptors on goblet cells around the time of eyelid opening (12–15 days after birth) implies that mucin secretion is regulated as the eyes open (Figure 2).

There is considerable evidence that stem cells of the conjunctival epithelium, including goblet cells, are distinct from the stem cells of the cornea. This is despite the fact that conjunctival cells can, in the case of a corneal wound involving the limbus, rapidly migrate over the wound and eventually form an epithelium similar to the normal cornea that does not contain goblet cells. However, when bulbar, fornical, and palphebral conjunctivae were grown separately, each with 3T3 feeder cells, they did not express the cornea-specific cytokeratin pair of K3/K12. In addition, when cultured conjunctival cells were injected into athymic mice, the epithelial cyst formed contained epithelial and goblet cells. Given these data, it is thought that conjunctival stem cells are different from stem cells of the cornea.

It is well established that corneal stem cells reside in the limbus, the area between the cornea and bulbar conjunctiva. The location of conjunctival stem cells is not as clear. In the mouse and rabbit, it is believed that the stem cells reside in the fornix based on the fact that slow-cycling cells are clustered in the fornix, and these cells do not incorporate tritiated thymidine or bromodeoxyuradine that label dividing cells. In addition, cells in the fornix have the highest rate of proliferation *in vitro*.

Cells grown from the bulbar conjunctiva and fornix had the same proliferative capacity as cells grown from

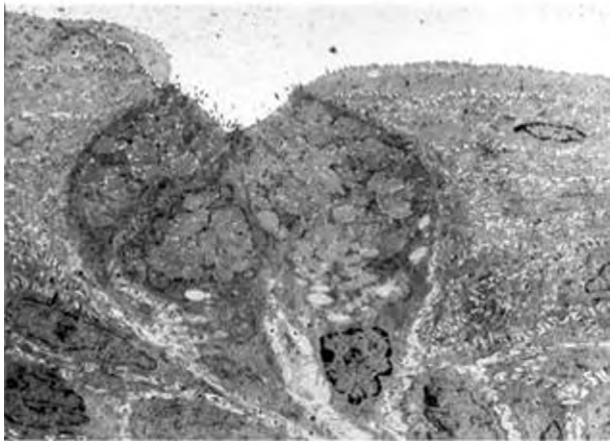

Figure 1 An electron micrograph of rat conjunctival goblet cells. Numerous secretory vesicles can be seen in the apical portion of the cells, while nuclei can be seen in the apical portion. With kind permission of Elsevier.

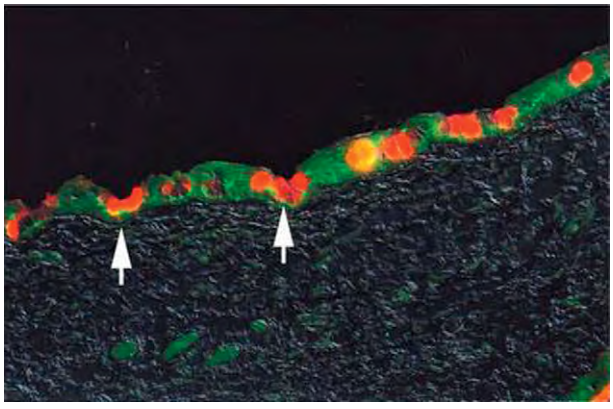

Figure 2 Co-localization of the M3 muscarinic receptor with goblet cells from the developing rat conjunctiva. Sections from a 17-day-old rat conjunctiva were incubated with an antibody against M3 muscarinic receptor (shown in green) and the lectin UEA-I conjugated to rhodamine (shown in red) which is specific for rat goblet cells. Goblet cells were visualized with differential interference contrast microscopy. Arrows indicate the presence of M3 muscarinic receptor subjacent to the secretory vesicles (shown in red). Magnification ×200.

the corneal limbus. Cells from all areas of the fornix and bulbar conjunctiva were capable of undergoing 80–100 cell divisions before reaching senescence, similar to limbal cells. Interestingly, goblet cells were present during the entire life span of the cultures of fornix and bulbar conjunctivae and the number of goblet cells increased during cultivation of the cell cultures. As goblet cells were present during the entire culture time, it seems likely that conjunctival stem cells are bipotent, that is, capable of differentiating into either goblet or stratified squamous cells. It is not known what causes the stem cell to differentiate into either cell type. Possible explanations include genetic programming as it was demonstrated that conjunctival cells with high proliferative capacity differentiate into goblet cells at specific times in their cell cycle of duplication. The first goblet cells appear after a cell has achieved 45–50 doublings and, subsequently, another 10–20 doublings before senescence occurs. It is also possible that environmental effectors such as cytokines or growth factors play a role in the differentiation of a goblet cell.

The number of goblet cells in the adult conjunctiva varies depending upon the location in the conjunctiva and species. For example, in the rabbit: (1) the tarsal conjunctiva contains the highest number of goblet cells while the bulbar conjunctiva contains the least, (2) the goblet cells of the tarsal conjunctiva were larger than those present in the bulbar conjunctiva, and (3) conjunctival goblet cells appeared as single cells interspersed throughout the stratified squamous epithelial cells. In contrast, in the rat: (1) the fornix contained the most goblet cells while very few were seen in the bulbar and limbal conjunctivae and (2) goblet cells appear as clusters with as many as 10 goblet cells present in some clusters in the fornix (**Figure 3**). Goblet cells in the human conjunctiva tend to appear as single cells (**Figure 4**), similar to the rabbit, though in certain areas, the density of goblet cells is high enough such that they appear to be clustered. The highest goblet cell density in human conjunctiva is in the inferior palpebral conjunctiva. It has been proposed that clusters of goblet cells, such as those that occur in rats, arise from the fact that goblet cells divide several times before senescence giving rise to the clusters. In contrast, in species such as rabbit and human, where goblet cells occur as single cells in the conjunctiva, differentiation into goblet cells occurs after the cell has undergone terminal differentiation.

Function of Conjunctival Goblet Cells

The tear film is a thin layer of fluid that covers the ocular surface. Tears are secreted in response to decreased humidity, bright light, mechanical stimulation, bacterial and viral pathogens, and other environmental factors. The tear film is a stratified fluid layer consisting of three layers: (1) the outermost, which is a lipid layer secreted by meibomian glands of the upper and lower eyelids and is thought to be a barrier to evaporation; (2) the middle, which is an aqueous layer secreted essentially by the main and accessory lacrimal glands and contains water, electrolytes, and proteins such as growth factors and antibacterial proteins necessary for the health of the ocular surface; and (3) the innermost, which is a mucin layer, containing mucins that are not only secreted mainly by the conjunctival goblet cells, but also the stratified squamous cells of the cornea and conjunctiva. The mucin layer moves freely over the ocular surface toward the nasolacrimal

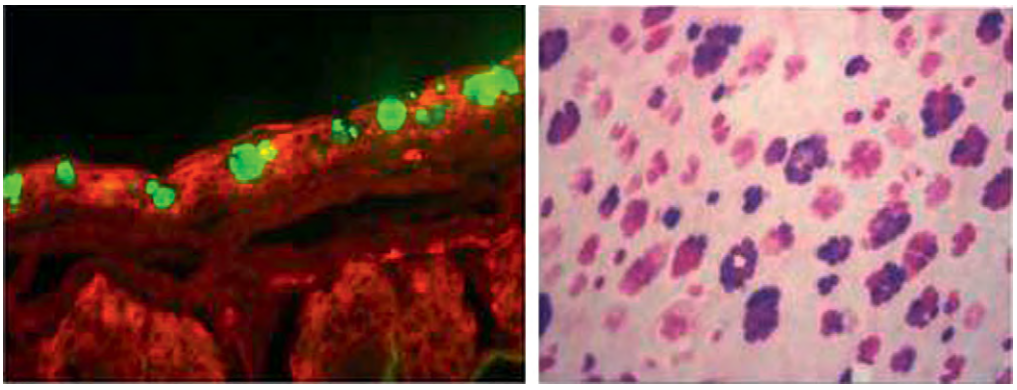

Figure 3 Goblet cell clusters in rat conjunctiva. Rat conjunctival sections were incubated with the EGF receptor (shown in red) the lectin UEA-I conjugated to fluorescein isothiocyanate (FITC; shown in green) which is specific for rat goblet cells (left). Flat mounts of rat conjunctiva were prepared and stained with AB/PAS (right). Goblet cells appear as pink-to-purple cells. These micrographs indicate the clusters of goblet cells in rat conjunctiva. Magnification ×200.

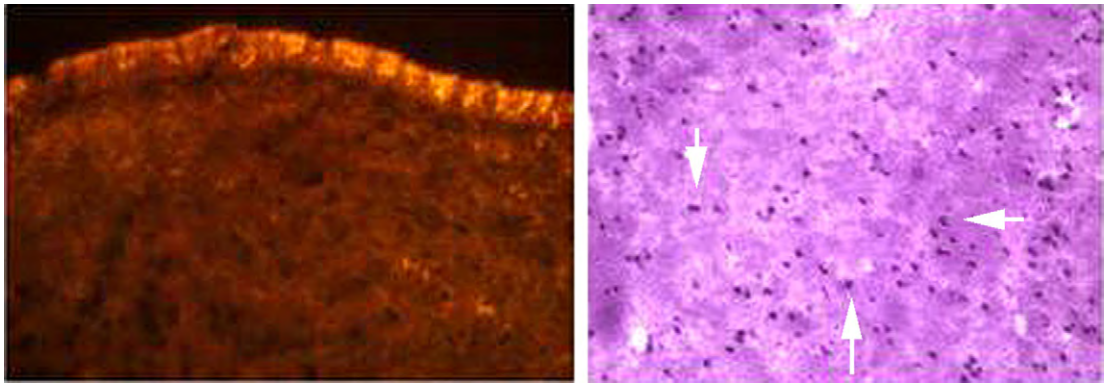

Figure 4 Goblet cell in human conjunctiva. Human conjunctival sections were incubated with an antibody specific to cytokeratin 7 (shown in red) which is specific for goblet cells (left). Impression cytology samples of human conjunctiva were prepared and stained with AB/PAS (right). Arrows indicate goblet cells. These micrographs indicate that goblet cells occur as single cells. Magnification ×200.

duct with the blink providing the mechanism of movement. As it moves, it traps debris and pathogens.

The function of conjunctival goblet cells is to synthesize and secrete mucins onto the ocular surface. Mucins are large, highly glycosylated proteins containing tandem repeats of amino acids that are rich in serine and threonine. Owing to the large amount of glycosylation, mucins are highly negatively charged molecules that are believed to be a barrier to pathogens. The glycosylation moieties are quickly hydrated upon exiting the cell, causing them to swell. Thus, mucins provide lubrication, water retention, and a barrier to infectious agents. Members of the mucin family can be subdivided based on whether they are secreted from the cell (secretory) or remain associated with the plasma membrane (membrane associated). While other members of the mucin family, namely MUC1, MUC2, MUC4, and MUC16, are present in the conjunctiva, only the gel-forming, secretory mucin MUC5AC has been identified in conjunctival goblet cells.

MUC5AC is a large gel-forming mucin that is closely related to the other gel-forming mucins MUC2, MUC5B, and MUC6. It contains four cysteine-rich domains (D domains), a tandom repeat region that can be duplicated 17–124 times, as well as a cysteine knot along with an additional cysteine region. The D domains, based on their large number of cysteines, form disulfide bridges with other MUC5AC molecules to form a large gel-like association of mucin molecules (**Figure 5**).

Control of Goblet Cell Proliferation and Mucin Secretion

It is vital for the mucin in the tear film be of sufficient quantity and quality. The quantity of mucin depends on the: (1) number of goblet cells present (proliferation or differentation), (2) amount of mucin synthesized and

stored in secretory granules, (3) rate of mucin secretion, and (4) rate of mucin degradation. There are no studies on the rate of mucin synthesis or mucin degradation.

Goblet Cell Proliferation

With the development of a method to culture conjunctival goblet cells, studies of goblet cell proliferation are now underway. One important stimulus of goblet cell proliferation is the epidermal growth factor (EGF) family as measured by both a cell proliferation assay kit and by immunoflouresence microscopy using the an antibody against Ki-67, a protein known to be present in cells that have entered the cell cycle. EGF, transforming growth factor α (TGFα), heparin-binding EGF (HB-EGF), and heregulin are present in rat conjunctiva as well as cultured rat goblet cells as determined by reverse transcriptase polymerase chain reaction (RT-PCR), Western blot analysis, and immunofluorescence microscopy. EGF, TGFα, and HB-EGF increased goblet cell proliferation through activation of the EGF receptor. There are four types of EGF receptors, namely ErbB1 (the EGF receptor), ErbB2 (HER), ErbB3, and ErbB4. Each receptor binds to specific members of the EGF family. Activated EGF receptors form homo- or heterodimers and then recruit adaptor molecules including Shc/Grb2, phosphoinositide-3 kinase (PI-3K), phospholipase C (PLC)γ, p38 mitogen-activated protein kinase (MAPK), and c-jun NH (2)-terminal kinase (JNK). Each of these kinases initiates a cascade of kinases leading to a cellular response. The downstream kinase activated by Shc/Grb2 is the extracellular-related kinase 1/2 (ERK1/2); the downstream kinase activated by PI-3K is AKT; the downstream kinase activated by PLCγ is protein kinase C (PKC); and the downstream kinase activated by JNK is c-jun (**Figure 6**).

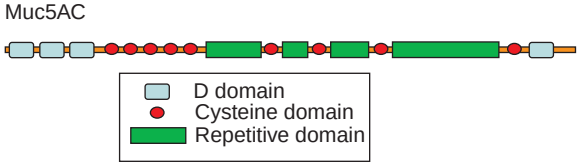

Figure 5 A schematic of MUC5AC.

Further investigation of the role of ERK in EGF-stimulated conjunctival goblet cell proliferation demonstrated that EGF increased the number of cells expressing ERK in their nucleus in a biphasic manner. Under basal conditions, ERK is present in the cytosol. Upon stimulation, ERK translocates to the nucleus where it phosphorylates proteins necessary for proliferation. The first, major peak occurs 1 min after the addition of EGF to cultured rat goblet cells. The number of goblet cells with ERK present in the nucleus returned to basal levels before increasing again approximately 18 h after the addition of EGF. The second peak corresponded with the appearance

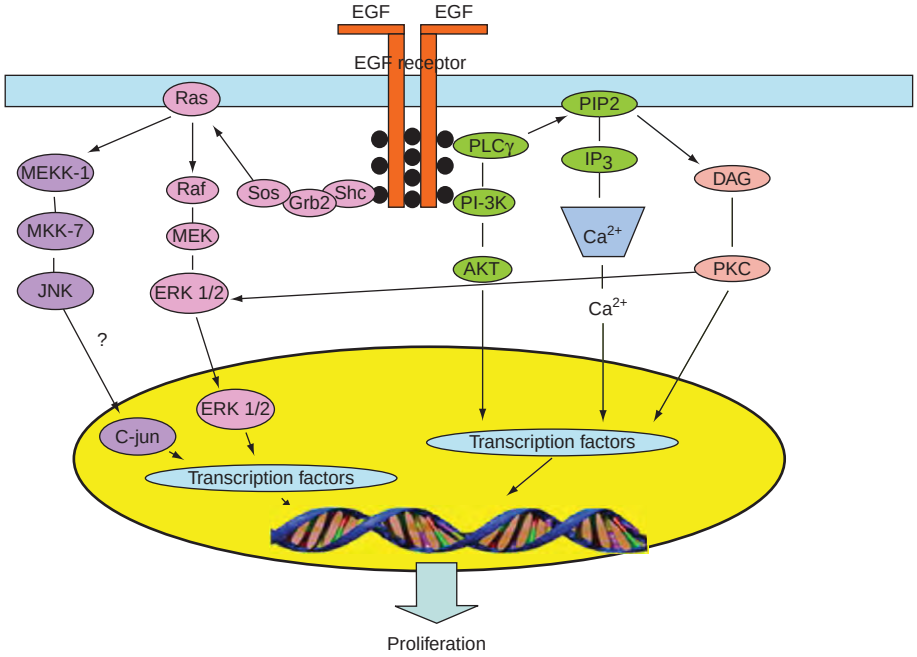

Figure 6 A schematic representation of the EGF pathway leading to goblet cell proliferation. EGF receptor dimerizes upon EGF binding, recruiting the adaptor molecules leading to cell proliferation. PI-3K, phosphoinositide-3 kinase; PLCγ, phospholipase Cγ; JNK, c-Jun NH (2)-terminal kinase; ERK1/2, extracellular-related kinase 1/2; PKC, protein kinase C; PIP2, phosphatidylinositol bisphosphate; IP_3, inositol trisphosphate; DAG, diacylglycerol; PKC, protein kinase C; MEK, mitogen-activated kinase kinase; MEKK-1, mitogen-activated kinase kinase-1; MKK-7, mitogen activated kinase kinase-7.

of Ki-67, indicating that goblet cells were starting to proliferate. The ERK inhibitor U0126, added 20 min prior to EGF, inhibited both peaks of the translocation of ERK as well as goblet cell proliferation. Interestingly, inhibition of the second peak of ERK translocation with U0126 also prevented EGF-stimulated proliferation. In addition to the activation of ERK, EGF also activates PKC isoforms -α and -ε to, in turn, stimulate proliferation.

Most proliferation studies to date have been performed on cultured goblet cells from rat. Several studies have examined the proliferation of human goblet cells in comparison to rat cells, and demonstrated that human goblet cells respond similarly to EGF. For example, EGF stimulates human goblet cell proliferation in a similar time- and concentration dependency. In both cell types, EGF activates ERK and PKC to stimulate proliferation. Due to the difficulty of obtaining a human conjunctiva and culturing human goblet cells, rat goblet cells are an excellent model for studying human goblet cell proliferation.

Goblet Cell Mucin Secretion

Goblet cell secretion occurs through an apocrine mechanism. In this mechanism, most or all the secretory vesicles fuse with one another upon stimulation and subsequently with the apical membrane releasing the mucin into the extracellular space. Therefore, the amount of mucin released is dependent upon the number of cells responding to a given stimulus. A strong stimulus would involve responses from more goblet cells than a weak stimulus. Taking advantage of this property, conjunctival samples can be treated with histochemical stains that recognize mucins in goblet cells, and the number of goblet cells can be counted. A decrease in the number of goblet cells would indicate an increase in secretion.

Another method to measure conjunctival goblet cell secretion is based on the fact that the lectins UEA-I and HPA bind to specific carbohydrate residues found in MUC5AC, depending on the species. The amount of secreted mucin can be determined by an enzyme-linked lectin assay (ELLA) and Western blot or dot-blot analyses.

Using the histochemical method of staining for mucins in a conjunctival button, it was demonstrated, for the first time, that goblet cell mucin secretion is neurally mediated, as a wound to the central cornea induced goblet cell mucin secretion. Sensory nerves in the cornea were activated by the wound causing a neural reflex arc in which the parasympathetic nerves that surround the goblet cells released their neurotransmitters to stimulate mucin secretion.

These results were confirmed when parasympathetic nerves containing the neuropeptide vasoactive intestinal peptide (VIP) were demonstrated to be present in the conjunctiva surrounding the goblet cells subjacent to the secretory granules. Addition of exogenous VIP or the cholinergic agonist carbachol (an analog of the parasympathetic neurotransmitter acetylcholine) stimulated goblet cell secretion. Other compounds which have been shown to stimulate conjunctival mucin secretion include activators of the purninergic receptor subtype $P2Y_2$, such as ATP, UTP, and INS365, the neurotrophins nerve growth factor, and bone-derived neurotrophic factor, and the drug OPC-12759, an antigastric ulcer drug. Interestingly, no sympathetic neurotransmitter has been shown to stimulate goblet cell secretion despite the presence of the receptors for these neurotransmitters on goblet cells.

The signal transduction pathways utilized by cholinergic agonists have been well studied. Cholinergic agonists bind to M2 and M3 muscarinic receptors which are present on conjunctival goblet cells. Classically, these receptors activate PLC, which hydrolyzes phosphatidylinositol-bisphosphate into 1,4,5-inositol trisphosphate (IP_3) and diacylglycerol (DAG) (**Figure 7**). IP_3 induces the release of Ca^{2+} from the endoplasmic reticulum into the cytosol. It is not known if this occurs in goblet cells; however, what is known is that an increase in intracellular Ca^{2+} alone is sufficient to cause mucin secretion from conjunctival goblet cells. Calcium can also activate Ca^{2+}-/calmodulin-dependent protein kinase. However, inhibitors of Ca^{2+}/calmodulin protein kinase do not have any effect on cholinergic agonist-stimulated mucin secretion.

DAG is a phospholipid activator that along with Ca^{2+} activates PKC. Though a direct role for PKC involvement in conjunctival goblet cell mucin secretion has not been demonstrated, activators of PKC (phorbol esters) do stimulate secretion.

In addition to the Ca^{2+} pathway, cholinergic agonists in goblet cells activate a second pathway leading to protein secretion. This pathway involves the transactivation of the EGF receptor through the stimulation of the focal adhesion kinase Pyk2. Pyk2, in turn, activates the nonreceptor tyrosine kinase p60Src. Pyk2 and p60Src are activated in goblet cells by Ca^{2+} and PKC as the addition of either a calcium ionophore or a phorbol ester increases phosphorylation (activation) of Pyk2 and p60Src and the use of PKC inhibitors inhibits cholinergic agonist-stimulated Pyk2 and p60Src phosphorylation (**Figure 7**). This again implies that PKC plays a vital role in conjunctival goblet cell secretion. The Pyk2/p60Src complex then transactivates the EGF receptor, recruiting the adaptor molecules Shc, Grb2, and the Ras guanine nucleotide exchange factor Sos. Sos binds to and activates the low molecular weight guanosine triphosphate (GTP)ase, Ras, causing the exchange of guanosine diphosphate (GDP) for GTP to activate Ras. Ras initiates another kinase cascade of Raf (also known as MAPK kinase kinase), mitogen-activated kinase kinase (MEK) (MAPK kinase), and ERK 1/2 (p44/p42 MAPK). Upon stimulation by cholinergic agonists, ERK activates proteins in the cytosol, leading to secretion. Inhibition of ERK inhibits cholinergic agonist-stimulated mucin secretion (**Figure 7**).

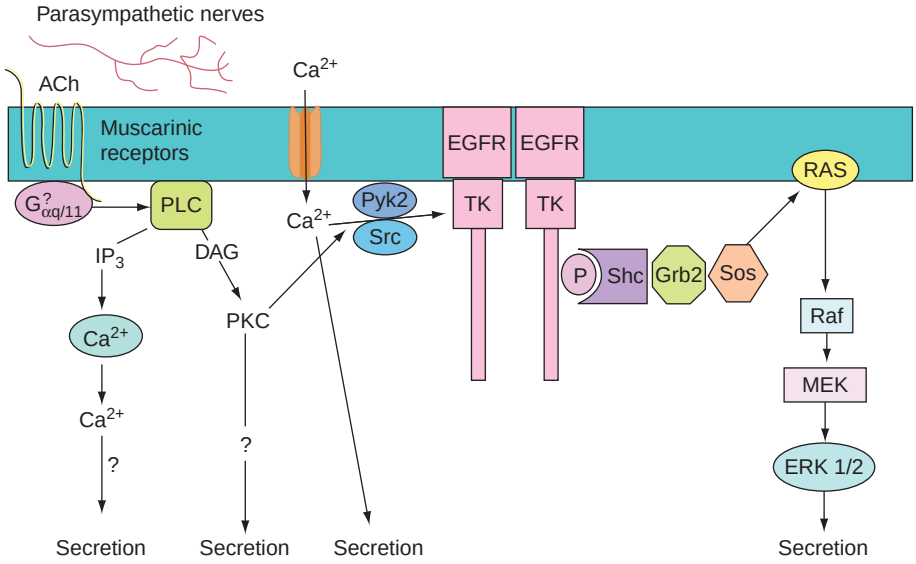

Figure 7 A schematic representation of the cholinergic pathway leading to goblet cell mucin secretion. Muscarinic receptors activate phospholipase C (PLC) to generate the production of inositol trisphosphate (IP_3), which releases intracellular Ca^{2+} and diacylglycerol (DAG), which activates protein kinase C (PKC). The EGF receptor (EGFR) is transactivated leading to the activation of Ras, Raf, mitogen-activated kinase kinase (MEK), and ERK 1/2.

In contrast, when ERK is activated by exogenous EGF, ERK 1/2 translocates to the nucleus where it stimulates proliferation.

The signaling pathways of the other compounds that stimulate mucin secretion are not well studied. Receptors for VIP (VPAC1 and VPAC2) are present on goblet cells both *in vivo* and *in vitro*. It is not known if exogenous VIP (which causes mucin secretion) acts through these receptors. As it is well established in other tissues that VIP increases the intracellular cyclic adenosine monophosphate (cAMP) concentration as well as the intracellular $[Ca^{2+}]$, it is likely that a similar mechanism occurs in goblet cells.

It is not know if the EGF family stimulates mucin secretion. As these growth factors activate ERK, which plays an important role in both secretion and proliferation, it is likely that they do. It is interesting that many of the same proteins and kinases are used by EGF to stimulate proliferation and by cholinergic agonists to stimulate mucin secretion. ERK1/2 is known to phosphorylate over 100 proteins. In order to confer specificity, ERK1/2, as is the case for many signaling molecules, is organized through the use of scaffold proteins. These proteins bind to two or more components of a signaling pathway in close proximity to assist with their interactions. Scaffolding proteins also target signaling molecules to particular areas of the cell in order to phosphorylate specific substrates. They can prevent cross talk between pathways. As the scaffolding proteins are also regulated, their stability can affect the duration of the signal. Several different scaffolding proteins have been identified in mammalian cells including kinase suppressor of Ras, MEK partner-1, Morg1, IQGAP1, and β-arrestins 1 and 2. Not surprisingly, scaffolding proteins are required for the translocation of ERK1/2 to the nucleus and other proteins are responsible for maintaining ERK1/2 in the cytosol. In fact, ERK1/2 translocation to the nucleus requires phosphorylation by MEK, which causes conformational changes in ERK1/2, allowing for the formation of ERK dimers. This dimerization facilitates the translocation of phosphorylated ERK1/2 into the nucleus. In contrast, PEA-15, a small phosphoprotein, has been shown to anchor ERK1/2 in the cytosol.

Clinical Implications of Mucin Deficiency on the Ocular Surface

The presence of goblet cells in the conjunctiva is of great importance to the health of the ocular surface. Dry eye, which is characterized by a deficient tear film or excessive evaporation, is a multifactorial disorder that causes damage to the ocular surface. One characteristic of dry eye is a decrease in the number of mucin-containing goblet cells. All *in vivo* studies to date identify goblet cells by their secretory product, either by staining with AB/PAS or by the presence of MUC5AC within the cell, and should be termed filled goblet cells. Thus, a decrease in the number of filled goblet cells in the conjunctival tissue indicates that goblet cells have secreted. Under chronic conditions, the decrease in filled goblet cells could indicate repeated stimulation such that mucin synthesis is unable to keep pace with secretion or indicate a loss of goblet cells through either a decrease in goblet cell proliferation,

dedifferentiation, or an increase in goblet cell death. It is difficult to know whether the loss of goblet cells is a cause of the disease or a result of it. Indeed, the mechanism by which goblet cells are lost from the conjunctiva has not been studied. In animal models of dry eye, proteins involved in apoptosis have been shown to be upregulated in conjunctival epithelial cells, though the effects on the goblet cells themselves were not clear. The loss of goblet cells in dry eye patients warrants further examination.

The presence or absence of conjunctival goblet cells has been examined in different types of dry eye. These have been described below.

Sjögren Syndrome

Sjögren syndrome is an autoimmune disease characterized by profound lymphocytic infiltration of the lacrimal and salivary glands, resulting in dry eye and dry mouth. It is not known whether the changes seen in the conjunctiva are a result of the autoimmune disease itself or as a result of the change in tears due to lacrimal gland destruction. Though the changes in the conjunctiva are relatively mild compared to the destruction of the lacrimal glands, there is a decrease in the number of mucin-containing goblet cells in patients with Sjögren syndrome, as determined by histochemical staining methods. In addition, the amount of MUC5AC mRNA is decreased in patients with Sjögren syndrome and the amount of MUC5AC detected in tears of these patients is also decreased.

Vitamin A Deficiency

Vitamin A is vital for the health of the ocular surface as it is essential for the development of goblet cells in the conjunctiva. Vitamin A deficiency has been shown to cause keratinization and squamous metaplasia of the conjunctiva. The lack of goblet cells in the conjunctiva in vitamin-A-deficient patients has been documented through the use of impression cytology and histochemical staining methods. It has also been demonstrated that in vitamin-A-deficient rats, not only were there no mucin-containing goblet cells, but the mRNA for MUC5AC and MUC5AC protein also disappeared 20 weeks after the initiation of a vitamin-A-deficient diet. Reintroduction of vitamin A into the diet has been shown to increase the number of conjunctival mucin-containing goblet cells.

Topical Preservatives

Preservatives, such as benzalkonium chloride, are often found in artificial tears and medications such as those used to treat glaucoma and anti-inflammatory medications. These patients often report the signs and symptoms of dry eye. Benzalkonium chloride has been shown to decrease the number of mucin-containing goblet cells present in the conjunctiva.

Ocular Cicatrical Pemphigoid

Mucous membrane pemphigoid is an autoimmune disease that is characterized by blisters in the mucous membranes of the body including the mouth, nose, trachea, and conjunctiva. When the conjunctiva is involved, it is known as ocular cicatrical pemphigoid (OCP). This condition causes chronic conjunctivitis and, eventually, complete keratinization of the conjunctiva, resulting in severe dry eye. It has been observed that the mucin-containing goblet cell number is reduced in the later stages of the disease, likely as a result of the keratinization. Interestingly, it has been shown that the expression of a specific glycosyltransferase present exclusively in goblet cells in normal human conjunctiva is altered in late stages of OCP. This enzyme, which is responsible for the glycosylation of mucins, is expressed in stratified squamous cells in areas of the conjunctiva that were nonkeritinized in OCP patients, and, as the disease progressed, the expression disappeared.

Laser *In Situ* Keratomileusis

Patients undergoing laser *in situ* keratomileusis (LASIK) often experience dry eye symptoms. These symptoms are usually temporary, but can develop into chronic dry eye. It is known that the number of mucin-containing goblet cells decreases significantly within 1 week postsurgery, but returns to preoperative levels by 3 months after surgery.

Diseases and disorders of goblet cells are a result not only of mucous underproduction, but also of mucous overproduction.

Ocular Allergies

The symptoms of allergic conjunctivitis include mucus production, ocular itching, foreign-body sensation, tearing, hyperemia, chemosis, and lid edema. Traditionally, allergic eye disease has been classified into: seasonal allergic conjunctivitis (SAC), perennial allergic conjunctivitis (PAC), vernal keratoconjunctivitis (VKC), atopic keratoconjunctivitis (AKC), and contact-lens-induced papillary conjunctivitis (CLPC). Each of the five categories of allergic conjunctivitis has a distinct pathology. In SAC and PAC, conjunctival inflammation is mild and of short duration. In VKC and AKC, conjunctival inflammation has an unclear history of exposure to allergen, is more severe, and lasts longer than SAC and PAC.

A common symptom of allergic conjunctivitis in the human is alteration in mucus production. One hypothesis as to how mucous production is altered in allergic conjunctivitis is that activation of sensory nerves in the cornea

and conjunctiva, manifested by itchiness, foreign-body sensation, and increased tearing, could occur. This, in turn, could activate the efferent parasympathetic and sympathetic nerves that surround conjunctival goblet cells to release the neurotransmitters acetylcholine and VIP, which are known to stimulate conjunctival goblet cell secretion. When goblet cells secrete, all secretory granules are released at once. Under these chronic conditions, the decrease in filled goblet cells could indicate repeated stimulation with mucin synthesis unable to keep pace with secretion. In support of this, a decrease in filled conjunctival goblet cells in VKC and AKC patients, respectively, compared to control subjects, has been noted. In addition, the amount of MUC5AC RNA in the conjunctiva was decreased in AKC and VKC patients versus control. The excess mucus seen on the conjunctiva in individuals with VKC is a stringy mucus and does not necessarily represent goblet cell MUC5AC, but could be stratified squamous cell membrane-spanning mucins, poorly hydrated mucins, or mutated mucin variations. Additional study of the role of goblet cell mucin secretion in different types of ocular allergy is warranted.

Results from animal models of allergic conjunctivitis, which most closely mimics SAC and PAC, found that the number of filled goblet cells decreased for 6 h after the final allergen challenge. Over 48 h, the number of filled goblet cells returned toward control values, indicating that goblet cell mucin secretion increased during delayed hypersensitivity, but that goblet cells refilled after allergen removal. MUC5AC RNA was also depleted by the final challenge and recovered at 6 h, indicating that the delayed hypersensitivity depletes MUC5AC RNA; however, it recovers quickly to begin synthesizing MUC5AC to refill the goblet cells.

Summary

Much information has been gathered regarding the role of conjunctival goblet cells in the health of the ocular surface. Goblet cell proliferation, mucin synthesis, and secretion control the amount of mucin present on the ocular surface. These processes are regulated as growth factors increase proliferation and neural stimulation causes mucin secretion. However, many questions remain. Are the three processes that regulate mucin amount coordinated so that one stimulus activates all three? While some of the intracellular pathways leading to proliferation or secretion are known, it is not known if these pathways are altered in diseases. The life span of a conjunctival goblet cell as well as the mechanisms by which goblet cells are lost in disorders of the tear film are unknown. It is also not known if goblet cells are able to secrete mucins multiple times, perhaps refilling secretory granules, in response to either a sustained signal or multiple stimuli. Further research into these questions may lead to the development of treatments for many of the ocular surface diseases.

Contact Lenses

N Carnt and Y Wu, Institute for Eye Research, Sydney, NSW, Australia
F Stapleton, University of New South Wales, Sydney, NSW, Australia

Glossary

Contact lens-induced papillary conjunctivitis (CLPC) – Enlarged papillae accompanied by redness of the upper palpebral conjunctiva. Symptoms include discomfort, itching, mucous discharge, and foreign body sensation.
Corneal infiltrates – Corneal inflammatory response which appears as single or multiple, focal or diffuse lesions in the corneal stroma.
Endothelial polymegethism – Variation in the size of the endothelial cells of the cornea as a result of disturbed metabolism.
HEMA – Hydroxyethylmethacrylate monomer forming the basis of many soft contact lens material polymers.
Hypermetropia – Also known as farsightedness, it is a defect of vision caused by an imperfection in the eye (often when the eyeball is too short or when the lens cannot become round enough), causing difficulty focusing on near objects.
Lens-induced chronic hypoxia – Corneal oxygen deprivation that results from contact lenses that greatly impede oxygen diffusion to the cornea. Chronic hypoxia may cause changes in corneal structure and neovascularization.
Multipurpose solutions (MPSs) – Solution for cleaning, rinsing, disinfecting, and storing your contact lenses.
Myopia – The ability to see close objects more clearly than distant objects. Myopia can be caused by a longer-than-normal eyeball or by any condition that prevents light rays from focusing on the retina.
Orthokeratology – The practice of reshaping the cornea by wearing specially designed rigid contact lenses. These lenses are usually worn only during sleep and they reshape the front surface of the eye, correcting the refractive error and allowing clear vision.
PMMA – Polymethylmethacrylate material used for oxygen impermeable hard contact lenses.
RGP – Rigid gas permeable materials used for oxygen permeable hard contact lenses.
Superior epithelial arcuate lesions (SEALs) – Whitish, opalescent lesions, located adjacent or at the superior limbus, caused predominantly by a mechanical interaction between the (usually) silicone hydrogel or hydrogel contact lens, the eyelid, and the superior peripheral cornea.

Introduction

Contact lenses provide a safe and reversible means of refractive error correction; lenses are currently worn by 150 million individuals worldwide. Contact lenses have many optical, sporting, cosmetic, therapeutic, and vocational advantages over conventional spectacles. The vast majority of wearers use contact lenses for the correction of simple low refractive errors but other applications include presbyopia, astigmatism, high refractive error, and other medical, cosmetic, or therapeutic indications.

Given their close association with the ocular surface, contact lens wear may have an impact on ocular surface anatomy and physiology and they may be associated with adverse effects, including ocular surface infection or inflammation. The impact of contact lens wear varies with lens type, mode of wear, indication for lens wear, and with wearer factors including demographics, hygiene, compliance, and behavior factors.

Types of Contact Lenses

Hard lenses, made from polymethylmethacrylate (PMMA), were first available in 1934 and soft lenses during the 1960s. Lens materials have evolved since with the advent of gas permeable rigid materials and more recently silicone hydrogel materials. An ideal material and lens design would maintain normal ocular surface physiology, have a low rate of complications, provide vision correction, and be comfortable during wear (**Table 1** and **Figures 1–6**).

Probably the most exciting recent innovation in the field has been the introduction of silicone hydrogel materials. The high oxygen permeability of these new silicone-based products has limited the effects of hypoxia and largely eliminated a range of physiological complications such as corneal edema, microcysts, corneal vascularization, endothelial polymegethism, overwear syndrome, and corneal exhaustion.

Lenses may be worn on a daily wear basis, where they are removed, cleaned and disinfected overnight, and reinserted the following day. Daily lens use is the most common modality prescribed. Complication rates are generally lowest with this wear modality; however, conditions associated with toxic or allergic responses to lens care products occur more commonly with daily lens use. Daily disposable contact lenses (lenses worn once during the day and discarded on removal) have eliminated many

Table 1 Contact lens types and materials

CL type	*Material*	*Comments*	*Illustration*
Rigid corneal contact lenses	PMMA: polymethylmethacrylate	• Readily machined and polished • Impermeable to oxygen • Average lens diameter range 7–12 mm	**Figure 1**
	RGP: rigid gas permeable (fluoro-siloxane acrylates, perfluoroethers)	• Higher oxygen permeability compared with PMMA • Average corneal lens diameter range 9–12 mm	**Figure 1**
	Orthokeratology lenses: generally highly oxygen permeable rigid gas permeable materials	• Overnight use of orthokeratology lenses reshapes the cornea to reduce the refractive error with overnight use • Larger diameter lenses with an oblate profile used to reduce myopic refractive errors	**Figure 2**
Soft contact lenses	Hydrogel: hydroxyethylmethacrylate (HEMA), with other monomers, such as vinyl pyrollidone, vinyl chloride, methacrylic acid and others, added to alter ionicity and water content of the material	• Flexible polymers which conform to the shape of the cornea and limbus • Average lens diameter 13–15 mm • Water content of polymer determines oxygen permeability	**Figure 3**
	Silicone hydrogel: silicone incorporated into a diverse group of hydrogel monomers. Wettability is enhanced by either surface treatment or by the incorporation of soluble polymers within the bulk material	• Higher oxygen permeability than hydrogel contact lenses, consequently less corneal hypoxia • Lens design similar to hydrogel contact lenses • Generally stiffer modulus than hydrogel contact lenses	**Figure 3**
Other contact lenses	Hybrid Hard/soft combination	• An RGP center with a soft hydrogel or silicone hydrogel periphery • Useful in fitting irregular corneas	**Figure 4**
	Scleral/semiscleral/mini-scleral lenses	• Scleral lenses use the sclera rather than the cornea as the bearing surface • Consequently a range of abnormal corneal topographies may be fitted • The overall diameter ranges from 16 mm (miniscleral) to 24 mm (full scleral) and lenses are made in RGP materials	**Figures 5** and **6**

complications related to care solution use and those due to inadequate contact lens or storage case hygiene. A proportion of daily lens users (13–23%) report occasional unscheduled overnight use of lenses of up to one night per week. Certain lenses may be prescribed for overnight use, where they are worn continuously for up to 30 consecutive nights.

How Contact Lens Wear Affects the Ocular Surface

Hydrogel and silicone hydrogel contact lenses are on average 2–3 mm larger than the cornea and overlay the limbus and surrounding bulbar conjunctiva, consequently contact lenses interact directly with the corneal, limbal, bulbar, and tarsal conjunctival epithelia, and with the tear film. Their impact on the ocular surface can be characterized as follows.

Effects of Contact Lens Wear on the Corneal and Limbal Epithelium

Lens-induced chronic hypoxia can lead to changes in the corneal epithelium such as thinning, lower oxygen uptake rates, and increased microcysts. In addition, limbal hyperemia is increased and encroachment of blood vessels into the corneal stroma can occur. The smaller diameter of rigid lenses results in less interaction between the lens and limbal or conjunctival epithelium, generally less corneal hypoxia and greater tear exchange compared with soft contact lenses.

Epithelial microcysts are one of the more obvious clinical markers of hypoxia, appearing as small, irregular dots in retro illumination of the cornea with a slit lamp biomicroscope at high magnification. They are comprised of degenerated cellular material and are most often seen after 3 months of extended wear of low oxygen transmissible

lenses. They are transitory, exhibiting a spike in numbers approximately 1 month after hypoxic stress is removed and returning to normal within 3 months.

All contact lenses slow the corneal epithelial cell renewal cycle by slowing epithelial cell proliferation and migration and lowering the exfoliation rate. At the limbus, stem cells continually provide new basal corneal epithelial cells, where the rate of production increases during ocular surface damage. Recurrent erosion, chronic inflammation, and blood vessel growth onto the cornea (vascularization) can occur as a result of compromise to the limbal stem cells. Basal epithelial cells produced from slow cycling stem cells replicate and migrate horizontally, differentiating upward, before undergoing either apoptosis (programmed cell death) or necrosis and exfoliation into the precorneal tear film. Soft contact lens wear, in particular, lens-related hypoxia, has been reported as a possible cause of limbal stem cell damage. To a lesser extent contact lenses may have a mechanical effect on the limbal stem cells, which are protected somewhat due to their location at the level of the basal epithelium.

Alteration of the Lens: Cornea Resurfacing Mechanism

The precorneal tear film maintains the normal optical, lubrication, and defence functions of the ocular surface. Wear of a contact lens may destabilize the tear film by compartmentalizing the tear film into prelens and postlens regions, by changing the tear film structure and components and by reducing tear exchange.

Compared with the normal precorneal tear film, the prelens tear film is thinner, less stable, and exhibits higher evaporation. The increased evaporation rate is thought to be related to a thinner lipid layer which is more prone to contamination. A thinner lipid layer, lens dehydration, and an unstable tear film can lead to corneal epithelial dessication.

All contact lenses inhibit normal tear exchange by trapping debris, toxins, antigens, and microorganisms beneath the lens and interfering with the normal resurfacing action of blinking. Increasing the retention time of metabolic debris, toxins, or antigens at the ocular surface has been implicated in the development of inflammatory conditions. The rate of tear exchange varies with lens type, material and wearer characteristics. For example, rigid gas permeable (RGP) contact lenses allow more rapid tear exchange than hydrogel or silicone hydrogel lenses and are associated with a lower rate of inflammatory complications compared to soft lens wear.

Adverse Events

Inflammation

Corneal inflammation occurs relatively often in contact lens wear, affecting 7% of wearers. The risk of inflammation varies with different lens materials and wear modalities. The severity of inflammation varies and several systems have been used to characterize and classify corneal inflammation. Contact lens-related corneal inflammation is characterized by white blood cells, usually polymorphonuclear leukocytes, invading the cornea stroma (infiltrates). The infiltrates appear as small, usually round, opaque lesions (focal) or dispersed in a haze (diffuse). Usually limbal and bulbar redness accompanies the infiltrates. Epithelial damage can be present. Inflammation can be as a result of mechanical trauma but more often results from toxic reactions to bacteria. In the closed eye environment, bacterial toxin concentration behind the lens as well as compromise to the normal lid-tear resurfacing and alteration of tear defence proteins may lead to more frequent inflammation in extended compared to daily wear.

Contact lens-induced papillary conjunctivitis (CLPC) is an inflammatory reaction of the upper palpebral conjunctiva, caused by mechanical trauma and/or allergic response to the lens or deposits on the surface of the lens. It is the most common contact lens-related adverse event that leads to discontinuation of lens wear. Clinically, it presents as raised papillae, which comprise lymphocytes and plasma surrounding central blood vessels and associated hyperemia. There are two forms of CLPC, one that involves the entire upper palpebral area (generalized) and the other a small cluster (localized). CLPC is more frequent in soft than rigid lenses, and more common in extended compared to daily wear. The generalized form is more common in softer, hydrogel lenses which attract more protein deposits; this form likely represents a hypersensitivity (both type I and type IV) response, whereas localized disease is more likely to be found with the stiffer silicone hydrogel lenses and is thought to be related to mechanical trauma.

Infection

Corneal infection is a rare but severe complication of contact lens wear, affecting 4 per 10, 000 wearers per year, with higher rates (20 per 10, 000) per year in overnight lens use. These estimates have remained remarkably consistent over a 20-year period, despite advances in contact lens materials, wear modalities, and care system technologies. Permanent vision loss occurs in 6 per 100, 000 wearers per year or in 10–15% of cases of infection. Lower rates of severe keratitis and vision loss have been reported with daily disposable contact lens use. A poorer disease outcome is strongly associated with recovery of an environmental pathogen and a delay in receiving appropriate treatment.

Unlike corneal infections in noncontact lens wearers, *Pseudomonas aeruginosa* is the most common pathogen associated with contact lens-related disease, accounting for 50–60% of culture proven cases. More recently, environmental organisms such as *Acanthamoeba* and the fungi

Fusarium have been associated with outbreaks of disease, particularly disease linked with the use of specific multipurpose solutions (MPSs). In the case of *Acanthamoeba keratitis*, strong links with contaminated water have been identified.

Mechanical effects

Contact lenses can cause mechanical effects on the cornea due to their physical presence. For soft contact lenses, superior epithelial arcuate corneal lesions (SEALs), white heaped lesions occurring adjacent to and concentric with the superior limbus are thought to be due to a combination of tight upper-lid pressure, stiffness of the lens material, poor surface, and tight fitting of soft lenses. These are usually associated with foreign body and discomfort symptoms and resolve with interruption to lens wear within 1 week. Erosions, a full thickness epithelial loss, appear as a plug of epithelium that has been lifted off the cornea. Resolution is rapid and often results in clumping of the epithelial cells as healing takes place. Care must be taken to observe good hygiene and not patch the lesion, as the break in the epithelium renders the cornea more prone to infection. Sometimes prophylactic antibiotic therapy is used. Symptoms can be quite painful and can be eased by use of ocular lubricants. For RGP lenses, the most common mechanical effect is abrasion due to debris trapped behind the contact lens. Corneal abrasions are more commonly seen with rigid lenses compared with soft. Often the patient is symptomatic despite quite spectacular appearances; resolution is rapid, usually within a day or two. Abrasions can also occur due to fingernail injuries on removal of lenses.

Current Hot Topics in Contact Lens Research

Contact Lens Care Products

MPSs dominate the CL care market and are used by 99% of soft lens wearers. In recent years, the industry has been focused on comfort and convenience for the wearer, formulating new preservatives and incorporating comfort additives into care products.

Corneal staining (visualization of damaged epithelial cells by instillation of sodium fluorescein) is the most reliable clinical way to assess corneal integrity. Solution-related corneal staining has been reported from a 2-h provocative test and over 3 months of lens wear with a range of lens and solution combinations. Performance has not been predictable in terms of solution preservative or across different silicone hydrogel lens types, likely due to the more complicated lens chemistry compared to hydrogel lenses. Solution-related corneal staining has been associated with decreased comfort and increased risk of low-grade inflammatory events. MPSs have been associated with decreased epithelial barrier function and increased susceptibility to bacterial binding; however, no evidence to date shows that solution-related staining is a risk factor for infection. Further exploration of the mechanisms and implications of short- and long-term corneal staining is underway.

Corneal Infection

Other than overnight wear of contact lenses, a range of hygiene, compliance, and demographic factors have been consistently associated with disease. In contemporary lens wearers these include increasing the degree of lens use in daily wear, poor-storage case hygiene, smoking, Internet purchase, less than 6 months wear experience, and socioeconomic class. Further study is directed toward exploration of new risk factors, particularly establishing the impact of wearer risk behavior such as internet purchase: evaluation of specific hygiene practice such as rub and rinse and establishing the impact of second generation silicone hydrogel lens materials on the risk of infection. Ongoing surveillance enables monitoring of disease outbreaks and new or unusual causative organisms.

In corneal infection associated particularly with daily wear of contact lenses, the storage case has been identified as the source of organisms. This has resulted in the uptake of antimicrobial technologies, such as silver, into contact lens storage cases to limit microbial adhesion and colonization of the contact lens storage case. Early reports indicate some reduction in levels of certain microorganisms, but the long-term impact of these technologies in clinical use has not yet been established.

Orthokeratology

Orthokeratology is a nonsurgical approach to temporarily correct or eliminate refractive error through rigid lens wear to reversibly change the curvature of the cornea. More recent approaches include using specially designed rigid contact lenses worn overnight to enable clear vision without lens wear during the daytime. In the case of myopia correction, a reverse-geometry lens with a base curve flatter than the peripheral curve of the back surface is worn. The reduction in myopia occurs through central corneal epithelial thinning. While these effects are reversible there is discussion whether the impact of orthokeratology lenses on the corneal epithelium increases the risk of corneal infection. Ongoing studies endeavor to optimize the refractive effects both in myopia and hypermetropia, to understand the mechanisms in epithelial thinning and to establish whether orthokeratology can be used to permanently reduce or eliminate refractive error or to prevent myopia progression.

Summary

A range of materials and wear modalities are available in contemporary contact lens practice to correct a wide range of refractive errors, potentially to slow or prevent refractive error development and to meet other medical or cosmetic requirements. Contact lenses interact closely with the ocular surface and all lenses, to a lesser or greater degree, will impact on the conjunctiva, lid, cornea, and tear film physiology. While the majority of their effects and complications are reversible and nonsevere, corneal infection remains the most severe response which can potentially result in vision loss due to scarring and perforation. Safe contact lens wear requires awareness by wearers to ensure that their eyes "Feel good, see well and look good" at all times. In the rare event of corneal infection, morbidity can be limited by prompt treatment by the practitioner. Recent outbreaks of corneal infection caused by unusual environmental organisms have resulted in the industry demanding more appropriate care solution testing for licensing purposes, and improved guidelines and recommendations for contact lens wearers. Research into the impact of care solutions on the ocular surface, optimization of orthokeratology, eludication of new risk factors for corneal infection, and ongoing disease surveillance will better inform practitioners and wearers and result in improved outcomes for contact lens wearers.

Contrast Sensitivity

P Bex, Schepens Eye Research Institute, Boston, MA, USA

Glossary

Channels – The groups of visual sensors that are selective for a narrow range of image spatial or temporal structure.
Contrast constancy – At high contrasts, apparent contrast is relatively independent of the parameters that strongly influence contrast-detection threshold.
Contrast-detection threshold – The statistical contrast boundary below which contrast is too low for an image to be detected reliably and above which contrast is high enough for frequent image detection. Often defined as the contrast that produces 75% correct target identifications in forced-choice paradigms.
Contrast sensitivity – The reciprocal of contrast-detection threshold that also represents the transition between visible and invisible images.
Critical flicker frequency – The highest flicker rate of a full contrast image that can be detected reliably.
Forced-choice paradigms – Robust behavioral method used to measure detection or discrimination thresholds. Observers are forced to select between two or more intervals, of which only one contains a target.
Fourier analysis – Analytical method that calculates the simple sine-wave components whose linear sum forms a given complex image.
Resolution limit – The highest spatial frequency of a full contrast image that can be detected reliably.
Spatial frequency – The number of image cycles that fall within a given spatial distance, typically 1° of visual angle.
Temporal frequency – The number of image cycles that fall within 1 s.
Wavelets/gabors – A local filter that is the point-wise product of a two-dimensional (2D) spatial sine wave and a 2D Gaussian envelope.

Most people are familiar with image brightness and contrast from their controls on computer and television displays. The brightness control adjusts the mean luminance of the display uniformly, in order that the intensity of every point in the image increases when brightness is increased or decreases when brightness is reduced. The contrast control adjusts the difference between the lightest and darkest areas of the image. Increasing contrast makes areas that are below mean luminance darker and areas that are above mean luminance lighter, without changing the mean value. Decreasing contrast draws all values toward the mean, thus making the whole image fainter, similar to viewing the image through fog.

Figure 1 illustrates the effect of changing the contrast of a sine-wave striped pattern (the reasons for using a sine-wave pattern are described below). The top panel shows images of gratings whose contrast increases from 12.5% on the left to 100% on the right. The mean luminance of each image is the same. The traces in the bottom row plot luminance versus position for a horizontal slice through each image.

Contrast-Detection Threshold

A powerful measure of visual sensitivity can be obtained by finding the minimum contrast that is necessary for an image to be detected. This minimum contrast is referred to as contrast-detection threshold (C_{thresh}) and it is important because it defines the transition at which an image moves from invisible to visible. One method to estimate C_{thresh} might be to allow a subject to adjust the contrast until an image is just visible. However, this method is highly subjective and large differences in individual criteria for just visible make this measure unreliable.

Psychophysical Assessment of Vision

To overcome these problems, most researchers employ forced-choice procedures that require an observer to identify which of two or more intervals (the more the better) contain the target. An example of a four-alternative forced-choice (4AFC) detection task is shown in Figure 2(a). In this case, a computer presents a target in one of four positions at random around a central fixation point. The observer's task is to fixate the central dot and to indicate the location of the target, usually by pressing a computer button. Targets that are below C_{thresh} (sub-threshold) are rarely detected, whereas targets that are above C_{thresh} (supra-threshold) are usually detected. Contrast-detection thresholds are therefore probabilistic and are defined as the contrast at which they are correctly detected midway between chance and perfect performance.

It is difficult to cheat on forced-choice methods or to change criteria – the target is either seen, in which case its position is correctly identified, or it is not seen, in which

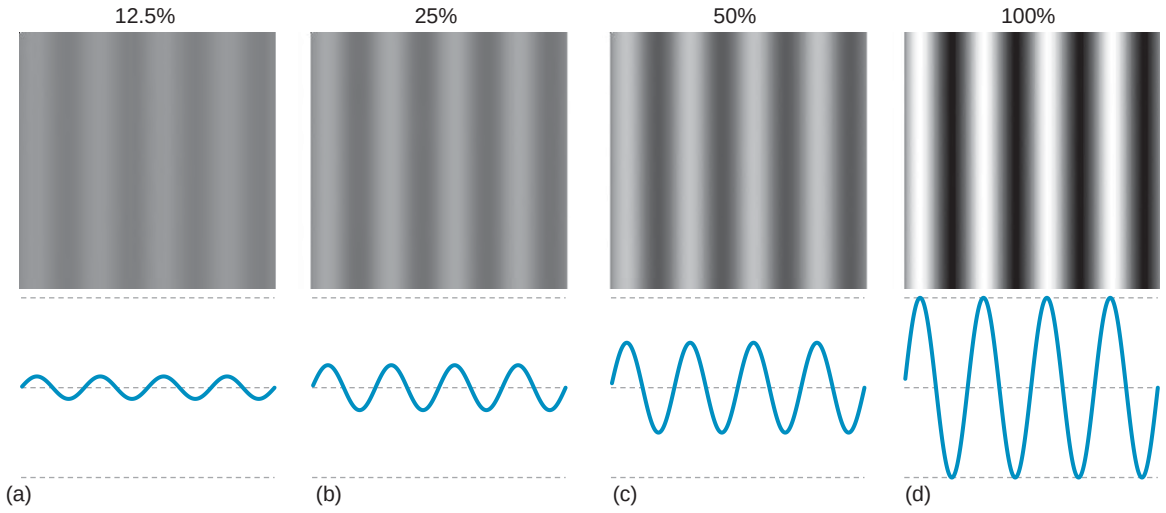

Figure 1 Image contrast. The top row shows the appearance of two-dimensional (2D) sine-grating patterns that are routinely used in vision research. The contrast of the sine grating increases from left (12.5%) to right (100%) as shown by the caption. The bottom row plots a horizontal section through each image and shows that contrast changes the luminance range separately from mean luminance.

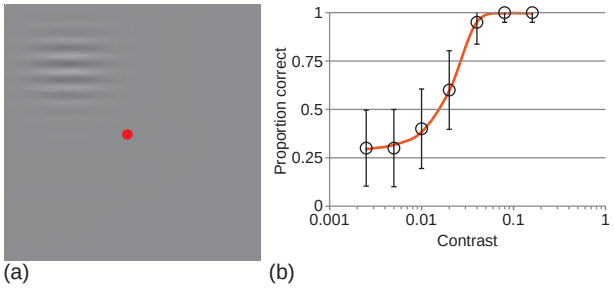

Figure 2 Contrast detection. (a) Example of a four-alternative forced-choice (4 AFC) task. The observer is required to fixate the central dot and to indicate whether the target appeared top left, top right, bottom left, or bottom right. The target contrast is adjusted by computer to a level that produces 75% correct detection. (b) A typical psychometric function. Circles show the proportion of trials the target was detected (ordinate) as a function of the target contrast (abscissa). Error bars show ±1 standard deviation. The curve shows the best-fitting cumulative normal function, from which the interpolated 75% correct point is taken as contrast-detection threshold.

case the subject is forced to guess. Notice that when guessing, the subject is still correct sometimes (25% if there are four alternatives, 33% if there are three, or 50% if there are two, etc.), as shown in the frequency of seeing curve in **Figure 2(b)**, where, at low contrasts, performance is 25% correct. The data have been fit with a curve known as a psychometric function, in this case a cumulative Gaussian:

$$Y = g + (1 - g)^{*}\mathrm{erf}(z/\mathrm{sqrt}(2))/2$$

where $z = (X - \mu)/\sigma$; g is the guess rate (0.25 in a 4AFC experiment). The mid-point (μ) of the psychometric function is often taken as C_{thresh} – for a 2AFC task, this is 75% correct. In the example shown, the observer achieved 75% correct at approximately 2.5% contrast. The slope (σ) can be used to infer how easily nearby contrasts can be discriminated from one another – a shallow slope means that a large contrast difference is required to achieve a given change in performance, whereas a steep slope means that a small change in the stimulus produces a large change in performance.

Spatial Frequency Channels

Based on behavioral observations in humans and single unit recordings in mammalian visual systems, researchers discovered around half a century ago that the visual system analyses images at a series of relatively narrow spatial scales and orientations known as channels. Thus, fine and coarse image details are encoded separately and Fourier analysis can be used to study the image structure that is encoded by different visual processing channels. Fourier analysis computes the sum of basic sine waves whose linear sum produces the image. To illustrate the representations of an image that are available at different spatial scales, **Figure 3(a)** shows a typical image, together with its coarse (**Figure 3(b)**) and fine (**Figure 3(c)**) spatial structure.

Visually responsive neurons in primary visual cortex, the first cortical projection from the retina through the lateral geniculate nucleus of the thalamus, respond to images only within a limited area of the visual field, known as the classical receptive field, and are selective for a limited range of spatial frequencies and orientations. These receptive fields are now routinely modeled as Gabor or wavelet functions, defined as:

Figure 3 Spatial frequency in real images. (a) An image of Albert Einstein's face is encoded at a range of spatial scales, from (b) coarse – low spatial frequency to (c) fine – high spatial frequency.

$$G(x, y, \lambda, \varphi, \sigma, \gamma) = \exp\left(-\frac{x'^2 + \gamma^2 y'^2}{2\sigma^2}\right)\sin\left(2\pi\frac{x'}{\lambda} + \varphi\right)$$

where $x' = x\cos\theta + y\sin\theta$ and $y' = -x\sin\theta + y\cos\theta$, λ represents the wavelength, θ the orientation, and ψ the phase of the sine-wave component. For the Gaussian window, σ is the standard deviation and γ is the spatial aspect ratio. Examples of Gabors are illustrated in **Figure 4**. On the top row, spatial frequency increases from left to right and all Gabors are of the same orientation 0° and contrast. On the bottom row, spatial frequency is fixed, but orientation is 45°, 90°, or 135° (from left to right). The visual system encodes image structure with a bank of such wavelet filters that represent the retinal image through patch-wise local analysis.

Figure 5 provides compelling demonstrations that our visual system employs a set of spatial frequency and orientation-selective channels. These demonstrations show that after prolonged viewing of a particular pattern (termed adaptation) the appearance of other patterns can be altered (termed an aftereffect). In these demonstrations, adapting to a pattern of one spatial frequency or orientation produces a loss in sensitivity in the channel that responds most to that pattern, but little change in channels tuned to other spatial frequencies or orientations. This localized loss in sensitivity produces a relative shift in the responses of our visual channels that cause us to experience changes in the appearance of the image.

These observations have led to the widespread use of sine-wave grating patterns in basic and clinical vision research. In order to derive a measure of vision that reflects the sensitivity across our set of visual channels and to reflect the fact that functional vision requires us to detect and interact with objects of various sizes, contrast-detection thresholds are measured for gratings of a range of bar widths, expressed as spatial frequency or the number of grating cycles per unit distance. **Figure 4** illustrates Gabors of differing spatial frequency; however, the size of one grating cycle on the retina depends on the distance

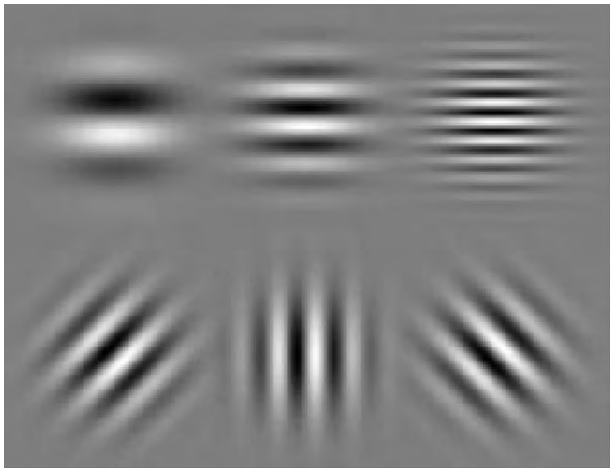

Figure 4 Gabor (wavelets) of differing spatial frequency and orientation. Top row: spatial frequency increases from left to right, orientation is fixed at 0°. Bottom row: Orientation increases from left to right: 45°, 90°, and 135°, spatial frequency is fixed.

from which it is viewed. Therefore, image sizes are usually calculated in terms of visual angle, which specifies the retinal image size. **Figure 6** shows how visual angle is calculated and its relationship to image size and viewing distance. A convenient rule is that 1 cm viewed from 57 cm subtends a visual angle of 1° and roughly corresponds to a finger nail viewed at arm's length.

Contrast Sensitivity Function

Many researchers have shown that for sine-grating patterns, C_{thresh} strongly depends on spatial frequency. This fundamental observation is demonstrated in the classic image shown in **Figure 7**. Spatial frequency increases from left to right and contrast increases from top to bottom, so that contrast is constant across any horizontal line. Contrast-detection thresholds can be visualized on this figure as the imaginary curve along

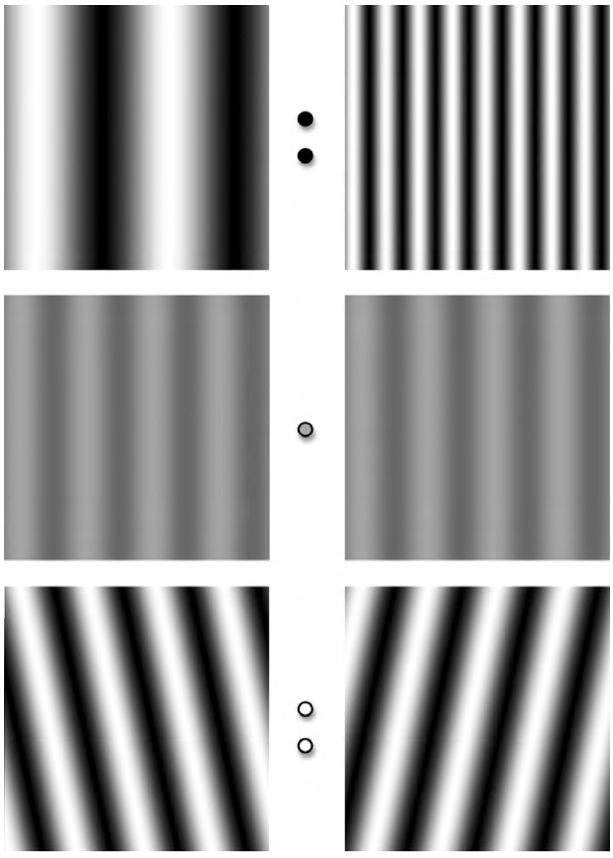

Figure 5 Demonstration of spatial frequency- and orientation-selective aftereffects. First note that when you fixate the centre gray dot, the gratings in the middle row are of the same spatial frequency and orientation. Next, look back and forth between the black dots in the top row for around 10 s. Now, when you look at the center gray dot, the grating on the left appears to be of higher spatial frequency than the grating on the right. Next, look back and forth between the white dots in the bottom row for around 10 s. Now, when you look at the center gray dot, the grating on the left appears tilted counterclockwise, while the grating on the right appears tilted clockwise. These aftereffects are robust even though you know that the gratings in the middle row are the same. These demonstrations provide compelling evidence that visual processing involves channels that are narrowly tuned for spatial frequency and orientation.

which the grating changes from invisible (toward the top of the figure) to visible (toward the bottom of the figure). Most people report that the function peaks somewhere near the middle of the figure. Notice that the peak shifts as you move the figure closer or further away. This demonstrates the importance of visual angle rather than physical image size. Note that the highest spatial frequency that can be detected at maximum contrast is given by the rightmost point on a contrast sensitivity function (CSF). This is referred to as the resolution limit and is a quick and convenient method of assessing visual sensitivity than measuring the entire CSF.

When measured with forced-choice procedures, (**Figure 2**) contrast-detection thresholds are lowest for gratings around 2–5 cycles per degree of visual angle (c deg^{-1}). By convention, the inverse of C_{thresh} ($1/C_{\text{thresh}}$) is usually reported and is termed contrast sensitivity. The rationale for the use of contrast sensitivity over contrast-detection threshold is most likely because the shape of the CSF is the same as that of the underlying modulation transfer function of the system. The circles in **Figure 8** show the author's contrast sensitivity as a function of spatial frequency measured with a forced-choice procedure. Error bars show 95% confidence intervals. The data have been fit (green curve) with the outputs of a set of spatial frequency channels shown by the colored curves. The channels are log spaced in spatial frequency (with peaks at 0.5, 1, 2, 4, 8, 16, or 32 c deg^{-1}) and have the same bandwidth (1.4 octaves). The summed outputs of the set of filters provide a good fit to the data and this channel-based system is now a widely accepted model of early visual processing.

The spatial frequency aftereffect shown in **Figure 5** is easily explained with this channel-based model. Adapting to one spatial frequency reduces the responses of the channel that is most sensitive to that spatial frequency, but has little effect on the responses of other channels. When a different spatial frequency is subsequently viewed, the overall activity across the channels is shifted away from the adapted channel. This shift in the population response produces a shift in apparent spatial frequency away from the adapting frequency. An analogous model explains the shifts in orientation in the lower row of **Figure 5**, except that orientation-selective channels are adapted rather than spatial-frequency-selective channels.

The CSF is highly dependent on the mean luminance of the display on which it is measured. This can easily be experienced by viewing **Figure 7** with a pair of dark sunglasses (possibly two pairs), which moves the curve down (reducing sensitivity) and shifts the peak to lower spatial frequencies. The data in **Figure 8** were collected on a standard computer monitor that has a mean luminance of 50 cd m^{-2} (candelas per square meter). Photopic, mesopic, and scotopic vision and changes in visual performance show that sensitivity to high spatial frequencies increases with mean luminance. This property is important because CSFs are routinely measured on relatively dim displays (e.g., 50–100 cd m^{-2}) in the laboratory and in the clinic; however, the luminance of the real world is typically much greater. For example, the luminance of a cloudy sky is around 35 000 cd m^{-2}, suggesting that standard experimental conditions may underestimate sensitivity to fine spatial structure.

Temporal Contrast Sensitivity

In addition to a dependence on spatial frequency, contrast sensitivity also depends strongly on temporal frequency. **Figure 1** illustrates spatial variation in luminance, but

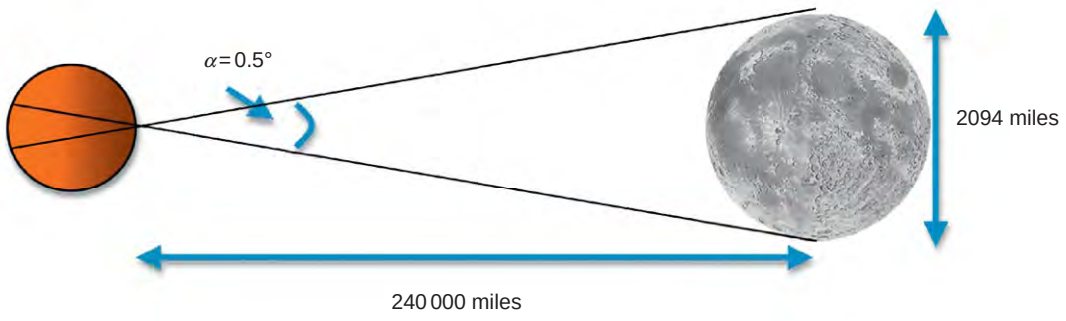

Figure 6 Visual angle and viewing distance. The angular size of an object is calculated as 2*tan((0.5*h)/d), where h is the height of the object and d is the distance from which it is viewed. The example, which is not to scale, shows the angular size subtended by the moon is 0.5°. For comparison, the nail of the average index finger viewed at arm's length subtends 1°.

Figure 7 Illustration of the contrast sensitivity function (CSF). Spatial frequency increases from left to right, contrast increases from top to bottom. The contrast along any horizontal line is fixed. Different spatial frequencies become visible at different contrasts and define an imaginary curve that separates seen from unseen structure. Notice that if you move the image closer to your eye, the peak moves to the right and if you move it further away, the peak moves to the left. This demonstrates that contrast sensitivity depends on retinal not physical image size. If you wear one or two pairs of dark sunglasses, the curve shifts down and the peaks moves left, which demonstrates the dependence of the CSF on mean luminance.

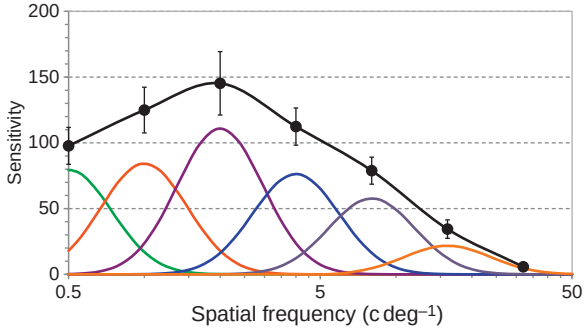

Figure 8 Spatial contrast sensitivity. Circles show contrast sensitivity (the reciprocal of contrast-detection threshold) for sine gratings of a range of spatial frequencies. Sensitivity peaks at around 2 c deg^{-1} under the conditions employed here and decreases at lower or higher spatial frequencies. The black curve is the summed sensitivity of the set of log-scaled channels shown by the colored curves and provides a good fit to the data.

imagine instead that the x-axis represents time, rather than space. Now the figure illustrates flicker. Flicker frequency can be varied in the same way as spatial frequency is varied in **Figures 3 and 7**. The circles in **Figure 9** show how the author's contrast sensitivity varies as a function of temporal frequency for a 2 c deg^{-1} grating pattern. Sensitivity peaks around 5 Hz, at the mean luminance used here (50 cd m^{-2}) and decreases at lower or higher temporal frequencies. These data are well fit (black curve) by a model with only two temporal channels, compared with the multiple channels that support spatial contrast sensitivity. One channel (red curve) is low-pass or sustained and is most sensitive to structure that is stationary or slowly changing over time. The second channel (blue curve) is band-pass or transient and is most sensitive to structure that changes at around 5 Hz.

The spatial resolution limit falls steadily with distance from the fovea, an effect that can be experienced by viewing **Figure 7** while fixating away from the center of the image. As you fixate further away, the threshold curve moves further down the figure and its peak shifts further to the left. Unlike spatial resolution, temporal resolution (the highest flicker rate that can be detected at any contrast, often called critical flicker fusion frequency)

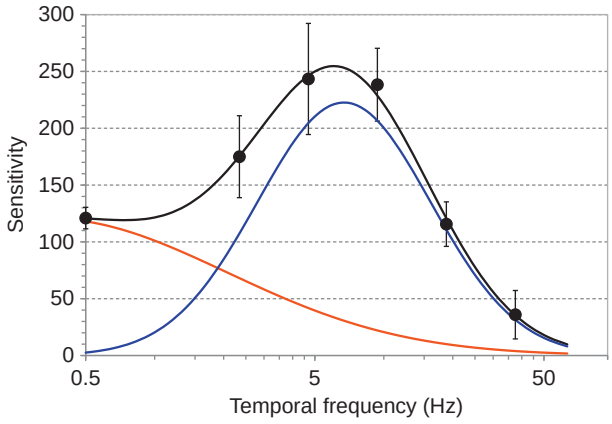

Figure 9 Temporal contrast sensitivity. Circles show contrast sensitivity (the reciprocal of contrast-detection threshold) for sine gratings of a range of temporal frequencies. The black curve is the summed sensitivity of the two log-scaled channels shown by the red and blue curves. The red curve has peak sensitivity at low temporal frequencies – that is, static images – and is termed a sustained channel. The blue curve has peak sensitivity around 6 Hz and is termed a transient channel.

increases moderately with distance from the fovea. This explains why older, 60-Hz computer displays can sometimes be seen to flicker when seen in the peripheral visual field, but not when viewed directly. Just as spatial contrast sensitivity depends on luminance, so does temporal contrast sensitivity. A 35-mm film is generally recorded at 24 frames per second, a refresh rate that could be easily detected at moderate light levels, as can be seen from Figure 9. For this reason, movie theaters are generally dark because sensitivity to high flicker rates is poor under those conditions. In addition, the visible 24-Hz image update rate is masked by flashing the illuminant at 48 Hz, so each frame is flashed twice.

At supra-threshold contrasts, apparent contrast is relatively independent of spatial or temporal frequency, a phenomenon termed contrast constancy.Contrast constancy can be experienced in Figure 7 – while the transition between visible and invisible gratings has a curved shape, toward the bottom of the figure, the gratings appear to have similar contrast regardless of spatial frequency. This has important implications for image enhancement, which should therefore target only image components that are below their C_{thresh}.

Control of Aqueous Humor Flow

J W McLaren, Mayo Clinic, Rochester, MN, USA

Glossary

Circadian rhythm – The repeated physiologic rhythm having an association with the 24-h period of the Sun.
Diurnal – Taking place during the day. In this article, we assume that normal alert wakefulness takes place during the day.
Nocturnal – Taking place at night. In this article, sleep is assumed to take place at night.
Ocular fluorophotometry – The measurement of fluorescence in the eye. For determination of aqueous humor flow rate, fluorescence originates from the dye fluorescein.
Ocular fluorophotometer – A device used to measure fluorescence in the living eye.

The Significance of Aqueous Humor Flow

The cornea and crystalline lens must be oxygenated, provided nutrition, and provided disposal of waste without the benefit of a direct blood supply; blood vessels that would serve this purpose as they do in other tissues of the body would interfere with light and degrade the image on the retina. This circulatory function is served by a unique local system, the aqueous humor circulation (**Figure 1**). Aqueous humor is secreted by the ciliary body, it flows through the posterior chamber between the posterior surface of the iris and the anterior surface of the crystalline lens, and enters the anterior chamber through the pupil. Convection and eye movements mix this warmer aqueous humor with the slightly cooler aqueous humor in the anterior chamber and provide flow across the endothelial surface of the cornea. Aqueous humor flows out of the eye at the perimeter of the anterior chamber through the trabecular meshwork and, through a parallel path, it percolates into the uveoscleral tissue. The continuous flow of aqueous humor brings nutrients to the crystalline lens and the cornea, it removes metabolites and waste, it prevents the accumulation of debris in the anterior chamber, and it mediates inflammatory responses to protect the eye from invasion by foreign substances and organisms. The cornea receives most of the oxygen it needs directly from the air, because it is thin enough for oxygen to diffuse through its entire thickness.

Continuous aqueous humor flow is also the source of intraocular pressure. The trabecular meshwork is not a simple open drain, but resists movement of fluid. This resistance requires a pressure difference to move aqueous humor out through the trabecular meshwork into Schlemm's canal, and into collector channels and episcleral veins, a pressure that bears on the sclera and inflates the eye. Intraocular pressure is related to flow rate as described by the Goldmann equation:

$$IOP = \frac{F - F_u}{C} + P_e \qquad [1]$$

where F is aqueous humor production rate, F_u is the rate of aqueous humor loss through the uveoscleral path and does not contribute to intraocular pressure, C is outflow facility (the inverse of resistance), and P_e is the pressure in the episcleral veins. Notice that aqueous flow through the trabecular meshwork contributes to the intraocular pressure above episcleral venous pressure.

When the resistance to outflow increases chronically (outflow facility, C, decreases), intraocular pressure increases. Chronic ocular hypertension is a primary risk factor for glaucoma. Ocular hypertension has been associated with decreased outflow facility, but not with hypersecretion of aqueous humor. To date, the only practical therapy for treating glaucoma is reduction of intraocular pressure. This can be accomplished by reducing the resistance to outflow at the trabecular meshwork, increasing the amount of aqueous humor that bypasses the trabecular meshwork through the uveoscleral path, or by reducing the production of aqueous humor by the ciliary body, and all of these approaches are used therapeutically. Studies of aqueous humor flow have assisted with the understanding of the mechanism of action of ocular hypotensive agents and have clarified certain aspects of the physiology and natural variation of aqueous humor formation in normal and diseased eyes.

Measuring Aqueous Humor Flow

Aqueous humor flow has been measured noninvasively in the living human eye since the early 1950s and the methods used today are in principle similar to these early methods. The rate of aqueous humor flow is usually determined indirectly from the rate of disappearance from the anterior chamber and cornea of the fluorescent tracer fluorescein, a nontoxic, fluorescent disclosing agent. This technique has allowed investigators to study

aqueous humor flow in humans under a variety of conditions, in a number of pathologic states, and under the influence of a wide variety of pharmacologic agents.

A high concentration of fluorescein (2–10%) is instilled in the conjunctival *cul-de-sac*, and after a brief time for the dye to penetrate the corneal epithelium, excess is rinsed from the eye and eyelids. A small amount of fluorescein (typically 200–500 ng) crosses the corneal epithelium and enters the stroma, and from here it passes through the corneal endothelium into the anterior chamber. In the anterior chamber, fluorescein mixes with aqueous humor. It is slowly diluted as unstained aqueous humor enters the anterior chamber through the pupil, and aqueous humor with fluorescein leaves the eye through the outflow pathways.

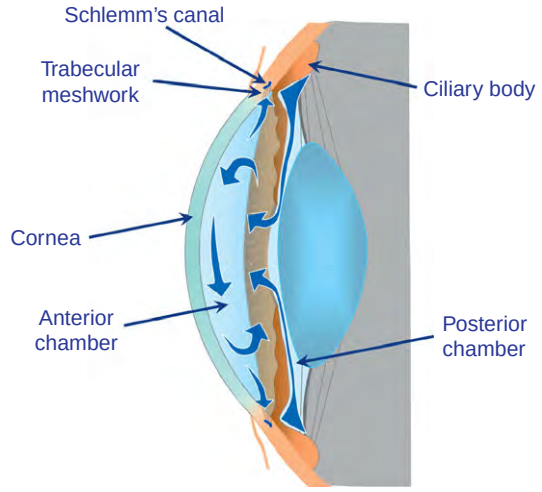

Figure 1 Circulation of aqueous humor. Aqueous humor is secreted into the posterior chamber by the ciliary body. It flows between the iris and lens, enters the anterior chamber though the pupil, and is mixed in the anterior chamber by convection and eye movements. Aqueous humor leaves the eye through the trabecular meshwork and the uveoscleral tissues at the angle between the iris and cornea.

Once the fluorescein is uniformly distributed in the stroma, its concentration is measured in the cornea and anterior chamber by fluorophotometry at the beginning and end of several intervals (**Figure 2**). The mean flow rate during each interval is calculated from the rate of loss of fluorescein from the eye between measurements:

$$flow = \frac{-\Delta m_t}{\overline{C}_a \Delta t} - d \qquad [2]$$

where Δm_t is the change in total mass of fluorescein in the cornea and anterior chamber on interval Δt, $\overline{C}_a$ is the average concentration of fluorescein in the anterior chamber during the interval, and d is the flow equivalent to loss of fluorescein by diffusion directly into vessels, but not by bulk flow of aqueous humor. Typically, the total mass of fluorescein is determined as the sum of the mass in the anterior chamber and cornea:

$$m_t = v_c C_c + v_a C_a \qquad [3]$$

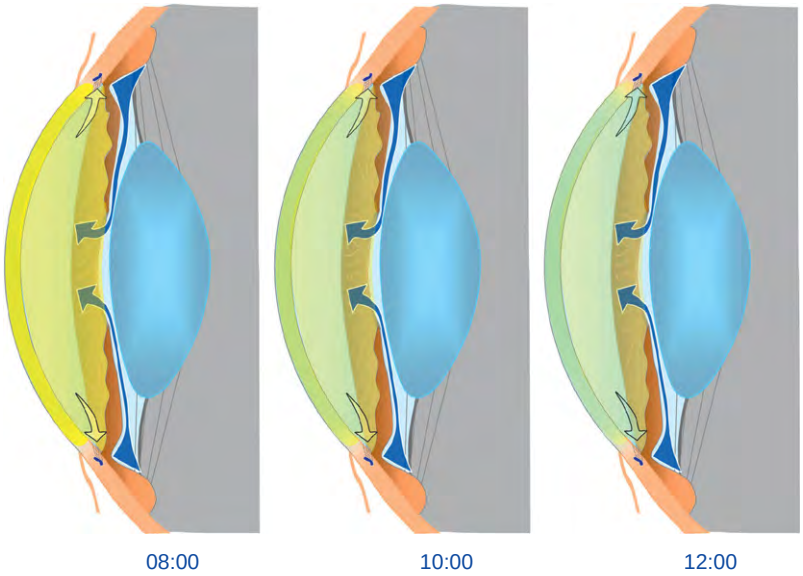

Figure 2 Aqueous humor flow rate is determined from the dilution of the fluorescent dye fluorescein. Fluorescein is instilled topically and a small amount enters the cornea. From the corneal stroma, it crosses the corneal endothelium and mixes with aqueous humor. As aqueous humor flows through the anterior chamber it carries fluorescein out of the eye, and by measuring the rate of fluorescein loss from the eye, we can determine the aqueous humor flow rate. Typically, fluorescein in the cornea and anterior chamber is measured at 1- or 2-h intervals. Adapted from Brubaker, R. F. (1998). Clinical measurements of aqueous dynamics: Implications for addressing glaucoma. In: Civan, M. M. (ed.) *The Eye's Aqueous Humor. From Secretion to Glaucoma*, pp. 233–284. San Diego, CA: Academic Press, with permission from Elsevier.

where v_c and v_a are the volumes of the cornea and anterior chamber, respectively, and C_c, and C_a are the concentrations of fluorescein in the cornea and anterior chamber, respectively.

What is the Aqueous Humor Flow Rate?

The Normal Eye

In normal eyes of men and women, mean aqueous humor flow through the anterior chamber during hours of wakefulness has typically been 2.2 –3.1 µl min^{-1}, depending on the study. Flow rate in a population is normally-distributed with a standard deviation of about 0.8 µl min^{-1} (**Figure 3**). This provides an efficient circulation; for persons with an average anterior chamber volume of 185 µl, aqueous humor production represents approximately 1.2% of the anterior chamber volume per minute. At this rate the fluid in the anterior chamber and any solutes or contaminants, have a half-life of 43 min. For fluorescein, a substance that fills the anterior chamber and corneal stroma, the half-life in these combined compartments is approximately 4 h.

Aqueous Humor Flow is not Affected by Elevated or Decreased Intraocular Pressure

Few, if any, conditions (other than sleep, as discussed later is this chapter) affect aqueous humor production. The ability of the ciliary body to change flow rate in response to changes in intraocular pressure has been examined in a variety of conditions. In an interesting experiment to test the dependence of flow on intraocular pressure, Dr. Keith Carlson suspended volunteers (including the author) upside down by their feet for 30-min intervals alternating with 30 min in an upright position, and measured aqueous humor flow from fluorescein concentrations at the beginning and end of each interval. Inversion increased central and episcleral venous pressure and raised intraocular pressure by an average of 11.2 mmHg. The intraocular pressure increase was not, however, associated with a compensatory change in aqueous humor production. In this and other experiments, the rate of aqueous flow appeared to be independent of transient changes in intraocular pressure, in a moderate range of pressures. If, of course, intraocular pressure were increased so high that blood flow to the ciliary body were compromised, this relationship would likely change. Measurements of flow rate in patients with glaucoma and other disorders have shown that aqueous humor production also does not change to compensate for chronic ocular hypertension or hypotension.

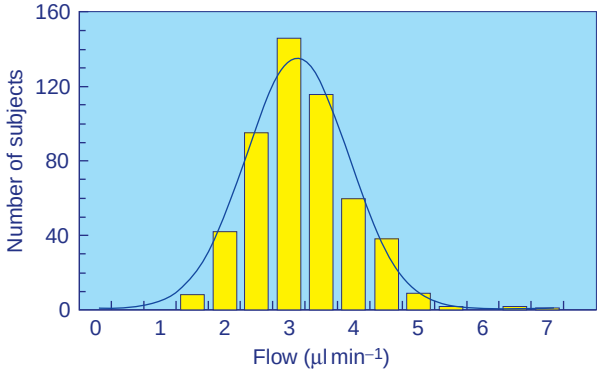

Figure 3 Distribution of aqueous humor flow in 519 subjects during the morning. Mean flow rate was normally distributed (solid line) with a mean of 3.0 ± 0.8 µl min^{-1}. Adapted from Brubaker, R. F. (1998). Clinical measurements of aqueous dynamics: Implications for addressing glaucoma. In: Civan, M. M. (ed.) *The Eye's Aqueous Humor. From Secretion to Glaucoma*, pp. 233–284. San Diego, CA: Academic Press, with permission from Elsevier.

Aqueous Humor Flow Decreases Slowly with Age

Aqueous humor formation gradually slows with age by about 4% per decade of life. One might expect this decrease to diminish the efficiency of the circulatory function, but the reduction in flow is accompanied by a reduction in the volume of the anterior chamber by approximately 14–24 µl per decade. The smaller anterior chamber requires less flow to maintain the same clearance. From age 20 to 80 years, aqueous humor flow rate decreases by approximately 25%, while anterior chamber volume decreases by 40%, and this combined change provides a 20% faster turnover rate of aqueous humor over a lifetime.

Aqueous Humor Flow Changes Dramatically during Sleep

Under most conditions, aqueous humor flow rate varies little from the flow rate during the day while subjects are alert and untreated. Sleep is an exception; during sleep, the rate of aqueous flow diminishes to approximately half the rate during wakefulness (**Figure 4**). This daily rhythm is driven by an internal circadian rhythm of the body and not simply by the environmental and postural conditions at night. It is partly preserved during a single episode of sleep deprivation and is not affected by ambient light at night or a supine position during the day while awake.

The strongest evidence for an origin of this circadian rhythm points to β-adrenergic stimulation during the day driving flow rate up during hours of wakefulness, and lack of this stimulation during sleep, allowing flow rate to diminish. During sleep, circulating catecholamines, including epinephrine, decrease. If a high blood concentration of epinephrine is artificially maintained during sleep, flow rate does not decrease as much as it normally would during sleep. Timolol, which blocks β-adrenergic receptors, suppresses flow during the day to rates that are similar to those

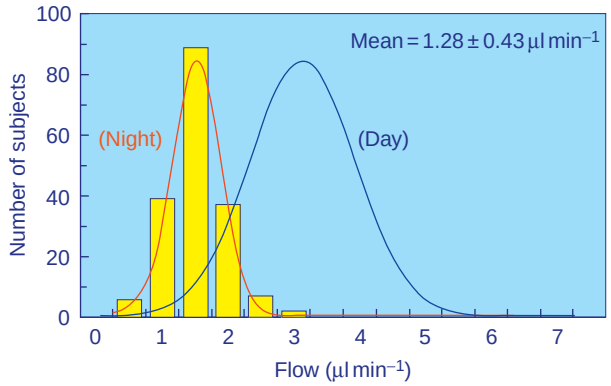

Figure 4 Distribution of aqueous humor flow in 180 subjects during sleep. Mean flow rate decreased to approximately half of the rate during the day. The Gaussian curve to show the distribution of flow in the morning was normalized to the nighttime curve for comparison. Adapted from Brubaker, R. F. (1998). Clinical measurements of aqueous dynamics: Implications for addressing glaucoma. In: Civan, M. M. (ed.) *The Eye's Aqueous Humor. From Secretion to Glaucoma*, pp. 233–284. San Diego, CA: Academic Press, with permission from Elsevier.

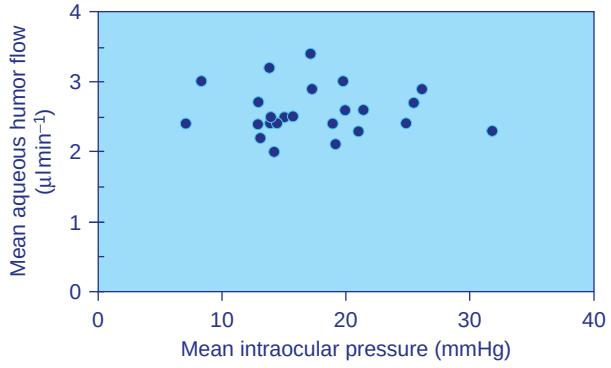

Figure 5 Mean aqueous humor flow was not correlated with mean intraocular pressure in 20 published studies of aqueous humor flow in pathologic conditions. Adapted from McLaren, J. W. (2009). Measurement of aqueous humor flow. *Experimental Eye Research*, 88: 641–647, with permission from Elsevier.

during sleep. However, if timolol is administered just before sleep, it does not suppress flow rate any further than the normal rate during sleep. Other ocular hypotensive agents that do not interact with the β-adrenergic system but reduce flow rate through other receptors do not suppress the circadian rhythm, although they diminish the magnitude of flow changes from wake to sleep.

The circadian variation of epinephrine activity seems to be at least partially responsible for modulating aqueous humor flow during a circadian day, although the control by epinephrine is far from simple. For example, the circadian rhythm of flow persists even in patients who have low circulating catecholamines because of adrenalectomy. Epinephrine supplied by sympathetic nerve activity also does not seem to drive the rhythm entirely; flow rate is normal in patients with sympathetic denervation. So far no single factor has been identified that would provide a comprehensive and sufficient explanation for the origin of the circadian rhythm of aqueous humor flow.

Flow in Abnormal Eyes

Aqueous humor flow has been studied in a number of systemic and ocular conditions, including chronic open-angle glaucoma, low-tension glaucoma, ocular hypertension, exfoliation syndrome, pigment dispersion, Horner's syndrome, Fuchs' dystrophy, myotonic dystrophy, diabetes mellitus, cystic fibrosis, and carotid stenosis. These studies reported a range of mean intraocular pressures from 7 to 32 mmHg. Remarkably, aqueous humor flow rate was largely unaffected by most of these conditions (**Figure 5**). Mean daytime flow rate ranged from 2.1 µl min^{-1} to 3.4 µl min^{-1}, and was not correlated with mean intraocular pressure. Patients with diabetes mellitus may be an exception; in a few studies, flow rates in diabetic patients were somewhat lower than normal, although their intraocular pressures were normal. In these conditions, aqueous flow certainly does not vary to the extent that would be regarded as clinically significant and is independent of intraocular pressure across the range of pressures experienced by most patients. Stated another way, the intraocular pressure does not appear to be regulated or stabilized by compensatory changes in aqueous humor flow in abnormal as well as in normal eyes. We do not know, however, if flow would change if intraocular pressure increased or decreased to extremes that would compromise blood flow or deflate the eye.

Pharmacologic Agents and Hormones

With a few exceptions, most pharmacologic agents and hormones have no measurable stimulatory effect on flow. Pharmacologic agents with β-adrenergic agonist activity are an exception, and these can, under some conditions, increase the rate of aqueous humor flow during the day by a small amount, typically, 15%. They are particularly effective when given at night when intrinsic concentrations of circulating and neuronal catecholamines are low. Other agents, notably those used as ocular hypotensives, suppress aqueous humor formation, and these fall into three categories: β-adrenergic antagonists, α_2-adrenergic agonists, and carbonic anhydrase inhibitors. Some of these agents are clinically relevant and their study has contributed to our knowledge of the physiologic properties of aqueous humor production.

β-Adrenergic Antagonists

The ocular hypotensive activity of systemically and topically administered propranolol, a β-adrenergic antagonist,

has been known since the 1960s. Timolol, another β-adrenergic antagonist and ocular hypotensive agent, was discovered shortly thereafter and developed for clinical use. Soon after the first clinical use of timolol, fluorophotometry was used to show that it lowered intraocular pressure by suppressing aqueous humor production by as much as 50%. Other β-adrenergic antagonists, such as betaxolol, a β_2-selective antagonist, and levobunolol, reduce intraocular pressure in a similar way, by suppressing aqueous humor flow.

β-Adrenergic antagonists affect aqueous humor flow differently, depending on whether they are administered during the day or during the night. The effects of β-adrenergic antagonists on aqueous humor flow were all originally studied during the daytime, when human subjects were awake and active. In contrast, at night during sleep, when flow is normally low, these drugs have no measurable effect on flow rate. The only exception is when flow is artificially stimulated by epinephrine at night during sleep; timolol can suppress the epinephrine-stimulated flow. The differential activity of β-adrenergic antagonists suggest that the circadian rhythm in aqueous flow is driven by an endogenous hormonal agent that can be blocked when the agent is high, during waking hours; however, because it is not present during sleep, it cannot be blocked during sleep. The best candidate for this agent is circulating epinephrine, from adrenal or neural sources. However, evidence for epinephrine being the sole driver of the circadian rhythm is circumstantial, and other hormonal agents, such as corticosteroids, may play a role in the behavior of this system.

α_2-Adrenergic Agonists

In the 1960s, clonidine was the first selective α-adrenergic agonist discovered to reduce intraocular pressure after systemic administration. It was later found to suppress aqueous humor flow by 21%, enough to explain the hypotensive effect. A derivative of clonidine, para-aminoclonidine (apraclonidine, aplonidine), was developed for topical application and also decreased aqueous humor flow by about 30%.

Apraclonidine and timolol suppress aqueous humor production by about the same amount in normal volunteers. These drugs when acutely administered together are not additive. In contrast to timolol, apraclonidine suppresses flow during sleep. Although these two classes of drug may have common features, the pathways to suppression of flow are not identical.

Carbonic Anhydrase Inhibitors

Systemic administration of acetazolamide has been associated with a reduction of intraocular pressure since the early 1950s, and this reduction is also associated with a reduction of aqueous humor flow. Systemic carbonic anhydrase inhibitors affect carbonic anhydrase activity all over the body and have many side effects. Two topically applied carbonic anhydrase inhibitors, dorzolamide and brinzolamide, were developed to reduce these side effects. These drugs, which minimized the systemic dose, also reduced aqueous humor flow, although to a somewhat lesser degree than did systemic carbonic anhydrase inhibitors. Both systemic and topical carbonic anhydrase inhibitors also reduce aqueous humor production during sleep, topical to a somewhat lesser extent than systemic.

Other Classes of Drugs and Hormones

Several other classes of pharmacologic agents that reduce intraocular pressure have shown little suppression of aqueous humor flow, if any. Epinephrine provided a weak stimulation of flow during the day in some studies and had no effect or a mild suppression of flow in others. Stimulatory effects were typically less than 15%, an increase that could be considered clinically unimportant. Other β-adrenergic selective agonists also stimulate aqueous humor flow weakly, and these include salbutamol, isoproterenol, terbutaline, and ibopamine. When β-adrenergic agonists are administered during sleep, they stimulate flow by a greater amount than they do during the day, although they do not stimulate flow to the daytime rate. These agents likely bind receptors that have low endogenous stimulation at night, and therefore are associated with reduced aqueous humor production during sleep, but are strongly stimulated during the day.

Cholinergic agonists and antagonists minimally affect aqueous humor flow. Pilocarpine, a cholinergic agonist that has been used to decrease pressure by opening the outflow pathways, may stimulate flow rate slightly, although not all studies agreed. Scopolamine, an anticholinergic usually administered transdermally through a patch, has no effect on flow.

Prostaglandins and their analogs are an important therapeutic agent to treat increased intraocular pressure. These drugs seem to enhance outflow of aqueous humor through uveoscleral pathways, removing flow from the trabecular pathway. These drugs, including prostaglandin $F_{2\alpha}$-isopropyl ester, bimatoprost, latanoprost, and travoprost, lower intraocular pressure without suppressing aqueous formation. In fact, some studies have indicated a small, clinically insignificant increase in flow rate.

Several hormones have also been studied to see if their circadian rhythms might drive the circadian rhythm in flow, either by administrating the hormones when they are normally at low concentrations in the blood or by measuring flow rate in patients who lack the hormone because of a clinical condition. Melatonin, norepinephrine, antidiuretic hormone, and hormones of pregnancy all have no direct effect on aqueous humor flow that could explain the circadian rhythm. Only epinephrine stimulates flow at night (when it is normally absent) by enough that could

explain the diurnal rise in aqueous flow. Other hormones, such as corticosteroids, may enhance the effects of epinephrine, although details of their role in adjusting the circadian rhythm are unknown.

Control of Aqueous Humor Production, the Basis of Pharmacologic Manipulation of Intraocular Pressure

Aqueous humor is secreted by 70–90 ciliary processes that extend into the posterior chamber (Figure 6). A bilayer of epithelium separates the stroma of each process from the aqueous humor and has a layer of pigmented and a layer of nonpigmented cells. The pigmented epithelium lies on the surface of the ciliary stroma, while the nonpigmented epithelium contacts the aqueous humor in the posterior chamber. The apical surfaces of the two cell types contact each other and their basolateral surfaces face the ciliary stroma (pigmented epithelium) or the aqueous humor (nonpigmented epithelium). These two layers of cells behave as a functional syncytium; gap junctions between their apical surfaces provide the structural basis of intracellular communication and movement of water and various ions. A small amount of aqueous humor is formed by ultrafiltration across this layer, but most is formed when this bilayer epithelium transfers solute between the ciliary process stroma and aqueous humor to create osmotic pressure that draws water passively along its chemical gradient into the posterior chamber.

The primary solutes that determine the rate of aqueous humor formation are sodium, potassium, and bicarbonate ions. This is a simplification; chloride movement is also important and several ion exchange proteins play a role in ionic balance and rates of ion and water movement. Sodium transfer is mediated by the enzyme sodium–potassium adenosine triphosphatase (Na,K-ATPase), which moves three sodium ions out of the nonpigmented cell and two potassium ions into the cell against their respective electrochemical gradients, at the expense of energy in the form of ATP. Bicarbonate ions move down their electrochemical gradient into the posterior chamber through a carrier molecule. In the nonpigmented epithelium, carbon dioxide and water react to form bicarbonate, and this reaction is catalyzed by carbonic anhydrase. This reaction is reversible, depending on the pH and the concentrations of bicarbonate and carbon dioxide. The transfer of sodium and potassium and the catalysis of bicarbonate are dynamic and determine the rate of aqueous humor production. As concentrations of solute increase on the aqueous humor side of nonpigmented cell membrane, water is drawn by osmotic pressure to form aqueous humor.

Figure 6 Ciliary processes. Approximately 70–90 ciliary processes extend into the posterior chamber and secrete aqueous humor. In this view from behind the iris, the crystalline lens has been removed, the posterior surface of the iris is visible at the bottom, and the cut edge of the sclera is visible at the top. Each of these processes is lined with a layer of pigmented and nonpigmented epithelium, with the nonpigmented epithelium in contact with the aqueous humor.

The activity of Na,K-ATPase and the movement of sodium and potassium are linked to adrenergic receptors on the nonpigmented ciliary epithelium through adenylate cyclase and an internal messenger system. As activity of adenylate cyclase is stimulated, activity of the Na,K-ATPase increases and aqueous humor production increases. Two broad classes of adrenergic receptors are linked to adenylate cyclase and have opposite effects: stimulation of β-adrenergic receptors increases adenylate cyclase activity and aqueous humor secretion, whereas stimulation of α_2-adrenergic activity suppresses adenylate cyclase activity and reduces aqueous humor secretion.

Intracellular carbonic anhydrase catalyzes the formation of bicarbonate somewhat independently of the Na,K-ATPase system, although this is a simplification. Rates of both reactions are determined by the availability of substrate, cellular pH, and other ionic composition, and may be interdependent. As bicarbonate concentration increases, bicarbonate moves across the cell membrane down its electrochemical difference into the aqueous humor. This transfer is dependent on carrier molecules that likely involve movement of other ions, and rates may be dependent on concentration and movement of these ions.

This model is consistent with our observations of circadian rhythms and pharmacologic manipulation of aqueous humor production. During sleep, when β-adrenergic activity is low, Na,K-ATPase activity is unstimulated and is also low. Aqueous humor is produced at a low rate (Figure 7). On awakening and becoming active, circulating and neural catecholamine activity increases and binds β-adrenergic receptors in the ciliary body, stimulating Na,K-ATPase and increasing aqueous humor production to rates observed during wakefulness (Figure 8). The daily rise and fall of β-adrenergic activity likely drives the circadian rise and fall of aqueous humor flow.

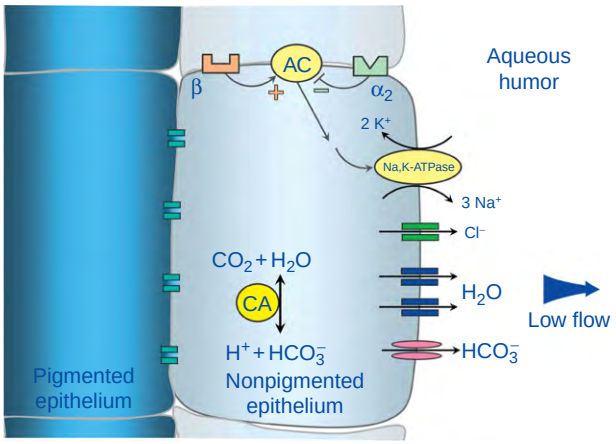

Figure 7 Basal secretion of aqueous humor. In the unstimulated state, sodium is transferred in and potassium is removed from the aqueous humor by a Na,K-ATPase. This process requires energy in the form of ATP. Bicarbonate is produced in the cell by the catalysis of water and carbon dioxide and moves into the aqueous humor through a carrier protein that likely involves co-transport of another ion. The increased concentration of sodium and bicarbonate draws water osmotically through water channels in the cell membrane (aquaporin-1) to form aqueous humor. Chloride likely transfers into the aqueous humor through a chloride channel to maintain electrochemical neutrality.

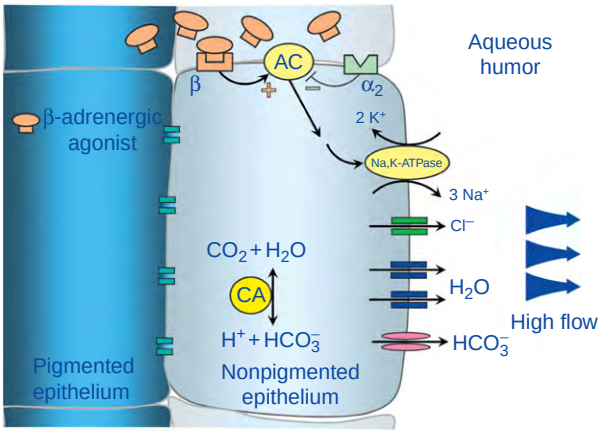

Figure 8 Flow is stimulated during the day by β-adrenergic activity. The activity of Na,K-ATPase, and the rate of sodium movement into the aqueous humor, is linked to adenylate cyclase through several steps. Adenylate cyclase is linked to two classes of receptors on the cell membrane, α_2-adrenergic and β-adrenergic receptors, that have opposite effects. When the β-adrenergic receptors bind transmitter, the linkage stimulates adenylate cyclase activity, which stimulates the Na,K-ATPase and increases aqueous flow. This is the normal state during the day when circulating and neural catecholamine concentrations are high.

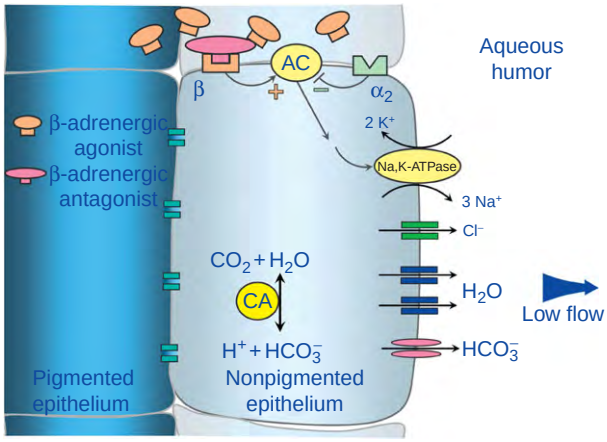

Figure 9 β-Adrenergic antagonists block β receptors and prevent the stimulation of adenylate cyclase. Flow rate decreases to approximately what it is during sleep when there is no intrinsic β-adrenergic stimulation.

The circadian variation in β-adrenergic stimulation of aqueous humor production provides an explanation of why β-adrenergic antagonists reduce flow during the day but not at night (**Figure 9**). During the daytime, when flow is high because of endogenous β-adrenergic activity, drugs such as timolol or betaxolol block the β-adrenergic receptors, and flow rate returns to its basal rate. These β-adrenergic inhibitors administered at night, when β-adrenergic activity is normally low, cannot suppress flow further because flow is not stimulated and there is no β-adrenergic activity to block. When epinephrine is given at night, it binds β-adrenergic receptors and stimulates aqueous humor flow. However, when β-adrenergic agonists are given during the day, they only poorly stimulate flow because most of the β-adrenergic receptors are already stimulated.

Apraclonidine and other α_2-adrenergic agonists decrease flow during the day by actively suppressing Na, K-ATPase through the adenylate cyclase messenger system (**Figure 10**). This pathway is also active at night, although flow does not decrease as much as it does during the day with α_2-adrenergic stimulation.

The transfer of bicarbonate into the posterior chamber is determined by the rate of catalysis of bicarbonate by carbonic anhydrase. Drugs that inhibit carbonic anhydrase, such as acetazolamide, dorzolamide, or brinzolamide, slow down the formation of bicarbonate, and the reduced movement of bicarbonate into the posterior chamber reduces water movement and aqueous humor production. (**Figure 11**) Suppression of carbonic anhydrase reduces aqueous humor production during the day, when flow rate is normally high, and is also effective at night.

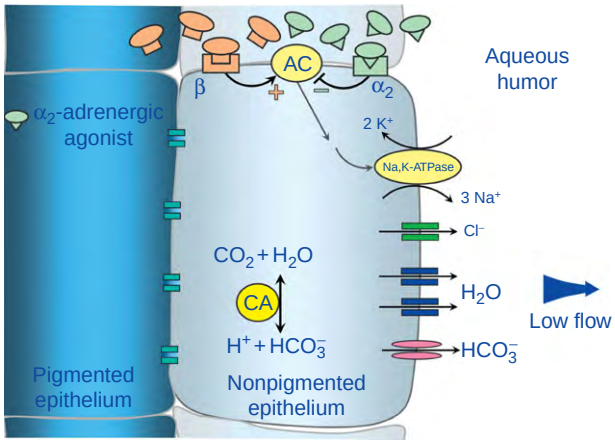

Figure 10 Adenylate cyclase is linked through a suppressive path to α_2-adrenergic receptors. Drugs with α_2-adrenergic activity bind these receptors and suppress activity of adenylate cyclase, and the reduced Na,K-ATPase activity reduces aqueous humor production.

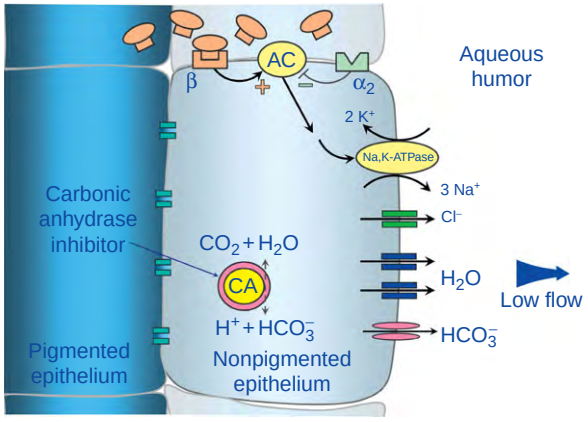

Figure 11 Movement of bicarbonate across the nonpigmented cell membrane is also responsible for a portion of aqueous humor production, and, as in other cells in the body, the reaction that produces bicarbonate is catalyzed by carbonic anhydrase. Drugs that inhibit carbonic anhydrase, such as dorzolamide or brinzolamide, reduce the production of bicarbonate in the cell and its movement into the aqueous humor, and aqueous humor flow decreases.

Summary

Much has been learned about aqueous humor dynamics and ocular hypotensive medications since aqueous humor flow was first measured over 50 years ago. Whereas aqueous humor production decreases slowly through life, it is unaffected by most afflictions and diseases. It varies greatly with the circadian cycle. During the morning, aqueous humor flow rate is the greatest and is about 3.0 µl min^{-1}, while at night during sleep, it drops to about half of this rate. The rate of aqueous humor production is determined by the activity of two enzymes, Na,K-ATPase and carbonic anhydrase, in the nonpigmented ciliary epithelium, and pharmacologic manipulation of these enzymes can reduce flow rate to treat ocular hypertension. Aqueous humor flow can be suppressed by β-adrenergic antagonists, which block β-adrenergic stimulation of Na,K-ATPase. This class of drugs has no effect at night when intrinsic β-adrenergic stimulation is minimal. The system is actively suppressed by α_2-adrenergic agonists, and these drugs also suppress flow rate at night. Carbonic anhydrase inhibitors reduce aqueous humor production by reducing the production and transfer of bicarbonate into the posterior chamber. Only drugs with β-adrenergic activity can stimulate flow, and then only poorly during the day when endogenous β-adrenergic stimulation is high. These drugs can increase flow rate during sleep, when natural β-adrenergic activity is low, but not to the extent that flow increases during the day. Our knowledge of fundamental dynamics and control of production and circulation of aqueous humor has provided a basis for understanding and developing better pharmacologic and surgical treatments of glaucoma.

Coordinating Division and Differentiation in Retinal Development

R Bremner and M Pacal, University of Toronto, Toronto, ON, Canada

Glossary

Cell birth – For the purposes of this article, cell birth is the activation of a new transcriptional program that is never seen in retinal progenitor cells (RPCs), but is limited to differentiating retinal transitional cell (RTCs). This definition excludes cell-cycle exit because, as discussed in this article, differentiating RTCs can be generated independent of exit. In normal cells, the timing of cell birth is usually measured by briefly labeling replicating DNA with bromodeoxyuridine (BrdU) or tritiated thymidine (^{3}H-thymidine) and then, days/weeks later, counting intensely labeled cells which, by definition, exited the cell cycle soon after the label was introduced. This tool is useless in mutants where cell birth occurs in the absence of cell-cycle exit. In that case, birth must be noted when it occurs using markers induced in differentiating RTCs that are never present in RPCs (e.g., Nrl in newborn rods).

Cell-cycle rate – It reflects the rate of cell expansion, which correlates with cell-cycle length.

Competence – This activity influences the ability of RPCs to generate certain cell types. It is permissive, but not instructive in that it creates potential, but it is not sufficient to force cell birth on its own. The competence of RPCs changes throughout development. Early RPCs are competent to produce ganglion, horizontal, amacrine, and cone cells, while late RPCs produce bipolar and Müller cells. Rods are generated throughout, but predominantly are a mid–late-born cell type.

Exit – Normally, cell birth is closely coupled to cell-cycle exit and ensures that a newborn RTC remains post mitotic until and after it becomes a terminally differentiated cell.

G0 – Cells can be driven out of G1 into reversible G0 by serum starvation or contact inhibition, or into irreversible G0 by terminal differentiation or senescence.

G1, S, G2, and M – Most cell cycles have four phases: S phase is when DNA is synthesized; M phase is when cells undergo mitosis to generate two offspring (often termed daughters); G1 and G2 are gaps between M and S or S and M, respectively.

Interkinetic nuclear migration (INM) – Cellular processes connect the RPC to the apical (also called outer or ventricular) and basal (also called inner or vitreal) surfaces of the retina. RPC nuclei move as they traverse the cell cycle. M-phase nuclei are located at the apical surface, then move more basally to go through G1 and start S, then finish S migrating back to the apical side, and go through G2 just before they reach the end of that journey.

Mitogen – Extracellular factor that induces cell division.

R – The restriction point in G1, beyond which a cell will continue into S phase even if mitogens are withdrawn.

Retinal progenitor cell (RPC) – A dividing cell in the normal developing retina.

Retinal transition cell (RTC) – Also termed precursor. These are newborn differentiating cells. They are distinguished from RPCs by a novel transcriptome that includes many mRNAs/proteins that are never detected in RPCs. Normally, RTCs are post mitotic. However, failure to exit does not prevent induction of the RTC transcriptome. Birth (induction of the differentiation program) and exit can be uncoupled and are, therefore, viewed as separate in this article.

Introduction

Cell division is driven by extrinsic mitogens that influence the intrinsic core cell-cycle machinery. Extrinsic factors can also influence the decision to exit and differentiate during development. In the retina, the earliest born cells are ganglion neurons (**Figure 1**) and these cells secrete factors that have crucial roles in influencing division and fate, such as Sonic Hedgehog. Beyond this stage, however, although many factors can influence division and fate, it is not clear whether they actually do so *in vivo*. Dissociated, well-separated, individual retinal progenitor cells (RPCs) can generate clones of cells that resemble clones *in vivo* in both size and composition, except for ganglion cells which do not survive *in vitro*. These data suggest that apart from ganglion cell births, much of retinal development is intrinsically programmed and thus, apart from a general requirement for mitogens, extrinsic factors may not play a major role in determining whether RPCs divide or exit. Further, we have introduced a few of the basic issues around cell-cycle regulation, discuss the role of some

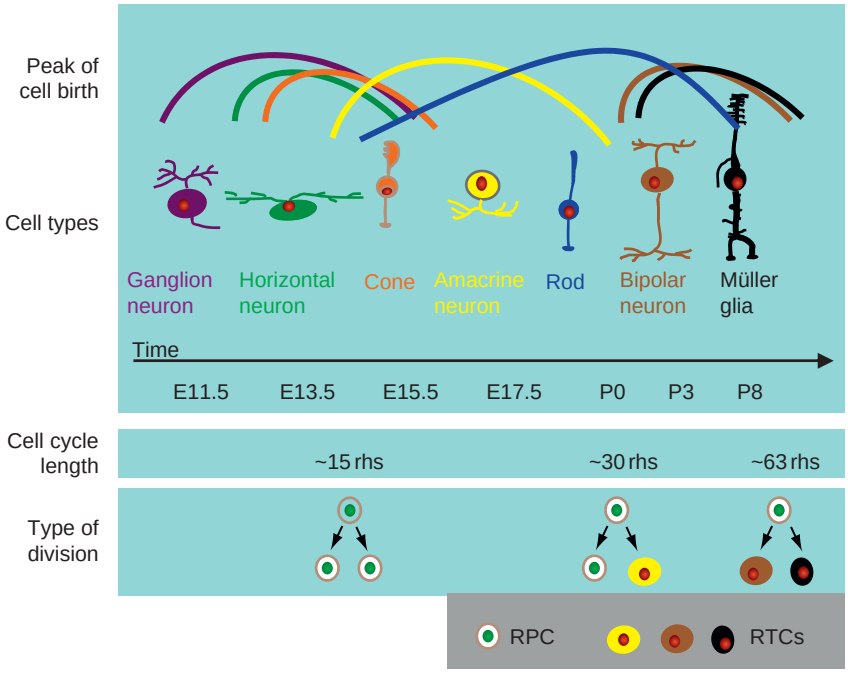

Figure 1 Retinal histogenesis. The upper schematic shows approximate time periods (E, embryonic; P, postnatal) of genesis for each of the seven major murine retinal cell types. The lower-half depicts when symmetric production of two RPCs gradually switches to symmetric production of two differentiating RTCs. This switch is matched by an increase in cell-cycle length. Dividing RPCs are depicted with white cytoplasm and green nuclei. Postmitotic differentiating RTCs are depicted with red nuclei and colored cytoplasm.

key cell-cycle regulators in retinal development, and finish with a discussion as to how RPC expansion versus neurogenesis is coordinated through the Notch pathway.

A Few Basics of Cell-Cycle Regulation

Extracellular positive (mitogenic) and inhibitory cues are sensed in cells through fluctuating levels of cyclins. These proteins are required to activate cyclin-dependent kinases (Cdks). Cyclin D-Cdk4/6 complexes form in G1, cyclin E-Cdk2 complexes act at G1-S, cyclin A-Cdk2 complexes drive S, and cyclin B-Cdk1 complexes drive M. However, these complexes may act in other phases and show considerable functional redundancy. Treatment of resting cells with mitogens induces *Cyclin D1* transcription through Ras–Raf–Erk-mediated activation of the immediate early gene Ap1 (Ap1/Ets). Glycogen synthase kinase 3 beta (Gsk3β)-mediated Thr phosphorylation of cyclin D reduces its stability and nuclear localization. Mitogens also activate the Ras–Pi3k–Akt pathway which phosphorylates and inactivates Gsk3β, doubling cyclin D1 half-life and promoting nuclear translocation. Cyclin D-Cdk4/6 complexes phosphorylate retinoblastoma (Rb) proteins on multiple sites. The cyclin D-Cdk4/6 complex also titrates the Cip/Kip family of Cdk2 inhibitors (CKI), discussed further below.

Rb inhibits division in two major ways (Figure 2). First, it binds the activating E2f transcription factors (E2f1, 2, and 3a). These are inducer genes that positively regulate the cell cycle (e.g., cyclins E and A) and other genes that are necessary for the nuts and bolts of DNA replication (e.g., PCNA, RRM1). Rb binds and quenches E2f activity, and recruits silencing cofactors to permanently shut down genes in terminally differentiating or senescent cells. Rb also binds E2f3b and E2f4, whereas its relatives p107 (Rbl1) and p130 (Rbl2) preferentially bind E2f4 and 5 – which are thought to be repressive E2fs that primarily mediate inactivation of target genes (although E2f3b can mimic some functions of E2f3a). However, p107/p130 can partner with activating E2fs if E2f4 is missing. E2fs 6–8 do not bind the Rb family of pocket proteins, but inhibit transcription by recruiting other co-repressors. The extent to which E2f target-gene induction involves direct activation (mediated by activator E2fs) versus derepression (loss of Rb pocket proteins from repressor E2fs) is not completely resolved.

Second, Rb – but not p107/p130 – binds the Cdh1 subunit of anaphase-promoting complex or cyclosome (APC/C) (Figure 2). APC/C ubiquitin ligase degrades securin and cyclins to permit passage through and escape from M phase, but in G1 it degrades Skp2 – part of another E3 ubiquitin ligase (SCF^{Skp2}) that degrades Cip/Kip CKIs to promote Cdk2 activity. Rb binds Skp2,

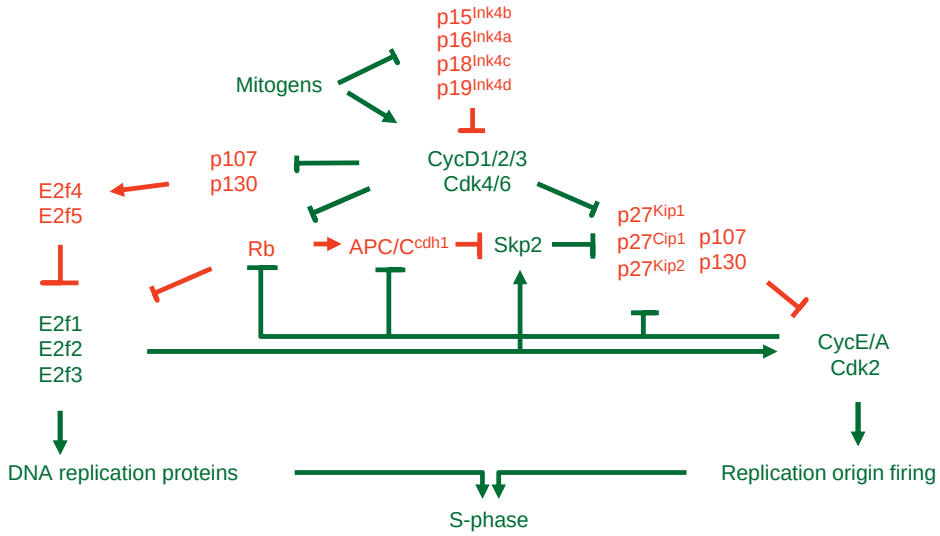

Figure 2 Some Key Regulators of G1/S transition. The two major axes of G1/S inhibition are the Rb–E2f and the Cip/Kip–Cdk2 axes. Mitogens stimulate division by inhibiting INK4a CKIs (e.g., $p19^{Ink4d}$) and increasing CycD levels. Activated Cdk4/6 phosphorylates and inhibits the Rb family. D-Cdk4/6 complexes also sequester Cip/Kip CKIs (e.g., p27). Active Rb binds and inhibits gene transactivation by E2f1-3. p107/130 form repressor complexes with E2f4/5 that target the same genes as E2f1-3. On the other axis, Cip/Kip CKIs bind and inhibit Cdk2 complexes. P107 and p130 – unlike Rb – can bind and inhibit Cdk2 complexes. There are also feed-forward and feedback links between the Rb–E2f and Cip/Kip–Cdk2 axes. Feed-forward effects include blockade of Skp2-mediated degradation of p27 by Rb-Cdh1, and E2f-mediated induction of CycE/A. Feedback effects include inhibition of Rb by Cdk2 (thus further activating both E2fs and Skp2). Positive regulators are in red, negative are in green. The figure does not, by any means, include all regulators and links.

presenting it for destruction to APC/C, thus preventing degradation of Cip/Kip CKIs and blocking Cdk2 action.

Rb phosphorylation weakens binding to E2f, resulting in induction of cyclin E, Cdk2 activation, further Rb phosphorylation, and induction of cyclin A – a sequential process that is necessary for cell-cycle progression. Cyclin D function is dispensable in Rb-deficient cells, but cyclin E is required for division even in the absence of Rb, indicating it has other targets. Indeed, independent of Cdk2 activation, cyclin E promotes loading of MCM proteins onto origins of replication, and E-Cdk2 phosphorylates this complex to trigger DNA replication. Cyclin E overexpression can drive the cell cycle even when E2f activity is blocked. Apart from unleasing E2f, Rb phosphorylation also releases it from both Skp2 and Cdh1 – thus activating Cdk2 by a second route (**Figure 2**). This positive-feedback loop allows cells to pass R and enter S; indeed, E2f1 behaves as a bistable switch to drive this irreversible transition.

Distinct CKI families bind and inhibit cyclin-Cdks (**Figure 2**). The Ink4 family, which includes $p16^{Ink4a}$, $p15^{Ink4b}$, $p18^{Ink4c}$, and $p19^{Ink4d}$ (encoded by *Cdkn2a/b/c/d*, respectively), inhibits Cdk4/6. Ink4 CKIs act upstream of Rb-E2f and need Rb plus p107 or p130, and E2f4 or E2f5 to block division. The Cip/Kip family of CKIs, which includes $p21^{Cip1}$, $p27^{Kip1}$, and $p57^{Kip2}$ (encoded by *Cdkn1a/b/c*, respectively), inhibit cyclin A/E-Cdk2 and cyclin B-Cdk1 and can act downstream of Rb. Notably, p107 and p130, but not Rb, also function as CKIs that inhibit Cdk2 activity as potently as $p21^{Cip1}$ (**Figure 2**). In the complete absence of the Rb family, mouse embryo fibroblasts (MEFs) lack a G1 restriction point, and progress even if mitogens are withdrawn, but these cells arrest at G2 due to the combined action of Cip/Kip CKIs and p53 tumor suppressor.

Inhibitory mitogens – such as transforming growth factor-beta (TGFβ), block cyclin D induction or inhibit its activity by inducing the expression of Ink4 CKIs. TGFβ also inhibits cell-cycle progression by triggering nuclear translocation of an E2F4/E2f5–p107–Smad3 complex that associates with Smad4 protein, and then binds and silences the c-*Myc* promoter through a Smad-E2f element.

In summary (**Figure 2**), Rb and Cip/Kip CKIs cooperatively inhibit division by constraining E2f- and Cdk2-mediated induction of S-phase gene transcription and replication origin firing, respectively. Rb and $p27^{Kip1}$ cross-talk positively by promoting Skp2 degradation and blocking Rb phosphorylation, respectively. Mitogen-activated cyclin-Cdks sequentially phosphorylate Rb, cyclin D-Cdk4/6 sequesters Cip/Kip CKIs, and Skp2, freed of Rb, stimulates CKI degradation, all of which leads to activation of E2f and Cdk2. E2f and Cdk2 cross-talk positively by inducing cyclins and phosphorylating Rb, respectively, This dual axis triggers the production and/or activation of the components needed for DNA replication.

Cyclins and Cdks in Retinal Development

RPCs express higher levels of cyclin D1 than any other embryonic tissue (Figure 3). D1 absence causes severe retinal hypocellularity. Downregulation/inhibition of D1 during differentiation is important since ectopic expression in differentiating photoreceptors prevents normal cell-cycle exit, mimicking the effect of pocket protein loss. The large induction in $p27^{Kip1}$ protein translation in newborn retinal neurons likely dwarfs any remaining D1-Cdk4/6 in these cells. D1 loss reduces RPC division beyond E16.5 but not earlier, suggesting that the earliest phase of RPC expansion is D1-independent. This delayed requirement for D1 may reflect the gradual increase in Rb and p107 expression in RPCs during development. Consistent with the role of D cyclins in inactivating Rb and sequestering CKIs (see above), the *D1*-null retina has hypophosphorylated Rb, no cyclin E–Cdk2 activity, and hypocellularity is rescued when $p27^{Kip1}$ is also missing. A cyclin $D1^{KE}$ point mutant binds but fails to activate Cdk4/6 and partially rescues the *D1*-null retina. Like normal D1-Cdk, $D1^{KE}$-Cdk complexes sequester $p27^{Kip1}$, and consequently both Cdk2 activity and Rb phosphorylation are increased in $D1^{KE}$ versus *D1*-null retinas.

The D family has two other members – D2 and D3. The defect in *D1*-null mice is rescued in mice expressing

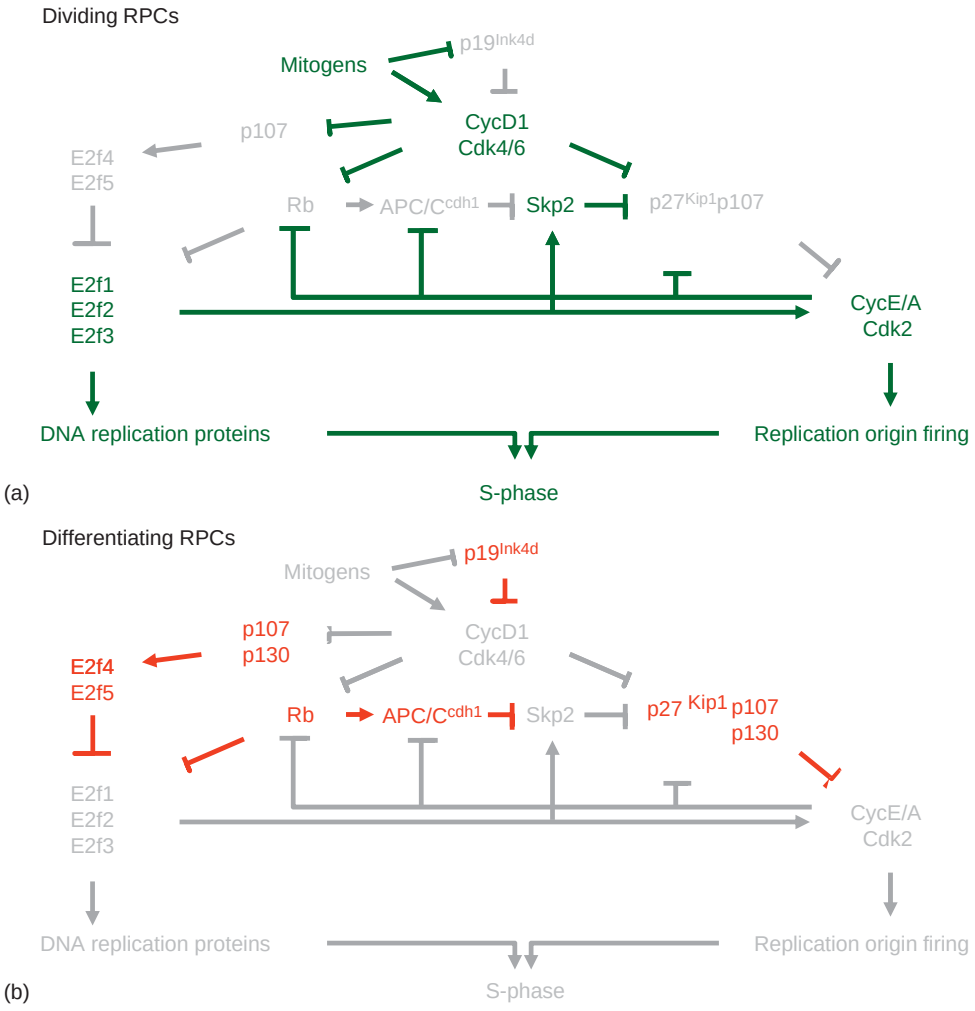

Figure 3 Cell-cycle regulation in RPCs versus differentiating RTCs. (a) In dividing RPCs, extremely high levels of CycD1 activate Cdk4/6 and maintain Rb and p107 in an inactive phosphorylated state and sequester $p27^{Kip1}$. The latter is also efficiently degraded, presumably due to high levels of Skp2. Inactive pocket proteins leave the activating E2fs free to induce transcription of genes required for DNA replication and CycE/A that activate Cdk2. $p27^{Kip1}$ absence leaves CycE/-Cdk2 free to fire DNA origins and further inhibit negative cell-cycle regulators (e.g., Rb, $p27^{Kip1}$). (b) In differentiating RTCs, both $p19^{Ink4d}$ and $p27^{Kip1}$ proteins are induced and inhibit Cyc–Cdk complex activity. Cyclin expression is downregulated. Pocket proteins are activated by dephosphorylation and quench E2f activity. p107/p130 act in other cells to form repressor complexes with E2f4/5, although whether this is the case in the retina has not been shown explicitly. Rb may facilitate $p27^{Kip1}$ stability by bringing Skp2 into contact with APC/C. However, in human retina, there is only brief overlap in Rb and $p27^{Kip1}$ expression in differentiating neurons. The picture is more complex than depicted.

D2 from the *D1* locus, so they are interchangeable in this regard. Normally, however, D2 is not expressed in the retina and while D3 is expressed in Müller glia, it is present at very low levels in RPCs. There is no induction of D2 or D3 in *D1*-null retinas and *D1/D2*- or *D1/D3*-null retinas do not show a more severe phenotype than the *D1* knockout (KO). The loss of $p27^{Kip1}$ in *D1*-null retinas also does not affect *D2* and *D3* expression. Triple-null mice survive to ~E15 and, consistent with the idea that D cyclins are not required for early RPC division the early triple-null retina also appears wild-type (WT).

The cyclin E family consists of E1 (formerly E) and E2, and both are expressed in retina. Apart from a spermatogenesis defect in *E2*-null males, *E1*- and *E2*-null mice are normal. $E1^{-/-};E2^{-/-}$ mice die around mid-gestation (~E10) due to defective endoreduplication (repeated S with no M-phase) in trophoblasts, and thus a defective placenta. By using tetraploid WT blastocysts, which form a normal placenta but do not contribute to the embryo proper – $E1^{-/-};E2^{-/-}$ embryonic stem (ES) cells injected into these blastocysts could, in about half the cases, generate a normal embryo that, like WT ES cells in this approach, survive to birth. Half of $E1^{-/-};E2^{-/-}$ embryos die with cardiac defects, all megakaryocytes (like trophoblasts) show defective endoreduplication, and while MEFs could divide normally, they were unable to exit quiescence. Importantly, no neural phenotypes were reported in $E1^{-/-};E2^{-/-}$ embryos, suggesting that cyclin E functions are redundant in RPCs, perhaps due to the combined actions of cyclins D1 and A.

Remarkably, knocking in cyclin *E1* to the *D1* locus partially rescues the cyclin *D1*-null retinal phenotype with retinal thickness reaching ~75% WT. Rb phosphorylation is only slightly higher than in the *D1* KO, suggesting that low levels of Rb phosphorylation are sufficient to permit RPC division. Indeed, cyclin E can override a cell-cycle block induced by overexpressing a mutated version of Rb lacking most of its phosphorylation sites. The Cdk-independent role of cyclin E in loading DNA-replication origins may be important in this context.

Like cyclins, there is also considerable redundancy among Cdks. Although $Cdk4^{-/-}$ mice are 20% smaller at birth, show pancreatic islet cell hypotrophy, and null MEFs divide more slowly due to elevated $p27^{Kip1}$, there are no obvious retinal defects. Apart from a mild hematopoietic defect $Cdk6^{-/-}$ mice are normal, and *Cdk4/6* redundancy in RPCs remains to be addressed since double-null mice die after E14.5. Cdk3 is rarely mentioned as it is defective in many mice and is thus dispensable. *Cdk2*-null mice appear normal except for a defect in meiosis, and deleting *Cdk2* does not affect fibroblast division. *Cdk2/4/6* triple-null mice die around E12.5 and retinal explant studies have not been attempted. The latter study also shows that Cdk1 (also called Cdc2) – the most ancient cell-cycle kinase best known for its role at G2/M in mammals – can substitute for other kinases to mediate much of the proliferation needed for embryogenesis. Moreover, it is required for the first division following fertilization. A conditional allele will be needed to study its role in later stages, including RPC expansion.

In summary, cyclin D1 promotes RPC division both by phosphorylating Rb proteins and sequesterating $p27^{Kip1}$, although early RPC expansion appears cyclin D-independent. E cyclins, Cdk4/6, or Cdk2 each seem redundant, but further studies are required to tease apart overlapping cyclin and Cdk roles and to determine if Cdk1 is essential for RPC division.

The Rb Family in Retinal Development

Rb is the tumor suppressor mutated in the familial cancer retinoblastoma. Rb and p107 pocket proteins are present in mouse and human RPCs as well as in postmitotic retinal transition cells (RTCs), whereas p130 seems to be confined to the latter. As expected, Rb loss triggers extra division. However, Rb and p107 seem to be inactive in RPCs as removing Rb or both Rb and p107 in mouse retina does not affect the number of M-phase or visual system homeobox 2 ($Vsx2^{+}$, also called Chx10) RPCs. Inactivation of Rb in RPCs may be due to the extremely high levels of cyclin D1 and, as noted above, Rb is hypophosphorylated in *D1*-null retinas. The logical explanation for Rb expression in RPCs may be that it is poised to act rapidly in newborn RTCs once D1 levels drop (**Figure 3**). Rb is also important for arresting division following DNA damage, which could also be employed in RPCs. Nevertheless, the irrelevance of Rb in controlling normal RPC division is a hard pill to swallow in view of multiple *in vitro* overexpression experiments implying that Rb tempers the expansion of all dividing cells. Yet Rb-null ES cells divide normally, and Rb-null embryos are not enlarged despite minimal apoptosis, and the same is true of p107/p130-null embryos, and there is not much compensation in either case. Moreover, Rb loss does not impact much of *Xenopus* embryonic development, again implying that it is already inactive.

Instead of tempering expansion, Rb is employed mainly to promote permanent cell-cycle exit, such as in terminally differentiating (**Figures 3** and **4**) or senescing cells, or to execute arrest in DNA-damaged cells. Thus, in contrast to the undetectable effect of *Rb* loss in RPCs, there is a dramatic effect in differentiating RTCs (**Figure 4**). RTCs missing Rb, or Rb and one or more of its relatives, divide ectopically. Some cell types choose apoptosis to defend the tissue from cancer, which is E2f1-dependent, but p53-independent. Indeed, most defects in the Rb-null retina are rescued in the *Rb/E2f1*-null retina, except for a notable cell-cycle and cell-death-independent differentiation defect in a subset of amacrine interneurons that is caused by E2f3a. Intriguingly, Rb repression of E2f3 is also

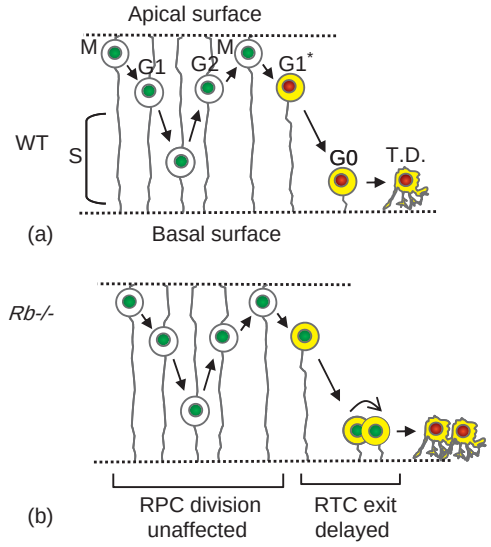

Figure 4 Uncoupling cell birth and cell-cycle exit. (a) In the WT retina, the RPC nucleus/cell body changes position as the cell progresses through the cell cycle. This process is termed interkinetic nuclear migration (INM). Following cell birth, the apical process begins to retract as the newborn RTC moves to its final destination and undergoes terminal differentiation (TD) Green and red nuclei depict whether the cell is dividing or post mitotic, respectively. Yellow cytoplasm indicates induction of a distinct transcriptome in the RTC. (b) In the absence of Rb, RPC division is unaffected, but differentiating RTCs divide ectopically (note green, instead of red, nucleus). However, the birth transcriptome (yellow cytoplasm) is activated. The response of different RTCs to Rb loss is cell-type specific. Some (as depicted here) survive, terminally differentiate and exit division via Rb-independent means. During ectopic division, these cells are at risk for neoplastic transformation (not shown). Other cell types (e.g., ganglion cells) escape transformation by undergoing apoptosis (not shown).

important to ensure proper migration of forebrain neurons against independent of cell cycle/apoptosis activities. Amacrine cells are one of a subset that survive loss of Rb proteins, and most escape tumorigenesis not by death, but by Rb-independent cell-cycle escape (**Figure 4**). However, rare *Rb/p107*-null or *Rb/p130*-null amacrine cells – likely through post-pocket protein events that override this arrest – can form sporadic retinoblastoma. Human retinoblastoma does not require p107 or p130 loss, likely reflecting broader expression of these proteins in other species. Intriguingly, long-term ectopic division of differentiating cells in fly tissues also requires disruption of multiple cell-cycle regulators. Ectopically dividing murine horizontal cells are also resistant to apoptosis, but they are better protected against transformation and require loss of *Rb*, *p130*, and one allele of *p107* to form tumors. Natural resistance to apoptosis is an attractive feature for a cancer cell-of-origin, especially one like retinoblastoma that requires fewer rate-limiting events than adult cancers. Several post-Rb events have been identified in human retinoblastoma and likely facilitate progression past a benign retinoma state, which ends in senescence.

In summary, pocket proteins apparently do not regulate the cell cycle in normal RPCs, but are poised to act in differentiating RTCs where Rb is required to quench E2f1 activity (**Figures 3** and **4**). p107 and p130, although nonessential, act as backups when Rb is removed. The CKIs $p19^{Ink4d}$ and $p27^{Kip1}$ may play an important role in activating Rb proteins in differentiating RTCs (**Figure 3**). Pocket protein loss creates a dangerous state where ectopically dividing RTCs risk neoplastic transformation. This risk is countered in some cells by apoptosis and others by Rb-independent means of cell-cycle exit.

Ink4 CKIs and $p19^{Arf}$ in Retinal Development

Cdkn1c encoding $p18^{Ink4c}$ is expressed weakly in the embryonic NBL, but is dispenable for retinal development. *Cdkn2b*, which encodes $p15^{Ink4b}$, lies adjacent to *Cdkn2a*, which encodes two transcripts that have distinct first, but shared downstream, exons and encode $p16^{Ink4a}$ and the p53-activating protein $p19^{Arf}$ ($p14^{ARF}$ in humans) from different reading frames. $p15^{Ink4b}$ expression has not been reported in the retina and, while deleting both *Cdkn2b/2a* loci (which removes all three proteins) renders mice extremely susceptible to tumorigenesis, eye defects in addition to those seen in *Cdkn2a* or *p19*^{Arf}-null mice were not described. $p19^{Arf}$ is expressed in embryonic vitreal pericytes where it represses platelet-derived growth factor receptor beta (PDGFRB) expression independent of double minute 2 (MDM2) or p53, limiting expansion of these endothelial support cells, thus its absence triggers abnormal expansion and severe defects in the adult eye. As expected, *Cdkn2a*-null mice, lacking both $p16^{Ink4a}$ and $p19^{Arf}$, also have this defect, but no obvious retinal defects – consistent with the absence of these proteins in RPCs. The fourth Ink4 protein – $p19^{Ink4d}$ – is encoded by *Cdkn2d*. Its expression pattern is consistent with a role in facilitating cell-cycle exit (**Figure 3**) and, indeed, null mice show abnormal division followed by elevated apoptosis. The defects may be a milder version of those seen in the absence of Rb or following overexpression of E2f1 or cyclin D1 in differentiating retinal neurons.

Cip/Kip CKIs in Retinal Development

Some $p21^{Cip}$ – encoded by *Cdkn1a* – is expressed in the WT retina, which increases in the absence of *Rb*, implying a context-specific role in retinal cell-cycle control. $p21^{Cip}$ absence alone does not affect retinal development, so it would be interesting to know its effect when combined with Rb loss.

In the embryonic retina, a few cells express $p57^{Kip2}$ (e.g., 3%, E14.5) and its loss triggers extra division, which

may reflect extra RPCs and/or ectopically dividing RTCs; the latter fits the observation that $p57^{Kip2}$ is expressed in late G1 or G0. Expression ceases around P0, and is reactivated in a subset of postmitotic amacrine cells, consistent with a role for $p57^{Kip2}$ in differentiation.

The most influential Cip/Kip CKI in the retina is $p27^{Kip1}$ (**Figure 3**), as suggested by its broader expression pattern in mouse and human retina (e.g., ~50%, E14.5). $p27^{Kip1}$ mRNA is high in mouse RPCs and low in differentiating RTCs but vice versa for protein, implying that rapid translation and mRNA degradation parallels differentiation. In human RTCs, $p27^{Kip1}$ expression seems, in general, to precede Rb protein expression, suggesting that a dual wave of inhibitors is employed to shut division down. $p27^{Kip1}$ is detected at G2 in RPCs, earlier than $p57^{Kip2}$, consistent with an early role in promoting cell-cycle exit in newborn RTCs. The *Cdkn1b*-null retina has excess dividing cells at least until P10, which could reflect extra RPCs and/or ectopically dividing differentiating RTCs.

Some adult $p27^{Kip1}$-deficient retinas contain focal hyperplastic lesions, possibly due to reactive gliosis. These lesions are more severe when the *Cdkn1b* gene is replaced by an altered protein ($p27^{CK-}$) that cannot bind cyclin–Cdk complexes. $p27^{+/CK-}$ mice do not get retinoblastoma, but do develop lung tumors. The increased phenotypic severity in $p27^{+/CK-}$ mice relative to $p27^{Kip1}$-null mice reveals that $p27^{Kip1}$, when freed from cyclin–Cdks, has a dominant disruptive function. This activity may relate to the cytoplasmic role of $p27^{Kip1}$ in regulating the Rho-Rock signaling pathway which, intriguingly, is also targeted by $p21^{Cip}$ and $p57^{Kip2}$. $p27^{Kip1}$ has other cytoplasmic activities such as binding the microtubule regulator stathmin. $p21^{Cip}$ and 27^{Kip} are distributed between the cytoplasm and nucleus in mouse retina.

Cell-cycle defects in the $p19^{Ink4d}$- or $p27^{Kip1}$-deficient retinas are enhanced when both are missing, consistent with cooperative Rb activation and Cdk inactivation to promote cell-cycle exit. Apoptosis and dysplasia are also more severe. As in the $Rb^{-/-}$ retina, deleting p53 does not rescue apoptosis, yet surprisingly it does reverse the dysplasia.

E2Fs in Retinal Development

Multiple E2f mRNAs have been detected in the retina, and protein expression has been confirmed for E2f1 as well as both a and b isoforms of E2f3. Deleting *E2f1* slows RPC division approximately twofold, whereas *E2f3* loss has no effect, suggesting redundancy. The superior role for E2f1 in RPCs differs from that in MEFs where E2f3 is more important. As noted above, E2f1 drives ectopic division in differentiating $Rb^{-/-}$ RTCs and transgenic E2f1 expression in photoreceptors also impairs cell-cycle exit. E2f3a perturbs differentiation in some $Rb^{-/-}$ amacrine cells, which is similar to its effect in the $Rb^{-/-}$ forebrain. E2f4 loss affects Shh expression in the telencephalon, but its role in the retina, similar to other E2fs, awaits further study.

Separating Rate, Birth, and Exit

The above discussion summarizes how cell-cycle regulators affect RPC expansion and RTC cell-cycle exit. We now turn to how the factors that promote cell birth influence the cell-cycle machinery. At this point, we encourage the reader to review the glossary definition of the terms competence, interkinetic nuclear migration (INM), cell birth, and exit. To facilitate discussion of the model below, we emphasize that birth and exit are viewed as separate activities that are temporally coupled. Birth is the new transcriptional program activated in a differentiating cell that defines its identity, and exit is the cessation of division.

Distance from Notch Predicts Birth

As already described, RPC nuclei undergo INM. Live imaging studies in zebrafish have indicated that nuclei that migrate deeper into the basal layer are more likely to generate a differentiating RTC when they return to the apical surface and undergo mitosis. These data raise the possibility that to achieve birth, nuclei must escape from a diffusable inhibitory signal. An attractive candidate is the antineurogenic factor Notch (**Figure 5**). Activated Notch is cleaved, releasing its intracellular domain (Nicd), which binds recombination signal-binding protein (Rbpj, also called Cbf1, Suh, Igkrb, Kbf2). Rbpj activates expression of hairy and enhancer of split (Hes) proteins, which are basic helix-loop-helix (bHLH) transcriptional repressors that block expression of proneurogenic genes. In line with the speculative model in **Figure 5**, Notch is more abundant at the apical side, but there is conflicting literature on whether the diffusable cleaved Nicd fragment or its gene targets (e.g., the Hes proteins) are more abundant/active in apically located nuclei. The Baier/Link groups found that antibodies to Nicd labeled apically located fish RPCs. Using live imaging, this group also found that a fluorescent protein expressed from the Nicd-inducible *her4* promoter was more abundant in RPCs with more apically located nuclei. However, the Reh group finds that Nicd is lowest in the apically located nuclei in the mouse retina, and both the Reh group and the Kageyama group report higher levels of Hes1 in progenitors when their nuclei are located at the basal side of the neuroepithelium in mouse and chick retina and mouse cortex (using highly destabilized Hes1 reporters). Given the highly transient

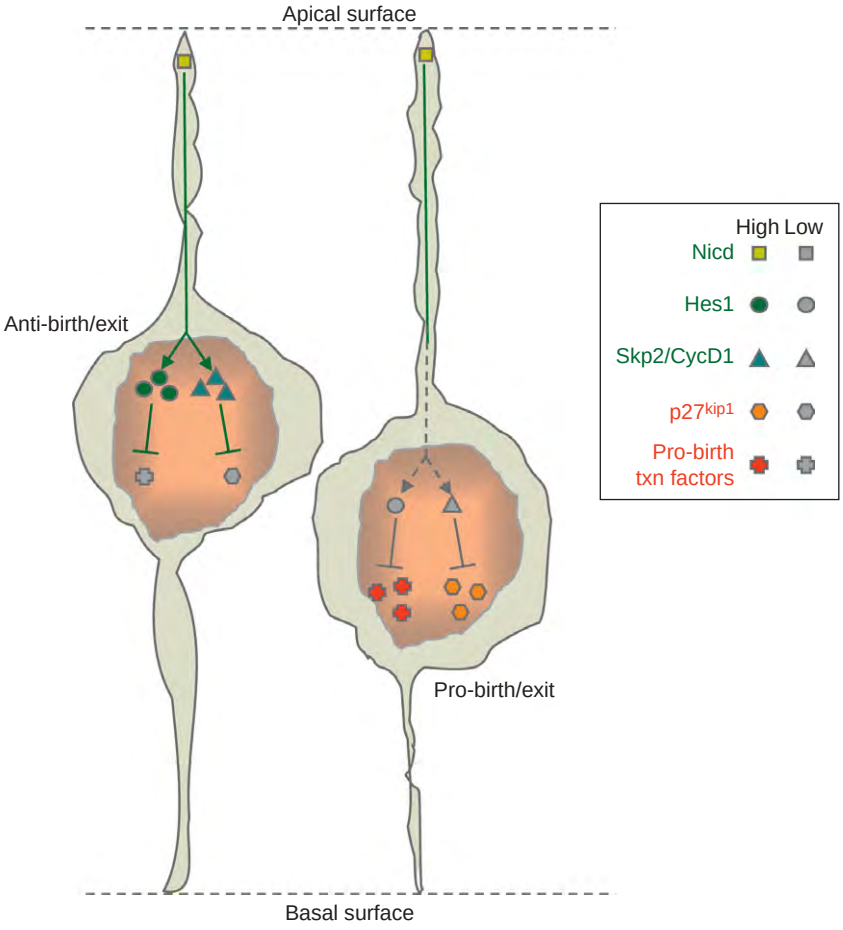

Figure 5 Notch and INM control birth/exit pathways. This Nicd gradient model is based on data from zebrafish studies, but is still controversial (see text for details). In addition, the link between Nicd and Skp2/cyclin D1 induction has been shown in other cell types but not, as yet, RPCs. In this speculative model, the RPC nucleus on the left migrates less basally than the RPC nucleus on the right. As a result, the former is under control of the apical gradient of Notch signaling mediated by the cleaved diffusable Nicd, which drives transcription of Hes1 (green) as well as Skp2 and Cyclin D1 (blue) which counter-expression of neurogenic bHLH factors and inhibit $p27^{Kip1}$, respectively. On the contrary, the nucleus that migrates deeper is less affected by Nicd because it has to diffuse further (dotted gray arrows), and the reduced levels of Hes1 and Skp2/CycD1 permit induction of pro-birth bHLH factors (red) and stabilization of $p27^{Kip1}$ (orange).

nature of Notch signaling, it will be important to use highly destabilized reporters, like those used in cortex by Kageyama's group, for future studies in retina, to better characterize cell-cycle-dependent changes in Notch signaling. Genetic studies prove that Notch is antineurogenic, so it will be important to deduce exactly how it achieves this end.

Genetic analysis in fish shows that, whether or not Nicd/Hes gradients are involved, INM plays a key role in determining birth. In dynactin-1 (mok) mutants, it was found that RPC nuclei migrated deeper (thus appearing to escape Notch signaling) and generated more early-born ganglion cells. The mechanisms that control INM distance are unclear, but both actin- and microtubule-based motors have been implicated. Notably, RPCs are in S-phase when they approach the basal side and neurogenic bHLH genes are induced in S-phase. Moreover, transplant experiments indicate that both cortical and retinal progenitors can change fate during this period. Together, these data build a model in which nuclei destined to undergo birth are moved a sufficient distance from the apical surface to escape influence of the Notch pathway, thus permitting induction of neurogenic factors required to activate the birth program.

Birth Does Not Require Exit

Birth and cell-cycle exit are intimately linked, so it is tempting to conclude they must be interdependent (birth needs exit). There is also a model proposing that slowing cell-cycle rate in the last division might also be critical to facilitating birth. Below, we summarize evidence for and against these issues.

In support of the notion that rate reduction favors birth, progenitor cell-cycle length increases with the gradual transition to symmetric production of two RTCs. In zebra fish, the average cell-cycle length does not predict birth, but, of two sibling RPCs, the one with the longer cycle is more likely to differentiate following M-phase. Moreover, amounts of the Cdk-inhibitor drug olomoucine that slow, but do not stop, division are sufficient to trigger premature neurogenesis in the telencephalon. In support of the idea that birth requires exit, the two are temporally coupled and $p27^{Kip1}$ induction occurs in the last G2 just prior to RTC birth. Moreover, overexpression of this CKI induces early birth.

The above data are not totally conclusive. Correlations do not distinguish consequence from cause. A longer final cycle in sibling RPCs might reflect deeper migration of the neurogenic partner trying to escape Notch. Olomoucine has targets other than Cdks and importantly, mutations in *E2f1*, *cyclin D1*, or *Vsx2* that lengthen cell cycle by specific genetic means do not cause a switch to early-born cell types. Thus, whether lengthening the cell cycle is necessary for birth remains moot.

What about exit, is it required for birth? Notch-pathway defects trigger both birth and exit, but this is also a correlation that does not distinguish whether they are interdependent or can be uncoupled. Genetic evidence supports the latter since neurogenesis in the retina, forebrain, cerebellum, and inner ear goes ahead in the absence of Rb and differentiating neurons divide ectopically. As discussed earlier, a subset of ectopically dividing neurons eventually undergo apoptosis, while others survive and exit independent of Rb, and these are the source of sporadic retinoblastoma. However, clearly, birth occurs despite these downstream defects. As with Rb loss, there is also not a shift to late-born cells in retinas lacking $p27^{Kip1}$ and/or $p19^{Ink4.}$ The interphotoreceptor retinoid-binding protein (IRBP) promoter is activated just before photoreceptors are born, yet its use to overexpress cyclin D1 or E2f1 does not prevent initiation of the birth program, and the resulting photoreceptors divide ectopically. CKI overexpression assays suggest that exit can drive birth, yet do not prove that this is the physiologically relevant or necessary route. Indeed, arresting division with hydroxyurea or aphidicolin in *Xenopus* embryos does not disrupt most central nervous system (CNS) differentiation, indicating that arrest *per se* is not neurogenic. Perhaps, CKIs induce early birth by affecting a process other than exit, and, indeed, a mutated version of $p27^{Kip1}$ incapable of binding and inhibiting Cdks induces neurogenesis through interaction and stabilization of neurogenin 2 (Neurog2 or Ngn2). Alternatively, active cell-cycle components may maintain expression and/or activity of Notch-pathway components and downregulation of the cell cycle would thus block Notch signaling, an intriguing possibility given that E2f regulates the expression of Hes family members.

In summary, while birth and exit are closely coupled, exit is not necessary for birth. They are both induced following escape from Notch-pathway signals, but in an apparently parallel rather than interdependent fashion.

Mechanisms Linking Birth to Exit

Despite functional independence, birth and exit are coupled temporally, which makes sense given that a single pathway, Notch, is so central in coordinating them both. It is well established that Notch downregulation leads to induction of neurogenic transcription factors through alleviation of Hes1-mediated repression. But how is Notch connected to cell-cycle exit? Hes1 also represses expression of $p27^{Kip1}$ mRNA, but in mouse retina $p27^{Kip1}$ protein induction during cell birth is regulated at a posttranscriptional level. There are many ways in which $p27^{Kip1}$ translation and stability are regulated, yet the specific approach used in the retina is unclear. Activated Notch can induce Skp2 through the same mechanism it uses to activate Hes1 expression and, as noted earlier, Skp2 promotes $p27^{kip1}$ ubiquitin-mediated degradation (**Figure 2**). Forkhead transcription factors can promote $p27^{Kip1}$ stability by downregulating a proteosome subunit. Notch loss downregulates Vsx2 and Tlx4, and both are required for high cyclin D1 and low $p27^{Kip1}$ levels, although the details are unclear. The intracellular cleaved domain of Notch can directly activate the cyclin D1 promoter, so this mechanism might be employed in the retina. Cyclin D1 downregulation likely ensures activation of Rb protein in newborn neurons. $p19^{Ink4d}$ induction would also facilitate this event, but – although it is regulated at both transcriptional and posttranscriptional levels – the mechanisms used in retinal cells are unclear. Once Rb is activated, it shuts down E2f, and the most critical target is E2f1 since removing the latter rescues all ectopic division and apoptosis in the Rb-null retina.

Conclusion

Birth and exit are coordinately regulated through escape from Notch signaling, which may involve a distance-dependent mechanism that relies on polarity signals and INM. It is unclear exactly how the decision to evade Notch is made. Despite their temporal proximity birth is not dependent on exit. The factors that activate the new transcriptional program can be induced independent of signals necessary to shut off division and neurons attempt to develop as they divide ectopically. Failure to couple birth to exit can lead to retinoblastoma, underscoring the importance of maintaining tight coupling. To avoid this catastrophe, some neurons undergo apoptosis, but others adopt Rb-independent means of exiting, which provides a window of time during which neoplastic clones may

evolve. Well-known cell-cycle regulators are downregulated and activated to ensure exit parallels birth, and many of these events are posttranscriptional. Exactly how evading Notch triggers these events in the retina remains to be resolved, although there are clues from work in other cell types.

Cornea Overview

P Asbell and D Brocks, Mount Sinai Hospital, Department of Ophthalmology, New York, NY, USA

Glossary

Conductive keratoplasty (CK) – Refractive surgery that uses heat from radio waves to shrink the collagen in the cornea. It is useful for patients with hyperopia and presbyopia.
Dry eye syndrome (DES) – Lack of quantity or quality of tears that lubricate the ocular surface.
Disodium ethylenediaminetetraacetic acid (EDTA) – Chemical that chelates calcium.
Descemet's stripping automated endothelial keratoplasty (DSAEK) – Surgical procedure where the Descement's basement membrane and endothelium of the host are removed and replaced with a thin posterior donor cornea lenticule in its place.
Hyperopia – Disorder of vision where the eye focuses images behind the retina instead of on it so that distant objects can be seen better than near objects.
Lamellar keratoplasty (LK) – Replacement of damaged or diseased anterior corneal stroma and Bowman's membrane with donor material.
Laser *in situ* keratomileusis (LASIK) – Refractive surgery that uses a laser to reshape the cornea.
Laser subepithelial keratomileusis (LASEK) – Refractive surgery that uses a laser to reshape the anterior cornea.
Laser thermokeratoplasty (LTK) – Refractive surgery using a mid-infrared laser shrinks the collagen of the corneal periphery.
Penetrating keratoplasty (PK) – Corneal transplant using the entire cornea from a donor.
Photorefractive keratectomy (PRK) – Refractive surgery where the corneal epithelium is removed and the stroma reshaped.
Phototherapeutic keratectomy (PTK) – Procedure where the corneal epithelium is removed and an excimer laser is used to smooth the surface of the cornea.
Radial keratotomy (RK) – Refractive surgery in which radial incisions are made in the cornea from the pupil to cornea.
Scheimpflug imaging – It measures central corneal thickness and anterior chamber depth.

Anatomy of the Layers

The cornea, often referred to as the window of the eye, is covered by the precorneal tear film, and provides a smooth, transparent medium for light rays to pass through. The average cornea measures approximately 12 mm horizontally and 11 mm vertically and seamlessly joins with the opacified sclera at its periphery. The normal cornea has five layers (epithelium, Bowman's membrane, stroma, Descemet's membrane, and endothelium), and has an approximate average central thickness of 540 μm.

Epithelium

The corneal epithelium is composed of approximately 5–6 rows of stratified squamous epithelial cells. It is these cells in this configuration, along with the overlying tear film that help create the smooth, clear surface. The tight junctions between epithelial cells help to prevent the penetration of microbes and fluid into the corneal stroma.

Epithelial cells are continuously being created by the basal limbal stem cells. New cells slowly migrate to the corneal surface where devitalized cells are lost and washed away in the tear film. The entire process takes approximately 2 weeks.

Epithelial Basement Membrane

Posterior to the epithelium of the cornea is the proteinacous epithelial basement membrane. Although only an ≈50-nm thick membrane, the importance of this layer to maintaining a compact, clear, thin anterior corneal surface is obvious when dysfunction occurs, such as in map-dot-fingerprint dystrophy (corneal epithelial basement membrane dystrophy). The thickened basement membrane present in this condition can be visualized on slit-lamp examination and it is the dysfunction of this layer that often leads to recurrent corneal erosions.

Bowman's Membrane

Beneath the epithelial basement membrane lies the acellular Bowman's membrane. This membrane marks the transition from the epithelium to the cornea stroma.

Stroma

A majority of the cornea (approximately 90% of the full corneal thickness) is the stroma. The stroma is composed of a mixture of lamellae of collagen fibrils, proteoglycans, and keratocytes. The collagen and proteoglycans are produced by the keratocytes, which are dispersed throughout the stoma. The arrangement of collagen fibrils in the stroma plays an important role in maintaining corneal transparency.

Descemet's Membrane

The endothelial basement membrane is termed Descement's membrane. This basement membrane is continually laid down throughout life by the corneal endothelium and is approximately 4-µm thick at birth and approximately 12-µm thick in adulthood. Descemet's membrane is firmly attached to the endothelium by hemidesmosomes (Figure 1).

Endothelium

The corneal endothelium is only a single cell-layer thick. These hexagonal cells are of vital importance to maintaining the clarity of the cornea. The endothelial cells lie adjacent to the anterior chamber and work to help maintain the relative dehydrated state of the cornea. The electrolyte pump of the endothelial cells creates an osmotic gradient that draws fluid from the stromal tissue.

Unlike the corneal epithelium, the endothelium is not replaced by limbal stem cells when damaged. The average person is born with approximately 3500 cells mm^{-2}, which declines to approximately 2500 cells mm^{-2} in the eighth decade of life. When endothelial cells are lost or lose functionality, adjacent endothelial cells must enlarge or change shape to attempt to maintain deturgescence. Once a significant portion of endothelial cells are damaged or not functioning properly, corneal edema ensues. The loss of endothelial function can be evaluated by slit-lamp exam, corneal thickness measurements, or through visualization with confocal microscopy, where the number, size, and shape of endothelial cells can be evaluated (Figure 2).

Function

The cornea performs vital functions as a protective barrier and as an optically clear media.

Protective Barrier

The corneal tear film is of vital importance to protecting the eye from invading pathogens. However, in addition to the tear film, it is the tight junctions between the posterior epithelial cells that act as the final barrier in preventing the entrance of microbes into the corneal stroma. This barrier also acts to prevent the inflow of excessive fluid to the stoma from the outside environment.

Transparency

There are three main attributes of the cornea that allow the tissue to maintain its transparency.

First, the water content of the cornea tissue must be maintained at approximately 78%. This water content is dependent on both the epithelial and endothelial cells. The epithelium functions as the physical anterior barrier to the influx of excessive fluid into the corneal stroma. The endothelium is not only a posterior physical barrier to the influx of fluid into the corneal stroma but also uses its sodium–potassium pump to create an osmotic gradient that draws water out of the corneal stroma.

Second, it is the compact arrangement and concentration of collagen, keratocytes, and extracellular matrix within the stroma that limits the scattering of light passing through the tissue.

Third, the lack of blood vessels in the cornea allows the light rays that pass through the clear tissue to not be

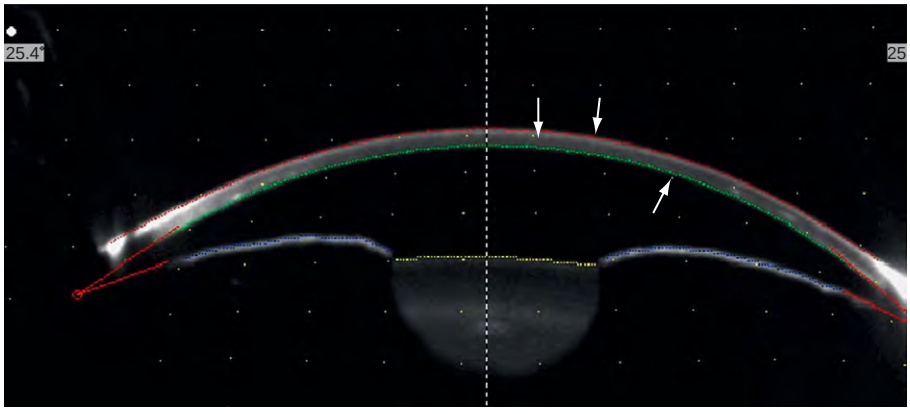

Figure 1 Layers of the cornea as visualized by Scheimpflug imaging. Yellow arrow indicates epithelium, pink arrow indicates stroma, and white arrow indicates endothelium.

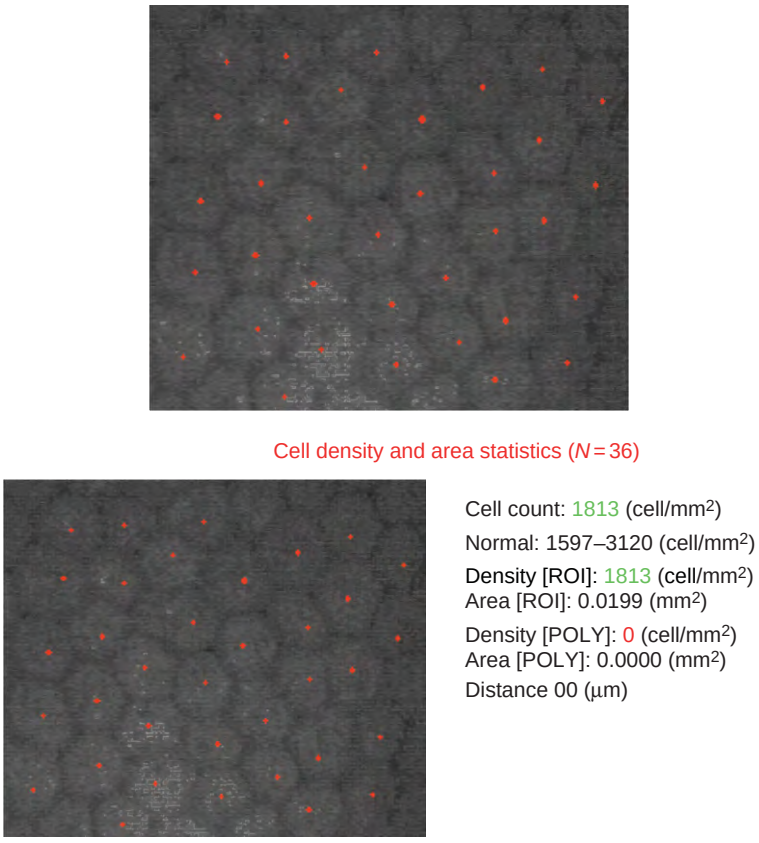

Figure 2 Endothelial cells and cell count as measured by confocal microscopy.

obscured, refracted, or diffracted in any way by blood vessels. The lack of blood vessels also limits the effect that egress or ingress of fluid into or out of the blood vessels could have on corneal deturgescence (Figure 3).

Disease Processes

The disease processes affecting the cornea are extensive. The following review is not meant as an exhaustive list, but rather as an introduction to many of the more commonly observed or discussed pathologies in clinical practice. The use of slit-lamp biomicroscopy to clearly identify which corneal layers are affected by the disease process is of vital importance to the corneal surgeon when choosing among the available medical and surgical treatment options.

Epithelial Disease

Epithelial staining patterns

The use of vital dyes is required to discern the disease process affecting the corneal epithelium. These dyes include fluorescein, rose bengal, and lissamine green. Fluorescein will stain areas with an epithelial defect, while rose bengal and lissamine green will stain areas of devitalized epithelium.

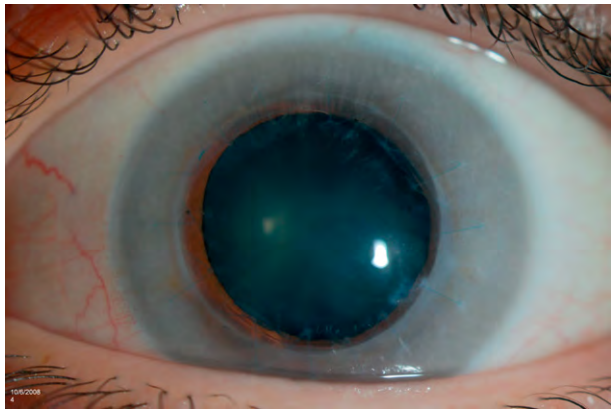

Figure 3 Loss of corneal transparency from a mucopolysaccharidosis. The peripheral cornea remains opacified, while the central cornea is transparent following a penetrating keratoplasty.

By analyzing the staining pattern on the corneal surface, the possible etiology of the disease process (Figure 4) may become apparent (Table 1).

Epithelial iron deposition

Often, the deposition of iron can be visualized on slit-lamp examination of the corneal epithelium. The deposition of

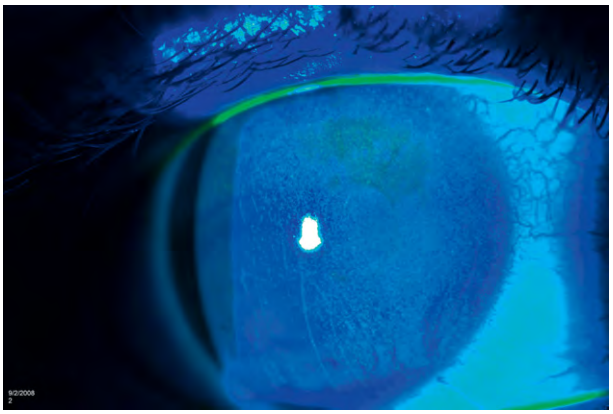

Figure 4 Diffuse damage to the corneal epithelium following the accumulation of environmental debris beneath the upper eyelid. Fluorescein was applied topically to show the epithelial defect (arrow).

Table 1 Examples of staining patterns associated with corneal pathology

Diagnosis	*Staining pattern*
Herpes Simplex Virus keratitis	Dendritic
Medication toxicity	Punctate inferior/inferonasal
Exposure keratitis	Punctate inferior
Superior limbic keratoconjunctivitis	Punctate superior
Superior palpebral conjunctiva foreign body	Vertical linear
Dry eye syndrome	Diffuse punctate, with filaments when severe

iron is believed to be related to the uneven distribution of the tear film over the corneal surface in these areas (Table 2).

Band keratopathy

Deposition of calcium in the epithelium and calcification of Bowman's membrane is termed band keratopathy. Of unknown etiology, this process tends to occur in eyes with significant chronic disease. It has also been seen in patients with elevated serum calcium levels, such as occurs with hyperparathyroidism.

Chemical/thermal burns

Significant chemical or thermal burns of the corneal epithelium can result in not only diffuse epithelial damage, but also damage to limbal stem cells, perhaps limiting the capacity of the epithelium to heal. These cases may require further surgical intervention, such as limbal stem cell transplant.

Medication toxicity

Topical and systemic medications and preservatives used in topical medications are an important cause of induced epithelial changes.

Table 2 Iron deposition in the corneal epithelium

Iron line name	*Iron line location*
Hudson-Stahli line	Horizontal line in lower third of cornea
Stocker's line	At edge of pterygium
Ferry's line	At edge of glaucoma filtering bleb
Fleischer's ring	Around keratoconus cone

The commonly used eyedrop preservative benzalkonium (BAK), non-steroidal anti-inflammatory eyedrops, trifluridine, proparacaine, and tetracaine are a few examples of medications that can result in nonhealing epithelial defects. Usually, if identified early enough and if without infection, the induced punctate epithelial defects will rapidly heal. However, if left unchecked and continued use of such medications occurs, corneal melt and even perforation can occur.

Deposition of material in the epithelium can occur with certain eyedrops and systemic medication. For example, the use of amiodarone can result in a whorl-like deposition of material. This is not an indication for stopping the medication, as it generally does not affect vision in any manner. Ciprofloxacin, when given topically, can result in a deposition of white crystals in epithelial defects. This can have visual symptoms, and, therefore, the medication should be stopped and replaced with an alternative antibiotic.

Thygeson's punctate keratitis

The presence of round central punctate white opacities without corneal edema is the hallmark presentation of Thygeson's punctate keratitis. The etiology of this disease is unknown. Patients generally present complaining of a significant foreign-body sensation and may have decreased vision if subepithelial haze is present. While usually controlled by steroid or cyclosporin topical treatment, this entity commonly recurs.

Subepithelial Disease

Epithelial basement membrane dystrophy

Also known as Cogan's dystrophy and map-dot-fingerprint dystrophy, this disease is characterized by areas of thickened epithelial basement membrane appearing as grey epithelial patches or lines along with microcystic epithelial changes appearing as epithelial dots. Although usually asymptomatic, the disease can result in recurrent corneal erosion which is frequently difficult to treat and requires medical or possibly even surgical intervention.

Subepithelial infiltrates

Following infection with adenovirus resulting in epidemic keratoconjunctivitis, patients may experience persistent haze in their vision. This may be related to persistent subepithelial infiltrates in the visual axis. These infiltrates

may improve with time. Although treatment with topical steroid may clear the infiltrates rapidly, they routinely reappear once steroid treatment is discontinued. A very slow taper is advocated in these situations. Overall, avoidance of topical steroids as primary treatment is recommended due to this issue of steroid dependence.

Stromal Disease

Infection

A variety of infections can result in significant damage to the corneal tissue. The pathogens include bacterial, viral, fungal, and parasitic microbes.

Differentiating between bacterial corneal ulcers on examination can be quite difficult. A broad-spectrum antibiotic is generally initially prescribed until further information is obtained from corneal cultures. The more common bacterial pathogens include staphylococcus, streptococcus, and pseudomonas, but cultures must be used to rule out the more rare bacterial organisms such as *Bacillus*, *Corynebacterium*, *Actinomyces*, and *Neisseria*. While most bacteria require an epithelial defect of some degree to allow bacteria to enter the corneal tissue, it is important to note *Neisseria* can penetrate through intact epithelium (**Figure 5**).

Herpes simplex virus is of significant importance to consider when evaluating a patient with infectious keratitis. While the characteristic dendritic appearance of the herpes virus moving along corneal nerves makes it fairly obvious to diagnose in these situations, the sometimes atypical appearing stromal infiltrates may require a culture to identify the causative organism.

Fungal corneal ulcers, though more rare than bacterial ulcers, recently had a resurgence possibly related to contaminated contact lens solution. The corneal infiltrates tend to have a feathery appearance along their edges and do not respond to antibiotics. Sending fungal cultures at the same time as bacterial cultures is key to avoid late diagnosis of these infections.

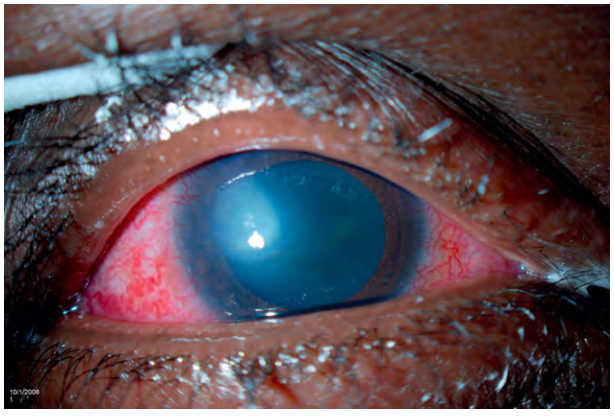

Figure 5 Infectious keratitis with diffuse conjunctival injection (dilated blood vessels), corneal edema, and a dense corneal infiltrate (arrow).

Even more rare are parasitic corneal ulcers, such as acanthameoba. Acanthameoba ulcers are most often seen in patients with a history of contact lens wear who frequently have a recent history of swimming. Generally these ulcers are more painful than they appear they should be. Initial appearance on slit-lamp examination can mimic Herpes keratitis, and these ulcers are often initially misdiagnosed as such. Later in the course of the disease a ring infiltrate can present, sometimes mimicking the corneal pattern seen in topical anesthetic abuse. The acanthameoba parasites can be difficult to culture and may require corneal biopsy for diagnosis. Sometimes, it is also possible to visualize the parasitic cysts on confocal microscopy.

Dystrophies

Stromal corneal dystrophies are rare, yet important, inherited corneal diseases to identify. There are three main types of stromal corneal dystrophies, including granular, macular, and lattice dystrophy. **Table 3** reviews the inheritance patterns, material deposited, and appropriate stain to visualize the material on pathologic specimen.

Degenerations

Corneal degenerations encompass a large category of corneal disease, which includes such more common processes as keratoconus, pellucid marginal degeneration, and arcus senilis.

Keratoconus has an unclear etiology, but pathological specimens reveal degeneration of the corneal stroma, Descemet's membrane breaks, and damage to Bowman's membrane. Clinically, progressive steepening and thinning of the central cornea can be seen, which eventually can create a cornea too irregular for even hard contact lens wear. Other corneal changes that may be visualized include an iron line around the area of corneal steepening (Fleischer's ring), stress lines on the posterior cornea (Vogt's striae), a scissoring reflex on retinoscopy, or areas of corneal opacification and edema from ruptures of Descemet's membrane (acute hydrops). These changes may be seen on slit-lamp examination; however, it may be necessary to employ computerized tomography or topography to diagnose early keratoconic (forme fruste) changes. Patients with advanced degeneration can consider either intrastromal ring segments or corneal transplantation (**Figure 6**).

Table 3 Stromal dystrophies

	Inheritance	*Material deposited*	*Stain*
Granular	Autosomal dominant	Hyaline	Masson trichrome
Macular	Autosomal recessive	Mucopolysaccharide	Alcian blue
Lattice	Autosomal dominant	Amyloid	Congo red

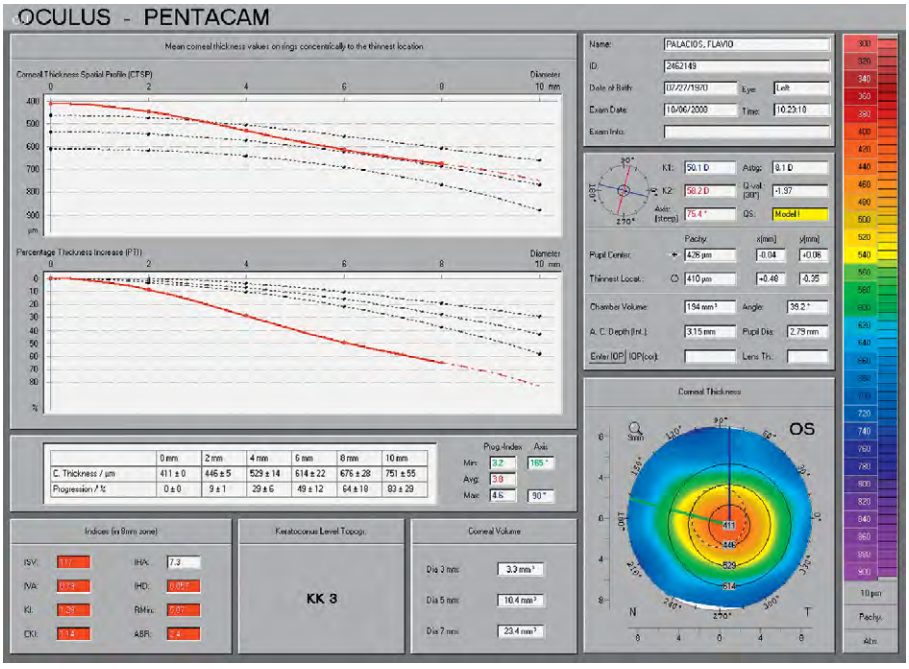

Figure 6 Corneal tomography revealing a central corneal elevation with corneal thinning in a pattern strongly suggestive of keratoconus. Color scale on right indicates thickness where purple is thickest and red is thinnest.

Pellucid marginal degeneration has a similar disease process as keratoconus; however, while the cornea in keratoconus is thinnest at the steepest location, the cornea in pellucid marginal degeneration is thinnest just below the steepest location, which is often near the inferior limbus. Similar pathologic changes can be seen and similar surgical interventions can be considered.

Arcus senilis is a peripheral corneal degeneration that is quite common in those 50 years of age or older. When examined pathologically, the white ring seen peripherally consists of lipid deposits. This can be a sign of systemic hyperlipidemia in those younger than 50 years of age or can be a sign of carotid stenosis in those with asymmetric arcus senilis.

Descemet's copper deposition

The deposition of copper in Decesmet's membrane can sometimes be seen in Wilson's disease. This often difficult to diagnose disease of copper transport, which leads to copper deposition in the liver and brain, can sometimes be diagnosed quickly at the slit-lamp examination with visualization of the green–brown deposition of copper in the posterior cornea (Kayser–Fleischer ring).

Endothelial Disease

Fuchs' dystrophy

Fuchs' dystrophy is characterized by dysfunction of corneal endothelial cells. Wart-like excrescences are deposited by the endothelium into Descemet's membrane, which can be visualized on slit-lamp examination and on confocal microscopy. Confocal microscopy can also reveal the change in size (polymegathism) and change in shape (pleomorphism) of the dysfunctional endothelial cells. As the endothelium becomes further damaged, corneal edema worsens and may require medical treatment with hypertonic eyedrops and, eventually, even surgical intervention with cornea transplantation to improve visual acuity.

Pseudophakic bullous keratopathy

During phacoemulsification of the lens, significant stress can be placed on the corneal endothelium, either mechanically with intraocular instruments, or through transfer of energy in the form of ultrasound. These processes can result in loss of endothelial cells, with resultant increased pleomorphism and polymegathism in an attempt to maintain corneal deturgescence. When too much endothelial damage has occurred, persistent corneal edema may present postoperatively and may worsen with time. These patients may require medical intervention with hypertonic eyedrops or, eventually, may require cornea transplantation.

Surgery

Once a thorough corneal examination is completed, a proposed medical or surgical intervention can be planned. To understand which surgical options are available, slit-lamp biomicroscopy must be used to accurately identify the layers of the cornea affected by the disease process.

The answer to this question will guide the physician to determine which of a vast array of surgical procedures could be undertaken.

The grand scope of the surgical treatment of corneal disease cannot be covered, in full, in this article. A brief overview of some of the more frequently used interventions will be reviewed.

Surgical Intervention of Epithelial Disease

Amniotic membrane graft

Amniotic membranes have many applications in ocular surgery. For nonhealing or slowly healing epithelial defects, this tissue can be sutured in place over the anterior surface of the cornea, where it helps protect against further corneal degradation and promotes epithelial healing. The amniotic membrane provides a matrix on which new cells can grow, helps prevent excessive inflammation, and aids in preventing corneal scarring and neovascularization.

Conjunctival flap

For poorly healing or nonhealing damage to the corneal surface, a conjunctival flap is an option. A partial or complete (Gunderson) flap can be dissected to cover the affected area, depending on the peripheral or central location of the corneal damage. Any patients with an active corneal process, such as infectious keratitis, are not good candidates for a conjunctival flap as it will not only interfere with appropriate treatment measures, but will also obscure the surgeon's view when attempting to examine the affected tissue.

Corneal glue

Cyanoacrylate tissue adhesive can be used to adhere small corneal perforations or severely thinned corneal tissue. Areas of perforated cornea from infection, trauma, postoperative wound leaks, or other etiologies can be treated with cynanoacrylate adhesive, which can at least temporarily renew the integrity of the globe.

Disodium ethylenediaminetetraacetic acid chelation

Band keratopathy can present as a dense deposition of calcium hydroxyapetite in the visual axis. Following removal of the corneal epithelium, the anterior corneal calcium deposition can be removed by soaking the affected tissue in disodium EDTA, and scraping away the residual calcium with an ophthalmic blade. Patching or bandage contact lens must be placed until the epithelium heals adequately (Figure 7).

Limbal stem cell transplant

Poorly healing epithelial defects may be a result of damaged epithelial limbal stem cells. When enough damage has occurred to these stem cells, vascularization of the corneal surface ensues. This can result from a variety of conditions such as infections, chemical burns, or post operatively. If the disease is unilateral, a stem cell autograft can be attempted from the fellow eye. If both eyes are affected, an allograft from donor tissue must be used, leading to a poorer prognosis and the necessity to systemically immunosuppress the patient postoperatively.

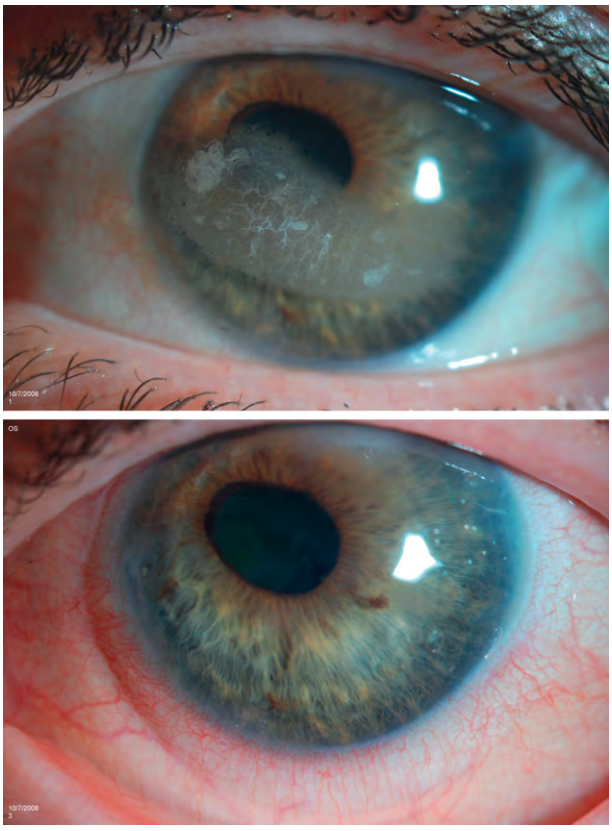

Figure 7 Pre- (top) and postoperative (bottom) band keratopathy following disodium-EDTA chelation. Notice the white calcium hydroxypatite in the top photograph.

Phototherapeutic keratectomy

Phototherapeutic keratectomy (excimer laser) can be used to remove diseased tissue in the anterior cornea, such as deposits associated with anterior corneal dystrophies or anterior corneal scars. Although typically no significant refractive change is induced, with the removal of more tissue, the risk of corneal flattening inducing hyperopia increases. Postoperative scarring can occur, and many advocate the use of topical mitomycin C intraoperatively to decrease the risk of scarring.

Pterygium excision

Pterygium refers to a benign growth of the conjunctiva. A pterygium commonly grows from the nasal side of the sclera and is associated with ultraviolet-light exposure.

The most successful technique for pterygium excision has been under much debate for many years. The options of leaving behind a bare sclera, using a conjunctival autograft, rotational graft, or amniotic membrane graft are all under current use. The debate centers around the question of which technique results in the lowest frequency of recurrence. The gold standard seems to be pterygium excision with conjunctival autograft, despite several ongoing studies reviewing the newer option of using the amniotic membrane graft.

Stromal puncture

The epithelial disease of anterior basement membrane dystrophy often leads to chronic recurrent corneal erosions. In an effort to create better adherence of the epithelium to its basement membrane and stroma, stromal puncture is attempted, usually with a 25-gauge needle inserted into the anterior stroma. Most commonly, this procedure is undertaken in affected areas outside of the visual axis and only in those patients that have failed medical therapy with lubrication and hypertonic solutions such as sodium chloride, which are also used to try to create a more firm adherence between the anterior cornea layers.

Tarsorrhaphy

Tarsorrhaphy is a surgical procedure in which the eyelids are sutured together to protect the cornea. A temporary or permanent tarsorrhaphy can be one of the most important options in the corneal surgeons armamentarium. Particularly helpful in creating a more hospitable environment for epithelial healing, this process can be used to promote epithelial healing in instances such as post operatively following penetrating keratoplasty (PK), neurotrophic epithelial defects, Bells palsy, or chemical burns. A newer option – using botulinum toxin A to create a temporary tarsorrhaphy – is currently being studied as an alternative, which perhaps affords similar protection to a sutured tarsorrhapy while allowing for easier slit-lamp examination.

Surgical Intervention of Stromal Disease

Anterior lamellar keratoplasty

Anterior corneal scars or deposits can be treated with an anterior lamellar keratoplasty. Rather than replacing a full-thickness corneal button as is accomplished in a PK, a partial-thickness trephination or dissection is accomplished to remove only the anterior diseased tissue without performing any manipulation of the posterior endothelial layer. This is an especially important option in young patients with excellent endothelial cell counts and morphology, but whose vision is obstructed by stromal opacities.

Penetrating keratoplasty

Unlike lamellar keratoplasty, a PK involves the full-thickness removal of diseased corneal tissue from the host and replacement of all layers of corneal tissue with a donor cadaveric corneal button. The procedural technique has evolved over the past 100 years, resulting in the high success rate that is now enjoyed by the thousands of patients that undergo full-thickness corneal transplantations each year (**Figure 8**). Topical immunosuppression, usually with prednisolone acetate 1%, is generally a long-term necessity to prevent rejection. Irregular astigmatism generally requires suture manipulation or hard contact lens placement post operatively to attain the best-corrected visual acuity.

Corneal biopsy

For those patients with unusual corneal processes without clear diagnosis despite corneal culture or scrapings, corneal biopsy is the next option. Removing a small anterior portion of corneal tissue from the periphery affords a tissue sample for further pathological examination.

Corneal laceration repair

With the advent of the 10-0 nylon suture, the ability of the corneal surgeon to repair the integrity of the globe following penetrating corneal injury improved significantly. Ensuring the absence of vitreous or iris incarceration in the wound, that the wound edges are well apposed, and that the wound is watertight are of vital importance. Fulfilling these objectives as soon as possible after the penetrating injury occurs will hopefully help to promote healing and lower the risk of endophthalmitis (vision-threatening inflammation of the internal ocular tissues).

Refractive surgery

Since its introduction, the field of corneal refractive surgery has grown exponentially. Earlier procedures, such as

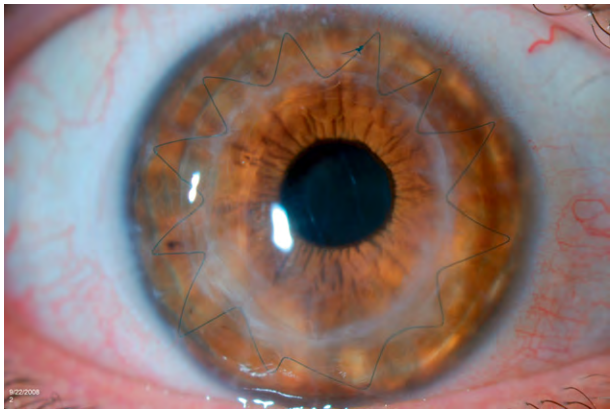

Figure 8 One-year status post penetrating keratoplasty. A single 10-0 prolene running suture remains.

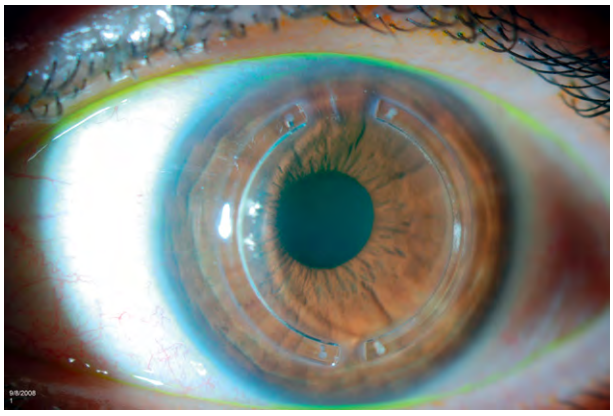

Figure 9 Status post intrastromal ring-segment implantation.

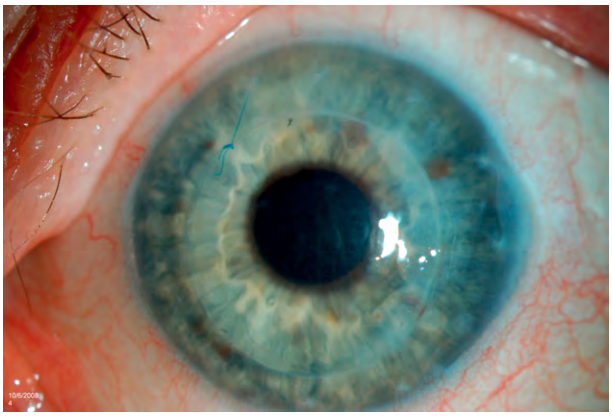

Figure 10 Status post Descemet's Stripping Automated Endothelial Keratoplasty. Notice the clear cornea.

radial keratotomy (RK) and laser thermokeratoplasty (LTK) – which have since fallen out of favor – provided important knowledge and insight into the manipulation of corneal tissue. The current options include procedures such as laser *in situ* keratomileusis (LASIK), photorefractive keratectomy (PRK), laser subepithelial keratomileusis (LASEK), conductive keratoplasty (CK), and intrastromal ring segments. The goal of these procedures is usually to remove the need for corrective lenses in all, or most, distance and/or near-daily situations. A thorough review of the importance of appropriate patient selection, preoperative evaluations, individual surgical options, the risks and benefits of each procedure, and the appropriate postoperative care is beyond the scope of this article (**Figure 9**).

Prosthetic keratoplasty

For those patients with extensive corneal neovascularization, severe damage to limbal stem cells, or who have failed prior PKs, the prosthetic keratoplasty is available (i.e., Boston type 1 keratoprosthesis). Although the technology has evolved substantially over the last 10 years, the keratoprosthesis generally still requires glaucoma surgical management concomitantly and is not appropriate for those patients requiring straightforward PK without a history of such issues as significant corneal vascularization or repeat PK failures.

Surgical Intervention of Endothelial Disease

The surgical manipulation and replacement of diseased corneal endothelium has taken substantial strides forward in recent years. After going through several generations of endothelial surgery with disappointing results, the ophthalmology community has arrived at the more promising current technique of Descement's Stripping Automated Endothelial Keratoplasty (DASEK).

Descements Stripping Automated Endothelial Keratoplasty

The most common diseases resulting in endothelial dysfunction are Fuchs' dystrophy and pseudophakic bullous keratopathy. Although it has been well understood for quite some time that corneal edema in these situations was a result of dysfunctional corneal endothelium, until recently, a full-thickness (penetrating) keratoplasty was the sole viable option. The well-documented time-consuming process of helping these patients obtain their best corrected visual acuity following PK could not be avoided. Now, however, with the advent of the DSAEK procedure, the corneal surgeon can carefully dissect off the Descement's basement membrane and endothelium of the host, and replace a thin posterior donor cornea lenticule in its place (**Figure 10**). Early studies suggest that, when successful, this process results in faster healing, less induced postoperative astigmatism, and patients reach their best-corrected visual acuity faster when compared to PK.

Corneal Angiogenesis

M S Cortina and D T Azar, University of Illinois at Chicago, Chicago, IL, USA

Glossary

Angiogenesis – The formation of new vessels from preexisting vascular structures.
Allograft – The tissue taken from one person for transplantation into another.
Autograft – The tissue transplanted from one part of the body to another part of the same individual.
Chemotaxis – The movement of neutrophils toward bacteria or an area of tissue damage.
Conjunctival metaplasia – An abnormal epithelial differentiation represented by a spectrum of skin-like changes of conjunctival epithelium.
Corneal extracellular matrix – The tissue that provides structural support to the cells in the cornea.
Corneal pannus – The fibrovascular connective tissue that proliferates in the anterior layers of the peripheral cornea in inflammatory corneal disease.
Growth factor – A naturally occurring protein capable of stimulating cellular growth, proliferation, and differentiation.
Hypercapnia – High levels of carbon dioxide.
Hypoxia – Oxygen deficiency.
Limbal stem cell deficiency – The loss of stem cells in the limbus (ring around the base of the cornea which supports health of the corneal epithelium).
Matrix metalloproteinases (MMPs) – The zinc-dependent endopeptidases capable of degrading all kinds of extracellular matrix proteins; they can also process bioactive molecules.
Penetrating keratoplasty (PK) – The procedure in which a full-thickness button of cornea is removed from the recipient and replaced with a similar-sized or larger button of tissue from a donor.
Vasculogenesis – The formation of new blood vessels from bone-marrow-derived angioblasts that occurs mainly during embryogenesis.

Introduction

Under homeostatic conditions, the cornea is avascular, which is critical for corneal light transmission and proper optical performance. Corneal avascularity is maintained by tightly controlled biological anti-angiogenic events that counterbalance the effects of pro-angiogenic factors in the cornea. Under pathological conditions, the balance may be shifted toward angiogenesis, leading to the formation of new blood vessels and lymphatic channels. New blood vessel formation or corneal neovascularization (NV) is a sight-threatening condition usually associated with inflammatory or infectious disorders. It is a major contributor to the loss of corneal transparency. The presence of corneal NV, in turn, elevates the risk of graft rejection and decreases the success of penetrating keratoplasty (PK).

Angiogenesis

Angiogenesis is the main process of blood vessel formation in nonembryonic tissue. It involves the formation of new vessels from preexisting vascular structures and is the primary mechanism underlying corneal NV. New blood vessels also form during vasculogenesis, which is the formation of new blood vessels from bone-marrow-derived angioblasts and occurs mainly during embryogenesis.

Angiogenesis is a complex process that starts with vasodilation of existing vessels and an increase in vascular permeability. This leads to extravasation of plasma proteins (such as fibrin), growth factors, and inflammatory mediators. The accumulation of plasma proteins in the surrounding tissue provides a supporting structure for subsequent endothelial cell (EC) migration. The combined presence of growth factors and inflammatory mediators stimulates the degradation of the extracellular matrix (ECM), making room for EC migration as well as releasing angiogenic factors anchored in the matrix. The newly released angiogenic factors then continue to activate ECs, which migrate from preexisting vessels and form sprouting tubes.

The avascularity of the cornea dictates that nutrients for this tissue be obtained from adjacent tissues. The three major sources of nutrients are tear film, aqueous humor, and the pericorneal capillary plexus at the limbus. This plexus nourishes the peripheral cornea and is derived from ciliary arteries, which are branches of the ophthalmic artery. These vessels do not normally enter the cornea. However, new blood vessels may sprout from capillaries and venules of the pericorneal plexus under pathological conditions, leading to corneal NV.

Etiology and Epidemiology of Corneal NV

Although the exact incidence of corneal NV is not known, it was estimated that this condition affects 1.4 million

patients in the United States annually and that 20% of corneal buttons obtained during PK show evidence of NV. The causes of corneal NV include immune, inflammatory, infectious, degenerative, and traumatic disorders. Corneal infections are the most common worldwide causes of corneal NV leading to vision loss. A classic example is trachoma, an infectious disease characterized by the formation of a superior pannus, which can extend to the central cornea and is often associated with corneal scarring, opacification, and loss of visual acuity. The incidence of trachoma in the US is low; however, this condition remains a major cause of blindness in other parts of the world (**Figure 1**).

Corneal NV is also commonly associated with other severe bacterial and viral infections. The herpes virus family (primarily herpes simplex and herpes zoster viruses) is the primary cause of keratitis-induced NV in transplant buttons. In herpes-simplex-induced stromal keratitis, NV is essential for the pathogenesis of keratitis, and inhibition of angiogenesis can reduce the formation of corneal lesions.

Although infections account for many US cases of corneal NV, the most common cause of corneal NV in the US is the use of contact lenses. In this case, hypoxia and hypercapnia are thought to be associated with the induction of NV (**Table 1**).

The incidence of corneal NV after PK can be as high as 40% at 6–9 months after surgery. The prognosis of transplanting grafts into heavily vascularized corneas is poor. Graft failure has been reported to contribute to >30% of the histopathological diagnoses obtained from vascularized corneal buttons. Risk factors for corneal NV after PK in patients without active inflammation, previous corneal NV, or persistent epithelial defects include suture knots buried in the host stroma, active blepharitis, and a large recipient bed.

Figure 1 Salzman's nodular degeneration with associated superficial corneal neovascularization.

Immune disorders also contribute to corneal NV (**Figure 2**). These disorders can result in significant vision loss and include ocular pemphigoid, rosacea, atopic keratoconjunctivitis, and Stevens–Johnson syndrome. The incidence of corneal NV among patients with these disorders can be considerable. Long-term follow-up of patients with atopic keratoconjunctivitis, for example, revealed that the rate of corneal NV was as high as 60% during the disease course.

Limbal stem cell deficiency, which may occur following trauma and chemical burns, is another cause of corneal NV. It may be also associated with aniridia and autoimmune disorders. Limbal stem cell deficiency produces not only corneal NV, but also corneal inflammation and conjunctivalization of the corneal epithelium. The restoration of corneal avascularity after successful limbal stem cell transplantation underscores the importance of the anti-angiogenic and anti-inflammatory activity of normal corneal epithelial cells.

Clinical Manifestations

Corneal NV can be classified as pannus or stromal NV. In the former, fibrovascular tissue is visible between the epithelium and Bowman layer. Inflammatory pannus is associated with prominent leukocyte infiltration and disruption of Bowman's layer. In contrast, degenerative pannus is characterized by fewer inflammatory cells, an intact Bowman's layer, and regression of the vascular component that leaves a layer of fibrous tissue. Stromal NV, located posterior to Bowman's layer, is more commonly seen in the anterior two-third of the stroma. In herpetic and syphilitic interstitial keratitis, deep stromal vessels (and ghost vessels in the late quiescent stages) are seen just anterior to Descemet's membrane (**Figure 3**).

Visual acuity is reduced by corneal NV. Reduced visual acuity may be secondary to multiple factors. For example, opacity caused by circulating blood cells may interfere with visual acuity. Acuity may also be reduced by irregular architecture of vascular walls, a feature that induces higher-order aberrations. Other effects contributing to diminished visual acuity may include alteration in the spacing of stroma collagen fibers, fluid leakage, edema and lipid deposition in the surrounding tissue, and corneal surface irregularities (**Figure 4**).

Mechanisms Underlying the Maintenance of Corneal Avascularity

Several mechanisms have been proposed to contribute to corneal avascularity. These include:

Table 1 Causes of corneal neovascularization

Inflammatory disorders	*Infectious keratitis*	*Degenerative/congenital*	*Traumatic/iatrogenic*
Ocular pemphigoid	Herpes simplex	Pterygium	Contact lens wear
Atopic conjunctivitis	Herpes zoster	Terrien marginal	Alkali burns
Rosacea	Pseudomonas	degeneration	Ulceration
Graft rejection	Chlamydia	Aniridia	Iatrogenic
Lyell's syndrome	Syphilis	Degenerative pannus	Stem cell deficiency
Stevens–Johnson	Candida		
syndrome	Fusarium		
Graft vs. host disease	Aspergillus		
	Onchocerciasis		

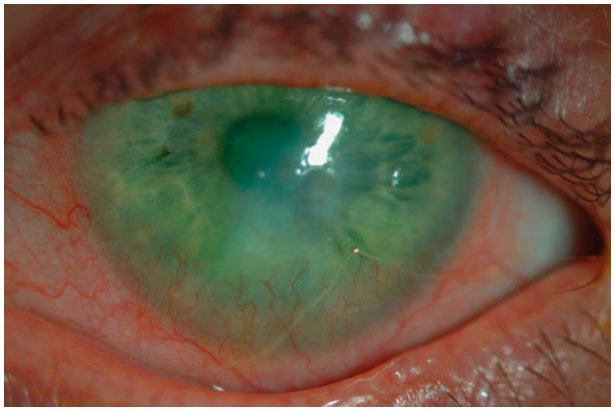

Figure 2 Corneal neovascularization and infectious keratitis in a patient with underlying severe dry eye syndrome secondary to rheumatoid arthritis.

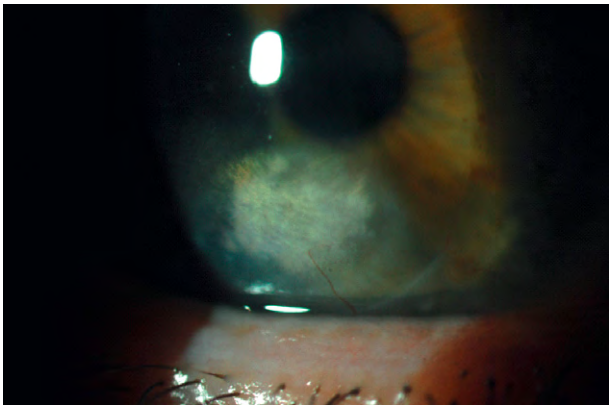

Figure 4 Lipid deposition secondary to corneal neovascularization. Note relative small vessel crossing the host-graft junction responsible for significant lipid deposit.

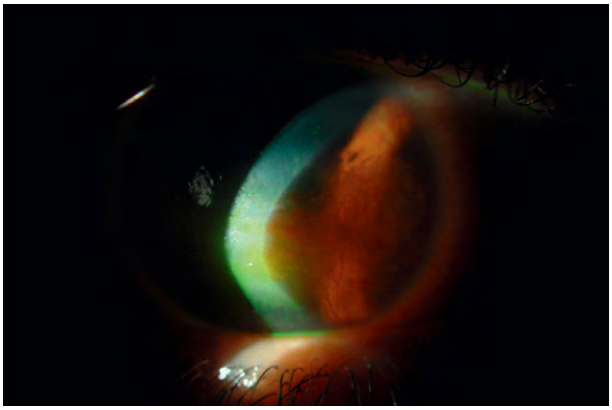

Figure 3 Superficial and deep stromal neovascularization in a patient with neurotrophic cornea.

1. *Corneal dehydration resulting in tightly packed collagen lamellae.* The relationship between corneal NV and corneal edema was first reported in 1949 by Cogan, who postulated that the distention and bursting of the vessels preceding formation of the capillary sprouts were due to a decrease in external pressure that reduced vessel wall support. However, subsequent studies showed that corneal edema alone is not sufficient to trigger corneal NV.
2. *The angiostatic nature of corneal epithelial cells.* Blood vessels are known to be capable of growing into corneas in the absence of epithelium. Early research suggested that corneal epithelial cells are a source of angiogenic factors. More recent studies suggest that the corneal epithelium has an anti-angiogenic effect. The presence of soluble vascular endothelial growth factor (VEGF) receptors 1 and 3, and other naturally occurring anti-angiogenic factors, in the corneal epithelium contributes to its angiostatic nature.
3. *The immune privilege of the cornea.* The mechanisms underlying corneal immune privilege include low expression of major histocompatibility complex (MHC) antigens on corneal cells, expression of Fas ligand by the cornea, a relative paucity of mature antigen-presenting cells, and the presence of immunomodulatory molecules in the anterior chamber. Importantly, this state can be reversed by inflammation, and such reversal may contribute to vascularization. For example, polymorphonuclear leukocytes have the potential to initiate corneal NV through

the release of chemical mediators. Accordingly, there is a clear association between corneal inflammation and NV. Nevertheless, corneal NV may occur in the absence of inflammation.

4. *Low corneal temperature, extensive innervation, and movement of the aqueous humor across the cornea.* The roles of these factors in the maintenance of corneal avascularity are currently unclear.
5. *The barrier function of limbal cells.* The limbus is thought to prevent corneal NV by acting as a barrier to conjunctival growth over the cornea. This barrier function may be attributable to the ability of limbal stem cells to replenish the corneal epithelium, thus preventing invasion of conjunctival epithelium and avoiding NV. This hypothesis has been used to account for corneal NV following experimental limbal damage and stem cell dysfunction. It is also one of the explanations for corneal pannus observed in aniridia. This hypothesized barrier function of limbal cells supports the use of limbal stem cell transplantation as a definitive treatment for ocular-surface disorders. However, a physical barrier may not completely explain corneal avascularity.
6. *Low levels of angiogenic factors and active production of potent anti-angiogenic factors in the cornea during homeostasis.*
7. *Active production of potent anti-angiogenic factors.* Although the five previously mentioned factors likely contribute to maintenance of corneal avascularity, available evidence supports this as the main mechanism responsible for maintaining corneal avascularity.

Table 2 Factors involved in the regulation of angiogenesis

Angiogenic factors	*Anti-angiogenic factors*
Fibroblast growth factor (FGF)	Endostatin
Vascular endothelial growth factor (VEGF)	Angiostatin
Placenta growth factor (PGF)	Prolactin
Transforming growth factor-α (TGF-α)	Matrix metalloproteinases (MMPs)
Transforming growth factor-β (TGF-β)	Tissue inhibitor of MMPs (TIMPs)
Insulin-like growth factor (IGF)	Thrombospondin
Leptin	Arresten
Integrins (αvβ3)	Canstatin
Platelet-derived growth factors (PDGF)	Tumstatin
Matrix metalloproteinases (MMPs)	Pigment-epithelium-derived factor (PEDF)
Angiogenin	Tumor necrosis factor α (TNF-α)
Hepatocyte growth factor-scatter factor (HGF-SF)	Interleukin-4 (IL-4)
Tumor necrosis factor-α (TNF-α)	Interleukin-13 (IL-13)
Connective tissue growth factor (CTGF)	Fibulin
Interleukin-8 (IL-8)	Endoperellin
Monocyte chemoattractant protein-1 (MCP-1)	Antithrombin
Platelet-activating factor (PAF)	Plasminogen activator inhibitor (PAI)
	Vasostatin
	Neostatin-7

Corneal Angiogenic Privilege: The Balance between Angiogenesis and Anti-Angiogenesis

Multiple local and systemic signals are responsible for regulating growth and regression of new blood vessels. These signals include cyclic adenosine monophosphate (cAMP), steroid hormones, protein kinase C (PKC) agonists, polypeptide growth factors, oxygen, free radicals, glucose, cobalt, and iron. In the cornea, the tight equilibrium between these pro- and anti-angiogenic signals may be disrupted under pathological conditions. Ultimately, this may tip the balance toward an upregulation of pro-angiogenic factors or a downregulation of anti-angiogenic factors, in either case leading to corneal NV (**Table 2**).

When the cornea is injured, wound healing often occurs in the absence of NV. This is the case for most adequately treated corneal infections. Healing after corneal surgery is also usually avascular. Corneal wound healing involves four phases. In the first phase, keratocytes near the area of epithelial debridement undergo apoptosis. In the second phase, adjacent keratocytes proliferate to repopulate the wound within 24–48 h after wounding. These keratocytes transform into fibroblasts and migrate into the wound area. This process may take up to a week and is not accompanied by corneal NV. In the third phase, fibroblasts may transform into myofibroblasts. This occurs in laser-inflicted wounds lacking Bowman's layer and in incisional wounds. Myofibroblasts may take up to a month to become apparent. Corneal NV is also absent in this phase of wound healing. The fourth and final phase involves stromal remodeling and is dependent on the original wound. When wound healing is accompanied by ECM turnover, angiogenesis in granulation tissue is usually observed.

Some of the molecules that regulate angiogenesis are discussed below.

Angiogenic Molecules

Vascular endothelial growth factor

VEGF is a dimeric 46-kDa glycoprotein. This growth factor stimulates angiogenesis by increasing EC proliferation, migration, proteolytic activity, and capillary tube formation. It also significantly increases vascular permeability. The VEGF family includes VEGF-A, -B, -C, -D, placenta growth factor (PlGF), and the viral VEGF

homolog VEGF-E. VEGF-B promotes nonangiogenic tumor progression, while VEGF-C and -D participate in angiogenesis and lymphangiogenesis. VEGF-A also participates in angiogenesis and increases vascular permeability.

Five isoforms of VEGF-A (VEGF115, 121, 165, 189, and 206) can be generated by alternative splicing of the same gene. The longer isoforms (VEGF189 and 206) are matrix-bound, whereas the shorter isoforms (VEGF121 and 165) are freely diffusible. These VEGF isoforms produce different actions when secreted. For example, all isoforms increase in vascular permeability, but only VEGF121 and VEGF165 have mitogenic activity. VEGF121 has greater angiogenic activity than VEGF165 or VEGF189. On the other hand, VEGF165 is more potent than VEGF121 in induction of inflammation, intercellular adhesion molecule-1 (ICAM-1) expression in ECs, and chemotaxis of monocytes. This suggests that alternate splicing of VEGF messenger RNA (mRNA) can be regulated to achieve a range of physiologic actions.

The VEGF family members act through binding to high-affinity receptor tyrosine kinases. Two high-affinity receptor tyrosine kinases have been identified for VEGF-A: VEGFR-1 (fms-like tyrosine kinase-1 or Flt-1) and VEGFR-2 (kinase insert domain-containing receptor or KDR). VEGFR-3 (fms-like tyrosine kinase-4 or Flt-4) serves as a high-affinity receptor for VEGF-C and -D. Both VEGFR-1 and -2 are expressed primarily in vascular ECs, while VEGFR-3 is predominantly expressed in lymphatic ECs. VEGF-B binds to VEGFR-1 and has mild mitogenic activity. In contrast, binding of VEGF-D and -C to VEGFR-3 regulates the growth and differentiation of blood vessels and lymphatic endothelium.

VEGF is produced by macrophages, T cells, astrocytes, pericytes, fibroblasts, retinal pigment epithelial cells, and smooth muscle cells. In addition, VEGF is expressed in all three cellular layers of the cornea. It is highly expressed in vascular ECs of limbal vessels and in new stromal vessels. Under inflammatory conditions, VEGF expression is increased in epithelial and vascular ECs, particularly near macrophage infiltrates and fibroblasts in corneal scars. Following corneal cautery, VEGF165 and 189 mRNA is increased at 48 h and returns to baseline by day 7. Immunohistochemistry has revealed that VEGF is initially expressed in neutrophils and later expressed in macrophages, demonstrating that VEGF production by leukocytes is associated with corneal NV. In addition, VEGF concentration is significantly increased in vascularized corneas as compared to normal corneas. In limbal-deficiency-induced corneal NV, VEGF mRNA and protein are induced after injury and are both temporally and spatially correlated with inflammation and NV. VEGF is not only induced during NV, but is also required for corneal angiogenesis. The indispensable role of VEGF in angiogenesis is shown by the finding that stromal implantation of anti-VEGF antibodies inhibits NV in a rat model. Conversely, implantation of a Hydron pellet containing VEGF into the stroma induces severe corneal NV without significant inflammation.

The effects of VEGF in the cornea are not limited to NV, as this growth factor has also been shown to regulate goblet cell migration. Studies analyzing the correlation between cornea NV and conjunctivalization showed that VEGFR-1 is present in the conjunctiva-like epithelium covering the cornea as well as in goblet cells, invading leukocytes, and the corneal vasculature. Inhibition of VEGF activity inhibited not only corneal NV, but also goblet cell density, suggesting that VEGF may promote goblet cell migration.

Evidence suggests that VEGF also participates in corneal lymphangiogenesis. Corneal lymphangiogenesis may contribute to graft sensitization and rejection, following high-risk keratoplasty of vascularized corneas. VEGF-C binds to VEFGR-3 and induces lymphatic growth in the cornea. Interestingly, inhibition of lymphatic growth is observed after administration of a VEGF trap that neutralizes VEGF-A, but not VEGF-C or -D. This could be explained by the chemotactic effect on macrophages that release VEGF-C in inflamed corneas observed with VEGF-A. Thus, VEGF-A amplifies signals essential for lymphatic growth. In general, corneal lymphangiogenesis seems to correlate well with the degree of corneal hemangiogenesis.

Recent studies have shown that VEGF, although present in the cornea, does not promote angiogenesis under normal conditions. VEGF-A found in corneal tissue is mostly bound to an alternative spliced secreted isoform of VEGFR-1 (sflt-1), which acts as a trap for secreted VEGF-A and in this way contributes to maintenance of corneal avascularity. In addition, VEGFR-3 is expressed in endothelial as well as epithelial cells in the cornea. When VEGF-C and -D bind to endothelial VEGFR-3, they stimulate proangiogenic signaling. In contrast, VEGFR-3 expressed by corneal epithelium acts as a decoy receptor sequestering VEGF but yet rendering it available when an angiogenic response is needed to enhance the immune defense. This VEGFR-3 sink system is a potent mechanism that inhibits inflammatory-induced angiogenesis.

Basic fibroblast growth factor

Basic fibroblast growth factor (bFGF) is another potent angiogenic factor. It is a member of the fibroblast growth factor (FGF) family, which includes 23 heparin-binding peptides widely expressed during cell differentiation, angiogenesis, mitogenesis, and wound healing. bFGF functions are mediated by the receptors FGFR-1, -2, -3, and-4. FGF recptor-1 (FGFR-1) is expressed in normal corneal epithelium, while bFGF is upregulated following injury. It is also upregulated following co-culture of corneal epithelial cells with vascular EC and keratocytes. The affinity of bFGF for its receptor differs according to the extent of

maturation of new vessels. This may be due to varying expression of heparan sulfate proteoglycans and highlights the role of ECM proteins in the regulation of corneal angiogenesis.

Matrix metalloproteinases

The matrix metalloproteinases (MMPs) constitute a multigene family of zinc-binding proteolytic enzymes that participate in ECM remodeling. Many of the growth factors that modulate angiogenesis also influence MMP expression. These growth factors include VEGF, FGF-2, and tumor necrosis factor-alpha (TNF-α). Vascular ECs respond by secreting proteolytic enzymes that degrade the ECM to facilitate migration and differentiation of ECs. The MMPs that have identified in the cornea are collagenases I and II (MMP-1 and -13), stromelysin (MMP-3), matrilysin (MMP-7), membrane-type MMP (MT-MMP-14), and gelatinases A and B (MMP-2 and -9). Both MMP-2 and MMP-9 are proteolytically activated primarily by MT1-MMP during capillary formation. Several reports suggest that these MMPs participate in vascular invasion by directly degrading the matrix or releasing matrix-bound cytokines and growth factors. Accordingly, inhibition of MMP-9 activity in the cornea decreases angiogenesis. However, given their ability to degrade ECM, MMPs exhibit a dual action in angiogenesis. For example, MMP-2 activation may release anti-angiogenic fragments, allow the production of potent angiostatic factors, or facilitate angiogenesis.

Lipid mediators

One of the initial events that occurs after corneal injury is the release of arachidonic acid. In the corneal epithelium, arachidonic acid is then metabolized by cyclooxygenase (COX) to generate eicosanoids (such as 12- and 15-HETE), lipoxin A4 (LXA4), and prostaglandins. 12(S)-HETE is a powerful angiogenic factor, and COX inhibitors have been shown to reduce corneal angiogenesis in animal models. Platelet-activating factor is another potent lipid mediator released from the cell membrane after corneal injury. It contributes to corneal NV by increasing expression of VEGF, MMP-9, and urokinase plasminogen activator (uPA), all of which subsequently stimulate vascular EC migration.

Anti-Angiogenic Molecules

Angiostatin

Angiostatin results from the cleavage of plasminogen. Several MMPs can cleave plasminogen to generate angiostatin-like molecules. The inhibitory effect of angiostatin on vascular ECs may be due to inhibition of adenosine triphosphate (ATP) synthesis in these cells, an effect that decreases EC migration and proliferation. Angiostatin binds to integrin alpha-v beta-3 ($\alpha v\beta 3$) and affects angiogenesis as well as developmental NV. It also induces vascular EC apoptosis mainly in areas of NV.

All three layers of the cornea are able to synthesize plasminogen and angiostatin. Tears collected after overnight eye closure contain a significant amount of angiostatin-related molecules known to have anti-angiogenic properties. This has also been shown in tears of contact lens-bearing patients, suggesting that these molecules play a role in preventing NV under hypoxic conditions. Corneal NV occurs following injection of anti-angiostatin antibodies into corneas having undergone post-excimer laser keratectomy. This supports the idea that plasminogen and angiostatin are important for the maintenance of corneal avascularity.

Endostatin and neostatins

Endostatin is a 20-kDa proteolytic fragment of collagen XVIII that exhibits anti-angiogenic activity. It was originally discovered as an angiogenic inhibitor purified from conditioned media of murine hemangioendothelioma cells. Endostatin inhibits bFGF-induced corneal NV as well as VEGF-induced vascular EC migration and proliferation. Collagen XVIII is localized mainly in the corneal vascular and epithelial basement membrane. Smaller fragments of collagen XVIII, known as Neostatins -7 and -14, are generated by the enzymatic activity of MMPs -7 and -14, respectively. They have potent anti-angiogenic and anti-lymphangiogenic properties. Local production of endostatin and Neostatins -7 and -14 may occur during wound healing. Endostatin is Food and Drug Administration (FDA)-approved for the treatment of cancer-related NV.

Pigment-epithelial-derived factor

Pigment-epithelial-derived factor (PEDF) is a potent anti-angiogenic and neurotrophic factor that is found in multiple eye tissues including the cornea. In contrast to VEGF, which is induced under low oxygen conditions, PEDF expression is suppressed during hypoxia. PEDF induces EC apoptosis. It also has antipermeability and anti-inflammatory activity that counterbalances VEGF actions. Studies have shown that PEDF-blocking antibodies induce corneal NV when implanted into the stroma and that recombinant PEDF inhibits bFGF-induced corneal NV. These findings are consistent with an essential role for PEDF in maintaining the avascularity of ocular tissues. Given its effectiveness at countering VEGF activity, PEDF may be a good pharmacological inhibitor of angiogenesis.

Arresten, canstatin, and tumstatin

Arresten is a 26-kDa protein derived from the non-collagenous (NCl) domain of the type IV collagen $\alpha 1$ chain. This molecule has been shown to inhibit bFGF-stimulated proliferation, migration, and tube formation of

cultured ECs. It also inhibits NV *in vivo*. Canstatin is a 24-kDa fragment of the type IV collagen α-chain. It also inhibits EC proliferation and tube formation. The mechanism of action appears to involve phosphoinositide 3-kinase/protein kinase B (PI3K/Akt) inhibition and depends on signaling events transduced through membrane-death receptors. Tumstatin, a 28-kDa fragment of the type IV collagen α3 chain, also has anti-angiogenic activity.

Therapy

Identifying and adequately treating the underlying cause of corneal NV is critical. Therapies for corneal NV may range from antimicrobial therapy for infectious keratitis to systemic immunosuppression for autoimmune diseases such as ocular cicatricial pemphigoid. Some of the established and investigational medical and surgical treatments for corneal NV are discussed below.

Medical Treatments

Anti-inflammatory compounds, such as steroids, have a long history of use for the suppression of inflammation and associated angiogenesis. The anti-angiogenic effects of steroid treatment are likely secondary to their anti-inflammatory actions and include inhibition of chemotaxis and cytokine synthesis. Steroids have also been shown to inhibit vascular EC proliferation and migration. Unfortunately, the side effects of these compounds make long-term administration difficult in some patients. Moreover, their role in corneal NV that is not associated with inflammation is limited.

Advances in our understanding of the mechanisms underlying ocular NV has led to the identification of new pharmacologic targets. Given the key role of VEGF in NV of the eye, attention has been directed to developing drugs that will counteract the activity of this factor. Bevacizumab is an anti-VEGF antibody that binds to all VEGF isoforms. This molecule inhibits VEGF-receptor interactions and in this way, blocks all VEGF actions. It is currently approved by the FDA to treat metastatic colorectal cancer. It has also been tested for the treatment of wet (neovascular) age-related macular degeneration (AMD). Ranibizumab is another anti-VEGF antibody that has been approved for use in the eye to treat wet AMD. Bevacizumab treatment of corneal NV has gained popularity since the successful use of this molecule to treat choroidal NV. Subconjunctival injection as well as topical application of this molecule has also been used with promising results to treat herpes simplex virus (HSV) keratitis, recurrent pterygia, rejection of corneal grafts, and Stevens–Johnson syndrome. However, data on these treatments are limited, and adverse effects such as loss of epithelial integrity and progression of thinning have been reported in a small number of patients. Further investigation is required to establish efficacy, adequate dosing, and safety in the different clinical scenarios that present with corneal NV.

Other forms of anti-VEGF therapy are currently undergoing clinical trials. One example is VEGF TRAP, a high-affinity VEGF antagonist designed to bind and neutralize VEGF in the circulation and within tissues. It binds to all isoforms of VEGF and to placental growth factor, which is a related pro-angiogenic factor. SIRNA-027, another anti-VEGF therapy, is a short interferon RNA designed to downregulate VEGFR-1 expression. PKC412 is an orally administered tyrosine kinase inhibitor that binds to the intracellular, enzymatically active domain of the VEGF receptor and prevents phosphorylation and activation of the VEGF signaling cascade. Some of these compounds may be available for use in the near future.

Surgical Treatment

One surgical approach for the treatment of corneal NV is laser therapy. The use of laser photocoagulation with a 577-nm yellow dye for the treatment of established corneal NV has been investigated. The effectiveness of this technique has been tested in clinically significant corneal NV resistant to medical therapy both before and after PK. Some reduction of corneal NV can be achieved; however, the benefit of laser photocoagulation prior to high-risk keratoplasty is unclear, and this technique does not appear to be useful for treating extensive corneal NV.

An alternative to laser occlusion is fine-needle diathermy. This procedure is easy to perform, requiring only a 10-0 nylon suture and a unipolar diathermy unit. It produces occlusion of 50–100% of corneal NV and has been show to moderately benefit visual acuity in a series of 17 patients.

Photodynamic therapy is currently used to treat choroidal NV. In this technique, a photo-sensitizer selectively accumulates in new vessels and is subsequently activated by a laser beam. This technique is currently under investigation in animal models of corneal NV.

Finally, in some cases, conjunctival, limbal, or amniotic membrane transplantation may be required to restore the ocular surface. Conjunctival autograft and allograft transplantation have been shown to decrease corneal NV. Amniotic membrane has anti-angiogenic properties as well. Limbal autograft transplantation has been successful in cases of stem cell deficiency and conjunctival metaplasia. This technique not only treats the stem cell deficiency and decreases the angiogenic stimulus from chronic ulceration, but also directly inhibits vascular ECs.

No ideal treatment is currently available for corneal NV. However, significant progress in the understanding of corneal angiogenesis has opened a new field of investigation that may lead to the development of novel therapeutic agents for the treatment of this condition.

Corneal Dystrophies

B H Feldman, Philadelphia Eye Associates, Philadelphia, PA, USA
N A Afshari, Duke University Medical Center, Durham, NC, USA

Glossary

Amyloid – Insoluble, fibrous, and primarily extracellular protein aggregates exhibiting beta-sheet structures that are deposited in many local and systemic diseases.
Anterior synechia – A pathological condition where the iris adheres to the cornea.
Corectopia – An iris defect involving displacement of the pupil from its normal position.
Corneal dystrophy – A bilateral inherited disorder of noninflammatory, progressive corneal disease.
Corneal guttata – Wart-like excrescences of Descemet's membrane that are associated with Fuchs' corneal dystrophy.
Lamellar keratoplasty – A partial thickness corneal transplant of either the anterior or posterior corneal layers.
Penetrating keratoplasty – Full thickness corneal transplant.
Phototherapeutic keratectomy – A surgical procedure in which the epithelium is removed and then an excimer laser is used to ablate abnormal anterior stromal tissue.
Recurrent erosion – A syndrome of repeated epithelial defects due to abnormal adhesion of the epithelial basement membrane.

Introduction

The corneal dystrophies are a group of noninflammatory, inherited, and bilateral disorders characterized by pathognomonic patterns of corneal deposition and morphological changes. These heterogeneous dystrophies are defined by their clinical characteristics, histological findings, and genetics. Traditionally, they have also been grouped anatomically into three categories of anterior, stromal, and posterior dystrophies. The anterior dystrophies affect the epithelium, epithelial basement membrane (EBM), or Bowman's layer. The stromal dystrophies primarily affect the stroma, but may extend into the anterior corneal layers and may rarely affect Descemet's membrane and the endothelium. The posterior dystrophies are primarily disorders of endothelial cells and the posterior portion of Descemet's membrane. They may also alter the structure of the stroma and anterior cornea.

There is a wide variation in the type and degree of symptoms caused by the corneal dystrophies. Progressive accumulation of tissue deposits can lead to vision loss from corneal opacification and astigmatism. Disruption of normal cell function can lead to abnormal epithelial adhesion with resultant painful recurrent epithelial erosions or loss of endothelial cell activity with resultant corneal edema. Several of the dystrophies are associated with vision-threatening ocular or systemic manifestations. Together, corneal dystrophies are the primary indications for approximately 10–15% of the corneal transplantations performed in the United States each year.

Anterior Dystrophies

Epithelial and EBM Dystrophies

EBM Dystrophy

Also known by the descriptive term, map-dot-fingerprint (MDF) dystrophy, or the eponym, Cogan's dystrophy, EBM dystrophy (EBMD) is arguably the most common dystrophy, found in approximately 5% of the adult population, with a slight preponderance of women. While in rare instances an autosomal dominant inheritance pattern has been identified, in the vast majority of cases this disease is sporadic, making its designation as a corneal dystrophy controversial.

On examination, several patterns of basement membrane and epithelial involvement can be observed, including dots or microcysts, map lines, and fingerprint lines. These abnormalities may fluctuate over time but are rarely progressive.

The most common symptoms of EBMD are recurrent erosions and blurred vision. The recurrent erosions arise because of poor epithelial adhesion to the underlying basement membrane. These erosions may be triggered by the lid trauma caused by an innocuous blink and are most often noted upon eye opening in the morning – with pain sometimes – waking the patient from sleep. The pain, foreign body sensation, and blurring associated with the erosions typically last only several minutes, but for some may be prolonged and severe. In addition to these transient symptoms, the surface changes from EBMD in the visual axis may lead to irregular astigmatism and adversely affect a patient's best-corrected visual acuity.

Recurrent erosions are managed acutely with lubricants, bandage contact lenses, patching, and prophylactic antibiotics. Medical options for prophylaxis against these recurrent erosions begin with aggressive lubrication and an

emphasis on the use of bedtime ointments to avoid epithelial dehydration which can potentiate poor epithelial adhesion. Additionally, it is beneficial to address co-existing ocular surface diseases such as blepharitis, and the use of oral tetracyclines may inhibit epithelial breakdown. Similarly, anti-inflammatory agents such as topical steroids may inhibit this breakdown, but the long-term use of these agents should be dealt with caution. If recurrent erosions persist despite medical interventions, epithelial adhesion can be improved through mechanical disruption with subsequent healing through debridement with diamond burr polishing, stromal needle puncture, or Nd:YAG laser puncture. For large or recurrent lesions in the visual axis, excimer laser phototherapeutic keratectomy may be preferred to avoid scarring due to other techniques.

Microscopic examination of EBMD reveals a thickened epithelial layer with a thickened or redundant basement membrane that has extended into the epithelium in either linear propagations or sheets, representing the map and fingerprint lines, respectively. The dots are microcysts formed by these abnormal extensions of basement membrane that have entrapped degenerated epithelial cells.

Meesman's

This rare anterior dystrophy is an autosomal dominant disorder characterized by the development of intraepithelial vesicles in the central cornea that appear as early as in the first few years of life. Over time, there is progressive involvement of the mid-peripheral cornea and an increase in the number and density of vesicles. As the disease progresses, vision may slowly deteriorate and the eye may become irritated as the intraepithelial vesicles rupture. In contrast to EBMD, recurrent erosions are uncommon in this dystrophy. While most patients are asymptomatic, those who have ocular irritation from ruptured vesicles are treated with lubricants or soft contact lenses to manage these microerosions.

The pathologic changes in the epithelium are thickening of the basement membrane and the formation of small epithelial cysts containing a material composed of degenerated keratin with cytoplasmic and nuclear debris, known as peculiar substance. Consistent with the epithelial nature of this dystrophy, Meesman's lesions are known to recur in cornea transplants as the host epithelium repopulates the surface of the donor button.

Genetic analysis has elicited responsible mutations in two genes (KRT3 and KRT 12) on chromosomes 12q13 and 17q12, respectively, which code for two corneal keratins (k3 and k12).

Bowman's Layer Dystrophies

Reis-Buckler's

Also known as corneal dystrophy of Bowman's type 1 (CDB-1) and granular dystrophy type III (GD-3), this is an autosomal dominant dystrophy that is marked by geographic opacification of Bowman's layer, beginning as fine granular deposits that evolve into confluent opacities over time. Reis-Buckler's arises during childhood or adolescence and often leads to frequent recurrent erosions and marked, progressive visual loss (Figure 1). The recurrent erosions can be managed in a manner similar to in EBMD, but the progression of opacification may necessitate extensive excimer laser phototherapuetic keratectomy. Despite initial clearing of the visual axis, these patients often have recurrence of opacities requiring additional treatment.

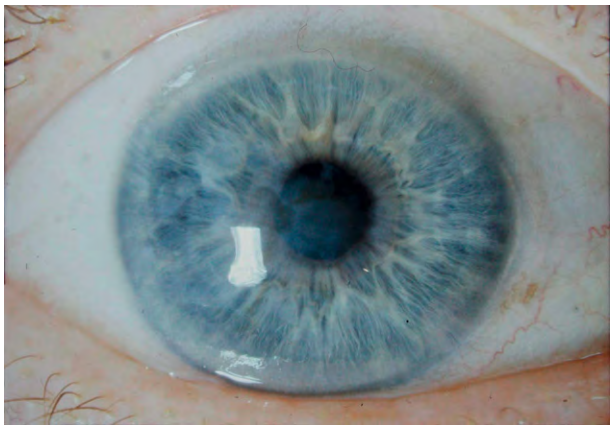

Figure 1 External photograph of Reis-Buckler's dystrophy (corneal dystrophy of Bowman's type 1 or granular dystrophy type 3) demonstrating geographic opacification of Bowman's layer.

Histological examination demonstrates that the normally acellular collagenous Bowman's is disrupted, noncontiguous, or absent and is replaced with fibrocellular tissues. The opacities in Bowman's layer are band-shaped, granular, and stain red with Masson's trichrome. Similar to other granular dystrophies, these lesions appear as rod-shaped bodies under electron microscopy.

Multiple mutations of the human transforming growth factor inducible gene (TGFBI) – previously known by the misnomer, keratoepithelin – on chromosome 5q31 may lead to the Reis-Buckler's phenotype. The most common mutations are Arg124 or Arg555 which are both thought to affect the solubility and stability of the TGFBI protein.

Thiel-Behnke

Initially classified as a variant of Reis-Buckler's, Thiel-Behnke, or corneal dystrophy of Bowman's type 2 (CDB-2), at times is similar in its clinical appearance but is always distinct in its histological and electron microscopic appearance. Also autosomal dominantly inherited, Thiel-Behnke has a slightly later onset of recurrent erosions, typically in the second decade of life, and vision loss is more slowly progressive. At the slit lamp, this dystrophy typically appears as honeycombed-shaped subepithelial

opacities. It can be managed similarly to Reis-Buckler's and recurrence after keratectomy is infrequent.

Examination of pathologic specimens reveals only weakly positive Masson's trichome staining, in contrast to the strongly positive staining of Reis-Buckler's. The pathognomonic features are the 8–10 nm curly fibers identified by electron microscopy.

Similar to Reis-Buckler's, this dystrophy is sometimes linked to the TGFBI gene. However, there is genotypic heterogenicity for Thiel-Behnke as evidenced by the discovery that mutations on chromosome 10q23-q24 can also lead to this phenotype.

Stromal Dystrophies

Lattice

There are three major types of lattice dystrophy and all are unified by the appearance of lattice lines on slit-lamp examination and amyloid deposition on histological examination.

Lattice type 1. In type 1 lattice, or Biber–Haab–Dimmer corneal dystrophy, amyloid is deposited in the cornea but is not found elsewhere in the body. It can vary in its appearance, and there is often progression from round, ovoid and white, or small, filamentous, and refractile anterior stromal lesions to more nodular, threadlike, and thicker linear lesions that extend into deep stroma (**Figure 2(a)**). Initially, the stroma between lesions remains clear, but over time these spaces opacify and assume a ground-glass appearance. The limbus is typically spared. Signs of lattice dystrophy most often appear in early childhood, but symptoms of surface erosions, irregular astigmatism, and vision loss usually begin in the second or third decades of life.

Recurrent erosions can be frequent and can be managed as described previously. Some authors believe that phototherapeutic keratectomy should be avoided (as well as laser-assisted *in situ* keratomileusis (LASIK) and photorefractive keratectomy (PRK)) because excimer laser, within the UV light spectrum, may trigger activation of TGFB and exacerbate this condition. For severe vision loss due to opacification, penetrating and lamellar keratoplasty may be warranted. Recurrence may occur in these grafts but presents differently than the primary lesions.

Specimens are positive for amyloid and stain with Congo red, periodic acid-Schiff's reagent (PAS), Masson's trichrome, and thioflavine-T fluorochrome, and are metachromatic with crystal violet (**Figure 2(b)**). As with all amyloid, they demonstrate apple-green birefringence under polarized light.

Lattice type 2. Type 2 lattice, also known as Meretoja's, familial, or Finnish amyloidosis syndrome, is characterized by both systemic and corneal amyloid deposition. Typically seen in families of Finnish, European, or Japanese origin, it is usually asymptomatic until early adulthood.

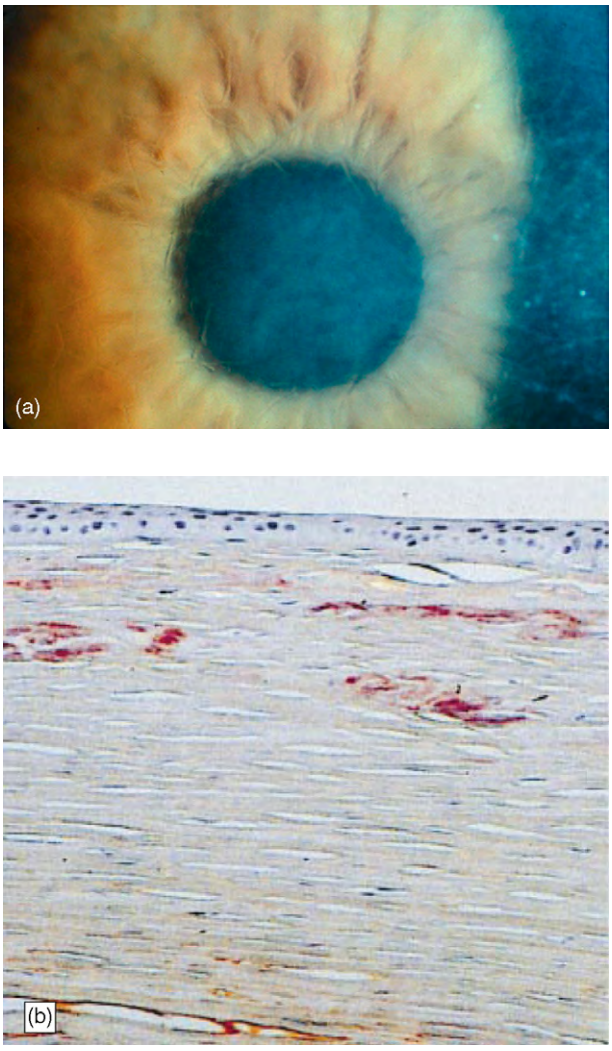

Figure 2 (a) Slit-lamp photograph of lattice type 1 dystrophy. Arrow indicates amyloid deposition. (b) Congo red stain of cornea in lattice type 1 demonstrating amyloid deposition. Afshari, N. A., Mullally, J. E., Afshari, M. A. et al. (2001). All rights reserved.

Corneal slit-lamp examination shows more peripheral deposits, with fewer and finer lattice lines, and a primarily sub-Bowman's location of deposition.

Patients begin to experience corneal changes in the third decade of life, but symptoms of reduced corneal sensation and frequent recurrent erosions are uncommon until the fifth decade. Overall, the visual prognosis is better than in type 1 with many patients not developing visual loss until late in the course of disease. While there is a decreased severity of corneal disease, the systemic manifestations can be serious and include dry, itchy skin, intermittent proteinuria, and cardiac abnormalities. Patients may develop severe mask-like facial paresis (loss of facial

muscle motor function), blepharochalasis (inflammation of eyelid), protruding lips, and pendulous ears from amyloid deposition and secondary muscular dysfunction.

Unique among the lattice dystrophies, type 2 does not arise from a mutation in the TGFBI gene. Instead, it has been linked to a dominant mutation of the gelsolin gene on 9q32–34 that encodes an amyloid precursor.

Lattice types 3 and 3a. Type 3 lattice is the least severe and has an autosomal recessive pattern of inheritance. The lattice lines in type 3 are thicker and ropier in appearance, and later in onset. Vision is often not affected until the sixth or seventh decade of life, and recurrent erosions are rare. Like type 1, type 3 is associated with a defect in the TGFBI gene. Type 3a is similar in presentation to type 3 but follows an autosomal dominant inheritance pattern.

Granular

Granular type 1

The most common of the stromal dystrophies, granular dystrophy is named for its typical appearance as crumb-like, discrete, grainy opacities in the anterior stroma. Initially, these opacities are fine dots or lines and with time they assume their more characteristic appearance of anterior stromal drops, rings, or crumbs with intervening clear spaces. As the dystrophy progresses, the lesions coalesce and extend into deeper stroma, and the intervening spaces take on a ground-glass appearance. The lesions rarely extend to the limbus (**Figure 3**). Symptoms of vision loss do not usually occur until the fifth decade. Despite the anterior location of the dystrophy, recurrent erosions are rare. There are exceptions to this mild course, and some variants of the disease cause earlier and more severe vision loss.

For patients with severe vision loss, management options include superficial keratectomy, phototherapeutic keratectomy, and lamellar or full thickness keratoplasty depending on the depth of involvement. Recurrence may occur even in full thickness grafts necessitating repeat procedures. With recurrence, the lesions may appear similar to primary disease or may consist of subepithelial lesions emanating from the graft periphery.

The pathology of granular type 1 shows eosinophilic, rod-shaped, trapezoidal hyaline deposits in the stroma that are bright red on Masson's trichome and weakly PAS positive. On electron microscopy, the amorphous material appears rod or trapezoidal in shape.

Granular dystrophy type 1 is also due to a defect in the TGFBI gene and at least two causative mutations have been identified.

Granular type 2

Previously known as Avellino dystrophy (because the initial reports were of families from Avellino, Italy) this variant of granular dystrophy is characterized both by granular deposits and lattice lines or stellate deposits. Early lesions are often ring-like and anterior and can appear similar to type 1 granular lesions. As the disease progresses, deeper lesions appear and the lattice-like

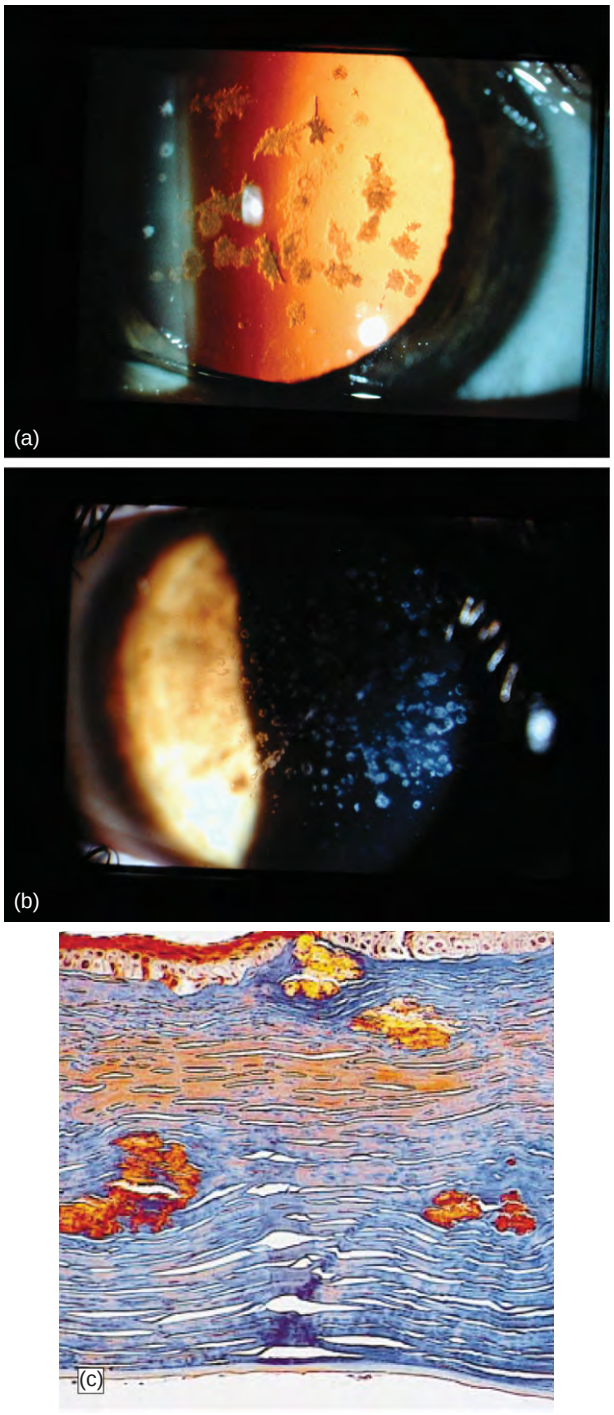

Figure 3 Slit-lamp photographs of mild (a) and moderate (b) granular type 1 corneal dystrophy. (c) Masson's trichrome staining of hyaline deposits in granular dystrophy. Afshari, N. A., Mullally, J. E., Afshari, M. A. et al. (2001). Survey of patients with granular, lattice, avellino, and Reis-Bücklers corneal dystrophies for mutations in the BIGH3 and gelsolin genes. *Archives of Ophthalmology* 119: 16–22.

lesions are observed. With progression, the intervening clear spaces between lesions assume a hazy appearance.

Symptoms may be more severe and the onset earlier than in type 1 granular dystrophy. Many patients experience vision loss by adolescence, but vision rarely drops below the 20/70 level. Recurrent erosions and related ocular discomfort occur in a minority of patients, but more frequently than in type 1 granular patients.

Not every patient displays clinical evidence of both granular and lattice lesions, but on histologic examination these patients uniformly demonstrate both hyaline and amyloid deposits, the distinguishing pathologic findings of the two respective diseases.

As both granular and lattice dystrophies can arise from dominant TGFBI gene defects, it is not surprising that TGFBI mutations have been found to be responsible for this dystrophy which displays characteristics of both diseases. The autosomal dominant inheritance of type 2 granular dystrophy has a high penetrance, but phenotypic expressivity is quite variable between family members.

Macular

The least common of three major stromal dystrophies, the autosomal recessive Macular dystrophy is also the most severe. Its clinical appearance is unique, seen at the slit-lamp as diffuse, cloudy, gray–white lesions that begin superficially and centrally and then spread downward and outward. By late adolescence, these lesions may progress to involve the entire cornea from limbus to limbus and from anterior stroma to the endothelium. Anteriorly protruding nodules may cause highly irregular astigmatism, and Descemet's membrane involvement may produce corneal guttata.

Vision loss can begin in the first decade of life and may be severe by the third decade. Recurrent erosions are more frequent and may also begin at an early age. Due to photophobia, many patients seek treatment with tinted lenses, phototherapeutic keratectomy, or lamellar and penetrating keratoplasty. Unfortunately, recurrence is common and may lead to significant vision loss even in penetrating keratoplasty recipients. This recurrence most often begins in the periphery near the graft–host junction, and has been found to be more common in smaller-sized grafts.

The key histopathologic finding of Macular dystrophy is glycosaminoglycan accumulation. This accumulation may occur both intracellularly and extracellularly and is found between stromal lamellae, subepithelially, and within keratocytes and endothelial cells. The deposits stain with Alcian blue, colloidal iron, metachromatic dyes, and PAS. The cornea may have decreased overall thickness with a thinned or absent Descemet's membrane and an epithelium that is stretched thin over anterior stromal deposits.

Unique in its autosomal recessive inheritance, Macular dystrophy is linked to various mutations on chromosome 16q2 and the CHST6 gene that encodes enzymes of keratan sulfate synthesis. This keratan sulfate defect is systemic and the varied expression of keratan sulfate in serum and cornea has led to the classification of several types of Macular dystrophy. In type 1, keratan sulfate is completely undetectable in the cornea and serum. In type 1a, the only detectable keratan sulfate is found within keratocytes, and in type 2 corneal keratan sulfate is present but levels are diminished.

Rare Stromal Dystrophies

Gelatinous drop-like dystrophy

Presenting in the first decade of life with photophobia, foreign body sensation and decreased vision, this autosomal recessive dystrophy, also known as familial subepithelial amyloidosis, resembles band keratopathy. The opacities are subepithelial and anterior stromal, and may, over time, assume a mulberry-like gelatinous appearance. Keratectomy and keratoplasty may be performed with variable success due to recurrence.

This dystrophy is linked to mutations in the M1S1 gene on chromosome 1p31. These defects lead to the accumulation of amyloid from a truncated surface glycoprotein.

Schnyder's crystalline dystrophy

Also known as Scandinavian dystrophy due to a reported cohort of patients in central Massachussets of Scandinavian origin, this autosomal dominant dystrophy occurs within the first year of life as central, crystalline, anterior stromal lesions that are either discoid, ring-like, or geographic in distribution. A significant minority may have a noncrystalline form which occurs later in life. As the lesions progress, they involve more posterior stroma. By the third decade a prominent arcus lipoides is seen, and by age 40 most patients have full thickness corneal opacities. While there is no correlation between this disease and elevated serum cholesterol, patients' lipid and cholesterol levels should be checked as early arcus, before age 50, and can be an indicator of hyperlipidemia. Important diseases in the differential diagnosis of central crystalline corneal deposits should also be ruled out and these include Bietti's corneoretinal dystrophy, cystinosis, and dysproteinemias such as multiple myeloma.

Pain is infrequent because many of these patients develop decreased corneal sensation. Vision loss is the most common presentation and may be treated with lamellar or penetrating keratoplasty. Histologic examination of the corneal buttons reveal that the crystals are composed of cholesterol and lipid and the pathogenesis is believed to involve a defect in local lipid metabolism or

transport. The genetic defect has been linked to chromosome 1p.

Central cloudy dystrophy

First described by Francois, this autosomal dominant or, rarely, sporadic dystrophy appears as bilaterally symmetric central and deep stromal cloudy, gray–white, ill-defined, snowflake-like lesions. The appearance is similar to posterior crocodile shagreen, and, similarly, is rarely symptomatic.

Congenital hereditary stromal dystrophy

This dystrophy, which is often static or slowly progressive, has been described in several families and occurs at birth as a diffusely hazy cornea of normal thickness. The lesions are diffuse, bilateral, small, and located primarily in the anterior stroma. This generalized opacification may lead to profound vision loss and early penetrating keratoplasty may be warranted to prevent amblyopia.

The pathogenesis involves disorganization of corneal lamellae with randomly arranged collagen fibrils and loss of corneal transparency. The inheritance pattern is autosomal dominant and a defect has been identified in the decorin gene that encodes a dermatan sulfate proteoglycan.

Posterior amorphous dystrophy

Remarkable for central stromal thinning without ectasia or astigmatism, this autosomal dominant dystrophy begins in childhood and slowly progresses. It is characterized by bilateral gray sheets in the deep stroma extending to the limbus. The stroma may thin to about 300μm, but vision is only mildly affected.

In addition to stromal thinning, histologic examination demonstrates a thick collagenous layer posterior to Descemet's membrane as well as relative absence of stromal keratocytes. The endothelium is unaffected.

Fleck dystrophy

Fleck dystrophy is usually discovered as an incidental finding, because it is asymptomatic in the majority of patients (recurrent erosions can rarely occur). It is autosomal dominant, may be present at birth or arise in infancy, and is rarely progressive. On slit-lamp examination, small white flecks can be seen in all stromal layers and represent swollen keratocytes with cytoplasmic vesicles due to membrane-bound vacuoles of lipid and mucopolysaccharide. On electron microscopy, flecks stain with oil-red O.

A causative mutation on chromosme 2q35 in the PIP5K3 gene has been identified. This gene codes for an enzyme involved in post-Golgi vesicle processing of protein and lipids.

Posterior Dystrophies

Fuchs' Endothelial

By far the most common corneal dystrophy to lead to corneal transplantation, Fuchs' is an autosomal dominant dystrophy that directly involves Descemet's membrane and the endothelium, and may indirectly impact all layers of the cornea. The classic lesion of Fuchs' is the central guttae, but a controversial nonguttate form has been described. Over time, the guttata spread peripherally and coalesce. Descemet's may assume a thickened, grayish, irregular appearance, and this may eventually mask the guttata. If corneal edema develops, it begins posteriorly as evidenced by Descemet's and deep-stromal wrinkles. As the corneal edema progresses, the stroma thickens and microcystic epithelial edema can usually be appreciated by the time the cornea thickness has increased by 100 μm. Later in the course of the disease, the cornea takes on a ground-glass appearance (**Figure 4**).

Fuchs' guttata are 2.5 times more likely to develop in women than men, and women are nearly 6 times more likely to develop Fuchs' corneal edema. Symptoms of blurring are often first seen in during the morning hours because the cornea swells overnight due to decreased evaporation and the increased hypotonicity of the tear film. Some patients find relief from hypertonic solutions, decreasing intraocular pressure, or by facilitating tear evaporation with external devices such as blow dryers. Recurrent erosions often occur in advanced cases due to edema-induced anterior basement membrane-like lesions and ruptured epithelial bullae. Repeat epithelial defects may lead to fibrous scarring and neovascularization. These epithelial lesions may be managed with bandage contact lenses. As mentioned previously, many patients require management with penetrating or endothelial keratoplasty, especially after other intraocular surgeries which may lead to further loss of endothelial cell viability.

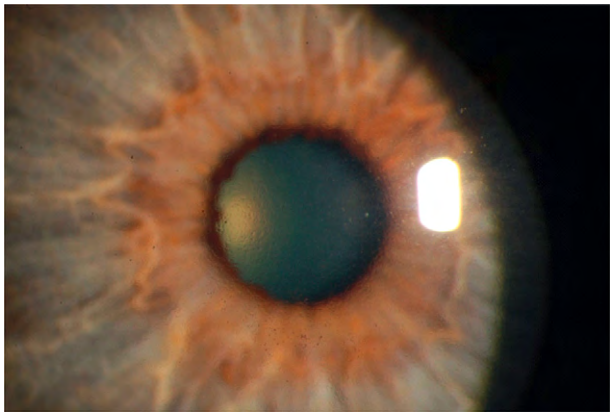

Figure 4 Slit-lamp photograph of Fuch's dystrophy.

The pathology of Fuchs' is well characterized and primarily consists of changes in endothelial cell architecture and number, and abnormalities of posterior Descemet's membrane. The number of endothelial cells decreases while the remaining cells show an increase in size, a less hexagonal and more irregular shape, and an eccentricity of cellular nuclei. This can be seen *in vivo* with specular microscopy as a decreased endothelial cell density, polymegathism, and cellular polymorphism. On electron microscopy the cells look more fibroblastic with an increase in rough endoplasmic reticulum, lysosomes, vacuoles, and cytoplasmic filaments. The posterior nonbanded zone of Descemet's membrane is thinner than normal, on an average less than 2 μm compared to 8 μm in a normal adult population. An abnormal PAS-positive posterior collagenous layer significantly increases the overall thickness of Descemet's to 2–3 times that of normal corneas, and this layer is contiguous with guttae that jut out posteriorly, thinning the overlying endothelial cells and pushing their nuclei aside into the intervening valleys. With corneal edema, the corneal lamellae thicken, and histologically this is evidenced by a decrease in artifactual clefting.

The genetic defects leading to Fuchs' are numerous and the identified mutations have been linked to chromosome 1p32-1p34, as well as chromosomes 7, 15, 17, and X.

Posterior Polymorphous Membrane

Typically beginning in the second or third decade of life, this autosomal dominant dystrophy of Descemet's and the endothelium is named for the diversity of clinical findings seen on slit-lamp examination. The hallmark lesions are posterior vesicles, and these may be accompanied by bands or by diffuse opacities in 50% and 10% of the cases, respectively. The vesicles, misleadingly, look like transparent cysts of Descemet's membrane. The bands, if present, are usually horizontal, have scalloped edges, and most commonly occur along the inferior paracentral cornea. The bands can be distinguished from tears or folds of Descemet's because they lack tapered edges. Diffuse opacities range in size from 500 to 2000 μM, have a peau d'orange texture and are associated with adjacent posterior stromal haziness. As in Fuchs', guttata may be seen and corneal edema can develop. Rarely, this dystrophy is associated with corneal steepening or ectasia.

For the majority of patients the dystrophy causes no symptoms, is nonprogressive and may be picked up incidentally in the second or third decade of life. However, there is a wide spectrum of disease severity and some cases are vision threatening. In fact, severe corneal edema and clouding may be present at birth or early childhood, and this dystrophy needs to be considered in the differential diagnosis of congenital corneal clouding. While most cases are bilateral, there may be a marked degree of asymmetry in its presentation. In addition to corneal symptoms, patients may develop high intraocular pressure as a result of the peripheral anterior synechiae.

For patients with corneal decompensation, penetrating keratoplasty has been the treatment of choice. The success rate of keratoplasty is much higher for patients without significant broad preoperative synechiae or high pressure, and may be extremely low for patients with these problems. Recurrence after keratoplasty may occur in the form of a retrocorneal membrane. The pressure elevations associated with this dystrophy are difficult to manage medically or surgically.

The pathologic findings demonstrate layered-endothelial cells that have assumed epithelial characteristics such as microvilli and rapid growth in culture, and stain with epithelial cell markers such as cytokeratin (CK), pancytokeratin, and CK7 (a glandular epithelial marker). Descemet's membane is irregular with a typically normal anterior-banded zone but an absent or markedly abnormal posterior nonbanded zone. Much of the posterior zone is replaced by heterogenous collagenous components that comprise a 15–25-μM-thick posterior collagenous layer. Posterior synechiae may be found in up to a quarter of patients, and may be accompanied by iris defects including atrophy and corectopia.

On specular microscopy, the various posterior polymorphous lesions can be further examined. The vesicles appear as well-demarcated dark round areas with lighter ridges and dots. The bands have shallow hills and valleys composed of confluent vesicles, and the diffuse lesions are well-demarcated reflective areas with enlarged, pleomorphic, indistinct endothelial cells that are surrounded by more normal appearing endothelial cells.

At least two different loci are associated with posterior polymorphous dystrophy and they are found on chromosomes 20q11 and 1p34.3–p32. The resultant defects may affect the production of type VIII collagen, the predominant component of the anterior-banded zone.

Congenital Hereditary Endothelial Dystrophy

Present at birth or in the early postnatal period, this dystrophy is bilateral, symmetric, and diffuse, with corneal haze spanning from limbus to limbus. The cornea is very thick – 2–3 times normal – and there are no other associated anterior segment defects. Rarely, this corneal edema begins later in infancy or early childhood. Treatment consists of early keratoplasty.

Examination of the excised corneal buttons reveals reduction, absence, or degeneration of endothelial cells and diffuse corneal edema. As in all posterior dystrophies, there is an abnormal posterior nonbanded zone which merges into a posterior collagenous layer.

Inheritance is most often autosomal recessive and linked to chromsome 20p13, but rarely may be inherited as a dominant trait on chromosome 20p11.2–q11.2.

Corneal Endothelium: Overview

D R Whikehart, The University of Alabama at Birmingham, Birmingham, AL, USA

Glossary

Autosomal dominant – The property of inheritance of a disease or trait from a single parent.
Chamber angle – This is the natural angle formed at the junction of the posterior limbus (at the trabecular meshwork), the ciliary body, and the iris.
Glycosaminoglycan – A general term for any sugar polymer of alternating sugars and aminosugars (aka a GAG).
Homeobox protein – A protein that is concerned with the embryological development of a multicellular organism. It is synthesized by a homeobox gene.
Keratocyte – A cell type found in the corneal stroma that makes and maintains collagens and glycosaminoglycans (aka a stromal cell).
Knock-out mouse – A genetically engineered mouse in which one or more specific genes have been made nonfunctional.
Schlemm's canal – A vessel behind the trabecular meshwork through which the aqueous fluid of the eye can drain into the venous system.
Stem cell – A primitive cell that has not differentiated into a functional cell of a multicellular organism.
Trabecular beam – A portion of the trabecular meshwork of the posterior limbus that consists of a rod of largely collagen material. When assembled in its typical complex pattern, trabecular beams offer resistance to the outflow of the aqueous fluid.
Transient amplifying cell – A cell in the process of differentiation from a stem cell as a functioning cell.

Anatomy

General Description

The corneal endothelium consists of a monolayer of polygonal cells, primarily hexagonal in shape, such that each has dimensions of 18–20 μm (width) by 5 μm (thickness). These cells produce a predominately collagenous product known as Descemet's membrane that is sandwiched between the anterior basal side of the endothelial cells and the posterior layer of the stroma. Descemet's membrane is a basement membrane that may act as a cushion for endothelial cell trauma and, in general, such basement membranes have been assigned roles associated with cell adhesion, migration, differentiation, and signal transduction. However, the exact roles of this membrane are presently unknown. Endothelial cells continually synthesize Descemet's membrane throughout life. On the posterior apical side, endothelial cells make direct contact with the anterior aqueous fluid in the anterior chamber. This pH neutral fluid (pH 7.4) is virtually absent in serum proteins and lipids, but contains nourishing glucose, antioxidants, and a variety of cytokines. At the boundary of the endothelium, endothelial cells are joined to a limbus whose transitional area is composed of cells that may contain precursor stem cells for the endothelium. The circular diameter of the corneal endothelium is approximately 11.7 mm in the adult. As with the remainder of the cornea, there are normally no blood vessels in this tissue. Although the anterior cornea does possess nerve endings, none are found in the endothelium (see **Figures 1–3**).

Cell-to-Cell Junctions

Corneal endothelial cells number about 3000 mm^{-2} in healthy, young adults and slowly decrease in number with age. The cells have a well-defined nucleus and their cytoplasm is packed with mitochondria necessitated by a high-energy requirement for the cells to act as a fluid pump. The cells also have a well-developed Golgi apparatus associated with the production of extracellular proteins needed for the assembly of Descemet's membrane. The cell-to-cell junctions are somewhat tortuous and interdigitated, a form that helps to keep the cells together. The cellular membranes at these junctions are held together with well-described joining proteins, of which one assembled complex has been called a zonula occludens (tight junction). However, there is still a controversy about whether or not this is a true zonula occludens. The reason for this is that the channel joining adjacent endothelial cells must allow both sodium and water to flow into the anterior chamber. This junctional form has been described to be more focal or point-like than that of the true riveted tight junctions of a zonula occludens. Gap junctions have also been shown to exist between the cells for the purpose of transporting small molecules between each cell. Additionally, adhesion junctions to strengthen cell-to-cell fastening can be found there. The membranes facing the anterior chamber have a number of microvilli, typical of many endothelial cell types. However, no roles for the microvilli in these cells have been described (see **Figures 3** and **4**).

Embryology

Initial Development

It has been known for a long time that the corneal endothelium originates from neural crest, stem cells. These

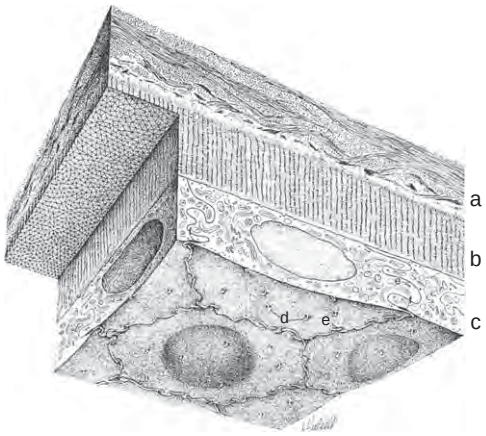

Figure 3 Three-dimensional, representational sketch of the corneal endothelium (c) with attached Descemet's membrane (b) and posterior stroma (a). Endothelial cell microvilli are shown at (d). Intercellular channels are indicated at (e) while quasi-tight junctions occur at (f). Adapted from Hogan, M. J., Alvarado, J. A., and Weddell, J. E. (1971). *Histology of the Human Eye,* p. 101. Philadelphia, PA: Saunders.

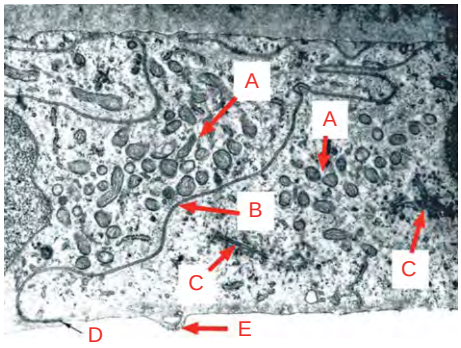

Figure 4 Cross-section of human corneal endothelial cells. The large population of mitochondria are evident at (A) while an intercellular channel may be seen at (B). Two Golgi apparatus are pointed out at (C). The intercellular channel, labeled at (B) is shown to empty out at the aqueous chamber at (D). At (E) can be seen a microvillus. Modified from Hogan, M. J., Alvarado, J. A., and Weddell, J. E. (1971). *Histology of the Human Eye,* p. 103. Philadelphia, PA: Saunders.

cells migrate from folds of the neural ectoderm at weeks 4–5 of embryonic development. This is illustrated in Figures 5–7. Since the developing embryo is relatively small and neural crest cells are localized along each section of the neural folds, from which they detach, migration is not very distant for each group of cells. In eye development, optic sulci (the primordial eyes) appear as shallow pits along the neural plate at week 4. These sulci begin to protrude outward as hollow optic vesicles from the proencephalon or forebrain of the neural plate. At just over 30 days, a wave of mesenchymal cells (in this case, neural crest cells) migrates over the optic cup into the space between the anterior surface of the lens and the surface ectoderm (corneal epithelium). These cells will become

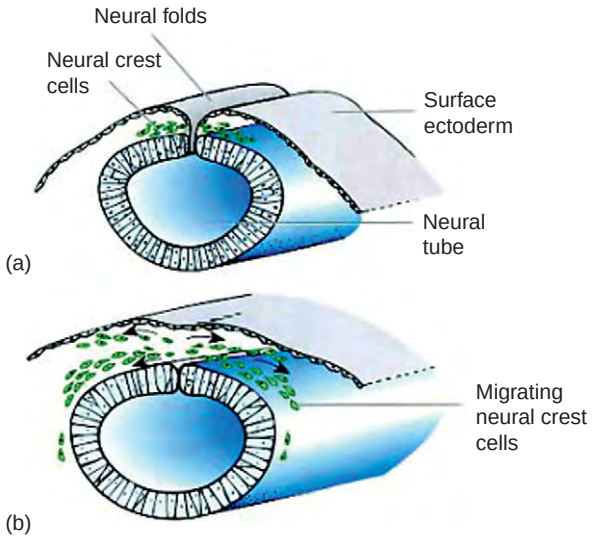

Figure 5 The developing neural folds and neural tube. As the neural folds move away from the neural tube (a and b), neural crest cells break away from the neural fold tissue (a) and begin their migration (b) to specific developing tissues. Modified from Forrester, J. V., Dick, A. D., McMenamin, P. G., and Roberts, F. (2008). *The Eye. Basic Science in Practice,* 3rd edn., p. 111. Edinburgh: Saunders.

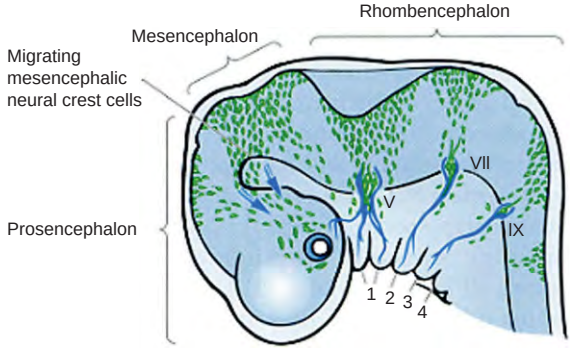

Figure 6 Migration pathways of neural crest cells. Neural crest cells are shown in green. The neural crest cells migrating to the eye originate primarily from the proencephalon (developing forebrain and brainstem) and the mesencephalon (developing midbrain). Migration is shown by dark blue arrows. Adapted from Forrester, J. V., Dick, A. D., McMenamin, P. G., and Roberts, F. (2008). *The Eye. Basic Science in Practice*, 3rd edn., p. 119. Edinburgh: Saunders.

the corneal endothelium. A second wave of mesenchymal cells (also neural crest cells) migrates around day 49 and places itself between the endothelium and epithelium. These cells are destined to become the keratocytes of the corneal stroma. Based on mouse model studies, it appears that those neural crest cells that will define the corneal endothelium at first remain in contact with the anterior lens and flatten out into a monolayer of cells. Then, the lens detaches from the endothelial monolayer to provide space for an anterior chamber where the aqueous fluid may enter (**Figures 8** and **9**). During this process, a third wave of neural crest cells migrates to the angle between the posterior cornea (endothelium) and the anterior edge of the optic cup (**Figure 10**). These cells eventually develop into the ciliary body and the iris.

During this development, the tissues anterior to the chamber angle between the anterior eye cup and the endothelium becomes occupied by a mass of mesenchymal (neural crest) cells that remain, at first, undifferentiated. These cells develop into flat endothelial-like cells that bring about the trabecular beams (trabecular meshwork) and, separately, Schlemm's canal cells. Some of the stellate cells, between the trabecular beams and the endothelial lining of Schlemm's canal, appear to remain undifferentiated. Evidence to support this is seen in a number of stem cell markers in this area which change with wounding (**Figure 11**). This is an important observation as it suggests the retention of stem cells in a niche for the replacement of cells in the posterior limbus and for the corneal endothelium. The point is made again that evidence strongly suggests that nearly all the mesenchymal cells that invade these areas of the anterior segment are neural crest in origin.

Role of Transcription Factors

Molecular biological mechanisms that control the overall development of the anterior segment remain incompletely described. This is also true for the corneal endothelium. What is known can explain some developmental effects. It is understood, for example, that inductive signals from the lens are partly responsible for endothelial cell differentiation. Defects in three lens genes that produce the homeobox proteins – MAF, FOXE3, and PITX3 – result in the inability of the lens to separate from the cornea (**Figure 12**).) Homeobox proteins assemble in a specific binding area of DNA to signal a specific RNA synthesis. They are required to bind to DNA in a set order for synthesis to begin. The three genes mentioned are concerned with producing genetic transcription factors that cause the synthesis of proteins necessary for lens–cornea separation. Other genetic abnormalities may also occur in the mesenchymal (stem) cells themselves that cause corneal development. In the endothelium itself, mutations in the genes PITX2, FOXC1, and PAX6, for example, are known to prevent satisfactory, functional corneal development. Normally, these genes produce the transcription factors for protein synthesis related to such development. PAX6, in particular, is required for making signaling molecules that cause transport of neural crest cells into the eye as well as the phenotypical development of the corneal endothelium itself. In addition, the amounts and origins of PAX6 proteins appear to be critical for the sequence signaling of corneal development. One signaling molecule that may be produced as a result of DNA binding of such transcription factors is transforming

growth factor, beta 2 (TGF-β2). In TGF-β2 knock-out mice, that cannot produce this protein due to a lack of PAX6, the corneal endothelium is completely absent. It is also known that the overexpression of TGF-β1 (a related molecule using similar receptors) results in an absent endothelium. So, the case is made that these controlling proteins must be present in specific amounts and at the right time sequence to allow proper corneal endothelial cell development to occur.

Biochemistry and Metabolism

Glucose and Energy Metabolism

The corneal endothelium is a cell type that is required to have large outputs of energy to maintain the process of deturgescence (discussed in the section entitled 'Proteins synthesized for external transport'). In this regard, corneal endothelial cells maintain a high amount of adenosine triphosphate (ATP)-producing mitochondria as well as a defined Golgi apparatus for the complete synthesis, retention, and export of proteins. In studies of comparative carbohydrate metabolism, it has been shown that the amount of aerobic glycolysis (glucose breakdown to produce ATP) is 3 times higher than it is in the cells of the corneal epithelium and stromal keratocytes. Compared to the cells of the lens, corneal endothelial cells use aerobic glycolysis at better than 6 times the amount used by the lens. On a per cell basis, it is even estimated that corneal endothelial cells produce more ATP energy than individual cells of the ciliary body by 40%. Only cells of the retina exceed the cells of the corneal endothelium in

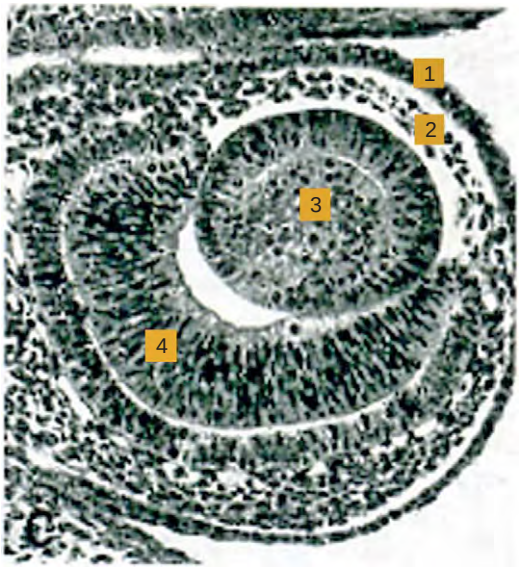

Figure 9 A developing eye of a human fetus past 6 weeks. 1. the outer cornea (epithelium). 2. coalescing stem cells forming the endothelium and keratocytes. 3. the developing lens. 4. the inner layer of the retina. Figure 10 Development of tissues at the angle of the posterior limbus at 12 weeks. The figure shows the pupillary membrane (PM) beginning to form the optic cup margin (OCM) and indentation caused by vascular mesenchyme (double arrows). At (1) are the corneal endothelium (1st wave of neural crest cells); (2) the forming keratocytes (2nd wave of neural crest cells) and collagen; and (3) possible 3rd wave of invading neural crest cells to form the trabecular meshwork. Modified from Forrester, J. V., Dick, A. D., McMenamin, P. G., and Roberts, F. (2008). *The Eye. Basic Science in Practice*, 3rd edn., p. 131. Edinburgh: Saunders.

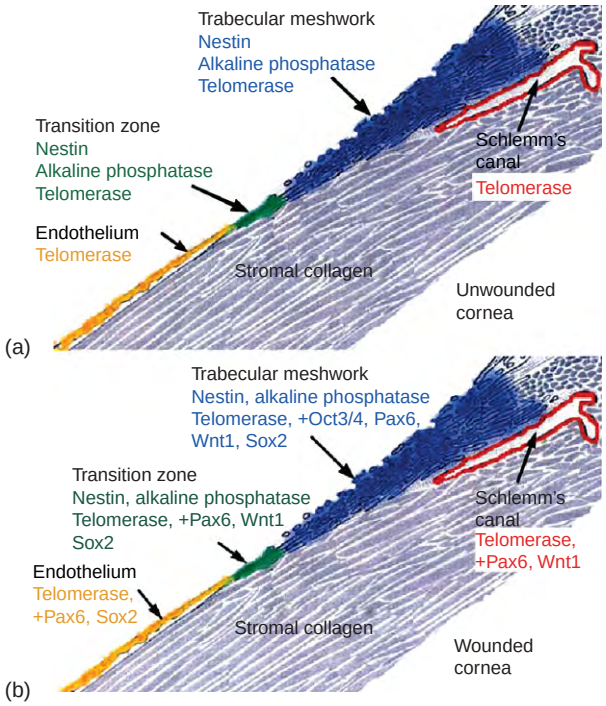

Figure 11 Stem cell and transient amplifying cell staining patterns at the peripheral corneal endothelium, transition zone, and trabecular meshwork of the posterior limbus in adult humans. Unwounded tissue is shown at (a) while wounded tissue is shown at (b). Tissues were stained with the following stem cell marker proteins: nestin, alkaline phosphatase, Wnt1, and Oct3/4. Tissues were stained with the following marker for both stem cells and transient amplifying cells: telomerase. Wounded tissues were stained with the following cell differentiation markers: Pax-6 and Sox2. Adapted from McGowan S. L., Edelhauser, H. F., Pfister, R. R., and Whikehart, D. R. (2007). Stem cell markers in the human posterior limbus and corneal endothelium of unwounded and wounded corneas. *Molecular Vision* 13: 1984–2000. http://www.molvis.org/molvis/v13/a224/.

metabolic energy produced. Although direct evidence is scarce, it seems that corneal endothelial cells are not insulin dependent and, therefore, are not starved of glucose in diabetes. On the contrary, it is perplexing that glycation of sodium, potassium-ATPase (Na, K-ATPase) does not cause an inhibition of the enzyme in the diabetic.

Cell Division and Replenishment

The lack of any ready, apparent replication of endothelial cells has been an ongoing problem when cell replacement might be required. In general, the population of these cells decline with age, but usually there remain sufficient numbers of cells at an advanced age to maintain corneal clarity. This has not seemed to be the case with wounding, trauma, and other dramatic forms of endothelial cell loss. Studies of the cell cycle in endothelial cell have indicated that the cells tend to remain in the G_1 phase (perhaps even the G_o temporary exit of cell division). This could be due to such factors as simple cell-to-cell contact inhibition or the presence of the TGF-β2 protein found in the aqueous humor. Departure from the G_1 stage toward replication can be artificially induced with the E2F2 transcription factor since the E2F2 protein is known to bring cells into the S-phase of the cell cycle. Cells that have been transformed either with the SV40 large T-antigen or with the E6/E7 human papilloma virus can also act to initiate replication. The SV-40 and E6/E7 proteins inactivate the activity of retinoblastoma (Rb) and p53 cell cycle suppressor proteins by interacting with

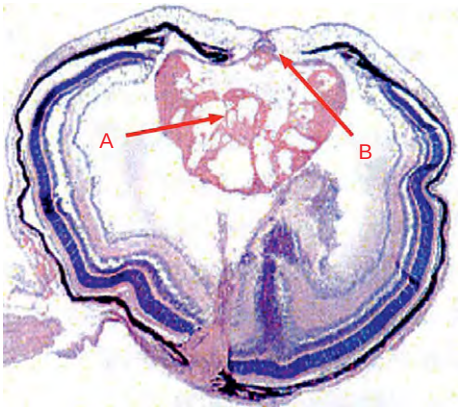

Figure 12 Cross-section of Foxe3$^{-/-}$(deficient) mouse eye showing small lens (A) and persistent attachment of lens to cornea (B). Adapted with permission from Medina-Martinez, O. and Jamrich M. (2007). Foxe view of lens development and disease. *Development* 134: 1455–1463.

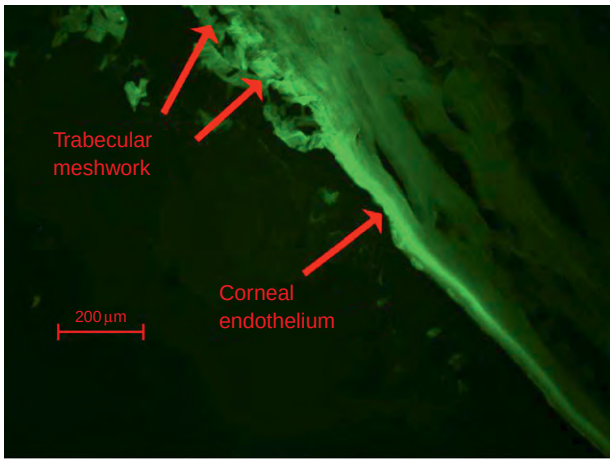

Figure 13 BrdU fluorescence shown in the peripheral corneal endothelium and trabecular meshwork 48 h after a mechanical wound to the endothelium. Adapted from Whikehart, D. R., Parikh, C. H., Vaughn, A. V., Mishler, K., and Edelhauser, H. F. (2005). them and allowing the E2F2 transcription factor to initiate the cell cycle. These are not the usual cell processes, however, and the lack of normal cell division remains unresolved. There is evidence, however, that endothelial cells are replaced *in vivo*. Studies have pointed to the existence of stem cells in the posterior limbus just beyond the boundary of the corneal endothelium (**Figure 11**). Initially, some investigators noted a higher than usual density of corneal endothelial cells that exist at the endothelial periphery. This suggested that replacement cells or germinating cells were present in this area. Later, stem cells were identified in the posterior limbus. This has been shown by labeling with stem cell markers such as Nestin and Oct3/4 in the limbus and the subsequent appearance of repair or developmental proteins such as PAX6 and Wnt1 in the limbus and the peripheral endothelium following wounding. The appearance of the transient amplifying cell marker telomerase in these areas strongly points to the possibility that stem cells, resident in the posterior limbus, give rise to new corneal endothelial cells. In fact, BrdU studies have confirmed the generation of new cells from the posterior limbus into the peripheral endothelium after wounding (**Figure 13**). This is analogous to what occurs in the corneal epithelium, but at a significantly lower rate of reproduction.

Cytokines and Immune Privilege

The existence of cytokines, generated by the lens and other cells adjacent to the anterior chamber in the aqueous fluid, suggests that the endothelium may be influenced by its neighboring tissues. Cytokines are a broad mixture of polypeptides or proteins that are able to communicate a signal to a cell to initiate some change or response from the cell. In fact, the distinction between a cytokine and a local hormone is considered moot by many. Cytokines were originally associated only with immune functions. An example of a cytokine that has both immune and nonimmune effects is the TGF-β, pointed out earlier. In the eye, TGF-β is known to modulate cell migration, proliferation, death, development, tissue repair, and many pathological processes as well. Generally, however, this cytokine is responsible for extracellular matrix production and the suppression of cell proliferation. There are three isoforms of TGF-β. Of the three, TGF-β2 is the predominant cytokine that is found in the aqueous fluid bathing the endothelium. The presence of TGF-β2 is essential to the cornea since its absence results in a failure of the endothelium to develop (see **Figure 14**).

Immune privilege in the eye is a process in which the eye protects itself from undesirable immune characteristics, such as inflammation, as a device to preserve vision. For the anterior segment, that means the ability of light to pass through its tissues unimpeded. Immune privilege is the summation of many complex molecular and cellular mechanisms whose operation, as a whole, remains incompletely understood. It is also the process by which corneal transplants are more likely to be free of immune reactions than transplants in other parts of the body. In an immune-privileged site, such as the corneal endothelium, active processes are set in motion to suppress immune reactions when an antigen enters the site. The aqueous humor is responsible for this action since it contains the necessary suppression cytokines that are released by cells bordering the anterior chamber. TGF-β2, in addition to its roles mentioned previously, inhibits T-cell activation and differentiation that are necessary to initiate inflammation.

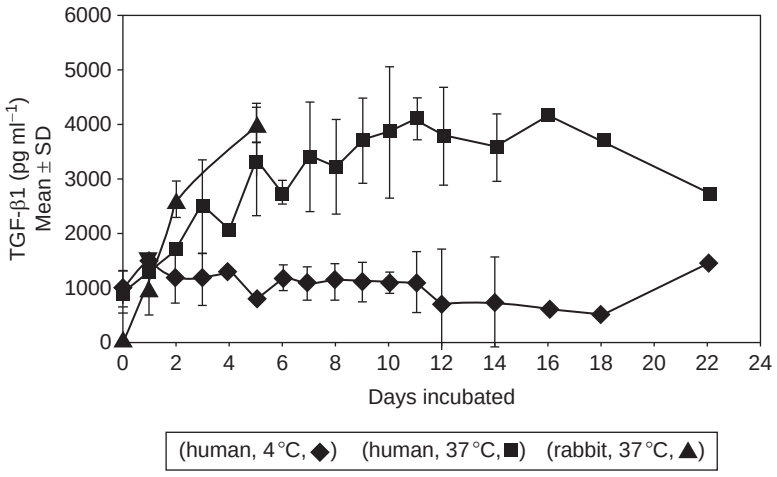

Figure 14 Levels of TGF-β1 in fluids bathing an excised cornea following mechanical wounding. At 37°C, it is seen that the levels of the cytokine, produced by the cornea, are increased as a mechanism to limit cell division about 48 h after wounding. Adapted from Whikehart, D. R., Parikh, C. H., Vaughn, A. V., Mishler, K., and Edelhauser, H. F. (2005). Evidence suggesting the existence of stem cells for the human corneal endothelium. *Molecular Vision* 11: 816–824. http://www.molvis.org/molvis/v11/a97/.

Other examples of cytokines that contribute to immune privilege are: α-melanocyte stimulating hormone, vasoactive stimulating peptide, calcitonin gene-related peptide, and somatostatin. A more recent finding has been the discovery of another cytokine: cluster of differentiation 95 ligand (CD95L) at immune-privileged sites. CD95L acts as a death signal that triggers apoptosis (programmed cell death) in CD95 sensitive T cells. The membrane protein form of CD95L, expressed on corneal endothelial cell membranes, has been shown to be important for the preservation of orthoptically placed corneal grafts and it does this by interacting with these T cells.

Some contradictions in the understanding of immune suppression also exist. For example, it is not understood how the soluble versus membrane forms of CD95 function and why the CD95L form is important for graft acceptance. In addition, many of the cells that surround the anterior chamber have receptors for tumor necrosis factor-α. This cytokine, unfortunately, plays an important role in intraocular inflammation (endotoxin-induced uveitis) when it occurs.

Proteins Synthesized for External Transport

In human corneas, there are known anatomical subdivisions found in Descemet's membrane: an anterior, banded zone and a nonbanded, amorphous zone (**Figure 15**). The banded zone is formed before birth while the amorphous zone is continuously synthesized during life. Four principal proteins have been found to constitute Descemet's membrane in both zones: collagens type IV and VIII as well as laminin and fibronectin. All are considered to be synthesized by corneal endothelial cells throughout the lifetime of an individual. However, recent suggestions

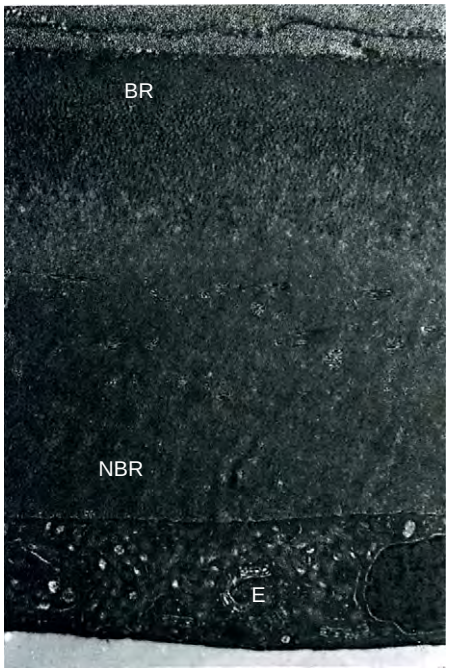

Figure 15 The banded (BR) and nonbanded (NBR) regions of Descemet's membrane. The BR is formed before birth while the NBR is made continuously throughout life. E, the endothelium. ×7000. contend that some evidence points to the posterior keratocytes as sources for some of this synthetic work. Collagen type IV was originally considered to be the principal collagen of Descemet's membrane. It is described as the main structural protein of all basement membranes. The α-1–α-6 chains are found in Descemet's membrane facing the stromal and endothelial sides of the membrane in both

infants and adults. Type VIII collagen is a short nonfibrillar protein that may determine cell phenotype. In the infant, it is found on the endothelial face of the membrane, whereas it occurs on the stromal face of the membrane in the adult. Laminin is a noncollagenous glycoprotein that binds to other proteins to form sheets. Its association with type IV collagen in basement membranes is well known. Laminin occurs on the stromal and endothelial faces of infants, but it is not found on the stromal face of adult Descemet's membrane. Fibronectin is a high-molecular-weight protein that can bind to membrane receptor proteins as well as collagen. It is involved in cell adhesion. Fibronectin only occurs on the stromal face of Descemet's membrane in both infants and adults. Mucin-1 (MUC-1), a cell surface protein that has largely been considered to be present on the surface of the corneal epithelium, has also been found to be synthesized by the endothelium and transported to its apical surface. Its function there would be as an interfacing protein to the aqueous fluid.

The Role of the Corneal Endothelium in Deturgescence

Introduction

The average human cornea in the adult is maintained at a thickness of 500 μm in the center to about 700 μm at the periphery (Figure 1). Keeping these parameters stable is important for corneal clarity. Deturgescence is the physiological process of maintaining such a clear cornea. The process is active and continuous. Two forces are at work during deturgescence. In one process, the cornea swells and tends to become cloudy. Due to the large volume of negatively charged glycosaminoglycans (GAGs) bound to the proteoglycans in the cornea, there is a constant influx of cations into the stroma from fluids outside of this tissue. These cations are accompanied by water as an osmotic compensation and bring about corneal swelling. The stroma is composed of layers of collagenous lamellae with each collagen strand separated from its neighbor by an aquous space. Disruption of the geometric regularity in the aqueous spaces that contain the GAGs brings about a loss in the mutual interference of light that is refracted through the cornea. This results in the beginning of a loss of clarity which can continue through progressive degrees of opacity (cloudiness). If unchecked, this process would result in functional blindness. In the second process of deturgescence, excess water is actively transferred out of the stroma by the corneal endothelium into the aqueous fluid of the anterior chamber. The corneal epithelium takes on a rather passive role in this process by acting more as a barrier to water flow. Early experiments demonstrated the existence of this active process to be predominately in the endothelium. This was accomplished by the selective removal of corneal outer layers to determine which side (epithelium or endothelium) was involved in pumping out water. A metabolic component was shown to exist when the deturgescent process was compared in experimental corneas at cold versus physiological temperatures (Figure 16).

The Biochemistry of Active Deturgescence

Active deturgescence is considered to occur as the result of the catalytic activity of two enzymes: sodium, potassium-stimulated adenosine triphosphatase (Na, K-ATPase) and bicarbonate-stimultated adenosine triphosphatase ($^{-}HCO_3$-ATPase). Na, K-ATPase resides in the basolateral membranes of corneal endothelial cells in sufficient quantities to ensure significant pumping activity.

As an enzyme, Na, K-ATPase exists with a minimal structure of four polypeptide chains of which two (the α-chains) are catalytic and two (the β-chains) are structural stabilizers in the cell membrane. In carrying out pumping activity, the enzyme is energized by the hydrolysis of ATP to adenosine diphosphate (ADP) in which energy, contained in the released inorganic phosphate group, is transferred to an α-subunit. This energy provides for the kinetic transfer of two potassium ions into an endothelial cell while three sodium ions are virtually, simultaneously moved to the cell exterior. The result is the net movement of one cation outside the cell (Figure 17). The osmotic consequence of this is the simultaneous flow of water into the anterior chamber either directly or through the channels that lie between endothelial cells. Water therefore flows osmotically, due to ion transfer, through endothelial cells by means of proteins known as aquaporins.

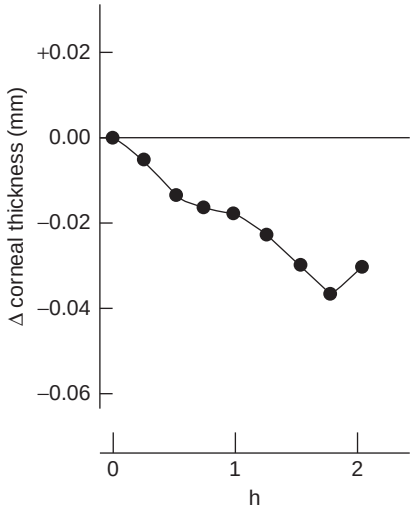

Figure 16 A temperature-reversal experiment in which a cornea is previously allowed to swell in the cold and then demonstrated to decrease in thickness when placed at room temperature for 2 h. From Dr. Henry Edelhauser.

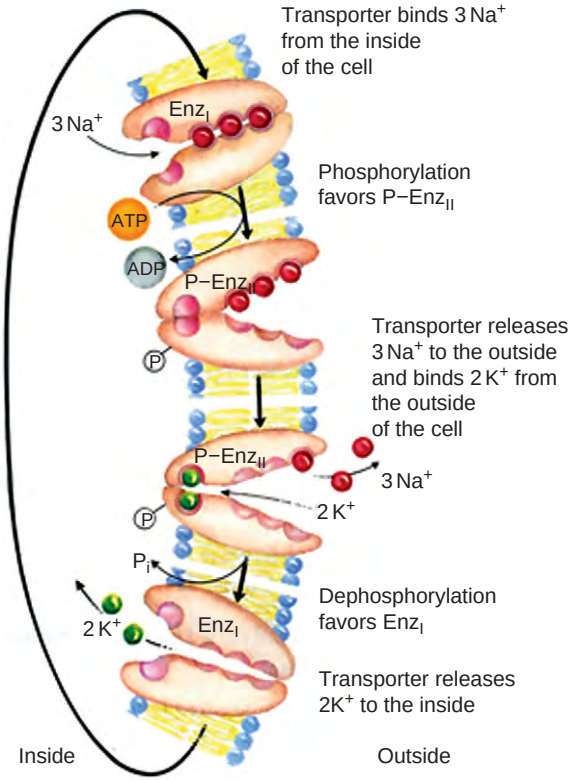

Figure 17 A postulated mechanism for the two α-subunits of Na, K-ATPase. The mechanism (beginning at the top of the figure) is initiated with the cytosolic binding of three sodium cations, followed by ATP hydrolysis, sodium external transport, two potassium cation external binding, potassium internal transport, and release. The cycle is then repeated. Adapted from Nelson, D. L. and Cox, M. M. (2005). *Lehninger. Principles of Biochemistry*, 4th edn., p. 399. New York: Freeman.

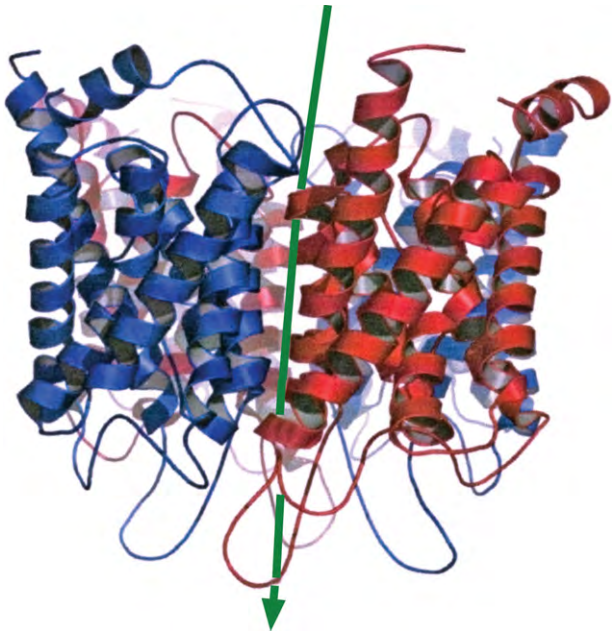

Figure 18 Aquaporin-1 consists of four polypeptide chains (shown here in red and blue). The channel for water that they form is shown as a green arrow. Modified from Wikipedia/Aquaporin.

The water transport protein in the cornea is known as aquaporin-1 (AQP-1; Figure 18).

Bicarbonate-ATPase has a role that is more difficult to define, but which has been considered by some to be supportive of the role of Na, K-ATPase. Evidence indicates that the enzyme has a molecular weight similar to the α-subunit of Na, K-ATPase. Part of the difficulty in understanding how or why this enzyme functions lies in the fact that it is resident in mitochondria rather than in plasma membranes. The enzyme functions, just as Na, K-ATPase, by obtaining energy from ATP hydrolysis and is, therefore, also a P-type ATPase. The energy incorporated into the enzyme causes it to transfer anions across membranes that include chloride as well as bicarbonate. In the literature, there has been considerable confusion about whether this enzyme is primarily a chloride or a bicarbonate transporting enzyme *in situ* in the corneal endothelium. Experimentally, it seems that either anion may be substituted for the other or that bicarbonate may be required to stimulate the transport of chloride. The importance of bicarbonate cannot be denied as, experimentally, a decrease in bicarbonate, and the use of carbonic anhydrase inhibitors clearly shows a loss of deturgescence. Carbonic anhydrase converts water and carbon dioxide into bicarbonate and a proton. At this point, whether chloride or bicarbonate is of prime importance is unclear.

The Physiological Control of Active Deturgescence

It is evident that moving a net amount of cations from the corneal endothelium (via Na, K-ATPase) to the anterior chamber will result in transferring water from the endothelium to the aqueous to maintain an osmotic balance. This activity serves to remove excess water from the stroma (via aquaporin transport through the corneal endothelium) while water leaks back into the stroma simultaneously. Normally, the concentration of Na^+ ions is higher in the anterior chamber than in the stroma, so the activity of Na, K-ATPase is required to push Na^+ ions against the gradient of the anterior chamber. The two processes (pump and leak) operate in a fashion analogous to water leaking into a basement while it is being removed by a sump pump at the same time. Since Na, K-ATPase requires a substantial supply of ATP as an energy source from mitochondria, it can be speculated that the membrane potential and pH of that organelle requires that the potential and pH stability be well maintained. To what degree the operation of a $^-HCO_3$-ATPase in the mitochondria contributes to these phenomena is unknown.

There remain other physiological observations that challenge further investigation of the pump-leak hypothesis of deturgescence. For example, do the aquaporins (AQP-1 in the endothelium and AQP-5 in the epithelium) play more than a passive role in deturgescence? What function might TRPV4 (an osmolar-sensing protein in the epithelium) play in regulating stromal volume?

Genetic Diseases of the Corneal Endothelium

Fuchs' Endothelial Dystrophy

This disease is considered to be the result of an autosomal dominant disorder. It is a true disease of the corneal endothelium rather than one that originates from another area of the cornea (Figure 19). It was first described in 1910. There are two forms of the disease: early onset (mutations associated with chromosomes 13 and 18) and late onset (perhaps found on chromosome 1 or at other locations). The early onset form is associated with a mutation of the COL8A2 gene which synthesizes collagen VIII, a major collagen of Descemet's membrane. The exact identity of the gene defect in the late onset form has been proposed to be SLC4A11, a gene that causes the synthesis of a transport protein in endothelial cells. Both forms of the disease manifest themselves initially in the formation of guttae (gutattae) or buttons on the endothelium. Later development of the condition occurs with the formation of edema or swelling in the posterior stroma. The edema spreads anteriorly and leads to the development of corneal cloudiness. The stroma may take on the appearance of ground glass as the disease progresses. This disease progresses slowly and is more common in females than in males. Effective treatment is a penetrating keratoplasty (corneal transplant).

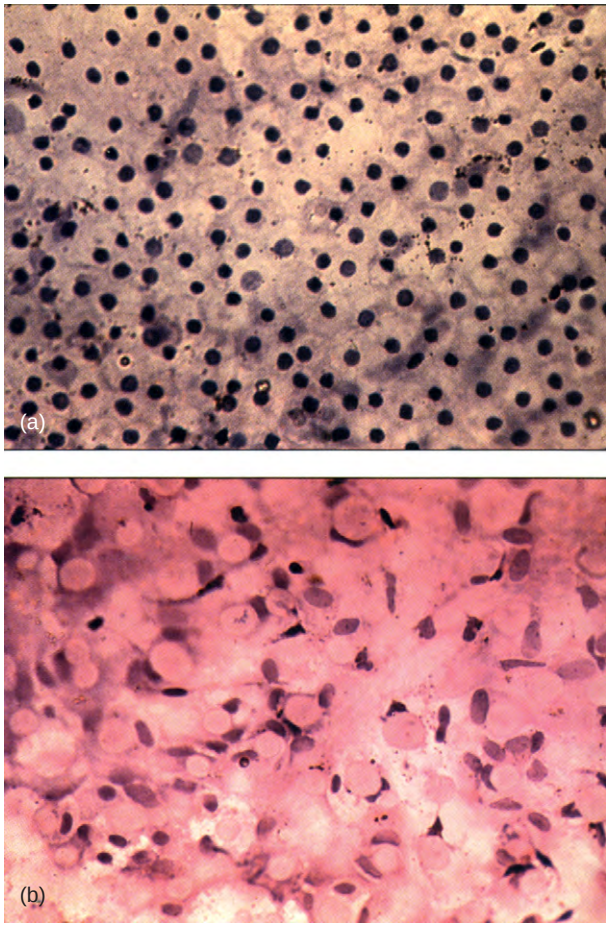

Figure 19 Endothelial cell layers as viewed from the posterior side of the cornea: (a) is a normal endothelium showing a regular pattern of polygonal cells and (b) is an example of moderately advanced Fuch's dystrophy. It shows a marked decrease in cell numbers, abnormal nuclei, and cell displacement by guttatae from Descemet's membrane. Adapted from Kratchmer, J. H., *et al.* (eds.) (2005). *The Cornea*, 2nd edn., vol. 1, p. 942. Philadelphia, PA: Elsevier.

Related Posterior Membrane Dystrophies

Two dystrophies that have some similarities to Fuch's dystrophy are posterior polymorphous dystrophy (PPMD) and congenital hereditary endothelial dystrophy (CHED). PPMD has been associated with four gene mutations on chromosomes 10 and 20 that affect the synthesis of collagens IV and VIII. In PPMD, there are differences in the effects on Descemet's membrane and the corneal endothelium versus the effects that occur in Fuchs' dystrophy. The nonbanded zone of Descemet's membrane becomes absent or minimal while the endothelial cells can take on the appearance of epithelial cells. PPMD patients are often asymptomatic, but those receiving penetrating keratoplasties sometimes develop increased intraocular pressure associated with iris attachments (synechiae). By contrast in CHED, the genetic abnormalities have been associated with one or more gene mutations only on chromosome 20. There is a decided loss of endothelial cells rather than a thinning of cells as occurs with Fuchs' dystrophy. The outcome of penetrating keratoplasty for CHED patients is mixed.

Corneal Epithelium: Cell Biology and Basic Science

M A Stepp, The George Washington University Medical Center, Washington, DC, USA

Glossary

Adhesion complex – The term used to refer to the different components of the cell: substrate junction that is present at the basal aspect of the stratified squamous epithelial tissues of the body, including the skin and the cornea. The adhesion complex includes not only the hemidesmosomes that contain $\alpha 6\beta 4$ integrin and collagen XVII, but also the inner hemidesmosomal plaque that contains plectin and BPA230, the anchoring filaments that are made of laminin 332, the anchoring fibers and the adhesions plaques that both contain collagen type VII. This structure forms during development and must partially or completely disassemble during wound healing and tissue regeneration and then reassemble after healing is complete. If the adhesion complex fails to form due to mutations in one of its components, blistering of the epithelial sheets covering the skin and cornea occurs.

Basement membrane zone – Sheets of epithelial cells that form the outer surfaces of the body are separated from their underlying mesechymal cells by basement membranes. Basement membranes are composed of the network-forming collagen type IV, the heparan sulfate proteoglycan perlecan, and several different types of laminins. The basement membrane zone consists of the basal plasma membrane surface of the basal epithelial cells, the hemidesmosomes, and the basement membrane itself. At the EM level, it consists of the inner and outer plaques of the hemidesmosomes, the lamina lucida, and the lamina densa.

Defensins – These are small cysteine-rich cationic proteins first characterized in leukocytes in 1985. The name was chosen because these proteins have antibacterial, antifungi, and antiviral activity. They consist of 18–45 amino acids including six (in vertebrates) to eight conserved cysteine residues. They bind to proteins on the surfaces of pathogens and form much of the basis of what immunologists call the innate defense system. Human tears have at least 4 different defensins and their presence in the tears is regulated during the healing of corneal wounds.

Glycocalyx – This term means sugar coat and in the cornea it refers to the thin film of sugar-containing material at the apical surface of the apical cells on the cornea. The primary molecules that make up the glycocalyx in the cornea are called mucins. There are several different types of mucins, some secreted and some cell-surface bound, on the healthy, wet ocular surface. The mucins of the glycocalyx help the tear film to spread over the ocular surface.

Integrins – A family of glycoproteins that function as heterodimers to mediate both cell:matrix interaction and cellular signaling. Integrins are integral membrane single pass proteins whose cytoplasmic domains bind to elements of the cytoskeleton including actin for most of the integrins and intermediate filaments for $\alpha 6\beta 4$. Their extracellular domains bind to extracellular matrix proteins including collagens, fibronectin, and laminins. Integrins are considered mechanotransducers of forces from outside cells and tissues to the cytoskeleton to allow cells to change shape during development and wound healing.

Niche – From the old French word *nichier* meaning to nest, this term is usually used to refer to the site where adult stem cells reside. In the cornea, the niche is believed to be located at the palisades of Vogt at the corneoscleral junction. Stem cell niches consist of both specialized extracellular matrix molecules that the stem cells adhere to as well as other cell types that play supportive roles by expressing cell:cell adhesion proteins and/or growth factors that act to maintain the stem cells within the niche and inhibit their differentiation.

Refractive surgery – This term refers to surgical procedures developed to improve the refractive state of the eye and decrease dependence of the patient on glasses or contact lenses. The major forms of refractive surgery are laser-assisted *in situ* keratomileusis and photorefractive keratectomy. According to the American Society of Cataract and Refractive Surgery, more than 900 000 refractive procedures were performed in the US in 2005.

The Corneal Epithelium Has Vital Functions in Vision

The corneal epithelium is a transparent covering that allows light entry into the eye. It is the outermost

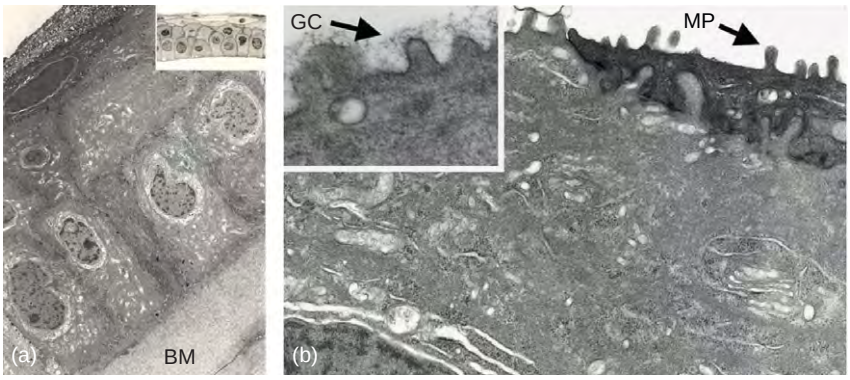

Figure 1 The surface epithelium of the cornea is specialized for light transmission and spreading of the tear film. (a) Transmission electron micrograph of the human corneal epithelium; a lower magnification image is in the inset. There are 3–5 cell layers and both apical and basal surfaces are flat and shear to minimize refraction of light. (b) The apical surface of the corneal epithelium has projections called microplicae. When shown at higher magnification as in the inset, the glycocalyx is seen covering the microplicae. The mucin proteins in the glycocalyx are hydrophilic and bind water which helps the tear film spread over the ocular surface. (a, b) Reproduced from Gipson, I. K. (1994). Anatomy of the conjunctiva, cornea, and limbus. In: Smolin and Thoft (eds.) *The Cornea: Scientific Foundations and Clinical Practice*, 3rd edn., Chapter 1, p. 8. New York: Little Brown and Company, with permission from I. K. Gipson.

layer of the cornea and is comprised of three to five anatomically distinct layers of stratified squamous nonkeratinizing epithelial cells (**Figure 1(a)**). It protects the inner neuronal tissues of the retina from microbial invasion and prevents water loss from the corneal stroma.

When light waves hit the curved corneal surface and pass from the air to an aqueous medium, they are bent. This refraction of light waves focuses the light on the fovea of the retina. The crystalline lens is less powerful than the cornea at bending light waves because the light waves are already in an aqueous environment when they pass from the cornea to the lens. Although the lens does refract light, the differences in the refractive indices of the corneal stroma, the aqueous humor, and the lens are small compared to the difference in refractive index between air and the tear film at the corneal surface. Thus the cornea is the major refractive surface of the eye. Because of its significant impact on the refraction of light, changes in the curvature of the cornea alter the position where light focuses on the retina. This property of the cornea has lead to the development of procedures to alter corneal curvature to reduce or eliminate refractive errors such as myopia and astigmatism. One of the most popular of these procedures worldwide is refractive surgery using laser-assisted *in situ* keratomileusis (LASIK) which involves cutting a flap of tissue at the front of the cornea through the epithelium and stroma, removing or ablating tissue from the stroma using an excimer laser, and repositioning the flap of tissue. LASIK patients will experience an immediate improvement in their sight; as a result, millions of these procedures are performed. It remains to be determined whether or not there will be long term consequences for people who have had LASIK or other corneal refractive procedures as their corneas age and for this reason basic researchers in the field of corneal wound healing are concerned over the popularity of this procedure.

The Apical Squames Possess Specializations to Promote Tear Film Spreading

The apical-most epithelial surface of the cornea has flattened cells called squames. The apical surfaces of these cells have protrusions called microplicae (**Figure 1(b)**). These are specialized structures that facilitate the spreading of the tear film. The microplicae have bound to them the glycocalyx that contains the membrane-associated mucins and other glycoproteins whose functions include facilitating tear film spread. The outermost layer of the tear film is a layer of lipid molecules that increases the stability of the tear film and prevents tear evaporation. The tear film itself has several functions. It prevents the eyelids from adhering to the corneal epithelium. It is the medium through which carbon dioxide, a product of corneal metabolism, is exchanged for oxygen from the air. In addition, it contains small molecules called defensins that inhibit the growth of microbial agents. When the corneal epithelium is injured, the concentration of these defensins in tears increases transiently and then, after the wound is closed, decreases back to the levels before wounding. These data suggest that defensins play important roles in protecting the cornea from infection especially after the epithelial barrier is disrupted during wound healing. Underneath the superficial apical layer are two to three layers of cells often referred to as wing cells by corneal biologists. The final layer that sits on the basement membrane is called the basal cell layer.

The Epithelial Basal Cells Adhere to the Underlying Basement Membrane via tight Adhesive Junctions called Hemidesmosomes

The corneal basal cells maintain the tight association of the epithelium with the basement membrane through specialized adhesion junctions called hemidesmosomes. A schematic representation of the adhesion complex, including the hemidesmosomes, is shown in **Figure 2(a)** and a transmission electron micrograph is shown in **Figure 2(b)**. The hemidesomosomes form a tight rivet holding the epithelial cells on to the basement membrane and anterior stroma. Unlike adherens junctions and focal adhesions, hemidesmosomes utilize intermediate filaments rather than actin to stabilize cell adhesion and maintain cell:matrix adhesions. Hemidesmosomes must disassemble when the corneal epithelium is injured to permit the sheet of epithelial cells to move. The failure of the hemidesmosomes to disassemble during wound healing can lead to delayed wound closure, and failure to reassemble after migration is complete can lead to corneal epithelial erosions. The molecules that are present within hemidesmosomes that mediate these events are beginning to be characterized. α6β4 integrin acts as the primary mechanotransducer of forces from the basal cells to the extracellular matrix molecule laminin 332 in the basement membrane. In addition, a membrane-associated collagen, collagen XVII/BPA180, is also important for the stability of these structures. The function of these integral membrane molecules within the hemidesmosome is to associate with laminin 332, which makes up the anchoring filaments and type VII collagen that makes up the anchoring fibers. The anchoring filaments are found in the basement membrane and the anchoring fibers in the anterior corneal stroma. Thus, the hemidesmosomes are an essential part of an adhesion complex that distributes sheering forces from the cell surface to deep within the stroma. This adhesion complex includes the intra- and extracellular aspects of the hemidesmosomal plaque at the plasma membrane as well as the anchoring filaments and anchoring fibers.

The need for rapid mobilization of the corneal epithelial cells after a corneal wound combined with the sheerness of the corneal epithelial basement membrane forced a compromise during evolution: the basal surfaces of the corneal basal cells are more exposed to sheering forces from the environment compared to the basal surfaces of the basal cells in skin. The enfolding and ridges in the epidermis result in a basement membrane surface area that is increased in the basal keratinocytes relative to their lateral and apical surfaces. This provides increased protection from debridement of the epidermis. Because of the sheerness of the corneal epithelial basement membrane, it is more prone to recurrent epithelial erosions compared to the skin. However, this sheer surface also permits the corneal epithelial sheet to migrate rapidly and thereby minimizes dessication of the cornea and allows wounds to close quickly to minimize infections.

While the cells that make up the corneal epithelial basal cell layer are the most proliferative of all the corneal epithelial layers, research has shown that the cornea epithelial basal cell layer does not contain the corneal epithelial stem cells (CESCs). If the CESCs were primarily located in the central cornea, they would be exposed to the DNA-damaging affects of ultraviolet light, and, lacking pigment to absorb light energy, would sustain irreversible mutations. To maintain the corneal epithelium throughout life,

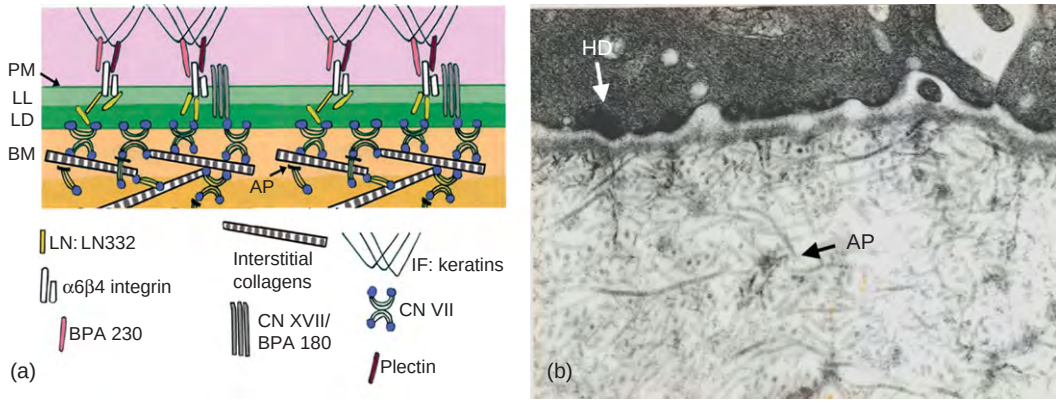

Figure 2 The adhesion complex maintains the tight adhesion of the corneal epithelium to the underlying basement membrane and Bowman's layer and is shown schematically in (a) and by transmission electron micrograph in (b). It consists of the inner plaque with keratins, plectin, and BPA230, hemidesmosomes (HD) at the plasma membrane (PM) containing α6β4 integrin and type XVII collagen (CN)/BPA180, anchoring filaments at the basement membrane zone and Bowman's layer containing laminin LN332, and the anchoring fibers and adhesion plaques (AP) containing type VII collagen. The lamina lucida (LL) and lamina densa (LD) contain type IV collagen (light green) and perlecan (dark green), respectively, in addition to numerous other proteins and proteoglycans. Type VII collagen indirectly links the intermediate filaments of the cytoskeleton to the interstitial collagens of the anterior lamellae of the corneal stroma. Adapted from Gipson, I. K. (1994). Anatomy of the conjunctiva, cornea, and limbus. In: Smolin and Thoft (eds.) *The Cornea: Scientific Foundations and Clinical Practice*, 3rd edn., Chapter 1, p. 10. New York: Little Brown and company, with permission from I. K. Gipson.

mammals maintain an epithelial stem cell population at the periphery of the cornea at an area called the corneoscleral junction or limbus. At this location, the CESCs are adjacent to a rich environment, often called a niche, which includes both melanocytes that produce melanin and absorb excess light to protect the stem cells from DNA damage, and blood vessels that release growth factors as well as immune cells. The idea that the limbus is a unique and distinct environment is supported by the fact that the composition of the basement membrane beneath the limbal basal cells is unique. It has different relative ratios of collagens and laminins compared to either the conjunctival or corneal basement membrane. Data characterizing the microanatomical relationships among the cells that make up the limbal niche are shown schematically in **Figure 3(a)**. Different integrin heterodimers have been studied as potential markers for the CESCs. **Figures 3(b)** and **3(c)** show the localization of integrins in the human and mouse limbus respectively. One integrin, $\alpha 9\beta 1$, is only expressed in the unwounded adult cornea at the limbus; detailed studies in the mouse using bromodeoxyuridine to study label retaining cells have shown that $\alpha 9\beta 1$ is not expressed on the stem cells themselves but is expressed on the cells that are the immediate progeny of the stem cells, which have been called transit amplifying cells. The CESCs have been shown to express high levels of $\alpha 6\beta 4$- and $\beta 1$-family integrins.

The Palisades of Vogt

The palisades of Vogt were first described over 90 years ago but were named by Vogt in 1921. They can be seen at the corneal periphery at the limbus by a clinician using an ophthalmoscope as shown in **Figures 4(a)–(c)**. A scanning electron micrograph of the palisades of Vogt is shown in **Figure 4(d)**. The palisades of Vogt consist of ridges of stromal tissue covered by epithelial cells. After noting their loss during progression of certain corneal disease states, recent studies have shown that the palisades of Vogt become increasingly less prominent as the cornea ages and disappear entirely in patients with conditions that are associated with CESC deficiency.

As discussed above and shown in **Figure 3**, the CESCs reside in the corneoscleral junction. These adult stem cells are small and relatively undifferentiated. Recently, *in vivo* confocal micrographs taken of human corneas as a function of age from 10- to 80-year olds show that the epithelial cells within the palisades of Vogt are smaller than those of the central cornea, that the palisades disappear with aging, and that the sizes of the corneal epithelial cells get larger as the palisades get smaller and disappear. These data are consistent with the hypothesis that the CESCs are located within the palisades of Vogt and that the aging cornea displays a progressive reduction in both the palisades and the stem-like cells that reside there. While palisades of Vogt have not been reported in non-human corneas, it is likely that similar structures are present but are not as morphologically distinct as those in the young human cornea.

Bowman's Layer Is an Acellular Zone Located Immediately under the Corneal Epithelial Basement Membrane

Bowman's layer is usually considered the second of the five layers of the cornea. It is a specialized acellular layer immediately beneath the epithelial basal cell basement membrane; in humans it is 12–18-μm thick and it begins at the corneoscleral junction. It is composed of an amorphous collection of collagen fibers intertwined with a rich collection of fine sensory nerve axons that mostly run parallel to the corneal surface. First observed in the chicken cornea, anatomically distinct Bowman's layers have been widely reported to be present only in avian, primate, and cat corneas. It can be seen in **Figure 1(a)**. Rabbits and mice were thought to lack a Bowman's layer. More recent studies suggest that Bowman's layers are found in mammalian, avian, and even fish corneas, but their thickness and composition vary significantly. The function of Bowman's layer has remained controversial primarily because there are no true markers for Bowman's layer and the lack of consensus regarding which species possess true Bowman's layers; a better understanding of what constitutes a Bowman's layer is necessary before its function can be determined. The most likely function for Bowman's layer is to enhance corneal strength and/or integrity perhaps by providing a mesh-like environment through which the thicker more uniform anterior stromal collagen lamellae insert into the type VII collagen containing adhesion complex. This insertion would link and stabilize the corneal epithelial basal cell adhesion complex in the anterior corneal stroma. A secondary function for Bowman's could be to facilitate nerve innervation of the ocular surface by providing a space through which axons can move during development.

The Collagen- and Proteoglycan-Rich Corneal Stroma with Its Stromal Cells, Descemet's Membrane, and the Corneal Endothelial Cells are all Vital to the Health of the Cornea

The third layer of the cornea is the stroma; it is transparent, compact, and fibrous and serves as a structural support. The clarity of the corneal stroma is due to the regularity of the diameter of the various collagen fibers that comprise it and the packing and specialized arrangement of these sheets, called lamellae, relative to one another. The collagen fiber spacing within and between lamellae is regulated by

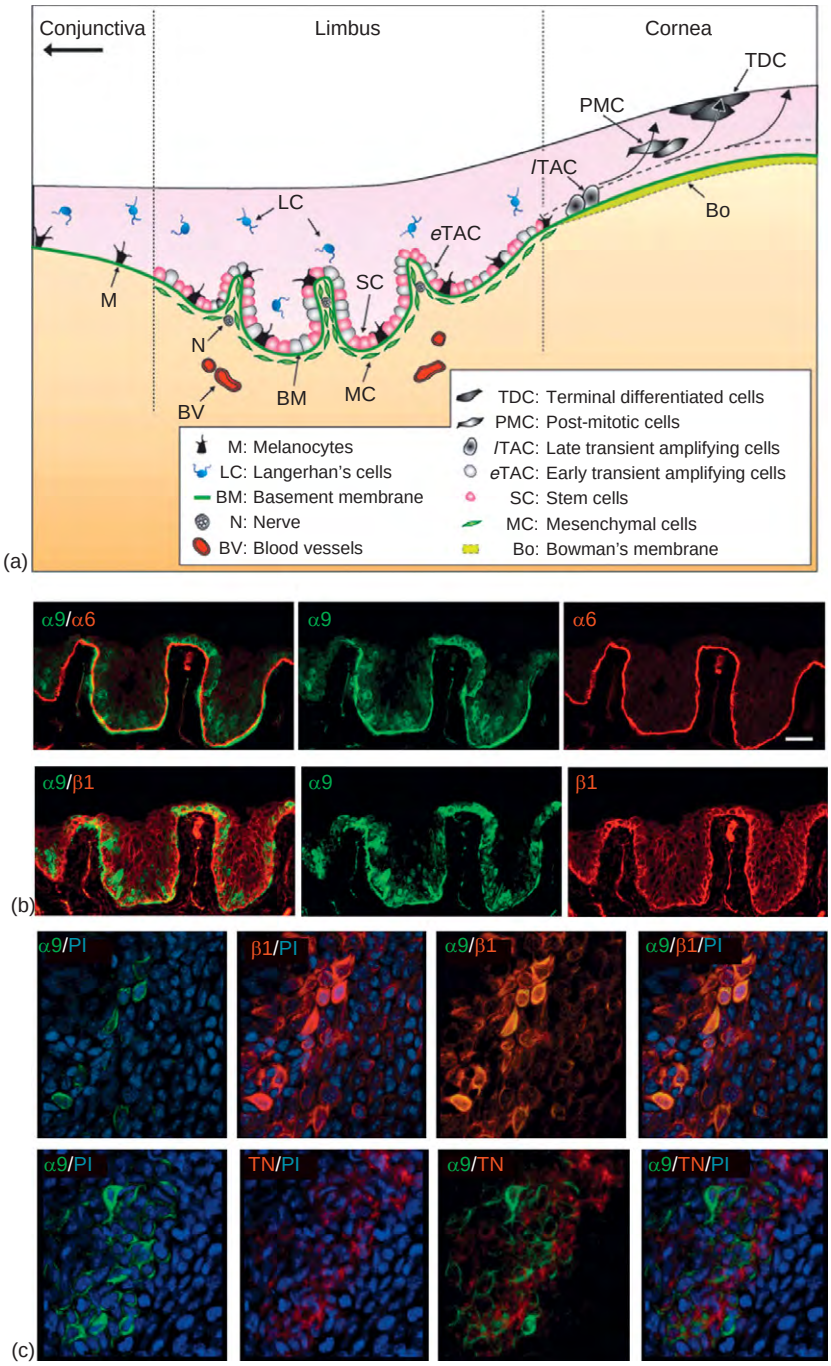

Figure 3 The CESCs are present within the limbus at the palisades of Vogt where the epithelial cells show distinctive integrin expression profiles. The schematic representation in (a) summarizes our knowledge on the different cell types reported to be involved in maintaining the stem cell niche at the limbus. (b) Cross sections through the human limbus showing the palisades of Vogt and stained (1) for α9 integrin, which is a marker for cells arising directly from division of the CESCs, and for α6 integrin, a component of the hemidesmosomes that stains the basement membrane zone at the limbus; or (2) for α9 integrin and β1 integrin, an integrin shown to be expressed at high levels on the CESCs. α9 integrin is present in subsets of the basal cells present at both apical and basal sites along the ridges. (c) En face images taken from whole flat mounted mouse corneas stained with antibodies to reveal the localization of α9 and β1 integrin or stained to reveal the localization of α9 integrin and tenascin-C, an extracellular matrix molecule present only at the limbus of the unwounded mouse cornea; nuclei have been stained with the nuclear marker DAPI. Note that there are many more β1 positive cells than α9 positive cells and that tenascin-C and α9 integrin do not appear to co-localize but rather tenascin-C is found beneath the cells that are α9 integrin positive. The magnification bar in (b) equals 25 μm and the magnification bar in (c) equals 5 μm. (a) Adapted from Li, W., Hayashida, Y., Chen, Y. T., and Tseng, S. C. (2007). Figure 4 The palisades of Vogt are undulating pigmented ridges of tissue at the periphery of the cornea at a region called the corneoscleral junction or limbus. (a–c) The ridges of the palisades can be seen *in vivo* on the ocular surface (a). They can also be seen on sheets of human corneal epithelium removed with dispase from less pigmented (b) and more pigmented eyes (c). The fact that the corneal epithelial sheets contain pigment suggests that melanocytes are present intermixed with the epithelial cells at the limbus. (d) The palisades of Vogt are revealed in detail in this scanning electron micrograph of the de-epithelialized ocular surface. (a–c) Adapted from Li, W., Hayashida, Y., Chen, Y. T., and Tseng, S. C. (2007). Niche regulation of corneal epithelial stem cells at the limbus. *Cell Research* 17: 26–36, with permission from Scheffer C. G. Tseng. (d) Adapted from Gipson, I. K. (1989). proteoglycans, including lumican, decorin, and bilycan. The proteoglycans bind and organize water molecules and constrain the spacing of the collagen fibers. The cells that produce and maintain the collagens and proteoglycans of the stromal matrix are mesenchymal cells of neural crest origin and are frequently referred to as corneal keratocytes. During wound healing, these cells become activated to become myofibroblasts and they function to facilitate wound closure.

Between the stroma and the corneal endothelial cells there is a specialized homogenous basement membrane known as Descemet's membrane. The single layers of flattened cells that make up the corneal endothelium are primarily responsible for secreting the extracellular matrix proteins that make up Descemet's membrane. They are absolutely essential for a healthy cornea. The corneal endothelial cells have numerous channel proteins in their plasma membrane that pump ions and excess water in and out of the cornea to maintain its hydration state. The clarity of the corneal stroma is readily lost if the stroma begins to dry out or desiccate. Dessication disrupts the organization of the collagen molecules by removing the ordered water molecules associated with the proteoglycans. The endothelial cells also pump nutrients from the aqueous humor into the corneal stroma. Nutrients diffuse across Descemet's membrane and then passively diffuse outward to nourish the corneal stromal and epithelial cells. Because the cornea is avascular, it requires the corneal endothelial cells to provide its nourishment. It is likely that Descemet's membrane acts as a sponge to trap nutrients delivered by the corneal endothelial cells. This would provide a sustained release of those nutrients to the rest of the cornea. In the healthy cornea, the corneal endothelial cells are more metabolically active compared to the corneal epithelium and corneal stromal cells. The generation of nutrient and ion gradients is energy dependent and these cells are constantly synthesizing channel and ion pump proteins. In contrast, in the unwounded cornea, the corneal stromal cells and the corneal epithelial cells are fairly quiescent and primarily utilize glycolysis to generate energy.

The Avascular Cornea

The healthy central cornea is avascular to permit light to fall on the retina without distortion; blood and

lymphatic vessels are present only at the corneal periphery at the limbus. Developing a better understanding of the mechanisms underlying the maintenance corneal avascularity is of extreme importance to cell biologists and many excellent studies have made progress in this area. We now know that the avascular status of the healthy cornea is maintained by the production by the corneal epithelial and stromal cells of several antiangiogenic factors, including angiostatin and endostatin. After corneal injury, corneal cells transiently produce angiogenic factors such as basic fibroblast growth factor and vascular endothelial growth factor (VEGF) disrupting the normal balance of pro- and anti-angiogenic factors and allowing for the ingrowth of blood vessels from the limbus. After healing is complete, these transient vessels undergo pruning and the avascular nature of the cornea is restored. However, prolonged inflammation or recurrent epithelial erosions can compromise corneal avascularity.

The clarity of the cornea and its accessibility has given rise to several widely used assays to assess the mechanisms underlying angiogenesis. One is called the corneal pocket assay. This assay has been used by researchers to identify factors that inhibit new blood vessel growth primarily as a tool to learn how to inhibit the growth of tumor cells in various different types of cancer. A small pellet is inserted into an incision made on the cornea surface. If the pellet contains pro-angiogenic growth factors such as FGF or VEGF, blood vessels will sprout from the limbus and grow toward the pellet. The number of vessels that form and the speed with which they move toward the pellet can be quantified, and drugs that inhibit or enhance angiogenesis can be tested. A second procedure used for similar types of studies of angiogenesis involves placing a suture on the cornea. If the suture is placed at a regular distance from the limbus then the ingrowth of vessels from the limbal vasculature can be measured and the ability of various drugs to enhance or inhibit angiogenesis can also be assessed.

Corneal Epithelium: Response to Infection

Elizabeth A Szliter-Berger and L D Hazlett, Wayne State University School of Medicine, Detroit, MI, USA

Glossary

Caspases – Humans express 11 different cysteine-aspartic acid proteases classified as either initiator or effector caspases, which play essential roles in apoptosis, necrosis, and inflammation.
CD44 – A type I transmembrane glycoprotein that regulates conformational changes of integrin heterodimers and their ability to microcluster and anchor to the actin cytoskeleton.
Desmosomes – A junctional complex of adhesion molecules and linking proteins in the plasma membrane for cell-to-cell adhesion and contributes to the structural integrity through linkage of keratin cytoskeletal filaments of adjoining cells.
Epidermal growth factor (EGF) – Expressed by corneal epithelial and stromal cells, it promotes cell migration and the attachment of corneal epithelial cells to fibronectin.
Hemidesmosomes – Integral membrane protein complexes of integrin hetrodimers in the basal cell plasma membrane anchoring cells to the extracellular matrix.
Langerhans cells – Unique subset of dendritic cells located in mucosal stratified squamous epithelium and skin epidermis; as professional antigen-presenting cells, they express toll-like receptors (TLRs) as well as C-type lectin receptors.
Melanocytes – Pigment-producing cells located within the uvea of the eye.
Nuclear factor-kappa B (NF-κB) – A protein complex that functions as a transcription factor; NF-κB is found in almost all animal cell types and is involved in cellular responses to stimuli such as stress, cytokines, free radicals, ultraviolet irradiation, and bacterial or viral antigens.
Pathogen-associated molecular patterns (PAMPs) – Small, highly conserved molecular motifs present in bacteria, yeast, or viruses but not in mammalian cells and induce inflammatory signaling via interaction with receptors families, such as TLRs.
Tritiated thymidine-labeling – Technique used to label cells actively undergoing DNA synthesis; it estimates the proportion of S-phase cells in a cell population.
Trophic – It refers to a nutrition-derived function.
Zonula occludens – Also known as tight junctions, these structures are primarily composed of occludins and claudins to form a virtual impermeable barrier between adjacent cell membranes.

Introduction

Basic Structure and Function

The corneal epithelium is a remarkably proficient tissue that combines structure and function to serve as the major refractive component of the eye and maintain ocular surface integrity; yet provide a critical barrier protecting the visual axis from the external environment. The corneal epithelium is the outermost layer of the cornea and is comprised of stratified, nonkeratinized, nonsecretory, squamous epithelial cells, intermixed with Langerhans' cells and occasional dendritic melanocytes. This tissue layer is a highly organized structure that is avascular and almost perfectly transparent in order to preserve the optical properties of the cornea. It is 5–7 cell layers thick and contains three cell types (posterior to anterior): basal cells, wing cells, and superficial cells. The deepest layer is comprised of cuboidal basal cells. This single cell layer of progenitor cells undergoes mitosis at a rate of 10–15% per day, followed by intermediate differentiation of daughter cells into one to three layers of wing cells as they migrate toward the surface. Superficial to wing cells is a three- to four-cell thick layer of terminally differentiated squamous cells. These cells constantly degenerate and desquamate from the corneal surface in a continuous cycle of shedding of superficial cells and proliferation of cells in the basal layer resulting in complete renewal of the epithelium every 7 days, as has been demonstrated by mitotic rate measurements in basal cells and by tracking the migration of tritiated thymidine-labeled cells to the ocular surface. This regenerative process is further maintained by a constant renewal of basal cells from the limbal epithelium via stem cells located in the limbus that differentiate into basal cells, followed by centripetal migration into the cornea. Although the corneal epithelium is constructed as a highly effective, semipermeable membrane on the ocular surface,

it is also well equipped to participate in the host response to invading pathogens and infection as described in greater detail below.

Corneal Infection

The corneal epithelium, similar to other mucosal epithelial linings in the body, constitutes the eye's first line of defense against microbial pathogens. The cornea has an immune-privileged status, which includes features such as avascularity of the cornea and dearth of antigen-presenting cells (APCs) in the central region of the cornea in order to protect the visual axis. Although resident dendritic cells or Langerhans cells, known for their global antigen-presenting properties, are present in the corneal periphery, they can readily be recruited into the central cornea when necessary. In addition, the corneal epithelium plays an active role in host defense against invading pathogens. Cells of the corneal epithelium: (1) recognize pathogens and their by-products and, as a result, (2) respond through expression and secretion of a network of proinflammatory cytokines and chemokines that recruit inflammatory cells into the cornea, (3) secrete antimicrobial products, and (4) promote wound healing and restoration of tissue homeostasis.

Keratitis is a condition of corneal inflammation, which can be caused by a number of bacterial, viral, and fungal pathogens. Clinically, it is associated with symptoms such as redness, tearing, reduced visual clarity, corneal discharge, and severe pain. Bacterial keratitis is the leading cause of corneal infection. Staphylococci are the most commonly occurring organisms in bacterial conjunctivitis and keratitis, including *Staphylococcus* (*S.*) *aureus*, *S. pneumoniae, S. intermedius,* and α-hemolytic streptococcus. *Pseudomonas aeruginosa* (*P. aeruginosa*) is most frequently encountered in keratitis cases associated with extended contact lens wear and constitute 19–42% of bacterial keratitis cases. Other bacteria known to cause keratitis include *Escherichia coli* and *Morganella morganii*. Common pathogens associated with viral keratitis include, yet are not limited to, herpes simplex virus (HSV) and adenovirus. HSV infection is the most common cause of corneal blindness in the United States at present time. Approximately 400, 000 people in the United States have been infected with ocular herpes and 50, 000 initial and recurring cases of HSV keratitis are diagnosed annually. *Fusarium, Aspergillus* (both filamentary fungi), and *Candida albicans* (a yeast) constitute those fungi associated with the majority of fungal keratitis cases. Sterile keratitis also incites an immune response from the corneal epithelium; however, instead of bacteria adhering to and invading the ocular surface (requisite for bacterial keratitis), the epithelium responds to the presence of bacterial endotoxin (lipopolysaccharide or LPS). Sterile keratitis can also occur when bacteria colonize contact lenses and subsequently, release endotoxin onto the corneal surface, a condition known as CLARE or contact lens-induced acute red eye.

The effects of both the invading pathogen on corneal tissue and the host immune response to the pathogen lead to many structural alterations that are otherwise essential to maintaining transparency of the cornea and, as a result, directly compromise visual acuity. As such, components of the corneal epithelium have evolved to respond to infection and these are described in greater detail below.

TLRs and TLR-Related Molecules

Toll-like receptors (TLRs) are evolutionarily conserved type I transmembrane protein receptors that are expressed by corneal epithelial cells (as well as inflammatory cells) and function to respond to pathogens as the corneal epithelium's first line of defense. These receptors initiate innate immunity and are essential for host defense against infection. TLRs recognize a broad spectrum of pathogen-associated molecular patterns (PAMPs), ranging from LPS (predominately recognized by TLR4), flagellin (TLR5), peptidoglycan (TLR2), single- or double-stranded RNA (TLR3,-7,-8), and unmethylated CpG DNA (TLR9). TLRs signal through several adaptor molecules, including the common adaptor protein myeloid differentiation factor (MyD)88 and MD-2; however, the reader is referred to Further Reading section for more information.

It has been proposed that corneal epithelial cells play a central role in regulation of inflammatory responses by expression of functional TLRs and adaptor molecules. Epithelial cells are thought to intrinsically respond to the presence of pathogens through TLR recognition of PAMPs. Of the 13 TLRs identified to date, human corneal epithelial cells have been shown to express TLR-1,-2,-4,-5,-6, and -9 either intercellularly or at the cell surface (and has yet to be fully elucidated). TLRs primarily associate as homodimers, with exceptions for TLR-1,-2, and -6, which form heterodimers. Upon recognition of PAMPs expressed by invading pathogens on the ocular surface, TLRs produce downstream signaling events which induce translocation of nuclear factor kappa B (NF-κB), a major transcription factor of numerous genes important in both innate and acquired immune responses. These genes include proinflammatory cytokines and chemokines, leading to activation of adhesion molecules, and subsequently resulting in macrophage and polymorphonuclear neutrophilic leukocyte (PMN) recruitment into the

cornea. Antimicrobial peptide expression by corneal epithelial cells is induced by TLR activation, as well. Although there is a common pathway for TLR activation (the myeloid differentiation protein–IL-1 receptor-associated kinase–tumor necrosis factor receptor-associated kinase (MyD88–IRAK–TRAF) pathway), individual TLRs most likely activate different, alternative, signaling pathways as well, and these remain under investigation (IL, interleukin).

Cytokines/Chemokines

The immune response of the corneal epithelium utilizes a variety of different substances to mount an attack upon organisms invading the ocular surface. Cytokines and chemokines are produced and endogenously released by corneal epithelial cells to directly and indirectly recruit and activate immune cells of both innate and adaptive immunity. Gram-negative bacterial endotoxin such as LPS, for example, elicit production of endogenous proinflammatory cytokines such as tumor necrosis factor (TNF)-α, interleukin (IL)-6, and IL-1. Protein levels for both IL-1α and IL-1β have been shown to be constitutively expressed in the normal human cornea. It has further been demonstrated that upon rupture of the epithelial cell membrane by infectious agents or trauma, IL-1α is passively released, contributing to increased vascular permeability, macrophage and lymphocyte infiltration and activation, angiogenesis, as well as regulatory effects on corneal fibroblasts. If left unchecked, these events would destroy the cornea; however, the epithelium also secretes both soluble and membrane-bound forms of IL-1RII, a receptor and natural antagonist of IL-1 in order to modulate the effects of this potent proinflammatory cytokine and consequently preserve visual function.

In addition to IL-1, *in vitro* studies using primary human corneal epithelial cells (HCECs) and telomerase-immortalized HCECs have revealed expression and secretion of IL-6, IL-8, and TNF-α following either *P. aeruginosa* or HSV-1 challenge. TNF-α is a major proinflammatory mediator that is known to promote apoptosis, inflammation, and regulate immune cells. IL-6 is both a pro- and anti-inflammatory cytokine that can potentiate the inflammatory response, yet also modulate inflammation through its inhibitory effects on TNF-α and IL-1, while activating IL-1 receptor antagonist and IL-10. IL-8 is a chemokine that is secreted by the epithelium under stress and functions as a strong chemoattractant for neutrophils (PMN); MIP-3α, also released by corneal epithelial cells after infection, promotes directed migration of leukocytes, such as immature dendritic cells and effector T cells. TGF-α,-β1, and -β2 are expressed also by corneal epithelial cells and contribute to re-epithelization, an essential step in resuming normal corneal function after infection. TGF-β1, in particular, is a potent anti-inflammatory cytokine that modulates lymphocyte activation and promotes wound healing; regarding the cornea, it is further known to promote proliferation and lamellar differentiation of corneal epithelial cells via keratocyte-mediated stimulation.

Antimicrobial Molecules

The corneal epithelium also employs the action of small (100 amino acids or less), positively charged (arginine- and lysine-rich) molecules known as antimicrobial peptides to further assist in combating invading pathogens. Over 500 naturally occurring antimicrobial peptides have been identified in mammals. Typically these molecules are cationic polypeptides that disrupt bacterial membranes through charge interactions and hydrophobic amino acids. Many antimicrobial peptides and their microbicidal effects are induced locally by inflammatory stimuli at the site of infection and act synergistically with other anti-inflammatory mechanisms (cytokines, inflammatory cells) in defending against microbial pathogenesis. Of the four distinct structural classes of antimicrobial molecules, recent studies have shown that corneal epithelial cells secrete peptides from the defensin and cathelicidin families, which are thought to help protect the eye through broad spectrum activity against microorganisms including Gram-positive and -negative bacteria, fungi, and certain enveloped viruses. These molecules and their roles in preventing microbial invasion and managing infection are discussed in greater detail below.

β-Defensins

The defensins include α- and β-defensin subfamilies, all of which are characterized by a β-sheet-rich fold and three disulfide bridges. A third class of θ-defensins has been recently identified in rhesus macaque leukocytes. Although θ-defensin mRNA is detectable in humans, these transcripts contain a premature stop codon preventing translation of functional protein. Leukocytes (PMN) and various types of epithelial cells have been shown to express both α- and β-defensins; however, the corneal epithelium has been demonstrated to produce and secrete only members of the β-defensin subfamily.

Human β-defensins (hBDs) include 28 members, of which three have been associated with the corneal epithelium. Human β-defensin-1 (hBD-1) is constitutively expressed by corneal epithelial cells; while studies have shown that hBD-2 is induced by bacterial infection and bacterial products such as lipoprotein and lipotechoic acid, and is mediated by TLR2. In addition, cytokines TNF-α and IL-1 upregulate hBD-2 expression by corneal epithelial cells. Expression of hBD-3 is more variable,

whereby some studies have indicated solely constitutive expression by corneal epithelial cells; and others have demonstrated inducible expression by TNF-α and interferon-gamma (IFN-γ). Regardless, hBD-3 was shown by McDermott and colleagues to exert most potent antibacterial activity against *S. epidermidis*, *S. aureus,* and *P. aeruginosa* using *in vitro* antimicrobial assays, followed by hBD-2; while hBD-1 showed moderate activity against *Pseudomonas*, but no activity against *Staphylococcus* strains. *In vivo*, it was recently demonstrated that murine (m) BD2, but not mBD1, was protective in the *P. aeruginosa*-infected mouse cornea. The importance of these antimicrobial peptides has been demonstrated by knocking out the mouse β-defensin-1 gene, which led to less effective clearance of *Haemophilus influenzae* from the lung and increased colonization of *Staphylococcus* in the bladder.

Cathelicidins

Of the numerous members of the cathelicidin family, only LL-37 has been described in humans. Cathelicidins express a highly conserved cathelin domain and a less conserved, more variable antimicrobial region. LL-37, as its name suggests, is a 37-amino acid linear peptide expressed by inflammatory/immune cells and epithelial tissue. It is derived by cleavage of the precursor, human cationic antimicrobial protein 18 (hCAP18) and appears to function as both an antibacterial peptide and immunomodulator. Low expression levels of LL-37 are detected constitutively and subsequently upregulated following injury, infection, and exposure to IL-1β, as well as heat-killed *P. aeruginosa.* Regarding antimicrobial properties, LL-37 is thought to function in a similar manner to that described for defensins and work synergistically with corneal epithelial proteins such as defensins, lactoferrin, and lysozyme (latter two present in tear film). LL-37 is able to bind and neutralize LPS and lipotechoic acid, thus reducing the inflammatory response associated with these molecules. In addition to eradicating ocular pathogens, studies have demonstrated that LL-37 enhances the innate and adaptive immune response in the corneal epithelium through modulation of cytokine/chemokine expression. Using an *in vitro* stimulation assay, LL-37 was shown to induce production of IL-1β, IL-6, IL-8, and TNF-α by human corneal epithelial cells. Furthermore, this molecule promotes wound repair through enhanced cell migration, including fibronectin-induced migration by stimulating corneal epithelial cells.

In addition to microbicidal activities of β-defensins and LL-37, these molecules also wield effects over immune cells and influence wound healing. They have been demonstrated to recruit and activate immune cells through the induction of cytokine and chemokine production by epithelial cells, which further actuate the cellular components of the immune response to corneal infection. Regarding postinfection, both hBD-2 and LL-37 have been shown to be upregulated in an *in vitro* organ culture model of corneal epithelial wound healing suggesting roles for corneal epithelial cell migration and proliferation.

Complement System

The complement system also contributes to the first line of innate immune defense against corneal infection. This critical system is composed of a series of effector and regulatory proteins that sequentially activate one another to generate biologically active molecules, such as opsonins and chemotaxins. The complement system is continuously activated at low levels in the eye under normal conditions, as supported by detection of soluble and membrane-associated complement regulatory proteins (e.g., rsCD59), which are also strongly expressed in the corneal epithelium for tight regulation of aberrant activation. Components of complement are also more heavily distributed in the peripheral versus the central cornea, potentially due to the diffusion of complement molecules from corneal limbal vessels. In response to infection activation of complement can occur via both the classical and alternate pathways.

Secretory IgA

Although this molecule is not essential in ocular defense, secretory IgA (sIgA) does play a major role in the prevention of some corneal infections, including *Pseudomonas* and *Acanthamoeba.* In fact, over 75% of the general population contain anti-*P. aeruginosa*-specific IgAs in their tear film. sIgA protects the corneal epithelium by accumulating in the ocular mucin layer and displays an antigen–antibody clearance function. Aggregated sIgA opsonizes bacteria for PMN phagocytosis and processing via recognition by sIgA receptors expressed on the immune cell surface. IL-8, which is secreted by corneal epithelial cells during infection, further enhances the ability of sIgA to induce release of reactive oxygen species by PMN.

Adhesion Molecules

Under normal conditions, integrity of the corneal epithelium depends upon a number of factors, including adhesion molecules. Corneal epithelial cells are interdigitated, particularly in the middle layers, and largely interconnected by desmosomes. Basal cells are firmly attached to the basement membrane, neighboring basal cells and overlying wing cells via hemidesmosomes. Tight junctional complexes, or zonula occludens, found only between superficial cells are

of great importance regarding the barrier function of the corneal epithelium. As such, superficial cells form a highly effective, semipermeable membrane on the corneal surface. Not only does the tight junctional barrier prevent decreases in net fluid transport out from the stroma, but it also prevents corneal penetration by pathogens. In addition, gap junctions connect the cells of all layers of the corneal epithelium and function as communication conduits between cells. These tight anatomical arrangements with virtual absence of intercellular spaces contribute to the remarkable transparency of the epithelium, but have deleterious effects when breached after infection (or wounding) and must be restored forthwith in order to restore/preserve visual function.

Upon infection of the corneal epithelium, breakdown of tight junctional integrity occurs due to the loss or disruption of the outermost layers of the epithelium by invading pathogens. This results in a collapse of cell membrane permeability and selectivity, in addition to creating an unrestricted portal for further pathogen intrusion into the cornea until the corneal epithelium and its adhesion molecules are regenerated. Additional adhesion molecules such as selectins, intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1), are modified after infection due to the secretion of epithelial-derived cytokines, such as TNF-α. As a result, these barriers are further breached to allow the transmigration of inflammatory cells into the injured or infected tissue site. Recruitment of activated leukocytes to sites of infection is essential to the function of both inflammation and innate immunity. However, the extent of leukocyte recruitment contributes largely to the intensity of the inflammatory response, and if this is not well balanced it can result in considerable tissue damage. However, the corneal epithelium does play an active role in regenerating and repairing itself after infection.

CD44 is among the molecules that corneal epithelial cells express to mediate wound healing after infection. This molecule is thought to be involved in cell–cell interactions that provide adhesive strength for the epithelial sheet and in cell–matrix interactions that occur during cell migration and the re-epithelialization process. Basal cells of the corneal epithelium have been demonstrated to secrete APLP2, an amyloid precursor-like protein that is suggested to influence reorganization of the extracellular matrix and dynamic cell–matrix adhesion during re-epithelialization. It has been demonstrated that the corneal epithelium (as well as stromal and endothelial cells) produces and secretes epithelial growth factor (EGF), which is thought to promote cell migration and mitosis of epithelial cells. Corneal epithelial cells then resume expression of molecules such as connexins 45/43 and $\alpha 6\beta 4$ integrin, which participate in the formation of gap junctions and hemidesmosomes/desmosomes, respectively, thus restoring homeostasis of an intact corneal epithelium.

Neuropeptides

Innervation of the Corneal Epithelium

The cornea is among the most densely innervated tissues in the body. In regards to the corneal epithelium, the subbasal epithelial nerve plexus originates from the ophthalmic division of the trigeminal nerve via the anterior ciliary nerves and provides innervation to the basal epithelial cell layer and terminates within the superficial epithelial layers. These nerve fibers are predominately sensory (most classified as nociceptors) and serve a protective role, typically responding to mechanical, thermal, and chemical stimuli. They are stimulated during corneal abrasions and ulcers, and are extremely painful. It is estimated that single corneal sensory neurons support approximately 200 and 3000 individual nerve endings in the mouse and rabbit, respectively, demonstrating the high density of innervation in the corneal epithelium. Corneal nerves in the epithelium have a trophic function, as well. In addition, neuropeptides have been associated with corneal nerves and include: substance P (SP), calcitonin gene-related peptide (CGRP) and vasoactive intestinal peptide (VIP), pituitary adenylate cyclase activating peptide (PACAP), and neuropeptide Y (NPY) among others. Nerve damage can lead to transient or chronic neurotrophic deficits following infection of the corneal epithelium. Corneal denervation also significantly impairs the ability of the corneal epithelium to heal itself and predisposes newly healed corneas to periodic, spontaneous epithelial erosions. Although the nerves coursing through the human corneal epithelium are known to produce a variety of neuropeptides, the following sections focus on the importance of two of these molecules: SP and VIP.

Substance P

SP is an 11-amino acid neuropeptide that is largely associated with proinflammatory events during corneal infection, including upregulation of TLR4 and TLR9 mRNA and of cytokines/chemokines IL-1β, TNF-α, IFN-γ, and MIP-2 as demonstrated in a murine model of *P. aeruginosa*-induced keratitis. Physiologically relevant concentrations of SP are present in the normal human (and mouse) cornea and corneal epithelial cells express the NK1 receptor, which is the major physiological receptor for SP. The neuropeptide also has been associated with wound healing properties and together with insulin-like growth factor-1 (IGF-1) has been demonstrated to have a stimulatory effect on corneal epithelial cell migration, adhesion, and wound closure.

Vasoactive intestinal peptide

VIP is a 28-amino acid neuropeptide that exerts immunomodulatory properties in the cornea following infection.

It has been demonstrated in a murine model of *P. aeruginosa*-induced ocular infection that VIP downregulates the production of several proinflammatory cytokines, including: TNF-α, IL-1, IL-6, IL-12, and IFN-γ, while stimulating the production of anti-inflammatory cytokines IL-1 receptor antagonist, IL-10, and TGF-β. Macrophage and PMN activation was also shown to be influenced by the presence of VIP. Studies in the mouse further support a role for VIP in wound healing and restoration of immune homeostasis in the cornea; however, it has yet to be determined the extent of which is carried out by the epithelium versus stroma.

Thymosin-β4

As previously stated, after eradication of the invading pathogen, the corneal epithelium must heal and promptly resume normal activity. Thymosin (T)β-4 is a 43-amino acid protein produced by corneal epithelial cells that contributes to the resurfacing of the epithelium and regeneration of cell adhesion molecules to reconstitute the epithelial barrier. Studies have shown that Tβ-4 levels are increased in murine corneas during re-epithelialization and also significantly enhance the migration of human corneal epithelial cells through upregulation of molecules associated with cell migration, including laminin-5 and matrix metalloproteinase 1 (MMP-1). Furthermore, Tβ-4 modulates corneal cytokine production in an anti-inflammatory manner by downregulating levels of MIP-2 and TNF-α, as demonstrated in the murine cornea. Tβ-4 has been demonstrated to inhibit apoptosis of human corneal epithelial cells through inhibition of caspases and suppression of Bcl-2 (an antiapoptotic factor) release from mitochondria. Lastly, this molecule has been demonstrated to modulate matrix metalloproteinase expression and prevent PMN infiltration in an alkali injured mouse cornea model, further supporting a key role for Tβ-4 in the repair and remodeling of the injured cornea.

Conclusion

The cornea generates approximately 80% of the eye's refractive power; therefore, it is imperative that the corneal epithelium possess the ability to effectively and appropriately activate an innate immune response when pathogens are encountered on the ocular surface. The protective mechanisms employed by the epithelium have evolved to balance recognition and elimination of pathogens while limiting corneal damage and preserving the visual axis. In order to do so, the corneal epithelium is able to recognize invading organisms through TLR signaling, generate a network of cytokines and chemokines to recruit and activate host inflammatory cells, produce antimicrobial molecules, and provide activation signals to the complement system, all of which coalesce into an effective and efficient immune response as depicted schematically in **Figure 1**. The corneal epithelium also possesses the ability to regenerate itself and promote wound healing through expression and secretion of adhesion molecules and Tβ-4; this process is enhanced by the presence of corneal nerve fibers that release neuropeptides such as SP and VIP, molecules that further contribute to the healing process and restoration of tissue homeostasis.

Glossary

Barrier – Protein-containing formations between cells in the more superficial layers of the corneal epithelium to prevent infiltration of pathogens into the underlying stroma.
Deturgescence – Physiological state of corneal hydration required for optimal transparency.
Electrochemical equilibrium – Membrane voltage and intracellular ionic activity at which there is no net flux of a specific ion across a membrane.
Net flux – Algebraic difference between unidirectional ionic fluxes across a membrane, which is indicative of active ion-transport activity.
Transient receptor potential protein – Membrane proteins in a superfamily of 27 different genes that arrange themselves in tetrameric configurations to form plasma membrane channels, which can be activated by a large variety of stimuli.

Introduction

Corneal epithelial ion transport and permeability underlie the ability of this tissue to maintain corneal transparency. In this article, we describe how different types of receptors modulate through second messenger-signaling control of ion transporter function and cell membrane permeability. Figure 1 depicts a schematic summarizing the current picture of ion transporters and channels mediating control of cornea epithelial renewal and tissue transparency. To provide insight into the outcome of dysregulation of transporter activity and permeability, we discuss strategies that may circumvent these pathophysiological consequences.

The cornea provides about 75% of the total refractive power required for normal vision. This function depends on the ability of the cornea to remain transparent. The corneal epithelial layer undergoes continuous renewal every 14–28 days. This process preserves its integrity and assures that the cornea is protected from environmental pathogenic infiltration. Such protection is provided by tight junctional continuity forming a moderately high resistance barrier between neighboring cells. This resistance is essentially only selectively permeable to low-molecular-weight ionic species. As the epithelial top layers continuously undergo terminal differentiation followed by being sloughed off, the maintenance of tight junctional integrity is critical for the corneal epithelial to provide its barrier function. Any disruption of upper cell layer apposition that is not rapidly repaired through wound healing renders the cornea vulnerable to infection, swelling, and opacification leading to losses in visual acuity. Losses in tissue transparency occur since swelling of the corneal ground substance leads to disruption of extracellular matrix organization and an irregular corneal surface. These changes cause impinging light to be reflected or scattered, instead of being refracted. Therefore, studies directed toward understanding how the corneal undergoes continuous renewal are relevant for delineating strategies to restore corneal transparency in a clinical setting.

Corneal Hydration Control and Transparency

In humans, the cornea is approximately 500–550 μm thick and is composed of three layers: epithelium, stroma, and endothelium. These tissues have different embryonic origin. Corneal thickness is dependent on the hydration state of the stromal ground substance, whose physiochemical properties cause continuous fluid imbibition. Excessive fluid uptake by the stromal ground substance lying between collagen lamellae results in corneal swelling and opacity.

The stromal ground substance continuously imbibes fluid from the tears and the aqueous humor in the anterior chamber facing the endothelium. This imbibing process is equivalent to a negative pressure of approximately −60 mmHg. In order for this suction effect not to lead to excessive swelling, it is essential that the corneal epithelium, in concert, with the underlying endothelial layer mediate osmotically coupled water flow outward from the stroma through net ion transport. The endothelial layer facing the anterior chamber provides most of the dehydrating function whereas the epithelial layer contribution is relatively minor. In other words, epithelial layer-mediated net fluid transport toward the tears from the stroma appears to play a fine-tuning role in maintaining a state of corneal hydration commensurate with normal vision. Nevertheless, under stimulated conditions, the rabbit epithelial layer can provide up to 25% of the total

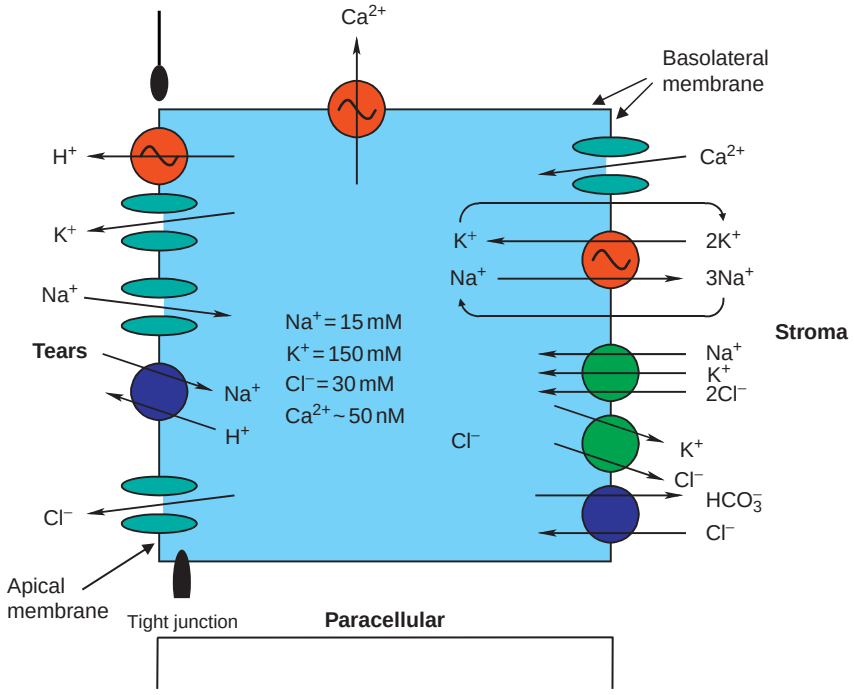

Figure 1 Current model describing ion transporters and channels in corneal epithelium: Arrow heads point in directions of net fluxes. At the tear-side facing apical membrane, there is a Na^+:H^+ exchanger and a conductive pathway for net Cl^- and K^+ efflux. There is also Na^+ entry at this membrane. At the stromal and paracellular sides is the basolateral membrane. It has a K^+ efflux pathway along with the Na^+–K^+ pump coupled to an electroneutral Na^+:K^+:2Cl^- cotransporter. A Cl^-:HCO_3^- electroneutral cotransporter and a Ca^{2+} channel reflective of different subtypes are shown. A K^+:Cl^- cotransporter is also indicated.

dehydrating function. However, if the epithelial layer integrity is damaged, fluid leakage from the tears cannot be compensated by the dehydrating function of the innermost endothelial layer. In this case, the stroma will continuously swell. Therefore, epithelial wound healing through cell proliferation, migration, and tight junction renewal is crucial for maintaining the corneal barrier function.

Importance of Transport Mechanisms to Epithelial Function

The corneal epithelial electrical resistance is dependent on the intactness of its tight junctions forming appositions in the upper layers of the epithelial functional syncytium. In order to provide an effective barrier function, the electrical resistance of the corneal epithelium has to be relatively high (i.e., at least 1 kΩ cm^2). In addition, the ability of the epithelium to mediate net ion transport from the stroma into the tears is dependent on tight junctional resistance. If the resistance falls due to injury, there is a corresponding decrease in net ion transport, resulting in compromise of the barrier function followed by a decline in osmotically coupled fluid flow toward the tears.

In all species studied, the corneal epithelial layer elicits secondary active chloride (Cl^-) transport from the stroma to the tears whereas net sodium (Na^+) transport occurs in the opposite direction, from the tears to the stroma. There is variability in the magnitude of active Na^+ transport due to differences in the Na^+ permselectivity of the tear-side-facing apical membrane. In rabbits and humans, the relative Na^+ and Cl^- permeabilities are similar to one another whereas in the amphibian this membrane is essentially Cl^- permselective. There is large variability among different species with regard to the ratio between tear-directed Cl^- transport and stroma-directed Na^+ transport. In the rabbit and human, this ratio under baseline conditions is about 50%, whereas in the amphibian (i.e., toad and bullfrog) it is at least 90%. Despite such differences, osmotically coupled fluid flow across this layer has been identified both in the isolated rabbit and amphibian cornea suggesting that net Cl^- fluxes toward the tears exceed stroma-directed Na^+ fluxes.

Corneal transparency is dependent on net influx and efflux of inorganic and organic osmolytes. For example, amino acid uptake mechanisms have been identified in this tissue. By definition, an active uptake mechanism depends on metabolic energy generated by aerobic and anaerobic metabolism. Its metabolic dependence is evident, since exposure to metabolic inhibitors results in

corneal swelling and the development of opacification. These changes occur because corneal deturgescence (i.e., physiological hydration state) and maintenance of epithelial health are dependent on the ability of this tissue to: (1) elicit osmolyte and drug extrusion against opposing electrochemical gradients and (2) accumulate organic substrates to levels above those in the extracellular bathing solution. This array of very different transport functions are performed by transporters of distinct ionic and substrate selectivity.

Primary and Secondary Ionic Transport Mechanisms

The corneal epithelial cells express both primary and secondary ionic transport mechanisms. As in all epithelial cells, Na^+:K^+ ATPase expression occurs along the basolateral membrane facing the stroma and the paracellular pathway between the neighboring epithelial cells. This transport mechanism is primary since its ATPase activity directly elicits electrogenic Na^+ extrusion into the stromal and paracellular media. Such efflux is coupled to intracellular K^+ accumulation above its predicted electrochemical value. On the other hand, secondary ionic transporter function is driven by the Na^+ and K^+ electrochemical gradients established by Na^+:K^+ ATPase activity. In all species, there is Na^+:K^+:$2Cl^-$ co-transport activity in the basolateral membrane, which is reflective of secondary active ion transport function. This cotransporter functions to accumulate intracellular Cl^- to levels above its predicted electrochemical values. Net Cl^- transport into the tears occurs as a consequence of its efflux by electrodiffusion across the tear-side facing essentially Cl^- permselective apical membrane. In order to maintain charge neutrality, Na^+ moves in parallel as a counter ion through the paracellular pathway.

Another primary active ion transporter identified in the corneal epithelium is the H^+ pump. Its activity in combination with two different types of cotransporters is required for mediating regulation of intracellular pH. These cotransporters are Cl^-:HCO_3^- and Na^+:H^+ antiporters whose transport directionality is determined by the electrochemical gradients of the involved ions. Specifically, the Cl^-:HCO_3^- antiport will drive HCO_3^- out of the cell, provided there is sufficient carbonic anhydrase activity to raise intracellular bicarbonate levels above those in the external medium. Under such conditions, Cl^- will be taken up from the stroma into the cell interior in exchange for bicarbonate efflux into the external medium. In this scenario, intracellular pH falls resulting in increases in the activity of two different alkalinizing mechanisms: Na^+:H^+ antiport activity in combination with H^+ pump ATPase activity. The Na^+:H^+ antiport can provide an alkalinizing function if the Na^+:K^+ pump activity is sufficient to establish a steep enough Na^+ gradient between the external milieu and the intracellular compartment to exchange H^+ from the cell interior for downhill Na^+ movement into the cell interior.

Cl^- efflux out of the epithelial cells across the apical membrane is dependent on membrane voltage electronegativity relative to the bathing solution. Numerous studies have shown that the intracellular membrane voltage is about -50 mV. This value is dictated to a large extent by the activity of the electrogenic Na^+:K^+ pump and the relative K^+ permeability of the basolateral membrane. The electrogenic Na^+:K^+ exchange pump contributes since its pump Na^+:K^+ stoichiometry exceeds a value of 1. In other words, with each pump cycle, more Na^+ ions are extruded than K^+ ions are taken up into the cell interior from the stroma. In any case, due to the activity of the Na^+:K^+ pump, Cl^- is accumulated into the epithelial cells above its predicted electrochemical equilibrium value. In turn, K^+ diffuses downward and outward, essentially across the basolateral rather than the apical membrane since the former barrier has a much higher K^+ permselectivity. This downward movement of K^+ establishes a negative membrane voltage which is dependent on the activity of the Na^+:K^+ pump and the relative basolateral membrane K^+ permeability. Another factor affecting the level to which K^+ is elevated above electrochemical equilibrium is the tightness of coupling between the Na^+:K^+:$2Cl^-$ cotransporter and the Na^+:K^+ pump. Stimulation of the Na^+:K^+:$2Cl^-$ cotransporter may occur as a consequence of increases in Na^+:K^+ pump activity leading to enhancement of intracellular K^+ accumulation. A rise in K^+ can then be compensated for by a rise in basolateral K^+ membrane permeability, which will increase outward directed K^+ efflux and the membrane voltage electronegativity. This chain of events will stimulate net Cl^- efflux from the stroma into the tears since the driving force for Cl^- efflux into the tears, across the highly Cl^- permselective apical membrane, is the magnitude of the membrane voltage electronegativity.

Therefore, it is through the concerted activity of the aforementioned transport mechanisms, along with appropriate regulation of the cell-limiting membranes, that the corneal epithelium can elicit net Cl^- transport from the stroma toward the tears and regulate its intracellular pH within bounds that are required for the maintenance of anterior ocular surface health.

Coupling of Ionic Transport Mechanisms to Stromal Deturgescence

It is commonly thought that the driving force for fluid transport out from the stroma across the epithelial cells into the tears is local osmosis. The fact that the corneal epithelium elicits net Cl^- transport into the tears suggests

that this ionic flux may be sufficient to account for the magnitude of outward-directed fluid transport. This expectation has been proven to be correct since, under open circuit conditions, net Cl^-transport is commensurate with measured isotonic fluid transport. The dependence of transepithelial fluid transport into the tears on net Cl^- transport was validated by showing that drugs which either stimulate or inhibit net Cl^- transport have corresponding effects on fluid transport.

The fact that there is a coupling between fluid and net Cl^- transport prompted investigators to probe for receptor-mediated control of net Cl^- transport since corneal epithelial health is dependent on innervation of this tissue. This dependence suggests that neurotransmitter release from nerve endings mediate – through receptor stimulation – responses supportive of corneal epithelial functions. Such a notion was validated by showing that loss of neural input results in impaired corneal epithelial regeneration and recurrent erosion. Accordingly, it has also been shown that the corneal epithelium expresses receptor subtypes responsive to adrenergic and cholinergic agonists released from sympathetic and parasympathetic branches of the autonomic nervous system. Other studies indicated that stimulation of these receptors elicit regulation of corneal epithelial renewal, ion transport activity, transparency, and fluid transport.

The regulation of cell volume by the aforementioned ionic transport mechanisms underlies the ability of the corneal epithelium to elicit net fluid transport from the stroma into the tears. It is possible that fluid transport is dependent on serial repetitive swelling and shrinking of cell volume. In this way, swelling occurs as a result of initial stimulation of net osmolyte uptake. Such rises occur in response to increases in Na^+:K^+ pump activity leading to rises in sodium chloride (NaCl) and potassium chloride (KCl) uptake through the Na^+:K^+:$2Cl^-$ cotransporter. As a consequence of an increase in osmolyte uptake, fluid flow into the cells increases. Subsequently, the epithelial cell volume decreases as a result of stimulation of ionic efflux (i.e., KCl) into the tears. The swelling response is referred to as regulatory volume increase (RVI) due to increases in NaCl and KCl uptake. Subsequent shrinkage occurs as a consequence of RVI and is dependent on increases in KCl efflux leading to osmotically coupled fluid loss. This cell shrinkage is known as regulatory volume decrease (RVD). Therefore, fluid transport is tightly regulated by alternating stimulation and inhibition of osmolyte uptake and efflux into the corneal epithelium. How such tight and time-dependent control of these different transport mechanisms is mediated is unknown. It may be dependent on the ability of different receptor types to elicit – through a variety of second messenger pathways – rapid changes in the activities of these ion transporters mediating alternating RVI and RVD responses.

In addition to mediating fluid transport under isotonic conditions as a possible result of differential activation and inhibition of ion-transport activity and membrane permeability, RVD and RVI responses can be induced through variations in bathing solution osmolarity similar to those encountered in daily living and those identified in some types of dry eye disease. In order for cell volume regulatory responses to change fluid transport rates and thereby maintain corneal homeostasis, despite being exposed to an environmental hypertonic or hypotonic challenge, it is also necessary to have a coordinated regulation of ion transporters and parallel cell membrane permeability. Such regulation occurs through receptor-mediated events that can modulate ion transporter rates to either increase or decrease net ionic influx or efflux from corneal epithelial cells. These receptors elicit control of ion transporter function and cell permeability through second messengers that either concomitantly increase or inhibit ion transport rates through stimulation or inhibition of active ion transporter, cotransporters, and cell membrane permeability.

Such coordinated control is required for the maintenance of corneal transparency since they underlie RVD and RVI responses driving fluid out of stroma into the tears. Depending on the type of osmotic challenge, these responses sustain corneal epithelial barrier function. However, in individuals afflicted with dry eye disease, one problem is compromise of barrier function leading to stromal infection. Even though, in these patients, there may be activation of a RVI response due to chronic exposure to hypertonic tears, it may not be adequate to restore isotonic cell volume resulting in disruption of barrier function. This suggestion has prompted a host of studies over the last 30 years that are focused on characterizing receptor-mediated regulation of corneal epithelial active ion transport underlying regulatory volume responses. Their results have pointed investigators in directions that may lead to the identification of novel strategies for improving the rates of corneal epithelial renewal as well as restoring its transparency and refractive properties following an injury.

Other Transport Mechanisms

The limited corneal epithelial layer permeability presents a formidable barrier to solute and drug permeation into the ocular interior. This hindrance has prompted efforts to probe for the expression of transporters that could facilitate their uptake into the eye. A number of different transporters were identified that can elicit this effect. They include a carnitine/organic cation transporter and a sodium-dependent amino acid transporter. On the other hand, rather than identifying a drug-influx mechanism,

a multi-drug-resistant (MDR)-1 efflux mechanism has been described. Such an efflux process does not promote drug uptake into the ocular interior if they are substrates for the MDR-1 pumps. Therefore, improving drug delivery into the ocular interior is in most cases focused on increasing their hydrophobicity so that they can more readily permeate by membrane diffusion. One example of such an improvement is exemplified by rendering epinephrine more lipid soluble through its derivatization with a lipid. An alternative is to inhibit MDR-1-elicited drug efflux. However, none of the currently used inhibitors have adequate selectivity for this purpose.

Receptor-Mediated Control of Corneal Epithelial Ionic Transport Functions

Adrenergic subtype (α_1, α_2, and β), serotonergic, and cholinergic receptor-linked functions have been identified in the corneal epithelium. Adrenergic receptors mediate their control of ionic transport and membrane permselectivity through second messenger pathways involving increases in intracellular Ca^{2+} and modulation of adenylate cyclase activity. Such variations change either the basolateral or apical membrane permeabilities resulting in modulation of active Cl^- transport through changes in the intracellular potential difference. For example, β-adrenergic receptor stimulation has a corresponding effect on net Cl^- transport by enhancing K^+ basolateral membrane permselectivity as well as increasing Cl^- electrodiffusion across the apical membrane into the tears. Less is known about the signaling pathways eliciting cholinergic and serotonergic receptor control of net ion transport.

The corneal epithelium and accessory anterior ocular tissues express a host of cytokines that are critical to the maintenance of corneal epithelial functions. In particular, cytokine expression is critical for inducing control of cell proliferation, migration, and terminal differentiation. Their importance has become self-evident from studies on the mechanisms of corneal epithelial wound healing induced by injury. Numerous cytokine expression levels are upregulated to hasten corneal epithelial wound healing through stimulation of cell migration and proliferation. Such a realization has heightened the interest in determining the mechanisms of regulation of cell-signaling pathways linking their cognate receptor activation to these responses. It is believed that these studies will identify potential drug targets to improve in a clinical setting the outcome of injury-induced corneal wound healing.

Active ion transporters and membrane channels underlying receptor activation are components of a myriad of cell signaling pathways that mediate cytokine receptor control of epithelial renewal. One of the most potent and efficacious mitogens hastening corneal epithelial renewal is epidermal growth factor (EGF). This mitogen induces increases in cell proliferation and migration through stimulation of different ion-transport mechanisms, ionic permeabilities, and receptor-linked channels. They include increases in the activity of the basolateral membrane localized Na^+:K^+:$2Cl^-$ cotransporter resulting from stimulation of plasma membrane Ca^{2+} influx and activation of the mitogen-activated protein kinase (MAPK) superfamily. The increase in Ca^{2+} influx through a Ca^{2+} channel is dependent on EGF receptor (EGFR)-induced stimulation of membrane-associated phospholipase C (PLC) followed by hydrolysis of a phosphoinositide to induce Ca^{2+} release from an intracellular Ca^{2+} store. Another ionic influx affected by EGFR stimulation is K^+ efflux through the basolateral membrane. In addition, mitogenic responses to EGF require that during cell-cycle progression cell volume is modulated to accommodate increases in the parent cell of genomic content prior to cell division. Such modulation is, in part, dependent on changes in K^+:Cl^- cotransporter expression and activity. Another example of a cytokine whose induced effects are dependent on modulation of channel activity is the tumor necrosis factor-alpha (TNFα).

Cell-Volume Control and Epithelial Renewal

Epithelial renewal is a dynamic process that is dependent on tight regulation of cell volume. Prior to cell division, volume expansion of a parent cell is required to accommodate doubling of the nuclear and cytoplasmic components in preparation for their equal distribution into daughter cells. Similarly, changes in cell volume are requisite for cell migration, as this process involves repeated and coordinated leading-edge cytoplasmic volume extension, along with retraction at the opposite pole. As modulation of ion-transport activity and membrane permeability underlie changes in cell volume, cytokine-induced control of renewal is, therefore, dependent upon modulation of ionic influx and efflux. Such control requires that there is synchronized release of specific cytokines that alter ion transport at appropriate times during the cell cycle. Numerous cytokines mediate the required regulation for error-free proliferation and migration. Therefore, cytokine receptor control of ion transport activity is of critical importance in the maintenance of corneal epithelial renewal, transparency, and its refractive properties.

Ca^{2+} Channel and Pump Activity

Receptor-induced Ca^{2+} signaling contributes to the regulation of net Cl^- transport and proliferation of corneal epithelial cells. In order for Ca^{2+} to link receptor activation to these responses, its intracellular concentration must be regulated at sub-micromolar levels.

Such regulation occurs through different types of Ca^{2+}/Mg^{2+}-ATPase plasma membrane and endoplasmic reticulum transporters and channels. The plasma membrane pump counterpart is selectively stimulated by

calmodulin, whereas one type of channel in this domain is activated as a direct consequence of emptying of intracellular Ca^{2+} stores. This channel is formed by a tetrameric configuration of transient receptor potential (TRP) protein subunits. Each of the different types of TRP channels identified in the corneal epithelium is activated by different stimuli. Currently, three different types are expressed and studied in corneal epithelial cells. Even though their activation leads in all cases to increases in plasma membrane Ca^{2+} influx, the types of responses elicited are very different from one another. The four identified types are TRPC4, TRPV1, TRPV4, and TRPM8. In human cornea epithelial cells, TRPC4 is activated during exposure to EGF. TRPV1 is stimulated by an agonist contained in an extract of red peppers (capsaicin) leading to increases in proinflammatory cytokine expression. TRPV4 is activated by a decreased bathing-solution osmolarity and elicits a RVD response. On the other hand, TRPM8 is temperature sensitive. The Ca^{2+} signaling role attributable to activation of each of these three different TRP isoforms is dependent on the ability of endoplasmic reticulum Ca^{2+} transporters to rapidly take up into intracellular stores the Ca^{2+} that has flowed in through these different plasma membrane TRP channels. Otherwise, a sustained rise in intracellular Ca^{2+} concentration may be cytotoxic. The importance of Ca^{2+} signaling in mediating receptor control of corneal epithelial renewal and transparency suggests that its modulation by drugs is of potential value in a clinical setting.

K^+, Cl^-, and Na^+ Channels

Modulation of K^+ channel activity is essential for mediating different responses associated with corneal epithelial function. For example, changes on K^+ channel activity mediate EGF-induced mitogenic responses, ultraviolet (UV) light-induced apoptosis, and adrenoceptor-induced increases in net Cl^- transport. In these cells, there is expression of Ca^{2+}-dependent and inwardly rectifying K^+ channels. Even though activation of these different K^+ channels types induces intracellular K^+ losses, the responses are very different from one another. Additional studies are required to understand how their activation leads to such disparate responses.

Chloride channel activity modulation occurs in response to adrenergic receptor-induced increases intracellular Ca^{2+} concentration and rises in intracellular cyclic adenosine monophosphate (cAMP) levels. Corneal epithelial cells express cystic fibrosis transmembrane regulator (CFTR) channels that are stimulated by rises in cAMP and underlie stimulation of net Cl^- transport. They also express a Cl^- channel designated as ClC-3 and their activation is suggested to underlie a regulatory volume response mediating shrinkage during exposure to a hypotonic challenge.

There is some evidence for the expression of tetrodotoxin-blockable Na^+ channels in corneal epithelial cells. The functional importance of such activity is unclear since their activation only occurs at membrane voltages far less negative than those described in corneal epithelial cells.

Summary

Ion transporter and membrane permeability regulation are essential to the maintenance of corneal epithelial health. Such control is essential for mediating responses that are required for corneal epithelial renewal and the maintenance of corneal transparency. The corneal epithelial cells express both primary and secondary ionic transport mechanisms whose regulation occurs through receptor activation. These ion transporters in concert with changes in membrane permeability underlie: (1) osmotically coupled fluid flow; (2) cell-volume regulation; (3) intracellular pH regulation; and (4) Ca^{2+} signaling. Such control assures that epithelial renewal maintains barrier function and the fine-tuning contribution capability of the corneal epithelium to elicit adequate fluid egress from the cornea for sustaining tissue transparency. Additional studies are warranted to identify novel drug targets in the signaling pathways mediating receptor control of ion transporter and channels. This endeavor will possibly identify improved techniques for restoring corneal epithelial function subsequent to injury.

Glossary

Apoptosis – The most common form of physiological (as opposed to pathological) cell death. Apoptosis is an active process requiring metabolic activity by the dying cell; often characterized by shrinkage of the cell, cleavage of the DNA into fragments that give a so-called laddering pattern on gels and by condensation and margination of chromatin.
Cytoskeleton – General term for the internal components of animal cells which give them structural strength and motility: plant cells and bacteria use an extracellular cell wall instead. The major components of cytoskeleton are the microfilaments (of actin), microtubules (of tubulin), and intermediate filament systems in cells.
Diabetic retinopathy – Damage to the retina caused by diabetes mellitus.
Dystrophic epidermolysis bullosa – A rare disorder caused by a mutation in the keratin gene and is characterized by the presence of extremely fragile skin and recurrent blister formation.
Filopodia – A thin protrusion from a cell, usually supported by microfilaments; may be functionally the linear equivalent of the leading lamella.
Idiopathetic pulmonary fibrosis – A chronic, progressive interstitial lung disease with an unknown cause.
Phagocytosis – Uptake of particulate material by a cell (endocytosis).
Phenotype – The characteristics displayed by an organism under a particular set of environmental factors, regardless of the actual genotype of the organism.
Recurrent corneal erosion – A disorder of the eye characterized by failure of the epithelial cells to attach to the basement membrane.

Corneal Epithelial Wound Healing: Introduction

The main function of the cornea is to prevent infectious invasion and to retain a smooth, optically clear surface to transmit light into the retina. The cornea has evolved a complex wound healing process for dealing with any insults to this tissue. The overall goal of corneal wound healing, as in most healing processes, is to repair the damaged tissue to resemble the unwounded tissue as closely as possible. In the cornea, this is especially important, as a failure to recapitulate an unwounded state can lead to visual impairments and a lower quality of life. The process of corneal wound healing is multifaceted involving many cell bound and secreted factors which work together to induce large-scale gene expression and phenotypic alterations in order to coordinate cell migration, proliferation, and survival rates for optimum regeneration and restoration of tissue function. While the process of corneal epithelial wound healing is well understood on the macro-molecular level (as will be discussed), there remain many micromolecular aspects to be elucidated if we are to completely understand this process.

Corneal Epithelial Wound Healing: Phases of Wound Healing Process

The corneal epithelial wound healing process can be described as having three overlapping phases: the lag phase, the migration phase, and the proliferation/restratification phase (**Figure 1**). The lag phase occurs immediately following any disruption of the corneal epithelium such as a scratch or puncture. During this phase, polymorphonuclear (PMN) cells from the tear fluid clear damaged and necrotic tissue from the wound area by phagocytosis, resulting in a microscopic enlargement of the wound area. These PMN cells generally disappear shortly after complete resurfacing of the wound by the epithelial cells though they can persist in cases of infection. Concurrently, a provisional matrix composed mainly of fibrin and fibronectin is secreted by the epithelial cells and the lacrimal gland and is laid down over the wound area. The provisional matrix acts as a substrate for migrating epithelial cells as well as an activator of integrin receptors on the cell surface to keep intact intracellular migration signals, mediated by the small GTPase proteins Rho and ROCK.

Also, during this phase, the epithelial cells must prepare themselves for the migratory phase. For cells proximal to the wound edge, this includes a dramatic alteration

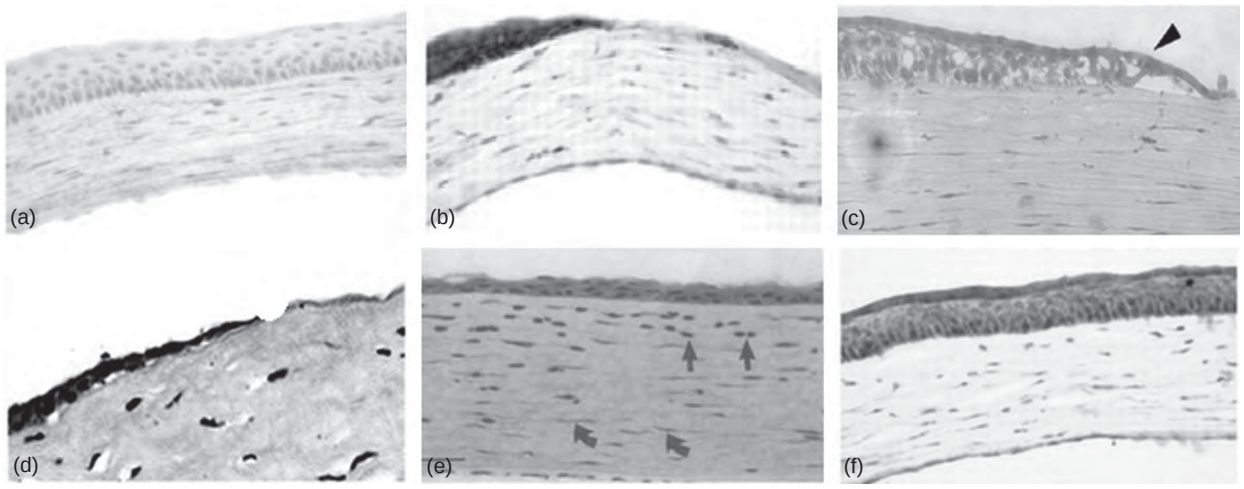

Figure 1 The stages of corneal epithelial wound healing. Histological examination of corneal resurfacing. (a) The unwounded cornea. (b) 1 h after removal of the corneal epithelium without penetrating the basement membrane cells at the wound margin have begun to alter their morphology and gene expression in preparation for migration. (c) 8 h and (d) 18 h after wounding, epithelial cells have begun to migrate over the provisional matrix. Note that there is a monolayer of migrating cells; the spacing between the cells and the basement membrane in (c) is an artifact of the sectioning process. (e) 24 h after wounding, cells have completely resurfaced the wound and begin the third phase: proliferation/restratification. By 7 days out (f), the corneal layers are repopulated and the ocular surface resembles the unwounded cornea. Arrowhead in (c) indicates leading edge; arrows in (e) indicate inflammatory cells. Curved arrows in (e) indicate fibroblasts.

in their gene expression profile including a secession of proliferation, and an alteration in cytokine and protease secretion, an alteration of the cytoskeleton including formation of lamellapodia and fillipodia, and an alteration of cell–cell and cell–matrix adhesions. Cells farther from the wound continue to proliferate to replace cells that enter into migratory phase. Additionally, during this phase, loss of superficial keratocytes due to apoptosis can be observed directly beneath the wound even when the basement membrane (BM) remains intact immediately following wounding. In a nonpenetrating wound, these stromal keratocytes are slowly replaced by proliferation of the surviving keratocytes without fibroblast activation or myofibroblast differentiation. In penetrating wounds, secreted factors induce fibroblast activation and proliferation and myofibroblast differentiation of the remaining keratocytes as will be discussed.

The second phase of corneal wound healing is the migratory phase. It is important that the wound resurfaces quickly, as prolonged or chronic wound healing scenarios may lead to degradation of the BM due to an increased proteolytic profile. This may in turn lead to ulceration of the underlying stroma, activation of the keratocytes into myofibroblasts, scarring, and possible visual impairments. The migratory phase is characterized by the centripetal migration of a continuous monolayer of nondividing corneal epithelial cells (CECs) over the wound and usually lasts between 24 and 36 h depending on the size of the wound and animal species. Cells at the wound edge flatten out and migrate while those more distal to the wound are induced to proliferate to replace the migratory cells. Cell migration rates vary by species, with rabbit CECs migrating at around 64 mm day^{-1} and mouse CECs at around 17 mm day^{-1}. During this phase, epithelial cells must be anchored enough to the underlying provisional matrix so that they are not removed casually (blinking, rubbing, etc.), but if the attachments are too strong, the cells will be unable to migrate. Laminin-5 has been implicated as a major determinant in the adhesion of epithelial cells to the underlying matrix. In the unwounded cornea, processed laminin-5 is present and helps hemidesmosomes in epithelial cells adhere strongly to the collagen VII anchoring fibrils. However, following wounding, the presence of the processed form becomes secondary to that of the unprocessed form which is not bound by cells as strongly. Unprocessed laminin-5 is deposited in the provisional matrix and, along with other provisional matrix components such as fibronectin, promotes the migration of epithelial cells rather than stationary adherence.

It has been proposed that epithelial cell migration is driven by an adhesion/deadhesion cycle that is regulated by two things: (1) a careful ratio of adherence molecules for attachment and proteolytic enzymes that degrade these attachments and (2) intracellular extension and contractile signals that alter the actin cytoskeleton morphology. Migratory cells first extend lamellapodia and fillopodia forward and form temporary focal adhesion complexes with the provisional matrix. Focal adhesions at the tail end of the cell are removed by a combination of proteolytic enzymes that cleave the complex and

intracellular contractile mechanisms that rip the trailing focal adhesions from the underlying stratum, sometimes even leaving part of the cell membrane behind. This cycle allows the cells to loosely adhere to the underlying matrix so that they can move due to contraction and reformation of the actin cytoskeleton.

The third phase of corneal wound healing is the proliferation/restratification phase. During this phase, the basal cells which have just finished the migratory phase and were kept in a nondividing state begin to proliferate once more in order to repopulate then differentiate and restratify the corneal epithelial layers and smooth out any irregularities in the BM. Also during this phase, the epithelial basement membrane (EBM) is reformed (in penetrating or large debridement wounds), the provisional matrix is broken down, and permanent attachments are reformed between the basal epithelial cells and the EBM. In nonpenetrating wounds, this phase is usually accomplished within a few weeks. In penetrating wounds, remodeling of the ECM may persist for months and even years after the insult, and may never completely regenerate.

Corneal Nerves

The cornea is one of the most densely innervated tissues of the body and corneal nerves have been shown to play a significant role in the maintenance of the cornea and in various corneal diseases. There are three networks of corneal nerves that enter the stroma and innervate the mid-stromal, bowman's layer, and epithelial layers. Regeneration of epithelial nerves has been shown to depend on the type of insult sustained. For example, reinnervation of the epithelial layer is much faster following laser ablation of the epithelium versus manual debridement and reinnervation density correlates with renewed corneal sensitivity. Following penetrating wounds, as in a laser-assisted in situ keratomileusis (LASIK) procedure, nerve bundles in the Bowmans layer and stromal flap (those that were severed) disappear completely. Within the first 6 months, nerves first reinnervate the stromal flap, then the Bowman's layer. A cycle of regeneration has been observed where the number of nerves is brought back to normal levels by 2 years post-LASIK, then reduced significantly by 3 years out though the reason and mechanism of this loss remains unknown. Nerve densities in the stroma below the wound remain unchanged following wounding.

Although there is much greater complexity involved in penetrating wound healing scenarios, including the drastic alteration of the stromal keratocyte phenotype with the possibility of permanent scarring, the overall phases of the penetrating corneal wound healing (i.e., lag, migration, and proliferation/restratification) is similar to those of the nonpenetrating process. Important additional differences include cell invasion from limbal blood vessels, the greater cytokine expression profile, and the much longer time frame for remodeling of the wound microenvironment due to the greater scale of remodeling that must take place in the stroma in order to maintain the optimal arrangement for light transmission.

Corneal Epithelial Wound Healing: Cell–Cell and Cell–Matrix Junctions

Cell–cell and cell–matrix junctions are critical components of both unwounded and wounded cell environments and every tissue in the body has a unique profile. Along with secreted factors, these junctions are responsible for all the possible signaling triggers that can alter gene expression and affect cell phenotype, function, and survival. Additionally, these junctions in combination with cellular cytoskeletons give a tissue its structure and help define function. Following wounding, some of these junctions must be broken down while others must be formed to allow cells to migrate while still others must remain to retain as much of a barrier to the outside environment and ensure a cohesive, coordinated sheet of cells resurfaces the wound rather than cells migrating individually. There are four known types of cell–cell interactions: gap junctions, tight junctions, adherins junctions, and desmosomes.

Cell–Cell Junctions: Gap Junctions

Gap junctions are formed by connexins which are homo- or heterohexameric proteins that form on the lateral side of cells and can form both homo- and heterotypic interactions with each other in order to connect the cytoplasm of two neighboring cells between an intercellular space. Gap junctions allow the passage of low-molecular-weight proteins (water, ions, secondary messengers, electrical impulses, and low-molecular-weight ($<$1 kDa) metabolites and nutrients) to pass freely from one cell to another, allowing cells to communicate quickly with each other in order to coordinate such physiological processes as development and regeneration.

Connexins(cxs) are named according to their molecular weight; thus, connxin43 is a 43-kDa protein. Multiple connexins have been observed in the cornea by studying various mammalian species (**Table 1**). Connexin 43 is the most well-documented connexin in the corneal epithelium and it is found primarily in the basal epithelial cells with expression decreasing progressively toward the superficial layers. Other connexins such as cxs26, 30, 31.1, 37, and 50 have been observed with spatially distinct patterns in the unwounded cornea. No connexins have been detected in migrating CECs following wounding though gap junctions in cells distal to the wound remain; thus, gap junctions in cells proximal to the wound are broken down during the lag phase and expression is downregulated throughout the

migration phase. Following resurfacing, gap junction reformation correlates with the reappearance of laminin-1 in the EBM. Expression of connexin43 has been attributed to Rho, but not ROCK signaling. The functional significance of the loss of gap junctions in migrating cells has yet to be determined.

Cell–Cell Junctions: Tight Junctions

Tight junctions are homeotypic interactions by transmembrane protein structures which link the actin cytoskeleton of neighboring cells and act like cellular gaskets. These structures are composed mainly of claudin occludin and junctional adhesion molecule A (JAMA) and have several purposes: they link neighboring cells, separate proteins in the apical cell membrane from those in the basal–lateral, and they prevent their passage of ions and other small molecules from penetrating between neighboring cells, thus contributing to corneal deturgesence. In the cornea, tight junctions have been detected in the superficial and wing cells. Early work in the field had found that tight junctions were reduced at the wound margin following wounding but reformed quickly behind the migrating front of epithelia. However, more recently, it has been shown that these junctions persist following corneal epithelial ablation with no significant alteration in expression. This newer finding correlates well with an older finding that showed a component of the tight junction complex, ZO-1, is upregulated following removal of superficial CECs. While there is no direct evidence yet, retention of tight junctions presumably helps ensure the integrity of the corneal surface as much as possible and helps to keep cells migrating together as a cohesive sheet.

Cell–Cell Junctions: Adherins Junctions

Adherins junctions are also found on the lateral side of cells and keep neighboring cells firmly attached to each other by anchoring to the actin cytoskeleton. Adherins junctions in the cornea are formed by homeotypic dimers of transmembrane E-cadherin molecules which bind each other in the intercellular space. E-cadherin is calcium dependent and is anchored intracellularly to the actin cytoskeleton by vinculin and α- and β-catenin molecules. E-cadherin-containing adherins junctions have been found throughout the cornea epithelium, and wounding does not seem to affect the expression or distribution of these junctions. Similar to tight junctions, adherins junctions may be retained in order to keep cells migrating together as a cohesive sheet, though again, direct proof is still lacking.

Cell–Cell Junctions: Desmosomes

The final type of cell–cell junction is the desmosome. Desmosomes are similar to adherins junctions in that they both function to keep neighboring cells attached to each other and they are both composed of molecules from the cadherin family. However, unlike adherins junctions which are composed of the cadherin family member E-cadherin, desmosomes are composed mainly of the caherin family members desmoglein and desmocollin. Also, while the adherins junction is anchored to the actin cytoskeleton, desmosomes are anchored by desmoplakin, plakoglobin, and plakophillin to the intermediate filament (IF), or cytokeratin, cytoskeleton. Interestingly, unlike adherins junctions, desmosomes do alter their expression pattern following wounding. It has been found that similar to connexin43, desmoglein is downregulated in migrating CECs, and this downregulation persists until resurfacing is complete and laminin-1 reappears below the epithelial cells. Like gap junctions, the functional significance of the loss of desmosomes in migrating cells has yet to be determined, though it may be necessary for the morphological changes needed for migration.

Cell–Matrix Junctions: Hemidesmosomes and Adhesion Complexes

In addition to cell–cell interactions, cell–matrix interactions are also critical components of tissue function and structure in normal, wounded, and diseased tissue, and a lack of adherence to an underlying matrix may result in apoptosis by ceratin cell types (such as epithelia) and a separation of the dermal and epidermal layers. Cells can be connected to an underlying extracellular matrix by

adhesions that are anchored intracellularly to either the actin or IF cytoskeleton, both of which utilize integrins to form these anchors.

Integrins are not only structural proteins which affect cell attachment, but they are also potent signaling molecules that can affect cell proliferation, migration, and survival properties. Intergins form heterodimers of an α- and β-chain and the different combination of chains determines the extracellular binding partner; some have only one substrate while others have multiple substrates with differing binding kinetics. In mammals, there are 19 known α-chains and 9 known β-chains which can assemble into about 25 distinct integrins. Integrins α2β1, α3β1, α6β1, α9β1, αvβ1, αvβ5, αvβ6, and α6β4 have all been localized to the corneal epithelium with the strongest expression being found in the basal epithelial cells and getting progressively weaker as the cells get closer to being sloughed off into the tear fluid. This progressive loss of integrins ensures that cells that migrate away from the basal epithelium proliferate less and provide a less adhesive surface for microbial adherence and infection of the corneal surface.

Hemidesmosomes are present at the basal membrane of unwounded basal epithelial cells and are composed of the α6β4 integrin as well as adaptor proteins for linking this protein to the IF cytoskeleton. In the unwounded cornea, hemidesmosomes are tightly bound to anchoring fibers composed of collagen VII which pass perpendicular through the BM then make a 90° turn and wrap around collagen III bundles. Following wounding, hemidesmosomes are broken down and are no longer detectable for 70–200 μm outside the wound area in order to allow cells to begin the migratory phase. Although the hemidesmosomes are absent, α6β4 integrin expression is actually increased during resurfacing, though these integrins are no longer associated with hemidesmosomes but instead form focal adhesion complexes (discussed earlier) which now connect the components of the underlying provisional matrix such as unprocessed laminin-5 with the actin cytoskeleton. In penetrating wounds, reformation of the basal lamina and hemidesmosome complexes occurs concurrently in about 6–8 weeks, though studies in monkeys have shown that reformation of the anchoring fibrils may take as long as 18 months to reform. All of these time frames are approximations and can be affected by variables such as the size of the wound, the age and species of the subject, and if there are any complicating factors such as infection or genetic abnormalities.

Secreted Factors Involved in Corneal Epithelial Wound Healing

Along with cell–cell and cell–matrix junctions, secreted factors such as cytokines, growth factors, and proteases are also responsible for regulating normal tissue maintenance and wound healing properties. Cytokines and growth factors are small molecules that can bind and activate their cognate cell surface receptors. These activated receptors then transduce the signal to the nucleus via various intracellular signaling pathways such as the mitogen-activated protein kinase (MAPK), Smad, and nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB) pathways. However, signaling is not necessarily linear and cross-talk between the pathways can and often does occur.

In other epithelia of the body, these factors are usually secreted by platelets or other cell types that enter a wound from the blood stream. The cornea, however, is an avascular tissue and thus all signals must come from either the tear fluid or the epithelial and stromal cells themselves. Corneal epithelial and stromal cells have been shown to secrete a host of cytokines and growth factors. Transcriptional analysis of primary corneal epithelial cultures has found insulin-like growth factor (IGF), epidermal growth factor (EGF), transforming growth factor (TGF)-α, b-fibroblast growth factor (FGF), TGF-β1, TGF-β2; in addition, all of their cognate receptors are expressed by both corneal epithelial and stromal cells, though to varying degrees, and may act via both autocrine and paracrine mechanisms. Some other important factors have more specific localization patterns and generally act via paracrine signaling. For example, both keratinocyte growth factor (KGF) and hepatocyte growth factor (HGF) are only expressed by stromal keratocytes though their cognate receptors are much more preferentially expressed by epithelial cells, while platelet-derived growth factor (PDGF)-bb is expressed by epithelial cells and its cognate receptor is only expressed in stromal cells. The inflammatory cytokines interleukin (IL)-1α and IL-1β are only expressed by epithelial cells in the unwounded state, but their cognate receptor is present on both epithelial and stromal cells. However, stimulation of keratocytes by IL-1 as occurs during penetrating wounds can induce an autocrine feedback loop; thus, keratocytes can express IL-1. Furthermore, this IL-1 feedback loop also induces other secreted factors such as HGF and KGF expression by keratocytes.

Cytokines can induce gene expression changes that can alter the proliferation, migration, and survival properties of a cell. For example, it has been shown that KGF and EGF can induce CEC proliferation. Also, while neither EGF, PDGF-bb, IL-1, nor TNF-α alone can induce epithelial cell migration, when combined with fibronectin as a substrate, these factors can all significantly speed up migration rates as compared to fibronectin alone. This further emphasizes the complex and combinatorial signaling that controls corneal epithelia wound healing. The role of the TGF-β family in epithelial migration is controversial with some labs showing that it enhances epithelial migration rates, and others finding that it slows down resurfacing rates. Further studies must be done to reconcile these seemingly opposite results.

Matrix Metalloproteinases

Matrix metalloproteinases (MMPs) are a family of structurally related zinc-dependent proteases with overlapping substrate specificities. MMPs are known regulators and effectors of many cellular processes, including tumor progression, development, and epithelial wound healing as well as normal tissue maintenance. The MMP family consists of over 20 members whose substrates have come to include all extracellular membrane proteins as well as many cell surface proteins (i.e., cadherins, heparin-binding EGF (HB-EGF), etc.) and secreted proteins (i.e., TGF-β, IL-1, TNF-α, etc.) which can be both activated and degraded by MMPs. Thus, MMPs can affect gene expression by alterating intracellular (nuclear) signaling by cleavage of cell–cell and cell–matrix interactions as well as by altering the active cytokine and growth factor microenvironment. Due to their broad substrate specificity and potent proteolytic activity, MMPs must be tightly controlled, and are regulated at the transcriptional and posttranslational levels. MMPs can be either secreted or membrane bound and contain a propeptide at their N-terminal that must be removed before they can become proteolytically active.

MMPs are critical components of the wound healing process, as global MMP inhibition by pharmacological agents results in a failure to resurface a wound. Similarly, an overexpression of MMPs is also involved in many epithelial disorders such as idiopathic pulmonary fibrosis in the lung, dystrophic epidermolysis bullosa in the skin, and diabetic retinopathy and recurrent corneal erosion in the eye. Therefore, a precise level of MMP expression is necessary for normal tissue maintenance and optimal wound repair.

In the unwounded cornea, most MMPs are expressed at basal or undetectable levels, except for MMP-7 and -14 which are expressed constitutively. Following removal of the epithelium, several MMPs are upregulated and various family members take on a distinct localization pattern, though the expression patterns of MMP-7 and -14 do not change significantly. MMP-9 is the most well-studied family member and is strongly upregulated at the very tip of the migrating epithelial cells. MMP-10 becomes upregulated by all migratory cells, and MMP-13 expression is upregulated by cells throughout the wound area and in the periphery of the wound. MMP-12 mRNA upregulation has also been detected in the peripheral cells, but this upregulation has not been detected for the actual protein. Penetration of the EBM induces expression of more MMPs such as MMP-2, -3, and possibly -8 which are used to remodel the stromal compartment.

Following resurfacing of nonpenetrating wounds, MMP levels are generally decreased, though MMP-9 expression persists and spreads distally from the wound closure with the timing of its expression correlating with degradation of the provisional matrix. This correlation has been confirmed using MMP-9 knockout (KO) mice which are unable to degrade the fibrin in the provisional matrix which remains as a corneal haze. However, a recent study in human eyes has found that people displaying uncomplicated LASIK surgeries (penetrating wound) may, up to 7 years later, still have EBM irregularities around the wound edges that lead to stromal–epithelial contact causing MMP expression and indicating a continuing wound healing process.

While MMP-9 is critical for overall corneal wound regeneration, it is not critical for corneal re-epithelialization, and in fact acts to slow the rate of re-epithelialization. Other MMPs, however, are critical for corneal resurfacing as global inhibition of MMPs retards resurfacing. However, which specific MMPs are necessary, what their substrates are, and why these MMPs are necessary is still unknown. These questions are especially difficult to answer because loss of an MMP, as in a knockout or knockdown model, can be compensated for by other MMPs due to the overlapping substrate specificities as indicated by the low number of MMP KO mice displaying drastically different phenotypes.

Corneal Epithelial Wound Healing: Conclusion

While the corneal epithelial wound healing process shares some similar properties with skin, lung, and gut epithelial wound healing, there are important differences. For example, whereas skin epithelia can heal by a scarring or vascularization process, the corneal wound healing process must minimize these parameters in order to retain optimal visual clarity. Formation of scar tissue on the molecular level means the accumulation of α-smooth muscle actin-containing fibroblasts also known as granular tissue myofibroblasts that form the fibrous tissue in the early scar before the secretion and formation of the older collagen scar tissue. As the central cornea is an avascular tissue, formation of α-smooth muscle actin expressing cells is initially derived solely from stromal keratocytes. Stromal keratocytes are induced to differentiate into α-smooth muscle actin expressing cells by secreted factors expressed by the CECs and present in the tear fluid such as TGF-β. In the unwounded eye, the EBM binds TGF-β and acts as a physical barrier to prevent the stromal keratocytes from being activated. Over a remodeling period of weeks, months, or even years, myofibroblasts can slowly disappear from a wound site via an unknown mechanism, possibly apoptosis. This disappearance is by no means guaranteed and even if it does occur, it may or may not improve visual acuity depending on whether or not a collagenous scar tissue has formed.

The severity of the wound response is correlated with the severity of the wound; wounds that do not penetrate the EBM tend to regenerate completely, whereas wounds

that do penetrate the EBM tend to induce myofibroblast differentiation, require much longer to heal, and may never quite regain the original architecture. Thus, the most important factor involved in corneal wound healing is whether or not the EBM has been disrupted. While penetration of the BM is arguably the most important factor in corneal wound healing, it is by no means the only determining factor; the size of the wound, the age of the subject, and the causative agent are also important factors. Additionally, any defect in the tear fluid composition or integrity may further impair the wound healing process. All of these factors can affect the cellular microenvironment by alteration of cell adhesion molecules (CAM) and secreted factors which both coordinate and drive the wound healing process.

Corneal Imaging: Clinical

S Garg and R F Steinert, University of California, Irvine, Irvine, CA, USA

Glossary

Confocal – Noncontact imaging modality based on the principle that light passed through an aperture and focused by an objective lens onto an area of interest.

Optical coherence tomography (OCT) – Noncontact imaging modality in which back-reflected light or backscattered infrared light from internal tissue microstructure is analyzed to achieve two or three-dimensional cross-sectional tomographic images of optical reflectivity.

Phototherapeutic keratectomy (PTK) – Surgery using a laser to treat various ocular disorders by removing tissue from the cornea.

Introduction

Assessment of anterior segment structures is an integral part of the ophthalmic evaluation. Clinical techniques for examining the human cornea *in vivo* have greatly expanded over the last several decades. The clinician's armamentarium includes slit lamp biomicroscopy, specular microscopy of the endothelium, computed corneal topography, high-frequency ultrasound, anterior segment optical coherence topography (OCT), and confocal microscopy. Advanced anterior segment imaging is a routine part of the anterior segment physicians' practice. Confocal microscopic evaluation of the cornea *in vivo* began in the late 1980s. The invention of OCT in the early 1990s initially centered on retinal imaging and was subsequently modified for anterior segment applications.

In the clinical setting, confocal microscopy and anterior segment OCT are noninvasive devices that allows for examination of normal and diseased corneas and anterior segment structures such as the angle, iris, and lens, aiding in both routine patient care and in managing complex pathology.

Confocal Microscopy

Historical Overview

Marvin Minsky invented the confocal microscope in 1955. His novel invention imaged tissue parallel to its surface. Traditionally, images of the tissue were oriented perpendicular to their surface. Minsky exploited the pinhole effect to accomplish his goal. He proposed that both the illumination (condenser) and observation (objective) systems could be focused on a single point (both have common focal points, and thus the name confocal). Using a pinhole eliminates unwanted optical artifacts from light reflected above and below the tissue of interest, improving image quality. However, this increased resolution comes at a cost of a small field of view. A full field of view is accomplished by scanning. In 1968, the first tandem scanning confocal microscope (TSCM) was developed. This improvement used a rotating Nipkow disk to simultaneously scan multiple points on a stationary specimen. In 1985, the confocal was first used to describe imaging of human corneas *ex vivo* and rabbit corneas *in vivo*. Around the same time of development of the TSCM, Svishchev introduced the scanning two-sided mirror confocal microscope. This was later modified by Thaer to enable real-time scanning, the precursor to the modern slit scanning confocal microscope (SSCM).

Current commercially available confocal microscopes include the Confoscan 4 (Nidek Technologies, Gamagori, Japan), Confoscan P4 (Tomey Corporation, Cambridge, MA, USA), Microphthal (Helmut Hund, Wetzlar, Germany), and the Heidelberg Retina Tomograpy II Rostock Cornea Module (Heidelberg Engineering, GmBH, Germany).

How it Works

Confocal microscopy is based on the principle that light passed through an aperture and focused by an objective lens onto an area of interest. The reflected light is then focused by a second objective lens through a second aperture to eliminate out of focus light. The ability of the system to discriminate light that is outside the focal plane results in images of higher *X*-, *Y*-, and *Z*-axis resolutions. The drawback is a small field of view (**Figure 1**). Moving the confocal system (scanning) over the stationary specimen allows for larger fields of view. The *Z*-axis resolution of the confocal microscope permits the dynamic scanning capability of the instrument, allowing *in vivo* corneal imaging without the need for stains or dyes. With computerized three-dimensional reconstruction, this technology has improved lateral and axial resolution to 1–6 and 4–15 μm, respectively, and increased magnification up to 600×. Image quality is affected by image contrast, the light source, the scanning method, the path of light in the cornea, and the optics of the objective.

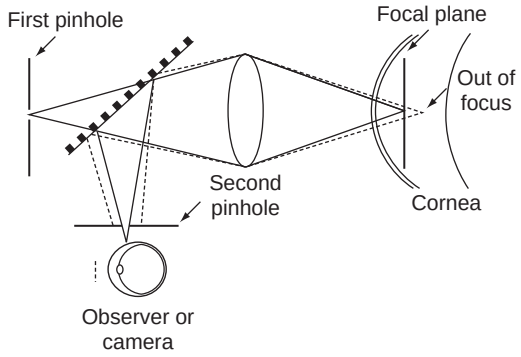

Figure 1 Schematic of the optical principles of confocal microscopy. White light that passes through the first pinhole is focused on the focal plane in the cornea by the condensing lens. Returning light is diverted through the objective lens and a conjugate exit pinhole and reaches the observer or camera. Scattered out of focus light from below or above the focal plane (broken lines) is greatly limited by the pinholes and does not reach the observation system. Reprinted with permission from BJO.

Image separation (depth) is recorded by the movement of the objective between images. Water immersion objective lenses of high numerical apertures are typically used, as they eliminate surface reflections and provide good depth resolution. This requires a short working distance. In clinical practice, subject preparation for the scan is of great importance. Topical anesthesia, patient counseling of the short working distance, bright illumination, and use of coupling agents all aid in capturing useful images. Maintaining a perpendicular orientation to the corneal surface is necessary to avoid oblique sectioning.

Clinical Applications

The normal cornea

The normal human cornea consists of five layers: epithelium, Bowman's layer, stroma, Descemet's membrane, and endothelium. All of these layers, with the exception of Descemet's membrane, can be imaged by confocal microscopy. It is important to note that the more a cellular component reflects light, the brighter the image will appear on a confocal scan.

From front to back, the corneal epithelium is composed of superficial, wing, and basal cells, with a normal thickness of approximately 50 μm. In the superficial layers, cells appear flat and polygonal with hyperreflective nuclei. Wing cells appear uniform in shape and size with dark nuclei. These cells are generally larger than basal cells, but smaller than superficial cells. The basal cells are smaller, more uniform in size, and have bright borders and highly reflective cell nuclei (**Figures 2** and **3**).

Between the basal epithelium and Bowman's layer are corneal nerves that appear as beaded, well-defined linear branching structures with homogeneous reflectivity (**Figure 4**).

Bowman's layer appears as an amorphous homogenous layer in the normal cornea. It is acellular, with randomly

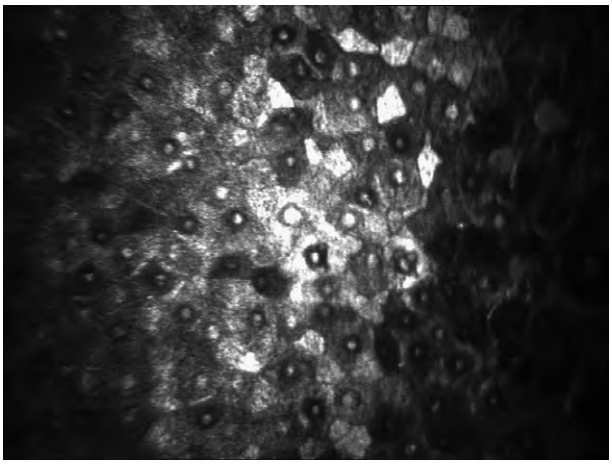

Figure 2 Superficial epithelium.

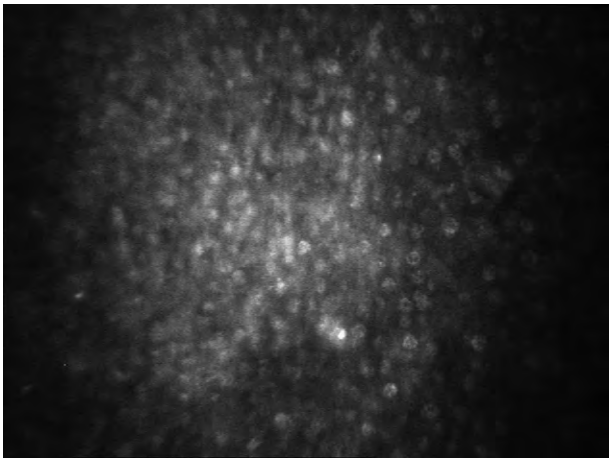

Figure 3 Basal epithelium.

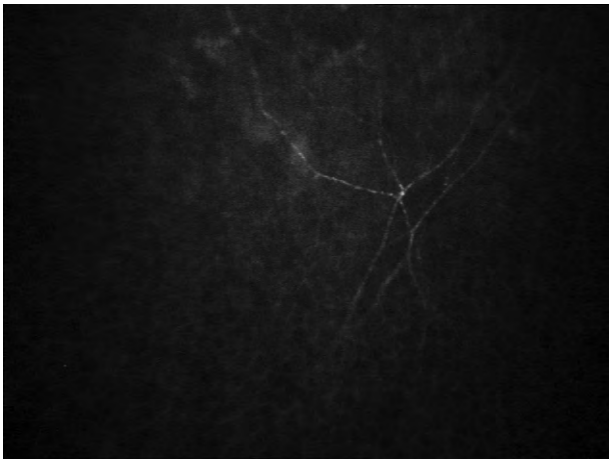

Figure 4 Basal nerve plexus.

dispersed collagen fibrils. On confocal microscopy, Bowman's layer is imaged poorly without the aid of anatomical landmarks such as the highly reflective subbasal nerve plexus due to an average thickness of only 15 µm.

In the corneal stroma, which typically is about 500-µm thick, keratocyte nuclei appear hyperreflective against a dark background. Confocal images exhibit poor reflectivity of stromal keratocyte cytoplasm, cell boundaries, and collagen substance. In the anterior stroma keratocyte nuclei appear as distinct, bright, and oval-round in random orientation. In the mid-stroma, keratocytes exhibit a more regular oval shape transitioning to elongated spindle-shaped as the scan approaches the posterior stroma. Additionally, hyperreflective nerve fibers are sporadically seen coursing within the anterior and mid-stroma, but they are absent in the posterior stroma (**Figures 5** and **6**).

Descemet's membrane thickens throughout life. It is the basement membrane of the inner layer of endothelial cells. Because of the lack of cellularity and thinness, it is poorly captured by confocal microscopy.

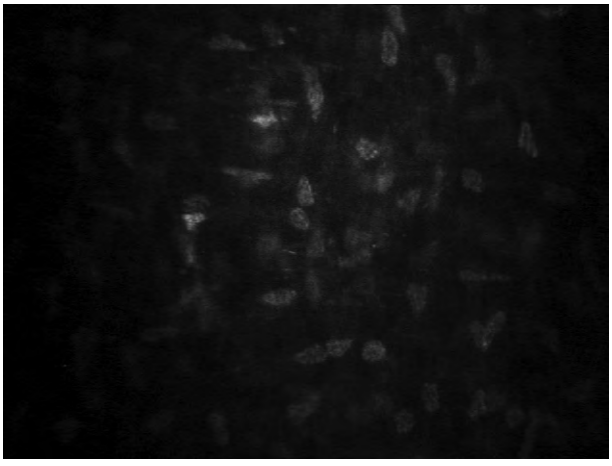

Figure 5 Anterior stroma.

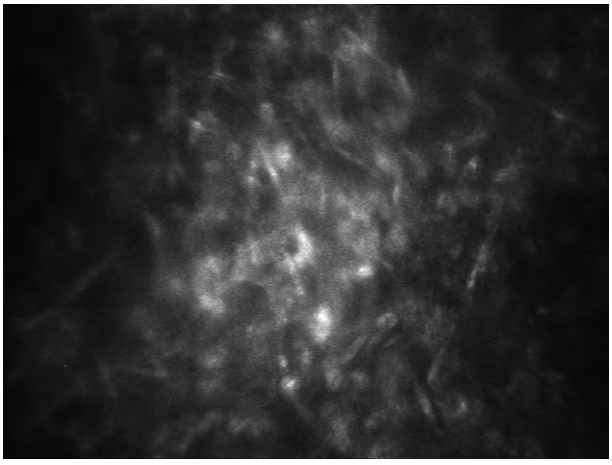

Figure 6 Deep stroma.

Corneal endothelial cells are single layered, normally characterized by a regular hexagonal hyperreflective cell body, void of nuclei, and surrounded by hyporeflective borders (**Figure 7**).

Pachymetry

Confocal microscopy can be used to determine corneal thickness through a function known as confocal microscopy through focusing (CMTF) on the TSCM. This is accomplished by focusing in the *Z*-axis and determining the amount of light backscattering which in turn is plotted as an intensity profile curve. The differences in scattering of the various corneal layers allows for determination of each layer's location. Overall, this method for determination of corneal thickness offers good repeatability, especially for determination of thin layers such as the epithelium and Bowman's membrane. Nontandem models such as the Nidek Confoscan 4 utilize a contact ring at the limbus.

Applications in Pathology

The treatment of infectious keratitis can be challenging. The golden standard for diagnosis of infectious keratitis is light microscopic examination and culture of corneal scrapings. However, confocal microscopy is a very useful tool in helping with diagnostic quandaries. Confocal microscopy is particularly helpful when *Acanthamoeba* or fungal elements are suspects as etiologies. Bacteria (2 µm) can theoretically be visualized; however, given their small size (near the typical resolution for confocal microscopy), clinical distinction is not possible. Fungal infections generally image as hyperreflective, elongated, filaments, or budding yeasts (**Figures 8** and **9**). In its cystic form, *Acanthamoeba* appears as a highly reflective, round, or ovoid double-wall structure with a diameter of 10–25 µm (**Figure 10**). Radial keratoneuritis may appear as irregularly enlarged nerve fibers.

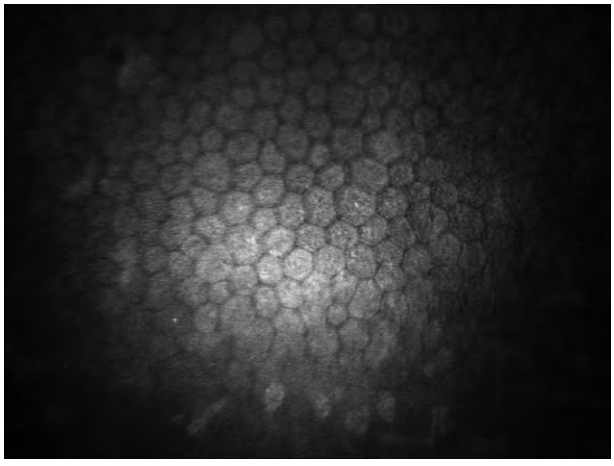

Figure 7 Endothelium.

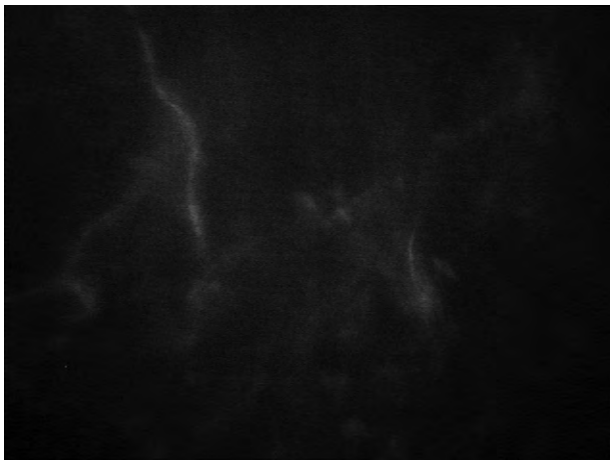

Figure 8 *Fusarium* keratitis.

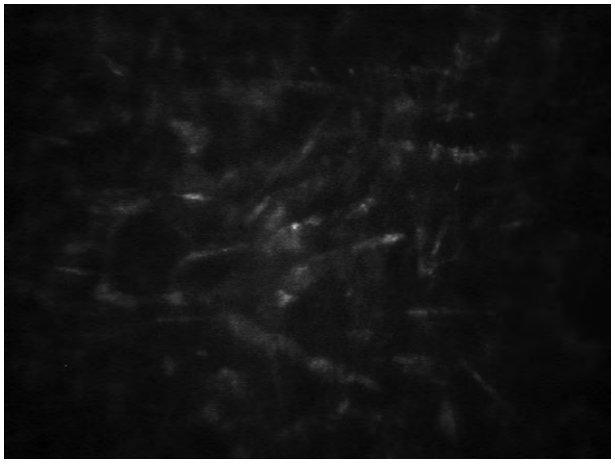

Figure 9 *Fusarium* keratitis.

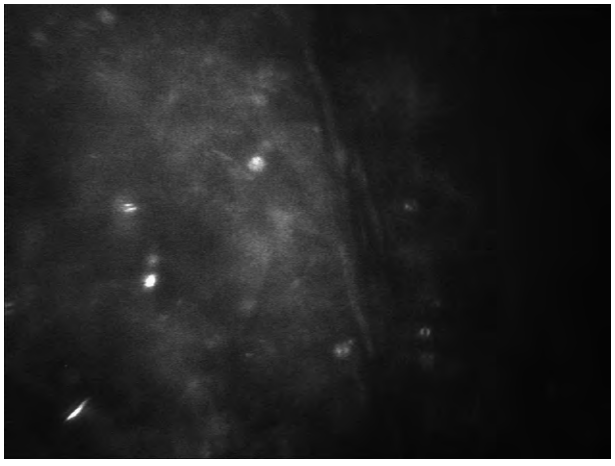

Figure 10 *Acanthaeomba*.

Other applications

Confocal microscopy has also been used to research and clinically evaluate the effects of refractive surgery on the cornea, evaluation of corneal deposits and stromal dystrophies, endothelial pathology, as well as evaluation of corneal ectatic disorders (**Figures 11** and **12**).

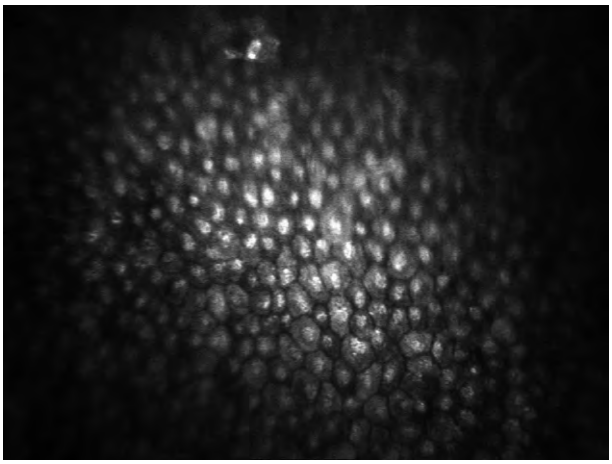

Figure 11 Iridocorneal endothelial syndrome (ICE). Note the epithelial-like endothelial cells with hyperreflective nuclei, which is characteristic of ICE syndrome in which the endothelium grows across the angle and iris. Notice irregular rows and shape of the endothelial cells.

Anterior Segment OCT

Historical Overview

David Huang and colleagues developed OCT in the early 1990s. Joseph Izatt and colleagues first demonstrated corneal and anterior segment OCT in 1994. Over the next decade, the majority of developments in OCT technology focused on retinal imaging. The use of longer wavelengths, telecentric transverse scanning, and very high-speed axial scanning with a grating-based rapid scanning optical delay (RSOD) mechanism in the

reference arm allowed for improved imaging of the anterior segment. In October 2005, the Food and Drug Administration in the United States approved the Zeiss Visante anterior segment OCT, the first commercially available OCT device designed for the anterior segment.

How it Works

Anterior segment OST (AS-OCT) is a noncontact imaging technique based on Michelson low coherence inferometry. In conventional interferometry with long coherence length (laser interferometry), interference of light occurs over a distance of meters. In OCT, this interference is shortened to a distance of micrometers. Light in an OCT system is broken into two arms – a sample arm (containing the item of interest) and a reference arm (usually a mirror). The combination of reflected light from the sample arm and reference light from the reference arm gives rise to an interference pattern, but only if light from both arms have traveled the same optical distance (same meaning a difference of less than a coherence length). By scanning the mirror in the reference arm, a reflectivity profile of the sample can be obtained (time domain OCT). Areas of the sample that reflect with greater intensity will create greater interference than areas that do not. Any light that is outside the short coherence length will not interfere. This reflectivity profile, called an A-scan, contains information about the spatial dimensions and location of structures within the item of interest (**Figure 13**). This is analogous to B-scan ultrasonography; however, OCT uses light as compared to sound waves. OCT was initially used for retinal evaluation, where images are optimized with an 820-nm light. AS-OCT evolved from retinal OCT. For the Visante AS-OCT, Zeiss uses a longer wavelength (1310 nm) that allows for greater penetration through tissues that scatter light intensely such as the sclera and limbus, which in turn permits visualization of anterior segment structures such as the angle, ciliary body, and ciliary sulcus. Approximately 90% of the 1310-nm light is absorbed prior to reaching the retina allowing for the AS OCT to be used as a higher power than retinal OCT. This results in real-time imaging and decreased motion artifacts. Currently, there are three commercially available anterior segment OCT devices: the Visante OCT (Visante OCT, Carl Zeiss Meditech Inc, Dublin, CA, USA), the Slit Lamp OCT (SL-OCT, Heidelberg Engineering GmbH, Heidelberg, Germany), and the Optovue (RTVue with Cornea-Anterior Module, Freemont, CA, USA). The Visante OCT provides high-resolution corneal scans, anterior segment scans (anterior-chamber depth, anterior-chamber angle, angle-to-angle distance), and pachymetry maps. It is reported to have an axial resolution of 18 µm and a transverse resolution of 60 µm. The SL-OCT is essentially a slit lamp biomicroscope-mounted OCT device allowing similar

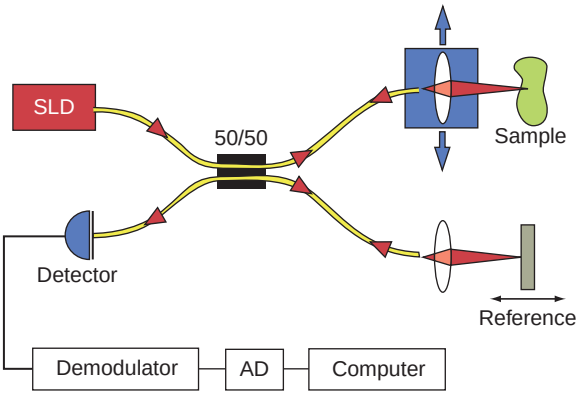

Figure 13 Schematics of the basic fiber-optic OCT system. Light from a superluminescent diode (SLD) is launched into a single mode-optical fiber. The light is equally split at the coupler into the sample and reference arms. Sample and reference reflections are recombined at the coupler and the interference pattern is converted to an electrical signal by the detector. The signal is demodulated and converted from analog to digital (AD) form for computer signal and image processing. To scan the reflections from various depths in the sample, the reference mirror is scanned over the equivalent range of delay. This produces a scan of sample reflectivity versus depth, also called an axial scan. From Steinert, R. E. and Huang, D. (2008). *Anterior Segment Optical Coherence Tomography.* Thorofare, NJ: SLACK Incorporated. Reprinted with permission from SLACK Incorporated.

measurements as the Visante OCT. The potential advantage of the SL-OCT is its attachment to the biomicroscope. The SL-OCT has a reported axial resolution of 25 µm and a transverse resolution of 20–100 µm. The speed of acquisition is 4–8 frame s^{-1} for the Visante OCT and 1 frame s^{-1} for the SL-OCT. The Optovue OCT employs an interchangeable lens system for anterior-segment images. Its principal advantage is the use of spectral domain OCT technology, with a substantially higher resolution. However, scans are limited in width, so only a portion of the cornea can be imaged at one time, and the retina-optimized wavelength does not allow useful imaging of the angle.

Clinical Applications

Anterior segment OCT is a powerful tool for the clinician. It can be used to measure corneal thickness, pachymetry maps, total corneal power, corneal backscatter, angle configuration, anterior-segment tumors, anterior-segment depth, lens vault, corneal opacities, and corneal refractive implants. The following discussion pertains to applications of the Visante OCT.

Keratoconus is a bilateral corneal ectasia characterized by progressive thinning and inferior protrusion. Diagnosis of this and other ectasias (e.g., pellucid marginal degeneration) is critical when evaluating patients for possible refractive surgery. Form fruste keratoconus is subclinical and can often be difficult to diagnose. Anterior segment OCT is a valuable tool in evaluating these patients

to aid in proper diagnosis. As both the Orbscan and Pentacam are based on slit-scanning principles, they tend to underestimate corneal thickness in keratoconic eyes. OCT has a higher resolution as compared to these other imaging modalities and therefore accurately maps the corneal thickness of normal, postoperative, and opacified corneas. The pachymetry map allows for accurate pachymetry readings over broad areas of the cornea allowing for detection of subclinical thinning suggestive of corneal ectatic disorders (**Figures 14** and **15**).

The Visante OCT can obtain high-resolution images of the cornea. The flap tool measures laser-assisted *in situ* keratomileusis (LASIK) flap thickness and residual stromal bed (RSB) in up to seven locations. This application allows for evaluation of LASIK flaps in uncomplicated and ectatic cases. RSB measurements are invaluable in providing

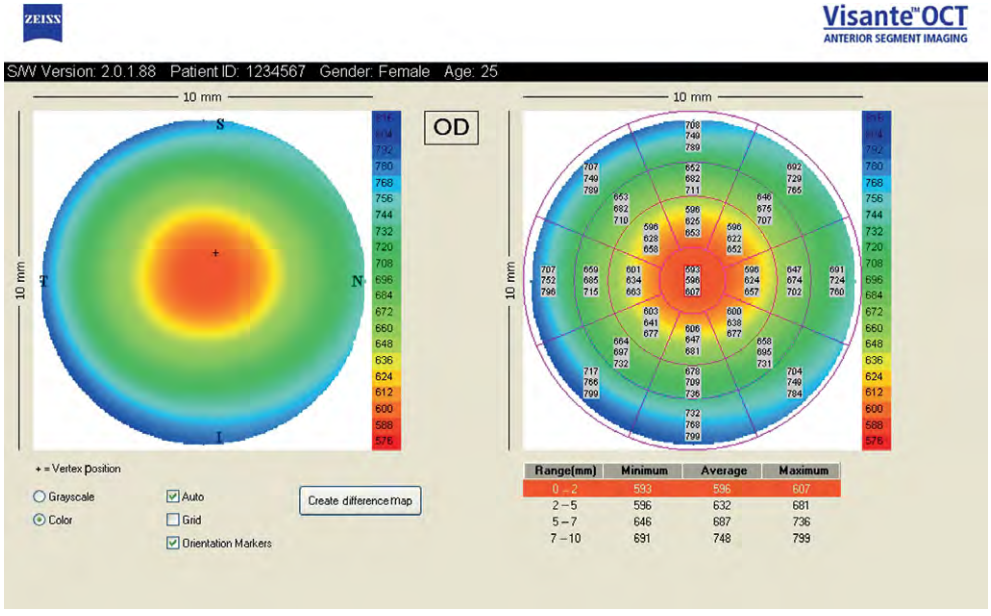

Figure 14 Normal visante OCT pachymetry map. The visante OCT allows for a global pachymetry map represented by numerical values and a corresponding color gradient. The cooler colors represent thicker pachymetry values and the warmer colors represent thinner pachymetry values.

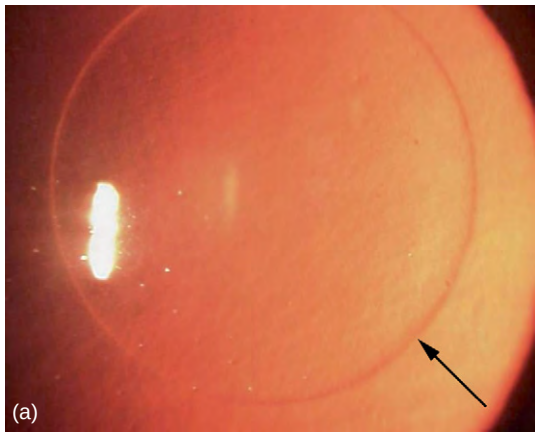

Figure 17 Continued

information regarding the potential safety of performing an enhancement when lifting the flap. Additionally, the flap tool can be useful when evaluating a patient with post-LASIK keraecastia (**Figure 16(a)–16(d)**). Likewise, OCT is useful in evaluations of refractive corneal inlays and intacs intracorneal ring segments (**Figures 17(a)–17(c) and 18**).

Assessment of the depth of corneal ulcers is another valuable application of AS-OCT. Involved tissue appears hyperintense on OCT images. The clinician is able to follow the progression of keratitis by imaging the depth of involvement, the density of the infiltrate, and evaluating for possible corneal thinning (**Figures 19(a)–19(e)** and **20(a)–20(e)**). Penetrating (full thickness) and lamellar (partial thickness) corneal transplantation has been the focus of several technologic and surgical advancements over the past several years. The development of posterior lamellar keratoplasty (Descemet stripping endothelial keratoplasty, or DSEK), and femtosecond laser-enabled keratoplasty have dramatically changed corneal transplantation techniques. AS-OCT evaluation of these patients pre- and postoperatively is helpful in surgical planning and clinical follow-up (**Figures 21–23**).

(2008). *Anterior Segment Optical Coherence Tomography.* Thorofare, NJ: SLACK Incorporated. Reprinted with permission from SLACK Incorporated.

Accurate measurement of corneal opacities is another clinical application of AS-OCT. Compared to ultrasonic pachymetry, ultrasound imaging, optical pachymetry, confocal microscopy, and optical low-coherence reflectometry, OCT has been shown to accurately map pachymetry in both normal and opacified corneas. This accuracy aids in clinical decision making with respect to ablative treatments such as phototherapeutic keratectomy, mechanical scraping and peeling, or their combination.

Peripheral corneal pathologies, such as peripheral corneal and scleral melts, are also amenable to OCT scans. The longer wavelength (1310 nm) allows for full thickness imaging of the cornea and sclera through overlying opacities such as infiltrate, pannus (flap of tissue), and calcium plaques. Measurement of the depth of involvement and thickness of remaining tissue is useful for clinical and surgical planning (**Figure 24(a)–24(c)**).

Beyond corneal applications, AS-OCT can also be utilized for glaucoma evaluations. Determination of angle configuration, visualization of normal angle structures (**Figure 25(a)–25(c)**), iris configuration (pupillary block configuration, pre- and postiridotomy (procedure to create a hole in the iris to enhance the drainage passages blocked by a portion of the iris), plateau iris configuration, pre- and postiridoplasty, a surgical procedure where the position of the peripheral iris is changed), and evaluation of peripheral anterior synechiae closure (condition where the peripheral iris adheres to the cornea) (**Figure 26(a)–26(c)**) are among the many applications of AS-OCT pertaining to glaucoma.

Conclusion

Confocal microscopy and optical coherence tomography imaging allow clinicians and researchers to evaluate the structure of the cornea and anterior segment at levels beyond slit lamp biomicroscopy. Each technology has its own advantages and drawbacks, with their applications generally complementing each other. Quantitative and qualitative measures of normal and pathologic states greatly improve the clinician's ability to follow and treat.

Corneal Nerves: Anatomy

C F Marfurt, Indiana University School of Medicine – Northwest, Gary, IN, USA

Glossary

Chemotropic guidance – A process whereby a chemical substance, usually secreted by some target cell, attracts growing axons.
Cochet–Bonnet esthesiometer – A hand-held instrument that uses the pressure transmitted by a nylon monofilament of known diameter and variable length to measure the mechanical sensitivity of the cornea.
Iridectomy – A surgical procedure that removes a small piece of the iris, most often for treatment of closed-angle glaucoma or melanoma of the iris.
Laser-assisted *in situ* keratomileusis (LASIK) – A form of refractive laser eye surgery designed to change the shape of the cornea.
Neurite – Any cytoplasmic extension from a neuron; the term is used frequently to describe developing or regenerating axons that have not yet attained their mature adult form.
Neurotrophic epitheliopathy – The minor degenerative changes of the corneal epithelium caused by damage or functional impairment of the corneal innervation, especially as occurs after LASIK surgery.
Neurotrophic keratitis – A serious degenerative condition of the cornea, affecting especially the corneal epithelium, caused by impairment of the corneal sensory innervation. It often manifests as corneal epithelial defects, ulceration, melting, and diminished wound healing.
Phacoemulsification – A procedure in which a cataractous lens is broken up (emulsified) by ultrasound and aspirated from the eye; an intraocular lens is then inserted.
Receptive field – The area of the cornea (or other body part) supplied by a single sensory nerve fiber.
Trabeculectomy – A surgical procedure that removes part of the trabeculum of the eye in order to facilitate drainage of aqueous humor. It is performed for the relief of increased intraocular pressure associated with glaucoma.
Trophic substances – The molecules that promote the growth, differentiation, and survival of specific cell populations.

Origins of Corneal Nerves

The cornea is richly supplied by sensory neurons located in the ophthalmic region of the trigeminal ganglion (Figure 1). Although the entire sensory innervation of the mammalian cornea is derived from a relatively small number (~50–450) of neurons, each neuron supports as many as 200–3000 individual corneal nerve endings. The sensory nerves reach the eye through the nasociliary branch of the ophthalmic nerve. In humans, the nasociliary nerve branches typically into two long ciliary nerves, one nasal and the other temporal, which course directly to the posterior pole of the eye, and a communicating branch carrying sensory fibers to the ciliary ganglion. Five to ten short ciliary nerves, carrying a mixture of sensory and autonomic fibers, emerge from the anterior pole of the ciliary ganglion and together with the long ciliary nerves pierce the posterior globe in the vicinity of the optic nerve. After penetrating the sclera, the nerves enter the suprachoroidal space and course anteriorly toward the cornea. While in transit to the anterior eye segment, the fibers branch repeatedly and eventually form a series of prominent, evenly spaced nerve bundles that approach the corneoscleral limbus uniformly from all directions.

Some mammalian corneas also receive a modest sympathetic innervation from the superior cervical ganglion; however, the existence and magnitude of this contribution vary widely among species. In rabbits and cats, corneal sympathetic nerves may constitute as much as 10–15% of the total corneal innervation, while in humans and other primates corneal sympathetic fibers are exceedingly rare or absent. A very sparse parasympathetic innervation has been reported in rat and cat corneas; however, the meager nature of this innervation and its absence from most mammalian corneas suggest that they are likely of little physiologic significance.

Architecture of the Corneal Innervation

Limbal Plexus

Prior to entering the cornea, the nerve bundles traverse the limbus and contribute fibers to the limbal, or pericorneal plexus, a dense, ring-like meshwork of nerve fibers that completely surrounds the peripheral cornea. The three-dimensional structure of the limbal plexus varies considerably in anatomical complexity according to species and contains complex mixtures of sensory, sympathetic, and parasympathetic nerves. Most limbal

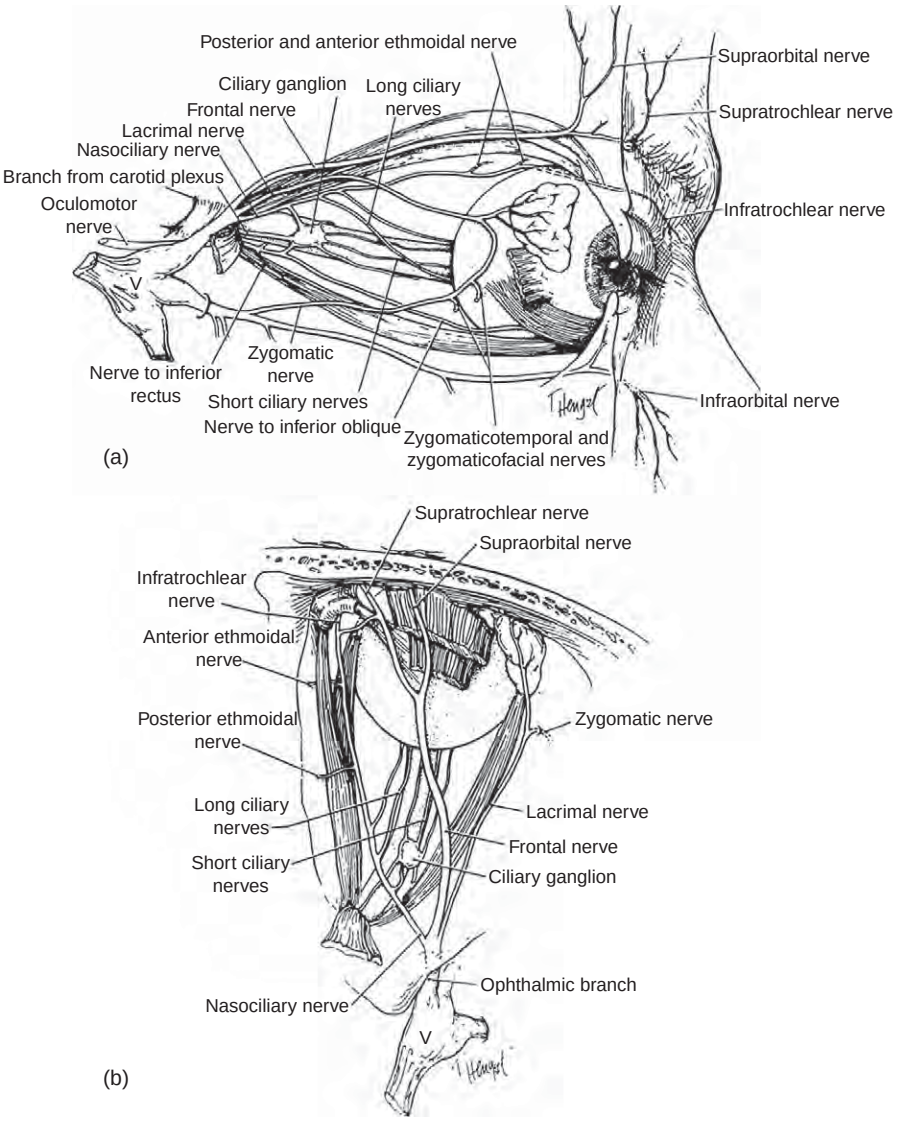

Figure 1 The branches of the ophthalmic division of the trigeminal nerve as seen from the lateral side (a) and from above (b). Sensory nerves to the cornea travel mainly in the nasociliary nerve and its ocular branches, the long and short ciliary nerves. Reproduced from figure 25-5 in Liu, G. T. (2004). The trigeminal nerve and its central connections. In: Miller, N. R. and Newman, N. J. (eds.). *Walsh and Hoyt's Clinical Neuro-Ophthalmology*, vol. 2, pp. 1233–1274. New York: Lippincott, Williams and Wilkins with permission from Lippincott, Williams and Wilkins.

nerves supply functional innervation to the limbal vasculature; however, occasional fibers travel through the limbal stroma unrelated to blood vessels and may provide sensory or autonomic innervation to resident cells.

Stromal and Subepithelial Plexuses

Most nerves enter the peripheral cornea in a series of radially directed major stromal nerve bundles, each containing as many as several dozen axons, arranged at regular intervals around the limbal circumference. On average, 60–80 major stromal nerves supply innervation to the human cornea, while 12–20 bundles supply rabbit, cat, and dog corneas. Additional numbers of smaller nerve fascicles enter the peripheral cornea slightly superficial to the main stromal bundles and provide limited innervation to the perilimbal and peripheral cornea. At their point of entry in the peripheral cornea, most corneal nerves are unmyelinated C-fibers; however, perhaps as many as 30% are finely myelinated A-delta fibers that shed their myelin sheaths within a millimeter or so after entering the cornea. The axons then continue into the stroma as flattened, ribbon-like fascicles surrounded only by Schwann cell cytoplasm and basal lamina.

Soon after entering the peripheral cornea, the major stromal bundles branch repeatedly to form elaborate, tree-like arbors whose distal branches anastomose extensively with neighboring branches to form a dense anterior stromal plexus. The plexus occupies approximately the anterior 25–50% of the corneal stroma, depending on the species, and consists of complex admixtures of seemingly randomly organized small and medium-sized nerve bundles and individual axons with straight, curvilinear, and tortuous trajectories. The plexus becomes increasingly denser and anatomically complex in the anterior direction. The most superficial layer of the anterior stromal plexus in humans and other large mammals is especially dense and is referred to as the subepithelial plexus (SEP). In contrast, the posterior half of the corneal stroma and the endothelium are, with rare exceptions, devoid of nerve fibers.

A small but indeterminate number of nerve fibers in the anterior stromal and SEPs appear to terminate in the stroma, usually as slightly bulbous terminal swellings or free nerve endings. At the electron microscopic level, the stromal fibers and their terminals resemble morphologically free nerve endings found in the corneal epithelium, suggesting that stromal nerve endings may subserve undetermined sensory transduction functions. Some stromal fibers form intimate relationships with keratocytes and are occasionally enwrapped in keratocyte cytoplasmic extensions that may provide a morphological substrate for reciprocal functional interactions.

Individual stromal axons entering at the corneoscleral limbus may travel as much as three-quarters of the way across the cornea before ending and, as a result of repetitive branching, possess receptive fields that range in size from less than 1 mm^2 to as much as 50 or more square millimeters and may cover up to 20% or more of the corneal surface. The receptive fields are generally round, oval, or wedge-shaped in outline and often extend several millimeters beyond the cornea onto the adjacent limbus and bulbar conjunctiva. The large sizes and extensive overlap between adjacent receptive fields, coupled with convergent mechanisms in the central nervous system, explain why stimulation of the corneal surface is poorly localized.

Subbasal Nerve Plexus

The subbasal nerve plexus comprises the densest part of the corneal innervation and is so-named because the nerves that comprise this plexus travel in the subnuclear part of the basal epithelium or between the basal epithelial cells and their basal laminae. Estimates of subbasal nerve fiber density in the central human cornea are expressed conventionally as the total length of all nerve fibers and branches per square millimeter, and range from 15–27 mm mm^{-2} (by *in vivo* confocal microscopy) to 40–55 mm mm^{-2} (by immunohistochemical staining of corneal whole mounts).

Approximately 400–500 widely spaced stromal nerves penetrate Bowman's membrane, mainly in the peripheral and intermediate cornea, to give origin to the human subbasal plexus. Additional subbasal nerves enter the peripheral cornea directly from the limbal plexus. Relatively few stromal nerves penetrate Bowman's membrane in the central 2 mm of the human cornea; hence, the latter region receives most of its epithelial innervation from long subbasal nerves that invade the central cornea from more peripheral origins.

Immediately after penetrating Bowman's membrane, each stromal nerve bends at a 90° angle and branches simultaneously into 2–20 thinner nerve fascicles termed subbasal nerves. Subbasal nerves course in the horizontal plane, roughly parallel to one another and to the epithelial basal lamina, for 1–2 mm in rats and up to 6 mm or more in humans. The neuroanatomical structure thus formed by a stromal axon branching into multiple, parallel subbasal daughter fibers is termed an epithelial leash, a unique, two-dimensional sensory nerve specialization found only in the cornea (**Figure 2**). At the electron microscopic level, human subbasal nerves average 1.5 μm in diameter and may contain up to 40 individual unmyelinated axons (**Figure 3**). Immediately upon entering the basal epithelium, the axons shed their Schwann cell investments and continue as naked axon cylinders. Subbasal nerves in adjacent leashes interconnect frequently with one another. As a result, the boundaries between individual leashes are soon lost and a composite subbasal nerve plexus is formed.

When viewed in its entirety, the subbasal nerve plexus forms a gentle spiral or whorl-like pattern on the curved corneal surface (**Figure 4**). The center of the spiral, often called the vortex, is located in human corneas approximately 2–3 mm inferior and nasal to the corneal apex. As a consequence of this arrangement, subbasal nerves in the superior and apical human cornea are oriented vertically, whereas subbasal nerves in other corneal regions may be oriented horizontally or obliquely, consistent with their geographical locations within the whorl-like plexus. The mechanisms that govern the formation and maintenance of this spiral-like pattern remain uncertain; however, it has been established that basal epithelial cells and subbasal nerves migrate centripetally in tandem. According to one theory, basal epithelial cells derived from stem cells in the corneoscleral limbus migrate centripetally in a whorl-like fashion toward the corneal apex in response to chemotrophic guidance, electromagnetic cues, and population pressures; the subbasal nerves, occupying cytoplasmic invaginations or narrow intercellular spaces between adjacent columns of migrating cells, are pulled along and undergo compensatory horizontal elongation. Alternatively, subbasal nerves may develop whorl-like,

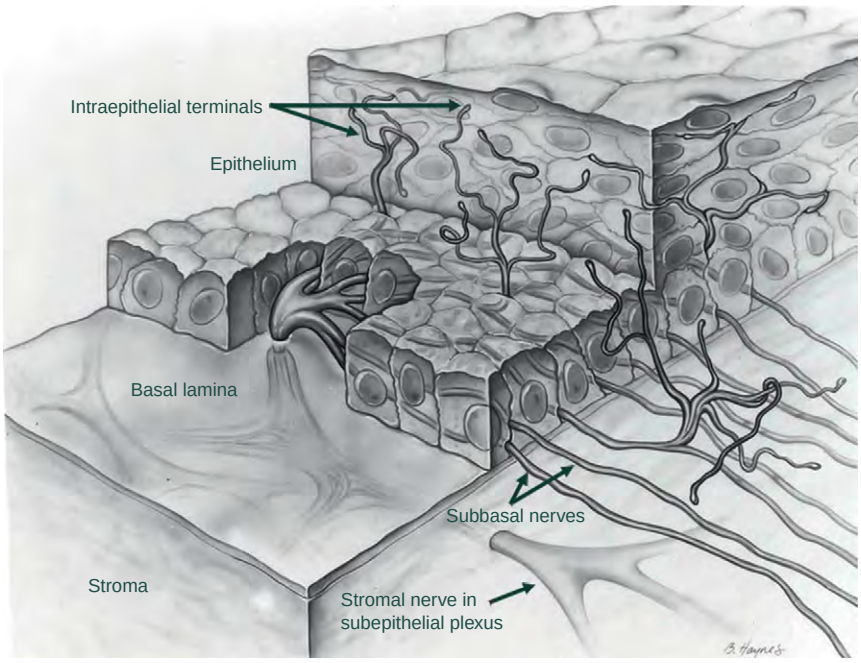

Figure 2 Innervation of the rabbit corneal epithelium. Stromal nerves penetrate the basal lamina and branch into a leash-like assemblage of horizontally oriented fibers called subbbasal nerves; the latter nerves give rise to a profusion of intraepithelial terminals. Modified from figure 6 in Rozsa, A. J. and Beuerman, R. W. (1982). Density and organization of free nerve endings in the corneal epithelium of the rabbit. *Pain* 14: 105–120. Figure 3 Electron micrograph of a subbasal nerve from a human cornea. The nerve, cut in cross section, contains eight individual unmyelinated axons. M, mitochondria. Calibration bar is 1 μm. Reproduced from figure 5c in Muller, L. J., et al. (2003). Corneal nerves: Structure, contents and function. *Experimental Eye Research* 76: 521–542. With kind permission from Elsevier.

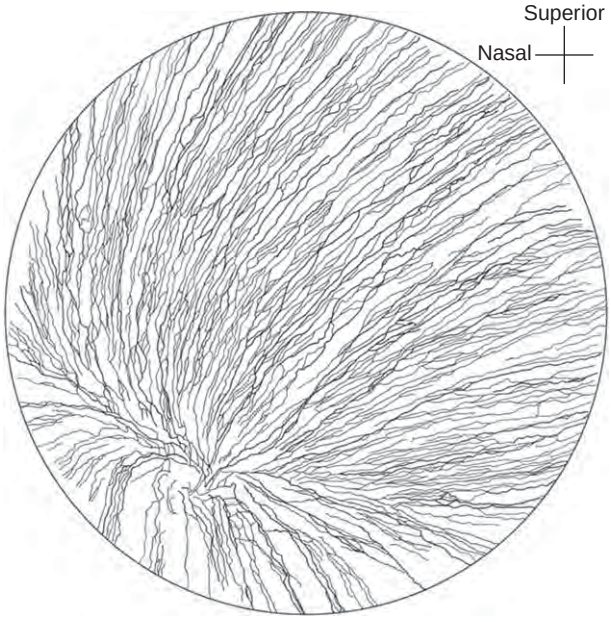

Figure 4 Architecture of the subbasal nerve plexus in the human cornea. The area illustrated is 6.5 mm in diameter and centered on the corneal apex. Subbasal nerves converge in a gentle, whorl-like pattern on a region approximately 2–3 mm inferonasal to the corneal apex known as the vortex.

curvilinear orientations independent of epithelial cell dynamics and may, in turn, provide a structural scaffold that patterns and directs epithelial cell migration.

Intraepithelial Nerve Terminals

As the subbasal nerves course horizontally through the basal epithelium, they give rise to a profusion of thin, occasionally beaded terminal axons that ascend vertically or obliquely, often with a modest amount of additional branching, into the more superficial epithelial layers before ending (**Figure 5**). In some mammalian corneas,

additional epithelial nerves originate as single axons directly from the SEP. The end of each intraepithelial fiber is tipped by a conspicuous, bulbous terminal expansion. At the ultrastructural level, these expansions contain abundant small clear vesicles, varying numbers of large dense-cored vesicles, mitochondria, glycogen particles, neurofilaments, and neurotubules. Morphologically, they resemble nociceptor nerve endings described in other tissues. The neurochemical content of the small clear vesicles is uncertain but may include excitatory amino acids, while the large, dense-cored vesicles likely contain substance P (SP), calcitonin gene-related peptide (CGRP), and/or other neuropeptides.

The terminals are located throughout all layers of the corneal epithelium but are especially numerous in the basal and wing cell layers. Some terminals may extend to within a few microns of the corneal surface. The epithelial cell membranes facing the nerve terminals often demonstrate numerous invaginations and, in many cases, the epithelial cell cytoplasm totally surrounds the nerve ending. The intimate morphological relationship thus formed between nerve terminal and epithelial cell does not constitute a true synapse, but may nevertheless provide a favorable environment for the exchange of diffusible substances and receptor-mediated interactions. The intimate contacts may also allow nerve endings to sense osmotic changes in epithelial cell shape and volume brought about by dessication of the ocular surface. When osmotic stimulation reaches threshold, the nerve fibers fire and activate brainstem circuits that promote reflex tear production and blinking in an effort to maintain the physiologic integrity of the ocular surface.

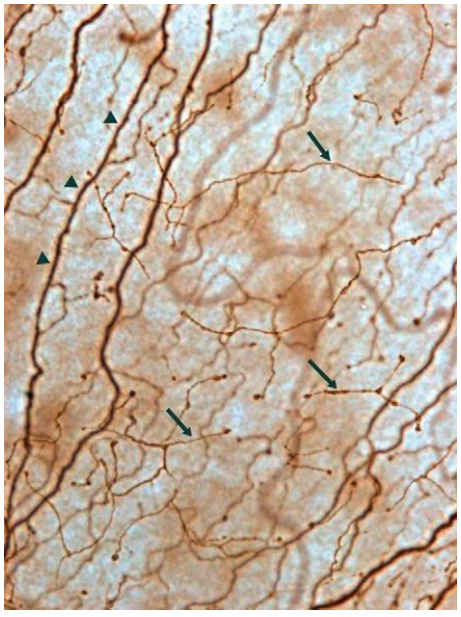

Figure 5 Intraepithelial nerve terminals (arrows) in the human corneal epithelium stained by neurotubulin immunohistochemistry. Arrowheads, subbasal nerve.

The innervation density of the corneal epithelium is probably the highest of any surface epithelium, and the central corneal epithelium of humans and rabbits contains approximately 5000–8000 nerve terminals per square millimeter. Both nerve terminal density and corneal sensitivity are greatest in the central cornea and decrease progressively in the peripheral direction. The richness of the corneal epithelial innervation provides a nociceptive detection system of unparalleled sensitivity and it is hypothesized that injuries to individual epithelial cells may be sufficient to trigger pain perception. Both corneal sensitivity and nerve density decrease progressively as a function of age and may contribute to the pathogenesis of dry eye disease in some elderly patients.

Corneal Nerve Neurochemistry

Corneal sensory nerves help maintain a healthy ocular surface by activating brainstem circuits that stimulate reflex tear production and blinking, and by releasing trophic substances, including numerous neuropeptides, which promote corneal epithelial physiologic renewal and wound repair. Corneal nerves contain, in varying proportions, the same neuropeptides that are expressed in other ocular nerves. Each corneal fiber population (sensory, sympathetic, and parasympathetic) maintains a distinctive phenotypic signature; however, the chemical coding is complex and most fibers likely express combinations of neuropeptides rather than individual markers. To date, 12 different neuropeptides have been detected by radioimmunoassay or immunohistochemistry in the mammalian cornea.

Corneal sensory nerves may contain one or more of six different neuropeptides. Two of these peptides, CGRP and SP, are found in especially high percentages of corneal nerves and remain the most studied and well characterized of the corneal peptidergic nerves (**Figure 6**).

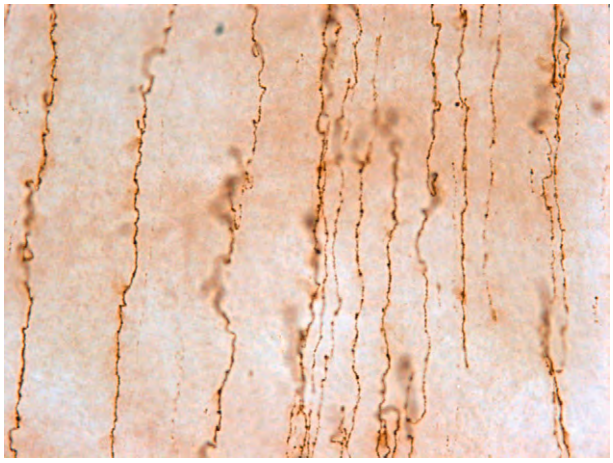

Figure 6 Calcitonin gene-related peptide (CGRP)-immunoreactive subbasal nerves in the rat corneal epithelium.

CGRP and SP are expressed in approximately 30–60% and 10–20% of corneal sensory nerves, respectively, and have been found in all mammalian corneas investigated to date. The vast majority of nerves that contains CGRP also contain SP and the two peptides probably co-localize in the same vesicles. Other neuropeptides expressed in more limited numbers of corneal sensory nerves include: neurokinin A (a member of the tachykinin family) secretoneurin (a member of the chromogranin/secretogranin family), pituitary adenylate cyclase-activating peptide (PACAP, a member of the vasoactive intestinal polypeptide (VIP)-glucagon-secretin super family), and galanin. The extent to which these peptides coexist with CGRP and SP or represent distinct populations of corneal sensory nerves remains to be determined.

Despite the richness of the corneal peptidergic innervation, it does not fully account for the known density of the corneal sensory innervation and it is therefore likely that many corneal sensory nerves do not express neuropeptides. Immunohistochemical investigations of rat corneal sensory nerves suggest that up to 40% of rodent corneal nerves do not express known neuropeptides. Most of the so-called nonpeptidergic nerves express a cell-surface glycoconjugate that binds the plant isolectin *Bandaireae simplicifolia* IB4 and contain the enzyme, fluoride-resistant acid phosphatase (FRAP). The neurotransmitters expressed by this prominent population of corneal IB4-positive nerves remain to be determined; however, excitatory amino acids such as aspartame and glutamate, or unknown neuropeptides that remain to be characterized, are likely candidates.

Corneal autonomic nerves, which constitute in most species only a small percentage of corneal nerve fibers, are also neurochemically diverse. Corneal sympathetic nerves express (in addition to noradrenalin) serotonin and neuropeptide Y (NPY), while corneal parasympathetic nerves express VIP, met-enkephalin, NPY, and galanin.

Functional roles of most neuropeptides in the mammalian cornea remain unclear and knowledge of their physiological roles has not kept pace with the results of immunohistochemical analyses. An important exception to this statement is SP, which exerts essential trophic functions on the corneal epithelium. SP receptors are present on corneal and limbal epithelial cells and it is thought that, under resting physiologic conditions, SP released from corneal sensory nerve terminals promotes corneal epithelial maintenance and physiological renewal by activating cellular pathways that stimulate epithelial cell proliferation, migration, and adhesion. In addition, topical application of SP has been reported to accelerate the rate of corneal epithelial wound healing in both experimental animal models and clinical patients with persistent corneal epithelial defects. Damage to corneal sensory nerves by surgery or trauma deprives the corneal epithelium of SP and other essential nerve-derived trophic substances and is associated with a variety of ocular surface disorders, including dry eye disease, epitheliopathy, and neurotrophic keratitis.

Even less is known of the functional roles of the cornea's limited autonomic innervation. In animal models, corneal sympathetic nerves act through adrenergic mechanisms to modulate corneal epithelial cell ion transport processes, epithelial cell proliferation and mitosis, and cell migration during epithelial wound healing. In the corneoscleral limbus, NPY augments the vasoconstrictor effects of noradrenalin and exerts strong angiogenic effects.

Corneal Nerve Remodeling

Corneal subbasal nerves and their intraepithelial terminals are dynamic structures that undergo morphological rearrangements continuously under normal physiologic conditions. Time-lapse, *in vivo* confocal microscopic examination of living human eyes reveals that subbasal nerves slide centripetally in tandem with their neighboring basal epithelial cells at rates of 10–20 $\mu m\, day^{-1}$ and that this nerve elongation occurs through the addition of new nerve material near the site of nerve penetration at Bowman's membrane. As subbasal nerves cannot elongate indefinitely, it is hypothesized that the distal nerve segments eventually degenerate or slough into the tear film. Intraepithelial nerve terminals also undergo continuous remodeling through combinations of long-term, nerve-directed reconfigurations and passive, short-term reorganization in response to outward migrations of differentiating epithelial cells.

Corneal Nerve Regeneration after Ocular Surgery
