Corneal nerves are transected during a variety of corneal and anterior-segment surgical procedures, including refractive surgery, perlimbal incisions performed for cataract surgery, iridectomy and trabeculectomy, and penetrating keratoplasty (PK; corneal transplantation). Corneal nerves depend for their survival on axoplasmic transport of essential substances from their parent nerve cell bodies in the trigeminal ganglion; thus, surgical procedures that interrupt corneal nerve fibers cause rapid degeneration of the distal axons, decreased corneal sensitivity, and compromised functional integrity of the ocular surface.

Corneal nerves are capable of regeneration; however, it is a slow, imperfect process and the regeneration that takes place after most corneal surgeries is characterized by reduced nerve density, alterations in nerve architecture, and diminished corneal sensitivity. The more proximally the nerves are cut, the more delayed and incomplete the regeneration process will be. Thus, surgical disruption of

the subbasal and subepithelial nerve plexuses produce, in general, less serious and more short-term damage to the corneal innervation than do deep or penetrating incisions that affect major stromal nerve bundles.

Refractive Surgery

In laser-assisted *in situ* keratomileusis (LASIK), a mechanical or femtosecond laser microkeratome is used to create a circular flap of corneal epithelium and superficial stroma with a hinge at one end; the flap is then folded back and an excimer laser is used to remove several tens of microns of stroma from beneath the flap. The microtome severs subbasal and subepithelial nerves all around the flap margin except at the hinge, and the excimer laser destroys additional nerves in the anterior stromal bed. Regenerating nerve fibers emerge first as neurites from the subbasal plexus at the hinge and, to a lesser extent, elsewhere around the flap margin, followed by a second generation of neurites originating from the transected stromal nerve trunks. Abnormal proteoglycans present at the LASIK scar interface between the stromal bed and the overlying flap are postulated to impede successful reinnervation from the anterior stromal plexus. Regeneration is slow and incomplete, with subbasal and stromal nerve densities returning to less than half of preoperative levels by 12 months after LASIK and failing to reach preoperative levels even 3–5 years later. In addition, the architecture and morphology of the regenerated subbasal nerve plexus are often abnormal. Long-term studies are needed to determine whether subbasal nerve density will eventually return to pre-LASIK levels.

Although corneal reinnervation after LASIK surgery is incomplete, the corneal sensitivity, as determined by Cochet–Bonnet esthesiometry, in most cases returns to preoperative levels by 6–12 months and the short-term clinical outcome in most patients is excellent. Most patients experience a decrease in corneal sensitivity and mild-to-moderate dry eye after LASIK surgery that lasts for only a few days; however, approximately 5% of LASIK patients suffer long-term dry eye symptoms that may be related at least in part to impaired corneal reinnervation and interruption of the neural circuits that drive reflex tear production. Some patients with chronic dry eye after LASIK experience persistent and aberrant pain sensations that likely reflect sensitization and altered responsiveness of the immature, regenerating nerves.

In photorefractive keratectomy (PRK), the corneal epithelium is removed and an excimer laser is used to ablate the most anterior portion of the corneal stroma. Nerve regeneration and recovery of corneal sensitivity under these conditions, in which a flap is not cut in the cornea, reportedly occurs more quickly than following LASIK surgery; nevertheless, subbasal nerve density, architecture, and corneal sensitivity remain depressed for up to 1–2 years postoperatively.

Cataract Surgery

Penetrating perilimbal incisions, such as those performed for cataract surgery, are curvilinear incisions that are a few millimeters in length, which transect small numbers of major stromal nerve trunks near their sites of entry into the cornea. Neural regeneration proceeds slowly through a combination of nerve regrowth and collateral sprouting from adjacent, uninjured stromal nerves. The success of nerve regeneration varies from individual to individual; some nerve trunks fail to regenerate and, the ones that do regenerate, often contain diminished numbers of axons or form tangled masses of disorganized nerves in previously denervated areas of the stroma. Since the advent of phacoemulsification, the incision sizes used in cataract surgery have decreased steadily to as little as 1 mm and the risk of significant injury to the corneal innervation has been minimized.

Penetrating Keratoplasty

PK requires a full-thickness, 360° corneal incision that cuts all corneal nerves and results in complete denervation of the transplanted cornea. Nerve regeneration proceeds from the peripheral recipient cornea into the donor cornea very slowly and, even many years later, the innervation density of the grafted tissue remains far less than that of the host, peripheral cornea (**Figure 7**). Stromal nerves, in particular, regenerate very poorly after PK, perhaps because when the graft is introduced Schwann cell channels in the donor cornea are misaligned with the stromal nerve stumps in the host cornea. This contrasts to the perlimbal incisions used in cataract surgery, where nerve trunks and Schwann cell channels on opposing sides of the incision remain closely aligned. The limited nerve regeneration that does take place following PK derives mostly from small numbers of subbasal nerve fibers that elongate through epithelial bridges at the graft margin to enter directly into the donor basal epithelium. Many of the regenerated subbasal nerves are shorter than normal and exhibit atypical orientations and morphologies. Even several decades after surgery, median subbasal nerve density and corneal sensitivity in clear grafts remain significantly reduced compared to healthy corneas, and in about one-half of cases no subbasal nerves are visible by routine *in vivo* confocal microscopy. The return of sensation to the donor tissue is highly variable and, in many cases, hypoesthesia persists for many years after initial surgery. Fortunately, a return to normal innervation levels is not necessary for corneal clarity. Transplanted corneas can have severe nerve deficits and hypoesthesia for many years but remain clear; nevertheless, it is theorized that the impaired sensory innervation after PK may contribute to the relatively high frequency of epithelial complications observed after this procedure.

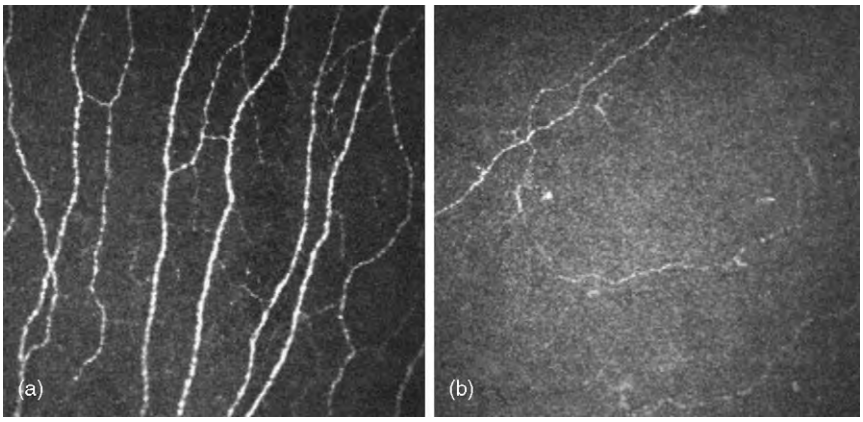

Figure 7 Subbasal nerve fibers in human corneas as demonstrated by *in vivo* confocal microscopy. (a) Normal subbasal nerves in a control subject. (b) Decreased subbasal nerve fiber density after penetrating keratoplasty. Reproduced from figure 1 in Niederer, R. L., et al. (2007). Corneal innervation and cellular changes after corneal transplantation: An *in vivo* confocal microscopy study. *Investigative Ophthalmology and Visual Science* 48: 621–626. With kind permission from Investigative Ophthalmology and Visual Science (IOVS).

Mechanisms of Nerve Regrowth

The mechanisms that stimulate and direct neurite outgrowth from injured and intact areas of the corneal innervation following local nerve injury are incompletely understood and, in most cases, these mechanisms are unable to restore the corneal innervation completely to its preoperative density, architecture, and sensory function. Growth factors expressed by corneal epithelial cells and released at the wound site following injury may play important roles. Nerve growth factor (NGF), a small protein that promotes the growth, survival, and maintenance of peripheral sensory nerve fibers, is constitutively expressed in corneal epithelial cells and is upregulated after epithelial wounding. Topical NGF administration stimulates corneal nerve regeneration and recovery of corneal sensitivity after PRK and LASIK in rabbits, and promotes healing of neurotrophic ulcers in clinical patients. Development of additional molecules that promote regeneration of injured nerves and restore the functional integrity of the ocular surface after corneal surgery is needed.

Corneal Nerves: Function

C Belmonte, Instituto de Neurociencias de Alicante, Universidad Miguel Hernández-Consejo Superior de Investigaciones Científicas, San Juan de Alicante, Spain

Glossary

Dysesthesias – Unpleasant abnormal sensations, spontaneous or evoked, such as burning, dryness, itching, electric shock, and pins and needles caused by the lesions of the peripheral or central nervous system.
Ectopic activity – The abnormal generation of propagated nerve impulses in areas of the sensory neuron membrane that are normally not spontaneously excitable, often generated by peripheral sensory axons or cell bodies of injured sensory ganglion neurons.
Ion channels – Pore-forming proteins located in the cell membrane of all living cells that selectively regulate the flow of ions (cations or anions) into and out of the cell. The ion channel switches between open and closed when the protein undergoes a conformational change, helping to establish and control a voltage gradient (membrane potential) across the plasma membrane.
Nerve impulse – The electrical signal conducted along the axon of neurons by which information is conveyed within the nervous system.
Neuropathic pain – Pain of pathological origin resulting of the abnormal functioning of the peripheral and/or central neural pathways involved in the detection of noxious stimuli.
Sensory afferents – Peripheral branches of sensory neurons located in the dorsal root or trigeminal ganglia that innervate body tissues and carry sensory information to the brain. When covered with a myelin sheath (myelinated or A fibers), they conduct nerve impulses at rapid speeds (over 3 m s^{-1}), while unmyelinated (or C) fibers lack the myelin sheath and have conduction velocities below 2 m s^{-1}.
Sensory receptors – The terminal portion of peripheral sensory axons specialized in the transduction of physical or chemical forces into a discharge of short-lasting (≈1 ms) membrane depolarizations, referred to as nerve impulses, which travel rapidly along the axon.
Signal transduction pathways – The binding of extracellular signaling molecules (or ligands) to cell-surface receptors triggers ordered sequences of biochemical reactions carried out by enzymes activated by second messengers that finally result in a cellular event as, for instance, the opening or closing of specific ion channels.

The cornea is innervated by different functional types of sensory afferent fibers that are selectively activated by physical and chemical stimuli. They give rise to conscious sensations of variable quality that are referred to the eye and/or the periocular region.

The cell bodies of corneal sensory afferents, most of which are of small or medium size, are located in the ipsilateral trigeminal ganglion and reach the cornea through the ciliary nerves. Sensory axons enter the cornea grouped into a variable number of radially oriented nerve bundles that branch extensively and form the sub-basal plexus below the basal epithelial cells. From this plexus, naked single fibers ascend vertically between the epithelial cells ending at variable depths. Immunocytochemical staining of the cell soma and axons of ocular sensory neurons reveals the presence of neuropeptides, principally substance P (SP) and calcitonin gene-related peptide (CGRP). Neuropeptides participate in neurogenic inflammation and promote corneal healing and/or maintenance of epithelial integrity either alone or in combination with growth factors.

Functional Properties of Corneal Sensory Receptors

Functional studies of corneal sensory fibers have been performed recording electrophysiologically in single corneal nerve fibers nerve impulses evoked by physical and chemical stimuli applied to the corneal surface. The majority of corneal sensory nerve fibers, about 70%, are polymodal nociceptors (Figure 1). They are activated by near-noxious mechanical energy, heat, chemical irritants, and by a large variety of endogenous chemical mediators released by damaged corneal tissue, resident inflammatory cells, or those which leak from vessels in the periphery of the cornea (the limbus). Some of the polymodal nociceptor fibers belong to the group of thin myelinated (A-delta) nerve fibers, but most of them are unmylelinated C fibers. Polymodal nociceptors respond to their natural stimuli with a continuous, irregular discharge of nerve impulses that persist as long as the stimulus is maintained. They have a firing frequency roughly proportional to the intensity of the stimulating force. Therefore, the impulse discharge of polymodal nociceptors not only signals the presence of a noxious stimulus, but also encodes its intensity and duration in a certain degree. Corneal polymodal nociceptors have a mechanical threshold slightly lower than mechanonociceptors

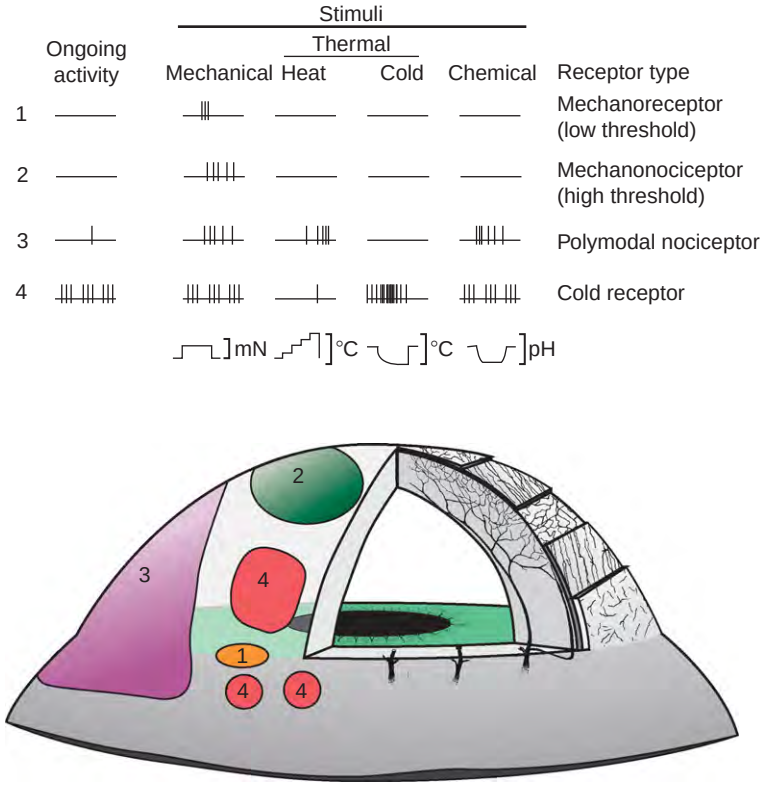

Figure 1 Schematic representation of the types of sensory receptors found in the cornea. In the upper part of the figure, the presence of ongoing activity at rest and the discharge of nerve impulses to the different modalities of stimuli have been displayed for each functional type of corneal sensory receptor type. The shape and time course of the stimulus applied are represented in the lower line. In the lower part of the figure, a scheme of the anterior segment of the eye shows the location and size of the receptor areas of the different types of receptors presented in the upper part of the figure. Modified from Belmonte, C., Aracil, A., Acosta, M. C., Luna, C., and Gallar, J. (2004). Nerves and sensations from the eye surface. *Ocular Surface* 2: 29–34.

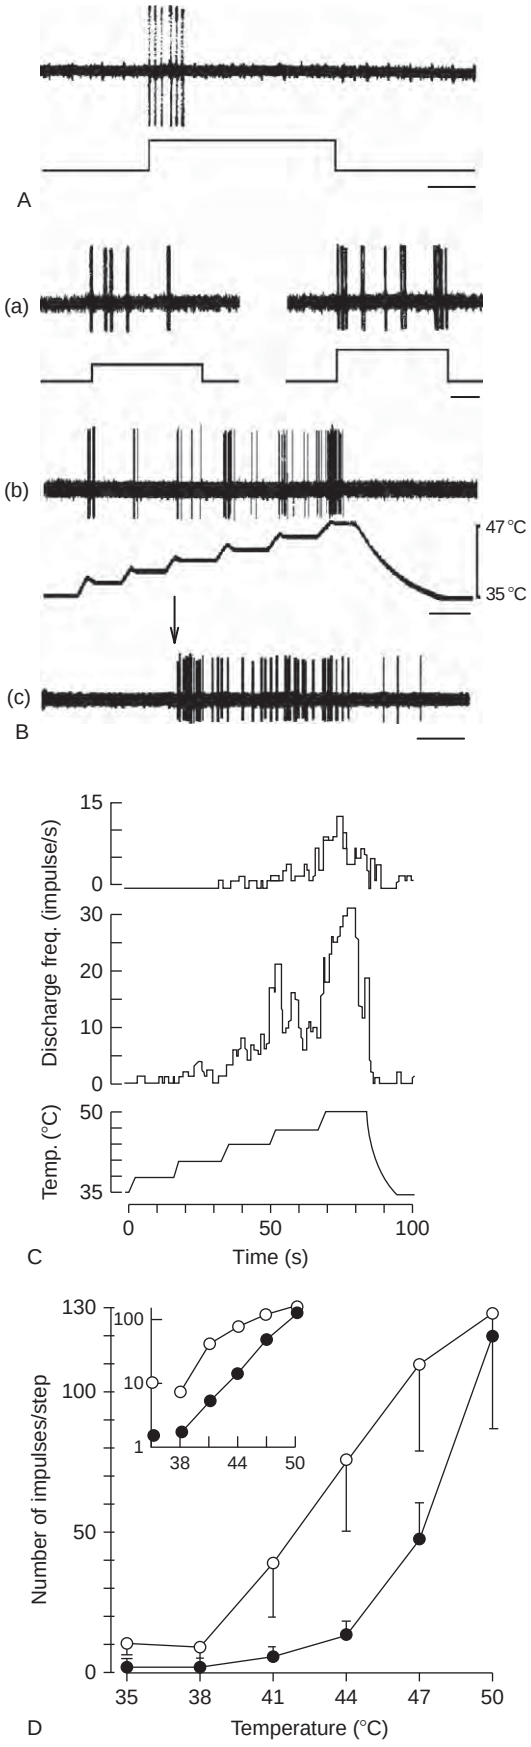
(**Figure 2B(a)**) and, when stimulated with heat, they begin to fire at temperatures over 39–40 °C (**Figure 2B(b)**). A fraction of polymodal fibers (*c.* 50%) also increase their firing rate when the corneal temperature is reduced below 29 °C. Many chemical agents known to excite polymodal nociceptors of other territories also activate ocular nociceptors. Acidic solutions (of pH 5.0–6.5), or gas jets containing increasing concentrations of CO_2 (that in contact with the aqueous corneal surface forms carbonic acid and drops the local pH), evoke an impulse discharge in corneal polymodal nociceptors (**Figure 2B(c)**). Polymodal nociceptors are likely the origin of unpleasant sensations evoked by near-noxious and injurious chemical, thermal, and mechanical stimuli acting on the cornea.

Approximately 15–20% of the axons innervating the cornea (all thin myelinated) respond only to mechanical forces in the order of magnitude close to that required to damage corneal epithelial cells. Accordingly, they belong to the mechanonociceptor type (**Figure 2A**). Fibers of this class of receptor fire only one or a few nerve impulses in response to brief or sustained indentations of the corneal surface and, often, also when the stimulus is removed. Thus, they are phasic sensory receptors that signal the presence of the stimulus and, in a very limited degree, its intensity and duration. The threshold force required to activate mechanonociceptors is apparently low (*c.* 0.6 mN), far below the force that activates mechanonociceptor fibers in the skin. However, this intensity might be sufficient to damage unkeratinized corneal epithelium. Mechanonociceptors in the cornea are probably responsible for the acute, sharp sensation of pain produced by touching the corneal surface. The after-sensations of pain elicited by noxious stimuli are probably explained by the more sustained activity exhibited by polymodal nociceptors.

Another category of corneal nerve fibers that represents 10–15% of the total population is cold-sensitive thermal receptors. These are A-delta and C fibers that discharge spontaneously at rest and increase their firing rate when the normal temperature of the corneal surface (*c.* 33 °C) is reduced while they are transiently silenced upon warming. They also increase their firing rate as soon as the temperature of the cornea drops because of evaporation at the corneal surface, application of cold solutions,



or blowing of cold air on the cornea. Cold receptor fibers are able to detect and encode as a change in impulse frequency and small temperature variations of 0.1 °C or less, thus allowing for the perception of decreases in corneal temperature as a conscious sensation of innocuous cooling.

Finally, it has been suggested that the cornea possesses mechanically insensitive, silent nociceptors, that is, nerve terminals that are not activated by mechanical or thermal stimuli when the tissue is intact, but, in the case of local inflammation, become responsive to these exogenous stimuli as well as to a variety of endogenous chemicals. Although the experimental evidence for their presence in the cornea is only indirect, they have been identified in virtually all other somatic tissues. Thus, it seems likely that such nociceptors also exist in the cornea. **Figure 1** presents a schematic diagram of the firing response to mechanical, thermal, and chemical stimuli of the various functional types of sensory endings identified electrophysiologically in the cornea.

The detection of stimuli by corneal receptor terminals, as occurs with sensory receptors of other tissues of the body, depends on membrane signaling proteins which convert the stimulus energy into a conformational change, leading to an alteration in ionic permeability and an electrical depolarization of the membrane of the nerve terminal, the generator potential. This potential change in the peripheral nerve endings gives rise to propagated nerve impulses in more proximal portions of the axon which travel centripetally to the brain. In nociceptors,

Figure 2 A and B: Impulse response to different stimulus modalities of corneal sensory fibers. A: Transient discharge evoked in a mechanonociceptor fiber by a sustained mechanical indentation. B: Response of a polymodal nociceptor fiber to (a) mechanical indentations of increasing amplitude (80 and 150 μm); (b) stepwise heating of the corneal surface from 34 to 47°C; and (c) application of a drop of 10-mM acetic acid to the corneal surface. In all cases, upper traces depict the nerve impulse recordings and lower traces the stimulus waveform; time scales: A and B(a) = 1 s; B(b) = 15 s; and B(c) = 0.5 s. C and D: Sensitization to heat of corneal polymodal nociceptors. C: Peristimulus histograms of a corneal unit showing the first (upper) and second (lower) response to two identical stepwise heatings separated by 3 min. Each bar indicates the number of impulses evoked per second and the lower trace shows the stimulus waveform. E: Mean stimulus response relation of eight corneal units in response to the first (filled circles) and the second (open circles) stepwise heating. Each point represents the mean number of impulses evoked at the temperature indicated in the abscissa. The bars indicate the standard error of mean. A and B reproduced from Belmonte, C. Gallar, J. The primary nociceptive neuron: A nerve cell with many functions. In: Rowe M. J. (ed.) Somatosensory processing: From single neuron to brain imaging. Sydney, NSW: Harwood Academic Publishers. C and D reproduced from Belmonte, C. and Giraldez, F. (1981). Responses of cat corneal sensory receptors to mechanical and thermal stimulation. *Journal of Physiology* 321: 355–368.

most transduction molecules are ion channels that are directly gated by the stimulus or open by intracellular messenger systems that can, in turn, be activated by a variety of membrane proteins.

Several classes of ion channels have been associated with the transduction of the various forms of energy and the production of the generator potential at nociceptor nerve terminals. A channel protein named transient receptor potential type vanilloid 1 (TRPV1) receptor, a nonselective cation channel with pronounced permeability for Ca^{2+} ions, is the main molecular substrate for the ability of polymodal nociceptors to respond to acid, heat, certain irritant chemicals, and inflammatory mediators. Another ion channel of the same family – transient receptor potential cation channel, subfamily A, member 1 (TRPA1) – also exhibits a prominent sensitivity to pungent chemicals. Thus, these channels serve as molecular integrators for multiple types of stimuli. The nature of the molecular entities involved in the transduction of mechanical forces at nociceptor endings is still uncertain. Stretch-activated ion channels have been identified in the membrane of mammalian sensory neurons. Extracellular matrix attachments have been proposed as the mechanism involved in the transmission of external mechanical forces to the neuronal surface and, subsequently, to ion channels activated or inactivated by stretch. Finally, TRPM8 and leak K^+ channels have been suggested as cold sensors in cold thermoreceptor corneal fibers. The depolarization of sensory nerve terminals in the cornea secondary to ion channel opening has a variable duration. In the case of rapidly adapting corneal mechanosensory endings, only one or few nerve impulses are generated. Thus, they serve primarily to signal the presence of a stimulus. Polymodal nociceptors and cold receptors encode the intensity and the time course of the stimulus in their firing rate and duration. They therefore provide information to the brain on both the modality and the characteristics of the stimulus (**Figure 1**).

Response of Corneal Receptors to Local Inflammation

One of the most prominent features of polymodal nociceptors is that sustained or repetitive stimulation tends to augment their response to new noxious stimuli. This phenomenon, referred to as sensitization, is also present in corneal nociceptors. Sensitization is characterized by a reduction of the impulse firing threshold such that impulse discharges are now evoked by intensities of the stimulus within the innocuous range. Moreover, noxious stimuli elicit a stronger and more sustained impulse discharge. Finally, sensitized corneal nociceptors often develop an irregular, low-frequency ongoing activity of nerve impulses in the absence of stimulation (**Figures 2D** and **2E**). This spontaneous activity, coupled with the enhanced responsiveness to stimulating forces, is the peripheral substrate of the augmented pain sensitivity and the presence of pain sensation in the absence of stimulus, exhibited by injured and/or inflamed corneas.

The sensitization of corneal nociceptors occurs as a result of the local release by injury of a large variety of inflammatory mediators from damaged cells and from resident and invasive cells of the immune system. Endogenous chemicals include H^+ and K^+ ions, adenosine and adenosine triphosphate (ATP), serotonin, histamine, platelet-activating factor, bradykinin, prostaglandins, leukotrienes, tromboxanes, interleukins, tumor-necrosis factor, and nerve growth factor (NGF). These mediators are responsible for local inflammatory reactions in the cornea and conjunctiva (vasodilatation, plasma extravasation, and cell migration), and act on membrane channels and receptor proteins at corneal nociceptor nerve endings, provoking short-term changes in their opening probability. TRPV1 and TRPA1 channels at the membrane of polymodal nociceptors are direct or indirect targets for many of the inflammatory mediators released upon corneal injury. The enhanced ion flow and increased membrane excitability resulting of ion channel activation create the augmented impulse firing and reduced threshold that characterize the process of sensitization of injured corneal nerve terminals (**Figures 2D** and **2E**). Inflammatory mediators use different signaling pathways to exert their effects on channel activity. For instance, prostaglandin E2, ATP, and adenosine or 5-hydroxytryptamine (5-HT) activate the protein kinase A (PKA) signaling pathway, whereas other mediators such as bradykinin act on protein kinase C to produce sensitization. The sensitization of corneal nociceptors develops within minutes of an acute corneal injury and normally fades when inflammation subsides. Long-lasting corneal inflammation, as occurs, for instance, in chronic dry eye, may produce more permanent changes in nociceptive terminals, including modified expression of the existing receptor molecules and expression of new ones possibly mediated by growth factors, in particular NGF.

The nerve impulses evoked by noxious stimuli in corneal nociceptors not only travel centripetally to the brain, but also invade antidromically other nonstimulated peripheral branches of the parent axon, causing the release of neuropeptides contained into their peripheral endings. CGRP and SP released by depolarized nociceptor endings contribute to local inflammatory responses and amplify the proinflammatory effect of other endogenous mediators. This neurogenic inflammation mediated by the sensory nerves affects noninjured areas of the cornea and conjunctiva and explains the extension of inflammation to distant, intact tissues (conjunctiva, iris, and ciliary body) following a limited corneal lesion.

Effects of Injury on Corneal Nerves

After ocular surgery, accidental trauma, and nerve injury secondary to certain ocular or systemic diseases, corneal sensory nerves may become damaged at different points of their trajectory. It is well established that peripheral axotomy changes the morphology and functional properties of nerve fibers projecting to the cornea substantially. Denervated areas are invaded by outgrowths of adjacent noninjured nerve fibers and sprouts of the injured axons. Some of terminal stumps of severed axons are entrapped by scar tissue and form microneuromas. The expression of genes that encode ion channels (in particular sodium and potassium channels) and receptor proteins by primary sensory neurons is also modified by peripheral nerve injury. This alters nerve excitability and favors the development of ectopic discharges and abnormal responsiveness in damaged neurons, giving rise to peripheral neuropathic pain.

Sensitivity of the Intact Cornea

Clinical exploration of the sensitivity of the cornea or conjunctiva to mechanical stimulation is normally performed by gently touching the ocular surface with a wisp of cotton, and observing the blink reflex or comparing the subjective sensation with that evoked in the fellow eye. A more quantitative approach is obtained using a calibrated hair of variable length (the Cochet–Bonnet esthesiometer). The Belmonte noncontact gas esthesiometer uses an air jet of adjustable flow and temperature that contains CO_2 in a variable concentration to reduce local pH, which allows separate mechanical, thermal, or chemical stimulation applied to a restricted area of the cornea or the conjunctiva. Using these procedures, changes in normal corneal sensitivity in relation to age, sex, pregnancy, iris color, and use of contact lenses; pathological changes associated to ocular surgery; corneal pathologies such as herpes virus infections, keratitis, iritis, uveitis, and glaucoma; or systemic diseases such as fibromyalgia or diabetes have been detected in multiple clinical and experimental studies.

Studies with the Belmonte esthesiometer have determined that the quality of the sensation evoked from the intact cornea and conjunctiva depends on the modality of the stimulus applied. Furthermore, electrophysiological recordings of nerve impulse activity in experimental animals applying mechanical, thermal, and acidic stimuli to the cornea with the Belmonte esthesiometer showed that each of them excited, in a variable degree, the various functional subpopulations of corneal nerve fibers. In humans, the sensations produced by suprathreshold mechanical, chemical, and heat stimulation of the cornea possessed, in each case, a distinct quality that allowed the psychophysical identification of the stimulus modality, but always included a component of irritation. In contrast, the application of cold pulses to a corneal spot that moderately decreased (1–3 °C) the local temperature evoked almost exclusively an innocuous cooling sensation, which acquired an additional component of irritation when more pronounced temperature reductions were applied. The psychophysical characteristics of sensations evoked by stimulation of the bulbar conjunctiva are quite similar to those of the cornea, except that sensitivity was comparatively lower and light mechanical stimuli were felt as nonirritating.

Sensitivity of the Injured Cornea

Following surgical procedures for cataract removal, retinal detachment, and glaucoma, and particularly after surgery performed to correct refractive defects (radial keratotomy, photorefractive keratectomy, laser *in situ* keratomileusis, and keratoplasty), nerves directed to the cornea are usually damaged in a degree that, for photorefractive surgery, depends on the extent of the corneal lesion. Severed nerves start to regenerate soon after injury, but only a part of them succeed in penetrating the injured corneal tissue, and corneal innervation remains disorganized and reduced in number, months and even years after surgery. In parallel with the morphological changes, functional alterations have been described. Axotomized corneal neurons and nerve fibers innervating the injured cornea exhibit an altered threshold to their natural stimuli and abnormal responsiveness to mechanical, chemical, and thermal stimuli.

As a result of the disturbances in peripheral innervation, corneal sensitivity to mechanical stimulation is impaired, with a remarkable increase in threshold of the denervated areas that takes months to recover, and may never return to normal values. Transplanted corneas or implanted lenticules in epikeratophakia remain totally anesthetic for years, or recover, at best, a very limited mechanical sensitivity usually restricted to the periphery of the transplant. After laser-assisted *in situ* keratomileusis (LASIK) surgery, corneal sensitivity to mechanical and chemical stimulation measured with the Belmonte esthesiometer remained significantly below control 3 and 6 months post-LASIK, becoming close to normal only 2 years postsurgery. However, at that time, a few patients with deep photo ablations presented severe sensory impairments.

In parallel with the hypoesthesia just described, spontaneous pain sensations and dysesthesias may appear following refractive surgery. The lower sensitivity of the cornea to external corneal stimulation is explained by the reduced number and the altered threshold of corneal

sensory nerve fibers after surgery. The additional development of unpleasant dryness sensations and/or pain referred to the eye in some patients is attributable to the spontaneous firing and abnormal responsiveness of some of the injured corneal nerve fibers that were unable to fully recover their transducing capacities and exhibit abnormal excitability after injury. These disturbances seem to affect mainly polymodal nociceptor and cold corneal nerve fibers. Thus, these two functional subpopulations of corneal nerves appear to be the main peripheral source of abnormal sensations following corneal surgery.

Corneal Scars

D G Dawson, Emory University School of Medicine, Atlanta, GA, USA

Glossary

Corticosteroid – A class of steroid hormones that are produced in the adrenal cortex and are involved in a wide range of physiologic systems, such as the stress response, the immune response, regulation of inflammation, carbohydrate metabolism, protein catabolism, blood electrolyte levels, and behavior. In wound healing, its primary role is in suppressing the immune response and reducing the release of inflammatory cell mediators.

Epikeratome laser-assisted *in situ* keratomileusis (EpiLASIK) – An anterior surface ablative refractive surgical procedure that uses a unique epikeratome (a microkeratome with a blunt, oscillating blade) to mechanically separate the epithelium from the Bowman's layer and stroma, while suction is applied, to make a hinged epithelial flap, similar to a traditional LASIK flap. Unlike LASIK, no sharp blades or intrastromal cuts are made. It is most similar to LASEK, but no alcohol is required.

Extracellular matrix (ECM) – Any material produced by cells and secreted into the surrounding medium, but it usually is applied to the noncellular portion of living tissues. It typically is classified as basement membrane or interstitial ECM.

Fibrosis – Formation of excessive fibrotic scar tissue in an organ or specific tissue of the body.

Hypertrophic scar – An abnormal, excessively large fibrotic scar due to a pathologic reparative wound-healing response, where the scar is raised above the surrounding adjacent normal tissue, but it does not grow beyond the boundaries of the original wound. It often regresses in size and improves in appearance over a few years after.

Keloid – An abnormal, excessively large fibrotic scar due to a pathologic reparative fibrotic wound-repair response, where the scar extends beyond the boundaries of the original wound in addition to being raised above the surrounding adjacent normal tissue. It is a more severe degree of pathologic scarring than a hypertrophic scar because it can carry on growing indefinitely into a large, benign growth that can present a significant cosmetic issue to the individual.

Laser-assisted subepithelial keratomileusis (LASEK) – An anterior surface ablative refractive surgical procedure that reshapes the cornea to correct refractive errors of the eye and is basically a modified form of photorefractive keratectomy (PRK). With LASEK, instead of removing or excising the epithelium completely as in PRK, the surgeon cuts a round semi-circular area of epithelium with a fine-bladed instrument called a trephine. A dilute alcohol solution is then applied to loosen the cut epithelium inside the semi-circle where it attaches to Bowman's layer and then the surgeon gently lifts and folds back the hinged loosened epithelial flap, exposing the underlying Bowman's layer and corneal stroma for the excimer laser treatment.

Mitomycin C (MMC) – Mitomycins are a family of aziridine-containing natural products isolated from the soil fungus, *Streptomyces caespitosus*. One of these compounds, MMC, finds use as a chemotherapeutic agent or as a scar-reducing agent by virtue of its potent DNA cross-linking.

Myofibroblast – An epithelial-, endothelial-, or mesenchymal-derived cell (e.g., keratocyte) that acquires morphological and biochemical features of smooth muscle cells, including the expression of alpha-smooth muscle actin (α-SMA). It can contract by using the actin smooth muscle filament complex, which can help speed up wound repair by contracting the edges of the wound and enhancing ECM deposition compared to that of simply an activated fibroblast. It has been suggested that in several fibrotic diseases (e.g., liver cirrhosis, kidney fibrosis, retroperitoneal fibrosis, corneal fibrotic scarring) that persistence of myofibroblasts and chronic wound contracture leads to a long-term fibrotic scar.

Platelet-derived growth factor (PDGF) – A family of growth factors (GFs) involved in stimulating fibrotic wound repair and angiogenesis. Three PDGF isomers are found in humans: PDGF-AA, PDGF-AB, and PDGF-BB. In wound healing, its primary cellular source is platelets, which degranulate and release PDGF-AB. This initiates a fibrotic repair response by chemotactic and proliferative effects on fibroblasts and inflammatory cells.

Regeneration – Regrowth of a damaged organ or tissue so that the original structure and function are restored back to normal.

Transforming growth factor-beta (TGF-β) – A family of cytokine proteins that are expressed by almost all mammalian cells in three isoforms (TGF-β1, TGF-β2, and TGF-β3), which have different functions in wound healing. All three TGF-β isoforms play major roles in wound healing including chemotaxis

(signaling migration of macrophages, monocytes, fibroblasts, and neutrophils), fibroblast proliferation, collagen production, and angiogenesis. They act on target cells to generate a specific molecular signaling response by binding to cell surface TGF-β receptors, types RI, RII, and RIII, which then initiates activation of several intracellular signaling pathways. All three TGF-β isoforms are secreted from cells as a large (125–160 kDa) latent TGF-β complex (LL-TGF-β complex), composed of an active TGF-β dimer, a latency-associated peptide (LAP), and one of four possible isoforms of the latent TGF-β-binding protein (LTBP). Overall, the LL-TGF-β complex covalently binds with high affinity to ECM, such as fibronectin, through its specific LTBP domain to create storage pools of latent TGF-β, whereas the free active TGF-β dimer binds to TGF-β cell receptors or creates more storage pools by binding to the core protein portion of dermatan sulfate and heparin sulfate protoglycans (PGs) in the ECM.

Introduction

Tissue or organs of mammalian embryos and fetuses up to the first-half of gestation heal through scar-free regenerative wound healing, whereas tissues in late gestation fetuses up to elderly adults heal more slowly (inversely related to postnatal age) and less efficiently through scar-forming fibrotic wound healing. At the microscopic level, a fibrotic scar is basically defined as disorganized extracellular matrix (ECM) containing repair mesenchymal cell phenotypes as opposed to regenerative or uninjured normal tissue, which have normal ECM architecture containing quiescent mesenchymal cell phenotypes, or tissue fibrosis, which has disorganized ECM containing quiescent mesenchymal cell phenotypes. At the macroscopic level, a fibrotic scar leaves a mark or cicatrix on the skin or tissue after injury, often leading to an alternation in function or cosmesis, whereas tissue fibrosis leaves an inconspicuous mark and regenerative tissue leaves flawless tissue restoration. Thus, fibrotic scarring represents reparation failure to complete tissue fibrosis and both represent failures to achieve true tissue regeneration. Research studies on prenatal embryos and fetuses suggest that the mechanisms involved in the regenerative response are intrinsic to the tissue itself and are not caused by the sterile prenatal environment in the womb. The evolutionary reason for the transition from the scar-free regenerative response to the scar-forming fibrotic repair response in higher mammals, such as humans, is that such a variation helped an individual live longer to reproduce and take care of their young (i.e., natural selection). The fibrotic repair response results in rapid inflammatory cell recruitment and subsequent wound contracture and filling of space, which can be organ or life saving. The main disadvantages of the fibrotic repair response are that it commonly results in the reconstitution of semi-functioning tissue or can fill the tissue with a cosmetically displeasing scar. In modern times, the result of this evolutionary mismatch is that a fibrotic scar can occur from even minor injury (e.g., sterile, simple surgical incision with suturing).

In humans, tissue fibrosis or fibrotic scarring occurs after almost any type of injury to any tissue in the adult human body, including the eye. One exception is injury in which ectodermal cells alone are damaged (e.g., first-degree burns, corneal abrasion, skin abrasion) and heal through scar-free cellular regeneration without any long-term fibrotic effects to the underlying interstitial mesenchymal cells. In fact, in certain cases where the context of the injury and the molecular signaling pathways invoked are shifted toward embryonic mechanisms, scar-free tissue regeneration may still occur as opposed to fibrotic scarring. Thus, tissue fibrosis or fibrotic scarring is not inevitable. For example, if oral mucosa (e.g., gums, palate, and inner cheek) is superficially damaged, complete regeneration occurs. Other examples include complete regeneration of the liver even if up to two-thirds of the liver is removed or complete regeneration of the skin in specific injury contexts, such as a pin-prick, a hypodermic needle stick, or multiple needle insertions (tattooing). In contrast, fibrotic scarring results from penetrating stab incision into the liver or various more severe injuries to the skin, such as: (1) a larger incision than a needle stick, (2) an excision, (3) suturing a wound closed with pro-inflammatory material (cat gut suture), and (4) leaving sutures in place too long or with incorrect tension. These examples illustrate the plasticity of the two wound-healing responses, fibrosis and regeneration. Differences between the desired responses (regeneration or secondarily minimal to mild tissue fibrosis) and the less desired responses (nonhealing wounds or excessive fibrotic scarring) are subtle, but fundamentally come down to three variables: (1) the molecular signaling pathways invoked, (2) the targeted responding cells, and (3) the context and degree in which the targeted responding cells are stimulated.

Central to our understanding of the pathogenesis of tissue regeneration versus fibrotic scarring (and tissue fibrosis) has been the identification of several cytokines and growth factors (GFs) involved in initiating and/or regulating the ongoing wound-healing responses. The relationship between these cytokines and GFs and their predicted cellular responses is now only being partially understood. As such, it is currently known that cytokines and GFs, their associated target cell surface receptors, and their molecular signaling pathways play a significant role

in directing cellular behavior and/or phenotype in normal, diseased, and wound-healing states. Currently, the cytokine best known to play the most crucial role in mediating either tissue regeneration or fibrotic scarring is transforming growth factor-beta (TGF-β). Three isoforms of TGF-β have been identified in mammals, TGF-β1, β2, and β3, all having major roles in wound healing. Studies comparing embryonic tissue regeneration versus adult fibrotic scarring have identified a variety of differences in their intrinsic cellular levels of expression and release. TGF-β3 elicits a regenerative response, whereas both TGF-β1 and TGF-β2 elicit a fibrotic-repair response. There are other notable disparities between the TGF β isoforms (Table 1). TGF-β is secreted extracellularly in a latent or inactive pro-peptide form, consisting of a 25 kDa disulfide-linked homodimeric TGF-β peptide, also known as the active form, that is bound to a latency-associated peptide (LAP), which itself is bound to a specific latent TGF-β-binding protein (LTBP). This 125–160 kDa TGF-β complex is known as a large latent TGF-β (LL-TGF-β) complex. It binds covalently to ECM (e.g., fibronectin) through its LTBP domain to create storage reservoirs of latent TGF-β. During wound healing or inflammation, proteolytic enzymatic cleavage (e.g., tissue plasminogen activator (TPA), plasmin, matrix metalloproteinases (MMPs), or cathepsin) or nonproteolytic dissociation (e.g., low pH, reactive oxygen species) of the active TGF-β dimer occurs from the LL-TGF-β complex, leading to TGF-β activation. Active TGF-β isoform dimer binding to its targeted cell surface receptor(s) leads to a cascade of intracellular signaling pathways, including a Smad pathway as well as other pathways, each resulting in a cell-specific set of responses.

Table 1 Comparison of embryonic and adult wound healing characteristics

Wound healing characteristics	*Embryo/fetus*	*Adult*
Fluid environment	Present	Absent
Sterile environment	Present	Absent
Oxygen tension	Lesser	Greater
Temperature	Warmer	Cooler
Speed of epithelialization/ wound closure	Faster	Slower
Fibroblast migration/ proliferation	Faster	Slower
Fibroblast cellularity	Greater	Lesser
Myofibroblastic differentiation	Absent	Present
Extracellular matrix deposition	Faster	Slower
Extracellular matrix architecture	Normal	Disorganized
Tensile wound strength	Normal	Reduced
Inflammation		
Immune system	Immature	Mature
Inflammatory response	Sparse	Great
Neutrophil transmigration	Absent	Present
Platelets/degranulation	Absent	Present
Cytokine profile the fibroblasts		
TGF-β1 and β2	Low	High
TGF-β3	High	Low
FGF	High	Low
PDGF	Absent	High
Angiogenesis	Lesser	Greater
Wound healing response	Tissue regeneration	Fibrotic scarring

Data from Ferguson, M. W. J. and O'Kane, S. (2004). Scar-free healing: From embryonic mechanisms to adult therapeutic intervention. *Philosophical Transactions of the Royal Society, London B* 359: 839–850.

In general, TGF-β/receptor-mediated intracellular signaling pathways stimulate the production of various ECM proteins and inhibit ECM degrading enzymes (increases inhibitors of MMPs and decreases expression of MMPs), although exceptions to these principles abound. TGF-β also modulates cellular functions such as apoptosis, motility, mitosis, and differentiation or transdifferentiation into new cellular phenotypes. With wound healing, the various cytokine or GF cascades sometimes result in overlapping specific cellular responses that are not completely well understood. For mesenchymal fibrocytes (e.g., keratocytes), this set of responses includes fibrocyte migration and proliferation and subsequent differentiation into a metabolically activated repair cell type known as a fibroblast. Fibroblast cellular behavior results in the synthesis and deposition of a provisional fibronectin matrix comprised of ECM adhesion molecules (fibronectin), ECM space-filling molecules (hyaluronic acid), and ECM signaling molecules (tenascin). The next step is the conversion to early mature ECM, comprised of collagen fibrils, sulfated protoglycans (PGs), and possibly epithelial- or endothelial-derived surface basement membranes (BMs). Under appropriate conditions, such as prolonged or excessive TGF-β exposure, some fibroblasts differentiate into another repair phenotype known as a myofibroblast, which is the central cellular mediators of the fibrotic repair response (Figure 1). Myofibroblasts originate by differentiation from fibrocytes or activated fibroblasts or by transdifferentiation, also known as metaplasia, from epithelial, endothelial, or local smooth muscle cells that are associated with blood vessels (Figure 1). Morphologically, myofibroblasts are larger than activated fibroblasts and uniquely express alpha-smooth muscle actin (α-SMA), an important morphologic marker identifying this cell type using immunohistochemistry techniques. Myofibroblasts are highly contractile repair cells that promote wound closure and contraction. Functionally, myofibroblasts also express and secrete greater amounts of cytokines and GFs, synthesize and deposit greater amounts of ECM, and have stronger and more focal ECM cell surface adhesion receptor sites compared to activated fibroblasts. Myofibroblasts first appear in the stroma directly under the epithelium and

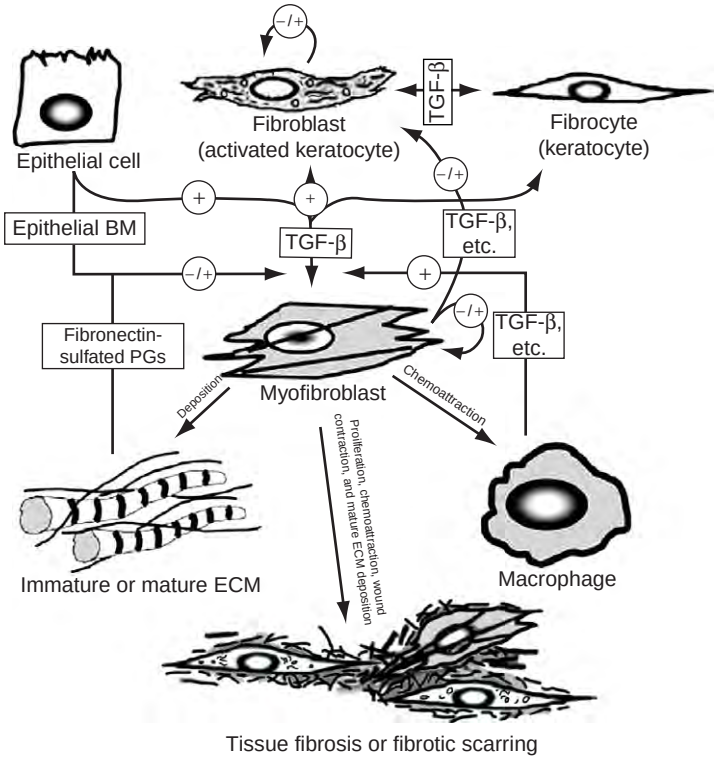

Figure 1 TGF-β is the main cytokine player and the myofibroblast is the main cellular player in the fibrotic repair response. A myofibroblast is derived from a fibroblast, an epithelial cell, a fibrocyte (bone-marrow derived cell?), or many other cell types, and it exerts a central role in cellular reconstitution, inflammation, and extracellular matrix (ECM) deposition in the pathogenesis of tissue fibrosis. Specific cell–cell interactions and ECM–cell interactions further modulate myofibroblast cell behavior. + = amplifying factor. − = suppressing factor.

then their domain advances to progressively deeper levels. Myofibroblast-mediated ECM deposition occurs in an orderly sequence from immature (primitive) to mature (fibrotic) stages: first fibronectin and other noncollagenous provisional ECM proteins (hyaluronic acid, tenascin, etc.), then collagen type III, and lastly collagen type I and sulfated PGs (e.g., decorin, lumican, biglycan). As the scar matures, most of the provisional ECM components are replaced by collagen fibrils (type I >> type III) and sulfated PGs. As judged by collagen fibril diameter and density, ECM usually first reconstitutes to the most mature and most fibrotic stage in the portion of the wound just under the epithelium and then it advances progressively to deeper levels. Additionally, during the evolution of maturation, the hypercellularity and hypervascularity decreases due to apoptosis and tensile strength increases due to increased maturity acquired collagen fibril cross-linking. The mechanism of late disappearance of myofibroblasts is uncertain, but probably is due to a combination of apoptosis and dedifferentiation of cells back to quiescent fibrocytes.

In humans, fibrotic scarring commonly causes major medical problems in a variety of tissues. In the eye, fibrotic scarring causes visual impairment or even blindness. In the peripheral and central nervous systems, glial scarring prevents neuronal reconnections and hence blocks reparative attempts at restoring normal neuronal function. In gastrointestinal and reproductive organs, strictures and adhesions can give rise to serious or life-threatening conditions, such as infertility, bowel obstruction, or chronic pain. In ligaments and tendons, fibrotic scarring restricts motility and decreases strength. Additionally, if the fibrotic repair response is incomplete, becomes excessive, or fails to appropriately terminate, pathologic wound healing occurs resulting in unhealed wounds, hypertrophic scars, or keloid scars, respectively. Overexpression and release of pro-fibrotic TGF-β1 and β2 cytokines, upregulation of TGF-β receptors RI and RII, and/or the formation of a positive, autoinducible feedback loop have been suggested as the primary reasons for excessive fibrotic scarring in hypertrophic or keloid scars. The potential for TGF-β autoinduction is usually self-limited in nonpathologic fibrotic repair responses through a negative feedback loop that terminates further TGF-β expression and release from that cell. In adult humans, the degree of fibrotic scarring versus tissue regeneration or tissue fibrosis depends on the following five factors: tissue site, sex, race, age, and magnitude and contamination of the wound. For tissue site, the gums, liver, and skin can either regenerate or scar, depending on the context of the injury. Most other tissues or organs in the body just repair themselves through tissue fibrosis or

fibrotic scarring, which is body site dependent. The deltoid, sternum, and conjunctiva scar more than the face, abdomen, legs, and cornea. Concerning sex, fertile females scar more than postmenopausal females and all males as estrogen has a major stimulatory effect on the fibrotic repair response. For race, darker pigmented individuals scar more than less pigmented individuals. Concerning age, young people in their teens and 20s scar more than infants and children, who have an immature immune response, and both heal better than older individuals, whose inflammatory response becomes sluggish and less effective with age and whose mesenchymal cells become senescent. Finally, the magnitude of injury and wound contamination alter the wound-healing response as larger, more inflamed, more contaminated wounds scar more than smaller, uncontaminated wounds.

Ocular Wound Healing

The ocular fibrotic wound-repair response is quite similar to that seen in other tissues in the human body. In the eye, fibrotic scarring most commonly occurs in the conjunctiva, cornea, iris, lens, retina, and choroid (**Figure 2**). In vascularized ocular tissues, like the conjunctiva, iris, choroid, or even the cornea or retina after having chronic ocular disease, fibrovascular scars are basically granulation tissue. Scars normally develop in response to vascular stromal injury whereby serum plasma or blood leaks into the wound resulting in a clot. This initiates a fibrovascular repair response predominantly through a platelet-derived growth factor (PDGF)-mediated platelet degranulation signaling pathway resulting in massive release of PDGF into the wound along with some TGF-β release. However, the eye also has several avascular transparent tissues (e.g., cornea, lens, vitreous, and portions of the retina) that also can repair themselves through fibrosis, albeit through four less intense TGF-β-mediated signaling pathways.

TGF-β-mediated wound healing occurs because TGF-β and its associated receptors are constitutively expressed in the normal state by almost all cells residing in or on ocular tissues. The external ocular surface has other factors to additionally consider in that it is bathed in a tear film composed of lacrimal gland secretions that are rich in latent TGF-β1. Similarly, internal intraocular structures are bathed in aqueous humor composed of ciliary and lens epithelial secretions that are rich in latent TGF-β2. Latent TGF-β2 is thought to be one of the principal factors promoting the normal naive immune status of intraocular tissues, including the cornea, due to its ability to maintain resident tissue immune cells in an immature state. Secondarily, latent TGF-β2 has a direct immunosuppressive effect whereby it inhibits immune cell proliferation and inflammatory cell cytokine and GF release. At the concentration levels found in the normal aqueous humor, latent TGF-β2 is also thought to participate in the inhibition of angiogenesis into transparent parts

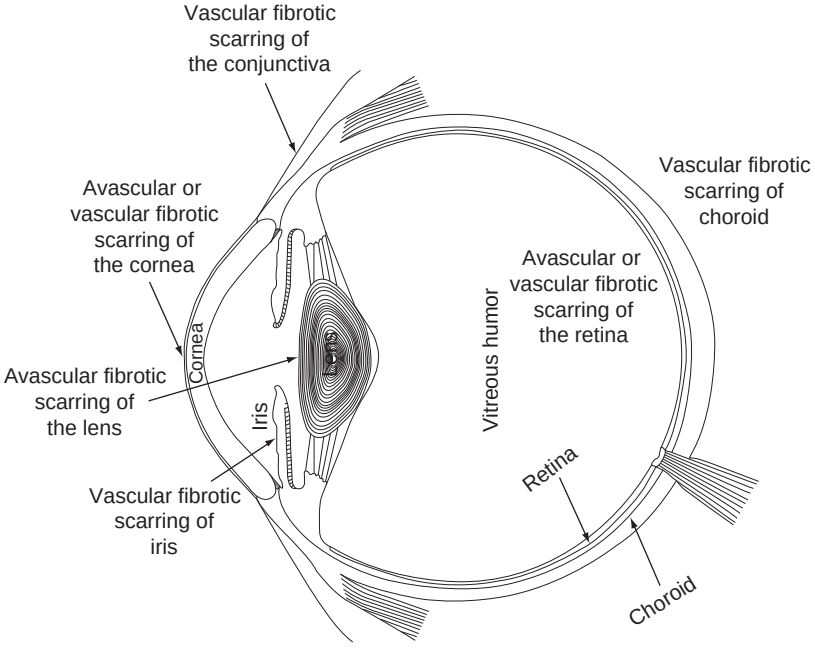

Figure 2 After injury, tissue fibrosis or fibrotic scarring occurs in the cornea, conjunctiva, iris, lens, retina, or choroid. The origin of the mesenchymal repair cell types (activated fibroblasts, myofibroblasts) in each case is either from local fibrocytes (keratocytes, subconjunctival fibrocytes), local epithelial cells (lens epithelium, retinal pigment epithelium), local endothelial cells (corneal endothelium), or local smooth muscle cells that are associated with blood vessels (iris, choroid). The lens undergoes only avascular fibrotic scarring, while conjunctiva, iris, and choroid only undergo fibrovascular granulation tissue scarring; the cornea and retina can undergo both, depending on whether preexisting corneal or retinal disease is present or on the context and severity of the initial injury.

of the eye, although a primary role for latent TGF-β2 in preventing vascularization in the cornea remains controversial. In various ocular diseases or after injury, TGF-β release and subsequent extracellular activation usually initiates a fibrotic repair response. The TGF-β-mediated fibrotic repair response can lead to significant visual impairment. TGF-β can cause overcorrection, undercorrection, or regression of refractive effect leading to refractive instability. TGF-β can also cause loss of refractive function by inducing irregular astigmatism or it can cause loss of transparency by inducing corneal haze, cataract, capsular fibrosis, or vitreous opacification. Tractional distortion of ocular structures, such as proliferative vitreoretinopathy, or other ocular complications, such as wound dehiscence, epithelial ingrowth, infection, hypotony (low intraocular pressure), epiretinal membranes, or retinal detachment, can also be caused by TGF-β . Thus, this molecule is a subject of intense research. Avascular transparent tissue fibrosis or fibrotic scarring in the cornea, lens, and retina is perhaps even more intriguing to researchers since it provides a unique opportunity to directly examine the cell biology during wound healing caused by the four TGF-β-mediated signaling pathways in isolation from the PDGF-mediated platelet degranulation signaling pathway.

Corneal Wound Healing

Although corneal neovascularization resulting from chronic ocular disease, such as corneal infection or chemical injury, may lead to a fibrovascular repair response (**Figure 3**, far-right), this type of repair response will not be focused on in this article. Instead, this article will strictly focus on the avascular corneal fibrotic repair response (**Figure 3**, middle). In the latter repair response, all cases have in common early inflammation that is minimally present up to 2 weeks after injury and maximally present up to 1 month after injury, at least some transient myofibroblast differentiation that is minimally present up to 4–6 months after injury and maximally present long-term, and the long-term presence of disorganized collagenous ECM (**Figure 4**).

Cell–Cell Communication

Cytokines and GFs

Corneal wound healing is an exceedingly complex process mediated by autocrine (affecting the same cell), juxtacrine (affecting adjacent similar cell types), or, most commonly, paracrine (affecting other adjacent cell types) cell–cell interactions involving cytokines and GFs produced by epithelial, stromal keratocyte, endothelial, immune, lacrimal gland, and corneal nerve cells (**Figure 4**). The paracrine interactions usually affect cells at most 50–75 μm from one another, while the other modes of interactions operate over shorter distances. The earliest event involves cell-mediated release of several cytokines and GFs by directly injured resident tissue cells or secretion by resident tissue cells just adjacent to the injury site and their subsequent extracellular activation. In the normal, uninjured state, the participating cytokines and GFs are expressed constitutively and stored intracellularly by the corneal epithelium, corneal nerves, keratoctyes, and corneal endothelium. These cytokines play a vital role in the maintenance of normal corneal health, structure, and function as some are secreted in a limited controlled fashion, mostly in the latent or inactive form. The adjacent tear film produced by the lacrimal gland and other ocular surface epithelia and the aqueous humor produced by ciliary and lens epithelial cells' secretions are another rich source of cytokines and GFs in the normal, uninjured state since these fluids supply various nutrients to the avascular cornea that otherwise would not be available. After wounding activates this direct resident tissue injury-induced

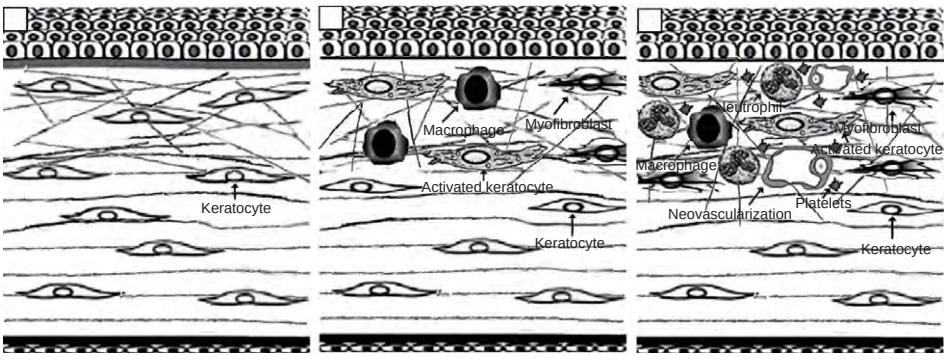

Figure 3 Schematic diagrams demonstrating the histology of the cornea during the active wound-healing phase, approximately 1 week after injury when re-epithelization has just been completed and epithelial thickness restored, in normal uninjured cornea (far-left), avascular fibrotic scarring (middle), and fibrovascular granulation tissue scarring (far-right). If these wounds eventually reach the conclusion of the remodeling phase (not shown), the middle illustration would end up with corneal tissue fibrosis or fibrotic scarring, whereas the far-right illustration would end up with fibrovascular corneal scarring.

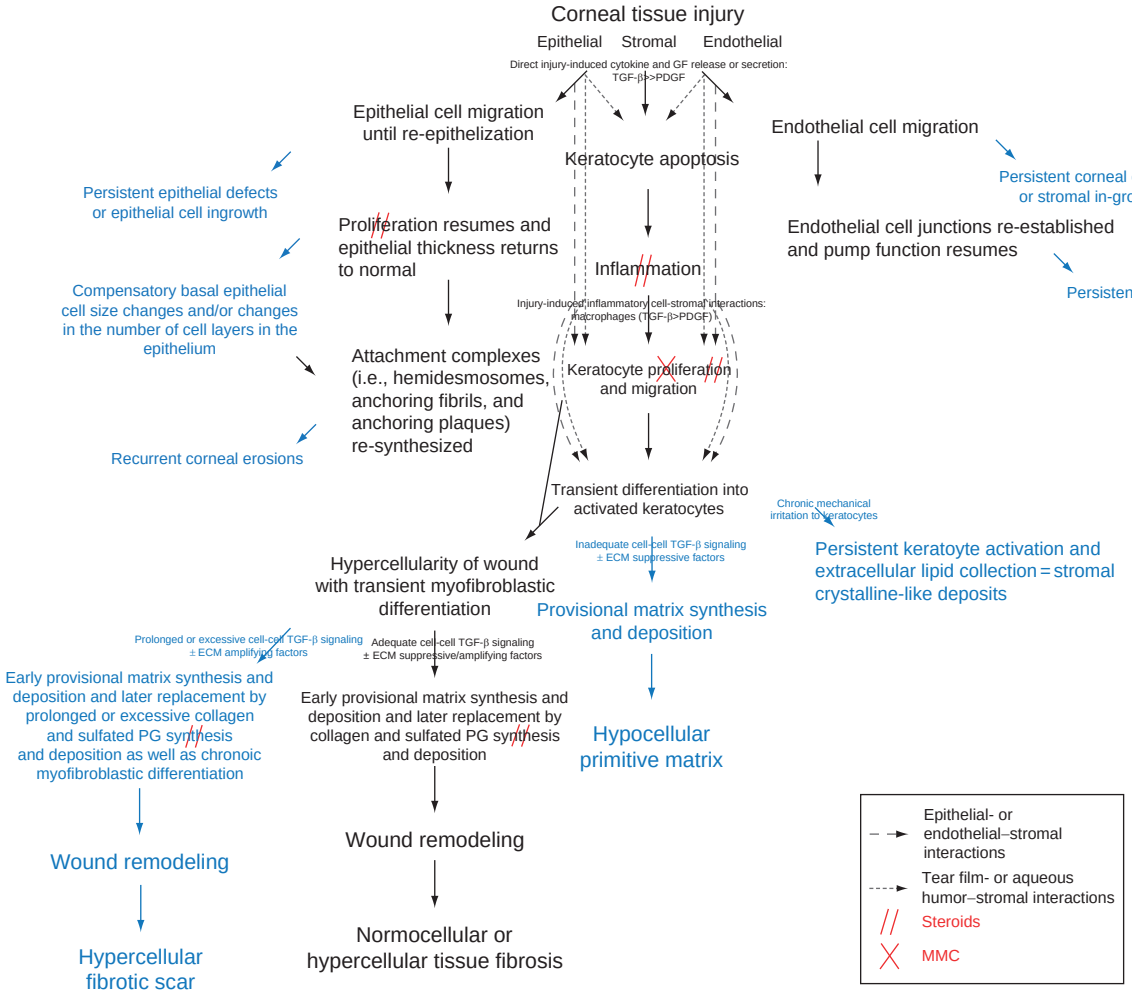

Figure 4 Diagram of normal corneal wound-healing pathways in black and abnormal or pathologic healing pathways in blue. Depending on the context of the injury and the molecular signaling pathways invoked, three types of long-term corneal stromal scars are possible: hypocellular primitive matrix, normocellular-to-hypercellular tissue fibrosis, and hypercellular fibrotic scars. The most functionally optimal type is that of normocellular-to-hypercellular tissue fibrosis as it is macroscopically transparent, yet still somewhat strong in tensile strength (~30%). Imbalances in the fibrotic repair response result in the other two stromal scar types. An incomplete fibrotic repair response results in a hypocellular primitive matrix scar, which is transparent, but very weak in tensile strength (~2–3%). An excessive, nonpathologic fibrotic repair response results in a hypercellular fibrotic scar, which is hazy, yet the strongest in tensile strength (~40%). Note that complete tissue regeneration is not possible in the *in vivo* adult human cornea, but if it could be manipulated to occur it would be the best option since it would be both transparent and back to normal tensile strength (100%). Topical corticosteroid drops suppress (i.e., decreases inflammation and blunts the intensity of some remaining wound-healing steps) the wound-healing pathways in both the epithelium and stroma (stroma > epithelium), while single intraoperatively applied mitomycin C (MMC) appears to block only the stromal wound-healing pathway by preventing keratocyte proliferation. Adapted from Dawson, D. G., Edelhauser, H. F., and Grossniklaus, H. E. (2005). Long-term histopathologic findings in human corneal wounds after refractive surgical procedures. *American Journal of Ophthalmology* 139: 168–178.

cytokine and GF cascade, supplemental exposure to additional cytokines and GFs may occur by four dynamic signaling pathways (**Figure 4**): epithelial– or endothelial–stromal interactions, inflammatory cell–stromal interactions, tear film– or aqueous humor–stromal interactions, and keratocyte mechanotransduction.

The major pertinent cytokines and GFs studied to date in regard to corneal wound healing include connective tissue growth factor (CTGF), epithelial growth factor (EGF), fibroblast growth factor (FGF), interleukin-1 (IL-1), nerve growth factor (NGF), PDGF, TGF-α, TGF-β, tumor necrosis factor-alpha (TNF-α), and vascular endothelial growth factor (VEGF). Currently, TGF-β is thought to be the most important one of this group in regard to stimulating a fibrotic repair response. The major resident cellular source of TGF-βs in the normal, uninjured cornea is the epithelium, which primarily expresses TGF-β2, while keratocytes and endothelial cells express only a little TGF-β1. No TGF-β3 expression has been found in the adult human cornea.

Resident cell surface TGF-β receptor sites are most numerous on keratocytes, while epithelial and endothelial cells have very little. After injury, increased expression of both TGF-β1 and -β2 and their associated receptors occurs, with TGF-β2 predominating in epithelial–stromal interactions (stroma within 75 μm from the epithelium) and TGF-β1 predominating in endothelial–stromal interactions (stroma within 75 μm from the endothelium). In contrast, stromal injury more than 75 μm from either surface invokes only slightly increased TGF-β1 expression and, most importantly, receives no paracrine supplementation from epithelial– or endothelial–stromal interactions.

Although the normal tear film contains high concentrations of latent TGF-β1, immediately following corneal epithelial injury, stimulation of the corneal nerve-lacrimal gland reflex arc causes hypersecretion of tears and increased secretion of several pro-fibrotic cytokines and GFs, such as PDGF-BB, NGF, and additional TGF-β1, all of which are normally stored intracellularly in lacrimal gland cells. The higher amounts of latent TGF-β1 as well as the newly secreted PDGF-BB and NGF are then activated by plasmin or MMPs, which are both released or secreted by injured or healing corneal epithelial cells into the wound. This corneal nerve-lacrimal gland reflex arc secretion and protease release usually returns to baseline levels within 7 days of epithelial defect closure; hence it is a transient event.

Other cytokines or GFs from the group listed above have intriguing complementary or antagonizing effects to TGF-β's pro-fibrotic effects. As discussed in the ocular fibrovascular repair response section, PDGF's pro-fibrotic effects are almost identical to TGF-β's pro-fibrotic effects. In the normal, uninjured cornea, small amounts of PDGF-BB are produced by the corneal epithelium that reacts with its receptors, which are most highly concentrated in the keratocytes of the stroma and the corneal endothelium. Also, a limited amount of PDGF-BB is secreted by macrophages and lacrimal gland cells. After epithelial injury, the expression, release, and activation of PDGF-BB increases in parallel to that of TGF-β. NGF, a trophic neuropeptide important in maintaining corneal epithelial health, is another GF that is complementary to TGF-β's pro-fibrotic effects as NGF is known to directly stimulate myofibroblastic transformation, but without the proliferative or ECM deposition effects of TGF-β. CTGF is also complementary to TGF-β as it too stimulates tissue fibrosis. However, CTGF is only potently expressed when stimulated by TGF-β, suggesting CTCF mediates several downstream actions of TGF-β. Thus, CTGF may be more important in chronic stages of fibrotic scarring as opposed to initiation or early regulation of the fibrotic repair response. Alternatively, CTGF may just synergize with TGF-β's pro-fibrotic effects since CTGF binds to TGF-β and potentiates TGF-β binding to TGF-β type II receptors. In contrast, TNF-α directly antagonizes TGF-β's pro-fibrotic effects by inhibiting the TGF-β/Smad pathway. This direct antifibrotic effect may seem counterintuitive since TNF-α is one of the major pro-inflammatory cytokines of the cornea. As can be appreciated, a correct combination and temporal sequencing of the various cytokines and GFs is required for proper healing to occur. Imbalances can result in incomplete wound repair, such as (1) persistent epithelial defects and corneal ulceration or melting, or (2) excessive pathological tissue fibrosis, such as stromal outgrowth, fibrodegenerative pannus formation, stromal ingrowth, or retrocorneal membrane formation.

TGF-β signaling pathways

Both historical clinical anecdotal observations and recent experimental investigations have suggested that epithelial–stromal interactions are the primary mediator of the avascular fibrotic repair response in the cornea. Thus, epithelial cell-derived substances substitute for those produced by platelets in the skin and other vascular tissues. The cornea consists of three cellular layers consisting of epithelium, interstitial stroma with interspersed keratocytes, and endothelium and two acellular layers consisting of an epithelial BM/Bowman's layer complex and an endothelial Descemet's membrane. Although Bowman's layer is not re-formed if damaged, both BM layers are re-formed if damaged because they are produced by epithelial or endothelial cells. Both acellular layers seem to function clinically as physiological barriers to separate the three cellular layers from direct contact or communication with one another to maintain normal corneal homeostasis. Disruption of the epithelial BM/Bowman layer complex induces maximal epithelial–stromal interactions that are intense enough even in a minimal injury state to cause a fibrotic repair response. This is seen clinically with bullous keratopathy – a pathological condition in which small blisters (vesicles or bullae) are formed in the corneal epithelium due to endothelial dysfunction, at the host–graft interface after penetrating keratoplasty (aka full-thickness corneal transplantation; a surgical procedure where a damaged or diseased cornea is replaced by full-thickness donated corneal tissue), or with Bowman's layer breaks (a degenerative disorder of the cornea in which structural changes cause it to thin and change in shape resulting an outward bulging of the tissue) as a subepithelial fibrotic scar, stromal outgrowth, or fibrodegenerative pannus formation (fibrocollagen connective tissue that proliferates in the anterior layers of the cornea in degenerative corneal disease). In some cases of bullous keratopathy, there may even be an no obvious microscopic full-thickness Bowman's layer break, but rather just separation of the of epithelium and its associated BM from Bowman's layer due to severe epithelial edema causing subepithelial bullae or blisters. In this extreme example of epithelial–stromal interactions, the keratocytes apparently migrate through trigeminal nerve fiber perforation sites found in Bowman's layer to the

subepithelial space created by the edema, where they undergo a fibrotic repair response. Separation or breaks in Descemet's membrane provide a similar trigger for causing a fibrotic repair response in the posterior cornea through endothelial–stromal interactions. For example, with penetrating corneal injury or breaks in Descemet's membrane, whether caused by trauma, disease (keratoconus), or surgery, endothelial–stromal interactions stimulate fibrotic scarring resulting in a supraendothelial fibrotic scar, stromal ingrowth, or retrocorneal membrane formation, depending on the degree of apposition of the broken Descemet's membrane wound margins. Therefore, current evidence suggests that the main TGF-β pro-fibrotic signaling pathway to block or suppress to prevent or reduce the chance for fibrotic scarring is that of direct epithelial–stromal or endothelial–stromal interactions.

Three other TGF-β pro-fibrotic signaling pathways are also present in the cornea and can initiate an avascular fibrotic repair response, but more often they just sustain the response already initiated by epithelial- or endothelial–stromal interactions. As already discussed earlier, a robust inflammatory cell response is part of a normal or nonpathologic fibrotic repair response. However, along with the advantages of stimulating an immediate innate immune response and thus preventing or at the very least lowering the risk for infection, leukocytes also secrete many pro-fibrotic cytokines and GFs, such as TGF-β and, to a lesser extent, PDGF. These pro-fibrotic factors are disadvantageous because they cause keratocytes in the corneal wound to undergo a higher degree of tissue fibrosis, which can lead to chronic nonpathologic scarring or even pathologic scarring. Usually after sterile clean injury, the inflammatory response in the avascular cornea is quite mild compared to that of the skin or other vascular tissues. However, dirty injuries or wounds complicated by infection or with preexisting immune-related disease may make the inflammatory response so massive that it becomes the primary pro-fibrotic signaling pathway resulting in varying degrees of severe corneal scarring. Another TGF-β pro-fibrotic signaling pathway was already discussed in the the section entitled 'Cytokines and GFs' when discussing the epithelial cell injury-induced corneal nerve-lacrimal gland reflex arc. These tear film–stromal interactions are usually transient (<7 days) and minor in comparison to the two already discussed. However, with persistent epithelial defects or chronic corneal ulceration, tear film–stromal interactions may become of paramount importance in causing fibrotic scarring in addition to the chronic increased release of epithelial cell-derived cytokines at the peripheral edge of the epithelial defect. The aqueous humor may have a similar role with posterior stromal injury. Finally, the fourth TGF-β pro-fibrotic signaling pathway involves keratocyte mechanotransduction interactions. Historically, wound tension has been known for years to promote a higher degree of fibrotic scarring. This mechanotransduction pathway was confirmed experimentally using cell culture experiments where mechanical strain on fibroblasts increased pro-fibrotic TGF-β1 expression, upregulated TGF-β receptors RI and RII, and markedly increased collagen expression. Findings by other researchers indicate that fibrocyte (e.g., keratocyte) cell surface integrins, which form cell–ECM adhesions, can act as strain gauges to external mechanical stress, triggering both direct intracellular signaling pathways or indirect release of paracrine cytokine and GFs factors, which stimulates the fibroblastic phenotype and augments ECM synthesis and deposition.

Cell–ECM Communication

Suppressing or amplifying factors

The ECM, through intrinsic binding and storage properties or cellular receptor-mediated adhesive properties, collaborates with cytokines and GFs in regulating cell behavior and phenotype through bidirectional cytokine and GF–ECM and cell–ECM interactions. In the latter, ECM adhesion and surface characteristics influence cellular behavior through interaction with cell surface receptors.

Clinical anecdotal observation supports the contention that having an intact corneal BM usually prevents fibrotic repair phenotypes from forming in the stroma and return of the BM usually correlates with loss of the fibrotic repair phenotype. Apparently, an intact epithelial BM or Descemet's membrane is the key factor in suppressing direct maximal epithelial- or endothelial–stromal interactions from taking place in the normal, uninjured state by binding and storing the soluble LL-TGF-β complex. Thus, epitheial BM or Descemet's membrane act as passive diffusion barriers to epithelial- or endothelial-derived latent TGF-β, respectively, and they ultimately regulate the bioavailability of TGF-β to the underlying or overlying corneal stroma. BMs are composed mainly of collagen type IV, entactin/nidogen, different laminins, and heparan and chondroitin sulfate PGs. The LL-TGF-β complex binding and storage property of BMs is likely related to heparin binding mechanisms intrinsic to the heparin sulfate PGs found in BMs, which bind to the soluble LL-TGF-β complex through either LTBP-1 or -3 domains. Fibronectin, which is found in the provisional matrix, also has LL-TGF-β complex binding and storage properties similar to that of BMs. Some sulfated PGs in the corneal stroma, like decorin, can even bind to the active dimer form of TGF-β through their core proteins; thus, additionally antagonizing the biological affects of TGF-β. BM-bound heparin sulfate PGs may have a similar function through their core proteins too.

With injury, corneal BM barriers are breached so that normal maximal epithelial- or endothelial–stroma interactions take place in addition to the acute wound-healing cascade already started by direct resident tissue injury itself. For example, with combined superficial epithelial

and stromal injury (photorefractive keratectomy (PRK), sterile corneal ulceration), this stromal wounding response is clearly seen clinically as it frequently stimulates excessive subepithelial fibrotic scarring resulting in prolonged or even permanent subepithelial haze. Apparently, removal of the epithelial BM directly exposes anterior stromal keratocytes to maximal pro-fibrotic effects of TGF-β released by the injured epithelial cells or found in the neurally stimulated tear film. Moreover, after injury, return of an intact epithelial BM suppresses normal epithelial cell-derived TGF-β2 intracellular expression and, more importantly, binds the TGF-β2 extracellularly secreted from epithelial cells. Thus, epithelial and presumably endothelial BMs represent an efficient ECM antifibrotic mechanism that goes slightly beyond just simple barrier function. However, this ECM antifibrotic mechanism is not foolproof since chronic subepithelial haze still persists long-term or episodic subepithelial haze still exacerbates after ultraviolet light overexposure, despite having an intact epithelial BM. This persistent haze seems to be best explained by TGF-β signaling pathways that work only in the stroma, such as mechanotransduction or inflammatory cell TGF-β signaling pathways, respectively. These two TGF-β signaling pathways can act directly on activated keratocytes and/or myofibroblasts in the stroma without having to send cytokines or GFs through a BM. Regarding the latter UV light example, quiescent or regressed myofibroblasts in a subepithelial fibrotic scar may have long-term upregulated TGF-β receptor sites densities, making them hypersensitive to any TGF-β, whether caused by inflammation or late resident cell injury. This may then lead to an autocrine positive feedback loop of more TGF-β production from a single myofibroblast or from a paracrine positive feedback loop due to macrophage infiltration and further TGF-β release.

Corneal cell–ECM interactions are an area that needs further study. Other disciplines have already shown that cells adhere to the ECM usually through their cell surface receptors (e.g., integrins, cell surface proteoglycans). For example, cell–ECM adhesion by integrins receptors regulates cellular homeostasis in multiple ways, including regulation through direct and indirect connections to the actin cytoskeleton, growth factor receptors, and intracellular signal transduction cascades. Integrins also sense mechanical strain arising from the ECM, thereby converting these stimuli to downstream signals modulating cell behavior. Disruption of this connection to the ECM has deleterious effects on cell survival, sometimes leading to a specific type of programmed cell death called anoikis. Anoikis is defined as apoptosis that is induced by inadequate or inappropriate cell–ECM interactions. Another direct extension of this cell–ECM interaction theme is clinical anecdotal reports and experimental animal research studies in which injury-induced stromal surface irregularity, also known as irregular surface nanotopography, results in increased TGF-β expression and a higher degree of corneal fibrotic scarring. Although irregular surface nanotopography is known to alter cell adhesion and positional information to the surface cells, such as epithelium and endothelium, it remains to be proven whether this pathway directly leads to myofibroblastic transformation since incomplete return of an intact epithelial BM has been reported as another possible cause.

Bone marrow-derived stem cells

Bone marrow-derived immune cells have been recently been detected in the corneal stroma and they may also participate in TGF-β molecular signaling pathways, especially the histiocytes (tissue macrophages). The relative contribution and importance of bone marrow-derived stem cells to regenerative or fibrotic repair responses needs to be explored further. Because of their extraordinary plasticity and their ability to secrete embryonic cytokines and GFs that promote tissue regeneration over fibrotic repair, bone marrow-derived stem cells are being explored as restorative cellular therapy in preclinical trials for myocardial infarction, neurodegenerative disorders, and osteogenesis imperfecta. However, some bone marrow-derived cells, or their progeny, may reside for prolonged periods in the stroma and could make an as yet unknown contribution to the wound-healing process.

Cellular responses

After injury-mediated induction of the TGF-β/receptor molecular signaling pathway, keratocytes undergo a series of repair phenotypic and behavioral changes that are temporally and spatially regulated during the corneal wound-repair process. Keratocytes are neural crest-derived mesenchymal cells that are sandwiched between collagenous lamellae forming a closed, highly organized syncytium. Keratocytes communicate with one another through gap junctions present on their long dendritic processes. The adult human corneal stroma has approximately 2.4 million keratocytes that occupy approximately 10% of the stromal volume. In postnatal life, they remain in the corneal stroma as modified fibrocytes, where they inconspicuously maintain the ECM of the corneal stroma. Depending on the type of injury and the molecular signaling invoked, keratocytes can be stimulated to undergo cell death (apoptosis) or transform to become a migratory keratocyte, an activated keratocyte, or a myofibroblast. Within minutes after injury, exposure to cytokines and GFs, such as IL-1 and TNF-α, found in the neurally stimulated tear film or released from injured epithelial cells is thought to lead to keratocyte apoptosis. The phenotypic transition (actin-cytoskeleton rearrangement) from a keratocyte to a migratory keratocyte appears to be initiated by loss of gap junction contact and possibly loss of keratocyte ion channels. Behaviorally, migratory keratocytes serve to reconstitute the cellularity of the tissue by once again re-forming a large intercommunicating network of keratocytes. The phenotypic transition

from a keratocyte to an activated keratocyte and then possibly to a myofibroblast depends on the TGF-β ligand/receptor occupancy rate and the duration of this occupancy rate. The myofibroblast phenotype may also require synergistic PDGF co-stimulation. Behaviorally, activated keratocytes promote provisional fibronectin ECM synthesis and deposition, while myofibroblasts promote mature collagenous fibrotic ECM synthesis and deposition. It has been postulated that at least partial ECM regeneration may still be possible *in vivo* since an adult keratocyte stem cell subpopulation has been discovered near the limbus. These progenitor cells express the ocular development gene *Pax6*, which is an embryonic marker not expressed by resident stromal keratocytes. Overall, it has been suggested that variations in these two repair phenotypes (activated keratocyte and myofibroblast), especially the degree and duration of myofibroblast differentiation, ultimately determine the final clinical outcome of the wound-healing process, resulting in either primitive, incomplete wound repair, acceptable tissue fibrosis, or excessive fibrotic scarring.

Three Phases of Corneal Wound Healing

Classically, corneal wound healing is typically divided into three overlapping phases (**Figure 5**): (1) inflammatory phase – cytokine release and amplified expression, keratocyte apoptosis, and inflammation; (2) active wound-healing phase – epithelial cell migration, proliferation, and regeneration, keratocyte migration and proliferation, keratocyte metabolic activation and eventual quiescence, myofibroblast development, ECM synthesis and deposition (immature primitive scar formation with or without transition to early mature fibrotic scar formation); and (3) remodeling phase – decrease in cellular density, persistence or disappearance of myofibroblasts, persistence or disappearance of primitive scar, and collagen fibril re-organization/remodeling (mature fibrotic scar formation).

Inflammatory phase (lasts up to 2–4 weeks after injury)

As described earlier, after injury, damaged resident cells in the cornea release or adjacent surviving cells secrete a variety of cytokines and GFs into the wound. As the local concentration of these cytokines and GFs increases and these compounds are converted to their active form, one of the first morphologically observable changes in the corneal stroma following injury is a 50–75 μm zone of keratocyte apoptosis surrounding the actual direct injury site. This is followed by a subsequent transient influx of mixed acute and chronic inflammatory cells. Keratocyte apoptosis usually peaks at approximately 4 h after injury, but may still occur minimally up until approximately 1 week after the initial insult. After the initial peak of keratocyte apoptosis, an increased proportion of cells die

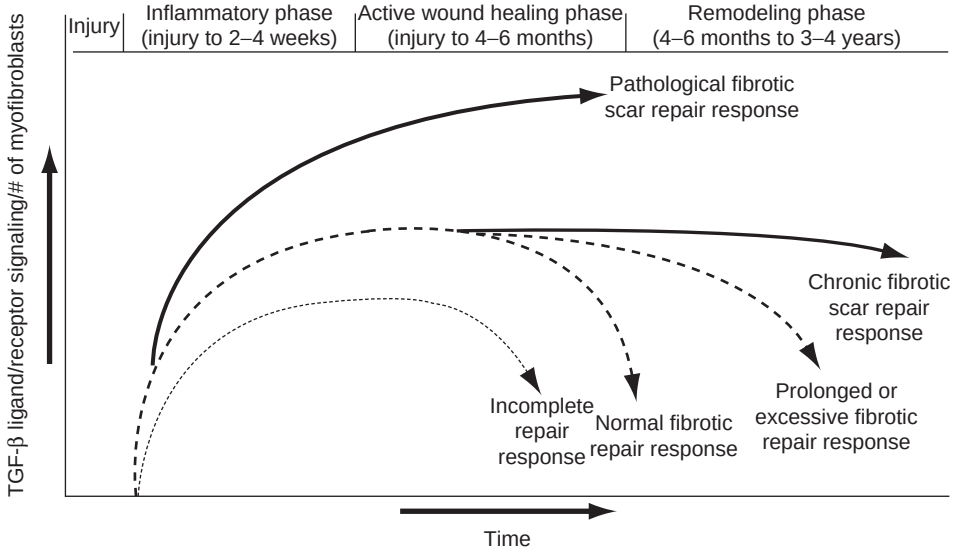

Figure 5 Representative line graph of a normal fibrotic repair response (dashed black line) in the cornea that results in tissue fibrosis (long-term fibrotic ECM, transient (<6 months) myofibroblast differentiation) at the end of the active wound-healing phase. If the transient myofibroblastic diffentiation extends into the remodeling phase, but eventually goes away, it still is considered a normal fibrotic repair response, albeit prolonged or excessive. If myofibroblastic differentiation is chronic (persistent or long-term), it is considered a fibrotic scar (solid black line). In comparison, representation plots for incomplete (dotted black line) or pathologic (thickest solid black line) fibrotic repair responses are shown. In normal corneal wound healing, myofibroblastic differentiation and ECM synthesis and deposition are both TGF-β dependent processes, which are appropriately terminated through negative regulatory mechanisms during the active wound-healing phase. However, prolonged or excessive TGF-β production occurs through four possible signaling pathways that may result in excessive tissue fibrosis, fibrotic scarring, or pathologic fibrosis. In comparison, incomplete TGF-β production results in primitive or provisional fibronectin matrix deposition long-term wound healing.

through necrosis. Within 8 h of injury, neutrophils are attracted to the wound site by chemokines and these inflammatory cells function by killing microbes and even host resident cells with their secretion of free radicals. Neutrophils serve no direct role in amplifying or suppressing the fibrotic repair response through its secreted cytokines or GFs, but may indirectly amplify it by damaging more resident tissue cells. Within 24 h of injury, monocytes are attracted to the wound site where they differentiate into macrophages, which serve to degrade and remove dead or damaged cells and ECM. Keratocytes and epithelial-derived proteases and collagenases help macrophages in this degradation and removal process. Macrophages also directly amplify the fibrotic repair response through secretion of pro-fibrotic TGF-β 1 and some PDGF, which can potentially result in a paracrine positive feedback loop, if intense enough. Finally, within 3 days of injury, lymphocytes enter the wound, where they secrete antifibrotic cytokines and GFs. Overall, this direct injury-mediated innate inflammatory response typically adds more pro-fibrotic cytokines and GFs to the original direct resident tissue injury-mediated cytokine and GF cascade. The innate inflammatory response amplifies the cascade of events already taking place, commonly resulting in additional keratocyte proliferation and migration, further keratocyte differentiation to one of the various fibrotic repair phenotypes including the myofibroblastic stage. Thus, inflammation has both positive and negative consequences of preventing infection and amplifying the fibrotic repair response, respectively.

Active wound-healing phase (lasts up to 4–6 months after injury)

Proliferation and migration of residual surviving keratocytes begins 12–24 h after injury to reconstitute the cellularity of the injured area and typically continues for only several days after injury. The migrating keratoctyes are spindle-shaped in appearance and highly motile. Subsequently, migratory keratocytes differentiate into a metabolically activated repair phenotype called an activated keratocyte. Within 1–2 weeks after injury, myofibroblasts first begin to appear in the stromal wound under the epithelium and then develop in the deeper stroma down to a depth of approximately 50–75 μm. Myofibroblasts are a fibrotic repair phenotype characterized by significant deposition of a disorganized collagenous ECM, significant hypercellularity, and extensive wound contraction. An important physical characteristic of myofibroblasts in the cornea is their reduced transparency relative to other cell types in the corneal stroma, which may be due to a loss of soluble cytoplasmic corneal crystallins in combination with assembly of insoluble actin stress fiber bundles.

Remodeling phase (occurs from 4–6 months to 3–4 years after injury)

During the remodeling phase, corneal cellularity in the repair tissue decreases closer to normal because of the disappearance or persistence of residual keratocytes or myofibroblasts. The stromal cells also revert back to a more normal nonfibrotic reparative phenotype as actin stress fibril bundles disappear and TGF-β receptor site density gets closer to baseline. The ECM reorganizes closer to normal as collagen fibrils become larger in diameter, more regular, more orderly in arrangement, richer in collagens type I molecules, less rich in type III molecules, and more cross-linked. In addition, any residual hyaluronic acid in the provisional ECM is replaced by more mature, sulfated PGs. The remodeling phase is the dominant process guiding the early mature scar to complete the maturation process. As such, this phase may be considered more or less a functional improvement phase. After remodeling, corneal scars gain increased tensile strength, have less haze and less wound contracture, and are more cosmetically pleasing with a reduction in size and improvement in structure.. During the remodeling phase, the collagen fibril turnover rate is still higher than normal, most likely due to ongoing MMP activity. Unfortunately, if only an immature provisional fibronectin ECM is present after completion of the active wound-healing phase, then the remodeling phase is incapable of making the transition from the immature provisional matrix to the mature collagenous ECM and a provisional fibronectin matrix remains permanently in the corneal stroma.

Termination of the fibrotic repair response (about 3–4 years after injury)

In humans, the long-term result of corneal wounding is the production of a hypercellular fibrotic scar (i.e., chronically hazy fibrotic scar) or a normocellular-to-hypercellular tissue fibrosis (i.e., transparent fibrotic tissue) in wound regions where epithelial– and endothelial–stromal interactions took place and a hypocellular primitive matrix (i.e., transparent immature provisional fibronectin ECM) in wound regions where keratocyte injury pathways took place in the absence of other supplemental healing responses (**Figure 4**). These three long-term histological tissue repair types have functional differences as the hypercellular fibrotic scar is strong (tensile strength approximately 40% of normal), but clinically hazy because of persistent myofibroblasts present in the repair tissue long-term. In contrast, the hypocellular primitive matrix is transparent, but it is very weak in tensile strength since it is composed of very little collagen fibrils (tensile strength approximately 2–3% of normal). Normocellular-to-hypercellular tissue fibrosis more or less is a hybrid of the two just described as it is macroscopically transparent and somewhat strong (tensile strength approximately 30% of normal). An additional variable to consider in this scheme

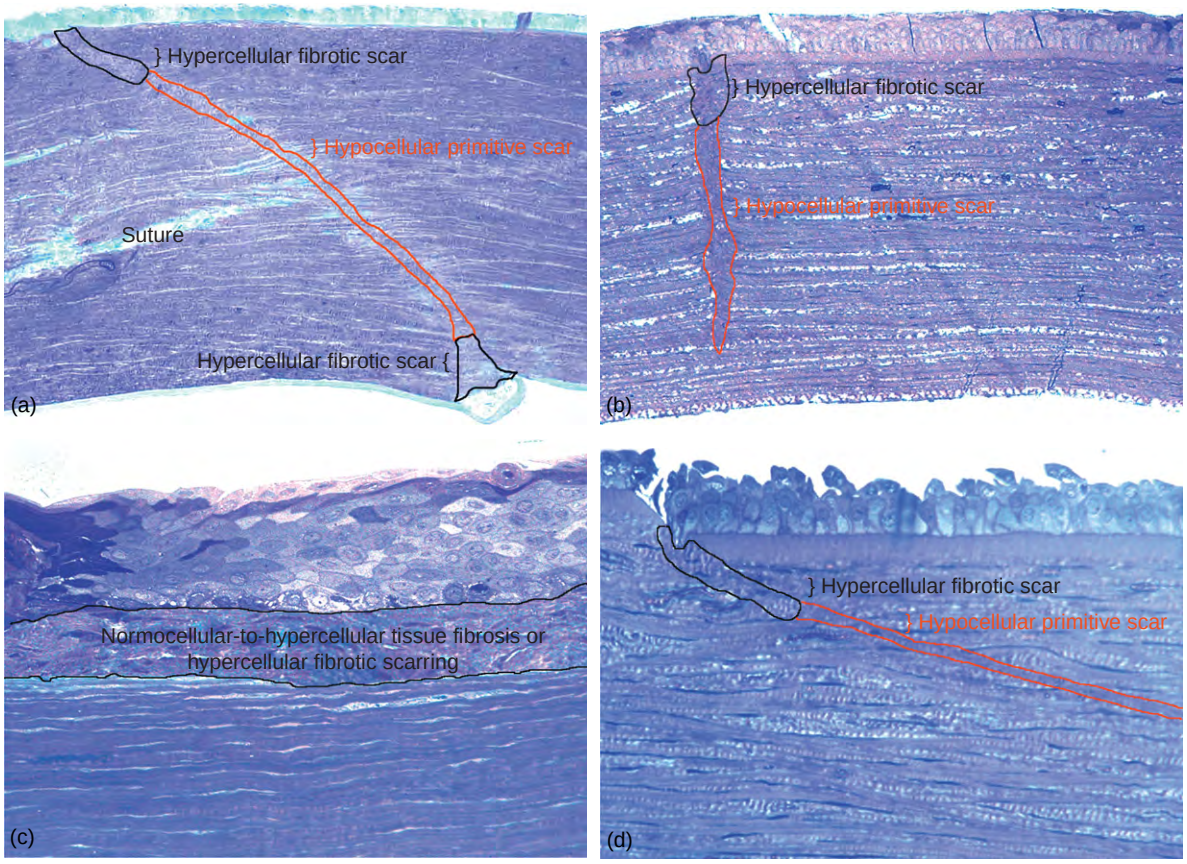

Figure 6 Long-term histologic findings of corneas that had undergone sutured, temporal, clear-corneal cataract extraction surgery (a), astigmatic keratotomy (b), photorefractive keratectomy (c), and laser-assisted *in situ* keratomileusis (d). All corneas shown are greater than 4 years after surgery and, technically, they have completed the remodeling phase and have terminated the fibrotic repair response (toluidine blue 15X for a, 25X for b, and 100X for c and d). Adapted from Dawson, D. G., Edelhauser, H. F., and Grossniklaus, H. E. (2005). Long-term histopathologic findings in human corneal wounds after refractive surgical procedures. *American Journal of Ophthalmology* 139: 168–178.

is the fact that more precisely realigned wounds, such as sutured and unsutured wounds with minimal gaping and no epithelial cell plugging, heal better than poorly aligned wounds, such as wounds with wide wound gaping; epithelial plugging; or incarceration of Bowman's layer, Descemet's membrane, or uvea (Figure 6).

Modulation of Scarring

Currently Available Scar-Reducing Therapies

Corneal fibrotic scars remain difficult to cure. Thus, the best approach is prevention. At present, there is no pharmacologic agent or surgical procedure that is universally effective in ameliorating fibrotic scarring. The best strategy currently entails a polytherapeutic empirical approach involving short-term (approximately 1–3 months in duration) topical corticosteroids, a single intraoperative local application of mitomycin C (MMC), and possibly several alternative or emerging options (Table 2). The

Table 2 Mechanism of action of scar-reducing agents

Agent	*Mechanism*
Corticosteroids	Inhibition of inflammatory response Possible inhibition of keratocyte proliferation and collagen synthesis
Chemotherapeutic agent (MMC)	Inhibition of keratocyte proliferation Promotes keratocyte and myofibroblastic apoptosis
Amniotic membrane	Suppression of epithelial-stromal interactions Potent anti-fibrotic, anti-inflammatory, and anti-angiogenic properties
Exogenous TGF-β3 supplementation	Partially shifts the fibrotic repair response over to the scar-free regenerative response
Anti-TGF-β1 and β2 agents	Decreased myofibroblast differentiation and collagen synthesis
Gene therapy	Gene transfer of TGF-β antagonists (e.g., fibromodulin) or blockers of TGF-β signaling (e.g., truncated TGF-β receptor II)

easiest way to understand the place that a drug is located in the range of possible treatment options is to consider the TGF-β signaling pathway or the wound-healing phase that the compounds act on.

Corticosteroids reduce scar formation primarily by suppressing the TGF-β-mediated inflammatory cell–stromal interactions and, secondarily, by possibly depressing steps in the active wound-healing phase, such as inhibition of fibroblast proliferation and diminished collagen synthesis. Regarding the fibroblasts, a previous study demonstrated that corticosteroids have a direct antiproliferative effect on ocular fibroblasts by altering the intracellular activity and expression of multiple genes that participate in fibrotic scar formation, including inhibition of TGF-β1, TGF-β2, and collagen expression. Thus, it should not be surprising that corticosteroids affect stromal wound healing to a greater degree than epithelial wound healing. Unfortunately, in randomized, placebo controlled, prospective clinical trials, corticosteroids produced no clinically significant long-term effects on either haze or refractive regression due to fibrotic scarring compared to placebo, but were definitely associated with a few unwanted side effects (high intraocular pressure and posterior subcapsular cataract formation). Thus, the role of steroids in the prevention of fibrotic scarring remains limited. Moreover, in view of their side-effect profile, steroids clearly would be unacceptable for long-term use in scar prevention and should be strictly used short-term (about 1–3 months from injury). Overall, corticosteroids will likely be used most effectively in future scar-reducing protocols as part of a polytherapeutic strategy since inflammation is just one of the four TGF-β signaling pathways involved in the avascular fibrotic repair response. When used, however, the timing of corticosteroid administration is crucial as the best results occur if used within hours of injury before neutrophils and profibrotic macrophages enter the wound. Once the injury-induced inflammatory response is initiated in the wound, it is somewhat self-amplifying, making it quite difficult to immediately suppress the response with corticosteroids.

The mechanism by which MMC prevents or reduces fibrotic scar formation has not been fully elucidated. It appears to work by inhibiting cell proliferation due to its potent alkylating chemotherapeutic effect by cross-linking DNA after metabolic activation by way of reduction. This effect is downstream from the initiating pro-fibrotic events in the four TGF-β-mediated signaling pathways of the cornea. Thus, MMC may affect all the four pathways, at least acutely while it remains in the tissue at therapeutic concentrations. MMC is potent because it affects cells in all phases of the cell cycle. In high concentration, MMC also is known to promote direct keratoctye and myofibroblast apoptosis in the inflammatory phase via free radical injury, which may be another mechanism by which it works. MMC combined with low-dose corticosteroids is the conventional treatment approach used today for corneal fibrotic scar prevention in high-risk cases. This combination is also used in the treatment of corneal fibrotic scars after additional maneuvers are performed to remove as much of the scar tissue as possible by surgical debridement (e.g., phototherapeutic keratectomy (PTK) before direct MMC local application).

An alternative or supplementary scar-reducing treatment is that of using fresh or cryopreserved amniotic membrane (AM) allografts to cover treated areas of exposed injured corneal stroma to prevent fibrotic scarring. Human fetal AM is composed of three layers: a cuboidal to columnar epithelial monolayer, a 200–300-nm thick BM, and an avascular stroma. This membrane suppresses the inflammatory and active wound-healing phases of the fibrotic repair response. Intact AM–BM suppresses epithelial–stromal interactions since the stroma has intrinsic antifibrotic, anti-inflammatory, and antiangiogenic properties, presumably due to cytokine and GF binding to sulfated PGs in the AM stroma. AM also aids in re-epithelization due to its epithelial surface and its BM, which contains cell adhesion molecules, such as fibronectin. The primary disadvantages of AM are its expensive cost and increased surgical time. Thus, AM is used more often for severe corneal and/or limbal stem cell disease rather than repair of simple corneal wounds.

Newer advanced surface ablation techniques, such as laser subepithelial keratectomy (LASEK) or epikeratome laser-assisted *in situ* keratomileusis (EpiLASIK), modify the PRK surgical technique using natural means to suppress direct epithelial–stromal interactions. For example, in LASEK surgery, the replaced epithelial flap retains as much intact epithelial BM as possible, which serves to bind and store direct injury-induced epithelial-derived TGF-β. Thus, LASEK ingeniously takes advantage of natural antifibrotic cytokine and GF–ECM interactions to reduce the degree of fibrosis. EpiLASIK goes one step further in that the epithelial flap retains much healthier, living corneal epithelium as well as an intact epithelial BM. Thus, EpiLASIK additionally blunts pro-fibrotic tear film–stromal interactions by natural means since a healthy, viable superficial squamous epithelial layer containing zonula occludens tight junctions serves as a physical barrier to direct stromal exposure to cytokines and GFs factors in the tear film.

Emerging Scar-Reducing Therapies

Extensive research has been performed to elucidate the fibrotic repair response, particularly in the skin, with the long-term goal of iatrogenically manipulating this response toward obtaining a clinical advantage. Recent molecular therapeutic investigations have concentrated on inhibiting myofibroblast differentiation by targeting TGF-β. A promising strategy currently being evaluated

in phase-I and-II clinical trials in the skin entails manipulating the ratio of the three TGF-β isoforms in the wound in favor of TGF-β3. Three independent, randomized, placebo controlled, prospective clinical trials have shown that exogenous TGF-β3 supplementary treatment resulted in clinically significant scar prevention or reduction with primary and multiple secondary endpoints in the skin. Inhibition of TGF-β1 and β2 binding to their associated receptors with topical anti-TGF-β antibodies has also been shown to reduce myofibroblastic differentiation, ECM deposition, and cell haze induced by PRK in animal models. By subtly altering the ratio of cytokines or GFs present in the wound during corneal wound healing, it is ultimately hoped that one day postnatal wounds could be induced to heal like embryonic wounds through tissue regeneration. An important caveat to these molecular therapies is that the timing of the application of these agents is critical, usually with the best results occurring if used immediately after injury or, at the very least, within 48 h of injury.

There have been a few published studies, limited to animal models, using gene therapy for scar reduction. To date, fibroblasts have been used as the primary targets. Further investigation into the role of gene therapy for scar reduction is still needed since the practical use of such an approach is not presently feasible.

Other possible emerging fibrotic scar-reducing therapies include systemically administered minocycline antibiotics, which significantly reduce the severity of hypertrophic scarring in a rabbit ear scar model. The mechanism by which minocycline reduces scar formation in this model remains unanswered, but the most plausible mechanism involves inhibition of MMPs resulting in the inhibition of fibroblast migration. Anti-intracellular Smad signaling pathway agents are another promising possibility.

Conclusion

Significant advances have been made in understanding the mechanisms controlling the adult fibrotic wound-repair response in comparison to the embryonic scar-free regenerative response. Discovery of four TGF-β signaling pathways and the central role of myofibroblasts in corneal wound healing have been crucial to this end. Currently, the most effective corneal scar-reducing therapies involve a rather crude polytherapeutic empirical strategy of management involving short-term topical steroids and single intraoperative MMC application. Hopefully, in the near future, the recent advances in understanding the molecular and cell biology of fibrotic wound repair can translate into the development and clinical use of more promising agents, such as molecular, gene, or stem cell therapies. The capability to successfully manipulate the fibrotic repair process in the cornea *in vivo* offers many tantalizing prospects from preventing blindness from corneal scarring to obtaining 20/8 perfect vision with optimal corneal wound healing after keratorefractive surgery to perfect tissue regeneration due to converting the adult fibrotic repair response back to an embryonic scar-free regenerative response to the possibility of restoring vision through tissue engineering of a human healthy cornea for replacement purposes.

Cortical Cataract

R Michael, Institut Universitari Barraquer, Barcelona, Spain

Glossary

Lens cortex – The part of the crystalline lens surrounding the nucleus and bound anteriorly by the epithelium and posteriorly by the capsule.
Lens equator – The border of the crystalline lens where the anterior and posterior parts meet. The zonular fibers, which hold the crystalline lens in place, are connected at the lens equator; also, the part of the lens farthest from the optical axis.
Lens nucleus – The core of the crystalline lens, surrounded by the cortex.
Refractive index – The ratio of the speed of light in a vacuum to the speed of light in a given material. According to Snell's law, the refractive index is also the ratio of the sine of the angle of incidence to the sine of the angle of refraction. The refractive index indicates the extent to which a light beam is deflected when passing from a vacuum into a given material.

Definition

Cataract is the clinical term for reduced visual function resulting from optical disturbances in the crystalline lens. These optical disturbances absorb and scatter light. Reduced lens transparency and scattered light induces straylight on the retina. The word itself is of Greek origin and means cascading water or waterfall. Its use in ophthalmology probably alludes to the white appearance of running water or the blurred view from behind a waterfall. Cataracts differ greatly in density, color, shape, size, and location inside the crystalline lens. Cortical cataract defines a cataract located in the lens cortex or periphery. The other two main subdivisions by location are nuclear cataract and posterior subcapsular cataract.

Morphology

The first changes to arise in the transparent lens cortex are small, spot- or star-like opacities measuring several micrometers in diameter (**Figures 1(a)** and **1(e)**). On the cellular level, they probably correspond to membrane-bound bodies or multilamellar bodies (**Figure 2(d)**) frequently found in the lens cortex inside or between otherwise normal lens fiber cells. More advanced changes include radial and circular shades (**Figures 1(b)** and **(f)**). These are located in the equatorial and pre-equatorial regions of the lens, close to the border between the lens cortex and lens nucleus (**Figure 1 (j)**). Radial and circular shades are often in close proximity (**Figure 1(f)**). Radial shades are usually diffuse and extend between the layers of lens fiber cells of the lens equator in a half circle in the anterior and posterior direction (**Figure 1(j)**). Radial shades consist of restricted parts of a small group of fibers in the deep cortex. The affected lens fiber cells are filled with medium-to-large globular elements (**Figure 2(e)**). The circular shades are well delineated and line-like (**Figure 2(c)**). They originate as fractures of a large group of fibers in the deep equatorial cortex, perpendicular to the course of the fibers. The fractured surfaces are slightly swollen, but the membranes on both sides of the fracture have normal ultrastructure (**Figure 2(f)**).

The most prominent cortical opacities are peripheral band-like and spoke-like opacities, which share a basic morphology despite wide variations in shape and severity (**Figures 1(c), 1(d), 1(g), 1(h), 1(k),** and **1(l)**). They have been referred to in the literature as wedge-shaped fiber opacities, spoke-shaped opacities, cuneiform opacities, water clefts, and supranuclear opacities. The development of these opacities probably starts in the anterior and posterior pre-equatorial zones. The first signs might be small numbers of opaque fiber bundles (**Figure 1(k)**), which develop into larger opaque areas and extend toward the lens pole and lens equator, finally progressing to thicker and denser opacities (**Figure 1(l)**) covering the entire equatorial and pre-equatorial zones and sometimes extending into the pupillary area. There is significant variability in the anterior and posterior extensions of the opacities (**Figures 1(c), 1(d), 1(k),** and **1(l)**). Scanning electron microscopy revealed small and large groups of cortical fibers with broken ends in the pre-equatorial zone at a depth corresponding to the cortical/nuclear interface (**Figures 3(e)** and **3(f)**). The portions of these fibers posterior and/or anterior to the breaks appeared folded and undulated, while both the deeper nuclear and more superficial neighboring cortical fibers exhibited normal structure and architecture. The sealed ends of the broken fibers might explain why these fibers remain arranged regularly and mutually connected despite their breaks; the sealed ends might also explain the lack of involvement of neighboring fibers. This is consistent with, and may in part explain, the generally slow progression of cortical opacities. Fluorescence microscopy (**Figures 3(h)** and **3(j)**)

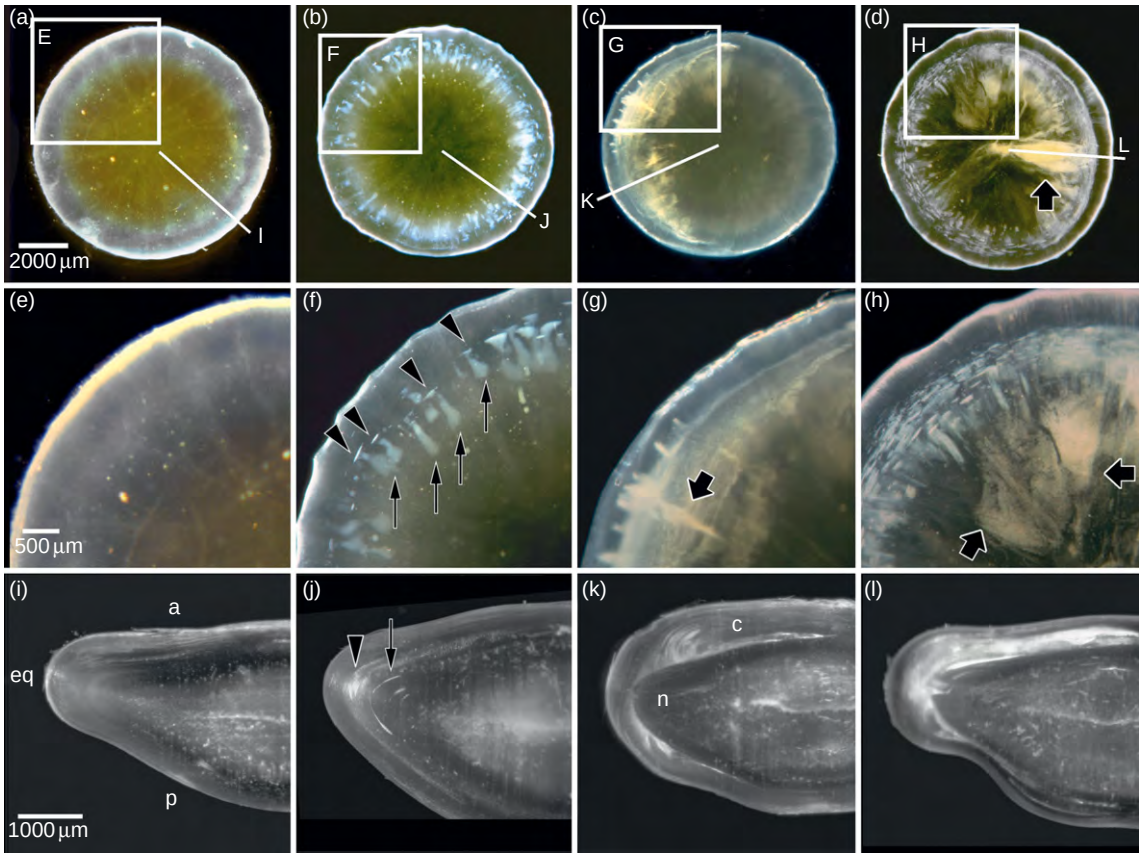

Figure 1 Panel of dark-field micrographs of aged human donor lenses (a–d). The boxed areas are magnified below (e–h). Except for nuclear coloration, a transparent lens with small, spot- or star-like opacities (a, e), a lens with radial shades (arrows) and circular shades (arrow heads) (b, f), a lens with peripheral, band-like and spoke-like opacities (bold arrows) (c, g), and a lens with mixed types of cortical opacities (d, h). Below are dark-field micrographs of slices cut in the axial plane of the fixed donor lenses (i–l); the lens equator (eq) and the anterior (a) and posterior (p) poles are indicated (l). The cutting plane is indicated by a white line in (a)–(d). In addition to some irregular scattering due to imperfect slicing, the central nuclear parts of the slices are free of opacification. The opacities extend in the anterior (a) and posterior (p) directions (j–l. Except for the spokes (bold arrows) (c, g), the opacities are outside the pupillary space and will not have seriously influenced vision (without regard to nuclear opacity). Adapted from Michael, R., Barraquer, R. I., Willekens, B., van Marle, J., and Vrensen, G. F. (2008). Morphology of age-related cuneiform cortical cataracts: The case for mechanical stress. *Vision Research* 48(4): 626–634, with permission from Elsevier.

supports the results of scanning electron microscopy studies demonstrating broken, folding, and undulating fibers in this border region as well as the presence, between the aberrant fibers, of small and large spaces that appear filled with fluid. This is in line with the clinical description of water clefts associated with cortical opacities.

Optical Effects

The transparency of the crystalline lens depends on the regular organization of its cells and proteins. This regularity must be maintained on the molecular level of the proteins, on the protein concentration level inside the lens fiber cells, and on the tissue level between the lens fiber cells.

At the molecular level, the short-range, liquid- or glass-like order of the protein molecules is required for lens transparency. At this level, the dimensions are shorter than the wavelength of light because the size of the protein molecules is less than 10 nm. Higher protein concentration in the cells indicates denser packing of the protein molecules, resulting in higher short-range order and less light scattering.

At the cellular level, local variations in the refractive index are the principal physical cause of light scattering. Here, the dimensions are greater than the wavelength of light. The average refractive index of living cells depends mostly on protein concentration. A typical mammalian cell has an average protein content of 18%, corresponding to a refractive index of about 1.37. The protein concentration in the center of the human lens is about 32%, with a refractive index of about 1.41. The main components of cell membranes are phospholipids, cholesterol, and membrane-spanning proteins and usually have a much higher refractive index than the proteins in the cytoplasm. The refractive index of membranes is about 1.48. When variations in

the refractive index are random, light will scatter in all directions. However, if there is a high degree of orderliness, destructive interference of locally scattered light will occur, and this will result in less total light scattering.

Membrane-bound bodies disturb the regular refractive index distribution of the protein-filled lens fiber cells and therefore scatter light; they are visible as small, spot- or star-like opacities (**Figures 2(a)** and **2(d)**). The globular material found at the location of the radial and circular shades (**Figures 2(e)** and **2(f)**) probably reflects variations in the protein concentration. This, along with the abnormal membranes at this location, induces light scattering (**Figures 2(b)** and **2(c)**). In the lens cortex, high spatial order in the lens fiber lattice (**Figures 3(d)** and **3(g)**) is required to compensate for light scattering caused by fluctuations in the refractive index between membranes and cytoplasm. This results in a relatively transparent lens cortex (**Figure 3(a)**). When this spatial order is disturbed (**Figures 3(e), 3(f), 3(h),** and **3(j)**), light is scattered, and the peripheral band- and spoke-like opacities become visible (**Figures 3(b)** and **3(c)**).

Impact on Vision

The location of the opacities and pupil size determine whether opacities affect vision. In daylight, the pupil diameter is small, about 3 mm. Small, spot- or star-like opacities and radial and circular shades, which are usually located outside this central area, do not affect vision (**Figures 1(a)** and **1(b)**). The same holds for peripheral band-like opacities (**Figure 1(c)**). Some spoke-like opacities (**Figure 1(d)**), however, extend into the pupillary area and will affect vision. At night, the pupil diameter increases to about 5–8 mm. Under these conditions, some radial and circular shades and peripheral, band-like opacities affect vision.

Optical disturbances reduce lens transparency and scatter light. This directly reduces visual acuity and contrast sensitivity because less light reaches the retina. Furthermore, the scattered light induces straylight on the retina, resulting in visual glare and halo effects around bright light sources at night when the pupil diameter is wide. Glare further reduces contrast in a visual scene.

Some cortical cataracts can induce changes in astigmatism. This probably results from localized refractive index changes along spoke-like opacities within the pupillary area.

Prevalence

Clinical observations have shown that the normal aging of the human lens, in the absence of disease, is accompanied by an increase in the overall light scattering of the lens. Up to age 40, light scattering remains rather

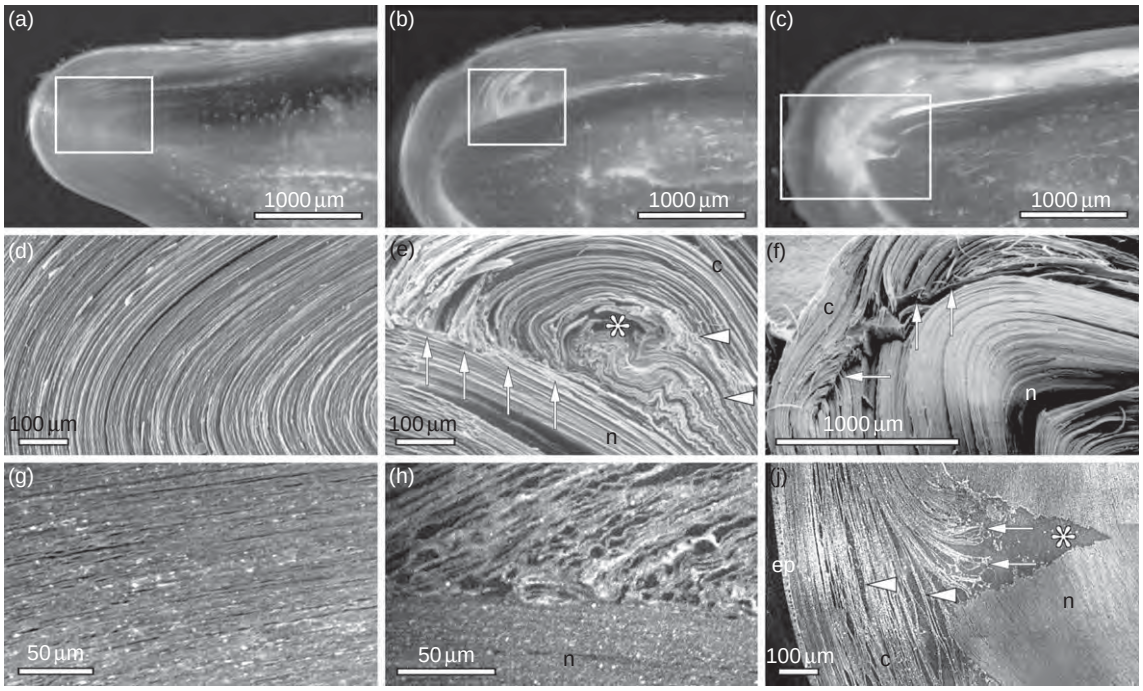

Figure 3 Fiber organization in a lens without cortical cataract (a) and in two cases of cortical opacities (boxed areas in (b) and (c)), as visualized by scanning electron microscopy (d, f) and fluorescence histology (g, h, and j). (e) Shows that fibers at the border zone between the nuclear and cortical lens regions are broken (arrows) and that the broken ends are directed against the nuclear fibers, which maintain regular, uninterrupted organization. Further, note the curled (asterisk) and folded (arrowheads) fibers in the region adjoining the broken fibers. Fluorescence histology of this type of opacification (h) shows the oblique orientation of the broken fibers on the regularly organized nuclear fibers. The dark regions in the fluorescence micrograph indicate the presence of spaces likely filled with fluid. The scanning electron microscopy micrograph of (f) shows broken fibers at several places (arrows) in the border zone between the cortex and nucleus. The nuclear fibers are regularly organized, as are the more superficial cortical fibers bridging the break zone. The fluorescence micrograph (j) shows the nuclear fibers and the most superficial fibers, which are regularly organized. The fibers between these layers are partly separated by water lakes (arrowheads). Some are broken (arrows), and there is a large triangular region (asterisk) (cf. (f)) free of fibers, most likely filled with fluid. ep, epithelium; n, nuclear side; c, cortical side. Reprinted from Michael, R., Barraquer, R. I., Willekens, B., van Marle, J., and Vrensen, G. F. (2008). Morphology of age-related cuneiform cortical cataracts: The case for mechanical stress. *Vision Research* 48(4): 626–634, with permission from Elsevier.

constant, thereafter increasing exponentially with age. Epidemiological studies have shown that, in developed countries, cortical cataract is by far the most prevalent age-related cataract, more common than nuclear cataract. However, since cortical cataracts may affect vision less often than nuclear cataracts, they may less often lead to cataract surgery.

The prevalence of radial and circular shades is age related, radial shades occurring earlier than circular shades. These are quite common, with a prevalence of approximately 20% at age 45 and about 75% above age 75. Peripheral band- and spoke-like opacities, which occupy more than 5% of the lens area, have a prevalence of about 5% at age 45, increasing to 30–50% after age 75.

Cortical cataracts can be restricted to either a sector or a quadrant (**Figure 1(c)**) or found around the entire circumference of the lens (**Figure 1(d)**); their extent is not directly related to age. Segmental cortical cataract is more prevalent in the lower nasal quadrant of the lens.

Causes

Unaltered transparency of the crystalline lens requires proper protein synthesis and the maintenance of equilibrium between water content, molecular compounds, and other constituents of the lens. Chemical agents and factors that disturb the equilibrium induce cataract. Such factors include metabolic disorders, certain drugs, different types of radiation, ocular inflammation, and physical injury. Age also plays an important role in cataract formation, as do nutrition, genetic factors, and race. Therefore, cataract is seen as an age-related, multifactorial disease.

Alterations and damage to the crystalline lens accumulates throughout life because there is no cell shedding. Lens cells developed before and after birth must remain transparent until old age. Any damage to these cells over the years will accumulate. Free radicals may play an important role in the damage process.

Exposure to ultraviolet radiation (UVR) is a major risk factor for cortical cataract. Several epidemiological studies

have demonstrated this by correlating the individual UVR dose from solar exposure with the incidence of cortical cataract. UVR-B (wavelengths between 280 and 315 nm) particularly correlates with cortical cataract formation. Shorter UVR wavelengths are completely absorbed by the cornea and do not reach the lens, while longer wavelengths are transmitted by the lens and therefore are less damaging. The common finding that cortical cataract appears more frequently in the lower nasal quadrant of the lens may indicate a role for sunlight in its etiology. The eye's exposure to the sun usually takes place from above and from the lateral side because the nose has a shadowing effect. Hence, solar radiation from above is focused on the lower quadrants of the lens, while radiation from the lateral side is focused on the nasal quadrants. There are a few reported cases in which people who received significant UVR doses from artificial sources subsequently developed cortical cataract that could be correlated with that exposure.

A relationship also seems to exist between cortical cataract and mechanical stress on the lens. During accommodation, the lens changes its shape by deforming its nucleus. With the onset of presbyopia, the elasticity of the nucleus decreases, and the lens no longer changes shape, although the ciliary muscle continues pulling on the lens, by way of the zonular fibers. This induces mechanical stress at the cortex–nucleus border zone, which might induce cortical cataract. The lens area under mechanical stress might become more vulnerable to environmental factors, such as ocular UVR exposure and nutrition.

Epidemiological studies suggest that some metabolic diseases, such as diabetes, vascular disease, hormonal factors in women, and corticosteroid intake, can induce cortical cataract. These studies have also shown that vitamin and antioxidant intake can delay nuclear cataracts, but the effect is not significant for cortical cataracts. Only the intake of polyunsaturated fats was associated with reduced prevalence of cortical cataract.

There might be racial factors for the development of cortical cataract, but they are often confounded by environmental factors, so there is no conclusive epidemiological data. Twin studies estimated the heritability of cortical cataract at about 50%, while the influence of individual environment is 35%, and age 15%.

Cranial Nerves and Autonomic Innervation in the Orbit

B C Anderson and L K McLoon, University of Minnesota, Minneapolis, MN, USA

Glossary

Abducens nerve – A general motor efferent which provides motor innervation to the lateral rectus muscle in the orbit. This nerve is often referred to as cranial nerve VI (CNVI).

Autonomic nervous system – This consists of motor nerve fibers that provide involuntary control of viscera, including smooth muscle, specialized conducting cells of heart muscle, as well as secretion in glandular cells. It consists of two divisions, a parasympathetic division and a sympathetic division.

Ciliary ganglion – A collection of neuronal cell bodies that give rise to the postganglionic parasympathetic nerve fibers that will innervate the ciliary and sphincter muscles of the eye. These are important for accommodation for near vision and for pupil closure in response to bright light.

Oculomotor nerve – A general motor efferent which provides motor innervation to the levator palpebrae superioris, superior rectus, medial rectus, inferior rectus, and inferior oblique muscles within the orbit. Additionally, it carries the preganglionic visceral efferents from the accessory oculomotor nucleus toward the ciliary ganglion. This nerve is often referred to as cranial nerve III (CNIII).

Parasympathetic nervous system – This consists of visceral motor nerves whose cells bodies of origin are located in craniosacral regions of the central nervous system. Four cranial nerves have parasympathetic components: oculomotor (CNIII), facial (CNVII), glossopharyngeal (CNIX), and vagus (CNX). Sacral levels S2–S4 also contain neurons that form nerve fibers which bring parasympathetic innervation to pelvic viscera.

Sympathetic nervous system – This consists of visceral motor nerves whose cell bodies of origin are located in the thoracic and upper lumbar regions of the spinal cord. The preganglionic nerve fibers exit in the spinal nerve, form white rami communicans which project into the sympathetic chain on each side of the vertebral column. The sympathetic chain runs the full length of the vertebral column, from the cervical to the sacral region. Within the sympathetic chain are sympathetic chain ganglia where the preganglionic nerve fibers synapse with postganglionic neurons. The postganglionic nerve fibers exit the sympathetic chain using gray rami communicans. These sympathetic nerve fibers join nearby nerves and blood vessels, which in turn carry them to all parts of the body.

Trigeminal nerve – This has three very large sensory roots and a small motor root. The sensory roots provide general somatic afferents to the face and the scalp anterior to the mid-auricular line and to a variety of structures within the head. This nerve is often referred to as cranial nerve V (CNV). There are three divisions of the trigeminal nerve: (1) the ophthalmic division, or V1, is sensory only and is the main sensory nerve of the orbit and the skin of the upper eyelid, forehead, and anterior half of the scalp; (2) the maxillary division, or V2, also is sensory only and provides sensory innervation to areas of the nasopharynx, parts of the nasal and oral cavities, as well as skin of the face lateral and inferior to the orbit; and (3) the mandibular division, or V3, has a sensory and a motor root. The mandibular division provides sensory innervation to parts of the oral cavity as well as to specific areas of the facial skin, including the mandibular region. The motor root innervates the muscles of mastication, as well as several other small muscles of the head.

Trochlear nerve – A general motor efferent which provides motor innervation to the superior oblique muscle in the orbit. This nerve is often referred to as cranial nerve IV (CNIV).

Weighted magnetic resonance imaging (MRI) – The signals from tissues of different densities create a difference in contrast and relaxation times (e.g., T1 and T2) and thus in the strength of the nuclear magnetic resonance signal that is produced in an MRI scanner. In a T_1-weighted MRI, the white matter appears white, the gray matter, containing the neurons, appears gray, and the cerebrospinal fluid appears dark. In a T_2-weighted image, the contrasts are reversed.

Complex Innervation Patterns Are Present in the Orbit

The paths of nerves found within the orbit are extremely complex, particularly when one considers the relatively small volume of each orbit. Knowledge of these patterns

of innervation is important for understanding both normal function, as well as impaired function when there is injury or disease affecting the nerve pathways. In addition, understanding the pattern of innervation can minimize injury during intraorbital surgical and/or injection procedures.

The orbit contains portions of five cranial nerves: the optic nerve or cranial nerve II, the oculomotor nerve or cranial nerve III, the trochlear nerve or cranial nerve IV, the ophthalmic division (VI) and the maxillary division (V2) which are both branches of the trigeminal nerve or cranial nerve V, and the abducens nerve or cranial nerve VI. In addition, the orbit receives autonomic nervous system innervation, and thus contains nerves that carry parasympathetic and sympathetic innervation to a number of structures. Each of these nerve pathways is described individually.

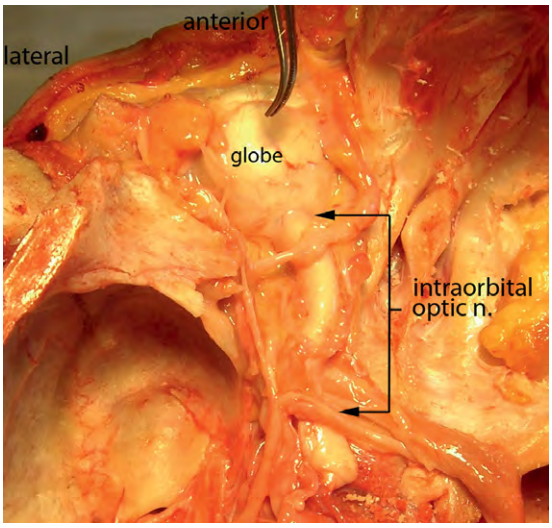

Figure 1 Superior view of the orbital contents in a human cadaver. The frontal bone that forms the orbital roof has been removed, as have the overlying levator palpebrae superioris and superior rectus muscles. The forceps tips are pointing to the globe, and the full extent of the optic nerve can be seen (indicated by the bracket between the two arrows). Note the S shape of the optic nerve, caused by the fact that the optic nerve is longer than the anterior to posterior length of the bony orbit.

Sensory Nerves

The Optic Nerve or Cranial Nerve II

The optic nerve is a special sensory nerve that carries information from the visual world to the brain. Embryologically, the optic nerve is derived from an outgrowth of the forebrain; therefore, it is part of the central nervous system (CNS) and is composed of CNS fiber tracts. It is surrounded by all the meningeal layers of the brain and has a subarachnoid space that contains cerebrospinal fluid. There are four parts to the optic nerve: intraocular or optic nerve head, intraorbital, interosseus, and intracranial. The optic nerve is formed as axons of the retinal ganglion cells exit the retina through the optic disc. This intraocular portion is approximately 1 mm in length and consists of unmyelinated ganglion cell axons. The intraorbital portion of the optic nerve contains mainly myelinated optic axons. The length of the optic nerve is greater than the distance from the optic nerve head to its entry into the optic foramen. The intraorbital portion of the nerve is approximately 30 mm long, while the distance from the posterior globe to the optic foramen is only 20 mm long (Figure 1). This generally gives the optic nerve an S shape within the orbit, and it is hypothesized that this extra length allows free movement of the globe without injuring the optic nerve. The optic nerve leaves the bony orbit via the optic foramen located within the lesser wing of the sphenoid bone. It travels through the optic canal and enters the intracranial space before joining with the contralateral optic nerve to form the optic chiasm.

Trigeminal Nerve or Cranial Nerve V

The trigeminal nerve is responsible for carrying general sensory information from the entire face, including the orbit and eyelids, to the brain. The cell bodies of origin of the sensory components of this large nerve are found in the trigeminal ganglion located in a cavity within layers of dura near the apex of the petrous portion of the temporal bone (Figure 2). Medial to the ganglion is the posterior cavernous sinus and the internal carotid artery. The human trigeminal ganglion contains approximately 27 000 sensory neurons. The central projections carry general sensory information to the sensory trigeminal nerve nuclei, which extend the whole length of the midbrain and medulla. There are three distinct nuclei from rostral to caudal: the mesencephalic nucleus involved in proprioception, the chief sensory nucleus involved in two-point touch discrimination, and the spinal trigeminal nucleus which mainly receives touch, pain, and temperature information. Three large divisions emanate from the trigeminal ganglion, each of which runs in a distinctly different direction and distributes to different parts of the face. These afferent branches are named for the region to which they form corrections: the ophthalmic division, often referred to as V1; the maxillary division, often referred to as V2; and the mandibular division, often referred to as V3 (Figure 2). Only the ophthalmic and maxillary divisions of the trigeminal nerve have branches within the orbit, and these are discussed individually.

Ophthalmic Division of the Trigeminal Nerve

The ophthalmic division is considered the first branch of the trigeminal nerve as it is the superior-most branch of the trigeminal nerve (Figure 2). It conveys general

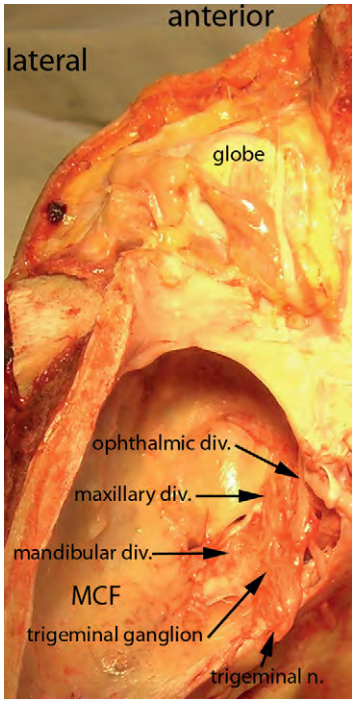

Figure 2 Superior view of the orbital contents and the middle cranial fossa (MCF) in a human. The trigeminal nerve and ganglion are visible on the medial wall of the middle cranial fossa after removal of the overlying dura mater. The three divisions can be seen each running toward their appropriate cranial foramina. The ophthalmic division of the trigeminal nerve is the most superior branch and enters the orbit through the superior orbital fissure (not seen). The maxillary nerve courses almost horizontally and leaves the middle cranial fossa through the foramen rotundum (not seen) to enter the pterygopalatine fossa. The mandibular division courses inferiorly through the foramen ovale (not seen) to enter the infratemporal fossa.

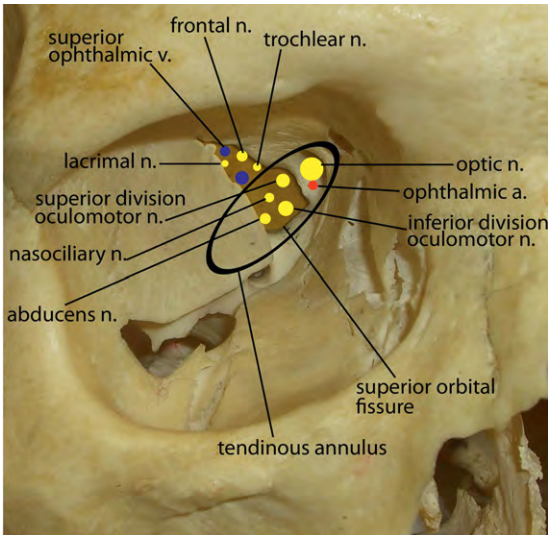

Figure 3 Photograph of the bony orbit in a dry skull from the anterior view. Medial is to the right and superior is at the top. The large opening between the greater and lesser wings of the sphenoid bone in the posterior of the orbit is the superior orbital fissure. Medial to the superior orbital fissure is the optic foramen, formed within the lesser wing of the sphenoid bone. There is a tendinous annulus at the posterior of the orbit, attaching to orbital bones medially and laterally. The rectus muscles take their origin from this connective tissue structure. The tendinous annulus separates the nerves entering the orbit into two groups: those that enter (1) superior to the annulus and (2) within the annular ring. A large number of nerves and veins pass through the superior orbital fissure superior to the annulus. From superior to inferior they are the superior ophthalmic veins, although these can be quite variable (blue circles); the frontal and lacrimal nerves which are branches of the ophthalmic division of the trigeminal nerve; and the trochlear nerve which innervates the superior oblique muscle. A large number of nerves enter the orbit within the annulus, and these are often referred to as intraconal. The optic nerve (yellow circle) and ophthalmic artery (red circle) enter the orbit through the optic foramen. The superior division of the oculomotor nerve, which innervates the superior rectus and levator palpebrae superioris muscles, and the inferior division of the oculomotor nerve, which innervates the medial rectus, the inferior rectus, and the inferior oblique muscles, pass through the superior orbital fissure. The nasociliary nerve, the third branch of the ophthalmic division of the trigeminal nerve, also enters via the superior orbital fissure. The final structure which enters the orbit within the annulus is the abducens nerve, which innervates the lateral rectus muscle.

sensory afferents that subserve pain, touch, and temperature sensitivity to the brain. As a sensory nerve, it is important to remember that the nerve branch consists of sensory afferents, with the information traveling into the brain. However, it makes the most sense to describe the complex branching pattern of the ophthalmic division of the trigeminal nerve starting from the apex of the orbit and working peripherally.

Separate branches of the ophthalmic division of the trigeminal nerve pass through the superior orbital fissure, as they do not coalesce into a single division until within the wall of the cavernous sinus intracranially. The superior orbital fissure is located between the lesser and greater wings of the sphenoid bone, and three distinct branches of the ophthalmic division of CNV can be seen traversing through this foramen (**Figure 3**).

Lacrimal nerve

The most superior and laterally placed is the smallest branch, the lacrimal nerve (**Figure 4**). The lacrimal nerve enters the orbit via the superior orbital fissure, outside the tendinous annulus formed by the origins of four extraocular muscles at the apex of the bony orbit (**Figure 3**). The nerve courses on the superior aspect of the lateral rectus muscle to enter the lacrimal gland. Prior to entry into the lacrimal gland, it receives a communicating branch from the zygomatic nerve which carries secretomotor innervation from the parasympathetic nervous system. The lacrimal nerve terminates on the conjunctiva and skin of the lateral part of the upper lid where it receives general sensory information.

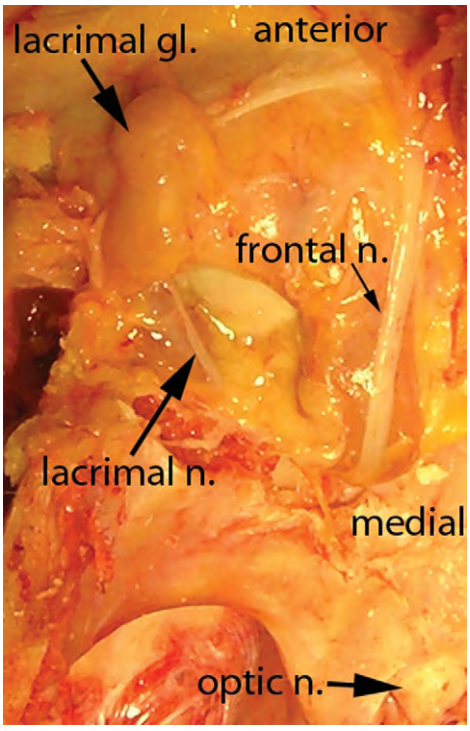

Figure 4 Superior view of the human orbital contents. The frontal bone that forms the roof of the orbit has been removed, as has the periorbita, a dense connective tissue that is the periosteal layer that lines the orbit. The most superior structures are visible. The lacrimal gland is located in the superior lateral part of the orbit. The superior-most structures are the frontal and lacrimal nerves, which are branches of the ophthalmic division of the trigeminal nerve. Just inferior to the frontal nerve is the levator palpebrae superioris muscle, which inserts into the eyelid skin to raise the eyelid.

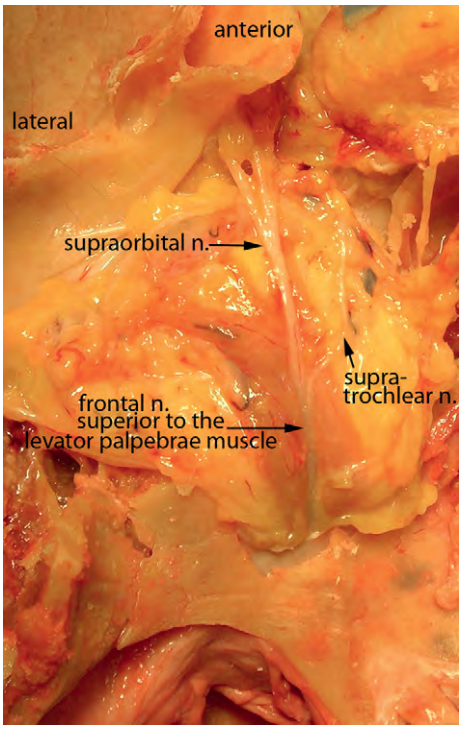

Figure 5 Superior view of the human orbital contents. The frontal bone that forms the roof of the orbit has been removed, as has the periorbita, a dense connective tissue that is the periosteal layer that lines the orbit. The most superior structures are visible. In this specimen, the frontal nerve can be seen forming its two terminal branches, the supraorbital and supratrochlear nerves. These exit the orbit anteriorly and provide sensory innervation to the upper eyelid, forehead and scalp.

Frontal nerve

The frontal nerve is the largest of the sensory branches of the ophthalmic division of the trigeminal nerve, entering the orbit within the uppermost part of the superior orbital fissure outside the tendinous annulus (**Figure 3**). It runs anteriorly between the periorbita, the dense connective tissue covering the orbital bones, and the levator palpebrae superioris muscle (**Figure 5**). Variably along its length, it divides into two terminal branches, the supratrochlear and supraorbital nerves (**Figure 5**). The small supratrochlear nerve runs superior to the trochlea, a cartilaginous structure attached superiomedially to the bony orbit, and exits the orbit anteriorly to supply the skin of the medial forehead, upper eyelid, and conjunctiva. The supraorbital branch is larger and continues anteriorly on the superior surface of the levator to exit the orbit through the supraorbital foramen or notch to provide sensory innervation to the conjunctiva and skin of the upper eyelid, forehead, and scalp anterior to the midauricular line. The supraorbital notch is located in the frontal bone which forms the superior orbital margin and is located approximately 31 mm from the midline bilaterally.

Nasociliary nerve

The nasociliary nerve passes through the superior orbital fissure between the two branches of the oculomotor nerve, running within the tendinous annulus (**Figure 3**). The course of this nerve in the orbit is particularly long and complicated (**Figure 6**). In the majority of cases, the nasociliary nerve turns medially and courses with the ophthalmic artery superior to the optic nerve, but deep to the superior rectus muscle. As it continues anteriorly, its path runs between the superior oblique and medial rectus muscles and in the process gives off five branches: sensory root of the ciliary ganglion, long ciliary nerves, posterior ethmoidal nerve, anterior ethmoidal nerve, and infratrochlear nerve.

Sensory root of the ciliary ganglion

These branches carry sensory information through the ciliary ganglion without synapsing. They run in both the short and long ciliary nerves, which pierce the sclera when they reach the globe. The sensory nerves here are very thin and vary between 5 and 12 mm in length.

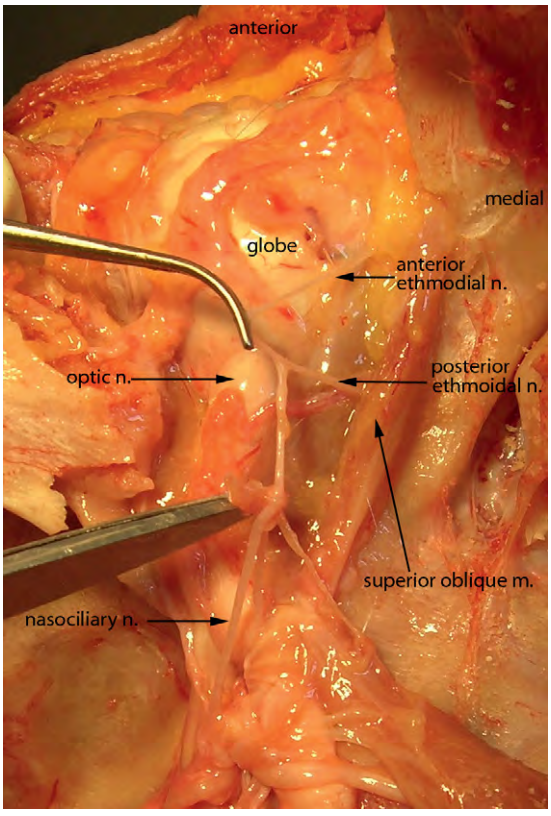

Figure 6 Deep dissection of the human orbit from the superior view. The levator palpebrae superioris and superior rectus muscles have been removed and the frontal nerve reflected. This allows the visualization of the nasociliary nerve, a branch of the ophthalmic division of the trigeminal nerve (note that the bony orbit posteriorly has been dissected open). The nasociliary nerve enters the orbit superior and lateral to the optic nerve, but rapidly moves medially and anteriorly where two sets of branches emerge: the posterior and the anterior ethmoidal nerves (lifted by the scissor tips and blunt probe). These enter the ethmoid air cells, which are part of the nasal sinuses in the mid-region of the head.

Long ciliary nerves

These nerves vary in number, although commonly there are two or three. These nerves course toward the globe, pierce the sclera, and extend anteriorly to provide sensory innervation to the iris, ciliary muscles, and cornea (Figure 7).

Posterior ethmoidal nerve

This is a small and variable branch that emerges off the nasociliary nerve and runs medially between the superior oblique and medial rectus muscles (Figure 6). It terminates in the sphenoid and posterior ethmoid sinuses, providing sensory innervation to these regions.

Anterior ethmoidal nerve

The anterior ethmoidal nerve runs anteriorly between the superior oblique and medial rectus muscles (Figure 6). It exits the orbit with the anterior ethmoidal artery through

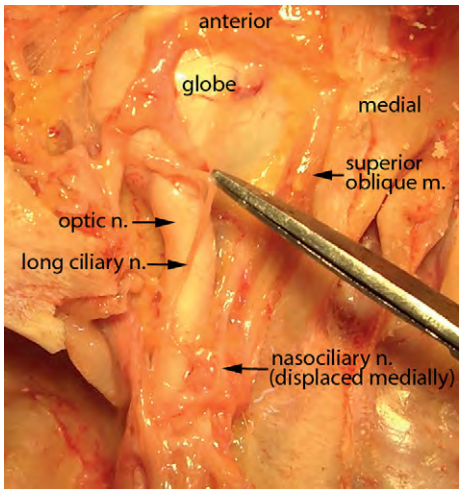

Figure 7 A deep dissection of the orbit seen from the superior view. The long ciliary nerves can be seen coursing between the nasociliary nerve, a branch of the ophthalmic division of the trigeminal nerve, and the globe (lifted at scissor tip). While this is largely carrying sensory information from the globe, recent studies have demonstrated that autonomic system nerves course in this structure.

the anterior ethmoidal canal, which is located between the ethmoid and frontal bones. It carries sensory innervation from the anterior and middle ethmoidal air cells as well as from the frontal sinus. The anterior ethmoidal nerve terminates by dividing to form internal and external nasal nerves, and the latter supplies the skin of the dorsum of the nose.

Infratrochlear nerve

This is the termination of the nasociliary nerve on the face, where it provides sensory innervation of the medial canthal area, the root of the nose, and the lacrimal sac and canaliculi. If this nerve is absent, the supratrochlear or anterior ethmoidal nerves provide the sensory innervation for these areas.

Maxillary Division of the Trigeminal Nerve

The maxillary division is considered the second branch of the trigeminal nerve, and similar to the ophthalmic division of CNV, it brings sensory information into the CNS via nerves whose cell bodies are located in the trigeminal ganglion. The maxillary division enters the pterygopalatine fossa via the foramen rotundum (Figure 2). It continues to course anteriorly and enters the inferior orbital fissure on the floor of the orbit within the maxillary bone. Within the fissure, two branches are formed: the zygomatic and infraorbital nerves. Only these two nerves, of the many branches of the maxillary division, are germane to a discussion of innervation within the orbit.

Zygomatic nerve

The zygomatic nerve emerges from the inferior orbital fissure and courses superiorly on the lateral orbital wall. Current dogma indicates that postganglionic parasympathetic fibers from the facial nerve (CNVII) run in this nerve, branch off in the lateral orbit, and enter the lacrimal nerve to provide secretomotor innervation to the lacrimal gland. Recent studies in nonhuman primates and humans indicate, however, that the parasympathetic nerves run directly to the lacrimal gland as 5–10 separate rami lacrimales (**Figure 8**). This is discussed in further detail in the section on the autonomic nervous system.

The zygomatic nerve divides into two terminal branches, the zygomaticotemporal and the zygomaticofacial, both of which supply skin over the temporal and buccal regions of the face, respectively.

Infraorbital nerve

This is the very large terminal branch of the maxillary nerve, which runs first in the inferior orbital fissure, then in the inferior orbital grove and canal to emerge on the face through the infraorbital foramen (**Figure 9**). This foramen is approximately 10 mm from the inferior orbital margin formed by the maxillary bone. This nerve provides sensory innervation to a large area of the face from the upper lip to the lower eyelid. Specific palpebral branches supply the skin and conjunctiva of the lower eyelid.

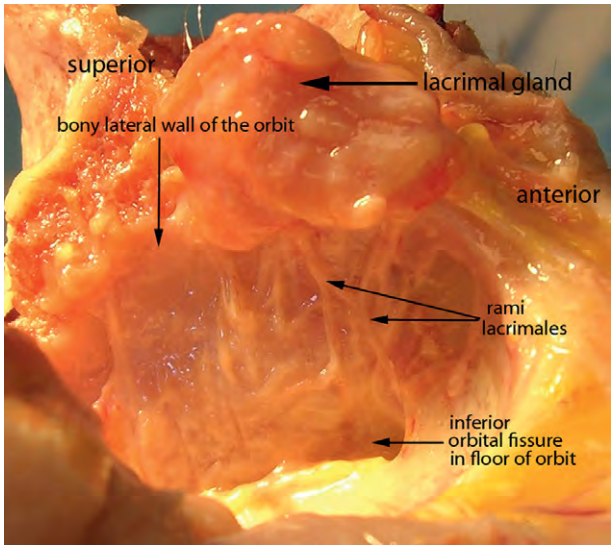

Figure 8 A view of the lateral wall of the orbit with the bony roof and all the orbital contents removed. This allows visualization of parasympathetic nerves coursing in a superior direction from the inferior orbital fissure on the bony orbit floor toward the lacrimal gland. These carry parasympathetic secretomotor postganglionic innervation to the lacrimal gland.

Motor Nerves

The Oculomotor Nerve or Cranial Nerve III

The oculomotor nerve provides motor innervation to the levator palpebrae superioris, the superior, medial and inferior rectus muscles, and the inferior oblique muscle. All these muscles insert directly onto the globe and move the eye within the orbit. In addition, as discussed in the section on autonomic innervation, the oculomotor nerve carries the parasympathetic preganglionic axons that synapses in the ciliary ganglion, and whose postganglionic axons innervate the pupillary sphincter and ciliary muscles of the eye.

The oculomotor neurons within the brainstem that give rise to the oculomotor nerve have a complex organization. The oculomotor nucleus is found at the level of the mesencephalon, ventral to the cerebral aqueduct. It extends from the posterior floor of the fourth ventricle to the trochlear nucleus. Generally, the oculomotor nucleus contains a midline dorsal nucleus and two lateral nuclei. Using a variety of tract-tracing techniques, it has been shown that the oculomotor nucleus is organized in a muscle-specific manner, with specific groups of neurons innervating single extraocular muscles. In addition, the muscles can receive ipsilateral, contralateral, or bilateral innervation. Each superior rectus muscle is innervated by contralateral oculomotor neurons located medially within the paired lateral nuclei. Each medial rectus is innervated by ipsilateral oculomotor neurons found in the inferior-most part of the paired lateral nuclei. Each inferior rectus muscle is innervated by ipsilateral oculomotor neurons located in the superior-most part of each of the paired lateral nuclei. The inferior oblique is innervated ipsilaterally by neurons located in the middle and lateral portion of the paired

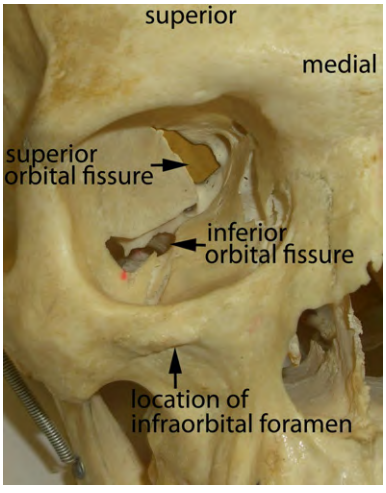

Figure 9 An anterior view of the orbit on a dry skull. Foramina, or openings in the bone, can be seen. The superior orbital fissure is found at the orbital apex. The inferior orbital fissure is found on the orbital floor. The optic foramen is found on the superior-medial wall.

lateral nuclei. Only the levator palpebrae superioris muscle receives bilateral innervation from the single dorsal caudal nucleus located in the midline. All the nerve fibers from these various topographically organized nuclei join together within the brainstem, and after running through the red nucleus and cerebral peduncle, exit the brainstem on its ventral surface in the interpeduncular fossa. In their cisternal location, they pass between the posterior cerebral and superior cerebellar arteries, and course anteriorly, deep to the posterior communicating artery. The intracranial course is on average 25 mm long before the nerves enter into the dural border of the lateral cavernous sinus at the level of the posterior clinoid process (**Figure 10**). The oculomotor nerve enters the orbit through the superior orbital fissure, where it divides into a superior and an inferior division and enters the tendinous annulus (**Figure 3**). The diameter of the oculomotor nerve, as it enters the superior orbital fissure, is on average 2.1 mm, while the superior and the inferior divisions are 1.6 and 1.9 mm in diameter, respectively. The superior division innervates the superior rectus and levator palpebrae superioris muscles; the nerve enters the conal surface of the superior rectus muscle (**Figure 11**), and nerve fibers continue to the levator by either piercing through the superior rectus muscle or passing on its lateral border. The inferior division innervates the medial rectus, the inferior rectus, and the inferior oblique muscles. To reach these muscles, the inferior division of the oculomotor nerve runs medially and inferiorly, dividing into three branches (**Figure 12**). One branch enters the medial rectus muscle and the second branch enters the inferior rectus muscle, both on their conal surfaces; a third branch courses anteriorly along the lateral border of the inferior rectus muscle and pierces the inferior oblique at the point where it crosses the inferior rectus muscle. All the oculomotor nerve branches enter the muscles between the middle and posterior 1/3 of each muscle. In the majority of cases, the branch to the inferior oblique gives rise to nerves that carry parasympathetic axons to the ciliary ganglion. This is discussed in the section on autonomic nervous system.

The course of the oculomotor nerve is easily seen using standard magnetic resonance imaging (MRI) techniques, both intracerebrally and intraorbitally.

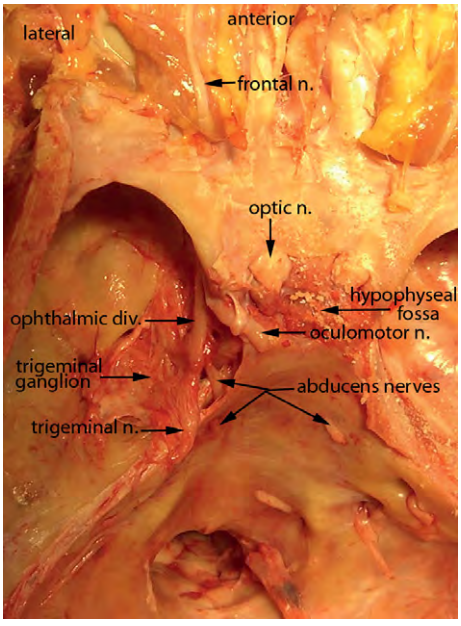

Figure 10 Superior view of the floor of the cranium. The orbital contents can be seen anteriorly. Four of the five cranial nerves can be seen. On the medial wall of the middle cranial fossa, the three divisions of the trigeminal nerve can be seen coursing from the anterior border of the trigeminal ganglion. The ophthalmic division can be seen coursing in the direction of the orbit. The oculomotor nerve can be seen crossing superior to the sella turcica of the sphenoid bone (which houses the pituitary gland in the hypophyseal fossa). The abducens nerve can be seen diving through the dura and coursing on the medial side of the trigeminal ganglion. The large foramen seen at the bottom of the photograph is the foramen magnum, where the spinal cord joins the medulla oblongata of the brain. The optic nerve can also be seen as it enters the optic canal.

The Trochlear Nerve or Cranial Nerve IV

The trochlear nerve provides innervation to one skeletal muscle only, the superior oblique. The motor neurons that form the trochlear nerve are located in the trochlear

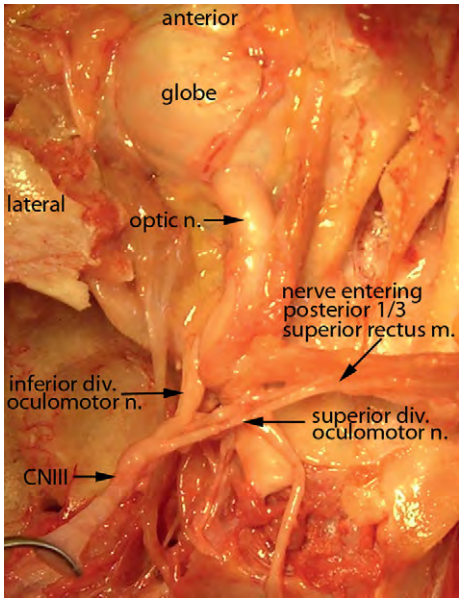

Figure 11 A deep dissection of the orbit from the superior view of the orbit. The optic nerve can be seen exiting the globe. The two divisions of the oculomotor nerve are dissected. The superior division is seen entering the superior rectus/levator palpebrae superioris muscles. The inferior division dives deep to the optic nerve on its way to innervate the medial and inferior rectus, and inferior oblique muscles. (Forceps is holding the cut proximal end of the oculomotor nerve.)

nucleus, which is located at the caudal end of the oculomotor nucleus at the level of the inferior colliculus. The nerve fibers run dorsally and slightly caudally, decussate (cross the midline), and emerge on the dorsal surface of the brainstem caudal to the inferior colliculus. This means that each trochlear nucleus innervates the contralateral superior oblique muscle within the orbit. However, a number of studies in various species unequivocally demonstrate that up to 5% of the superior oblique muscle innervation originates in the ipsilateral trochlear nucleus; this means that there is a small bilateral component to the innervation of the superior oblique muscle.

The course of the trochlear nerve is long, with an intracranial course of 60 mm. It also has the smallest cross-sectional diameter, averaging between 0.75 and 1 mm. The trochlear nerve courses on the lateral side of the midbrain running anteriorly to enter the cavernous sinus. Prior to entering the sinus wall, in 90% of specimens examined, the trochlear nerve is associated with the superior cerebellar artery, which usually runs superior to the nerve. Upon entering the cavernous sinus, the oculomotor nerve is medial and superior to the trochlear nerve and, more anteriorly, the oculomotor nerve ends up inferior and lateral to the trochlear nerve. The ophthalmic division of the trigeminal nerve consistently runs inferior to the trochlear nerve. Interestingly, in over 25% of trochlear nerves examined, there were nerves interconnecting V1 and trochlear nerves, presumably carrying general sensory information from the superior oblique muscle. The mean length of the intracavernous portion of the trochlear nerve is 26.8 mm.

The trochlear nerve enters the orbit through the superior orbital fissure in its most superior-lateral part, entering superior to the tendinous annulus (**Figure 3**). In this location its diameter is approximately 1.18 mm. Within the orbit, the trochlear nerve runs anteriorly and medially, with only periosteum separating the nerve from the sphenoid bone. The trochlear nerve terminates within the posterior half of the superior oblique muscle (**Figure 13**); in 76% of the orbits it ends in the medial aspect of the muscle and in the remaining 24% it ends in the superior aspect of the muscle. Generally, the total length of the trochlear nerve in the orbit is approximately 25 mm. Nerve branches first enter the muscle 17.25 mm from the muscle origin. Branches continue to dive into the muscle surface for an additional 7 mm.

Due to its small diameter, the trochlear nerve is difficult to image consistently using normal T1-weighted MRI, although T2-weighted fast spin-echo or T2-weighted

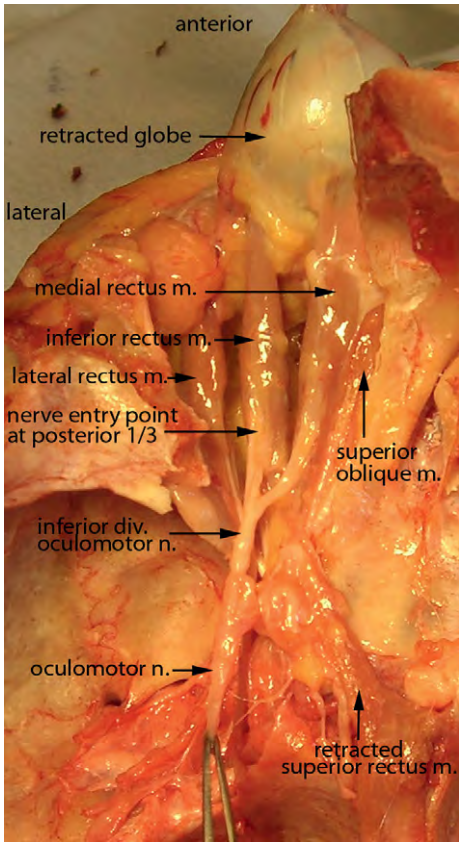

Figure 12 Superior view of a deep dissection of the human orbit. The globe has been retracted so we can see its inferior surface. This allows visualization of the lateral, the inferior, and the medial rectus muscles. The inferior division of the oculomotor nerve can be seen coursing directly into the posterior 1/3 of the inferior and medial rectus muscles. (Forceps is holding the cut proximal end of the oculomotor nerve. The lacrimal gland is covering the anterior portion of the lateral rectus muscle.)

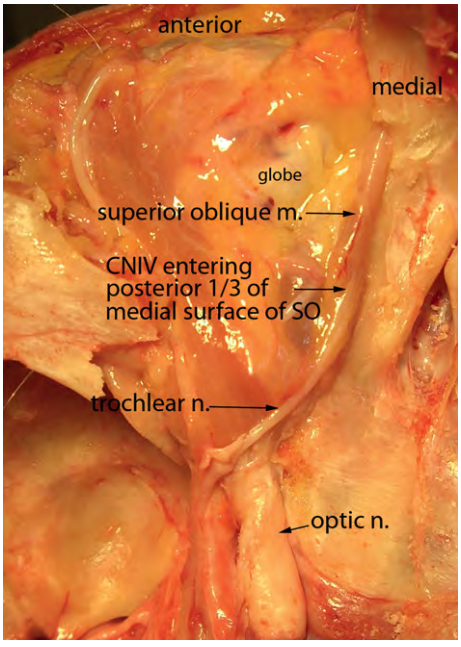

Figure 13 Superior view of a superficial dissection of the human orbit. The trochlear nerve is dissected to its entry point into the posterior 1/3 of the medial surface of the superior oblique muscle. The globe is obscured by orbital fat and the superiorly located muscles.

three-dimensional sequences, such as 3D-CISS, were able to visualize the trochlear nerve in up to 95% of patients examined.

The Abducens Nerve or Cranial Nerve VI

The abducens nerve provides motor innervation to only one extraocular muscle in humans, the ipsilateral lateral rectus muscle. While CNVI innervates the retrobulbar muscle in animals such as rats and rabbits, nonhuman primates and humans do not have a retrobulbar muscle. The motor nucleus for the abducens nerve lies inferior to the floor of the fourth ventricle. Nerve fibers leave the nucleus and run anteriorly, laterally, and caudally through the pons, emerging in the medullary–pontine sulcus, a groove between the medulla and the pons. In this location the nerve is intracisternal, deep to the pons. The nerve is in close proximity to the anterior inferior cerebellar artery, and in approximately 80% of dissected human cadavers, the artery is inferior to the nerve. The nerve courses over the lateral edge of the dorsum sellae, pierces the dura of the clivus, runs in a canal formed by the petrosphenoidal ligament superiorly and a bony ridge in the petrous ridge of the temporal bone (Dorello's canal), and passes through the inferior petrosal sinus as it courses anteriorly, lateral to the petrous part of the temporal bone. It crosses superior to the petrous ridge and deep to the petrosphenoidal ligament, lateral to the bend of the internal carotid artery. Unlike CNIII, CNIV, and CNV1, the abducens nerve does not sit within the wall of the cavernous sinus; it floats free within the cavernous sinus, where it is medial to the trigeminal ganglion (**Figure 10**). The total length of the intracranial abducens nerve is on average 53 mm in adults.

The abducens nerve enters the orbit through the superior orbital fissure within the tendinous annulus (**Figure 3**). In this location its mean diameter is 1.54 mm, and it is found lateral to both branches of the oculomotor nerve and inferior to the nasociliary nerve and the superior branch of CNIII. It rapidly gains the medial surface of the lateral rectus muscle, splits into three to four branches, and enters the muscle within the posterior 1/3 of its length (**Figure 14**). The intraconal length of the abducens nerve is about 5 mm.

In contrast to the trochlear nerve, the abducens nerve, from its exit at the brainstem to its entry into the lateral rectus muscle, can be visualized using MRI.

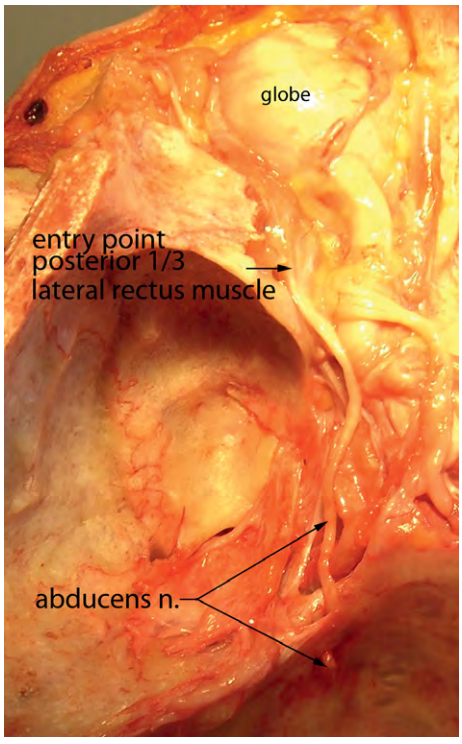

Figure 14 Superior view of the floor of the cranial fossa in a human cadaver. The abducens nerve was dissected from its entry into the dura, through the cavernous sinus on the lateral side of the sella turcica (medial to the trigeminal ganglion). It enters the orbit through the superior orbital fissure (lesser sphenoid bone has been removed to open the fissure), and its entry into the posterior 1/3 of the lateral rectus muscle is visible.

Autonomic Nervous System Contributions to Orbital Innervation

The autonomic nervous system is ubiquitously located throughout the body and is responsible for controlling involuntary structures, including smooth muscle, the conducting cells of the heart, and glandular secretion. The autonomic nervous system is divided into two systems: the sympathetic and the parasympathetic nervous systems. As a rule, these two parts of the autonomic nervous system have opposing functions. Simplistically speaking, the sympathetic nervous system helps the body respond to stress, such as increasing blood flow to the muscles in preparation for activity. The parasympathetic nervous system, in general, actively promotes normal bodily functions at rest, such as increasing blood flow to the intestines and aiding in peristalsis.

The main anatomical differences of the two parts of the autonomic nervous system are based on the location of the preganglionic neuronal cell bodies and what nerves conduct their axons to the periphery. Each autonomic circuit consists of a two-neuron chain. In general, the sympathetic nervous system has short preganglionic nerves and long postganglionic nerves. The opposite is true of the parasympathetic nervous system, where the preganglionic nerves are long and the postganglionic nerves are short. The preganglionic sympathetic neuronal cell bodies are located in the thoracic and upper lumbar regions of the spinal cord, while the preganglionic parasympathetic neuronal cell bodies are located in specific brainstem nuclei as well as in lower sacral levels of the spinal cord.

Parasympathetic Innervation in the Orbit

As is typical of parasympathetic innervation, the nerve fibers originate in specific brainstem nuclei. The axonal paths of these parasympathetic nerves within the orbit are extremely complex. Four of the twelve cranial nerves have parasympathetic components (CNIII, CNVII, CNIX, and CNX). Of these, both the oculomotor (CNIII) and facial (CNVII) nerves send parasympathetic innervation into the orbit. The preganglionic neuronal cell bodies are located in brain nuclei, while the postganglionic cell bodies are located in peripherally located ganglia.

Parasympathetic innervation within the oculomotor nerve

The accessory oculomotor nucleus is the site of origin of the preganglionic nerve fibers that enter the orbit with the oculomotor nerve. This nucleus is located both rostral and dorsal to the oculomotor nucleus. Its nerve fibers run into and travel along with the superior aspect of the ipsilateral oculomotor nerve. Within the orbit, these preganglionic parasympathetic nerve fibers run with the inferior division of the oculomotor nerve, and eventually extend nerve branches to the ciliary ganglion. The ciliary ganglion is located on the lateral side of the optic nerve close to the orbital apex. It is between 1 and 3 mm in diameter. In approximately 8% of the orbits, the ciliary ganglion is located directly on either the inferior division of the oculomotor nerve or the nerve to the inferior oblique muscle. In addition, many authors have described accessory ciliary ganglia as well as scattered ganglion cell neurons within the ciliary nerves themselves. We use the term ciliary ganglion to encompass all three of these ganglion locations.

Within the ciliary ganglion are postganglionic neuronal cell bodies that receive synapses from the preganglionic nerve fibers. The postganglionic nerve fibers, for the most part, travel within the short ciliary nerves and enter the sclera on the temporal side of the globe. These nerves innervate the ciliary muscles and iris sphincter muscles; roughly 95% go to the ciliary muscles and 5% innervate the sphincter muscles. Thus, this parasympathetic innervation is responsible for pupil constriction in response to light as well as for accommodation needed for near vision.

It should also be noted that experimental evidence demonstrates that intraocular parasympathetic projections also can arise from the pterygopalatine ganglion. These fibers arrive in the orbit by either (1) joining the retro-orbital plexus and then traveling anteriorly to the globe with the ciliary artery, long ciliary nerve, short ciliary nerve, and/or within the optic nerve sheath, or (2) they travel retrogradely with the ethmoidal or infratrochlear nerves and join the long ciliary nerves to enter the globe.

An additional source of parasympathetic innervation to the globe itself is supported by the fact that removal of the ciliary ganglion only reduces the cholinergic nerve fibers within the cornea, iris, and choroid by 60%.

Parasympathetic innervation to the lacrimal gland

The brainstem neurons, which every basic anatomy textbook describes as giving rise to the parasympathetic secretomotor nerve fibers of the lacrimal gland, are found within the ventral subgroup of neurons in the superior salivatory nucleus located between the root of the facial nerve and the superior olive nuclei. The preganglionic parasympathetic secretomotor fibers exit the brainstem within the intermediate root of the facial nerve. The intermediate root joins the motor root of the facial nerve and exits the cranium through the internal acoustic meatus. Within the temporal bone, the parasympathetic fibers exit the facial nerve at the geniculum and leave the temporal bone as the greater petrosal nerve. This nerve courses anteriorly, crosses the middle cranial fossa, and enters the pterygoid canal where it is joined by the deep petrosal nerve, which brings sympathetic nerve fibers that ascended from the superior cervical ganglion by running on the internal carotid artery. These two nerve branches unite and form the nerve of the pterygoid canal (formerly called the vidian nerve). The nerve of the pterygoid canal courses to the pterygopalatine ganglion, which is associated with V2 within the pterygopalatine fossa. Here in the pterygopalatine ganglion, the preganglionic parasympathetic nerve fibers synapse with neurons that will form the postganglionic nerve fibers. These secretomotor fibers have been described as coursing with the zygomatic nerve, which runs on the floor and lateral wall of the orbit. Eventually, a nerve root anastamosis with the lacrimal nerve forms and carries the postganglionic secretomotor fibers that originated in CNVII to the lacrimal gland. A number of scientists question this pathway, as it is extremely complex and the anastamosis between the zygomatic and lacrimal nerve is often nonexistent. In addition, section of the connecting ramus between the zygomatic and lacrimal nerves does not reduce lacrimation.

Recent studies using modern tract-tracing techniques have demonstrated that, in fact, there is a direct pathway from the pterygopalatine ganglion to the lacrimal gland via a retro-orbital autonomic plexus. In humans and in the nonhuman primates, 5–10 rami can be traced directly from the pterygopalatine ganglion to the retro-orbital nerve plexus, and rami from this plexus are easily traced directly to the lacrimal gland. In other studies, nerve rami were followed that passed directly from the pterygopalatine ganglion to the lacrimal gland. These studies demonstrate that, contrary to current dogma, pterygopalatine

postganglionic parasympathetic efferents course to the lacrimal gland without using branches of the maxillary (zygomatic branch) nerve as a route.

Sympathetic Innervation in the Orbit

The sympathetic innervation of the body is extremely ubiquitous. It has long been understood that preganglionic sympathetic neuronal cell bodies are located in the intermediolateral portion of the spinal cord at the thoracic and upper lumbar levels. The sympathetic nerve fibers exit the spinal cord in the ventral root and branch off as white rami communicans to join the sympathetic chain running on the lateral sides of the vertebral bodies. First-order central sympathetic fibers arise from the posterolateral hypothalamus and descend to terminate in the intermediolateral cell column of the spinal cord at the level of C8–T2. Second-order preganglionic pupillomotor fibers exit the spinal cord at the level of T1 and ascend in the cervical sympathetic chain which is found on the lateral sides of the cervical vertebrae. The fibers synapse in the superior cervical ganglion at the level of the bifurcation of the common carotid artery (C3–C4). After the postganglionic fibers leave the superior cervical ganglion, the pupillomotor fibers ascend along the internal carotid artery and enter the cavernous sinus. Some axons leave the carotid plexus to join the abducens nerve (CNVI) in the cavernous sinus and enter the orbit through the superior orbital fissure along with the ophthalmic branch of the trigeminal nerve (V1). These axons course toward the globe in the long ciliary nerves, which innervate the iris dilator and superior and inferior tarsal muscles within the upper and lower eyelids, respectively. In addition, these sympathetic nerves control the diameter of all vasculature.

The standard view that the only route of entry of sympathetic nerve fibers into the orbit is the ophthalmic artery, a branch of the internal carotid artery that enters the orbit through the orbital foramen, has been challenged in recent years. A large proportion of the sympathetic innervation does enter the orbit hitchhiking on the ophthalmic artery and traveling along its branches within the orbit. However, with the use of specific enzymatic labeling methods, the sympathetic nerve routes within the orbit have turned out to be much more numerous and complex than previously described in standard anatomy textbooks. Sympathetic nerves now are known to enter the orbit by a significant number of other routes, including the first and second divisions of the trigeminal nerve (the ophthalmic and maxillary nerves) as they enter the orbit through the superior orbital fissure. All branches of the ophthalmic division of the trigeminal nerve within the orbit contain sympathetic nerve fibers. Sympathetic nerves from these sensory branches of the trigeminal nerve join and travel within the extraocular motor nerves in the posterior orbit. The smooth muscles that open the eyelid and the superior and inferior tarsal muscles receive their sympathetic innervation from terminal branches of the lacrimal nerves and the infratrochlear branch of the nasociliary nerve. Sympathetic nerve fibers from the nasociliary nerve also run directly through the ciliary ganglion without synapsing and travel distally toward the sclera in long ciliary nerves. Sympathetic innervation also has been seen in the short ciliary nerves by some authors, although there appears to be some variability in this pathway. Within the sclera, the sympathetic nerves reach the iris dilator muscle, the ciliary body, and the trabecular meshwork anteriorly. Injury to these nerves anywhere along their pathway results in Horner's syndrome, which refers to a constellation of signs produced when sympathetic innervation to the eye is interrupted. This results in moderate ptosis due to denervation of the superior tarsal muscle, slight elevation of the lower lid due to denervation of the inferior tarsal muscle, a muscle analogous to the superior tarsal muscle in the upper lid, as well as miosis and dilation lag, that is, pupillary dilation is slowed in the affected pupil.

The zygomatic branch of the maxillary division of the trigeminal nerve carries sympathetic nerve fibers; thus, sympathetic innervation is carried to the lacrimal gland within both the zygomatic and lacrimal nerves. This innervation not only controls vascular diameter, but also directly innervates the secretory acini within the gland. In addition, sympathetic nerve fibers have been demonstrated to enter the orbit within the optic nerve, trochlear nerve, and abducens nerve, again contrary to what has been believed historically.

In summary, the postganglionic sympathetic fibers appear to be distributed to and course in all cranial nerves entering the orbit, as well as within more distal branches. While a large number enter the orbit with the ophthalmic artery as traditionally described, the ophthalmic division of the trigeminal nerve provides a major route for entry of sympathetic fibers into the human orbit.

Defense Mechanisms of Tears and Ocular Surface

A M McDermott, University of Houston, Houston, TX, USA

Glossary

Antigen-presenting cell – Bone-marrow-derived cell that ingests antigen and presents it to T lymphocytes to trigger adaptive immune response.
Antimicrobial peptide – Small protein, typically cationic, with broad spectrum antimicrobial activity.
Pattern recognition receptor – Cell surface or intracellular protein receptor that binds conserved motifs (pathogen-associated molecular patterns) on microorganisms.
Siderophore – Iron chelating compound secreted by bacteria and fungi to facilitate uptake of this essential nutrient.

Introduction

The ocular surface is composed of the epithelia of the cornea, limbus, and conjunctiva, the anatomy and physiology of which are discussed in detail elsewhere in this encyclopedia. The tear film coats the epithelia and is a complex structure composed of an outer anterior-most lipid component that prevents evaporation, an aqueous component that has ions, soluble mucins, enzymes, and a range of other proteins and closest to the epithelial surface is a thick mucus, primarily composed of the gel-forming mucin MUC5AC. Together, the ocular surface epithelia and tears: (1) create a formidable barrier that helps prevent microbial attachment in the first place, (2) bombard organisms with a plethora of chemicals to stop them dead in their tracks (or at least stop them proliferating), and (3) provide a detection system such that when an organism actually manages to circumvent the primary innate defenses, adaptive immunity can be activated to provide further help to eliminate the offending organism.

The defense mechanisms are remarkably effective, as despite constant exposure to the external environment and frequent interaction with unwashed fingertips, the ocular surface rarely succumbs to infection. Generally only when there is physical disruption of the epithelial barrier such as occurs with contact lens wear or injury do the defenses encounter serious challenge and infections become a significant cause of morbidity. Infection can affect both the cornea (infectious keratitis) and conjunctiva (infectious conjunctivitis), but is most serious when the cornea is involved as this structure provides the majority of the refracting power of the eye and loss of visual acuity or even blindness may be the consequence. Given appropriate circumstances, a range of organisms can infect the ocular surface. The most common bacterial species are *Pseudomonas aeruginosa*, *Serratia marcescens*, *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Streptococcus pneumoniae*. Herpes simplex virus is the most common viral culprit. Fungal infection is less common than bacterial or viral infection, but is on the rise, with the most frequently isolated species in the USA being *Aspergillus*, *Candida*, and *Fusarium*. Some of the ocular surface and tear defenses that help prevent these infections are depicted in Figure 1 using the corneal epithelium as a model.

Defense Mechanisms of Tears

Tears provide both physical/mechanical and chemical defense to the ocular surface. The act of blinking moves tears toward the puncta and into the lacrimal sac, thus helping to wash away any potential pathogens before they have had time to interact with and invade the ocular surface epithelial cells. Furthermore, reflex tearing increases tear volume which helps to rapidly dilute harmful substances released by invading pathogens.

Chemical entities with antimicrobial properties present in tears primarily originate from lacrimal and accessory gland secretions and the ocular surface epithelial

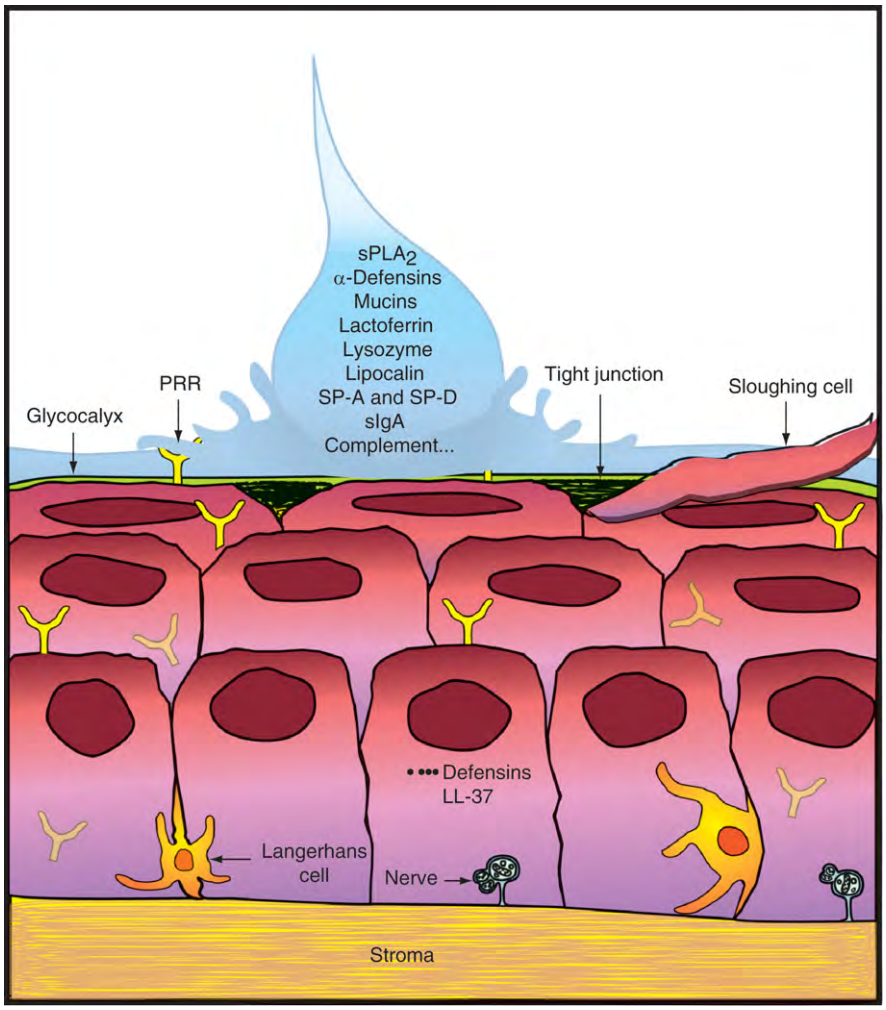

Figure 1 Summary of defense mechanisms of tears and ocular surface. Schematic diagram of some of the various defenses used by tears and ocular surface epithelia to prevent infection (additional ones are discussed in the text). The corneal epithelium is depicted (note not all cell layers are shown) but as described in the text similar mechanisms are used by conjunctival epithelial cells. PRR, pattern recognition receptor (e.g., TLRs); SP-A, surfactant protein-A; SP-D, surfactant protein-D; sIgA, secretory IgA; $sPLA_2$, secretory phospholipase A_2.

cells. Other components include serum exudates and secreted products of neutrophils and other infiltrating cells. Several tear film components have been identified that have direct antimicrobial activity or which can otherwise limit pathogen entry and growth. The first identified was lysozyme which was shown to kill Gram-positive bacteria by Alexander Fleming (of penicillin fame) in 1922. This enzyme accounts for 20–40% of total tear protein and has the ability to catalyze the hydrolysis of 1,4-beta-linkages between *N*-acetylmuramic acid and *N*-acetyl-D-glucosamine in the peptidoglycan backbone of bacterial cell walls. It is also able to cleave chitodextrins in fungal cell walls. The compromised cell wall is then no longer able to maintain a stable osmotic environment and lysis of the organism ensues. Secretory phospholipase A_2 ($sPLA_2$) has been identified as the major tear protein active against Gram-positive bacteria, although it has no activity against Gram-negatives in the normal ionic environment of tears and notably is some 50-fold less abundant in tears than lysozyme. Secretory PLA_2 hydrolyzes the *sn*-2-fatty acyl moiety from phospholipids, in particular, phosphatidylglycerol, which is abundant on bacterial cell membranes.

Other tear fluid components showing direct microbial killing include the cationic antimicrobial peptides (AMP; see the section entitled 'Defense mechanisms of the ocular surface epithelia') and the α-defensins human neutrophil peptide (HNP) 1, 2, and 3. As implicated by their names these peptides are produced by neutrophils and while present in only low concentrations under normal circumstances their level in tears rises after ocular surface injury. As depicted in **Figure 2**, these positively charged peptides exert their activity by interacting electrostatically with the negatively charged microbial cell membrane and form pores or otherwise disrupt the membrane

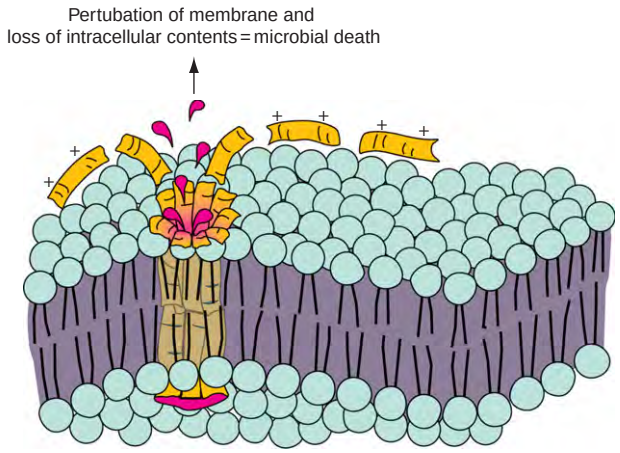

Figure 2 Mechanism of action of antimicrobial peptides. Positively charged peptides (shown in yellow) such as defensins and cathelicidin (LL-37) interact with negatively charged microbial membranes leading to disruption of the membrane, and possibly transient or stable pore formation, which results in leakage of intracellular contents, disturbance of metabolism, and death of the organism.

leading to disturbances of respiration and metabolism, leakage of cell contents, and eventual death of the organism. A lytic effect of these peptides is also possible. Betalysin and secretory leukocyte protease inhibitor (SLPI) are other examples of cationic proteins found in tears, which also interact with bacterial cell membranes and cause cell lysis. SLPI, which comes from lacrimal gland and ocular surface epithelial cells, has a defensin-like domain that confers antimicrobial activity and is also a potent inhibitor of neutrophil elastase. Thus, SLPI can both help prevent infection and protect host cells from the damaging effects of neutrophil enzymes. Elafin is another protein, which exerts similar dual functionality. Histatins, which are small histidine-rich AMPs with antifungal activity, have also been detected in the tears.

A number of tear components limit bacterial growth rather than actually killing the invading organism. Lactoferrin represents some 21% of the total reflex tear protein and has a high capacity to bind divalent cations including iron, thus depriving many bacteria of this essential nutrient for growth. Furthermore, a highly basic sequence at the N-terminus (referred to as lactoferricin) allows lactoferrin to act as a cationic detergent and disrupt the cell membrane of some organisms. Tear lipocalin represents approximately 25% of the reflex tear proteins and was recently shown to be capable of binding siderophores produced by a range of bacteria and fungi. Siderophores are chelating compounds that transport iron into microorganisms. Thus, like lactoferrin, lipocalin exerts a bacteriostatic effect by interfering with the ability of pathogens to take up iron.

The tear film also contains members of the collectin family of C-type lectins, surfactant proteins (SP)-A and -D. Collectins bind to carbohydrates on the surface of various microorganisms and to receptors on phagocytic cells, which in turn promotes their phagocytic activity. SP-A and SP-D are produced by lacrimal gland cells and also corneal and conjunctival epithelial cells. SP-D is known to exert growth inhibitory effects on some Gram-negative bacteria, to promote pathogen phagocytosis by mononuclear cells and through an interaction with lipopolysaccharide (LPS), which is present on the outer membrane of Gram-negative bacteria, can inhibit bacterial adhesion to target cells. SP-D inhibits corneal epithelial cell invasion by *P. aeruginosa* (a Gram-negative pathogen that commonly causes ulcers in contact lens wearers), possibly via an LPS-dependent mechanism.

Secretory IgA (sIgA) is the predominant immunoglobulin in the tear film. This antibody is of great importance as it facilitates removal of pathogens right at the point of entry at the ocular surface. sIgA is not a particularly efficient activator of complement (important for preventing unwanted inflammation) or a good opsonin (although neutrophils do have receptors for sIgA which when engaged could trigger phagocytosis). The major effector mechanism of sIgA is neutralization, which prevents attachment to host cells. sIgA can also bind to lectin-like adhesin molecules on pathogens causing them to aggregate and trapping them within the tear film. sIgA is produced by plasma cells (terminally differentiated B lymphocytes) residing in the lacrimal gland and in specialized areas of the conjunctiva referred to as conjunctival-associated lymphoid tissue. sIgA binds to specific receptors on lacrimal gland acinar cells, conjunctival epithelial cells, and is taken up by endocytosis, and then traverses the cell by transcytosis. This antibody is then released into the tears attached to a protein called secretory component, a fragment of the receptor to which the antibody was bound during its passage through the cells. Secretory component stabilizes the antibody and masks proteolytic sites so conferring resistance to host and pathogen proteases.

Low levels of functionally active complement and complement regulatory proteins have also been detected in tears. An overview of the complement pathway is presented in **Figure 3**. The relative amounts of different components, namely abundant C3 and factor B, but less C1q, suggest that activation via the alternative pathway (i.e., spontaneous hydrolysis of C3) is the predominant mechanism. Possible sources of the various complement components are leakage of plasma through the conjunctival vessels during sleep, infiltrating neutrophils, and local synthesis by corneal and conjunctival epithelial cells. Activation of the complement pathway generates fragments involved in acute inflammatory responses, fragments that act as opsonins which facilitate target recognition by neutrophils and results in the formation of membrane attack complexes that can lyse pathogens

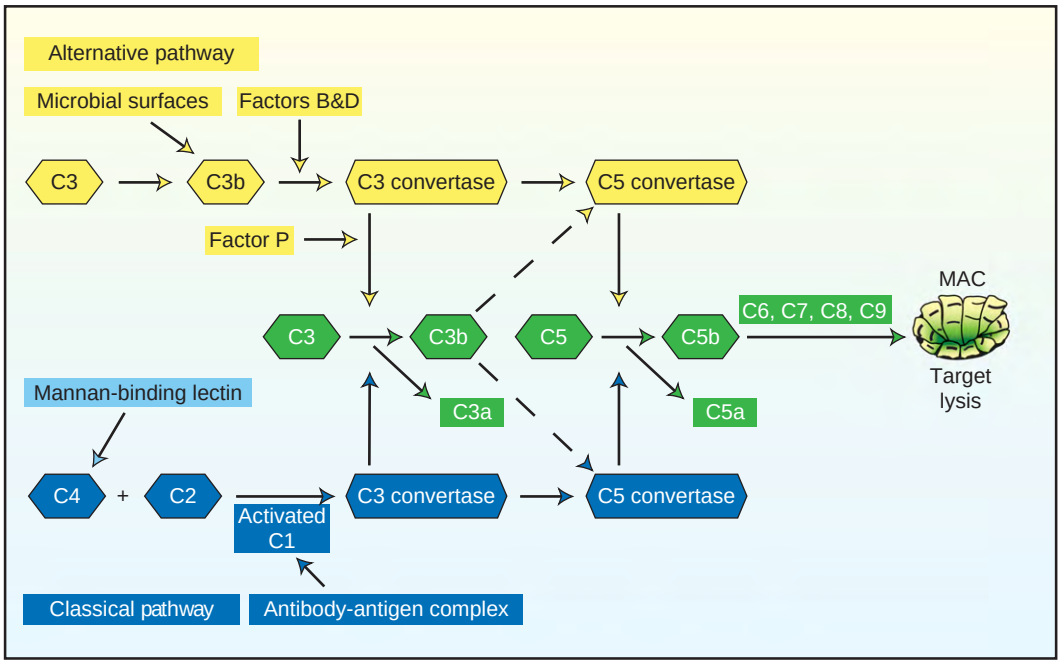

Figure 3 Overview of the complement pathway. The major components of the three known pathways (classical (blue), alternative (yellow) and mannan-binding lectin (light blue)) that lead to activation of complement are shown. In tears the primary pathway is believed to be the alternative pathway but, as can been seen, regardless of the mechanism of activation the outcome is the same (green), i.e., production of intermediaries with enzymatic activity (the convertases), generation of inflammatory mediators such as C3a and C5a and of opsonins such as C5b which bind to pathogen surfaces to facilitate their recognition by phagocytes. The final product of the pathway is the membrane attack complex (MAC) in which several complement components come together to form pores on a pathogen surface leading to lysis and death of the pathogen.

(and host cells). The complement pathway is believed to be most active when the eyes are closed (see comments below on closed-eye tears). To prevent unnecessary activation and hence tissue damage, the complement pathway is regulated by a number of factors. This pathway is inhibited by molecules such as lactoferrin and vitronectin both of which are present in the tears and CD55 (decay accelerating factor) as well as CD59 which are membrane-bound molecules expressed by corneal and conjunctival epithelial cells.

In immediate apposition to the superficial epithelial cells is a blanket of mucus, composed primarily of the gel-forming mucin MUC5AC which is secreted by goblet cells in the conjunctiva in response to parasympathetic stimulation. This blanket interacts with the glycocalyx coating the superficial cells. Membrane spanning mucins MUC 1, 4, and 16 produced by the epithelial cells are important components of the glycocalyx and can be cleaved from the cell surface and released into the tear film. Mucins are known to help prevent bacteria from reaching epithelial surfaces. This function has been attributed to a number of mechanisms, for example, mucin can bind and trap the bacteria, which are then effectively removed from the ocular surface by blinking. It should be noted, however, that the ability to interact with mucins varies widely among different organisms. There is also evidence that sIgA and positively charged proteins such as lysozyme and SLPI accumulate in the mucous blanket, thus providing a reservoir of antimicrobial agents. Therefore, mucins may trap microbes, which are then killed by accumulated antimicrobials or aggregated by sIgA and then cleared by blinking.

Thus, tears are equipped with a plethora of chemical entities capable of neutralizing invading pathogens. While many tear components have independent antimicrobial effects, several are thought to cooperate in a synergistic fashion to yield maximal effect. For example, sequestering of cations by lactoferrin destabilizes the cell wall of Gram-negative bacteria making the peptidoglycan layer more accessible to cleavage by lysozyme. Also, it should be brought to the reader's attention that the composition of the tears changes during sleep. Open-eye and reflex tears have primarily lysozyme, lactoferrin, lipocalin, and sIgA, whereas closed-eye tears have increased amounts of sIgA (up to 80% of total tear protein), complement components, and of serum-derived proteins. There is also a large influx of neutrophils within 2–3 h of eye closure, which provides additional defense factors in the guise of AMPs and reactive oxygen species, for example. Overall, these changes appear to represent a shift to a subclinical state of inflammation, which is believed to be necessary to protect the ocular surface from invasion by entrapped pathogens while the lids are closed. There is also an increase in proteins such as SLPI and elafin, which have potent

antiprotease activity, and vitronectin, which inhibits complement, which serve to protect the ocular surface cells in this proinflammatory environment.

Defense Mechanisms of the Ocular Surface Epithelia

Mechanical/Physical Defenses

The outermost superficial epithelial cells are bound by tight junctions, which effectively seal two cells together forming a barrier against free diffusion of fluids, electrolytes, and macromolecules as well as microorganisms and their secreted products. Tight junctions are also important in establishing and maintaining cell polarity. Polarized cells are characterized by differences in the composition and distribution of proteins and other surface molecules between apical and basolateral surfaces. This arrangement is maintained by the aforementioned tight junctions that segregate the domains and targeted delivery that sends the molecules to their correct location. Disruption of polarity, such as occurs with corneal epithelial cells migrating to recover an injured area, has been shown to increase susceptibility to infection. This may be the result of a number of factors, for example, host cell receptors with which pathogens interact may be more abundant on basolateral surfaces. Also, loss of polarity disrupts the apical mucin-containing glycocalyx, which normally helps restrict bacterial attachment.

Another important feature contributing to defense is the constant turnover of the ocular surface epithelial cells. Both corneal and conjunctival epithelia have a population of strategically located stem cells that provide new cells to replace those being shed into the tear film. In the absence of a penetrating injury, infection begins in the most superficial epithelial layers and so through the constant renewal of cells, outer infected cells may be sloughed off before there is time for the infection to spread to the lower epithelial layers.

Pathogen Recognition

While the tear film acts to prevent pathogens from reaching the ocular surface epithelial cells in the first place, it is very important that the cells have a system to recognize the presence of invading organisms if they do happen to conquer the outer defenses. Host cell proteins that mediate pathogen recognition are often referred to as pathogen recognition receptors (PRRs) and they recognize pathogen-associated molecular patterns present on bacteria, viruses, and fungi. The primary PRRs on epithelial cells are toll-like receptors (TLRs). These are type I transmembrane glycoproteins, which have an extracellular leucine-rich domain and a cytoplasmic domain homologous to the signaling domain of the interleukin (IL)-1 receptor.

Of the 10 functional human TLRs that have been identified all have been reported to be expressed by corneal and conjunctival epithelial cells. **Figure 4** shows a simplified diagram of the distribution of TLRs, their ligands, and signaling pathways. TLR1, 2, 4, 5, 6, and 10 are typically located at the cell surface. TLR2 forms heterodimers with TLR1 and with TLR6 and so can recognize a large variety of microbial products. For example, TLR2/6 heterodimers recognize lipoteichoic acid from Gram-positive bacteria and TLR2/1 heterodimers recognize triacyl lipoprotein/peptides of bacterial cell walls. TLR4 forms a complex with MD2 (also known as lymphocyte antigen 96) and cluster of differentiation 14 (CD14) protein and recognizes LPS from Gram-negative bacteria, while TLR5 recognizes flagellin, a component of bacterial flagella. TLR10, the ligand for which is unknown, is able to dimerize with TLR1 and TLR2. TLR3, 7, 8, and 9 are (typically) all located intracellularly, on endosomal membranes and recognize nucleic acids. TLR3 recognizes double-stranded RNA, a by-product of the replication of some viruses, whereas TLR7 and 8 recognize viral single-stranded RNA. TLR9 responds to unmethylated cytosine–phosphate–guanosine dinucleotide motifs found in both bacterial and viral DNA. Thus, by interacting with specific pathogen-derived molecules TLRs can detect the presence of a wide range of organisms, including those that replicate intracellularly.

The engagement of TLRs with their specific microbial ligand results in activation of intracellular signaling pathways, leading to a variety of functional changes in the ocular surface epithelial cells. The latter include production of inflammatory cytokines such as IL-6 and chemokines such as IL-8 that will attract neutrophils for phagocytosis and AMPs such as human β-defensin-2 that can directly kill invading pathogens (see the section entitled 'Antimicrobial peptides').

It is important that members of the normal ocular flora do not trigger TLR activation and hence cause unwanted inflammatory reactions at the ocular surface. To this end, it has been observed that flagellin from pathogenic, but not from nonpathogenic bacteria, can activate TLR5 in corneal epithelial cells. Expression of TLR5 (and possibly TLR4) appears to be restricted to basal and wing cells suggesting that TLR5 will only be activated when there is a breach in the corneal epithelium. Also, rather than being surface bound, TLR4 may be expressed intracellularly and so would not be available.

Evidence for the expression of another class of PRRs, the cytoplasmic nucleotide-binding and oligomerization domain (NOD) proteins, has yet to be investigated for the human ocular surface. However, mouse anterior eye tissue expressed both NOD1 (which recognizes meso-DAP, a component of peptidoglycan in Gram-negative organisms) and NOD2 (which recognizes muramyl dipeptide found in both Gram-positive and -negative bacteria).

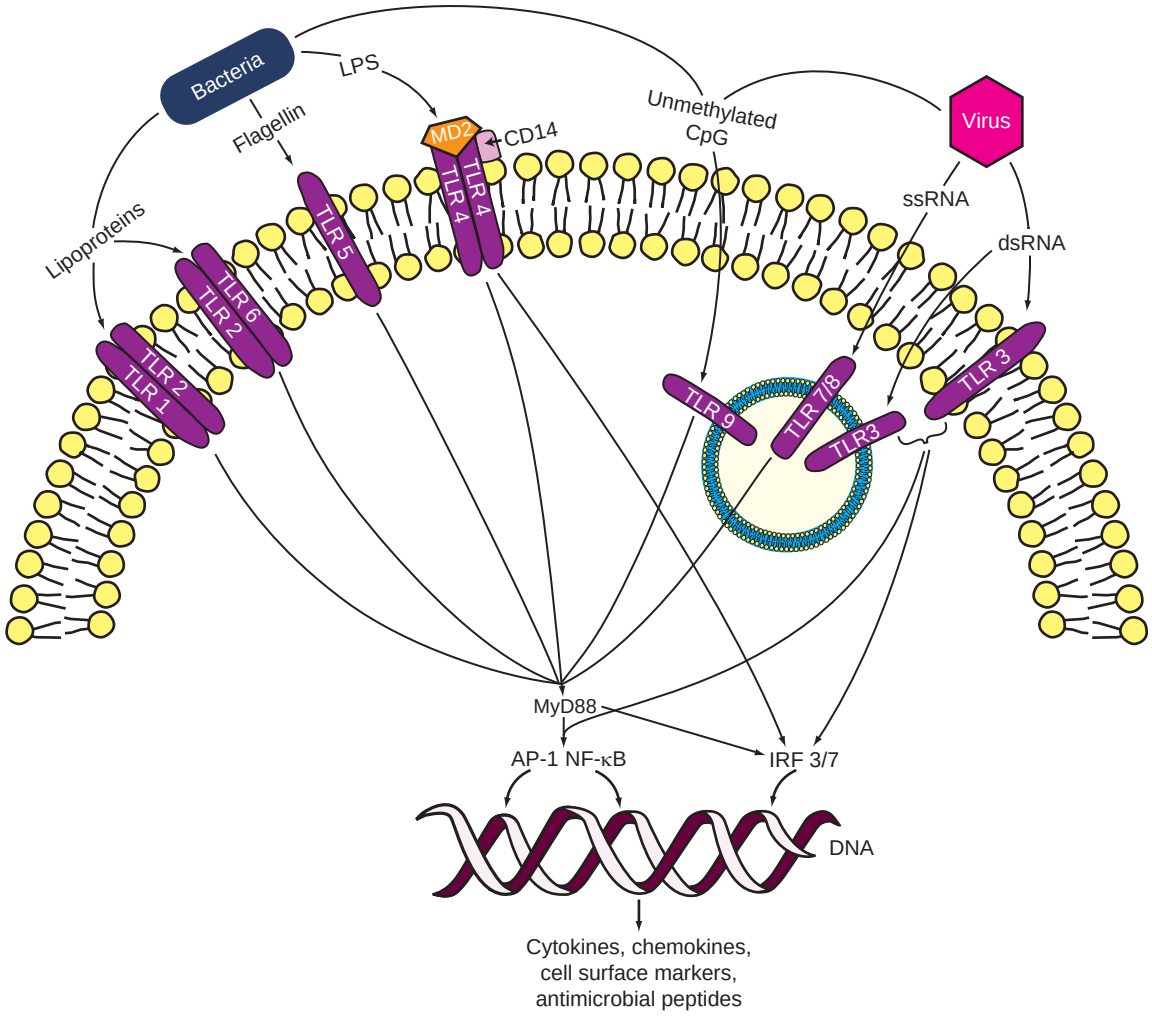

Figure 4 Toll-like receptor activation. The major TLRs expressed by ocular surface epithelial cells and their known bacterial and viral ligands are shown. For clarity the details of the several signaling pathways that lead to transcription factor activation and gene transcription have been omitted. LPS, lipopolysaccharide; CpG, cytosine–phosphate–guanosine dinucleotide; ssRNA, single stranded RNA, dsRNA, double stranded RNA, MyD88, myeloid differentiation protein 88; IRF 3/7, interferon regulatory factor 3/7; AP-1, activating protein-1; NF-κB, nuclear factor κB.

Antimicrobial Peptides

AMPs are small peptides, most less than 50 amino acids, that are amphipathic and typically carry an overall positive charge (+2 or greater) due to a relative excess of amino acids such as arginine and lysine. These peptides show a broad spectrum of antimicrobial activity and many have additional effects on mammalian cell behavior.

The two major categories of mammalian AMPs are the defensins and cathelicidins. Human defensins are characterized by the presence of six cysteine residues that interact to form three disulfide bonds (the specific pattern of connectivity gives rise to two classes referred to as α and β). Both corneal and conjunctival epithelial cells express at least three β-defensins (hBDs). hBD-1 and hBD-3 are constitutively expressed, whereas the expression of hBD-2 is variable, being expressed by normal tissue only occasionally. Ocular surface hBD-2 expression is known to be inducible by exposure to both Gram-negative and -positive bacteria and bacterial products such as LPS, peptidoglycan, and lipoproteins. This upregulation is chiefly mediated via the activation of TLRs such as TLR2. In a recent study, expression of a novel beta defensin gene DEFB 109 was detected in the ocular surface epithelia, and interestingly its expression was decreased in inflammation and infection. As noted earlier, α-defensins HNP-1 through -3 are produced by neutrophils and are present in the normal tear film. They can also be detected in the cornea and conjunctiva when neutrophils infiltrate in response to a specific stimulus.

The cathelicidins have a highly conserved N-terminal cathelin domain and a variable antimicrobial domain. Only one, LL-37, is expressed in humans. LL-37 is expressed by both corneal and conjunctival epithelial cells and its expression is increased in response to corneal epithelial injury

and bacterial challenge with *P. aeruginosa* and *S. aureus*. LL-37 is also a major component of neutrophil granules; thus, its ocular surface levels are expected to rise in situations leading to infiltration of these and other inflammatory cells.

While defensins and LL-37 represent the main AMPs present at the ocular surface, others have been reported including liver expressed AMP-1 and -2, statherin, CCL28 and CXCL-1 (two of many antimicrobial cytokines), MIP3α, and thymosin β-4. However, as most of these molecules have other recognized functions, it is unlikely that antimicrobial effects are the major facet of their action at the ocular surface.

The primary site of AMP action is the microbial cell membrane, electrostatic disruption of which leads to permeabilization, loss of essential intracellular components, and death (see **Figure 2**). However, intracellular targets may also be utilized leading to inhibition of protein, peptidoglycan, and nucleic acid synthesis and interference with the activity of bacterial heat-shock proteins. Epithelial β-defensins and LL-37 are effective against common ocular surface bacterial pathogens *in vitro* with hBD-3 and LL-37 showing the broadest spectrum and most potent activity. Animal studies have revealed that experimental infection with *P. aeruginosa* in genetically modified mice unable to express cathelicidin causes much more severe disease and corneal damage than in normal wild-type mice, thus showing that AMPs are important for ocular surface defense *in vivo*.

In addition to exerting direct antimicrobial effects, AMPs have other properties that help protect against pathogens and their destructive actions. For example, LL-37 is known to bind and neutralize LPS. The latter is a product from Gram-negative bacteria and through activating TLR4 induces an inflammatory response and likely mediates much of the ocular surface damage that results from infections with pathogens such as *P. aeruginosa*. Thus, LL-37 may have a role in dampening LPS-mediated ocular surface inflammation and damage. Also, both defensins and LL-37 have been shown to be chemotactic for a variety of immune and inflammatory cells, including lymphocytes, monocytes, and immature dendritic cells thus may help draw these cells to a site of infection. AMPs also stimulate inflammatory and immune cell cytokine production, which in turn can modulate cellular functions. Additionally, hBD-3 has been shown to activate dendritic cells, raising the possibility that corneal/conjunctival epithelial hBD-3 may be able to activate epithelial Langerhans cells and stromal dendritic cells which in turn may initiate an adaptive immune response.

Other Contributions to Ocular Surface Epithelial Defense

As noted earlier, the outermost superficial cells of both the cornea and conjunctiva are coated in a matrix of carbohydrate referred to as the glycocalyx. By projecting from the epithelial cell surface, membrane spanning mucins MUC 1, 4, and 16 of the glycocalyx physically prevent pathogens from reaching the cell membrane. Also, some organisms are repulsed by negatively charged glycosaminoglycans present on the mucin.

The ocular surface epithelial cells also produce a variety of cytokines and chemokines that are important in protection from microbial invasion. IL-1 is an important cytokine released in response to trauma and injury and among a plethora of activities serves to regulate production of other molecules such as IL-6, growth regulated oncogene (GRO)-α, -β, -γ, TNF-α, and IL-8, which in turn modulate inflammatory and immune cell infiltration and activation.

Dispersed between the epithelial cells of the cornea and conjunctiva are bone-marrow-derived dendritic cells called Langerhans cells. These cells are highly potent antigen-presenting cells which capture antigen and when mature present it to T lymphocytes in nearby secondary lymphoid tissues so activating adaptive immunity. The Langerhans cells are typically found between basal epithelial cells and in the cornea their density is lowest in the central region and gradually increases toward the periphery. Also, most cells in central cornea appear to be small immature cells. In the periphery, larger mature major histocompatibility complex class II (MHC II) expressing cells with prominent dendritic processes are observed. Overall Langerhans cells perform a surveillance function, screening their environment for pathogens that have breached the defenses of the tear film and the epithelial barrier. If successful in their search they then activate adaptive immunity to help eliminate the invader.

Sensory nerves, which are particularly abundant in the cornea, also provide an important contribution to ocular surface defense. When triggered nerves induce the production of reflex tears, which, by virtue of their increased volume, help wash pathogens from the ocular surface and dilute out their toxic products. Release of neuropeptides such as substance P from the nerve termini may also affect epithelial cell cytokine production that, as noted above, may modulate other aspects of host defense.

The presence of a complement of nonpathogenic organisms also assists in preventing infection. Such commensals deplete the tears of nutrients, occupy attachment sites so preventing binding of pathogens, and produce bacteriocins that kill members of nonrelated species.

Concluding Remarks

In summary, the ocular surface and tears possess a wide range of chemicals and physical attributes that help prevent infection. Such redundancy is commonplace in biological systems, but is particularly important at the ocular surface where the inability to control and eliminate

an infection can have dire consequences for visual function. Having multiple protective mechanisms is also necessary as pathogens are very adept at developing strategies to circumvent host defenses. While countering one specific mechanism is relatively easily achieved, developing multiple strategies is rather more challenging.

Development of the Retinal Vasculature

T Chan-Ling, University of Sydney, Sydney, NSW, Australia

Glossary

Angiogenesis – The growth of new blood vessels through the process of budding from existing vessels. Angiogenesis occurs in response to a stimulus such as hypoxia.
Inner plexus – The network of superficial blood vessels that lies on the inner surface of the retina.
Mural cells – Includes pericytes and smooth muscle cells. These cells surround the endothelial cell tubes and contribute to the formation of stable vessels.
Outer plexus – The deeper network of blood vessels that lies at the junction of the inner nuclear layer and the outer plexiform layer of the retina. This layer of vessels forms by budding from the inner plexus, and consists entirely of capillaries.
Pericytes – Mesenchymal cells that are associated with small vessels. These cells are critical for vessel stability and for the formation of the blood–retinal barrier.
Vasculogenesis – The process of vessel formation through the organization of vascular precursor cells into chords and vessels. Vasculogenesis proceeds in the absence of stimuli such as VEGF.

Introduction

The development of the vascular network of the human retina follows a very specific topography and series of events, producing a network of vessels that precisely meets the metabolic demands of the healthy adult retina. Disruption of this process can lead to the under- or overproduction of vessels and/or the formation of vessels with pathological characteristics, including a breakdown of the blood–retina barrier (BRB) and inappropriate pericyte ensheathment leading to vessel instability. In this article, we describe the process through which the vasculature develops, and the intrinsic and extrinsic signals that control its formation.

An Overview of Human Adult Retinal Vasculature

The retina has the highest metabolic demand of any tissue in the body. The conflicting requirements of sufficient blood supply and minimal interference with the light path to the photoreceptors are met by two vascular supplies: inherent intraretinal vessels supply the inner two-thirds of the retina, and the choroidal vasculature supplies the outer third of the retina.

The vasculature of the adult retina enters and exits through the optic disk (**Figure 1(a)**). As shown in the fundus photo (**Figure 1(b)**), four main artery/vein pairs supply the human retina. These vessels are termed the superior nasal, inferior nasal, superior temporal, and inferior temporal branches of the central retinal artery and vein. Smaller arterioles branch off these four main arteries, whereas terminal branches bifurcate toward the peripheral retina. The fovea, a region of the retina that contains the highest density of photoreceptors, remains avascular throughout development and in the adult retina. The inner plexus ramifies in the ganglion cell and nerve fiber layers. Some of these vessels dive down through the inner plexiform and inner nuclear layers to form the outer, or deep, plexus at the junction of the inner nuclear and outer plexiform layers of the retina (**Figure 1(c)**). Vessels in the inner plexus cover the spectrum from arterioles and venules to capillaries and postcapillary venules, whereas vessels in the outer plexus are mainly capillary in size. Both vascular layers reach almost to the edge of the adult retina, leaving an avascular rim that is thin enough to be adequately oxygenated through diffusion from the choroid. A third intraretinal vascular network, the radial peri-papillary capillaries (RPCs), forms a limited plexus in the nerve fiber layer around the optic disk. The RPCs radiate out from the optic nerve head (ONH) and supply the thick nerve fiber bundles where they exit the retina.

Figure 1(d) is a schematic representation of central nervous system (CNS)/microvascular interface, as would be found typically in the human retina. CNS vessels are characterized by tight junctions between adjacent vascular endothelial cells; the tight junctions are responsible for creating the BRB. Outside the endothelial cell layer lays the basal lamina, which is laid down by endothelial cells and pericytes. This layer is composed predominantly of collagen IV, fibronectin, and laminin. Pericytes are located within the basal lamina, between the vascular endothelial cells and the astrocytic endfeet that form the glia limitans, or glial limiting membrane. In addition to astrocytes, ultrastructural evidence suggests that the glia limitans also includes perivascular cells and microglia.

Vasculature of the Primordial Retina

During embryonic development, the retina forms as an extension of the diencephalon. The rudimentary structures

of the eye are distinguishable by 4–5 weeks gestation (WG). At the earliest stages in development, the primordial lens and retinal tissues are oxygenated through the hyaloid vasculature, a vascular network that begins as an artery entering the eye through the optic nerve (the central hyaloid artery), splits into hyaloid vessels as it continues forward through the vitreous and around the developing lens, and exits at the front of the eye. This vascular network is present early in human embryonic development and regresses as the retinal vasculature forms and is able to meet the increasing metabolic demands of the eye. Typically, the hyaloid vasculature has totally regressed by the ninth month of gestation.

Formation of the Human Retinal Vasculature Takes Place Through Vasculogenesis and Angiogenesis

Blood vessels can be formed by one of two distinct mechanisms. Vasculogenesis is the *de novo* formation of vessels by the aggregation of endothelial precursor cells. Vessels develop from vascular precursor cells (VPCs) that aggregate into solid vascular cords, which then become patent and differentiate to form primitive endothelial tubes. Formation of vessels by angiogenesis occurs through budding from existing vessels; this process takes place through proliferation of vascular endothelial cells and serves to vascularize neighboring tissues. The process of angiogenesis is driven by signals that are produced in response to hypoxia, including vascular endothelial growth factor$_{165}$ (VEGF$_{165}$), whereas the process of vasculogenesis is independent of hypoxia.

Vasculogenesis: Vascular formation through transformation from VPCs

The first event in the development of the retinal vasculature is the *de novo* formation of vessels by vasculogenesis. This stage, detectable in the human retina before 12 WG, initiates with the migration of spindle-shaped cells of mesenchymal origin from the ONH. The individual cells can be Nissl stained and express CD39, vascular endothelial growth factor receptor 2 (VEGFR2), and ADPase, an ecto-enzyme found on the luminal surface of endothelial cells in the adult retinal vasculature. The VPCs migrate outward from the optic disk, as shown in **Figure 2(a)**.

Patent vessels form through the transformation of solid vascular chords. The VPCs localize to the inner surface of the retina, between nerve fiber bundles, and orient their longitudinal axes along the direction of migration. The population of VPCs proliferates and differentiates to form a primordial vascular bed centered on the optic disk (**Figure 2(b)**). As early as 14–15 WG, vascular chords begin to coalesce on the surface of the retina behind the wave of spindle cells, beginning in the region proximal to the ONH and progressing outward (**Figure 2(c)** and **2(e)**). **Figure 2(d)** shows the transition from vascular chords and the discrete spindle cells located more peripherally.

Vascular chords begin to establish themselves as vessels that express CD34 and support blood flow as early as 18 WG (**Figure 2(f)**). These first primordial vessels formed through vasculogenesis are typically radial, have uniform diameter and have low capillary density (**Figure 3(a)**). The formation of primitive vessels lags behind the leading edge of VPCs by a distance of at least 1 mm. Vasculogenesis and the formation of the primordial vessel architecture is complete by 21 WG, at which point spindle cells are no longer detectable in the retina (**Figure 3(b)**).

Spindle cells (and the formation of cords and vessels behind the leading edge of spindle cells) migrate outward from the optic disk in a four-lobed pattern, as seen in **Figure 3(b)**. The lobes extend the farthest in the temporal and superior directions, and they correspond to the future location of the four major artery–vein pairs in the adult retina (**Figure 1(b)**). The lobes curve around the region of the incipient fovea, leaving this area free of spindle cells and vascular cords. The fovea and perifoveal region remains avascular through 25 WG.

Although vasculogenesis is responsible for the primordial vessels that form in the inner two-thirds of the developing retina, this primitive network with its low capillary density is very inefficient in meeting the metabolic demands of the underlying retinal tissue. As a result, the remaining vessels in the retina form through the process of angiogenesis, which is driven by physiological levels of hypoxia. Angiogenesis is responsible for the increasing vascular density in the central retina (**Figure 3(c)**), vessel formation on the inner surface (the inner plexus) of the peripheral retina, and the formation of the outer, deep plexus and the radial RPCs near the ONH.

Angiogenesis. Angiogenesis in the retina is driven by physiological hypoxia, which occurs as a result of the increasing synaptic activity in the retinal tissues. As the retina thickens and the cell layers start to differentiate and become active, the tissue becomes hypoxic. In response to hypoxia, the astrocytes in the nerve fiber and ganglion cell layers (GCLs) express VEGF$_{165}$, which in turn stimulates endothelial cell growth. Once these vessels become patent and can direct blood flow, the demand for oxygen is met and local VEGF expression decreases. It is important to note that the physiologic levels of hypoxia are too low to damage the surrounding tissue, but are sufficient to signal the need for increased oxygen supply to the tissue.

Inner plexus: Angiogenic filopodial extension is mediated by an astrocytic template and basal lamina components. As with vasculogenesis of the retina, formation of the superficial vascular plexus through angiogenesis begins in the region around the optic disk and spreads outward toward the periphery. As early as 17–18 WG, an exuberant network of broad capillaries starts to grow out from the primary

vasculature, filling the area that lies between the primordial vessels (**Figure 3(d)**). Between 18 and 30 WG, the sprouting of new vessels is led by the filopodia of endothelial tip cells (**Figures 3(e)** and **4(b)**). These filopodia orient along the net-like framework that has been set up by astrocytes in the wake of the leading edge of APCs, initially producing a capillary bed that closely follows the structure and organization of the astrocyte scaffold (**Figure 4(a)** and **4(c)**). Although endothelial tip cells serve to orient the growth of the capillary network, the tip cells themselves do not divide. Instead, rapid cell growth occurs at the level of the trailing stalk cell (**Figure 4(b)**).

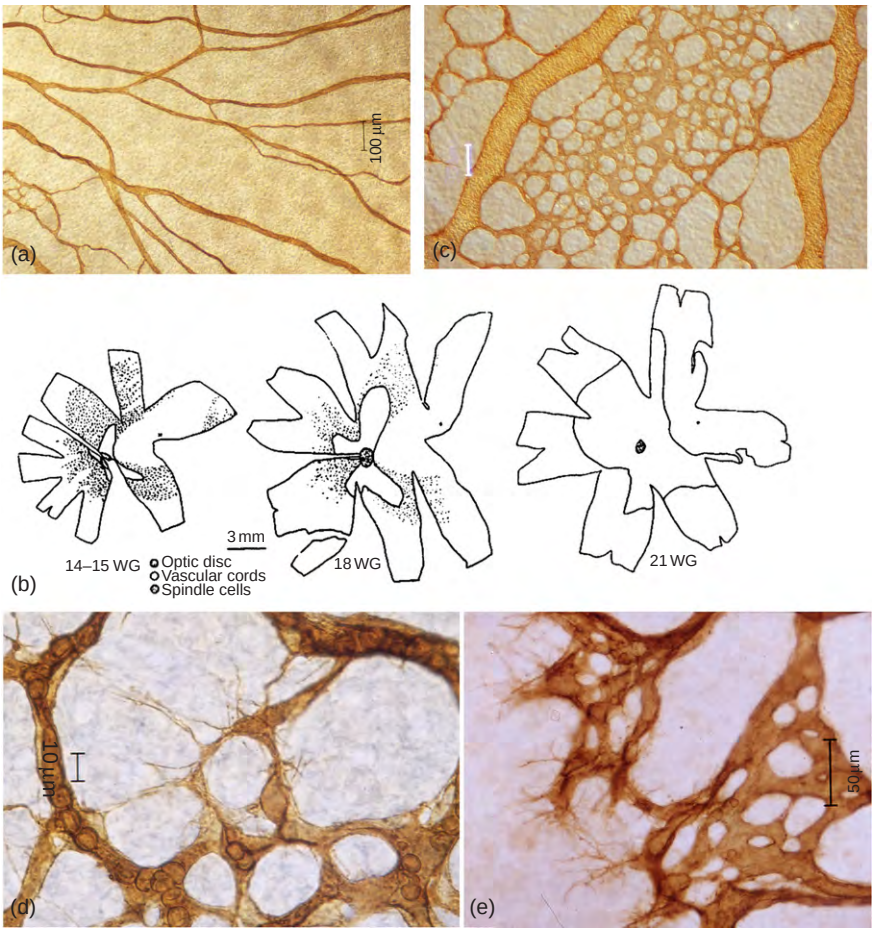

Figure 3 Vascularization of the human fetal retina. (a) Immunohistochemical analysis of $CD34^+$ vessels in the central retina at 18 WG. These near-radial vessels all extend predominantly radially from the optic disk. (b) Topographical maps of the outer limits of spindle cells and vascular chords in the human fetal retina at 14–15, 18, and 21 WG. (c) $CD34^+$ vessels in a human fetal retina at 21 WG. Note the extensive capillary network that has formed in the space between the major vessels. (d) $CD34^+$ vasculature in a human fetal retina at 26 WG. Vessel development follows the extension of numerous filopodia. Capillary sprouting (angiogenesis) is responsible for increasing capillary density in central retina. (e) $CD34^+$ vasculature in a region of filopodial extension at the leading edge of patent vessel formation in a human fetal retina at 25 WG. Red blood cells evident in the vessel lumen in the vessels just central to the region of filopodial extension demonstrate that these vessels are patent. From Hughes, S., Yang, H., and Chan-Ling, T. (2000). Vascularization of the human fetal retina: Roles of vasculogenesis and angiogenesis. *Investigative Ophthalmology and Visual Science* 41: 1217–1228. Copyright Association for Research in Vision and Ophthalmology.

In the human fetal retina, Pax-2 expression is limited to cells of the astrocyte lineage. Glial fibrillary acidic protein (GFAP) is expressed in mature astrocytes. $Pax\text{-}2^+/GFAP^-$ astrocyte precursor cells (APCs) can be detected at the ONH around 12 WG. This population of cells appears at a slightly later time than the VPCs, and can readily be distinguished from VPCs by their rounded shape and by the expression of Pax-2. Like the VPCs, the APCs migrate outward from the optic disk. The leading edge of APCs is immediately peripheral to the leading edge of vessel formation, preceding the region of vessel formation by no more than 120 µm (**Figure 4(c)**). Beginning at 18 WG, astrocytes loosely ensheath the newly formed vessels, where they play a role in the induction of the BRB. APCs migrate outward from the optic disk behind the spindle cells. Similar to the spindle cells, they also remain excluded from the incipient fovea as they migrate outward. VPCs (and the primordial vasculature formed from these cells) are limited to the inner two-thirds of the retina (**Figures 2(b)** and **3(b)**) but APCs continue to migrate toward the peripheral retina. As they mature, APCs begin to express GFAP. The $Pax\text{-}2^+/GFAP^+$ astrocyte cells reach the edge of the retina around 26 WG.

In addition to driving the formation of capillaries in the space between the primitive vascular network, angiogenesis also controls the peripheral spread of vessels beyond the inner two-thirds of the retina. The growth of vessels in this region closely follows the central-to-peripheral migration of astrocytes. **Figure 4(c)** and **4(d)** show the relationship between patent vessel formation, APCs, and differentiated astrocytes. Again, the increasing metabolic demands of the maturing tissues lead to hypoxia and the

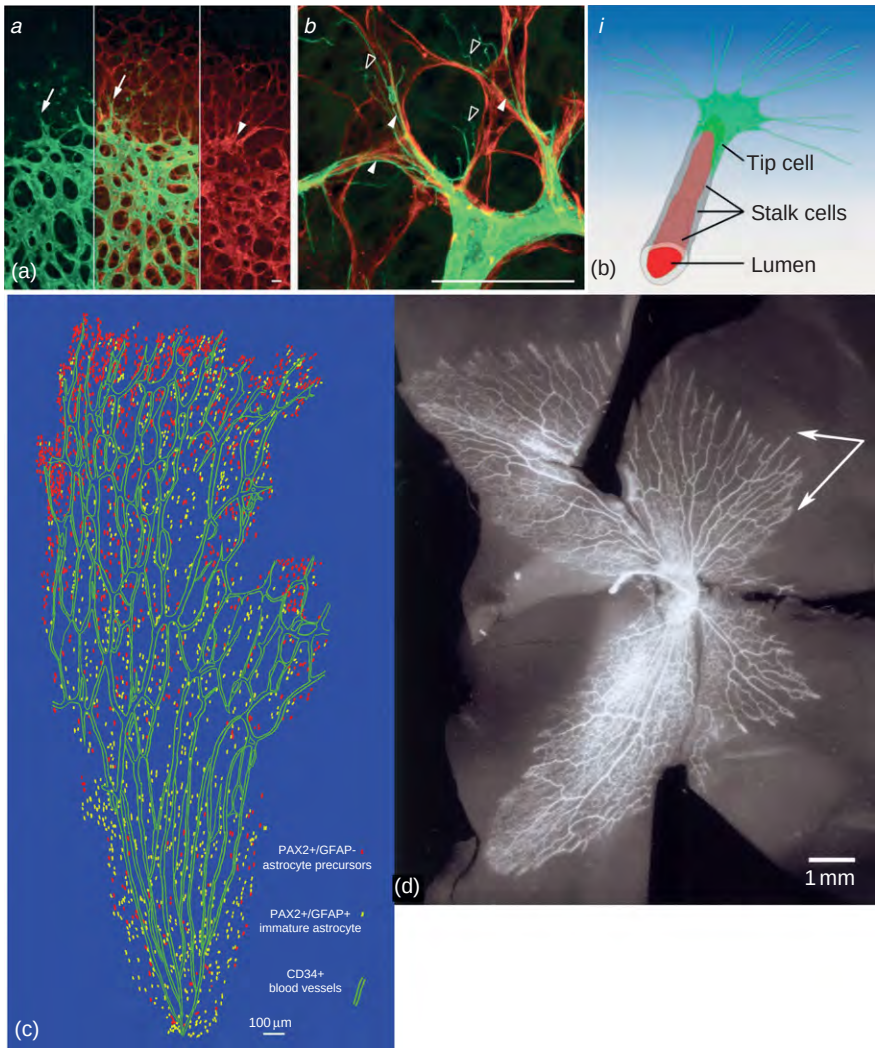

Figure 4 Angiogenesis and association of the developing vasculature with an astrocytic scaffold. production of VEGF by the network of astrocytes that has formed on the surface of the retina; the dense capillary mesh forms along the astrocyte scaffold. Conversely, the endothelium may also influence astrocytic differentiation, as vascular endothelial cells have been shown to induce the expression of GFAP in APCs.

Outer plexus: Angiogenic growth is driven by neuronal maturation. The outer or deep layer of vessels also forms by the process of angiogenesis. Beginning around 25–26 WG, the superficial vessels start to bud and grow radially down from the inner plexus of the retina (**Figure 5**). At the junction of the inner nuclear layer and the outer plexiform layer, the vessels start to ramify among the two layers. This stage in fetal development coincides with the peak period of eye opening, when the visually evoked potential, indicative of a functional visual pathway and photoreceptor activity, is first detectable in the human infant. The radial growth of these descenders is not preceded by either VPCs or APCs. VEGF expression in this region correlates with the soma of Müller cells, suggesting

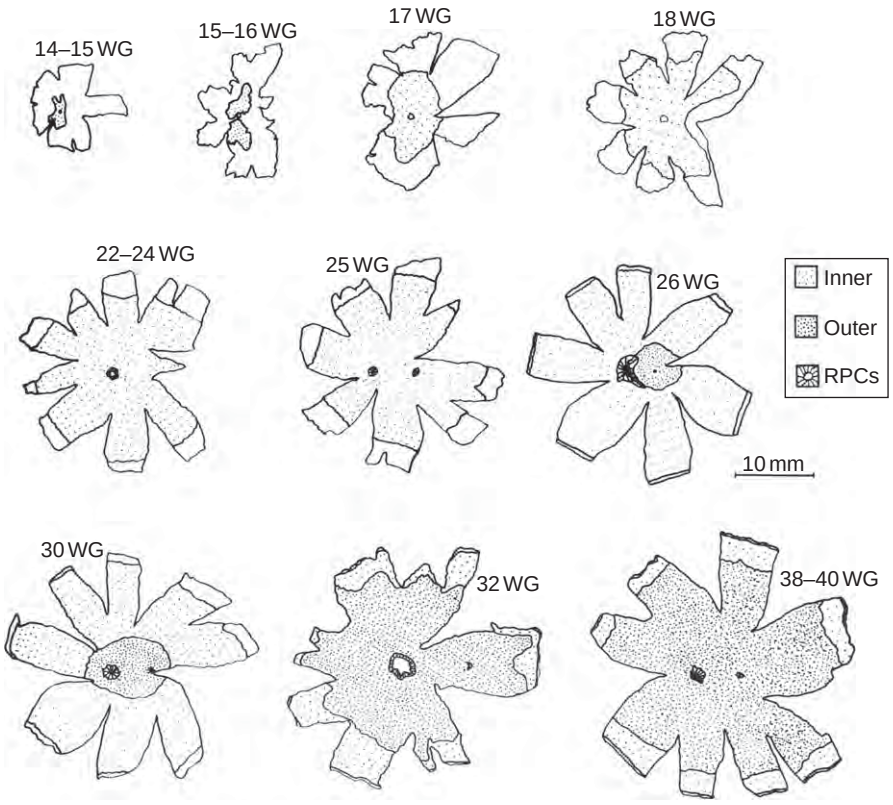

Figure 5 Outer limits of the inner and outer plexuses and the RPCs during development of the human fetal retina. Shown are representative maps of human vascular development from 14–40 weeks gestation. From Hughes, S., Yang, H., and Chan-Ling, T. (2000). that these cells produce the VEGF that stimulates and guides endothelial cell growth in the outer vascular plexus.

Unlike the inner plexus, the formation of the outer plexus is centered around the fovea. Formation of the outer plexus exactly matches the pattern of maturation of the neuronal retina, suggesting that increased metabolic demands from active neurons produce local, physiological hypoxia and drive the growth of vessels to these tissues (**Figure 5**). In this region, the vasculature is limited to capillary-sized vessels; larger vessels are not found in the outer plexus.

Foveal and perifoveal region. The vasculature of the inner plexus surrounds, but does not enter, the fovea; the fovea is supported by the outer plexus alone. The area of greatest cone density in the retina lies in the center of the avascular area, in a region called the fovea centralis (**Figure 6(a)–6(c)**). The absence of surface vessels in this region allows for maximal light penetration with minimal shadowing of the densely packed cones. The fovea itself, an oval of 500 – 600 μm in diameter, remains completely avascular through 25 WG (**Figure 6(d)**). The developmental cues that direct this aspect of retinal vascularization are not well understood, but recent evidence suggests that the developing fovea expresses antiangiogenic factors including pigment epithelium derived factor (PEDF), natriuretic peptide precursor B, and collagen type IVα2.

More recently, it has been shown that expression of Eph-A6 directs vascularization in the fovea and perifoveal region. Immunohistochemistry from fetal primate retinas suggests that a gradient of Eph-A6 is centered at the fovea. This gradient, which is highest at the inner GCL and lowest near the inner plexiform layer, serves to repel astrocytes and angiogenesis from the inner layer of the retina toward the inner plexiform layer, where the vessels are found in the primate fovea. Because the incipient fovea lacks an astrocytic scaffold to set up the framework for vascularization, the pattern of formation of vessels in the outer plexus of the fovea and perifoveal region is different from that of the capillary networks in the inner plexus. As shown in **Figure 6(e)**, from the time they are formed, the vessels are much more regular in their size and spacing than are newly formed capillary networks elsewhere in the retina (**Figure 6(f)**).

Radial peri-papillary capillaries. The third vascular plexus of the retina, the RPCs, begins to form around 21 WG (**Figure 5**). These capillary-sized vessels typically extend radially from the ONH (**Figures 5** and **7(a)**) and cover a small rim surrounding the optic papilla (ONH); for this

Copyright Association for Research in Vision and Ophthalmology.

reason, they have been given the name RPCs. These vessels extend from the inner vasculature to supply the nerve fiber layer near the ONH (**Figures 5** and **7(b)**). The RPCs form a very limited plexus, extending no further than 1 mm from the ONH throughout human fetal development (**Figure 5**). As with other retinal vessels that are formed through angiogenesis, the timing and extent of RPC formation suggests that it is driven by hypoxia-mediated VEGF resulting from increased metabolic demands of the underlying tissues. Their superficial location and lack of mural cell ensheathment, leading to a thin vascular wall, makes RPCs particularly prone to hypoxia resulting from raised intraocular pressure in glaucoma (the ischemic model of glaucoma susceptibility).

Lack of Involvement of VEGF in Early Stages of Vascularization

Although retinal angiogenesis is driven by hypoxia-induced VEGF expression, vasculogenesis in the human retina is independent of metabolic demand and hypoxia-induced VEGF expression. Most of the vessels formed by vascularization develop prior to the expression of VEGF. By 18 WG, the inner plexus covers more than half of the

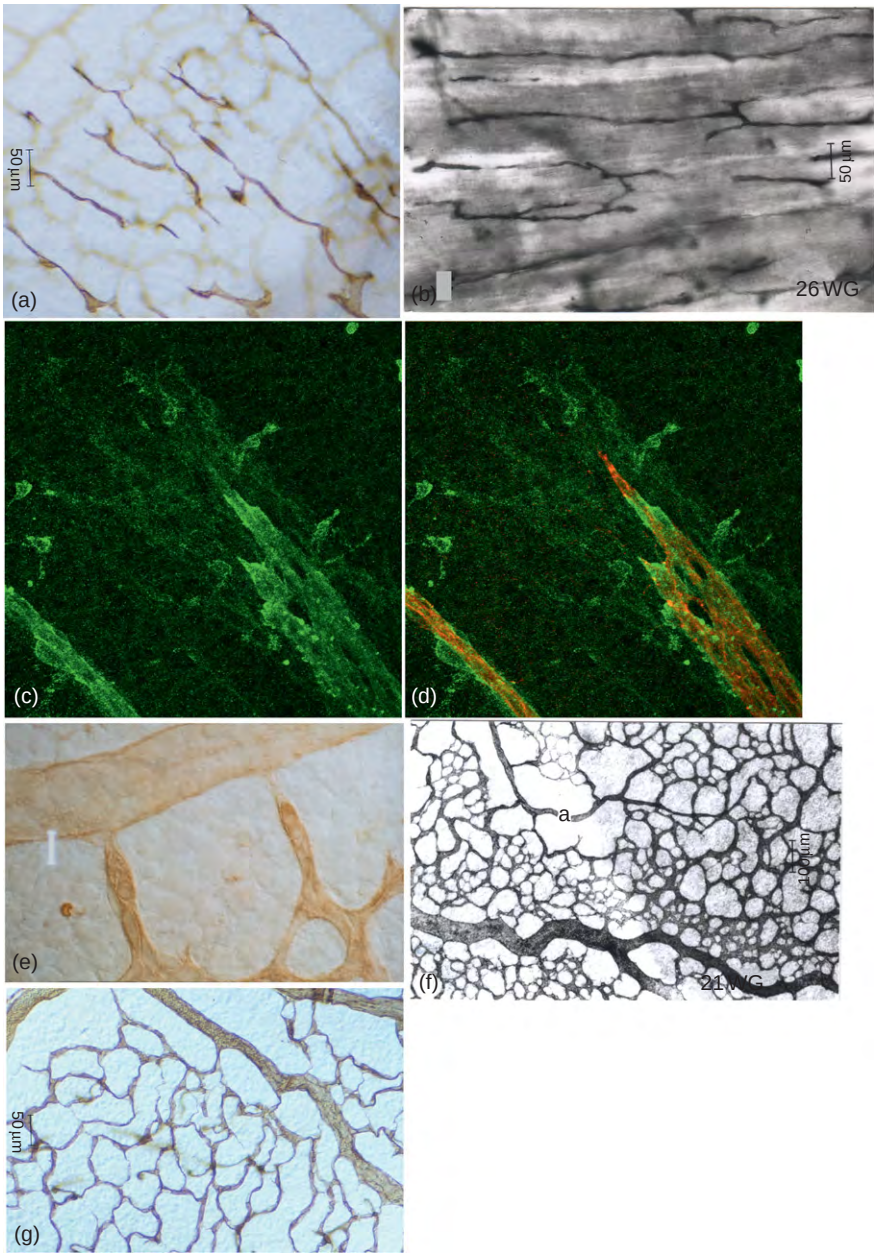

Figure 7 Later stages in the development of human retinal vasculature. (a) and (b) Radial peri-papillary capillaries in the region of the optic nerve head at 25 (a) and 26 (b) WG. retinal area. However, VEGF mRNA is not detectable in the human retina until 20 WG. Formation of the inner plexus is well underway by 14–15 WG, prior to the differentiation of most retinal neurons. Finally, the development of the inner plexus is centered at the optic disk, whereas neuronal maturation is centered at the fovea. In contrast, development of the outer plexus by angiogenesis is centered on the fovea.

Angiogenic and anti-angiogenic factors

Retinal angiogenesis is controlled by a balance of pro-angiogenic and antiangiogenic factors. VEGF is a pro-angiogenic factor that has several forms: VEGFA (there are four isoforms, including $VEGFA_{165}$), VEGFB, VEGFC, and VEGFD. There are at least three VEGF receptors: VEGFR1, 2, and 3. VEGFA is not only a pro-angiogenic factor, but it also has protective functions. Further, it prevents vessel regression and appears to stabilize the mature vasculature, rendering mature vessels resistant to fluctuations in tissue oxygen levels. VEGFA also has a protective effect in the maintenance and function of the neuronal and Muller cells of the retina. VEGFR3 is required for normal retinal vascular development and is upregulated during VEGFA-induced angiogenesis. Its ligand, VEGFC, can cause blood vessel enlargement and tortuosity, and *in vitro* has a synergistic effect on angiogenesis with VEGFA.

Anti-angiogenic factors in the retina include PEDF and vascular endothelial growth inhibitor (VEGI). PEDF is synthesized by cells of the retinal pigment epithelium (RPE), and is present in the developing embryonic and adult human RPE, choroid, and retina. In the human, it is unclear as to how the expression of PEDF relates to the developing vasculature. VEGF stimulates PEDF expression by RPE cells but suppresses PEDF expression by Müller cells. VEGI inhibits endothelial cell proliferation and causes the apoptosis of proliferating endothelial cells. It is expressed by endothelial cells and is thought to play a role in the maintenance of a quiescent adult vasculature. Little is known about VEGI expression in ocular tissues. $VEGI_{192}$ may not be expressed during retinal and choroidal vessel formation but instead may be expressed by the endothelial cells of the quiescent adult vasculature, and may be associated with mural cell maturation. The relative expression of pro- and antiangiogenic growth factors ultimately determines whether neovascularization takes place once a stable quiescent vascular plexus is reached in young adulthood.

Cell–Cell Interactions in the Formation of the Human Retinal Vasculature

Müller cell–endothelial cell interactions

Along with astrocytes, Müller cells are found surrounding the vessels of the inner plexus of the retina, and are thought to be involved in the establishment of the BRB. However, astrocytes are not found in the deeper plexus of the retina; these vessels are ensheathed solely by Müller cells. The existence of an intact BRB and the presence of tight junction proteins in the deep plexus suggest that in this layer of vasculature, Müller cells are capable of inducing the formation and maintenance of barrier properties.

Pericyte–endothelial cell interactions: Vessel stability

Pericytes are another integral component of the mature retinal vasculature. These cells are found within the basal lamina that ensheaths capillary-sized vessels, and play a role in vessel stabilization, control of blood flow, and possibly in modulating vascular permeability and maintenance of the BRB. Pericyte density in the retina is the highest of any tissue, and these cells are also the first to be lost in diabetic retinopathy. Although immature pericytes associate with newly formed retinal vessels (**Figure 7(c)** and **7(d)**), the presence of these immature mural cells does not prevent vessel regression. However, mature vessels that are ensheathed by mature pericytes are quite stable and resistant to $VEGF_{165}$ withdrawal, suggesting that pericytes must be mature and fully differentiated to contribute to vessel stability. A reciprocal relationship exists between endothelial cells and pericytes; whereas pericytes express $VEGF_{165}$ and contribute to vessel stability, retinal endothelial cells express PDGFB, which induces recruitment and proliferation of pericytes.

Pericytes and smooth muscle cells constitute the mural cells, an important component in the maturation and stabilization of vessels. Mural cells are recruited to ensheath immature endothelial tubes by the localized expression of platelet-derived growth factor (PDGF). The inappropriate expression of PDGF interferes with the recruitment of mural cells and leads to abnormal retinal vascular remodeling. More specifically, the endothelial tube must be ensheathed by three components for a new vessel to become patent and stable: mural cells, a basal lamina, and astrocytes. Without any one of these components, vessels are leaky and unstable. Although the presence of immature pericytes along vessels does not protect these vessels from hyperoxia-induced regression, a mature vasculature with mature mural cells, astrocytes, and basal lamina is stable and resistant to the effects of hyperoxia. It appears that the extent of desmin expression by pericytes ensheathing immature vessels imparts upon its associated vascular segment vascular stability.

Vascular Remodeling

With the formation of an exuberant capillary plexus (**Figure 3(c)**) coupled with decreased metabolic demand as endothelial cell growth slows, the newly vascularized region becomes hyperoxic. Hyperoxia in turn leads to vascular remodeling, a paring back of the new vascular network to more precisely meet the metabolic needs of the underlying retina. Remodeling of the vascular network of the retina includes two processes: coalescence of smaller vessels into larger vessels and the retraction of endothelial cells from vessels that are pruned back (**Figure 7(e)**), followed by redeployment of most of these cells to areas where the vascular network is actively

forming. Most noticeably, capillaries retract near the arteries, forming a capillary-free space in this region (**Figures 6(d)** and **7(f)**). Although some apoptosis is evident in the retracting vessels, cell death is not the main mechanism for vessel retraction. As the vascular network is remodeled and the metabolic demands of the tissue stabilize, the capillary network becomes very well organized and regular in appearance (**Figure 7(g)**). The process of vascular remodeling occurs over an extended period of time during human embryonic development.

Vascularization and the Health of the Eye

Interruptions to the normal cellular and molecular mechanisms of retinal vascular formation/function can lead to blindness. In infants, retinopathy of prematurity (ROP) develops when premature delivery and supplemental oxygen exposes an infant's developing retina to elevated oxygen levels. This hyperoxygenation of the retina leads to a loss of the normal molecular cues that drives vessel formation such that when the infant is returned to room air, the rate of retinal vascularization is significantly delayed relative to neuronal maturation. A subsequent return to normoxic conditions generates retinal hypoxia that exceeds the normal physiologic levels, triggering the formation of leaky, tortuous vessels. This abnormal vasculature can lead to intraretinal hemorrhage and partial or complete retinal detachment.

In adults, the effects of tissue hypoxia and hyperglycemia can be seen in diabetic retinopathy. In this disease, the physiologic processes of diabetes prevent the retinal vasculature from meeting the metabolic demands of the active retina and generate locally high levels of hypoxia, in addition to the damaging effects of prolonged hyperglycemia. This retinal hypoxia stimulates angiogenesis in the context of a mature, fully developed retinal vasculature. Subsequent retinal neovascularization produces tortuous, fragile vessels over the surface of the retina. These vessels often leak fluid into the vitreous and can cause macular edema. In addition, the development of fibrous tissue in association with these vessels can lead to traction retinal detachments or vitreous hemorrhages.

Conclusions

The human retina is vascularized by a combination of two mechanisms: vasculogenesis and angiogenesis. Vasculogenesis is responsible for the formation of the earliest vessels of the inner plexus, starting at the ONH and reaching the inner two-thirds of the retina. Between that boundary and the inner periphery of the retina, in the space between these early vessels, reaching down to the outer plexus, under the fovea and over the nerve bundles at the optic nerve, the process of angiogenesis drives the formation of the remaining vasculature. The formation of these vessels is controlled by physiological hypoxia – a level of hypoxia that is well tolerated by the tissue but is insufficient to cause tissue damage. Physiological hypoxia is sufficient to stimulate VEGF production (mediated by hypoxia inducible factor-1α (HIF-1α)) by astrocytes and Müller cells and to direct endothelial growth where it is needed. Once this proliferation of new vessels becomes patent and directs blood flow to the developing retinal tissues, a modest level of hyperoxia then orchestrates vascular remodeling and retraction, a process that is still ongoing in a full-term neonate. The balance between physiological hypoxia and hyperoxia, vessel growth and vessel retraction, leads to the formation of a vasculature that precisely meets the metabolic demands of the human retina.

Developmental Anatomy of the Retinal and Choroidal Vasculature

B Anand-Apte and J G Hollyfield, Cleveland Clinic, Cleveland, OH, USA

Glossary

Angiogenesis – The formation of new blood vessels from preexisting ones, generally by sprouting.
Central retinal artery – A branch of the ophthalmic artery that enters the eye via the optic nerve.
Choriocapillaris – An exceptionally dense capillary bed that nourishes the posterior choroid up to the level of the equator of the eye.
Circle of Zinn – An annular artery surrounding the optic nerve. Its branches contribute to the pial circulation, the optic nerve at the level of the lamina cribrosa and to the nerve fiber layer of the optic disk.
Fenestrae – The circular openings in the choriocapillaris facing Bruch's membrane that measure approximately 800 Å. The fenestrae of the choriocapillaries have a diaphragm covering.
Posterior ciliary arteries – The branches of the ophthalmic artery that form the blood supply to the choroid.
Vasculogenesis – The formation of new blood vessels through *de novo* formation of new endothelial cells.
Vortex veins – The venous collecting vessels draining the choroid, ciliary body, and iris.

Choroidal Vascular Network

Embryology

At the fourth week of gestation in humans (5-mm stage), the undifferentiated mesoderm surrounding the optic cup begins to differentiate and form endothelial cells adjacent to the retinal pigment epithelium (RPE). These early vessels are the precursors of the choriocapillaris, which ultimately envelop the exterior surface of the optic cup. Concurrently, the hyaloid artery branches from the primitive dorsal ophthalmic artery and passes along the embryonic (choroidal) fissure to enter the optic cup. Shortly thereafter, the condensation of the mesoderm occurs at the site of future choroidal and scleral stroma with the gradual onset of pigmentation in the outer neuroepeithelial layer of the optic cup, the RPE. By the fifth week of development (8–10-mm stage), the RPE becomes more melanized and the vascular plexus extends along the entire exterior surface of the cup from the posterior pole to the optic cup rim. By the sixth week (12–17-mm stage), the choriocapillary network begins to develop a basal lamina. This, together with the basement membrane of the RPE, forms the initial boundaries of Bruch's membrane separating the neural retina from the choroid. Concomitantly, rudimentary vortex veins develop in all four quadrants of the eye. Except for the two basal lamina (of the RPE and choriocapillaris), the only other component of Bruch's membrane at this stage is a collagenous central core. The choroidal capillary network becomes almost completely organized by the eighth week (25–30-mm stage) with connections to the short posterior ciliary arteries. By the eleventh week (50–60-mm stage), the posterior ciliary arteries show extensive branching throughout the choroid. It is only following the third and fourth months of gestation that most of the choroidal vasculature matures.

While the molecular mechanisms regulating choroidal development have not been fully defined, it is largely accepted that the presence of differentiated RPE and its secretion of growth factors, such as vascular endothelial growth factor (VEGF) and fibroblast growth factor 9 (FGF-9), are critical for the physiological development and differentiation of the choroidal vascular network.

Gross Anatomy

Almost the entire blood supply of the eye comes from the choroidal vessels, which originate from the ophthalmic arteries. The left and right ophthalmic arteries arise as the first major branch of the internal carotid, usually where the latter break through the dura to exit the cavernous sinus. In some individuals (around 10%), the ophthalmic artery arises within the cavernous sinus, while in others (around 4%), it arises from the middle meningeal artery, a branch of the external carotid.

The ophthalmic artery shows a wide variation in the branching pattern as it approaches the eye. The posterior ciliary arteries, which form the blood supply to the choroid, and the central retinal artery, which enters the eye via the optic nerve, are branches of the ophthalmic artery (**Figure 1**). Other branches of the ophthalmic artery supply the lacrimal gland, extraocular muscles, and lids.

The choroid (also referred to as the posterior uveal tract) is vascularized by two separate arterial systems: (1) the short posterior ciliary arteries, which supply the posterior choroid and (2) the long posterior ciliary arteries, which supply the anterior portion of the choroid (as well as the iris and ciliary body).

Approximately 16–20 short posterior ciliary arteries penetrate the sclera in a circular pattern surrounding the optic nerve, with the distance between these vessels and the nasal side of the nerve being closer than that on the temporal side. These arteries anastomose within the sclera to form the circle of Zinn, an annular artery surrounding the optic nerve (**Figures 1** and **2**). The branches from the circle of Zinn contribute to the pial circulation, the optic nerve at the level of the lamina cribrosa, and the nerve fiber layer of the optic disk. Other branches from the circle of Zinn along with direct branches from the short posterior ciliary arteries enter the choroid to provide the arterial blood supply to the posterior uveal track. These arteries divide rapidly to terminate in the choriocapillaris, an exceptionally dense capillary bed that nourishes the posterior choroid up to the level of the equator of the eye.

The two long posterior ciliary arteries penetrate the sclera on either side of the optic nerve near the level of the horizontal meridian of the eye. The temporal long posterior ciliary artery enters the sclera approximately 3.9 mm from the temporal border of the optic nerve while the nasal long posterior ciliary artery enters approximately 3.4 mm from the nasal border of the optic nerve. Additional long posterior ciliary arteries are present that course farther toward the anterior segment before penetrating the sclera, usually more anterior than the entry of the temporal and nasal long posterior ciliary arteries. The long posterior ciliary arteries course through the suprachoroid, begin to branch just anterior to the equator, and contribute to the circulation of the iris and ciliary body. Just anterior to the equator, some branches of these vessels course down into the choroid and branch to terminate in the choriocapillaris from the ora serrata back to the equator of the eye.

In general, the larger diameter arteries of the choroid are found most proximal to the sclera, in an area referred to as the lamina fusca. These arteries continue to branch and ultimately form the extensive choriocapillaris adjacent to the acellular Bruch's membrane located on the basal side of the RPE (**Figure 3**). The capillary network of the choriocapillaris is approximately 3–18 μm in diameter and oval shaped in the posterior eye, becoming gradually wider and longer as it moves toward the equatorial region (approximately 6–36 μm wide by 36–400 μm long). The network becomes irregular in the peripheral third of the choroid owing to the entrance and exit of arterioles and venules. Compared to capillaries in other organs, the choriocapillary lumen are significantly larger, with a diameter of nearly 20 μm in the macular region and 18–50 μm in the periphery. A network of collagen fibrils surrounds the choriocapillaris and provides a structural supportive framework.

From the choriocapillaris, venous collecting vessels emerge that ultimately exit the eye through the vortex veins (**Figure 1**). In addition to the choroid, the vortex veins also drain the ciliary body and iris circulation. The number of vortex veins is variable, with at least one per

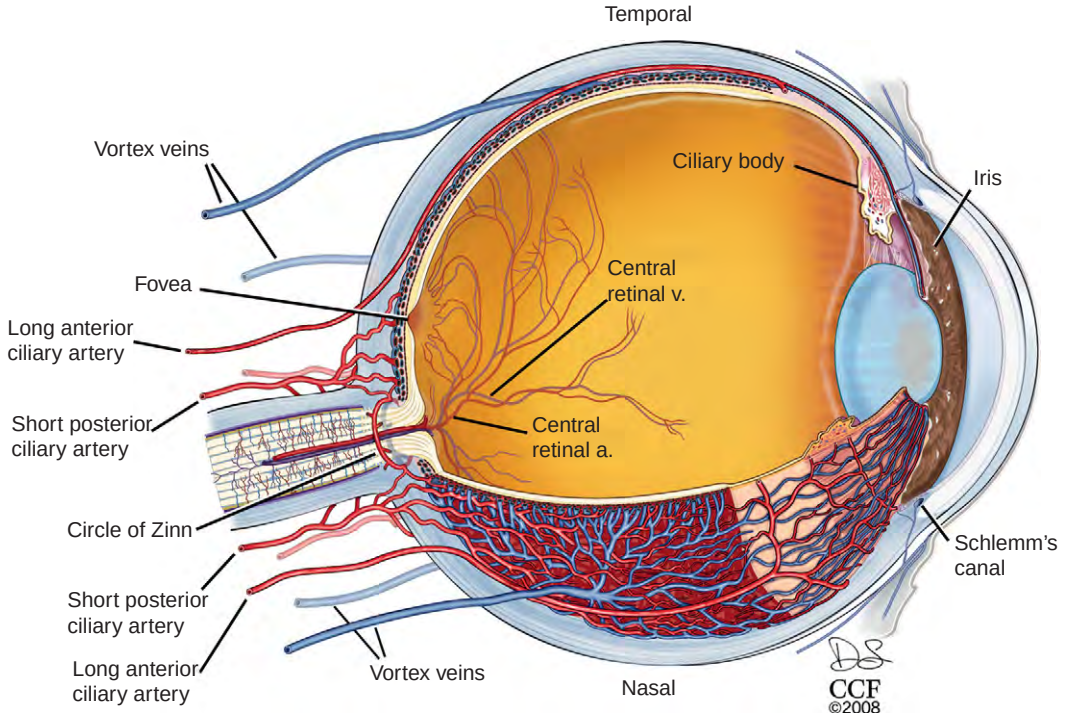

Figure 1 A cutaway drawing of the human eye showing the major blood vessels supplying the retina choroid and anterior segment. The view is from a superior position over the left eye and the horizontal section passes through both the optic nerve and the fovea. Drawing by Dave Schumick.

eye quadrant; however, the total number per eye is usually seven, with more found on the nasal side than are found temporally. The vortex veins usually exit the sclera at the equator or up to 6 mm posterior to this location after forming an ampulla near the internal sclera. The venous branches that open into the anterior and posterior regions of the vortex venular network are oriented along the meridian and are mostly straight, while those joining on the lateral and medial sides have a circular orientation. The vortex veins, in turn, empty into the superior and

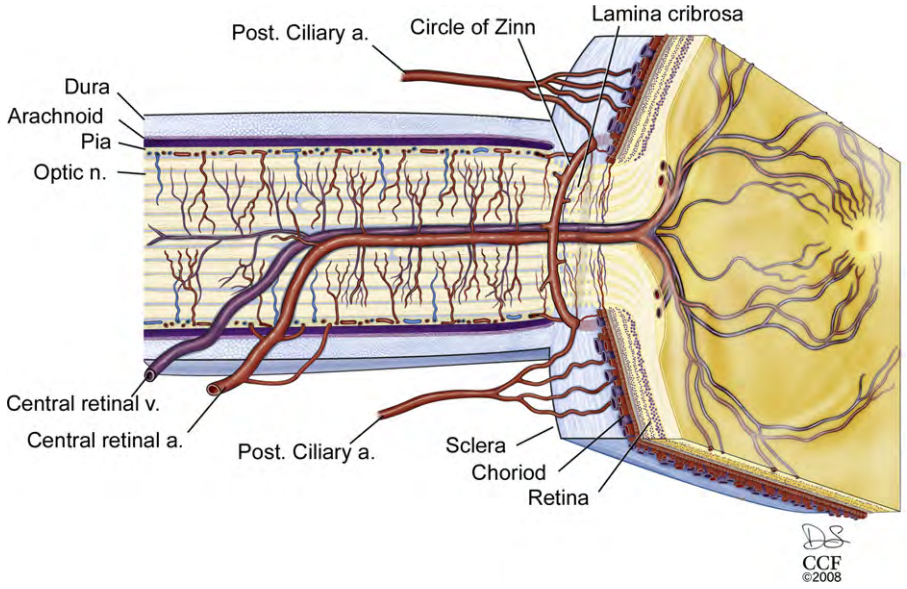

Figure 2 A cutaway drawing along the superior–inferior axis of a left human eye through the optic nerve, showing details of the vascular supply in this location. The fovea is present on the right side of the drawing at the center of the termination of the central retinal vessels. Drawing by Dave Schumick.

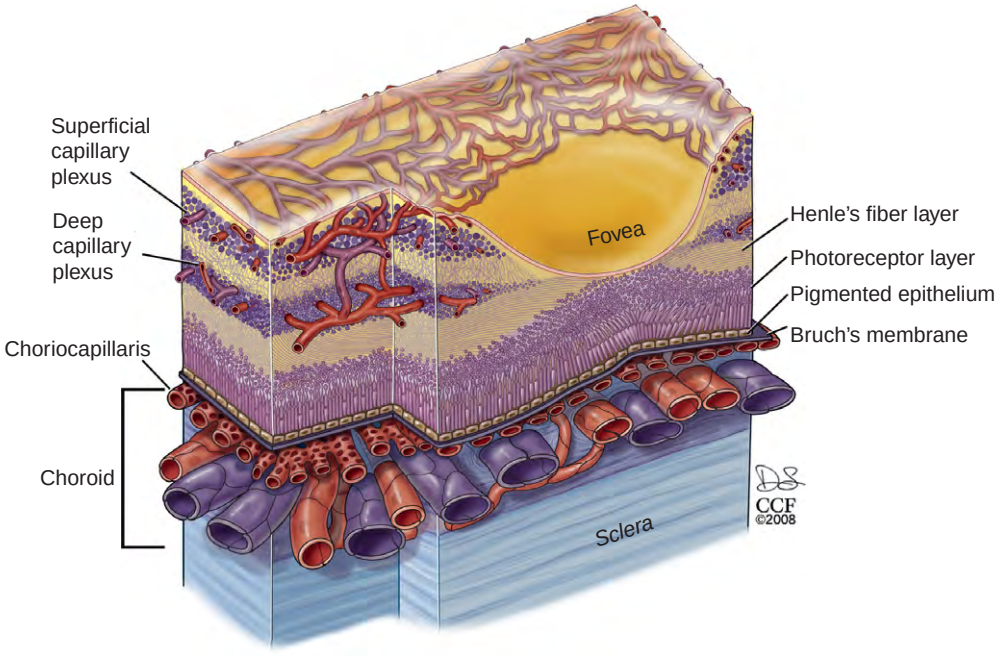

Figure 3 A diagram showing details of the retinal and choroidal vasculature and changes that occur at the level of the human fovea. The branches from the central retinal circulation form two distinct capillary plexi within the ganglion cell layer (the superficial capillary plexus) and in the inner nuclear layer (the deep capillary plexus). These two vascular plexi end as the ganglion cell and inner nuclear layer disappear in the foveal slope. The choroid contains a dense vascular network terminating with the fenestrated choriocapillaris adjacent to Bruch's membrane. Drawing by Dave Schumick.

inferior ophthalmic veins, which leave the orbit and enter the cavernous sinus.

Physiology

The primary function of the choroid vasculature is to provide nutrients and oxygen to the outer retina. The loss of the choriocapillaris, as occurs in central areolar choroidal sclerosis, results in atrophy of the overlying retina. The choriocapillary network is unique in that it lies in a single plane below Bruch's membrane. Normal choroidal circulation occurs when both choroidal arterial and venous pressures are above 15–20 mm of Hg, which is the normal physiological intraocular pressure. In addition, since the blood flow rate through the choroid is relatively high compared to other tissues and is regulated by the arterial vessel diameter, it causes relatively lower amounts of oxygen to be extracted from each milliliter of blood.

The wall of the choriocapillaris facing Bruch's membrane is fenestrated with circular openings (fenestrae) measuring approximately 800 Å. The fenestrae of the choriocapillaries are unique in that they have a diaphragm covering them, unlike those seen in the renal glomerulus. These fenestrae allow easy movement of large macromolecules into the extracapillary compartment. Fluid and macromolecules escaping from these leaky vessels percolate through Bruch's membrane and have access to the basal side of the RPE. The passive movement of fluid and macromolecules from this leaky circulation is blocked from reaching the subretinal space (interphotoreceptor matrix) by zonula occludens junctions that form a continuous belt-like barrier near the apical border of the RPE. Thus, the RPE is able to block the passive movement of the large molecules and fluid from the choroid, allowing the RPE to function as the outer portion of the blood retinal barrier.

Pathology

The exudative (wet form) of age-related macular degeneration (AMD) is characterized by an abnormal proliferation of the choriocapillaris with occasional invasion through Bruch's membrane into the subretinal space. Leakage of the fluid and/or blood often leads to retinal or RPE detachment and loss of central vision. VEGF, basic fibroblast growth factor (bFGF), and pigment epithelial-derived growth factor (PEDF) have been postulated to play a role in the development of choroidal neovascularization (CNV). Some studies have suggested that the thickening of Bruch's membrane that occurs with age and in AMD could result in decreased permeability. The survival factors for the choriocapillaris, such as VEGF, which are secreted basally from the RPE, could remain sequestered in Bruch's membrane and be unable to reach the endothelial cells of the choriocapillaris. This could potentially lead to atrophy of the choriocapillaris that is seen in dry AMD and may be the initiating event for local hypoxia, and upregulation of VEGF and CNV. Myopia is the second most common cause of CNV. Presumed ocular histoplasmosis syndrome, multiple white dot syndrome, multifocal choroiditis, punctate inner choroidopathy, birdshot chorioretinopathy, and the healing phase of choroidal ruptures are the other causes of CNV.

Hyaloid Vascular Network

Embryology

During the first gestational month, the posterior compartment of the globe contains the primary vitreous comprised of a fibrillary meshwork of ectodermal origin and vascular structures of mesodermal origin. At the 5-mm stage, the primitive dorsal ophthalmic artery sprouts off the hyaloid artery, which passes through the embryonic choroidal fissure and branches within the cavity of the primary optic vesicle. Behind the lens vesicle, some of the branches make contact with the posterior side of the developing lens (capsula perilenticularis fibrosa), while others follow the margin of the cup and form anastomoses with confluent sinuses to form an annular vessel. The arborization of the hyaloid artery forms a dense capillary network around the posterior lens capsule (tunica vasculosa lentis, TVL) and surrounding the lens equator. In addition, capillary branches are given off that course throughout the vitreous (vasa hyaloidea propria). The capsulopupillary vessels anastomose with the annular vessel around the rim of the optic cup and connect to the choroidal vasculature through which venous drainage occurs. By the sixth week (17–18-mm embryo), the annular vessel sends loops forward and centrally over the anterior lens surface. By the end of the third month, the anterior portion of the TVL is replaced by the pupillary membrane, which is supplied via loops from the branches of the long posterior ciliary arteries and the major arterial circle. The development of the hyaloid vasculature is almost complete at the ninth week (40 mm) stage. The venous drainage from the vessels of the anterior lens capsule and, subsequently, from the pupillary membrane and from the capsulopupillary vessels occurs through vessels that assemble into a network in the region where the ciliary body will eventually form and will anastomose and feed into the venules of the choroid.

Normally, the hyaloid vascular system begins to regress during the second month of gestation. This process begins with atrophy of the vasa hyaloidea propria, followed by the capillaries of the TVL, and, finally, the hyaloid artery (by the end of the third month). The occlusion of the regressing capillaries by macrophages appears to be a critical step for atrophy to occur. As the vascular structures regress, the primary vitreous retracts, and collagen fibers and a ground substance of hyaluronic acid are produced, forming a

secondary vitreous. By the fifth to the sixth month of gestation, the posterior compartment is primarily composed of the secondary vitreous, and the primary vitreous is reduced to a small, central structure, the Cloquet canal, which is a thin, S-shaped structure that extends from the disk to the posterior surface of the lens.

Physiology

The hyaloid vascular system apparently supplies the nutritive requirements of both the lens and the developing retina before the acquisition of the retinal vasculature. The localization of VEGF in the TVL and papillary membrane may be responsible for fenestrae being present only in the hyaloid capillaries facing the lens. The hypoxia-inducible factor and VEGF have been postulated to play a role in the development and regression of the hyaloid. Other factors that have a part to play in regression are Wnt receptor (Lrp5), Frizzled-4, collagen-18, Arf, Ang2, and BMP-4.

Pathology

Persistent hyperplastic primary vitreous occurs owing to the failure of the hyaloid vasculature to completely regress. The TVL, the anterior extension of the primary vitreous, is comprised of a layer of vascular channels originating from the hyaloid artery, the vasa hyaloidea propria, and the anterior ciliary vessels. The anterior part of this system is supplied by the ciliary system and the posterior part by the hyaloid artery and its branches. The posterior system usually regresses completely by the seventh month of gestation, while the anterior part follows by the eighth month. Two clinical forms of persistent hyperplastic primary vitreous have been identified based on the vascular system that fails to regress: (1) persistent TVL that mainly affects the anterior segment and is now termed anterior hyperplastic primary vitreous and (2) posterior hyperplastic primary vitreous. The hallmark of posterior hyperplastic primary vitreous is the presence of a retinal fold. The lens is usually clear, but may form a cataract over time if the membranous vessels grow forward to enter the lens through the posterior capsule. Other complications include secondary angle-closure glaucoma, microophthalmia, vitreous membranes, tractional retinal detachment at the posterior pole, and a hypoplastic (underdeveloped) or dysplastic (disorganized) optic nerve head. Patients with the anterior hyperplastic primary vitreous often have the best prognosis for visual recovery. The posterior pole is usually normal, with no evidence of a retinal fold or abnormalities in the optic nerve or macula. Patients characteristically present with the appearance of a whitish mass behind the lens (leukokoria) early in life. Occasionally, elongated ciliary processes are present and the eye is microphthalmic. Intralenticular hemorrhage can occur if the fibrovascular membrane invades the lens. Other complications include secondary angle-closure glaucoma, strabismus, and coloboma iridis.

Retinal Vascular Network

Embryology

Until the fourth month of gestation, the retina remains avascular as the hyaloid vasculature provides the nutrients to the developing retina. At the fourth month (100-mm stage), the primitive vascular mesenchyme cells near the hyaloid artery invade the nerve fiber layer. At later stages in development, the hyaloid artery regresses back to this point, which marks the posterior origin of the retinal circulation. In the fourth month of gestation, the first retinal vessels appear when solid endothelial cords sprout from the optic nerve head to form a primitive central retinal arterial system. By the sixth month, these vessels start developing a faint lumen that occasionally contains a red blood cell. At this time, the vessels extend 1–2 mm from the optic disk and continue to migrate outward extending to the ora serrata nasally and to the equator temporally by the seventh to eighth month. Pericytes or mural cells are conspicuously absent from the vessels at this time and do not appear until 2 months after birth. The retinal vasculature achieves the adult pattern by the fifth month after birth. The relative roles of angiogenesis versus vasculogenesis in the development of the retinal vascular network are still controversial. However, it is generally accepted that VEGF secreted in a temporal and spatial pattern by microglia and astrocytes plays a critical role in the development of the superficial and deep layers of the retinal vasculature. Platelet-derived growth factor (PDGF) produced by the neuronal cells induces the proliferation and differentiation of astrocytes, which respond to the hypoxic environment by secreting VEGF. These cells establish a gradient of VEGF and a track for endothelial cells to follow. The hypoxia-inducible factor has been shown to be critical in the hypoxia-induced regulation of retinal vascular development. VEGF isoforms have been shown to perform highly specific functions during developmental retinal neovascularization.

Gross Anatomy

Usually, the only arterial blood supply to the inner retina is from the central retinal artery that runs along the inferior margin of the optic nerve sheath and enters the eye at the level of the optic nerve head (**Figure 2**). Within the optic nerve, the artery divides to form two major trunks and each of these divides again to form the superior nasal and temporal and the inferior nasal and temporal arteries that supply the four quadrants of the retina. The retinal venous branches are distributed in a relatively similar pattern. The major arterial and venous branches and the successive divisions of the retinal vasculature are present in the

nerve fiber layer close to the internal limiting membrane. The retinal arterial circulation in the human eye is a terminal system with no arteriovenous anastomoses or communication with other arterial systems. Thus, the blood supply to a specific retinal quadrant comes exclusively from the specific retinal artery and vein that supply that quadrant. Any blockage in blood supply therefore results in infarction. As the large arteries extend within the retina toward the periphery, they divide to form arteries with progressively smaller diameters until they reach the ora serrata where they return and are continuous as a venous drainage system. The retinal arteries branch either dichotomously or at right angles to the original vessel. The arteries and venules generated from the retinal arteries and veins form an extensive capillary network in the inner retina as far as the external border of the inner nuclear layer. Arteriovenous crossings occur more often in the upper temporal quadrants with the vein usually lying deeper than the artery at these crossings.

Branches from the central retinal vessels dive deep into the retina forming two distinct capillary beds, one in the ganglion cell layer (superficial capillary plexus) and the other in the inner nuclear layer (deep capillary plexus). Normally, no blood vessels from the central retinal arteries extend into the outer plexiform layer (**Figure 3**). Thus, the photoreceptor layer of the retina is free of the blood vessels supplied by the central retinal artery. The choriocapillaris provides the blood supply to photoreceptors. Since the fovea contains only photoreceptors, this cone-rich area is free of any branches from the central retinal vessels (**Figure 3**).

In some individuals (18%), a cilioretinal artery derived from the short posterior ciliary artery (from the choroid vasculature) enters the retina around the termination of Bruch's membrane, usually on the temporal side of the optic nerve, and courses toward the fovea, where it ends in a capillary bed and contributes to the retinal vasculature. In approximately 15% of eyes with a cilioretinal artery, the branches supply the macula exclusively, whereas in other individuals, they can nourish the macular region and regions of the upper or lower temporal retina.

Physiology

The rate of blood flow through the retinal circulation is approximately 1.6–1.7 ml g^{-1} of retina with a mean circulation time of approximately 4.7 s. The flow rate through the retinal vessels is significantly slower than that through the choroidal vasculature.

The arteries around the optic nerve are approximately 100 μm in diameter with 18-μm-thick walls. These decrease in diameter in the branched arteries located in the deeper retina to around 15 μm. The walls of the retinal arteries have the characteristics of other small muscular arteries and are composed of a single layer of endothelial cells: a subendothelial elastica, a media of smooth muscle cells, a poorly demarcated external elastic lamina, and an adventitia comprised of collagen fibrils. Near the optic disk, the arterial wall has five to seven layers of smooth muscle cells, which gradually decrease to two or three layers at the equator and to one or two layers at the periphery. These vessels continue to have the characteristics of arteries, and not arterioles, up to the periphery. The retinal arteries lose their internal elastic lamina soon after they bifurcate at the optic disk. This renders them immune from developing temporal arteritis and distinguishes them from muscular arteries of the same size in other tissues. As a compensatory mechanism, the retinal arteries have a thicker muscularis, which allows increased constriction in response to pressure and or chemical stimuli.

The major branches of the central vein close to the optic disk have a lumen of nearly 200 μm with a thin wall made up of a single layer of endothelial cells having a thin basement membrane (0.1 μm), which is continuous with the adjacent media comprised predominantly of elastic fibers, a few muscle cells, and a thin adventitia. The larger veins in the posterior wall have three to four layers of muscle cells in the media. As the retinal veins move peripherally from the optic disk, they lose the muscle cells, which are replaced by pericytes. The lack of smooth muscle cells in the venular vessel wall results in a loss of a rigid structural framework for the vessels, resulting in shape changes under conditions of sluggish blood flow (e.g., diabetes mellitus) or increased blood viscosity (polycythemia), or with increased venous pressure (papilledema or orbital compressive syndromes).

The retinal capillary network is spread throughout the retina, diffusely distributed between the arterial and venous systems. There are three specific areas of the retina that are devoid of capillaries. The capillary network extends as far peripherally as the retinal arteries and veins up to 1.5 mm from the posterior edge of the troughs of the ora serrata (ora bays), leaving the ora serrata ridges (ora teeth) without any retinal circulation. The 400-μm-wide capillary-free region centered around the fovea is another area lacking retinal capillaries. Finally, the retina adjacent to the major arteries and some veins lacks a capillary bed.

The retinal capillary wall is comprised of the endothelial cells, basement membrane, and intramural pericytes. The retinal capillary lumen is extremely small (3.5–6 μm in diameter), requiring the circulating red blood cells to undergo contortions to pass through. Unlike the choriocapillaris, the endothelial cells of retinal capillaries are not fenestrated. The edges of endothelial cells show interdigitation and are joined by the zona occludens at their lumenal surface. The endothelial cells of the retinal arteries are linked by tight junctions, which prevent the movement of large molecules in or out of the retinal vessels. These tight junctions, in concert with the Muller

cells and astrocytes, establish the blood–retinal barrier that prevents the passage of plasma proteins and other macromolecules in or out of the capillary system. The pericytes (also called mural cells) are embedded within the basal lamina of the retinal capillary endothelium. The pericytes are believed to play an important role in the stabilization of the retinal capillary vasculature.

Pathology

Diabetic retinopathy (maculopathy) is the leading cause of vision loss in patients with type 2 diabetes and is characterized by the hyperpermeability of retinal blood vessels, with subsequent formation of macular edema and hard exudates. Early changes in the retinal vasculature include thickening of the basement membrane, loss of pericytes, formation of microaneurysms, and increased permeability. It is generally hypothesized that these changes lead to the dysfunction of the retinal vessels, loss of vessel perfusion, hypoxia, induction of retinal VEGF expression, and pathological neovascularization as seen in proliferative diabetic retinopathy. In severe cases, retinal detachment can occur as a result of traction caused by fibrous membrane formation. Laser photocoagulation and VEGF-blocking agents are currently being used as therapeutic approaches for this disease.

Retinopathy of prematurity is a potentially blinding disorder affecting premature infants weighing 1250 g or less and with a gestational age of less than 31 weeks. This disease is characterized by abnormal retinal vascularization and can be classified into several stages ranging from mild (stage I), with mildly abnormal vessel growth, to severe (stage V), with severely abnormal vessel growth and a completely detached retina. The pathophysiology of this disease has been extensively studied and several factors have been implicated. The premature birth of an infant before the retinal vasculature has extended to the periphery results in stoppage of the normal blood vessel growth that is driven by the hypoxia-mediated expression of VEGF. This is compounded by the oxygen therapy given to alleviate the respiratory distress, which reduces VEGF expression leading to vaso-obliteration. Once the infant is taken off oxygen, there is a relative hypoxia, upregulation of VEGF, and florid abnormal neovascularization.

Differentiation and Morphogenesis of Extraocular Muscles

D M Noden, Cornell University, Ithaca, NY, USA

Glossary

Mesenchyme – Embryonic cells with a fibroblast-like appearance, surrounded by extracellular matrix, lacking tight junctions with their neighbors, and often capable of undergoing extensive migratory movements. These can be of several different embryonic origins, and include cells that will contribute to many lineages.

Morphogenesis – It includes those processes that establish the correct locations and three-dimensional organization of tissues and organs. This includes the proper positioning of extraocular muscles around the globe and their attachments to the sclera and orbital skeleton.

Myoblasts – Mitotically active cells committed to the skeletal muscle lineage but not yet expressing muscle-specific proteins such as desmin and myosins, which generally are not evident until after myoblasts fuse to form multinucleated myofibers.

Myotome – The several regions of each somite that contain progenitors of skeletal muscle progenitors.

Neural crest – Mesenchymal cells that are derived from neural fold tissues and that move peripherally along well-delineated pathways to form neurons and glia of the peripheral nervous system and, in the head region, the connective tissues of the midface and branchial regions.

Paraxial mesoderm – Early embryonic cells that are located beside and beneath the developing brain and spinal cord, and include the precursors of most skeletal muscles.

Introduction

Muscles that move and stabilize the eye have been highly conserved during vertebrate evolution. While a few remarkable adaptations have occurred, such as co-opting of the dorsal (superior) oblique muscle to generate protective heating for the brain in some fishes, these muscles have retained an anatomical organization linking axes of the body and the eye that arose hundreds of millions of years ago.

Considering their ancient status, it is logical to assume that the early development of extraocular muscles would similarly be well conserved among different species, and therefore amenable to comparative analyses that supplant the absence of direct examination in mammals, including humans. However, compared to trunk and limb muscles, our understanding of the origins of ocular muscles and the mechanisms that initiate then maintain their development is at best fragmentary.

Myogenesis of skeletal muscles is a lengthy process, with several parameters continuing to be function-dependent throughout the life of an animal. Primary myogenesis spans the period during which populations of myoblasts – committed, mitotically active muscle progenitors – arise, emigrate to their sites of differentiation, fuse to form multinucleated innervated myofibers, and establish intimate connections with connective tissues. This population forms a scaffolding, including the delineation of global and orbital domains, within which secondary myogenesis occurs. During secondary myogenesis stages, previously sequestered latent myoblasts are activated to proliferate and differentiate, forming more than 90% of the myofibers present in mature muscles and generating region-specific specialized fiber types that in most species are present before or soon after birth.

Origins of Extraocular Muscles

Striated (skeletal) muscles throughout the body arise within paraxial mesoderm, which is located in close apposition to the embryonic brain and spinal cord. Exceptions to this are the avian striated ciliary muscle that is of neural crest origin, and possibly the striated muscles of the esophageal wall; however, both of these are involuntary. Among voluntary muscles, some of the more ventrally located branchial muscles arise from lateral mesoderm that is contiguous with paraxial mesoderm.

Many early accounts of head myogenesis placed the embryonic origin of some eye muscles, especially the lateral rectus, in the same category as branchial (pharyngeal) arch muscles, and ascribed both to a lateral mesoderm origin. These claims were based on the sites at which muscle condensations are first grossly evident in the embryo. However, with the advent of mapping methods and assays for early muscle-specific gene expression patterns, separate and distinct sites of origin for all eye muscles within preotic (i.e., located rostral, in front of the developing inner ear) paraxial mesoderm was confirmed (Figure 1).

The sites of origin of extraocular muscles parallel the sites of emergence of the three cranial motor nerves that

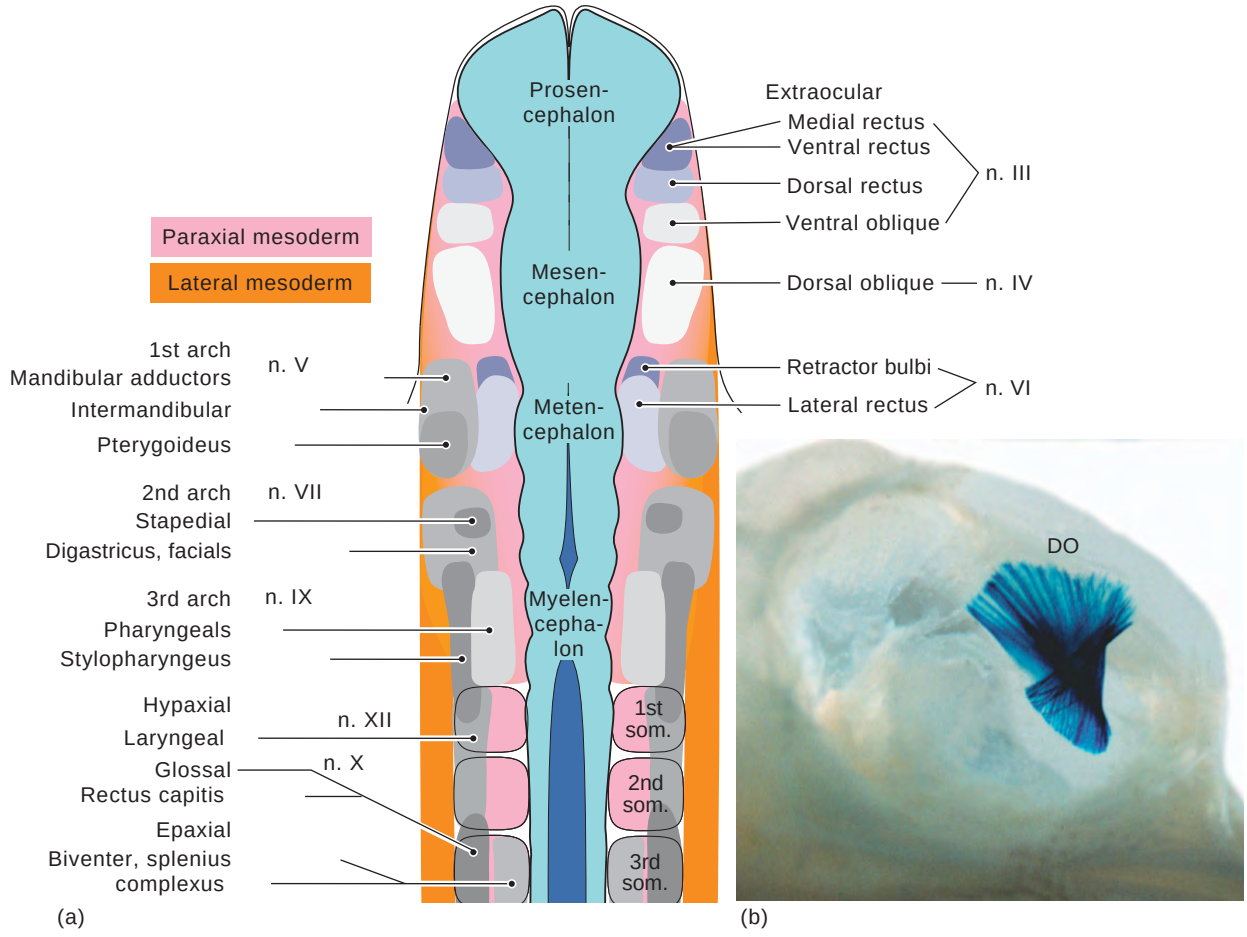

Figure 1 Sites of origin of craniofacial striated muscles in avian embryos. Panel (a) shows, in dorsal view, the locations of each muscle primordia within paraxial and lateral mesoderm. Panel (b) illustrates one mapping method used in avian embryos, wherein a small bolus of replication-incompetent retrovirus injected into early mesoderm and the embryo harvested 2 weeks later and stained for the appropriate reporter gene, in this case a bacterial galactosidase. In this embryo, in which the eye has been removed to reveal underlying tissues, only the dorsal (superior) oblique muscle was labeled.

innervate them. However, in contrast to axial and branchial muscles, sites of myogenesis are not congruent with locations of motor nerve emergence. Indeed, each of these cranial nerves needs to elongate considerably through peripheral tissues before initial contacts with target muscles are established. Some axons, such as those of the abducens nerve, must extend longitudinally beneath the brain to reach their target lateral rectus muscles, while others, such as the oculomotor nerve fibers, project perpendicular to the floor of the brain before decussating to approach their several target muscles.

In extant vertebrates, head paraxial mesoderm constitutes a sparse population of mesenchymal cells (Figure 2). This contrasts with the situation in the neck and trunk regions, where paraxial mesoderm first forms somites, which are segmentally arranged, cuboidal aggregates of epithelial cells. As each somite matures, it becomes delineated into distinct myogenic (myotome) and connective tissue-forming (sclerotome) regions. The most cranial somite is located beside the hindbrain, immediately caudal to the otic vesicle, and paraxial mesoderm rostral to this site fails to form epithelial tissues and lacks overt evidence of segmentation.

Head paraxial mesoderm is present adjacent to the prospective eye-forming regions of the rostral neural plate, but is largely displaced caudally as the optic vesicles emerge and expand lateral to the diencephalon. In the midline just in front of the notochord, this population of loose paraxial mesoderm cells is contiguous with a sparse and species-variable population of prechordal mesenchymal cells. Mapping experiments in avian embryos have shown that prechordal mesoderm contributes to the genesis of extraocular muscles innervated by the oculomotor nerve (Figure 3), but it is not known whether this contribution is exclusive of or supplementary to that of paraxial mesoderm. It is not known if the same occurs in mammalian embryos.

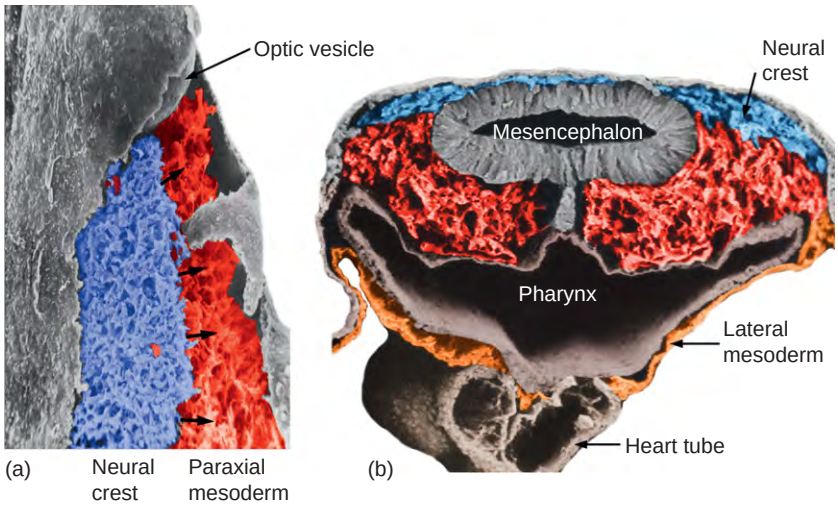

Figure 2 Colorized scanning electron micrographs showing the early relations of neural crest (blue) to mesodermal (red) populations in dorsal (a) and transverse (b) views. Small arrows indicate the direction of movement of the neural crest cells.

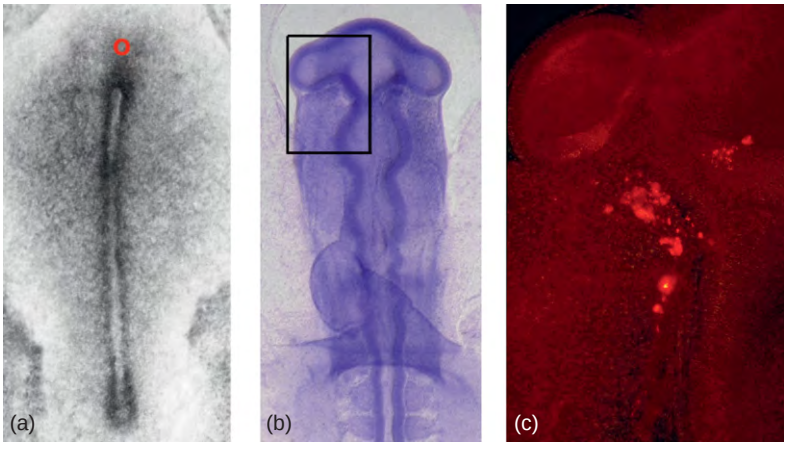

Figure 3 Contributions of prechordal mesoderm to developing extraocular muscles is shown by labeling their precursors at stage 4–5 (early gastrulation) with DiI, a fluorescent membrane-binding tag (site 'o' in (a)), and fixing the embryos over a day later((b), stage 12, ventral view). Labeled cells in (c) are within the eye muscle-forming region of paraxial mesoderm.

Determination of Eye Muscle Precursors

Head paraxial mesoderm contains progenitors for many tissues in addition to skeletal muscle. These include cartilages and bones associated with the braincase, loose connective tissues such as meninges and adipocytes, and endothelial cells. In contrast to somites, wherein these progenitor populations are largely segregated, it appears based on mapping studies that these diverse precursors are either intermingled or contiguous in head mesoderm.

The significance of this lies in the problem of generating diverse lineages. Somite cells are held in fixed positions relative to the dorsal and ventral parts of the adjacent neural tube (hindbrain and spinal cord) and overlying surface epithelium, all of which provide combinations of positive and negative regulators of early myogenesis and skeletogenesis.

A further complication – and one essential for the development of all craniofacial musculoskeletal systems – is the presence of a large, later-arising population of mesenchymal cells called the neural crest (Figure 2). Derived from neural folds either during (mammals) or shortly following (birds) closure of the cephalic neural tube (brain), these cells acquire a mesenchymal phenotype and quickly move peripherally, mostly atop underlying paraxial mesoderm.

Neural crest cells from the rostral midbrain level move rostrally and caudally around the optic stalk and posterior part of the optic vesicle, then spread outwardly as the vesicle is transformed into the optic cup. After delineation of the lens from the lens placode, crest cells secondarily invade the space created anterior to the lens and establish the posterior epithelium (endothelium) and stromal populations of the cornea.

In the trunk, members of the *wnt* family of growth factors are secreted by surface ectoderm and provide essential positive stimuli for muscle differentiation. The same are released by head surface epithelium, but here their effects are to retard myogenesis of branchial muscles. Arriving neural crest cells separates branchial muscle progenitors from the source of these negative effects and, augmented by the release of additional myogenesis-promoting factors, allows myogenesis to progress.

The extent to which eye muscle progenitors follow a similar scenario is unclear. Some extraocular precursors, particularly the lateral rectus progenitors, are embedded deep within paraxial mesoderm and are therefore quite distant from both surface ectoderm and, at early stages, neural crest cells. This deep location places the lateral rectus precursors close to the neural epithelium at the level of the future metencephalon (pons).

Several experiments have established that this location provides essential cues for lateral rectus formation. When newly formed trunk paraxial mesoderm cells were excised, before they had formed somites, then grafted into the head, in place of prospective lateral rectus mesoderm cells, the transplanted cells formed a muscle that expressed molecular markers unique to the lateral rectus and established proper anatomical connections with the braincase and sclera. Small changes in the location of the implants resulted in grafted cells contributing to the dorsal oblique or branchial arch musculature. Thus, the sites within head paraxial mesoderm at which each muscle primordium forms and is specified as to its identity are highly localized.

Placing a barrier between the brain and paraxial mesoderm at this region does not prevent myogenesis, but the developing muscle cells lack molecular features that define their specific identity. Together, these experiments suggest that a rich tableau of local signals is necessary for early eye muscle differentiation, with both general myogenic and individual eye muscle-specific components.

Molecular Signatures and Muscle Differentiation

All skeletal myoblasts use members of a closely related set of muscle-specific transcription factors to promote and coordinate their differentiation. Two of these, *myf5* and *myoD,* are cross-activating regulators that are among the earliest muscle-specific genes expressed. The upstream regulatory components of these genes are body region- and muscle group-specific, and serve to integrate the diverse micro-environments surrounding each muscle group with a highly shared set of outcomes, for example, activation of genes for desmin, myosins, muscle-specific actins, and junctional receptors.

Expression of *myf5* then *myoD* genes in eye muscle precursors generally is slightly later than expression in trunk axial muscles, but is simultaneous with that of branchial muscles (**Figure 4**). Expression of these regulatory genes coincides with the onset of aggregation of most muscle precursors (**Figure 5**), although it is not known whether these aggregates represent the totality of muscle precursors or only a subset of primary myoblasts.

By these criteria, extraocular muscles appear similar to other head and also to trunk and appendicular muscles. However, as additional features of trunk and head myogenic regulatory networks have been identified, the number of differences has exceeded the similarities, and a heretofore underlying complexity has been revealed (**Table 1**). This area of investigation is rapidly expanding, and rather than detail each gene currently described, a few examples of categories of differences among muscle groups will be presented.

Pax3 is a regulatory gene expressed in axial and appendicular muscle precursors, and null mutations of this transcription factor (e.g., *Splotch* mutation) result in severe depletion of trunk muscles. However, it is not expressed in head muscle precursors, and null mutations have no discernable effect on branchial or extraocular muscles. Another pronounced difference is in the hepatocyte growth factor (HGF) – cMet growth factor-receptor complex, which is functionally required for the correct dissemination and differentiation of appendicular and tongue muscle precursors. Again, this pathway has no known role in eye and branchial myogenesis, even though HGF is expressed in and around the precursors of branchial arch, lateral rectus, and both oblique muscles.

The latter example further illustrates the considerable heterogeneity among extraocular muscles. The lateral rectus is particularly enigmatic, being the only head muscle that expresses the ubiquitous trunk paraxial mesoderm marker *paraxis*, and together with the dorsal oblique, the transcription factor *lbx1*, which is present in trunk hypaxial (thoracic and abdominal wall) muscle precursors.

A further complexity arises from the often-changing patterns of gene expression during the early stages of head paraxial mesoderm development. The transcription factor *pitx2*, which is a key mid-level participant in the integrated formation of left-right asymmetry for the heart and mid-gut, is initially expressed symmetrically and ubiquitously throughout head paraxial mesoderm (**Figure 6**). However, a day later, during early myogenesis stages, its expression becomes more restricted but includes the first branchial arch, lateral rectus, and both oblique muscles in addition to periocular neural crest cells. Another regulatory gene, *Tbx1*, which is located in the region of chromosome 22 wherein deletions cause the DiGeorge syndrome, is similarly expressed over a wide domain of mesoderm (and pharyngeal endoderm) before becoming restricted to branchial arch and the lateral rectus muscles.

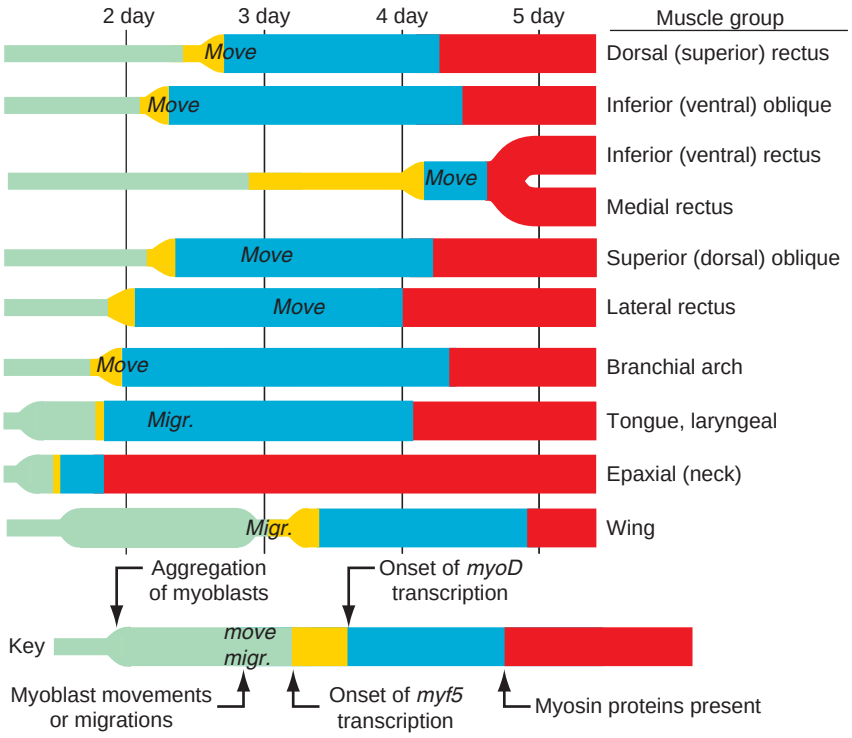

Figure 4 Timetable of gene activation in extraocular and other head and trunk muscles. The most consistent difference between trunk and head muscles is that the latter show a prolonged delay between the onset of *myoD* expression and the synthesis of muscle-specific proteins.

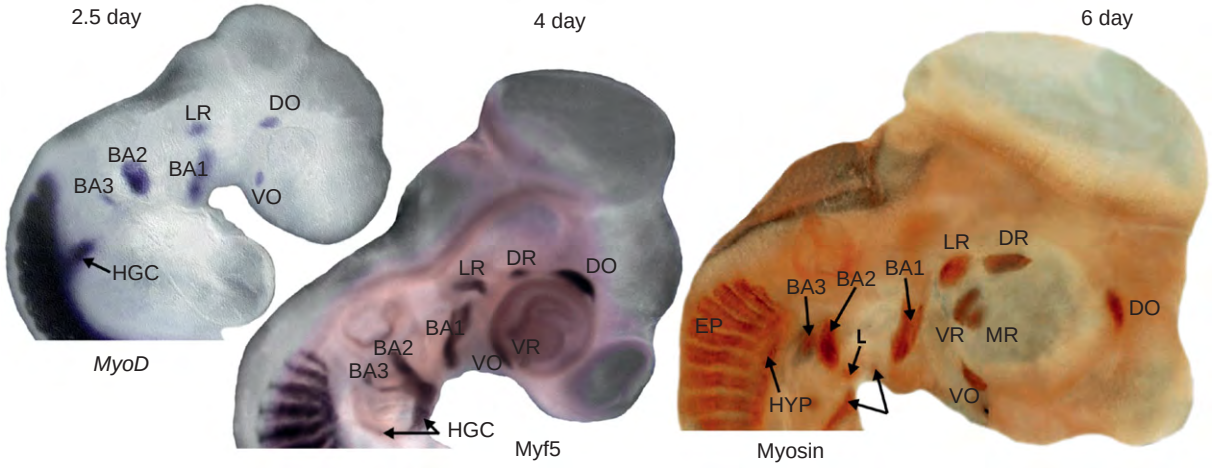

Figure 5 Early differentiation and morphogenesis of head muscles in chick embryos. BA1, 2, 3, branchial arches; DO, dorsal oblique; DR, dorsal rectus; Ep, epaxial muscle precursors; Hyp, hypaxial precursors, HGC, hypoglossal cord that forms tongue muscles; LR, MR, VR, lateral, medial and ventral rectus muscles; VO, ventral oblique.

At present the significance of these spatially and temporally dynamic expression patterns is unknown. It is possible that early expressions presage the later focal appearance of certain muscles, but it is equally plausible that each of these genes has multiple and distinct functions associated with each stage.

As extraocular muscles mature, they exhibit a progression of fiber types, evidenced by changes in the myosin isoforms and related contractile and energy metabolism proteins expressed. Emergence of these complex patterns requires a series of interactions among developing myofibers, surrounding connective tissues, and innervation. In the avian embryo, the primary myofibers of most extraocular muscles express embryonic slow myosin isoforms. However, one muscle, the quadratus nictitans, which is homologous to retractor bulbi muscles and is innervated

	myoR	−	−	+	DO, VO, L1

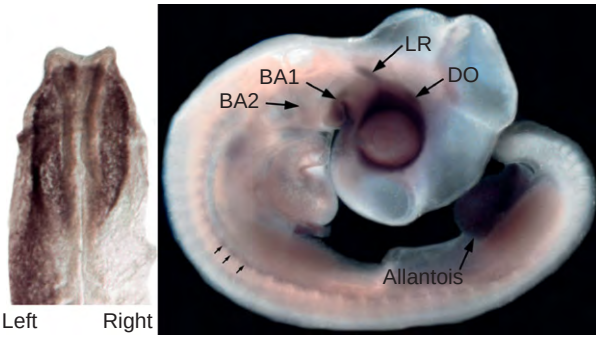

Figure 6 At stage 8 ((a), dorsal view) *Pitx2* is expressed symmetrically throughout head paraxial (and lateral) mesoderm populations, but only on the left within trunk mesoderm. By stage 21 ((b), 4 days) it is restricted to a subset of eye muscles, the first and second branchial arch muscle masses, and periocular mesenchyme.

by the accessory abducens nerve, the myofibers are either completely fast myosin expressing, as in the quail embryo, or mixed, as in the chick embryo (**Figure 7**). To explore the basis for these distinct, species-specific patterns, periocular neural crest cells of the chick were replaced with comparable populations from a quail embryo. The quadratus muscle in these chimeric embryos exhibits the quail donor phenotype (**Figure 7**), indicating that initial differentiation of fiber types requires interactions among myofibers and encompassing connective tissues.

Muscle Morphogenesis

Except for muscles that remain closely associated with the vertebral column and skull, all muscle progenitors leave their sites of origin in paraxial mesoderm and disperse into peripheral tissues. Body wall muscles do so together with sclerotome-derived connective tissue precursors, and maintaining these close spatial relations is essential for the morphogenesis of thoracic and abdominal muscles. For appendicular myogenesis, lateral myotome-derived cells move in sequential waves of primary and secondary myoblasts into nearby limb buds, where they form longitudinal bands of future dorsal and ventral groups before segregating into individual muscles. In the hindlimbs, some of these undergo secondary dispersal to form muscles of the perineal region.

Branchial muscles are comparable to body wall muscles in that they initially exhibit a constant juxtaposition with the precursors of their connective tissues, which in the head are all derived from neural crest cells, and also with the motor nerves that innervate them. This maintained registration permits continuous exchange of signals among all three components during all stages of muscle differentiation and morphogenesis.

This constant contiguity has most dramatically been demonstrated for the trapezius muscle, whose precursors arise among caudal branchial arch mesodermal populations and secondarily shift caudally to attach to the scapula. Mapping studies in both bird and mouse embryos revealed that the neural crest-derived connective tissues move with, and perhaps somewhat in advance of, these myoblasts and indeed contribute to the scapula. This recapitulates an ancestral condition in which the forelimb girdle articulated with the back of the skull, as is still present in fish.

Again, however, the extraocular muscles exhibit a developmental scenario unlike any other muscles. As illustrated in **Figures 5** and **8**, these muscle precursors move towards, then around, the equatorial region of the developing eye to assume their definitive locations. During this process, each muscle leaves the company of surrounding mesoderm cells and becomes fully encompassed by neural crest cells, which secondarily penetrate the muscle mass and form internal (e.g., endomysium) as well as surrounding (perimysium, fascia, and tendon) connective tissues.

These periocular crest cells need not have originated at the same axial level as the muscles. For example, the lateral rectus muscle, the neural crest cells that will form

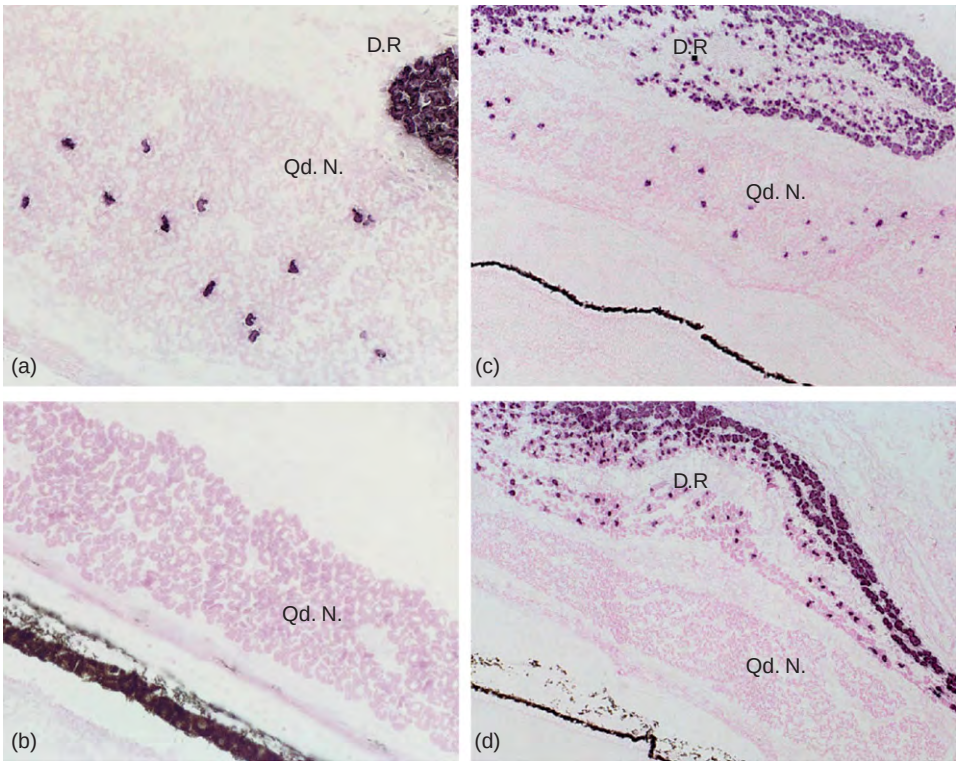

Figure 7 Fiber-type determination in the quadratus nictitans (Qd. N.) muscle. (a, b) Sections through this muscle in chick and quail embryos processed with antibodies to slow myosin isoforms. The quail Qd. N. lacks slow fibers, whereas in the chick both fast and slow fibers are present. (c) A control embryo in which chick neural crest cells were transplanted into a chick host, and the Qd. N. developed normally. However, when quail crest cells were grafted into a chick host embryo (d), the exclusive fast donor phenotype resulted.

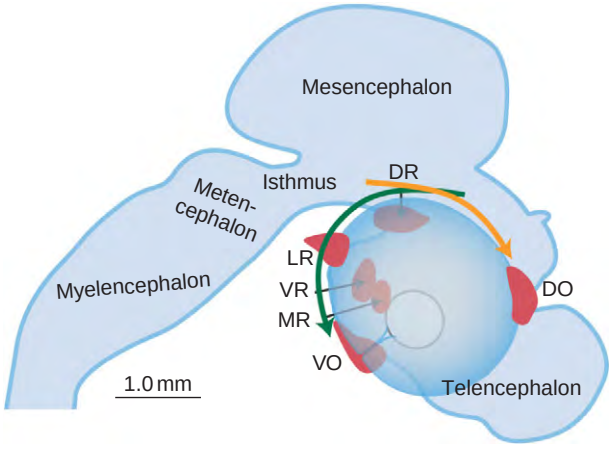

Figure 8 The movements of the dorsal (yellow arrow) and ventral (green arrow) oblique muscles from their sites of origin to their terminal locations along the equatorial zone of the globe.

its connective tissues, and the abducens nerve that innervates it originate at three separate axial levels. Indeed, these primordia do not become intimately associated until each has independently approached the periocular environment. This negates the possibility of prolonged interactions among contiguous progenitor populations, as occurs for branchial musculoskeletal systems.

The mechanisms by which aggregates of extraocular muscle primordia change both absolute and relative positions remain enigmatic. There is no precedence elsewhere in the embryo for condensations of cells moving actively through surrounding tissues. However, several lines of evidence support a model based on passive displacement of eye muscle primordia. As was shown in **Figure 2**, the interface between neural crest and myogenic paraxial mesoderm is initially a flat plane. Changes in the relative positions of the eye due to flexures and differential growth of the brain and expansion of the optic cup introduce distortions in this plane, but the extent to which this might affect individual eye muscles has been difficult to define.

In screening for a wide range of gene expression patterns, several were found that coincided with the patterns of movements taken by some extraocular muscles (**Figure 9**). These reveal a set of localized distortions of the neural crest-mesoderm interface. Finger-like projections of paraxial mesoderm expand dorsally and caudally around the optic cup, becoming interdigitated with periocular neural crest populations and passively bringing the dorsal and ventral oblique muscle primordia to their definitive

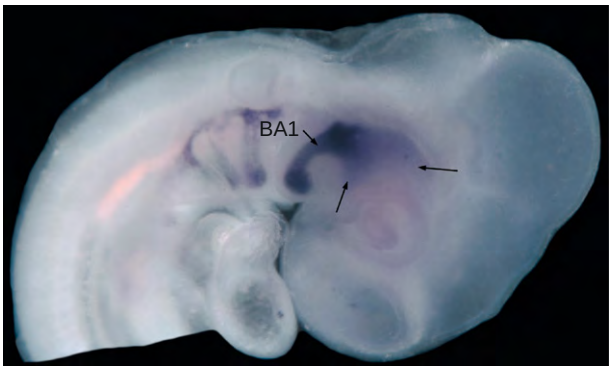

Figure 9 Lateral view of a 3.5-day chick embryo showing the sites of expression of the *MyoR* gene. Note the finger-like projections (arrows) extending dorsal and caudal to the optic vesicle, along the sites at which the dorsal and ventral oblique are expanding.

locations. Subsequently, crest cells close behind each of these muscle primordia, creating the appearance of an island of myoblasts/myofibers amid a sea of crest cells. How these focal distortions are established is unknown. The cell surface adhesion molecule semaphorin 3A is expressed by mesodermal cells in these projections, but its role in not known.

Summary

The early stages of extraocular muscle formation are well described but poorly understood mechanistically. They arise at discrete sites within unsegmented head paraxial mesoderm then launch into developmental programs that share some features with trunk and branchial muscles but are largely and surprisingly unique. Passive distortions of the mesoderm-neural crest interface bring these muscle primordia to their definitive locations around the ocular globe, where they become surrounded then infused by connective-tissue forming neural crest cells, which largely direct both the gross and microscopic differentiation of these muscles.

Drug Delivery to Cornea and Conjunctiva: Esterase- and Protease-Directed Prodrug Design

R S Talluri, S Hariharan, P K Karla, and A K Mitra, University of Missouri–Kansas City, Kansas City, MO, USA

Glossary

Amidases – The enzymes that catalyze the cleavage of carbon–nitrogen bonds in amides.
Bioreversion – The conversion of a prodrug to an active form.
Esterases – The enzymes that catalyze the hydrolysis of an ester into its alcohol and acid.
Peptidases – The enzymes that catalyze the hydrolysis of peptides into amino acids.
Prodrug – The drugs designed to be inactive until *in vivo* activation generates the active form of the drug.
Transporter – The protein that translocates materials in biological systems resulting from expenditure of metabolic energy.

Topical Ocular Drug Delivery

Topical drug delivery is the most acceptable form of treatment for the diseases affecting the anterior segment such as corneal epithelial and stromal keratitis, glaucoma, conjunctivitis, dry eye syndrome, iritis, uveitis, and blepharitis. The structure of the eye is shown in **Figure 1**. Topically applied drugs can reach the intraocular tissues either by corneal and/or noncorneal (conjunctival–scleral) pathway(s). Drugs traversing the corneal pathway should permeate through the corneal epithelium and stroma which are rate-limiting barriers for hydrophilic and lipophilic molecules, respectively. Conjunctival absorption could result in higher drug concentrations in the anterior as well posterior chambers depending on the mechanism of absorption. Conjunctival–scleral pathway is favored for the treatment of diseases in the posterior segment, as it can bypass the anterior chamber and thus permit direct access to intraocular tissues like sclera retina and vitreous humor. However, nasolacrimal drainage, tear dilution, as well as the outer conjunctiva and cornea, act as barriers to drug absorption. As a result, therapeutic concentrations in intraocular tissues following topical administration are difficult to achieve and about 1–5% of topically instilled dose reaches the anterior segment of the eye. Moreover, a larger fraction of the applied drug is eliminated from the precorneal area within 5 min, through drainage across nasolacrimal duct into the systemic circulation. Fifty percent of the normal human tear film is replaced every 2–20 min. Such a high tear-turnover rate also reduces the drug-residence time in precorneal and conjunctival areas. Therefore, rapid tear-film drainage can also impede the drug absorption following topical administration. Topically administered agents have a low probability of reaching the posterior segment in significant amounts, as passage through the corneal and conjunctival epithelia, aqueous humor, and lens is required to reach the retina.

Various strategies have been investigated in order to improve the corneal and conjunctival absorption of drugs instilled topically. Prodrug approach is one of the most promising and effective strategies currently being investigated for ophthalmic drug delivery. Exploring the inherent drug metabolism capability of ocular tissues is one of the important aspects of prodrug design. In this strategy, the drug molecule is modified chemically by attaching it to a promoiety to improve the physicochemical characteristics, such that higher drug absorption into the tissues can be achieved.

Prodrugs are designed to be therapeutically inactive until *in vivo* activation to generate the parent drug. The compounds are synthesized by linking an appropriate chemical moiety to the parent drug, usually linking by an ester or an amide bond. Upon absorption into the tissue, the prodrug will be subjected to enzymatic hydrolysis (bioreversion by esterases/peptidases) to release the active parent drug (**Figure 2**). The rate of bioreversion depends upon various factors, including affinity of the prodrug linkage toward hydrolyzing enzyme(s), the capacity and turnover rate of the enzyme, etc. The enzymes responsible for hydrolysis of prodrugs are present ubiquitously in all biological fluids and tissues. For example, esterases are expressed throughout the body and can be utilized in the hydrolysis of an ester functional group. In ocular tissues, the esterase activity has been found to be the highest in iris-ciliary body followed by the cornea and the aqueous humor. Among ocular esterases, butyrylcholinesterase (BuChE) constitutes the major proportion compared to acetylcholinesterase (AChE) – except in the corneal epithelium of albino rabbits. Drugs and prodrugs containing ester linkages can undergo varying extents of esterase-mediated hydrolysis while permeating the cornea/conjunctiva and upon entering into the aqueous humor, iris, and ciliary body. Proteases or peptidases are primarily responsible for hydrolysis of amide linkage in

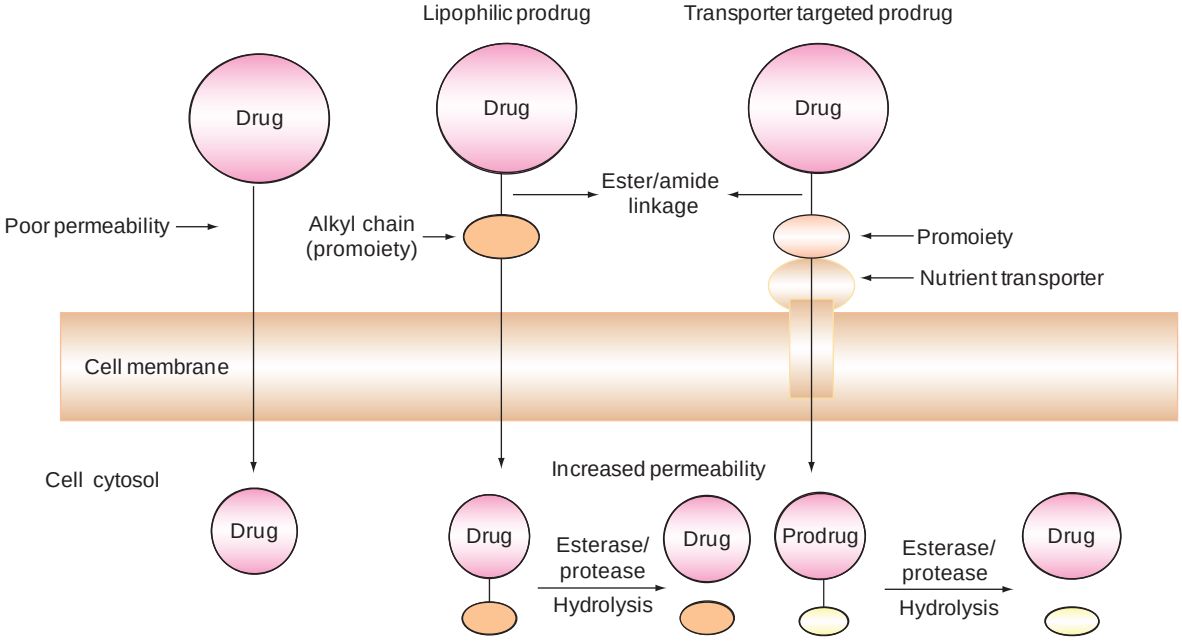

Figure 2 Schematic: Lipophilic and transporter targeted prodrug design.

peptides or peptide-based prodrugs. These enzymes are classified as either 'endo-' or 'exo-' depending on whether they cleave internal or external peptide bonds. The aminopeptidase activity is the highest in the corneal epithelium and iris-ciliary body followed by conjunctiva and corneal stroma.

Kashi and colleagues have shown that aminopeptidases, dipeptidyl peptidase, and dipeptidyl carboxylpeptidase are

involved in hydrolysis of enkhaphilins in rabbit ocular-tissue homogenates including conjunctiva, corneal stroma, iris ciliary body, lens, and tears.

Prodrugs targeted toward membrane transporters expressed on the epithelial cells are perhaps the most exciting of all the current drug-delivery strategies. Epithelial cells express various nutrient transporters and receptors on their membrane surface. Analogs or prodrugs targeted toward these transporters can significantly enhance the absorption of poorly permeating therapeutic agents. Such prodrugs are recognized by membrane transporters as natural substrates and are translocated across the epithelial membranes. Once inside the cell, the conjugate will release the parent drug by enzymatic hydrolysis (**Figure 2**). Various nutrient transporters are expressed on the cornea and conjunctiva. Their utility in drug delivery will be discussed in subsequent sections.

Role of Cornea in Topical Drug Delivery

Cornea is the outermost avascular and transparent dome-shaped structure of the eye. It consists of five layers (in the direction from anterior to posterior): epithelium, Bowman's layer, stroma, Descemet's membrane, and corneal endothelium (**Figure 3**). The lipoidal corneal epithelium is comprised of five to six layers of tightly adherent columnar cells with tight-junction proteins called zonulae occludens – acting as a major barrier to hydrophilic drugs. On the other hand, the stroma – which is comprised of 90% water – lies directly beneath the corneal epithelium and acts as a rate-limiting barrier to lipophilic drugs. Thus, even if a molecule is sufficiently lipophilic to rapidly cross the epithelium, penetration through the stroma is still rate limiting. In addition, the physicochemical properties of the drug itself limit its permeability across the cornea. More recently, the expression of multidrug resistance proteins such as the P-glycoprotein (P-gp) and multidrug-resistance-associated proteins (MRPs) has been reported on rabbit and human corneal epithelium. They have gained attention lately, since majority of the drug molecules applied topically have been categorized as substrates to one or more of these efflux pumps. In fact, P-gp and MRP-2- localized on the rabbit corneal epithelium can act as a barrier to *in vivo* drug absorption through cornea.

Lipophilic prodrug derivatization has been considered as a viable strategy to enhance transcorneal permeation of ocular therapeutic agents. High octanol/water coefficient of these prodrugs can facilitate permeation across the corneal epithelium. The water-laden stroma, in turn, does not act as a barrier to the regenerated hydrophilic parent drug – thereby enhancing the overall permeability of the prodrug across cornea. Esterase activity has been reported to be the highest in iris-ciliary body followed by cornea and the aqueous humor. Even though high levels of esterases are reported in the iris-ciliary body, the activity in the cornea is highly relevant since cornea acts as a major permeation pathway to these lipophilic ester prodrugs. Bulk of esterase-mediated hydrolysis takes place in the corneal epithelium where the esterase activity is about 2 times to that of stroma and endothelium.

Lipophilic ester prodrug design has been employed for a variety of ocular therapeutic agents, which suffer from poor ocular absorption. Esterification of prostaglandin $F_{2\alpha}$

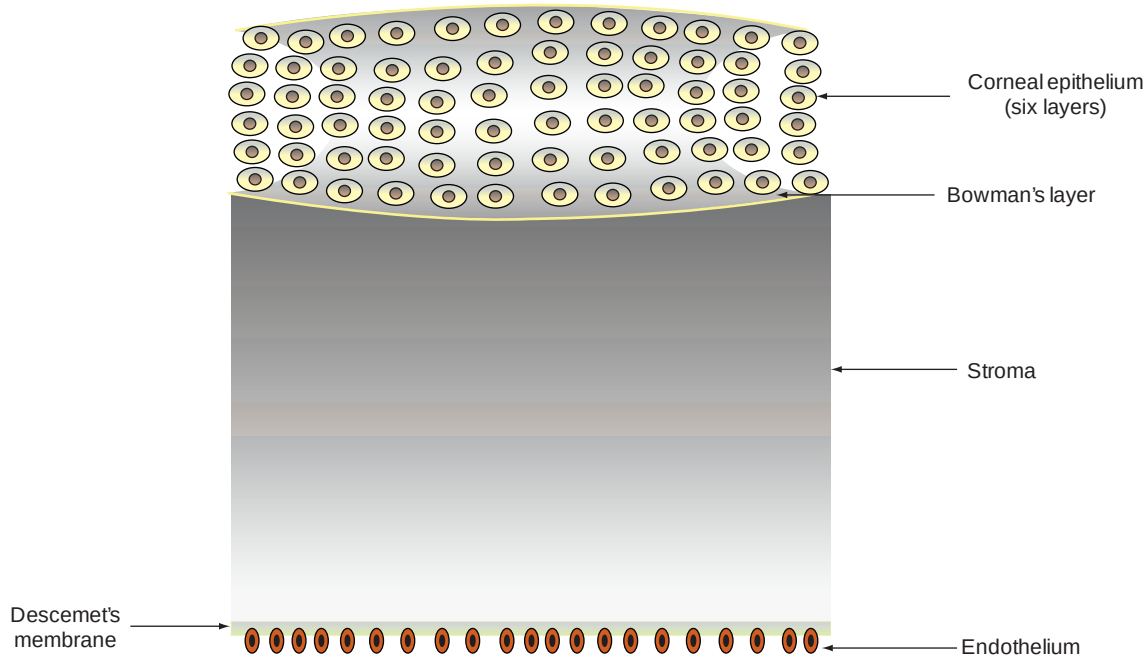

Figure 3 Structure of cornea.

($PGF_{2\alpha}$) analogs which exhibit higher potency than $PGF_{2\alpha}$ have resulted in blockbuster drugs such as bimatoprost, travoprost, latanoprost, and isopropyl unoprostone. Travoprost, latanoprost, and isopropyl unoprostone are isopropyl esters of $PGF_{2\alpha}$ analogs, whereas bimatoprost is an ethyl amide prodrug (**Figure 4**). The free acid form of all the above prodrugs has shown poor permeability across cornea, thus obviating the need for lipophilic ester prodrug design. Such strategy is particularly applicable to β-blockers such as timolol – widely used in the treatment of glaucoma – which suffers from high incidence of cardiovascular and respiratory side effects due to systemic absorption of the topically administered dose. Lipophilic prodrug derivatization of timolol to acetyl, propionyl, and butyryl ester prodrugs resulted in corneal permeabilities 2–3 times higher than timolol. Moreover, the enhanced corneal permeation leads to a four- to sixfold increase in the aqueous humor concentrations. Better corneal permeation and high aqueous humor concentration of lipophilic ester prodrugs of timolol consequently resulted in a twofold reduction in the topical dose. Reduced dose can, in turn, decrease the concentration in the systemic circulation, thereby reducing the incidence of cardiovascular and respiratory side effects.

The lipophilic ester prodrug design has been extended to antiviral agents such as acyclovir (ACV) and ganciclovir (GCV). These are highly potent against Herpes simplex virus (HSV). Currently available therapy for HSV keratitis involves the use of a 1%-trifluorothymidine (TFT) solution. However, long-term treatment with TFT raises potential concerns due to its high cytotoxicity. ACV is a potent candidate effective against HSV which is available as a 3% ophthalmic ointment. However, due to various problems associated with the use of ointments in the eye, it has not been approved in the United States. Ocular bioavailability of these compounds is extremely limited because of poor corneal permeability. Corneal permeability coefficients increase with increasing lipophilicity for monoester prodrugs of GCV, with the optimal prodrug form having three or four carbon atoms in the side chain. The apparent permeability (P_{app}) of the valerate-ester prodrug of GCV was sixfold higher than the parent drug GCV, across the cornea. Acylation of ACV also led to improved corneal permeation of the parent drug. There is a linear relationship between the corneal permeability coefficient and the octanol/water partition coefficient with a positive slope, except for ACV isobutyrate – which displayed an anomalously low corneal permeability despite improved lipophilicity. The anomaly with branched alkyl side chain could be explained due to enhanced stability of these prodrugs toward esterases present in the corneal epithelium. The branched side chain offers steric hindrance for enzyme accessibility. The concept has been proven where the stability of homologous series of oxprenolol esters increases with increasing carbon chain length of the side chain. It has been shown that hydrolysis rates are moderate for *O*-propionyl, *O*-butyryl, and *O*-valeryl prodrugs of oxprenolol, with *O*-acetyl-oxprenolol being highly unstable and *O*-pivaloyl-oxprenolol being highly stable (**Table 1**). Again, the steric hindrance offered by the bulky tertiary butyl group in the pivaloyl derivative has been cited as the primary reason for superior enzymatic stability. However, all of these prodrugs described above are highly lipophilic and possesses very low aqueous solubility to be formulated into aqueous drops for topical administration. Reports indicate that the aqueous solubility of the lipophilic ester prodrugs decrease with increasing carbon side-chain length. Low aqueous solubility has been considered as a major drawback for formulating these lipophilic ester prodrugs into eyedrops. Thus, for a compound to be effective topically and to be formulated into eyedrops, it must possess sufficient hydrophilicity and at the same time exhibit sufficient permeability across the cornea to reach therapeutic levels.

Recently, transporter-targeted prodrug approach has received significant attention and a number of membrane transporters have been discovered in various ocular tissues such as the cornea, conjunctiva, and retina. These transporters are involved in the translocation of essential nutrients and xenobiotics across biological membranes. Ocular transporters include carriers for peptides, amino acids, glucose, lactate, and nucleosides/nucleobases and are primarily localized on the corneal epithelium, corneal endothelium, retinal pigmented epithelium (RPE), and retinal capillary endothelium. Prodrugs or analogs designed to target these transporters can significantly enhance the absorption of poorly permeating parent drug. Both solubility and the desired membrane permeability can be achieved by proper selection of the promoiety. Such prodrugs are recognized by the membrane transporters as substrates and are translocated across the epithelia. Subsequently, the prodrugs are enzymatically cleaved to release the parent drug and free ligand which in most cases is a nutrient and nontoxic.

Of late, such transporter-targeted prodrug design has been applied to the antiviral drugs ACV and GCV. The existence of an oligopeptide transport system (PEPT1) on the rabbit corneal epithelium has been demonstrated which can transport peptidomimetic prodrugs of acyclovir. Permeation of valine-ester prodrug of acyclovir (L-Val-ACV) across the cornea has been found to be much higher than that of the parent drug ACV (**Table 2**). The transport of L-Val-ACV is saturable at higher concentrations, pH dependent, and competitively inhibited by other known PEPT1 substrates indicating its translocation by PEPT1 present on the cornea. This result prompted the investigators to synthesize a series of water-soluble dipeptide prodrugs of acyclovir targeting the peptide transport system on the cornea to improve the ocular bioavailability.

Data from Anand, B. S., Nashed, Y. E., and Mitra, A. K. (2003). Novel dipeptide prodrugs of acyclovir for ocular herpes infections: Bioreversion, antiviral activity and transport across rabbit cornea. *Current Eye Research* 26: 151-163, with permission from Taylor & Francis.

The structures of ACV, valine-based amino acid ester of ACV (VACV), and valine- and glycine-based dipeptide conjugate of acyclovir – valine–valine–acyclovir (VVACV) and glycine–valine–acyclovir (GVACV) are shown in **Figure 5**. VACV is found to be hydrolyzed primarily by esterases to release ACV, whereas VVACV is hydrolyzed initially by aminopeptidases to release VACV, which is further acted upon by esterases to release ACV (**Figure 6**). Direct conversion of VVACV to ACV appears to be minimal. These prodrugs exhibited excellent solution stability and solubility allowing formulation into suitable eyedrops. All dipeptide prodrugs of ACV exhibited enhanced transcorneal permeability resulting in higher ocular bioavailability in rabbits, with GVACV being the highly permeable prodrug (**Table 2**). The prodrugs also exhibit higher antiviral efficacy against HSV epithelial keratitis and stromal keratitis and are less cytotoxic and more effective than trifluorothymidine (TFT) – a current drug of choice.

In addition to peptide transporters, even amino acid transporters such as ASCT1 (Na^+-dependent neutral amino acid transporter) and $B^{0,+}$ (Na^+-dependent neutral and cationic amino acid transporter) have been explored for ocular delivery of ACV. A series of amino acid ester prodrugs including alanine-ACV, serine-ACV, isoleucine-ACV, γ-glutamate-ACV, and valine-ACV were synthesized and evaluated by Katragadda and colleagues for *in vivo* corneal absorption against the parent drug, ACV. Results showed that the amino acid-ester prodrug, serine-ACV – owing to its enhanced stability – exhibited higher area under the curve, C_{max} and C_{last} values, in comparison to ACV and seemed to be a promising candidate for the treatment of ocular HSV infections. Gunda and colleagues have applied similar chemical derivatization to GCV – an acyclic guanosine analog. GCV has shown to exhibit excellent antiviral activity against the herpes viruses but suffers from poor corneal permeability due to its hydrophilicity. Hence, in order to enhance the corneal permeability and ocular bio availability, dipeptide monoester prodrugs of GCV targeting the peptide transporter on the corneal epithelium were synthesized. Among the synthesized prodrugs, tyrosine–valine–GCV and valine–valine–GCV, exhibited significantly higher transcorneal permeability *ex vivo* and *in vivo* leading to higher ocular bioavailability when compared to GCV.

Role of Conjunctiva in Ocular Drug Delivery

Conjunctiva is a transparent, highly vascularized mucous membrane that covers the sclera and lines the inner surfaces of eyelids. It covers almost 80% of exposed ocular surface and is comprised of many small blood vessels and tiny secretory glands. These glands produce tear film that lubricates and protects the eye during its movement in the socket. Three different types of conjunctival membranes have been identified based on its location. Palpebral or tarsal conjunctiva is the one lining the eyelids. Bulbar or ocular conjunctiva is a semipermeable and colorless membrane covering the eyeball, over the sclera. Fornix conjunctiva is where the inner part of the eyelids and the eyeball meet. It is loose and flexible, allowing free movement of the lids and eyeball. The tissue consists of pseudostratified columnar epithelium rich in goblet cells and it contains ductules of main lachrymal gland, accessory lachrymal glands, and lymphoid follicles. The space between the palpebral and bulbar conjunctiva is called the conjunctival *cul-de-sac*. Conjunctiva is typically composed of two layers, an outer epithelium and underlying

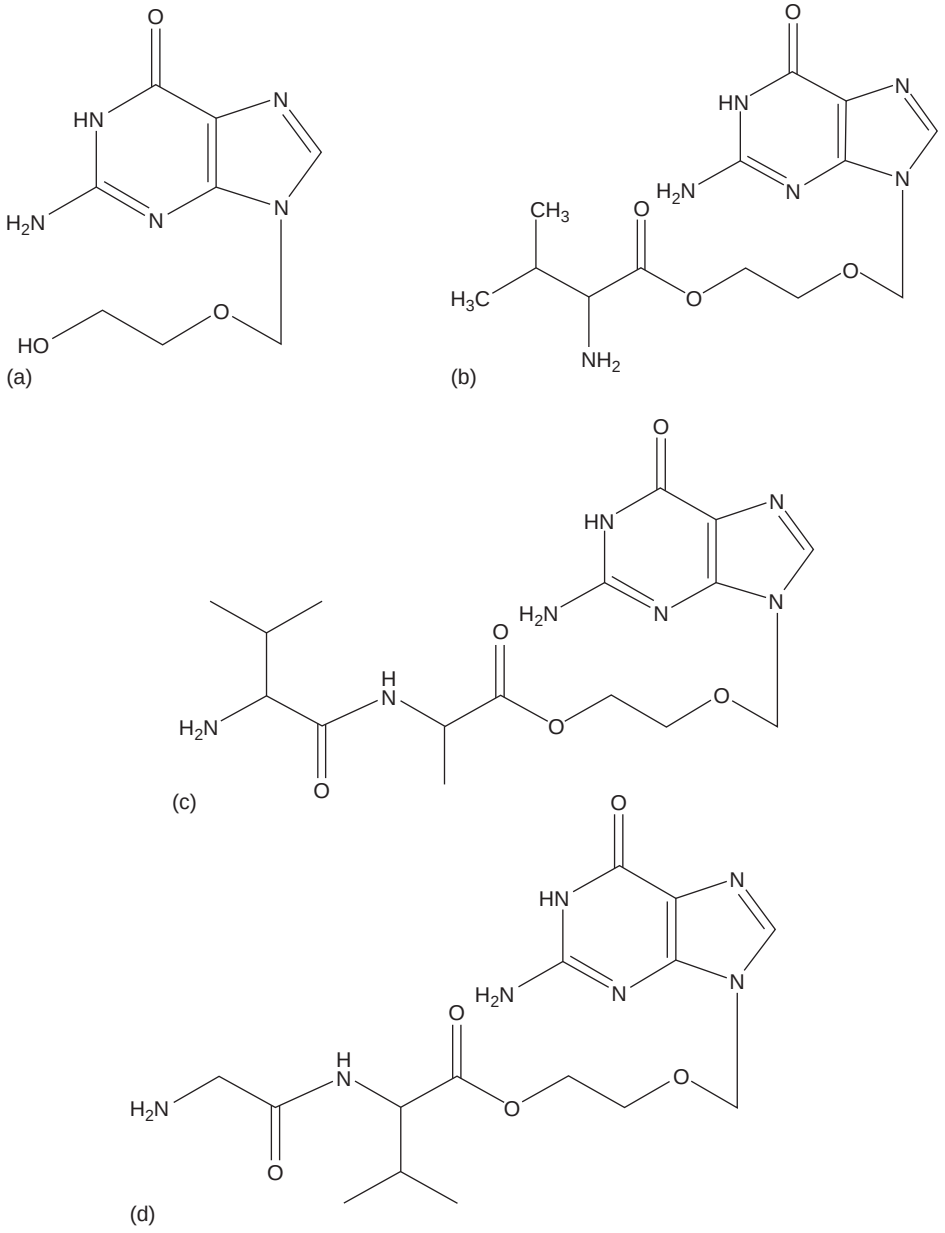

Figure 5 Chemical structures: (a) acyclovir, (b) valine–acyclovir, (c) valine–valine–acyclovir, and (d) glycine–valine–acyclovir.

stroma. The epithelium consists of 5–15 layers of stratified epithelial cells and is covered with microvilli. The stroma loosely attaches to the underlying sclera. It contains all the lymphatics and blood vessels.

The larger surface area and pore density coupled with expression of various nutrient transporters listed in the subsequent sections makes the conjunctiva more amenable for topical drug delivery. The surface area of the conjunctiva is almost 9 and 17 times larger than that of cornea in rabbits and humans, respectively. Compared to cornea, the paracellular pore size as well as the pore density in conjunctiva is larger. Due to such increased pore size and density small peptides and oligonucleotides can permeate across conjunctival pores. However, for hydrophilic drugs instilled topically, the lipophilic conjunctival epithelium acts as rate-limiting barrier for drug absorption. In addition, an external enzymatic barrier in the conjunctival epithelium – specifically the proteases – restricts the penetration of peptide drugs like enkephalins, substance P, and insulin. One of the major disadvantages associated with conjunctival absorption following topical administration is drainage of drug molecules by conjunctival blood vessels into the systemic circulation. Moreover, it has been shown that the conjunctiva expresses efflux transporters including P-gp on the apical side of conjunctival epithelium. These can limit the absorption of several

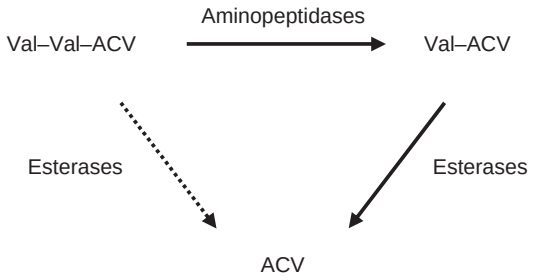

Figure 6 Metabolic pathway of valine–valine–acyclovir (VVACV) to valine-based amino acid ester of acyclovir (VACV) and acyclovir (ACV). From Anand, B. S., Nashed, Y. E., and Mitra, A. K. (2003). Novel dipeptide prodrugs of acyclovir for ocular herpes infections: Bioreversion, antiviral activity and transport across rabbit cornea. *Current Eye Research* 26: 151–163, with permission from Taylor & Francis.

fluoroquinolones such as levofloxacin, gatifloxacin, and grepafloxacin instilled topically. Thus, improving the drug absorption across conjunctiva is one of the major challenges needed to be overcome. Based on the target tissue, conjunctival drug delivery can be divided into subconjunctival and transconjunctival delivery.

Transconjunctival Pathway

In this route, agents can be targeted toward the conjunctiva for treatment of local conjunctival infection as well as other anterior chamber diseases such as dry eye syndrome and glaucoma. Transconjunctival absorption could also result in higher concentrations in posterior ocular tissues through conjunctival–scleral pathway. However, subconjunctival pathway is widely exploited to deliver drugs to posterior ocular segment.

Hydrophilic molecules can permeate through paracellular pathway between epithelial cells through the tight junctions. However, their penetration will be extremely low due to the small surface area of paracellular pathway compared to transcellular route. Transconjunctival drug penetration can be enhanced by increasing the lipophilicity of the drug molecule through chemical modification, mostly as prodrugs or analogs. Propranolol – with a log partition coefficient between octanol and water (log P) of 3.21 – is absorbed through cornea and conjunctiva up to tenfold greater than a hydrophilic drug of similar size, for example, sotalol with a log P of −0.62.

Prodrug strategy has not been exploited in conjunctiva as extensively as in cornea. As discussed earlier, *in vivo* activation of the prodrug is very essential for the success of this approach. As ester and amide linkages are widely utilized in prodrug design, it is important to know the activities of esterases and amidases in conjunctiva. As mentioned before, esterase and aminopeptidase activity has been reported in conjunctiva along with the cornea and iris-ciliary body. These play a role in hydrolysis of ester and amide bases prodrugs in the conjunctiva. The peptidases can also hydrolyze short-chain, biologically active peptides such as methionine and leucine enkephalins. There is good number of studies demonstrating esterases/amidases targeted prodrug approach to enhance drug absorption across conjunctiva. A few of them are discussed below.

PGs can lower intraocular pressure (IOP) in open-angle glaucoma. However, due to the low permeability of $PGF_{2\alpha}$ across the cornea, a relatively high concentration of $PGF_{2\alpha}$ is necessary for effective IOP reduction. This can result in conjunctival hyperemia, ocular discomfort, headaches, and other side effects. Chen and colleagues have evaluated lipophilic $PGF_{2\alpha}$ ester prodrugs for improving the permeability of $PGF_{2\alpha}$ following topical administration. A series of lipophilic esters such as $PGF_{2\alpha}$ 1-isopropyl, 1, 11-lactone, 15-acetyl, 15-pivaloyl, 15-valeryl, and 11, 15-dipivaloyl esters have been evaluated for transport and bioreversion in rabbit cornea, conjunctiva, and iris-ciliary body (**Figure 7**). All of the prodrugs penetrated the rabbit cornea and conjunctiva faster than $PGF_{2\alpha}$ except the 15-acetyl ester prodrug, which is equally permeable as $PGF_{2\alpha}$ across conjunctiva. However, a direct relationship is not observed between the degree of apparent permeability and prodrug lipophilicity. The two most lipophilic prodrugs – the 15-valeryl and 11, 15-dipivaloyl esters – were less permeable in the cornea and conjunctiva than other prodrugs with comparatively lower lipophilicity. The high permeabilities of 1-isopropyl ester and 1, 11-lactone is attributed to their state of ionization at the site of absorption where they exist more in unionized form. The prodrug 1, 11-lactone hydrolyzed at a slower rate in the ocular tissues probably due to the intracyclic ester linkage. The bulky pivaloyl group in 15-pivaloyl prodrug rendered it enzymatically more stable than the 1-isopropyl and other 15-monoester prodrugs. Bulky moiety (steric hindrance) might have impeded access of esterases to hydrolyze the pivaloyl ester linkage. Similarly, the prodrug with two pivaloyl groups – 11, 15-dipivaloyl prodrug – is much more stable as expected. Thus, the size and structural branching of the promoiety can influence enzymatic hydrolysis of prodrugs which, in turn, can further determine the permeability across tissues.

Corticosteroids find applications in the treatment of uveitis and postsurgical inflammation. However, these drugs can cause significant adverse effects such as increase in IOP, cataract, and herpetic reactivation. Dexamethasone (DX) is the one drug mostly indicated for ocular corticosteroid treatment. Several lipophilic esters of dexamethasone prodrugs have been evaluated for their ocular permeability and bioreversion in bovine conjunctival epithelial cell line (BCEC) and isolated rabbit cornea (**Figure 8**). This study is mainly aimed at selecting an optimum prodrug that improves the delivery of dexamethasone to the target tissue with minimum permeation across other

ocular tissues to reduce adverse effects. The permeability of these dexamethasone prodrugs correlated well with their lipophilicity until a maximum value is reached, which corresponded to dexamethasone butyrate (log $P = 3.95$). DSP and DSB prodrugs are hydrophilic and thus do not permeate across BCEC as expected. Other prodrugs exhibited higher permeability with increase in lipophilicity till DBU, after which it started to plateau as observed with DVA (**Figure 9**). A similar trend has been observed across the cornea with exceptions at the extreme ends of log *P* values (DSP and DVA) which has been attributed to the rate of hydrolysis of prodrugs in corneal tissue and BCEC an epithelial layer. DVA being highly lipophilic gets absorbed into corneal epithelium and its further permeation is limited by hydrophilic corneal stroma unless it is hydrolyzed to relatively more hydrophilic dexamethasone. However, the hydrolysis of DVA to dexamethasone is very poor in cornea, confining the prodrug in the corneal epithelium (**Table 3**). This may be optimum for delivery of dexamethasone to cornea, where the prodrug in the corneal epithelium can hydrolyze slowly and sustain the release. Thus, it reduces the drug concentrations in aqueous humor and other intraocular tissues minimizing its side effects. Unlike in BCEC,

DSP has been found to hydrolyze rapidly in the cornea creating a concentration gradient for higher absorption into cornea. DBU is the prodrug that is completely hydrolyzed both in BCEC and cornea and also has tremendously improved the permeability of dexamethasone. This may be more suitable prodrug to deliver dexamethasone to other intraocular tissues. These studies clearly show that both the promoiety as well as the ability of the prodrug to get hydrolyzed are important in designing an optimum prodrug in ocular drug delivery.

A series of alkyl, cycloalkyl, and aryl ester prodrugs of timolol has been evaluated to examine the effect of enzymatic lability of prodrugs on corneal and conjunctival penetration of timolol. Straight-chain alkyl and the unsubstituted cycloalkyl esters hydrolyzed more rapidly than their corresponding branched-chain and substituted analogs as well as the aryl esters. This might be due to free accessibility of the ester linkage to esterases in straight-chain alkyl esters. The slower hydrolysis of branched chain alkyl esters might be due to steric hindrance to hydrolyzing enzymes. As expected, the esters with enzymatically labile straight-chain alkyl chains penetrated the cornea and conjunctiva at faster rates than the esters with branched alkyl chains that are less labile toward enzymatic hydrolysis. Thus, this study has shown that the rate of enzymatic hydrolysis can highly influence the corneal/conjunctival absorption of prodrugs.

Carrier-mediated transport represents an area of growing interest to pharmaceutical scientists. These transport systems play an important role in absorbing nutrients as well as their mimetic drugs. Transporter-targeted prodrug delivery can be an effective strategy to improve the permeability of poorly absorbed drugs, as conjunctiva has been shown to express various transporters for nutrients such as amino acid, peptides, L-lactate, and nucleosides. These transporters can be utilized for improved drug absorption across the conjunctiva. However, such a strategy has not been explored to a large extent.

Functionally active sodium-dependent, carrier-mediated, monocarboxylate transport system has been reported on the mucosal or tear-side of the rabbit conjunctival epithelium. It has been shown to recognize and translocate nonsteroidal anti-inflammatory drugs (NSAIDs) and fluoroquinolone antibiotics administered topically. The conjunctiva expresses Na^+-glucose transporter (SGLT1) on the mucosal side and a sodium-dependent nucleoside transporter has been characterized that can be targeted by nucleoside mimetic antivirals on conjunctiva. Various amino acid-transporter systems including L-lysine and $B^{0,+}$ are present on the apical side of rabbit conjunctiva. Among various transporters exploited for drug delivery, peptide transporters (PEPT1 and 2) have become

popular due to their high capacity and wide substrate specificity. These play an important role in the translocation of di- and tripeptides and peptidomimetic drugs across various tissues. A proton-coupled dipeptide transporter process has been reported to be present on pigmented rabbit conjunctiva. A proton-coupled, saturable, and temperature-dependent uptake of a dipeptide on rabbit conjunctival epithelial cells (RCEC) was reported. However, the expression level of the dipeptide transporters seems to be rather low in conjunctiva. Overall, the presence of a variety of influx transporters on the conjunctiva offers an immense potential for targeted delivery after topical prodrug administration.

Subconjunctival Delivery

This approach of drug delivery is more popular and safer and less invasive than intravitreal injection. Moreover, it offers the potential advantage of localized, sustained delivery in the treatment of ocular diseases affecting the posterior segment such as age-related macular degeneration (AMD) and diabetic retinopathy. As this route can circumvent both the corneal and conjunctival barriers, it has immense potential for delivery of both small molecules and macromolecular drugs to posterior ocular tissues including choroid and retina. Moreover, sclera is much more permeable than conjunctiva. Drug delivery by this route exploits the large surface area, easy accessibility, and relatively high permeability of sclera. By this route, sustained intraocular therapeutic drug concentrations can be achieved without surgical implantation of controlled-release drug-delivery implant in the vitreous humor or by repeated intravitreal/periocular injections. In this regard, a subconjunctival injection of drug-loaded nanoparticulate system offers potential alternative. These systems can release the drug in a sustained manner as well as achieve higher drug concentrations in the target tissues. Drug-loaded nanoparticulate systems prepared with biodegradable polymers have been widely used in sustaining the drug release. Nanoparticles are usually taken up into the cell by endocytosis which will significantly enhance the uptake of nanoparticles into the targeted cells. Moreover, receptor-mediated endocytosis have attracted attention due to high capacity and targeting feasibility. Expression of various receptors by RPE will enable this strategy to be successfully applied for subconjunctival administration of receptor-targeted nanoparticles. In this strategy, a promoiety is conjugated to the polymer, which is used to prepare these nanoparticles. It is also ensured that these targeting promoieties are present on the surface of nanoparticles, such that it is recognized by a specific receptor present on the RPE and undergo receptor-mediated endocytosis. Thus, drug loaded nanoparticles improve drug absorption into RPE, enable targeting, and sustain the release for prolonged periods of time.

In addition to this, a sustained drug release can also be achieved by dispersing the drug/prodrug in a thermosensitive gelling polymer. These are the polymers that are liquids at room temperature and gels at body temperature. Drug/prodrug can be mixed homogenously in the polymer solution and injected subconjunctivally. Upon injection, the polymer solution gels and sustains the release of drug. The drug loading and release can be optimized to maintain therapeutic concentrations for prolonged periods of time.

Conclusion

Prodrugs have proven to be an effective strategy for drug delivery to the anterior segment. Several examples of successfully marketed ophthalmic prodrugs including dipivalyl ester of epinephrine (dipivephrine) are available. In addition, ester prodrugs of PGF2α analogs such as bimatoprost, travoprost, and latanoprost are highly effective. However, the application of this strategy to a particular drug molecule depends upon its chemical structure. The drug molecule needs to have a specific functional group such as carboxyl/hydroxyl/amine group to facilitate the conversion to an ester or amide-based prodrug. Despite this, a significant amount of research needs to be performed to examine the feasibility of extending the prodrug strategy to deliver macromolecular drugs like proteins and antibodies which have been highly effective in treatment of various ocular diseases, especially the AMD.

Dry Eye: An Immune-Based Inflammation

M E Stern, Allergan Inc, Irvine, CA, USA
S C Pflugfelder, Baylor College of Medicine, Houston, TX, USA

Glossary

Autoimmunity – An immune response of an organism against any of its own tissues, cells, or cellular components. Diseases, such as rheumatoid arthritis, systemic lupus erythematosus, multiple sclerosis, and dry eye are considered autoimmune based.
CD4+ T cells – T helper cells (T_h), a subgroup of lymphocytes that play an important role in establishing and maximizing the capacity of the immune response against invading extracellular pathogens, for example, bacteria and parasites. The CD4+ T cells bearing T-cell receptors that recognize self-antigen, that is, autoantigen, contribute to the immunopathogenesis of several autoimmune diseases, for example, rheumatoid arthritis, multiple sclerosis, and dry eye.
Dry eye – An ocular surface immune-based inflammatory disease resulting from an unstable tear film composition mediated by dysfunction of a complex Lacrimal Function Unit (LFU: cornea, conjunctiva, lacrimal glands, and meibomian glands), which causes damage to the interpalpebral ocular surface and is associated with symptoms of ocular discomfort. Dry eye is also known as lacrimal keratoconjunctivtis (LKC) and most recently, dysfunctional tear syndrome (DTS).
Desiccating stress (DS) – Following exposure to DS in low humidity (<40%) mice display similar clinical and histopathological features to human patients with dry eye, including rapid and coordinated upregulation of proinflammatory cytokines, decreased tear production and goblet cell number, surface epithelial apoptosis, and increased cellular infiltration, for example, CD4+ T cells into the LFU.
Goblet cells – Glandular simple columnar conjunctival epithelial cells that function to secrete mucus.
Lacrimal glands – Glands located in the upper, distal portion of the orbit of each eye that secrete the aqueous layer of the tear film.
Lacrimal function unit (LFU) – The lacrimal functional unit is composed of the lacrimal glands (both main and accessory), the ocular surface (cornea, conjunctiva, goblet cells, and meibomian glands), and the interconnecting innervation that coordinates afferent (ocular surface to the brain) and efferent (brain to the ocular surface tissues and associated glands) signals. The LFU is responsible for maintaining the quantity and quality of the tear fluid.
Meibomian glands – Sebaceous glands at the rim of the eyelids responsible for the supply of sebum, an oily substance that prevents evaporation of the eye's tear film.
MHC class II (major histocompatability complex class II) – This is responsible for presenting antigen fragments to T helper cells by binding exclusively to the T-cell receptor present of the surface of CD4+ T cells. The MHC class II is involved in presentation of antigen derived from extracellular pathogens, thus providing specificity for the generation of adaptive immunity. The MHC class II molecules bearing self-antigen (autoantigen) may trigger activation of autoreactive CD4+ T cells and autoimmunity.

Defining the Problem

Epidemiology of Dry Eye

In 1993 the National Eye Institute (NEI)/Industry workshop formally defined dry eye as a "disorder of the tear film due to tear deficiency or excessive evaporation, which causes damage to the interpalpebral ocular surface and is associated with symptoms of discomfort." Recently, we and others proposed a more comprehensive definition of dry eye based on the increasing evidence demonstrating that ocular surface immune-based inflammation and ocular surface epithelial diseases result from dysfunction of a complex Lacrimal Function Unit (LFU) and the resultant unstable tear film. To provide guidelines for selection of treatment, the Delphi panel of experts coined the term dysfunctional tear syndrome (DTS) based on symptoms and signs (not tests) of dry eye disease.

Dry eye is a highly prevalent condition and one of the leading causes of visits to ophthalmologists and optometrists in the United States. Epidemiologic studies have reported that dry eye affects up to 11% of people 30–60 years of age and 15% of those 65 years of age or older. As many as 12 million Americans have moderate to severe dry eye and this number is likely to increase as the population ages. Dry eye affects 0.1–33% of the worldwide population; the wide range of variability is dictated by the study and diagnostic criteria used.

Dry Eye Syndrome in Peri- and Post-menopausal Women

Dry eye is more common in women than men (2:1) and the incidence increases with age. The role of sex hormones in dry eye has been reported in several studies. For example, data from 36 995 female health professionals ranging from age 49 to 89 years old (estimated at least 3.2 million (or 7.8%) women aged 50 years and older) suffer from dry eye disease in the US. The incidence appears to be higher among older women (9.8%, $\geq$75 years) than women under 50 years of age (5.7%). The incidence of clinically significant rosacea is also higher among aging females and occurs in approximately 30% of menopausal women. In fact, it is predicted that up to 75% of peri-menopausal women with facial rosacea will develop ocular involvement.

Estrogen may have detrimental effects on the tear film and could influence the development of dry eye; although the ratio between estrogens and androgens may be a better indicator. It was reported that women who receive hormone replacement therapy, especially with unopposed estrogen therapy, have an increased risk of developing dry eye disease. On the other hand, androgen deficiency and/or imbalance in estrogen–androgen levels are also associated with dry eye. Along these lines, androgen deficiency as seen in Sjögren syndrome and Sjögren's syndrome keratoconjunctivitis sicca (KCS) occurs almost exclusively in women. Furthermore, women who suffer from premature ovarian failure lack both estrogens and androgens and exhibit more ocular surface damage and dry eye-related symptoms than age-matched controls.

Patients on Anti-androgen Therapy

Androgenic hormones play an important role in supporting the secretory immune function of the lacrimal glands and meibomian glands. The meibomian glands are the main androgen target organs on the ocular surface. Androgen deficiency that may occur during menopause, aging in both sexes, autoimmune disorders (e.g., Sjögren's syndrome, Systemic Lupus Erythematosus, rheumatoid arthritis, RA), complete androgen insensitivity syndrome (i.e., women with dysfunctional androgen receptors, congenital androgen insensitivity syndrome), and the use of anti-androgen medications (e.g., for prostatic cancer or hypertrophy) is associated with meibomian gland dysfunction, tear film instability, and a significant increase in dry eye signs and symptoms. Studies showed that anti-androgen treatment is paralleled by significant changes in the fatty acid profiles of neutral lipid fractions in meibomian gland secretions. Conversely, treatment with androgens has been reported to alleviate dry eye conditions and stimulate tear flow in Sjögren's syndrome patients.

Clinical Features of Dry Eye

Chronic Pain

Ocular surface neuropathy in dry eye

Ocular surface pain and discomfort in severe sicca disease may partially result from the well-documented neuropathy associated with Sjögren's syndrome, which is categorized with the neuropathies associated with connective tissue disease. Indeed, clinical evidence has shown that peripheral sensory neuropathy may be an important presenting sign for Sjögren's patients. In accordance, ocular surface discomfort is often the initial motivation for dry eye patients to visit the ophthalmologist. In affected individuals, ganglioside-specific antibodies are found in peripheral nerves, dorsal root ganglia, and dorsal roots, and inflammatory cells are localized within the ganglia. Although the trigeminal system has not been studied in as much detail, the ocular surface discomfort of dry eye may be a form of sensory neuropathy; however, this theory requires confirmation. Small diameter myelinated and unmyelinated axons in the cornea are potential targets for peripheral nerve disorders, and inflammatory cells infiltrating the ocular surface are well documented in dry eye. These cells, in combination with ganglioside-specific antibodies and other neural proteins, could cause local degeneration of small diameter axons and axon terminals. Cranial neuropathies may be more common in Sjögren's syndrome than is currently recognized, and the dysthesias associated with the cornea may indicate an inflammatory neuropathy within the trigeminal system.

Comorbidities

Patients with lacrimal keratoconjunctivitis (LKC) typically experience ocular discomfort. The most common symptoms include scratchiness, grittiness, foreign body sensation, burning, and itching; these symptoms are exacerbated by prolonged visual activity (e.g., viewing a video display terminal) and environmental stresses, such as low humidity and air drafts. The LKC patients often complain of blurred and fluctuating vision that stimulates increased blink frequency, an unconscious response to clear the visual field. Together, these symptoms contribute to severe ocular fatigue and many patients report that they are unable to read or concentrate for more than a few minutes at a time.

Also, LKC can cause considerable ocular morbidity. The thinned and unstable precorneal tear layer and the altered corneal epithelial barrier function that accompany LKC are major risk factors for sterile keratolysis (loss of uppermost layer of cells in cornea) and microbial keratitis (infection of the cornea). Severe and recurrent corneal ulceration mediated by LKC can ultimately lead to reduced vision, blindness, and in severe cases, loss of the eye.

Pre-existing LKC is an important cause of complications following corneal surgery. Complications include

penetrating keratoplasty and LASIK, and may lead to decreased vision, pain, epithelial and stromal wound healing problems, haze, ulceration, and predisposition to microbial infections. Surgical amputation of the corneal sensory nerves that drive glandular secretion, a direct consequence of LASIK and other refractive procedures, negatively impacts the integrated ocular surface secretory gland functional unit. This exacerbates pre-existing LKC and most likely results in new cases of dry eye.

Quality of Life Impact

The LKC symptoms significantly impact quality of life documented by utility scores. Utility scores quantify how many years a subject would give up from the end of his/her life in exchange for avoiding a particular malady. Utility scores for dry eye were found to be similar to those from patients with angina. The chronic and unremitting nature of dry eye syndrome can lead to despair, depression, decreased productivity, and in some cases permanent job disability. The physical and psychological impact of LKC symptoms is similar to that experienced by patients with other chronic regional pain syndromes, such as those affecting the lower back.

How We Secrete Normal Tears

The Lacrimal Functional Unit

The ophthalmic pathology seen in Sjögren's syndrome and chronic dry eye surrounds an immune-based inflammatory disruption of the LFU (**Figure 1**). The LFU is composed of the ocular surface (cornea, conjunctiva, conjunctival blood vessels), the lacrimal glands (main and accessory (Wolfring and Krauss)), and the interconnecting innervations (V, VII). This tear secreting reflex is also modulated by hormonal and immune factors. The role of the LFU is to secrete a precise tear film composition that maintains a homeostatic environment around the epithelial cells of the ocular surface.

The general role of the LFU in homeostasis and disease

The purpose of the tightly controlled ocular surface environment is to preserve corneal clarity and vision. The main and accessory lacrimal glands, the corneal limbus, and the meibomian glands provide the vital supportive function to protect the sensitive epithelial surfaces of the conjunctival and corneal tissues from environmental injury that results in pain and decreased visual acuity. The

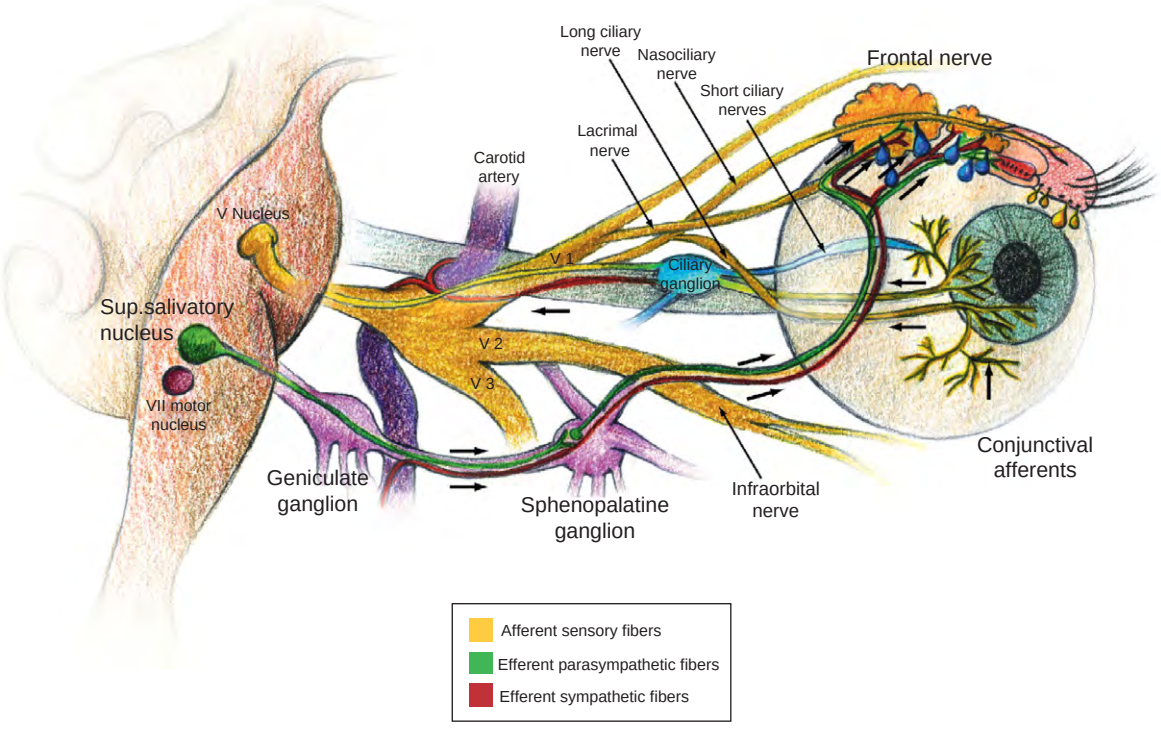

Figure 1 The lacrimal functional unit. Subconscious stimulation of the free nerve endings within the cornea generates afferent nerve impulses through the ophthalmic branch of the Trigeminal Nerve (V) to the midbrain (pons). The afferent signals are integrated in the midbrain and then travel via the efferent branch through the pterygopalatine ganglion, terminating in the main and accessory (Wolfring and Krause) lacrimal glands. Evidence suggests that this pathway also controls secretion from meibomian glands and conjunctival goblet cells. Proper function of the LFU supports homeostasis on the ocular surface by controlling secretion of the three major tear film components (mucin, aqueous, and lipid) to maintain the optimal quantity and quality of tear fluid; however, dysfunction of the LFU may lead to altered tear film composition and dry eye disease.

function of the LFU is to control secretion of tear constituents that help sustain a stable, anti-infective, and epithelial supportive tear layer essential for optimal optical performance. Signals emanating from ocular surface sensory nerves supply continuous input into the CNS that tells the brain what changes are occurring within the ocular surface milieu. The brain then sends signals to the specialized support tissues, for example, lacrimal and meibomian glands that are programmed to secrete the optimal tear quantity and composition.

The process by which normal tears are secreted is initiated following corneal nerve stimulation. The process occurs unconsciously and in response to many stimuli; however, environmentally induced dry spot formation is thought to be among the most common. Out of necessity for survival, evolution has shaped the cornea to become the most densely sensory nerve innervated epithelial surface in the body. Conduction of pain originates from myelinated and unmyelinated nerves that terminate in the cornea, limbus, and conjunctival epithelium. Neural receptors in the cornea are free nerve endings that terminate in all of the corneal epithelial layers and are protected from direct irritation by zonula occludens and the tear mucin gel. Afferent (ocular surface to the brain) nerve traffic through the ophthalmic branch of the Trigeminal Nerve (V) enters the central nervous system in the area of the pons (midbrain) and the para spinal sympathetic tract. These signals are integrated with cortical and other inputs and are then transmitted to the efferent (brain to ocular surface tissues and associated glands) secretomotor impulses resulting in secretion of the homeostatic tear-film components.

Tear secretion by the lacrimal gland also occurs in response to neural stimulation. The acini, ducts, and blood vessels of the lacrimal gland are innervated by parasympathetic, sympathetic, and sensory nerves. The initial signal originates from the parasympathetic cholinergic nerves via acetylcholine release, which then binds to M_3 muscarinic acetycholine receptors on the basolateral cell membrane of secretory epithelia. At the same time, vasoactive intestinal peptide (VIP) binds to VIPergic receptors, and norepinephrine, a sympathetic neurotransmitter binds to α_1- and β-adrenergic receptors. Neural innervation of the accessory lacrimal glands has also been reported and fibers positive for CGRP and substance P are associated with secretory tubules, interlobular and excretory ducts, and blood vessels. However, the degree of neural influence over accessory lacrimal glands is still being elucidated.

Sensory, sympathetic, and parasympathetic neuropeptides are present in the ocular surface tissues and associated glands. Conjunctival goblet cells have a secretory response to the parasympathetic cholinergic muscarinic output from the pterygopalatine ganglion. Goblet cells express M_3-muscarinic receptors on their membranes. The M_1 and M_2 receptors are located throughout the conjunctiva. The presence of α_{1A}- and β_3-adrenergic receptors on conjunctival goblet cells suggests the presence of sympathetic innervation. In addition, transmission electron microscopy of meibomian glands revealed the presence of unmyelinated axons with granular and agranular vesicles. Substance P- and CGRP-positive axons have also been identified, but their function is uncertain, as these neurological peptides would be expected to conduct information into, rather than away from, the CNS. It is predicted that parasympathetic fibers innervating the meibomian glands are indeed present at higher levels. Parasympathetic neurotransmitters neuropeptide Y and VIP have been found around the meibomian glands, as well as tyrosine hydroxylase in sympathetic axons, implicating that both types of autonomic nerves may play an important role in stimulating lipid secretion onto the ocular surface.

Patients with LKC commonly complain of constant corneal sensations normally described as a gritty, sandy, or itchy. These complaints are usually accompanied with a pathophysiological state that indicates a chronic state of inflammation and a disadvantageous change in tear film composition. Infiltrating inflammatory cells within the ocular surface tissues have been reported in dry eye. These inflammatory cells, in addition to ganglioside-specific antibodies and other neural proteins, may result in regional degeneration of small diameter axons and their terminals. Chronic dysfunction of the LFU results in a shift toward inflammation and persistent psychological distress.

Events on the Ocular Surface

Environmental Impact on the Ocular Surface

The immune response is designed to defend against stress and/or microbial assaults on the ocular surface and paradoxically may also contribute to autoimmunity. Along these lines, regulatory mechanisms have evolved to modulate the afferent and efferent arms of the immune response to preserve tissue and limit activation of autoreactive lymphocytes following acute inflammation. The afferent events leading to cellular immunity include antigen processing and presentation by ocular surface antigen presenting cells (APCs) and migration of these cells to the draining lymph nodes. Afferent immune processes are modulated by a wide variety of anti-inflammatory factors that include cellular, for example, T regulatory cells (Tregs), and diffusible factors, for example, transforming growth factor beta (TGF-β) and interleukin (IL)-1 receptor antagonist, that favor protective immunity without breaking self-tolerance. The afferent arm of the immune response dictates the efferent response, the phase involved with antigen driven homing of primed and targeted lymphocytes to tissue-specific inflammatory sites. The efferent response is initiated in the secondary lymphoid organs and amplified on the ocular surface via

cell-to-cell interactions between lymphocytes and APCs; activation and differentiation of lymphocytes and migration to the ocular surface is tightly regulated to control the efferent immune response. Indeed, immunoregulation on the ocular surface is the result of the coordinated effort between a wide variety of immune players. However, when these mechanisms are compromised the ocular surface may become susceptible to chronic and/or autoimmune-mediated ocular disease, such is the case with dry eye.

Afferent arm of the immune response: immunoregulation

Redundant mechanisms regulate the afferent immune response to guard against activation and infiltration of autoreactive lymphocytes to the ocular surface tissues. For instance, there is a predominance of intraepithelial lymphocytes, for example, CD4+/CD8+Tregs and gamma delta T cells in the normal conjunctival epithelium; these cells are thought to harbor immunoregulatory functions similar to those found in other mucosal tissues, such as the intestine. The conjunctiva and cornea are also covered by mucin, which forms a barrier, guarding against unwarranted infiltration of inflammatory cells into the epithelium. Furthermore, the cornea lacks lymphatic and blood vessels, mature APCs, and resident T cells, thereby reducing the incidence of chronic inflammation and bystander cell damage on ocular surface following an acute inflammatory insult.

The tear fluid also contains high concentrations of soluble immunoregulatory factors that help maintain homeostasis before, during, and after environmental challenge. For example, androgenic hormones provide an immunosuppressive umbrella to help protect the secretory function of the lacrimal and the meibomian glands. In addition, the corneal epithelium expresses vascular endothelial growth factor (VEGF) receptors that function in part to sequester soluble VEGF, which ultimately reduces the stimulus for neovascularization after ocular surface challenge. Neurotrophic factors produced by the limbal corneal epithelia, such as glial cell line-derived neurotrophic factor (GDNF) also appear to have immunoregulatory activity. Transforming growth factor beta (TGF-β), a cytokine that can inhibit the function of APCs and effector T-cell proliferation, is secreted by goblet cells and is found in high levels within the tear fluid. Indeed, the presence of TGF-β may bias conjunctival APCs to activate Tregs instead of effector T cells, thereby preventing the activation/infiltration of autoreactive T cells. In addition, interleukin 1 receptor antagonist (IL-1RA) mutes the effects of the potent proinflammatory cytokine IL-1. The action of tissue inhibitor of matrix metalloproteinase (TIMP-1) inhibits matrix metalloproteinases (MMPs), which play a dominant role in promoting immune cell infiltration into ocular surface tissues during inflammation.

Efferent arm of the immune response: immunoregulation

The efferent arm of the immune response includes several mechanisms to prevent spurious activation and infiltration of autoreactive lymphocytes to the ocular surface during acute inflammation. It is critically important that the immune response is sufficient to eliminate the current threat, and then tempered to avoid chronic inflammation and tissue destruction. Similar to the afferent arm, recent studies have shown that the efferent arm of the immune response is also regulated by the concerted effort of Tregs, anti-inflammatory cytokines, and other factors vital for preventing autoimmunity.

Activation and differentiation of CD4+ and CD8+ Tregs in the secondary lymphoid organs are critical for limiting bystander tissue damage and maintaining self-tolerance and are emerging as important efferent immune modulators in the eye. Indeed, CD4+ Tregs present in C57BL/6 mice decrease clinical and histopathological disease in a mouse model of dry eye, which are exacerbated when mice are depleted of CD4+CD25+FoxP3+ Tregs. In addition, *in vitro* expanded CD4+CD25+Foxp3+ Tregs mute ocular surface inflammation in a Th1-mediated adoptive transfer model of dry eye disease. These data suggest that CD4+CD25+ Tregs present in the secondary lymphoid organs and ocular surface tissues inhibit the pathogenic effect of autoreactive effector T cells in an effort to maintain homeostasis.

Restricted homing of effector T cells from the regional lymphoid organs to the ocular surface also facilitates immunoregulation following acute insult. For example, the programmed death ligand-1 (PD-L1) has been implicated in protecting the ocular surface from unwanted T cell infiltration and tissue injury. The PDL-1 is a negative regulator of T-cell activation; the interaction between PDL-1 and the PD-1 receptor (expressed on activated T cells) inhibits lymphocyte proliferation and cytokine secretion. Furthermore, PD-1-deficient mice develop spontaneous autoimmunity. The PDL-1 is expressed constitutively on the ocular surface and is upregulated in both human cell lines stimulated with proinflammatory cytokines and in patients with ocular inflammation. In a mouse model of corneal allograft transplantation, PDL-1 was shown to promote apoptosis of the infiltrating CD4+ and CD8+ T cells that was associated with sustained corneal allograft survival. By contrast, PDL-1 blockade resulted in increased lymphocyte infiltration within the ocular surface tissues and enhanced allograft rejection.

Exactly where and how CD4+ and CD8+ Tregs exert their regulatory affects is a current area of intense research. Activation and differentiation of antigen-specific Tregs is mediated by interaction with APCs within the lymphoid organs and is influenced by the local cytokine milieu. It is clear that CD4+ Tregs are involved in suppressing inflammation on the ocular surface; however, the underlying

mechanisms driving activation and differentiation of these cells are currently unknown. Following ocular surface insults, it is suspected that Tregs function to suppress inflammation by dampening T-cell priming in the lymphoid organs, and inhibit T-cell effector function within inflamed ocular surface tissues. The immunosuppressive properties of Tregs are likely to occur by cell contact-dependent, for example, Treg:APC and/or Treg:T cell, and cell contact-independent mechanisms, that is, anti-inflammatory cytokine production. One possibility is that CD4+ Tregs temper the inflammatory response on the ocular surface by secreting TGF-β and IL-10, which may bias APC-mediated activation and differentiation of other regulatory lymphocytes in the lymphoid tissue and/or decrease Th1-mediated inflammation locally within ocular surface tissues.

Afferent arm of the immune response during autoimmune-based inflammation

During dry eye the afferent arm of the immune response is initiated following environmental stress-mediated desiccation and/or increased tear osmolarity (**Figure 2**). The initial response disrupts the protective barrier by promoting proteolysis of tight junction proteins and alters the pattern of epithelial differentiation towards squamous metaplasia and decreased mucus production. Osmotic stress activates signaling pathways in a variety of cell types, including the ocular surface epithelia. Exposure to increased osmolarity *in vivo* or *in vitro* activates mitogen-activated protein kinase (MAPK) pathways, including p38 and c-Jun N-terminal kinases, and nuclear factor (NF)-κB in the ocular surface epithelia; desiccating and osmotic

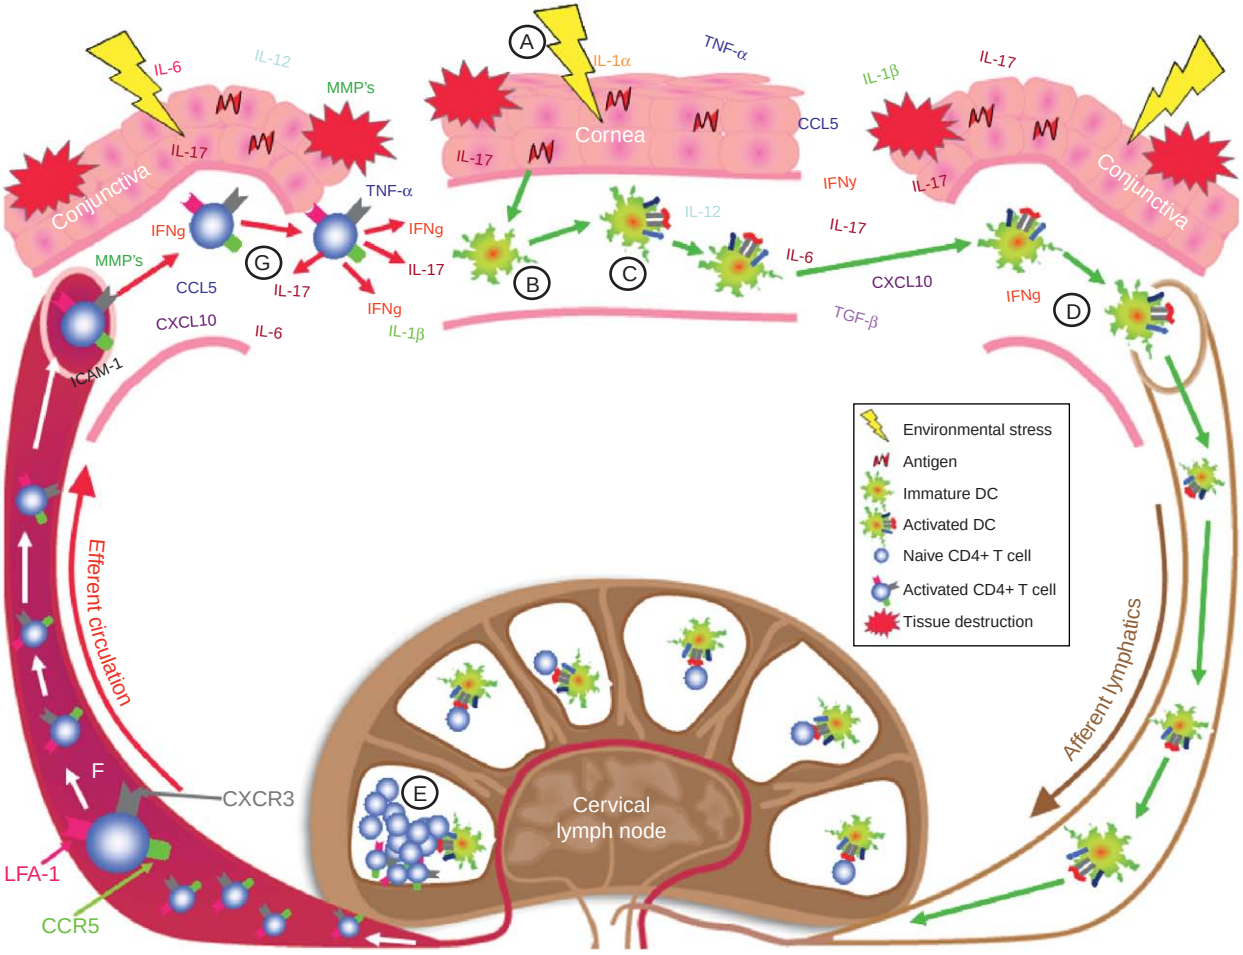

Figure 2 Autoimmune cycle of chronic inflammation during the immunopathogenesis of dry eye disease. Afferent arm of the immune response: (a) An environmental stimulus initiates acute inflammation on the ocular surface stimulating upregulation of proinflammatory cytokines (e.g., TNF-α, IL-1α and IL-1β), matrix metalloproteinases (MMPs), adhesion molecules (e.g., ICAM-1), and chemokines (e.g., CCL5 and CXCL10) within the conjunctival and corneal epithelium that act in concert to perpetuate the immune response; (b) Antigen presenting cells (e.g., dendritic cells) process autoantigen and (c) following activation, (d) traffic to the draining cervical lymph nodes (CLNs) via the afferent lymphatics, where they (e) present antigen to autoreactive CD4+ T cells. Efferent arm of the immune response: (f) Activated CD4+ T cells bearing specific adhesion molecules and chemokine receptors (e.g., CCR5 and CXCR3) migrate specifically to the ocular surface tissues (conjunctiva and cornea are shown), including the meibomian and lacrimal glands where they infiltrate the tissue and (g) release proinflammatory cytokines (IFN-γ and IL-17) that promote chronic inflammation and tissue destruction.

stress-mediated MAPK activation stimulates corneal epithelial cells to produce of a variety of proinflammatory mediators. In addition, the altered barrier facilitates diffusion of soluble inflammatory factors into the epithelium and stroma and inflammatory cell infiltration into the ocular surface tissues.

Exposure to desiccating stress (DS) initiates ocular surface epithelial cells to release proinflammatory cytokines and chemokines (e.g., IL-1β, TNF-α, IFN-γ, IL-8, CXCL10, MMP-1, -3, -9, -10, and -13). For instance, IFN-γ upregulates the adhesion molecule ICAM-1 expression within the epithelium, stromal fibroblasts and vascular endothelium, and increases vascular permeability in animal models and patients with non-Sjögren's or Sjögren's syndrome-mediated dry eye. Indeed, effector CD4+ T cells express high levels of lymphocyte function-associated antigen 1 (LFA-1), the cognate binding partner to ICAM-1. The upregulation of adhesion molecules on T cells and endothelial cells coupled with increased vascular permeability results in peripheral immune cell infiltration. The IL-1α and IL-1β levels are also elevated in the tears and conjunctiva from Sjögren's syndrome-associated tear deficiency patients and in a mouse model of dry eye. The IL-1 also induces upregulation of adhesion molecules localized on endothelial cells and stimulates expression of chemokines, which act in concert to facilitate leukocyte infiltration. The TGF-β-dependent suppression of DC activation is also compromised as TGF-β2-secreting conjunctival goblet cells undergo apoptosis during the immunopathogenesis of dry eye. Along these lines, IL-1 and TNF-α also activate immature APCs in the cornea and conjunctiva, which results in increased expression of MHC class II antigens, co-stimulatory molecules, VEGFr3, and CCR7. These molecules act together to coordinate APC migration to the draining lymph nodes and activation of effector T cells that drive the efferent arm of the immune response.

Efferent arm of the immune response during autoimmune-based inflammation

The efferent arm of the immune response is mediated by autoreactive T cells that (1) are activated within secondary lymphoid tissue via cell-to-cell contact with ocular surface-derived APCs, (2) are targeted to ocular surface tissues by acquisition of trafficking molecules and chemokine receptors, and (3) compromise the integrity of the ocular surface and contribute to prolonged inflammation (**Figure 2**). During the immunopathogenesis of dry eye, activation of autoreactive CD4+ T cells is thought to be driven within secondary lymphoid tissue by ocular surface-derived dendritic cells bearing self-antigen presented in the context of MHC class II. This theory is well supported by animal studies demonstrating that CD4+ T cells from the cervical lymph nodes of dry eye mice specifically home to the ocular surface tissue and mediate dry eye disease when adoptively transferred to athymic nude recipient mice. Importantly, DS-specific CD4+ T cells are not detected in any other tissues indicating that these cells are targeted to the ocular surface during activation within the secondary lymphoid organs.

Tissue-specific targeting of autoreactive T cells occurs within secondary lymphoid organs and is dictated by interactions between adhesion molecules and chemokine receptors that bind and respond to ligands expressed locally within inflamed tissues. Expression of LFA-1 on the T cells from patients with non-Sjögren's or Sjögren's syndrome-mediated dry eye and high-level ICAM-1 expression within ocular surface tissues of these patients suggest that LFA-1:ICAM-1 binding contributes to T-cell infiltration. Chemokine receptor signaling also appears to contribute to efferent homing of autoreactive T cells during dry eye disease. Elevated expression of the chemokine receptors CCR5 and CXCR3 and the chemokine ligands, CCL3, CCL4, CCL5, CXCL9, and CXCL10 has been detected within the cornea and conjunctiva of dry eye mice. In addition, CCR5 is also expressed on cells within conjunctival epithelium of patients with dry eye and CCL5 and CXCL10 are upregulated in human conjunctival epithelium cells in response to cytokine stimulation. These results suggest that the CCL5:CCR5 and CXCL9/CXCL10:CXCR3 signaling axes play a role in T-cell trafficking during dry eye disease.

The T-cell infiltration compromises the integrity of the ocular surface and drives chronic autoimmune-mediated inflammation. In the mouse model of dry eye, accumulation of CD4+ T cells within ocular surface tissues correlates with increased cytokine production (e.g., IFN-γ, IL-1β, TNF-α, and MMP-9), epithelial cell apoptosis, and decreased goblet cell density, tear production, and turnover. The presence of T cells in human dry eye patients also correlates with similar pathology. Indeed, CD4+ T cells are a prominent source of IFN-γ, which can induce expression of a variety of proinflammatory factors, including trafficking molecules, such as ICAM-1, CCL5, and CXCL10, and the pro-apoptotic proteins, Fas-FasL. These factors may contribute to chronic inflammation on the ocular surface by attracting infiltrating T cells and macrophages and perpetuate bystander tissue damage, including epithelial cell apoptosis and nerve damage. The IFN-γ was also shown to activate a cornified envelope precursor and genes involved in conjunctival epithelial differentiation, implicating CD4+ T cells as mediators of epithelial cell abnormalities and keratinization of the ocular surface. The CD4+ T cell accumulation is also associated with increased levels of IFN-γ in the tears of dry eye mice and is inversely related to goblet cell density and conjunctival squamous metaplasia. Furthermore, exogenous administration of IFN-γ to IFN-γ-deficient mice results in goblet cell loss. These findings suggest that CD4+ T-cell-derived IFN-γ is a major

component of chronic inflammation, epithelial cell metaplasia, and tissue destruction observed during dry eye. Emerging evidence demonstrating (1) the presence of Th17-specific CD4+ T cells within the draining cervical lymph nodes of mice with experimental dry eye and (2) high-level expression of IL-6 and IL-17 in experimental dry eye and human patients suggests that in addition to IFN-γ-producing Th1 cells, IL-17-producing Th17 cells also play a pivotal role in the underlying immunopathogenesis of dry eye.

Past, Future, and Current Therapies

Artificial Tears

Individuals with aqueous tear deficiency have decreased tear film stability and diminished tear volume. There are several therapeutic options for these patients. Artificial tears, applied topically to the ocular surface, are polymer-based. The type of polymer used determines the artificial tear viscosity, retention time, and adhesion to the ocular surface. For example, artificial tears containing hyaluronic acid exhibit non-Newtonian properties and relatively long retention times. Other types of polymers used in different artificial tears include cellulose esters (increases tear viscosity), polyvinyl alcohol (provides optimal wetting), povidone (superior wetting), and carbomers (longer retention times). There are tear gels made with polyacrylic acid that provide greater retention times than artificial tears. Some formulations add a lipid component, such as castor oil, that helps to prevent evaporation. Many tears contain electrolytes and buffers to help normalize the tear pH. Artificial tears offer provisional relief of eye irritation but do not reverse conjunctival squamous metaplasia. Preservatives in artificial tears such as benzalkonium chloride can induce ocular surface epithelial toxicity if frequently applied on patients with low tear turnover or individuals that have punctual occlusion. Preservative-free artificial tears may be a consideration for patients using artificial tears more than four times per day. Artificial tears provide a palliative therapy to dry eye patients, but do not prevent the underlying cause of disease. Inflammation!

Corticosteroids

Dry eye is an immune-based inflammatory disease. Chronic dry eye requires topical treatment with therapies designed to manage inflammation. Corticosteroids effectively block multiple inflammatory pathways including proinflammatory cytokine and chemokine secretion, synthesis of matrix metalloproteinases and prostaglandins, and cell adhesion molecule expression. Activated steroid receptors bind to DNA and control gene expression and impede transcriptional regulators (AP-1 and NFκB) of proinflammatory genes. Topical corticosteroid use, while effective, is normally prescribed for short-term use (up to 4 weeks) due to the plethora of potential side effects including glaucoma, cataracts, and ocular infection. Topical non-preserved methylprednisolone (1%) treatment of 15 Sjögren's syndrome patients three times daily for 2 weeks followed by punctual occlusion resulted in moderate to complete relief of disease symptoms.

Cyclosporine

Restasis (topical CsA, 0.5%) is the only FDA-approved therapeutic for dry eye syndrome. A fungal-derived peptide, CsA, inhibits nuclear translocation of cytoplasmic transcription factors that are necessary for T-cell activation and the production of pro-inflammatory cytokines. The CsA was first identified as therapy for dry eye in dogs with spontaneous keratoconjunctivitis sicca. In human dry eye patients, treatment with topical CsA reduced conjunctival cellular infiltration, IL-6 levels, and increased conjunctival goblet cell numbers. In two 6-month independent FDA Phase III clinical trials CsA treatment resulted in a significant ($p \leq 0.05$) improvement in corneal fluorescein staining and anesthetized Schirmer test values in patients treated with CsA (0.05 or 0.1%) compared to patients treated with vehicle alone. There was no indication of a dose-dependent effect with a safety profile of 0.05% and 0.1%. Moreover, patients did not show any serious adverse effects other than occasional burning and stinging. In addition, CsA also increased tear production in patients. There were no detectable levels of CsA in the blood of patients treated with CsA for 12 months, suggesting that topical CsA does not reach high enough levels to impact the systemic immune response. In addition to the clinical improvement in CsA-treated patients, there was also a marked decrease in expression of HLA-DR and IL-6 by conjunctival epithelial cells. Infiltration of CD3+, CD4+, and CD8+ T cells was also decreased in the conjunctiva of patients treated with CsA, but increased in those treated with vehicle alone.

Mucin Secretagogues

Secretagogues induce tear production by the lacrimal glands and the ocular surface epithelia. Pilocarpine and cevimeline are cholinergic agonists approved for oral administration. Patients taking Pilocarpine 5 mg four times daily reported a significantly greater overall improvement in ocular problems. Patients taking cevimeline had improvement in ocular irritation symptoms and aqueous tear production. A potential future secretagogue, Diquafosol tetrasodium, is an agonist for the P2Y2 receptor. Small molecule tyrosine kinase receptor agonists that induce mucin MUC5AC secretion from conjunctival goblet cells have also been developed.

Tetracyclines

Tetracyclines, traditionally used as antibiotics, have been reported to have a number of anti-inflammatory properties including inhibition of proinflammatory cytokines, MMP production, and nitric oxide production. On the ocular surface, tetracyclines reduce human corneal epithelial production of IL-1 and MMPs, preserving the ocular surface epithelial barrier, and blocking the activation of destructive cytokines.

Dynamic Immunoregulatory Processes that Sustain Immune Privilege in the Eye

J Y Niederkorn, University of Texas Southwestern Medical Center, Dallas, TX, USA

Glossary

ACAID (anterior chamber-associated immune deviation) – A dynamic antigen-specific downregulation of T-cell-mediated immunity that is elicited when antigens are introduced into the anterior chamber of the eye. ACAID is believed to be a mechanism to maintain homeostasis in the eye and reduce the likelihood of T-cell-dependent inflammation in response to noninfectious, nominal antigens that enter the eye. ACAID is also believed to be induced by orthotopic corneal allografts and promotes their survival.

Alloantigens – Histocompatibility antigens that provoke immune rejection of organ transplants. These include both major histocompatibility complex antigens and antigens encoded by a wide diversity of minor histocompatibility genes.

Delayed-type hypersensitivity – The T-cell- and immune-mediated inflammation that contributes to resistance to intracellular pathogens but also carries a heavy burden of collateral damage to innocent bystander tissues.

TGF-β (transforming growth factor-β) – A cytokine that is produced by many cells and has pleiotropic effects on the immune system. TGF-β is present in the anterior chamber of the eye and is crucial for altering the behavior of ocular antigen-presenting cells within the eye such that they induce ACAID.

T_{regs} (T regulatory cells) – These are T lymphocytes that can be induced in multiple ways and suppress T-cell-dependent immune processes. Introducing antigens into the anterior chamber or the vitreous cavity of the eye elicits the generation of T regulatory cells.

VCAID (vitreous cavity-associated immune deviation) – Antigens introduced into the vitreous cavity or into the subretinal space elicit an immune deviation that is indistinguishable from ACAID and is characterized by antigen-specific suppression of T-cell-dependent inflammation.

Introduction

The immune privilege of the eye was recognized over a century ago by the Dutch ophthalmologist van Dooremaal, who introduced a variety of foreign bodies and tissues into the eyes of animals as a means of studying cataractogenesis, and, in the process, unwittingly discovered the prolonged survival of mouse skin grafts placed in the anterior chamber (AC) of the dog eye. Evidence suggesting that tissue grafts might also enjoy prolonged survival in the eyes of humans surfaced when the first successful corneal transplant in a human subject was reported in 1905, a landmark event that occurred over 60 years before antirejection drugs were used in the first human heart transplant. In the 1940s, experimental pathologists transplanted human tumor cells into the AC of the rabbit eye as a bioassay for determining the malignancy of biopsy specimens. We now know that the survival of such tumor implants in the AC of the rabbit eye was not a property of malignant cells *per se*, but like the survival of corneal transplants, was a manifestation of ocular immune privilege. It was not until the early 1950s that the preeminent immunologist and Nobel Laureate, Sir Peter Medawar, recognized the significance of the prolonged survival of skin grafts placed into the eye and the brain and coined the term "immune privilege." Although the concept of ocular immune privilege is widely recognized, it is frequently misunderstood or over-simplified. There are two common misconceptions of ocular immune privilege. The first misconception is that corneal transplants are universally exempt from immune rejection. While it is true that corneal allografts benefit from immune privilege and enjoy a high success rate compared to other categories of transplants, they can undergo immune rejection and, in some cases, the rejection cannot be prevented, even with potent immunosuppressive drugs. The second misconception is that ocular immune privilege is due to the absence of lymph vessels draining the interior of the eye, which would sequester antigens in the eye and deny them access to regional lymph nodes where they would elicit an immune response. Although there are no anatomically detectable patent lymphatics draining the interior of the eye, antigens and cells placed into the AC do in fact reach

the cervical lymph nodes in rodents. Thus, other explanations are needed to account for ocular immune privilege.

Important clues as to the possible underlying mechanisms for ocular immune privilege surfaced in the mid-1970s in seminal studies from J. Wayne Streilein and colleagues, who demonstrated that introducing antigens into the AC elicited a deviation in the systemic immune responses resulting in the suppression of T-cell-mediated immunity. This anterior chamber-associated immune deviation (ACAID) is characterized by the antigen-specific suppression of Th1 immune responses, such as delayed-type hypersensitivity (DTH), and Th2-based inflammation, such as experimental allergic asthma in mice. Although antigens introduced into the AC suppress Th1- and Th2-based immune inflammation, other immune elements are preserved. Noncomplement fixing antibodies are generated, while complement-fixing antibody production is silenced. Initial studies demonstrated that the induction of ACAID was associated with the production of IL-10, which at the time was considered a Th2 cytokine, and the suppression of the Th1 cytokine, interferon-γ (IFN-γ). This led some to conclude that ACAID was simply the preferential cross regulation of Th1 immune response by Th2 cytokines. However, further analysis revealed that ACAID also suppressed Th2-based inflammatory responses and that ACAID did not require the participation of a key Th2 cytokine, IL-4.

Not only does ACAID suppress classical Th1 immune responses, but it also mitigates Th2-mediated allergic inflammatory lung disease. ACAID also deviates antibody responses by preserving the production of noncomplement-fixing antibodies while blocking the generation of complement-fixing antibodies. This reduces the likelihood of immune inflammation, which is precipitated by activation of the complement cascade. Once activated by complement-fixing antibodies, the complement cascade spins off pro-inflammatory molecules that stimulate granulocytic inflammation. Thus, ACAID suppresses both Th1- and Th2-based inflammation and the generation of complement-fixing antibodies and thereby reduces the likelihood that antigens entering the eye will elicit immune inflammation that could injure tissues in the eye that possess little or no regenerative properties.

Induction of ACAID

Studies conducted over the past 30 years have shed light on the molecular and cellular basis of ACAID and have revealed the remarkable complexity of this systemic immunoregulatory phenomenon. The eye, thymus, spleen, and sympathetic nervous system are required for the induction of ACAID. Chemical sympathectomy prior to AC injection of antigen or removal of any of these organs within 3 days of AC injection prevents the induction of ACAID, and in many cases, allows the development of robust Th1 immune responses, such as DTH.

Ocular Phase of ACAID

The induction of ACAID begins when antigens enter the AC. The eye is an active participant in the induction of ACAID, as enucleation of the eye within 3 days of AC injection not only prevents the induction of ACAID, but also results in active immunization and development of DTH to the antigens that were introduced into the AC. It is widely believed that within the eye, antigen is captured by $F4/80^+$ macrophages, which under the influence of TGF-β (which is present in the aqueous humor), are imprinted to produce IL-10 while simultaneously extinguishing IL-12 production. The preferential production of IL-10 by ocular macrophages is crucial for the induction of ACAID, as macrophages from IL-10 knockout mice are incapable of inducing ACAID. TGF-β also stimulates ocular macrophages to produce macrophage inflammatory protein-2 (MIP-2), which is a potent chemokine that is pivotal in the splenic phase of ACAID (see below).

Thymic Phase of ACAID

Within 72 h of antigen entering the eye, $F4/80^+$ ocular macrophages capture antigen and migrate to the thymus. Within the thymus, they evoke the generation of $CD4^-$, $CD8^-$, and $NK1.1^+$ T cells (NKT cells), which then emerge from the thymus and enter the bloodstream where they migrate to the spleen. Other $F4/80^+$ ocular macrophages are believed to migrate directly from the eye to the spleen. Both populations of $F4/80^+$ ocular macrophages contribute to the generation of $CD4^+$ and $CD8^+$ T regulatory cells (T_{regs}) within the spleen.

Splenic Phase of ACAID

After entering the spleen, $F4/80^+$ ocular macrophages secrete MIP-2, which attracts $CD4^+$ NKT cells. The NKT cells in turn interact with the ocular macrophages and secrete the chemokine, RANTES, which recruits other cells into the marginal zone of the spleen. Within the marginal zone, $F4/80^+$ ocular macrophages, NKT cells, B cells, and $CD4^+$ T cells, in the presence of the third component of complement, collaborate to generate $CD8^+$ T_{regs}. The $CD8^+$ T_{regs} are the end-stage effector cells of ACAID that inhibit Th1- and Th2-based immune-mediated inflammation and promote corneal allograft survival.

Sympathetic Nervous System and ACAID

All three organs involved in the induction of ACAID – eye, spleen, and thymus – possess dense sympathetic innervations. Many immune responses are influenced by

the sympathetic nervous system, including ACAID. Animals subjected to chemical sympathectomy prior to AC injection of antigen fail to develop ACAID. It is not clear at what level the sympathetic nervous system exerts its effect, but it appears that it is not at the ocular phase, as chemical sympathectomy does not affect the generation of $F4/80^+$ ocular macrophages. Thus, the induction and expression of ACAID are remarkably complex and require the active participation of multiple organs and organ systems including the circulatory system, sympathetic nervous system, thymus, spleen, and eye (**Figure 1**).

ACAID T Regulatory Cells

Two phenotypically and functionally distinct populations of T_{regs} are induced in ACAID. $CD4^+$ T_{regs} inhibit the induction of T-cell-mediated immune responses, but do not suppress T-cell effector responses, such as DTH. Thus, $CD4^+$ ACAID T_{regs} act at the afferent arm of the immune response and prevent the initiation of immune responses, but have no effect if an immune response has already been initiated. $CD4^+$ afferent T_{regs} are also needed for the generation of $CD8^+$ T_{regs} that suppress immune responses at the effector stage. $CD8^+$ T_{regs} are the end-stage regulatory cells of ACAID that block effector immune responses, such as DTH, even if the host has been previously immunized and is capable of mounting a robust DTH response. Both the $CD4^+$ afferent T_{regs} and the $CD8^+$ efferent T_{regs} are antigen-specific. It is not clear how the $CD8^+$ ACAID T_{regs} suppress DTH and other T-cell immune effector responses, but evidence to date indicates that these T_{regs} do not lyse immune cells via a perforin-dependent mechanism or induce apoptosis by Fas/FasL interactions. Interestingly, $CD8^+$ efferent T_{regs} express IFN-γ receptors and require IFN-γ to exert their suppressive properties. However, the precise molecular mechanisms whereby $CD8^+$ efferent T_{regs} produce their effects remain to be elucidated. Although two distinct T_{reg} populations have been detected in ACAID (i.e., $CD4^+$ and $CD8^+$), it is possible that other T_{regs} might also participate

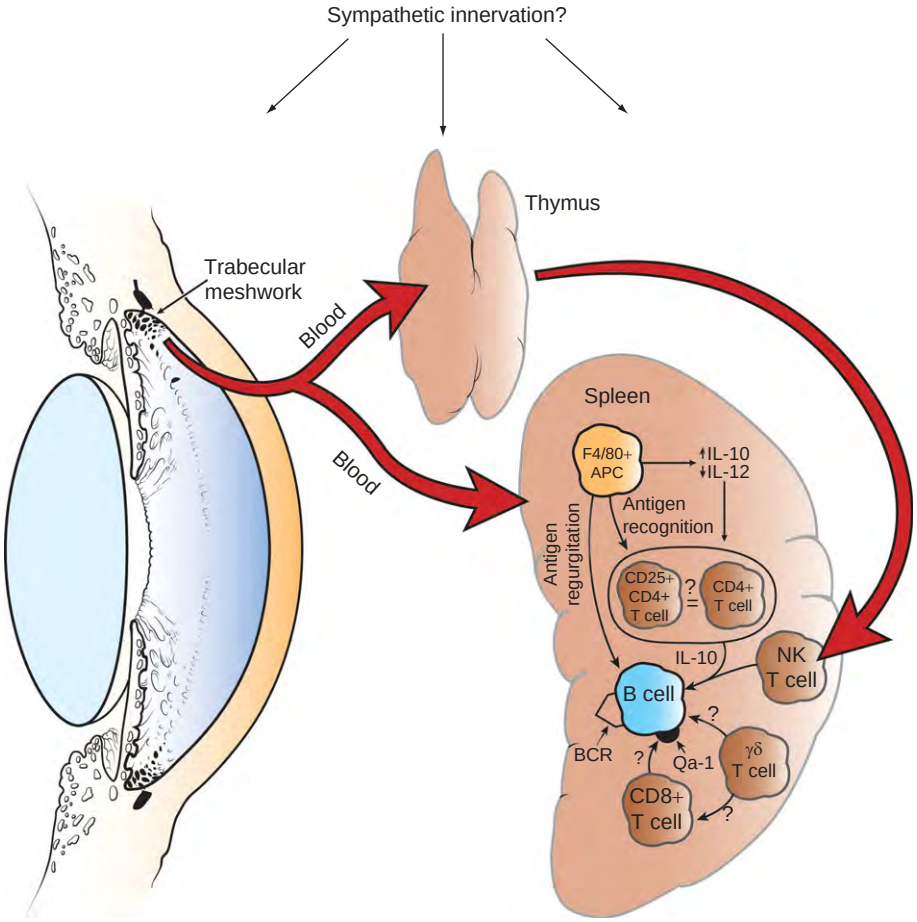

Figure 1 Organ systems and immune cells involved in the induction of ACAID. Removal of the eye, thymus, or spleen within 72 h of AC injection prevents the induction of ACAID. Chemical sympathectomy prior to AC injection of antigen also prevents the induction of ACAID. BCR, B-cell receptor. Reproduced from Niederkorn, J. Y. (2006). See no evil, hear no evil, do no evil: The lessons of immune privilege. *Nature Immunology* 7: 354–359, with permission from Nature Publishing Group.

in the induction and expression of ACAID. Although, most, if not all, of the studies performed to date have examined T_{regs} in the spleens of mice with ACAID, it is entirely possible that T_{regs} may also be present in lymph nodes, such as the cervical and submandibular lymph nodes.

What is the Relevance of ACAID?

One might argue that ACAID and immune privilege create an immunological blind spot that renders the eye potentially vulnerable to infectious agents. However, the eye and the brain are part of the central nervous system and possess very limited regenerative properties. Thus, limiting the immunological options to viral or bacterial infections is desirable for the preservation of vision. DTH is crucial for controlling intracellular pathogens, while activation of the complement cascade is an important mechanism for clearing bacterial infections. However, DTH and complement elicit granulocytic inflammation. Granulocytes produce a potpourri of reactive oxygen species and proteases that are notorious for producing extensive collateral damage to innocent bystander tissues. If unrestrained, such inflammation would produce extensive necrosis of ocular tissues leading to blindness. Thus, suppressing DTH and the complement cascade has a clear benefit for preserving the functional integrity of the visual apparatus.

The eye is also at risk from other T-cell-mediated immune responses, such as cytotoxic T lymphocyte (CTL)-mediated immunity. During virus infections, viral antigens are displayed on major histocompatibility complex (MHC) class I molecules of the virus-infected cells. The MHC class I/viral antigen complex serves as a docking station for CTL, which kill the virus-infected cells, and thus, eliminate the viral invaders. Although this is a highly efficient mechanism for controlling virus infections in most parts of the body, it would be devastating in the eye. However, CTL responses are suppressed as a consequence of ACAID. Interestingly, corneal endothelial cells and cells of the retina do not express the critical MHC class I molecules that are necessary for recognition and elimination of virus-infected cells by CTL. Thus, the active downregulation of CTL responses to ocular antigens combined with the absence of MHC class I molecules shield ocular cells from CTL-mediated injury. The preferential production of noncomplement fixing antiviral antibodies provides a level of protection by neutralizing viral particles without activating the complement cascade and provoking granulocytic inflammation.

Although ACAID seems to be an adaptation to prevent unwitting immune-mediated injury to ocular tissues, it may also benefit the corneal transplant recipient. Animal studies have shown that hosts bearing successful long-term orthotopic corneal allografts display an immune deviation that is reminiscent of ACAID. Moreover, AC injection of donor cells prior to transplantation results in a dramatic enhancement of corneal allograft survival in rodent models of penetrating keratoplasty.

Vitreous Cavity-Associated Immune Deviation

Immune privilege is not restricted to the AC, but appears to be equally expressed in the vitreous cavity and in the subretinal space. Although less is known about the immune privilege in the poster segment of the eye, it is clear that antigens introduced into the vitreous cavity elicit an immune deviation that appears to be identical to ACAID and has been termed vitreous cavity-associated immune deviation (VCAID).

Ocular Regulatory Cells Induced *In Situ*

The aqueous humor contains a myriad of anti-inflammatory and immunosuppressive molecules. Iris and ciliary body (I/CB) cells line a major portion of the AC and secrete constituents of the aqueous humor. I/CB cells not only secrete immunosuppressive and anti-inflammatory molecules such as TGF-β, but they also have the capacity to suppress T-cell proliferation and the secretion of pro-inflammatory cytokines, such as IFN-γ, by cell contact-dependent mechanisms, which are independent of soluble anti-inflammatory molecules such as TGF-β, IL-10, and tumor necrosis factor-α (TNF-α). I/CB cells are strategically located at sites where T cells can enter the eye and, thus, are positioned to exert their influence by inhibiting T-cell proliferation and production of IFN-γ shortly after T cells enter the eye.

Alpha-melanocyte-stimulating hormone (α-MSH) is one of the numerous immunosuppressive constituents of the aqueous humor. In addition to suppressing the production of pro-inflammatory cytokines, α-MSH stimulates T cells to produce anti-inflammatory cytokines such as TGF-β. Moreover, α-MSH converts Th1 cells into $CD4^+$, $CD25^+$ T_{regs}, which suppress DTH and mitigate experimental autoimmune uveitis (EAU).

The induction of ACAID requires penetration of the eye (i.e., antigen injection via a needle) in order to introduce antigens into the AC. AC injections, even if performed in the least possible traumatic manner, elicit the local production of pro-inflammatory cytokines including TNF-α. Thus, ACAID can be envisioned as a form of immune tolerance induced by antigens entering the AC as a consequence of perforating injuries to the eye. However, the eye may need to regulate immune responses to endogenous ocular antigens. During ontogeny, some structures in the eye are isolated from the immune system and

Table 1 Ocular-induced regulatory cells

Induction	*Antigen pecificity*	*Organs involved in induction*	*Regulatory cell phenotype*
ACAID	Yes	Eye, spleen, thymus, sympathetic nervous system	$CD4^+$; $CD8^+$; $CD4^+CD25^+$
VCAID	Yes	Eye	ND
I/CB	No	Iris and ciliary body	I/CB cells
Endogenous retinal neoantigens	Yes	Retina	ND
EAU[a]	Yes	Retina/uveal tract	$CD4^+$
α-MSH[b]	Yes	AC and retina	$CD4^+$

[a]T regulatory cells that develop following resolution of EAU.
[b]Alpha-melanocyte stimulating hormone-induced regulatory cells induced *in situ* in the AC or in the retina.
ND, not determined.

express tissue-specific antigens that, under some circumstances, can initiate an immune response. This has led some to suspect that ACAID and VCAID might be fail-safe mechanisms that generate T_{regs}, which prevent immune responses to tissue-specific ocular antigens (e.g., lens crystallins and retinal antigens). Studies using transgenic mice have demonstrated that novel neoantigens engineered to be exclusively expressed in the retina induce the development of T_{regs} that suppress DTH responses, yet are significantly different from the T_{regs} induced by AC injection of antigens. Thus, endogenous ocular antigens arising *in situ* in an intact eye can elicit the generation of T_{regs}, which presumably maintain immune homeostasis in the eye and serve as buffers against autoimmune inflammation, although through mechanisms that are likely distinct from ACAID and VCAID.

Conclusions

Ocular immune privilege is the product of multiple anatomical and physiological properties of the eye. The blood–eye barrier restricts entry of inflammatory and immune cells into the eye. Moreover, once in the eye, cells of the immune system encounter a milieu that is rich with soluble immunosuppressive and anti-inflammatory molecules. Cells lining the interior of the eye are decorated with membrane-bound molecules such as FasL, programmed death ligand-1 (PD-L1), and tumor necrosis factor-related apoptosis-inducing ligand, each of which can induce apoptosis of activated T cells. In addition, the limited expression of MHC complex molecules on the corneal endothelium and the retina render these cells invisible to CTL.

Immune privilege is also maintained by dynamic immunoregulatory processes that are initiated when antigens are introduced into the eye by injection, corneal transplantation, or endogenous ocular antigens. Each of these dynamic immunoregulatory processes relies on T_{regs} that act to either prevent the induction or expression of immune processes that inflict injury on tissues with little or no regenerative properties, while preserving immune effector mechanisms that provide protection against pathogens without damaging innocent bystander cells in the eye (Table 1). As stated over two decades ago by the preeminent ocular immunologist J. Wayne Streilein, the eye and the immune system are engaged in "a dangerous compromise." This compromise protects the eye from unwitting immune-mediated injury at the risk of being vulnerable to ocular infections and perhaps blindness. The reader's capacity to read through the articles in this encyclopedia is a testament to the success of this compromise.

Glossary

Agenesis – Failure of an organ to develop during embryonic growth and development.
Anophthalmia – Absence of the eye as a result of a congenital malformation during development.
Coloboma – Congenital malformation due to failure of fusion of optic fissure.
Hyperplasia – Abnormal increase in cell proliferation within an organ or tissue due to the disregulation of cell-cycle control mechanisms.
Induction – Change in cell fate resulting from an external signal (inducer). This signal secreted by a group of cells instructs target cells to acquire specific properties.
Invagination – Morphogenetic process leading to the coordinated inward folding of a cell layer forming a pocket on the surface.
Mesenchyme – Embryonic mesodermal connective tissue composed of loosely packed unspecialized cells characterized by the ability to migrate into other tissues.
Phenotype – Expression of a specific trait based on genetic and environmental influences.
Prosencephalon – Anterior-most division of the developing vertebrate brain (forebrain) that further subdivides into the telencephalon and the diencephalon.

Embryology

Eye development starts at late gastrula stages with the specification of retinal precursor cells within the eye field in the anterior neural plate. At this stage, retinal progenitor cells occupy a medial position and are surrounded rostrally and laterally by telencephalic precursors and caudally and medially by cells that will form the diencephalon. During neurulation, coordinated rearrangement of the cells that form each of these presumptive regions results in a new cell organization, whereby retinal progenitor cells now become laterally positioned. *In vivo* monitoring of retinal progenitor cell movement has shown that, at least in fish, dorsal diencephalic cells – positioned caudally to the eye field – move inward and forward, displacing prospective eye and optic stalk tissue forward and then sidewise. At the same time, laterally positioned telencephalic precursors fold toward the midline leaving retinal precursors cells to the side of the neural tube (Figure 1). As these movements happen, the cells of the left and right eye, which were initially intermingled, segregate in their respective domains forming two visible optic vesicles.

At the present time, it is not clear whether similar morphogenetic movements occur in other vertebrate species. In mammals, for instance, these early events might be slightly different as the first visible sign of eye formation are two small depressions (optic pits) in the anterior neural tube, which appear well before folding of the tube occurs.

Independent of these initial differences, in all vertebrates the optic vesicles are formed by a single pseudostratified neuroepithelium that is surrounded by cephalic mesenchyme, including migrating neural crest cells, and limited at the most distal tip by the surface ectoderm. The cells that compose the optic vesicle neuroepithelium are initially morphologically and molecularly indistinguishable but reach their final complexity through a series of inductive and morphogenetic events that, in part, depend on their interaction with the surrounding tissues. The extension of thick cytoplasmic processes emanating from the basal surface of both optic vesicle and ectodermal cells establishes cell-to-cell contact and initiates a series of temporally correlated structural changes in both structures. A fibrillar extracellular matrix (ECM) builds up between the neuroectoderm and the ectoderm,

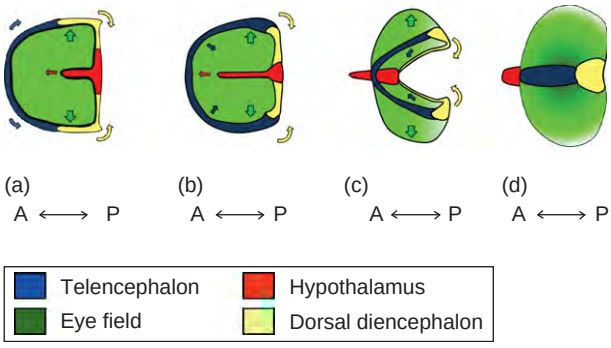

Figure 1 Optic vesicle morphogenesis in zebrafish. (a) The eye field (in green) in the anterior neural plate is surrounded anteriorly and peripherally by telencephalic precursors (blue), posteriorly by the dorsal diencephalon (light yellow) and medially by cells that will form the hypothalamus (red). (b, c) The hypothalamic and dorsal diencephalic precursors move forward beneath the eye field displacing it to the front and laterally. The lateral edges of the neural plate fold toward the midline. (c, d) The lateral telencephalon cells meet at the dorsal midline, leaving two optic vesicles at the side. Adapted from Egland, S. J., Blanchard, G. B., Mahadevan, L., and Adams, R. J. (2006). A dynamic fate map of the forebrain shows how vertebrate eyes form and explains two causes of cyclopia. *Development* 133: 4613–4617.

favoring strong adhesion, while the ectoderm immediately adjacent to the optic vesicle thickens forming the lens placode (**Figure 2**).

Once formed, the lens placode and the adjacent optic vesicle begin a coordinated invagination to form the lens pit and the optic cup. ECM-mediated adhesion between the two tissues is important for coordinating morphogenetic movements. In addition, some of its components, such as laminin and fibronectin, may participate in lens cell differentiation, which occurs concomitantly. As a result, the lens pit deepens and gradually assumes a spherical shape that finally breaks away from the ectoderm forming the lens vesicle. A spatio-temporally restricted massive apoptosis contributes to this separation. Thereafter, the lens vesicle undergoes an asymmetric differentiation acquiring a characteristic polarity: cells located in the most proximal region (facing the neuroepithelium) elongate to form the primary lens fibers, whereas those in the most distal portion (facing the ectoderm) form a cuboidal monolayer known as the anterior lens epithelium.

Concomitant with lens formation, the optic neuroepithelium undergoes a series of rearrangements that culminates with the formation of a bi-layered optic cup (**Figure 2(c)** and **2(c′)**). The distal inner layer will give rise to the future neural retina (NR), while the distal outer layer to the retinal pigmented epithelium (RPE), which acquires specialized epithelial characteristics. The proximal ventral region forms the optic stalk, from which the optic nerve derives. The transition zone between the future retina and the RPE forms the ciliary margin (CM), or periphery of the retina. Despite its neural origin, the CM differentiates into non-neural structures: the proximal part into the ciliary epithelium while the distal part becomes the iris. In fish and amphibians, the CM harbors bona fide stem cells, which continue to proliferate throughout life to increase the eye size. Cells with stem-like properties also appear to be present in the CM of birds and mammalian eyes. These cells, however, are quiescent in physiological conditions.

Although there are common features in the way the optic cup is formed among vertebrates, differences do exist. In fish and amphibians, the optic vesicles, which develop as flat wing-like protrusions, undergo a process of cavitation, rotation, and invagination that shifts cells that were originally in a ventral position to the medial layer, from which the RPE progenitors derive. These progenitors stretch over the prospective NR, occupying the dorsal aspect of the optic cup. In mammals and birds instead, the optic vesicle neuroepithelium undergoes two simultaneous foldings (**Figure 2(b)**): (1) the spherical vesicle becomes concave outward, resembling the bowl of a spoon where the optic stalk is the handle and (2) at the same time, the ventral portion of the entire vesicle folds inward giving rise to the groove of the optic (choroid) fissure. Differential growth rates are associated with these events. In the future RPE as well as in the CM, the proliferation rate is quite slow in comparison to that of the perspective NR. There are also differences along the dorso-ventral axis, with an initial higher proliferation rate in the ventral part, which enables the formation of the optic fissure.

The optic fissure can be divided into two adjoining parts – the retinal fissure and the optic groove – which derive from the progressive invagination of the ventral surface of the optic vesicle and stalk, respectively. The transition between the retinal fissure and the optic groove dictates the position where the optic disk, or blind spot of the retina, will form. This structure, a real interface between the optic stalk and the retina, enables the entrance of surrounding mesenchymal cells into the developing eye chamber, which will form the hyaloid artery, the main blood supply for the eye. At the same time, it allows the egression of retinal axons from the eye cup.

As a last step in the formation of a complete optic cup, its dorsal portion begins to proliferate more rapidly enabling the shallow bowl to become deeper, while its lateral edges meet ventrally across the optic fissure. The eye rudiment now has the appearance of a hemispheric cup where the RPE completely surrounds the NR. The sealing of the optic fissure completes these morphogenetic events (**Figure 2(c)** and **2(c′)**). Although this is a poorly understood process, in humans the fusion usually begins in the middle portion of the fissure and extends anteriorly and posteriorly.

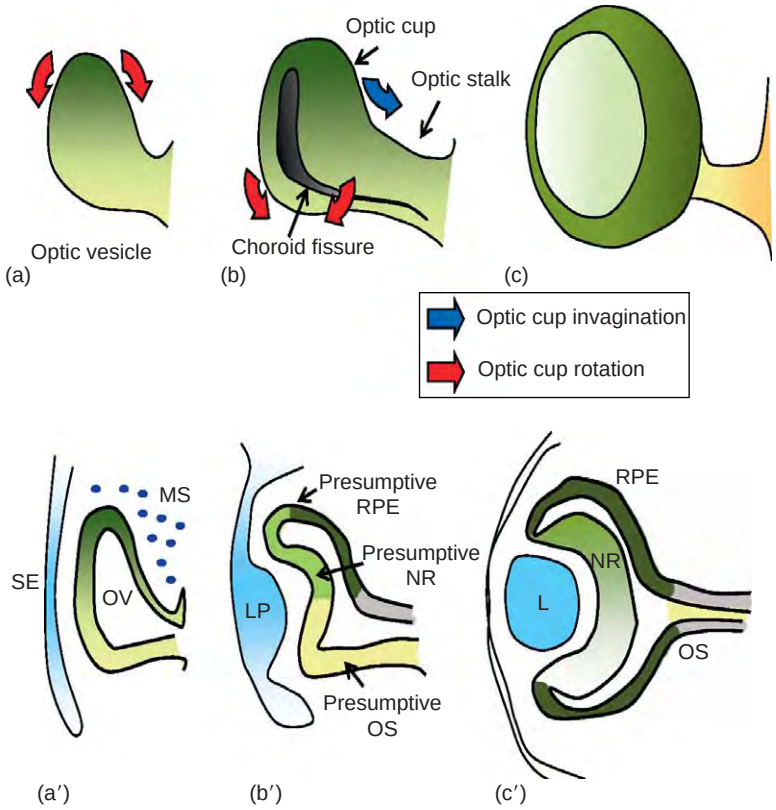

Figure 2 Schematic representation of initial eye morphogenesis. (a) The optic vesicle appears as a protrusion of the anterior neural tube. (b) Folding of the distal and ventral neuroepithelium generates the optic cup and the optic (choroids) fissure. (c) The optic fissure seals and a spherical eye cup forms. (a′) The optic vesicle neuroepithelium is composed of the cells that are morphologically and molecularly indistinguishable. (b′) As the vesicle folds, the dorsal neuroepithelium specifies as presumptive RPE (dark green), the distal region as presumptive neural retina (light green), while the ventral portion as optic stalk (light yellow). The surface ectoderm thickens forming the lens placode (blue). (c′) Complete folding of the vesicle results in an optic cup, where the RPE completely surrounds the neural retina. Table 1 Summary of extracellular molecules and transcription factors implicated in early eye development

Events in eye development	*Secreted molecules*	*Transcription factors*
Proximo-distal patterning of OV	Shh, nodal	Pax2, Pax6, Vax1
Specification of NR and RPE	FGF, TGFβ; Activin/BMPs	Chx10, Six3, Six6, Lhx2, Pax6, Mitf, Otx1, Otx2
Dorso-ventral patterning of the optic cup	BMP4, BMP7, Shh, RA, ventroptin, noggin	Pax6, Pax2, Vax, Tbx5

Shh, Sonic hedgehog; FGFs, Fibroblast grow factors; BMPs, bone morphogenetic proteins; RA, retinoic acid.

Early Patterning

The morphogenetic movements and the tissue interactions described above are orchestrated by specific genetic programs coordinated by cell-signaling mechanisms – inductive signals – and regulated by the activity of a relatively small number of transcription factors (see **Table 1**). Many of the genes involved in the specification of the eye field, including retinal homeobox (Rx), paired box 6 (Pax6), hairy enhancer of split 1 (Hes1), orthodenticle homolog 2 (Otx2), LIM homeobox 2 (Lhx2), and SIX homeobox 3 (Six3), are also involved in the early patterning events that convert eye-field cells into the structures that compose the optic cup (**Figure 3(a′)**). However, changes in the expression levels, as well as combinatorial interaction with other factors, diversify the activity of these genes enabling the progressive acquisition of different fates and functions. As mentioned above, cells that compose the optic vesicle are initially morphologically and molecularly undistinguishable and, therefore, are all potentially competent to originate the NR, the optic stalk, or RPE. Information, in the form of signaling molecules, derived from the surrounding tissues and the neuroepithelium itself modulates and restricts the expression of different transcription factors to a specific

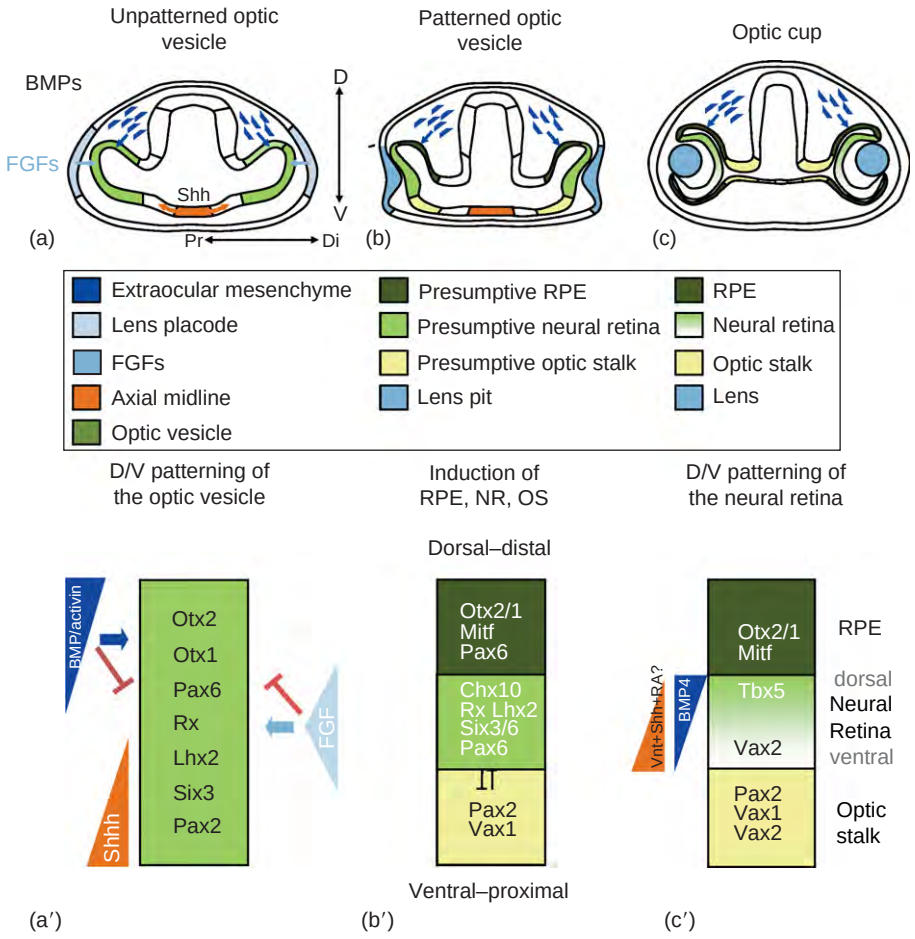

Figure 3 Distribution of inductive signals and transcription factors involved in early patterning of the eye. Progressive tissue specification during the transition from unpatterned (a) to patterned optic vesicle (b) and optic cup (c) where the different colors represent the distinct territories. In (a′)–(c′) color bar graphs represent the distribution of molecular components implicated in the patterning of the optic vesicle into optic cup. In (a) and (a′) all the neuroepithelial cells are indistinguishable (light green) and express a common set of transcription factors. Shh signaling from the axial midline is required for the specification of the proximo-ventral optic stalk (orange in (b) and (b′)). TGFβ-like signals from the extraocular mesenchyme promote RPE character (dark green in (b) and (b′)), whereas FGF signals from the lens placode repress RPE and activate neural retina identity (light green in (b) and (b′)). During optic cup formation the graded distribution of BMP4 dorsally and ventroptin, possibly together with RA and Shh, in the ventral side establish the dorso-ventral polarity of the neural retina (shaded green in (c) and (c′)). Shh, Sonic hedgehog; FGFs, fibroblast growth factors; BMPs, bone morphogenetic proteins; RA, retinoic acid; Vnt, ventroptin.

domain of the vesicle, initiating its patterning along the proximo-distal and dorso-ventral axis.

Proximo-Distal Patterning of the Optic Vesicle

The optic vesicles are bulges of the neural tube and thus their subdivision is often described according to a proximal–distal axis. In this view, future optic stalk precursors occupy a proximal location, while distal cells constitute the NR and RPE precursors (**Figure 3(b)**).

Proximo-ventral cells of the optic stalk are generated under the influence of signaling molecules, emanating from the axial ventral midline, including Sonic hedgehog (Shh) and nodal, a member of the transforming growth factor-beta (TGFβ) family (**Figure 3(b)**). Mutations in these genes cause severe anterior neural tube defects that include the formation of a single midline (cyclopic) eye, lacking optic stalk tissue. The phenotype is the result of Shh-mediated regulation of the spatial expression of Pax6 and Pax2 – two homeobox transcription factors of the paired type – which normally demarcate the distal and proximal optic primordium, respectively (**Figure 3(b′)**). Indeed, overexpression of Shh causes the expansion of the Pax2 domain at the expense of the Pax6-positive tissue, while the opposite occurs in absence of Shh. A similar dependence on Shh signaling has also been observed for the expression of Vax genes, other homeobox transcription factors involved in optic stalk generation.

Targeted inactivation of Pax2 or Vax1 in mice results in severe optic nerve abnormalities, consistent with a role

for these genes in proximal eye development. The phenotype of these mice is characterized by the presence of coloboma of the ventral optic fissure, and, in the case of Pax2, an extension of the RPE into the optic nerve region. In contraposition, the Pax6 gene is necessary for the formation of the distal vesicle, including the lens tissue. Mutations in this gene impair both lens and optic vesicle formation, ultimately causing anophthalmia. In these mice, the only remnant of the eye primordium has optic stalk characteristics. Conditional inactivation of Pax6 at different time points of eye development, however, has highlighted additional functions for this gene both in NR and RPE development (see below).

In summary, acquisition of the ventral optic stalk phenotype depends on the Shh-dependent expression of transcription factors that impose ventral character to optic vesicle precursors. The establishment of a precise boundary between the presumptive optic stalk and the distal optic vesicle may result from the reciprocal transcriptional repression between Pax6 and Pax2 (**Figure 3(b′)**).

Specification of the RPE and NR

Extracellular signals, derived from the surface ectoderm in contact with the prospective NR or from the periocular mesenchyme surrounding the presumptive RPE, pattern the distal optic vesicle (**Figure 3(a)**).

Removal of the surface ectoderm induces prospective NR cells to acquire the characteristics of RPE cells. This is because the ectoderm secretes high levels of two members of the fibroblast growth factor (FGF) family of signaling molecules – FGF1 and FGF2 – while the prospective retina expresses the FGF receptor 1. The addition of either one of the two factors is sufficient to rescue NR formation after ectoderm removal. On the contrary, exposure of the presumptive RPE to FGF confers to the cells NR properties. Therefore, FGF signaling normally activates NR specification but inhibits RPE formation. The future retina itself expresses other FGFs, such as FGF3, FGF8, FGF9, and FGF15, which may contribute to maintain the properties of the retina, but are not sufficient to induce them, since addition of these FGFs cannot rescue the phenotype caused by surface ectoderm removal.

The activity of the FGF is complemented by other signals, originating from the dorsal extraocular mesenchyme, which have opposite effects on the specification of these territories. Members of the TGFβ superfamily of signaling molecules, such as activins or the related bone morphogenetic proteins (BMP) – Bmp4 and Bmp7 – are expressed in the surrounding mesenchyme and/or the presumptive RPE itself. Interference with the activity of these molecules prevents RPE development and induces NR-specific genes, whereas their addition activates RPE characteristics in the entire vesicle.

Thus, TGFβ/BMP and FGF signaling act antagonistically on the specification of RPE and NR precursors. Directly or indirectly, their activity seems to impinge upon the expression of specific transcriptional regulators, such as *Caenorhabditis elegans* homeo domain 10 (Chx10) and Otx2 or microphthalmia-associated transcription factor (Mitf), the function of which is instrumental to the acquisition of either RPE or NR identities. Indeed, FGF signaling activates the expression of Chx10 in the retina but represses that of Otx2 and Mitf in the RPE, while opposite results have been observed with manipulations of TGFβ/BMP signaling.

Besides those mentioned above, a number of additional transcription factors are also specifically expressed in the presumptive neural retina and RPE (**Figure 3(b′)**). Currently, it is not clear how many of them are really needed to impose tissue specificity. The paired-like homeobox gene Chx10 (also known as Vsx1) is possibly the best candidate to impose a neural retina character to the naive optic vesicle cells (**Figure 3(b′)**). The onset of Chx10 expression is restricted to the presumptive NR domain and mutations in the human or mouse gene lead to microphthalmia, cataracts, and abnormal iris development. The expression of two members of the Six family of homeobox transcription factors, Six3 and Six6, initially expressed in the entire vesicle, is also soon restricted to the prospective NR. The overexpression of these factors in fish embryos causes retinal hyperplasia and ectopic formation of retinal-like tissue. In mice, genetic inactivation of Six3 leads to complete loss of the forebrain, while that of Six6 impairs retinal proliferation and differentiation. It is, therefore, still unclear whether the two genes are essential pieces of the genetic program that establishes NR identity. Nevertheless, overexpression of either one of them in the RPE cells leads to the acquisition of a NR phenotype, suggesting that their function is at least incompatible with the acquisition of the RPE character.

Similarly to Six3, the expression of Lhx2 becomes restricted to the prospective NR. Mice deficient in Lhx2 function are characterized by anophthalmia, like that observed in mice mutants for the Pax6 gene. Although the two genes seem to act independently, both are required during the period of close contact between the surface ectoderm and optic vesicle. Whether this implies that their activity participates in the specification of the NR domain still needs to be established.

The function of at least four transcription factors – Otx1, Otx2, Mitf, and Pax6 – is at the core of the transcriptional network required to establish the RPE character. Functional inactivation of either Mitf or Otx1 and Otx2 genes (bHLH and homeo-domain-containing transcription factors, respectively) impairs RPE differentiation. On the contrary, retinal cells transfected with either Otx or Mitf genes acquire a RPE phenotype and accumulate granules of pigment. Although it is unclear whether Otx and Mitf

act in a feedback loop or in parallel, they synergize in the activation of melanogenic gene expression, including tyrosinase or the tyrosinase-related protein 2. Although Pax6 expression in the prospective RPE is transient, its function – possibly together with that of Pax2 – seems necessary to initiate Mitf expression. Indeed, Pax6 binds directly to the Mitf promoter and in embryos deficient in both Pax2 and Pax6 optic vesicles are small and composed of Mitf-negative cells that instead co-express Otx2 and the NR marker, Chx10.

As in the case of the proximo-distal patterning of the optic vesicle, subdivision of the distal vesicle in the NR and RPE is reinforced by reciprocal repression of transcription factors. Mitf is expressed ectopically in the neuroretina of Chx10-deficient mice, driving cells toward an RPE-like identity. Conversely, misexpression of Chx10 in the developing RPE caused downregulation of Mitf with a consequent loss of pigment, strongly suggesting an antagonistic interaction between Chx10 and Mitf.

Chx10 function also appears to be required to establish a boundary between central and peripheral retina, the CM. In Chx10 null mutants, in fact, peripheral structures, including the ciliary body, are abnormally expanded. Similar expansions are also observed upon stabilization of β-catenin, a key effector of canonical wingless pathway (Wnt) signaling. In addition, ectopic expression of Wnt ligand induces abnormal expression of CM markers, such as Otx1 and msh homeobox 1 (Msx1), in the central retina. This suggests that canonical Wnt signaling plays a crucial role in establishing a difference between central and peripheral retina, imposing identity to the ciliary body and iris.

Dorso-Ventral Patterning of the Optic Cup

As mentioned above, the transition between the optic vesicle and the optic cup establishes a new position for most of the optic vesicle precursors. Once this rearrangement is accomplished, the optic cup undergoes a new wave of polarization along the dorso-ventral axis.

A gradient of BMP signaling is primarily responsible for this new pattern (**Figure 3(c)** and **(c′)**). Bmp4 is expressed in the dorsal retina of most vertebrate species analyzed. Mis-expression of Bmp4 in the ventral portion of the optic cup suppresses the expression of Pax2 and Vax and activates that of Tbx5, a transcription factor of the T-box class normally expressed only in the dorsal portion of the optic cup. The counterbalance for this dorsalizing activity is ventroptin, a BMP signaling antagonist expressed in the ventral optic cup. Forced expression of ventroptin in the dorsal cup decreases Bmp4 expression and expands that of Vax genes. Thus, the ventral character of the optic cup seems to depend on the inhibition of Bmp4-mediated dorsalizing activity.

Structures that are typical of the ventral optic cup – such as the optic fissure, the hyaloid artery, and the pecten (a vascular-like structure in birds) – also depend on BMP signaling, although this may be due to actions of other members of the family. Overexpression of the BMP antagonist noggin in the chick ventral optic cup alters its development and induces ectopic expression of optic stalk markers in the region of the ventral retina and RPE. Furthermore, in Bmp7 null mice the optic fissure does not form. Retinoic acid (RA) is an additional signal that may be involved in establishing the ventral optic cup identity, although its precise functions are controversial. Enzymes involved in the synthesis and degradation of RA as well as RA receptors are expressed in the eye with complex and polarized patterns. RA treatment upregulates Pax2 expression in the eye of zebrafish embryos, while deprivation of vitamin A during embryogenesis, inactivation of RA receptors, or inhibition of RA synthesis all lead to embryos with defects in the ventral retina. Despite this, embryos deficient in Raldh1, Raldh2, and Raldh3, genes coding for RA-synthesis enzymes, develop an optic cup with a normal dorso-ventral patterning, questioning the relevance of RA in this process.

Equally unclear is whether Shh signaling contributes to impose a ventral character to the optic cup. Although Shh is needed to control the initial expression of Pax2 and Vax genes in the optic vesicle, its forced dorsal expression at slightly later stages of development does not ventralize the dorsal optic cup, although BMP4 expression is downregulated. Defects are, instead, observed in the optic disk and the NR, where Shh causes activation of Otx2 expression and pigmentation. Conversely, interference with Shh signaling perturbs Otx2 expression and pigment formation in the ventral RPE, which loses its characteristics. Thus, Shh signaling may have a more specific function in the specification of the ventral RPE cells as well as of those that compose the optic fissure.

Independent of the signaling mechanism, the transcriptional control of dorso-ventral polarization of the optic cup depends largely on the activity of Tbx5 in the dorsal portion of the cup and Vax genes in the ventral part. Overexpression of Tbx5 causes dorsalization of the optic cup while overexpression of Vax leads to its ventralization. Pax6 seems to regulate the expression of both genes but in opposite directions establishing an intermediate zone that separate the two domains.

The significance of a dorso-ventral polarity in the NR at this stage and, thus, of the function of Tbx5 and Vax genes might be tightly linked to the establishment of the proper spatial order of the retino-tectal projections through the regulation of the expression of members of the ephrin (Eph) family of receptor tyrosine kinases and their ephrin ligands, which are axon-guidance cues essential for target recognition of RGC axons.

Conclusions

Early eye patterning in vertebrates is controlled by an evolutionary conserved genetic program, although initial morphogenetic events may vary from species to species. This program is regulated by the interplay among a number of signaling pathways and transcription factors. The information available at present represents an important backbone that needs to be extended for full understanding of eye development. *In vivo* imaging of eye morphogenesis as well as additional characterization of the involved genetic networks may help to understand the causes of inborn eye malformation such as anophthalmia, microphthalmia, and coloboma.

Extraocular Muscles: Extraocular Muscle Anatomy

L K McLoon, University of Minnesota, Minneapolis, MN, USA
S P Christiansen, Boston University, Boston, MA, USA

Glossary

Abducens nerve (CNVI) – The cranial motor nerve which controls contraction of the lateral rectus muscle.
Aponeurosis – A large flat and dense connective tissue layer which anchors a muscle to its origin or insertion.
Excyclotorsion – An outward rotation of the upper pole of the vertical midpoint of each eye.
Incyclotorsion – An inward rotation of the upper pole of the vertical midpoint of each eye.
Myosin heavy chain (MyHC) isoforms – The major contractile protein in muscle is myosin, which in turn is composed of two heavy and four light chains. MyHC isoforms are responsible for the shortening velocity of muscle fibers during muscle contraction.
Oculomotor nerve (CNIII) – The cranial motor nerve which controls contraction of the levator palpebrae superioris muscle, the inferior, medial, and superior rectus muscles, as well as the inferior oblique muscle. It also contains parasympathetic preganglionic axons that are destined for the ciliary body and iris sphincter muscles of the eye.
Ora serrata – The junction between the neurosensory retina and the ciliary body.
Satellite cells – Myogenic precursor cells that reside between the sarcolemma of the muscle fiber and its surrounding basal lamina. They are responsible for myofiber repair and regeneration after injury or in disease.
Strabismus – A disorder characterized by altered tonus or restrictive disease of the extraocular muscles resulting in loss of conjugate binocular vision.
Trochlear nerve (CNIV) – The cranial motor nerve which controls contraction of the superior oblique muscle.

The extraocular muscles (EOMs) have an extremely complex anatomy, both at the gross anatomical and histological levels. The main function of the EOM is to move the eyes in the orbit such that the eyes can be precisely positioned to allow focusing of the visual world on corresponding regions of each retina. Within each bony orbit the EOM includes four rectus muscles (superior, lateral, inferior, and medial) and two oblique muscles (superior and inferior; Figure 1). A seventh skeletal muscle within the human orbit is the levator palpebrae superioris (LPS) muscle. It is the superior-most muscle in the orbit directly inferior to the frontal bone forming the orbital roof. The levator lies directly inferior to the periorbita and inserts via a large aponeurosis into the eyelid skin. The descriptions of the EOM will be primarily based on human muscles for ease of presentation. The general characteristics of size, shape, fiber type, and the like are similar for all EOM in principle, although they vary in detail for each specific animal that has been examined.

Gross Anatomy of the EOM within the Orbit

The four rectus muscles originate from the apex of the bony orbit by a common tendinous annulus (of Zinn). The tendinous annulus attaches to the greater and lesser wings of the sphenoid bone as well as to the periosteum, the dense connective tissue lining the orbit. The annulus crosses over the inferior portion of the superior orbital fissure and runs superior and medial to the optic foramen (Figure 2). The superior (Figure 3) and medial rectus muscles arise from the superior part of this annulus, while the inferior and lateral rectus muscles arise from its inferior part. These muscles are all surrounded by a connective tissue capsule called Tenon's capsule and are described as forming the muscle cone. The superior oblique (SO) muscle originates from the periosteum slightly superior and medial to the tendinous annulus. The inferior oblique (IO) muscle is the only EOM that does not arise from the orbital apex, but rather originates from the lateral border of the lacrimal fossa, which is anterior and nasal within the orbit.

The rectus muscles run anteriorly to insert on the sclera on the anterior pole of the globe, at a location superficial to the ora serrata. The lateral and medial rectus muscles in human adults are approximately 41 mm in length. The superior rectus (SR) is the longest, averaging 42 mm, while the inferior rectus is the shortest averaging 40 mm. The insertions of the muscles onto the globe vary in their distance from the corneal limbus, with the SR furthest and the medial rectus closest. According to a study by Fuchs in 1884 on cadaver eyes, the distance from the limbus of rectus muscle insertions onto the globe

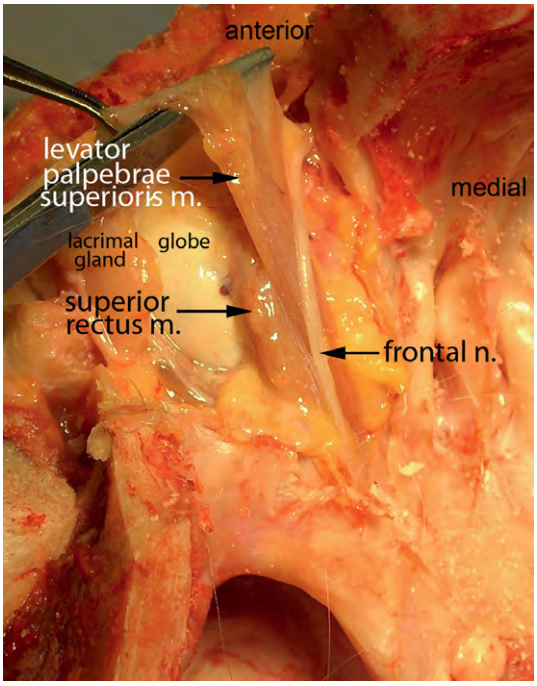

Figure 3 Dissection of the human orbit from the superior view with the orbital bony roof and the periorbita removed. The most superficial structure is the frontal nerve. Directly inferior to the frontal nerve is the levator palpebrae superioris (LPS, elevated by scissor tips). Inferior to the LPS is the superior rectus muscle.

decreases as one progresses sequentially in the following order: SR at 7.7 mm, lateral rectus at 6.9 mm, inferior rectus at 6.5 mm, and medial rectus at 5.5 mm. However, when measured *in vivo* during strabismus surgery the distances were shorter for all muscles: SR at 6.7 mm, lateral rectus at 6.2 mm, inferior rectus at 5.89 mm, and medial rectus at 4.5 mm. The insertions typically are circumferential to the limbus. However, wide variations in obliquity and regularity of the insertions are common, both from patient to patient and from muscle to muscle, even in the same eye. These differences are important in the context of planning surgery on the EOM for treatment of eye motility disorders, such as strabismus. Recent studies convincingly show that the distance from muscle insertion to the limbus has a high inter-individual variability, and there appears to be no correlation between insertional distance and the amount of deviation in strabismus patients.

The lateral rectus is innervated by the abducens nerve (CNVI) on its intraconal or deep surface (Figure 4). The SR muscle is innervated on its intraconal surface by the superior division of the oculomotor nerve (CNIII), while the inferior and medial rectus muscles and the IO muscles

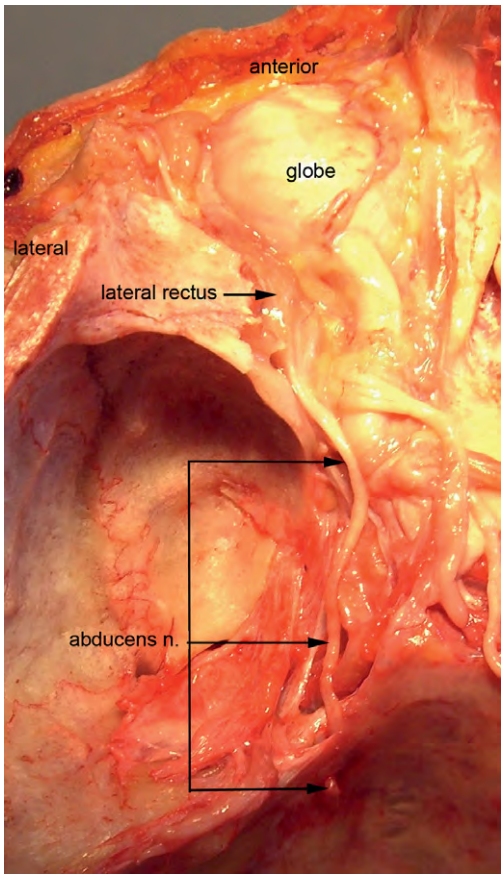

Figure 4 Dissection of the human orbit from the superior view. The bony roof, periorbita, levator palpebrae superioris, and superior rectus muscles are removed. The abducens nerve can be traced from where it pieces the dura in the posterior cranial fossa, through the superior orbital fissure, which has been opened in this dissection, to where it enters the lateral rectus muscle which it innervates.

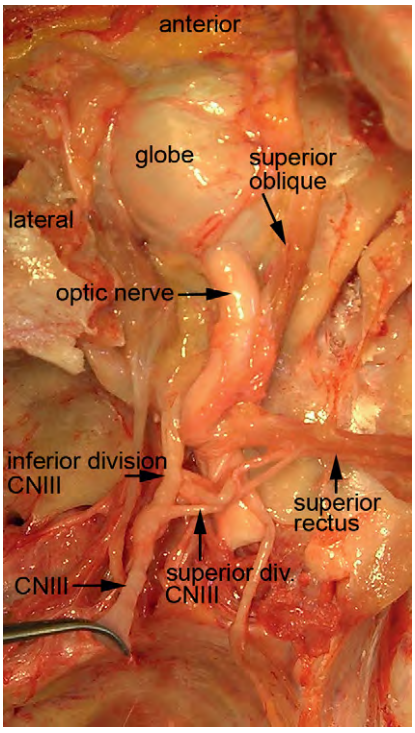

Figure 5 Deep orbital dissection from the superior view. The levator palpebrae superioris and superior rectus muscles are reflected medially to allow visualization of the superior and inferior divisions of the oculomotor nerve (CNIII).

are innervated by the inferior division of CNIII (Figure 5). All the cranial motor nerves except for the trochlear nerve (CNIV) enter the muscles intraconally, and all the motor nerves enter at approximately one-third of the muscle's length from the orbital apex (Figure 6). The six EOMs control the position of the eye in the orbit while orbital fat and fascia constrain the paths of the muscles within the orbit.

The two horizontal rectus muscles of each eye are agonist–antagonist pairs with relatively straightforward function; the medial rectus adducts the eye and the lateral rectus abducts it (Figure 7). By contrast, the SO and the IO muscles and the two vertical rectus muscles have far more complex functions. The primary direction of movement caused by the superior and inferior rectus muscles is elevation and depression, respectively. However, due to the shape of the bony orbit and their sites of origin and insertion, the vertical recti have secondary and tertiary actions that are torsional and horizontal, respectively. The SR, for example, is a secondary incyclorotator, moving the superior pole of the eye toward the nose; its tertiary function is adduction. The inferior rectus muscle, by contrast, is also a secondary excyclorotator, but similar to the SR is a tertiary adductor (Figure 8). Thus, the SR, if acting unopposed, would elevate, adduct and incyclotort the eye such that the eye would be looking up and in. The inferior rectus, if acting unopposed, would depress, adduct, and excyclotort the eye such that the eye would be looking down and in. The superior and IO muscles have a similarly complex cyclovertical functions. The primary action of these two muscles is rotation or torsion, but due to the angle which they take in the orbit toward their insertion on the sclera, they will also elevate (IO) or depress (SO) the eye; both abduct the eye. The remarkable balance and integrity of the ocular motor plant becomes evident when one considers that to look straight superiorly without moving the head, both the IO (a primary excyclorotator, secondary elevator, and tertiary abductor) and the SR (a primary elevator, secondary incyclorotator, and tertiary adductor) coordinately contract. The same is true for the inferior rectus and SO muscles moving the eye straight inferiorly.

The SO muscle is the thinnest, roundest, and longest of the EOM. The muscle runs 32 mm along the border of the medial wall and roof of the orbit, and 10–15 mm from the orbital margin it becomes tendinous and passes through

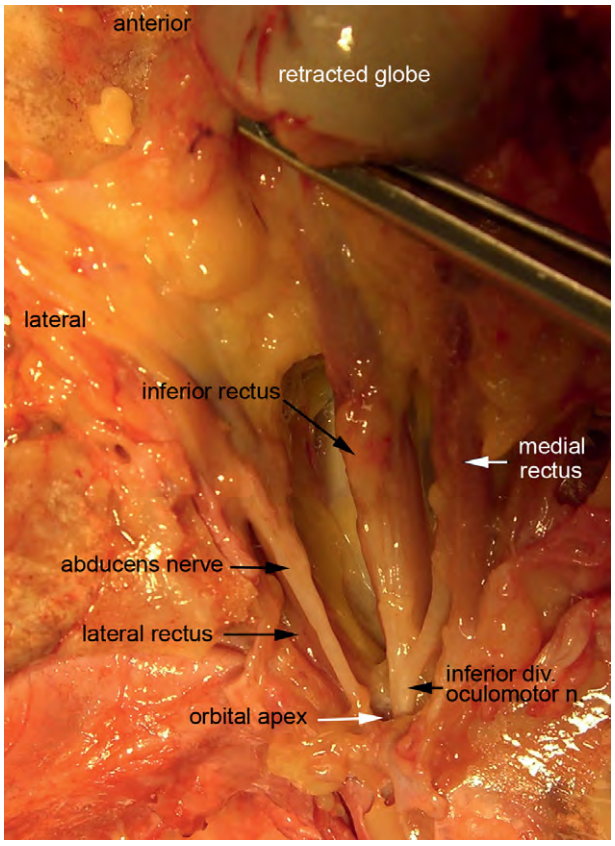

Figure 6 Deep orbital dissection from the superior view. The lateral, inferior, and medial rectus muscles are clearly visible, as are the nerves entering each muscle. The globe has been retracted anteriorly (by scissors).

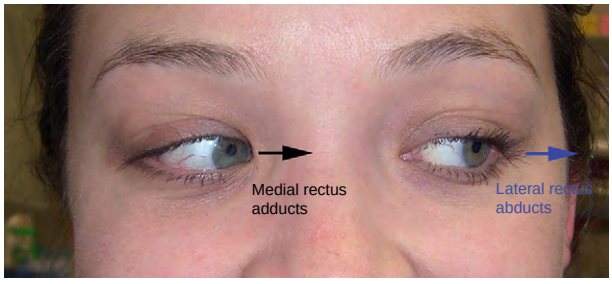

Figure 7 The lateral rectus (LR) and medial rectus (MR) muscles move the eyes in the horizontal plane. The MR adducts the eye, moving the eye toward the midline. The LR abducts the eye, moving the eye away from the midline. These muscles are antagonists; they have opposite functions.

Figure 8 The primary role of the superior rectus (SR) muscles is to elevate the eye; however, they have a secondary role in adducting the eye. The primary role of the inferior oblique (IO) muscles is to extort the eye, rotating the eye upward (elevation) and outward (abduction).

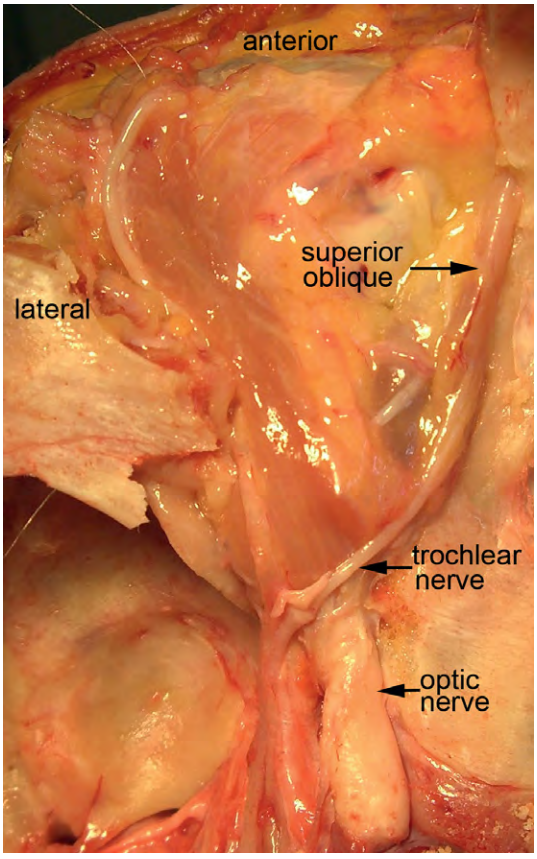

Figure 9 The superior oblique muscle can be seen along the medial wall of the orbit. The trochlear nerve (CNIV) is seen coursing along the muscle's superior surface and enters into the posterior 1/3 of the muscle on its medial side.

a fibro-fascial structure called the trochlea, located anteriomedially under the orbital roof. The trochlea changes the orientation of the muscle, becoming the functional origin of this muscle. The tendon of the SO courses deep to the SR muscle to insert into the sclera laterally on the posterior pole of the globe. The position of the SO tendon insertion, posterior and temporal to the center of rotation of the globe, explains the complex cyclovertical function of the muscle. The trochlear nerve (CNIV) innervates this muscle, coursing first on the muscle's superior side, and finally entering the muscle superiomedially at about the proximal one-third of the muscle's length (**Figure 9**).

The IO muscle is approximately 37 mm in length and travels in a similar orientation to the reflected tendon of the SO distal to the trochlea. The muscle runs inferior to

the inferior rectus muscle and inserts into the sclera of the posterior pole on the lateral side of globe. The insertion is relatively close to the macula of the retina. The IO is innervated by the inferior division of the oculomotor nerve (CNIII) on its superior surface with the nerves entering the muscle at approximately the posterior one-third.

Histological Anatomy of the EOMs

Overall Organization

The EOMs have a complex anatomical organization at the microscopic level. These muscles differ from those in the limbs and body in that the muscle fibers themselves have extremely small cross-sectional areas, with an average in human EOM of $340 \pm 200\,\mu m^2$ (**Figure 10**). In addition, there is a great deal of variability in the myofiber cross-sectional areas; this heterogeneity is quite striking. In cross-section, two distinct layers can be seen in all six EOMs, the orbital and the global layers. The orbital layer faces the bony orbit and is composed of myofibers with extremely small cross-sectional areas, with a mean of $260 \pm 160\,\mu m^2$. The global layer faces the globe, and the myofibers are markedly bigger than those in the orbital layer with a mean of $440 \pm 200\,\mu m^2$. However, they are still very small compared to body and limb skeletal muscle myofibers, which typically range from 3500 to $4000\,\mu m^2$ in the human soleus muscle, as an example.

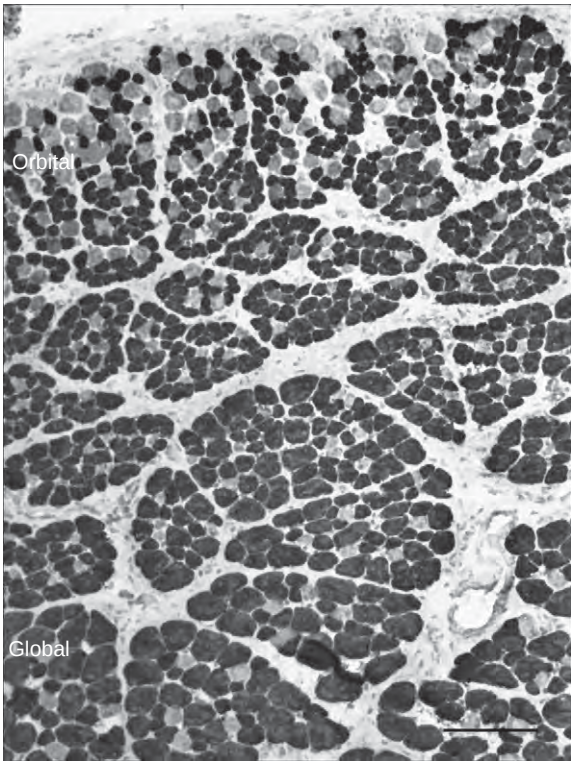

Figure 10 A cross section of the medial rectus muscle from a Rhesus monkey immunostained for the presence of the fast myosin heavy chain (MyHC) isoform, which labels all forms of the fast MyHC. The orbital layer is composed of myofibers with extremely small cross-sectional areas, while myofibers in the global layer are somewhat larger. Bar is 50 μm.

The total number of myofibers found within each of the six EOMs varies significantly. When measured in the mid-belly region of the muscles, the numbers of myofibers in the orbital layer in human EOM range from 7400 to 14 600 and in the global layer the numbers range from 8000 to 16 400 myofibers. This variation in myofiber number is seen in other species where the fiber number has been examined, although the range varies significantly from human. For example, monkey EOMs have approximately half the number of myofibers compared to human EOM. In addition, total myofiber number decreases along the length of each muscle as the insertions are approached. This variation in fiber number is due to the fact that the majority of myofibers within the EOM does not run tendon to tendon, as has been shown by a number of investigators. This can be demonstrated quite easily by serially sectioning muscles and following individual myofibers in consecutive sections (**Figure 11**). This is also supported by electrophysiological evidence demonstrating that the force produced by stimulating two separate motor unit groups individually is often more than the force produced by stimulating both motor groups simultaneously. This nonlinearity, or loss of force in summated motor units, is postulated to be caused by the lateral dissipation of force due to myofibers that do not reach the tendon ends.

Innervation

Most skeletal muscles receive their motor nerve innervation in approximately the middle, and the neuromuscular junctions form a single endplate zone. Neuromuscular junctions are a pentomer composed of four distinct subunits: α (2), β, γ, and δ. During maturation, the γ subunit is replaced with an ε subunit, forming the adult acetylcholine receptor. In contrast to limb skeletal muscle, the EOM maintains a subpopulation of neuromuscular junctions with the immature subunit configuration.

While the vast majority of EOM muscle fibers is fast-twitch fibers and receive a typical *en plaque* type of neuromuscular junction somewhere along their length, the EOM also contains two types of multiply innervated myofibers. These account for approximately 10% of the fibers in the global and orbital layers. In the global layer, these multiply innervated myofibers contain slow-tonic myosin and appear to be innervated by small *en grappe* endplates along their length. These *en grappe* neuromuscular junctions retain the γ subunit of the acetylcholine receptor, rather

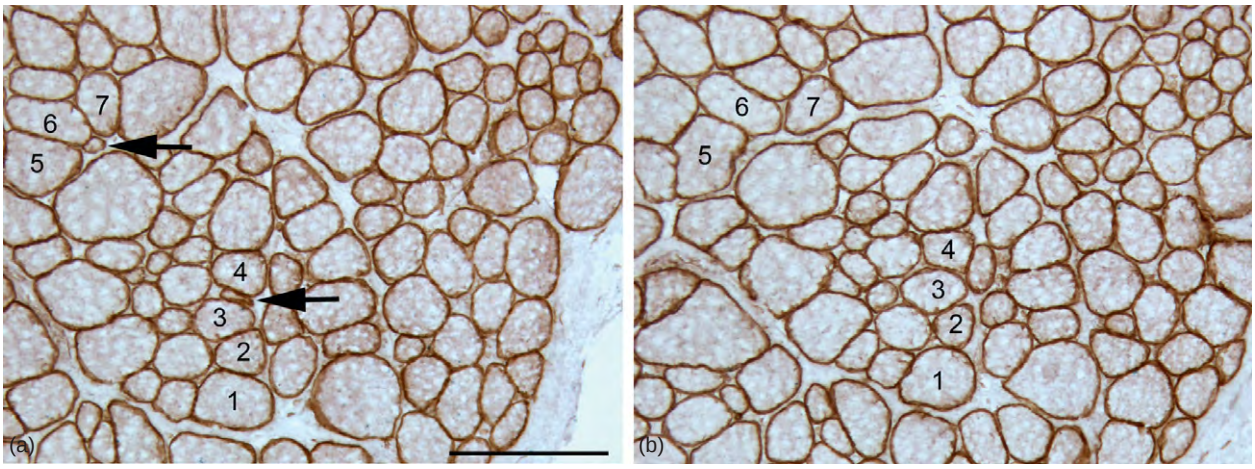

Figure 11 Two serial sections from a normal rabbit superior rectus muscle. Several sets of muscle fibers in cross section are numerically identified. (a) Note two small myofibers present in this section, one to the right of group 5, 6, and 7 (black arrow), and one between fibers 3 and 4 (black arrow). (b) Note that in a section 20 μm from the section in (a) that those two small fiber ends have ended and thus are no longer present in the cross-section. Muscle sections immunostained to visualize dystrophin on the sarcolemma. Bar is 40 μm.

than the ε subunit of the mature neuromuscular junction. There are reports in the literature that the *en plaque* endings in mammalian EOM can also express the immature γ subunit of the acetylcholine receptor. This type of multiply innervated myofiber develops a slow-graded or tonic tension when the nerves are stimulated. The orbital layer has a second type of multiply innervated myofiber. These fibers have a neuromuscular junction in the central one-third of their length with typical *en plaque* structure. In addition, however, there are multiple *en grappe* endings at the myofiber ends. Thus, the central region displays fast-twitch properties with nerve stimulation while the fiber ends display slow-tonic contractile properties.

As a result of fibers that do not run the origin-to-insertion length of the muscles and the presence of neuromuscular junctions on fiber ends, neuromuscular junctions are found throughout the length of the EOM. This has important implications for pharmacologic and surgical manipulations of the muscles in the treatment of eye motility disorders such as strabismus and nystagmus.

Skeletal Muscle Fiber Types

From a physiological perspective, the EOMs have extremely fast contractile properties, produce low levels of force, and are relatively fatigue resistant. These properties are conferred on muscle fibers by their expression of specific contractile proteins such as the myosin heavy chain isoforms (MyHC), as well as differences in cellular organelles such as mitochondria and other cellular metabolic pathways. One unusual aspect of EOM histology is the expression, within and between these two layers, of a complex pattern of MyHC expression.

Myosin Isoform Complexity in the EOM

Skeletal muscle fibers in body and limb muscles have generally been described as fast, expressing MyHC type IIa, IIb (nonhuman), and/or IIx/d, or slow, expressing MyHC type 1. However, this fiber type organization breaks down in the EOM, as was described by Mayr in 1971. On average, only 16% of the myofibers within the orbital layer are positive for the slow MyHC (MYH7), while 14% of the myofibers in the global layer are positive for slow MyHC. Thus, the vast majority of myofibers expresses the fast MyHC2a isoform (MYH2) which is responsible for the extremely fast contractile properties of the EOM. However, the EOMs express, in total, at least eight distinct MyHC isoforms: 2a, 2x/d, 1 (β-cardiac), developmental (embryonic), neonatal (perinatal), α-cardiac, slow-tonic, and EOM-specific. If serial sections of individual myofibers are examined immunohistochemically, it quickly becomes evident that single myofibers express more than one isoform (**Figure 12**). In the Kjellgren et al. study of adult human EOMs, single fibers immunostained for the slow or MyHC type 1 isoform can co-express either or both slow-tonic MyHC and α-cardiac MyHC. If just the slow myofibers are considered, they can express:

1. only MyHC type 1,
2. only slow-tonic,
3. only α-cardiac,
4. only EOM-specific,
5. MyHC type1 and slow-tonic,
6. MyHC type 1 and α-cardiac,
7. myosin type 1 and EOM-specific,
8. slow-tonic and α-cardiac,
9. slow-tonic and EOM-specific,

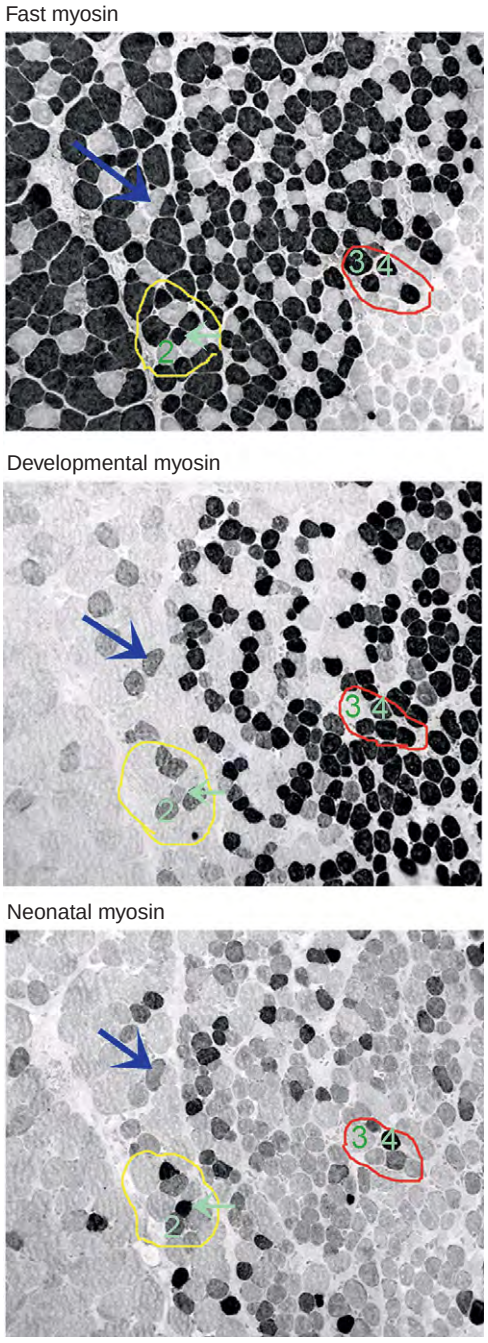

Figure 12 Three serially cut cross sections from a region of a rabbit lateral rectus muscle approaching the anterior 1/3 of the muscle. They have been immunostained for fast, developmental, and neonatal myosin heavy chain (MyHC) isoforms. One group of muscle fibers has been circled in yellow with two fibers identified by a light-green arrow and a fiber numbered 2. Note that the fiber indicated by the green arrow is positive for fast and neonatal MyHC but negative for developmental MyHC. Note that fiber 2 is negative for fast MyHC but positive for developmental and neonatal MyHC. A second group of muscle fibers has been circled in red with two fibers identified as fiber 3 and 4. Fiber 3 is positive for fast MyHC but negative for both developmental and neonatal MyHC, while fiber 4 is positive for all three of these isoforms. The fiber indicated by the large blue arrow is negative for fast MyHC, but positive for both developmental and neonatal MyHC.

10. α-cardiac and EOM-specific,
11. slow type 1, slow-tonic, and α-cardiac,
12. slow type 1, slow-tonic, and EOM-specific,
13. slow-tonic, α-cardiac, and EOM-specific, or
14. all four isoforms (**Figure 13**).

These combinations may result in 14 types of fibers. It is also known that embryonic (developmental) and neonatal-specific MyHC isoforms are also expressed by some of these fibers as well. The same complexity is seen with the myofibers positive for the fast MYHC type 2A. Single fibers can also express one of one or more of these isoforms: developmental, neonatal, EOM-specific, and 2x/d. These types of myofibers are referred to as hybrid fibers, and they can be seen, albeit to a lesser extent, in other muscles such as the diaphragm. Even when only MyHC expression characteristics are considered, the high degree of individual myofiber polymorphism seen in the collective data from many laboratories strongly supports the view that there is a continuum of myofiber types within the EOM. In some ways, trying to fit the EOM into the classical fiber typing scheme is misleading, as it does not deal effectively with the hybrid and mismatched fibers.

This complexity has significant ramifications for muscle function. MyHC isoforms control muscle-shortening velocity, and it has been proposed that this type of polymorphism allows for fine-tuned control over a wide range of forces, velocities, and fatigue properties. From a teleological perspective, these coexpression patterns would allow the EOM to contract at high velocities but with minimal fatigue, a characteristic that is important for muscles that are continually functioning in order to maintain fixation of gaze on the fovea in an infinite number of eye positions. Additionally, studies have shown that the EOMs show rapid alterations in MyHC isoform expression in response to stretch, alterations in hormones, botulinum toxin treatment, denervation, and the like.

Nonuniform Expression of MyHC Isoforms along the Muscle Length

Immunohistological examination of cross-sections taken from the tendon ends and the middle region of an EOM shows that the overall percentages of specific MyHC isoforms change dramatically depending on the location along the muscle length (**Figure 14**). For example, in a study of rat EOM, within the orbital layer the mid-belly region expresses EOM-specific MyHC but this isoform is completely excluded from the tendon ends where the embryonic (developmental) MyHC isoform is present. This is seen even at the level of single isolated myofibers, where the fiber ends express neonatal MyHC and the mid-region of the same myofiber expresses fast MyHC. This type of non-uniform expression of MyHC along the length of single fibers also is seen in the intrafusal muscle

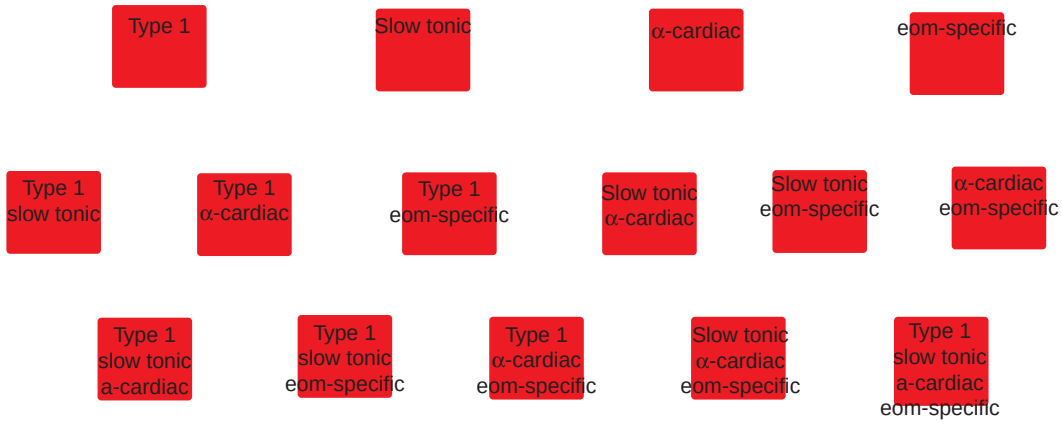

Figure 13 Diagrammatic representation of possible co-expression patterns when four myosin heavy chain isoforms are considered. Each red rectangle represents a single myofiber. Based on Kjellgren, D., Thornell, L. E., Andersen, J., and Pedrosa-Domellof, F. (2003). Myosin heavy chain isoforms in human extraocular muscles. *Investigative Ophthalmology and Visual Sciences* 44: 1419–1425.

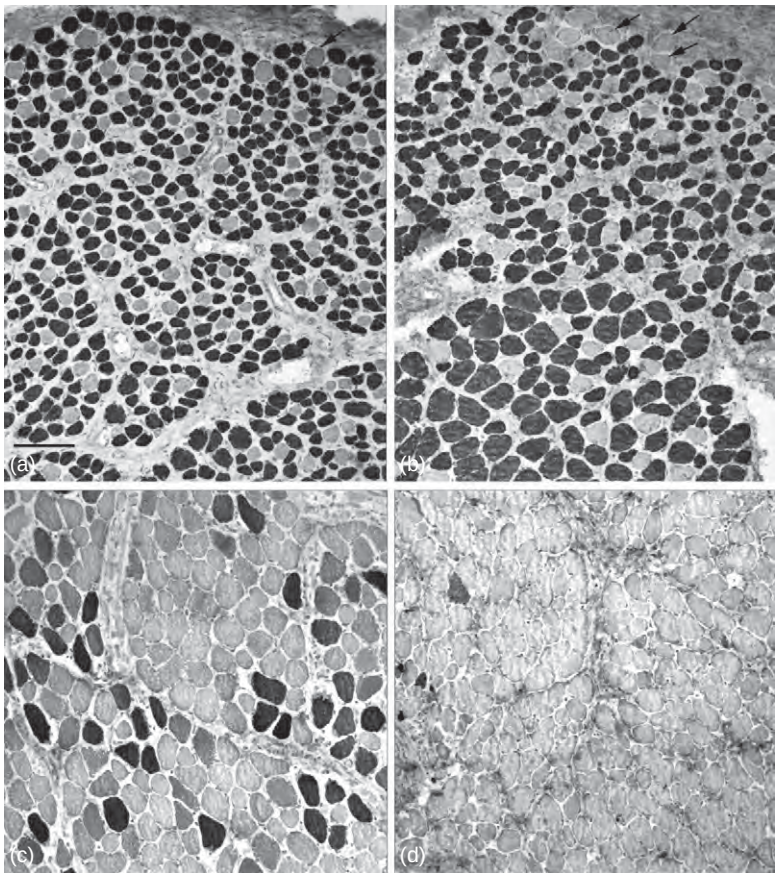

Figure 14 Cross section from a single superior rectus muscle of an adult monkey taken from the orbital (a, b) and global (c, d) regions of the mid-region of the muscle (a, c) and the tendon end (b, d) immunostained for fast myosin heavy chain isoform (MyHC) (a, b) and neonatal MyHC (c, d). The orbital region is at the top of the photomicrographs in (a) and (b). Note that the orbital layer is thicker in (a), but that the individual myofibers have a smaller cross-sectional area in the mid-region compared to the tendon end. Additionally, there are more fast-negative fibers in the tendon region of the orbital layer. In the global layer, the mid-region has 20% of its myofibers positive for the neonatal MyHC, while the tendon end is almost devoid of this isoform. Bars is 50 μm.

fibers found in muscle spindles, another specialized myofiber structure. Using single myofiber reconstructions to localize neonatal MyHC isoform expression in single fibers, myofibers are found that are neonatal MyHC-positive from fiber tip to fiber tip, but it is more common to find single myofibers with variable percentages of the total fiber length expressing this isoform, including fibers where the expression is discontinuous. It is emerging that these types of hybrid fibers are present in other craniofacial muscles, such as jaw and laryngeal muscles.

In limb and body skeletal muscles, innervation, neuromuscular activity, exercise (use/disuse), mechanical loading or unloading, hormones, and aging all cause adaptive changes in contractile properties and metabolic profiles. This supports the view that expression of contractile proteins within muscle fibers is extremely dynamic and possesses an incredible adaptability to meet the physiological demands placed upon them. EOMs are constantly active and appear to represent the far end of a continuum of skeletal muscle types relative to their ability to react and adapt to changing functional needs. As the MyHC controls shortening velocity, this MyHC polymorphism would result in a gradation of function within populations of single myofibers. In other words, a continuum of force and movement would be possible, as the contractile properties of each myofiber would reflect its particular subset of contractile proteins. An example of this is shown in Figure 15, where force was determined using a single fiber preparation and the MyHC content was analyzed for each single fiber using polyacrylamide gel separation. As can be seen, fibers that produce the same amount of force can have significantly different MyHC isoform expression patterns.

While it has not been demonstrated specifically within EOM myofibers, it is a well-known characteristic of multinucleated myofibers that each myonucleus controls the expression of proteins in what is called its myonuclear domain. An elegant study by the Hardeman laboratory showed that transcription occurs in pulses within individual myonuclei, and the activities of single nuclei are not in sync with each other. Each nucleus, and thus each myonuclear domain, is individually controlled, and protein synthesis is a dynamic process that is altered at the local level to respond to the particular stress or strain.

The advantage conferred by this complexity within populations of individual EOM myofibers can be hypothesized as an adaptation to the functional needs of eye movements in maintaining binocular vision and highly coordinated vergence movements, where a continuum of contraction forces and speeds would be required. Functionally, the complex MyHC co-expression patterns, and their presumed continuous modulation, would allow finely tuned control over these movements, as the kinetics of the EOM would cover a wide range of eye positions and velocities.

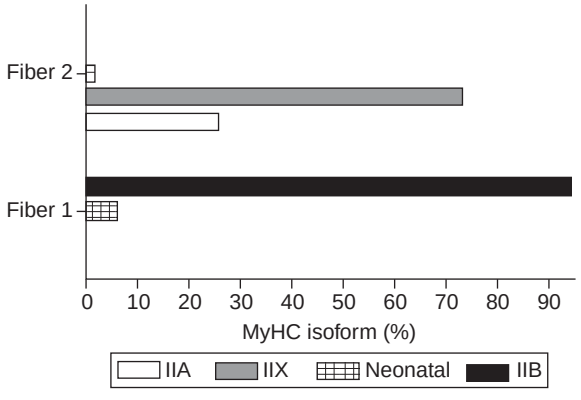

Figure 15 Relative percentages of four myosin heavy chain isoforms from two single-skinned myofibers with the same shortening velocity of 9.4 fiber lengths per second as determined using single-skinned fiber physiology in the EOM of rabbits. Note that fiber 1 has three isoforms expressed, and it contains type IIX as its main isoform, while fiber 2 has only two isoforms expressed, and IIB is the isoform with the greatest amount of expression.

Other Molecules Heterogeneously Expressed

The heterogeneity of individual myofibers is made even more complex not only by differences in other contractile proteins, such as myosin light chains and troponin, but also by other metabolic differences. Of the molecules that have been specifically examined, the EOM often has patterns of expression not seen in limb muscle. For example, myosin-binding protein C has three isoforms. Despite the fact that the vast majority of myofibers within human EOM is positive for fast MyHC, the EOM does not express the fast form of myosin-binding protein C. Recent work showed that, in contrast to limb skeletal muscles, high levels of glycolytic and oxidative pathways coexist within single myofibers in the EOM. This molecular mismatch would provide these very active muscles with both fatigue resistance and fast contractile properties.

Continuous Remodeling in Normal Adult EOM

Early studies by Moss and LeBlond demonstrated that the myonuclei within mature, multinucleated myofibers are postmitotic. However, muscle has regenerative capacity that resides in myogenic precursor cells called satellite cells, and these cells become activated, divide, and are responsible for muscle repair and/or regeneration of new fibers in disease and after injury. The EOM in normal adult mammals maintain an elevated number of satellite cells throughout life (Figure 16), which divide and integrate continuously into apparently normal muscle fibers. Concomitantly with nuclear addition, apoptosis of individual myonuclei is seen with apparent segmental cytoplasmic remodeling. The factors that control this process are

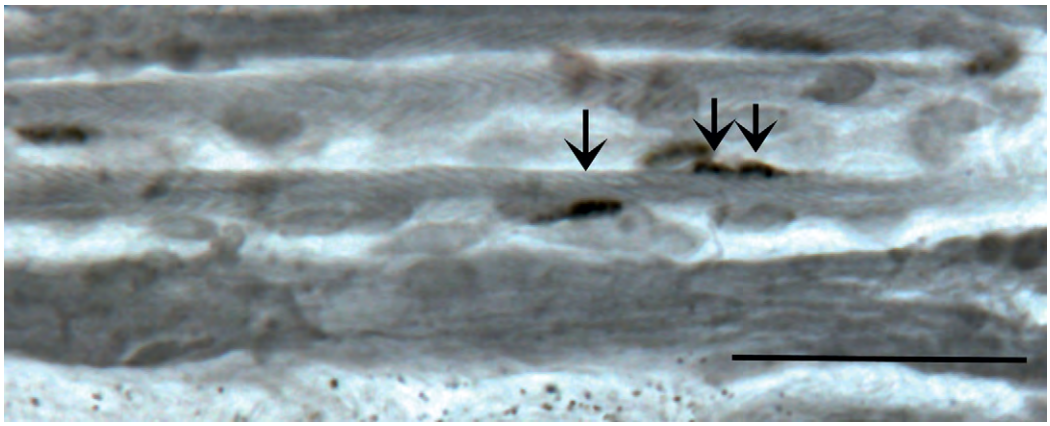

Figure 16 Several longitudinally sectioned myofibers from the inferior oblique muscle of a human cadaver donor. Note three satellite cells positive for Pax-7, a marker of all satellite cells. Two satellite cells in close proximity to each other is a common observation in the extraocular muscles.

unknown, but this process represents another dynamic physiological property of the EOM that would allow continuous adaptation of single fiber functional properties in response to physiological needs. The existence of ongoing remodeling in normal adult EOM suggests that there may be ways to modulate this process *in vivo* to alter muscle size, force, or response to injury or disease. In particular, it suggests new hypotheses to explain the preferential sparing or involvement of the EOM in skeletal muscle disease.

Extraocular Muscles: Extraocular Muscle Involvement in Disease

F Pedrosa-Domellöf, Umeå University, Umeå, Sweden

Glossary

Amyotrophic lateral sclerosis (ALS) – A progressive neurodegenerative disease where the motor neurons degenerate, resulting in loss of voluntary control over movement.
Arreflexia – The absence of a reflex, usually due to nerve damage.
Ataxia – A brain disease of the cerebellum and associated brain areas that affects the ability to make coordinated movements.
Duchenne muscular dystrophy – An X-chromosome-linked disease caused by a mutation in the gene for dystrophin; a protein important for structural stability of muscle fibers. It is characterized by progressive muscle degeneration, resulting in loss of mobility and death.
Juvenile spinal muscular atrophy – A slowly progressive disease characterized by proximal muscle weaknesses and wasting, beginning in childhood. It is due to the death of the motor neurons in the spinal cord.
Miller Fisher syndrome – A rare nerve disease related to Guillain–Barré syndrome, characterized by abnormal muscle coordination, paralysis of eye muscles, and loss of tendon reflexes.
Myasthenia gravis – An autoimmune disease characterized by weakness of the skeletal muscles.
Ophthalmoplegia – A condition where one or more of the extraocular muscles are weak or paralyzed, resulting in abnormal eye movements.
Poliomyelitis – A disease caused by an acute viral infection, which can cause motor neuron degeneration. This results in muscle weakness and flaccid paralysis.

Introduction

The extraocular muscles (EOMs), defined as the superior, lateral, inferior, and medial rectus and the superior and inferior oblique muscles, are the most fascinating muscles in the human body because of their complex structural and physiological characteristics adapted to meet the motility requirements of fovea-based binocular vision and, in particular, their unique responses to disease.

At one extreme of the spectrum, the EOMs are able to remain intact in devastating neuromuscular diseases affecting all other muscles in the body, such as the muscle dystrophies and motor neuron disease. At the other extreme, they are the only or the preferential muscles to be involved in myasthenia gravis (MG), mitochondrial myopathies (MMs), oculopharyngeal muscular dystrophy, thyroid-associated orbitopathy, and the Miller Fisher syndrome.

The EOMs are considered to be a separate muscle allotype, that is, a separate class of muscles with intrinsically different properties that differ significantly from those of the other two allotypes, that is, limb and masticatory muscles. A large body of data collected so far strongly defines the EOMs as a unique class of muscles at the structural, cellular, molecular, and gene level, suggesting that the special behavior of these muscles in disease most likely reflects their unique identity in all respects and that further studies are needed to understand the mechanisms determining their response in disease. On the other hand, deeper knowledge of the mechanisms involved in the selective sparing of the EOMs may provide the groundwork for further advances toward breakthrough therapies for devastating neuromuscular diseases with lethal outcomes.

The EOMs Are Selectively Spared in Muscular Dystrophies

Muscle fiber integrity is dependent on a functionally intact connection between the extracellular matrix molecules on the cell surface, a number of transmembrane proteins, and the complex cytoskeleton inside the cell. Of particular importance are laminin 211 (merosin), the sarcoglycans, and caveolin-3, which are all members of the so-called dystrophin-associated protein complex and dystrophin itself; a gene defect in any of these components gives rise to a muscular dystrophy.

Duchenne muscular dystrophy (DMD) is the most well-studied form of human dystrophy, and a large number of mutations and deletions in the dystrophin gene have been reported. The dystrophin molecule is a part of the cytoskeleton located under the sarcolemma. The muscles of patients with DMD undergo a successive process of fiber degeneration and regeneration and, with time, show increased amounts of connective tissue and fatty replacement. Clinically, there is progressive muscle weakness and wasting starting in childhood, loss of ambulation at

an early age, and precocious death due to respiratory complications and respiratory failure.

The EOMs are clinically and microscopically spared in patients with DMD and in several relevant animal models of dystrophies, including the mdx mouse (Figure 1) and cmdx dog, the γ- or δ-sarcoglycan-deficient mouse, and the merosin-deficient mouse. The reasons for the selective sparing of the EOMs in these dystrophies are not fully understood, with the exception of merosin-deficient congenital muscle dystrophy. It is noteworthy that in animal models, the true EOMs are unaffected, whereas the retractor bulbi and the levator palpebrae muscles are not spared.

The EOM fibers of the mdx mouse express utrophin extrasynaptically, suggesting that this cytoskeletal protein may compensate for the lack of dystrophin. However, approximately half of the fibers are still spared in the EOMs of mice lacking both dystrophin and utrophin, indicating that other mechanisms are also of importance for the selective sparing of these muscles in DMD. Very small fiber size and small loads to work against, as well as an enhanced capacity to regulate calcium homeostasis, may protect the EOMs against mechanical stress and allow for the maintenance of fiber integrity even in the case of absent dystrophin or a defective dystrophin-associated protein complex.

The human and mouse adult EOM fibers co-express α-4, α-5, and β-2 laminin chains on the surface of the extrasynaptic sarcolemma in addition to the α-2 and β-1 laminin chains found on all adult skeletal muscle fibers. This indicates the possible coexistence of laminins 411, 421, 511, and 521 in the EOMs in addition to laminin 211 and 221. The α-4 chain of laminin is normally expressed in all skeletal muscle fibers during development and is later downregulated in the limb muscle. The presence of these additional laminin isoforms in the basal lamina of normal adult human EOM fibers is most likely the mechanism behind the selective sparing of the EOMs in merosin-deficient congenital muscle dystrophy. This hypothesis has been confirmed in the dy^{3k}/dy^{3k} mice, which completely lack the α-2 laminin chain and develop the corresponding muscle dystrophy, but their EOMs are spared.

Using markers of satellite cell activation validated in other skeletal muscles and experiments using bromodeoxyuridine (brdU) labeling, data from human, monkey, rabbit, and mouse indicate that the EOMs normally have a significant population of activated satellite cells resulting in a continuous myonuclear addition to individual muscle fibers in the absence of injury or disease. Thereby, the EOMs appear to normally have an ongoing remodeling process that is likely to be advantageous in disease situations such as the muscular dystrophies. Microarray data revealed increased expression of genes related to growth, development, and regeneration in the EOMs in comparison to the limb muscles, supporting the concept of increased regenerative capacity as an important factor for the selective sparing of the EOMs in disease.

The EOMs Are Spared in Motor Neuron Disease

Motor neuron disease such as amyotrophic lateral sclerosis (ALS), juvenile spinal muscular atrophy, and poliomyelitis generally do not involve the EOMs, or at least do not affect the EOMs to the same degree as the limb, trunk, and other cranial muscles. Abnormal ocular motility in ALS patients may be (1) due to supranuclear or extrapyramidal dysfunction and (2) underestimated due to the more dramatic consequences of the other denervation symptoms, such as loss of ambulation or swallowing difficulties.

Recent data indicate that the EOMs in the terminal stage of ALS are not completely spared, although they are remarkably well preserved compared to the limb muscles (Figure 2). We have found signs of ongoing denervation,

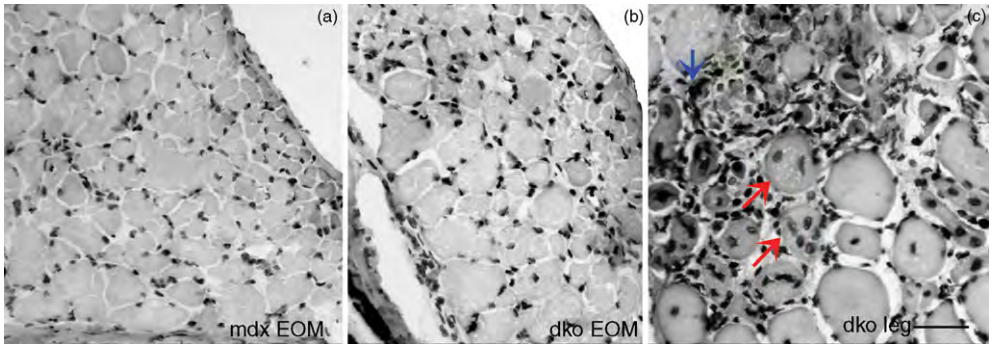

Figure 1 Extraocular muscles (EOMs) of two mouse models of Duchenne muscle dystrophy (mdx mouse in (a) and double knockout for dystrophin and utrophin (dko) in (b) show normal morphology, in strong contrast to the dystrophic leg muscle shown in (c)). Red arrows show muscle cells with centrally placed nuclei, indicating ongoing regeneration and the blue arrow shows the presence of infiltrating nonmuscle cells. Section stained to visualize all nuclei. Bar is 20 μm. Courtesy of Dr. Linda McLoon, University of Minnesota.

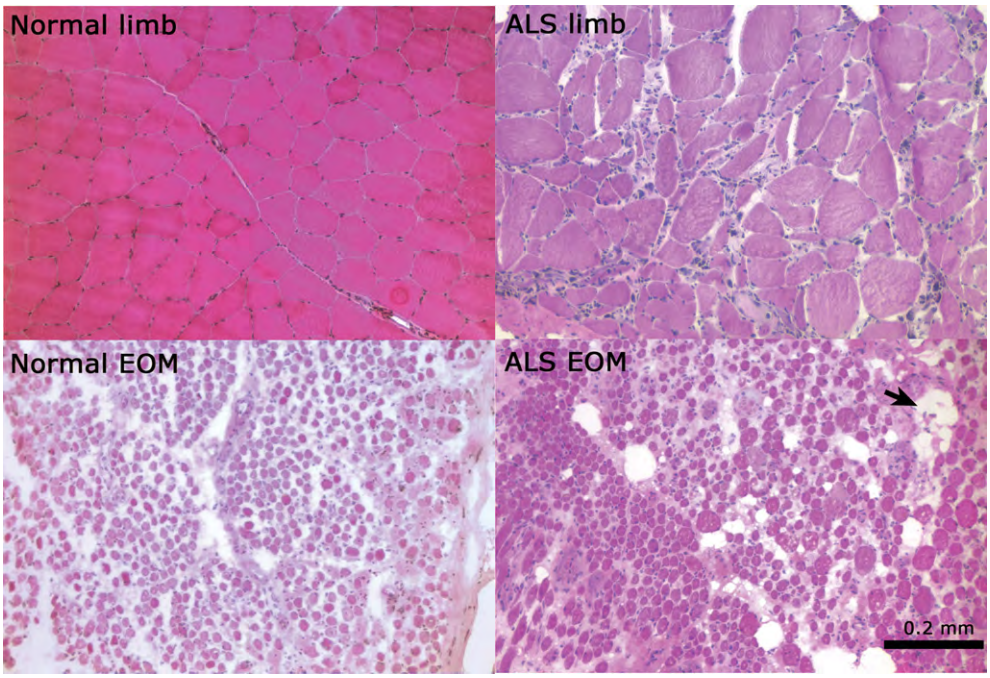

Figure 2 Limb and extraocular muscle (EOM) samples from normal subjects and from patients with amyotrophic lateral sclerosis (ALS). In the terminal phase of ALS, the EOMs are not truly spared and show wide variation in fiber size and some areas of fatty replacement (the arrow and white areas in the lower right panel).

regeneration, and overuse of some fibers in the EOMs collected at autopsy from both familial and sporadic forms of ALS.

Differences in calcium-binding protein composition between the spinal motor neurons and those supplying the EOMs have been reported and may be an important factor determining the different susceptibility of the EOMs in ALS.

The EOMs Are Selectively Affected in the Miller Fisher Syndrome

The Miller Fisher syndrome is a milder form of the Guillain–Barré syndrome, characterized by the clinical triad of ophthalmoplegia, ataxia, and arreflexia as well as the presence of autoantibodies against GQ1b gangliosides. Autoantibodies against other structurally similar gangliosides may also be present, and a mechanism of molecular mimicry has been proposed, whereby these autoantibodies are postulated to arise following a variety of intestinal and respiratory infections, such as by *Campylobacter jejuni*. A complement-mediated inflammatory reaction at the neuromuscular junction, where the gangliosides reside outside of the blood–nerve barrier, is responsible for the muscular paralysis.

Recent data clearly show differences in ganglioside composition between the EOM and limb muscle synapses (Figure 3), providing a molecular basis for the paralysis of the EOMs in this syndrome. The fact that the EOMs have the highest capillary density reported for any human muscle may be a very important factor facilitating the access of the circulating ganglioside autoantibodies to the neuromuscular junctions of the eye muscles.

The EOMs Are Frequently Involved in Myasthenia Gravis

MG is a chronic autoimmune disorder affecting the neuromuscular junctions of skeletal muscles and causing muscle fatigue and weakness. The EOMs and the levator palpebrae muscle are almost invariably involved, and they are often the first muscles to be affected. The EOMs and the levator palpebrae muscle can, in fact, be the only muscles to be affected, and the disease is then referred to as ocular myasthenia. Untreated and over time, the majority of patients with ocular myasthenia will progress toward the generalized form.

Typical symptoms of MG and ocular myasthenia are diplopia (double vision) and ptosis (drooping of the upper eyelid) that vary in intensity over time and improve after rest or cooling down (see below, ice-pack test).

Autoantibodies against acetylcholine receptors are highly specific for MG, but may be absent in patients with ocular myasthenia. False positive detection of autoantibodies against acetylcholine receptors occurs, however, in a number of autoimmune disorders, such as

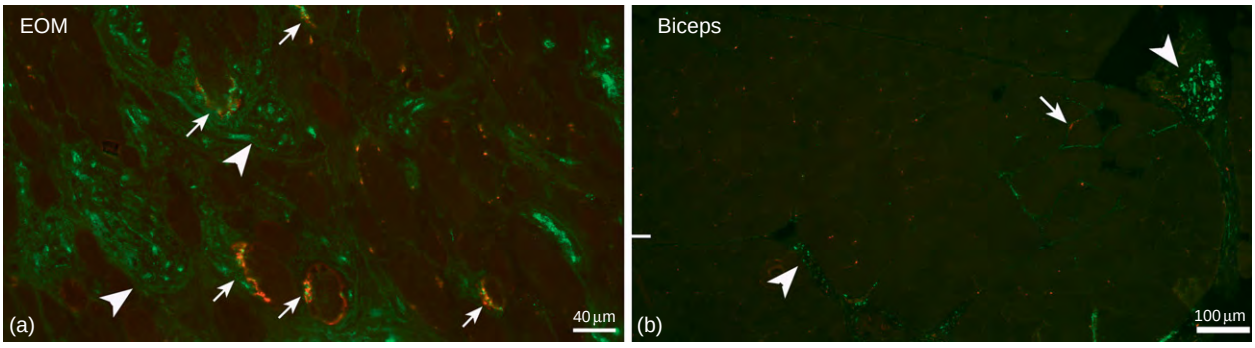

Figure 3 Human extraocular (EOM) (a) and biceps brachii muscle sections (b) immunostained with an antibody against GQ1b/GT1a ganglioside (green). Neuromuscular junctions were labeled by rhodamine-conjugated α-bungarotoxin (red; yellow where there is co-localization with the ganglioside staining). Massive staining with anti-GQ1b/GT1a ganglioside is shown at neuromuscular junctions (arrows) around the EOM fibers and in the nerves (arrow heads) (a), whereas there is very scarce staining in limb muscles (b).

systemic lupus erythematosus, rheumatoid arthritis, liver disease, and thyroid-associated ophthalmopathy, as well as in ALS.

Tests aimed at increasing the concentration of acetylcholine at the synaptic cleft typically reveal improvement of muscle function in myasthenic patients, with less ptosis or better function in a paretic (weak, with partial paralysis) EOM, and therefore are very useful diagnostic tools. These tests are done either by intravenous administration of edrophonium chloride (a rapid-acting reversible inhibitor of acetylcholinesterase) under careful monitoring, by cooling of the ptotic eyelid with an ice pack for 2–5 min, or by letting the patient close the eyelids for 5 min. The amount of ptosis, measured in millimeters as the distance between the upper and the lower eyelid margins, is carefully measured before and after the test, for comparison.

Electrophysiologically, MG is characterized by a reduction in the so-called safety factor, that is, the normal difference between the actual endplate potential and the action potential threshold needed to depolarize the muscle cell. In other words, in MG, there is a loss of the normal overcapacity of the endplate potential and, with stress, the endplate potential is not enough to generate an action potential. In the EOMs, the safety factor is normally low or absent, and the firing frequencies required for the saccades can be up to 4 times those recorded in limb muscles. Moreover, force generation in the multiinnervated, slow-tonic fibers is solely dependent on the endplate potentials, as no action potential generation occurs. These special properties of the EOMs partly explain their early involvement in MG, as reductions in endplate potentials due to the loss of acetylcholine receptors will have immediate consequences.

Morphologically, MG is characterized by a loss of synaptic folds and acetylcholine receptors due to autoantibody-triggered and complement-mediated lesions of the neuromuscular junctions. The molecular basis for the preferential involvement of the EOMs in MG is not fully understood, but it is apparently not necessarily related to the presence of autoantibodies against the acetylcholine receptor. The γ subunit of the acetylcholine receptor is found in multiply innervated fibers of the EOMs, but not in other adult muscles, especially not in the levator palpebrae, a muscle which is as likely to be involved in MG or ocular myasthenia as are the true EOMs. Furthermore, although antibodies against the acetylcholine receptor γ subunit have been detected in MG patients, there seems to be a lack of correlation between the presence of these antibodies and the involvement of the EOMs and levator palpebrae. Because ocular myasthenia tends to be accompanied by lower levels or the lack of autoantibodies against the acetylcholine receptor, it has been proposed that the low expression in the EOMs of decay accelerating factor, important to moderate the complement cascade involved in the destruction of the neuromuscular junction, may be an important factor making these muscles more susceptible.

Although our understanding of MG and ocular myasthenia has steadily increased over the past years, more research is needed to understand these two forms of the disease at the molecular level and thereafter be able to devise better therapeutic strategies.

The EOMs Are Frequently Involved in Mitochondrial Myopathies

Mitochondrial disorders are a large and heterogeneous group of diseases caused by impaired oxidative phosphorylation and, consequently, compromised mitochondrial energy output. Due to the contribution of both the nuclear and the mitochondrial genomes to the synthesis of the respiratory chain elements and the possible coexistence of normal and mutated mitochondrial DNA in the same cell, the genetic basis of these diseases is rather complex. A number of mitochondrial disorders have a myopathy component, and these, in turn, typically show EOM involvement.

Chronic progressive external ophthalmoplegia (CPEO) is the most common mitochondrial disorder affecting muscles. It is a slowly progressing MM that primarily affects the EOMs. It usually has a late, albeit varying, age of onset and insidious progression of ptosis followed by EOM weakness, leading to severe restriction of ocular motility. In some cases, downward gaze may be preserved until late stages of the disease. Weakness of the orbicularis oculi muscle may also be a feature of CPEO, and ptosis and ocular motility restriction can show different courses of development. The ophthalmoplegia is often rather symmetric and compensated for by head movements, so that the patients do not necessarily experience diplopia or functional impairment due to limited ocular motility. There is indication that the symmetry of the ophthalmoplegia may reflect supranuclear involvement, rather than being solely due to EOM dysfunction. Proximal muscle weakness, muscle wasting, and exercise intolerance are also typical features of CPEO.

CPEO can result from both single and multiple deletions and from point mutations of mitochondrial DNA; approximately 15% of cases are autosomal dominant, and in rare cases autosomal recessive inheritance has been reported. Mutations in the ADP/ATP translocator ANT-1 (adenosine diphosphate/adenosine triphosphate translocator ANT-1), a nuclear-encoded mitochondrial protein, have been detected in patients with an autosomal form of CPEO. Pathological changes have been reported in the EOMs of mice lacking this protein, even though there was no evidence of ocular motor or functional abnormalities in these animals.

Additionally, there are more severe forms of MM that involve the eye muscles. Patients with the Kearns–Sayre syndrome have CPEO combined with short stature, pigmentary retinal degeneration, cardiomyopathy, cardiac conduction block at an early age, ataxia, and neuropathy. External ophthalmoplegia occurs in approximately 13% of patients with a syndrome comprising MM and encephalopathy, lactate acidosis, and stroke-like episodes, so-called MELAS. These patients also have short stature and muscle weakness, and their clinical course is dominated by the stroke-like episodes and seizures. The EOMs are also involved in a very rare mitochondrial syndrome characterized by sensory ataxic neuropathy, dysarthria (difficult speech articulation), and ophthalmoplegia, described with the acronym SANDO, and is considered to be a variant of autosomal dominant CPEO. External ophthalmoplegia may also be part of other mitochondrial disorders, such as myoclonus, epilepsy, myopathy with ragged-red fibers (MERRF), mitochondrial neurogastrointestinal encephalomyopathy (MNGIE), and a condition characterized by neuropathy, ataxia, and retinopathia pigmentosa (NARP).

A skeletal muscle biopsy, showing ragged-red fibers and abnormal mitochondrial morphology and/or enzymatic activity, and genetic analysis for mitochondrial DNA mutations are helpful in the diagnosis of MM. An extremely high mitochondrial content and high oxidative enzyme activity are hallmarks of the EOMs and, in part, the reason why these muscles are so susceptible to MMs. However, our understanding of the cellular and molecular basis for the involvement of the EOMs in some mitochondrial disorders, but not in others, where defective oxidation–phosphorylation coupling is a common denominator, is very rudimentary. The development of animal models of CPEO, such as the recently reported mouse lacking ANT-1, a nuclear-encoded mitochondrial protein implicated in an autosomal form of CPEO, may help to advance this quest.

The EOMs Are Involved in Oculopharyngeal Dystrophy

Oculopharyngeal muscular dystrophy is a late-onset dystrophy, typically starting in the fifth or sixth decade of life, and is manifested clinically by the presence of ptosis and subsequently includes swallowing difficulties. With time, both the EOMs and other muscles, including the tongue and the masticatory muscles, are also affected. Diplopia may eventually occur, and there is impairment of ocular motility, although not a total external ophthalmoplegia. Typically, it is an autosomal dominant disease, but recessive inheritance and sporadic cases have also been reported. The genetic defect consists of short $(GCG)_{8–13}$ expansions in the nuclear poly(A)-binding protein 1 (PABPN1) gene (chromosome 14q11.1), causing polyalanine tract expansions. The molecular mechanisms behind muscle dystrophy due to these expansions are not yet fully understood.

Miscellaneous

There are numerous case reports of EOM involvement or sparing in a wide array of systemic disorders. While the EOMs are very rarely the site of primary tumors (e.g., rhabdomyosarcomas, granular cell tumors, and liposarcomas), non-Hodgkin T-cell lymphomas have been reported in these muscles. The EOMs may also be the site of solitary metastasis from primary tumors of the breast, lung, and skin.

Involvement of the EOMs, with detectable contrast enhancement in computed and in magnetic resonance tomography, has been reported in a case of Behcet's syndrome with orbital inflammation. Behcet's syndrome is a multisystem vasculitis, clinically characterized by uveitis, with recurrent oral and genital ulcers. At least one case of primary systemic amyloidosis with initial involvement of an EOM has been reported. Polymyositis may have extensive EOM involvement, although the EOMs are often spared in dermatomyositis.

EOM involvement has been documented to occur during or after systemic infectious diseases. For example, acute onset, noncomitant strabismus with documented thickening of the EOMs has been reported following streptococcal infection of the upper airways. Cysticercosis, infection with the tapeworm *Taenia solium*, may involve the EOMs, in addition to the skeletal muscles, and the globe itself. The cysts may be painful, cause diplopia, and even require surgical removal.

In summary, the EOMs show complex patterns of disease involvement and disease sparing. While some evidence for the causes of these differential propensities for or sparing from pathology exists, most are not well understood. This is an area of active research, as understanding the mechanism for the differential disease susceptibility of the EOMs may help elucidate potential approaches for the treatment of these largely devastating skeletal muscle diseases.

Extraocular Muscles: Extraocular Muscle Metabolism

F H Andrade, University of Kentucky Medical Center, Lexington, KY, USA

Glossary

Adenine nucleotide translocator – An inner mitochondrial protein that exchanges adenosine diphosphate (ADP) and adenosine triphosphate (ATP) between the mitochondrial matrix and the cytoplasm. It is also known as the ADP/ATP translocator.

Chronic progressive external ophthalmoplegia – A syndrome characterized by progressive inability or difficulty to move the eyes and elevate the eyelids. It is a common manifestation of some mitochondrial diseases.

Electron transport chain – The set of mitochondrial protein complexes that couples the oxidation of electron donors (such as NADH) to the reduction of electron acceptors (such as oxygen) in order to produce ATP.

Gene expression profiling – The measurement of the activity (or expression) of large numbers of genes simultaneously.

Glycolysis – The metabolic pathway that converts glucose to pyruvate, with a net result of 2 ATP and 2 NADH.

M line – A dark band or line seen in the center of the sarcomeres, using electron microscopy.

NADH – Nicotinamide adenine dinucleotide (NAD^+) and its reduced form NADH are coenzymes involved in oxidation/reduction reactions as electron acceptors and donors.

Oxidative phosphorylation – The metabolic pathway that uses the energy released during the oxidation of nutrients to produce ATP.

The extraocular muscles exhibit the greatest diversity among mammalian skeletal muscles, a likely consequence of the varied functional requirements imposed by the ocular motor system. Extraocular muscle fibers differ from typical limb and respiratory skeletal muscles in mitochondrial content, innervation/contractile patterns, contractile protein isoforms, hormone receptors, cell surface markers, and a variety of other cell and molecular properties that may relate to their unique functions. The divergence from the skeletal muscle stereotype is further exemplified by the fact that extraocular muscles do not conform to traditional fiber type classifications, which are based primarily on myosin isoform expression. The most accepted fiber-type classification scheme for extraocular muscles includes six fiber types based upon: (1) distribution into orbital and global layers, (2) innervation status, single versus multiple nerve contacts per fiber, and (3) mitochondrial/oxidative enzyme content. **Figure 1** shows representative micrographs of extensor digitorum longus (EDL, which is a predominantly type IIB fiber – fast, fatigable – limb skeletal muscle), diaphragm (mixed fiber type, fatigue-resistant respiratory muscle), and the extraocular muscle from rats. EDL is recruited sporadically and diaphragm is constantly active as is the extraocular muscle. Despite the wide difference in activity, EDL and diaphragm sections are mostly indistinguishable. For sure, there are important biochemical differences between the two muscles that reflect their specific adaptations to their respective activation patterns. However, the divergent requirements of EDL and diaphragm motor systems are met with fairly stereotypical muscle fibers, as evident from the micrographs. In contrast, the extraocular muscle fibers are very different: small round fibers with prominent mitochondria, suggestive of atypical contractile and metabolic properties. This article outlines newly identified unique aspects of extraocular muscle metabolism and how they may correspond to contractile function.

Insights from Gene Expression Profiling

The fast and constant contractions of the extraocular muscles necessitate well-developed energy supply systems. It might be expected *a priori* that these muscles would upregulate all the main energy-supply metabolic pathways, from glycolysis to mitochondrial metabolism. Surprisingly, this may only apply to mitochondrial content, which is the highest reported in mammalian skeletal muscles. Studies comparing the gene expression profile of extraocular and limb muscles found that genes coding for key enzymes of glycogen synthesis and breakdown were repressed in the extraocular muscles. Glycogen content in the extraocular muscles is correspondingly reduced. These findings indicate that the extraocular muscles are seemingly less dependent on stored glycogen as a metabolic fuel than other skeletal muscles. They also suggest that the extraocular muscles rely, instead, on constant transport of blood-borne glucose and fatty acids through their extensive microvascular network. Interestingly, the expression of the lactate dehydrogenase (LDH) isoform that preferentially oxidizes lactate to pyruvate is increased

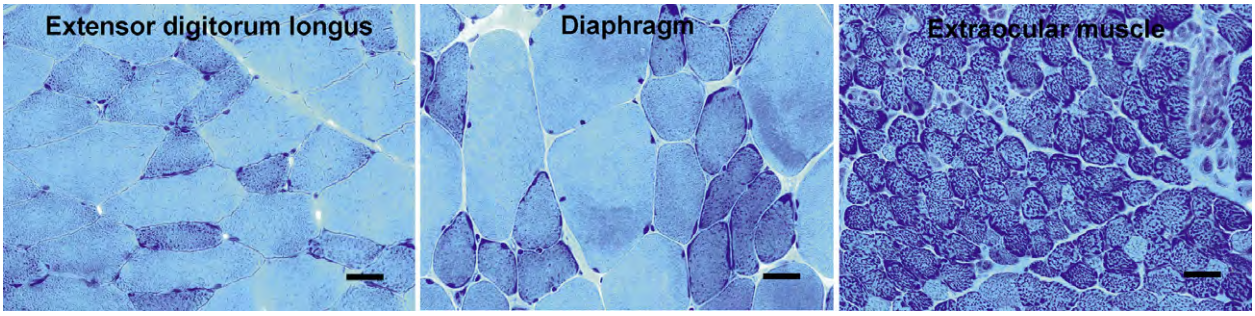

Figure 1 The extraocular muscles are not typical skeletal muscles. The figure shows representative micrographs of limb (left, extensor digitorum longus), respiratory (middle, diaphragm), and extraocular (right) muscle sections stained with Gomori's trichrome. This technique stains mitochondria (and sarcoplasmic reticulum) a darker reddish-blue. Despite the differences in functional profiles (occasionally active limb muscle vs. constantly active diaphragm), notice the similarity in fiber size and shape: large polygonal muscle fibers with peripheral myonuclei (left and middle panels). Some fibers have darker cytosolic staining indicating higher mitochondrial content. In contrast, the extraocular muscle shows significantly smaller fibers with clumpy cytosolic and subsarcolemmal staining due to abundant mitochondria (right panel). Scale bars = 25 μm.

in the extraocular muscles, compared to typical skeletal muscles, and that may allow them to use lactate as a fuel for aerobic pathways. The importance of these alternative metabolic pathways is now being tested in extraocular muscles.

Lactate: An Oxidizable Substrate for the Extraocular Muscle

In limb skeletal muscles, glycogen breakdown drives glycolysis only during brief bursts of intense activity (Figure 2). In most muscles, metabolic demand during moderate activity is met by aerobic (mitochondrial) pathways. During periods of sustained peak activity, when mitochondrial capacity is exceeded in skeletal muscle, lactate is the end product of glycolysis in a reaction that reduces pyruvate at the expense of NADH and is catalyzed by LDH. For this and other reasons, increased production and accumulation of lactic acid during exercise has been associated with muscle fatigue. However, cells can also use the LDH reaction in the reverse direction from lactate oxidation to pyruvate, and lactate then goes on to become a substrate for aerobic metabolism. As mentioned above, the expression of the LDH isoform that preferentially oxidizes lactate to pyruvate is higher in the extraocular muscles. Combined with their high aerobic capacity, this reaction would allow the extraocular muscles to use lactate as a metabolic substrate. Cinnamate, a blocker of lactate transport, alone or in combination with exogenous lactate can be used to evaluate the role of lactate on fatigue resistance. Cinnamate accelerates fatigue in the extraocular muscles significantly: treated muscles lose their ability to generate force at a faster rate than untreated extraocular muscles. Conversely, cinnamate treatment does not affect the endurance or residual force of limb muscles. Replacing glucose with exogenous lactate increases limb-muscle fatigability but has no effect on the extraocular muscles. However, the extraocular muscles fatigue faster when exposed to exogenous lactate combined with cinnamate treatment. These results indicate that LDH oxidation of lactate to pyruvate seems to be an important source of metabolic substrate for aerobic metabolism in the extraocular muscles. This conclusion is a significant deviation from the traditional view of lactate as a final waste product of glycolysis; increased lactate production and accumulation during vigorous contractile activity is typically associated with fatigue. Muscle fatigue is a complex phenomenon: substrate depletion, metabolite accumulation, and ionic imbalances are some of the factors that combine to reversibly impair contractile function. In the particular case of the extraocular muscles, lactate can be used via the LDH reaction as an additional substrate source for aerobic metabolism, a concept developed recently for other aerobic muscles and one that also applies to the nervous system.

Creatine Kinase, the Missing ATP Buffer in the Extraocular Muscle

Skeletal muscles and other tissues with fluctuating metabolic needs rely on the creatine–phosphocreatine system to buffer intracellular ATP concentration: creatine kinase (CK) catalyzes the reversible transfer of the phosphoryl group from phosphocreatine to ADP in order to maintain constant ATP levels. Cellular CK activity is due to a family of oligomeric enzymes: two cytosolic, ubiquitous brain-type CK-B and muscle-type CK-M, and two mitochondrial isoforms, ubiquitous mitochondrial CK (uCK) and sarcomeric mitochondrial CK (sCK). In differentiated skeletal muscle, CK-MM and sCK are the predominant isoforms. In fast-twitch muscles, most CK activity is due to the CK-MM isoform, some of which is found

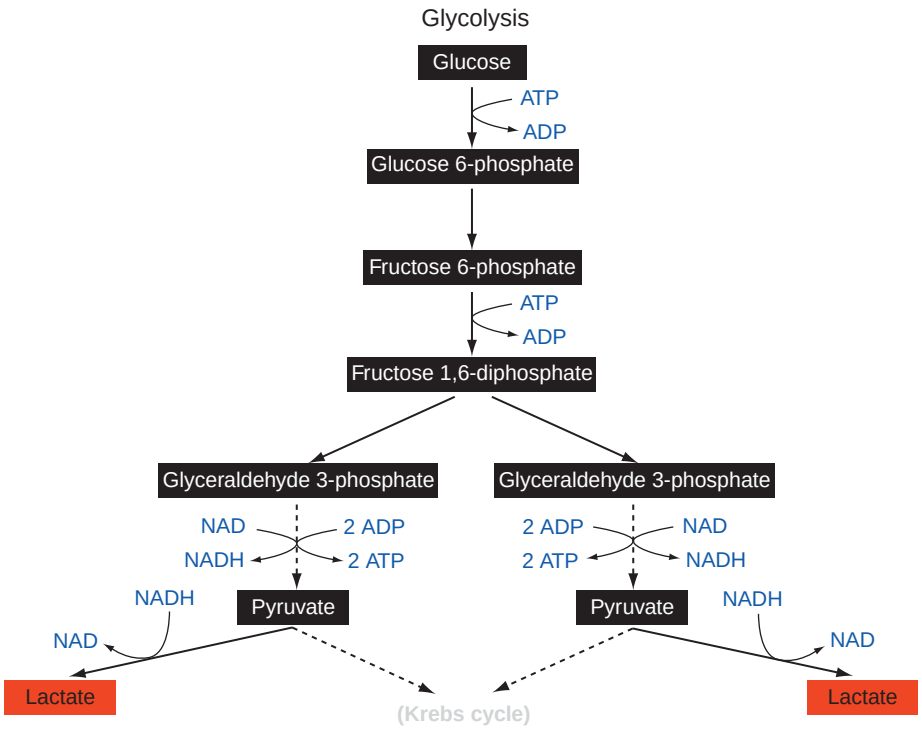

Figure 2 Glycolysis, the anaerobic breakdown of glucose. The figure presents a diagram showing the sequence of steps in glycolysis, from glucose to pyruvate. The end product, pyruvate, may move on to the Krebs cycle (inside the mitochondria) to continue substrate oxidation, or it may be reduced to lactate in the reaction catalyzed by LDH that restores NAD. Dashed arrows represent omitted steps.

associated with the sarcomeric M line, the sarcoplasmic reticulum, and T-tubules. This arrangement couples the CK-dependent ATP-buffering system to the cellular sites with the highest ATPase activity, and is needed for normal contractile function. Given the predicted need for ATP buffering in the extraocular muscles, we proposed that (1) CK isoform expression and activity in rat extraocular muscles would be higher and (2) the resistance of these muscles to fatigue would depend on CK activity. Instead, we found that messenger ribonucleic acid (mRNA) and protein levels for all (cytosolic and mitochondrial) CK isoforms are lower in the extraocular muscles than in limb muscles. The muscle-enriched isoforms, CK-M and sCK, are less abundant in extraocular muscle, despite the fact that the extraocular muscles have a higher mitochondrial content than limb muscles. Total CK activity is also correspondingly decreased in the extraocular muscles. Moreover, cytoskeletal components of the sarcomeric M line, where a significant fraction of cytosolic CK activity is found, are downregulated in the extraocular muscles as was initially suggested by gene expression profiling. To explore the role of CK activity on muscle function, the CK inhibitor 2,4-dinitro-1-fluorobenzene (DNFB) was used during an *in vitro* fatigue protocol. Treatment with DFNB accelerates the development of fatigue in limb muscle, but has no detectable effect on the extraocular muscles. These data support the conclusion that CK activity is not an important ATP buffer in the extraocular muscles. The myokinase reaction ($2\ ADP \rightarrow ATP + AMP$), catalyzed by adenylate kinase (AK), serves as an additional ATP-buffering system in skeletal muscle. While total AK activity is similar in extraocular and limb muscles, the mRNA content for two putative mitochondrial AK isoforms (AK3 and AK4) is over 13-fold more abundant in the extraocular muscles. This suggests that the relative lack of CK in the extraocular muscles may be compensated by upregulation of selected AK isoforms.

Mitochondrial Content in the Extraocular Muscles

Aerobic capacity is typically measured by mitochondrial volume density (percentage of muscle fiber volume occupied by mitochondria). In general, mitochondrial volume density is well matched to the metabolic needs of skeletal muscle and it scales almost linearly with maximal oxygen uptake among muscles and across mammalian species. In other words, the consensus is that changes in the oxidative (aerobic) capacity of mammalian skeletal muscles are met by corresponding increases or decreases in mitochondrial volume density. Since the mitochondrial content and the

activity of respiratory complexes and enzymes of mitochondrial metabolic pathways change in parallel, enzymatic activities are used as indices of mitochondrial content and aerobic capacity. Highly aerobic muscle groups in mammals have abundant capillaries and elevated mitochondrial volume density. The extraocular muscles have, arguably, the highest mitochondrial content of all mammalian skeletal muscles. However, the mechanism responsible for maintaining mitochondrial abundance in the extraocular muscles remains unclear. We have identified a number of transcription factors that influence mitochondrial biogenesis and that are upregulated in the extraocular muscles. Surprisingly, these factors are different from the mitochondrial biogenesis program initiated in response to endurance training.

Mitochondria as Calcium Sinks in the Extraocular Muscle

The fast-contracting extraocular muscles rely on tight regulation of free cytosolic calcium concentration ($[Ca^{2+}]_i$). In principle, the extraocular muscles have the profile of very efficient calcium handling capacity: extensive and well-developed sarcoplasmic reticulum and the expression of fast calcium ATPase isoforms. Moreover, the extraocular muscles contain parvalbumin, a low-weight calcium-binding protein that serves as a temporary buffer to accelerate the removal of calcium off its binding sites on the myofilaments and facilitates muscle relaxation. Other investigators have already shown that the kinetics of calcium flux into mitochondria are fast enough to influence very rapid events such as neurotransmitter release from motor nerve terminals. The specific inhibition of mitochondrial calcium transport slows the relaxation of mitochondria-rich skeletal muscles. We recently reported that the magnitude and speed of calcium uptake by mitochondria are sufficient to influence contractile function. This property of the extraocular muscles appears to serve at least two complementary functions. First, it couples metabolic supply to demand because higher mitochondrial calcium stimulates enzymes that control substrate oxidation: pyruvate dehydrogenase, 2-oxoglutarate dehydrogenase, isocitrate dehydrogenase, and glycerol 3-phosphate dehydrogenase. The combined activity of these enzymes sustains a high $NADH/NAD^+$ level and maximizes oxidative phosphorylation and ATP production. Second, by limiting the $[Ca^{2+}]_i$ increase during contractions in response to submaximal stimulation frequencies, mitochondria widen the dynamic range of the extraocular muscles. In other words, the capacity of the extraocular muscles to produce force is spread over a wider stimulation frequency range, increasing the fine control of the effector arm of the ocular motor system.

Are Extraocular Muscle Mitochondria Different?

The adenine nucleotide transporter 1 (*Ant1*) gene encodes an inner mitochondrial membrane protein that transports ADP into mitochondria and ATP from mitochondria to the cytosol. Mutations within *Ant1* have been shown to produce a syndrome of chronic progressive external ophthalmoplegia (CPEO) in humans. *Ant1* knockout ($Ant1^{-/-}$) mice develop cardiomyopathy and severe exercise intolerance. Despite this dramatic phenotype, the extraocular muscles are mostly unaffected. Histologically, the extraocular muscles from $Ant1^{-/-}$ mice present a relatively mild mitochondrial myopathy. There are no measurable ocular motor abnormalities in $Ant1^{-/-}$ mice, and their peak eye velocities overlap with those measured in control mice. Moreover, their extraocular muscles do not show evidence of increased fatigability. In addition, the extraocular muscles have higher levels of *Ant2* mRNA compared to the limb muscles. *Ant2* is a nonskeletal muscle isoform previously described in the heart. Its presence in the extraocular muscles may explain the lack of effects of *Ant1* loss, and it was the first documented difference between extraocular muscle and limb muscle mitochondria.

The ability of muscles to perform aerobic work depends on their mitochondrial volume density, with the assumption that the composition of these organelles is fairly constant across muscle types and mammalian species. One of these components is the electron transport chain, a series of multimeric complexes (complexes I–IV, plus the ATP synthase which is sometimes called complex V) in the inner mitochondrial membrane responsible for most of the aerobic ATP generation (**Figure 3**). Recently, we found that the extraocular muscle mitochondria have lower content or lower activity of some enzyme complexes of the electron transport system, causing them to respire at slower rates. This is puzzling given that the extraocular muscles are constantly active and aerobic capacity was predicted to be elevated, given their high mitochondrial content. These findings are not explained by differences in the ultrastructure of extraocular muscle mitochondria: the surface area of their inner membrane is comparable to values reported for other skeletal muscle. Furthermore, the differences are not generalized or systematic: complex II content and activity, and complex III content are similar in mitochondria from triceps surae (a limb skeletal muscle) and extraocular muscle. Complexes I and IV give a more puzzling result: their activities are lower, but their content is higher in the extraocular muscle mitochondria. These are multimeric protein complexes, and differential expression of isoforms of some subunits has been described in skeletal muscle and other tissues.

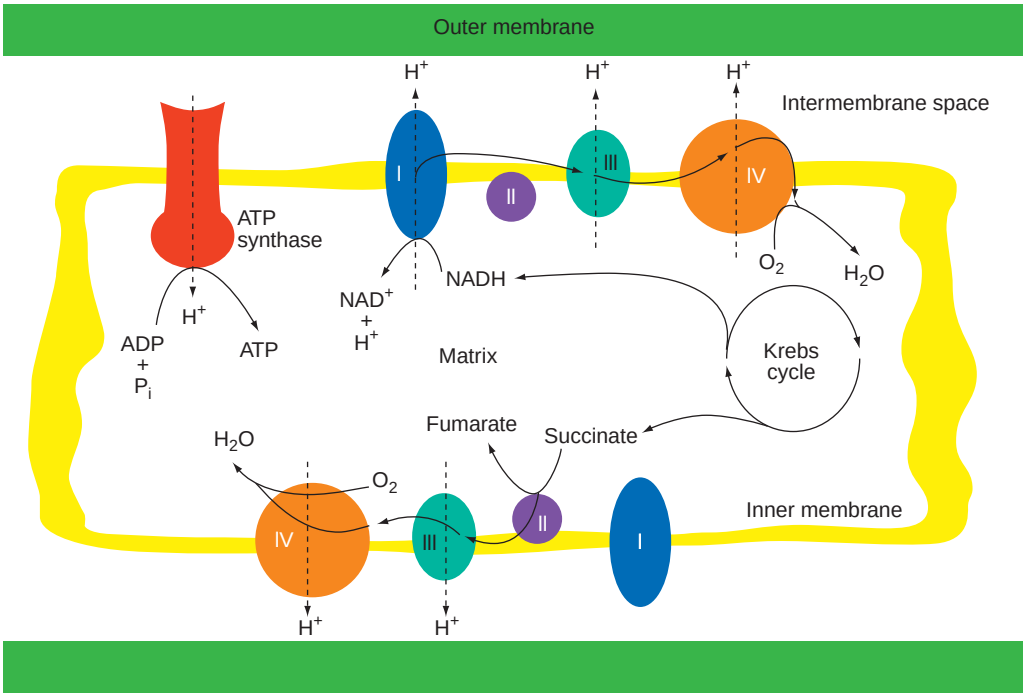

Figure 3 Mitochondrial electron transport chain and ATP synthase. The figure presents a drawing showing the oxidative phosphorylation steps that couple the final substrate oxidation to the reduction of oxygen to water, pumping hydrogen ions (protons, H^+) from the mitochondrial matrix to the intermembrane space. The substrates for this chain are NADH or succinate, shown here as originating from the Krebs cycle. Complex I (NADH dehydrogenase) oxidizes NADH and transfers the electrons to complex III, which in turn transfers the electrons to complex IV (cytochrome c oxidase). The latter is the complex that reduces oxygen to water. Complex II (succinate dehydrogenase) is not an H^+ pump; it funnels electrons from succinate to complex III, and then complex IV. The ATP synthase (complex V) is driven by the trans-inner membrane electrochemical potential generated by the movement of H^+ to the intermembrane space.

Therefore, the content of some electron transport chain complexes (I, IV, and V) and the subunit composition of some others (I and IV) may not be the same in the extraocular muscles compared to limb muscles. This demonstrates that the metabolic divergence between extraocular and limb muscles includes major differences in the composition and basic function of their respective mitochondrial populations. Intrinsic differences in mitochondrial structure and function may explain the susceptibility of the extraocular muscles to some hereditary and acquired mitochondrial myopathies such as CPEO and related syndromes. For example, the extraocular muscles present the most severe age-dependent loss of mitochondrial respiratory complex activity among muscles. There is a significant increase in the number of fibers with cytochrome c oxidase defects in the extraocular muscles of humans and other primates, even when compared to other highly aerobic muscles such as the diaphragm and heart. This can be at least partially explained by mitochondrial DNA mutations, presumably due to reactive oxygen species generated during mitochondrial respiration or present as part of a more generalized cellular oxidative stress.

Matching Mitochondrial Capacity to Contractile Function

The primary role of mitochondria is to generate ATP. Recent studies lead to an obvious question: How do extraocular muscles sustain their contractile function with mitochondria that respire half as fast as mitochondria from other muscles? The content of respiratory complexes is one parameter behind tissue variations in mitochondrial respiration, although some argue that it is not particularly relevant for metabolic control. Under experimental conditions, mitochondrial respiration in the skeletal muscle and heart is regulated at the level of the respiratory chain, while in the liver, kidney, and brain it is controlled mainly at the phosphorylation level by ATP synthase (complex V) and phosphate carrier. That may not be the case *in vivo*, where different parameters such as cellular steady state, the energy demand, and the energy supply of the tissue may also regulate mitochondrial respiration. In the case of the extraocular muscles, allosteric regulation of respiratory complexes may combine with changing metabolite concentrations to maintain mitochondrial respiration closer to its theoretical maximum.

For example, a mechanism to enhance energy production in the extraocular muscle is mitochondrial calcium influx during contractile activity in order to activate enzyme systems that exert strong control on substrate oxidation, as mentioned above.

Matching Energy Supply to Demand

Initially inspired by morphological characteristics and gene-expression-profiling results, a more global perspective of extraocular muscle metabolism is beginning to emerge. First, glycogen content is low and the glycogenolysis pathway seems to be downregulated in the extraocular muscles. Second, CK activity and content, including the mitochondrial isoform, are lower in the extraocular muscles, indicating that phosphocreatine may be a less important temporal and spatial ATP buffer in these muscles. In other words, mitochondrial ATP production may be sufficiently high and close to cellular sinks as to obviate the need for an energy buffer. Third, the extraocular muscles can use lactate as an oxidizable substrate due to the presence of a LDH isoform that catalyzes the conversion of lactate to pyruvate that then goes to the Krebs cycle. Finally, the mitochondrial population in extraocular muscles appears to respond to a different biogenesis program, and exhibits atypical functional characteristics that may influence the contractile activity of these muscles significantly.

Glossary

Binocular vision – The simultaneous perception by both eyes of two slightly disparate images of the same target on corresponding retinal elements resulting in a single three-dimensional image.
Cover test – The use of an ocular occluder over one eye or alternately occluding the eyes, either alone or in conjunction with prisms, to detect the presence of an ocular deviation and to measure its magnitude.
Diplopia – Double vision caused by a misalignment of the eyes resulting from the same image stimulating noncorresponding retinal elements in the two eyes.
Esotropia – A form of strabismus where there is a nasal-ward deviation of the nonfixing eye.
Exotropia – A form of strabismus where there is a temporal deviation of the nonfixing eye.
Phoria – This is a latent misalignment of the eyes kept under control by fusional mechanisms and is contrasted with a tropia which is a manifest constant or intermittent deviation of the eyes. A phoria can be seen only when fixation is interrupted, as during a cover test.
Recession surgery – In recession surgery, the overacting extraocular muscle is surgically removed from the sclera and resutured in a more posterior location on the globe. The goal is to decrease the rotational effect of muscle contraction.
Resection surgery – In resection surgery, the underacting extraocular muscle is surgically removed from the sclera, a portion of the insertional end is removed, and the remaining, now shorter, muscle is resutured to its original insertional site on the globe. The goal is to increase the rotational effect of muscle contraction.
Strabismus – A latent or manifest misalignment of the eyes.
Tropia – A manifest misalignment of the visual axes of both eyes.

Normal Eye Movements

There are six extraocular muscles responsible for eye movement within each orbit. These muscles are innervated by cranial nerves III (superior rectus, medial rectus, inferior rectus, and inferior oblique), IV (superior oblique), and VI (lateral rectus). The medial rectus muscles are primarily responsible for adduction, pulling the eyes toward the nose. The lateral rectus muscles are responsible for abduction, pulling the eyes temporally. These horizontal movements are the most straightforward of the six extraocular muscles. The remaining four are cyclovertical muscles and have more complex function related to the fact that forward-oriented eyes are housed in laterally directed orbits. This means that the midline of these muscles does not consistently lie over the center of rotation of the globe in any position of gaze.

If examined from the superior view, the bony medial orbital walls are parallel to each other and are in the sagittal plane. The lateral walls, however, are at a 45° angle from the plane of the medial walls. Since all but the inferior oblique muscles take their origin from the orbital apex, contraction of the superior and inferior rectus and superior oblique muscles will have a rotational or torsional component. The same is true for the inferior oblique, which originates from the anterior and inferior nasal orbital wall and courses posteriorly and laterally to insert onto the globe inferior to the belly of the inferior rectus muscle. The direction of contraction of the inferior oblique muscle thus also results in both a torsional and vertical movement of the eye. The function of the individual extraocular muscles has been more extensively covered elsewhere in this encyclopedia. To summarize, however, the superior rectus muscle and the inferior oblique muscles are the principal elevators of the eye while the inferior rectus muscle and superior oblique muscle are the principal depressors of the eye. The incyclotorters of the eye are the superior oblique and the superior rectus while the excyclotorters are the inferior oblique and the inferior rectus muscles. Each of the cyclovertical muscles also has minor horizontal function. It is important to recognize that the vertical or torsional component of each of the cyclovertical muscles changes depending on whether the eye is held in adduction or abduction.

There are two basic kinds of eye movements: saccade and pursuit. Saccades are rapid and subserve fast changes in fixation. They are generated by a pulse-step pattern of innervation from the brainstem. An estimate of saccadic velocity can be gained by clinical observation alone, often with the use of an optokinetic nystagmus (OKN) drum or flag that the examiner uses to drive repeated changes in fixation, first in one direction and then in another.

(b)

Figure 1 (a) Composite photographs showing a subject displaying the nine cardinal positions of gaze and (b) Chart showing the principal yoked muscles from the right (pink) and left (green) eyes responsible for movement of the eyes into the nine cardinal positions of gaze.

A decrease in saccadic velocity can be seen in patients with extraocular muscle palsy. Pursuit movements are slower, and are driven by smooth following movements in response to a target moved slowly before the patient. There should be no lag or saccadic interlude during pursuit movements.

Gaze refers to movement of both eyes together. Gaze is conjugate if both eyes move the same amount, at the same speed, and in the same direction. Thus, in right gaze, both eyes look to the right and reach the intended target at the same time. Gaze is disconjugate if both eyes move in opposite directions or there is substantial failure of one eye to reach the target. Therefore, convergence and divergence movements are disconjugate. Ductions are movements of one eye examined under monocular viewing conditions. For example, we refer to adduction as a nasalward movement of an eye when the other eye is covered, eliminating any binocular adjustment in eye position. In contrast, versions are movements of both eyes examined under binocular viewing conditions. Dextroversion is movement of both eyes to the right; levoversion is movement of the eyes to the left. Version testing is helpful for assessing over- or under-action of a muscle compared to its yoked muscle in the other eye.

As conjugate gaze position shifts, yoked muscles contract in response to gaze-evoked increases in innervational frequency (**Figures 1(a) and 1(b)**). However, innervation to the antagonist muscles is inhibited. Therefore, for gaze right, the right lateral and the left medial muscles contract, but the right medial and left lateral rectus muscles are innervationally inactive. Because the eyes must move in an accurate, balanced, and coordinated fashion when gaze position is changed, complex central nervous system control mechanisms are required. Input from the frontal and parietal cortex and from the cerebellum is routed through a neural integrator in the brainstem whose function and control is still being investigated. Feedback from the afferent visual system and from proprioceptive input from the extraocular muscles modulates innervational tone to all the extraocular muscles and is important for long-term calibration of eye movements.

Ocular Motility Assessment in the Clinic

When an individual is looking straight ahead, in what is called primary gaze, a light falling on the eyes from a distance will be perceived by an examiner as a corneal reflex or reflection in approximately the same position in the pupil of each eye (**Figure 1(a)**, central photograph). If the eyes are not aligned, there will be a nasal, temporal, or vertical offset of the corneal reflex in one eye compared to the other eye. The amount of offset of the reflex can be estimated subjectively by the examiner or measured with prisms. Care must be taken in the patient who has a very small degree of misalignment as these tests are not sensitive enough to detect it.

To confirm normal alignment of the eyes, a cover test is performed. If there is no refixation movement of either eye

when the other eye is covered, the alignment of the eyes is considered orthotropic. This does not imply, however, that the eyes are normally aligned since latent misalignment of the eyes may be controlled by fusional mechanisms that can be remarkably robust. To determine if an individual's eyes are normally aligned, an alternate cover test is performed. Here, the eyes are alternately occluded. If no refixation movement of the eye under cover occurs when the cover is moved to the other eye, then the individual is considered to have normal eye alignment and is deemed orthophoric. The alternate cover test can be used in all the cardinal positions of gaze to determine if changes in gaze position result in any misalignment. If refixation movement is detected with alternate cover testing, then prisms may be used with the cover test to measure the magnitude of the misalignment. A convergent misalignment of the eyes is called esotropia; divergent misalignment is called exotropia; and vertical misalignment is called hypertropia.

In addition to alignment testing, an examiner performs certain sensory tests to determine the quality of binocular function. These tests detect the presence of normal or abnormal retinal correspondence, the presence of suppression or diplopia, even if not subjectively present, the quality of stereoacuity if present, and the presence of torsion. The nature of this text does not allow an in-depth review of such testing, but it is useful to document, as binocular function is an important aspect of normal visual experience, and is critical to the assessment of outcomes after treatment for strabismus.

Children with strabismus typically do not experience diplopia unless the onset of misalignment has been rapid as might be seen in an acute CN VI palsy due to increased intracranial pressure or due to a brain tumor. More often, children with strabismus suppress the nonfixing eye, an adaptive mechanism that obviates diplopia, but places the child at risk for the development of amblyopia, a nonorganic loss of vision that may be permanent if not treated during the child's period of visual plasticity. Therefore, during the examination of children being evaluated for strabismus, careful assessment of visual acuity is essential.

During a motility examination, all patients should be carefully observed for the presence of nystagmus (rhythmic to and-fro movements of the eyes), muscle weakness (paresis), muscle restriction, or binocular-gaze deficits along with abnormal head posturing, head nodding, or other adaptive mechanisms that may arise as a result of an abnormal ocular motor condition.

Clinical Treatment for Primary Eye Motility Disorders

Once strabismus has been diagnosed, then a decision must be made regarding how to treat it. In children, glasses are an important consideration. Children with esotropia who are hyperopic (far-sighted) will often have an accommodative component to their strabismus. Control of accommodation by correcting the hyperopia may eliminate or reduce the angle of esotropia. Glasses are occasionally used in children with exotropia as well. Certainly, if a child has a significant refractive error, glasses will be required to optimize acuity.

A child with strabismus and amblyopia will likely be given treatment for the amblyopia which may include occlusion therapy or optical penalization with atropine drops. Treatment of amblyopia is usually recommended before more definitive treatment of the strabismus is undertaken. Other nonsurgical treatments for strabismus include prisms, if the angle of misalignment is small or, in less common scenarios, exercises such as convergence training.

When a decision has been made to proceed with surgery, there are several available options. Typical incisional surgery addresses the misalignment mechanically. If a muscle is overacting, then it is weakened. This is usually done by recession surgery in which the muscle insertion on the sclera is transected and then attached with sutures more posteriorly on the globe. This decreases the mechanical advantage of the muscle by reducing the arc of contact of the muscle on the globe. By contrast, if a muscle is underacting relative to its antagonist, then the muscle insertion is resected. In this surgery, a portion of the insertion is removed and the shortened muscle is reattached to the original muscle insertion on the sclera. This surgery works by shortening the tether length of the muscle and increasing its mechanical advantage relative to its antagonist. The amount of recession or resection is titrated to the angle of the strabismus with larger amounts of surgery for larger angles of misalignment. There are numerous variations on this theme, and the literature is full of unique means of weakening or strengthening muscles. In certain situations, such as when a muscle is significantly paralyzed, healthy muscle insertions may be transposed to approximate the insertion of the paralyzed muscle to assist its function. Sometimes, this is done in conjunction with botulinum toxin injection into the antagonist muscle to weaken it and to improve the rotation of the globe in the direction of the paralyzed muscle.

Botulinum toxin A has heralded the beginning of a new era in strabismus surgery. First introduced into clinical use in the early 1980s by Dr. Alan Scott at Smith-Kettlewell in San Francisco, botulinum toxin weakens muscle by chemical denervation of the muscle. Release of the neurotransmitter, acetylcholine, into the synaptic cleft of neuromuscular junctions (NMJs) of treated skeletal muscle (including extraocular muscle) is blocked. This temporary paralysis of the synapses of the NMJs results in a spread of NMJ sites across the surface of the muscle. Treatment effect is maximal for approximately 6 weeks and then begins to diminish as the terminal nerves regrow and form new NMJs. Ultimately, there is a return of

function at the sites of the original NMJs and retraction of the sprouted nerves. Treatment effect is essentially void by 3 months postinjection.

Botulinum injection has been used by some clinicians for the treatment of infantile and childhood forms of strabismus, especially esotropia, but its use has not been widely adopted because of the frequent need for reinjections, especially for larger angles of misalignment. However, pharmacologic treatment of strabismus is attractive because of decreased operative times required for injection compared with typical incisional surgery, decreased scarring, and preserved biomechanical relationships of the muscle, and orbital soft tissues. In the recent literature, there have been a number of reports of the use of new candidate drugs for both weakening and strengthening extraocular muscle in experimental animals. Although much research is still needed, the era of drug treatment for strabismus is dawning, and heralds the possibility of both reducing the short-term risks of strabismus surgery and improving the long-term outcomes of our interventions.

Extraocular Muscles: Proprioception and Proprioceptors

R Blumer, Medical University of Vienna, Vienna, Austria

Glossary

Choline acetyltransferase – The enzyme responsible for the synthesis of the neurotransmitter acetylcholine, causing the transfer of acetate to choline.
Choline transporter – These recapture choline from the synaptic cleft after acetylcholine release and degradation. This process is critical for new acetylcholine synthesis at the synapse.
Golgi tendon organ – A proprioceptive organ that provides information to the brain about changes in muscle tension. In contrast to muscle spindles, these are in series with muscle fibers, interwoven with the collagen in the muscle tendon. Tension on the tendon caused by muscle contraction activates these proprioceptors.
Muscle spindles – Proprioceptive organs that provide the brain with information about changes in muscle length and are organized in parallel with the skeletal muscle fibers. They contain modified muscle fibers called intrafusal fibers, in contrast with the muscle fibers themselves, which are called extrafusal fibers. They have a complex structure; they are surrounded by a connective tissue capsule, and contain several types of modified myofibers within them. They are innervated by sensory afferents.
Myotendinous cylinders or palisade endings – Proprioceptive organs found at the myotendinous junction consisting of dense axonal branching which invests the tips of single muscle fibers. These are unique to the extraocular muscles. The nerves establish synaptic contacts with both collagen fibrils and muscles fibers at the myotendinous junction. The function of these structures is unknown.
Proprioception – The sense that provides information about the location of various parts of the body in relation to each other and in relation to the space.
Proprioceptors – Sensory receptors which are found in muscles and tendons that bring sense of body position to the brain.
Vesicular acetylcholine transporter – A membrane protein which is necessary for the uptake of acetylcholine into synaptic vesicles.

Proprioception

Proprioception refers to a sense that provides information about the location of various parts of the body in relation to each other and in relation to space. It is of practical importance for activities in everyday life and allows a person to use the foot pedal of a car properly while driving or to learn to walk in darkness. Moreover, sportsmen use specific training devices to sharpen their proprioceptive sense. Proprioceptive signals come from specialized sensory nerve endings called proprioceptors that occur throughout skeletal muscle. Typical proprioceptors in skeletal muscle are muscle spindles and Golgi tendon organs which constantly transmit information to the brain. In this way the brain knows, at any given time, the spatial position of our body parts.

The eyes are the most mobile organs of the body, and vision is useful only if the brain knows the position of the eyes in the orbit. By knowing where the eyes are pointing, the brain is aware of the position of objects in the surrounding space: if objects are leftwards, straight ahead, or rightwards. Several studies indicate that the brain has access to proprioceptive information from the extraocular muscles (EOMs). Specifically, neuronal tracing experiments have demonstrated projections from the EOM to various peripheral and central nervous system structures, including the trigeminal ganglion, the mesencephalic trigeminal nucleus, the superior colliculus, the vestibular nuclei, and the cerebellum. A recent physiology experiment showed that the primary somatosensory cortex, which receives proprioceptive input from all other skeletal muscles, also receives signals from EOM. This new finding completes the somatotopic representation of the body in the primary somatosensory cortex which, thus far, had lacked a map of the eye muscles.

Indication that there is proprioceptive input from the EOM has also come from psychophysical investigations. Patients suffering from strabismus were tested after surgery, and it was detected that they had deficits in spatial perception. These results were interpreted to mean that the surgical intervention has damaged the proprioceptors at the myotendinous junction resulting in a loss of eye position signals.

Despite this evidence for EOM proprioception, there are also counterarguments. Specifically, no stretch reflex has been observed in the EOM of monkey. By cutting the ophthalmic nerve, which is supposed to carry the afferent fibers from EOM, deficits in eye movements would be

expected. However, findings indicate that deafferentation does not affect ocular alignment or eye movements, including saccades and smooth pursuit. Such observations led scientists to doubt whether EOM proprioception really exists. Instead, it has been hypothesized that the motor command that is sent to the EOMs is copied, called efference copy, and this copy provides the necessary information for the brain to be aware of the eye's position.

If there is sensory feedback from EOM, the eye muscles should have proprioceptors. In the last century, the EOMs of several mammalian species and man have been screened for muscle spindles and Golgi tendon organs. Interestingly, the endowment with classical proprioceptors varies widely among the species, and there are even some species that do not have proprioceptors at all. In view of these interspecies variations, it is not clear where the source of EOM proprioception lies. By searching for alternative sensory organs in the EOMs, palisade endings (also called myotendinous cylinders) have been detected, and so far, palisade endings have been observed in each species investigated. In the following section, we discuss EOM proprioceptors, including muscle spindles, Golgi tendon organs, and palisade endings. We give an overview about the occurrence, distribution, number, and structure of these organs and speculate about their putative function. Recent studies have focused on the molecular characteristics of palisade endings, and we also refer to these findings.

Muscle Spindles

Occurrence, Distribution, and Number of Muscle Spindles

Muscle spindles are regularly observed in the EOMs of even-toed ungulates (sheep, cow, camel, goat, and pig) and in the EOMs of primates (monkey and man). In other animal species, including fellidae (cat), rodents (rat and guinea pig), odd-toed ungulates (horse), and lagomorphs (rabbit), muscle spindles have not been found (Table 1).

In the EOMs of even-toed ungulates, muscle spindles are uniformly distributed throughout the entire muscle length. The number of muscle spindles is remarkably high, and counts per muscle yield between 146 and 333 muscle spindles in pig; between 100 and 181 muscle spindles in camel; and more than 200 muscle spindles in cow. In man the distribution of muscle spindles exhibits differences when compared with that in even-toed ungulates. Specifically, muscle spindles are located predominantly in the proximal and distal parts of the EOM, and each muscle has a spindle-free zone approximately in the middle. The number of human EOM spindles varies between 13 and 42. Only in the inferior oblique muscle has a lower number of muscle spindles been counted (3–7). The density of human EOM spindles is comparable to that of muscle spindles in finely controlled skeletal muscle such as the hand lumbrical and deep dorsal neck muscles. In monkey (rhesus monkey and cynomolgus monkey), very few muscle spindles (2–6) have been observed in some EOMs, and none in the others.

Table 1 Occurrence of muscle spindles, Golgi tendon organs, and palisade endings in the extraocular muscles of man and mammals

Species	*Muscle spindles*	*Golgi tendon organs*	*Palisade endings*
Man	+	−	
Monkey	+	−	+
Fellidae	−	−	+
Even-toed ungulates	+	+	+[a]
Odd-toed ungulates	−	−	[b]
Lagomorphs	−	−	+
Rodents	−	−	+

[a]So far, palisade endings have only been demonstrated in sheep.
[b]So far not analyzed for palisade endings.

Structure of Muscle Spindles

Muscle spindles in the EOMs of even-toed ungulates conform in their structure with those in other skeletal muscles. The muscle spindles have a fusiform shape with a wide central region (equatorial region) and two narrow polar regions. Muscle spindles are ensheathed by a capsule consisting of several layers of perineural cells. The capsule space is filled with a viscous fluid containing acidic mucopolysaccharides. Inside the capsule two types of intrafusal muscle fibers (nuclear chain fibers and nuclear bag fibers) can be distinguished, which both exhibit modifications concerning their myonuclei in the spindle's equatorial region. Nuclear chain fibers have a single row of centrally arranged nuclei, whereas nuclear bag fibers show an accumulation of nuclei. In the muscle spindle's equatorial region, a large tissue-free space (periaxial space) separates the intrafusal muscle fibers from the capsule.

Muscle spindles in the EOMs of even-toed ungulates receive a double innervation from sensory and motor nerve fibers. In the equatorial region, both types of intrafusal muscle fibers are endowed with sensory nerve endings (annulospiral sensory endings) which are wrapped spirally around the muscle fibers. Whether a second type of sensory nerve ending (flower-spray ending) that is common in other mammalian skeletal muscle spindles is also present in ungulate EOM spindles is unclear. Fine structural analyses have shown that sensory nerve terminals contain mitochondria and a few clear vesicles. The synaptic cleft separating the nerve terminal from the muscle fiber surface is free from a basal lamina. At the muscle spindle's pole, intrafusal muscle fibers receive motor terminals. Motor terminals contain mitochondria

and dense aggregations of clear vesicles, and the synaptic cleft is filled with a basal lamina.

Muscle spindles in EOM of primates exhibit structural differences when compared with those in even-toed ungulates. Specifically, in most muscle spindles of monkey and man the periaxial space exhibits little or no expansion. Only in human infants have some muscle spindles with a wide periaxial space been observed. Thorough analyses of the intrafusal fiber composition have been done in human EOM spindles. The findings indicate that human EOM spindles contain nuclear chain fibers but most of them lack nuclear bag fibers. Only 2% of the spindles contain nuclear bag fibers and, when present, the bag region is poorly developed with only two nuclei lying side by side. In addition to nuclear chain fibers, anomalous muscle fibers are also regularly observed in human EOM spindles. Anomalous muscle fibers exhibit no nuclear modification in the spindle's equatorial region and are indistinguishable from muscle fibers outside the spindle. The unique morphology of human EOM spindles was initially described in aged persons (67–83 years old) and later was confirmed in infants (**Figure 1(a)**).

The innervation pattern of primate EOM spindles has only been analyzed in humans. In human EOM spindles, sensory nerve endings have been observed on nuclear chain and, when present, on nuclear bag fibers, but only 7% of the anomalous fibers are endowed with sensory nerve terminals. In their fine structure, sensory nerve terminals in human EOM spindles do not differ from sensory nerve terminals in EOM spindles of even-toed ungulates. At the muscle spindle's pole, intrafusal muscle fibers are equipped with motor terminals. Motor terminals in human EOM spindles are identical in their structure with those in EOM spindles of even-toed ungulates (**Figure 1(b)**).

Function of Muscle Spindles

Muscle spindles in mammalian skeletal muscle are stretch receptors which register changes in muscle length. Indications that muscle spindles in the EOMs of even-toed ungulates are capable of monitoring muscle length have come from electrophysiological investigations. Specifically, in goat and sheep the EOMs were stretched and afferent signals were recorded in the sensory trigeminal ganglion. Recorded signals exhibited characteristics that are the same as muscle spindles in other skeletal muscles.

There is controversy whether muscle spindles in human EOMs are functional. Due to their unusual morphology, some authors suppose that human EOM muscle spindles are not functional. On the other hand, muscle spindles in human EOMs are numerous, and their nerve terminals exhibit a normal morphology. This is why other authors suggest that human EOM spindles are functional, and their unusual morphology might indicate special functional properties. In particular, as most human EOM muscle spindles lack nuclear bag fibers, muscle spindles might have a predominantly static function and monitor the degree of muscle stretch rather than the contraction velocity of muscle fibers.

Golgi Tendon Organs

Occurrence, Distribution, and Number of Golgi Tendon Organs

Golgi tendon organs are exclusively found in the EOMs of even-toed ungulates (pig, sheep, camel, and cow). They have not been found in other mammals and man. In even-toed ungulates, Golgi tendon organs are distributed throughout the proximal and distal EOM tendons, their number always being higher in the distal tendons (**Table 1**). The number of Golgi tendon organs per muscle has been counted to be

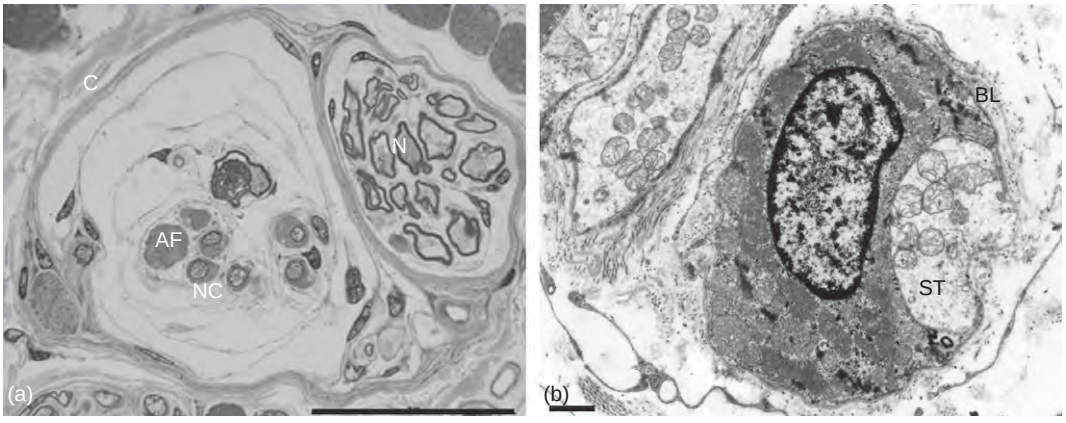

Figure 1 (a) Semi-thin cross section through an extraocular muscle spindle of a 2-year-old human infant and (b) ultra-thin cross section through a nuclear chain fiber. (a) The muscle spindle contains six nuclear chain fibers (NF) and one anomalous fiber (AF). The anomalous fiber is indistinguishable from muscle fibers outside the spindle. N, nerve and C, capsule. Scale bar = 100 μm. (b) Nuclear chain fiber (NF) with a sensory nerve terminal (ST). BL, basal lamina. Scale bar = 1 μm.

46–128 and 30–90 in pig and camel, respectively. In both species, Golgi tendon organs are more frequent in the rectus EOMs than in the oblique EOMs.

Structure of Golgi Tendon Organs

Golgi tendon organs in EOMs of even-toed ungulates exhibit a fusiform shape and are enclosed by a capsule of perineural cells. The capsule space is filled with a viscous fluid containing acidic mucopolysaccharides. The main component of the Golgi tendon organs are collagen bundles that pass through the organ. At one end of the organ the collagen fascicles are attached to muscle fibers, and at the other end the fascicles merge with the tendon of the muscle. Many Golgi tendon organs contain only collagen bundles, but there are others which contain both collagen bundles and muscle fibers. Such intracapsular muscle fibers penetrate the Golgi tendon organ at one end and either terminate in collagen bundles or, more rarely, pass through the tendon organ. All Golgi tendon organs in the EOMs of even-toed ungulates exhibit a wide space in the central region that separates the collagen bundles and muscle fibers, if present, from the capsule (**Figure 2(a)**).

Each Golgi tendon organ is innervated by a single sensory nerve fiber. The nerve fiber penetrates the capsule at various points. Inside the organ, the axon divides into several preterminal branches which finally establish nerve terminals that contact the surrounding collagen fibrils. Nerve terminals are only partly covered with Schwann cells, and at the area of contact only a basal lamina lies between the nerve terminal and the neighboring collagen. Nerve terminals contain mitochondria and a few clear vesicles (**Figure 2(b)**).

With the exception of intracapsular muscle fibers and a more pronounced capsule space in the central region, Golgi tendon organs in even-toed ungulates share the structural features of Golgi tendon organs found in other mammalian skeletal muscles.

Function of Golgi Tendon Organs

Golgi tendon organs in mammalian skeletal muscle are sensitive to muscle contraction. During muscle fiber contraction collagen bundles are stretched, and the nerve terminals within the collagen are deformed, thereby generating a receptor potential. Golgi tendon organs in EOMs of ungulates are supposed to function analogously and register muscle fiber contraction. Muscle fibers passing through Golgi tendon organs are supposed to regulate the sensitivity of the organ.

Palisade Endings

Occurrence, Distribution, and Number of Palisade Endings

Palisade endings (myotendinous cylinders) are sensory end organs that are unique to EOMs. So far, palisade endings have been found in the EOMs of almost all species investigated, including fellidae (cat), lagomorphs (rabbit), even-toed ungulates (sheep), rodentia (rat), and primates (monkey and man). These organs are located at the distal and proximal myotendinous junctions. Palisade endings are plentiful in the EOMs of monkey and cat (**Table 1**). In the distal myotendon of a monkey medial rectus 350 palisade endings have been counted, and in a

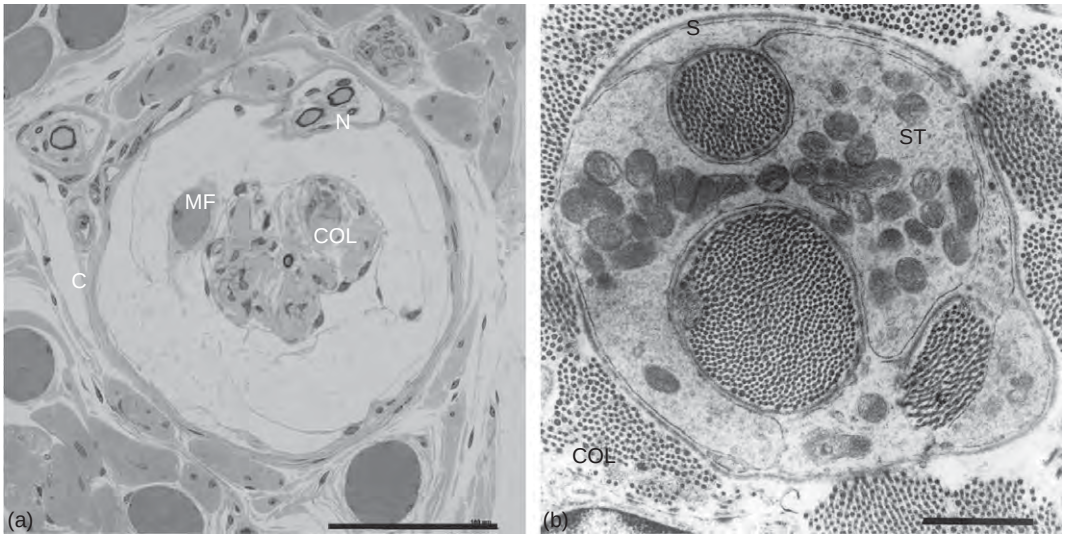

Figure 2 (a) Semi-thin cross section through a Golgi tendon organ of a calf extraocular muscle and (b) ultrathin section through a sensory nerve terminal. (a) The Golgi tendon organ is ensheathed by a capsule (C) and contains collagen bundles (COL) and one muscle fiber (MF). Nerve fiber (N). Scale bar = 100 μm. cat medial rectus 94. A smaller number of this EOM-specific organ have been found in the distal EOM myotendons of rat (27) and human (20–30).

Structure of Palisade Endings

Innervation for the palisade endings arises from nerve fibers that come from the muscle and extend into the tendon. Within the tendon, the nerve fibers make a 180° loop and return to the muscle. At the muscle–tendon junction, the returning axons divide into preterminal branches. Preterminal axons establish nerve terminals around the muscle fiber tips which have the appearance of a palisade fence (**Figure 3**), which is also the reason why this formation is called a palisade ending. The whole palisade complex is ensheathed by a capsule of fibroblasts.

Palisade ending is exclusively associated with the multiply innervated muscle fibers of the global (inner) layer of the EOMs. Such muscle fibers have several motor contacts along their length, and with respect to contraction they exhibit nontwitch characteristics. The multiply innervated muscle fibers have a unique innervation from small motoneurons located outside the borders of the main EOM nuclei.

The fine structure of palisade endings was initially analyzed in cat and monkey and later in sheep, rabbit, and man. It was observed that the majority of palisade nerve terminals contact the collagen fibrils of the tendon, and only a few of them contact the muscle fiber tip. Nerve terminals contacting the collagen fibrils are only partly enwrapped with Schwann cells, and at the area of contact with the collagen only a basal lamina covers the nerve terminals. Such neurotendinous contacts contain dense aggregations of clear vesicles and mitochondria. Palisade nerve terminals contacting the muscle fiber are free from a basal lamina in the synaptic cleft, thereby resembling sensory nerve terminals on intrafusal fibers of muscle spindles. Identical to neurotendinous contacts, neuromuscular contacts contain mitochondria and a large number of clear vesicles. Interestingly, in palisade endings of man and monkey, neuromuscular contacts have a basal lamina in the synaptic cleft which is a feature of motor terminals. Palisade endings in rabbits and rats are an exception. In both species, the palisade endings lack neurotendinous contacts and neuromuscular contacts are present exclusively.

Molecular Characteristics of Palisade Endings

In cat and monkey, it has been recently demonstrated that palisade endings have a cholinergic phenotype. Utilizing immunohistochemistry, palisade endings have been labeled with all commercially available cholinergic markers, including antibodies against choline transporter (ChT), choline acetyltransferase (ChAT), and vesicular acetyl choline transporter (VAChT), as well as α-bungarotoxin. In the nervous system, ChT is used for the uptake of choline, ChAT is the synthesizing enzyme of acetylcholine, and VAChT is used to transport acetylcholine into the synaptic vesicles. α-Bungarotoxin is a snake venom that binds to nicotinic acetylcholine receptors, and this neurotoxin is widely used to detect motor terminals in skeletal muscle.

In cat and monkey, it has been shown that the nerve fibers supplying palisade endings are ChAT immunoreactive. The palisade complexes, including palisade nerve terminals, are ChAT positive as well. In monkey, it also has been demonstrated that palisade nerve terminals exhibit ChT/VAChT immunoreactivity, and neuromuscular contacts, when present, exhibit α-bungarotoxin binding. Finally, in some cases it has been detected that nerve fibers supplying palisade endings establish α-bungarotoxin-positive neuromuscular contacts outside the palisade complex (**Figure 3(b)**).

Function of Palisade Endings

So far, physiological studies on palisade ending are missing, and their function remains speculative. Indication that palisade endings are sensory organs comes from morphological studies and a single neuronal tracing experiment. Specifically, morphological studies show that palisade endings have nerve terminals contacting the tendon, and nerve terminals in apposition to collagen are arguably sensory. Palisade nerve terminals contacting

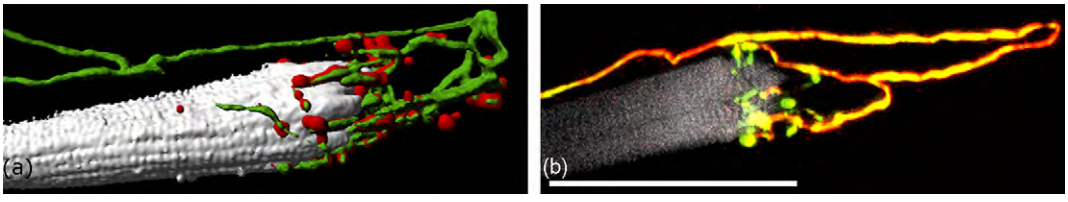

Figure 3 Palisade endings: (a) three-dimensional reconstruction of a palisade ending and (b) palisade ending labeled with anti-neurofilament (general marker for nerve fibers) and anti-ChAT (marker for cholinergic nerve fibers). Muscle fibers are counterstained with phalloidin. The tendon is not labeled and is continuous with the muscle fiber tip to the right. (a) A nerve fiber (green) coming from the muscle extends into the tendon and turns back to establish nerve terminals (red) around a muscle fiber tip. The muscle fiber is white. (b) This shows a nerve fiber forming a palisade ending. The nerve fiber and the palisade ending are positive for neurofilament (red) and ChAT (green). Muscle fiber (white). Scale bar = 100 μm.

the muscle fibers lack a basal lamina in the synaptic cleft which is common with sensory nerve terminals in muscle spindles. Moreover, by injecting neuronal tracer into the sensory trigeminal ganglion, structures resembling palisade endings have been labeled. Palisade endings lie in series to the multiply innervated muscle fibers of the global (inner) EOM layer, and it is supposed that palisade endings register contraction of such muscle fibers.

Although a consensus exists that palisade endings are sensory, there are other findings which favor a motor role for palisade endings. In particular, immunohistochemical studies have demonstrated that palisade endings are cholinergic, a feature common with motor nerve terminals. Nerve fibers forming palisade endings also establish motor neuromuscular contacts outside the palisade complex. In a nerve degeneration experiment a lesion of the oculomotor nucleus was performed and, in addition to the expected loss of motor terminals, the palisade endings degenerate as well. The functional significance of palisade endings with a motor nature is difficult to predict. In particular, it is unclear what effect cholinergic neurotendinous contacts would have on the surrounding collagen. At the moment the function of palisade endings is still a matter of discussion, and for clarification physiological studies are highly warranted.

Eye-Field Transcription Factors

M E Zuber, SUNY Upstate Medical University, Syracuse, NY, USA

Glossary

Aniridia – Congenital condition resulting in the underdevelopment or lack of an iris.
Anophthalmia – Congenital absence of one or both eyes.
Ectopic eye – An eye that has formed in an abnormal location (an additional eye).
Eye field – A region of the anterior neural plate of vertebrate embryos that is fated to generate the eyes.
Gene homology – Two genes are homologous if they are derived from the same gene in a common ancestor.
Hypomorphic mutant – A mutation in which the altered gene product has reduced activity or in which the wild-type gene product is expressed at a reduced level.
Iris – Colored portion of the eye surrounding the pupil.
Microphthalmia – Congenital defect resulting in small eyes.
Retina – Light-sensing part inside the inner layer of the eye. The vertebrate retina consists of seven major cell classes.

Discovery and Structural Features of Eye-Field Transcription Factors

Pax6

Vertebrate Pax6 (paired box gene 6) was identified, in 1991, in mouse and humans as a member of a multigene family of paired-box-containing (Pax) genes. Small-eye (Sey) mutant mice were found to have mutations in the Pax6 gene predicted to interrupt gene function. The *Drosophila melanogaster* (fly) mutant eyeless (ey) was subsequently shown to be homologous to vertebrate Pax6. Remarkably, the mouse Pax6 was shown to functionally rescue the eyeless phenotype in flies, demonstrating functional conservation of Pax6 from flies to mammals. Pax transcription factors contain a paired domain and either a partial or complete (as in the case of Pax6) homeodomain (see **Figure 1** and **Table 1** for EFTF structure and characteristics). In addition, Pax6 contains a proline–serine–threonine-rich (PST-rich) C-terminus. The paired domain is an approximately 126-residue DNA-binding domain originally described in the *Drosophila* gene of the same name. Two distinct DNA-binding domains are present in the paired-type domain in the form of N-terminal and C-terminal subdomains. Alternative splicing of the Pax6 gene results in alternate isoforms with distinct DNA-binding activities with functional consequences. The 60-residue homeodomain forms a helix-turn-helix structure at the carboxy-terminal end that also binds DNA. As with the paired domain, an altered homeodomain can result in developmental defects. The PST-rich region acts as a trans-activating domain with binding sites for other proteins such as transcriptional coregulators. Pax6 mutants that truncate the C-terminal-half of the protein remove the PST-rich region, retain their DNA-binding capacity, but act dominantly to repress normal Pax6 function.

Six3

The first Six (Sine oculis homeobox) family member was identified in 1994 as the gene altered in the *Drosophila* mutant *sine oculis* (*so*), the most striking phenotype of which is the lack of eyes. Vertebrate Six3 (*sine oculis* homeobox homolog 3) was first identified in mouse in 1995 and shown to share significant amino-acid homology with *so*. Members of the Six family of homeobox transcription factors are characterized by two conserved domains – the Six domain (SD) followed by a more carboxy-terminal homeodomain (HD). The Six domain is typically 115 residues and is required for protein–protein interactions between Six genes and their binding partners. The homeodomain is a 60-residue DNA-binding domain (as described above). Both the SD and HD are required for normal function of the protein. The more recent identification of additional *Drosophila* Six family members also demonstrated vertebrate Six3 (and section titled 'Six6') share greater sequence homology with fly *Optix* than its namesake *sine oculis*. Based on sequence homology, intron–exon boundries, and the proteins with which they form complexes, Six family members are divided into three subfamilies. Six3 and Six6 have been assigned to the Six3/6 subfamily.

Six6

A second Six gene structurally related to Six3 was identified, in 1998, in zebrafish, chicken, and mouse as Six6 (*sine oculis* homeobox homolog 6) and Optx2 (optic six gene 2). Among the family of Six genes, Six6 shares greatest sequence homology and expression pattern with Six3,

suggesting they may have arisen via gene duplication. Despite their similarities, Six6 and Six3 can be easily distinguished at the amino-acid level. The most highly divergent regions lie at the amino- and carboxy-terminals to the Six and homeodomains. In particular, the region of Six6 amino-terminal to the Six domain is dramatically smaller than the corresponding region of Six3. For example, only nine residues are present at the amino-terminal to the Six domain in mouse Six6, while 88 residues are present in the Six3 protein.

Rax

Vertebrate Rax (retina and anterior neural fold homeobox) was identified, in 1997, by three independent groups in Xenopus, mouse, and zebrafish, and is shown to be expressed in the developing eyes and required for normal mouse eye formation. Rax – like Pax6 – is classified as a member of the paired homeobox class of transcription factors. In contrast to Pax6, however, Rax contains a paired-like homeodomain, but no paired domain. Within the amino-terminal, Rax contains an octapeptide motif consistent with this homeobox gene subfamily. In the carboxy-terminal, a 15-residue region present in other paired-like genes termed the paired tail or OAR (otp, aristaless, and rax) domain is also conserved. Finally, the sequence carboxy-terminal to the paired-like homeodomain is PST-rich. These regions (octapeptide, OAR, and PST-rich) may function as transactivation domains.

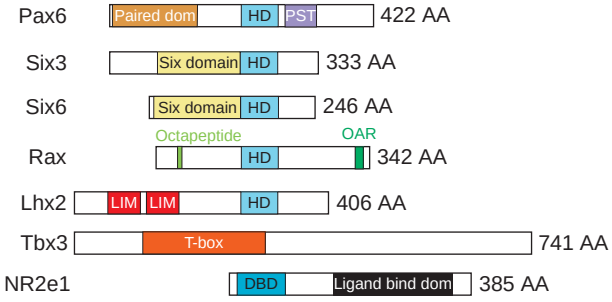

Figure 1 Schematic illustrating the location of structural domains in the mouse eye-field transcription factors. The EFTFs – with the exception of the Six genes Six3 and Six6 – have distinct domain structures and are members of different transcription-factor families. Five of the seven bind DNA targets via a homeobox domain (HD). While Tbx3 (via the T-box) and Nr2e1 bind DNA through DNA-binding domains (DBDs) specific to their transcription factor family. Each EFTF also contains protein motifs that allow it to complex with other proteins. These protein–protein interactions serve to facilitate (or sometimes block) the ability of the transcription factor to bind its DNA targets. Co-regulatory proteins that bind to these regions can serve as co-activators or co-repressors to increase or decrease, respectively, the rate of expression from a target gene. Courtesy of Andrea Viczian.

Lhx2

First identified in rat as LH-2 (LIM Hox gene 2) in 1993, vertebrate Lhx2 (LIM homeobox-2) is a member of a large LIM-domain (Lin 11, Isl-1, Mec-3)-containing family of genes with diverse structure and biological functions. Mouse Lhx2 was subsequently shown to be required for normal eye formation. The LIM domain (two of which are found in Lhx2) is a cysteine- and histidine-rich zinc-finger motif involved in protein–protein interactions. The LIM domains of Lhx2 protein are located in the amino-terminal region and followed by a carboxy-terminal, highly conserved, DNA-binding homeodomain. There is little evidence that LIM domains of the LHX class can bind DNA directly, but may regulate DNA binding of the protein via interactions with other proteins.

Tbx3

Vertebrate Tbx3 was identified, in 1994, in mouse as a member of a large gene family characterized by a shared T-box protein motif. Mutation of the founding member of this family caused truncated tails in mice and was shorthand named T for short-tail. Once the gene was identified, the DNA-binding region of the T protein (which is 180–190 residues and can be located at any position in the protein) was subsequently named the T-box. The more than 50 T-box family members identified have been classed into five subfamilies. Tbx3 is a member of the Tbx2 subfamily that includes Tbx2-5 and is most similar to Tbx2.

Nr2e1

Vertebrate NR2E1 (nuclear receptor subfamily 2, group E, member 1) was originally identified in 1994 as Tlx,

Table 1 Names and the null phenotypes of EFTF homologs

EFTF	*TF family*	*Fly homoloq*	*Vertebrate alias(es)*	*Eye phenotype of mouse null*
Pax6	Paired homeobox	eyeless, twin of eyeless	AN2, WAGR	small or no eyes
Six3	Six homeobox	sine oculls/optix	Holoproencephaly 2 (HPE2)	lack of anterior brain (no eyes)
Six6	Six homeobox	sine oculis/optix	Optx2, Six9	small eyes
Rax	Paired-like homeobox	DRx	Rx	no eyes
Lhx2	LIM homeobox	apterous	LH-2	no eyes
Tbx3	T-box	optomotor blind	ET, XHL, UMS	embryonic lethal (eye normal)
NR2E1	Nuclear receptor type	tailless	XTll, Tlx	degenerated retina

a unique vertebrate nuclear receptor with structural homology to the previously described fly gene, *tailless* (*tll*). Tll was classified as a member of the steroid receptor superfamily of proteins. Nr2e1 (and tll) are orphan nuclear receptors, implying – although their protein sequence predicts a hormone-binding domain – the hormone ligand that binds to it has not been identified. The NR2E1 DNA and ligand-binding domains are located in the amino- and carboxy-terminal regions of the protein, respectively. NR2e1 shares the highest similarity with tll in these regions. *In vitro* DNA-binding assays, and misexpression of vertebrate Nr2e1 in the fly shows that the vertebrate and fly proteins share similar target-gene specificity, which is unique among the nuclear receptor superfamily.

The EFTFs are Expressed during and are Required for Normal Eye Formation

Transplantation experiments performed in the beginning of the last century demonstrated that the amphibian eye field (originally called the eye anlagen or, sometimes, eye primordia) is located in the neural plate. Removing the anterior portion of the neural plate resulted in the creation of eyeless animals. When this same region was transplanted to the belly-wall or grown in culture, a histologically normal eye would form. These remarkably simple experiments clearly demonstrated that the eye primordia is specified in embryos at the neural plate stage, and that all the genes required to initiate eye formation were being expressed in the tissue at that time. Subsequent, detailed mapping experiments using more modern tools precisely defined the location and shape of the eye field as a single crescent of cells spanning the breadth of the early anterior neural plate.

During embryonic development, eye and brain formation are tightly coordinated. Neural induction results in an early neural plate with a propensity to form anterior structures (including the eyes). This early neural plate is subsequently patterned in response to diffusible molecules that help to form the different brain regions (the forebrain, midbrain, and hindbrain). The signaling systems known to regulate this patterning include the wingless (Wnts), fibroblast growth factors (FGFs), bone morphogenetic proteins (BMPs), Nodals, and retinoic acid. Inactivation or modification of any one of these signaling systems can result in abnormal eye formation. These abnormalities are often coincident with changes in the expression of the EFTFs. These effects may sometimes be indirect, however, as some of these molecules are required for neural induction and not directly responsible for the formation of the eye field. Nevertheless, EFTF expression can be regulated by these signaling systems. For example, cultured embryonic stem cells treated with BMP, Wnt, and/or Nodal antagonists express EFTFs and are directed to a retinal progenitor lineage. Precise control of the Wnt signaling system appears to be critical for patterning of the forebrain – the brain region in which the eye field and ultimately the eyes form. Disrupting Wnt activity by modifying the ligand or its signaling cascade can have dramatic effects on eye formation. Either too much or too little Wnt activity can lead to abnormal eye formation. The evidence suggests that a precise Wnt gradient is required to pattern and appropriately position the eye field within the forebrain.

The location and timing of eye-field specification in the anterior neural plate is synchronized with the expression of the EFTFs. The expression patterns of the individual genes are distinct and extend to other regions of the neural plate and beyond. However, all are to some extent expressed in the eye field in one or more species. For example, the expression pattern of the frog (*Xenopus laevis*) EFTFs overlap in the eye field during and immediately following its specification (**Figure 2**). The EFTFs of other species have similar patterns of coordinated expression. At neural plate stages, for example, Pax6, Rax, Six3, and Six6 are also observed in a single band of expression in chicken, zebrafish, and mouse embryos.

The single band of EFTFs expressing eye-field cells generates both eyes. Since all vertebrate embryos have a pair of eyes organized symmetrically across the body midline, the single eye field described above must be split into two lateral eye primordia. Infrequently, this separation does not take place due to environmental toxins or genetic mutations. This results in cyclopia, the formation of one large midline eye. One toxin long known to induce cyclopia is 11-deoxyjervine (also known as cyclopamine). A US Department of Agriculture study, in the 1950s, showed that pregnant ewes feeding on corn lily (a naturally occurring source of cyclopamine) bore one-eyed lambs (**Figure 3**). More recent studies have demonstrated that diffusible factors secreted by cells near the eye field regulate its splitting. Signaling pathways regulated by the ligands hedgehog and nodal converge and are required for eye-field separation. Hedgehog represses the EFTF Pax6 and since hedgehog is normally expressed underneath the eye field midline, it is likely that hedgehog expression is required for normal eye-field separation and the formation of two eyes (**Figure 3**). Consistent with this interpretation, humans, mice, and fish lacking functional nodal or hedgehog signaling are cyclopic. Interestingly, the action of cyclopamine also appears to be through the hedgehog signaling pathway. Cyclopamine regulates the activity of Smoothened, the receptor for the hedgehog ligand.

Evidence that the EFTFs are required for normal eye formation is abundant. The most extensively studied of the EFTFs, Pax6, was originally identified as the gene mutated in the small eye (Sey) mouse which, when

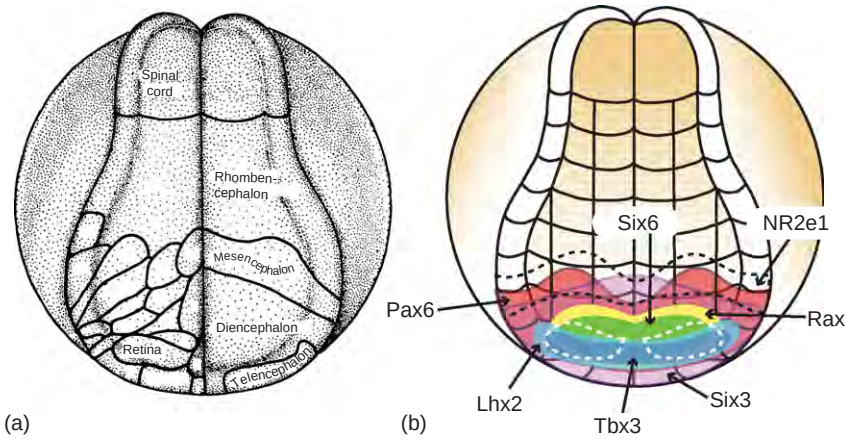

Figure 2 Schematic diagrams of stage 15 *Xenopus laevis* embryos. (a) Fate-map illustrating the areas of the neural plate that will eventually form the major brain regions. (b) Expression patterns of the frog eye-field transcription factors. The approximate location of the eye field is outlined in white. No two EFTFs have identical expression patterns, yet all (but Nr2e1) are expressed in the eye field. Nr2e1 is expressed posterior to the eye field proper at stage 15. However, only a few hours later, its expression overlaps that of the other EFTFs in the eye primordia. Courtesy of Andrea Viczian.

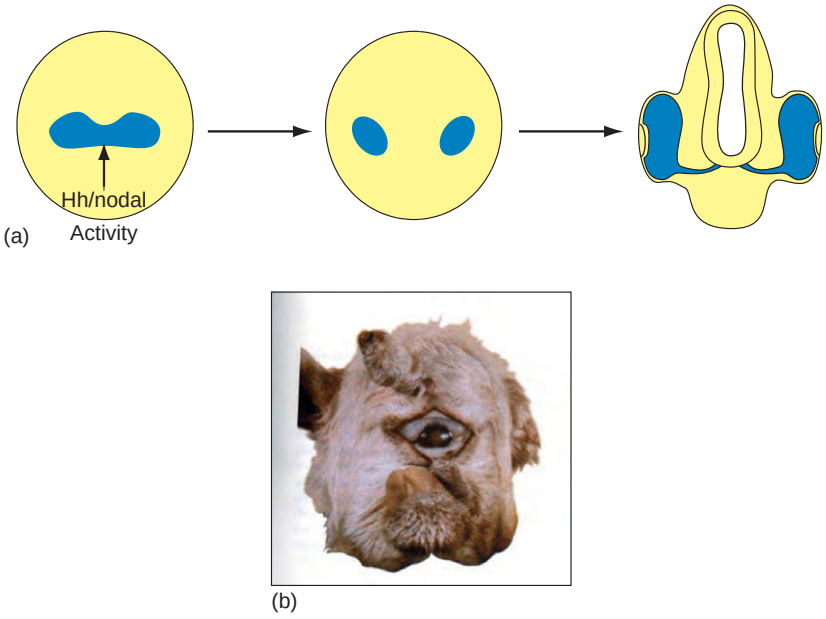

Figure 3 Generation of two eyes from a single eye field. (a) The single eye-field spans the entire anterior neural plate. For two eyes to form, this single EFTF-expressing domain must be split into the two (left and right) eye primordia. Cells posterior to and underlying the midline are required for this process. Signaling via the hedgehog (Hh) and nodal systems are thought to repress midline eye-field fate. (b) When these signaling systems are abnormal, eye-field separation does not take place and a single midline eye forms. The mother of this lamb fed on corn lily while pregnant. Cyclopamine made by corn lily blocks hedgehog signaling with dramatic effects. Courtesy of L. James, USDA Poison Plant Laboratory.

homozygous, lacks eyes. A large number of null and hypomorphic mutant alleles have been generated – with variable eye phenotypes including lens/cornea fusion, microphthalmia, cataracts, and anophthalmia. Flies with a mutant version of the *Drosophila* homolog of Pax6 (eyeless) also lack eyes, while frog eye development can be arrested using a function-blocking (dominant negative) version of Pax6. As with Pax6, functional inactivation of Six3, Six6, Rax, Lhx2, and Nr2e1 results in flies, frogs, fish, and/or rodents with abnormal or no eyes.

Mutation of human EFTFs also results in abnormalities affecting the eyes. Pax6 mutations result in aniridia, microphthalmia, and Peters' anomaly – in which patients have cornea and iris abnormalities. Anophthalmia and microophthalmia have also been attributed to mutations in the human Six6 and Rax genes. Six3 mutation results in

holoprosencephaly, a failure of the forebrain to divide properly into the two hemispheres. Holoprosencephaly is, in most cases, fatal. In less severe cases, facial deformities affecting the eyes are observed.

The EFTFs Form a Self-Sustaining Feedback Network

As described briefly above, many of the vertebrate EFTFs were originally identified as *Drosophila* genes required for fly eye formation or that have fly homologs. In some instances, the vertebrate versions can functionally restore the corresponding fly mutant or induce ectopic eyes in the fly. For example, mis-expression of mouse eyes absent (eya) and Pax6 in flies can induce ectopic eye development and rescue eye formation in loss-of-function mutants. Based on its remarkable evolutionary conservation, requirement for normal eye formation in multiple species, and the ability of mammalian Pax6 homologs to induce ectopic fly eyes, ey/Pax6 was originally hailed as a potential master regulator of eye formation. In initial models, eyeless was placed atop a hierarchy of genes that drove eye formation in the eye portion of the eye-antennal imaginal disk complex. However, a much more complex set of interactions has emerged. The genes twin-of-eyeless (toy), *sine oculis* (*so*), optix, eyes absent (eya), dachshund (dac), eye gone (eyg), and twin-of-eyegone (toe) are all required for fly eye formation. Individually or in combinations, these genes can also induce ectopic eyes, sometimes in the absence of eyeless. For instance, both toy and optix can induce ectopic eyes via an *ey*-independent mechanism. In the fly, a model has developed in which the retinal determination genes described above behave as a network with both hierarchical components and regulatory feedback loops.

In recent years, it has been discovered that an analogous – but by no means identical – transcription factor network may also be at work during vertebrate eye formation. As described above, fly retinal determination genes have the ability to induce ectopic eyes. Similarly, some EFTFs can induce ectopic retinal tissue and lenses in vertebrates. For example, in the frog, ectopic expression of Pax6 leads to the formation of ectopic eye-like structures. Lineage-tracing experiments show that the lens, retina, and retinal pigment epithelium of these eyes all arose in response to Pax6. Molecular markers confirmed the presence of some retinal cell types in the induced eyes. In a similar manner, ectopic expression of either fish or mouse Six3 promotes the formation of ectopic lens and retina cells. Remarkably, Six3 mis-expression was also reported to promote the formation of ectopic tissues with an optic vesicle-like structure in the hindbrain–midbrain region of developing mouse embryos. Experiments performed in fish and frogs also show that Rax homologs can induce eye tissues. The mechanisms by which individual EFTFs induce the formation of eye tissue are still unclear. Dosage is important. In the case of frog Six6, relatively low doses stimulate the proliferation of eye-field cells, dramatically increasing the size of the eye field and eventually resulting in the growth of eyes nearly twice their normal size. At higher doses, ectopic eyes form in the rostral brain, suggesting that tissue which would normally form midbrain is respecified to form retina.

A likely mechanism is the ability of the vertebrate EFTFs to induce each other's expression. Pax6, Six3, Rax, and Six6 activate each other's expression, while inactivation of each, sometimes, reduces the expression of the others. When high doses of Six6 or Six3 sufficient to drive ectopic eye formation are injected into frog or fish embryos, the expression of genes normally present in the rostral brain is lost, while Pax6 and Rax are induced in their place. When eye-inducing levels of Pax6 are injected into frogs, ectopic expression of Rax and Six3 are detected. Some of these EFTF interactions are direct – that is, they involve one transcription factor binding to and activating the regulatory sequences of another. For instance, experiments using *in vitro* and transgenic approaches in mouse have demonstrated that Pax6 and Six3 bind directly to regulatory sequences in each other's gene. In addition to regulating each other's expression, both Pax6 and Six3 induce their own expression in developing embryos. Not all the inductive effects of the EFTFs on one another's expression are direct. For example, in $Pax6^{-/-}$ mice, early expression of Rax, Six3, and Lhx2 is unaffected. Similarly, Pax6, Six3, and Rax expression are normal in the small-eyed $Six6^{-/-}$ mouse. Intervening, yet-to-be-discovered signaling cascades remain to be identified. Nevertheless, these results demonstrated that EFTFs form a genetic network that has been partially conserved during evolution, which, in the anterior neural plate of vertebrate embryos, is required for eye primordia formation.

The Coordinated Expression of EFTFs is Sufficient for Eye Formation

As described above, the EFTFs are coordinately expressed in the eye of multiple species during its formation and they can regulate each other's expression. There is clear evidence from experiments with the retinal determination genes in flies that they can act coordinately, forming protein–protein interactions to activate downstream targets necessary for ectopic eye formation. For example, *Drosophila sine oculis* physically interacts with eyes absent through the Six domain, and, together, they can induce ectopic compound-eye formation. Vertebrate EFTFs have also been shown to act synergistically. In frogs, mis-expression of Six6 dramatically increases eye

size by stimulating the proliferation of eye-field cells. In contrast, Pax6 alone has no effect on eye size. However, when co-expressed in the eye field of developing frogs, Pax6 potentiates the effect of Six6 on eye enlargement. Recent evidence also suggests that Pax6 and Lhx2 act synergistically by binding to and regulating Six6 expression. As in fly, functional interactions have also been detected among the vertebrate EFTFs. *In vitro* and *in vivo* assays show Rax physically associates with and can enhance the Pax6-mediated transactivation of a minimal promoter. Pax6 can also associate with Six3 and Lhx2 *in vitro*. Dach is the mouse homolog of the eye-inducing fly gene dachshund. Six6 physically associates with Dach and, together, they regulate mouse retinal cell proliferation by co-repressing the cyclin-dependent kinase inhibitor p27Kip1. Peculiarly, while fly dachshund mutants lack eyes, mouse Dach – which is expressed in developing eyes – does not appear to be required for mouse eye formation.

Together, these observations lead to the proposal that, in vertebrates – as in the *Drosophila* compound eye – specification might be driven by the coordinated expression of the EFTFs. This model was tested in vertebrates by co-expressing the EFTFs in developing *Xenopus* embryos. Coordinated expression of the EFTFs Tbx3, Rax, Pax6, Six3, Nr2e1, and Six6 with the anterior neural patterning gene Otx2 was found to be sufficient to induce ectopic eye fields and eye structures (**Figure 4**). In contrast to ectopic retinal tissues induced by individual EFTFs, cocktail-induced eyes were generated at a higher frequency, were larger, and develop outside the nervous system at various locations on the body including the belly. EFTF cocktail subsets and inductive analysis has also been used to begin to characterize the network of interactions between vertebrate EFTFs in frogs and generate a working model for the interactions required for eye-field specification. In the model, coordinated expression of the EFTFs specifies the eye field within the presumptive forebrain (**Figure 5**). These results suggested the vertebrate EFTFs redirect noneye cells to an eye-field-like fate since their coordinate mis-expression induced eyes.

To some extent, the model outlined for frog eye-field specification is consistent with results generated using targeted knockout of mouse EFTFs (**Table 1**). In the frog model, Rax is predicted to be upstream of Pax6. Consistent with this order, $Rax^{-/-}$ mice lack normal Pax6 expression in the optic primordia, while Rax expression is unaffected in the $Pax6^{-/-}$ mice. Neither Six6 nor

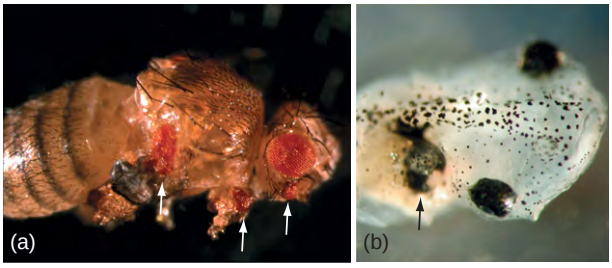

Figure 4 Ectopic Fly and Frog eyes can be generated by misexpression of the Eye Field Transcription Factors. (a) Ectopic eyes (red, white arrows) form on the wing, leg and antennae in response to the misexpression of the *Drosophila eyeless* (*ey*) gene. (b) Similarly, misexpression of a cocktail of vertebrate EFTFs including the frog *Pax6* (a homolog of *Drosophila ey*), *Tbx3*, *Rax*, *Six3*, *Nr2e1, Six6,* and *Otx2* induces the formation of extra frog eyes (white arrow). Figure 5 Simplistic model of eye field specification in the anterior neural plate of the frog embryo. (A) The initial neural plate (lightly shaded in a) is patterned to form fate-restricted areas. Otx2 expression is required for patterning of the early fore- and midbrain (b). Finally, the EFTFs form a self-sustaining feedback network that specifies the eye field (darkly shaded in c). (B) Neural induction (initiated by factors including noggin) results in an only partially patterned neural plate. Neural patterning genes like Otx2 then specify different neural regions. The early-expressed EFTFs Tbx3, Rax, Pax6, Six3, and Lhx2 act coordinately to specify the eye field. Although not required for the initial specification of the eye field, evidence suggests Nr2e1 and Six6 play later roles in eye formation. Arrows and bars indicate the induction and repression of target gene expression, respectively. Evidence for some, but not all, aspects of this predicted network are found in other species. Illustration courtesy of Andrea Viczian.

Nr2e1 are required for the initial specification of the eye field in frog. Six6$^{-/-}$ mice have normal (although small) eyes and Nr2e1$^{-/-}$ mice do not develop retinal defects until 3 weeks after birth. In mouse as well as frog, altering Six6 levels does not effect Pax6, Six3, or Rax expression.

Despite these similarities, inconsistencies and clear differences exist between the networks driving eye formation in vertebrates. In the frog model, Tbx3 is positioned upstream of Rax and is required for early eye formation. Although Tbx3$^{-/-}$ mice die as embryos, there are no obvious early eye abnormalities. Mutation of Rx3 (one of three Rax genes in fish) results in eyeless fish. Directly contradicting the frog model, Tbx3 expression is lost in the developing retina. These differences may be species specific or result from the use of different analytical methods. Additional work is needed to more clearly define the genetic interactions among these genes and their role in specification of the vertebrate eye field.

Conclusions

Experiments first performed over a century ago established that the eyes form from the most anterior region of the vertebrate neural plate. However, only recently have genes responsible for eye-field specification been identified. Using multiple techniques and model systems, researchers have identified a network of transcription factors that are required and, in some cases, sufficient for eye formation. In spite of recent work, the functional relationships among the EFTFs are still not clear. In addition to understanding how these gene products regulate each other's expression, future work is also needed to determine the upstream regulators and downstream targets of the EFTFs.

Eyelid Anatomy and the Pathophysiology of Blinking

C Evinger, SUNY Stony Brook, Stony Brook, NY, USA

Glossary

Blepharospasm – A dystonic muscle contraction disorder characterized by forceful, bilateral, and uncontrolled closure of the eyelids.
Hemifacial spasm – A muscle contraction disorder characterized by forceful uncontrolled contraction of the facial muscles on one side of the face.
Levator palpebrae superioris muscle – A skeletal muscle innervated by cranial motor nerve 3 whose primary function is elevation of the upper eyelid.
Müller's muscle – A smooth muscle that runs from the inferior surface of the tendon of the levator palpebrae superioris to insert into the tarsal plate. It receives sympathetic nervous system innervation.
Omnipause neurons – Part of the brainstem neural circuit that controls saccades. These neurons fire during fixation and cease firing before and during saccadic movements. Stimulation of omnipause neurons interrupts saccades.
Orbicularis oculi muscle – A circumferential muscle of facial expression innervated by the facial nerve that lies just deep to the skin within both eyelids as well as the surrounding bones of the orbital margin. Its main function is closure of the eyelid.
Paresis – Partial paralysis of a skeletal muscle resulting in muscle weakness.
Retractor bulbi muscle – Skeletal muscles innervated by cranial nerve 6 whose function is to retract the eyeball into the orbit causing movement of the nictitating membrane over the surface of the eye.
Saccades – Rapid eye movements that redirect the line of sight so that the image of interest falls on the fovea of the retina.
Vergence – The coordinated movements of both eyes in opposite directions in order to maintain binocular vision.

Organization of the Eyelid System

To understand the neural control of eyelids, the basis of neurological diseases affecting eyelid control, and how the eyelids protect the eye, think about the evolutionary origins of eyelids. For fish, a class of vertebrates without eyelids, eye protection primarily requires avoiding objects hitting and damaging the cornea. To avoid objects hitting the eyeball, fish retract their eyes into the orbit by co-contracting their extraocular muscles. Thus, cornea protection was initially linked to neural circuits whose primary goal was to move the eye. When vertebrates moved onto the land, the development of eyelids was a critical step in reducing the dehydrating effects of air on the cornea. Although goblet cells, lacrimal and meibomian glands produce the fluids to coat the corneal surface, it is blinking of the eyelid that spreads the tears to restore the tear film, which maintains corneal hydration. In addition, blinking removes small objects from the surface of the eye and provides some protection from objects getting into the eye. Although blinking is essential for maintaining the cornea, lid closure has the undesirable side effect of blocking vision. Thus, an eyelid control system must generate blinks that minimally disrupt vision while adequately protecting the cornea. The nervous system deals with this constraint by developing fast eyelid closure and opening without carefully controlling absolute eyelid position. The other restriction on the nervous system's management of the eyelids is that they must move synchronously with vertical eye movements to avoid blocking vision. Overcoming this problem requires the nervous system to control eyelid position accurately. The eyelid control system accomplishes this feat by linking itself to the eye movement system. The melding of the eyelid system with the eye movement system reveals itself first in the anatomical organization of the eyelids.

Only four forces act on the upper eyelid (**Figures 1(a)** and **2**). (1) The phasically active orbicularis oculi (OO) muscle actively closes the eyelid. The ipsilateral facial (VII) nucleus innervates the OO muscle. (2) The tonically active levator palpebrae superioris (LP) muscle actively elevates the upper eyelid. LP innervation arises from the oculomotor (III) nucleus. (3) Raising the eyelid stretches the superior transverse (Whitnall's) ligament and the lateral and medial canthal tendons to create a passive downward force. Thus, the lowest energy state for the eyelid is closed. (4) Müller's smooth muscle (**Figure 2**), which bridges the belly and the tendon of the LP, raises the eyelid approximately 1.5 mm with sympathetic activation. Post-ganglionic nerves from the superior cervical ganglion innervate Müller's muscle. The interaction between the first three forces (OO, LP, and passive downward forces) enables

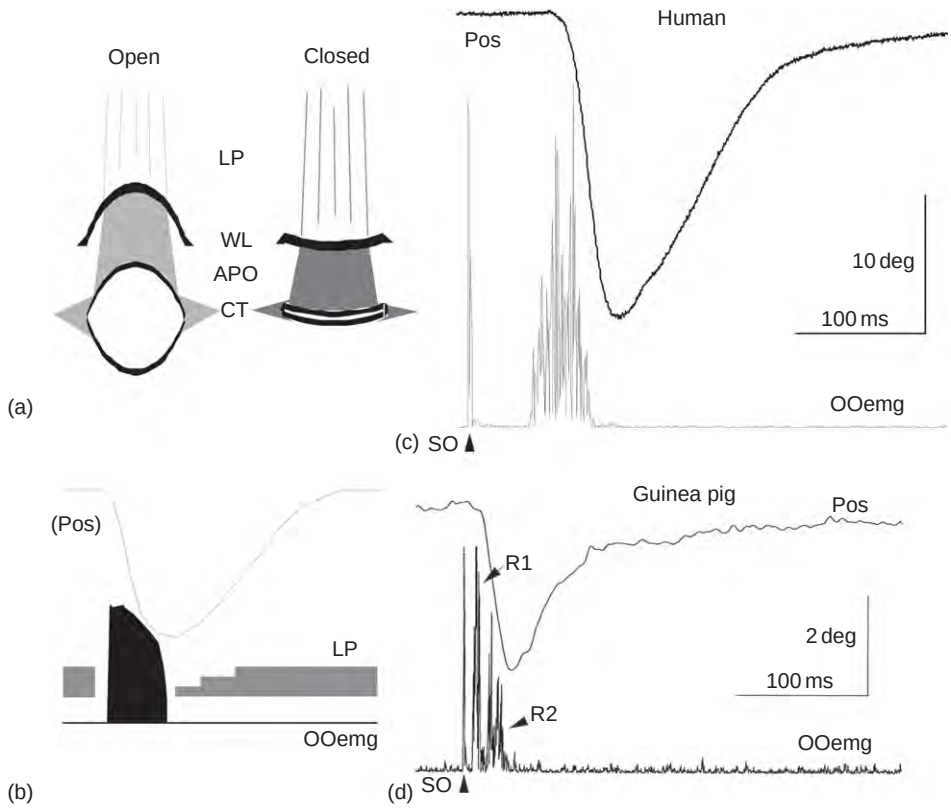

Figure 1 Forces acting on the eyelid and mammalian blinking. (a) Opening the eye stretches the levator palpebrae (LP) aponeurosis (APO), the superior transverse ligament (Whitnall's ligament, WL), and the medial and lateral canthal tendons (CT) to create passive downward forces. The lowest energy state for the eyelid system is closed. (b) Lid (Pos) lowering during a blink results from a transient relaxation of the LP followed by a phasic activation of the orbicularis oculi (OO) muscle. Raising the eyelid occurs as the LP resumes its tonic activity following the completion of OO activity. Gray indicates LP activity and black indicates OO activity. (c, d) Individual examples of a reflex blink evoked by stimulation of the supraorbital branch of the trigeminal nerve (SO ▲) for a human (c) and a guinea pig (d). R1 is the short latency response and R2 is the long latency response seen after nerve stimulation. Abbreviations: OOemg, orbicularis oculi EMG; Pos, upper eyelid position.

the eyelids to blink rapidly yet accurately match the vertical position of the eyeball.

The characteristic rapid eyelid closure of a blink followed by lid opening at approximately half the speed of lid closure follows directly from the anatomical organization of the eyelid (**Figures 1(b)–1(d)**). A blink begins with relaxation of the tonically active LP muscle. LP relaxation releases the passive downward forces to initiate lid closure. The phasically active OO muscle discharge combines with the passive downward forces to lower the eyelid rapidly. As the OO muscle relaxes, the LP muscle slowly resumes its tonic discharge. This LP contraction raises the upper eyelid. Eyelid elevation is slower than lid closure because the LP muscle must work against the passive downward forces. The point at which the tonically active LP force matches the passive downward force created by tendon and ligament stretching determines final lid position. This anatomical organization is conserved so that the pattern of blinking is similar among mammals (**Figures 1(c)** and **1(d)**).

In contrast to the interactions between the OO and LP muscles and passive downward forces with blinking, the coordination of eyelid motion with vertical eye movement arises from the antagonistic interactions between the LP muscle and the passive downward forces. The linkage with eye movements occurs because the LP behaves like the superior rectus muscle, which rotates the eye upward. Embryologically, the LP muscle arises from the superior rectus muscle, and LP motor neurons are always adjacent to superior rectus motor neurons in the oculomotor nucleus. LP and superior rectus motor neurons exhibit similar patterns of activity except during a blink. The tonic firing frequency of superior rectus and LP motor neurons correlates with vertical eye position. With an upward saccadic eye movement, superior rectus and LP motor neurons generate a burst of action potentials followed by an increased tonic firing frequency that holds the eye in the new elevated position. A downward saccade results from a cessation of tonic activity followed by a lower frequency tonic discharge to hold the eye in the

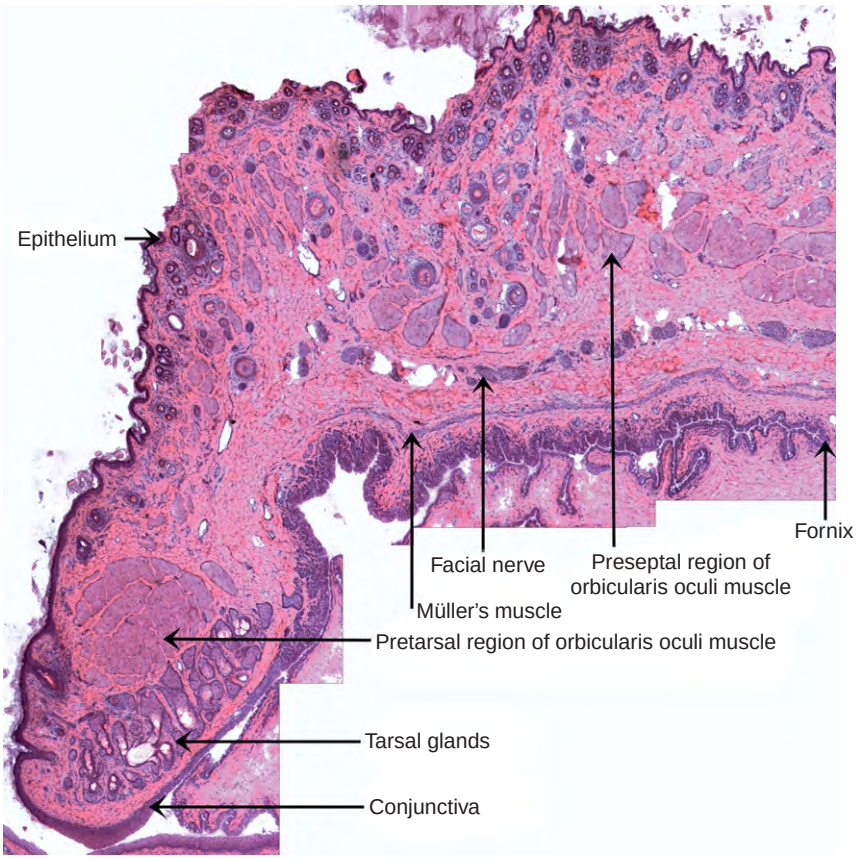

Figure 2 Montage of a sagittal section of the eyelid from an adult rabbit stained with hematoxylin and eosin. Courtesy of Dr. Linda K. McLoon.

depressed position. When the LP motor neurons transiently cease discharging during a downward saccadic eye movement, unopposed passive downward forces lower the eyelid. When the LP motor neuron resumes its activity at a lower tonic firing frequency, the new balance point between passive downward forces and active upward LP muscle force establishes the final eyelid position. With an upward eye movement, the increased LP motor neuron firing frequency pulls the eyelid upward until the LP muscle and passive downward forces match. Although it seems counter-intuitive that passive downward forces rather than the OO muscle act as the antagonist to the LP muscle with eye movements, it is clear that the OO does not participate in eyelid movement with vertical saccades. For example, individuals with OO denervation created by seventh nerve palsy exhibit nearly normal saccadic lid movements with vertical saccadic eye movements, but abnormally slow blinks.

Further evidence of the evolutionary linkage of blinking with the oculomotor system is that blinks frequently occur with saccadic eye movements. These gaze-evoked blinks most commonly accompany large saccades to visual targets that do not have a strong behavioral significance. The advantage of combining blinks with saccades is that visual suppression occurs during both blinks and saccades. A gaze-evoked blink refreshes the tear film, but does not produce more loss of vision than the saccadic eye movement. The evolutionary linkage also appears in the eye movements associated with blinking, blink-evoked eye movements. When looking straight ahead, there is an adducting and downward rotation of the eye with each blink. Nevertheless, the state of the eyelid system determines the trajectory of blink-evoked eye movements. These movements exhibit an upward trajectory in both eyes and are smaller than normal in individuals with a unilateral seventh nerve palsy. Eyeball retraction is also a component of these blink-evoked eye movements. For mammals, the eyeball retraction with blinking results from extraocular muscle co-contraction and contraction of the retractor bulbi muscle. This accessory extraocular muscle is innervated by motor neurons in the accessory abducens nucleus that send their axons to the orbit as part of the VIth nerve. Extraocular muscle co-contraction with blinking in mammals appears to reflect the evolutionary origins of the eyelid control system from eye retraction of fish. Despite blink-evoked eye movements accompanying all blinks, neither gaze-evoked nor reflex blinks occurring with a saccade prevent the eye from achieving its desired endpoint. With a simultaneous blink and saccade, the eyes follow a complex trajectory instead of the nearly straight path of a saccadic eye movement alone. This complex

trajectory results in a significantly slower saccade than when the saccade occurs alone.

The linkage between blinking and saccadic eye movements indicates that blinking interacts with the brainstem circuits that generate saccadic eye movements. This interaction is apparent when reflex blinks increase the speed of saccadic eye movements in individuals with abnormally slow saccades, initiate saccade oscillations, and alter the speed of vergence eye movements where the eyes are moving in opposite directions. The neurophysiological mechanism that may underlie these effects is the activity of omnipause neurons, which control fixation, and are associated with reflex blinks. Tonically active omnipause neurons gate saccadic eye movements. Omnipause neurons cease discharging immediately before and during all saccadic eye movements and reflex blinks. Microstimulation of omnipause neurons blocks reflex blinks as well as saccadic eye movements. The evolutionary origins of eyelid control functionally intertwine blinking and saccadic eye movements so that blinks frequently occur with saccadic eye movements, blinking modifies the trajectory of eye movements, and blinking and saccadic eye movements utilize some of the same brainstem neuronal circuits.

Modifiability of the Blink System

In order to respond to challenges to the eyelid's protective function, the neural control of blinking exhibits significant adaptive plasticity. The most common challenge to the protective function of blinking is the development of dry eye. Cornea irritation created by tear film inadequacy rapidly initiates several changes. First, the trigeminal system becomes more excitable, so that a given blink-evoking stimulus elicits a bigger blink than before cornea irritation. In addition to increased blink excitability, the trigeminal reflex blink circuit begins to 'oscillate' in response to a blink-evoking stimulus (**Figure 3**). In this condition, a single stimulus evokes a reflex blink followed by blink oscillations, one or more additional large blinks. Blink oscillations occur at a constant interblink interval. These modifications compensate for dry eye in at least two ways. The reduced threshold for evoking a blink produces more frequent blinking so that blinks can occur before significant disruptions of the tear film. The larger blinks increase the amount of meibum released over the tear film. Increasing the thickness of the oily meibum layer superficial to the aqueous layer reduces aqueous evaporation. Disruptions of these normally adaptive mechanisms may underlie neurological disorders involving the eyelids, benign essential blepharospasm (BEB) and hemifacial spasm (HFS).

We have an outline of the neural basis for these adaptive modifications of the blink reflex initiated by eye irritation. The adaptive changes occur in trigeminal blink circuits, but not at OO motor neurons or reticular neurons receiving bilateral trigeminal inputs. If just one eye experiences irritation, stimulating the ophthalmic branch of the trigeminal nerve on the irritated side elicits adaptive blink modifications in both eyelids. Stimulating the contralateral trigeminal nerve associated with the unaffected eye, however, elicits normal, unadapted blinks in both eyes. Consistent with this result, spinal trigeminal neurons in the corneal-evoked blink circuit discharge before blink oscillations, and this discharge correlates with the pattern of OO activity producing the blink oscillation. Although the adaptive processes clearly involve the trigeminal system, the cerebellum is also essential for blink adaptation. Blink-related neurons in the cerebellum are active with blink adaptation, and lesioning the cerebellum blocks this form of motor learning. A hypothesis for the function of this brainstem–cerebellum circuit is that the cerebellum recognizes an error signal produced by eye irritation and then initiates modifications in spinal trigeminal blink circuits to compensate for the eye irritation. These adaptive modifications in the trigeminal blink circuits may involve long-term potentiation (LTP)- and long-term depression (LTD)-like processes.

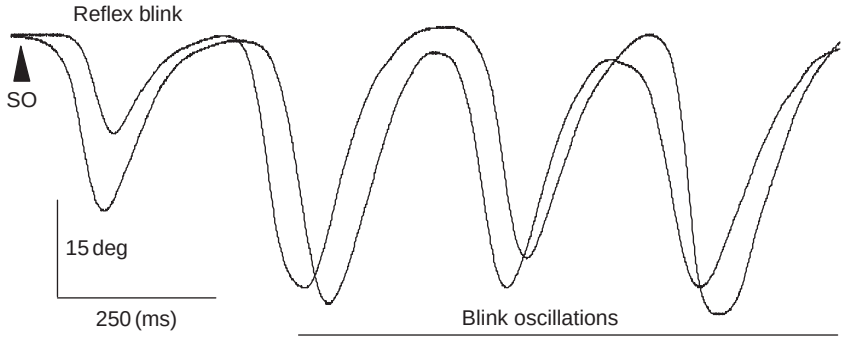

Figure 3 Stimulating the supraorbital branch of the trigeminal nerve (SO ▲) evokes a reflex blink followed by additional blinks with a constant interblink interval, blink oscillations. Each upper eyelid position trace is a record from a single trial from an individual with dry eye.

As discussed in the next section, the cerebellum appears to be an important element in creating the symptoms of dystonic movement disorders such as BEB.

Benign Essential Blepharospasm and Hemifacial Spasm

BEB is a focal dystonia characterized by involuntary bilateral spasms of lid closure, trigeminal reflex blink hyperexcitablity, and photophobia (i.e., excessive sensitivity to light). BEB frequently begins with a complaint of ocular discomfort. The available evidence indicates that BEB arises from the confluence of a predisposing and a precipitating factor. Although the predisposing factor has not been identified, the genetic basis for other forms of dystonia suggests that the predisposing factor for BEB is genetic. The precipitating factor appears to be ocular irritation. Consistent with eye irritation as the precipitating factor is that BEB characteristics appear to be an exaggeration of the normally adaptive response to dry eye. For most individuals, the spasms of lid closure in BEB are rapid, repetitive contractions of the OO muscle. This spasm pattern is equivalent to shortening the interblink interval of the blink oscillations developed in response to dry eye (**Figure 3**). BEB patients exhibit trigeminal reflex blink hyperexcitability. One adaptive response to dry eye is to elevate trigeminal reflex blink excitability, although this increase accompanying dry eye is not as profound as occurs with BEB. The trigeminal hyperexcitability with BEB is sufficient to explain the photophobia. Consistent with the exaggeration of dry eye hypothesis, photophobia is present with dry eye although the light sensitivity is not as debilitating as with BEB. Thus, the exaggerated dry eye hypothesis proposes that BEB begins with the onset of dry eye or significant eye irritation. The nervous system initiates blink modifications to compensate for this irritation, but the genetic predisposition prevents the nervous system from recognizing that the adaptive changes corrected the ocular irritation. The nervous system responds by further increasing these adaptive modifications until the normally compensatory mechanisms becomes so maladaptive as to create the BEB syndrome.

Although genetic modifications probably create the predisposing environment for BEB, the genetics underlying this focal dystonia are not yet clear. Most investigators argue that there is an autosomal dominant transmission with reduced penetrance in BEB. One challenge to linking genetics to specific types of dystonia, however, is that individuals with the same genetic mutation may exhibit very different forms of dystonia. For example, individuals with the DYT1 mutation responsible for the most common form of generalized dystonia may exhibit generalized dystonia, focal dystonia, or may be asymptomatic. Individuals with generalized dystonia, focal dystonia, and asymptomatic DYT1 carriers all exhibit a similar pattern of abnormal brain activity. Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) scans reveal hyperactivity in the basal ganglia, primary motor cortex, supplementary motor area, putamen, thalamus, and cerebellum. In patients with BEB, these areas are also active, but the focus of abnormal activity is in the brainstem and cerebellum. Abnormal cerebellar activity with BEB supports the hypothesis that abnormal blink adaptation involving the cerebellum is critical in the development of BEB. Consistent with the hypothesis that a genetic predisposing factor affects adaptation or motor learning, individuals with BEB exhibit exaggerated LTP-like plasticity of blink circuits relative to normal subjects.

There are two clear examples in which exaggeration of the adaptive processes initiated by eye irritation or dry eye leads to BEB. A small number of individuals with Bell's palsy develop blepharospasm. The ocular irritation produced by incomplete eye closure, the precipitating factor, initiates unabated modifications that produce the BEB syndrome. As predicted by the exaggerated dry eye hypothesis, implanting gold weights in the paretic (weakened) eyelid, enabling nearly complete closure of the paretic eyelid, reduces eye irritation and allows a resolution of BEB signs. Combining predisposing and precipitating factors can also create a BEB-like syndrome in rats. In this model, a chemical lesion reducing approximately 30% of the dopamine neurons in the substantia nigra pars compacta elevates the excitability of the trigeminal blink reflex circuits. This increased trigeminal excitability acts as the predisposing factor. Transient eye irritation produced by crushing a facial nerve branch providing a portion of the OO innervation acts as the precipitating factor. The reduced eyelid mobility created by this procedure causes eye irritation that initiates adaptive blink modifications. Although the eye irritation resolves following nerve regrowth, rats continue to exhibit spasms of lid closure caused by repetitive bursts of OO activity and hyperexcitable trigeminal reflex blinks. Thus, the evidence indicates that BEB occurs in individuals genetically predisposed to the disorder who experience a precipitating condition, ocular irritation. The ocular irritation initiates a series of normally adaptive modifications. In the presence of the predisposing condition which creates an abnormal environment for motor learning, these modifications become exaggerated to create the signs of BEB.

HFS begins as spontaneous, unilateral spasms of eyelid closure. Over a period of weeks to months, the spasms expand to include the rest of the facial muscles on that side of the face. Another characteristic of HFS is synkinesis in which there is an involuntary activation of multiple muscles that normally do not act together. An example of synkinesis is that stimulating the supraorbital branch of the trigeminal nerve would strongly activate the mentalis muscle, as well as the OO, in HFS patients. Unlike BEB,

HFS is unilateral and involves most of the ipsilateral facial muscles in addition to the OO. There is strong evidence, however, that HFS also arises from a combination of predisposing and precipitating factors that disrupt normal motor learning.

The accepted precipitating factor for HFS is arterial compression at the root entry zone of the facial nerve. The most common blood vessels affecting the facial nerve in HFS are the anterior inferior cerebellar artery, the posterior inferior cerebellar artery, or the vertebral artery. Microsurgical decompression of the facial nerve typically reduces or eliminates the spasms and synkinesis of HFS so that spasms disappear in 64% and synkinesis in 53% of HFS patients within the first week following surgery. After 2–8 months, 90% of patients are spasm or synkinesis free. If arterial compression of the facial nerve alone is responsible for these signs of HFS, however, then decompression surgery should eliminate the spasms and synkinesis in less than 2–8 months. To understand the basis for this delay, it is important to consider what neural modifications might occur in response to pulsatile arterial compression of the facial nerve. A strong argument that facial nerve compression alone is insufficient to cause HFS is that 15–25% of the population exhibits arterial compression of the facial nerve, but do not develop HFS. This observation shows that HFS requires a predisposing factor as well as the precipitating factor, arterial compression of the facial nerve.

Pulsatile arterial compression of the facial nerve can generate many modifications in brainstem neural circuits. Compression injury to motor neuron axons effectively weakens facial muscles, which initiates adaptive modifications. Repetitive antidromic activation of facial motor neurons by pulsatile compression of axons can alter facial motor neuron excitability or motor neuron excitability may increase because of facial motor neuron axotomy, severing the facial nerve fibers. Repetitive orthodromic activation of facial muscles by pulsatile compression of motor neuron axons can lead to a reorganization of sensory trigeminal circuits. Simultaneous orthodromic (electrical impulses traveling in the normal direction) activation of muscles that normally do not act together, for example, mentalis and OO, causes trigeminal primary afferent sensory signals from mentalis and OO muscle contraction to reach second-order trigeminal neurons synchronously. This abnormal pairing of sensory inputs can restructure trigeminal receptive fields so that the second-order trigeminal neurons respond strongly to inputs from both mentalis and OO activity instead of weakly to one and strongly to the other. Pulsatile activation of the facial nerve can also augment reflex circuit excitability because of synchronous activation of circuit elements. Second-order trigeminal neurons receiving synchronous afferent inputs innervate facial motor neurons that are already depolarized by antidromic activation. This activity pattern can strengthen trigeminal inputs onto facial motor neurons in a spike timing-dependent plasticity-like manner.

It is clear that pulsatile activation of the facial nerve can produce blink modifications, but these changes should not cause HFS by themselves. The eyelid system normally modifies itself so as to perform appropriately in the face of changes in the motor system or sensory inputs. For example, creating unexpectedly large blinks by adding weights to the upper eyelids initiates a rapid reduction in the trigeminal drive onto OO motor neurons. Similarly, chronic, repetitive facial nerve stimulation, such as occurs with pulsatile facial nerve compression, reduces blink amplitude. Thus, pulsatile facial nerve compression is insufficient to cause spasms of lid closure because the blink system will modify itself to prevent spasms of lid closure. The significant number of humans not experiencing HFS, but exhibiting arterial compression of the facial nerve, further supports this interpretation. These observations indicate that HFS, like BEB, requires a predisposing factor to develop spasms. Like BEB, an autosomal-dominant genetic mutation with low penetrance may provide the predisposing condition, which disrupts normally adaptive processes to create a pathological condition.

Glossary

Calycal processes – The microvillus-like projections extending from the distal end of the photoreceptor inner segment ellipsoid to form a chalice-like support around the base of the outer segment.
Ciliary axoneme – The cytoskeletal scaffold of the photoreceptor outer segment, which is composed of nine microtubule doublets that extend from the basal body lying at the distal end of the photoreceptor ellipsoid.
Cyclic adenosine monophosphate (cAMP) – A nucleotide that is generated from adenosine triphosphate (ATP) in response to hormonal stimulation of cell surface receptors coupled to adenyl cyclase. cAMP acts as a signaling molecule by activating A-kinase; it is hydrolyzed to AMP by a phosphodiesterase.
Cytochalasin D – A drug that inhibits polymerization of actin monomers into actin filaments, and thus inhibits actin-dependent motility.
Dynein – A member of a family of large motor proteins that undergo ATP-dependent movement along microtubules toward the microtubule's slow-growing (minus) end.
Ellipsoid – The mitochondria-rich distal region of the photoreceptor inner segment between the myoid and the outer segment.
K_d – Dissociation constant, measure of the tendency of a complex to dissociate.
Kinesin – A member of a family of motor proteins that undergo ATP-dependent movement along microtubules toward the microtubule's fast-growing (plus) end.
Myoid – The neck-like region of the photoreceptor inner segment between the nucleus and the ellipsoid, so called because it elongates and contracts in lower vertebrates.
Polymerase chain reaction (PCR) – The technique for amplifying specific regions of DNA by multiple cycles of DNA polymerization, each followed by a brief heat treatment to separate complementary strands.
Sodium/potassium adenosine triphosphatase (Na^+/K^+ ATPase) – The sodium pump, transmembrane carrier protein found in the plasma membrane of most animal cells, which pumps Na^+ out of and K^+ into the cell, using the energy derived from ATP hydrolysis.

Nature and Occurrence

In fish, photoreceptors and retinal pigment epithelium (RPE) undergo retinomotor movements in response to changes in ambient light conditions and to circadian signals. Retinomotor movements include elongation and contraction of the myoid regions of rod and cone photoreceptors and migration of melanin pigment granules (melanosomes) within long apical projections of the RPE (**Figure 1**). In light, cone outer segments are positioned first in line to absorb incoming light and rod outer segments are buried in the dispersed shielding pigment granules of the RPE. In the dark, rods are positioned first in line and RPE pigment granules are aggregated, fully exposing the rod outer segments. Thus, the retina's entire light capture area is rod-dominated at night and cone-dominated in the day.

Cone length changes range from 15 to 80 μm; while rod length changes are generally more modest. Since rates of elongation and contraction are in the range of 1–4 μm min^{-1}, transitions between light-adapted and dark-adapted positions are slow, requiring as much as 60 min in some species. This slowness may explain why mammals evolved the more agile strategy of pupillary dilation for light adaptation.

As these dramatic morphological changes can be easily detected in light micrographs of sectioned retinas, many early studies of retinal morphology were focused on the properties and species distribution of retinomotor movements. After Kühne's initial paper in 1856, the late eighteenth and early nineteenth century produced a huge literature describing retinomotor movements in various vertebrate groups. Retinomotor movements are modest or nonexistent in mammals, urodeles, and reptiles, more robust and widespread in anurans and birds, and most extensive and widely distributed in fishes with duplex retinas. In the pure cone retinas of early fish larvae and in the pure rod retinas of benthic fishes, retinomotor movements are absent.

Retinomotor movements are regulated not only by light but also by an endogenous circadian rhythm. In animals maintained in constant darkness (DD), retinomotor movements persist at expected dawn and dusk. In constant illumination, the cycles of retinomotor movements are suppressed. Circadian cone retinomotor movements have been observed in most fish species studied;

*Adapted from Burnside, B. and King-Smith, C. (2009). Retinomotor movements. In: Squire, L. R. (ed.) *Encyclopedia of Neuroscience.* Oxford: Academic Press.

circadian rod and RPE retinomotor movements are considerably less common. In all species studied to date, cones have been found to contract to their light-adaptive position in anticipation of expected dawn. Thus, for fish in natural environments, a circadian signal, rather than light onset, is the natural trigger for light-adaptive retinomotor movements.

Mechanisms of Force Production for Retinomotor Movements

Many of the earliest studies of retinomotor movement grappled with whether retinomotor movements required energy or represented passive accommodations to other forces. More recent studies using isolated cells have demonstrated that rod, cone, and RPE retinomotor movements can each occur in the absence of other cell types; even in photoreceptor fragments consisting of inner/outer segments only. Thus, force production for photoreceptor elongation and contraction and for pigment migration appears to be locally autonomous for each cell type.

Force Production for Photoreceptor Elongation and Contraction

In photoreceptors, retinomotor movements are effected by cell shape change. Photoreceptors elongate and contract by changing the length of the photoreceptor inner segment, that is, the part of the photoreceptor between the photopigment-bearing outer segment and the junctional complexes of the outer limiting membrane, where photoreceptors are attached by adherens junctions to supportive Müller cells. The motile portions of photoreceptors protrude into the subretinal space between retina and RPE, where they interdigitate with the long apical projections of the RPE cells (**Figure 1**). The interphotoreceptor matrix filling the subretinal space thus lubricates, or at least permits, the shear produced by rods and cones moving in opposite directions. The photoreceptor inner segment is comprised of the distal ellipsoid, containing a mass of aggregated mitochondria, and the more proximal myoid, so named for its ability to undergo retinomotor contraction. Retinomotor shape change is primarily mediated by change in myoid length (**Figures 2** and **3**).

In most vertebrate cells, force production for cell shape change is generated by actin filaments or microtubles, or both. Rods and cones are highly asymmetric cells with highly polarized and paraxially aligned actin and microtubule cytoskeletons (**Figures 2** and **3**). From the distal end of the inner segment, microvillus-like calycal processes extend up around the base of the outer segment. Paraxial bundles of highly cross-linked actin filaments form the cores of the calycal processes, continue through the peripheral cytoplasm of the ellipsoid, and then splay

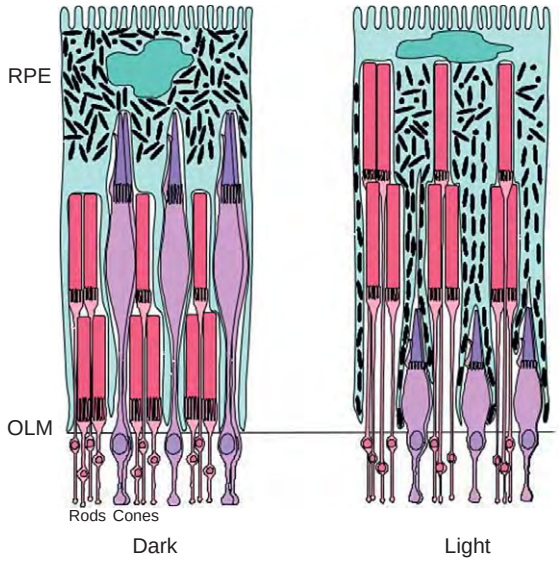

Figure 1 Retinomotor positions of rods, cones, and RPE pigment granules in light- and dark-adapted fish retinas. In dark-adapted retinas, cone myoids (purple) are long, rod myoids (pink) are short, and pigment granules (black) are aggregated to the base of the RPE cell. In light-adapted retinas, cone myoids (purple) are short, rod myoids (pink) are long, and pigment granules (black) have migrated into the long, interdigitating apical projections of the RPE. RPE, retinal pigment epithelium; OLM, outer limiting membrane.

out into a less tightly cross-linked, but still longitudinally oriented, actin filament array in the photoreceptor myoid. The calycal, ellipsoid, and myoid actin filaments are polarized and uniformly oriented with their fast-growing (plus) ends toward the outer segment. Since each type of myosin motor can walk in only one direction along an actin filament, the polarity of actin filaments determines the vector of force production for actin-based motility. Thus, a plus-end-directed myosin motor would walk along a photoreceptor inner segment actin bundle toward the outer segment, while a minus-end-directed motor would walk toward the nucleus. Of the more than 18 classes of myosins, only the class VI myosins have been found to be minus-end-directed motors. All other classes are plus-end directed. Myosins IIA, IIIA, IIIB, VI, VIIA, and IXB have all been shown to be present in fish photoreceptor inner segments. Thus, both plus- and minus-end-directed motors are present in or near the regions of elongation and contraction.

The microtubule cytoskeleton of the photoreceptor consists of two functionally distinct microtubule populations with different properties: the highly stable $(9+0)$ ciliary axoneme of the outer segment, and the more labile paraxially aligned cytoplasmic microtubules of the photoreceptor cell body. Relatively parallel microtubules populate the sleeve of cytoplasm surrounding the mitochondrial mass in the ellipsoid and extend throughout the myoid and axon. As with actin, microtubule polarity and the orientation of the microtubules within a cell play

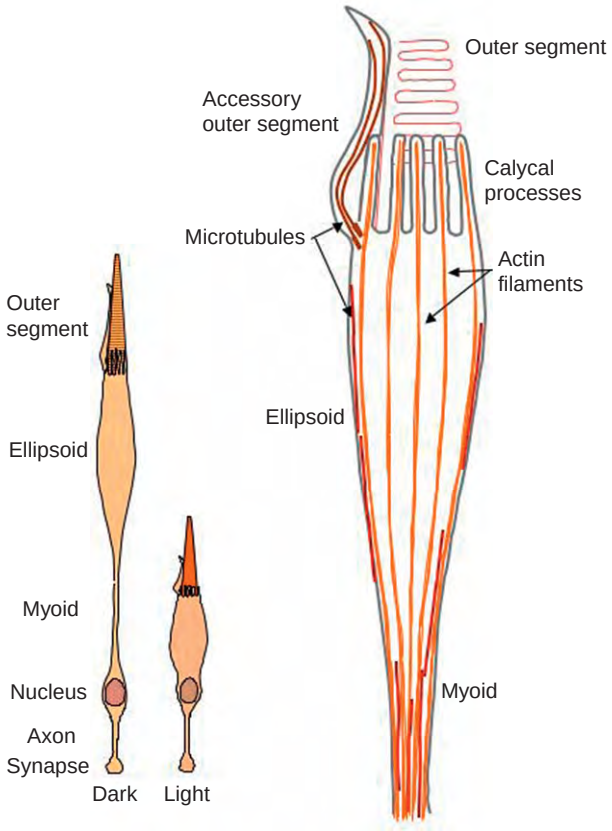

Figure 2 Schematic illustration of teleost cone retinomotor cell shape change and cytoskeleton. Retinomotor length change is mediated primarily by the cone's myoid region. Paraxially aligned actin filaments form the core bundles of cone calycal processes and course through the peripheral ellipsoid and the myoid. Cones possess two populations of microtubules: the axonemal microtubules of the accessory outer segment and the cytoplasmic microtubules of the ellipsoid, myoid, and axon.

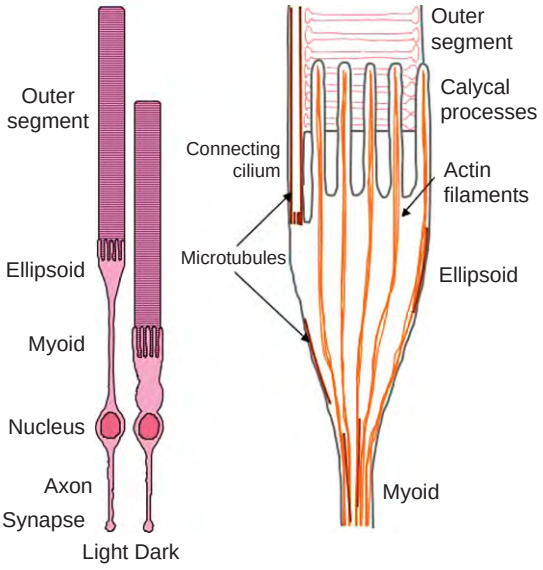

Figure 3 Schematic illustration of teleost rod retinomotor cell shape change and cytoskeleton. Retinomotor length change is mediated primarily by the rod's myoid region. Paraxially aligned actin filaments form the core bundles of rod calycal processes, and course through the peripheral ellipsoid and the myoid. Rods possess two populations of microtubules: the axonemal microtubules of the connecting cilium and outer segment and the cytoplasmic microtubules of the ellipsoid, myoid, and axon.

critical roles in microtubule-based motility. Dynein motors move toward the microtubule minus end and most kinesins move toward the plus end. Both cytoplasmic dynein and kinesin II are found in photoreceptor inner segments. The polarity of the inner segment and axonal microtubules is uniform, with virtually all microtubules oriented with minus ends toward the outer segment. Thus, in a photoreceptor, a minus-end-directed microtubule motor, like dynein, would walk toward the outer segment, while a plus-end-directed microtubule motor, like kinesin, would walk toward the synapse.

Cytoskeletal inhibitors have been used to identify the roles of microtubules and actin filaments in teleost rod and cone retinomotor movements. In cones, dark-adaptive myoid elongation is microtubule dependent (and actin independent), while light-adaptive cone myoid contraction is actin dependent (and microtubule independent). The mechanisms of both microtubule-based elongation and actin-dependent cone myoid contraction are not established. Myosin IIA, a cytoplasmic myosin capable of forming bipolar filaments, is concentrated in the myoids of trout and bass cones, suggesting that muscle-like sliding filaments of actin and myosin might be responsible for cone contraction. Since isolated cone inner/outer segment fragments undergo myoid contraction *in vitro*, it is clear that force production and regulatory machinery necessary for contraction both reside within the inner segment.

In rods, myoid elongation and contraction are both actin dependent and microtubule independent, although microtubules are present in the rod ellipsoid and myoid. Studies using the actin inhibitor cytochalasin D indicate that inhibition of elongation is produced at concentrations so low that actin assembly is blocked but preexisting actin filaments are not disrupted, suggesting that force production for rod elongation depends upon actin assembly. Since quantitative assessment of F-actin indicates that there is no net actin assembly in elongating rod inner outer segments, actin polymerization at the minus ends of filaments must be coupled with depolymerization at filament plus ends. The mechanism of rod contraction is less well studied. Since rod inner–outer segment fragments can both elongate and shorten in culture, it is clear that all necessary machinery is resident in the myoid/ellipsoid (Figure 3).

The RPE Cytoskeleton and Force Production for Pigment Granule Dispersion and Aggregation

Light-induced dispersion of melanin pigment granules (melanosomes) out into the apical projections of fish

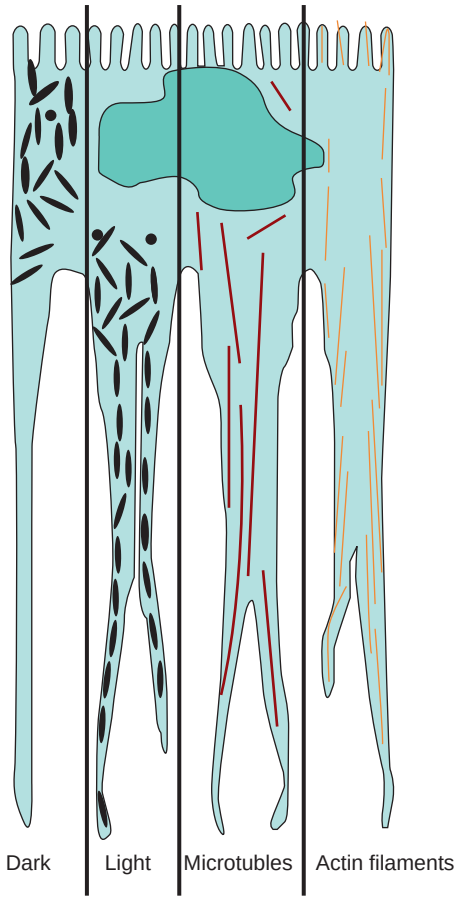

Figure 4 Schematic illustration of teleost RPE retinomotor pigment migration and cytoskeleton. Pigment granules aggregate into the cell body in the dark and disperse into apical RPE projections in the light. Both microtubules and actin filaments are found in the cell body and the apical projections.

RPE cells and dark-induced aggregation of granules back into the RPE cell body results from translocation of individual pigment granules within apical projections of the RPE cells, not from extension and retraction of the apical projections themselves. Apical projections extend from the RPE cell apical surface out into the subretinal space where they interdigitate with photoreceptor inner and outer segments. Thus, when the membrane-bound pigment granules are dispersed, they shield and protect rod outer segments from full bleach in bright light. RPE apical projections may be up to 100 μm long in some fish species and they remain extended throughout the light and dark phases of pigment granule migration.

Apical projections of fish RPE cells contain both actin filaments and microtubules. Microtubule disruption by intraocular injection of inhibitors *in vivo* blocks motility of pigment granules both in the cell body and in the apical projections; this finding would suggest that melanosome movement is microtubule dependent. However, when inhibitor studies are carried out using dissociated RPE cells in culture, microtubule disruption has no effect on melanosome aggregation or dispersion. Presumably, this discrepancy results from the need for microtubules to provide structural support for apical projections, *in vivo*, or to maintain patent tracks or pathways through which pigment granules can move. In isolated cells, on the other hand, the attachment of the projections to the substrate likely keeps projections intact enough to permit pigment granule translocation. Isolated cell studies therefore suggest that microtubules are needed for the structural integrity of RPE apical projections, but the forces that actually power pigment granule translocation are microtubule independent.

In contrast, if the actin cytoskeleton is disrupted by cytochalasin D in dissociated RPE cells, both aggregation and dispersion of pigment granules are reversibly blocked, and maintenance of full aggregation or full dispersion is compromised. Thus, actin filaments are necessary and sufficient for both aggregation and dispersion. The actin dependence of pigment granule translocation in RPE cells suggests that myosin motor proteins are likely to play a role in force production. Polymerase chain reaction (PCR) screens of fish RPE have identified 11 distinct myosins expressed in RPE. Immunocytochemistry with antibodies to four of these myosins indicated that the fish RPE has abundant levels of myosins IIIA, VI, and IXb, and lower levels of myosin VIIa. Myosin VIIa has been immunolocalized on pigment granules in RPE of humans, rodents, and fish, and defective localization of pigment granules to the RPE apical projections in mice with a mutant myosin VIIA gene has been reported. *In vitro* motility assays have shown that isolated teleost RPE pigment granules do support plus-end-directed, actin-dependent motility.

A role for nonmuscle myosin II in RPE pigment granule movement has been implicated in studies using the myosin II inhibitor, blebbistatin, which partially blocked pigment granule aggregation in isolated sunfish RPE cells, but did not affect dispersion. Similarly, inhibitors of Rho guanosine triphosphate (GTP)-binding protein-activated kinase (ROCK), which is involved in myosin II activity, also blocked aggregation. These results suggest myosin II may contribute to pigment granule aggregation, possibly by contracting an actin network with which pigment granules are associated. Myosin IIa was identified in striped bass RPE by PCR amplification of a complementary DNA (cDNA) library.

Intracellular Regulation of Retinomotor Movements: The Role of Cyclic Adenosine Monophosphate

Numerous experimental observations demonstrate that cyclic adenosine monophosphate (cAMP) plays a critical role in the regulation of retinomotor movements in both photoreceptors and RPE. Studies using both intraocular

injections *in vivo* and isolated retinas in culture have shown that a variety of treatments that elevate cAMP (but not cyclic guanosine monophosphate (cGMP)) produce retinomotor movements characteristic of darkness (night). Similar effects were obtained *in vitro* using isolated RPE cells, permeabilized cones, and isolated photoreceptor fragments (inner/outer segments), suggesting that increased cytoplasmic cAMP has a local and direct effect of triggering dark-adaptive retinomotor movements in each cell type. These findings are consistent with many other reports showing that elevated cAMP levels in the dark are a general feature of diurnal and circadian signaling cycles in vertebrate photoreceptors. For example, light and circadian control of photoreceptor melatonin release is closely correlated with changes in intracellular cAMP levels in photoreceptors.

Since inhibitors of cAMP-dependent kinase (protein kinase A (PKA)) block dark-adaptive retinomotor movements in both isolated cone and rod fragments and in intact retinas, it seems likely that cAMP regulates the photoreceptor cytoskeleton via protein phosphorylation. cAMP triggers elongation in detergent-permeabilized cone models, further suggesting that PKA and its targets are detergent-insoluble, and thus likely to be physically associated with the cytoskeleton (or pigment granules). Pharmacological studies of rod inner–outer segment fragments suggest that PKA phosphorylation is enhanced in darkness and that dephosphorylation is required for light-induced elongation (**Figures 5** and **6**).

Regulation of Photoreceptor Retinomotor Movements by Paracrine Messenger

Dopamine

A role for paracrine signaling in light regulation of retinomotor movements is implicated by spectral sensitivity studies of cone retinomotor movements *in vivo*. The action spectrum for light-adaptive cone and RPE retinomotor movements most closely fits the absorption curve of the rod photopigment, suggesting that in cones and RPE, retinomotor movements are not directly triggered by light but are activated indirectly through a rod-mediated pathway. Two experimental observations demonstrate that the

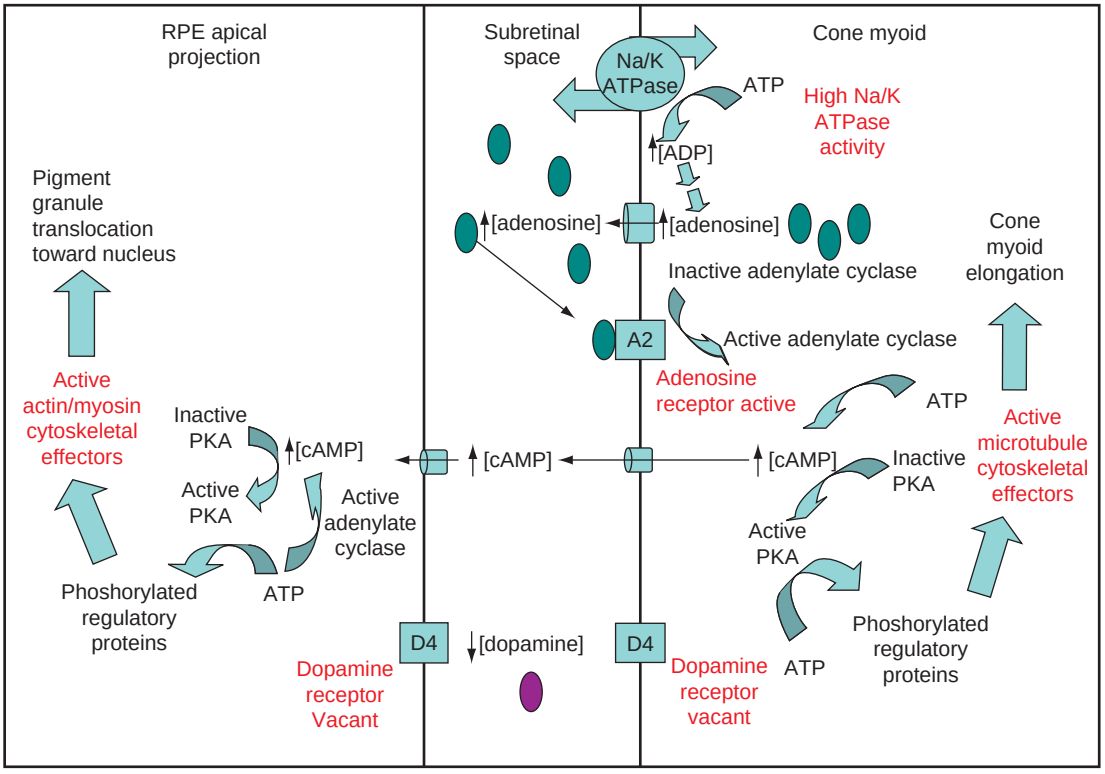

Figure 5 Model of first- and second-messenger signaling in teleost RPE, subretinal space, and cone myoid in darkness. The elevated dark activity of the cone Na/K ATPase elevates cytoplasmic adenosine, which exits through adenosine transporters to the subretinal space. Elevated extracellular adenosine enhances intracellular cAMP level via A2 receptors in cones but not in RPE. Extracellular dopamine levels are low. Elevated cone cytoplasmic cAMP triggers phosphorylation of regulatory proteins that activate microtubule-mediated cone elongation. Cone cytoplasmic cAMP also exits to the subretinal space through organic ion transporters in the cone plasma membrane. From the subretinal space cAMP enters the RPE cell through organic ion transporters, thereby elevating cAMP levels in the RPE cytoplasm and stimulating phosphorylation of regulatory proteins that activate actin-filament-mediated pigment aggregation.

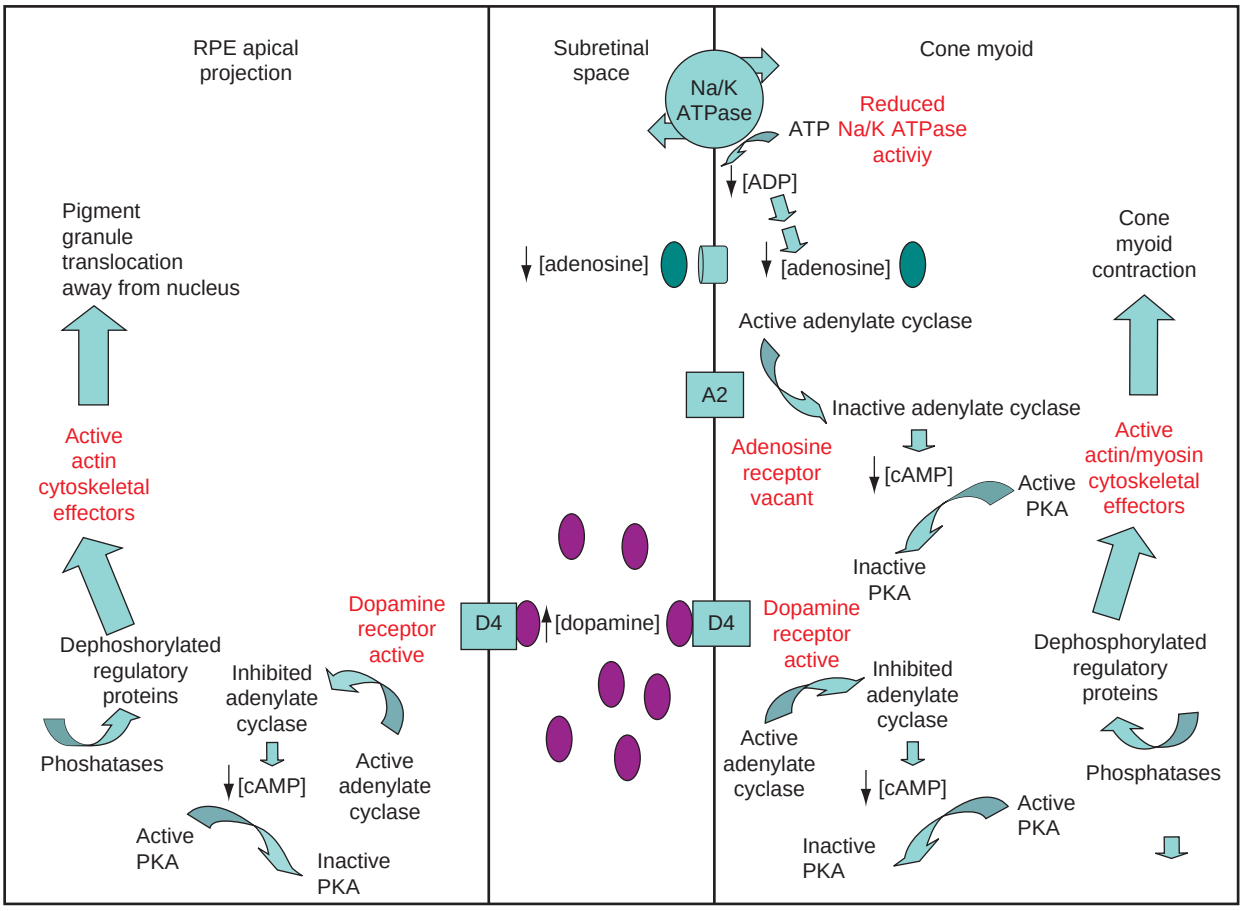

Figure 6 Model of first- and second-messenger signaling in teleost RPE, subretinal space, and cone myoid in the light. Reduced activity of the cone Na/K ATPase in the light reduces adenosine levels in the cone cytoplasm and subretinal space, thus decreasing cAMP production by cone A2 receptors. Increased dopamine release from interplexiform cells in the light produces elevated dopamine levels in the subretinal space. Dopamine activates D4 receptors on the cones and the RPE cells, thereby inhibiting adenylate cyclase and reducing intracellular cAMP in both cell types. Dephosphorylation of cytoskeletal regulatory proteins in cones inactivates microtubule-mediated cone elongation and triggers actin-filament-mediated contraction. Simultaneously, dephosphorylation of cytoskeletal regulatory proteins in RPE activates actin-filament-mediated pigment granule dispersion.

neuromodulator dopamine is a key player in this rod-mediated pathway:

1. intraocularly injected dopamine triggers light-adaptive cone contraction and RPE pigment granule dispersion in animals maintained in the dark, and
2. dopamine antagonists block light-induced cone contraction and RPE pigment granule dispersion in animals moved from darkness to light.

Further evidence that dopamine plays a central role in paracrine regulation of cone retinomotor movements is provided by pharmacological studies using intraocular injection *in vivo*, isolated retinas in culture, and isolated cone inner–outer segment fragments *in vitro*. In each of these preparations, light and/or dopamine promote cone contraction, whereas darkness and/or the adenylate cyclase stimulator, forskolin, promote cone elongation. Pharmacological profiles indicate that dopamine is acting through D4-like or other D2 family dopamine receptors. This class of dopamine receptors causes inhibition of adenylate cyclase and, thus, would be expected to lower cone cytoplasmic cAMP levels, consistent with observations that experimentally increasing cAMP produces dark-adaptive movements.

The ability of light and dopamine to regulate retinomotor movement in isolated cone inner–outer segment fragments indicates that these agents can act directly on cones. Thus, light can trigger cone contraction in isolated cones, even though action spectra indicate that *in vivo* light acts through a rod-mediated pathway. These studies also indicate that D4 dopamine receptors are present on cone inner and/or outer segments. In teleost retinas, the source of dopamine is the interplexiform cell. Since projections of this inner retinal cell extend only into the outer plexiform layer, released dopamine would have to diffuse over tens of microns to reach receptors on the inner

segments *in vivo*. The very high affinity of D4 receptors (dissociation constant (K_d) in the nM range) may facilitate this paracrine mode of signaling.

Light is much more effective than dopamine in triggering myoid elongation in rod fragments, and light and circadian regulation of rod movement was unaffected by treatment with 6-hydroxydopamine, which kills dopaminergic interplexiform cells. Light activation of myoid elongation in rod inner–outer segment fragments *in vitro* requires relatively high light intensities (20% bleach). The photoreceptive mechanism responsible for this activation can apparently count photons accurately for light pulse durations up to at least 10 min, suggesting that the critical factor in light activation of rod elongation is quantum catch, rather than duration of the light stimulus. Similar high-intensity thresholds and photon counting have been reported to mediate entrainment of circadian rhythms in several species.

The observation that dopamine plays a role in circadian as well as light regulation of cone retinomotor movement is suggested by results obtained by intraocular injection of dopamine agonists and antagonists in animals maintained in DD. Cone myoid contraction can be induced at midnight by intraocular injection of dopamine or D4 receptor agonists. Partially contracted cones of DD animals at subjective midday can be induced to contract fully by intraocular injection of dopamine or D4 agonists, or to elongate by injection of the D4/D2 family antagonists. The predawn cone contraction observed in DD animals in response to circadian signals can be completely eliminated by intraocular injection of the D4/D2 antagonist shortly before the expected time of light onset. These observations suggest that circadian regulation of cone myoid length is mediated by endogenous dopamine, acting through D4/D2 family receptors.

Consistent with these findings, retinal dopamine release is higher in the light than in the dark, and dopamine release is higher in subjective day than in subjective night in DD in many species. These diurnal and circadian cycles of dopamine release are inversely correlated with diurnal and circadian cycles of cAMP and protein phosphorylation levels in photoreceptors. Recent findings suggest that dopaminergic amacrine cells contain an autonomous circadian clock that drives dopamine release and metabolism. Although dopamine plays a critical role in regulating fish retinomotor movements, it is nonetheless unlikely to be the sole circadian regulator, since both light-induced and circadian cone movements persist (at reduced amplitude) in fish retinas after lesion of interplexiform cells by 6-hydroxydopamine.

Adenosine

This neuromodulator has an opposite effect to that of dopamine on cone retinomotor movements. In isolated cone inner–outer segment fragments, adenosine A2 receptor agonists activate and A2 antagonists inhibit cone myoid elongation. Since A2 receptors are positively coupled to adenylate cyclase, adenosine effects on cone fragments are consistent with observations that elevating cAMP triggers dark-adaptive retinomotor movements. These findings indicate that A2 receptors must be present on cone inner (and/or outer) segments. Since cones elongate at subjective dusk in fish maintained in DD, and since adenosine stimulates cone elongation, adenosine could provide an endogenous circadian signal for expected dark onset in addition to the decrease in dopamine release occurring at that time.

Adenosine effects on cone movements could be a local effect, reflecting photoreceptor metabolic activity. Since an adenosine transporter is present in photoreceptors, increases in adenosine in photoreceptor inner segments are likely to be accompanied by an increase in adenosine level in the subretinal space. The increased sodium/potassium adenosine triphosphatase (Na^+/K^+-ATPase) activity in photoreceptor inner segments occurring in darkness is likely to be accompanied by an increase in intracellular adenosine levels, and consequently, increased release of adenosine into the subretinal space. The binding of released adenosine to photoreceptor A2 receptors might then enhance dark adaptation of the photoreceptors by stimulating adenylate cyclase, thereby reinforcing the dark signal. Other studies have shown that adenosine triphosphate (ATP) is released across the apical membrane of the RPE into the subretinal space in response to various triggers. This ATP is dephosphorylated into adenosine by extracellular enzymes (ectoenzymes) on the RPE apical membrane. Regulation of adenosine release and ectoenzme activity in response to light signals could also alter the balance of purines in subretinal space and, thus, influence retinomotor movements in cones.

Regulation of Retinomotor Movements in RPE Cells by Paracrine Messengers

RPE pigment migration in frogs has an action spectrum most closely resembling that of the rod photopigment. These observations suggest that for RPE, as for cones, a rod-mediated pathway triggers light-adaptive retinomotor movement. Pigment position is not affected by light in isolated sheets of teleost RPE, further demonstrating that light acts indirectly through a photoreceptor-mediated, paracrine pathway.

In isolated sheets of teleost RPE in culture, dopamine and D2 family agonists induce pigment granule dispersion, while treatments that elevate cAMP induce pigment granule aggregation. In isolated RPE cells aggregated in cAMP, pigment dispersion is induced by microinjection of PKA inhibitors, suggesting that continuous phosphorylation of PKA targets is required to maintain the aggregated state. Since aggregation can also be induced by the phosphatase inhibitor okadaic acid, it seems likely that PKA

and phosphatases are simultaneously active in RPE cells, and that their relative activities are altered by light and dark signals from the retina.

Surprisingly, underivatized cAMP is just as effective as membrane-permeant cAMP analogs at activating pigment granule aggregation in isolated RPE sheets. Washout of exogenous cAMP induces dispersion. This cAMP directly enters the RPE cell through organic ion transporters is suggested by observations that ATP and adenosine are ineffective at triggering aggregation and that organic ion transport inhibitors block cAMP – but not forskolin-induced pigment aggregation. Recently, it has been shown that isolated RPE takes up cAMP in a saturable manner. Thus, it seems clear that cAMP from the subretinal space can actually enter RPE cells through organic ion channels to activate pigment aggregation. These findings indicate that an increase in cAMP in the subretinal space in the dark would activate pigment granule aggregation in RPE cells. cAMP efflux has been shown to be associated with increased intracellular cAMP accumulation in many cell types, including pinealocytes. Thus, diurnal cycles of cAMP levels in retinal photoreceptors might be expected to produce increased cAMP efflux into the subretinal space at night. This extracellular cAMP in the subretinal space could then function as a retina-to-RPE signal for darkness.

cAMP and intracellular calcium often interact in cellular signaling pathways, either antagonistically or synergistically. Pigment granule migration is regulated by calcium in several types of dermal chromatophores. However, increasing extracellular or intracellular calcium has no effect on pigment granule position in either aggregated or dispersed isolated RPE cells. Furthermore, intracellular calcium levels are unaffected when RPE pigment granule motility is triggered by cAMP or cAMP washout. These findings suggest that RPE pigment granule movements are regulated directly by cAMP, that is, by phosphorylation and dephosphorylation of PKA targets, and that calcium does not act downstream of cAMP in the regulatory process.

Carbachol (an acetylcholine analog) triggers dispersion in isolated fish RPE. The carbachol receptor acts through a pathway commonly linked to calcium mobilization and carbachol-induced pigment granule dispersion is blocked by the calcium chelator 1,2-bis(*o*-aminophenoxy) ethane-*N,N,N′,N′*-tetraacetic acid (BAPTA), suggesting that a rise in intracellular calcium plays a role upstream of cAMP in carbachol-induced dispersion.

Functions and Significance of Retinomotor Movements

What role retinomotor movements play in retinal function has been a topic of inquiry and speculation for more than a century. Direct experimental demonstration that retinomotor movements affect vision has been difficult to achieve, primarily because of the difficulty in interfering with retinomotor movements without compromising other aspects of retinal function. Nevertheless, several likely functions for retinomotor movements have been suggested. Occurring generally in species that lack pupillary movements, rod and RPE retinomotor movements provide an alternative mechanism to pupillary movements for shielding rods from full bleach in bright light while permitting optimal exposure for dim-light vision. Repositioning the rod and cone photoreceptors likewise provides an efficient mechanism for optimizing space by positioning the rods first in line to detect light at the focal plane across the entire retinal surface under dim-light conditions, and then moving cones to this position for bright-light vision. These movements permit the entire retinal surface to be used alternately for rod and cone vision. Some have noted that each photoreceptor type is elongated when it is expected to be silent, and suggested that the cable properties of the elongated myoid might contribute to attenuation of the signal from outer segment to synapse. The great morphological variation in retinomotor movements perhaps reflects the optimization of one or the other of these functions in different species.

Summary

Although retinomotor movements are most pronounced in lower vertebrates, their study contributes to a broader understanding of diurnal and circadian regulation of photoreceptor and RPE physiology. Retinomotor movements provide excellent models for investigating the roles of cytoskeletal elements in cell shape change and intracellular transport. Studies of retinomotor movements have called attention to the importance of cyclic changes in intracellular cAMP levels in the diurnal and circadian regulation of other aspects of photoreceptor physiology and metabolism. The recognition that light induction of cone and RPE movements depends on a rod-mediated paracrine pathway has contributed to recognition of the role that dopamine plays in light and circadian signaling. Since retinomotor movements exhibit properties of light and circadian regulation, characteristic of many other aspects of retinal physiology, they provide excellent experimental models for understanding light and circadian-regulatory processes.

Formation and Regression of the Primary Vitreous and Hyaloid Vascular System

S Rao, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA
R A Lang, University of Cincinnati, Cincinnati, OH, USA

Glossary

Angiogenesis – The process of forming new blood vessels from existing blood vessels.
Choroid fissure – A transient opening on the ventral side of the optic cup which provides an entry site for newly forming blood vessels and an exit for newly born retinal axons. Failure of the choroid fissure to close during eye development results in ocular colobomas.
Laser capture microdissection (LCM) – A method for isolating pure cells of interest from specific microscopic regions of tissues or tissue sections.
Lymphangiogenesis – The formation of lymphatic vessels from preexisting lymphatic vessels.
Norrie disease (ND) – An inherited disorder that leads to blindness at birth or soon after, hearing loss, and developmental delay. Mutations in the NDP gene on the X chromosome cause Norrie disease.
Osteoporosis-pseudoglioma syndrome (OPGG) – An autosomal recessive disorder that affects vision and bones. Individuals suffering from this disease exhibit characteristic eye lesions very early in childhood followed by bone fractures that occur later in childhood due to low bone density.
Persistent fetal vasculature (PFV) – Used to be known as persistent hyperplastic primary vitreous (PHPV), it is a congenital developmental anomaly of the eye that results due to the failure of the fetal primary vitreous and hyaloid vasculature to regress.
Pupillary membrane (PM), tunica vasculosa lentis (TVL), and vasa hyaloidia propria (VHP or hyaloid vessels) – The three temporary embryonic vasculatures that provide nutrition to the developing eye. In humans, this vasculature regresses in the third trimester, while in rodents it occurs postnatally.
Retrolental mass – A fibrous mass posterior to the lens and is very commonly observed in many ocular anomalies.

The Anatomy of the Temporary Ocular Vessels

In the developing eye of mammals, there are three connected but anatomically distinct embryonic vascular networks called the pupillary membrane (PM), tunica vasculosa lentis (TVL), and vasa hyaloidia propria (VHP or hyaloid vessels) (Figure 1). These vascular networks have a nutritive function and provide the molecular building blocks as well as the oxygen required for rapid growth of the eye during its developmental phases. These vascular networks are also temporary. In humans, they regress in the third trimester and in rodents, during the first few weeks after birth.

Although a number of species have embryonic ocular vessels, their developmentally scheduled regression appears to be a unique feature of mammals and is presumably an adaptation to allow light transmission from the cornea, through the lens, and to the retina. In humans, congenital defects such as osteoporosis pseudoglioma, and persistent fetal vasculature (PFV) where the hyaloid vessels fail to regress, results in a serious vision deficit. Perhaps this means that in species where embryonic ocular vessels are retained, such as the zebrafish, they may diminish the quality of images formed on the retina.

For the most part, studies of development and regression of the ocular vessel networks have been performed in rodents. Thus, besides occasional reference to other species, this article refers to developmental mechanisms that have been revealed in the mouse and rat. It is highly likely that these same mechanisms apply to humans also.

Development of the Hyaloid Vessels

The hyaloid vessels can first be observed in the mouse eye at about embryonic day (E) 10.5 (Figure 2). At this stage, the surface ectoderm of the embryo has just invaginated to form the lens pit. Lens pit development occurs in coordination with formation of the optic cup which in turn requires invagination of the optic cup along the ventral midline to form the ventral choroidal fissure. The hyaloid artery that is the origin of the hyaloid vessels is engulfed

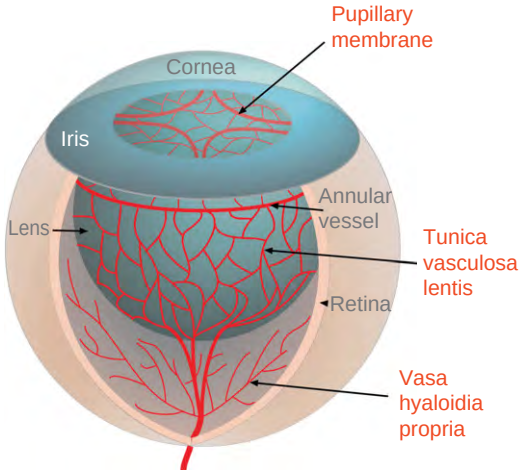

Figure 1 The temporary vessels of the rodent eye. This schematic shows the major components of the temporary vascular networks including the pupillary membrane, the annular vessel, the tunica vasculosa lentis, and the vasa hyaloidia propria (hyaloid vessels). The hyaloid vessels lie against the vitreal face of the retina, and the tunica vasculosa lentis and pupillary membrane against the posterior and anterior hemispheres, respectively, of the lens.

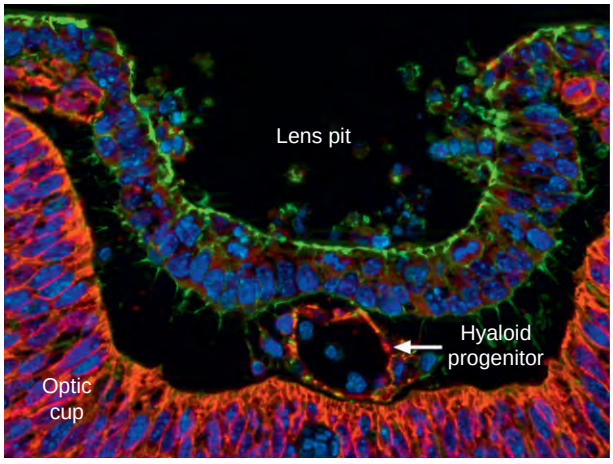

Figure 2 The hyaloid artery at embryonic day 10.5 in the mouse. This micrograph shows the hyaloid progenitor lying between the epithelia of the presumptive lens and retina. Nuclei are labeled blue and filamentous actin is green. The red labeling is junctional β-catenin that can be observed in optic cup and hyaloid artery but not in presumptive lens because this particular example is a mutant conditional for *β-catenin* deletion in the lens lineage.

into the central axis of the eye as the ventral choroidal fissure wraps around it. After this complex morphogenesis, the head of the hyaloid artery is located between the epithelia of the lens pit and presumptive retina (Figure 2).

The presumptive hyaloid vasculature is not a mature network with a hierarchy of vessel sizes but appears more like a vascular sinus. Over the period of E10.5 to E18.5 (the day of birth in the mouse) this early vascular structure changes to appear more like a vascular plexus and then finally into the hierarchical form of a mature structure. As this is occurring, vessels expand from the hyaloid artery over the posterior surface of the developing lens and anterior surface of the developing retina to form the TVL and hyaloid vessels, respectively (Figure 1). While there is a likelihood that this vessel expansion is mediated by the process of angiogenesis (growth of new vessels from existing ones), this has not been directly documented.

Establishment of the PM occurs after the lens vesicle has separated from the surface ectoderm at E12.5. At this time, vessels within the ocular mesenchyme can extend across the anterior eye underneath the presumptive corneal epithelium. As the layers of cornea are formed by successive migrations of neural crest-derived mesenchyme, the PM vessels are displaced toward the lens and ultimately lie in direct contact with the extracellular matrix of the lens capsule that overlies the lens epithelium. After birth, in the mouse, the vessels of the PM are incorporated into the structure of the iris diaphragm as it migrates into the anterior chamber.

As the embryonic ocular vessels develop, they form connections that allow blood flow. As its name would imply, the hyaloid artery directs blood flow into the eye. Blood flowing through the hyaloid artery continues to flow in an anterior direction through the hyaloid vessels and TVL until it reaches the annular vessel. The annular vessel runs in a ring around the lens anterior to the lens equator just underneath the ciliary process and iris (Figure 1). In turn, the annular vessel makes connections with arcades of the PM that extend along the anterior lens posteriorly and underneath the developing iris. The pattern of blood flow in the PM is a little more complex. It has two opposing quadrants in which arterioles direct flow from the iris into the PM. In the two alternating opposing quadrants, venules direct flow from the PM into the iridal vasculature.

Development of the TVL and PM Is Dependent on VEGF Signaling

Vascular endothelial growth factor A (VEGFA) is a key regulator of physiological and pathological angiogenesis and is a member of a larger family of signaling ligands that have a variety of effects on different cell types. Three conventional tyrosine kinase receptors belong to the VEGFA receptor family but only receptors 1 and 2 mediate signaling by VEGFA (Figure 3). The VEGFR2 (aka Flk1) is expressed on vascular endothelial cells (VECs) and is the major mediator of the angiogenic, survival-enhancing, and mitogenic effects of VEGFA. The biology of VEGFR1 (aka Flt1) is more complex as it may act as a VEGFA-sequestering decoy receptor (Figure 3) that prevents VEGFR2 signaling and is expressed on other cell types. The VEGFR1 activation in VECs can result in the

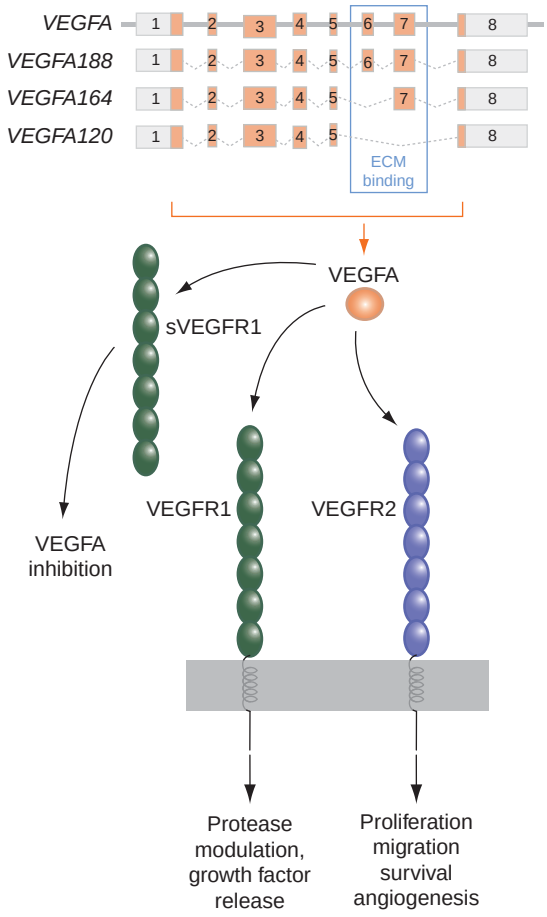

Figure 3 The VEGFA isoforms and receptor signaling. The *VEGFA* gene is shown schematically on the top line as exonic regions that are noncoding (gray) and coding (orange). The mouse isoforms VEGFA188, VEGFA164, and VEGFA120 are the result of alternative splicing patterns for exons 6 and 7 that encode extracellular matrix (ECM) binding domains. The VEGFA isoforms can signal through VEGFR1 (green) or VEGFR2 (blue) that comprise seven extracellular Ig domains and a cytoplasmic tyrosine kinase domain. The VEGRF2 is primarily responsible for the proliferation, migration, and survival responses that constitute angiogenesis. The VEGFR1 signaling can elicit protease modulation responses and can act as a VEGFA inhibitor when it is cleaved from the cell surface into a soluble form.

release of growth factors and matrix metalloproteinases that may be important for VEC migration during angiogenesis and vascular remodeling.

Mouse mutants of VEGFA and VEGFR1 and 2 have defects in development and regression of the ocular vessel networks. In work performed by the Beebe group, conditional deletion of *VEGFA* from the developing lens results in a failure of development of the TVL and the PM, the vessel networks that reside on the surface of the lens. When coupled with studies showing that ECM-binding isoforms of VEGFA are expressed in the lens, this has suggested that VEGFA associates with the matrix of the lens capsule as a way of stimulating angiogenesis locally. Interestingly, *VEGFA* deletion from the developing lens does not obviously affect development of the hyaloid vessels. It is most likely that a retinal source of VEGFA is critical for their development.

Through alternative splicing, VEGFA can form a number of isoforms that are named according to the number of amino acids present (**Figure 3**). These isoforms have distinct characteristics. The VEGF188 incorporates exons 6 and 7 that both encode ECM-binding domains and this binds strongly to the matrix. The VEGF164 incorporates only exon 7 and so is more freely diffusible. The VEGF120 incorporates neither exons 6 nor 7 and is the most freely diffusible. Thus, VEGFA isoforms have a range of biological characteristics.

The D'Amoré group has shown that these three VEGFA isoforms have biological significance for ocular vessel development. In mice that produce only VEGF165, both retinal angiogenesis and regression of the PM, TVL, and hyaloid vessels are normal indicating that this isoform is sufficient for all these processes. Mice that produce only VEGF188 have largely normal retinal angiogenesis (with the exception of a reduced number of arterioles) but have a hyaloid vessel persistence. Similarly, mice that produce only VEGF120 have both a severe retinal angiogenesis defect and persistent hyaloid vessels.

Regression of the Temporary Ocular Vessels Is Macrophage Dependent

Researchers have long wondered about the function of the resident population of ocular macrophages (**Figure 4**), sometimes known as hyalocytes. They may have multiple functions, including perhaps being precursors for retinal microglia, but were more recently shown to be required for regression of the temporary ocular vessels. This was demonstrated by the Lang group using a macrophage-specific diphtheria toxin-expressing transgene and the *PU.1* mutant mouse that shows a complete absence of mature tissue macrophages. In the *PU.1* mutant, all the temporary ocular vessel structures persist suggesting a common regression mechanism. The analysis performed has shown that macrophages are necessary for VEC apoptosis, which is the driving force behind programmed vascular regression. It has also been shown that injected bone-marrow macrophages can restore the regression process in the *PU.1* mutant. This demonstrated that macrophages are sufficient for programmed vascular regression. The suggestion that VEC apoptosis and programmed vascular regression were macrophage-dependent was initially quite controversial but has now generally been accepted. This notion is also very much supported by analysis indicating that in *Caenorhabditis elegans*, the apoptotic cell recognition machinery of phagocytes acts as a backup pathway for actively induced target cell death. Together, these data suggest metazoan conservation of phagocyte-induced cell death.

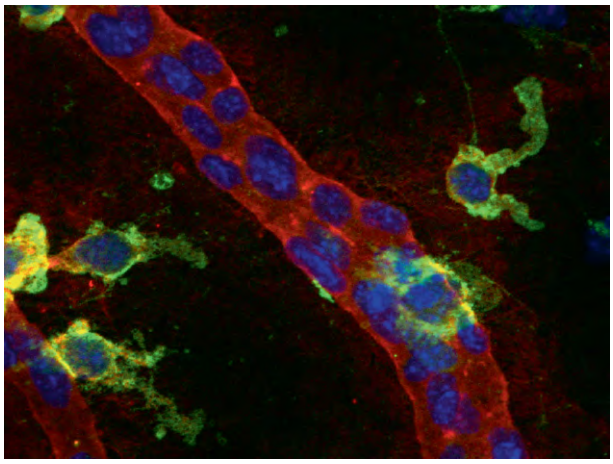

Figure 4 Resident macrophages associated with the hyaloid vessels. Macrophages (yellow-green) are labeled with F4/80 antibody. They associate closely with laminin-labeled capillaries (red). Nuclei are labeled blue.

The Wnt Signaling Pathway

There are a number of possible pathways downstream of Wnt receptor complexes. Since the canonical pathway is critical for hyaloid regression, only this branch is mentioned here. The canonical Wnt signaling pathway has been a major focus of attention because it is critical in embryonic development and tumorigenesis. The signaling system is complex but well characterized (**Figure 5**). There is a family of 18 known Wnt ligands that are lipid modified and therefore poorly soluble. For this reason, it is most likely that the Wnt signaling action occurs upon cell–cell contact. Optimal Wnt signaling requires two transmembrane components, the Frizzled family receptors and the Drosophila arrow-related coreceptors Lrp5 or Lrp6. In the mouse, there are nine Frizzled-related receptors. The Lrp5 and Lrp6 are part of a larger class of receptors related to the low-density lipoprotein receptor, but only Lrp5 and Lrp6 are closely related to arrow, the *Drosophila* Wnt signaling coreceptor.

Engagement of a Frizzled/Lrp5/6 complex by a Wnt ligand results in the activation of Disheveled (Dvl) and, in turn, suppression of the activity of the glycogen synthase kinase-3β (GSK3β), axin, APC complex. In the absence of Wnt ligands, GSK3β phosphorylates β-catenin and causes its degradation via the tumor suppressor gene product APC and the proteasome. When Dvl suppresses GSK3β, β-catenin is stabilized, binds to the TCF/Lef transcription factors, and regulates the target genes. There is a large set of genes known to be directly regulated at the transcriptional level by the canonical Wnt pathway (http://www.stanford.edu/~rnusse/wntwindow.html) and presumably some of these participate in hyaloid regression.

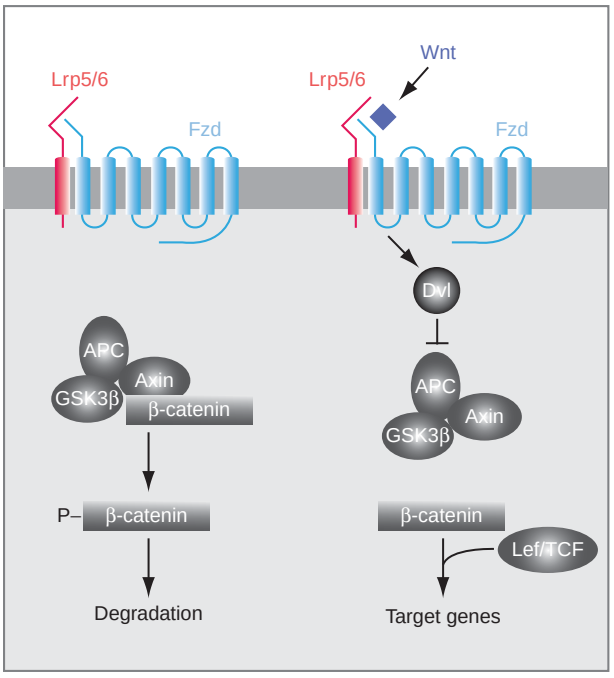

Figure 5 The canonical Wnt signaling system. In the absence of a Wnt ligand, a complex consisting of APC, axin, and GSK3β causes the phosphorylation-mediated degradation of β-catenin. In the presence of a Wnt ligand, Disheveled (Dvl) is activated by the receptor complex and suppresses the APC–axin–GSK3β complex allowing β-catenin to stabilize. In turn, β-catenin associates with transcription factors of the Lef/TCF family and regulates target gene transcription.

Wnt7b Is a Macrophage Ligand Critical for Hyaloid Vessel Regression

The hyaloid vessel persistence characteristic of the human syndrome osteoporosis pseudoglioma is caused by a mutation in the Wnt pathway coreceptor Lrp5. This prompted the Lang group to examine involvement of the Wnt pathway in regulating hyaloid regression. Examination of hyaloid vessel structures in the *lacz* expressing Wnt reporter mouse TOPGAL showed that hyaloid VECs were Wnt-responsive. Reduced numbers of Wnt-responsive VECs in *PU.1* mutant mice suggested that macrophages might be a source of Wnt ligands and this was born out with expression studies performed on hyaloid macrophages isolated by laser capture micro-dissection. Among the Wnt ligands expressed, Wnt7b was an interesting candidate because it was expressed in hyaloid but not in cultured macrophages. Analysis of Wnt7b mutant mice revealed hyaloid vessel persistence. Furthermore, when injected into the eye, wild-type but not *Wnt7b* mutant macrophages could rescue the failure of regression in the *PU.1* mutant. Thus, Wnt7b is a macrophage Wnt ligand critical for hyaloid regression.

The Angiopoietin and Wnt Pathways Integrate to Regulate Hyaloid Regression

The discovery of the Tie2 receptor, a conventional receptor tyrosine kinase expressed in VECs, led directly to identification of the angiopoietin family of Tie2 ligands. Angiopoietin 1 and 2 have been well characterized experimentally. Angiopoietin 1 (Ang1) is an agonist of the signaling pathway and among other responses can promote cell survival through the PI3 Kinase-Akt signaling axis. The function of Ang2 is context-dependent. In some settings (like lymphangiogenesis) it is an agonist of the angiopoietin pathway. In other settings (the hyaloid vessels) it is an antagonist and thus promotes cell death.

The Ang2 mutant mice, like the Wnt pathway mutants, show a failure of hyaloid vessel regression and this prompted an investigation of mechanisms of Wnt–angiopoietin pathway integaration. Several mechanisms were revealed. First, both pathways influenced the cell cycle behavior of hyaloid VECs (**Figure 6**). As might be expected given direct targets like *myc*, the Wnt pathway promotes cell cycle entry. In doing so, the Wnt pathway sensitizes VECs to the effects of Ang2 in suppressing survival signaling and promoting cell death in G1 phase of the cell cycle. Second, the angiopoietin pathway stabilizes β-catenin through signaling mechanisms that are incompletely understood. This means that both the conventional Wnt pathway and the angiopoietin pathway converge on β-catenin and regulate cell cycle entry. Finally, Ang2 (probably produced by pericytes) is required for the expression of Wnt7b in macrophages (**Figure 6**). This configuration of signaling interactions means that Ang2 has two functions; suppression of cell survival and, via macrophage Wnt7b expression, an alternative pathway to promote cell cycle entry. This signaling pattern is also a means to ensure that when cell death occurs, the macrophage and its phagocytic disposal capability are on hand.

Fzd4 and Norrin in Hyaloid Regression

Norrie disease is an inherited disorder in which blindness is the major feature. The Norrie disease protein (Ndp) – also called Norrin – was recently shown by the Nathans group to be an unconventional ligand for the receptor Fzd4 and that Norrin activated the canonical Wnt signaling pathway. The phenotypes of the Fzd4 and Ndp mutant mice are similar and include defective retinal angiogenesis and persistence of the hyaloid vessels – both being reasons for blindness. Currently, it is unclear how this information can be integrated with the macrophage-dependent hyaloid regression mechanisms described above. There may be local effects of Fzd4 and Norrin that cause hyaloid persistence but it is equally possible that the hyaloid and retinal vessels interact hemodynamically to influence regression and angiogenesis respectively.

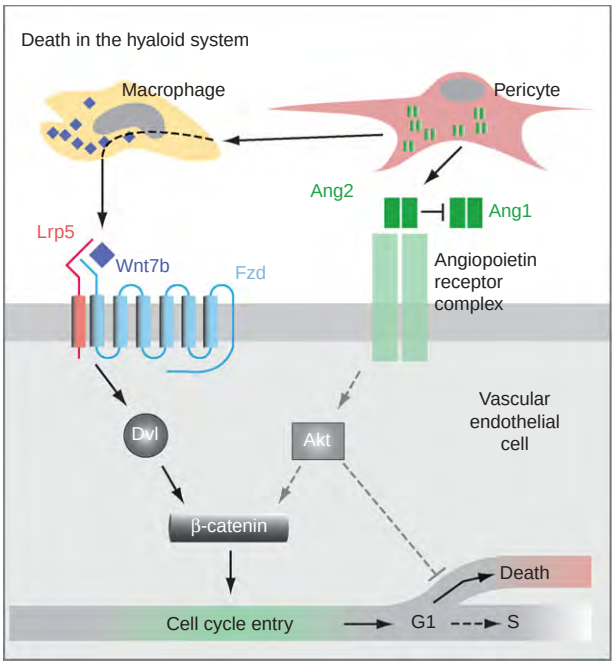

Figure 6 A model for regulation of VEC death in the hyaloid system. Hyaloid VECs will die when Ang2 promotes cell death via suppression of Akt and cell cycle entry by upregulating Wnt7b in macrophages. In the absence of survival signals the cycling hyaloid VECs will undergo apoptosis in the G1 phase of the cell cycle. Adapted from Rao, S., Lobov, I. B., Vallance, J. E., et al. (2007). Obligatory participation of macrophages in an angiopoietin 2-mediated cell death switch. *Development* 134: 4449–4458.

Collagen 18 and Endostatin in Hyaloid Regression

Endostatin was originally isolated as an inhibitor of angiogenesis and was proposed as an antitumor therapeutic agent. It was shown to be a proteolytic cleavage product of collagen 18. While the therapeutic potential of endostatin has not thus far been realized, the collagen 18 mutant mouse, in which no endostatin production is possible, does have a defect in hyaloid regression. This interesting observation from the Olsen group indicated that collagen 18, and perhaps endostatin, promote vessel regression and is consistent with the originally identified anti-angiogenic activity of endostatin.

The mechanism of action of collagen 18 in hyaloid regression is currently unclear but there are several possibilities. First, since collagen 18 is normally a component of hyaloid vessel basal lamina, it may be involved in regulating the macrophage–endothelial cell interaction. Presumably, given the hyaloid vessel persistence of the mutant mouse, collagen 18 would normally promote the interaction and thus facilitate regression. An alternative, or perhaps an additional mechanism, may be modulation of the Wnt pathway signaling by the collagen 18 fragment endostatin. As work from the Sokol group has suggested

that endostatin is an inhibitor of Wnt signaling, it is possible that like a defective Wnt pathway, the Wnt pathway activation predicted for the collagen 18/endostatin mutant might also perturb the hyaloid regression.

The Arf Tumor Suppressor and PHPV

Persistent hyperplastic primary vitreous (PHPV) is an ocular developmental defect in which the hyaloid vasculature within the vitreous overgrows and fails to regress. The disease is most often detected in infants as a fibrovascular, retrolental mass that in severe cases causes retinal detachment. The Skapek group has identified a good model of PHPV in mice mutant for the Arf tumor suppressor.

The *Arf* gene encodes $p19^{Arf}$, a nuclear protein that can complex with Mdm2 and thus influence activity of the p53 tumor suppressor. In addition, $p19^{Arf}$ has p53-independent effects. Since Arf mutant mice, unlike p53 mutants, reliably show a PHPV-like phenotype, it is likely that the p53-independent effects are responsible. In Arf mutant mice, PDGFRβ expressing cells with the characteristics of vascular mural cells populate the vitreous and envelop the hyaloid vessels to form the retrolental mass. In a revealing experiment it was shown that mutation of the *PDGFR*β gene can rescue the PHPV defect of the Arf mutant mice. Furthermore, through mechanisms that are not currently defined, p19Arf normally suppresses the PDGFRβ and in the Arf mutant, an overly sensitive signaling pathway leads to greater recruitment of mural cells. This is consistent with the general role of the PDGFRβ signaling system in recruitment of vascular mural cells by PDGFB-expressing VECs. The hyaloid vessel hyperplasia of *TGF β* mutant mice also suggests that this pathway will be involved in regulating development of the hyaloid system. In the Arf and TGFβ2 mutant models, early developmental perturbation of hyaloid vessel development is the primary defect and hyaloid vessel persistence, likely a secondary consequence. This contrasts with the Wnt and angiopoietin models described above where there are no detectable defects in hyaloid vessel development but there are major consequences for hyaloid regression.

Future Directions

The temporary vascular networks of the eye have so far served as an excellent model system to understand the mechanisms of vascular regression. This is clearly of interest to developmental and vascular biologists and with the involvement of macrophages, also to those interested in this versatile cell type. In studying these vascular networks, the greatest payoff may be when these mechanisms are applied to disease systems where antivascular therapy is advantageous. An important outstanding question is whether the Wnt ligands produced by macrophages have a role in regulating the vascularity – and therefore the progression – of tumors. Thus, it may be that the ocular vessels can provide the basis for future antitumor therapies of novel design. An additional challenge will be the work that allows us to understand how vascular regression pathways are integrated. While some progress has been made, more sophisticated methods of analysis will be required to understand, for example, the influence of VEGF signaling on the Wnt pathway or the influence of collagen 18 on Wnt signaling.

Functional Morphology of the Trabecular Meshwork*

E R Tamm, University of Regensburg, Regensburg, Germany

Glossary

Inner-wall region – Comprised of the inner-wall endothelium of Schlemm's canal, its basement membrane, and the adjacent juxtacanalicular tissue. It is the site of resistance in the trabecular meshwork outflow pathways.

Juxtacanalicular tissue – The outermost part of the trabecular meshwork that lies directly adjacent to Schlemm's canal. It does not form lamellae, but represents a loose connective tissue. An alternative term is cribriform meshwork.

Mechanosensor – The terminal of an afferent nerve ending that is in contact with fibrillar components of the extracellular matrix and measures stress or strain in those. An alternative term is mechanoreceptor.

Myofibroblast – A resident cell in some connective tissues that shows structural and functional characteristics of both fibroblasts and smooth muscle cells, and appears to be an intermediate form of those.

Schlemm's canal – A circular vascular tube that lies in the scleral sulcus, a circular groove on the inner aspect of the corneoscleral limbus. It is part of the trabecular outflow pathways. The inner aspects of Schlemm's canal are in contact with the juxtacanalicular tissue.

Scleral spur – A wedge-shaped circular ridge protruding from the sclera posterior to Schlemm's canal.

Trabecular meshwork – A porous, filter-like tissue in the irido-corneal angle consisting of connective tissue strands (trabecular beams or lamellae) that attach to one another and are covered by cells.

Introduction

The major drainage structures for aqueous humor (AH) are the conventional or trabecular outflow pathways, which are comprised of the trabecular meshwork (made up by the uveal and corneoscleral meshworks), the juxtacanalicular connective tissue (JCT), the endothelial lining of Schlemm's canal (SC), the collecting channels, and the aqueous veins. When AH has passed through the trabecular outflow pathways, it drains into the episcleral venous system. In addition, there is an unconventional or uveoscleral outflow route which is open to AH at the chamber angle in the region of the anterior insertion of the ciliary muscle, since there is no complete endothelial or epithelial layer that covers the anterior surface of the ciliary body. The trabecular meshwork (TM) outflow pathways are critical in providing resistance to AH outflow. Intraocular pressure (IOP) builds up in response to this resistance until it is high enough to allow flow of AH across the TM into SC. AH passes through the TM as bulk flow driven by the pressure gradient, and active transport is not involved as neither metabolic poisons nor temperature affects AH flow across the TM. At steady-state IOP, fluid flow rate across the trabecular outflow resistance equals the rate of aqueous production by the ciliary body. Outflow resistance in the TM outflow pathways increases with age and primary open-angle glaucoma (POAG). This article reviews the functional morphology of the TM outflow pathways.

The TM Outflow Pathways

The tissue structures of the TM outflow pathways are embedded in the internal scleral sulcus, a circular groove on the inner aspect of the sclera in region of the corneoscleral limbus. The scleral sulcus extends from the peripheral edge of Descemet's membrane to the scleral spur, a wedge-shaped circular ridge protruding from the inner sclera (**Figure 1(a)**). SC, a circular, vascular-like collecting channel, lies in the outer portion of the scleral sulcus, while the TM occupies most of its inner aspects (**Figure 1(a)**).

The TM is formed by connective tissue beams or lamellae that have a core of collagenous and elastic fibers, and are covered by flat cells which rest on a basal lamina. The beams attach to one another in several layers and form a porous filter-like structure. Anteriorly, the trabecular beams are attached near the end of Descemet's membrane (Schwalbe's line) and extend posteriorly to the stroma of the ciliary body and iris at their junction, and to the scleral spur (**Figure 1(a)**). As SC is shorter in anterior–posterior direction than the TM, a filtering portion of the TM can be differentiated from a nonfiltering

*An adaptation and extension of Tamm, E. R. (2009). The trabecular meshwork outflow pathways: Structural and functional aspects. *Experimental Eye Research* 88: 648–655. http://www.sciencedirect.com/science/journal/00144835.

portion which has no SC next to its external aspect (**Figure 1(a)**). Those cells of the nonfiltering portion of the TM, which reside close to the attachment of the TM at Schwalbe's line, differ in structure from that of the TM proper. There is some evidence that this region serves as a niche for cells with adult stem cell-/progenitor cell-like properties that are capable of dividing and repopulating the filtering part of the TM after injury.

The TM consists of three regions that differ in structure: the inner uveal meshwork, the deeper corneoscleral meshwork, and the JCT or cribriform region that is localized directly adjacent to the inner-wall endothelium of SC (**Figure 1(b)**). The uveal meshwork, which originates from the anterior aspect of the ciliary body, consists of one to three layers of trabecular beams or lamellae (**Figure 1(b)**). The corneoscleral meshwork forms 8–15 trabecular layers, which are thicker than those of the uveal TM and originate from the scleral spur (**Figure 1(b)**). The JCT, which is localized directly to the endothelial lining of SC, is the smallest part of the TM with a thickness of only 2–20 μm. It does not form trabecular lamellae or connective tissue beams, but rather represents a typical loose connective tissue with two to five layers of scattered cells that are embedded in a loosely arranged fibrillar extracellular matrix (ECM) (**Figures 1(b)** and **2(a)**).

The Trabecular Lamellae

Each lamella or beam of the uveal or corneoscleral TM contains densely packed collagen and elastic fibers. The collagen fibers are mostly collagens type I and III. The elastic fibers, which localize to the core of the beams (**Figure 2(b)**), differ in their ultrastructure from those in other parts of the body, as they contain considerable amounts of electron-dense material. TM elastic fibers are surrounded by a sheath that thickens with age and

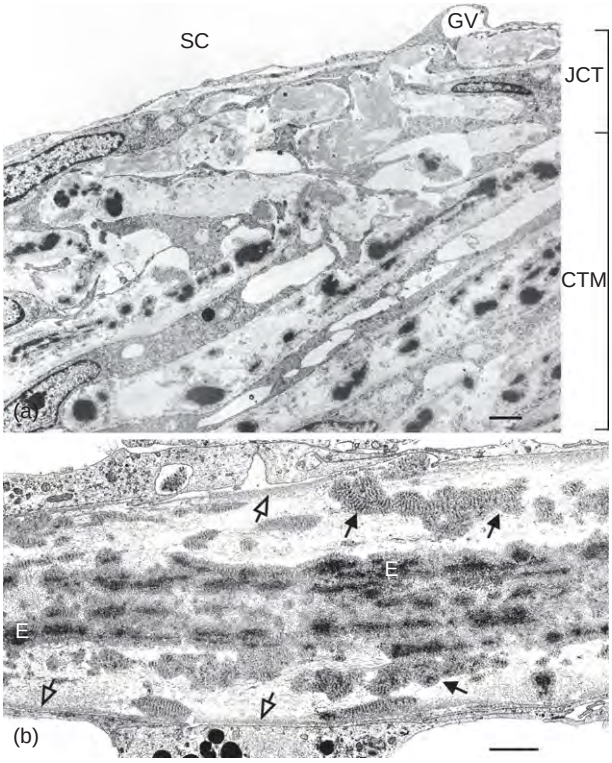

Figure 2 Electron micrographs of the trabecular meshwork. (a) Cells and extracellular fibrils in the juxtacanalicular tissue (JCT) are arranged in an irregularly network in contrast to the more regular structure of the beams in the corneoscleral trabecular meshwork (CTM). (b) Ultrastructure of a corneoscleral trabecular meshwork beam. The core of the beam contains elastic fibers (E) that are surrounded by banded sheath material. Open arrows denote the basal lamina of the trabecular meshwork cells, while solid arrows point to aggregates of long-spacing collagen in the cortical region of the beam. The beam is completely covered by flat trabecular meshwork cells. SC, Schlemm's canal; GV, giant vacuole. Magnification bar = 2 μm. From Tamm, E. R. (2009). The trabecular meshwork outflow pathways: Structural and functional aspects. *Experimental Eye Research* 88: 648–655.

that may show an 80–120-nm periodicity. Clumps of similar material and periodicity have been referred to as long-spacing collagen and are found in the cortical zone of the beams, between the elastic fiber core and basal lamina of the TM cells (**Figure 2(b)**). Fine fibrils that enter the aggregates of long-spacing collagen have been shown to label with antibodies against collagen type VI. The cells covering the TM beams reside on a basal lamina that is rich in collagen type IV and laminin (**Figure 2(b)**). A three-dimensional network is established by TM cells that bridge intertrabecular spaces to cover two adjacent beams. TM cells are capable of phagocytosis and may contain pigment particles, and these particles in TM cells probably derive from the iris and their phagocytosis by TM cells may be part of an important self-cleaning mechanism of the trabecular filter. TM regions that contain a high number of pigmented cells appear to be preferentially localized adjacent to collector channels, suggesting preferential AH flow pathways in the TM.

The Juxtacanalicular Tissue

TM cells in the JCT are surrounded by fibrillar elements of the ECM to form a loose connective tissue. As JCT cells and ECM fibrils are arranged in an irregular network (in contrast to the more regular structure of the beams in the inner parts of the TM), some authors prefer the term cribriform meshwork. The cells in the JCT form long processes by which they attach to one other, to ECM fibrils or to the cells of the endothelial lining of SC (**Figure 2(a)**). The spaces between JCT cells and ECM fibers serve as pathway for AH and contain a ground substance consisting of various proteoglycans and hyaluronan. The extent to which this ground substance fills the spaces between cells and fibrillar ECM is not clear as proteoglycans are not readily retained during processing of tissue for conventional electron microscopy. Recent studies using quick-freeze/deep-etch methodology visualized considerably more ECM in the JCT compared to that seen by conventional electron microscopy.

A characteristic structural element of the JCT is a network of elastic fibers (cribriform plexus), which is arranged tangentially to the SC endothelial lining. The elastic fibers of the cribriform plexus show ultrastructural characteristics similar to those in the trabecular beams as they consist of an electron-dense core and a sheath of banded material. The molecular nature of the sheath material has not been identified, but there is evidence that collagen type VI and fibronectin are associated with it. Fibers of the cribriform plexus connect with the SC inner-wall endothelium through either their sheath material or fine fibrils that emerge from it (**Figure 3(a)**). Fibronectin-based cell–matrix connections appear to be very important for the adhesion of SC endothelial cells to the fibrillar ECM

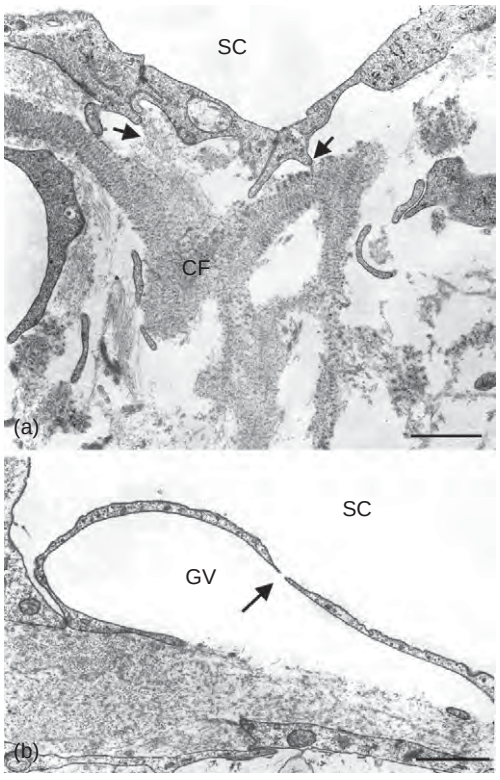

Figure 3 Electron microscopy of the SC inner-wall region. (a) Connecting fibers (CF) in the juxtacanalicular tissue, which emerge from the cribriform elastic plexus, connect the plexus with the inner-wall endothelium of Schlemm's canal (SC). The connection with the inner-wall endothelium is made through either the banded sheath material of the fibers or fine fibrils that emerge from it (solid arrows). (b) A giant vacuole in the inner wall of SC forms an intracellular pore (arrow). Magnification bar = 1 μm. From Tamm, E. R. (2009). The trabecular meshwork outflow pathways: Structural and functional aspects. *Experimental Eye Research* 88: 648–655.

of the JCT, as treatment of perfused anterior segment organ cultures with the integrin/syndecan-binding domain of fibronectin, called the heparin II (Hep II) domain, leads to a focal detachment of SC endothelium from the JCT, and to a significant increase in outflow facility.

The ECM in the JCT does not only contain structural elements, but also matricellular proteins such as thrombospondin-1 and SPARC. Matricellular proteins are secreted ECM proteins that influence cell function by modulating cell–matrix interactions. Another important component of the JCT ECM is myocilin, one of the most highly expressed molecules in the TM. Myocilin has been shown to associate with fibrillar elements of the JCT ECM, but its biochemical function is largely unclear.

Synthesis and degradation of ECM molecules in the JCT is under control of autocrine and paracrine growth factors, such as transforming growth factor beta 2 (TGF-β2), connective tissue growth factor (CTGF), bone morphogenetic protein 7 (BMP7), and BMP4. In addition, glucocorticoids and prostaglandin derivatives appear to modulate

ECM turnover in the JCT. A characteristic structural change in the eyes of patients with POAG and steroid-induced glaucoma is an increase in fibrillar ECM in the JCT.

Because of their high porosity, the uveal and corneoscleral parts of the TM do not provide a significant resistance to AH outflow. Support for this comes from experimental studies, which show that cutting through the inner parts of the TM does not affect outflow facility, and from theoretical calculations using Poiseuille's law. In contrast, there is considerable evidence that normal AH outflow resistance resides in the inner-wall region of SC, which is formed by the JCT and SC inner-wall endothelium. As of today, there is active debate and research regarding the specific role of SC inner-wall endothelium and/or JCT for the formation of resistance in the TM outflow pathways.

Schlemm's Canal

A characteristic aspect of the SC inner-wall endothelium is the formation of cellular outpouchings (the so-called giant vacuoles) in response to the pressure gradient associated with AH flow (**Figure 3(b)**). Endothelial cells of the SC inner wall rest on an incomplete basal lamina and considerable areas of their basal cell membrane are not supported by ECM, but are in direct contact with the open spaces of the JCT and AH flow. Giant vacuoles form when AH pushes against the basal side of SC cells, and are often associated with intracellular pores that have diameters from 0.1 to 2 μm. In addition to intracellular pores, paracellular pores have been observed, which usually have diameters comparable to that of intracellular pores, but are less common in most eyes. Paracellular pores are very likely the morphological correlate for paracellular flow through SC endothelium, which has been described in perfusion studies using cathionized ferritin. The junctional complexes between SC cells contain tight junctions and very likely restrict paracellular flow. Inner-wall pores allow passage of microparticles 200–500 nm in size. In their 1972 work, Bill and Svedbergh calculated the hydraulic conductivity and the flow resistance generated by inner-wall pores and concluded that the inner-wall endothelium could not generate more than 10% of total TM outflow resistance. More recent experiments indicate that the number of intracellular pores increases with the amount of fixative perfused through the TM outflow pathways and with the postmortem time of the enucleated donor eye, strongly indicating that the total number of pores identified by electron microscopy in fixed tissues is likely considerably smaller than that in the living eye. The number of paracellular pores was not affected by the amount of fixative or postmortem time, but increased with increasing fixation pressure. As fixation conditions can influence the apparent pore density in the inner-wall endothelium significantly, the conclusion reached previously that pores contribute only 10% of die aqueous outflow resistance, may require reevaluation. Nevertheless, it appears to be reasonable to assume that not all intracellular pores are artifacts, since the SC inner-wall endothelium has one of the highest hydraulic conductivities in the body, comparable only to that of fenestrated endothelia.

The molecular processes that contribute to or cause formation of intracellular pores in SC inner-wall endothelium are largely unknown. Small minipores that are covered by a diaphragm (**Figure 4**) may be involved. Diaphragmed minipores (DMPs) have similar ultrastructural characteristics as those forming the fenestrae of fenestrated capillaries, for example, in ciliary body or choroid. These are regularly found in SC inner-wall endothelium, but are considerably rarer than the fenestrae in fenestrated epithelia. In their 1995 work, Bill and Maepea hypothesized that DMPs represent an early stage in pore formation. The thin diaphragm, which in blood vessels is probably supported by the basal lamina, has no such support in the inner-wall cells and so may tend to burst.

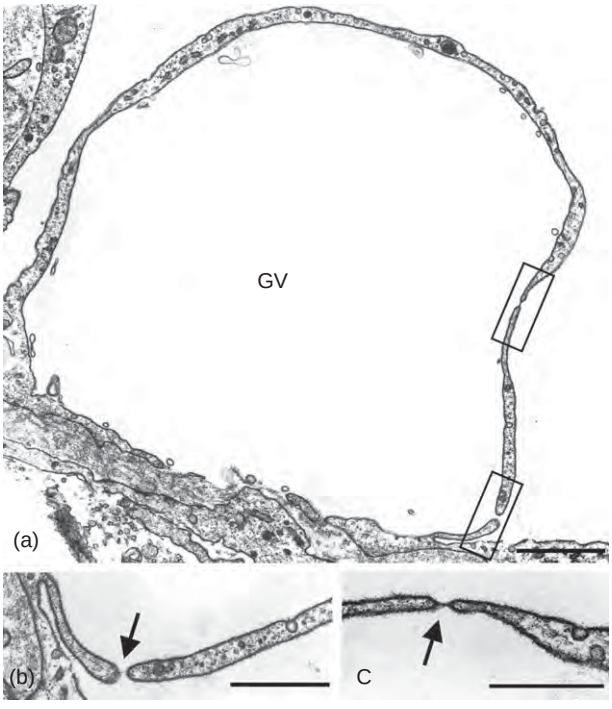

Figure 4 Electron microscopy of an inner-wall giant vacuole (GV) that forms two intracellular pores (boxed areas in (a)). Both boxed areas are shown in (b) and (c) at higher magnification. While the pore in (b) is largely open and only covered by very fine filamentous material, the pore in (c) is covered by a diaphragm (arrow). Magnification bar = 1 μm (a), 0.5 μm (b), 0.5 μm (c). From Tamm, E. R. (2009). The trabecular meshwork outflow pathways: Structural and functional aspects. *Experimental Eye Research* 88: 648–655.

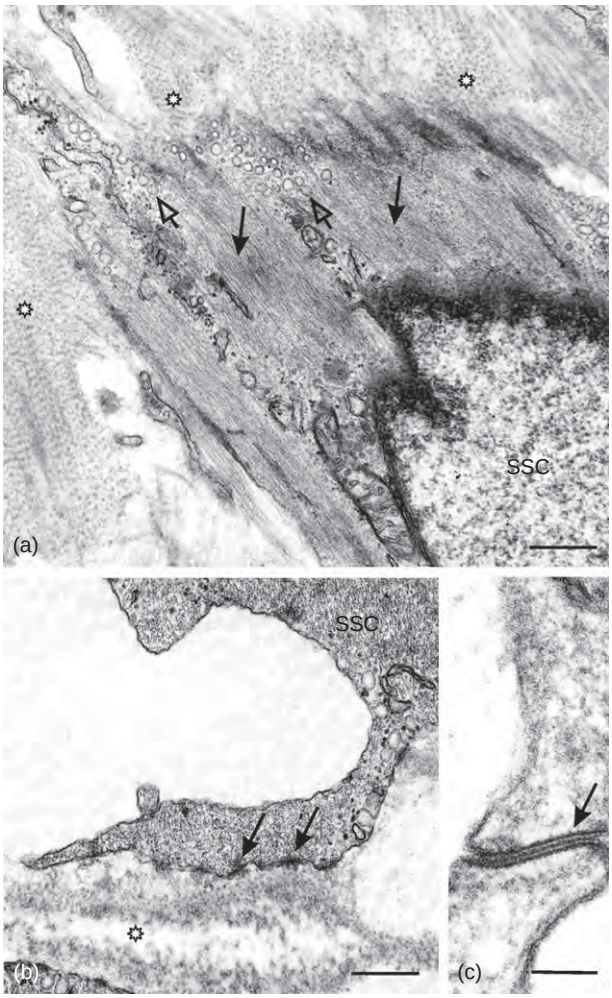

Figure 5 Electron microscopy of scleral spur cells. (a) Scleral spur cells (SSC) are in close contact with banded sheath material (asterisks) of elastic fibers. The cytoplasm of the cells is filled with abundant 6–7-nm-thin (actin) filaments which run parallel to the long axis of the cells (solid arrows). The cell membrane shows numerous membrane bound caveolae (open arrows). (b) Scleral spur cells may form long processes to contact the elastic fibers (asterisk) in the scleral spur. In region of contact, dense bands (arrows) are formed at the cell membrane of the scleral spur cell. (c) Scleral spur cells are connected by gap junctions (arrow). Magnification bar = 1 μm (a, b); 125 nm (c). From Tamm, E., Flügel, C., Stefani, F. H., and Rohen, J. W. (1992). Contractile cells in the human scleral spur. *Experimental Eye Research* 54: 531–543.

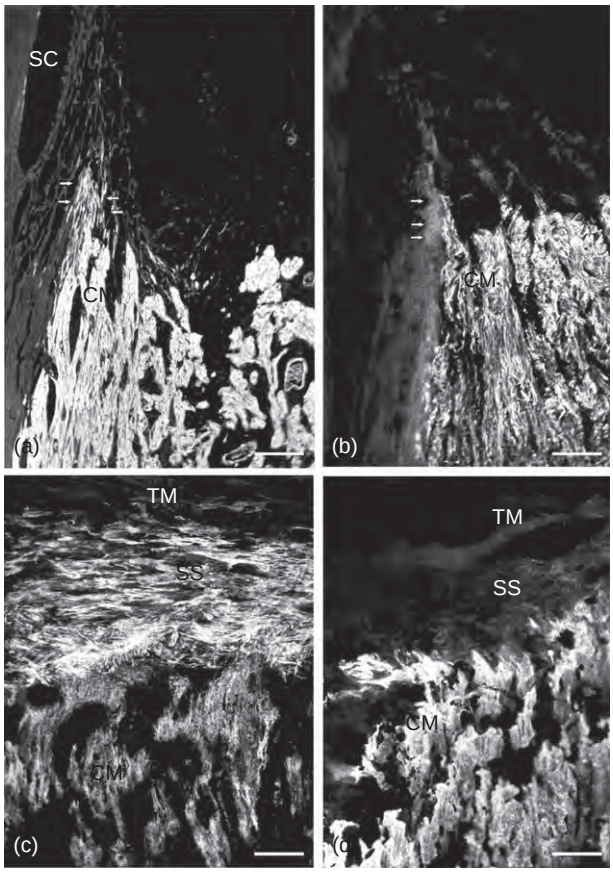

Figure 6 Meridional (a, b) and tangential sections (c, d) through ciliary muscle (CM), scleral spur (SS), and trabecular meshwork (TM) stained with antibodies against α-smooth muscle actin (a, c) or desmin (b, d). (a) Ciliary muscle cells and vascular smooth muscle cells stain positively with antibodies against α-smooth muscle actin. Arrows indicate the scleral spur, where all cells show intense immunoreactivity for α-smooth muscle actin. (b) Immunostaining with antibodies against desmin. Ciliary muscle cells stain brightly positive, whereas the scleral spur is not labeled for desmin. (c) Tangential section of scleral spur, trabecular meshwork, and ciliary muscle. Positively stained cells oriented in a circular direction are seen throughout the entire spur tissue. While ciliary muscle cells also stain positive, no staining is seen in the trabecular meshwork. (d) Tangential section of scleral spur and ciliary muscle after staining for desmin. The plane of the section is the same as in (c). Ciliary muscle cells stain brightly positive, whereas the cells of the scleral spur remain unstained. Magnification bar = 30 μm. From Tamm, E., Flügel, C., Stefani, F. H., and Rohen, J. W. (1992). Contractile cells in the human scleral spur. *Experimental Eye Research* 54: 531–543.

Contractile Influence on Trabecular Outflow

The muscle bundles of the ciliary muscle form tendons in region of their anterior insertion, which attach to the scleral spur or are continuous with the ECM of the TM. Because of the structural connections between ciliary muscle, scleral spur, and TM, contraction of the ciliary muscle pulls the spur posteriorly and/or widens the trabecular spaces, thereby inducing changes in TM geometry that lead to a reduction in outflow resistance.

In addition to ciliary muscle cells, there is another contractile cell population in this area, which very likely affects the TM tone. The resident cells within the scleral spur contain numerous actin filaments (**Figure 5(a)**), stain with antibodies against α-smooth muscle (SM) actin (**Figures 6(a) and 6(c)**), and generally express a myofibroblast-like phenotype. α-SM actin is an actin isoform that is typically expressed in vascular SM cells and myofibroblasts, cells that are present in healing

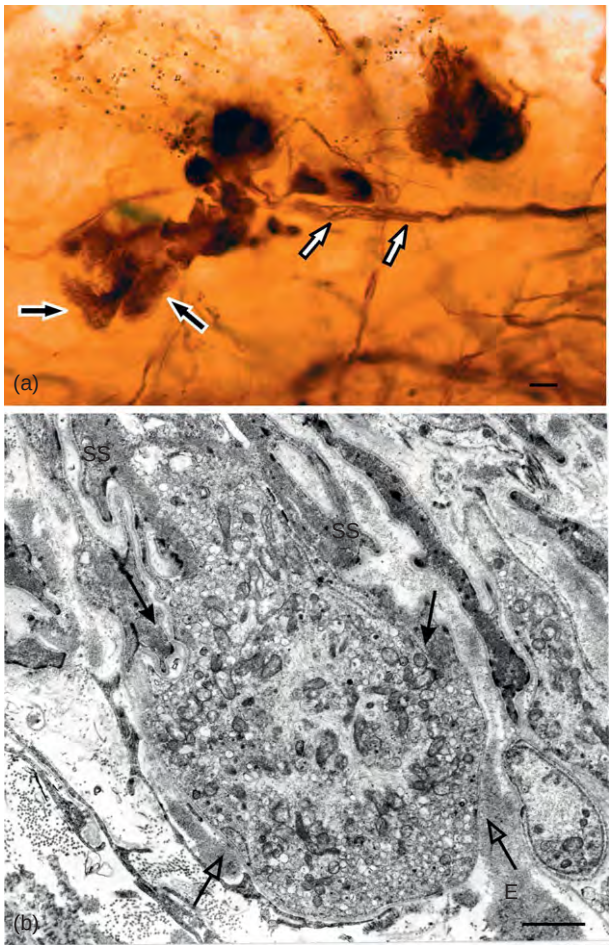

Figure 7 Mechanosensors in the scleral spur. (a) Whole mount of the scleral spur stained with antibodies against neurofilament proteins. Axons are labeled that terminate as bulb or club-shaped structures (arrows). (b) Electron micrograph of a mechanoreceptive nerve terminal in the scleral spur. The terminal is a bulb or club shaped and contains numerous neurofilaments, mitochondria, and vesicles of different sizes. The elastic fibers of the scleral spur (E, open arrows), and the scleral spur cells (solid arrows) are in close proximity to the terminal. Magnification bar = 10 μm (a), 1 μm (b). From Tamm, E. R. (2009). The trabecular meshwork outflow pathways. Functional morphology and surgical aspects. In Shaarawy, T. M., Sherwood, M. B., Hitchings, R. A., and Crowston, J. G. (eds.) *Glaucoma*, vol. II, pp. 31–44. Philadelphia, PA: Saunders.

wounds and scars. In contrast to the ciliary muscle cells that attach to the spur, scleral spur cells are circumferentially oriented (**Figure 6(c)**), and do not stain for desmin, the intermediate filament that is characteristic for ciliary muscle cells (**Figures 6(b)** and **6(d)**).

Scleral spur cells are innervated, coupled to each other by gap junctions (**Figure 5(c)**), and form tendon-like contacts with the elastic fibers within the scleral spur and their nonelastic sheath material (**Figures 5(a)** and **5(b)**). Since scleral spur elastic fibers are directly continuous with the elastic fibers in the TM beams and the cribriform plexus in the JCT, changes in scleral spur cell tone are likely to modulate outflow resistance by altering the architecture of the TM outflow pathways. In addition to scleral spur cells, some scattered cells in the TM proper have also been shown to express α-SM actin. The expression of α-SM actin induced by TGF-β1 has been shown to substantially enhance cell traction force in myofibroblasts, a scenario that might be also true for TM cells where TGF-β1 has similar effects on the expression of α-SM actin. There is experimental evidence that TM cells influence the hydraulic conductivity of the inner-wall region and outflow resistance by actively changing cell shape and altering the geometry of the outflow pathways. An increase in TM cell tone is correlated with an increase in outflow resistance.

Throughout the entire circumference of the scleral spur, club-shaped nerve endings are found, which derive from myelinated axons (**Figure 7(a)**). The ultrastructure of the nerve endings is very similar to that of mechanosensors in other parts of the body (**Figure 7(b)**).

The cell membrane of the nerve endings is in direct contact with the elastic fibers of the scleral spur. The contact between nerve terminal and connective tissue fibers is a very characteristic feature of mechanosensors, as it is required to measure the tone of the extracellular fibers. The mechanosensors of the scleral spur may act as proprioreceptive tendon organs for the ciliary muscle, or modulate the tone of the scleral spur cells. Alternatively, scleral spur mechanosensors could perform a baroreceptor-like function in response to changes in IOP. Indeed, physiological studies indicate that such sensors might exist, as sensory discharges have been recorded in experimental animals in response to changes in IOP.

Fundamentals of Stereopsis

L M Wilcox, York University, Toronto, ON, Canada
J M Harris, University of St. Andrews, St. Andrews, UK

Glossary

Binocular disparity – The positional differences between two retinal images generated at any instance by the two eyes. The brain uses this information to extract an estimate of the depth of an object or point.
Horopter – The set of points having zero binocular disparity that represent an arc passing through the fixation point.
Stereoacuity – The smallest binocular disparity that can reliably be discriminated.
Spatial frequency – A mathematical term describing the amount of detail in a scene and any scene can be broken down into a set of constituent sinuosoidal waveforms of different frequencies.
Stereoscope – Instrument invented by Wheatstone in 1838, which uses a pair of mirrors set at right angles to focus pictures separately to the two eyes as stereograms.

Defining Stereopsis

Stereopsis is a powerful cue to depth that arises as a consequence of having two eyes that are laterally offset in the head. This means that each eye receives a slightly different image of the world, a fact one can easily confirm by holding a finger in front of the face, and looking at it with each eye in turn. The two retinal images generated at any instant are identical in most respects, except for a positional shift which makes it appear that the finger is jumping back and forth as one changes the viewing eye. This positional difference is illustrated in **Figure 1**, which shows a cluster of grapes as a stereo pair (one image for each eye, photographs taken from each eye's viewpoint). Notice that the upper grape of the central group of three occludes part of the background on the left (right-eye image) that is visible on the right (left-eye image).

These differences in image position are known as binocular disparity, and this is the information the brain uses to extract an estimate of the depth of an object or point, relative to where the observer is fixating. This disparity may also be thought of as the angular difference between a pair of points on the retinas. The geometry is straightforward as illustrated in **Figure 2**.

Figure 2 shows two eyes fixating point F, so it stimulates the fovea, while point P is further away from the observer. Relative binocular disparity, η, is defined as the angle subtended at the eyes by one point (ω) minus the angle subtended by the other point (θ):

$$\eta = \omega - \theta \qquad [1]$$

This equation can be re-expressed in terms of distances, rather than angles. Notice that

$$\tan\left(\frac{\omega}{2}\right) = \frac{\text{io}d}{2d} \text{ and } \tan\left(\frac{\theta}{2}\right) = \frac{\text{io}d}{2(d+\Delta d)} \qquad [2]$$

Next, if we assume that the viewing distance, d, is large relative to the distance between F and P, Δd, then we can assume that $\tan(\omega/2) \approx (\omega/2)$, $\tan(\theta/2) \approx (\theta/2)$, and $d \approx d + \Delta d$, where the angles are expressed in radians. Equations [1] and [2] can then be rearranged to reduce approximately to

$$\eta \approx \frac{\text{io}d\Delta d}{d^2} \qquad [3]$$

In this example, point P lies beyond the fixation point F. However, the computation of binocular disparity is the same for an object in front of the fixation point. Points in space with images that fall on corresponding points on the two retinas have zero disparity and are said to lie along the horopter (**Figure 3**).

In **Figure 3**, points F, L, and M have zero binocular disparity and lie on the horopter, while points P and C do not lie on the horopter and therefore do have binocular disparity. Point P lies beyond the fixation point and therefore its lines of sight do not cross in front of the horopter; it is said to have uncrossed disparity. The lines of sight for point C do cross in front of the fixation point, and therefore have crossed disparity. Points with zero disparity are fused by the visual system such that we perceive a single image. However, points still appear fused as long as the disparity does not exceed a certain limit, which is known as Panum's fusional area. Panum's fusional area is illustrated in **Figure 4** as the shaded zone on either side of the horopter. Even though points within the fusional area are seen as one, their disparity creates an impression of depth. Points with a disparity greater than the fusion limit appear double or diplopic and we see that, up to a certain limit, diplopic points also produce a percept of depth.

From the geometry outlined here, it is clear that the critical information for stereopsis is the distance of an object relative to the fixation point, not relative to the

Figure 1 A stereoscopic image pair taken with two cameras. Right eye view on the left, left eye view on the right. To view, cross your eyes, until the two squares align, and focus on the middle image. Courtesy of Zeb Hodge, as posted on Flickr.

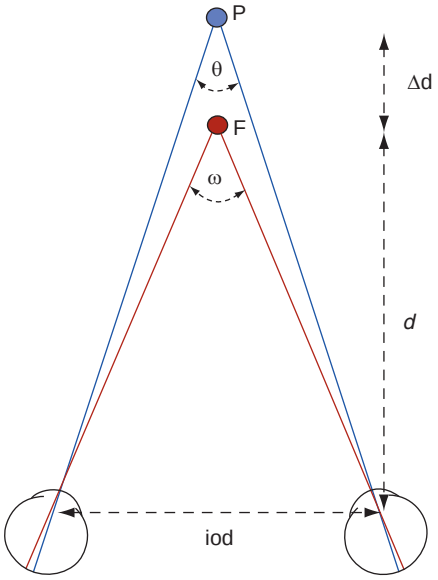

Figure 2 The geometry of binocular disparity. The two eyes view a point P while fixating point F, at distance *d* from the observer. The distance between F and P is given by Δd and the interocular distance is iod. Angles ω and θ give the angular subtense of points F and P, respectively.

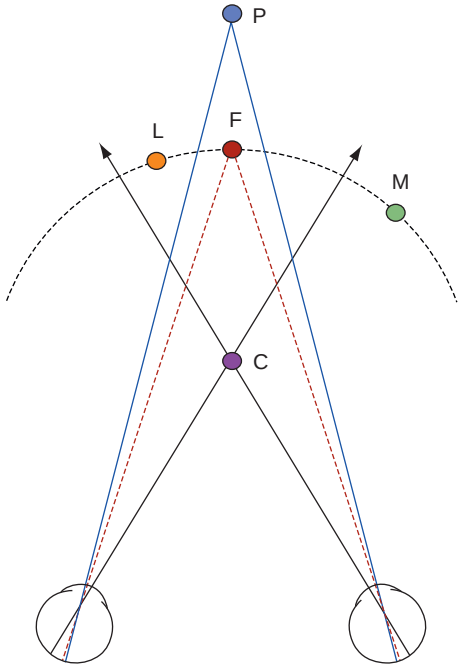

Figure 3 The horopter and crossed vs. uncrossed disparities. The horopter is the set of points having zero binocular disparity, given by the dotted arc passing through the fixation point, F. In this example, L and M lie on the horopter while P (with uncrossed disparity) and C (with crossed disparity) do not.

observer. Thus, in Figure 3, point C has a larger disparity than P (though of opposite sign), even though C is closer to the observer. There is an extensive literature on the concept of the horopter, and the coordinate systems for binocular stereopsis. Ian Howard and Brian Rogers provide a more complete account in their excellent review of binocular vision and stereopsis.

Stereograms and Binocular Viewing

The study of binocular vision has a long history extending back to Euclid's *Optics*, written in 300 BC, and in the neglected writings of Alhazen (AD 965–1040). However, it was only 150 years ago when Sir Charles Wheatstone discovered the link between the geometry of binocular vision and depth perception. Wheatstone invented the stereoscope which uses a pair of mirrors set at right angles to present pictures separately to the two eyes (stereograms). When pictures of the same object or scene taken from different vantage points are viewed in the stereoscope, the observer obtains a compelling view of space and volume (Figure 5).

Wheatstone's invention of the stereoscope inaugurated the empirical study of stereoscopic vision. While considerable research has since been devoted to this topic, the

study of how binocular information is extracted by the brain, and then interpreted to provide an extremely precise estimate of relative depth, remains a fascinating puzzle. In the remainder of this article we review how stereopsis is currently assessed, when it excels and fails, and describe the neural mechanisms that support it.

Classic Stereograms

There are two main types of stereoscopic stimuli used by researchers today. What have traditionally been referred to as local stimuli consist of isolated single targets presented relative to a reference point or frame. Much like the examples used by Wheatstone in his original paper, the monocular form, or structure, of the stimulus is obvious, although the direction of the disparity and depth relationships may not be. Even simpler line patterns (**Figure 6**) have often been used by scientists to investigate the fundamental properties of human stereopsis.

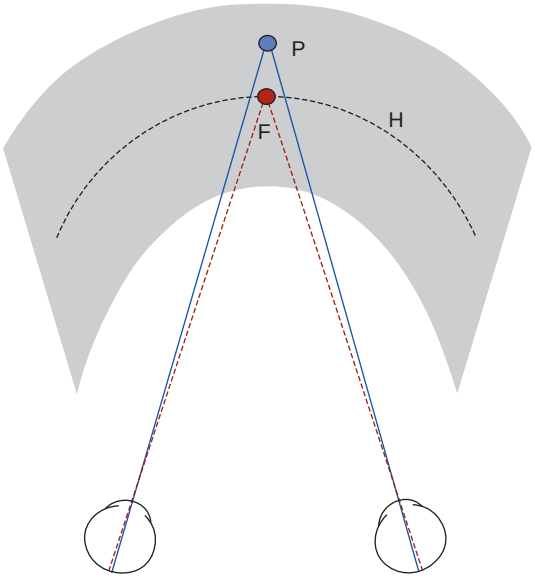

Figure 4 Panum's fusional area is illustrated here in gray. Within this region (exaggerated here for purpose of exposition) points such as P, which lie off the horopter, H, have binocular disparity but are seen as single and in depth relative to the fixation point, F.

Random-Dot Stereograms

In the early 1960s, while working at Bell Laboratories, Bela Julesz created computer-generated random-dot stereograms (RDSs), stimuli that were to have far-reaching effects on the study of stereopsis. To generate an RDS, a pattern of random elements is produced and duplicated to provide a pair of images, one for each eye. A selected region of elements is shifted in equal and opposite directions in the two patterns. This procedure overwrites elements on one side, and leaves empty spaces on the other, in both images. The empty spaces are then filled with samples of the random pattern. When viewed in a stereoscope, the shifted region appears to float (or recede) in depth, by an amount proportional to the size of the lateral shift (**Figure 7**). Julesz used the RDS to highlight the problem of how the human visual system correctly matches the images in the two eyes, an issue which became known as the binocular correspondence problem. Julesz's RDS took this problem to its extreme by providing hundreds of identical dots in the two eyes, any of which could be matched with any other dot when viewed stereoscopically.

Julesz and others suggested that the brain's strategy to solve this problem is to correlate small regions of the retinal images to identify corresponding areas. Julesz noted that the correlated area would have to scale in size with the amount of disparity in the image (called the size-disparity correlation). While there is still some debate as to how the size of the required correlation region can be estimated prior to knowing the binocular

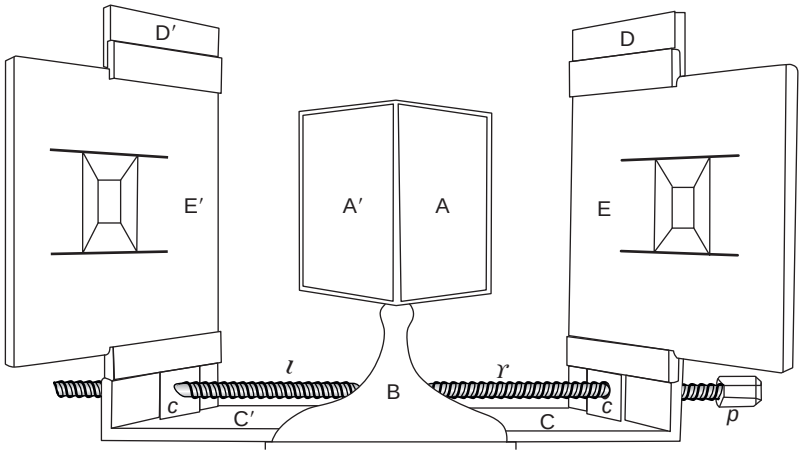

Figure 5 Wheatstone's diagram of his stereoscope as published in 1838. A′ and A are mirrors, which reflect images of the stereo pair (E′, E) separately to the two eyes. The same principle is used in laboratories today.

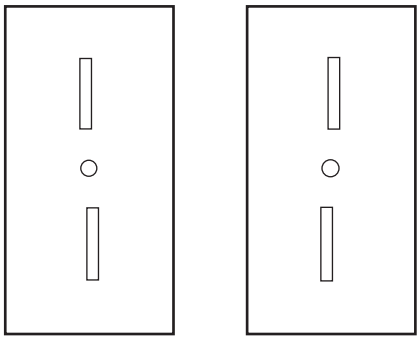

Figure 6 A simple line stereogram. By cross-fusing (left image to right eye, right image to left eye) the two dark frames and the central dot, the relative depth of the unfilled bars become apparent. The upper bar should appear closer to the observer than the central dot and frame, while the lower bar should appear further away.

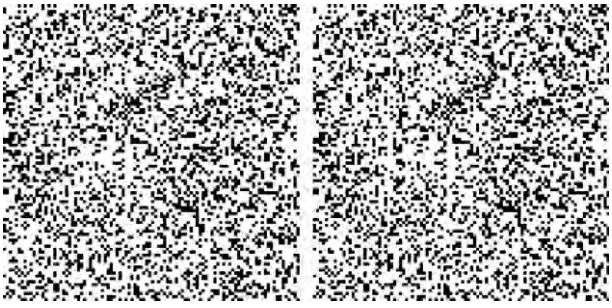

Figure 7 A random-dot stereogram image similar to that presented by Julez in 1964. By cross-fusing this stereo pair, one can observe a central square region displaced in depth in front of the surrounding region.

disparity, this approach remains the first step for many computational models of stereopsis. The concurrent introduction of the RDS and growth of the field of computational vision was responsible for new directions in the study and computational modeling of stereopsis as exemplified by David Marr.

Although Julesz's demonstrations prove that we solve the correspondence problem, other work has shown that we do not appear to use each element in the display as an independent depth sample. Julie Harris and Andrew Parker measured the efficiency of stereopsis by adding binocular disparity noise to a stereogram and comparing human depth judgments with those of an ideal detector that correctly extracted the disparity of each element. Human efficiency was very low, particularly when observers viewed displays with jagged, rather than smooth, depth profiles. This suggests that although we experience highly stable percepts of scenes in depth, only a small proportion of the available disparity information is actually used.

Prior to Julesz's introduction of the RDS, Gestalt psychologists believed that the percept of depth in stereograms followed the internal creation of two forms, or Gestalten, that then resulted in a percept of depth. Julesz recognized immediately that since no coherent monocular form is visible in either of the random-dot images prior to fusion into a cyclopean percept, his stereograms provide strong proof against the Gestalt interpretation of stereopsis. To summarize, there are several important consequences in the introduction of RDSs to vision science including:

1. The robust depth percepts obtained from RDSs suggest that there must be a neural mechanism which is able to resolve the ambiguous matches inherent in binocularly camouflaged stimuli, without relying on higher level interpretation of form.
2. The RDSs lead to the creation of simple, easy to apply, clinical tests of stereopsis in which monocular form or disparities could not be used instead of stereoscopic depth.
3. The ambiguous nature of RDSs highlighted the correspondence problem, and the need to understand the constraints on binocular matching, which gave rise to computational models of stereopsis.

The Empirical Study of Stereopsis: Thresholds and Upper Limits

Stereoacuity

Stereoacuity is defined as the smallest binocular disparity that can reliably be discriminated. While fixating a reference stimulus, the observer indicates if a target stimulus is closer or further away from the fixation stimulus. Several different psychophysical procedures may be used, but in all the disparity of the target is varied so the experimenter can assess the stereothreshold (typically defined as 75% correct). Under ideal conditions, the stereoacuity threshold tends to range from 2 to 6 s of arc, less than the width of a human hair held at an arm's length. Ideal stimuli are of high contrast, with sharp edges, and viewed at approximately an arm's length; however, the following variables dramatically influence stereoacuity.

Contrast

It is well established that stereoacuity for luminance-defined stimuli depends on stimulus contrast, or the relative intensity of dark and light regions in an image. Stereoscopic thresholds increase substantially at very low contrasts (near the contrast threshold for stereopsis) but this effect plateaus at higher contrasts where the stimuli are clearly visible. At high contrasts, stereoacuity is influenced more by the interocular contrast ratio than the overall binocular contrast, an effect that is also contingent on the spatial frequency content of the stimulus.

Spatial frequency/size

Spatial frequency is a mathematical term describing the amount of detail in a scene and, formally, any scene can be

divided into a set of constituent sinuosoidal waveforms of different frequencies. A high-frequency sinusoid is one with lots of narrow stripes, whereas a low-frequency sinusoid has only a few broad stripes. Much of the research on human stereopsis in the later part of the twentieth century has been based by a model of visual processing as a form of linear systems analysis, proposed by Fergus Campbell and John Robson in 1968. Thus, the receptive fields of cortical neurons were often discussed in terms of their preferred spatial frequency, and it was widely held that the visual system processed information through a series of spatial frequency-tuned channels. In accordance with this, there have been numerous psychophysical investigations of stereoacuity as a function of the frequency of sinusoidal luminance variations. Experiments have shown that stereoacuity improves with increasing spatial frequency in periodic (striped) stimuli up to 2.4 cycles per degree (c/deg), at which point performance flattens. However, in studies in which the stimulus size was scaled with changing frequency, improvements were found up to 5 c/deg.

Modulation frequency

While luminance-defined spatial frequency may be important for many visual functions, stereopsis has another dimension, and it stands to reason that there may be detectors that are tuned to the depth modulation frequency of a scene. For example, an egg provides a smooth change in disparity and contains a low modulation frequency, while a leafy tree contains many regions of rapidly changing disparity and therefore a high modulation frequency. Christopher Tyler created RDS patterns that contained random luminance variations but, when fused, appeared to modulate smoothly in depth. The frequency of the modulation could be manipulated, and stereoacuity measured, to provide an estimate of a modulation frequency transfer function (MTF) for disparity, independent of luminance frequency. The data from such cyclopean patterns show much lower peak sensitivity than reported for luminance frequency, near 0.4 c/deg.

Duration

Stereoacuity for luminance-defined stimuli shows a clear dependence on exposure duration, with thresholds improving with increasing duration up to a full second. As we observe from the next section, this dependence on viewing time is specific to luminance-defined stimuli such as bars, or dots, presented at small disparities. Investigators have suggested that such performance reflects the operation of a slow, sustained stereoscopic mechanism, which responds best to small disparities.

Configuration

An often-overlooked attribute that influences disparity processing is the configuration of the parts of the stereogram. Consider the work of Suzanne McKee, who showed in 1983 that stereoacuity for a pair of thin vertical lines was dramatically altered by the addition of two horizontal lines to form a box. As shown in **Figure 8** below, even the addition of a single line connecting the vertical lines, results in a large threshold increase. In all cases the observer is asked to judge the relative depth of the two vertical lines. In **Figure 8(a)**, the lines are unattached and thresholds are low. The addition of a single connecting horizontal line in **Figure 8(b)** increases thresholds by a factor of 4. The addition of two horizontal lines forming closed **Figures 8(c)** and **8(d)** further degrade performance. As shown in **Figure 8(e)**, the horizontal connectors need to only imply a cohesive figure to cause a doubling of the threshold.

Such effects are difficult to account for based on low-level information alone. Instead, it appears that even though the original disparity signal is present in the box configuration, the stereoscopic system is unable to make use of it with the same precision because the two parts now belong to a single figure. There is other evidence of mid-level configural effects on perceived depth via stereopsis, for instance, the perception of shape in biological motion figures influences observers' ability to discriminate the length of body parts as they receded in depth. These phenomena show that the perceptual grouping of parts into a whole can degrade our ability to make simple depth discrimination judgments, and demonstrate that the extraction of binocular disparity is the first stage of a complex process that extracts the depth and shape of objects around us.

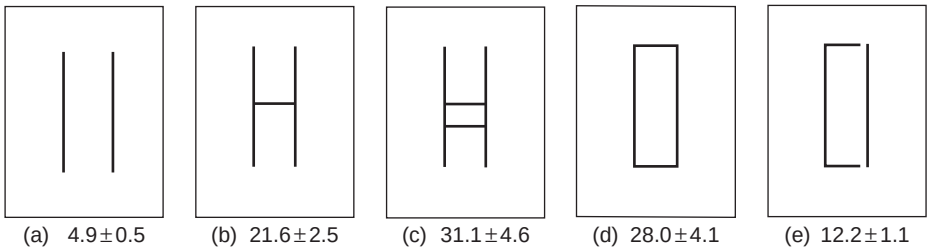

Figure 8 Stimuli adapted from, and thresholds (in seconds of arc) reported by Suzanne McKee in 1983. In each instance the two vertical lines are displaced in depth to assess stereoacuity and are identical in all conditions (a–e).

Stereopsis at Large Disparities

As described above (**Figure 4**), the stereoscopic system processes disparity information over a wide range of disparities at which, depending on the nature of the stimulus, the image may appear either fused or diplopic. On the horopter there is no binocular disparity between a point and the fixation location, therefore the point is perceived as equidistant with fixation. As disparity is increased, the point is perceived at different locations in depth relative to fixation, with perceived depth increasing with increasing disparity. Within Panum's fusional area, the disparate object appears single, fused, and in depth. At some point, as disparity continues to increase, fusion will be lost and the object will become diplopic or doubled. Surprisingly, as Kenneth Ogle documented in 1952, the percept of relative depth is not lost at the diplopia point. Instead, there remains a compelling sense of depth over a large range of disparities until, for very large disparities, the now diplopic object appears to return to the fixation plane. The disparity at which the percept of depth is lost is called the upper disparity limit. Ogle categorized the high-resolution range of disparities, which provides good relative depth information, as patent stereopsis; this range of disparities extends beyond the fusion limit. At some point, as disparity is increased, the quality of the depth percept changes and we are no longer able to judge the amount of depth, but simply have a sensation of the direction of the depth offset. Ogle named this latter range as qualitative stereopsis.

Spatial frequency/size

We have not included specific disparity estimates at which the upper limit for stereopsis occurs, for research has shown that this limit (D_{max}) depends critically upon the size of the stimulus, with larger D_{max} obtained for wider stimuli. Laurie Wilcox and Robert Hess demonstrated that for Gabor stimuli (a luminance sinusoid enveloped by a Gaussian distribution), the size of the Gaussian envelope is the only attribute that influences D_{max}; changing the center spatial frequency of the Gabors (the width of the stripes in the pattern) has no effect on the upper limit. They concluded that depth percepts from diplopic targets are mediated by the second-order, or envelope-based system, which is insensitive to the luminance-defined detail within a stimulus.

Duration

High-resolution stereoacuity judgments for edges and lines improve with increasing viewing time. Quite a different pattern of results is emerging for stimuli that access a more coarse stereoscopic mechanism (second order or qualitative stereopsis). In such cases, it appears that the stereoscopic system is more transient and, so as proposed by Mark Edwards and colleagues, operates best when the viewing time is brief, less than 200 ms. Recent work has shown that for this type of stimulus, increasing the viewing time over 50 ms results in no improvement in performance; but results in, if anything, performance decline.

Similarity

There is evidence suggesting that depth percepts for diplopic stimuli are robust to large interocular stimulus differences. Donald Mitchell and Gerald Westheimer used diplopic stereopairs containing, for example, a circle in one eye and a cross in the other and measured depth discrimination. Similar resilience of stereopsis to the dissimilarity of the stimuli in the two eyes has been reported by a number of investigators, who have shown that depth perception for large disparities is not significantly influenced by interocular differences in contrast, or orientation.

The Mechanisms of Fine and Coarse Disparity Processing

As is evident from the preceding sections, there are some substantial differences in the processing of fine- and large-scale disparity information, particularly when the large disparities are outside the fusion range. There have been a number of attempts to capture these differences and use them to categorize stereopsis. For instance, Ogle argued that the range of disparities that can be used to make quantitative depth estimates involve patent stereopsis, and the binocular disparities that give rise to a more vague percept of depth involve qualitative stereopsis. Importantly, Ogle's limits are contingent on the scale of the line stimuli used to make the measurements, so they will change as stimulus size is varied. The sustained or transient stereopsis distinction mentioned above appears to be based solely on the temporal properties of stimuli. However, the link between the transient process and large disparities suggests the existence of separate coarse and fine mechanisms that have different temporal properties. This proposal is consistent with the series of experiments by Wilcox and Hess describing first- and second-order stereoscopic mechanisms. The current consensus is that stereopsis has a high-resolution system that is sensitive to luminance changes in an image. This is the classic stereoscopic mechanism studied since Wheatstone's invention of the stereoscope. The second-order system is sensitive to contrast variation, and so is able to abstract over the fine detail in an image to provide a disparity signal for an object as a whole. This mechanism is most similar to Ogle's qualitative stereopsis, and is likely responsible for many of the puzzling results in the literature of stereopsis from dissimilar stimuli.

The Depth of Moving Objects

The details of stereoscopic vision described up to this point have been restricted to static stereoscopic images. However, very often in the natural world objects are in motion, and we must determine their positions in the world as they move in depth. When an object moves in depth, its binocular disparity changes with respect to the stationary background. In principle, the mechanisms that underlie binocular disparity processing could be used to detect motion in depth, if the change in depth is then monitored across time. But there is another potential source of binocular visual information. When a point moves directly toward an observer, the retinal image of that point moves over the left retina in a leftwards direction and moves rightwards on the right retina. If the visual systems were to first use monocular motion-sensitive mechanisms to detect the motion, and then use a binocular mechanism to compare those motion signals, motion in depth could be detected without the explicit use of disparity detectors. Using a dynamic random-dot stereogram (DRDS) that contains no consistent monocular motion information, Julesz showed that the former information, from changing binocular disparity, supports the perception of motion in depth. More recently, visual stimuli have been designed to isolate the motion information. In a time-correlated random-dot stereogram (TCRDS), each eye views consistent leftwards or rightwards motion but, point for point, there is no consistent binocular disparity information. As discussed by Harris and colleagues in their recent review of this topic, currently there is much debate in the literature about which source of information is used, and when. Motion in depth does appear to be perceived in a TCRDS, at least for some observers, yet thresholds for detecting the minimum amount of motion in depth are not improved by the addition of consistent motions to a DRDS stimulus. Further, there is a correlation between static stereoacuity and acuity for motion in depth, suggesting a crucial role for disparity detectors. A very small number of studies have demonstrated that some observers, who cannot see changing disparity in a DRDS (some with misaligned eyes, and some with no history of ocular problems), can instead use the motion information provided by a TCRDS. This suggests that there may be two separable binocular mechanisms for detecting motion in depth: one that relies on changing disparity and another that uses monocular motion signals. It appears that, when present, the changing disparity information is the default signal used by most observers.

The Neural Basis of Stereopsis

Nonhuman Animal Studies

Our understanding of the neural basis of stereopsis has grown exponentially since David Hubel and Torsten Wiesel's Nobel-prize winning work in the 1960s and Horace Barlow's studies of disparity selective neurons in 1967. These investigators were the first to record responses of binocular neurons in the cat visual cortex, and laid the foundation for subsequent work on the neural underpinnings of stereopsis. Subsequently, Gian Poggio and David Ferster showed that disparity-tuned neurons exist in cortical areas V1 and V2 of the monkey and that further, they could be classified according to their response properties as tuned excitatory, tuned inhibitory, and near and far. Tuned neurons have response properties consistent with high-resolution depth judgments, while the near and far cells provide a more coarse disparity signal, and respond over a larger range of disparities. The link between neural disparity detectors, and the percept of depth was firmly established when Blake and Hirsch conducted experiments in which cats were raised with alternating monocular deprivation. They showed that:

1. Binocularly deprived cats, while visually normal on monocular tasks, had no stereopsis. This makes the link between perception and the cortical effects of deprivation.
2. Animals that viewed the world monocularly alone did not develop binocular neurons; hence simultaneous binocular input is critical to the normal development of binocular neurons.

Based on such deprivation experiments, it is clear that disparity detectors are the basis for perception of depth through stereopsis. Electrophysiological studies from the late 1970s onward have revealed much about the neural coding of stereopsis. For instance, Bruce Cumming and Andrew Parker have demonstrated that neurons in primary visual cortex respond to anticorrelated RDS patterns, that is, RDSs with a zero-disparity region defined by identical dots in the two eyes surrounding a region of elements that have the opposite contrast (black vs. white) in the two eyes. Human observers do not see consistent depth in the anticorrelated region, but some V1 neurons respond reliably to these stimuli. This suggests that the primary visual cortex codes disparity but this signal is not sufficient to support our perception of depth. However, cells in the V2 area are specifically sensitive to correlated RDSs. Recent electrophysiological experiments strongly indicate that extrastriate cortical areas (beyond V1) respond to different patterns of binocular disparity. For example, investigators have shown that disparity tuning is a dominant attribute of medial temporal (MT) neurons, which traditionally have been cast as motion-sensitive units. In a recent study, Takanori Uka and Greg DeAngelis used electrical stimulation of neurons in monkey MT region to bias their near or far response to a stereoscopic stimulus. Note that, this result was obtained for coarse disparity-tuned neurons, but not for fine. In the inferotemporal cortex (IT), which is well known for its role in coding

faces and complex forms, researchers have identified neurons that respond to the three-dimensional (3D) shape (i.e., convex vs. concave) of disparity-defined surfaces. There is ongoing debate regarding the implications of the widespread presence of disparity selectivity throughout cerebral cortex. One possibility is that disparity processing occurs for different purposes along separate pathways in the visual system. Along the dorsal pathway, which includes MT, there may be specialization for coarse disparity processing, which is useful for the guidance of vergence eye movements. Along the ventral pathway, which involves V2 and IT, higher-resolution disparity signals are combined to provide precise estimates of shape and location. This proposal is the focus of much of the ongoing electrophysiological research on stereopsis.

Brain Imaging in Humans

Human functional magnetic resonance imaging (fMRI) experiments have mirrored electrophysiological studies in showing that stereoscopic stimuli activate most, if not all, of the visual areas of the cerebral cortex. The important factors in isolating specific regions are, not surprisingly, the nature of the stimulus (e.g., correlated vs. anticorrelated RDS patterns) and the task. For example, in the first systematic fMRI study of the cortical areas involved in human stereopsis, Benjamin Backus and colleagues found elevated activity in area V3A when observers were asked to make depth discrimination judgments, instead of passively viewing stereoscopic stimuli. In the past 10 years, fMRI research on human stereopsis has flourished, and for the most part appears to map well onto the electrophysiological data. The field of fMRI is advancing, and investigations of stereopsis are moving from identification of where it occurs to how it occurs. For instance, Andrew Welchman and colleagues recently used fMRI to examine the visual areas in which stereoscopic information is combined with other depth cues, and how the combination process is reflected in the variance of the scanning signal.

Conclusion

Since Wheatstone's introduction of the stereoscope in 1838, we have all enjoyed stereograms of one form or another. From the impressive large-format three-dimensional (3D) movies shown in IMAX theaters to the Magic Eye books, there is a quality of magic in the experience of depth from stereopsis. Scientists too have that sense of wonder that the simple physical fact of having two simultaneous views of the world results in such a vivid sense of the space between and taken up by objects in the world. Our goal is to understand how the brain achieves this feat. Although we are making considerable progress, several questions remain unanswered, including: What types of neural pathways are responsible for stereopsis? How is stereoscopic information integrated with other cues to depth? How does the stereoscopic system represent extended surfaces in depth?

G

GABA Receptors in the Retina

S Yazulla, Stony Brook University, Stony Brook, NY, USA

Glossary

Disinhibition – A synaptic interaction in which the inhibitory input to a neuron is itself inhibited, thereby relieving the neuron of inhibitory control.
Endocannabinoids – Natural chemicals in the body whose actions on metabotropic cannabinoid receptors are mimicked by the active component of marijuana.
Ionotropic receptors – Membrane proteins that, when activated by specific ligands, directly alter membrane conductance.
IPSC – Inhibitory post synaptic current counteracts excitatory input to a neuron, for example by hyperpolarization or induction of a shunt current.
Metabotropic receptors – Membrane proteins that, when activated by specific ligands, indirectly alter a wide variety of cellular properties through G-protein-coupled enzyme cascades.

Introduction

Gamma-aminobutyric acid (GABA) is the major inhibitory amino acid transmitter in the retina. It is overwhelmingly represented in lateral inhibition, being most prominent in one class of horizontal cell and in numerous subtypes of amacrine cell. GABAergic transmission requires the synthesizing enzyme glutamic acid decarboxylase (GAD) and the degradative enzyme GABA transaminase (GABA-T) that may or may not be found in the same cells. The physiological actions of GABA are effected by receptors that may be broadly defined as proteins that bind to and respond to the presence of GABA. Under this scheme, there are three functional types of GABA receptor: (1) a vesicular transporter that concentrates cytoplasmic GABA into synaptic vesicles, (2) a membrane transporter that translocates GABA from the extracellular space into glia or neurons, and (3) plasma membrane receptors that mediate the cell's response to synaptically released GABA. This article highlights the properties and functions of these major types of the GABA receptor. Numerous sources on the history, physiology, and molecular biology of these receptor types are provided. Table 1 illustrates the major types of the GABA receptor with representative agonists, antagonists, and most common cellular locations in the outer plexiform layer (OPL) and inner plexiform layer (IPL). The pharmacology of GABA transporters (GATs) is less well developed than it is for the synaptic receptors and continues to be an area of intensive research.

Vesicular Transporters

Cytoplasmic GABA is concentrated into synaptic vesicles by a vesicular inhibitory amino acid transporter (VIAAT) that uses H^+-antiport activity to drive the uptake of GABA or glycine into synaptic vesicles. VIAAT is the only member of the solute carrier 32 (SLC32) family of H^+-coupled amino acid transporters; it is not related to the vesicular transporters for glutamate, monoamines, or acetylcholine. VIAAT, referred to as the vesicular GAT (VGAT), when applied to GABAergic neurons, is essential for the vesicular release of GABA and glycine. The existence of a common vesicular transporter for GABA and glycine is consistent with reports of a small percentage of amacrine cells that co-localize and likely release both GABA and glycine.

VIAAT was localized by immunohistochemistry (IHC) in zebrafish, mouse, rat, cat, and human retinas. In the inner retina, synaptic boutons throughout all layers of the IPL contain VIAAT immunoreactivity (IR), consistent with data showing that virtually all amacrine cells in the retina are either GABAergic or glycinergic. Data from salamander, cat, and human suggest the existence of

Table 1 GABA receptor types, agonists, antagonists, and localization in the retina

Synaptic receptors		*Agonist*	*Antagonist*	*Location OPL*	*Location IPL*
	$GABA_A$	Muscimol	Bicuculline	Cones	Amacrine cells
		Isoguavacine	Picrotoxin	Horizontal cells	Cone bipolar cells
		THIP	SR 95531	Bipolar cells	Ganglion cells
		TACA			Mueller's Cells
	α1–3,5$\beta\gamma$2 subunits	Benzodiazapines	Flumazenil	Horizontal cells	Amacrine and ganglion cells
	$GABA_B$	(R)-Baclofen	CGP 35348		Presynatic amacrine
		SKF 9751	SCH 50911		Postsynaptic ganglion
	$GABA_C$	TACA	Picrotoxin	Cones	Rod bipolar cells (mammals)
		CACA (partial)	Isoguavacine		Mixed bipolar cells (fish)
		Muscimol (partial)	TPMPA		
Transporter (plasma)		Uptake substrate	Uptake inhibitor		
	GAT-1	GABA	Cl 966		Amacrine cells (major)
			NO 711		Mueller's cells (minor)
			(R)-tiagabine		
			SKF 89976A		
	GAT-2	GABA	EF1502	Horizontal cells (fish)	
		β-Alanine	Nipecotic Acid		
	GAT-3	GABA	Nipecotic Acid	Horizontal cells (fish)	Mueller's cells
		β-Alanine	(S)-SNAP 5114		
	BGT-1	GABA	(S)-SNAP 5114		
		Betaine			
Transporter (vesicular)	VIAAT (VGAT)	GABA	Vigabatrin	Horizontal cells	Amacrine cells
			Nipecotic Acid		Bipolar cells (subset)

This listing is representative and not meant to be exhaustive regarding GABA receptor pharmacology. The most common sites for localization are listed to provide a general framework. Species-specific exceptions are listed in the text.

subpopulations of bipolar cells that likely release both GABA and glutamate. For example, certain OFF cone bipolar cells in the cat retina contain not only VIAAT-IR and GAD65-IR, but also vesicular glutamate transporter-IR (VGLUT-IR). In the outer retina, VIAAT-IR is present in horizontal cell dendrites in zebrafish, mouse, rat, and human. The presence of $GABA_A$ receptors on the photoreceptor terminals of some mammals supports the notion that GABA is synaptically released in the OPL. VIAAT-IR in the OPL most likely includes not only the horizontal cell dendrites, but also the boutons of GABAergic and glycinergic interplexiform cells. These processes, however, have a relatively low density and are unlikely to be confused with the more numerous horizontal cell dendrites. Electron microscopy shows that VIAAT-immunoreactive horizontal cell dendrites innervate rods and cones in mouse and rat, suggesting that A-type and B-type horizontal cells of the mammalian retina are capable of vesicular GABA release. In fish horizontal cells, the subcellular localization of VIAAT-IR has not been determined by electron microscopy; there are no data to indicate whether VIAAT-IR is restricted to the H1 GABAergic horizontal cells, innervating only cones, or distributed among all four types, innervating both rods and cones.

In the outer retina of mammals and nonmammals, the classification of neurons as GABAergic can be difficult. The presence of VIAAT alone does not necessarily indicate the presence of GABA for vesicular release. Other indicators, such as the presence of glutamate decarboxylase (GAD), the enzyme that catalyzes decarboxylation of glutamate to form GABA, or GABA uptake, are needed to support a GABAergic identity. For example, in most nonmammalian species, VIAAT-positive horizontal cell dendrites do not contain synaptic vesicles or synaptic specializations. Rather, a sodium-dependent GAT appears to facilitate GABA release from horizontal cells. To complicate matters further, the presence of GABA or GAD in an outer retinal neuron does not necessarily stipulate that GABA is synaptically released. For example, although GAD-IR and GABA-IR have been found in cone terminals in primate, lizard, and toad retinas, VIAAT-IR has not been localized to photoreceptor terminals in any species. Lastly, although horizontal cells of some mammals

contain VIAAT-IR, GABA-IR, and GAD-IR, neither GABA uptake nor GATs have been described in the horizontal cells of any mammal.

Plasma Membrane Transporters

GATs are members of the SLC6 family that belongs to the Na^+/Cl^--dependent neurotransmitter transporter superfamily. GATs are arranged in 12 transmembrane domains. Molecular cloning studies identified three subtypes of high-affinity GAT (GAT-1, GAT-2, and GAT-3) and one lower-affinity betaine/glycine transporter that also transports GABA (BGT-1). GATs are responsible for the clearance of GABA from the extracellular space and, conceivably, could be present on the presynaptic neuron, postsynaptic neuron, or surrounding glia. In general, GAT-1 is present in neurons of the inner retina, GAT-3 in Müller's cells, and GAT-2 in the retinal pigmented epithelium (RPE) and ciliary epithelium of the mammalian retina (Figure 1). Overall, there is excellent agreement in the cellular distributions of ^{3}H-GABA uptake, GABA-T, which degrades GABA, and GATs in amacrine cells across species. However, in regard to horizontal cells and Müller's cells, there are notable species differences and inconsistencies.

Neuronal Localization

In a wide variety of mammals and nonmammals, from humans to teleost fish, GAT-1 is the predominant GAT/type in amacrine cells, displaced amacrine cells, and interplexiform cells. This distribution is consistent with the patterns of GAD-IR, GABA-IR, and ^{3}H-GABA uptake. Mammalian Müller's cells are labeled intensely with GAT-3 and, to a lesser extent, by GAT-1, consistent with observations that Müller's cells contain high levels of GABA-T and are the initial site for ^{3}H-GABA uptake. For the most part, nonmammalian Müller's cells neither take up ^{3}H-GABA nor display GAD-IR or GABA-IR. One exception is the skate retina, in which Müller's cells express GAT-1 and GAT-3, display a GAT current, and take up ^{3}H-GABA. Another exception is the salmon retina, in which Müller's cells have GABA-IR, but do not contain GAT-1. Cultured chick Müller's cells contain GAT-1 and GAT-3, while bullfrog Müller's cells contain GAT-1 and GAT-2 and display a GAT current. The implication of these findings in chick and bullfrog is not clear, given the absence of supporting evidence from ^{3}H-GABA uptake or GABA-T immunohistochemical studies. Given the high density of GAT on chick and bullfrog Müller's cells, including the end feet at the inner margin of the retina, it is surprising that ^{3}H-GABA uptake has never been demonstrated in Müller's cells of these species, regardless of how the ^{3}H-GABA was administered.

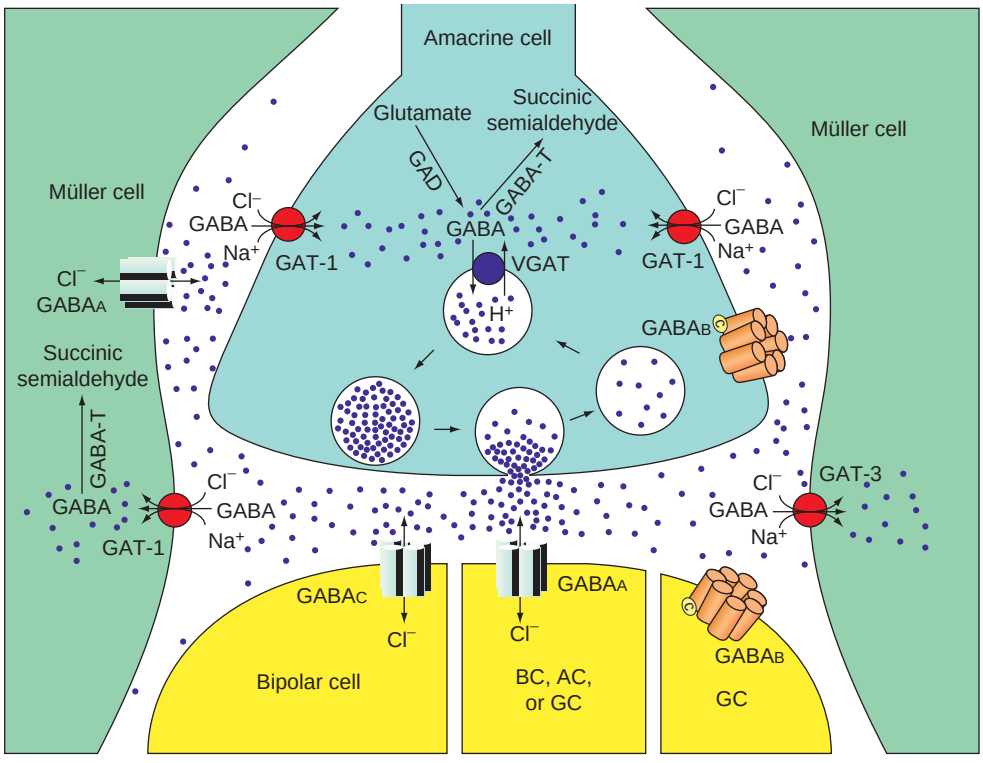

Figure 1 Schematic representation of GABA metabolism, receptor type, and localization in the inner retina. Receptor and transporter types have been placed in the most common locations. See text for details and listing of species-specific exceptions. GAD, glutamic acid decarboxylase; GABA-T, GABA transaminase; AC, amacrine cell; BC, bipolar cell; GC, ganglion cell.

Although horizontal cells in many mammals contain GABA-IR and GAD-IR, they do not take up ^{3}H-GABA. As would be expected, GATs have not been localized to any mammalian horizontal cells. The evidence for a class of GABAergic horizontal cell is overwhelming for nonmammals. Horizontal cells of fish, amphibians, birds, and reptiles take up ^{3}H-GABA with great avidity. GAT-1, present in the inner retina, has not been localized to horizontal cells of any species. Studies on the localization of GAT-2 and GAT-3 in nonmammalian horizontal cells are sporadic, with studies usually focusing on one or the other. Exceptions are goldfish and zebrafish in which GAT-2 and GAT-3 were localized to a subtype of the cone horizontal cell, the H1 luminosity type. GAT-3 was not found in horizontal cells of skate, salamander, or bullfrog. GAT-2, absent in bullfrog horizontal cells, was not studied in skate, salamander, or salmon.

Except for goldfish and zebrafish, the lack of horizontal cell labeling by GAT in other nonmammals could be due to the general use of antibodies against the C-terminus of rat GAT-2 and GAT-3. There is a strong homology in the GAT amino acid sequence in the animal kingdom. Torpedo GAT-3 shows a 77% identical amino acid sequence with the mammalian GAT-3. Immunoblots of the goldfish brain with GAT-3 show a band between 60 and 75 kDa, consistent with the expected weight of 71 kDa. However, regardless of the overall homology or the sequence homology at the C-terminus, the site of antibody production is more critical in determining the validity of the labeling. Except for fish, the negative finding of GAT-2 and GAT-3 on horizontal cells in nonmammals has not been resolved. A curiosity is that ^{3}H-muscimol, a $GABA_A$ agonist, is transported avidly by amacrine cells in mammals and nonmammals, but not to any great extent by horizontal cells in any species, including fish and bird. This is a further indication of the difference in the type of GAT present on amacrine cells and nonmammalian horizontal cells.

A small percentage (~10%) of bipolar cells in some retinas may be GABAergic. In salamander, the vast majority of bipolar cells that contain GAT-1-IR also contain GABA-IR, as well as VGAT and GAD. Two types of OFF bipolar cell in zebrafish contain GABA and likely correspond to the OFF bipolar cells that display a GAT current. However, in primate retina, the variable reports of GABA-IR in bipolar cells are not supported by data localizing GAD, GAT-1, GAT-2, GAT-3, or GABA-T. These findings are significant because of the possibility that some bipolar cells release GABA and glutamate as neurotransmitters.

A GABA/taurine transporter was identified in bullfrog at the apical surface of the RPE. It was suggested that the RPE could take over the clearance of GABA released from horizontal cells in the distal retina of nonmammals because there are no reports that Müller's cells transport ^{3}H-GABA. Despite the reports of GATs in bullfrog Müller's cells, this seems to be an attractive idea that would be supported by the demonstration of GABA-T localization and GABA-T activity in the nonmammalian RPE.

Function

The major function of the GATs is to clear GABA from the extracellular space to either re-enter the vesicular pool or enter the tricarboxylic acid cycle after GABA-T action (**Figure 1**). There are at least three other consequences of the transporter activity. The first is that GABA transport is electrogenic with two Na^{2+}, one Cl^-, and one GABA per cycle, resulting in one-net inward positive charge. The depolarization that accompanies GABA uptake could modulate neuronal excitability by triggering Ca^{2+} influx and the subsequent release of Ca^{2+} from intracellular stores. For example, a nonsubstrate blocker of GABA transport (NO-711) reduced cellular edema, presumably by blocking the ionic influx that accompanies GABA uptake. This strategy has proven useful in treating seizures and could apply to protecting retinal ganglion cells following ischemia or an excitotoxic release of glutamate from bipolar cells. As a second consequence of transporter activity, neuronal depolarization or a breakdown of the Na^+/Cl^-/GABA gradient can cause the GATs to operate in the reverse direction, thus releasing GABA. For example, an excitotoxic assault on the chick retina increases extracellular GABA by reversal of the GAT. This calcium-independent GABA release has been suggested to be the normal mode of release in horizontal cells, glia, and, perhaps, in starburst amacrine cells. This form of GABA release does not require adenosine triphosphate (ATP), except to maintain the ionic gradients. Third, the activity of GATs can limit the spillover of GABA in the extracellular space and regulate inhibition. This has been shown in the inner retina, in which inhibition of GATs by NO-711 enhances the light-evoked inhibitory postsynaptic currents (IPSCs) at $GABA_C$ receptors on bipolar cells, but has no effect on $GABA_A$ receptors on ganglion cells. The difference in response is due to the observation that $GABA_A$ receptors desensitize, whereas $GABA_C$ receptors do not. Thus, the GAT selectively modulated the transmission of signals from bipolar cells to ganglion cells. In all these cases, the effect of GAT activity is to regulate excitability.

Synaptic Receptors

There are three general classes of synaptic GABA receptors: two ionotropic and one metabotropic. These are differentiated by ligand-binding affinities and molecular-cloning techniques. $GABA_A$ receptors are heteropentameric structures that form a chloride channel using structurally related subunits α1–6, β1–4, γ1–3, δ, ε, and π. The most common pentamers are composed of $\alpha\beta\gamma$ subunits, with δ often substituting for γ. The subunit composition determines receptor pharmacology and kinetics.

For example, $GABA_A$ receptors mediate the effects of benzodiazepines (BDZ), and the γ subunit is necessary for BZD sensitivity, while the type of α subunit determines BZD affinity. The β subunit affects channel properties and BZD efficacy. Substitution of an α4 or α6 subunit for an α1 subunit eliminates BZD sensitivity as does substitution of the δ subunit for a γ subunit. $GABA_A$ receptors are blocked by bicuculline, the nonselective chloride channel blocker, picrotoxin, and can be modulated allosterically by barbiturates, BZDs, ethanol, and steroids. The action of the $GABA_A$ receptor tends to be phasic. The ionotropic $GABA_C$ receptor also is a chloride channel that is composed mostly of homoligomeric ρ subunits (ρ_1, ρ_2, and ρ_3). $GABA_C$ receptors are insensitive to bicuculline, more sensitive to GABA than $GABA_A$ receptors, and can also be blocked by picrotoxin. $GABA_C$ receptors do not desensitize; therefore, their effect is tonic. Metabotropic $GABA_B$ receptors are guanine nucleotide-binding protein-coupled receptors and regulate potassium or calcium channels. $GABA_B$ receptors are activated by baclofen, antagonized by phaclofen, insensitive to bicuculline and picrotoxin blockade, and less sensitive to GABA than $GABA_A$ receptors.

Photoreceptors

The source of GABA in the OPL of nonmammals is a type of horizontal cell, so-called H1 or luminosity cells. In mammals, GABA can be released from a type of interplexiform cell as well as from horizontal cells. $GABA_A$ receptors were localized to the OPL by *in vitro* autoradiography (ARG) of ^3H muscimol binding, $GABA_A$ receptor subunit-specific IHC, and single-cell electrophysiology. ^3H-BZD-binding sites were localized by *in vitro* ARG in the OPL of rat, monkey, and human, but were not present in the OPL of fish, salamander, or bird. There is evidence for $GABA_A$ receptors on rod terminals in goldfish and rat, and on the cone terminals in goldfish, tiger salamander, bullfrog, turtle, chicken, rat, mouse, pig, and cat. Most evidence shows β2/3 subunits on photoreceptor terminals. Data for α subunits are inconsistent, with negative results from *in situ* hybridization and positive results with IHC. In contrast to the localization of γ1 and γ2 subunits to salamander cone terminals by IHC, negative results with ^3H-BZD binding indicate an absence of γ subunits. This discrepancy could be due either to the nonspecific nature of IHC using antibodies that are not against salamander γ subunits or to low sensitivity of *in vitro* ARG using photoaffinity labeling of BZD ligands.

GABA-induced responses in cones of all species are reduced by bicuculline, indicating $GABA_A$ receptors. In addition, there is a component of GABA-induced responses in mammalian (pig and mouse) cones that is resistant to bicuculline, but sensitive to antagonists of $GABA_C$ receptors, indicating participation of $GABA_A$ and $GABA_C$ receptors. $GABA_C$ receptors have not been identified on photoreceptors in nonmammals as yet. In mouse, both $GABA_A$ and $GABA_C$ components of the response to GABA are potentiated by pentobarbital, suggesting heteromeric channels of $GABA_C$ ρ1 and $GABA_A$ receptor subunits. In bullfrog, $GABA_B$ receptors contribute to the GABA response along with $GABA_A$ receptors. GABAergic negative feedback onto cones is well established and involves a suppression of presynaptic Ca^{2+} currents. The function of GABA feedback onto photoreceptors is still controversial; it may have limited participation in the formation of the cone receptive field surround. More likely, the modulation of voltage-gated Ca^{2+} currents could set the gain at the cone synapse to maintain sensitivity to changing light conditions. The nondesensitizing nature of $GABA_C$ receptors on mammalian cones may compensate for the lower level of GABA release that is available from horizontal cells and interplexiform cells in the OPL of mammals compared to the high GABA content of H1 horizontal cells in nonmammals.

Horizontal Cells

The information regarding GABA receptors on horizontal cells is based primarily on data obtained with electrophysiology and, to a lesser extent, on immunohistochemical evidence. In addition, there is considerable species variability. $GABA_A$ and $GABA_B$ receptors have been localized by IHC on horizontal cells of some mammals and nonmammals, while $GABA_C$ receptors have been localized to horizontal cells of perch and goldfish. $GABA_B$ receptor-mediated responses have not been reported for horizontal cells in any species. $GABA_A$ responses have been recorded from horizontal cells in catfish, salamander, mouse, rabbit, and cat, while $GABA_C$ responses are prominent in horizontal cells in fish (goldfish, perch, and catfish) and salamander. Skate and zebrafish horizontal cells reportedly show neither $GABA_A$ nor $GABA_C$ responses. In goldfish, $GABA_A$ responses are present in isolated chromaticity horizontal cells, while $GABA_C$ responses are present in the cell body and axon terminal of the GABAergic H1 horizontal cells. In contrast, in perch, $GABA_C$ responses are restricted to the rod horizontal cells. The $GABA_A$ response in isolated mouse horizontal cells is enhanced by the BZD, diazepam, and pentobarbital, consistent with the localization of ^3H-BZD-binding sites in the mammalian OPL by ARG. $GABA_C$ receptor-mediated responses of GABAergic horizontal cells are complicated by the presence of the electrogenic GAT current. H1 horizontal cells release GABA at some steady rate under ambient illumination. They are depolarized by decrements in light intensity, resulting in increased GABA release by the transporter. During the hyperpolarizing response to light onset, the reuptake of GABA will depolarize the horizontal cells, reducing the light response and establishing a

positive-feedback loop that allows for further GABA release from the H1 horizontal cells. In turn, the released GABA, via $GABA_A$ receptors, will depolarize the other cone and rod horizontal cells. In addition, the $GABA_C$ response shows a run-up with repetitive application of GABA, further depolarizing the horizontal cells. However, $GABA_A$ and $GABA_C$ receptors are suppressed by Zn^{2+} that is co-released with glutamate. This dampening effect by Zn^{2+} is especially important to downregulate the tonic $GABA_C$ response.

Bipolar Cells

Bipolar cells form functionally diverse groups that are differentiated on the bases of rod and cone input as well as ON or OFF response. On anatomical grounds, bipolar cells can receive GABAergic input from horizontal cells and interplexiform cells in the OPL and from a multitude of amacrine cell types in the IPL. Species differences among mammals and nonmammals and the effects of dissociation techniques on GABA receptors have resulted in considerable variability in the data. However, $GABA_A$ receptors are generally more prominent on dendrites in the OPL and the ratio of $GABA_A$ to $GABA_C$ receptors on axon terminals in the IPL is high for cone bipolar cells and low for rod bipolar cells. In mammals, IR to $GABA_A$ receptors ($\alpha1$, $\beta2/3$, and $\gamma2$) and the $GABA_C$ ρ subunit is present at nonoverlapping, extrasynaptic sites on the dendrites of rod and cone bipolar cells. The contribution of $GABA_A$ and $GABA_C$ receptors to GABA-evoked IPSCs is balanced in dendrites of isolated mouse rod bipolar cells, whereas, in the ferret retinal slice, $GABA_A$ receptors overwhelmingly dominate the response to GABA puffed at dendrites in all types of the bipolar cell. Dendrites of bipolar cells are insensitive to GABA in salamander and display $GABA_A$ properties in goldfish and $GABA_C$ properties in zebrafish. In bullfrog, all bipolar cells show $GABA_A$ and $GABA_C$ sensitivity at dendrites, though $GABA_A$ receptors dominated, particularly for on bipolar cells.

In the IPL, GABA-evoked IPSCs are carried mostly by tonic $GABA_C$ receptors in rod bipolar cells and by phasic $GABA_A$ receptors in cone bipolar cells (**Figure 1**). This difference in GABA receptor type likely corresponds to the rapid kinetics of the photopic pathway and slower kinetics of the scotopic pathway. This is illustrated in the ferret retina in which activation of $GABA_C$ receptors more effectively inhibits the output to AII and A17 amacrine cells than $GABA_A$ receptors. When co-expressed ON bipolar cell axons, $GABA_A$ and $GABA_C$ receptors are differentially distributed. For example, in the ON mixed rod/cone bipolar cell of goldfish, $GABA_C$ receptors are clustered at the distal (vitreal) margin of the terminal, while $GABA_A$ receptors are more proximal to the cell body, near the connecting axon. Unlike the photoreceptors, there is a very high density of GABA receptors on glutamatergic bipolar cell terminals. Zn^{2+}, likely to be co-released with glutamate, suppresses the amplitude of responses mediated by $GABA_C$ receptors more so than $GABA_A$ receptors. The effects of zinc on the kinetics of $GABA_A$ receptors are variable and likely due to differences in $GABA_A$ subunit composition. The hyperpolarizing effect of GABA on all bipolar cells strongly inhibits glutamate release. This powerful inhibition is buffered by Zn^{2+} and other endogenous modulators including dopamine, neuropeptides, and endocannabinoids that control the transmission of signals to amacrine and ganglion cells.

Amacrine Cells and Ganglion Cells

At least two-thirds of the amacrine cells in all species utilize GABA as the primary neurotransmitter; GABAergic amacrine cells have additional secondary transmitters including acetylcholine, glycine, dopamine, and a wide selection of neuropeptides. Their processes are present in all layers of the IPL and they make extensive feedback contact with bipolar cells, serial contacts with other amacrine cells, and feed-forward contacts with ganglion cells. This makes for an inordinately complicated series of nested inhibitory circuits. In all species, $GABA_A$ receptors are expressed postsynaptically on amacrine cells and ganglion cells. $GABA_B$ receptors are located presynaptically on amacrine cells and postsynaptically on ganglion cells (**Figure 1**). $GABA_C$ receptors are found on ganglion cells in salamander, but apparently not in other species, and only rarely on amacrine cells. $GABA_A$ receptors on subtypes of GABA-receptive amacrine and ganglion cells are characterized by specific subunit compositions. Cholinergic amacrine cells are the only retinal neurons shown, as yet, to express the δ subunit, the presence of which should eliminate BZD sensitivity. The various α subunits aggregate at different synaptic sites. For example, the $\alpha2$ subunit is found on cholinergic amacrine cells, while the $\alpha4$ subunit is found on ganglion cells. Also, for the most part, $GABA_A$ receptors in the inner retina are enhanced by barbiturates and BZDs, indicating the presence of the γ subunit. In general, the effect of $GABA_A$ stimulation of amacrine cells is to suppress the transient component of the light response. The application of GABA tends to suppress the spontaneous activity and light responses of ganglion cells without having a great effect on the center-surround organization. However, $GABA_A$ antagonists abolish directional and orientation selectivity in ganglion cells, presumably by interacting with $GABA_A$ receptors on bipolar cells and other amacrine cells.

In general, the activation of $GABA_B$ receptors on amacrine cells and ganglion cells makes the light response more transient and reduces spike frequency in ganglion cells. In rabbit retina, baclofen facilitates the light-evoked release of ACh. $GABA_B$ receptors are found at limited but discrete locations on the dendrites of starburst and other

types of amacrine cells. A feedback circuit involving the disinhibition of glycine onto starburst amacrine cells could account for the facilitatory effect of baclofen. GABAergic modulation of ganglion cell activity involves a complicated interaction of the subtypes of $GABA_A$, $GABA_C$, and $GABA_B$ receptors that are present ON bipolar and amacrine cells and act on chloride channels and a variety of calcium channels. While $GABA_A$ influence is rapid in onset and offset and likely participates in phasic inhibition, $GABA_B$ and $GABA_C$ influences are slower and likely participate in tonic inhibition. As $GABA_B$ receptors are less sensitive to GABA than $GABA_A$ or $GABA_C$ receptors, their influence may be more prominent during excessive GABA release that could occur with intense stimulation or excitotoxic release of glutamate from bipolar cells.

Müller's Cells

In addition to expressing GATs, Müller's cells in skate, baboon, and human express $GABA_A$ receptors (**Figure 1**). GABA-evoked currents in skate and human Müller's cells show $GABA_A$ pharmacology, including enhancement by Zn^{2+} and, in human, enhancement by barbiturates and BZDs. In human, the $GABA_A$ response is depolarizing and sensitivity is higher at the endfoot, soma, and sclerad margin. The efflux of Cl^- in response to $GABA_A$ activation on Müller's cells could have a variety of consequences. For example, it could regulate extracellular Cl^- homeostasis following Cl^- influx into neuronal $GABA_A$ and $GABA_C$ receptors. It could also accelerate the clearance of extracellular GABA by stimulating uptake, which requires cotransport of Na^+ and Cl^-. This latter function could be critical given data in mouse showing that $GABA_A$ activation could play a role in ganglion cell death following oxidative stress. In rabbit, Müller's cells synthesize and release the diazepam-binding inhibitor (acyl coenzyme A-binding protein, ACBP) in response to protein kinase A activation, mimicking intense neuronal activity. ACBP binds to an α subunit to reduce the Cl^- current, and hence, the level of inhibition. The reduction of Cl^- influx could reduce the osmotic entry of water into neurons, thereby preventing cell swelling. Thus, in mammals at least, Müller's cells that extend across the thickness of the retina play a major role in regulating neuronal GABAergic transmission, with the additional consequence of maintaining extracellular ionic and osmotic balance.

Ganglion Cell Development: Early Steps/Fate

N L Brown, Cincinnati Children's Research Foundation, Cincinnati, OH, USA

Glossary

Atonal – Basic helix–loop–helix transcription factors involved in development. Atoh7, also called Ath5, is important in ganglion cell development.
Basic helix–loop–helix (bHLH) – A basic protein–DNA and helix–loop–helix protein–protein interaction domain found in some transcription factors.
Ganglion cell layer (GCL) – The innermost retinal cell layer, which contains retinal ganglion cell bodies and, in many vertebrates, displaced amacrine interneurons.
POU-domain transcription factors – A large group of transcription factors containing a bipartite DNA-binding domain called a POU domain.
Retinal progenitor cell (RPC) – A developing retinal cell that undergoes mitotic cell division to produce cells that can differentiate into retinal neurons or glia.
Transitional cell – A retinal progenitor cell that is newly postmitotic, but not yet differentiated as a particular retinal neuron or glial cell type.

Retinal Ganglion Cell Formation

Ganglion cells are the first neurons generated by retinal progenitor cells (RPCs) in the developing optic cup. Retinal ganglion cells (RGCs) differentiate first in all vertebrates. In birds and mammals, retinal neurogenesis begins in the center of the cup with the cell cycle exit of a group of RPCs near the optic stalk. Many, but not all, early neurons differentiate as RGCs. From this initiation zone, RGC genesis spreads outward to the periphery of the optic cup. However, in zebrafish, retinal neuron formation initiates in the ventral, nasal cup and propagates around the circumference of the eye as a wave. Ganglion cell layer (GCL) formation is the initial step of optic cup lamination, which results in a mature retina organized into three cell layers (outer nuclear layer, inner nuclear layer, and GCL) separated by two synaptic layers (outer and inner plexiform layers).

Over the past 15 years, considerable progress has been made toward understanding of how mitotically active RPCs choose the RGC fate, terminally differentiate as RGC neurons, extend their axons, and establish synaptic connections in the brain. Yet, this gene network remains incomplete, with more work needed to define RGC formation in molecular terms. Within the hierarchy, both intrinsic transcription factors and extrinsic signaling pathways provide integrated regulation of progenitor development into an RGC. While this article emphasizes intrinsic regulation of RGC fate specification, a short description of extrinsic signaling pathways known to regulate RGC development is also included.

Atoh7/Ath5 Function is Critical for RGC Development

The onset of retinal neurogenesis in a subset of optic cup RPCs is characterized by the activation of the basic helix–loop–helix (bHLH) transcription factor Atoh7/Ath5. The bHLH factors regulate many characteristics of retinal neuron formation. The encoded proteins contain both a basic DNA-binding and helix–loop–helix protein dimerization domains. These factors are expressed by RPCs, in which one or more cells ultimately becomes a neuron. Atoh7/Ath5 occupies a critical node in the RGC gene hierarchy, since zebrafish or mouse mutants lacking the gene have a profound to total loss of RGC differentiation and abnormal optic nerve formation. Adult mutant animals are viable, but have no optic nerves or chiasmata. Overexpression of frog and chick Ath5 during retinal development induces ectopic RGCs, but mammalian Atoh7 does not seem to have this ability. This difference correlates with the observation that, in the mouse retina, Atoh7-expressing cells (the Atoh7 retinal lineage) give rise to all seven major classes of retinal neurons and glia in the adult retina, and do not strictly produce RGCs. This indicates that Atoh7 function is needed to acquire the potential to become an RGC, but is insufficient to commit a cell to this fate. During embryonic retinal neurogenesis, the Atoh7 lineage is hypothesized to predominantly give rise to RGCs, but after the peak of RGC genesis, Atoh7-expressing cells are better able to adopt other retinal fates. This change in developmental ability is presumably due to input from signals secreted by differentiated RGCs and possibly other (non-Atoh7) retinal lineages. Such signals may either promote the adoption of non-RGC retinal neuron or glial fates, block RGC fates, or both.

One role for Atoh7 in the mouse retina is to facilitate cell cycle exit, since mutant cells appear to stall at a cell cycle checkpoint, unable to either resume mitosis or differentiate as RGCs. Eventually, these cells erroneously adopt the last retinal fate, that of Müller glia. Mouse

retinal cells expressing Atoh7 fit the definition of transitional cells, because they are nonmitotic, migratory RPCs that commit to a particular fate, but remain undifferentiated when they express Atoh7. Atoh7+ cells co-express the cyclin kinase inhibitor Cdkn1b/$p27^{Kip1}$, which has multiple functions, including promoting exit from mitosis of cells at the G_1/G_0 checkpoint. Without Atoh7, the percentage of Cdkn1b+ cells fluctuates in both number and arrangement during the peak of RGC genesis. However, questions remain about the relationship between Atoh7 and Cdkn1b. Does mouse Atoh7 directly regulate the activation of Cdkn1b, or do Atoh7 and Cdkn1b act cooperatively to drive RPCs out of mitosis? The latter possibility has been proposed for frog Ath5 and cyclin-dependent kinase inhibitor xic1 (p27Xic1), although it is unclear whether this represents protein–protein interactions, coordinate regulation of shared downstream genes, or cross-regulation. Alternatively, the shifts in mammalian cyclin-dependent kinase inhibitor 1B ($p27^{Kip1}$) expression in Atoh7 mutant eyes may be correlative, but not indicative, of either type of interaction. Since cyclin-dependent kinase inhibitor 1B (Cdkn1b) transcription, translation, and protein stability are independently regulated during development, distinguishing among these possibilities will require further in-depth analyses.

Integrated Regulation of Atoh7/Ath5 Retinal Expression

Many proneural bHLH genes autoregulate their expression, including fruit fly atonal and mouse Atoh1, the most closely related bHLH factors to Atoh7. However, multiple lines of evidence show that Atoh7/Ath5 does not regulate its own expression. Atoh7/Ath5 appears in the optic cup slightly ahead of other proneural bHLH factors and has a very dynamic expression pattern first detectable in a subset of transitional cells that give rise to the earliest retinal neurons. Therefore, determining which transcription factors and signal transduction pathways directly influence Atoh7/Ath5 expression is essential for comprehending how broadly acting factors regulate the precise spatiotemporal patterns of retinal neurons. Among the early optic cup transcription factors, only Pax6 has been shown to directly activate retinal expression of Atoh7/Ath5 via binding to its highly conserved enhancer. Because Atoh7/Ath5 expression initiates in a subset of Pax6-expressing cells, other factors must simultaneously restrict Atoh7/Ath5 expression to newly postmitotic transition cells (**Figure 1**). Another equally important aspect of Atoh7/Ath5 regulation is its turnover, since Atoh7 mRNA disappears abruptly from transitional cells at their entry into the GCL. Therefore, repression is just as important as initial activation for the proper regulation of Atoh7/Ath5 (**Figure 1**).

There are several factors that genetically suppress Atoh7/Ath5 expression, including hairy and enhancer of split 1 (Hes1), neurogenic differentiation 1 (Neurod1), and neurogenic differentiation 4 (Neurod4/Ath3). Because Hes1 is a transcriptional repressor, it is not surprising that it blocks Atoh7 expression. Hes1 similarly suppresses the expression of other retinal proneural bHLH factors like neurogenin 2 (Neurog2) and achaete-scute complex homolog 1 (Ascl1). In the absence of Hes1, Atoh7, Neurog2, and Ascl1 are each prematurely activated in the mouse optic cup. Although Hes1 regulates the overall

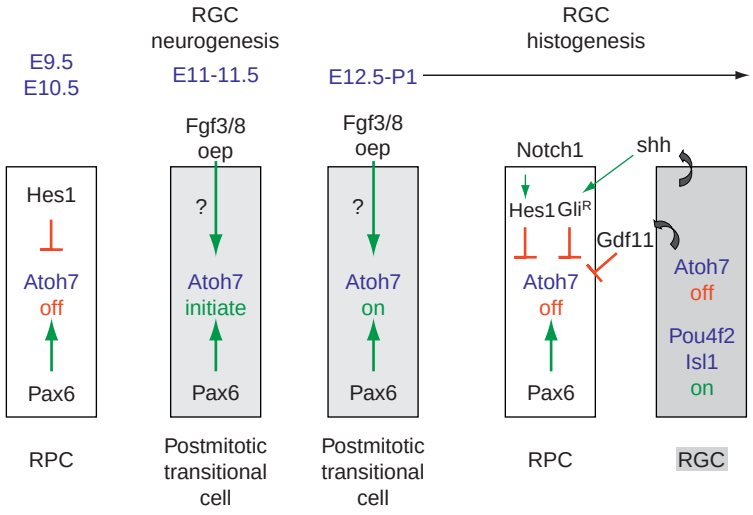

Figure 1 Regulation of Atoh7/Ath5 in postmitotic retinal progenitors. Combinatorial regulatory input for Atoh7/Ath5 transcription in the optic cup. Paired box gene 6 (Pax6) provides cells with the competence to express Atoh7, but Hes1 prevents activation from occurring prematurely. When Hes1 is downregulated, localized Fgf signaling triggers a subset of RPCs to express Atoh7. Retinal cells adopting the RGC fate express Atoh7 for a relatively short time, after which multiple signaling pathways (Notch, Shh, and/or Gdf11) abruptly shut off Atoh7, particularly as differentiating RGCs enter the GCL. Mature RGCs control their own number by secreting Shh and Gdf11, which block Atoh7 expression.

timing of neurogenesis, other regulatory inputs control the precise onset of each proneural bHLH gene. The timing function of Hes1 reflects its role as a downstream effector of Notch signaling, although not all Hes1 functions are Notch dependent. Other factors that suppress Atoh7 expression are Neurod1 and Neurod4, which do so synergistically. Embryonic mouse retinas that are mutant for both genes have expanded Atoh7 expression and a dramatic increase in RGCs, along with a profound loss of amacrine neurons. Thus, Neurod1 and Neurod4 repress Atoh7 expression (directly or indirectly) in RPCs that normally give rise to amacrine cells.

Multiple extrinsic signals influence vertebrate Atoh7/Ath5 expression, particularly for RGC formation. These include fibroblast growth factor 3 (Fgf3), fibroblast growth factor 8 (Fgf8), one eyed pinhead/nodal-like (oep/nodal-like), notch homolog 1 (Notch1), growth differentiation factor 11 (Gdf11), and sonic hedghog (Shh) signaling pathways (**Figure 1**). As shown in the zebrafish and chick retina, Fgf and oep signaling are required for Ath5 activation, while Notch (chick, frog, mouse), Gdf11 (mouse), and Shh (zebrafish, chick, mouse) each suppresses Atoh7/Ath5 expression. Intriguingly, chick Fgf3 and Fgf8 are both expressed in the central optic cup, just prior to the onset of retinal neurogenesis and Fgf protein-coated beads induce Ath5 expression. Although no role during early mouse retinal development has been reported for the orthologous genes, the secretion of stimulatory signals from the central optic cup (Fgf3 or 8) and/or optic stalk (Fgf8 and oep) would be sufficient to explain the onset of Atoh7/Ath5 expression in a restricted retinal domain. By contrast, the extrinsic pathways that negatively regulate Atoh7/Ath5 expression emanate from two distinct sources, RPCs and RGCs. The Notch pathway functions in multiple and complex ways during neurogenesis, but its classic role is to transduce a competitive signal between two adjacent progenitors, in which one cell (expressing more ligand) laterally inhibits the other (expressing more receptor) from differentiating. Therefore, Notch+ cells remain proliferative by suppressing neuron promoting factors like Atoh7. The other two signals, Gdf11 and Shh, are made and secreted by differentiated RGCs to provide negative feedback regulation to RPCs so that the number of neurons is not drastically overproduced. But, to date none of these pathways have been shown to directly activate or repress Atoh7/Ath5 transcription.

Atoh7/Ath5 Activates Pou4f/Brn3 Expression in RGCs

Atoh7/Ath5 activation of Pou4f/Brn3b expression is the principal molecular pathway directing RGC specification and differentiation. Studies in the chick, frog, and mouse eye all suggest that this activation is direct, although definitive biochemical assays have not yet been performed. In the mouse optic cup, Atoh7 and Pou4f2 expression are 90% overlapping, with Atoh7 appearing slightly earlier than Pou4f2 in cells completing their final mitosis, migrating toward the GCL, and differentiating (**Figure 2**). Importantly, Atoh7 is abruptly turned off as nascent RGCs enter the GCL, while Pou4f2 expression is maintained by mature RGCs, even into adulthood.

The Pou4f/Brn subfamily of POU-domain transcription factors is comprised of Pou4f1/Brn3a, Pou4f2/Brn3b, and Pou4f3/Brn3c. Each of these genes acts as key regulators of sensory neuron development, particularly projection neurons. But, each POU-domain factor is required by different kinds of projection neurons. Although a particular class of projection neuron can express all three Pou4f factors, the one that is activated first performs the critical functions. For example, in the retina, all three factors are present in overlapping subsets of differentiated RGCs, but Pou4f2/Brn3b expression initiates expression

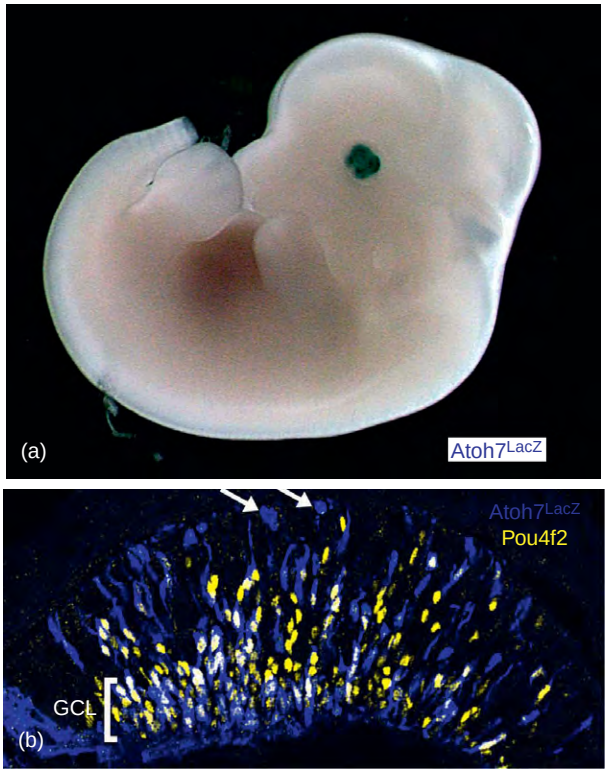

Figure 2 Atoh7 and Pou4f2 expression during RGC development. (a) E11.5 Atoh7$^{LacZ/+}$ embryo expressing β-galactosidase in the optic cup (detected through a chromagenic reaction that turns cells in the eye blue). (b) Anti-β-galactosidase (which detects cells with Atoh7^{LacZ} expression) and anti-Pou4f2 double immunofluorescent staining of E13.5 central optic cup section. Arrows point to Atoh7-expressing cells completing mitosis, which then migrate to the GCL. During migration, these cells initiate Pou4f2 expression (in yellow). Atoh7/Pou4f2 co-expressing cells are in white. Pou4f2 activates downstream target genes for RGC differentiation, axon outgrowth/guidance or survival. The bacterial β-galactosidase has a long half-life in mouse tissues, thus is present in mature RGCs, while endogenous Atoh7 is absent from the GCL (bracket).

about 2 days ahead of the others. The loss of either Pou4f1/Brn3a or Pou4f3/Brn3c has no effect on RGC development, although trigeminal and dorsal root ganglia critically require Pou4f1, and cochlear and vestibular neurons need Pou4f3. However, Pou4f2/Brn3b is a key regulator of RGC development, and mutant adult eyes have extremely thin optic nerves lacking 70% of the RGCs. In contrast to Atoh7 mutants, Pou4f2 mutants have differentiated RGCs that extend axons through the optic nerve, but subsequently fail to innervate the correct regions of the brain and die because these cells lack a critical survival factor. Although Pou4f1 and Pou4f3 seem dispensable for retinal development, they act redundantly with Pou4f2. Pou4f1−/−;Pou4f2−/− and Pou4f3−/−;Pou4f2−/− double mutants have a more profound loss of RGCs than Pou4f2 single mutants. Moreover, overexpression of individual Pou4f genes in chick RPCs demonstrated that each is fully capable of inducing RGCs. Finally, Pou4f3 rescues the loss of Pou4f2 in retinal explant cultures; and targeted replacement of Pou4f1 into the Pou4f2 locus restores RGC development and survival.

Pou4f2 regulates two distinct molecular pathways during RGC development. In the first, Pou4f2 turns on unknown downstream genes within the earliest differentiating RGCs. This subset of RGCs can develop as if Pou4f2 independent, because in Pou4f2 mutants Pou4f1 and Pou4f3 expression rescues them. The second, Pou4f2-dependent pathway produces the bulk of RGCs at later embryonic ages. Here, Pou4f2 regulates a distinct set of downstream genes from those found in the earliest RGCs, including the transcription factors distal-less homeobox 1 and 2 (Dlx1 and Dlx2). When Pou4f2 function is removed from the mouse optic cup, the early RGCs persist, due to Pou4f1 and Pou4f3 compensation. However, the larger, Pou4f2-dependent RGC population cannot complete neuronal differentiation, correctly innervate the brain or express survival factors. This results in mutant eyes with abnormally thin optic nerves. Interestingly, these circumstances point to the Pou4f2 mutant mouse as an excellent system in which to study optic nerve regeneration. For instance, could *ex vivo* cultured (and introduced) RPCs, or early differentiating RGCs, use the Pou4f2 mutant reduced optic nerve, as a substrate for projecting their axons to the correct regions of the brain? Or, could Pou4f1 and Pou4f3 expression be manipulated (activated or derepressed) within the second, later group of developing RGCs to rescue their outgrowth and survival defects?

Pou4f2/Brn3b Controls Numerous RGC Processes

Multiple studies indicate that Pou4f2 is strictly a transcriptional activator, with numerous potential downstream target genes. The list of identified downstream genes includes Pou4f2 itself (autoregulation), Pou4f1 (cross-regulation), the transcription factor eomesodermin homolog (Eomes), the anti-apoptosis factor B-cell lymphoma-2 associated protein (Bcl2), the signaling molecule Shh and multiple cytoplasmic or cell surface proteins, including actin-binding LIM protein 1 (Ablim1), which participate in axon outgrowth, guidance, or vesicular trafficking at synapses. Among these Eomes, Ablim1, and Shh are described here as examples that highlight the diverse set of genes that Pou4f2 directly or indirectly regulates in nascent RGCs. First, Eomes is a transcription factor with a T-box DNA-binding protein motif. During the period of maximal Pou4f2 embryonic expression, Pou4f2 directly activates Eomes transcription in differentiated RGCs. Eomes is also expressed by a subset of inner nuclear retinal cells, potentially amacrine cells, but the role of this factor in the inner nuclear layer remains unexplored. When Eomes function was removed during retinal development, mutant mice have thinner than normal optic nerves, which reflect a postnatal loss of RGCs. Although initial RGC development does not require Eomes activity, myelination of RGC nerve fibers does, and this defect causes elevated RGC death in Eomes mutants. This myelination defect is very similar to the one that has been described for Pou4f2 mutant mice.

Pou4f2 function is also necessary for the proper expression of proteins that direct neurite outgrowth, axon guidance, and neuronal function at synapses. One such gene is Ablim1, encoding an actin-binding protein, with a LIM protein–protein interaction domain. Misexpression of a mutant form of Ablim1 during chick optic nerve development causes RGC axon guidance defects. But paradoxically, Ablim1 mutant mice have no retinal or optic nerve defects. This implies that Ablim1 acts redundantly with another molecule during RGC axon outgrowth. Because there are two other Ablim genes in mammals, future studies are needed to test the role of these genes, singly and in combination with each other and Ablim1, to understand if Pou4f2 regulation of Ablim expression is sufficient to explain the RGC axon guidance defects of Pou4f2 mutant mice. Finally, the search for additional genes regulated by Pou4f2 uncovered the secreted signaling molecule Shh.

Islet1 Acts Parallel to Pou4f2 During RGC Development

Although Atoh7 activation of Pou4f2 deploys an important molecular mechanism for generating RGCs, other factors also act at this same step in the genetic hierarchy of RGC. These genes, which largely encode transcription factors, require Atoh7/Ath5, but not Pou4f2, for their activation. There are several possibilities for how these additional factors act during RGC genesis. They may

regulate a separate set of target genes, cross-regulate or interact with Pou4f2 and its downstream targets, or both. Several candidates that appear to act parallel with Pou4f2 are lim-homeodomain protein 1, Islet1 (Isl1), transducin-like enhancer of split 1 homolog (Tle1), and myelin transcription factor (Myt1). At present only Isl1 is known to function during RGC formation, and retinal-specific deletion of Isl1 results in adult mice lacking 95% of RGCs. This profound loss is more like the Atoh7 phenotype than it is to that of Pou4f2, with the main difference being the developmental age when RGCs are affected. The Isl1 transcription factor contains both a protein–protein interaction LIM-domain and a DNA-binding homeo-domain. Isl1 function is not only important during development in multiple tissues, like the spinal cord and pancreas, but also for cholinergic amacrine and bipolar neuron genesis in the retina. In optic cups devoid of Isl1 function, RGCs are specified and differentiate on schedule, including activating expression of Pou4f2 and other differentiation markers. But by birth, most RGCs down-regulate Pou4f2 expression and then rapidly die. Closer examination of Isl1 mutant RGCs showed both aberrant axon projections and reduced Ablim1 expression, reminiscent of Pou4f2 mutants. Importantly, Pou4f2 and Isl1 act synergistically to control the activation of shared downstream genes, like Pou4f2, Pou4f1, and Shh. Thus, more work is needed to determine which genes Isl1 and Pou4f2 regulate in common versus those controlled by one factor or the other. Since presumably Tle1 and Myt1 also regulate similar processes during RGC formation, working out the combinatorial code of which transcription factors regulate each downstream gene is still needed.

Conclusion

As the genetic hierarchy of RGC development is deciphered, these studies draw us increasingly closer to understanding the sequence of steps for directing RPCs out of the cell cycle to differentiate as RGCs, and how these neurons make appropriate connections in the brain.

Glossary

Alloantigen – An antigen that is the part of an animal's self-recognition system. The common alloantigens are the major histocompatibility complex and red blood cells.
Astigmatism – The inability of the eye to focus sharp image on the retina due to the irregular shape of the cornea or lens.
Capsid – The protein shell that surrounds genetic material of the virus.
Corneal graft or penetrating keratoplasty – The replacement of the central diseased cornea with a healthy donor cornea. This process is also called corneal transplantation.
Corneal neovascularization – The ingrowth of new blood vessels from limbal plexuses toward clear cornea.
Corneal scarring or haze – The loss of corneal transparency and appearance of scar because of injury or abnormal wound healing.
Corneal stroma – The tissue between the epithelium and endothelium of the cornea. It constitutes approximately 90% of corneal thickness and comprises collagens, keratocytes, and extracellular matrix.
CRE-adenovirus vector – An adenovirus vector generated with the helper vector that has a packaging sequence flanked by Cre/*lox*-P system using human embryonic kidney 293 cells stably transfected with Cre recombinase. This results in selective deletion of packaging sequence from helper virus.
Dominant-negative mutant construct – A plasmid encoding for a mutant protein that competes with wild-type (normal) protein within the same cell to inhibit its function.
Enhanced green fluorescent protein (EGFP) – A 27-kDa protein isolated from jelly fish. It fluoresces green when exposed to blue light and is commonly used as a marker for gene transfer studies.
Hyperopia – A term used to define eye defect in which near objects appear blurred because images are focused on the back of the retina instead of on the retina. This medical condition is also known as far- or long-sightedness.
Keratitis – The inflammation in the cornea causing pain and discomfort.
Myopia – A term used to define eye defect in which distant objects appear blurred because images are focused in front of the retina instead of on the retina. It is also called near- or short-sightedness.
Orthotopic graft/transplant – The transplantation or grafting of tissue at its normal position in the body.
Reporter/marker gene – The gene(s) used to track and/or quantify levels of gene delivery in the cell. The common reporter genes are green fluorescent protein, beta galactosidase, etc.
Serotype – A characteristic set of antigens used to distinguish closely related virus strains.
Sonoporation – A technique used to produce small pores temporarily in the cell membrane using ultrasonic waves for introducing RNA, DNA, or small drugs into the cells.
Vector – Virus or nonviral materials used as a vehicle for carrying genes into the cells.

Introduction

Gene therapy is an attractive approach to treat ocular surface diseases and disorders (Table 1). Recent reports of improved visual function in adult patients with Leber's congenital amaurosis with gene therapy attest the potential of this form of molecular medicine to cure eye disease and prevent blindness. The front of the eye, commonly referred as ocular surface, primarily consists of the tear film, cornea, and conjunctiva. The lids, tears, and lacrimal glands are also considered integral parts of the ocular surface, as they spread tears and protect the eye. Nearly all ocular surface diseases entail an abnormality in the cornea. Consequently, more research has been performed to develop gene therapy approaches for the cornea compared to other ocular surface constituents. This article provides an overview of ocular surface gene transfer studies performed by us and many other investigators.

Corneal Gene Therapy Methods

Cornea is an attractive target for gene therapy because of its accessibility, immune-privileged status, and ability to be monitored visually. Gene transfer research in the

Table 1 Genes used for gene therapy of the ocular surface

	Gene	*Vector*	*Mode of transfection*	*Effect on resolution of disease process*
Cornea				
Graft rejection	Cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4)	Adenovirus	Topical application	+/−
	CTLA-4	Adenovirus	IV injection	+
	CTLA-4	Adenovirus	IP injection	+
	CTLA-4	Minimalistic immunolistic immunologically defined gene expression vector	Gene gun	+/−
	Inducible T-cell co-stimulator (ICOS)	Adenovirus	IP injection	−
	Interleukin (IL) 10 antagonist	Adenovirus	Organ culture	+ in ovine − in rat
	Interleukin 12 antagonist	Adenovirus	Organ culture	+ in ovine − in rat
	Interleukin 4	Adenovirus	Organ culture	−
Wound healing	Soluble type II transforming growth factor (TGF)β receptor	Adenovirus	IM injection	+
	Decorin	Adeno-associated virus	Organ culture	+
	Tissue plasminogen activator	Plasmid	Electroporation in the anterior chamber	+
Alkali burns	SMAD 7	Adenovirus	Topical application	+
	Bone morphogenic protein 7	Adenovirus	Topical application	+
	Peroxisome proliferator-activated receptor(PPAR)-γ	Adenovirus	Topical application	+
Scarring or haze	Herpes simplex virus (HSV) thymidine kinase	Retrovirus	Topical application	+
	Dominant-negative cyclin G1	Retrovirus	Topical application	+
Neovascularization	Vascular endothelial growth factor receptor FLT-1	Plasmid	Intrastromal injection	+
	Vascular endothelial growth factor receptor FLT-1	Adenovirus	Injection into anterior chamber	+

	Vascular endothelial growth factor receptor FLT-1	Adeno-associated virus	Subconjunctival injection	+
	FLT23K	Plasmid	Intrastromal injection	+
	FLT24K	Plasmid	Intrastromal injection	+
	Endostatin/kringle-5 domain of plasminogen fusion protein	Lentivirus	*In vitro*	+
	Kringle 5 plasminogen	Electroporation	Organ culture	+
	Angiostation	Adeno-associated virus	Organ culture	+
	IL12	Plasmid	Topical application or intrastromal injection	+
	IL 10	Plasmid	Topical application or intrastromal injection	+
Dystrophies	β-Glucuronidase	Adenovirus	Injected into anterior chamber or intrastromal injection	+
Disorders				
Increase immunity against HSV-induced ocular keratitis	HSV-1 glycoprotein D, B1	Plasmid	Topically, subconjunctival, IP, or IM injection	+
Herpes keratitis	IL2, 4, 10, interferon, tumor necrosis factor	Plasmid	Topical application	−
Lacrimal gland				
Sjögren syndrome	IL10	Adenovirus	Injected into lacrimal gland	+
	TNF	Adenovirus	Injected into lacrimal gland	+
Conjunctiva				
Wound healing	Dominant-negative p38MAPK	Adenovirus	Topical application	+
	SMAD 7	Adenovirus	Topical application	+
	PPARγ	Adenovirus	Topical application	+

cornea primarily focuses on developing therapeutic modalities for common clinical problems such as corneal neovascularization, graft rejection, corneal scarring, and wound healing. The scope of developing novel interventional gene therapy strategies has been markedly enhanced because of an increased understanding of the molecular mechanisms and pathogenesis of corneal diseases. Multiple vectors, techniques, and strategies have been utilized to deliver foreign genes in the cornea. Employing *in vitro*, *ex vivo*, and *in vivo* models, the efficiency of numerous viral and plasmid vectors to deliver genes in the ocular surface tissues has been evaluated. Among viral vectors, adenovirus, adeno-associated virus (AAV), retrovirus, and lentivirus vectors were found to efficiently introduce genes in the cornea. However, none of these vectors is ideal, and each had its own pros and cons.

Viral Vectors

Adenovirus and retrovirus vectors provided short-term transgene expression in the mouse and rabbit cornea with moderate-to-severe inflammatory response. These vectors also transduced corneal and conjunctival epithelium efficiently in human cornea but failed to deliver genes in rat, rabbit, and sheep corneal epithelium. Interestingly, adenovirus vector showed the best transduction efficiency for corneal endothelial cells when compared to the vectors developed from equine immunodeficiency virus, lentivirus, or bacculovirus. Nonetheless, both adenovirus and retrovirus vectors are of limited use for corneal gene therapy because of their inability to transduce nondividing cells, low transduction efficiency for corneal cells, and propensity to induce immune reactions. AAV and disabled lentivirus vectors can transduce nondividing cells and provide long-term transgene expression, thus offering good alternatives for delivering genes into keratocytes and endothelium of the cornea. However, limited studies have been performed to evaluate the utility of these vectors for corneal gene therapy. We, for the first time, showed selective transgene delivery into keratocytes of the rabbit cornea *in vivo* with AAV2 vector using a lamellar flap technique. Figure 1 shows the levels and locations of β-galactosidase (β-gal) reporter gene expression in the rabbit cornea. This study also revealed that direct contact of vector to stroma is critical for introducing therapeutic genes into rabbit keratocytes *in vivo*. Our subsequent studies with AAV serotypes 2 and 5 showed that AAV vectors provide long-term transgene expression in the mouse and rabbit stroma *in vivo*. The mouse eyes continued to express enhanced green fluorescent protein (EGFP) in the corneal stroma for 10 months, without showing any significant side effects (Figure 2).

In recent years, several hybrid AAV vectors have been engineered using the genome of AAV serotype 2 and capsid protein of AAV serotypes 1–9 for gene therapy. The newly produced hybrid AAV vectors have shown improved trangene delivery in many tissues including the eye. However, besides the AAV2/5 vector, transduction efficiency of other newly developed hybrid AAV vectors for the cornea has not been investigated. Recently, our laboratory tested the transduction efficiency of AAV2/6, AAV2/8, and AAV2/9 vectors for the human corneal fibroblasts and epithelial cells *in vitro* and for mouse cornea *in vivo*. The results showed that the tested hybrid AAV vectors are more efficient when compared to nonhybrid AAV2 serotypes for each corneal cell type. Figure 3 demonstrates the levels of transgene delivery in human corneal epithelium (a) and human corneal fibroblast (b) delivered with AAV2/6 vector. The analysis of AAV2/6, AAV2/8, and AAV2/9 gene transfer data revealed that AAV2/6 vector is the most efficient among the three tested vectors for human corneal fibroblasts and epithelial cells *in vitro*. Although AAV vectors are efficient and safe for delivering genes in the cornea, unfortunately they are incapable of transporting large genes (>1.8 kb).

Disabled lentivirus vectors have been used to deliver large genes to all three major cells of the human cornea *in vitro* and to mouse corneal endothelium *in vivo*. In addition, transgene delivered with lentivirus vectors showed long-term expression. Our research team noted efficient EGFP gene delivery into keratocytes of the mouse cornea *in vivo* with lentivirus vector that was applied to the mouse stroma for 2 min after removal of

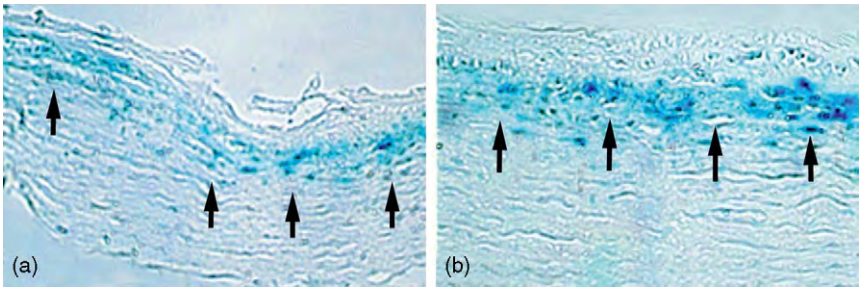

Figure 1 AAV-mediated targeted transgene delivery into keratocytes of the rabbit cornea *in vivo* using lamellar flap technique. The AAV2 vector was topically applied on the stromal bed after making corneal flap with microkeratome. Significant levels of transgene delivery in the rabbit stroma at day 3 and day 10, respectively, are shown in (a) and (b).

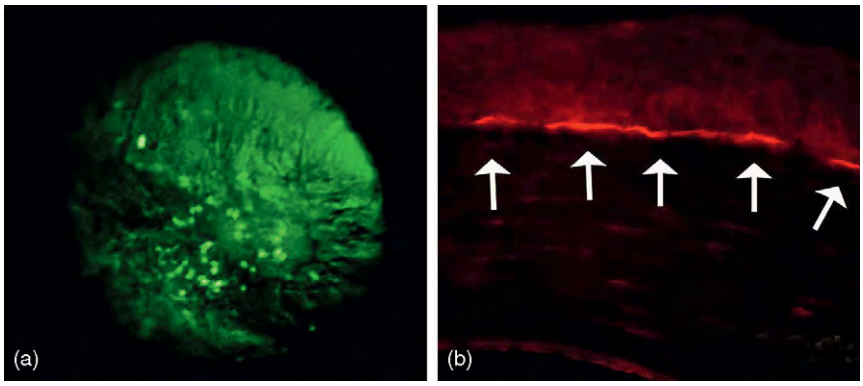

Figure 2 AAV-mediated transgene transduction into keratocytes of the mouse cornea *in vivo* observed at 10 months. Representative stereomicrograph of the cornea surface (a) and tissue section (b) images demonstrate detection of high levels of fluorescent GFP reporter gene expression in the mouse cornea *in vivo* delivered into mouse keratocytes with AAV5 vector applied topically.

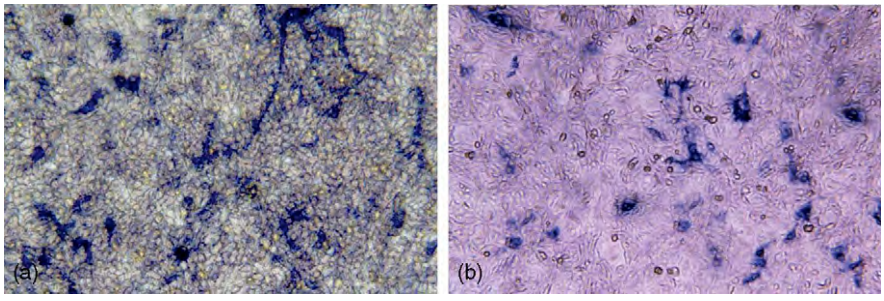

Figure 3 Efficient transduction of cultured human corneal epithelial (a) and fibroblast (b) cells by the AAV2/6 hybrid vector detected 40 h after vector treatment. The transduction efficiency of AAV2/6, AAV2/8, and AAV2/9 vectors to transduce human corneal epithelial and fibroblast cells was compared. AAV2/6 vector showed the highest transduction efficiency for tested corneal cultures. Transduced cells expressing human placental alkaline phosphatase reporter gene are stained blue.

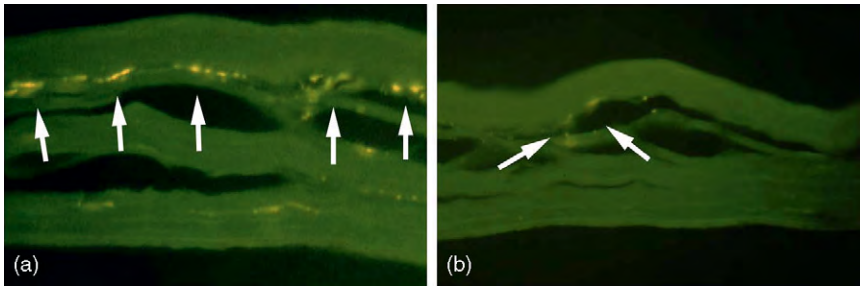

Figure 4 Lentivirus-mediated transgene delivery in the mouse cornea *in vivo* noted after 6 weeks of vector application. Two microliters of lentivirus titer was either topically applied for 2 min or microinjected in the cornea using a glass needle. Transgene delivery in the rabbit stroma noted at 2 weeks in the tissue sections of the cornea, shown in (a) and (b), which received vector through topical application (a) or microinjection (b) techniques.

epithelium. Figure 4 shows the quantity and distribution of transgene in the mouse cornea with lentivirus vector administered in the stroma topically or through microinjection technique. Detection of distinctly different levels and locations of transgene in the cornea supports our hypothesis that gene delivery in the cornea is regulated by both vector and vector-delivery techniques and not by the vector alone. No serious cytotoxicity or side effects have been reported with the AAV- or lentivirus-mediated gene delivery, suggesting that these vectors may be suitable for gene therapy treatments for patients. However, safety remains a major concern for using lentivirus vectors because of their origin from human immunodeficiency virus.

Nonviral Vectors

Contrary to viral vectors, nonviral vectors are nontoxic, nonpathogenic, and nonimmunogenic, and can deliver large genes. Additionally, their production is simple and

cost effective. Various surgical, mechanical, electrical, or chemical approaches were used to administer plasmid DNA in the cornea *in vitro*, *ex vivo*, and *in vivo*. Intrastromal injection of plasmid DNA encoding reporter, vascular endothelial growth factor, or interleukin-1 receptor antagonist successfully delivered transgene into the mouse cornea. A major advantage of this method over viral technology was that it provided rapid transgene expression in the mouse cornea *in vivo*. Transgene expression was detected as early as 1h after administration, with a peak occurring in 12–24 h. Furthermore, the plasmid-injected corneas remained clear and free of inflammation. Plasmid applied during stromal hydration and filtration bleb surgeries delivered genes in rabbit corneas, *in vivo*.

Techniques using electric current plasmid DNA delivery in corneal epithelium, keratocytes, and endothelium have been reported. Electrical current up to 200 V cm^{-1} did not cause trauma, edema, or inflammation in the cornea but introduced only low levels of transgene. Higher electrical current increased transgene delivery but was associated with substantial corneal damage.

Firing of DNA- or RNA-coated gold microparticles on the cornea with a gene gun introduced transgene in the corneal epithelium. However, gene-gun-mediated gene delivery was limited to epithelium and was associated with corneal damage.

Lipids and polymers have been used frequently to deliver genes in corneal cells *in vitro* but provide inadequate levels of transgene in the cornea *in vivo*. Low transfection efficiency and short-term transgene expression are among the major challenges of nonviral gene therapy that need to be addressed. Use of nanoparticles as vectors has great potential for improving nonviral gene transfer.

Use of Gene Therapy to Treat Corneal Diseases

Corneal Graft Rejection

Many gene therapy studies for prevention of corneal graft rejection have focused on the use of cytotoxic T-lymphocyte-associated antigen-4 conjugated to human immunoglobulin G (IgG) heavy chain (CTLA-4 Ig). The rationale for this therapy is based on the fact that helper T-cell activation primarily involves the interaction between T-cell receptor/cluster of differentiation 3 (CD3) and the alloantigen/major histocompatibility complex II (MHCII) of the antigen-presenting cells (APCs). An additional, essential stimulus for T-cell activation is provided by the interaction between co-stimulatory molecules, such as APC B7 antigens, and the CD28 molecule of T cells. T-cell activation can be prevented by blocking this interaction with administration of chimeric protein, CTLA-4 Ig. Multiple studies have evaluated the efficiency of CTLA-4 Ig gene therapy to control corneal graft rejection. The CTLA-4 Ig gene therapy was delivered to the donor rat corneas with adenovirus prior to transplantation topically or after transplantation by a single intravenous or intraperitoneal injection. Topical application of adenovirus expressing CTLA-4 Ig had a marginal effect on preventing graft rejection, whereas systemic administration markedly prolonged graft survival. In another study, minimalistic immunologically defined gene expression (MIDGE) vector encoding for CTLA-4 was delivered in the corneal epithelial cells with a gene gun 10 days after orthotopic corneal transplantation. A marginal beneficial effect of CTLA-4 expression was noted for graft survival in the tested model. However, a subsequent study of MIDGE-mediated CTLA-4 gene transfer in mice demonstrated significant prolongation of graft survival when gene therapy was delivered 1 day before corneal transplantation. Contrary to the encouraging CTLA-4 gene transfer studies, the results have been disappointing when other co-stimulatory pathways of T-cell activation are inhibited. Adenovirus-mediated ICOS, which is an inducible co-stimulatory receptor expressed by activated T cells, *ex vivo* or systemic gene therapy did not result in a significant prolongation of corneal graft survival.

Cytokines play an important role in corneal graft survival and rejection. Consistently elevated levels of proinflammatory cytokines, such as Th (T-helper cell) type 1, have been detected in the corneal tissues and aqueous humor of eyes with graft rejection. Th type 2 cytokines, such as interleukin (IL)-10 and IL-4, exert inhibitory effects on Th1 cytokines. The effects of elevation of anti-inflammatory Th type 2 cytokines or inhibition of proinflammatory Th type 1 cytokines on graft survival have been the focus of many gene therapy studies. Significantly increased corneal graft survival, from 18–20 days to 45–55 days, was observed in ovine donor corneas transduced with adenovirus-expressing IL-10 or IL-12 antagonist. On the other hand, adenovirus-mediated IL-10 or IL-12 antagonist gene therapy did not prevent corneal transplant rejection in a rat model. This disparity in results could be due to differences in the kinetics of graft rejection in the two animal species. Interestingly, IL-4 gene therapy was found to be ineffective in both the species.

Corneal Wound Healing

Wound healing plays important role in maintaining corneal transparency and normal visual function. Injury to the cornea is known to trigger unregulated wound-healing response that can lead to scar formation and loss of vision. Multiple growth factors and cytokines have been shown to regulate wound healing in the cornea. Out of many cytokines influencing corneal wound healing, transforming growth factor beta (TGFβ) has been shown to play a central role in corneal wound healing, myofibroblast generation, and haze development. Soluble

type II TGFβ receptor binds TGFβ and blocks its biological activity. Soluble type II TGFβ receptor gene therapy has been shown to reduce corneal opacification in corneal injury model. A single intramuscular injection of recombinant adenovirus encoding for soluble type II TGFβ receptor in the mouse eye prevented corneal edema, angiogenesis, inflammatory cell infiltration, and deposition of extracellular matrix in the cornea. High levels of soluble TGFβ receptor were detected in the serum and corneal fluid of treated animals for 10 days but several side effects were also observed. This study demonstrated the potential application of gene therapy to treat corneal disorders but several issues such as safety, immunological reaction, etc., associated with adenovirus-based gene therapy still need to be resolved.

AAV-mediated gene therapy may address some of these issues. Our laboratory, for the first time, demonstrated efficient transgene delivery into keratocytes of the normal and diseased (hazy and neovascularized) rabbit corneas *in vivo* with AAV2 and AAV5 vectors. The tested AAV vectors showed high levels and long-term transgene expression (over 4 months) in the rabbit corneas. Our ongoing gene transfer experiments include evaluation of AAV-mediated decorin gene therapy to control corneal scarring and angiogenesis. Decorin is a small leucine-rich proteoglycan and blocks biological activity of TGFβ. Our *in vitro* studies revealed that decorin gene delivery into rabbit and human keratocytes significantly reduces TGFβ-driven transdifferentiation of keratocyte to myofibroblasts. This transformation is believed to cause corneal haze *in vivo*.

Employing nonviral gene transfer approach, the role of fibrin deposition on corneal transparency was also studied in laser-induced fibrin clot formation model *in vivo*. Administration of plasmid-DNA-expressing tissue plasminogen activator gene through electroporation in the anterior chamber of the eye markedly reduced extracellular matrix deposition in treated eyes. The beneficial effects lasted for 4 days.

Corneal Alkali Burn

Alkali burn injury to the cornea is a serious clinical problem that often leads to permanent visual loss due to ulceration, scarring, and/or neovascularization. A gene therapy approach has been used to treat corneal alkali burn by targeting modulation of TGFβ super family genes using adenovirus vectors. Mothers against decapentaplegic homolog 7 (Smad7) is well documented to inhibit TGFβ signaling. Topical application of Cre-adenovirus encoding for Smad7 effectively prevented alkali-induced corneal scaring. Bone morphogenic protein-7 (BMP7) is another member of TGFβ super family and has been shown to antagonize the effects of TGFβ. Adenovirus-mediated BMP7gene transfer in the cornea has been shown to accelerate re-epithelilization of corneal surface and suppress myofibroblast generation, monocytes/macrophages infiltration and macrophage chemoattractant protein-1 (MCP-1), and TGFβ and collagen expression in the corneal stroma in alkali-induced corneal injury mouse model. However, BMP7 gene therapy was ineffective to suppress stromal neovascularization. Another study reported that topical application of Cre-adenoviral vector encoding for peroxisome proliferator-activated receptor-gamma (PPARγ) reduced inflammatory and fibrogenic responses in the alkali burn mouse cornea. Adenovirus-mediated PPARγ overexpression inhibited growth factors and upregulation of matrix metalloproteinases, monocytes/macrophages infiltration, and myofibroblasts production in healing cornea *in vivo*. Further, accelerated re-epithelization and basement membrane reconstruction was observed in mouse cornea overexpressing PPARγ gene.

Corneal Scarring or Haze

Corneal scarring is primarily caused by injury or infections to the eye. It is also a common side effect of the photorefractive keratectomy (PRK) surgery, particularly in patients undergoing high myopia correction. The PRK surgery is frequently used worldwide to treat myopia, hyperopia, and astigmatism. Accumulating evidences suggest that corneal scarring occur due to abnormal wound healing, deposition of disorganized extracellular matrix, keratocyte activation, and transdifferentiation of keratocytes to fibroblasts and myofibroblasts. Gene therapy offers a unique approach for intercepting the molecular events involved in the development of corneal haze. Blockade of keratocyte proliferation is an attractive approach for controlling corneal haze *in vivo*. Rabbit corneas transduced with retroviral vector encoding for herpes simplex virus (HSV) thymidine kinase gene after keratectomy, followed by topical application of ganciclovir, showed significant inhibition of laser-induced corneal haze. Another approach that has been tested to control corneal haze is the blockade of cyclins and cyclin-dependent kinases that play an active role in controlling cell division. Again using a retroviral vector, a dominant-negative mutant construct for cyclin G1 was delivered in the rabbit cornea after transepithelial phototherapeutic keratectomy surgery. Analysis of corneal tissues showed that dominant-negative cyclin G1 delivery decreased extracellular matrix production and markedly reduced the development of corneal haze in tested rabbit model. Apoptosis of activated keratocytes by the delivered dominant-negative cyclin is believed to be a mechanism for the decrease in corneal haze appearance. As noted above, we have also shown the potential of decorin gene therapy to inhibit corneal haze using an *in vitro* model.

Corneal Neovascularization

Corneal insults, such as infection, degenerative disease, chemical damage, mechanical/surgical injury, and immunologic disease, can cause corneal neovascularization (CNV) that affects about 1.4 million Americans each year. Multiple lines of evidence suggest that cytokine vascular endothelial growth factor (VEGF) plays a key role in CNV development. Various gene therapy strategies have been developed and examined to suppress VEGF-induced corneal angiogenesis using experimental models. Intrastromal injection of plasmid encoding a soluble form of the VEGF receptors Flt-1, which neutralizes VEGF, significantly inhibited CNV in the mouse eye. Similar inhibition of CNV was demonstrated by sFlt1 gene transfer with adenovirus and AAV. In a novel approach for controlling CNV with gene therapy, plasmids encoding for Flt23K or Flt24K peptide (VEGF-binding domains of sFlt-1) coupled with endoplasmic reticulum-retaining peptide have been developed. These peptides are not secreted outside the cell and therefore are capable of neutralizing intracellular VEGF. Intrastromal injection of these plasmids in mouse eye inhibited CNV by as much as 50% in the experimental models of corneal angiogenesis. Recently, these scientists reported CNV reduction up to 40% in the mouse cornea after delivering Flt23K gene with albumin nanoparticles.

Gene therapy has also been evaluated in a corneal transplant rabbit model to study the effect of gene transfer of a fusion protein. These rabbit corneas were transduced *ex vivo* with lentiviral vector encoding for endostatin and kringle-5 domain of plasminogen fusion protein. Endostatin is an anti-angiogenic peptide derived from type XVIII collagen, and Kringle 5 domain of plasminogen is a specific inhibitor for endothelial cell proliferation derived from the proteolytic fragment of human plasminogen. The endostatin-kringle-5 fusion protein effectively inhibited allogenic transplantation-induced neovascularization. Delivering kringle-5-plasminogen gene through electroporation was also demonstrated to be effective in reducing CNV in a rat model. Angiostatin is another potent, recently identified anti-angiogenic agent. AAV vectors encoding angiostatin gene effectively reduced alkali-induced CNV in rat corneas. In another study, mouse corneas transfected with plasmid encoding for IL12 or IL10, using topical application or intrastromal techniques, showed marked suppression of CNV. Interestingly, a careful review of the literature reveals that few gene transfer studies of CNV in experimental disease models have reported, discussed, or investigated the side effects or downsides of the gene transfer methods that were investigated.

Corneal Dystrophies

In the past decade, several genes and gene mutations, such as BIGH3, TGFβ1, gelsolin, and CHTS6 have been identified to cause granular, lattice, Avellino, and/or Reis–Bücklers corneal dystrophies. However, a paucity of experimental models for evaluating the usefulness of gene therapy to cure genetic corneal dystrophies remains a major obstacle to the development of therapeutic interventions for these vision-threatening disorders. Very few gene transfer studies using corneal buttons collected from patients or rodent models have been performed to evaluate the efficacy of gene therapy in corneal dystrophies. Gene therapy approaches can be used as a tool for creating animal models of corneal dystrophies by overexpressing aberrant proteins in the cornea.

Mucopolysaccharidosis is a group of metabolic disorders characterized by deficiency of lysosomal enzymes needed to degrade glycosaminoglycans. This disorder causes corneal abnormalities, including the loss of corneal transparency. Delivering human beta-glucuronidase gene in the cornea induced significant clearance of corneal clouding in mouse model of type VII mucopolysaccharidosis. The adenovirus vector encoding human beta-glucuronidase gene was injected in the anterior chamber or intrastromal region to deliver transgene in the eye. A rapid clearance of lysososmal-storage vesicles in keratocytes and clearing of the cornea were observed.

Other Corneal Disorders

HSV keratitis is a leading cause of infectious blindness. Developing vaccination using gene transfer approaches have been the focus of several studies. Most of these studies used plasmid DNA encoding for HSV-1 glycoproteins, such as glycoprotein (g) D, gB1, or a cocktail of glycoproteins in an effort to increase immunity against HSV-induced ocular keratitis. The plasmids were administered in test animals through either topical application, or subconjunctival, intramuscular, or intraperitoneal injection. The intramuscular route of administration has been found to confer total protection against HSV keratitis, whereas topical application and subconjunctival administration prevented stromal keratitis but not the epithelial keratitis. In another study, enhancement of gD glycoprotein was observed when it was administered in combination with IL-2. Conversely, many investigators have reported limited success in controlling herpes keratitis with gene therapy, as a topical application of naked plasmid vector encoding for cytokines, such as IL2, IL4, IL10, interferon (IFN), or tumor necrosis factor (TNF) alpha, demonstrated very little or no benefit. Nonetheless, cytokine gene therapy has been shown to inhibit corneal lesion severity if used 3 days prior to HSV infection. Clinically, such treatment may be beneficial for preventing primary HSV keratitis.

Lacrimal Gland Gene Therapy

Lacrimal glands produce tears and tear proteins which lubricate, and supply nutrition and protection to ocular

surface tissues. Several autoimmue disorders such as Sjögren syndrome, rheumatoid arthritis, systemic lupus erythematosus, and uveitis affect lacrimal gland function and result in dry eye syndrome. This syndrome affects about 4% people in the United States. Unlike conventional therapy that demands repeated lubricant application, gene therapy could potentially require just one treatment. Genes delivered to lacrimal glands can modulate tear composition and flow rate. Initial studies tested the efficacy of vaccinia, herpes, and adenovirus vectors for delivering genes in lacrimal gland using *ex vivo* rat lacrimal gland. Vaccinia viral vector showed highest transgene delivery followed by adenovirus and herpes viral vector. Histological examination of tissues revealed that vaccinia vector delivered transgene in the lacrimal duct cells and acini, whereas adenovirus vector mainly transduced myoepithelial cells surrounding the lacrimal acini. Cellular degradation response was also noted with adenovirus vector, possibly due to vector's toxicity. Subsequent studies showed IL-10 and TNF inhibitor gene delivery in cultured rabbit lacrimal gland epithelial cells by the adenovirus. *In vivo* studies examined the efficacy of these cytokines-based gene therapy for Sjögren syndrome, using a rabbit model of dacryoadenitis. The prophylactic adenovirus-mediated IL-10 gene delivery resulted in protection against lacrimal gland immunopathology, ocular surface disease, and decrease in tear production. On the other hand, adenovirus-mediated TNF inhibitor gene delivery increased basal tear production and its stability, and reduced corneal surface defects and intensity of immune cell infiltration in lacrimal gland.

Adenovirus-mediated gene delivery has also been utilized to investigate cellular and physiological functions of the lacrimal gland. Examples include investigation of androgens in the pathophysiology of Sjögren syndrome and the role of dyneins, protein kinases, and cytoskeletal proteins in the secretory functions of the lacrimal gland. Besides adenovirus, not many other viral vectors have been evaluated for lacrimal gland gene delivery *in vivo*. Retroviral vectors expressing the E6 and E7 genes of the human papillomavirus have been employed to generate immortalized lacrimal gland epithelial cell lines for laboratory studies.

Conjunctiva Gene Therapy

A handful of gene transfer studies have been performed for the conjunctiva. Recently, transfection efficiency of hyaluronic acid–chitosan nanoparticles to deliver genes in human conjuctival cells has been examined. These nanoparticles were found to be nontoxic to the conjuctival cells and exhibited moderate transfection efficiency (15%) for the conjunctiva. Topical application of these nanoparticles to the rabbit eye demonstrated a successful delivery of reporter gene into conjunctival epithelium. Sonoporation (application of sound waves), following subconjuctival injection in the eye, delivered considerable levels of EGFP in the rat conjunctiva.

Among viral vectors, adenovirus has been most widely investigated for transgene delivery in the conjunctiva. Modulation of wound healing and prevention of scarring in the conjunctiva has been the primary focus of conjunctival gene therapy studies. As in corneal injury, TGFβ has been shown to play a critical role in conjunctiva wound healing and scarring. Activation of p38 mitogen-activated protein (MAP) kinase is one of the key signaling pathways activated by TGFβ Adenovirus-mediated delivery of p38 MAPkinase suppressed myofibroblast generation and decreased messenger RNA (mRNA) expression of connective tissue growth factor (CTGF) and monocyte/macrophage chemoattractant protein-1 (MCP-1) in the mouse model of conjunctival injury. The protective effects of Smad7 gene transfer on conjunctival fibrosis have also been reported using a mouse model. Cultured subconjunctival fibroblasts transduced with adenoviral vector expressing Smad7 inhibited type-I collagen, α smooth muscle actin, and CTGF, whereas topical application of adenoviral vector expressing Smad7 gene prevented macrophage invasion and decreased VEGF and α smooth muscle actin levels in conjunctival fibroblasts *in vivo*. More recently, adenovirus-mediated PPARγ gene transfer was found to be protective against conjunctival fibrosis. PPARγ overexpression suppressed expression of type I collagen, fibronectin, and CTGF in cultured human conjunctival fibroblasts both at mRNA or protein level. *In vivo* experiments showed that PPARγ gene delivery significantly decreased monocyte/macrophage invasion, myofibroblast generation, and blocked upregulation of cytokines/growth factors, collagen I, and α2 mRNA in the healing conjunctiva.

In summary, many studies have demonstrated the ability of gene therapy to treat ocular surface diseases and improve visual function. Numerous vectors, techniques, and strategies have been identified for establishing novel gene therapy modalities to treat ocular surface disorders. Although the proof-of-principle experiments validated the potential and promise of gene therapy for ocular surface disorders, several obstacles remain to be cleared before gene therapy clinical trials for these diseases are instituted.

Genetic Dissection of Invertebrate Phototransduction

B Katz and B Minke, Hebrew University, Jerusalem, Israel

Glossary

Electroretinogram (ERG) – *In vivo* extracellular recording of the voltage response to light of the entire retina.

G protein – Guanine nucleotide-binding protein, a ubiquitous biological switch that is turned on by receptor-activation-induced exchange of bound guanosine diphosphate (GDP) with cytoplasmic guanosine triphosphate (GTP) and turned off by hydrolysis of the bound GTP.

Phosphoinositide (PI) signaling – Also designated as inositol-lipid signaling, it is a ubiquitous enzymatic cascade that uses phospholipids or their products for signaling.

Phospholipase C (PLC) – A superficial membrane-bound enzyme that hydrolyzes a minor plasma membrane phospholipid, phosphatidylinositol-4,5-bisphosphate (PIP_2), and produces two messengers: inositol 1,4,5-trisphosphate ($InsP_3$) and diacylglycerol (DAG).

Photochemical cycle – A multistep process that begins by absorption of a photon by the light-sensitive receptor, rhodopsin, which undergoes multiple modifications and ends by the regeneration of the original molecule.

Phototransduction – The process by which absorption of photons by light-sensitive receptors lead to production of electrical signal comprehensive to the nervous system.

Prolonged depolarizing afterpotential (PDA) – The light-induced electrical signal that continues in the dark long after light is turned off, produced in invertebrate photoreceptor cells. The PDA phenomenon has been widely exploited to screen for visual defective *Drosophila* mutants.

Rhabdomere – The photosensitive organelle of *Drosophila* photoreceptors which is composed of tightly packed microvilli.

Transient receptor potential (TRP) channels – A family of cation channel proteins that mediate a large variety of physical stimuli such as light, temperature, and chemical compounds.

Phototransduction is a process by which light is converted into electrical signals understood by the central nervous system. Initial studies of invertebrate phototransduction used *Balanus* and *Limulus* as the preparations of choice, due to their extremely large photoreceptor cells and the assumption that they constitute a simplified model system that represents phototransduction in general. However, later studies revealed that although both invertebrate and vertebrate photoreceptors use rhodopsin (R) as a receptor and a G (guanine nucleotide-binding)-protein-coupled signaling cascade to produce the electrical response to light; the rest of their enzymatic cascade of vision is entirely different. Phototransduction in vertebrate rods and cones uses cyclic guanosine monophosphate (cGMP) phosphodiesterase as an effector enzyme and cGMP-gated ion channels as its target. In contrast, phototransduction in the microvillar photoreceptors of invertebrates (photoreceptors in which the photosensitive organelle is composed of microvilli – the rhabdomere) uses a phosphoinositide (PI) signaling cascade, which is characterized by phospholipase C (PLC) as the effector enzyme and, at least in *Drosophila*, the TRP channels as its target. Nevertheless, phototransduction in invertebrate microvillar photoreceptors has become a model system for investigating inositol-lipid signaling and its role in TRP channel regulation and activation. The great advantage of using invertebrate microvillar photoreceptors is the accessibility of the preparation, the ease of light stimulation, the robust expression of key molecular components, and most importantly, the ability to apply the power of molecular genetics. The latter feature is mainly attributed to *Drosophila melanogaster* as a preferred preparation.

Although the phototransduction cascade of invertebrate microvillar photoreceptors is clearly different from that of vertebrate rods and cones, it may be similar to that in the intrinsically photosensitive retinal ganglion cells (RGCs) in vertebrates. The light-sensitive RGCs contain the visual pigment melanopsin and provide photic input to the circadian pacemaker of the master circadian clock. Both *Drosophila* photoreceptors and the light-sensitive RGCs are characterized by a bi-stable R that initiates a phototranduction cascade with TRP channels as the final target. It is now widely accepted that the detailed knowledge that has been obtained through studies of *Drosophila* photoreceptors constitute guidelines for research of the melanopsin-containing RGCs, and that a striking commonality has been found in both cell types.

Extensive genetic studies of the fruit fly, *D. melanogaster*, initiated at the turn of the twentieth century, by the Nobel prize laureate, Thomas Hunt Morgan, and greatly advanced by many other laboratories, has established the *Drosophila* as an extremely useful experimental model for genetic

dissection of complex biological processes. The relatively small size of the *Drosophila* genome, ease of growth, rapid generation time, and high fecundity make this system ideally suited for screening large numbers of mutagenized individual flies for defects in virtually any phenotypically observable or measurable trait. The creation of balancer chromosomes – containing dominant markers and multiple inversions – which prevent recombination with the native chromosomes, allows any mutation – once recognized – to be rapidly isolated and maintained. Importantly, germ line transformation, using P-element transposition, combined with the availability of tissue-specific promoters, allows the introduction of cloned genes into specific cells of the organism. This provides a way to study *in vitro* modified gene products in their native cellular environment. These powerful molecular genetic tools, combined with the available genome sequence, allow screening for mutants defective in critical molecules, while devoid of *a priori* assumptions. Indeed, this methodology has produced large numbers of mutants defective in novel proteins the existence of which would have been difficult to otherwise predict. The following sections emphasize the unique contribution of the research in *Drosophila* photoreceptors, which has led to the discovery of novel molecules and processes important not only for phototransduction but also for many other biological mechanisms (**Figure 1**).

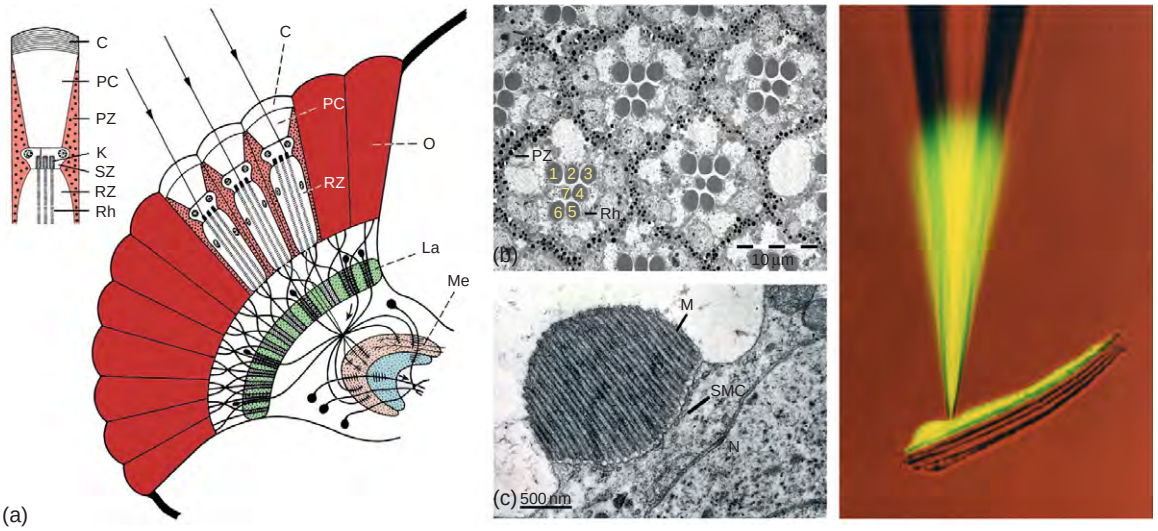

Figure 1 The morphology of the compound eye. The *Drosophila* compound eyes are made up of ~800 repeat and well-organized units termed ommatidia ((a) and (b)). The ommatidium consists of 20 cells, eight of which are the photoreceptor cells (RZ; (a)). (b) and (c) show an electron microscopic (EM) cross section of ommatidia and a rhabdomere (Rh) at the upper region of the photoreceptors, respectively. (d) shows an isolated ommatidium in which one photoreceptor cell is marked by a yellow fluorescent dye introduced by a patch pipette. Each ommatidium contains a dioptric apparatus composed of transparent chitinous cuticle, which forms the cornea (C;(a)) and an extracellular fluid-filled cavity, called the pseudocone (PC; (a)). The floor of the cavity is formed by four Semper cells (SZ; (a)) and the walls by primary pigment cells (PZ; (a) red and (b)), which together circle the pseudocone, shielding the photoreceptor from light coming from adjacent ommatidia. Below this rigid structure of the optical apparatus lie eight photoreceptor cells (RZ; (a), (b), and (d)). The photoreceptor cells are highly polarized epithelial cells, having a specialized compartment known as the rhabdomere (Rh; (a), (b), and (c)), consisting of a stack of ~30 000–50 000 microvilli (M; (c)) each ~2-μm long and ~60 nm in diameter. The transduction machinery is arrayed in these tightly dense structures, while the nucleus (N; (c)) and cellular organelles, such as submicrovillar cisternae (SMC; (c)), reside at the cell body. These highly ordered rhabdomeres form wave-guides that have been widely exploited for optical methods. The eight photoreceptors can be divided into two functional groups according to their position, spectral specificity and axonal projection. The R1–R6 cells (marked 1–6 in (b)) represent the major class of photoreceptors in the retina and are involved in image formation and motion detection. These cells have peripherally located rhabdomeres extending from the basal to the apical side of the retina where they terminate in a rhabdomere cap (K; (a)). They express a single opsin called Rh1, which when combined with 11-*cis* 3-hydroxy retinal, forms a blue-absorbing rhodopsin (R) or orange-absorbing metarhodopsin (M). The R1–6 cells (b) project their axons to the first optic lobe, the lamina (La; (a) green). The second group consists of two cells in the center of each ommatidium termed, R7 (marked 7 in (b)) and R8 (not shown) each spanning only half of the retina in length. The R7 rhabdomere is located distally in the retina and expresses one of two opsins, Rh3 or Rh4, characterized by a UV-absorbing R and blue-absorbing M. The R8 rhabdomere is located proximally in the retina, beneath the R7 rhabdomere (not shown) and expresses one of three opsins – Rh3, Rh5, or Rh6 – characterized by a UV, blue, or green-absorbing R, respectively. The R7 and R8 cells project their axons to the second optic lobe, the medulla (Me; (a) pink). On the basis of opsin expression in the R7 and R8 cells, three ommatidia subtypes can be distinguished. The R7 and R8 cells in ommatidia residing in the dorsal rim area both express Rh3 opsin. The 'pale' ommatidia subtype express Rh3 in R7 cells and Rh5 in R8 cells and constitute ~30% of the total ommatidia, while the 'yellow' ommatidia subtype express Rh4 in R7 cells and Rh6 in R8 cells and constitute ~70% of the total ommatidia. The central cells R7/8 function in color vision and detection of polarized light. This intriguing repeated structure has been a major scientific preparation for research of various aspects of retinal-cell differentiation and development. The *Drosophila* Phototransduction Cascade

Genetic Screens for Mutants Defective in Phototransduction Proteins

A genetic screen is a procedure to identify and select mutated individuals that possess a phenotype with a specific malfunction in a specific trait. This method requires a large number of mutated individuals, usually obtained by the use of mutagens or by random DNA insertions (transposons) and a simple, but powerful, isolation procedure. Additionally, this method requires genetic tools to isolate and maintain the stability of the mutation through generations. These requirements make *Drosophila* an ideal organism for genetic screens. Wide genetic screens targeting the two autosomes (II and III) and the X chromosome of *Drosophila*, have produced many mutants with identified phenotypes linked specifically to genes involved in visual behavior or photoreceptor cell function. These screens used defects in a number of visual functions such as optomotor response, phototaxis, and electrophysiological response to light. The isolation of mutants, specifically defective in the visual transduction pathway initially made use of the electroretinogam (ERG), which measures the electrical activity of the eye at the corneal level (**Figure 1(a)**). However, the ERG methodology failed to isolate the large numbers of mutants expected from a multistep and complex process such as the phototransduction cascade. The main reasons for this failure are that the phototransduction proteins are highly abundant and the upper limit in the depolarization signal is reached even when only a small fraction of the signaling molecules are excited. Therefore, mutations causing even a significant reduction in concentration or subtle malfunction of the phototransduction components could not be identified by this method. This necessitated the employment of a more sensitive, and yet simple, method for isolation of mutants.

In order to find mutants that are specifically affected in the phototransduction cascade and to identify those with subtle phenotypes, Pak and colleagues employed the electrical phenomenon devised by Hillman Hochstein and Minke designated prolonged depolarizing afterpotential (PDA; **Figure 2(a)**, upper trace). This method is based on a large net photoconversion of R to its dark stable photoproduct metarhodopsin (M) with a minimal conversion back to R (**Figure 3**), which brings the capacity of the phototransduction process to its upper limit. PDA is achieved in the fly by genetically removing the red screening pigment (**Figure 1(a)**) and by applying blue light, which is preferentially absorbed by the R state of the Rh1 photopigment. Rh1 is the photopigment expressed in photoreceptors R1–R6 in the *Drosophila* eye (**Figure 1(a)** and **(b)**). A large net photoconversion of R to M (**Figure 3**) prevents phototransduction termination at the photopigment level. As a result, excitation is sustained long after the light is turned off, and the PDA-producing cells are unable to respond further (termed inactivation, **Figure 2(a)**, upper trace). Subsequently, application of orange light reconverts the activated M back to R and terminates the sustained excitation after the light is turned off. Since the PDA tests the maximal capacity of the photoreceptor cell to maintain excitation for an extended period and is strictly dependent on the presence of high concentrations of R and other signaling molecules, it detects even minor defects in R biogenesis, or exhaustion of critical signaling molecules. Thus, defects in the PDA easily reveal deficiencies in the concentration of phototransduction components. Indeed, the PDA screen yielded a plethora of novel and interesting visual mutants. One group of PDA mutants exhibited a loss in several features of the PDA. They were termed *nina* mutants, which stands for neither inactivation nor afterpotential (**Figure 2(a)**, lower trace). Most *nina* mutants were caused by reduced levels of R. The second group of PDA mutants lost the ability to produce the voltage response associated with the PDA, but were still inactivated by strong blue light and the inactivation could be relieved by orange light (**Figure 2(a)**, middle trace). These mutants, consisting of seven allelic groups, are termed *inaA–G*, which stand for inactivation but no afterpotential (no PDA-voltage response). The *ina* mutants were found to have normal R levels but are deficient in proteins associated with the function of the TRP channel. The *nina* and *ina* mutants have led to the identification of most of the crucial components of *Drosophila* phototransduction, many of which are novel proteins of general importance for many cells and tissues.

The Photochemical Cycle and the Mechanism Underlying Termination of M Activity

The *ninaE* mutant, having reduced Rh1 opsin levels, was isolated by Pak and colleagues using the PDA screen. R belongs to the super family of seven transmembrane G-protein-coupled receptors. It is activated by the absorption of a photon that isomerizes the chromophore (11-*cis* 3-hydroxy retinal), resulting in a conformational change of the opsin molecule and production of the physiologically active M state of the photopigment. To ensure high sensitivity, high temporal resolution, and low dark noise of the photoresponse, the active M has to be quickly inactivated and recycled (**Figure 3**). The latter requirement is achieved, in invertebrates, by two means: the absorption of an additional photon by the dark stable M – which photoconverts M back to R – or by a multistep photochemical cycle (**Figure 3**). The termination of vertebrate M activity is a two-step process initiated by M phosphorylation, followed by the binding of the protein arrestin (ARR) to phosphorylated M. Invertebrate M also undergoes

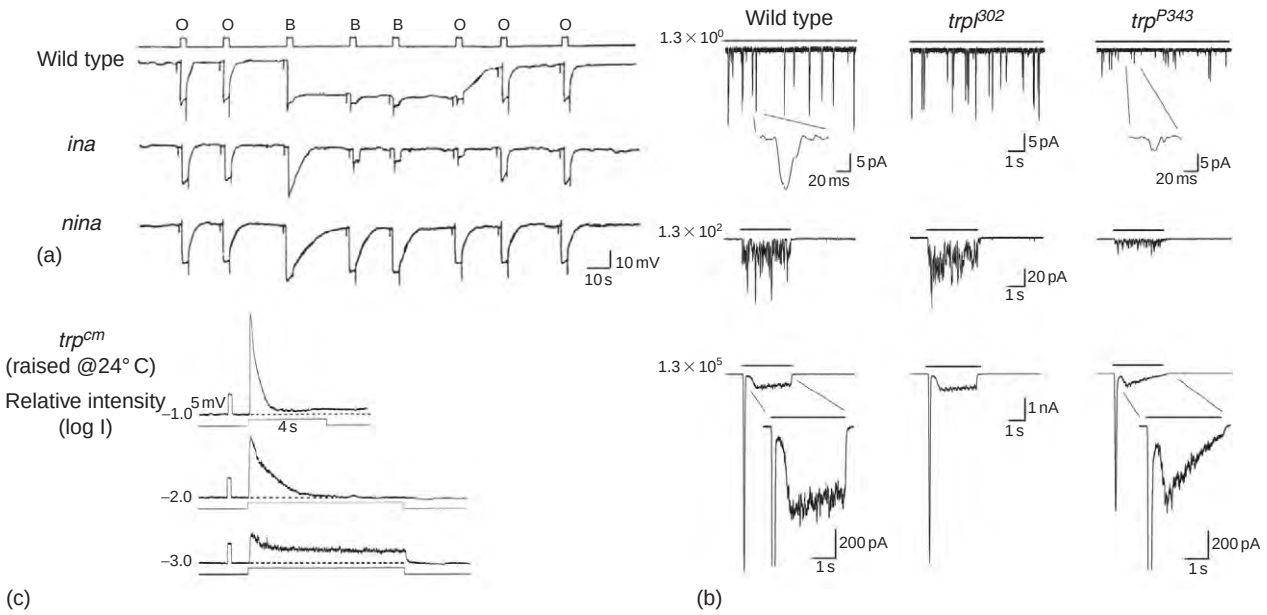

Figure 2 The electrophysiological responses to light of *Drosophila.* (a) The prolonged depolarization afterpotential (PDA) response of wild-type *Drosophila* and its modifications in the *nina* and *ina* mutants: Upper trace: ERG recordings from a wild-type fly in response to a series of intense blue (B, Schott, BG 28 broad-band filter) and orange (O, Schott OG 590 edge filter) light pulses used for induction and suppression of the PDA. This paradigm included two intense orange light pulses followed by an intense blue light pulse which converted ~80% of the Rh1 photopigment from R to M and resulted in prolonged corneal negative response that continued in the dark. Two additional intense blue lights elicited small responses that originated from the central cells (R7 and 8) in which PDA was not induced, due to their UV-absorption spectra, while the R1–6 cells were nonresponsive (inactivated) due to maximal activation of the channels. The following orange light suppressed the PDA after light is turned off. Middle trace: The paradigm of the upper trace was repeated in an *ina* mutant. In contrast to wild type, the response to the intense blue light declined to baseline. However, the R1–6 cells remained inactivated and additional blue lights elicited responses only in R7 and 8 cells while the following orange light removed the inactivation and allowed recovery of the R1–6 cells response to light. Bottom trace: The paradigm of the upper traces was repeated in a *nina* mutant. The first blue light elicited a short PDA that quickly declined to baseline and additional blue lights elicited responses in all photoreceptor cells and allowed additional activation of R1–6 cells by orange lights. (b) (Top) Whole-cell patch-clamp recordings (clamped at −70 mV) from photoreceptor cells of wild-type (WT, left column), $trpl^{302}$ mutant, expressing only the TRP channels (middle) and trp^{P343} mutant, expressing only the TRPL channels (right). Quantum bumps are elicited in response to very dim orange light (1.3 effective photons s^{-1}). The inset shows single bumps in faster time scale of WT fly and the trp^{P343} mutant. The bump amplitudes in the trp^{P343} mutant are significantly smaller than in WT or the $trpl^{302}$ mutant. Middle: In response to 100-fold more intense light, the bumps sum up to produce a noisy light induced current (LIC, note the change in scale). Bottom: A further increase of 1000-fold in the light intensity induced a large response with an initial fast transient that declined to a small steady-state response, due to fast Ca^{2+}-dependent light adaptation in both WT and the $trpl^{302}$ mutant. In the trp^{P343} mutant, the steady-state response declined to baseline during light. The inset shows amplified responses where the initial transient is off scale (note the change in scale). (c) Intracellular recordings from the trp^{CM} mutant, raised at 24 °C, in which the TRP channels are not functional. Responses to increasing intensities of orange light pulses are shown. The response to dim light (bottom trace) showed a sustained response during light. In contrast, the responses to medium and intense orange lights declined to baseline during illumination, showing the typical transient receptor potential of the *trp* mutant. (a) Modified from Pak, 1979.

light-dependent phosphorylation (**Figure 3**; Mpp), but this process is not required for response termination. This was demonstrated in experiments which showed that two *Drosophila* transgenic mutants, P[$Rh1^{\Delta 356}$] and P[$Rh1^{S\ to\ A}$], expressing Rs that lack the putative phosphorylation sites exhibit normal inactivation and ARR binding. However, as in the photoreceptors of vertebrates, the binding of ARR to M in *Drosophila* photoreceptors inactivates M (**Figure 3**). *Drosophila* has two protein homologs to the vertebrate ARR, both undergo light-dependent phosphorylation: the 49-kDa ARR (ARR2) and the 39-kDa ARR (ARR1). The phosphorylation of ARR2 is evident at dim light, while phosphorylation of ARR1 requires stronger light intensities. Both arrestins are phosphorylated by a Ca^{2+}-calmodulin-dependent protein kinase II (CaMK II). ARR phosphorylation is required for the dissociation of ARR from the phosphorylated M (Mpp) upon photoconversion and for preventing endocytotic internalization of the ARR2–Mpp complex (**Figure 3**).

Based on an understanding of the photochemical cycle, Minke and Selinger explained the PDA phenomenon as follows: cellular ARR2 is present at a concentration which is insufficient to inactivate all the M generated by a large net photoconversion of R to M, leaving an excess of M persistently active in the dark. This explanation easily accounts for the elimination of the PDA response by mutations or by carotenoid deprivation which reduce the cellular level of R. It also accounts for the need to

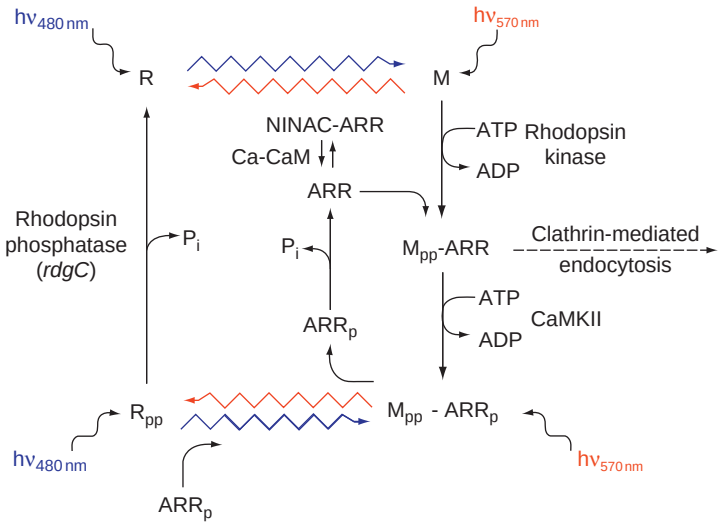

Figure 3 The photochemical cycle: the turn-on and turn-off of the photopigment. The arrestin (ARR) family of proteins play a key role in regulating the activity of G-protein-coupled receptors (GPCR). In *Drosophila,* two protein homologs of vertebrate arrestin exist. Both undergo light-dependent phosphorylation by Ca^{2+} calmodulin-dependent kinase (CaMK II), as shown by Matsumoto and colleagues. Their binding is essential for M inactivation. The study, which clarified the regulatory role of ARR2 was initiated by Selinger, Minke, and colleagues, using *in vitro* assays of ARR2 and M, in *Drosophila* and *Musca* eyes. They showed that upon photoconversion of R to M by illuminating with blue light (wavy blue arrow), the fly ARR2 was found predominantly in the membrane fraction, while photoconversion of phosphorylated M (Mpp) back to phosphorylated R (Rpp), by illuminating with orange light (wavy red arrow), resulted in the detection of ARR2 in the supernatant fraction (cytosol). ARR1 on the other hand always remains membrane bound (not shown). These studies indicated that the functional role of ARR2 binding to M is to terminate its activity. Binding of ARR2 also protects the phosphorylated metarhodopsin (Mpp) from phosphatase activity. Only upon photoregeneration of Mpp to Rpp, is ARR2 released and the phosphorylated rhodopsin (Rpp) is exposed to phosphatase activity by rhodopsin phosphatase (encoded by the *rdgC* gene discovered by O'Tousa and colleagues). These combined actions are crucial for preventing reinitiation of phototransduction in the dark as the reversible binding of ARR2 directs the protein phosphatase only toward the inactive Rpp. Subsequent studies by Dolph and colleagues and by Ranganathan and colleagues revealed that both CaMKII-dependent phosphorylation of ARR2 at Ser366 and the photoconversion of Mpp are required to release phosphorylated ARR2. They, furthermore, showed that the phosphorylation of ARR2 is required for its dissociation from Mpp upon photoconversion and that ARR2 phosphorylation prevents endocytotic internalization of the ARR2–Mpp complex. Montell and colleagues showed that ARR2 binds to myosin III kinase (NINAC). Recent studies by Hardie and colleagues suggest that, under low Ca^{2+} conditions, ARR2 is prevented from rapid binding to M because it is sequestered by NINAC. Ca^{2+} influx acting via CaM, during light (Ca-CaM), rapidly releases ARR2 and allows its binding to M and consequently, M inactivation.

photoconvert large net amounts of R to M to elicit the PDA response. Electrophysiological analysis performed by Zuker and colleagues on strong ARR2 (*arr2*) and ARR1 (*arr1*) mutant alleles revealed a set of phenotypes consistent with the stoichiometric requirement of ARR binding for M inactivation *in vivo*. In their study, they showed that a significant reduction in ARR2 levels leads to abnormally slow termination of light-activated currents and production of a PDA in mutants with low R levels.

Coupling of Photoexcited R to Inositol Phospholipid Hydrolysis

Light-Activated Gq Protein

It has been well established in photoreceptors of several invertebrate species that photoexcited R activates a heterotrimeric G protein. The first experiments, conducted on fly photoreceptors, were carried out by Minke and Stephenson who showed that when pharmacological agents known to activate G proteins were applied to photoreceptors in the dark, they mimicked the light-dependent activation of the photoreceptor cells. Later studies used genetic screens, which resulted in the isolation of two genes encoding visual specific G-protein subunits. These genes – *dgq* and *gβe* – encode, respectively, the alpha and beta subunits of the guanine nucleotide-binding G protein ($G_q\alpha$ and $G_q\beta$). The *Drosophila* eye-specific $G_q\alpha$ ($DG_q\alpha$), cloned by Hyde and colleagues, showed ~75% identity to mouse $G_q\alpha$ known to activate PLC. The most direct demonstration that $DG_q\alpha$ participates in the phototransduction cascade came from studies of mutants defective in $DG_q\alpha$ which showed highly reduced sensitivity to light. In the $G\alpha q^1$ mutant – isolated by Scott, Zuker, and colleagues – $DG_q\alpha$ protein levels are reduced to ~1%, while $G_q\beta$, PLC, and R protein levels are virtually normal. The $G\alpha q^1$ mutant exhibits an ~1000-fold reduced sensitivity to light and slow response termination, thus strongly suggesting that there is no parallel pathway mediated by another G protein. Manipulations of the $DG_q\alpha$ protein level by the inducible heat-shock promoter made it possible to show a strong correlation between the

sensitivity to light and $DG_q\alpha$ protein levels, further establishing its major role in *Drosophila* phototransduction.

The eye-specific $G_q\beta$ ($G_q\beta_e$) shares 50% amino acid identity with other Gβ homolog proteins. Analysis of mutants, isolated by Zuker and colleagues, which are defective in $G_q\beta_e$ ($G\beta_e^1$ and $G\beta_e^2$), showed a greatly (~100-fold) decreased sensitivity and slow response termination. Studies conducted by Selinger, Minke, and colleagues revealed that $DG_q\alpha$ is dependent on $G_q\beta\gamma$ for both membrane attachment and targeting to the rhabdomere, suggesting that the decreased light sensitivity of these mutants may result from the mislocalization of the $DG_q\alpha$ subunit. Previous studies showed that the attachment of $DG_q\alpha$ to $G_q\beta\gamma$ prevents spontaneous guanosine diphosphate and guanosine triphosphate (GDP–GTP) exchange. Analysis of Selinger, Minke, and colleagues of the stoichiometry between the $DG_q\alpha$ and $G_q\beta$ subunits revealed a twofold excess of $G_q\beta$ over $DG_q\alpha$. Genetic elimination of the $G_q\beta$ excess led to spontaneous activation of the visual cascade in the dark, demonstrating that $G_q\beta$ excess is essential for the suppression of dark electrical activity produced by spontaneous GDP–GTP exchange of $DG_q\alpha$.

Light-Activated PLC

Evidence for a light-dependent activation of PLC by $G_q\alpha$ in fly photoreceptors came from combined biochemical and electrophysiological experiments. These experiments were conducted by Selinger, Minke, and colleagues, in membrane preparations and intact *Musca* and *Drosophila* eyes. The eye membrane preparations responded to illumination with a $G_q\alpha$-dependent accumulation of inositol-1,4,5-trisphosphate ($InsP_3$) and inositol-bisphosphate ($InsP_2$), derived from phosphatidylinositol-4,5-bisphosphate (PIP_2) hydrolysis by PLC (**Figure 4**, lower panel). However, genetic elimination of the single $InsP_3$ receptor, performed by Zuker and colleagues and by Hardie and colleagues, had no effect on light excitation, thus putting in question the role of $InsP_3$ in phototransduction.

The key evidence for the participation of PLC in visual excitation of the fly was provided by Pak and colleagues, who isolated and analyzed the PLC gene of *Drosophila*, designated no receptor potential A (*norpA*). The *norpA* mutant has long been a strong candidate for a transduction defective mutant because of its drastically reduced receptor potential. The *norpA* gene encodes a β-class PLC that is predominately expressed in the rhabdomeres (**Figure 4**) and has extensive amino acid homology to a PLC extracted from bovine brain. Transgenic *Drosophila* carrying the *norpA* gene on a null *norpA* background rescued the transformant flies from all the physiological, biochemical, and morphological defects associated with the *norpA* mutants. The *norpA* mutant thus provides essential evidence for the critical role of inositol-lipid signaling in phototransduction, by showing that no excitation takes place in the absence of functional PLC. However, the events required for light excitation downstream of PLC activation remain unresolved.

The TRP Channels

The *trp* Mutant and the Discovery of the TRP Channel

A spontaneously occurring *Drosophila* mutant (isolated by Cosens and Manning), showing a decline in the receptor potential to baseline during prolonged illumination, was designated transient receptor potential (*trp*) by Minke and colleagues (**Figure 2(b) and (c)**). Minke and Selinger suggested that the *trp* gene encodes a Ca^{2+} channel/transporter mainly because application of the Ca^{2+} channel blocker La^{3+} to wild-type photoreceptors mimicked the *trp* phenotype. Subsequently, the cloning of the *trp* locus by Montell and Rubin revealed a novel membrane protein with a sequence of a channel. The available sequence of the *trp* gene led, several years later, to the discovery of mammalian TRPs and the TRP superfamily. However, the significance of the *trp* sequence – as a gene encoding a putative channel protein – was only first appreciated after a *trp* homolog, *trp-like* (*trpl*), was cloned by Kelly and colleagues. They used a screen for calmodulin-binding proteins and found a transmembrane (TM) protein. A comparison of its TM domain to that of voltage-gated Ca^{2+} channels and the TRP protein led to the conclusion that this protein is a putative channel protein with large identity to TRP (**Figure 5**). Strong evidence supporting the notion that TRP is the major light-activated channel came from a comparative patch-clamp study of isolated ommatidia (**Figure 1(d)**) of wild-type and the *trp* mutant conducted by Hardie and Minke. The use of Ca^{2+} indicator dyes and Ca^{2+}-selective microelectrodes, by Minke and colleagues, directly demonstrated that the TRP channel is the major route for Ca^{2+} entry into the photoreceptor cell. The final evidence showing that TRP and TRP-like protein (TRPL) are the light-activated channels came from the isolation of a null mutant of the *trpl* gene, by Zuker and colleagues, who demonstrated that the double mutant, *trpl;trp*, is blind. The notion that the *trp* gene encodes a Ca^{2+} channel has been recently confirmed by Hardie and colleagues by using a mutant with a point mutation at the suspected pore region of the channel, altering its Ca^{2+} permeability properties (**Figure 5**, D621 at the pore region of TRP channel).

Biophysical Properties of the TRP Channel

The *Drosophila* light-sensitive channels – TRP and TRPL – could be studied separately by utilizing the $trpl^{302}$ and trp^{P343} null mutants, respectively. The channels are permeable to a

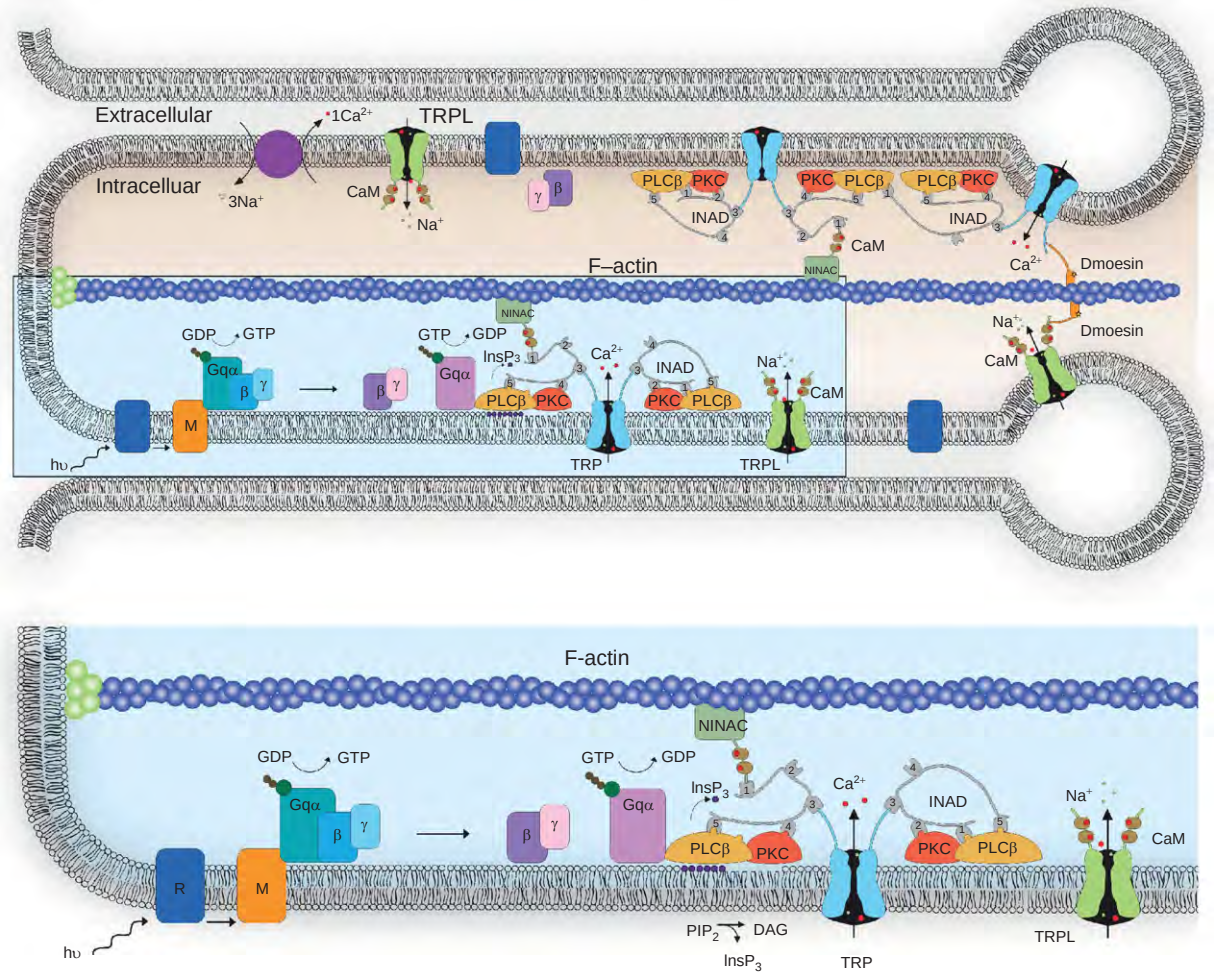

Figure 4 The phosphoinositide cascade of vision. The signaling proteins of the phototransduction cascade are tightly assembled in the microvillar structure (upper panel). The upper panel emphasizes the link of the signaling proteins to the actin cytoskeleton (F-actin) via two proteins: Dmoesin that binds the TRP and TRPL channels, at the base of the microvilli to F-actin and NINAC that associates INAD to F-actin. The only protein that diffuses during the phototransduction cascade is Gqα. The lower panel highlights the molecular components that directly participate in the phototransduction cascade. The numbers on the INAD indicate the various PDZ domains. Upon absorption of a photon, R (encoded by the *ninaE* gene, lower panel) is converted into the active state of the photopigment, M. This, leads to the activation of heterotrimeric G protein (G_q) by promoting the GDP to GTP exchange. In turn, this leads to activation of phospholipase Cβ (PLCβ, encoded by the *norpA* gene), which hydrolyzes the minor phospholipid, PIP_2 into the soluble $InsP_3$ and the membrane-bound diacylglycerol (DAG). Subsequently, two classes of light-sensitive channels, the TRP and TRPL, open by a still unknown mechanism. PLC also promotes hydrolysis of the bound GTP, resulting in $G_q\alpha$ bound to GDP and this ensures the termination of $G_q\alpha$ activity. The TRP and TRPL channel openings lead to elevation of calcium ions extruded by the Ca^{2+}/Na^+ exchanger CALX (violet circle, upper panel). Elevation of DAG and Ca^{2+} promote eye-specific protein kinase C (PKC, encoded by the *inaC* gene) activity, which regulates channel activity. PLC, PKC, NINAC (encoded by the *ninaC* gene), and the TRP ion channel form a supramolecular complex with the scaffolding protein INAD (encoded by the *inaD* gene). Recent studies by Minke and colleagues have shown a light- and phosphorylation-dependent dynamic association of Dmoesin to the *Drosophila* TRP and TRPL channels involved in rhabdomere maintenance. Dmoesin belongs to the ezrin–radixin–moesin (ERM) protein family, which is known to regulate actin–plasma membrane interactions in a signal-dependent manner. Dmoesin is localized to the base of the microvilli in adult *Drosophila* and its function is still unknown.

variety of monovalent and divalent ions including Na^+, K^+, Ca^{2+}, and Mg^{2+} and even to large organic cations such as tris(hydroxymethyl)aminomethane (TRIS) and tetraethylammonium (TEA). The reversal potential of the light-induced current (LIC) shows a marked dependence on extracellular Ca^{2+} indicating a high permeability for this ion. Hardie and colleagues measured the permeability ratios for a variety of divalent and monovalent ions determined under bi-ionic conditions and confirmed a high Ca^{2+} permeability of $\sim 57{:}1 = Ca^{2+}{:}Cs^+$ in the *trpl* mutant and $\sim 4.3{:}1 = Ca^{2+}{:}Cs^+$ for the *trp* mutant.

The TRP and TRPL channels show voltage-dependent conductance during illumination. An early study by Hardie and Mojet revealed that the light response can

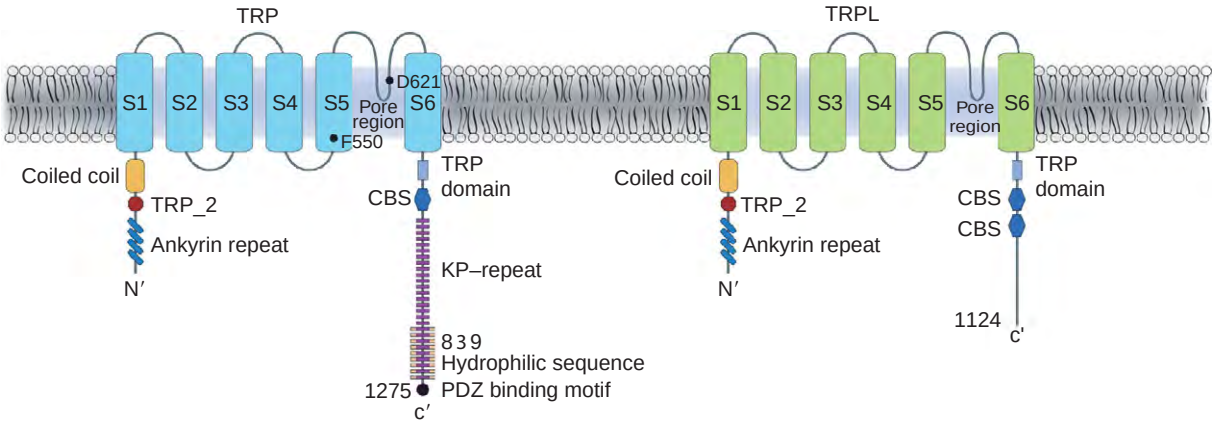

Figure 5 Structural features of the *Drosophila* TRP and TRPL channels. The *trp* and *trpl* genes encode a 1275- and 1124-amino acid membrane protein, respectively, which are presented schematically. The TRP channels share overall 40% amino acid sequence identity with TRPL and a greater similarity (~70%) in the putative transmembrane regions but little homology (~17%) in the C-terminal. The transmembrane domain (TM) of TRP and TRPL channels shows significant identity of ~40% with the TM of vertebrate voltage-gated Ca^{2+} channels; all contain six TM helices and a pore loop between S5 and S6. The S5 pore loop and S6 region are likely the pore-forming region of TRP, as evidenced by a study of Hardie and colleagues. They replaced Asp^{621} (D621) with glycine or asparagine and the mutated TRP channel showed reduced Ca^{2+} permeability. Voltage-gated Ca^{2+} channels are formed by a single peptide and contain charged residues in the putative S4 helix, believed to form the voltage sensor. TRP and TRPL channels, on the other hand, assemble by four peptides as homo- or hetromultimeres and do not contain charged residues in S4. While the gating mechanism of the TRP and TRPL channels is unclear, a study conducted by Yoon, Pak, Minke, and colleagues showed that the substitution of Phe^{550} (F550) to isoleucine in S5 of the TRP channel (in the mutant fly trp^{P365}) forms a constitutively active channel leading to extremely fast light-independent retinal degeneration. The TRPL channel was originally identified as a calmodulin (CaM)-binding protein and contains two CaM-binding sites (CBS) in the C-terminal of the channel. One of these is unconventional in the sense that it can bind CaM in the absence of Ca^{2+}. The C-terminus fragment of the TRP sequence also has been reported to bind CaM in a Ca^{2+}-dependent manner. Both channels have a designated TRP domain located adjacent to the S6 with a EWKFAR motif found in many members of the TRP family. At the C-terminal region of the TRP there is a proline-rich sequence with 27 KP repeats, which overlap with a multiple repeat sequence, DKDKKP(G/A)D termed 8 × 9. Such proline-rich motifs occur widely and are predicted to form a structure involved in binding interactions with other proteins, including cytoskeletal elements such as actin. This region is unique to TRP and has not been found in any other member of the TRP family. The last 14 amino acids in the C-terminal of TRP are essential for the binding of INAD (see **Figures 4** and **7**) and form a PDZ binding domain. At the C-terminal, between the CBS and the KP-repeat domains, there is an unmarked sequence with low homology to a proline, glutamic acid, serine, and threonine (PEST) sequence commonly found in CaM-binding proteins and which is believed to be a target for rapid degradation by the Ca^{2+}-dependent protease calpain. The N-terminal regions of the TRP and TRPL proteins contain four ankyrin repeats and a coiled-coil domain. Both domains are believed to mediate protein–protein interactions. The N-terminal regions also contain a TRP_2 domain with unknown function, predicted recently as involved in lipid-binding and trafficking.

be blocked by physiological concentrations of Mg^{2+} ions. The block mainly influenced the TRP channel and affected its voltage dependence. Detailed analysis by Parnas, Katz, and Minke described the voltage dependence of heterologously expressed TRPL in S2 cells and of the native TRPL channel, using the *Drosophila trp*-null mutant. These studies indicated that the voltage dependence of the TRPL channel is not an intrinsic property, as is thought for other members of the TRP family, but arises from divalent open-channel block that can be removed by depolarization. The open-channel block by divalent cations is thought to play a role in improving the signal-to-noise ratio of the response to intense light and may function in light adaptation and response termination.

A comparison with voltage-gated K^+ channels and cyclic nucleotide-gated (CNG) channels, postulates that both TRP and TRPL are assembled as tetrameric channels, thus raising the question whether they assemble as homomultimers or as heteromultimers. Since both null *trp* and *trpl* mutants respond to light, each can clearly function without the other. However, a study by Montell and colleagues – based on heterologous coexpression studies and coimmunoprecipitation – led to the suggestion that the TRP and TRPL channels can assemble into heteromultimers. Detailed measurements of biophysical properties performed by Hardie and colleagues, questioned this conclusion since they found that the wild-type conductance could be quantitatively accounted for by the sum of the conductances determined in the *trp* and *trpl* mutants. In addition, Paulsen, Huber, Minke, and colleagues have demonstrated that the TRPL, but not the TRP, channel reversibly translocates from the rhabdomere to the cell body upon illumination, further implying that TRP and TRPL do not form heteromultimeres.

Lipids Activate the Light-Sensitive Channels in the Dark

The activation of PLC results in the hydrolysis of PIP_2 into DAG (Figures 4 and 6) and $InsP_3$. The pathway which recycles DAG back to PIP_2 – the PI pathway – has emerged to be most important for activation of the TRP and TRPL channels. The most familiar action of DAG is to activate the classical protein kinase C (PKC) synergistically with Ca^{2+}. However, mutations in the eye-specific PKC (PKC, *inaC*; Figures 4 and 7) lead to defects in response termination with no apparent effects on activation. A second role for DAG in *Drosophila* photoreceptors is to act as a precursor for regeneration of PIP_2 via conversion to phosphatidic acid (PA) by DAG kinase (DGK, *rdgA*; Figure 6). Mutations in DGK (*rdgA*) lead to a severe form of light-independent degeneration. Other mutations in the PI pathway – the CDP–diacylglycerol synthase (CDP–DAG Syntase, *cds*; Figure 6) and the PI transfer protein (PITP, *rdgB*; Figure 6), also lead to severe forms of light-dependent degeneration. The degeneration phenotype – assumed to be caused by toxic increase in cellular Ca^{2+} due to constitutive activity of the TRP channels – suggested a possible involvement of the PI pathway in channel activation. Accordingly, a hypothesis has been put forward whereby DAG acts as an intracellular messenger leading directly to TRP and TRPL channel activation (see below). However, application of DAG to isolated *Drosophila* ommatidia did not activate the channels.

DAG is also a precursor for the formation of polyunsaturated fatty acids (PUFAs) via DAG lipase (Figure 6). Studies conducted by Hardie and colleagues showed that application of PUFAs to isolated *Drosophila* ommatidia, as well as to recombinant TRPL channels expressed in *Drosophila* S2 cells, reversibly activated the TRP and TRPL channels. Moreover, they showed that, in the *rdgA* mutant, TRP and TRPL channels are constitutively active, while elimination of TRP by a mutation (in the double-mutant

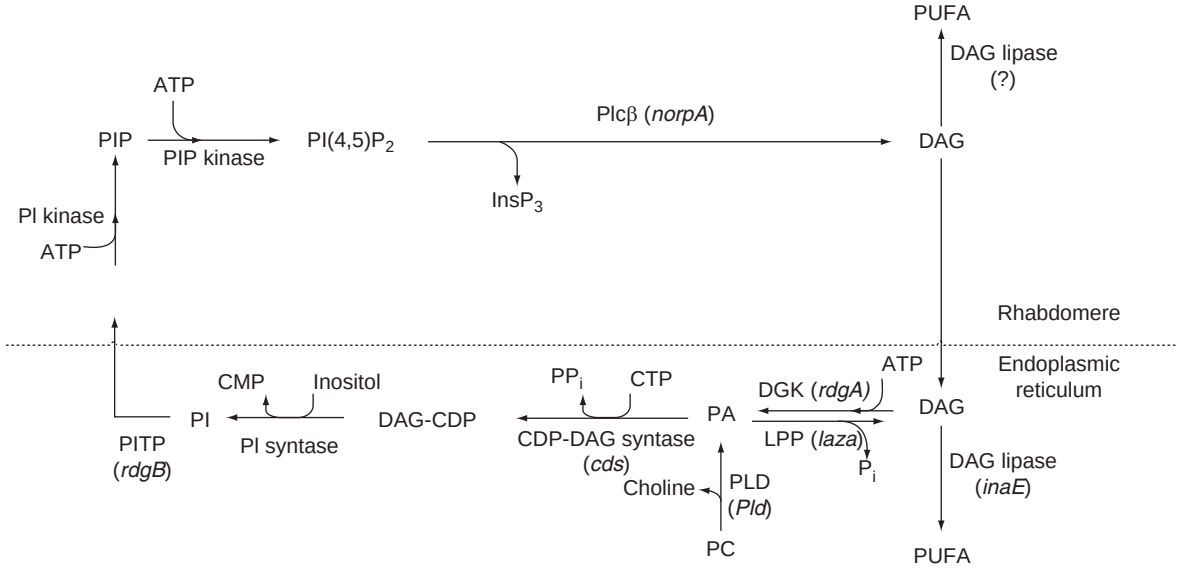

Figure 6 The inositol lipid cycle. In the phototransduction cascade, light triggers the activation of phospholipase Cβ (PLCβ). This catalyzes hydrolysis of the membrane phospholipid phosphatidylinositol-4,5-bisphosphate (PIP_2) into water-soluble inositol-1,4,5-trisphosphate ($InsP_3$) and membrane-bound diacylglycerol (DAG). The continuous functionality of the photoreceptors during illumination is maintained by rapid regeneration of PIP_2 in a cyclic enzymatic pathway (the PI pathway). DAG is transported by endocytosis to the endoplasmic reticulum (submicrovillar cisternae (SMC)) and inactivated by phosphorylation into phosphatidic acid (PA) via DAG kinase (DGK, encoded by the *rdgA* gene and cloned and localized by Hotta and colleagues) and to CDP–DAG via CDP–DAG syntase (encoded by the *cds* gene and cloned by Zuker and colleagues). PA can be converted back to DAG by lipid phosphate phosphohydrolase (LPP; also designated phosphatidic acid phosphatase (PAP)) encoded by *laza* (cloned by Raghu and colleagues and by Montell and colleagues). PA is also produced from phosphatidyl choline (PC) by phospholipase D (PLD, encoded by *Pld).* DAG is also hydrolyzed by DAG lipase (encoded by *inaE*) into polyunsaturated fatty acids (PUFA). This DAG lipase was predominantly localized outside the rhabdomeres, putting in question the participation of PUFA in channel activation *in vivo*. Subsequently, CDP–DAG is converted into phosphatidyl inositol (PI), which is transferred back to the microvillar membrane, by the PI transfer protein (PITP; encoded by the *rdgB* gene and cloned by Hyde, O'Tousa, and colleagues). Both RDGA and RDGB proteins have been immunolocalized to the SMC of the smooth endoplasmic reticulum at the base of the rhabdomere (Figure 1(c)). PIP and PIP_2 are produced at the microvillar membrane by PI kinase and PIP kinase, respectively. The SMC in *Drosophila* has been proposed to posses Ca^{2+} stores endowed with $InsP_3$ receptors ($InsP_3R$). Genetic elimination of the single $InsP_3R$ did not produce any phenotype, suggesting that Ca^{2+} release from stores does not participate in the production of the response to light. It is important to realize that the PI-recycling enzymes – which are essential for continuous production of PIP_2 and hence for the maintained light response – are localized at the SMC. Therefore, the function of the SMC as a lipid-supplying organelle and its role in phototransduction should be further explored.

rdgA;trp), partially rescued the degeneration. The authors suggested a hypothesis in which the elimination of DAG kinase – by the *rdgA* mutation – leads to accumulation of DAG and hence of PUFAs. According to this model, a still undemonstrated accumulation of DAG or PUFAs – acting as messengers of excitation – constitutively activate the TRP and TRPL channels, which in turn leads to a toxic increase in cellular Ca^{2+} and thereby degeneration. Recently, Pak and colleagues identified the *inaE* gene as encoding a homolog of mammalian *sn-1* type DAG lipase and showed that it is expressed predominantly in the cell body of *Drosophila* photoreceptors. Mutant flies expressing low levels of the *inaE* gene product have an abnormal light response, while the activation of the light-sensitive channels was not prevented. Thus, the participation of DAG or PUFAs in TRP and TRPL activation *in vivo* needs further exploration.

It is important to realize that PLC activation, which converts PIP_2 – a charged molecule containing a large hydrophilic head-group – into DAG, which is devoid of the hydrophilic head-group, may cause major changes in lipid packing and lipid-channel interactions. It is, therefore, possible that neither PIP_2 hydrolysis nor DAG production affect the TRP and TRPL channel as second messengers but rather act as modifiers of membrane lipid-channel interactions. This may, in turn, act as a possible mechanism of channel activation.

Organization in a Supramolecular Signaling Complex via the Scaffold Protein Inactivation No Afterpotential D

An important step toward understanding *Drosophila* phototransduction has been achieved by the finding that some of the key elements of the phototransduction cascade are incorporated into supramolecular signaling complexes via a scaffold protein, inactivation no afterpotential D (INAD; **Figure 7**). The INAD protein was discovered by a PDA screen of defective *Drosophila* mutants (*inaD*). The first-discovered *inaD* mutant – the $InaD^{P215}$ – was isolated by Pak and colleagues and subsequently was cloned and sequenced by Shieh and Zhu. Studies in *Calliphora* by Paulsen Huber and colleagues have shown that INAD binds not only TRP but also PLC (NORPA) and PKC (INAC). The interaction of INAD with TRP, NORPA, and INAC was later confirmed in *Drosophila*. It was further found by Zuker, Tsunoda, and colleagues that *inaD* is a scaffold protein, which consists of five ~90-amino acid protein-interaction motifs called postsynaptic density protein (PSD95), *Drosophila* disc large tumor suppressor (DlgA), and zonula occludens-1 protein (zo-1) (PDZ) domains. These domains are recognized as protein modules which bind to a diversity of signaling, cell-adhesion, and cytoskeletal proteins by specific binding to target sequences typically, though not always, in the final three residues of the C-terminal. The PDZ domains of INAD bind to the signaling molecules as follows: PDZ1 and PDZ5 bind PLC, PDZ2 or PDZ4 bind PKC, and PDZ3 binds TRP. This binding pattern is still in debate due to several contradictory reports. On the other hand, TRPL appears not to be a member of the complex, since unlike INAC, NORPA and TRP it remains strictly localized to the rhabdomeral microvilli in the $inaD^{1}$-null mutant isolated by Zuker, Tsunoda, and colleagues. Several studies by Montell and colleagues have suggested that, in addition to PLC, PKC, and TRP, other signaling molecules such as calmodulin, R, TRPL, and neither inactivation nor afterpotential C (NINAC) bind to the INAD-signaling complex. Such binding, however, must be dynamic. Biochemical studies by Huber, Paulsen, and colleagues conducted in *Calliphora* have revealed that both INAD and TRP are targets for phosphorylation by the nearby PKC. Accordingly, the association of TRP into transduction complexes may be related to increasing the speed and efficiency of transduction events as reflected by the proximity of TRP to its upstream activator, PLC, and its possible regulator, PKC.

TRP plays a major role in localizing the entire INAD multimolecular complex. Association between TRP and INAD is essential for correct localization of the complex in the rhabdomeres. This conclusion was derived by Tsunoda, Zuker, and colleague and by Montell and colleagues using *Drosophila* mutants in which the signaling proteins which constitute the INAD complex were removed genetically, and by deletions of the specific binding domains which bind TRP to INAD. These experiments show that INAD is correctly localized to the rhabdomeres in *inaC* mutants (where PKC is missing) and in *norpA* mutants (where PLC is missing), but severely mislocalized in null *trp* mutants. This indicates that TRP, but not PLC or PKC, is essential for localization of the signaling complex to the rhabdomere. To demonstrate that specific interaction of INAD with TRP is required for the rhabdomeric localization of the complex, the binding site at the C-terminal of TRP was removed or the three conserved residues in PDZ3 – which are expected to disrupt the interaction between PDZ domains and their targets – were modified. As predicted, both TRP and INAD were mislocalized in these mutants. The study of the above mutants was also used to show that TRP and INAD do not depend on each other to be targeted to the rhabdomeres; thus, INAD–TRP interaction is not required for targeting but for anchoring of the signaling complex. Additional experiments on TRP and INAD further show that INAD has other functions in addition to anchoring the signaling complex. One important function is to preassemble the proteins of the signaling complex. Another important function, at least for the case of PLC, is to prevent degradation of the unbound signaling protein.

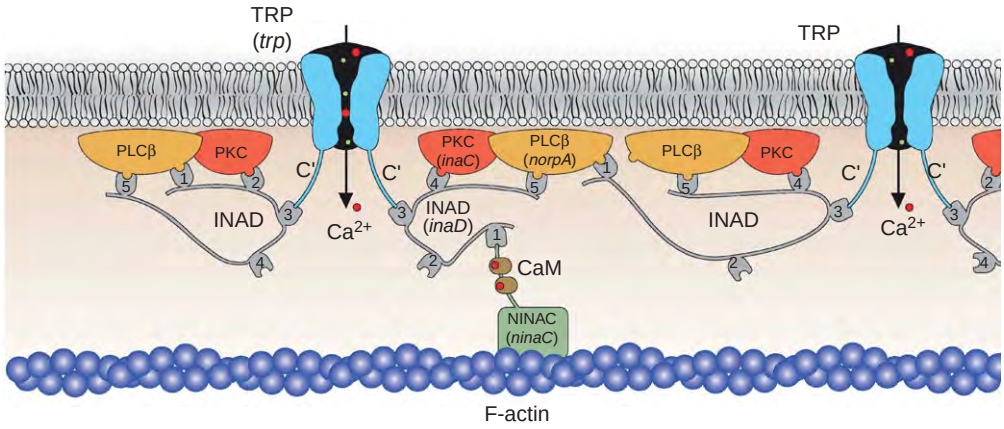

Figure 7 The INAD-signaling complex. The INAD is a 674-amino acid-scaffold protein with homology to cytoskeleton-associated proteins, which include PSD-95 (implicated in clustering of *N*-methyl-D-aspartate (NMDA) receptors and K^+ channels), *Drosophila discs large*, and the epithelial tight-junction protein ZO-1. These proteins all include a variable number of so-called PDZ domains – now recognized as protein modules – which anchor a variety of receptors, ion channels, and other signaling molecules, by specific binding to target sequences. The TRP protein anchors the INAD complex adjacent to the plasma membrane while the disruption of the interaction between these two proteins does not influence the target of either protein in pupae, while disrupting their retention at adulthood. The INAD sequence contained five consensus PDZ domains and identified specific interactions between PKC and PDZ2 or PDZ4, TRP and PDZ3, PLC with PDZ1 and PDZ5 and NINAC with PDZ1. This binding pattern is still in debate due to several contradictory reports. It was also reported that the INAD contains a Ca^{2+}-calmodulin-binding site which may be involved in its regulation. Several authors have commented that the close association of elements of the transduction cascade may be essential for the rapid response kinetics, which characterizes *Drosophila* phototransduction, by minimizing or eliminating diffusional delays. The slow response termination in $InaD^{P215}$ mutant (disrupting INAD–TRP interaction) also leads to speculation that one function of the INAD complex is to target Ca^{2+} influx via the TRP channels directly to PKC, which appears to be required for Ca^{2+}-dependent inactivation of the light response. It is also speculated that PLC activity may be regulated by TRP-mediated Ca^{2+} influx. With regard to activation, any *norpA* or *inaD* mutation which prevents association of PLC and INAD leads to severe defects in excitation. This can be explained by a large reduction of PLC in the microvillar membranes, which would be expected to be essential for normal phototransduction in any model. Interestingly, the specific dissociation of TRP from the INAD complex in the $inaD^{P215}$ mutant, leads to very minor, if any, defect in excitation, except in older flies where TRP levels begin to decline. Nevertheless, several authors have speculated that the INAD complex may provide a mechanism for direct gating of the light-sensitive channels by protein–protein interactions. At present, the only functional roles of INAD, as determined experimentally, are to protect its binding proteins from mislocalization and degradation. These functions are important for maintaining the specific stoichiometry among the signaling proteins (see the section titled 'The photoreceptor cells are sensitive to single photons').

A recent study by Ranganathan and colleagues has suggested that the binding of signaling proteins to INAD may be a dynamic process that allows additional levels of phototransduction regulation. Their study showed that two crystal structural states of the isolated INAD PDZ5 domain differ mainly by the formation of a disulfide bond. This conformational change has a light-dependent dynamic that was demonstrated by the use of transgenic *Drosophila* flies expressing the INAD with a point mutation that disrupts the formation of the disulfide bond. They proposed a model in which PKC phosphorylation of INAD at a still-unknown site promotes a light-dependent conformational change of PDZ5 which distorts its binding site for PLC and thus regulates phototransduction.

The Photoreceptor Cells Are Sensitive to Single Photons

Dim-light stimulation induces discrete voltage (or current) fluctuations in most invertebrate species, which are called quantum bumps (**Figure 2(b)**). Each bump is assumed to be evoked by the absorption of a single photon and these bumps sum up to produce the macroscopic response to more intense lights (**Figure 2(b)**). The bumps vary significantly in latency, time course, and amplitude, even when the stimulus conditions are identical. Bump generation is a stochastic process described by Poisson statistics whereby each effectively absorbed photon elicits only one bump. However, in at least three *Drosophila* mutants (*cam*, *ninaC*, and *arr2*) absorption of a single photon elicits a train of bumps with a rather fixed interval. This phenomenon is explained by a failure of M molecules to be inactivated in these mutants (**Figure 3**) and the existence of a positive and negative feedback and a refractory period in the bump-generating mechanism. The single-photon-single-bump relationship requires that each step in the cascade includes not only an efficient turn-on mechanism, but also an equally effective turn-off mechanism. The functional advantage is the production of a very sensitive photon counter with a fast transient response, very well suited for both the sensitivity and the

temporal resolution required by the visual system. The requirement for efficient turn-off mechanisms is revealed when either M (see above) or PLC fail to inactivate and lead to continuous production of bumps long after light is turned off. Cook, Minke, and colleagues demonstrated that *Drosophila* PLC functions as a GTPase-activating protein (GAP). PLC thus terminates its own activity by accelerating the GTPase activity of the $G_q\alpha$ protein thereby causing the dissociation of $G_q\alpha$ from its target, the PLC (**Figure 4**). The inactivation of the G-protein by its target PLC ensures that each activated G-protein activates only one PLC and thus produces only one bump. It also ensures that every activated G-protein will eventually encounter a PLC molecule and thereby produce a bump. The accurate stoichiometry between PLC and G-protein molecules in the rhabdomere of wild-type flies is maintained by the binding of PLC to the scaffold protein INAD (**Figure 7**). This accurate stoichiometry ensures instantaneous inactivation of all activated G-proteins, when light is turned off, and fast response termination. However, in *norpA* or *inaD* mutants, in which the PLC level is reduced, excessive numbers of active $G_q\alpha$ proteins – relative to scarce PLC molecules – leads to continuous production of bumps in the dark until the last $G_q\alpha$-GTP encounters a PLC and is thereby inactivated by the GAP activity of PLC. This remarkable mechanism makes the photoreceptor cell a photon counter and ensures the high temporal and light-intensity resolutions of the response to light.

Conclusions

Drosophila photoreceptors use the ubiquitous inositol-lipid signaling for phototransduction with TRP channels as its target. While mammalian TRP channels are also modulated by the PI cascade and are activated by a large variety of stimuli, the physiological function and mechanism of activation is not entirely clear. In contrast, the physiological function of the *Drosophila* TRP channels as light-activated channels is well established, as well as the requirement of PLC for their activation. It is, therefore, important to direct future efforts toward investigating the activation mechanism of the various TRP channels in the native cells. Genetic tools seem to be especially suitable for such investigation. The similar structural features of the pore domain in all members of TRP channels and the involvement of PLC in their activation/modulation suggest that, in principle, they may share a common mechanism of activation. Thus, studies of *Drosophila* TRP channels is important for the understanding of this diverse and important family of channel proteins.

Genetics of Age-Related Cataract

A Shiels, Washington University School of Medicine, St. Louis, MO, USA
J F Hejtmancik, National Institutes of Health, Bethesda, MD, USA

Glossary

Association – A tendency for two characters (e.g., disease phenotypes, genetic variants or alleles) to occur together at nonrandom frequencies.
Epidemiology – The study of disease epidemics aimed at discovering the cause(s).
Genome – The complete set of different DNA molecules of an organism, cell or subcellular organelle (e.g., mitochondria). Humans have 25 different DNA molecules, the mitochondrial DNA molecule, and the 24 chromosome DNA molecules (22 autosomes plus 2 sex chromosomes, X and Y).
Genotype – The genetic composition of an organism, either overall or at a specific chromosomal location or locus, as distinct from its phenotype.
Linkage – The tendency of characters (disease phenotypes, genetic variants or alleles) located on the same chromosome to be inherited together, or co-segregate, in a family.
Phenotype – The physical appearance of an organism, tissue, or cell as distinct from its genotype.

Introduction

Clouding of the eye lens, or cataract, is a common symptom of aging (>50 years), and age-related or senile cataract is a leading cause of visual impairment. The World Health Organization estimates that, despite recent advances in its surgical treatment, age-related cataract still accounts for 40–50% of global blindness, and with continued growth and aging of the world's population; the prevalence of age-related cataract is projected to double. In the United States alone, age-related cataract afflicts more than 22 million Americans over age 40 (~17% of this age range), and by age 80 over 50% have cataract. Currently, about 1.5 million cataract surgeries are performed annually and age-related cataract surgery represents a major healthcare expense. It has been estimated that delaying the onset of age-related cataract by 10 years would decrease the demand for surgery by about 45%.

Despite the prevalence of age-related cataract in humans and many domestic animals, the underlying molecular pathology is poorly understood. Epidemiological studies indicate that age-related cataract is a multifactorial disease involving complex interactions between environmental risk factors (e.g., cigarette smoking status and ultraviolet sunlight exposure), and significant genetic risk factors. The discovery of these genetic factors is at an early stage, and here we outline recent progress in the molecular genetics of age-related cataract.

Age-Related Cataract Phenotypes

Clinical classification of age-related cataract is largely based on the location, size, shape, density, and color of opacities when visualized in the lens by slit-lamp examination (Figure 1). Defined by lens location, age-related cataract may be divided into three pure subtypes referred to as nuclear cataract, cortical cataract, and posterior subcapsular cataract. Nuclear cataract, often associated with a brown discoloration, affects the central core of the lens and is prevalent in most white populations and indigenous populations from Africa, India, and Southern China, whereas, cortical cataract, which usually appears as wedge-shaped opacities, affecting the outer cortex of the lens is more common in Icelandic, African-American, and certain East Asian populations. Posterior subcapsular cataract, which usually appears as a granular deposit or plaque-like opacity, is confined to the back of the lens, lying just beneath the capsule or basement membrane that envelopes the lens mass, and represents the least prevalent type in all populations studied. Pure types of age-related cataract can be further graded for severity according to their size and density by evaluation of lens photographs taken with a slit-lamp camera (Figure 1). In practice, however, age-related opacities often occur in combination (i.e., mixed nuclear and cortical with or without posterior sub-capsular) and may eventually progress to total opacification of the lens.

Genetic Epidemiology of Age-Related Cataracts

Increasing epidemiological evidence, which is primarily based on statistical analyses, points to the importance of genetic factors in the pathogenesis of age-related cataract. However, as compared to inherited forms of congenital or childhood cataract, age-related cataract by definition has a late age of onset, so that multi-generation families with age-related cataract tend not to be readily

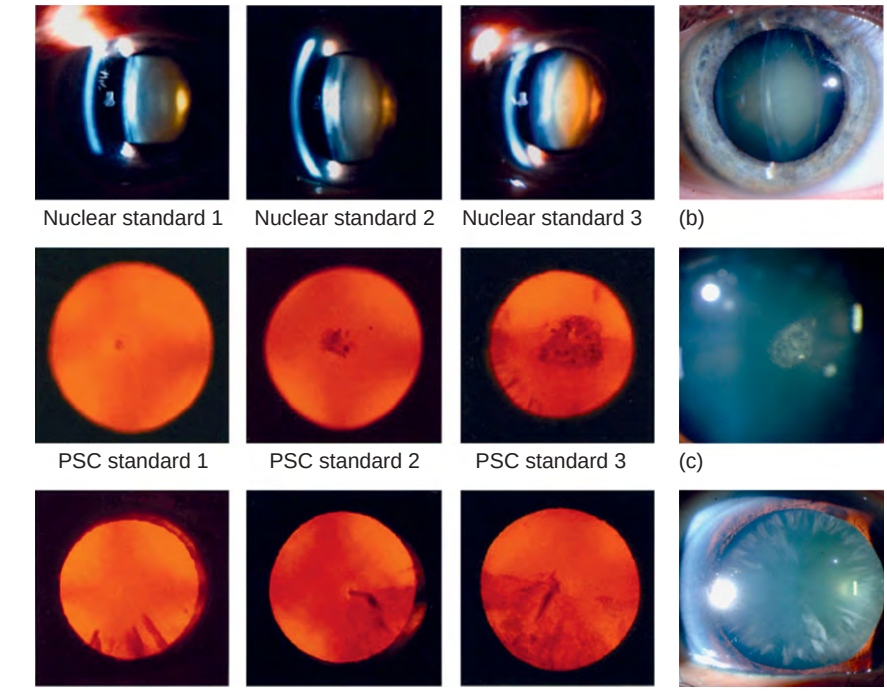

Figure 1 Three main types of age-related cataracts. (a) The age-related eye disease study (AREDS) system for classifying cataracts from photographs. (b) Nuclear cataracts. available. This necessitates the study of either, siblings, twins and parent-offspring trios, or genetically unrelated case-control cohorts of affected and unaffected individuals. Initially, studies of affected sibling-pairs revealed that a positive family history was strongly correlated with age-related nuclear and posterior subcapsular cataract (more thanthreefold increased risk), consistent with clustering of lens opacities within families due to genetic or environmental factors. Subsequently, affected sib-pair and twin studies indicated that genetic factors may directly account for 14–48% of the heritability for age-related nuclear cataract, and 24–75% of the heritability for age-related cortical cataract. However, the molecular identity of such genetic risk factors cannot be resolved by purely statistics-based approaches.

Genes Associated with Age-Related Cataract

In contrast to inherited congenital or childhood forms of cataracts, relatively few genes have been unambiguously associated with risk of age-related cataracts (Table 1). Several studies have taken a candidate gene approach in which genes are selected for investigation based on their known biological function and/or suspected dysfunction. Polymorphisms in the genes coding for the antioxidant enzymes known as glutathione-S-transferases (GSTs) have been variously associated with age-related cataract in different populations. Homozygous deletion of the GSTM1 gene (i.e., the null genotype) has been implicated in risk of age-related cataract in Japanese, Chinese, Iranian, and Turkish populations; however, no such association was replicated in Italian or Chinese populations. Notably, in the Iranian and Turkish studies the association of the GSTM1-null genotype was restricted to females, and in the latter study combination of the GSTM1-null and GSTT1-positive genotypes was associated with nuclear cataract in females. Conversely, the GSTM1-positive genotype, either alone or in combination with the GSTP1*A allele, was identified as a possible risk factor for age-related cortical cataract in an Estonian population. Thus, the association of GSTM1 with age-related cataract remains controversial.

The Osaka variant of the gene for galactokinase-1 (GALK1), which catalyzes the first step in galactose metabolism to glucose, has been detected at increased frequency (~7%) in a Japanese cohort with age-related cataract. This heterozygous protein coding variation involves an amino acid substitution (Ala198Val) that results in reduced stability of the variant enzyme and mild galactokinase deficiency equivalent to about 20% of normal levels. The Osaka variant was also present in Koreans (frequency 2.8%) but had a lower incidence in Chinese, and was not detected in blacks and whites from the United States or in a North Italian cohort with

age-related cataract. These observations suggest that the genetic contribution to age-related cataract might vary in different populations. Interestingly, severe homozygous mutations in the GALK1 gene are usually associated with classic autosomal recessive galactokinase-1 deficiency and isolated congenital cataracts as a result of galactitol (a sugar alcohol) accumulation in the lens. These findings show that different variations in the GALK1 gene can contribute to both congenital and age-related forms of cataract – a principle that is also borne out by an increased incidence of pre-senile cataract in individuals (age range 20–55 years) heterozygous for GALK1 deficiency.

Sequence variations in the gene for heat-shock transcription factor-4 (HSF4) have been associated with age-related cortical cataract in a Chinese population. HSF4 regulates the expression of several heat shock proteins, including the abundant lens protein alphaB-crystallin, in response to elevated temperature and other stress stimuli such as photo-oxidation. Mutations affecting the protein coding regions, or exons, of the HSF4 gene have been shown to underlie autosomal dominant and autosomal recessive forms of familial cataract. Several of the HSF4 variants associated with age-related cataract were found within intervening sequences or introns, which are located between the protein coding exons of the gene. Other variants found within exons only resulted in silent changes that did not alter the amino acid composition of HSF4. However, two of the coding variants resulted in amino acid substitutions (Gln61Arg and Arg116His) that were predicted to impair the DNA binding activity of HSF4. Interestingly, one of the coding variants (Arg116His) was also found in two control subjects suggesting that it should be excluded as a risk variant for age-related cataract. However, both control subjects were aged in their mid-40s and may have been pre-symptomatic for age-related cataract. These studies highlight the necessity for acquiring well matched (age and gender, etc.) cases and controls for association studies of age-related cataract.

In addition to the arbitrary testing of candidate genes for association with age-related cataract, the first systematic scan of the human genome using linkage analysis of affected families and sibling-pairs, has recently mapped a number of major and minor susceptibility loci for age-related cortical cataract in whites from the United States. The most statistically significant loci were found on chromosome 6 (6p12-q12), and the short arm of chromosome 1 (1p36), with up to ten potential loci on eight other chromosomes. The disease interval on chromosome 6 spanned the centromere and contained a large number of positional-candidate genes (about 260) for age-related cataract; however, the identity of the susceptibility gene remains to be determined. The disease interval on chromosome 1p also contained a large number of positional-candidate genes (about 400). However, this region also appeared to overlap loci for inherited forms of childhood cataract that were associated with mutations in the gene coding for Eph-receptor type-A2 (EPHA2), which functions in the ephrin cell signaling and guidance pathway. Subsequent candidate gene association analysis identified single nucleotide polymorphisms (SNPs) in the EPHA2 region of chromosome 1 that were associated with age-related cortical cataract in an Italian population, further suggesting that EPHA2 variants may underlie both inherited and age-related forms of cataract.

Summary and Future Prospects

Beyond aging and certain environmental risk factors for age-related cataract, it is increasingly clear that genetic

risk factors are involved in this common multifactorial disease; however, their identity remains uncertain. The association of GST gene variants with age-related cataract, albeit inconsistent, supports the general belief that variants of genes that function in antioxidant metabolism, especially to combat photo-oxidative stress, are likely to be involved in age-related cataract. The association of GALK1, HSF4, and EPHA2 gene variants with age-related cataract further raises the likelihood that genes underlying inherited forms of cataract also contribute to age-related cataract. In addition, variants of several other genes involved in diverse biological functions have been tentatively implicated in age-related cataract; including those mediating estrogen metabolism, systemic inflammation, DNA repair, folate metabolism, and kinesin motor transport. Further replication and validation studies of these genes, coupled with functional expression studies of their variant proteins, will be required to substantiate their role in age-related cataractogenesis. However, it is likely that all of the currently implicated genes will account for a relatively small percentage of the genetic risk for age-related cataract.

In the future, family-based linkage studies and case-control association studies will continue to identify, test, and validate candidate genes for age-related cataract. In addition, the advent of whole genome sequencing techniques capable of deciphering genetic variation in large numbers of individuals will provide powerful insights regarding the molecular genetic basis of age-related cataract. Ultimately, a molecular genetic understanding of age-related cataract may aid the design of targeted drugs to help treat and manage cataract, thereby reducing the need for surgery, and permit better evaluation of environmental risk factors in order to promote lifestyle interventions (e.g., diet) that help to delay or even prevent cataract onset.

Published by Elsevier Ltd.

Glossary

Anterior segment of eye – The front part of the eyeball including the sclera, conjunctiva, cornea, anterior chamber, iris, and lens.
Genotype – The genetic makeup of an organism with reference to a single trait, a set of traits, or an entire complex of traits.
Lens crystallin – The structural proteins of the eye lens that contribute to transparency by providing a constant refractive index.
Mendelian – In accord with Gregor Mendel's laws including independent assortment. A Mendelian trait is one that is controlled by a single locus in either a dominant or recessive fashion.
Phenotype – The physical appearance of an organism or part of an organism as distinguished from its genetic makeup.
Transcription factor – A protein that binds to specific parts of DNA using DNA-binding domains and controls the transfer (or transcription) of genetic information from DNA to RNA.

Introduction

Definition

The human lens is derived from surface ectoderm that begins to thicken and forms the lens placode, then invaginates toward the developing optic cup to form the lens pit. The lens pit closes, and the resulting lens vesicle is pinched off from surface ectoderm. The resulting lens can first be detected at 3–4 weeks of gestation. Cells along the posterior layer of the optic vesicle elongate to fill the vesicle by the seventh week of development and become primary fiber cells. These eventually become the embryonic lens nucleus (the central nonnucleated fiber cells). The remaining cells become the cuboidal anterior epithelium, some of which divide and differentiate to become secondary fibers. Fiber cells make up the bulk of the lens. Layers of nucleated cortical fiber cells form highly ordered concentric shells around the nonnucleated central fiber cells which make up the lens nucleus. The ends of the more peripheral fiber cells abut in branched anterior and posterior sutures (**Figure 1**).

Cataract can be defined as any opacity of the crystalline lens. Lens opacity results when the refractive index of the lens varies significantly over distances approximating the wavelength of the transmitted light. Changes in either lens cell structure or lens protein constituents or both can cause variation in the refractive index sufficient to cause opacity. The cellular architecture of the fiber cells and, particularly, their sutures is important for light transmission and lens transparency. There is little extracellular space between the fiber cells, which have many interdigitations. Cataracts can be associated with breakdown of the lens microarchitecture, including vacuole formation, cell dysplasia or degradation, or death. High-molecular-weight protein aggregates, roughly 1000 Å or more in size can also result in light scattering and opacity. The short-range ordered packing of the crystallins, which make up over 90% of soluble lens proteins, is important for the maintenance of lens transparency, as are the support systems that keep the lens in a reduced state under osmotic and ionic equilibrium.

Cataract can be defined by age at onset. A congenital or infantile cataract is visible within the first year of life. A juvenile cataract appears within the first decade of life, and a presenile cataract occurs before the age of 45 years. The boundaries between different types of cataract are approximate. Moreover, subtle cataracts might not be seen for years after they occur, especially if they are asymptomatic. The age of onset of a cataract does not necessarily indicate its etiology. Congenital cataracts may be hereditary or secondary to a prenatal infection (e.g., rubella), and cataracts associated with a systemic or genetic disease such as retinitis pigmentosa may not occur until the second or third decade.

It seems likely that when mutations in crystallins or other lens proteins are sufficient in and of themselves to cause protein aggregation they usually result in congenital cataract, while if they merely increase susceptibility to environmental insults, such as light, hyperglycemia, or oxidative damage, they might contribute to age-related cataract. Thus, hereditary congenital cataracts tend to be inherited in a Mendelian fashion with high penetrance, making them significantly more amenable to genetic and biochemical study.

Overview

Between 8.3% and 25% of congenital cataracts are estimated to be inherited, depending to some extent on the

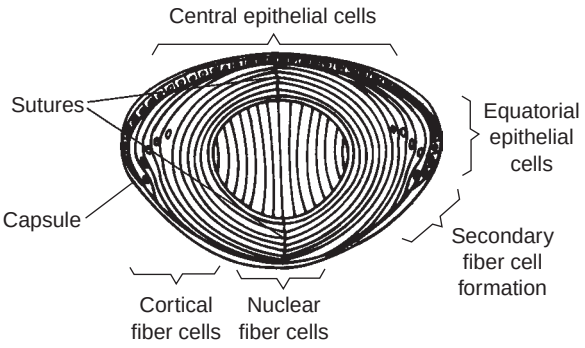

Figure 1 Simplified structure of the adult lens.

population studied. Inherited cataracts may involve the lens alone, or may be associated with other ocular anomalies including microphthalmia (abnormally small eyes), aniridia (underdevelopment of the iris), and other anterior chamber developmental anomalies. For example, mutations in the transcription factors PITX3 or FOXC1 can cause cataracts associated with anterior segment mesenchymal dysgenesis (heterogeneous group of complex diseases including aniridia). Cataracts may also be part of multisystem genetic disorders such as chromosome abnormalities, Lowe syndrome, or neurofibromatosis type 2. In some cases, this distinction is blurred. Inherited cataracts may be isolated and mild in some individuals and associated with additional findings in others, as in the developmental abnormality anterior segment mesenchymal dysgenesis including corneal opacification and optic nerve atrophy resulting from abnormalities in the PITX3 gene 6. The most frequent inheritance pattern for Mendelian cataracts is autosomal dominant, although they can also be inherited as autosomal recessive or X-linked traits. It is difficult to derive phenotype–genotype relationships for congenital cataracts.

Phenotypically identical cataracts can result from mutations at different genetic loci and may have different inheritance patterns. Conversely, phenotypically variable cataracts can be found in a single large family. The most common classification system which has been developed based on the anatomic location and morphologic appearance of the opacity is that of Merin. In this system, polar opacities involve either the anterior or posterior pole of the lens and may include the posterior subcapsular lens cortex (PSC) extending to the lens capsule. Zonular cataracts include specific regions of the lens and include nuclear cataracts, which affect the fetal or embryonic lens nucleus and lamellar cataracts. Nuclear lamellar cataracts tend to affect lens fibers that are formed at the same time, resulting in a shell-like opacity. Zonular cataracts can also be characterized as dense or pulverulent (dusty appearing), and can be accompanied by arcuate opacities extending into the lens cortex, called cortical riders. Sutural cataracts, also called stellate, affect the sutural regions of the fetal nucleus, at which the ends of the lens fiber cells converge. Cerulean cataracts, also called blue-dot cataracts, have numerous small bluish opacities in the lens cortex and nucleus. Finally, membranous or capsular cataracts can result from resorption of lens proteins after capsular rupture, often from a traumatized or severely dysfunctional lens. In addition, there are a number of morphologically distinctive types of cataract such as the ant egg cataract and corraliform cataracts that are not well described by the above system. Total (mature or complete) cataracts can often occur as the end result of a process that began as one of the above cataract types, and capsular or membranous cataracts can result from resorption of lens proteins after capsular rupture (**Figure 2**).

Most mutant genes responsible for congenital cataracts have been identified by a combination of linkage analysis and screening candidate genes for mutations. Linkage analysis, a powerful tool to sort out the different genetic loci which can cause human cataracts, localizes mutant genes causing inherited cataracts to a specific chromosomal region by comparing their inheritance patterns to those of known genetic markers. Usually candidate genes in this region are sequenced in order of the perceived likelihood of their involvement. New analytical approaches, using homozygosity mapping methods to identify genomic regions identical by descent, promise to be increasingly useful in studying rare autosomal recessive cataracts from isolated populations.

Genetic Causes of Congenital Cataract

Isolated Congenital Cataract

Currently there are about 41 genetic loci to which isolated or primary cataracts have been mapped (**Table 1**), although the number is constantly increasing. Of these, eight are associated with additional abnormalities, primarily in the anterior chamber of the eye. Two notable exceptions are cataracts associated with the αB-crystallin gene, mutations in which can cause either isolated cataracts or cataracts associated with myopathy, and the ferritin light chain gene, which causes the hyperferritinemia-cataract syndrome (**Table 1**). With the exception of heat-shock transcription factor 4 (HSF4), most inherited cataracts caused by mutations in growth or transcription factors can be associated with extralenticular abnormalities. In some cases including some connexin 50, αA-, and γD-crystallin mutations, inherited congenital cataracts are associated with microcornea and even microphthalmia, although this may represent early severe disruption of the lens with consequent effects on anterior chamber and eye development.

Of the mapped isolated congenital or infantile cataract loci, over 25 have been associated with mutations in specific genes. Of the cataract families for whom the mutant gene is known, about 40% have mutations in crystallins,

about 17% have mutations in connexins, with the remainder largely split between the genes for transcription factors (including HSF4, NHS, macrophage activating factor (MAF), VSX2, PITX3, and eyes absent homolog 1 (EYA1), 20%), aquaporin-0 (AQP0, MIP, 3%), and beaded filament structural protein-2 (BFSP2, 3%). The remaining represents mutations in a group of other unrelated genes (5%) or are currently unknown (19%).

Phenotype–Genotype Correlations

Overall, it is difficult to draw phenotype–genotype correlations for congenital cataracts. However, the limited experience available suggests some rules of thumb, as described below. However, inheritance of the same mutation in different families or even the same mutation within the same family can result in radically different cataract morphologies and severities. This suggests that additional genes or environmental factors might modify the expression of the primary mutation associated with the cataracts. Conversely, cataracts with similar or identical clinical presentations can result from mutations in quite different genes, perhaps reflecting the limited spectrum of responses of the lens cells to a variety of insults.

Specific Genes Implicated in Congenital Cataracts

α-Crystallins

In addition to being of clinical interest, examination of the genes implicated in congenital cataracts and the resultant lens pathology provide insight into those biological pathways important for lens transparency. Mutations in the αA-crystallin gene have been implicated in both autosomal recessive and dominant cataracts. The autosomal recessive cataracts are associated with a chain-termination mutation near the beginning of the protein, which would be expected to cause loss of function of the mutant protein without affecting protein synthesized from the normal gene. The viewpoint that heterozygotes have clear lenses suggests that half the normal levels of α-crystallin provide sufficient chaperone-like activity and structural crystallin packing to establish and maintain lens transparency. Autosomal dominant cataracts result from nonconservative missense mutations in the αA-crystallin gene. These presumably cause cataracts by the mutant αA-crystallin protein exerting a deleterious effect that actively damages the lens cell or its constituent proteins, or inhibits the function of the remaining normal α-crystallin, rather than acting through loss of chaperone or structural function as the recessive cataract appears to do.

The αA- and αB-crystallins are found in the lens associated together into large multimeric complexes and function similarly *in vitro* as chaperones. This might suggest that mutations in αB-crystallin would behave similarly to those in αA-crystallin, at least in the lens. However, the first human mutation reported in αB-crystallin, a missense mutation that reduces αB-crystallin chaperone activity dramatically and causes aggregation and precipitation of the protein under stress, was associated with desmin-related myopathy and only discrete cataracts. The myopathy associated with this mutation is probably related to the expression of αB-crystallin, but not αA-crystallin, in muscle cells. In these cells αA-crystallin, binds and presumably stabilizes desmin. Similarly, an αB-crystallin knockout mouse exhibits myopathy without cataracts, confirming that αB-crystallin is necessary for normal myocyte function. However, a deletion in the αB-crystallin gene resulting in a frameshift and expression of an aberrant 184-aminoacid protein causes autosomal dominant cataracts in the absence of myopathy. This is consistent with the dominant αA-crystallin-associated cataract in which the aberrant protein is likely to have a toxic effect on the lens cells. Both αA- and αB-crystallin mutations tend to be associated with nuclear or nuclear lamellar or on occasion posterior polar cataracts.

βγ-Crystallins

Most mutations described in the βγ-crystallins would be expected to cause major abnormalities in the protein structure, presumably resulting in an unstable protein. This then precipitates from solution and serves as a nidus for additional protein denaturation and precipitation, perhaps in some cases as an amyloid-type fibril. This process overcomes the chaperone activity of the α-crystallins and results in cataract formation. The specific mutations include missense mutations, insertions changing the reading frame and causing expression of aberrant peptides with premature termination, and splice. Although phenotypes can vary significantly, mutations in γ-crystallins tend to produce nuclear or nuclear lamellar cataracts, consistent with their high level of expression in the lens nucleus. The cataract phenotypes reported with mutations in the β-crystallins is somewhat more varied, ranging in different families and even individuals within families from zonular pulverulent with or without involvement of the sutures to cerulean cataracts. These cataracts can also be progressive in nature. This variability emphasizes the importance of modifying genes or perhaps random developmental events in the phenotypic expression of these mutations. In contrast to those mutations that produce unstable proteins, two mutations in γD-crystallin have been shown not to alter the protein fold, but rather to alter the surface characteristics of the protein, lowering the solubility and enhancing the crystal nucleation rate so that they precipitate out of solution, in at least one case actually forming crystals in the lens. Similarly, a third mutation, the protein also maintains a normal protein fold, but is susceptible to thiol-mediated

aggregation. Thus, βγ-crystallins need not undergo denaturation or other major changes in their protein folds to cause cataracts.

Feritin Light Chain

In the hyperferritinemia-cataract syndrome, cataracts are associated with hyperferritinemia without iron overload. The ferritin L iron-responsive element, a stem-loop structure in the 5′-untranslated region of the ferritin messenger RNA (mRNA) normally binds a cytoplasmic protein, the iron regulatory protein, which then inhibits translation of ferritin mRNA. Mutations in this structure and overexpression of ferritin by loss of translational control result in ferritin L (light chain) levels in the lens increasing to levels approaching those of a crystallin. This results in crystallization of ferritin in the lens, similar to that described above for certain γD-crystallin mutations, and the appearance of breadcrumb-like opacities in the cortex and nucleus. Both of these emphasize the necessity for crystallins or other proteins to be exceptionally soluble to be expressed at such high levels in the lens without causing dysfunction.

Connexins

The avascular lens depends on gap junctions with their constituent proteins connexins 46 and 50 are for nutrition and intercellular communication, and mutations in either gene often result in nuclear or nuclear lamellar cataracts. At least one cataract-associated mutation in the connexin 50 gene has been shown to result in a connexin that fails to form functional gap-junctional channels with incorporation of even a single mutant protein molecule into a gap-junction-inhibiting channel function. Two mutations in connexin 46 also fail to form intercellular channels; however, these mutant connexins are not able to participate in gap-junction formation at all, indicating that inhibition of channel function by products of the normal gene is not necessary for cataract formation. Mutations in connexin 50 can also be associated with microcornea.

Membrane Proteins

In addition to connexins, a diverse group of other membrane proteins has been associated with early-onset cataracts. Lamellar, sutural, and polymorphic cataracts, often progressive, have been associated with mutations in the aquaporin-0 gene (AQP0, MIP), which codes for a water channel that represents the most abundant intrinsic membrane protein in the lens. Two missense mutations have been shown to act by interfering with normal trafficking of AQP0 to the plasma membrane and thus with water-channel activity. In addition, both mutant proteins appear to interfere with water-channel activity by normal AQP0, consistent with a dominant-negative mechanism for the autosomal dominant inheritance of the cataracts. Mutations in LIM2, the second most abundant intrinsic membrane protein of the lens fiber cells, have been described as causing either presenile cortical and nuclear sutural cataracts or severe congenital total autosomal recessive congenital cataracts. Similarly, mutations in TMEM114, a transmembrane protein homolog of LIM2, have been associated with congenital lamellar cataracts, and mutation of the gene for a solute transporter protein (SLC16A12) has been associated with juvenile cataracts, microcornea, and renal glucosuria. Finally, mutations in the gene for a charged multivesicular body protein (CHMP4B), a membrane-associated component of the endosome sorting complex, has been linked with autosomal dominant posterior polar cataracts.

Beaded Filament-Specific Proteins

Beaded filaments are a type of intermediate filament unique to the lens fiber cells in which they replace vimentin filaments in the epithelial and elongating cortical cells. They are made up of BFSP1 (also called CP115 or filensin) and BFSP2 (also called CP49 or phakinin), highly divergent intermediate filament proteins that combine in the presence of α-crystallin to form the appropriate beaded structure. Cataracts associated with mutations in BFSP2 are often nuclear with a sutural component and progressive in nature, consistent with fiber-cell-specific expression of the beaded filament proteins. In contrast, a family with a frameshift mutation in BFSP1 shows fluffy and cystic cortical cataracts requiring surgery in early childhood.

Transcription Factors

Mutations in a number of transcription factors can also cause congenital cataracts. HSF4 is a member of the HSF family, members of which regulate expression of heat-shock proteins, including lens αB-crystallin, in response to elevated temperature and other stress stimuli (e.g., oxidation). Mutations in HSF4 have been associated with both autosomal dominant and recessive cataracts. The dominant cataracts tend to present in early childhood are described as total, lamellar, or stellate with an anterior polar component, including the historically important Marner cataract. Recessive cataracts tend to have a congenital or early childhood onset and range in severity from nuclear with some cortical involvement to total lens opacities. Interestingly, the dominant mutations in HSF4 lie within the α-helical DNA-binding domain, whereas the recessive mutations lie outside this highly conserved functional domain. Mutations in many other growth factors tend to be associated with extralenticular findings, including anterior segment mesenchymal dysgenesis (ASMD). Mutations in FOXE3 and PITX3 have been associated with ASMD and cataracts. EYA1 has been associated with ASMD and

cataracts as well as BOR, central corneal opacity, and Peter anomaly. Mutations in VSX2 have been associated with cataracts and microphthalmia, inferior iris coloboma, and absence of papillary apertures, and mutations in MAF with cataracts, microcornea, and iris coloboma. Finally, mutations in NHS are usually associated with total congenital cataracts with the dental anomalies and dysmorphic features that make up the Nance Horan syndrome.

Enzymes

Two genes for enzymes involved in diverse aspects of carbohydrate metabolism have been associated with autosomal recessive forms of congenital cataracts. Mutations in GALK1, which encodes the first enzyme in galactose metabolism, underlie galactokinase-deficiency cataracts, which may be treated by dietary, rather than surgical, intervention. Second, homozygous mutations in the gene for glucosaminyl (*N*-acetyl) transferase-2 (*GCNT2*), a blood group (Ii) glycosylation enzyme, result in persistence of the fetal I-antigen on red blood cells. This failure to synthesize the adult I-antigen has been associated with congenital cataracts in Asian and Arab families.

Current State of Knowledge and Future

While the eye lens is appealing as a relatively simple system with only epithelial and fiber cells, both derived from one progenitor cell type, it is still a remarkably complex tissue. This is reflected by the large number of genes which, when mutated, can cause cataract. While it has been estimated that there are 30 autosomal dominant congenital cataract loci in man, the number of currently identified loci is well past that figure. This in part reflects the complex systems required to maintain lens transparency over the lifetime of an organism. However, not all proteins necessary for lens transparency are common causes of cataracts in all populations. For example, while some studies suggest that crystallin and connexin mutations, the two most frequently found groups of mutant genes in families reported to date, account for as much as 75% of familial childhood cataracts in a European population, others in Indian and Australian populations suggest that the figure might be much lower. It seems likely that each population might have its own set of genes responsible for congenital cataracts, and that at least some largely remain to be delineated.

Glutamate Receptors in Retina

M M Slaughter, University at Buffalo School of Medicine, Buffalo, NY, USA

Glossary

Alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) – A ligand for ionotropic glutamate receptors mediating fast synaptic transmission. AMPA is also used as the name of the receptor.
D-2-Amino-5-phosphonovalerate (D-AP5) – An antagonist at NMDA glutamate receptors.
D-(-)-2-Amino-7-phosphonoheptanoic acid (D-AP7) – An antagonist at NMDA glutamate receptors.
(5R,10S)-(-)-5-Methyl-10,11-dihydro-5H-dibenzo [a,d]cylc ohepten-5,10-imine maleate (MK801) – A noncompetitive antagonist at NMDA-type glutamate receptors.
Glutamate receptors (GluRs) – The receptors that bind and respond to the excitatory amino acid transmitter, L-glutamate. They fall under two classes called ionotropic and metabotropic. Ionotropic receptors are composed of multiple subunits and are named after pharmacological agents (NMDA, kainate, AMPA) that activate them. Metabotropic receptors are generally guanine-nucleotide-binding protein (G-protein)-coupled receptors.
Metabotropic glutamate receptors (mGluRs) – The glutamate receptors that act through an indirect or metabotropic mechanism. They are members of the class of guanine-nucleotide-binding protein (G-protein)-coupled receptors.
***N*-methyl-D-aspartic acid (NMDA)** – An agonist binding to ionotropic glutamate receptors. The receptors themselves are generally referred to as NMDA receptors.
(RS)-α-Cyclopropyl-4-phosphonophenylglycine (CPPG) – An antagonist of group III metabotropic glutamate receptors in the retina.
6-Cyano-7-nitroquinoxaline-2,3-dione (CNQX) – An antagonist of AMPA and kainate glutamate receptors.
6,7-Dinitroquinoxaline-2,3-dione (DNQX) – An antagonist of AMPA and kainate glutamate receptors.
2-Amino-4 phosphonobutyric acid (APB, AP4) – The selective agonist for group III metabotropic glutamate receptors in the retina.
(2S)-2-Amino-2-[(1S,2S)-2-carboxycycloprop-1-yl]-3-(xan th-9-yl) propanoic acid (LY341495) – An antagonist for group III metabotropic glutamate receptors in the retina.
2,3-Dioxo-6-nitro-1,2,3,4-tetrahydrobenzo[f] quinoxaline-7-sulfonamide (NBQX) – An antagonist of AMPA and kainate glutamate receptors.

Glutamate Pathways

Glutamate serves as the primary excitatory neurotransmitter in both plexiform layers of the retina. Rods and cones release glutamate, which activates postsynaptic, metabotropic receptors on the ON bipolar cells and alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/kainic acid (KA) ionotropic receptors on horizontal and OFF bipolar cells. In turn, both ON and OFF bipolar cells release glutamate, which excites amacrine and ganglion cells by activating AMPA/KA and *N*-methyl-D-aspartic acid (NMDA) receptors. Finally, ganglion cells also use glutamate to excite neurons in visual centers throughout the brain. Thus, glutamate mediates the entire straight-line synaptic circuit in retina. In addition, there are metabotropic glutamate receptors that modulate voltage-activated calcium channels at each of these synapses, generally serving to suppress transmitter release.

The retina has exemplified a number of unique features of glutamate receptors. These include the exclusive utilization of metabotropic receptors to form a sign-inverting synapse, the complexity of desensitization in signal coding, the direct control of neurotransmitter release by ionotropic glutamate receptors, and information encoding by glutamate receptor subtypes.

Glutamate Receptor Pharmacology

Retina possesses AMPA, kainate, NMDA, as well as several metabotropic glutamate receptors. The first three, ionotropic receptors, are tetramers. The AMPA receptors are made from four glutamate receptor subunits (GluR1–4), with additional variability added by splice variants. The kainate (KA) receptors are formed from GluR5–7 and KA1&2 subunits. The NMDA receptors contain NR1, NR2, and NR3 subunits, again with variations. Eight metabotropic glutamate receptors have been identified and divided into three groups based on sequence homology. They likely exist as dimers.

One means of separating receptors is the use of pharmacological agents. This works best for NMDA receptors, where its namesake (*N*-methyl-D-aspartate) is a very selective agonist, and there are reasonably selective and potent antagonists such as D-AP5, D-AP7, and MK-801. AMPA and kainate receptors are difficult to separate. For example, kainate is actually a better agonist at AMPA receptors than is AMPA, because it does not desensitize the receptor as much. There are a number of antagonists that block AMPA/kainate receptors selectively, not affecting NMDA receptors, such as 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX), 2,3-dihydroxy-6-nitro-7-sulfamoyl-benzo[f] quinoxaline-2,3-dione (NBQX), and 6,7-dinitroquinoxaline-2,3-dione (DNQX). However, these antagonists do not discriminate between AMPA and kainate receptors. Sometimes agents that block desensitization are used to distinguish between KA and AMPA receptors, notably cyclothiazide, which reduces AMPAR desensitization.

Among the metabotropic receptors, there is a very good selective agonist for group III receptors (L-AP4, also called 2-amino-4 phosphonobutyric acid (APB)), which is important in retina. There are also several reasonable antagonists, including (RS)-α-cyclopropyl-4-phosphonophenylglycine (CPPG) and LY341495. There are selective agonists and antagonists for the groups I and II as well, but they are not as effective.

Glutamate Receptors in Distal Retina

The glutamate receptors postsynaptic to photoreceptors present an instructive example of information processing by receptor specialization. The ON and OFF bipolar cells read the output of photoreceptors but respond oppositely. The OFF bipolar and horizontal cells use ionotropic AMPA and kainate receptors to follow the voltage polarity of photoreceptors. However, the ON bipolar cells utilize metabotropic glutamate receptors to produce a sign-inverting synapse. In each case, receptor desensitization produces tonic and phasic responses.

The ON Bipolar Cell Metabotropic Glutamate Receptor

Metabotropic glutamate receptors are omnipresent in retina. The most striking member is the mGluR6 metabotropic receptor, which is exclusively localized at ON bipolar cell dendrites and inverts the polarity of photoreceptor light responses. The ON pathway in vision, conveyed by half the visual pathways throughout the brain, originates at this synaptic receptor. The mGluR6 is selectively activated by 2-amino-4-phosphonobutyrate (APB, AP4) and is linked to a pertussis-toxin-sensitive G-protein cascade. L-AP4 activates all of the group III metabotropic receptors, found in many retinal neurons. However, its effect in eliminating light responses of ON bipolar cells is so prominent, and its effects at other group III receptors so subtle, that it is used as a selective agonist for the ON bipolar synapse. The activation of the mGluR6 activates guanine-nucleotide-binding proteins (G proteins) of the Go type, leading to closure of cationic channels and hyperpolariztion of ON bipolar cells. This is analogous to the effect of rhodopsin activation in photoreceptors, which initially led to the erroneous assumption that the transduction mechanisms were similar. Instead, cyclic guanosine monophosphate (cGMP) potentiates the postsynaptic response to light and may be particularly important in the detection of responses to dim light. Calcium has the opposite effect: by activating calcineurin, it reduces postsynaptic responses to light (the removal of glutamate). Consequently, ON bipolar cell light responses have a peak and then a plateau phase due to the negative effect of calcium influx during the light response. There are two types of ON bipolar cell: one in which the plateau phase is about half the peak response and another type in which the plateau is only about 10% of the peak. Furthermore, these two types of bipolar cells can be correlated with sustained and transient ganglion cells, respectively. Thus, the rate and extent of desensitization of the mGluR6 pathway account for the transient and sustained pathways throughout the ON system.

Fish ON bipolar cell dendrites possess an APB-sensitive metabotropic receptor and a glutamate transporter that gates a chloride channel. The former produces a glutamate-induced hyperpolarization due to a conductance decrease in a cationic channel, while the latter induces a conductance increase in a chloride channel. Rods relay information through metabotropic receptors, while cones utilize the transporter channel.

The OFF Bipolar Cell AMPA and Kainate Receptors

AMPA receptors dominate the dendritic synapses of OFF bipolar and horizontal cells, with a smaller contribution from kainate receptors. Curiously, NMDA receptors are absent. Kainate and AMPA receptors generally desensitize rapidly, an apparent paradox at a synapse with tonic transmitter release. One explanation is that a specific synaptic release site is used so infrequently that desensitized receptors can fully recover before they are likely to be recruited again. However, it has also been found that subtypes of OFF bipolar cell have glutamate receptors with widely differing desensitization rates, indicating that desensitization can be an important information mechanism in labeled lines of the OFF pathway.

In the all-cone ground squirrel retina, there are three types of OFF bipolar cell and each has a distinct AMPA or kainate receptor with discrete desensitization properties. The time course of desensitization filters the photoreceptor

signal both by truncating the response to glutamate during desensitization and by reducing the responsiveness to ensuing glutamate inputs. This is postulated to prevent receptor saturation and ensure that the OFF bipolar cells can follow the full dynamic range of the cones.

In an additional layer of processing, the AMPA-containing and kainate-containing OFF bipolar cells sense very different glutamate levels. One type of OFF bipolar cell sends its dendrites into the synaptic invagination and responds to high concentrations of glutamate with a rapidly desensitizing AMPA receptor that produces transient responses. The dendrites of a second bipolar cell type are at basal synapses further from the glutamate release site, detect smaller and more gradually changing levels of glutamate, and produce sustained responses through activation of kainate receptors.

Glutamatergic Feedback to Photoreceptors

Photoreceptor presynaptic output can be suppressed by glutamate acting on either metabotropic receptors or transporter-associated channels. These receptors may mediate autoreceptor negative feedback or lateral inhibition from other photoreceptors. Metabotropic group II receptors suppress the output of both rods and cones. The mGluR8, a member of the group III family, has also been found in photoreceptor terminals where it suppresses calcium currents, a mechanism to reduce photoreceptor output.

In addition, glutamate activates a transporter in salamander rods and cones. This transporter protein contains a chloride channel so that it can perform the dual functions of an ionic channel and an amino acid carrier. From noise analysis in cones the single-channel conductance is very low (0.7 pS) and opens briefly (mean openings are 2 ms), yet high glutamate levels shut the terminal and suppress calcium influx in cones.

These two feedback systems may mediate different pathways. They likely have different glutamate sensitivities; metabotropic receptors respond to low micromolar concentrations, while the transporter is active when glutamate levels approach millimolar concentrations.

Modulation of Glutamate Receptors

Postsynaptic ionotropic glutamate receptors in distal retina can be modulated by two mechanisms. One is suppression by zinc, which is apparently released by photoreceptors. The AMPA receptors in horizontal cells are suppressed by zinc, although the physiological impact is unclear because the half maximal inhibitory concentration (IC_{50}) is several hundred micromolar. The other mechanism is enhancement by dopamine, an interplexiform cell or paracrine transmitter that activates sites throughout the distal retina. In fish horizontal cells, dopamine slows the desensitization of AMPA receptors. Single-channel recording in perch horizontal cells shows that dopamine increases receptor current by increasing the opening rate and decreasing the closing rate. In salamander, dopamine increases the glutamate current in OFF bipolar cells by almost 50%, acting through D1 receptors to increase cyclic adenosine monophosphate (cAMP). In Xenopus horizontal cells, which apparently possess only one type of GluR, the AMPA and glutamate currents were small and transient under photopic conditions, larger and more sustained in dark-adapted retina. In contrast, the responses to kainate were largest in light-adapted retina and potentiated by D1 dopamine agonists. The suggestion is that even though one receptor population is used, the receptors at rod and cone synapses are differentially modulated.

Glutamate Receptors in Inner Retina

Similar to the photoreceptors, bipolar cells are capable of tonic glutamate release. The postsynaptic amacrine and ganglion cells possess AMPA, kainate, and also NMDA receptors. There are also pre- and postsynaptic metabotropic glutamate receptors. The synaptic input to ganglion cells is mediated predominantly by AMPA receptors; kainate receptors may be more relevant in at least some types of amacrine cells. There are a number of interesting aspects to the glutamate receptors at these synapses. One is the appearance of NMDA receptors, which play no role in the outer retina. Another is the placement of different receptors on each side of a single ribbon synapse, an exquisite refinement of the receptor specialization observed in the distal retina. Then, there is the continued importance of receptor desensitization in the shaping of transiently responding amacrine and ganglion cells.

The Mystery of the NMDA Receptors

The NMDA-type glutamate receptors are present in amacrine and ganglion cells, where exogenous application of NMDA agonists is as stimulatory as AMPA/KA agonists. Ganglion cells are particularly sensitive. In rabbit, it is estimated that 87% of ganglion cells and 58% of amacrine cells are excited by NMDA. Strangely, synaptically driven NMDA receptors are difficult to detect. Spontaneous miniature synaptic events stimulate AMPA, but not NMDA currents. The relative effectiveness of weak competitive antagonists suggest that NMDA receptors are exposed to lower concentrations of synaptic glutamate, consistent with NMDA receptors being further from presynaptic release sites than AMPA receptors. Often, inhibition has to be blocked using gamma aminobutyric acid (GABA) and glycine receptor antagonists, before prominent synaptic NMDA currents are evident. Under these conditions, some studies indicate that NMDA receptors can linearize the synaptic response since they are larger at

depolarized potentials (due to removal of magnesium block), where diminished driving force has reduced the AMPA/KA currents. In addition, in the presence of GABA and glycine receptor antagonists, transient excitatory postsynaptic currents (EPSCs) in salamander ganglion cells can be separated into an early AMPA receptor current and delayed, longer-duration NMDA receptor current.

The NMDA receptor is a tetramer that is activated by the simultaneous binding of two glutamate molecules and two glycine molecules. In some parts of the central nervous system, D-serine replaces glycine as the essential coagonist. This seems to be the case in retina, where experiments using D-serine degradative enzymes reduce the endogenous activation of NMDA receptors, which may eventually explain the disparity between the large number of NMDA receptors and the small endogenous activation, if receptor activation may be dependent not on glutamate release but on D-serine levels. A major potential source of D-serine is glial cells, leading to speculation that glia cells can control synaptic transmission.

Glutamate Receptor Diversity at the Synapse

One feature of retinal glutamatergic synapses is the diverse yet discrete receptor distribution at a single synapse. This theme starts in the distal retina. Photoreceptor glutamate activates metabotropic receptors on ON bipolar cells and different types of ionotropic receptors at different types of OFF bipolar cells. In salamander retina, the dendrites of rod-dominant OFF bipolar cells have AMPA receptors with larger conductances and slower rates of desensitization than the corresponding cone-dominant OFF bipolar cells. In rat rods and cones, the GluR6/7 kainate receptors are found in horizontal cells postsynaptic to rods and cones, but in only one of the two horizontal cell processes that enter each invagination. This theme is repeated in the inner plexiform layer (IPL). Rod bipolar cells synapse onto AII, S1, and S2 amacrine cells. Only the AIIs have GluR2/3 or 4 subunits, while only the S1 has delta1/2 subunits. Thus, the three postsynaptic amacrine cells can respond differently to the same glutamate signal. Even at a single synaptic dyad, the subunit expressed at one side is different from that expressed on the other. The KA receptor subunits are found postsynaptic to rod and cone bipolar cells, but generally only one of the two postsynaptic elements at the dyad possesses a particular kainate receptor subunit. Remarkably, mGluR feedback may be just as specialized. The mGluR7 receptors are bipolar cell autoreceptors likely to mediate negative-feedback regulation of glutamate release. They are found only on one side of the dyad, presumably allowing separate control of glutamate release on each side of this single ribbon synapse. In addition, kainate GluR6/7 receptors are postsynaptic to bipolar cells, but not at the ribbon synapse dyads. Based on several studies, it seems likely that kainate receptors are on amacrine but not on ganglion cells. Furthermore, receptor expression occurs in sublayers within the IPL. For example, in primate retina, although GluR2,2/3, and 4 are concentrated throughout the IPL, NR2A subunits are found in two bands at the center of the IPL.

This receptor diversity in the IPL is linked to release. In salamander retina, spontaneous events can be separated into release of single vesicles or multiple vesicles that stimulate fast-activating AMPA receptors and other release sites where there are clusters of vesicles released, which more slowly activate either AMPA or NMDA receptors.

Calcium-Permeable AMPA Receptors

Although the NMDA-type glutamate receptor is noted for its unusually high calcium permeability, the earliest evidence that AMPA receptors could also pass high levels of calcium came from the retina. Two intriguing ramifications are the direct control of transmitter release and the long-term modulation at a synapse. A central dogma of neurophysiology is that voltage-gated calcium channels allow for the increase in internal calcium that initiates vesicle fusion. However, there is a circuit in retina where this is not necessary. Bipolar cells activate AMPA receptors on A17, the amacrine cell, leading to a direct influx of calcium. This stimulates GABA transmitter release and inhibitory feedback to the bipolar cell. This type of regulation has a number of unique potential properties, such as voltage-independent transmitter release that is localized to a specific synaptic location rather than controlled by electrical spread throughout the neuron.

Receptor Desensitization

It is well established that kainate and AMPA receptors exhibit rapid desensitization, while NMDA receptors do not. The AMPA desensitization found at the bipolar to ganglion cell synapse makes the responses of some ganglion cells more phasic than that of the bipolar cells that drive them. This is of particular relevance in retina because ganglion cells can be divided into tonic and phasic light responders, carrying different components of the decomposed image. It has been suggested that the transient responses are formed by AMPA receptor desensitization in ganglion cells. However, this is likely to be a supplementary mechanism, with the primary formation of this dichotomy occurring in distal (outer) retina.

Pre- and Postsynaptic Metabotropic Glutamate Receptors

In bipolar cell terminals, the group III metabotropic receptors suppress glutamate output. As might be expected, this

feedback is minor or absent during weak light stimulation, but becomes saturating under strong light stimulation. Experimental evidence indicates that one function of this feedback is to extend the dynamic range at the synapse by requiring a stronger stimulus before the synapse becomes saturated.

Postsynaptically, ganglion cells possess a plethora of metabotropic receptors that act to suppress calcium channels. This is unrelated to transmitter release (unless ganglion cells are presynaptic within the retina) but these receptors may be important in regulating calcium-activated potassium channels that are found in most, if not all, ganglion cells. Thus, activation of mGluRs will facilitate excitatory responses in ganglion cells.

H

Hemangiogenesis versus Lymphangiogenesis

A Kaipainen, University of Calgary, Calgary, AB, Canada
D R Bielenberg, Harvard Medical School, Boston, MA, USA

Glossary

Angioblast – A mesodermal cell committed to the endothelial lineage; primitive endothelial cell.
E9.5 – It denotes embryonic day 9.5 or 9.5 days following fertilization; total gestation in a mouse requires 18–20 days depending on the strain.
Hemangioblast – A stem cell that can give rise to cells of both the endothelial lineage and the hematopoietic lineage.
Hemangiogenesis – It is also called angiogenesis – widely used as a general term to mean the growth of blood vessels yet more exactly means the sprouting of a capillary to form new capillaries.
Lymphangiogenesis – The growth of new lymphatic vessels by sprouting or the enlarging of existing vessels due to proliferation.
Vasculogenesis – The formation of *de novo* blood vessels by the assembly of angioblasts.

Hemangiogenesis

Overview

All cells in the body require oxygen and nutrients to survive. Therefore, all tissues in the body are vascularized (with a few exceptions: cartilage, cornea, lens, epidermis); and nearly every cell is located within the diffusion distance of oxygen (100–150 μm) from a capillary. In a developing embryo, new blood vessels are needed to supply oxygen and nutrients to the newly developing organs and tissues; therefore, it is not surprising that the vascular system is one of the first organ to develop. In fact, endothelial cells, the cells that line blood vessels, provide trophic cues during organ morphogenesis and help to guide organogenesis.

Vasculogenesis, the *de novo* formation of blood vessels, is the process responsible for the first vessels in life. This process occurs via the aggregation and assembly of angioblasts, endothelial cell precursors, to form a primitive vascular plexus. This plexus is then remodeled by a process called hemangiogenesis (or angiogenesis) that consists of the pruning of some vessels and the sprouting and growth of other vessels. Vasculogenesis occurs primarily during development, whereas hemangiogenesis can be induced throughout life. The development of the vascular system consists of a series of interrelated steps, including commitment of mesodermal cells toward the endothelial lineage or the formation of angioblasts, the alignment of angioblasts into cords, the formation of lumens within these cords, and the organization into functional channels.

Angioblasts

Endothelial cells and circulating hematopoietic cells share a close relationship in proximity, locality, and ancestry as their precursor cells, angioblasts and hemangioblasts, share a common lineage. Hemangioblasts are pluripotent cells that can give rise to cells of both the endothelial lineage and the hematopoietic lineage. Angioblasts originate from mesodermal cells and express two key markers: vascular endothelial growth factor receptor-2 (VEGFR2, also called Flk1) and a basic helix–loop–helix transcription factor called Tal1/Scl. As angioblasts differentiate into endothelial cells, they lose expression of Tal1 but VEGFR2 expression remains. The new endothelial cells begin to express platelet endothelial cell adhesion molecule-1 (PECAM-1, also called CD31), CD34, vascular endothelial (VE)-cadherin, and later the angiopoietin receptor, Tie2. A specialized subset of endothelial cells derived from angioblasts has hemogenic potential indicating that these endothelial cells can spawn hematopoietic cells.

Vasculogenesis

Vasculogenesis refers to the *in situ* differentiation of mesodermal cells (angioblasts) into endothelial cells and the subsequent morphogenesis and organization into a vascular plexus. This vascular development process depends upon both intrinsic (pre-patterned) criteria as well as extrinsic responses to stimuli. Vasculogenesis occurs in two spatially and temporally distinct phases within the embryo: (1) the formation of the extra-embryonic vessels and (2) the formation of intra-embryonic vessels. Intra- and extra-embryonic vessels are derived from different cell populations. First, yolk sac angioblasts, a subset of Brachyury-positive cells expressing VEGFR2, migrate out from the posterior primitive streak (mice E6.5–8.0) into the extra-embryonic yolk sac and coalesce into blood islands. These angiogblasts migrate, aggregate, expand, and differentiate to form a labyrinth of small vessels. These cords of endothelial cells form tight cell–cell connections followed by the formation of an internal lumen.

The second wave of endothelial cell differentiation occurs inside the embryo together with the formation of the endocardium from progenitor cells (mice E7.3). At the same time as the heart is developing, intra-embryonic angioblasts migrate out from the lateral plate mesoderm to the midline, coalesce, and differentiate to form the dorsal aorta (mice E7.6) just ventral to the notochord. The angioblasts also form the posterial cardinal vein ventral to the aorta. The dorsal aorta and the cardinal vein are formed directly without an intermediate plexus phase. Between E8.0 and E8.5 in mice (end of third week of development in humans), a rudimentary circulatory system is completed. With the first heartbeat, the vascular channels become perfused for the first time. From E8.5 (mice), the vitelline vein is first seen to transport nutrients from the yolk sac out into the embryo.

Angiogenesis

Secondary vessels are formed via the angiogenic process. Hemangiogenesis (also called angiogenesis) is widely used as a general term to describe the growth of blood vessels yet more exactly defines the sprouting of a capillary from a preexisting one. The first new sprouts form the intersegmental (intersomitic) vessels (which align dorsoventrally at the myotomal boundary between the somites) and the parachordal vessels (which align longitudinally at either side of the notochord).

During the angiogenic phase, the plexus composed of endothelial cells gradually expands by means of sprouting, proliferation, pruning, apoptosis, and remodeling into a network of hierarchical vessels consisting of larger vessels branching into smaller ones. Very early in this process, the endothelial cells already have acquired an arterial or venous specification, suggesting that the fate is genetically programmed and not determined solely by external factors such as hemodynamic forces. The Notch family of factors drives arterial differentiation, whereas the transcription factor, COUP-TFII, drives the venous genetic program. The heart pumps oxygenated blood into arteries, the largest vessels, which branch into smaller vessels called arterioles, which ramify into smaller vessels called capillaries. Capillaries exchange oxygen and nutrients between the blood and the surrounding tissues. Then they return the (usually de-oxygenated) blood back toward the heart via larger vessels called venules to still larger vessels called veins. During the final steps of maturation, vessels recruit smooth muscle cells called pericytes to surround and stabilize the vessel. Pericytes provide strength and help to regulate perfusion.

Lymphangiogenesis

Structure and Function of the Lymphatic System

The lymphatic system forms a one-way route, carrying lymph from the periphery of tissues through the thoracic duct or the right lymphatic duct into the venous blood. These two main lymphatic ducts are connected with the venous system at the junction of the left internal jugular vein and the left subclavian vein and at the veins of the right jugulo-subclavian confluence, respectively. However, other potential lymphaticovenous communications (e.g., iliac and renal areas) may become functional when lymphatic pressure rises or in a pathological situation.

Beyond its main function, the drainage of extravasated tissue fluid back to the venous circulation, the lymphatic system serves several other functions which include transport for immune defense and absorption of lipids from the intestine. Nearly all vascularized tissues, except the central nervous system (CNS), are invested with lymphatic vessels. The CNS lacks lymphatics since it has a blood-neural barrier that is less permeable than other tissues and is immune-privileged. In the eye, lymph drainage is present in the conjunctiva, sclera, and choriocapillaris, while there is no lymph drainage for the anterior chamber, vitreous cavity, subretinal space, or cornea.

In the peripheral tissues, lymphatic vessels and blood vessels are found in close proximity, yet the two systems never intermix (**Figure 1**). Lymphatic functions are reflected in the particular structure of the lymphatic vessels. A main characteristic is the discontinuity of the basement membrane at the interface between the lymphatic endothelium and the surrounding connective tissue that facilitates active fluid transport. In some tissues, including intestine, lung, and skin, lymphatic vessels completely lack a basement membrane. A second major characteristic is the tight connection of the lymphatic endothelial cells (LECs) to the surrounding matrix through anchoring filaments (AFs). It has been proposed

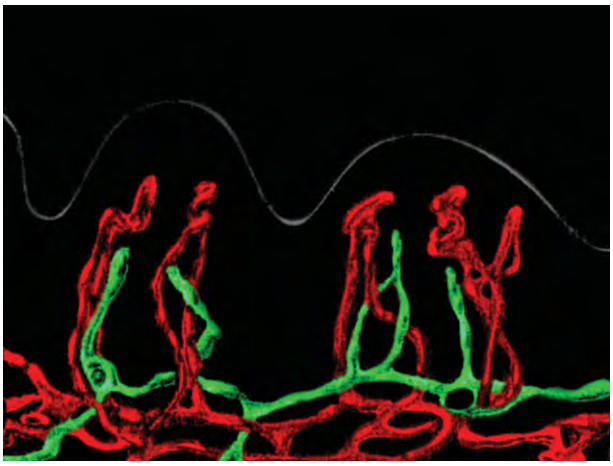

Figure 1 Schematic depicting the blood vascular system (red color) and the lymphatic system (green color) in the skin. Notice that the two systems are closely aligned but never mix. The blood vascular system is a closed circulatory system, with arteries leading to capillary loops (shown close to the epidermis) and draining to veins. The lymphatic capillaries are blind-ended, finger-like projections that begin near the epidermis and drain into larger collecting lymphatic vessels.

Table 1 Differences between the vascular and lymphatic systems

Blood vessels	*Lymphatic vessels*
Circular system	Unidirectional system
Artery → capillary → vein	Capillary → collector → TD → vein
Formed E6.5–9.5 (mice)	Sprout from vein at E9.5–12.5 (mice)
Capillaries have BM	Capillaries have discontinuous or lack BM
SMC may surround capillaries	Capillaries lack SMC
No anchoring filaments	Capillaries have anchoring filaments
Flow is dictated by heart beat	Flow is dictated by interstitial pressure
No valves in capillaries	Capillaries have valves
Blood inside the vessels	Lymph inside the vessels
Contain all the hematopoietic cells	Contain immune cells and no RBC
Retina has blood vessels	Retina lacks lymphatic vessels

BM, basement membrane; RBC, red blood cells; SMC, smooth muscle cells; TD, thoracic duct.

that tissue expansion due to excess interstitial fluid tightens the AFs, which pull on the lymphatic capillaries, thereby creating gaps between the LEC to increase the intake of fluid. A third characteristic of the lymphatic vessels is that valves in the vessel wall are already present at the level of capillaries, unlike in the venous blood system where they are found only in venules and larger vessels. These valves ensure unidirectional flow of the lymphatic fluid, which starts in the blind-ended capillaries. Furthermore, LECs are significantly larger than the blood endothelial cells; this enables elongation of the cells to accommodate the tissue stretch (see **Table 1** for a list of differences between lymphatic vessels and blood vessels).

Short Historical Perspective on Studying the Lymphatic System

The discovery of the lymphatic system was based upon intestinal absorption of fat particles, which color lymphatic capillaries white and stand out from the red-colored blood capillaries. Although Hippocrates described lymph nodes and termed lymphatic fluid as white blood in the fifth century BC, it was not until 1622, when Gasparo Aselli, an Italian anatomist and surgeon, provided a more accurate description of the lymphatic system. However, it took three more centuries before any detailed investigations were performed on the developmental origin of the lymphatic system. At the turn of the twentieth century, three different theories of the formation of the lymphatic system were proposed. These theories were based on studies from serial sections of fixed tissues or on ink injections into the lymphatic system. Florence Sabin hypothesized that the lymphatic system originates from the venous system as sprouts (lymph sacs) growing in a centrifugal manner. Huntington and Kampmeier proposed that lymphatics are derived from mesenchymal cells that grow in a centripetal manner. According to a third theory, the lymphatic system is in part derived from the venous endothelium and in part, notably at the periphery, through mesenchymal differentiation.

Lymphangiogenesis in Development

Modern molecular biological analysis predominantly supports Sabin's theory. She demonstrated that lymphatic vessel development is initiated by budding of six lymphatic sacs from the venous endothelium. These include the paired jugular lymph sacs, the paired posterior iliac lymph sacs, the retroperitoneal sac, and the cisterna chili, which are localized at sites where large veins merge and are separated from veins with valves. The lymphatic vessels grow radially outward from these lymph sacs as continuous channels into the periphery. In humans, the lymphatic system starts to develop at gestational day 35, when the jugular lymph sacs begin to bud. By gestational day 56, the primitive lymphatic system, which includes all six lymph sacs, is complete.

The first molecular clues supporting Sabin's theory came from Alitalo and co-workers in 1995 who reported the first gene whose expression pattern is highly specific for lymphatic tissue: *VEGFR3*. VEGFR3, a member of the VEGF receptor family, which also comprises VEGFR1 and -2, is expressed already at E7.5 (mice) in the

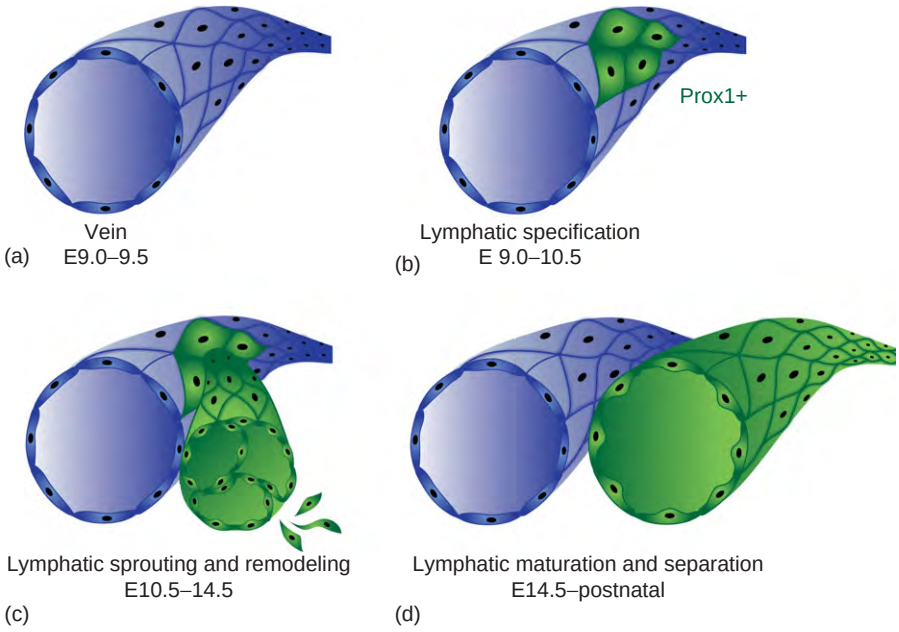

Figure 2 The formation of the lymphatic system during development in mice.(a) The first lymphatic vessel sprouts from the cardinal vein. (b) A subset of venous endothelial cells express Prox1. (c) Prox1 induces lymphatic-associated genes necessary for migration of lymphatic endothelial cells. (d) Lymphatic vessel remodeling and maturation results in separate venous and lymphatic vessels.

endothelium of the cardinal vein and between developing somites and in angioblasts of the head mesenchyme. At approximately E14.5 (mice), its expression becomes restricted predominantly to the lymphatic endothelium. One possible trigger for the downregulation of *VEGFR3* in blood endothelium is the interaction of the endothelium with smooth muscle cells.

More recently, Guillermo Oliver has proposed a four-stage model for the differentiation of the lymphatic vasculature: (1) lymphatic competence, (2) lymphatic bias, (3) lymphatic specification, and (4) LEC differentiation (**Figure 2**). He defines LEC competence (stage 1) as an autonomous ability of a venous endothelium to respond to one or more specific lymphatic-inducing signal(s), which is controlled by a developmental timer. Studies, performed in mice at E9.0–E9.5, suggest that the earliest indication that differentiation has started is the random expression of lymphatic vessel endothelial hyaluronan receptor 1 (LYVE1) in some of the endothelial cells of the anterior cardinal vein. However, LYVE1 is not a competence factor as *LYVE1*-deficient embryos lack any obvious lymphatic phenotype.

The fate of the LEC is determined during bias (stage 2). On one side of the anterior cardinal vein shortly after cells start expressing LYVE1 a subpopulation of venous endothelial cells starts expressing the transcription factor, prospero-related homeobox-1 gene, *Prox1* (**Figure 2(b)**). Expression of Prox1 in the venous endothelial cells is necessary and sufficient to drive lymphatic cell differentiation. However, signals that switch on Prox1 expression are not known.

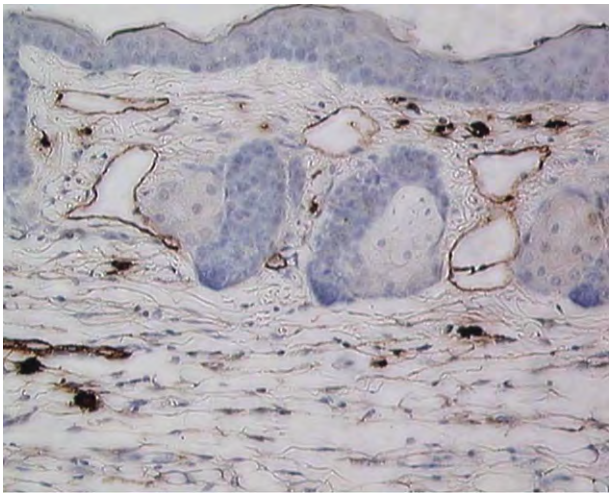

Figure 3 Lymphatic vessels in the skin. Immunohistochemistry using anti-podoplanin antibodies reveals lymphatic vessels (brown color) near the murine epidermis. The section is counterstained with hematoxylin. Notice the large lumens and presence of valves in the lymphatic capillaries.

During specification (stage 3) the cells differentiate into the desired phenotype independently from their regional environment. Once the cells express Prox1, they begin to express, in a stepwise manner, other lymphatic markers, such as neuropilin-2 and podoplanin (**Figure 3**). Concomitantly, they lose the expression of blood endothelial cell markers, such as CD34 and laminin. In the final stage of LEC differentiation (stage 4), first the lymphatic sacs and then the mature vessel network is

formed. In order to form lymphatic sacs, Prox1-positive cells have to migrate. This process requires VEGFC, a ligand for VEGFR3, expression by stromal cells. Thus, mice deficient for *VEGFC* fail to form primary lymph sacs. VEGF-C driven early sprouting and migration of LEC is modified by another ligand for VEGFR3, VEGF-D. Unlike blood capillaries, which sprout during angiogenesis at right angles from the original capillary, lymphatic capillaries sprout at a more acute angle to the vein or subsequent lymphatic vessel (**Figure 2(c)**).

Molecular studies have demonstrated that at E14.5, mouse embryos that are deficient for cytoplasmic signaling proteins Syk, SLP76, or phospholipase-Cγ2 (PLCγ2) exhibit backflow of blood into lymphatic sacs and vessels. This deficiency indicates that at the sites of budding, the valves did not develop, and/or that the anastomoses did not close. Syk, SLP76, and PLCγ2 are only expressed on hematopoietic cells, and the underlying mechanism for the defect seen in embryos lacking these factors is still unclear. However, a noncell autonomous mechanism is possible. In this model, these three genes stimulate a nonendothelial cell (e.g., a hematopoietic stem cell) to secrete factors that activate developmental processes in lymphatic endothelium that are needed for the separation of blood and lymphatic vessels. Alternatively, a cell autonomous mechanism is also possible in which Syk, SLP76, or PLCγ2 are transiently expressed in hematopoietic stem cells which can differentiate into lymphatic endothelial precursor cells.

Several genes involved in lymphatic vessel maturation and patterning have now been identified. A forkhead transcription factor, FOXC2, is required for the establishment of the pericyte- and smooth muscle cell (SMC)-free lymphatic capillaries, a process thought to happen through a specific repression of PDGFBB in lymphatic vessels. In addition, FOXC2 is important in lymphatic vessel patterning and in the genesis of valves in the collecting lymphatic vessels. Neuronal guidance molecules, such as ephrinB2 and neuropilin-2, are also involved. Mice lacking the carboxy-terminal PDZ domain in the ephrinB2 receptor display hyperplastic collecting lymphatics, lack luminal valves, and fail to remodel their primary lymphatic capillary plexus. Similarly, neuropilin2-mutant mice have a reduced number of lymphatic capillaries in the gut, dermis, heart, and lung. *In vitro* experiments show that Semaphorin 3F (SEMA3F), a ligand of neuropilin-2, repels LECs, suggesting that guidance molecules also regulate lymphatic vessel patterning in a similar manner as has been shown for the vascular system.

Defects in the lymphatic system have been found in various gene knock-out mouse strains. *Angiopoietin-2*-deficient mice develop large vessels with irregular edges and capillaries with abnormal patterning. Mice deficient in *podoplanin*, a mucin-type transmembrane glycoprotein (**Figure 3**), have dilated and disorganized intestinal and skin lymphatics, yet the subserosal lymphatic capillaries appear normal. Lymphatic vessels are filled with blood in mice deficient for *Fiaf* (fasting-induced adipose factor), while *Elk3*-(ETS-domain protein), *Integrin α9*-, *Prox1*-, *VEGFC*-, and *Ang2*-null mice have chylous ascites, and mutated *ephrinB2* mice have a chylothorax.

During the last 15 years immense progress has been made in understanding the mechanisms of lymphatic vessel development, notably the identification of genes that are essential for normal development, yet open questions remain, among which the most salient are: what are the signals that switch on expression of Prox1, a key trigger of LEC differentiation in the venous endothelium? Do mammals have lymphatic precursor cells capable of differentiating into LEC? And what controls the budding and separation of lymph sacs from the venous system?

Corneal Lymphangiogenesis

In adults, physiological lymphangiogenesis is an important component of normal wound healing as well as estrus and ovulation in the female reproductive tract. Pathological lymphangiogenesis can occur during lymphedema, lymphatic malformations, inflammatory diseases, and tumor metastasis. In the eye, the healthy cornea is devoid of both blood and lymphatic vessels. Therefore, corneal lymphangiogenesis, secondary to keratitis, graft rejection, limbal insufficiency, and chemical burns, is an undesirable process. On the other hand, because of its avascularity, the cornea displays an excellent in vivo model system to determine mechanisms of lymphangiogenesis. Indeed, several groups have established corneal lymphangiogenesis models to determine growth factor responses, test inhibitory factors, and study tumor lymphatic vessels. Cursiefen, Dana, and Streilein have established several models to determine the mechanisms involved in corneal lymphangiogenesis during corneal inflammatory processes and graft rejection.

Folkman and his coworkers have established a corneal lymphangiogenesis assay, which has allowed investigators to demonstrate that (1) lymphangiogenesis can occur, against existing dogma, without preexisting angiogenesis; (2) a pleotropic growth factor, fibroblast growth factor 2 (FGF2), can stimulate only lymphangiogenesis; and most importantly (3) this assay can identify factors that can inhibit lymphatic vessel growth. It is noteworthy that in this assay, while an 80ng-pellet of FGF2, which is routinely used in corneal angiogenesis assay, stimulates both angiogenesis and lymphangiogenesis, a 12.5ng FGF2-pellet only stimulated lymphatic vessel growth by inducing the production of VEGF-C and-D in corneal keratinocytes. FGF2-driven lymphangiogenesis could be inhibited with systemic administration of soluble receptors, sVEGFR2 or sVEGFR3, via adenoviruses or by neutralizing antibodies to these

receptors, as well as with the small molecule COX-2 inhibitors, rofecoxib and celecoxib.

A variety of modifications of the corneal lymphangiogenesis assays now exist which provide a powerful tool, not only to investigate diseases of the cornea and to evaluate possible therapies, but also to determine the more general mechanisms of lymphangiogenesis involved in, for example, tumor metastasis.

Summary

Hemangiogenesis and lymphangiogenesis are two important processes that occur early in development just before and during organogenesis. The development of the circulatory system allows nutrients and oxygen to be delivered in the blood throughout the body to all organs and tissues. The lymphatic system returns the fluid that leaks into the interstitial space back to the blood vascular system. Both systems are necessary for normal tissue homeostasis. Lymphatic vessels differ from blood vessels in many aspects, including their structure, function, expression of growth factor receptors, and response to ligands or cytokines. Hemangiogenesis and lymphangiogenesis are rare in the adult, but do occur during physiological processes such as wound healing and ovulation/menstruation. Pathological processes such as tumor progression also induce neovascularization to support the growing tumor cells with oxygen and nutrients. Likewise, these tumor vessels are leaky and result in increased interstitial pressure and lymphangiogenesis.

Hereditary Vitreoretinopathies

S Meredith and M Snead, Cambridge University Hospitals NHS Foundation Trust, Cambridge, UK

Glossary

Dominant negative effect – An altered gene product is produced that interacts with, and prevents the normal functioning of, the normal protein that is present.
Haploinsufficiency – A mutation resulting in a single copy of the normal gene is present so that only 50% of normal protein is produced, which is not enough for normal function.
OMIM – An online compendium of human genes and genetic phenotypes derived from the Mendelian Inheritance in Man (MIM) database.
Phenotype – The observable characteristics of an organism which are dependent on both genetic and environmental factors.
Pseudoexotropia – The appearance of a divergent squint when both eyes are fixing on the fovea measurable as a large angle kappa.

Introduction

The inherited vitreoretinopathies are collectively characterized by abnormalities in vitreous development and architecture. Since the development of the primary, secondary, and tertiary vitreous is largely complete by the first trimester, abnormalities of vitreous phenotype are present at birth, providing a useful and often pathognomonic diagnostic hallmark. In addition however, it is important to remember that the congenital anomalies of gel development and architecture will not be exempt from the more generalized age-related biochemical and structural changes.

Classification of the Hereditary Vitreoretinopathies

There have been significant, recent advances in both the clinical and molecular genetic analysis of the inherited vitreoretinopathies. Classification on clinical grounds (Table 1) is a helpful and convenient way to approach the investigation and diagnosis of the hereditary vitreoretinopathies. Four principal categories are currently recognized as follows: vitreoretinopathies that are associated with (1) skeletal abnormalities, (2) retinal dysfunction, (3) retinal vascular abnormalities, and (4) corneal guttata. Other varieties of inherited vitreoretinopathies do not fit easily into any of these subgroups and it is inevitable that a classification will be expanded as further clinical and molecular genetic heterogeneity is resolved.

Clinical Features of the Hereditary Vitreoretinopathies

The clinical features in each of the individual hereditary vitreoretinopathies are summarized in Table 2. Of the clinical features, the vitreous is the only category in which an abnormality has been universally described in the disorders collectively known as the hereditary vitreoretinopathies.

Vitreoretinopathies Associated with Skeletal Abnormalities

Stickler syndrome (OMIM #108300, #604841, and #184840)

The Stickler syndromes are a group of interrelated dominantly inherited disorders of collagen connective tissue which results in an abnormal vitreous embryology and a variable degree of orofacial abnormality, deafness, and arthropathy. Unlike some other hereditary arthro-ophthalmopathies, patients with Stickler syndrome have normal stature. In many patients with Stickler syndrome, systemic features may not be immediately obvious and the diagnosis of Stickler syndrome depends primarily on the recognition of characteristic congenital vitreous changes.

Stickler syndrome is the most common hereditary vitreoretinopathy. The majority of patients with Stickler syndrome have type 1 Stickler syndrome, which is part of the spectrum of type II collagen disorders. The type II collagenopathies, including type 1 Stickler syndrome, are characterized by a membranous vitreous appearance on biomicroscopy (Figure 1). Type 2 Stickler syndrome refers to Stickler syndrome associated with defects of type XI collagen and has a different vitreous appearance described as beaded or fibrillar (Figure 2). More recently, a recessive form of Stickler syndrome associated with mutations in a gene coding for type IX collagen has been described.

Table 1 Clinical classification of the hereditary vitreoretinopathies

	Syndrome		*OMIM classification*
Vitreoretinopathies associated with skeletal abnormalities			
1.	Stickler syndrome	Type 1	#108300
		Type 2	#604841
			#184840
2.	Kniest dysplasia		#156550
3.	Sponyloepiphyseal dysplasia congenital (SEDC)		#183900
4.	Marshall syndrome		#154780
5.	Knobloch syndrome		#267750
6.	Marfan syndrome		#154700
Vitreoretinopathies associated with progressive retinal dysfunction			
7.	Wagner syndrome		#143200
8.	Goldmann–Favre syndrome/Enhanced S-cone dystrophy		#268100
Vitreoretinopathies associated with abnormal retinal vasculature			
9.	Familial exudative vitreoretinopathy (FEVR)		#133780
			#601813
			#305390
10.	Autosomal dominant vitreoretinochoroidopathy (ADVIRC)		#193220
Vitreoretinopathy associated with corneal changes			
11.	Snowflake vitreoretinal degeneration		#193230

Weissenbacher–Zweymuller syndrome is sometimes included in the classification of the hereditary vitreoretinopathies. This syndrome is not associated with a vitreoretinopathy. The ocular features are hypertelorism, refractive errors, and strabismus. It results from mutations in the COL11A2 gene which is not expressed in the eye and is therefore not considered further in this article.

In contrast to the developmental myopia in the general population, myopia in Stickler syndrome is typically congenital, of high degree, and nonprogressive. It is important to remember that although the disorder is associated with congenital megalophthalmos, up to 20% of patients are not refractively myopic due to associated cornea plana.

Stickler syndrome is associated with a high risk of retinal detachment. The lifetime risk of retinal detachment is probably approaching 80% in type 1 Stickler syndrome, the majority of which is bilateral frequently as a result of a giant retinal tear at the pars plana (**Figures 3(a)** and **3(b)**). Other ocular findings are radial paravascular lattice, congenital quadrantic lamellar cataract (**Figure 4**), and early-onset nuclear sclerosis.

Orofacial abnormalities are common in Stickler syndrome and, even in the absence of a history of a cleft palate, it is important to examine the oral cavity for evidence of a submucous cleft or high-arch palate (**Figure 5**). Conductive hearing loss is an acknowledged association with any midline cleft via associated eustachian tube dysfunction, but the audiometry in Stickler syndrome will often reveal an additional high-tone (4000 Hz) sensorineural deficit as a result of associated developmental abnormalities of the cochlea.

Both collagen type II alpha 1 (COL2A1) and collagen type XI alpha 1 (COL11A1) are expressed in cartilage accounting for the combined ocular and skeletal manifestations in Stickler syndrome. The arthropathy typically manifests as joint laxity and hypermobility from an early age and a premature degenerative osteoarthropathy by the third to fourth decade, characteristically affecting the lumbosacral spine, hips, and knees.

The majority of patients with Stickler syndrome will exhibit both vitreoretinal and systemic involvement. A smaller but important subgroup presents with a predominantly ocular, or ocular-only, phenotype as a result of a mutation which is preferentially expressed in ocular tissues. Ophthalmologists have a key role to play in recognition and diagnosis of this important subgroup who are otherwise frequently undiagnosed until retinal detachment occurs.

Other more severe chondrodysplasias result from dominant negative changes within the type II collagen triple helix and include kniest dysplasia, spondyloepiphyseal dysplasia congenita (SEDC), and dominant spondylo-epi-metaphyseal dysplasia (SEMD). Similar to Stickler syndrome, these disorders present with congenital vitreous abnormalities, retinal detachment, deafness, and midline clefting, but with more pronounced arthropathy than Stickler syndrome and disproportionate (rhizomelic) limb shortening.

Kniest dysplasia (OMIM #156550)

Kniest dysplasia is an autosomal dominant vitreoretinopathy associated with skeletal dysplasia presenting with shortening of the trunk and limbs (**Figure 6**). The vitreous is congenitally abnormal and associated with megalophthalmos, cleft palate, and midfacial hypoplasia. Both conductive and sensorineural hearing loss are common and the joints display characteristic enlargement, particularly of the proximal interphalangeal joints, with the fingers appearing long and knobbly (**Figure 7**).

Spondyloepiphyseal dysplasia congenital (OMIM #183900)

SEDC is an autosomal dominant vitreoretinopathy presenting at birth with shortening of the trunk and thereafter progressively disproportionate (proximal) limb shortening, with the hands and feet appearing relatively normal in contrast to Kniest dysplasia, and flattening of the midface (**Figure 8**). The chest is barrel shaped with associated kyphosis and increased lumbar lordosis. The ocular phenotype is very similar to Stickler syndrome with congenital megalophthalmos and a type 1 (membranous) vitreous anomaly.

Marshall syndrome (OMIM #154780)

There is some uncertainty as to whether or not the Stickler and Marshall syndromes are clinically separate entities.

Table 2 Clinical features of the hereditary vitreoretinopathies

	Description of the clinical features								
Name of the syndrome	*Refractive error*	*Cornea*	*Lens*	*Vitreous*	*Retina*	*ERG*	*Optic disk*	*Other ocular features*	*Systemic features*
Vitreoretinopathies associated with skeletal abnormalities									
Stickler syndrome	Congenital nonprogressive myopia		Quadrantic lamellar or early-onset nuclear sclerosis	Membranous or beaded vitreous anomaly	Giant retinal tears, retinal detachment, and radial perivascular lattice degeneration		Myopic/ peri-papillary change	Megal-ophthalmos	Midfacial hypoplasia, cleft palate, joint hypermobility, arthropathy, and sensorineural deafness
Kniest dysplasia	Myopia			Membranous vitreous anomaly				Megal-ophthalmos	Shortening of trunk and limbs, midfacial hypoplasia, cleft palate, and hearing loss
SEDC	Myopia			Membranous vitreous anomaly				Megal-ophthalmos	Shortening of trunk and disproportionate proximal limb shortening, kyphosis, lumbar lordosis, and barrel-shaped chest
Marshall syndrome	Myopia		Congenital or juvenile cataracts	Syneresis				Ocular hypertelorism	Spondyloepiphyseal abnormalities, short stature, flat midface, cleft palate, sensorineural deafness, ectodermal dysplasia with hypotrichosis and hypohidrosis , dental structure abnormalities, calvarial thickening, and falx cerebri calcification
Knobloch	High myopia		Subluxated, cataract	Degenerative	Retinal detachment, macular degeneration				Occipital encephalocele, lung hypoplasia, cardiac dextroversion, flat nasal bridge, midface hypoplasia, joint hyperextensibility, unusual palmer crease, and unilateral duplicated renal collecting system
Marfan syndrome	Myopia	Cornea plana	Ectopia lentis, early nuclear sclerosis	Vitreous degeneration	Retinal detachment			Increased globe length, hypoplastic iris, and glaucoma	Increased height, scoliosis, lumbar lordosis, joint laxity, narrow high-arched palate, anterior chest deformity, mitral valve prolapse, mitral and aortic regurgitation, and dilatation of aortic root
Vitreoretinopathies associated with progressive retinal dysfunction									
Wagner syndrome/ erosive vitreoretinopathy	Myopic		Early-onset cataract	Syneresis and condensation, membranes	Chorioretinal atrophy, tractional and rhegmatogenous retinal detachment, and retinal pigment epithelial change	Subnormal		Ectopic fovea with pseudoexotropia, and hemeralopia	

Continued

Table 2 Continued

	Description of the clinical features								
Name of the syndrome	*Refractive error*	*Cornea*	*Lens*	*Vitreous*	*Retina*	*ERG*	*Optic disk*	*Other ocular features*	*Systemic features*
Goldmann–Favre syndrome/ enhanced S-cone dystrophy			Cortical lens opacities	Liquefaction and fibrillar changes	Equatorial chorioretinal atrophy and pigment clumping, peripheral and macular schisis, and diffuse vascular leakage	Dysfunctional cone mechanism			
Vitreoretinopathies associated with abnormal retinal vascularization									
FEVR				Peripheral 'snowflake' vitreous changes	Avascularity of peripheral retina, retinal exudates, retinal traction			Macular pucker, tractional and exudative detachment	
ADVIRC		Micro cornea	Congenital cataract	Fibrillar condensation	Circumferential hyperpigmented band, punctuate white opacities, choroidal atrophy, retinal neovascularization, posterior staphyloma	EOG abnormal at level of RPE		Nano-ophthalmos, and closed-angle glaucoma	
Vitreoretinopathy associated with corneal changes									
Snowflake vitreoretinal degeneration		Corneal guttata	Cataract in young adulthood	Fibrillar degeneration with thickened cortical vitreous	Peripheral retinal abnormalities (small, shiny, snowflake like), sheathing and obliteration of retinal vessels		Waxy pallor		

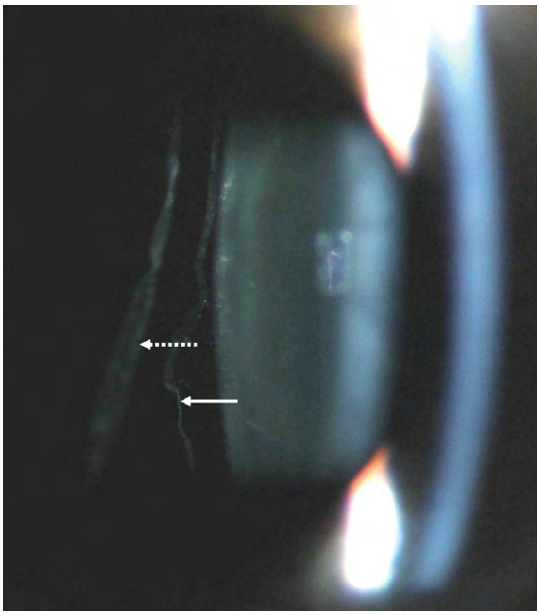

Figure 1 Membranous vitreous phenotype in type 1 Stickler syndrome. Dotted line indicates detached posterior hyaloid membrane; solid line indicates the type 1 membranous anomaly.

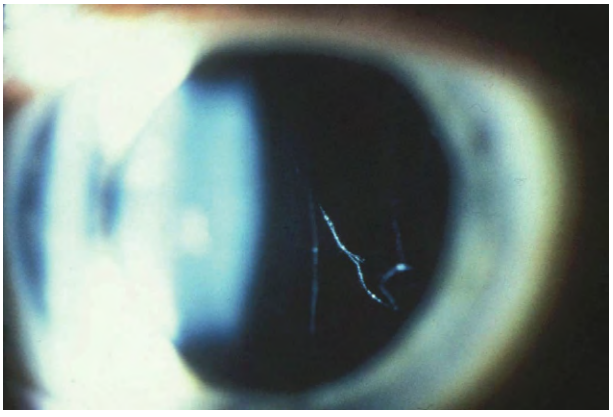

Figure 2 Beaded vitreous phenotype in type 2 Stickler.

Many features are shared such as midfacial hypoplasia, spondyloepiphyseal abnormalities, cleft palate, and sensorineural hearing loss, but patients with Marshall syndrome are reported to also have ectodermal dysplasia with hypertrichosis and hypohyidrosis, calvarial thickening, and ocular hypertelorism. The term Marshall–Stickler syndrome has been used but is potentially confusing and best avoided until Marshall syndrome is better characterized on clinical and molecular genetic grounds.

Knobloch syndrome (OMIM #267750)

Knobloch syndrome has been molecularly characterized and results from a mutation in the gene coding for type XVIII collagen. It has a more extensive systemic phenotype than Stickler or Marshall syndrome with developmental abnormalities described in several major systems of the body, including lung hypoplasia, cardiac dextroversion, and renal abnormalities as well as the ocular features of a degenerative vitreous appearance, high myopia, and retinal degeneration with retinal detachment. The distinguishing clinical feature of Knobloch syndrome is the presence of an occipital encephalocele.

Marfan syndrome (OMIM #154700)

Marfan syndrome is an autosomal dominant connective tissue disorder associated with an abnormal vitreous appearance, myopic astigmatism, and characteristic skeletal features of increased height with disproportionately long limbs and digits, scoliosis and lumbar lordosis, joint laxity, narrow, high-arched palate, and anterior chest deformity (**Figure 9**). Ectopia lentis (with the lens typically dislocated superior and temporally; **Figure 10**) is the ocular major Ghent criterion for the diagnosis of Marfan syndrome. Retinal detachment, myopia, increased globe length, cornea plana, hypoplastic iris, glaucoma, and early nuclear sclerotic cataract are all minor criteria. Marfan syndrome has cardiovascular manifestations of mitral valve prolapse,

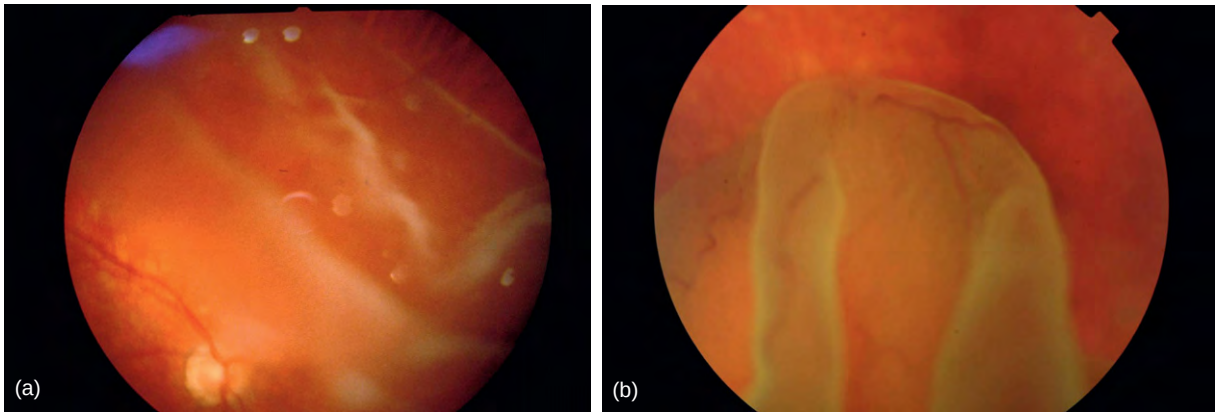

Figure 3 (a) Giant retinal tear characteristic of the retinal break seen in Stickler syndrome. (b) Retinal detachment caused by a giant retinal tear.

mitral regurgitation, dilation of the aortic root, and aortic regurgitation, with aneurysm of the aorta and aortic dissection being major life-threatening complications.

Vitreoretinopathies Associated with Progressive Retinal Dysfunction

The remaining hereditary vitreoretinopathies described in this article are purely ocular disorders. Those that are associated with retinal dysfunction – Wagner syndrome, erosive vitreoretinopathy, Goldmann–Favre syndrome, and enhanced S-cone syndrome (ESCS) – all have measurable electrophysiological changes of the retina demonstrated by recording a subnormal electroretinogram (ERG).

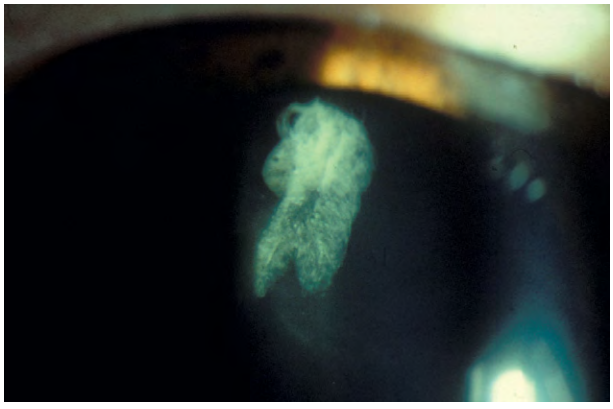

Figure 4 Congenital, quadrantic, lamellar cataract seen in both type 1 and type 2 Stickler syndrome.

Wagner syndrome (OMIM #143200)

The most striking finding in Wagner syndrome is the thickening and incomplete separation of the posterior hyaloid membrane, which tends to occur in a circular band and is variously described as a veil, sheets, or ropes. A large range of chorioretinal abnormalities have been described with the typical finding being chorioretinal atrophy with pigment migration into the retina (**Figure 11**). Electroretinographic responses are progressively subnormal (**Figure 12**) and visual-field testing demonstrates ring scotomas with eventual loss of central visual acuity. The chorioretinal pathology results in gradual progressive visual loss in the absence of retinal detachment, and has a progressive course. There is an association with early-onset cataract and mild myopia. Wagner syndrome is also associated with large angle kappas indicative of an ectopic fovea (**Figure 13**).

Prognosis in Wagner syndrome is poor with progressive visual loss. The risk of rhegmatogenous retinal detachment with Wagner syndrome is higher than that of the normal population, but the incidence does not appear to be as high as that seen in the Stickler syndromes.

The term Jansen syndrome has been used to describe a hereditary vitreoretinopathy but the clinical features reported are consistent with Wagner syndrome and linkage has been demonstrated in the original family to the same area as the causative gene in Wagner syndrome. The syndrome referred to as erosive vitreoretinopathy is reported to be associated with vitreous changes, hemeralopia with accompanying grossly reduced rod and cone responses, progressive chorioretinal atrophic changes, and combined traction-rhegmatogenous retinal detachments. Affected family members also had large angle kappas.

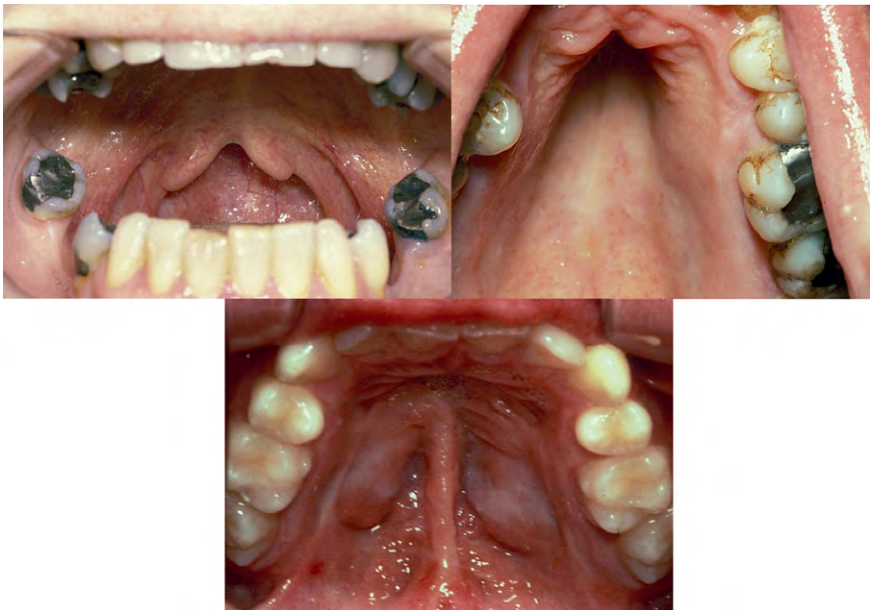

Figure 5 Bifid uvula and high-arch palate in Stickler syndrome.

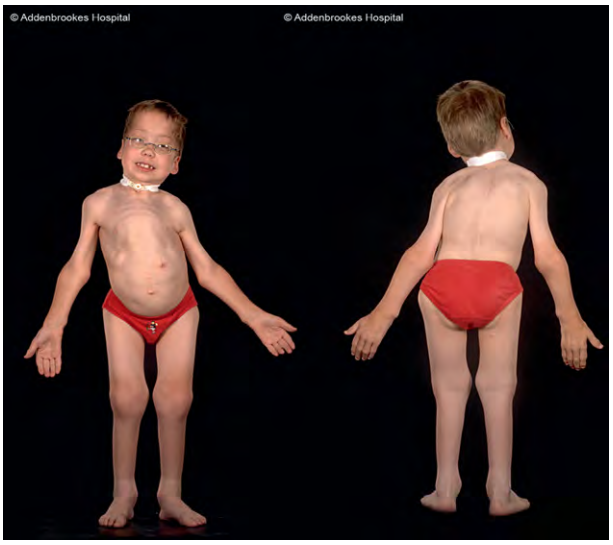

Figure 6 Kniest dysplasia demonstrating shortening of trunk and limbs.

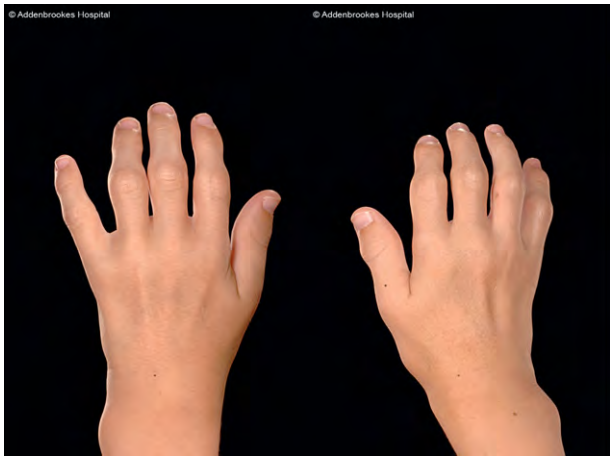

Figure 7 Interphalangeal dysplasia in Kniest dysplasia.

Mutations in the same gene that cause Wagner syndrome have been implicated in erosive vitreoretinopathy. It is likely both Jansen syndrome and erosive vitreoretinopathy are phenotypic variants of Wagner syndrome.

Goldmann–Favre syndrome/enhanced S-cone dystrophy (OMIM #268100)

Patients with Goldmann–Favre syndrome have liquefaction and fibrillar changes of the vitreous, night blindness, equatorial chorioretinal atrophy and pigment clumping, peripheral and macular schisis, cortical lens opacities, rod–cone dysfunction, and diffuse vascular leakage on fluorescein angiography. Goldmann–Favre syndrome is inherited as an autosomal recessive disorder and is now known to be caused by a mutation in the same gene that causes ESCS (the NR2E3 gene). ESCS is the only inherited retinal disease

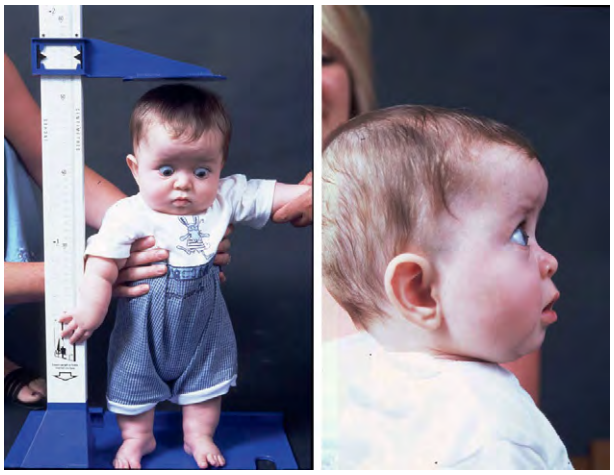

Figure 8 Spondyloepiphyseal dysplasia congenital demonstrating short stature and flattening of the midface.

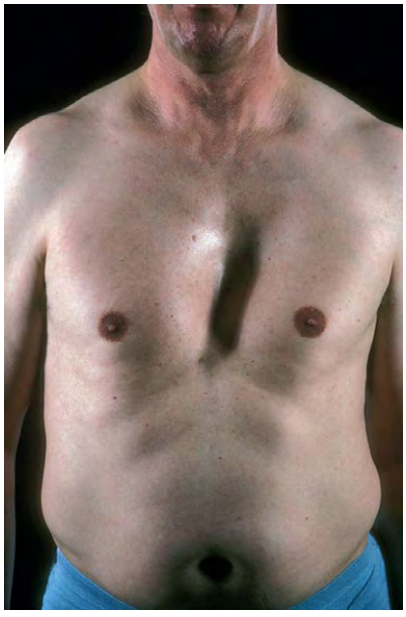

Figure 9 Pectus excavatum in Marfan syndrome.

which exhibits a gain in photoreceptor function, with patients showing enhanced sensitivity to blue (short wavelength) light, with night blindness and loss of sensitivity to long and medium wavelengths. The ERG findings in this group of disorders demonstrate undetectable rod-isolated responses and reduced combined rod–cone responses.

Vitreoretinopathies Associated with Abnormal Retinal Vasculature

The clinical feature on ocular examination of the hereditary vitreoretinopathies in this category is an abnormal

vascular pattern on the retina. This is demonstrated in more subtle cases using fluorescein angiographic studies.

Familial exudative vitreoretinopathy (OMIM #133780, #601813, and #305390)

The primary pathological process in familial exudative vitreoretinopathy (FEVR) is believed to be a premature arrest of retinal angiogenesis and vascular differentiation resulting in incomplete vascularization of the peripheral retina. The failure to vascularize the retina is the unifying feature seen in all affected individuals but, by itself, is usually asymptomatic. Secondary changes include neovascularization, retinal exudates, peripheral snowflake vitreous changes, and retinal traction. Epiretinal traction from vitreous and retinal surface membrane is the usual cause of retinal detachment and severe retinal distortion is a common finding resulting in retinal folds and tractional or combined tractional and rhegmatogenous retinal detachment (Figure 14). The prognosis is highly variable with some individuals blind by age 10 and others (sometimes within the same family) asymptomatic throughout adult life. The eye with the milder phenotype may have only a small avascular area, visible only on fluorescein angiography.

Figure 10 Ectopia lentis with dislocation of the lens superiorly in Marfan syndrome.

Autosomal dominant vitreochoroidopathy (OMIM #193220)

Autosomal dominant vitreochoroidopathy (ADVIRC) is characterized by vitreous liquefaction with or without peripheral vitreal condensations. Peripheral pigmentary changes typically occur at the equatorial region with a discrete posterior boundary associated with diffuse retinal vascular leakage, cystoid macular edema, and early-onset cataract. The peripheral pigmented band extends from the ora serrata to the equator for 360° of the retina. Other ocular associations are vitreous cells and condensation, puntate opacities in the retina, choroidal atrophy, and early nuclear sclerosis. The ERG responses are normal although the electroculogram (EOG) has been shown to be abnormal in ADVIRC.

Vitreoretinopathy Associated with Corneal Changes

The remaining category contains only one hereditary vitreoretinopathy called snowflake vitreoretinal degeneration named after the retinal appearance.

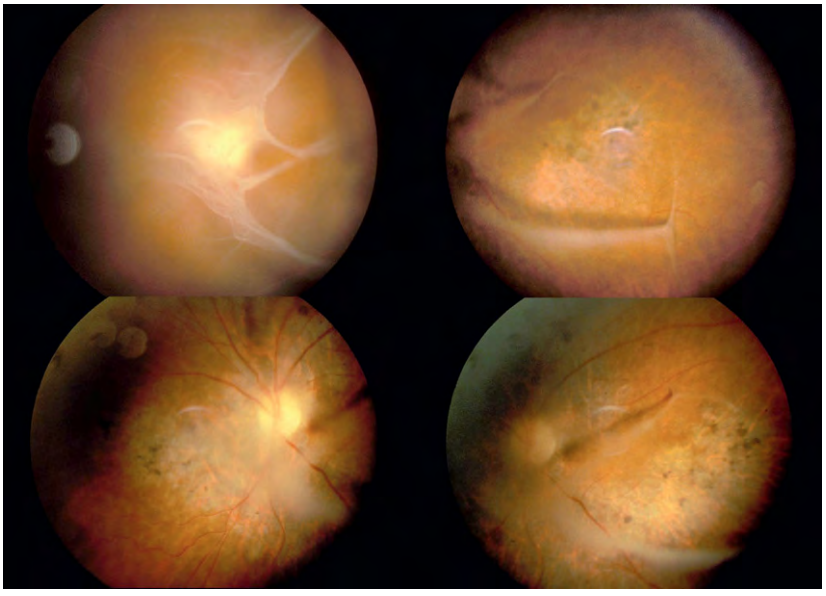

Figure 11 Fundal images showing vitreous condensations and chorioretinal atrophy characteristic of Wagner syndrome.

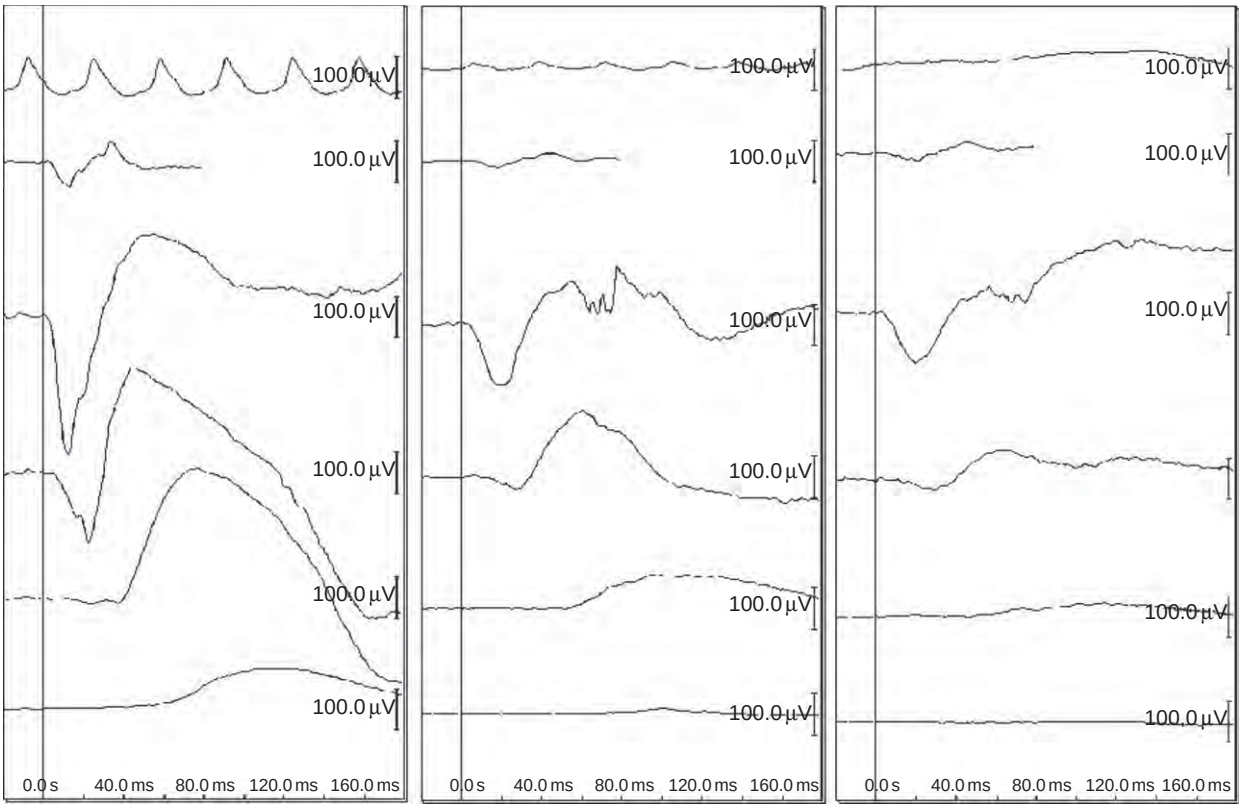

Figure 12 Rod and cone electroretinograms. (a) Representative normal responses, (b) responses from the left eye of a patient with Wagner syndrome aged 55, and (c) responses from the left eye of the daughter aged 19 who had inherited Wagner syndrome. The top two traces are light-adapted cone responses to 30-Hz flicker and to a bright flash; lower four traces are dark-adapted rod and mixed rod–cone responses to a range of stimulus intensities from dim (bottom) to bright (fourth from bottom).

Snowflake vitreoretinal degeneration (OMIM #193230)

The pathognomic feature of snowflake vitreoretinal degeneration is the association with corneal guttata. Disk pallor is also a key feature of snowflake vitreoretinal degeneration not described in any of the other hereditary vitreoretinopathies. The vitreous has a fibrillar appearance. The snowflake-like opacities in the retina are small and may not be immediately obvious. Minor vascular abnormalities of small retinal vessels have been described in snowflake vitreoretinal degeneration.

Molecular Genetics of the Hereditary Vitreoretinopathies

The classification in Table 1 correlates with genotype. Table 3 lists the causative genes that have been identified to date in the hereditary vitreoretinopathies with the protein affected (Table 3).

Mutations in genes coding for the structural components of vitreous result in a hereditary vitreoretinopathy. In common with connective tissues in other parts of the body, vitreous is composed of an extracellular matrix with relatively few cells and the arrangement of the collagenous proteins, along with the high water content, maintains transparency. Vitreous collagen fibrils are heterotypic and have a core of type II and V/XI collagen, with type IX collagen on the surface. Mutations in genes coding for chains which comprise these three types of collagen result in the most common hereditary vitreoretinopathy, Stickler syndrome.

The majority of patients with Stickler syndrome have type 1 Stickler syndrome which is part of the spectrum of type II collagen disorders along with Kniest dysplasia and SEDC. Most have premature termination mutations of the COL2A1 gene and are characterized by a membranous vitreous appearance on biomicroscopy. Other pedigrees exhibit a different beaded vitreous phenotype and are associated with mutations in one of the genes coding for type V/XI collagen (COL11A1). Type 1 Stickler syndrome, in the majority of cases, results from haploinsufficiency from nonsense-mediated decay through point mutations or frameshifts, whereas type 2 Stickler syndrome results from dominant negative mutations.

Collagen types II and IX are expressed in both vitreous and cartilage, so Stickler syndrome is characterized by an

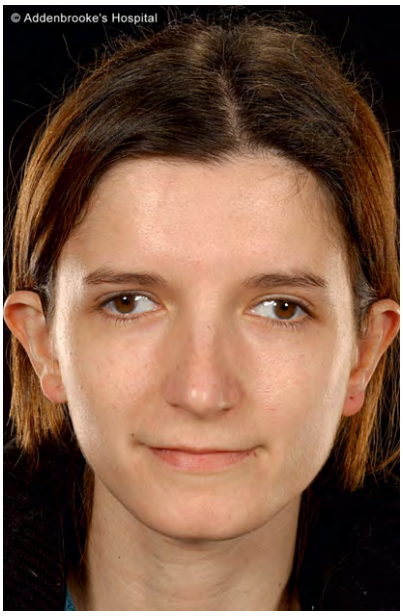

Figure 13 Pseudoexotropia in Wagner syndrome.

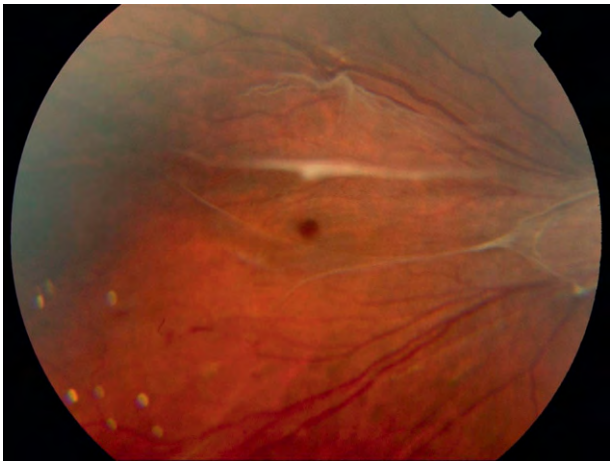

Figure 14 Retinal folds seen in familial exudative vitreoretinopathy.

ocular and skeletal phenotype. Cartilage also contains type XI collagen, which is similar to the type V/XI collagen of vitreous and they share the α1(XI) chain that is encoded by COL11A1; so mutations in this gene have an ocular and skeletal phenotype. A subgroup of Stickler syndrome, designated predominantly ocular, or ocular-only, has been shown to result from mutations of COL2A1 which are preferentially expressed in ocular tissues. Exon 2 of COL2A1 is spliced out of cartilage type II collagen and therefore mutations in exon 2 have a normal skeletal phenotype while displaying the characteristic ocular features of Stickler syndrome. Prior to detailed understanding of the molecular genetics of Stickler syndrome, the existence of patients demonstrating ocular features without systemic findings was a source of confusion between Stickler syndrome and other vitreoretinal degenerative conditions without systemic involvement.

Fibrillins are one of the main constituents of extracellular microfibrils and these provide structural support in many tissues. Mutations in FBN1, encoding for fibrillin 1, are the major cause of Marfan syndrome. Mutations in a second gene, transforming growth factor beta receptor II (TGFBR2), have been found in patients fulfilling the clinical criteria for Marfan syndrome, but the mechanism for this remains to be clarified.

Wagner syndrome is a further example of a hereditary vitreoretinopathy which results from a mutation in a gene coding for a structural protein in the vitreous. CSPG2 encodes the core protein of a chondroitin sulfate proteoglycan called versican. Versican binds hyaluronan and therefore may contribute to the structure of the vitreous. Versican undergoes alternative splicing and several splice variants have been identified in the eye. All causative mutations to date affect the splicing of exon 7 of the CSPG2 gene which represents one of two glycosaminoglycan attachment sites. In Wagner syndrome there is an altered appearance to the vitreous, and progressive retinal dysfunction and hemeralopia even in the absence of retinal detachment, suggesting that versican has additional roles to being a structural component of the vitreous.

FEVR is also genetically heterogenous. All the causative genes to date in FEVR code for proteins involved in the Wnt signaling pathway. Frizzled homolog 4 (Drosophila) (FZD4) is a presumptive Wnt receptor, lipoprotein-receptor-related protein 5 (LRP5) can transduce Wnt signaling *in vitro*, and Norrie disease (Pseudoglioma) (NDP) encodes for norrin. Norrin is present in extracellular matrices and is thought to act as a ligand-receptor pair with FZD4. Although unrelated to Wnts, norrin may act on the Wnt signaling pathway through the frizzled receptor. Wnt receptors are implicated in retinal neovascularization. NDP mutations can also cause Norrie disease (characterized by incomplete retinal vascularization along with more extensive retinal degenerative changes, microphthalmia, and progressive mental disorder).

In general, the molecular genetics of the hereditary vitreoretinopathies demonstrate how mutations of key genes involved in ocular development and structure can result in different phenotypes. Goldmann–Favre syndrome is allelic with enhanced S-cone dystrophy (ESCD). The responsible gene encodes a retinal nuclear receptor involved in signaling pathways. ADVIRC is allelic with Best's macular dystrophy and results from mutations in the VMD2 gene encoding a transmembrane chloride channel. Snowflake vitreoretinal dystrophy is caused by a mutation in a gene encoding a different transmembrane channel.

Of the hereditary vitreoretinopathies associated with skeletal abnormalities, the majority are inherited as an autosomal dominant trait. The exceptions are Stickler

Table 3 Causative genes identified to date and the protein affected in the hereditary vitreoretinopathies

Vitreoretinopathy	*OMIM number*	*Causative gene*	*Affected protein*	*First reference*
Stickler syndrome	#108300	COL2A1	Type II collagen	Ahmad et al. (1991)
	#604841	COL11A1	Type XI collagen	Richards et al. (1996)
	#108300	COL9A1	Type IX collagen	van Camp et al. (2006)

syndrome specifically associated with COL9A1 mutations, and Knobloch syndrome, both of which have an autosomal recessive pattern of inheritance. Wagner syndrome/erosive vitreoretinopathy is inherited in an autosomal dominant pattern. Favre–Goldmann syndrome/ESCD is autosomal recessive. Vitreoretinopathies associated with abnormal retinal vascularization are again inherited as autosomal dominant traits for the majority with the one exception being an X-linked form of FEVR. Snowflake vitreoretinal dystrophy is autosomal dominant.

Histogenesis, Cell Fate, and Signaling Factors

M Cwinn, B McNeill, A Ha, and V A Wallace, Ottawa Hospital Research Institute, Ottawa, ON, Canada

Glossary

Cell extrinsic signaling – It refers to the activation of a biological pathway within a particular cell by an extracellular factor such as a hormone and morphogen.

Cell intrinsic signaling – It refers to the activation of a biological pathway within a particular cell by a factor that is produced by that cell and is not secreted, such as a transcription factor.

Differentiation – The process whereby a less-specialized cell, such as a progenitor, becomes a specialized cell type. In general, a cell undergoing a differentiation program will exit the cell cycle and become restricted in the number of lineages it can adopt.

Lineage commitment/fate specification – The process whereby cell intrinsic and extrinsic cues will direct a progenitor cell toward differentiating into a specific cell lineage or cell type.

Multipotency – The ability of a particular progenitor cell to give rise to a limited number of different cell lineages.

Retinal progenitor cell (RPC) – An undifferentiated, proliferating, multipotent cell located in the neuroblast layer of the developing retina. RPCs are competent to give rise to the six neural and one glial cell types found in the mature retina; however, as retinal development proceeds, the competence of an RPC becomes restricted. The undifferentiated state, proliferative capacity, and multipotency of RPCs is controlled by both cell extrinsic and intrinsic signaling factors.

Introduction

The six different types of neurons and the one glial cell type in the adult vertebrate retina are generated in a conserved temporal sequence from a pool of multipotential retinal progenitors cells (RPCs). Retinal ganglion cells (GCs), cone photoreceptors, horizontal cells, and half of the amacrine neurons are born during the embryonic period, while the remaining amacrine neurons, bipolar neurons, and Müller glia are born in the postnatal period. Rod photoreceptors are generated throughout histogenesis. To explain the temporal sequence of neuron generation from multipotential progenitors, a competence model has been proposed in which RPCs progress irreversibly through a series of stages where they are competent to generate a limited number of cell types. Because, depending upon the species, retinal histogenesis occurs over several days to weeks, factors that influence proliferation, timing of differentiation, as well as cell fate will impact this program. The role of transcription factors in lineage specification of RPCs is well established and a growing body of evidence also implicates a role for intercellular signaling in this process. Here, we review the impact of major developmental signaling pathways such as Hedgehog, Wnt, Notch, transforming growth factor-β (TGF-β), and retinoic acid (RA) on the histogenic program in the vertebrate retina.

Notch

The notch pathway is an evolutionarily conserved intercellular signaling mechanism that regulates numerous cellular programs. Activation of notch signaling is initiated through interaction of the notch extracellular domain on the surface of one cell with the DSL ligands (Delta, Serrate, and Lag2) on the surface of a neighboring cell (**Figure 1**). Upon binding to the DSL ligand, notch is cleaved by the γ-secretase complex releasing the notch intracellular domain (NICD). NICD translocates to the nucleus where it interacts with C-promoter binding factor 1/suppressor of hairless/longevity assurance gene 1 (CSL) complex and converts it from a transcriptional repressor to an activator. In the absence of notch signaling, CSL recruits corepressor proteins to form a transcriptional repressor complex, which inhibits target gene expression. The association of NICD with CSL displaces corepressors and recruits coactivators which results in transcriptional activation of basic helix–loop–helix (bHLH) transcription factors such as hairy and enhancer of split 1 and 5(Hes1 and Hes5).

Findings from early studies on the role of notch signaling in the retina suggest that one of its major functions is in controlling the timing of cell cycle exit and maintenance of the retinal progenitor pool. For example, in the frog, fish, rat, chick, and mouse retina the level of notch signaling is inversely proportional to the rate of cell cycle exit and neuronal differentiation. Similar to its actions in other regions of the central nervous system (CNS), the antidifferentiation effects of notch activity in the retina are associated with inhibition of proneural bHLH gene

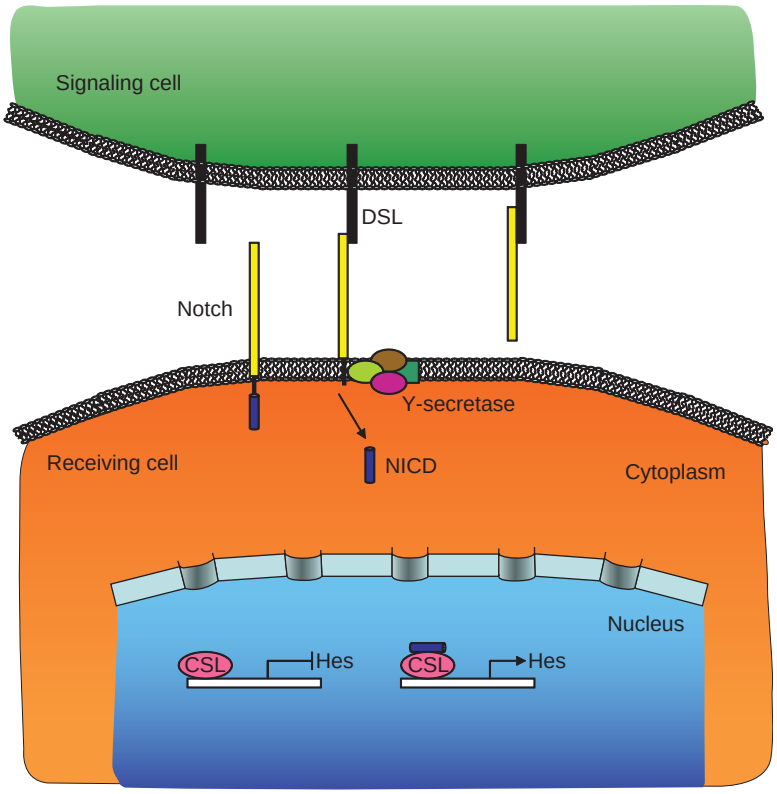

Figure 1 The notch signaling pathway. Ligand binding to the notch receptor leads to a γ-secretase-mediated proteolytic cleavage resulting in the release of the notch intracellular domain (NICD). NICD is able to enter the nucleus and associate with CSL (CBF1, Su(H), Lag1) resulting in transcription activation of target genes such as Hes genes.

expression. While notch activity does not appear to influence the temporal competence of retinal, it has been implicated in cell fate selection. Notch pathway inactivation at early stages of retinal development results in the preferential production of GC or cone photoreceptors and increased notch signaling or expression of its downstream effectors, Hes1 and Hes5, at later stages of retinal development promotes Müller glial cell development. If notch signaling maintains RPCs in cycle, it follows that notch signaling has to be reduced for RPCs to differentiation. Recent work in zebrafish suggests that regional differences in the localization of notch ligands contribute to the variability in notch signaling levels in the retinal neuroepithelium, thereby promoting the balance between cell cycle reentry and exit.

The Wnt Pathway

Wnt signaling has been shown to regulate a number of cellular processes, including differentiation, proliferation, polarity, and migration. Wnt molecules are lipid-modified secreted glycoproteins and 21 vertebrate Wnt homologs have been identified to date. Wnt binding to frizzled (Fzd) receptors and low-density lipoprotein-related receptor 5/6 (Lrp5/6) coreceptors induces the activation of the cytoplasmic phosphoprotein disheveled (Dsh). Three distinct signaling pathways have been described that function downstream of Dsh activation: canonical, planar cell polarity (PCP), and the Wnt/calcium pathway (**Figure 2**). The canonical Wnt pathway, the best characterized of the three, functions to regulate the stability and transcriptional activity of β-catenin. In the absence of Wnt signaling, β-catenin is phosphorylated and targeted for proteosome-dependent degradation by the axin/adenomatous polyposis coli (APC)/glycogen synthase kinase-3β (GSK-3β) destruction complex. Wnt signaling inhibits the activity of the degradation complex, which allows stabilized β-catenin to translocate to the nucleus where it interacts with T-cell factor (TCF)/lymphoid enhancing binding factor (LEF) transcription factors to regulate target gene expression. In the PCP pathway, which is involved in cell and tissue polarity, Rho GTPases are activated leading to alterations in the cytoskeleton. Finally, the Wnt/calcium pathway stimulates the release of intracellular calcium and activates protein kinase C and calcium/calmodulin-dependent protein kinase II to regulate cell fate and movement.

Gene expression profiling has revealed the expression of a number of Wnt pathway components, including Wnt ligands and Fzd receptors in the developing retina.

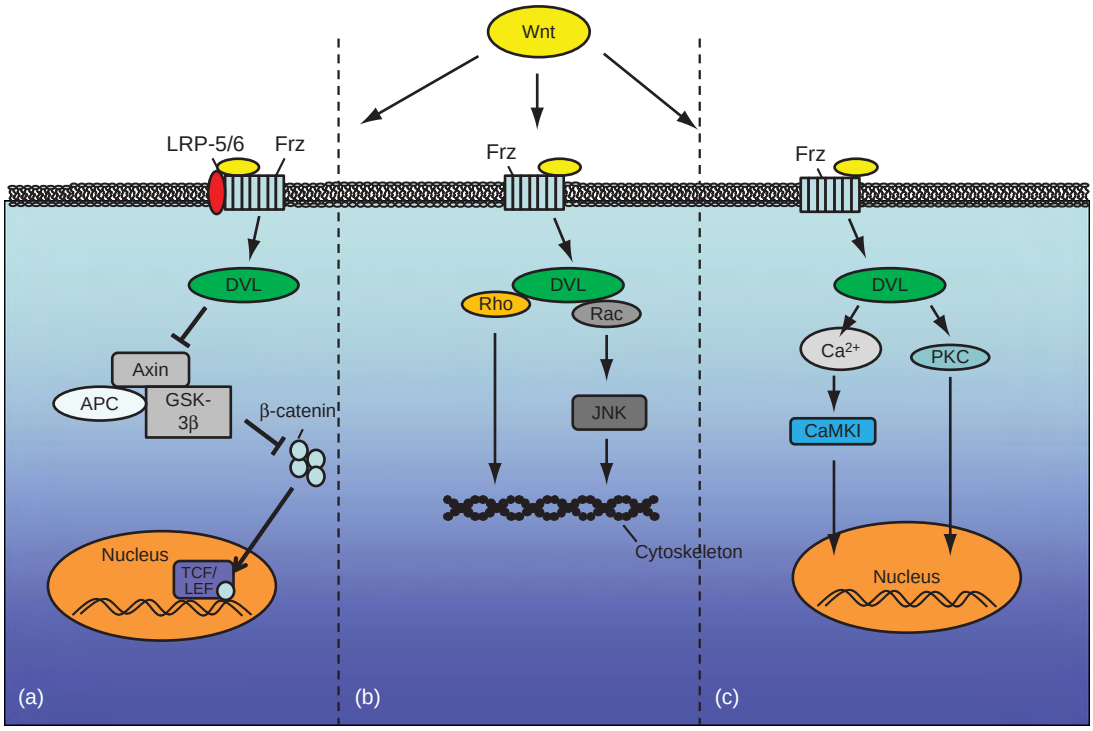

Figure 2 Wnt signaling pathway. Wnt signaling is initiated with the binding of a Wnt protein to its transmembrane receptor frizzled (Frz), leading to activation of one of three main branches of the Wnt signaling pathway. (a) Canonical signaling pathway, where the inhibition of the Axin/APC/GSK-3β destruction complex leads to an accumulation of β-catenin that is able to translocate into the nucleus and regulate transcription. (b) Planar cell polarity (PCP) pathway, where activation of Rho GTPases, Rho, and Rac results in changes to the cytoskeleton. (c) Wnt or calcium pathway, where an increase in intracellular calcium activates protein kinase C (PCK) and calcium or calmodulin-dependent protein kinase II (CaMKII) to regulate cell fate and movement.

The analysis of TCF/LEF transgenic Wnt reporter mice suggests that canonical Wnt signaling is active during eye development. Numerous studies published in recent years on chick, fish, frog, and mammals have implicated Wnt activity in retinal field establishment, retinal regeneration, and lens development. The role of Wnt signaling in retinal histogenesis is more controversial. In the frog, Fzd5 signaling through β-catenin is required for the induction of *Sex determining Y-box 2* (*Sox2*) expression and retinal neurogenesis. In the mouse and chick, however, canonical Wnt pathway activation suppresses neurogenesis and neuronal differentiation. The function of Fzd5 and β-catenin in retinal development is not conserved, as retinal cell specification and proliferation are normal in knockout mice for these genes, although β-catenin is required for lamination and cell adhesion in the retina. Moreover, the effect of Wnt/β-catenin on proliferation appears to be context and species dependent. Increased canonical Wnt signaling promotes proliferation in the frog and fish retina as well as at the marginal zone in the chick retina, but it inhibits proliferation in peripheral regions of the mouse and chick retina. One common theme that has emerged from these studies is the effect of Wnt/β-catenin signaling at the peripheral region of the developing eyecup. In mouse and chick, Wnt/β-catenin promotes the acquisition of peripheral eyecup fates, including the ciliary marginal zone, ciliary body, and iris. Thus, the conservation of Wnt/β-catenin signaling in eye development might be at the level of the localization of the signal, rather than its developmental outcome.

The Hedgehog Signaling Pathway

Members of the Hedgehog (Hh) protein family are secreted signaling molecules that mediate patterning and growth in a number of tissues and organs during embryonic development. In mammals, there are three members of the hedgehog family: Sonic Hedgehog (Shh), Desert Hedgehog, and Indian Hedgehog. The biologically active amino-terminal fragment of Hh proteins is generated by autoproteolytic cleavage of the precursor protein, which is catalyzed by residues in the carboxy terminal domain of the precursor protein. Fully processed Hh-N is lipid modified with palmitate at the amino terminus and cholesterol at the carboxy terminus. For simplicity, we will refer to fully processed Shh-N as Shh. The Hh signaling cascade is initiated by Hh binding to its receptor, the 12-pass transmembrane protein, Patched (Ptc), and subsequent derepression of Smoothened (Smo), a seven-transmembrane domain

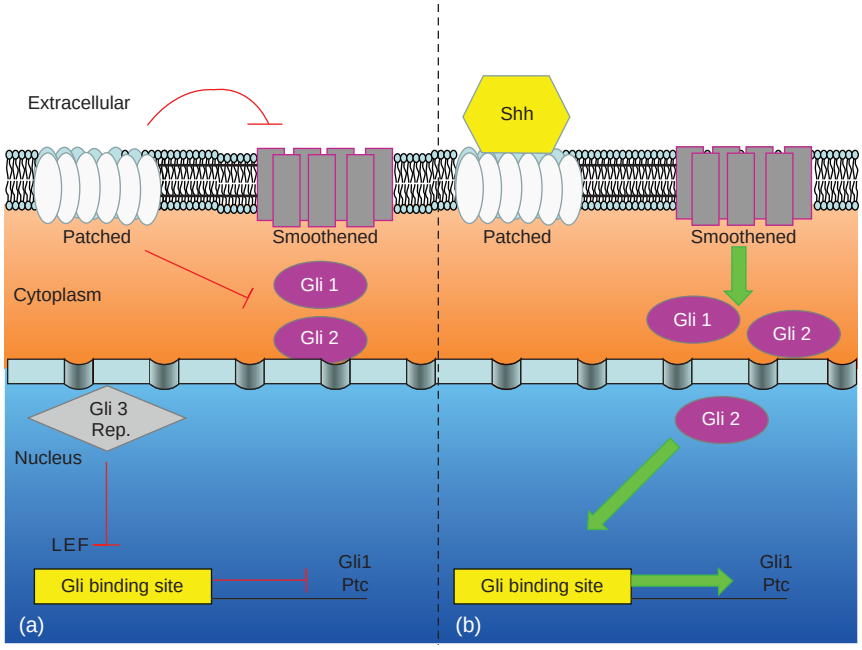

Figure 3 The hedgehog signaling pathway. (a) In the absence of Shh ligand, Patched (Ptc) represses Smoothened (Smo), leading to the inactivation of the Shh pathway. In this scenario, Gli3 repressor can also bind Gli consensus motifs to further repress hedgehog pathway activity. (b) The binding of Shh to Ptc derepresses Smo. The signaling cascade then converges on the Gli1 and Gli2 transcription factors that translocate into the nucleus to induce the transcription of target genes, such as Gli1 and Ptc.

receptor that mediates signal transduction leading to target gene activation (**Figure 3**). The signaling cascade converges on the activity of the *Gli* transcription factors, which regulate target gene expression, in part, through binding to conserved sequences in the promoters and enhancers of these genes. In vertebrates, there are three *Gli* proteins: *Gli1, Gli2*, and *Gli3*. *Gli1* and *Ptc* are direct targets of the Hh signaling pathway and the presence of mRNA for these genes indicates regions of active Hh signaling in tissues.

Retinal expression of Hh pathway components has been described in a number of vertebrate species. Several lines of evidence indicate that Shh expression in GCs is the primary mediator of Hh signaling during retinal development. The timing of Shh and Gli induction in GCs and RPCs, respectively, mirrors the central to peripheral wave of GC differentiation. GCs and Shh are required for Gli induction in RPCs, as GC ablation in explant culture or through conditional endotoxin expression abrogates *Gli1* expression, as does conditional inactivation of *Shh* in the retina. In the adult murine retina, *Shh* is also expressed in the inner nuclear layer most likely in amacrine neurons and *Ptc* is expressed in Müller glia; however, the functional significance of Hh pathway expression at this stage is not known.

Shh signaling has been shown to play a critical role in the histogenic program of RPC in a number of vertebrate species. Shh functions as a mitogen for RPCs, thereby regulating the total cell number in the retina. The mitogenic effect of Hh signaling in this context is mediated, in part, through its effects on the kinetics of the cell cycle and the regulation of G1 and G2 cell cycle genes. Shh signaling also exerts species-dependent effects on the timing of cell cycle exit of RPCs. In the mouse, Hh is required to maintain RPC in the cell cycle, possibly by regulating expression of Hes1, an antidifferentiation bHLH transcription factor. Conversely, in zebrafish, Hh signaling is required for driving cell cycle exit, in part through the induction of p57, a cyclin-dependent kinase inhibitor. These Hh-dependent effects on cell cycle exit are associated with alterations in retinal histogenesis, as loss of Hh signaling in both species results in a deficit in late born retinal cell types. Shh signaling also exerts cell cycle-independent effects on GC development. Gain and loss of function studies in chick and mouse have demonstrated a requirement for Shh in negatively regulating GC development, thereby providing a mechanism by which GC control their number by feedback inhibition.

These studies on Hh signaling in the retina highlight the importance of GC-derived signals on the histogenic program in the retina and they also show how impacting the cell cycle and timing of differentiation contribute toward the establishment of the correct balance of retinal cell types.

Transforming Growth Factor-β

The TGF-β superfamily of signaling molecules is comprised of a number of subgroups, including the TGF-β,

the bone morphogenic protein (BMP), and the growth and differentiation factor (GDF) subgroups. The TGF-β family members are involved in a variety of different developmental processes, including proliferation, migration, and cell death. Classical TGF-β signaling (**Figure 4**) involves ligand binding to a heteromeric receptor complex consisting of two type I and type II receptors that results in the activation and dimerization of homolog of mothers against Dpp (Smad) transcription factors, which then translocate into the nucleus where they interact with a number of cofactors to regulate target gene transcription. Signaling through different receptor combinations and Smad coactivators/corepressors allows members of the TGF-β superfamily to induce a multitude of cell-type and context-specific outputs. In the context of the retina, members of the TFG-β superfamily have been implicated in several aspects of retinal histogenesis including, the regulation of programmed cell death (PCD), progenitor proliferation, and patterning.

TGF-β signaling proteins (TGF-β1, -β2, and -β3) are important for the regulation of PCD, proliferation, and cell fate determination. Single TGF-β2 or double TGF-β2, and TGF-β3 null mice exhibit retinal hypercellularity likely as a consequence of reduced PCD during retinal development. TGF-β1 may also play a role in PCD as explants from early postnatal mice exhibit increased PCD in the presence of TGF-β1. In the early postnatal retina, TGF-β2 is the most abundantly expressed TGF-β family subtype, and it has been implicated in the induction of mitotic senescence of retinal progenitor cells and Müller glia. In addition to controlling PCD and proliferation, TGF-β2 plays a role in cell fate determination, as it negatively regulates amacrine cell genesis.

Studies to date have implicated BMP4 and BMP7 in early eye formation, retinal patterning, and retinal cell survival. The majority of BMP4 null embryos die prior to the stage of eye development; however, the cohort that survives to later stages fail to form a lens and some exhibit malformed optic vesicles. Consistent with a role for BMP4 signaling in eye development, mutations in BMP4 are associated with eye abnormalities in humans, the most severe being anopthalmia. Within the retina proper, BMP4 plays a role in the patterning of the retina by regulating transcription factors required for dorsal retina identity. Interestingly, BMP4 gene dosage is important for normal eye development, as haploinsufficiency for BMP4 in mice is associated with eye defects, such as a reduction in the number of ganglion and inner nuclear cells. BMP7 dosage is also important for eye development as gain and loss of function for BMP7 is associated with apoptosis in the retina and microopthalmia and anophthalmia. BMP signaling is also important for the specification of peripheral eye fates, such as the ciliary body. BMP4 and BMP7 are expressed in the ciliary margin, the distal part of the eye cup, and BMP signaling is required to maintain this structure, as it differentiates into neurons in the presence of ectopically expressed Noggin, a soluble BMP antagonist.

Studies employing mice that are conditionally null for type 1 BMP receptors have provided further evidence in support of a general role for BMP signaling in retinal

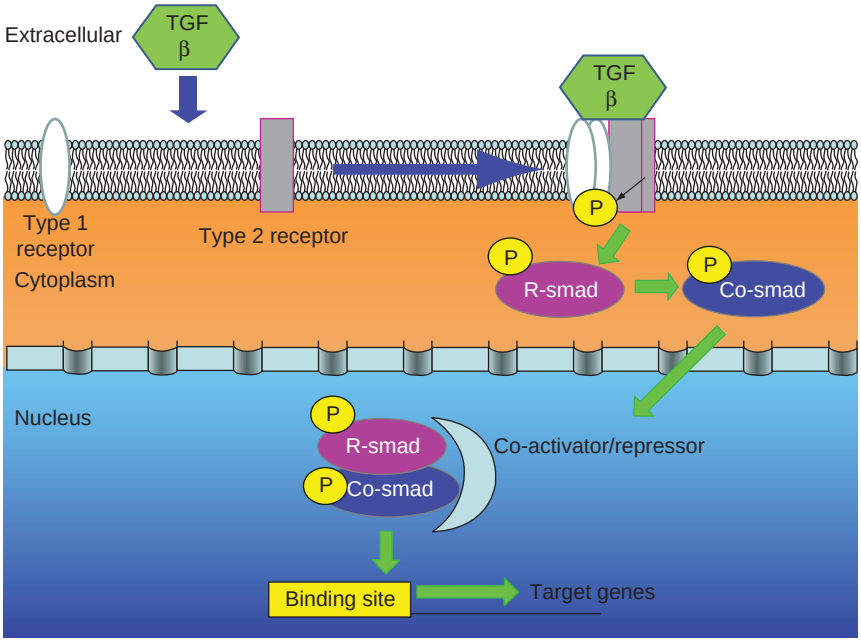

Figure 4 The TGF-β signaling pathway. The TGF-β signaling molecule binds to the heteromeric receptor complex consisting of type-1 and type-2 receptors, resulting in the phosphorylation of the type-1 receptor. This leads to the phosphorylation of a receptor Smad (R-Smad) which then dimerizes with a common-Smad (Co-Smad). The Smad complex then translocates to the nucleus where it can associate with a variety of coactivators or corepressors and modulate gene expression.

development. Two type I BMP receptors, BMPR-Ia and BMPR-Ib, are expressed in the retina. Deletion of either BMP-Ia or BMP-Ib alone does not have a drastic phenotype, likely due to compensatory functions of the two receptors. However, compound BMPR-1a$^{-/-}$BMPR-1b$^{+/-}$ mutant mice have dorsal retina patterning defects and mice null for both genes initially develop an eye structure but the retina undergoes extensive apoptosis and the mice are anopthalmic or microopthalmic at birth. Thus, the effects of BMPR-I deletions further demonstrate the roles of BMP's in eye development and patterning as well as cell survival and confirm the requirement for correct BMP dosage during eye development.

Although it is evident that TGF-β signaling is crucial for retinal development, the functions of other TGF-β family members in retinal development and histogenesis are still being uncovered. For example, GDF-11 has recently been shown negatively regulate ganglion cell genesis by controlling the time that RPCs are competent to produce this cell type. Thus, in GDF-11 null mice, an increase in RGCs occurs at the expense of amacrine cells and photoreceptors. Although it is not as defined as in the murine retina, some of the effects of TGF-β signaling in retinal development may also be conserved in other vertebrate species. For example, TGF-β and BMP signaling molecules are expressed in the chick and frog retina. In the chick, both TGF-β and BMP4 may play a role in mediating PCD.

Signaling Molecules and Photoreceptor Development

Cell extrinsic factors have also been implicated in rod photoreceptor development. Rods are highly specialized sensory neurons that have a complex morphology that is essential for their light-capturing function. Rod differentiation is a protracted process, in that there is a considerable lag between the cell cycle exit of rod precursors and the expression of end stage markers of the phototransduction cascade, including rhodopsin. Thus, differences in rhodopsin expression can be a consequence of altered cell specification or differentiation. To distinguish between these two possibilities, it is important to determine whether the signaling pathway under investigation exerts its effects on dividing or postmitotic cells and to assay early stage markers of rod development.

RA is a vitamin A derivative that regulates a number of aspects of development. RA enters the nucleus where it binds to RA receptor (RAR) heterodimers to regulate context-specific target gene expression (Figure 5). RA is synthesized by RPCs, differentiated neurons in the retina as well as the RPE in the adult eye. At early stages in ocular development, RA signaling plays an important role in regulating the growth of the ventral optic cup. RA signaling has also been shown to promote photoreceptor

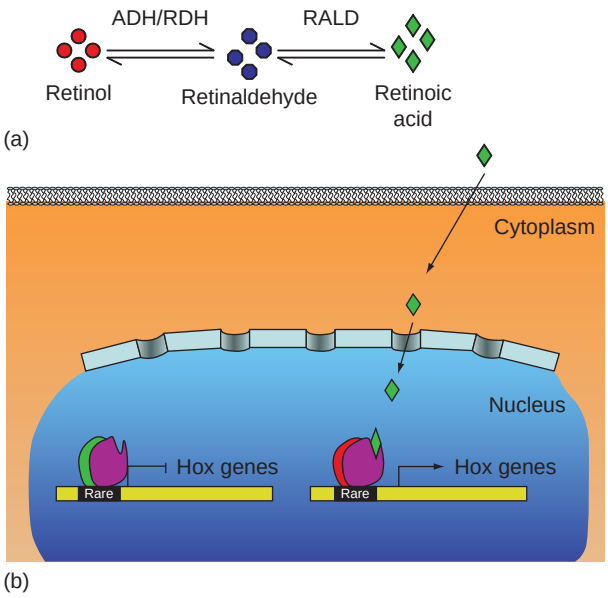

Figure 5 The retinoic acid (RA) pathway. (a) The metabolic pathway for the synthesis of RA from vitamin A. RA is synthesized through a series of oxidation reactions beginning with the oxidation of vitamin A (retinol) to retinal by aldehyde dehydrogenases (ADHs) and/or by retinol dehydrogenase (RDHs). Retinaldehyde dehydrogenase (RALD) converts retinal to RA. RA is able to enter the nucleus and bind to RAR/RXR heterodimers at RARE sites leading to transcriptional activation.

development in several vertebrate species. Whether RA mediates these effects by acting at the stages of rod specification or differentiation is more controversial. There is evidence that RA functions at the level of dividing progenitor cells to promote rod development. Conversely, RA has been shown in other studies to promote rhodopsin expression in postmitotic cells, and perturbation of RA signaling is associated with reduced or delayed rhodopsin expression rather than photoreceptor specification. Consistent with a role in differentiation, RA has been shown to regulate a number of photoreceptor-specific genes, including *arrestin*, *Cone rod homeobox* (*Crx*), and *Neural retina leucine zipper* (*Nrl*). Additional photoreceptor promoting molecules include taurine, an amino acid, that promotes the differentiation of postmitotic rod-precursor cells, b2-laminin and, depending on the context, fibroblast growth factor 2 (FGF2). Differential effects of Hh signaling on photoreceptor development have also been reported, with some studies finding positive effects of Hh signaling on rod development and others reporting an inhibitory effect.

In contrast, epidermal growth factor (EGF) has been reported to inhibit rod development. EGF might mediate this suppressive effect at the level of rod specification, as increased EGFR signaling in RPCs promotes Müller cell development at the expense of rods; however, a role for EGF signaling in rod development *in vivo* has not been established. Ciliary neurotropic factor (CNTF) exerts

pleiotropic effects on neurons and glia in the developing and adult nervous system. In the retina, it exerts opposite effects on the development of postmitotic rod precursors in the rodent and chick. In rodents it is a powerful inhibitor of rod differentiation, whereas in chick it promotes rod development. The timing of CNTF receptor downregulation in rod precursors is coincident with the induction of rhodopsin expression. Thus, in conjunction with other extrinsic cues, CNTF signaling may coordinate the timing of final photoreceptor maturation with the development of other retinal components.

Conclusion

A primary theme that emerges from this overview of notch, Wnt, Hh, and TGF-β signaling in retinal histogenesis is the function of these pathways in controlling patterning, proliferation, and cell survival and to a more limited extent, cell fate. Key questions remain regarding the downstream events controlled by these pathways and how they converge on the cell intrinsic processes that regulate cell fate, competence, and the cell cycle machinery. Addressing these issues will lead to a deeper understanding of neurogenesis in general and will be beneficial in the development of techniques to manipulate stem cells for therapeutic applications.

Hyalocytes

T Kita, Y Hata, and T Ishibashi, Kyushu University, Fukuoka, Japan

Glossary

Autocrine – One of three fundamental types (with paracrine and endocrine) of cellular regulation by intercellular diffusible factors, where the diffusible factor exerts a regulatory influence primarily on the same cell that secreted it.
Epitope – A small site on an antigen where an antibody binds via its variable region.
Green fluorescent protein (GFP) – A protein from jellyfish. The GFP converts blue light (activation light) to green light (emission light). It has been widely used as a report protein because of its ability to label living cells.
Isoforms – The different forms of a protein that may be produced from different genes, or from the same gene by alternative splicing.
Paracrine – One of three fundamental types (with autocrine and endocrine) of cellular regulation by intercellular diffusible factors, where the diffusible factor exerts a regulatory influence primarily on cells in the immediate area of the cell that secreted it.
Transgenic mouse – A mouse which carries experimentally introduced DNA in its genome. Linear DNA is injected into a fertilized embryo at the pronuclear stage and may be incorporated into the genome. Injected embryos are implanted into a foster mother. Progenitors are screened for transgene in their genome.

Existence and Distribution of Hyalocytes

The vitreous body makes up the greatest volume of the eye. The body is a clear, jellylike substance composed mainly of water and delicate collagenous network associated with hyaluronic acid. The vitreous not only offers support to the structures within the eye but also helps maintain the transparency of the media.

The embryonic vitreous contains relatively numerous cells, the number of which gradually decreases, and only a small number of cells are in the vitreous cavity in the adult eyes under physiological conditions. In 1840, Hannover first described cells in the vitreous body of the eye. The term hyalocytes was introduced in 1959 by Balazs in order to define a homogeneous population of cells in the cortical layer of the vitreous body of various animal species. Hyalocytes are on average 50 μm from the inner surface of the retina entangled within the collagen fibrils in the vitreous cortex (**Figure 1(a)–1(d)**). The average number of hyalocytes in human cortical and basal vitreous is about 150 per mm^2 and in pig or bovine eyes is reported to be around 100 per mm^2. It has been noted that the hyalocytes are arranged in tree-like branching patterns, following the course of the retinal vessels (**Figure 2**).

Morphological Characteristics of Hyalocytes

Morphological studies using both light and electron microscopes demonstrate that the shape of hyalocytes varies from oval to spindle or stellate, and that hyalocytes possess lysosomes, mitochondria, ribosomes, and micropinocytotic vesicles with numerous microvilli on their surface, indicating that hyalocytes are morphologically very similar to the so-called macrophages. Therefore, hyalocytes are considered to belong to the monocyte/macrophage lineage (**Figure 1(b)**).

From immunocytochemical analyses, hyalocytes possess antigenic determinants that react with antibodies directed against CD45 (leukocyte common antigen), CD64 (Fc receptor I), CD11a (leukocyte-function antigen-1), histocompatibility complex (MHC) class II antigens, and S100 protein. The presence of CD45, which is selectively expressed by all hematopoietic cells, excluding mature erythroid cells, and CD11a, which is present on virtually all leukocytes, strongly suggests that hyalocytes are derived from a leukocytic cell lineage. In addition, Fc receptor I is the particular IgG receptor which is expressed constitutively only by monocytes and tissue macrophages. The expression of MHC class II antigens and S100 protein, although not unique to the monocyte/macrophage lineage, is consistent with this cellular origin.

Although hyalocytes do not react with CD11b, CD11c, or CD14, these antigenic determinants are variably expressed by tissue macrophages. They differ from other cells of the mononuclear phagocytic system in that they lack immunocytochemically detectable CD68 antigen, an epitope that is highly expressed by peripheral blood monocytes and macrophages of virtually all tissues. Furthermore, antigens that are typically associated with epithelial cells (cytokeratin and epithelial membrane antigen), fibroblasts (prolyl 4-hydroxylase and vimentin), endothelial cells (CD31 and von Willebrand factor), neuroglial cells

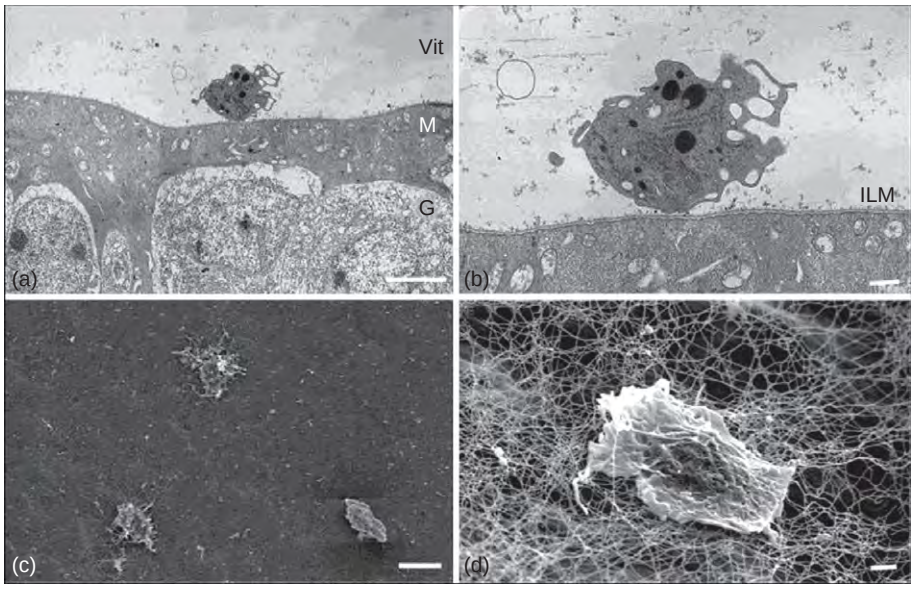

Figure 1 The morphological characteristics and the distribution of hyalocytes in the vitreoretinal interface: (a) Transmission electron micrograph shows a hyalocyte in the vitreous cavity close to the retina. (b) Higher magnification shows that hyalocytes are completely free from but close to the inner limiting membrane (ILM) of the retina. The hyalocyte possesses lysosome-like granules, mitochondria, and micropinocytotic vesicles, features characteristic of cells of the macrophage lineage. (c) Scanning electron micrograph showing free hyalocytes in the vitreous cortex that are very close to the retina, which lies in the background of the image. (d) A higher magnification view showing that the cell is entangled in a collagen fibril network in the vitreous cortex, a few protuberances can be observed at the cell surface. (Original magnification a, 62 600x, bar 5 μm; b, 66 000x, bar 1 μm; c, 61 100x, bar 10 μm; d, 64 300x, bar = 1 μm). Qiao, H., Hisatomi, T., Sonoda, K. H. *et al.* (2005). The characterization of hyalocytes: The origin, phenotype, and turnover. *British Journal of Ophthalmology* 89: 513–517, with permission from BMJ Publishing Group.

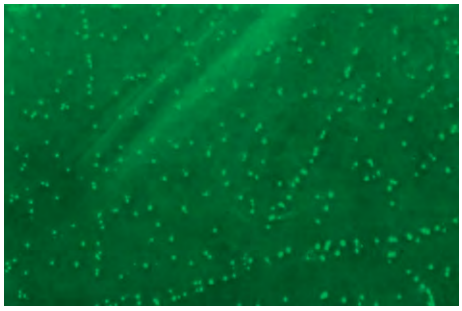

Figure 2 Hyalocytes in the extracted vitreous. The hyalocytes were present mainly on the vitreous gel surface and arranged in branching patterns that are thought to follow the patterns of blood vessels in the retina.

(glial fibrillary acidic protein: GFAP), neuronal cells (neuron-specific enolase) and RPE cells, and Muller cells (cellular retinaldehyde binding protein) are not present on hyalocytes.

In addition, other immunophenotypic analysis demonstrated that most (90%) of the hyalocytes are positive against ED2 antibody, which recognizes membrane and cytoplasmic antigens of tissue macrophages, and a few (15%) hyalocytes were positive against ED1 antibody, which recognizes an antigen in monocytes and in most macrophages, free and fixed. Only 5% of hyalocytes showed both ED1 and ED2 positive staining. Antibodies directed against ED1, bearing the characteristic phenotype of monocyte derived macrophages, only label a small proportion of hyalocytes. Antibodies directed against ED2 typically associated with hyalocytes, illustrate that vitreous hyalocytes have the characteristic phenotype of tissue macrophages.

Origin of Hyalocytes

Numerous theories regarding the origin of the vitreous hyalocytes, including derivation from neuroglia of the retina, mesenchymal cells of the retinal vasculature, or cells of the hyaloid system, have been proposed. However, evidence to date suggests that hyalocytes belong to the monocyte/macrophage lineage; thus the recent popular concept about their origin has proposed that hyalocytes originate from blood monocytes.

To confirm the origin of the hyalocytes we created chimeric mice by transplanting the bone marrow cells from enhanced green fluorescent protein (GFP) mice into them. In these chimeric mice, the hyalocytes were GFP negative immediately after transplantation of bone marrow cells. However, more than 60% of total vitreous hyalocytes were replaced within 4 months and approximately 90% within 7 months under physiological conditions, suggesting that bone marrow derived cells differentiate into hyalocytes and turn over even under physiological conditions.

The large number of bone marrow derived cells lining in the vitreous cavity suggests that they might contribute to the maintenance of homeostasis within the vitreous cavity.

Role of Hyalocytes During Development

One interesting example of tissue regression occurs during development of the eye, where arcades of the hyaloid capillary network (called the vasa hyaloidia propria) disappear from the vitreous between 5 and 7 days after birth and other branches (called the tunica vasculosa lentis) between 7 and 21 days after birth in the mouse eye. Histological studies have shown that the embryonic vitreous contains relatively numerous hyalocytes, which are closely associated with the hyaloid vasculature prior to and during the phase of remodeling. The two transient ocular structures, the hyaloid vasculature and the pupillary membrane, which normally regress according to a defined developmental timetable, are found to persist in macrophage ablation transgenic mice. Hyalocytes are associated with the loss of capillary integrity, leakage of erythrocytes into the vitreal compartment, and phagocytosis of the apoptotic endothelium. It has also been reported that hyalocytes are directly responsible for the endothelial cell death in the system. Furthermore, it has been reported that hyalocytes secrete some antiangiogenic factors. Those experiments provide direct evidence for the active involvement of macrophages in developmentally programmed tissue remodeling and identify hyaloid vessels and pupillary membrane in the eye as targets of macrophage-mediated remodeling, and suggest that hyalocytes actively elicit targeted cell death during development of the mouse eye.

In addition, it has been suggested that hyalocytes contribute toward the formation of the extracellular matrix of the vitreous. However, recent experiments have shown that the major source is the nonpigmented ciliary epithelium, so if they do make a contribution, it is likely to be minor.

Role of Hyalocytes Under Physiological Conditions

Hyalocytes are thought to function as resident macrophages of the vitreous cavity under physiological conditions. Phagocytic activity of hyalocytes has been confirmed experimentally by the injection of foreign substances into the vitreous and in experiments with cultured hyalocytes. Thus, hyalocytes are thought to be active in maintaining the vitreous cavity as an avascular and transparent tissue.

Hyalocytes also show fibrinolytic activity. The platelet-derived growth factor (PDGF) enhances the expression of urokinase-type plasminogen activator (uPA) by hyalocytes and stimulates the (uPA)-plasmin activity. This activity was demonstrated *in vitro* where plated fibrin was shown to be lysed using fibrin zymographic analysis. In the vitreous cavity, the humoral element circulates poorly because of the gelatinous structure of the vitreous. Therefore, a vitreous hemorrhage tends to remain in the cavity for a long time. The fibrinous material not only affects the visual acuity because it is opaque, but the fibrinous membranes on the retinal surface can also function as a scaffold for infiltrating cells, resulting in fibrous membrane formation and tractional retinal detachment through its cicatricial contraction. It is thus reasonable to suggest that hyalocytes digest the fibrinous material in the vitreous cavity as a physiological function, thus indicating that one of the physiological properties of these cells is to maintain vitreous transparency.

In addition, hyalocytes are also assumed to be involved in ocular immune privilege, which serves the purpose of limiting the extent of immune responses that can lead to intraocular inflammation. After antigen inoculation into the vitreous cavity, antigen-specific delayed type hypersensitivity responses are impaired. The form of systemic tolerance was similar to anterior chamber-associated immune deviation (ACAID) and named vitreous cavity-associated immune deviation (VCAID). Hyalocytes, which are also F4/80 positive, are presumed to function as antigen-presenting cells (APCs) responsible for mediating VCAID, which could also serve to maintain vitreous transparency.

Functional Properties of Hyalocytes in Vitreoretinal Interface Diseases

Proliferative Diabetic Retinopathy and Proliferative Vitreoretinopathy

Proliferative diabetic retinopathy (PDR) and proliferative vitreoretinopathy (PVR) still remain common causes of severe vision loss or blindness in spite of the dramatic development of vitreoretinal surgery. The PDR and PVR cause tractional retinal detachment due to the formation of contractile preretinal fibrous membranes as a result of excessive wound healing under the pathological conditions. Previous studies revealed that various types of ocular cells, such as retinal pigment epithelial cells (RPEs) which contribute especially to the pathogenesis of PVR, glial cells, vascular endothelial cells, myofibroblast-like cells of unknown origin, and hyalocytes, organize into the proliferative membranes. Specifically, in human diabetic eyes the hyalocytes have a different shape compared with those in normal eyes, and their numbers appear to be increased. Hyalocytes may participate in the initiation and progression of PDR and PVR through the formation of proliferative membranes and subsequent cicatricial contraction.

Formation of proliferative membranes

The formation of proliferative membrane is characterized by the proliferation and migration of cells, and the excessive synthesis and deposition of extracellular matrix (ECM) proteins. This tissue repair process is regulated by a number of polypeptides including cytokines and growth factors. Growth factors such as PDGF, HGF (hepatocyte growth factor), and MCP-1 (monocyte chemoattractant protein-1) regulate the proliferation and migration of the cells. The PDGF stimulates the proliferation of hyalocytes through p44/p42 MAPK, PI3 kinase, and p38 MAPK, and promotes migration of hyalocytes through PI3 kinase and p38 MAPK, but not p44/p42 MAPK. In addition, TGF-β (transforming growth factor-β), which is overexpressed in the vitreous and proliferative membranes in those diseases, is involved in the production of extracellular matrix proteins such as collagen and fibronectin by various types of cells. Also in hyalocytes, TGF-β promotes the expression of fibronectin, which is one of the major extracellular matrix proteins observed in the epiretinal proliferative membranes. Furthermore, TGF-β stimulates the expression of its downstream mediator, CTGF (connective tissue growth factor) by hyalocytes via activation of Smad signaling, which is mediated through Rho/Rho kinase (ROCK) pathway and at least partially through p38 MAPK. Various types of vitreoretinal cells other than hyalocytes, such as RPEs, Muller cells, and retinal endothelial cells can also be sources of CTGF, with CTGF stimulating cell growth and extracellular matrix synthesis by hyalocytes and RPEs. Therefore, hyalocytes could modulate the formation of proliferative fibrous membranes along with other neighboring cells, in both an autocrine and paracrine manner. In addition, CTGF stimulates the expression of the angiogenic factor VEGF (vascular endothelial growth factor) by hyalocytes and RPEs, so hyalocytes might have a paracrine angiogenic effect on retinal endothelial cells leading to retinal neovascularization.

Cicatricial contraction of the proliferative membrane

Cicatricial contraction of the preretinal proliferative membranes causes tractional retinal detachment, which leads to photoreceptor apoptosis and ultimately to permanent visual loss. Hyalocytes are incorporated into the proliferative membranes and get contractile properties in response to various contractile promoting factors, the expression of which are enhanced in PDR or PVR vitreous and proliferative membranes. Recent investigations have revealed some of the responsible growth factors and their cellular mechanisms in hyalocytes, thereby suggesting potential pharmacologic strategies for the management of these conditions.

Human vitreous samples collected from PDR or PVR patients significantly enhanced the contraction of hyalocyte-containing collagen gels, an established *in vitro* cicatricial contraction model, compared with vitreous from patients with nonproliferative diseases such as macular hole and rhegmatogenous retinal detachment. In addition, PDR/PVR-induced collagen gel contraction is dramatically but incompletely suppressed by TGF-β blockade. Furthermore, contraction of hyalocyte-containing collagen gels strongly correlates with the concentration of activated TGF-β2 in the vitreous.

In addition, PDR/PVR vitreous enhances α-smooth muscle actin (α-SMA) expression and phosphorylation of myosin light chain (MLC) in hyalocytes and RPEs, both of which were dramatically suppressed by TGF-β blockade. Overexpression of α-SMA indicates transdifferenciation of hyalocytes and RPEs into myofibroblasts, and phosphorylation of MLC is associated with actin–myosin interaction to form stress fibers and contractile rings, facilitating cell contraction and motility. Therefore, PDR/PVR vitreous may exert their contractile property by furthering myofibroblastic transdifferentiation and MLC phosphorylation in target cells such as hyalocytes. Furthermore, the results single out TGF-β as one of the main factors responsible for the procontractile property of PDR/PVR vitreous. Certainly, recombinant TGF-β2, the predominant isoform of three TGF-β isoforms (TGF-β1, 2, and 3) in the posterior segment of the eye, remarkably stimulates the contraction of hyalocyte-embedded collagen gels, and enhances α-SMA expression and MLC phosphorylation by hyalocytes. However, as TGF-β blockade does not abolish the procontractile property of PDR/PVR vitreous, other factors such as PDGF, IGF-1 (insulin-like growth factor-1), and endothelins may also significantly contribute to the cicatricial contraction of the proliferative membrane, albeit to a lesser extent than TGF-β.

Rho-kinase (ROCK), a target protein of Rho, regulates MLC phosphorylation both directly and via inactivation of the MLC phosphatase. Fasudil, a potent and selective ROCK inhibitor, abolished the PDR/PVR-induced hyalocyte-containing collagen gel contraction as well as contraction induced by recombinant TGF-β2. Fasudil almost completely suppressed MLC phosphorylation by hyalocytes, which is a common downstream mediator of various contractile growth factors including TGF-β, PDGF, IGF-1, and endothelins. In addition, while PDR/PVR-induced α-SMA expression by hyalocytes was unaffected by fasudil, α-SMA organization, which modulates the contractile property of myofibroblastic cells, was effectively disrupted. This suggests that fasudil might diminish the contractile property of proliferative membranes, which are supposed to be at least partly composed of transdifferentiated hyalocytes, by abolishing MLC phosphorylation and perturbing α-SMA organization (**Figure 3**).

Hyalocytes play a crucial role in the formation and contraction of proliferative membrane in response to growth factors overexpressed in eyes with proliferative vitreoretinal diseases such as PDR and PVR (although RPEs play a central role in PVR complicating rhegmatogenous retinal

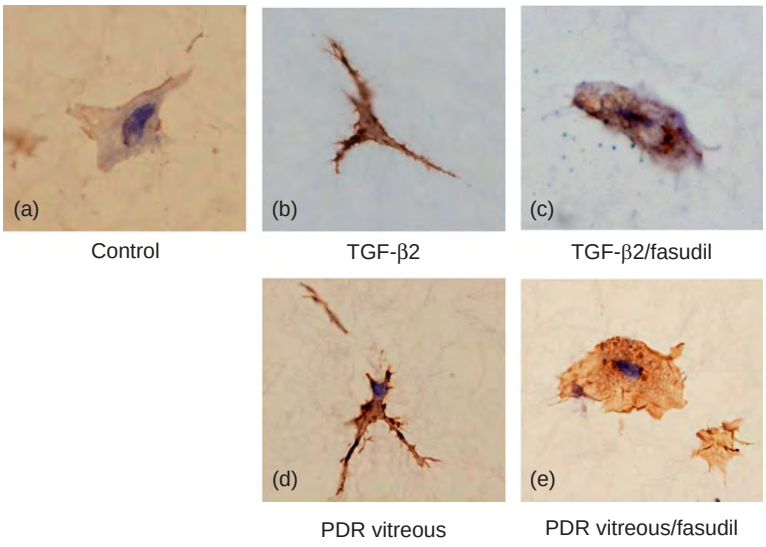

Figure 3 Immunocytochemical analysis of α-SMA (*brown*) in hyalocytes embedded in collagen gels. Representative micrographs, showing hyalocyte-containing collagen gels that were treated with: (a) control (DMEM), (b) recombinant TGF-β2, (c) recombinant TGF-β2 with fasudil (20 μM), (d) PDR vitreous, and (e) PDR vitreous with fasudil (20 μM). The TGF-β2 and PDR vitreous treatment increase α-SMA expression. Fasudil disrupted α-SMA organization without affecting its expression.

detachment), and ROCK inhibition might become a therapeutic strategy in the management of these diseased states.

Idiopathic Epiretinal Membrane and Macular Hole

Idiopathic epiretinal membrane (iERM) are preretinal fibrotic lesions containing various cell types that are located on the inner retinal surface and cause mild to moderate visual disturbance or metamorphopsia.

In 1978, Machemer first showed that iERMs could be removed using vitrectomy techniques. Since then, there have been several ultrastructural and histopathologic studies of iERM specimens removed during vitreous surgery. Those studies have demonstrated that four types of cells are observed in the simple ERMs including (1) fibrocyte-like cells, (2) macrophages, (3) myofibroblast-like cells, and (4) glial cells; the fibroblast-like cells and macrophages are thought to be hyalocytes.

Regarding the pathogenesis of ERM formation, older theories hypothesized that posterior vitreous detachment (PVD) could result in dehiscences in the internal limiting membrane and subsequent glial cell migration and process extension onto the retinal surface then causes ERM formation. However, this hypothesis has never been confirmed histologically.

It has been shown that PVD may leave a portion of posterior vitreous cortex attached to the macular area, and even in the absence of PVD, a premacular liquefied pocket is often present in adult eyes as a result of age-related vitreous liquefaction, the vitreous cortex then forms the posterior wall of the premacular liquefied pocket. This premacular vitreous cortex may play a key role in the development of iERMs. In addition, it has been suggested that when anomalous PVD results in vitreoschisis this process may contribute to the formation of iERMs.

A recent immunohistochemical study has demonstrated that iERMs contain both GFAP immunopositive cells and α-SMA immunopositive cells, but no double positive cells were observed. The α-SMA immunopositive cells were located mainly at the contracted foci of ERMs. On the other hand, GFAP immunopositive cells were present at the periphery of ERMs. In line with previous reports, α-SMA positive myofibroblast-like cells are thought to be the main contributors to the membrane contraction similar to PDR and PVR.

In vitro studies showed that the diameter of hyalocyte-containing collagen gels decreased and there was α-SMA overexpression in the presence of TGF-β2 or vitreous from patients with iERM, which was almost completely abolished by anti-TGF-β2 antibody. By contrast, cultured human astrocytes had no apparent contractile properties of collagen gels in the presence of TGF-β2 and TGF-β2 has little effect on human astrocytes and did not cause myofibroblastic transdifferentiation. The TGF-β2 is constitutively expressed to some level and it is expressed in iERM specimens, so hyalocytes may be the primary component of the contracted ERM foci since they abound in the posterior hyaloid and they undergo myofibroblastic transdifferentiation and have contractile properties in the presence of TGF-β. Therefore, the premacular vitreous cortex containing hyalocytes might cause ERM formation. Once the ERM contracts, it may cause dehiscence in the

internal limiting membrane with subsequent glial cell process extension or migration onto the retinal surface. That could provide an explanation as to why glial cells are observed only at the periphery of ERMs.

Several histological studies examining postmortem cases of macular hole have noted a high incidence of epiretinal membranes, which contain macrophages, fibrocyte-like cells, glial cells, and myofibroblast-like cells. Therefore the histological appearance is very similar to that of iERMs. These thin, delicate, hypocellular preretinal membranes were associated with most lamellar and full-thickness macular holes. Thus, epiretinal membranes are also considered to play an important role in the pathogenesis of macular hole formation. In addition, myofibroblastic differentiation has been observed in epiretinal membranes associated with idiopathic macular holes, which suggested that contraction of these cells is at least partly responsible for formation and enlargement of macular holes. The similarities between epiretinal membranes associated with idiopathic macular holes and simple iERMs indicate a common pathogenesis of these two entities. In addition, because these membranes result from cellular proliferation, migration, and myofibroblastic transdifferentiation resulting in membrane contraction, they share many features in common with PDR and PVR, so these diseases might be interpreted as quiet PVR.

One of the recent hypotheses underlying these diseases is the unifying concept of anomalous PVD. Collapse of the liquefied vitreous body without sufficient dehiscence at the vitreoretinal interface can induce vitreoschisis, a split within the posterior vitreous cortex, leaving the outermost layer of the posterior vitreous cortex attached to the macula. If anomalous PVD is an important event in macular hole formation and ERMs, there must be some other factors to account for the dissimilar clinical and topographic features of the two conditions. The ERM tissues are reported to be hypercellular, whereas the tissue surrounding macular holes is hypocellular in composition. Sebag has hypothesized that the difference could be due to the level at which vitreoschisis splitting occurs during anomalous PVD; if vitreoschisis occurs anterior to the hyalocytes then the residual membrane is hypercellular, but if it is posterior to the hyalocytes the membranes are hypocellular and this results in macular hole formation.

Conclusion and Perspective

Accumulating studies are clarifying the important roles of hyalocytes in the pathogenesis of various vitreoretinal interface diseases, along with their contribution to the maintenance of vitreous transparency. The careful removal of posterior vitreal cortex containing hyalocytes during vitreoretinal surgery, in combination with surgical adjuvants such as triamcinolone acetonide, is thought to result in an improvement of the outcome. Further understanding of the role of hyalocytes in the pathogenesis of vitreoretinal interface diseases might contribute to better management of the diseases by both surgical and/or pharmacological treatment.

Hyperopia

E Harb, New England College of Optometry, Boston, MA, USA

Glossary

Accommodation – Increase in optical power by the eye in order to maintain a clear image (focus) as objects are moved closer. It occurs through a process of ciliary muscle contraction and zonular relaxation that causes the elastic-like lens to round up and increase its optical power. Natural loss of accommodation with increasing age is called presbyopia.
Amblyopia – Decreased vision in one or both eyes due to an amblyogenic factor (e.g., refraction, strabismus, and cataract) without detectable anatomic damage in the eye or visual pathways.
Asthenopia – Vague eye discomfort arising from use of the eyes; it may consist of eyestrain, headache, and/or brow ache. It may be related to uncorrected refractive error or poor fusional amplitudes.
Astigmatism – Optical defect in which refractive power is not uniform in all directions (meridians). Light rays entering the eye are bent unequally by different meridians that prevent formation of a sharp image focus on the retina.
Convergence – Inward movement of both eyes toward each other, usually in an effort to maintain single binocular vision as an object approaches.
Cycloplegic – An agent (typically eye drops) that paralyzes the accommodation system of the crystalline lens to eliminate variability in retinoscopy or refraction measures.
Emmetropization – An active growth process in which the eye grows toward a refractive error of plano.
Esotropia – Eye misalignment in which an eye deviates inward (toward nose) while the other fixates normally.
Strabismus – Eye misalignment caused by extraocular muscle imbalance: one fovea is not directed at the same object as the other.

Definition and Classifications of Hyperopia

Hyperopia, also termed hypermetropia or farsightedness, is a common refractive error in children and adults. In a hyperopic eye, parallel rays of light entering the eye reach a focal point behind the plane of the retina, while accommodation is in a relaxed state. Hyperopia can produce variable symptoms, depending on the magnitude of hyperopia, the age of the individual, the status of the accommodative and convergence systems, and the demands placed on the visual system (distance vs. near). Individuals with uncorrected hyperopia may experience symptoms such as blurred vision, asthenopia, accommodative/binocular dysfunction, amblyopia, and/or strabismus.

The vast majority of cases of hyperopia are of a physiological nature. In terms of physiological optics, hyperopia occurs when the axial length of the eye is shorter than the refracting components the eye requires for light to focus precisely on the photoreceptor layer of the retina. Hyperopia may result in combination with or isolation from a relatively flat corneal curvature, insufficient crystalline lens power, increased lens thickness, short axial length, or variance of the normal separation of the optical components of the eye relative to each other. Astigmatism, the most common refractive error, is often present in conjunction with hyperopia. High hyperopia is associated with high levels of astigmatism, suggesting a breakdown in the process of emmetropization that results in a component-type refractive error. Hereditary factors are probably responsible for most cases of refractive error, including physiologic hyperopia, with environment playing some role in influencing the development and degree of the error.

The American Optometric Association Clinical Practice Guideline has outlined the classifications for hyperopia in the following ways:

1. Hyperopia can be classified on the basis of structure and function. These three classifications are based solely on the structure of the eye:
   - simple hyperopia, due to normal biological variation, can be of axial or refractive etiology;
   - pathological hyperopia is caused by abnormal ocular anatomy due to mal-development, ocular disease, or trauma; and
   - functional hyperopia results from paralysis of accommodation.
2. Clinically, hyperopia may also be categorized based on degree of the refractive error. The magnitude of hyperopia can be classified in the following three ways:
   - low hyperopia consists of an error of +2.00 diopters (D) or less;

- moderate hyperopia includes a range of error from +2.25 to +5.00 D;
- high hyperopia consists of an error over +5.00 D.

3. An additional classification may be based upon the outcome of noncycloplegic and cycloplegic (1.0% cycloplentolate) refractions and takes the patient's accommodative system in consideration:
   - manifest hyperopia, the amount of refractive error that is detected by noncycloplegic refraction;
   - latent hyperopia, the amount of refractive error that is detected only by cycloplegia, can be overcome by accommodation under noncycloplegic conditions.

The sum of latent and manifest hyperopia is equal to the magnitude of hyperopia.

Active accommodation mitigates some or all of hyperopia's adverse effects on vision. The impact of accommodation is highly dependent on age, the amount of hyperopia and astigmatism, the status of the accommodative and vergence systems, and the demands placed upon the visual system. Latent hyperopia is typically overcome in the young patient by the action of accommodation, but may not be sustainable for long periods of time under conditions of visual stress. Signs and symptoms such as blurred vision, asthenopia, accommodative and binocular dysfunction, and strabismus may develop. These signs and symptoms occur more readily and to a greater degree in manifest hyperopia. In general, younger individuals with lower degrees of hyperopia and moderate visual demands are less adversely affected than older individuals, who have higher degrees of hyperopia and more demanding visual needs.

Pathological hyperopia is a rarer type of hyperopia, is typically greater in magnitude, and may be due to several etiologies: mal-development of the eye during the prenatal or early postnatal period, a variety of corneal or lenticular changes, aphakia, chorioretinal or orbital inflammation or neoplasms, neurological- or pharmacological-based etiologies, micro- or nan-ophthalmia, anterior segment malformations, and acquired disorders. A number of congenital and/or genetic developmental disabilities and syndromes are also associated with high hyperopia.

Prevalence

Although it is difficult to discuss the prevalence of hyperopia due to variations in its definition by researchers (e.g., with or without cycloplegia, spherical equivalent, and least hyperopic meridian), the prevalence of hyperopia is age related. Most full-term infants are mildly hyperopic (approximately +2.00 D), while premature infants and those of low birth weight tend to be either less hyperopic or myopic (approximately +0.24 D). The prevalence of refractive error among full-term infants has a normal bell-shaped distribution (see **Figure 1**). Up to 9% of 6–9-months-old infants have hyperopia greater than +3.25 D, but this prevalence decreases to 3.6% in the 1-year-old population. Over the next 10–15 years of life, there is a further decrease in the prevalence of hyperopia and an increase in the frequency of myopia. With the development of presbyopia, latent hyperopia becomes manifest, contributing to an apparent increase in the prevalence of hyperopia.

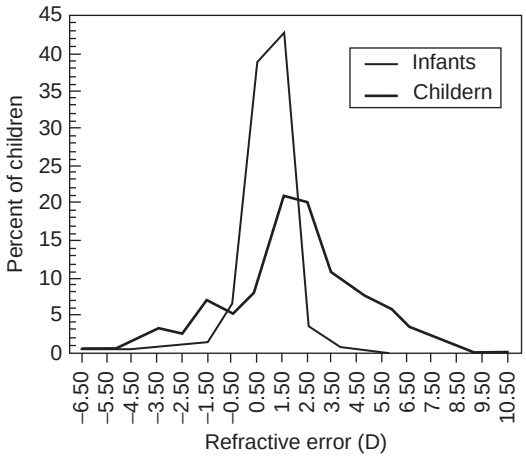

Figure 1 Comparison of refractive error distributions between newborns and children illustrates a shift away from hyperopia during the emmetropization process. Reprinted from Cotter, S. A. (2007). Management of childhood hyperopia: A pediatric optometrist's perspective. *Optometry and Vision Science* 84(2): 103–109.

Normal Time Course of Hyperopia

Emmetropization results in a gradual decrease in the level of hyperopia in most patients (see **Figure 2**), but in patients who have high degrees of hyperopia the change occurs more rapidly. However, infants with high hyperopia are more likely to remain significantly hyperopic throughout childhood. These infants may also have an increased incidence of against-the-rule astigmatism, which appears to further decrease the reduction in hyperopia during emmetropization compared to hyperopic infants without significant astigmatism.

During the school years, there is a slow but continued decreasing trend in the incidence and the magnitude of hyperopia, except in patients with high hyperopia, whose refractive error is more likely to remain relatively unchanged. During the years of presbyopia development, latent hyperopia may become manifest requiring the implementation of both distance and near correction, yet in older individuals (>75 years of age) a myopic refractive shift may ensue likely due to crystalline lens changes.

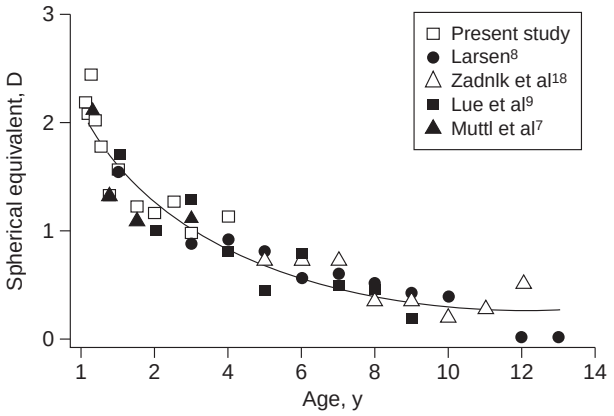

Figure 2 Mean spherical equivalent refractive errors, as reported by several studies, plotted by age. A smooth curve (single exponential function) was plotted to illustrate the change in refractive error with age. Reprinted from Mayer, L., Hansen, R., Moore, B., Kim, S., and Fulton, A. (2001) Cycloplegic refractions in healthy children aged 1 to 48 months. *Archives of Ophthalmology* 119: 1625–1628.

Clinical Presentations of Hyperopia

Young persons with hyperopia generally have sufficient levels of accommodation to maintain clear vision without producing asthenopia symptoms. However, when the level of hyperopia is too great or the accommodative reserves are insufficient due to age or fatigue, blurred vision and asthenopia may develop. Presbyopia brings an increase in absolute hyperopia, causing blur, especially at near. The influence of accommodation on the vergence system also plays a role in the presence or absence of symptoms in patients with hyperopia. Individuals with esophoria and inadequate negative fusional vergence ability are frequently symptomatic and may become esotropic as a result of the uncorrected hyperopia.

Among the signs and symptoms of hyperopia are red or tearing eyes, squinting and facial contortions while reading, ocular fatigue or asthenopia, frequent blinking, constant or intermittent blurred vision, focusing problems, decreased binocularity and eye–hand coordination, and difficulty with or aversion to reading. The presence and severity of these symptoms varies widely. Some young patients with hyperopia, including those with moderate and high hyperopia, may be relatively free of signs and symptoms.

Early detection of hyperopia may help prevent the complications of strabismus and amblyopia in young children. In older children, uncorrected hyperopia may affect learning abilities and in individuals of any age, it can contribute to ocular discomfort and visual inefficiency.

Risks of Uncorrected Hyperopia

The major complications of moderate and high physiologic hyperopia in children are amblyopia and strabismus. Infants with moderate to high hyperopia (>+3.50 D) are up to 13 times more likely to develop strabismus by 4 years of age if left uncorrected, and they are 6 times more likely to have reduced visual acuity than infants with low hyperopia or emmetropia. Children who had significant hyperopia during infancy are much more likely to develop amblyopia and strabismus by 4 years of age. The presence of anisometropic hyperopia further increases the risk of strabismus and amblyopia, especially if found beyond 3 years of age. The American Optometric Association has published guidelines stating that levels greater than 1.00 D of hyperopic anisometropia and 5.00 D of isometropic hyperopia are amblyogenic.

Early detection and treatment of hyperopia may reduce the incidence and severity of consequential amblyopia and strabismus and is a major justification for universal vision evaluation of young children.

Importance of Early Detection of Significant Hyperopia

Atkinson and colleagues showed that uncorrected hyperopia (>3.5 D in one meridian) might contribute to poor motor and cognitive development in younger children (9 months to 5.5 years) and/or learning problems in some older children. The precise mechanism of this relationship is unclear, but optical blur, accommodative and binocular dysfunction, and fatigue all appear to play roles. In fact, uncorrected infant hyperopia has been associated with mild delays in visuo-cognitive and visuo-motor development, but has appeared to reach the level of their emmetropic counterparts after 6 weeks of full time hyperopic spectacle wear in 3–5-year-olds. The substantial number of school-age children and young adults who have uncorrected significant hyperopia is evidence of the potential impact of this learning-related vision problem and the need for early detection screening programs.

Examination Techniques of Hyperopia

Optical correction should be based on both static (normal accommodation) and cycloplegic (e.g., 1% cyclopentolate) retinoscopy, accommodative and binocular assessment, and AC/A (accommodative convergence/accommodation) ratio. The correction should then be modified as needed to facilitate binocularity and compliance. Plus-power spherical or sphero-cylindrical lenses are prescribed to shift the focus of light from behind the eye to a point on the retina. Accommodation plays an important role in determining the prescription. Some older patients with hyperopia do not initially tolerate the full correction indicated by the manifest refraction, and many patients with latent hyperopia do not tolerate the full correction of hyperopia indicated under cycloplegia.

However, young children with accommodative esotropia and hyperopia generally require only a short period of adaptation to tolerate full optical correction. Patients with latent hyperopia who prove intolerant to the use of full or partial hyperopic correction may benefit from initially wearing the correction only for near viewing; or alternatively, trial use of a short-acting cycloplegic agent may enhance acceptance of the optical correction. Patients with absolute hyperopia are more likely to accept nearly the full correction, because they typically experience immediate improvement in visual acuity.

Management of Hyperopia

The specific elements of treatment (e.g., final spectacle prescription) should be tailored to individual patient needs. Among the factors to consider when planning treatment and management strategies are: the magnitude of the hyperopia (under dry and cycloplegic conditions), the presence of astigmatism and/or anisometropia, the patient's age, the presence of an associated esotropia and/or amblyopia, the status of the accommodative and convergence systems, the demands placed on the visual system, and any symptoms.

Among several available treatments for hyperopia-related symptoms, optical correction of the refractive error with spectacles and contact lenses is the most commonly used modality. Newer high-index lens materials and aspheric lens designs have reduced the thickness and weight of high plus-power lenses, increasing wear ability and patient acceptance. Spectacles, especially those with lenses of polycarbonate material, provide protection against trauma to the eye and orbital area and are imperative in children.

Soft or rigid contact lenses are an excellent alternative for some patients. Contact lenses not only provide better cosmesis and compliance, but they reduce aniseikonia in persons with anisometropia, improving binocularity. Multifocal or monovision contact lenses may be considered for patients who require additional near correction, but resist the use of multifocal spectacles because of their appearance. Patients who wear contact lenses are at increased risk for ocular complications due to corneal hypoxia, mechanical irritation, or infection; but nevertheless, improved vision makes contact lens wear a valuable treatment option for compliant patients.

Vision therapy and modification of the patient's habits and environment can be important in achieving definitive long-term remediation of symptoms. Such modifications include, but are not limited to, improved lighting, longer near working distances, using better-quality-printed material, taking frequent breaks when reading or working on a computer for sustained periods of time. These modifications all work to reduce the accommodative demand placed on the patient and can allow, irrespective of spectacle wear, the patient to perform their daily near activities with less symptoms.

Several refractive surgery techniques to correct hyperopia are under development. The major procedures currently being studied as possible therapies for hyperopia are – Holmium: YAG laser thermal keratoplasty, automated lamellar keratoplasty, spiral hexagonal keratotomy, excimer laser, and clear lens extraction with intraocular lens implantation. The American Academy of Ophthalmology has recently reviewed 36 research articles studying the efficacy and safety of refractive surgery for hyperopia and found that the surgery provides an effective and safe correction for lower ranges of hyperopia ($<$3.00 D). Although still considered to be investigative on a long-term treatment basis, laser-assisted *in situ* keratomileusis (LASIK) is Food and Drug Administration (FDA) approved for hyperopia up to +6.00 D.

There is no universal approach to the treatment of hyperopia. The goals of treatment are to reduce accommodative demand and to provide clear, comfortable vision and normal binocularity at all distances. It is not simply determination of the lens power required to focus light onto the retina, but a complex approach encompassing the patient's visual needs, magnitude of accommodation, coexisting amblyopia and/or strabismus, and sensitivity. The following are specific management strategies appropriate for different age groups and conditions as outlined by the American Optometric Association's Clinical Guidelines for Hyperopia.

Young children (birth–10 years of age) with low to moderate hyperopia, but without strabismus, amblyopia, or other significant vision problems, usually require no treatment. However, even occasional evidence of decreased visual acuity, binocular anomalies, or functional vision problems may signal the need for treatment. Whereas the effects of uncorrected hyperopia may manifest as visual perceptual dysfunction, reading difficulties, or failure in school, any child with hyperopia who is experiencing learning or other school difficulties needs careful assessment and may require treatment.

In most young hyperopic children, the process of emmetropization leads to a gradual reduction in the degree of hyperopia by 5–10 years of age. Some children do not go through this process, however. They remain significantly hyperopic and at increased risk for developing strabismus and amblyopia. Patients under age 5 who have hyperopia over 3.25 D appear to benefit from early optical correction to reduce the risk for strabismus and amblyopia. Clinical pediatric studies suggest that partial hyperopic prescriptions do not impede infants' emmetropization by 36 months.

Optical correction of hyperopia should generally be prescribed for young children who have moderate to high hyperopia. However, there are many differences in

prescribing patterns within and between pediatric optometrists and ophthalmologists. Lyons and colleagues surveyed pediatric optometrists and ophthalmologists prescribing thresholds for hyperopia in 2-year-olds and found that 65% of pediatric optometrists used +3.0 D of bilateral asymptomatic hyperopia as their threshold for prescribing and 25% used +5.0 D, while pediatric ophthalmologists had less conservative thresholds with 66% using +5.0 D and 25% using +3.0 D. It should also be prescribed, along with other interventions (e.g., occlusion or active vision therapy), for all young patients with actual or suspected amblyopia or strabismus. Optical correction may be deferred for some patients with moderate hyperopia, but such patients should be considered at risk and re-examined periodically.

Careful follow-up is essential, and frequent lens changes may be needed. It is not unusual for a significant increase in hyperopia to occur after optical correction has been worn for even a short time, due to the manifestation of latent hyperopia. It is also important to continually monitor for the presence of an esotropia during all follow-up visits. When compliance proves difficult, the clinician may encourage acceptance of the prescribed treatment by using cycloplegic agents to blur uncorrected vision. Contact lenses may be a good alternative for patients who do not comply with prescriptions for spectacle wear, especially those with anisometropia, high hyperopia with or without nystagmus, and hyperopia with accommodative esotropia.

Special consideration should be given to several specific categories of problems in young children who have significant hyperopia. Prior to the onset of accommodative esotropia, which usually becomes evident at about 2–3 years of age, few children exhibit obvious signs of ocular problems, with the exception of intermittent esotropia in children who are ill or very tired. Early screening for refractive error usually detects hyperopia, but due to the relative infrequency of refractive screening, many children with underlying moderate to high hyperopia go undetected until the appearance of frank strabismus. Appropriate treatment includes the use of either single vision or multifocal spectacles depending on the patient's binocular and accommodative status. Concurrent amblyopia, when present, may be treated by patching and active vision therapy.

Less commonly, young children with bilateral high hyperopia develop isoametropic amblyopia due to the resulting constant state of severely blurred vision. Such patients may have an associated esotropia, or conversely, may not manifest esotropia because they make no attempt to accommodate. Optical correction of this condition is indicated in order to prevent or treat the associated amblyopia and/or strabismus; however, careful monitoring is warranted a previously nonexistent esotropia may present itself following correction. Partial correction may inadvertently stimulate accommodative esotropia, because the patient now has good reason to attempt to overcome the remaining uncorrected hyperopia. Treatment to improve vision in the child with amblyopia may take a few years, but improvement is usually possible with full time spectacle wear and/or patching or pharmacological penalization.

Many persons between the ages of 10 and 40 years who have low hyperopia require no correction because they have no symptoms. Ample accommodative reserves shelter them from visual problems related to their hyperopia. Under increased visual stress, such persons may develop symptoms that require correction. Wearing prescribed lenses with low amounts of plus power usually alleviates the problem. Patients with moderate degrees of hyperopia are more likely to require at least part-time correction, especially those who have significant near demands or have accommodative or binocular anomalies. Accommodative or binocular dysfunction associated with uncorrected low to moderate hyperopia may be treated by optical correction or vision therapy. Vision therapy may be instituted initially or after optical correction in patients who have significant binocular vision problems. The effects of visual habits and environment play an increasing role in determining the need for and characteristics of treatment.

By the age of 30–35 years, most previously asymptomatic, uncorrected hyperopic patients begin to experience blur at near and visual discomfort under strenuous visual demand. Facultative hyperopia can no longer be sustained comfortably due to decreasing accommodative amplitudes. Latent hyperopia should be suspected when symptoms occur in conjunction with lower amplitude of accommodation than expected for the patient's age. Cycloplegic retinoscopy can help identify this latent component. By the mid-1930s, accommodation takes noticeably longer while facility decreases, causing associated visual problems in many hyperopic persons previously free of symptoms. A prescription for the distance manifest (noncycloplegic) refraction for the patient to wear as needed (i.e., part time at near) often suffices. The patient may require additional correction with increasing age and visual demands at near. Before prescribing a permanent pair of spectacles, the optometrist may lend the patient a pair of spectacles (i.e., over-the-counter reading glasses) to demonstrate the potential benefits of optical correction of latent hyperopia.

With the onset of presbyopia (loss of accommodation), maintaining focus at near becomes progressively more difficult, especially in poor illumination. Prescribing an optical correction for most or all of the distance manifest refraction, along with a near addition, can greatly improve vision and comfort. Hyperopia equal to or greater than +1.00 D to +1.50 D generally requires full-time distance correction, with a near addition for patients over about

age 45. As facultative hyperopia becomes absolute, more plus power at distance is required. Progressive multifocal lenses enable clear focusing at a range of finite distances. A monovision, bifocal, or multifocal contact lens prescription is an option in some patients.

Physiological hyperopia is not progressive. Therefore, the prognosis, which can be given at diagnosis, is generally excellent, except for those patients with both hyperopia and amblyopia or strabismus, for whom it is less certain. Appropriate optical correction almost always leads to clear and comfortable single binocular vision. Younger children who have significant hyperopia associated with amblyopia, strabismus, or anisometropia require intensive follow-up and treatment for their more complex problems, starting as early as 3–6 months of age. The timing of periodic preventive optometric care for uncomplicated hyperopia depends on the patient's age and circumstances. For children with hyperopia, follow-up may be required as often as every 3–6 months depending on the concern for strabismus and/or amblyopia, while for asymptomatic adults, every 1 or 2 years is generally sufficient.

The underlying cause, rather than hyperopia itself, is the chief concern in patients with pathologic hyperopia. Because the causes of pathologic hyperopia are both uncommon and diverse, general statements concerning treatment must be limited to the need to correct the hyperopia in the best manner possible, depending on the underlying etiology. Conditions of a developmental or anatomic nature are rarely progressive. When useful vision is thought to be obtainable, the treatment of hyperopia resulting from nonprogressive conditions is similar to that for physiologic hyperopia. Patients with pathological hyperopia require treatment of their underlying conditions and, when indicated, referral to another eye care provider for special services. All patients treated for hyperopia with persistent symptoms require additional follow-up care to remediate their problem.

Conclusion

Hyperopia is a common refractive disorder that has a close association with other consequential disorders, namely amblyopia and strabismus, especially in children. This makes hyperopia a greater risk factor for more permanent vision loss than myopia. In addition, it appears that uncorrected hyperopia has a detrimental effect on a child's learning and development. Therefore, the early diagnosis and treatment of significant hyperopia and its consequences can prevent a significant amount of visual disability in the general population. Because hyperopia is usually not readily apparent, preventive examination of all young children is essential. Although there is no clear consensus on the prescribing practices for hyperopia, clinicians must examine the visual needs and binocular system of each patient to best determine their final treatment plan. Periodic eye examinations are needed thereafter to help ensure the provision of treatment appropriate to the changing visual needs of the hyperopic patient.

Imaging of the Cornea

S C Kaufman, M Fung, D Raja, and N Kramarevsky, University of Minnesota, Minneapolis, MN, USA

Glossary

Chemosis – Swelling of the iris due to swelling of the bulbar conjunctiva.
Corneal verticillata – Congenital whorl-like opacities in the cornea.
DSAEK – Descemet's Stripping Automated Endothelial Keratoplasty, a form of keratoplasty which involves the removal of the host's central Descemet's membrane and corneal endothelium, which is subsequently replaced with a disc shaped graft of donor corneal stroma, Descemet's membrane and endothelium.
Follicles – Lymphoid tissue in the conjunctival stroma.
Fuchs' dystrophy – A common adult-onset form of corneal dystrophy with autosomal dominant inheritance. In this disease, the endothelial cells in the cornea gradually deteriorate.
Guttae – Drop-like.
Keratic precipitates – Fibrous deposits on the posterior surface of the cornea, usually associated with uveitis.
Laser-assisted *in situ* keratomileusis (LASIK) – Refractive surgery to correct myopia, hyperopia, and astigmatism.
Lattice dystrophy – Hereditary corneal dystrophy in which there is an accumulation of amyloid deposits throughout the middle and anterior stroma of the cornea.
Lenticle – Relating to the lens.
Pappillas – Small projection of tissue commonly triggered by constant irritation of the conjunctiva by contact lenses.
Pachymetry – Measurement of the thickness of the cornea.
Pigment dispersion syndrome (PDS) – Condition when the iris pigment epithelium and the lens come into contact. This leads to mechanical disruption of the iris resulting in release of pigment granules into the posterior chamber, which follows the flow of aqueous into the anterior chamber angle. The pigment can block the aqueous outflow resulting in elevated intraocular pressure with possible damage to the optic nerve.
Posterior polymorphous dystrophy – Disease involving metaplasia and overgrowth of corneal endothelial cells.
Pseudoexfoliation syndrome – Characterized by flakes of granular material at the pupillary margin of the iris and throughout the inner surface of the anterior chamber. It is also associated with secondary open-angle glaucoma.
Pseudophakic bullous keratopathy – Corneal edema occurring following cataract extraction.
Sclerotic scatter – Biomicroscope illumination that scatters light throughout the cornea.
Subluxation – Partial dislocation of an organ.

Slit-Lamp Biomicroscopy

The slit-lamp biomicroscope is a versatile device that is the primary diagnostic instrument used during the clinical examination of the cornea and the external structures of the eye and adenexa. It has two primary components mounted on a common axis – the slit illuminator and the biomicroscope. The slit-beam-illumination unit is essentially a projector with a light beam that is adjustable in height, width, direction, and intensity. The examiner can create a sharply focused narrow slit beam which can illuminate and isolate fine detail in otherwise translucent tissue. The biomicroscope component is a binocular Galilean telescope that can produce excellent resolution at multiple magnifications. A headrest stabilizes the patient, and adjustable oculars allow the examiner to focus a stereoscopic image.

The biomicroscope and the illuminator are arranged to be parfocal (focus on the same plane) and isocentric (the slit beam is centered in the field of view), which is necessary for its function. This essential setup allows for both direct illumination and – with shifting of the alignment – indirect illumination.

During diffuse illumination, the light beam is broadened to its largest aperture and kept at both low magnification and reduced intensity. The illuminator is directed at the eye from an oblique angle and rotated through its arc of travel from side to side. When the light is applied tangentially, surface changes are enhanced and dimensionalized through the effect of creating highlights and shadows. Subtle alterations from normal topography become more clearly noticeable. Direct illumination can highlight conjunctival changes such as chemosis, follicles, and papillae and can further direct the examiner's exam.

Broad-beam illumination can help the examiner visualize opaque lesions that may reflect or absorb light. This technique can be invaluable in evaluating the anterior segment structures from the cornea to the iris. When no abnormalities are seen with this technique, other forms of illumination should be explored.

Narrow-beam illumination allows the examiner to evaluate transparent tissues such as the cornea and lens through virtual cross-sections. When used under high magnification, the principal layers of the corneal can be distinguished clearly with great precision. In addition, a narrow beam can be used to identify the presence of anterior chamber cell and flare. Cell and flare is best seen against the background of the dark pupil with an intense but shortened slit light beam.

Specular reflections represent the normal light reflexes that bounce off of an ocular surface. These reflections actually correspond to the mirrored reflections from the light source itself. The most important application of specular reflection is in the evaluation of the corneal endothelium. This involves arming the slit beam at an angle of 40–60° from the viewing arm and using a short slit. Then, the specular reflection of the light bulb's filament is identified on the tear film. Adjacent to this area (on the side away from the light source), the less bright endothelial reflection can be viewed. Moving the biomicroscope slightly forward will bring the endothelial cellular detail into focus. A magnification of 25× to 40× is usually needed to obtain a clear view of the endothelial mosaic. Cell density and morphology can be evaluated; guttae and keratitis precipitates will appear as nonreflective dark areas.

Indirect illumination can provide unique information. In this method of illumination, the light beam is directed to an area adjacent to the area needing to be examined. Under higher magnification powers, the light beam may need to be decentered from the normal isocentric position. The area being evaluated is seen via retro-illumination from the deeper layers. This method is highly effective for observing detail in areas that are deep to more anterior lesions which may prevent light from penetrating through. For example, an embedded foreign body that is obscured by tissue reaction can be better mapped out through proximal illumination.

Sclerotic scatter takes advantage of the optical phenomenon total internal reflection seen in the cornea. The examiner should direct a de-centered – but intense – light beam at the corneoscleral junction. In a normal cornea the light is only seen where it intersects and reflects the sclera. A ring of light around the limbus is seen, but the cornea will remain dark against an essentially dark background. In an abnormal cornea, the light that is reflected at the sclera will illuminate an abnormality. Thus, abnormalities can be seen in totality and be better recognized as part of a broader disease pattern (e.g., corneal verticillata).

Retro-illumination of the iris combines both direct illumination and indirect retro-illumination to reveal different details about the area being examined. When the light beam is directed tangentially toward the cornea, direct retro-illumination from the iris can reveal opaque corneal lesions. In contrast, the areas adjacent to the light beam can reveal subtle refractile changes of lower density in the cornea, through indirect retro-illumination from the iris. The interface against both light and dark backgrounds is what shapes the light to reveal details through retro-illumination. Examples of corneal pathology which are best revealed through retro-illumination from the iris include folds in Descemet's membrane, and the linear stromal corneal changes in Lattice dystrophy. Retro-illumination from the fundus reflects light from the retinal pigment epithelium through the pupil to reveal changes in the cornea, lens, and anterior vitreous. A well-dilated pupil will achieve the most effect because light will not be scattered from the iris. In contrast to sclerotic scatter where abnormalities are best seen against a dark background, this technique uses brightfield illumination to reveal pathology. Lenticular changes, such as posterior subcapsular cataracts or subluxation, can be clearly visualized against the color reflected from the retinal pigmented epithelium. Retro-illumination of the iris and lens can reveal iris defects seen in glaucomatous diseases such as pigment-dispersion syndrome and pseudoexfoliaiton syndrome.

Specular Microscopy

Specular microscopy was developed by David Maurice in 1968. This device was used to examine the corneal endothelium, *ex vivo,* in the laboratory. This first microscope had an effective magnification of 500×, but was not practical for clinical use. In 1975, Bourne, Kaufman, and Lange developed clinical specular microscopes. Specular reflections arise from light which is reflected from the interfaces of materials with different indices of refraction. This occurs when the angle of incidence is equal to the angle of reflection. Thus, the difference between the index of refraction between the corneal endothelium

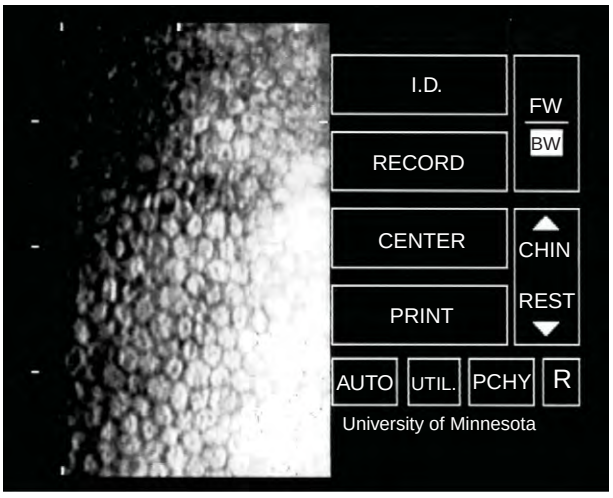

Figure 1 The specular photomicrograph shows a typical image from a noncontact specular microscope. From the information in this image, a cell count can be obtained and the degree of polymegathism and pleomorphism can be assessed.

and the aqueous produces a specular reflection. Many types of specular microscopes exist, which can be divided into contact and non-contact, and clinical (horizontal) and upright (which is used by eyebanks). Other types of specular microscopes are capable of visualizing other layers within the cornea.

The advent of the specular microscope allowed the ophthalmologist direct observation of the corneal endothelium in patients with Fuchs' dystrophy, posterior polymorphous dystrophy, psuedophakic bullous keratopathy, and other disorders of the corneal endothelium (**Figure 1**). If the cornea is significantly edematous, the specular reflection can be masked – which prohibits the visualization of the corneal endothelium. Specular microscopy is also used by eye banks to examine the corneal endothelium of donor corneas. The endothelial cell counts – which are reported as cells per square millimeter – are used to determine the suitability and health of the transplant tissue. Corneal endothelial cells typically demonstrate a hexagonal shape. A deviation from the normal hexagonal endothelial mosiac is termed pleomorphism. Although the size of corneal endothelial cells may vary slightly, in a healthy cornea, the cells should be similar in size. When there is great variablity in cell size, this is termed polymegathism.

Confocal Microscopy

Confocal microscopy employs a point source of light, which is focused on a thin section of the specimen. The confocal point detector is used to collect the resulting reflected signal. The use of a pinhole light source and its conjugate pinhole detector trades field of view for enhanced resolution by eliminating light which is reflected from structures above and below the focal plan under observation. A full field of view must be obtained by scanning many regions of the specimen. This can be achieved by rotating discs that contain multiple conjugate point detectors-pinhole light sources that allow for even scanning of the tissue. Other confocal systems use a slit beam which scans the specimen with a mechano-optical mirror system. White-light or a laser can be used at the light source. These systems are respectively termed white light confocal microscopes or laser scanning confocal microscopes.

The confocal microscope examines the cornea in coronally oriented sections versus the typical sagittal sections that are common to most histological tissue preparations (**Figure 2**). The corneal epithelium appears as a large cellular mosaic with bright, hyper-reflective central nuclei (**Figure 2(a)**). The basal epithelium consists of smaller cells and, generally, does not exhibit visible nuclei (**Figure 2(b)**). The corneal stroma appears as a collection of hyper-reflective, bean-shaped keratocyte nucei (**Figure 2(d)** and **2(e)**). The dendritic-appearing cell bodies of the keratocytes are only visible when the keratocytes are active. Corneal nerves can be seen passing through the stroma (**Figure 2(c)**). The deeper corneal nerves are large compared to the subepithelial nerve plexus, which resembles a fine filamentous membrane (**Figure 2(e)**). The corneal endothelium appears next (**Figure 2(f)**). Because the confocal microscope is able to eliminate aberrant light, corneal edema rarely obscures the corneal endothelium – unlike in the specular microscope.

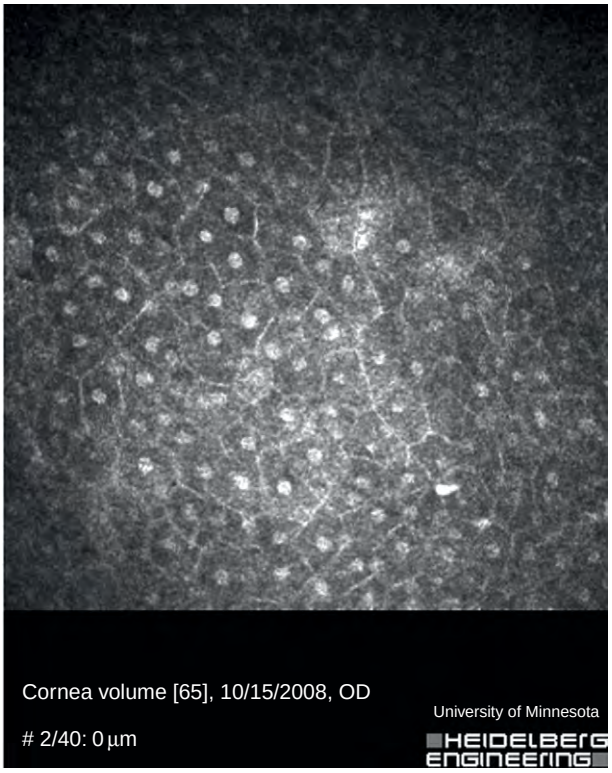
Images that are obtained during confocal microscopy are native video; individual still-frames can be captured, as well as video. The images can be stored digitally or on video tape. Because of the ability to scan through the cornea and other tissues, video images can be particularly informative. Furthermore, the images are typically registered by *z*-axis location (depth within the cornea or other tissue). Thus, three-dimensional (3D) reconstructions can be produced which reveal *ex vivo* histopathology – like those depicting sections of the cornea.

The advantages of confocal microscopy are as follows: (1) the resolution can be better than the resolution obtained with the conventional light microscopy, allowing for imaging of the epithelial surface, stroma, nerves, and endothelium (2) high-resolution images can be obtained *in vivo* without the need for staining or processing of the cornea.

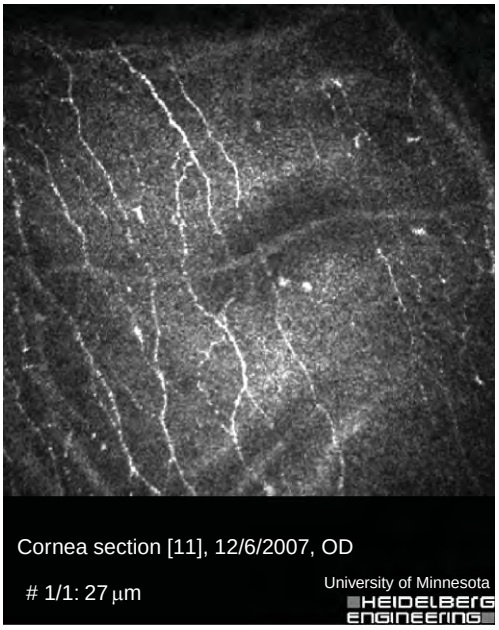
The clinical applications of confocal microscopy include the identification of corneal infectious agents, including bacteria, fungi, and *Acanthamoeba*. It has been used in clinical research to assess the effect of corneal wound-healing responses after refractive surgery and to characterize corneal dystrophies (**Figure 3**). Because the device can measure in the *z*-axis, it can be used to determine the depth of structures within the cornea, such as the thickness of the laser-assisted *in situ* keratomileusis (LASIK) flap or the residual bed, and the depth of corneal scars. These devices may also be useful in diagnosing neoplasia of the cornea and conjunctiva.

Ultrasound Biomicroscopy

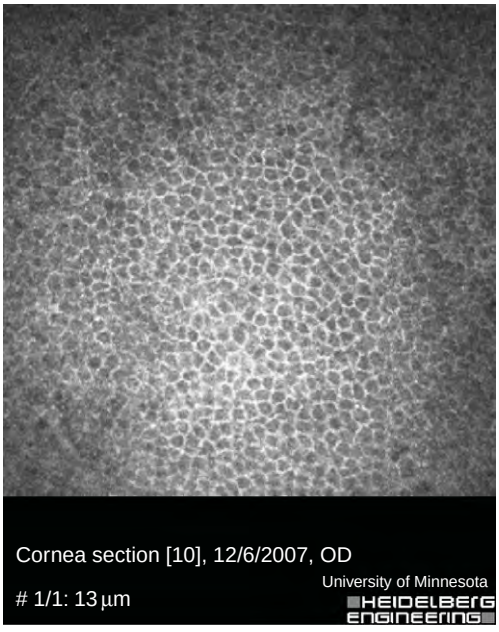
High-frequency ultrasound biomicroscopy (UBM) produces high-resolution images of the anterior segment. Cross-sectional images of the eye are produced using a frequency range of 25–100 MHz. Resolution ranges from 20 to 100 μm. Higher frequencies provide higher resolution but the signal is increasingly attenuated, thereby limiting penetration of the signal. Newer technology can amplify the returning signal based on the depth of the structure under examination. The transducer has also evolved. An arc transducer follows the curvature of the cornea and permits the visualization of the entire cornea and anterior segment. The analog signal is digitized and can be used to construct a 3D-representation of the anterior segment. The required use of a water bath – as a fluid coupler – may limit the applicability of the UBM.



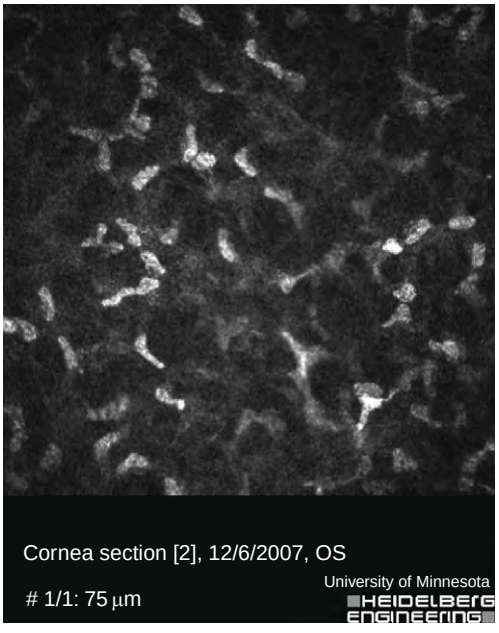
(a)



(c)

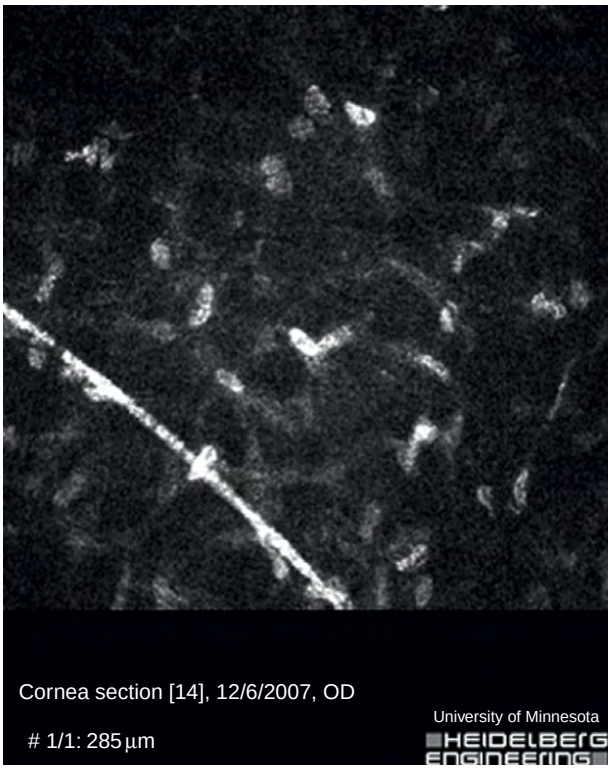


(b)

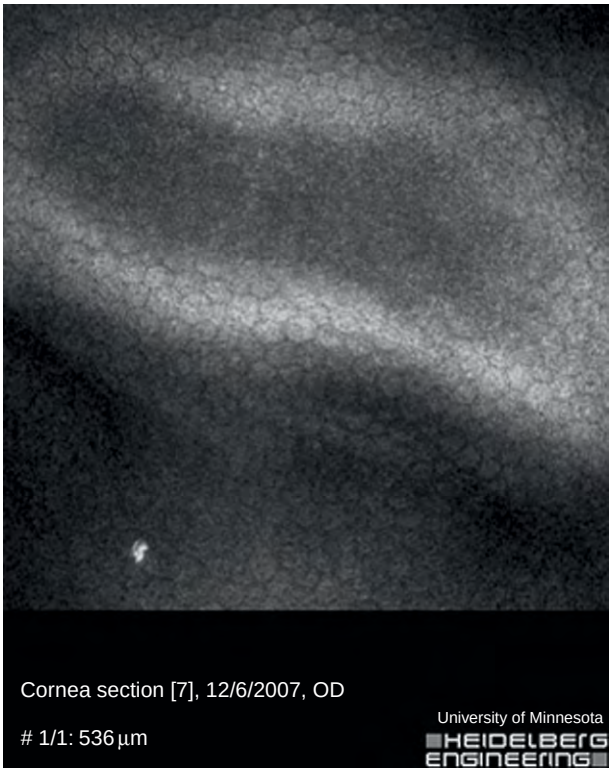


(d)

Figure 2 (Continued)



(e)



(f)

Figure 2 Confocal microscopy permits the examination of each layer of the cornea. (a) The superficial corneal epithelium appears as a cellular mosaic of nucleated cells. (b) The basal corneal epithelial cells are smaller than the more superficial layers of epithelium. (c) Just below the corneal epithelium lies the subbasal nerve layer. This fine meshwork of corneal nerves is responsible for the exquisite sensitivity of the cornea. (d) Confocal images of the anterior corneal stroma reveal the nuclei of the keratocytes. Contrasting the density of the anterior stromal keratocyte nuclei with the keratocyte density in (e), demonstrates that there is a greater density of keratocytes in the anterior stroma. (e) This confocal image of deep corneal stroma reveals a field of keratocyte nuclei and a corneal nerve (hyper-reflective linear structure). (f) The hexagonal mosaic of the corneal endothelium is seen with the confocal microscope.

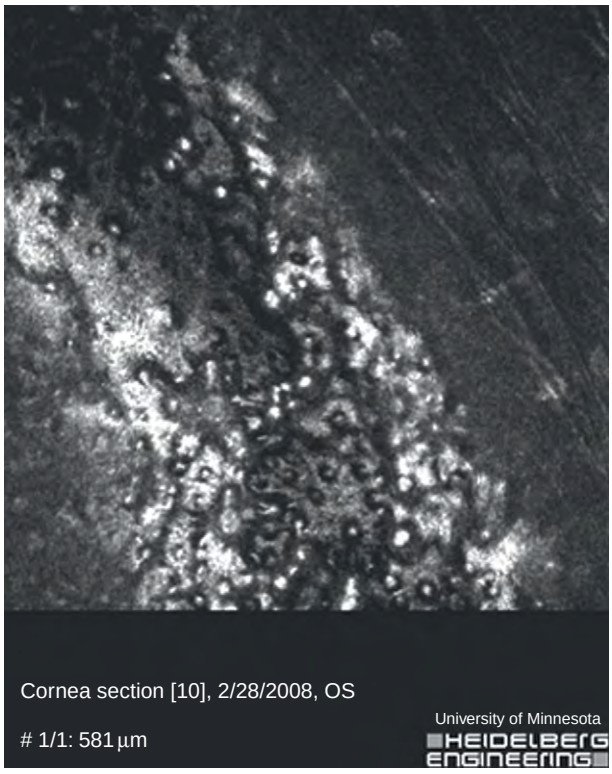


Figure 3 A confocal micrograph of the corneal endothelium of a patient with Fuchs' dystrophy. The scant number of corneal endothelial cells is evident.

UBM is used to examine many pathological conditions of the cornea, ocular adnexa, tumors of the anterior segment, intraocular lens, and diseases of the sclera. Because the UBM can image intraocular structures, it can be used to view intraocular cysts, narrow anterior chamber angle, and intraocular foreign bodies.

Anterior Segment Optical Coherence Tomography

Anterior segment optical coherence tomography (OCT) is an imaging technique that can provide detailed *in vivo* visualization of the anterior chamber. This noninvasive, noncontact device uses OCT to produce direct cross-sectional images that can be measured and used for diagnostic purposes.

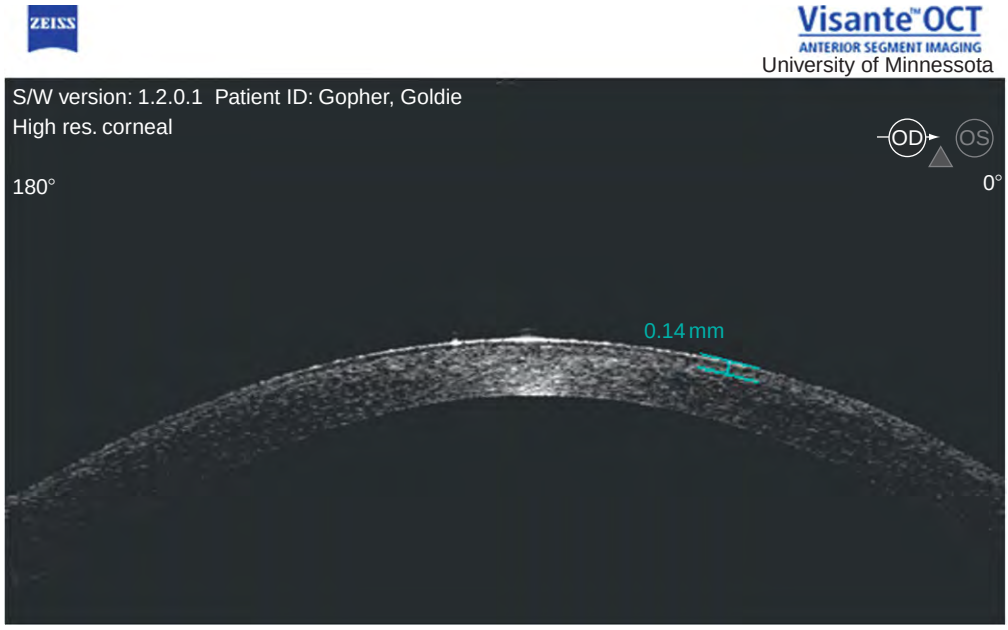

Figure 4 An OCT of the cornea of a LASIK patient. The blue caliper demonstrates the measurement of the thickness of the LASIK flap.

Using low coherence tomography, the light is set along two different optical paths: a sample path into the eye and a reference path of the interferometer. The light source is a 1310-nm superluminescent light-emitting diode (SLD). The light returning from the sample and reference paths are then combined at the photo-detector. The strength of the return signal is a measure of the reflectance of a small volume of tissue. Varying the optical lengths of the reference paths at each of the scanning points determines the axial depth of the tissue signal. By moving the scanning spot across the eye, multiple A-scans align to form a two-dimensional image.

There are many versatile uses of this device in assessing the anterior segment. The anterior chamber dimensions (depth, diameter, etc.) can accurately be measured. The iris and pupil – as well as the crystalline, pseudophakic, and refractive lens implants – can also be evaluated. A highly detailed evaluation of the angle structures can be assessed as well. *In vivo* measurements of the cornea can be evaluated in aid of surgical and refractive procedures as well as in diagnosing pathological processes. The device can measure post-LASIK corneal flap and residual stromal bed thickness, as well as produce full-thickness pachymetry maps which can assist both in refractive and glaucoma surgical planning (Figure 4). With the growing number of Descemet's Stripping Automated Endothelial Keratoplasty (DSAEK) surgeries being performed, this tool has found an additional role in post-surgical lenticle-placement evaluation.

Despite its numerous uses, using light as its medium limits its penetration into the eye. For example, ciliary body tumors cannot always be adequately visualized. In addition, image quality can be greatly reduced when imaging dense corneal opacities.

Imaging of the Orbit

R A Zaldívar, M S Lee, and A R Harrison, University of Minnesota, Minneapolis, MN, USA

Glossary

Angiography – A method for imaging blood vessels that uses the injection of a radioopaque dye that outlines and facilitates their visualization on X-ray images.

Computed tomography (CT) – An imaging method where a large series of X-rays, taken in two dimensions, is computer-processed to result in the generation of a three-dimensional body image around a single axis of rotation. It is also called computed axial tomography, or CAT scan.

Magnetic resonance imaging (MRI) – An imaging method that uses powerful magnetic fields to align specific molecules in the body, such as the hydrogen in water, to produce high contrast images of the soft tissues in the body.

Imaging of the orbit and periorbital regions has revolutionized the way in which diseases of the orbit are managed both pre-operatively, intra-operatively, and post-operatively. The various imaging modalities that have been developed allow us to adequately plan pre-operatively for surgical intervention, including performing three-dimensional reconstruction. Intra-operative imaging can be used to assess our anatomic location or whether an intra-operative treatment has had its effect, as with vascular lesions. Once a diagnosis is made, monitoring the condition of the patient with the use of imaging further augments our clinical assessment. The rapid pace in which orbital imaging technology has developed also allows it be accessible throughout the country.

Computed Tomography

In the early 1970s, the use of computers allowed radiologists to visualize differences in densities among tissues and structures; this first method of computer-processed imaging became known as computed tomography (CT). In the 1980s and 1990s, the technology continued to improve and became the principal modality for orbital imaging as it is effective and cost efficient. Today we use a 64-slice CT scanner that combines speed, resolution, and processing, allowing complex image processing. These new scanners allow for axial and coronal imaging without the need to reposition the patient and can acquire the images in as little as 5 s with resolution up to 0.4 mm. The speed of the image acquisition also allows for rapid imaging in the pediatric patient often with little or no anesthesia. The use of computers to re-process the images, without quality degradation, eliminates additional radiation exposure from the second acquisition plane.

All aspects of the orbit can be analyzed via CT and has become the screening examination of choice by most orbital specialists. In particular, the changes of the orbital bone either by trauma or by compression (lysis or erosion) are better appreciated than by any other imaging modality. Various aspects of bony changes can be seen with CT, that is, compact and spongy layers in fibrous dysplasia (**Figure 1**) or the compact bone layer in meningioma (**Figure 2**). Bony changes secondary to trauma are also well visualized using both the coronal and axial planes of section. The coronal sections are especially useful in evaluating orbital floor fractures. If there is a complex fracture or need for craniofacial reconstruction, use of three-dimensional CT reconstruction may aid in conceptualization of orbital bone changes and in preparation for surgery (**Figure 3**).

From anterior to posterior, the soft tissues of the orbit and the periorbital structures, including most orbital pathology, can be evaluated efficiently with CT. Periorbital imaging, specifically of the eyelids, is primarily performed in conjunction with orbital imaging when there is suspicion of orbital cellulitis (**Figure 4**). In conjunction with the clinical exam, the integrity of the eye can be evaluated in situations of trauma (**Figure 5**). Computed tomography is also an excellent modality to evaluate the extraocular muscles. One or more muscles can be affected either by infectious, inflammatory, vascular, or neoplastic processes. Myositis, either due to infection or inflammation, appears as an enlargement of the involved extraocular muscle. The muscle tendon may be thickened in up to 50% of patients with inflammatory orbital pseudotumor, in contrast with thyroid eye disease in which the muscle insertions are generally spared (**Figure 6**). An important periorbital structure to evaluate during orbital imaging with CT is the optic nerve. The course of the optic nerve can be tracked with both axial and coronal planes of section. These two views are critical in evaluating the optic nerve for tumors (e.g., gliomas and meningiomas) and compression or stretch as in thyroid eye disease and intraconal tumors. Although CT images of the optic nerve do provide excellent imaging, when available we prefer magnetic resonance imaging for optic nerve disease (see the following section).

Figure 1 Fibrous dysplasia with thickened sclerotic bone of the right sphenoid. Note the ground glass appearance and destruction of the ethmoid sinus.

Figure 2 Optic nerve meningioma. Note enhancement of the optic nerve sheath on the right.

The morphology and pathology of orbital and periorbital structures are quickly and effectively viewed by today's modern CT scanners; however, when certain soft tissues and vascular lesions need to be assessed, other modalities, such as magnetic resonance imaging (MRI) and angiography, provide the clinician with important additional information.

Figure 3 T1 MRI, Coronal view of orbit posterior to globe. Note the bright signal of the orbital fat.

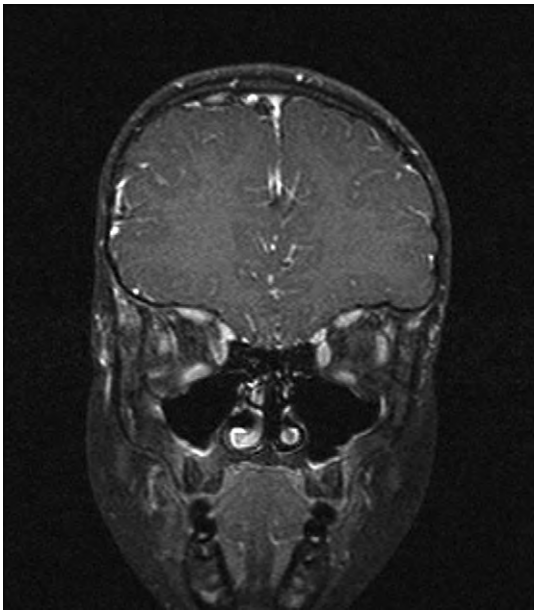

Figure 4 T2 MRI, coronal view of orbit posterior to globe. Note bright signal of the CSF around the optic nerve and nasal mucosa.

Magnetic Resonance Imaging

MRI is a noninvasive imaging technique that does not expose the patient to ionizing radiation. An image is created when a tissue containing hydrogen atoms is placed in a magnetic field and excited by a radiofrequency. The nuclei undergo an alignment that emits a radiofrequency. This radiofrequency can be captured and processed to produce the image. The quality of the images produced by MRI studies is determined by the magnet potency, signal to noise ratio, field of view, pixel size, slice

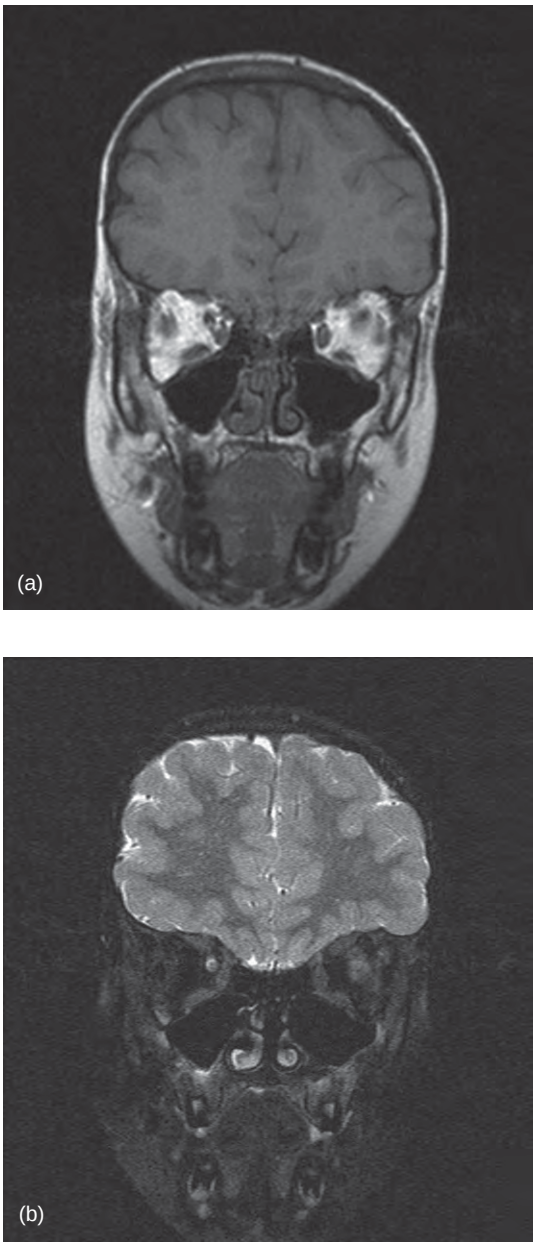

Figure 5 (a) Three-dimensional reconstruction of the face following orbital trauma. This may assist in pre-operative planning for reconstructive surgery. (b) Left orbital subperiosteal abscess secondary to ethmoid sinusitis. Note the enhancment of the thickened periorbita.

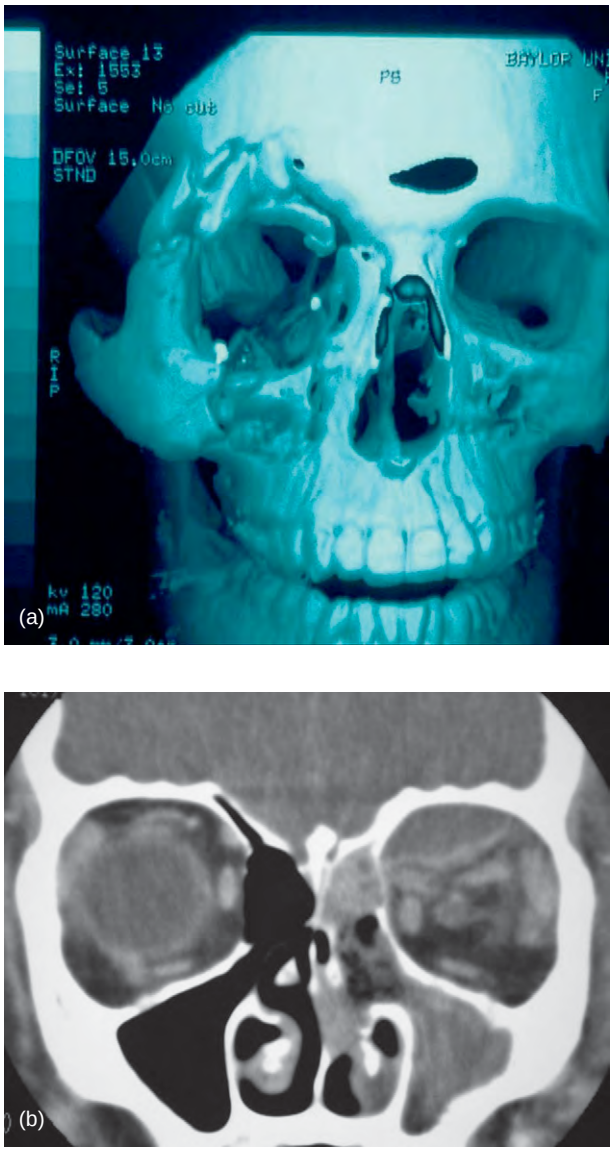

Figure 6 (a) Right ruptured globe. Note the tenting of the globe and intraocular hemorrhage. (b) Right eye ruptured globe. The pupil is peaked temporally secondary to prolapse of uvea.

thickness, and pulse sequences. The use of intravenous gadolinium helps to enhance vascularized lesions and provide additional information.

Based on the time it takes the hydrogen atoms in the tissue to realign, two images can be formed: T1 (longitudinal relaxation time) or T2 (transverse relaxation time). These two views help in differentiating various lesions. T1-weighted images generally offer the best anatomic detail of the orbit and require less acquisition time, therefore reducing the potential for motion artifact. However, the orbital fat in T1 images produces a bright signal that requires fat suppression (Figures 7 and 8). T2-weighted images can differentiate methemoglobin from melanin. As an example, this is useful in differentiating melanotic lesions from hemorrhage. The T1 and T2 image types produce different signal intensities for different tissues in the body. Most lesions seen on T1 MRI images of the orbit are dark except for fat, lipoma, liposarcoma, mucus as seen in mermaid cysts and mucoceles, and melanin.

Advantages of MRI over CT include: no ionizing radiation, excellent soft tissue resolution of the orbit and cavernous sinus, multiplanar imaging, and the ability to perform noninvasive arteriography. However, the disadvantages include: poor bony detail, longer scan times,

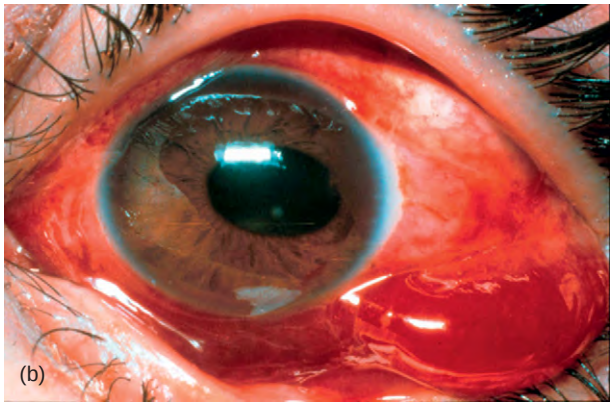

Figure 7 (a) Classical myopathy of thyroid eye disease. Note the enlarged medial recti with sparing of the muscle insertions. (b) Left lateral rectus orbital myositis. Differentiated from myopathy of thyroid eye diease in that the muscle insertions are involved.

images sensitive to motion artifact, difficulties for claustrophobic patients, contraindications for patients with ferromagnetic metallic foreign bodies, aneurysm clips, and pacemakers, as well as cost.

Specific indications for obtaining an MRI include demyelinating disease such as optic neuritis and multiple sclerosis, neurogenic tumors such as gliomas and meningiomas, visualization of lesions of the orbital apex or

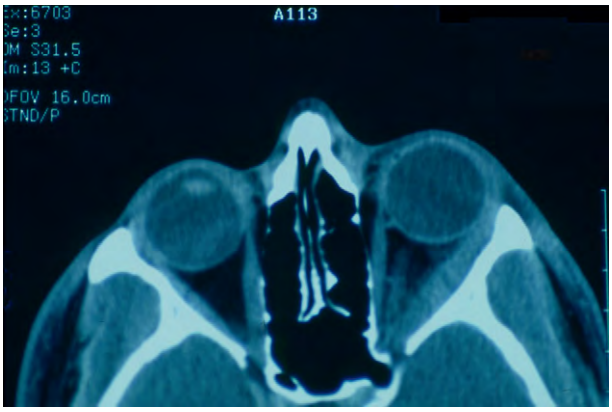

Figure 8 Pre-gadolinum T1-fat suppressed MRI, coronal view of orbit posterior to globe. Note the enhancment of the nasal mucosa.

cavernous sinus, optic nerve lesions, tissue specific signals such as for blood, lipid, mucus and melanin, and wooden or other less dense foreign bodies.

Angiography

Both venography and arteriography angiography were the original modalities used to study vascular lesions. However, because of the risk involved with these procedures and the development of other imaging techniques, there has been a decline in their use in the evaluation of orbital lesions. Some of these techniques include magnetic resonance angiography which allows for noninvasive visualization of large and medium-sized vessels of the arterial system but do not provide the detail seen in angiography.

Immunobiology of *Acanthamoeba* Keratitis

J Y Niederkorn, University of Texas Southwestern Medical Center, Dallas, TX, USA

Glossary

Clodronate – Drug that preferentially kills macrophages, but has no known deleterious effects on other cells of the innate or adaptive immune responses.

Interferon-γ (IFN-γ) – Cytokine produced by T cells that activates macrophages and enhances their capacity to kill *Acanthamoeba* trophozoites.

Mannose-binding protein (MBP) – Lectin receptor that is expressed on *Acanthamoeba* trophozoites and facilitates their adherence to mannosylated proteins that are expressed on corneal epithelial cells.

Major histocompatibility complex (MHC) class-I antigens – Antigens that allow cytotoxic T lymphocytes to recognize and kill cells infected with viruses and some protozoal parasites.

Mannose-induced protease 133 (MIP-133) – The 133-kDa protease that is induced when *Acanthamoeba* trophozoites engage mannose in the cell walls of bacteria or upon mannosylated proteins on corneal epithelial cells. This protease facilitates invasion of *Acanthamoeba* trophozoites by degrading basement membranes and it also induces apoptosis of corneal cells.

Mucosal immunity – Immune responses that are primarily in the form of secretory immunoglobulin A (IgA) antibodies, which preferentially accumulate in the milk, tears, and in mucosal secretions. This form of T-cell-dependent immunity acts primarily to prevent pathogens from entering the body via mucosal surfaces and rarely directly kills microorganisms.

Trophozoite – Amoebic phase of *Acanthamoeba* spp. *Acanthamoeba* spp. can exist as either dormant cysts or as the active trophozoite (amoebic) phase. Unlike cysts, trophozoites are invasive, produce pathogenic proteases, and directly kill host cells by apoptosis and direct cytolysis.

Introduction

Acanthamoeba spp. are the causative agents for *Acanthamoeba* keratitis (AK) and can be isolated from virtually any terrestrial, aquatic, and marine environment. Viable *Acanthamoeba* spp. have even been isolated from eyewash stations, bottled water, and contact lens cases of asymptomatic contact lens wearers. *Acanthamoeba* can exist either as a dormant cyst or as the active amoebic stage called the trophozoite. Trophozoites are the active vegetative stage that normally exist as free-living amoebae and feed on bacteria and fungi. Trophozoites are approximately the size of a leukocyte (10–25 μm) and are readily identified by their spiny pseudopodia that give them a sea urchin-like appearance. *Acanthamoeba* cysts are the dormant stage and are approximately half the size of the trophozoite. The cyst wall is comprised primarily of protein and cellulose. Interestingly, the latter molecule is not normally found in animals, but is restricted to members of the plant kingdom including bacteria and fungi. The cyst is remarkably resistant to environmental agents and can remain viable even after 20 years of storage at room temperature or following treatment with over 250 000 rads of gamma irradiation or doses of ultraviolet B (UVB) irradiation that are known to kill every category of mammalian cells. Although AK is believed to be caused by corneal infections produced by trophozoites adhering to contact lenses, cysts can also adhere to contact lenses, and, under certain circumstances, can produce corneal infections in experimental animals. Cysts can persist in corneal tissue for up to 31 months following antiamoebic treatment and may be the underlying cause for recrudescence in patients, especially those who receive corneal transplants to restore the vision lost as a consequence of AK. Corticosteroids are often used to extinguish the inflammation that is provoked in AK. However, corticosteroids have been shown to induce cysts to excyst and transform into infectious trophozoites. Moreover, corticosteroids activate trophozoites and render them more pathogenic and invasive. Thus, corticosteroid treatment may unwittingly exacerbate AK and contribute to the recrudescence that has been reported in AK patients who are treated with topical corticosteroids to prevent immune rejection of their corneal transplants.

In spite of the ubiquitous distribution of *Acanthamoeba* spp. in the environment and widespread contact lens wear, AK is remarkably rare. Moreover, environmental exposure to *Acanthamoeba* spp. is commonplace; up to 100% of the normal individuals with no history of AK possess serum antibodies to *Acanthamoeba* antigens, suggesting previous environmental exposure to *Acanthamoeba* spp. Viable *Acanthamoebae* can be isolated from the contact lens cases of individuals with no symptoms or history of AK. Collectively, these findings suggest that a large portion of the population is exposed to *Acanthamoeba* spp. and

may express some degree of immunity against corneal *Acanthamoeba* infection. This proposition begs the obvious question as to which immune component provides protection and how does it do it.

Anatomical and Physiological Barriers to Corneal Infections with *Acanthamoeba*

Clinicians have long suspected that contact lenses served as vectors for transmitting *Acanthamoeba* trophozoites to the corneal surface, and that antecedent injury to the corneal surface created epithelial defects that permitted trophozoites to gain a foothold in the cornea. Less than one-third of the cases of AK involve both eyes, even though contact lens wearers typically store their lenses in the same contact lens case, use the same contact lens solutions, and use the same finger for inserting their contact lenses. If a preexisting corneal epithelial barrier defect were not necessary, one would expect that the overwhelming majority of AK cases would be bilateral. Studies in animal models of AK confirm the importance of preexisting corneal epithelial defects in the development of AK that is produced by applying *Acanthamoeba*-laden contact lenses to the abraded corneal surface. However, other animal studies have shown that breaching the intact corneal epithelium by direct injection of trophozoites into the corneal stroma produces AK. Thus, the intact corneal epithelium provides a barrier for preventing the establishment of ocular infections with *Acanthamoeba* trophozoites.

In addition to the physical barrier provided by an intact corneal epithelium, the ocular surface is bathed in tears, which contain multiple factors that inhibit trophozoite binding and cytopathic effects. Although never formally proven, it is suspected that the shear forces produced by the blinking eyelid interfere with trophozoite adherence to the corneal epithelium and reduce the likelihood of the trophozoites gaining a foothold in the cornea.

Innate Immune System and Resistance to *Acanthamoeba* Infections

The immune system is divided into two functionally distinct components: (1) the innate immune apparatus – which is characterized by its nimble response, but lack of antigen specificity – and (2) the adaptive immune apparatus – which, although slower in its response, provides long-lasting immunity and memory. Elements of the innate immune apparatus are the first responders via their detection of pathogen-associated molecular patterns (PAMPS) that are widely and promiscuously expressed by many microorganisms. By utilizing PAMPS, macrophages and neutrophils are able to rapidly identify invading microorganisms and mount an initial response that restrains the infectious agents, thereby providing much-needed time for the development of the adaptive immune response.

Role of Macrophages in the Resistance to *Acanthamoeba* Infections

In vitro studies have demonstrated that macrophages are capable of killing *Acanthamoeba* trophozoites. Moreover, depletion of periocular macrophages by subconjunctival injection of liposomes containing the macrophagicidal drug clodronate results in a dramatic exacerbation of AK in experimental animals. Likewise, *in vitro* or *in vivo* exposure to liposomes containing interferon-γ (IFN-γ) activates macrophages, increases their capacity to kill *Acanthamoeba* trophozoites, and mitigates AK in experimental animals. In animal models, AK is a self-limiting disease that resolves in 4–5 weeks. However, depletion of conjunctival macrophages results in progressive AK that does not resolve and mimics the human counterpart. The extraordinarily low incidence of AK is not commensurate with the enormous number of contact lens wearers and the ubiquitous distribution of *Acanthamoeba* spp. This suggests that the presence of an additional risk factor is involved in the development of AK. It is tempting to speculate that patients who develop AK represent a small population of individuals who have underlying deficiencies in their conjunctival macrophage population or altered macrophage function.

Role of Neutrophils in the Resistance to *Acanthamoeba* Infections

The neutrophil is another constituent of the innate immune system that plays an important role in the resistance and resolution of AK. Neutrophils are consistently found in AK lesions – both in patients and in experimental animals. Neutrophils are highly effective in detecting the presence of both trophozoites and cysts. They kill both cysts and trophozoites in a myeloperoxidase-dependent manner. Blocking chemotactic responses of conjunctival neutrophils or depleting neutrophils with anti-neutrophilic antiserum results in progressive AK. Likewise, intracorneal injection of macrophage inflammatory protein-2 (MIP-2) – a potent chemoattractant for neutrophils – results in a swift infiltration of neutrophils into the central cornea and in an accelerated resolution of AK in experimental animals.

Ocular *Acanthamoeba* infections rarely progress beyond the cornea and are not known to produce endophthalmitis. Only three reports in the literature suggest that *Acanthamoeba* infections of the cornea progress to the posterior segment of the eye and involve the choroid or retina. Moreover, only one publication provides histopathological documentation of *Acanthamoeba* cysts in the posterior segment of the eye in a single AK patient. Moreover, the patient in this study had received four

separate corneal transplants in the affected eye. Likewise, more than 16 years of experience with both the pig and Chinese hamster models of AK has failed to produce any evidence of *Acanthamoeba* infections progressing posterior from the cornea or involving the uveal tract or retina. *In vitro* studies have shown that trophozoites can penetrate Descemet's membrane and are, theoretically, capable of entering the anterior chamber. Further studies showed that intraocular injection of 1 million trophozoites into the anterior chamber of the eye in Chinese hamsters did not produce intraocular infection. A swift neutrophilic infiltrate eliminated the injected trophozoites without inflicting collateral damage to the intraocular tissues.

Humoral Factors of the Innate Immune System that Affect Resistance to *Acanthamoeba* Infections

Tears contain a potpourri of antimicrobial factors that protect the ocular surface from pathogenic insults. Among these are lysozyme, lactoferrin, and complement components. Lysozyme is active against Gram-negative bacteria and some fungi, but is ineffective against Gram-positive bacteria. By contrast, lactoferrin and transferrin are effective in controlling Gram-positive bacteria. Complement is present in tears and can be activated by the alternate pathway via bacterial products or by the classical pathway by antibodies. Thus, the complement system straddles the innate and adaptive immune systems. Complement appears to have little or no effect in controlling AK, as pathogenic *Acanthamoeba* spp. express complement-regulatory proteins – including decay-accelerating factor – which disable the complement system. Tears and milk also contain a factor that inhibits trophozoite adherence and cytolysis of corneal cells. Interestingly, the factor in both milk and tears is not an Ig. The milk-borne factor is >100 kDa and is inactivated by proteinase K, indicating that it is a protein. The two major proteins in milk – α1-antitrypsin and α1-antichemytrypsin – are not the milk-borne factors, as neither of these proteins blocks trophozoite adherence or cytolytic activity.

Thus, both humoral and cellular elements of the innate immune system can contribute to the resistance to AK (**Table 1**).

Adaptive Immune System and Resistance to *Acanthamoeba* Infections

Elements of the innate immune system serve as the first responders to pathogens and are characterized by capacity to act immediately in response to microbial infections. However, the innate immune system acting alone cannot clear all microbial infections. Unlike the innate immune system, the adaptive immune apparatus needs a jump start to generate its effector elements, but – once engaged – is crucial for the recovery from microbial infections and the establishment of immunity to future infections. The innate and adaptive immune systems do not function in isolation, but communicate with each other in a coordinated immune response. Macrophages and dendritic cells present antigens to T and B cells, which process is facilitated by another innate immune system component – complement. T and B cells have the capacity to generate an endless array of antigen receptors that, when confronted with antigens expressed on antigen-presenting cells, culminates in the generation of antibodies and T cells that possess exquisite specificity and are used by antibodies to identify and kill bacteria and neutralize viruses. T cells utilize their antigen receptors and CD8 surface molecules to identify and kill virus-infected cells. The adaptive immune system is characterized by its exquisite specificity and memory. The efficacy of preventive immunization relies entirely on the capacity of the vaccine to activate crucial elements of the adaptive immune system. One has to look no further than the biology of acquired immune deficiency syndrome (AIDS) to recognize the importance of the adaptive immune system. With few exceptions, recovery and survival from microbial infections is contingent upon the effective activation of the adaptive immune system. However, AK is a notable exception to this rule.

There is no evidence to date that patients with AIDS have an increased incidence of AK, suggesting that a disabled adaptive immune system does not increase the susceptibility to corneal infections with *Acanthamoeba* even though *Acanthamoeba* spp. express antigens that are capable of activating the adaptive immune system. Fifty to one hundred percent of the individuals with no past history of AK possess serum and tear antibodies specific for *Acanthamoeba* antigens – indicating that *Acanthamoeba* antigens can

Table 1 Elements of the innate immune system that control ocular *Acanthamoeba* infections

Component	*Function*	*Evidence for role in protection*
Neutrophils	Kill trophozoites	Treatment with anti-neutrophil serum exacerbates AK; stimulating neutrophil infiltration into the cornea mitigates AK; neutrophils kill trophozoites *in vitro*.
Macrophages	Kill trophozoites	Depletion of conjunctival macrophages exacerbates AK; activating conjunctival macrophages mitigates AK; macrophages kill trophozoites *in vitro*.
Nonimmunoglobulin tear-borne factor	Prevents trophozoite adherence to cornea	*In vitro* assays demonstrate that tears from normal animals block adherence of trophozoites to corneal cells and prevent trophozoite-mediated cytolysis of corneal cells.

activate the adaptive immune system and that exposure to these antigens is remarkably widespread. The T-cell arm of the adaptive immune system is also activated by *Acanthamoeba* antigens, as 50% of the normal population with no known history of AK demonstrate T-cell lymphoproliferative responses to *Acanthamoeba* antigens. In spite of this, patients whose initial AK has been brought under control with antimicrobial therapy can experience recrudescence. This suggests that even if the adaptive immune system has been activated, it is ineffectual in controlling AK. This impression has been confirmed in animal models of AK. Both in Chinese hamsters and pigs, subcutaneous immunization with *Acanthamoeba* antigens elicits robust IgG antibody and T-cell responses, yet fails to protect the animals against ocular challenge with *Acanthamoeba* trophozoites. Moreover, resolution of AK does not render animals resistant to second ocular infections with trophozoites; repeat ocular *Acanthamoeba* infections are as severe as the primary infections.

Role of the Mucosal Immune System in Resistance to AK

On first blush, it would appear that the adaptive immune system is utterly incapable of preventing or resolving AK. However, animal studies and serological studies on human AK patients suggest that secretory IgA antibodies in the tears may prevent initial corneal *Acanthamoeba* infections. It is widely accepted that corneal infection with *Acanthamoeba* spp. begins when trophozoites adhere to mannosylated proteins on the corneal epithelium. Mannosylated proteins appear to be key ligands for trophozoite attachment – which is facilitated by the expression of a 136-kDa mannose-binding protein (MBP) that is expressed on the trophozoite cell membrane. Mannose expression on the corneal epithelium is dramatically upregulated by contact lens wear or by mild trauma to the ocular surface. In addition to promoting the adhesion of trophozoites, mannose stimulates the trophozoites to secrete a 133-kDa pathogenic protease (mannose-induced protease-133 (MIP-133)), which facilitates trophozoite invasion and cytolysis of corneal cells. Upregulation of mannosylated protein expression on the corneal epithelium is crucial for the establishment of AK. However, blocking the interaction between mannosylated glycoproteins on the corneal epithelium and the MBP on the trophozoite cell membrane is an effective strategy for preventing AK. Immunization through mucosal surfaces such as the gastrointestinal tract preferentially stimulates the generation of secretory IgA antibodies that appear in the tears and in mucosal secretions. Animals immunized orally with the *Acanthamoeba* MBP develop secretory IgA antibodies in the tears, which prevent the development of AK. Secretory IgA antibodies block the adhesion of *Acanthamoeba* trophozoites to corneal epithelial cells, and thereby, disrupt the first key step in the pathogenic cascade of AK. Anti-MBP secretory IgA antibodies are not toxic to trophozoites, even in the presence of complement and are ineffectual if they are generated after a corneal infection had been established. Thus, IgA antibodies in the tears are the only known component of the adaptive immune system that has an effect on the development of AK (**Table 2**).

Evading the Adaptive Immune Response

Exposure to *Acanthamoeba* antigens is commonplace as evidenced by the high incidence of serum antibodies and T-cell responses to *Acanthamoeba* antigens in individuals with no previous history of *Acanthamoeba* infections. In experimental animals, subcutaneous and intramuscular immunization with *Acanthamoeba* antigens elicits high titers of IgG antibodies and T-cell activation, yet fails to protect against AK. Although the adaptive immune

Table 2 Role of adaptive immunity in preventing ocular acanthamoeba infections

Immune element	*Role in AK*	*Evidence for effect*
Serum IgG	None	Animals and humans with anti-*Acanthamoeba* IgG antibodies can develop AC. Anti-*Acanthamoeba* antiserum fails to kill trophozoites *in vitro*, even in the presence of complement.
Delayed-type hypersensitivity	None	Subcutaneous immunization with *Acanthamoeba* antigens induces robust delayed-type hypersensitivity to *Acanthamoeba* but fails to prevent or mitigate AK.
Complement	None	Trophozoites resist complement-mediated lysis due to their expression of complement decay accelerating factor.
Cytotoxic T lymphocytes	None	Trophozoites are extracellular pathogens that do not express the crucial major histocompatibility complex class I restricting elements that are necessary for cytotoxic T lymphocyte function.
Secretory IgA	Prevents initial corneal infection	Mucosal immunization with surface antigens expressed on trophozoites induces production of secretory IgA in the tears; anti-*Acanthamoeba* IgA prevents trophozoite adherence to corneal cells and prevents trophozoite-mediated cytolysis of corneal cells; passive transfer of IgA monoclonal antibody against *Acanthamoeba* surface eptiotpes protects animals against ocular *Acanthamoeba* infections.

system is capable of eliminating a wide range of microbial agents, it is ineffectual in preventing corneal infections with *Acanthamoeba* or recrudescence of previous corneal infections. *Acanthamoeba* spp. employ at least three strategies to evade immune elimination: (1) inactivating immune effector elements; (2) escaping detection by cytotoxic T lymphocytes; and (3) forming dormant cysts that escape immune detection (**Table 3**). *Acanthamoeba* trophozoites can activate the complement cascade via the alternate pathway or by the direct pathway by complement-fixing IgG antibodies that recognize surface determinants on the trophozoite cell membrane. Complement components are present in the tears and at the ocular surface, yet trophozoites escape complement-mediated cytolysis – both *in vitro* and *in vivo*. The ability of trophozoites to elude the ravages of complement is ostensibly due to their expression of complement-regulatory proteins (i.e., decay-accelerating factor) – which disable the complement cascade. Complement-regulatory proteins are also present on the corneal epithelium and may further interfere with complement-mediated cytolysis of trophozoites at the ocular surface.

Trophozoites secrete a variety of proteases that are known to degrade Igs, including secretory IgA antibodies in the tears. The importance of this evasive strategy is limited, as IgA antibodies in the tears can prevent the initial establishment of *Acanthamoeba* infections of the cornea.

Acanthamoeba trophozoites are extracellular pathogens and thus, escape detection and elimination by cytotoxic T lymphocytes – which are only able to kill intracellular pathogens whose antigens are presented on host cells that are expressing major histocompatibility complex (MHC) class-I molecules.

Table 3 *Acanthamoeba* immune escape mechanisms

Factor or mechanism	*Potential effect in Acanthamoeba keratitis*
Secretion of serine proteases	Degrade immunoglobulins; induce apoptosis of leukocytes
Complement decay accelerating factor	Inactivate complement and disable complement-fixing antibodies
Encystment	Escape detection by inflammatory and immune cells; resistant to phagocytosis by non-activated macrophages; weakly immunogenic; do not produce chemoattractants for leukocytes
Immune privilege of cornea	Corneal infections fail to elicit IgG antibody or delayed-type hypersensitivity responses to *Acanthamoeba* antigens
Extracellular infection	Trophozoites are extracellular pathogens and do not reside in host cells that express MHC class I antigens. Thus, they escape recognition and attack by cytotoxic T lymphocytes

Protozoal parasites have the capacity to encyst and, thereby, escape immune detection and elimination. *Acanthamoeba* spp. are one of the few protozoal parasites of humans that form cysts in tissues. Although most intestinal protozoal parasites can encyst, the cysts reside transiently within the lumen of the large intestine and are typically eliminated in the feces. *Toxoplasma gondii* can encyst within mammalian cells and not in extracellular sites. *Acanthamoeba* cysts occur in tissue and have been reported to persist in corneal tissue for up to 31 months. *Acanthamoeba* cysts are remarkably resistant to a variety of agents and can remain viable for decades. Moreover, *Acanthamoeba* cysts are poor immunogens, have only weak chemoattractive properties, and often reside in an immune-privileged site (i.e., the cornea), thereby enhancing their ability to escape immune detection.

Anti-Disease Vaccine for AK

Effector elements of the adaptive immune system appear to be incapable of killing or inactivating *Acanthamoeba* trophozoites. Thus, immunotherapeutic strategies are limited to two potential targets: (1) preventing the initial adherence of trophozoites to the corneal surface, or (2) inactivating the trophozoite-borne pathogenic molecules that damage the cornea. As stated earlier, secretory IgA antibodies directed against the cell-membrane molecules on the trophozoite can prevent the establishment of corneal infections by blocking the adherence of trophozoites to the corneal epithelium, but only if the antibodies are present in the tears when trophozoites are first introduced to the corneal surface. IgA antibodies are unable to alter the course of disease once the trophozoites have gained a foothold in the cornea.

Trophozoites elaborate a variety of proteases that produce extensive cytolysis and apoptosis of corneal cells, degradation of basement membranes, and melting of the stroma. One of the most important trophozoite-borne proteases is a 133-kDa serine protease – MIP-133 – which is secreted in response to trophozoites binding to mannosylated glycoproteins on the corneal epithelium. Mucosal immunization with MIP-133 elicits the generation of secretory IgA antibodies that inhibit the cytolysis of corneal cells and neutralize the enzymatic degradation of stromal proteins. Hosts mucosally immunized with MIP-133 have much milder disease compared to controls. An attractive feature of eliciting mucosal immunity against a pathogenic molecule is that the ocular surface is bathed in tears containing neutralizing antibodies which are continuously replenished. An anti-disease vaccine could be implemented at the time AK is diagnosed and used in combination with conventional anti-*Acanthamoeba* chemotherapy.

Conclusions

The immunobiology of AK is puzzling. *Acanthamoeba* spp. are free-living amoebae that can be found in virtually any environmental niche, yet rarely cause disease. Environmental exposure to *Acanthamoeba* spp. is commonplace and results in the activation of the adaptive immune response as evidenced by the high percentage of individuals who display antibody and T-cell responses to *Acanthamoeba* antigens. The low incidence of AK combined with the high frequencies of anti-*Acanthamoeba* antibody and T-cell immunity suggest that the adaptive immune response protects against corneal infection with *Acanthamoeba* spp. However, animal studies suggest otherwise and indicate that – with the exception of secretory IgA antibodies – the adaptive immune system is incapable of preventing or controlling *Acanthamoeba* infections. By contrast, the innate immune apparatus appears to control ocular *Acanthamoeba* infections.

This article offers the following theory to explain the immunobiology of AK. Environmental exposure to *Acanthamoeba* spp. is common and occurs via mucosal surfaces by breathing airborne *Acanthamoebae* that can readily be isolated from heating and cooling vents or by ingestion of *Acanthamoebae* that are found in a variety of vegetables and fruits. Most environmental isolates of *Acanthamoeba* spp. are nonpathogenic, but are immunogenic. The presence of anti-*Acanthamoeba* IgA antibodies in the tears protects against ocular infection, especially in individuals without corneal epithelial defects. Occasionally, *Acanthamoeba* trophozoites will reach the ocular surface and escape detection by IgA antibodies in the tears, but are eliminated by neutrophils and macrophages. The small number of individuals who develop AK might have underlying deficiencies in their tear antibody titers or in their periocular neutrophil and macrophage repertoire. Such immunological blind spots might account for corneal *Acanthamoeba* infections. This theory remains to be confirmed, but is consistent with results from animal studies and with clinical findings from AK patients.

Immunobiology of Age-Related Macular Degeneration

R L Ufret-Vincenty, University of Texas Southwestern Medical Center at Dallas, Dallas, TX, USA

Glossary

Adaptive immune system – An arm of the immune system that recognizes and responds to specific antigens. It is composed mainly of lymphocytes (T cells and B cells) and antigen-presenting cells that present antigen to T cells. B cells produce antibodies, which recognize antigens with high specificity. One of the properties of the adaptive immune system is immunological memory, which enables the body to respond in a faster and stronger manner to an antigen that is encountered a second time.

Drusen – The deposits of extracellular material lying between the basement membrane of retinal pigment epithelium (RPE) cells and the inner collagenous zone of Bruch's membrane. Drusen are readily visible as yellowish deposits lying deep to the retina. They vary in size and shape and may have a crystalline appearance due to calcification. They are often the earliest clinical sign of AMD.

Innate immune system – It comprises the cells and molecules that defend the host from infection by other organisms, in a nonspecific manner.
The components of the innate (nonadaptive, non-antigen-specific) system recognize pathogens in a generic way. The innate immune system does not confer memory (long-lasting and enhanced immune responses). Components of the innate immune system include the complement system, and cells such as natural killer cells, mast cells, eosinophils, basophils, macrophages, and neutrophils.

M2 macrophages – Macrophages are cells that phagocytose (engulf and digest) cellular debris and pathogens. They can then stimulate or modulate lymphocytes and other immune cells. In a simplified scheme, macrophages can be sub-classified into M1 and M2. M1 macrophages are microbicidal and inflammatory, while M2 macrophages are immunomodulators. Among other things, M2 polarization is induced by interleukin-4, interleukin-10, interleukin-13, immune complexes, and glucocorticoid hormones. M2 macrophages express high levels of legumain (an endopeptidase) and this molecule can be used as a phenotypical marker for polarization. Macrophage polarization has been shown to be reversible.

Neoantigen – A newly acquired and expressed antigen that elicits an immune response. Examples include the antigens present in cells infected by viruses, those on tumor cells, or those induced by damage of normal molecules during tissue injury (e.g., oxidative damage to normal proteins).

Opsonization – A process by which a molecule (opsonin) enhances the binding of immune system cells to an antigen or cell surface, for example, by coating the negatively charged molecules on a cell membrane. This helps in the process of phagocytosis. Examples of opsonins are antibodies and complement molecules.

Single nucleotide polymorphism (SNP) – A type of mutation or allelic variant of a gene in which the DNA sequence differs only in a single nucleotide.

Vascular endothelial growth factor (VEGF) – A critical regulator of both physiological and pathological angiogenesis. It is involved in pathologic ocular neovascularization as seen in proliferative diabetic retinopathy, retinopathy of prematurity, and AMD. VEGF also promotes vascular permeability. It is strongly upregulated by hypoxia.

Epidemiology and Clinical Findings of Age-Related Macular Degeneration

Approximately 1.75 million Americans have advanced age-related macular degeneration (AMD). In fact, an estimated 30% of the population older than 75 years of age has some degree of macular degeneration. AMD is classified into a dry or non-neovascular form and a wet or neovascular form. About 12% of patients with AMD end up having advanced disease (neovascular AMD or central geographic atrophy (GA)). Presentations of dry AMD include drusen and a wide range of abnormalities of the retinal pigment epithelium (RPE), going from focal areas of hypopigmentation and hyperpigmentation, to the more advanced GA. Several studies have shown that self-reported quality-of-life scores for patients with choroidal neovascularization (CNV) secondary to AMD are worse than those reported by patients with acquired immune deficiency syndrome (AIDS; receiving treatment) and chronic obstructive pulmonary disease. Moreover, the levels of anxiety and depression were comparable. Genetic factors, smoking, and increased body mass index seem to have the highest impact on the likelihood of progression of AMD.

Despite recent advances in the treatment of CNV, clinical outcomes remain suboptimal. Furthermore, there is still no effective therapy for atrophic AMD. The Age-Related Eye Disease Study (AREDS) demonstrated that using high doses of certain vitamins and minerals (15 mg of β-carotene, 500 mg of vitamin C, 400 IU of vitamin E, 80 mg of zinc oxide, and 2 mg of cupric oxide) leads to a 25–30% reduction in the risk of development of advanced AMD. These vitamins and minerals mostly act as antioxidants. Their efficacy, combined with the observation that smoking is a significant risk factor for AMD, suggests an important role of oxidative damage in the early stages of macular degeneration. Current therapies for neovascular AMD include laser photocoagulation, photodynamic therapy, and anti-VEGF (VEGF, vascular endothelial growth factor) agents. All of these attempt to close or cause regression of the already-formed neovascular membranes. Although the newer anti-VEGF agents such as bevacizumab (Avastin) and ranibizumab (Lucentis) can lead to an average improvement in vision of up to two lines from the time of the detection of the neovascularization, this still means a significant loss in vision for many patients. The goal of newer therapeutic modalities should be to stop the process that leads to atrophy of the RPE and retina or to the formation of neovascularization before irreversible damage has occurred. This, of course, requires a better understanding of the pathogenetic mechanisms involved in the early stages of disease. Most experts now suspect that the immune system plays an important, although poorly understood, role in those early events.

The Immune System in AMD

Multiple lines of evidence imply a role of the immune system in AMD, including the presence of chronic inflammatory cells in retinal lesions and antiretinal antibodies in the serum of AMD patients. Macrophages, lymphocytes, and mast cells have been detected in CNV membranes and near ruptures of Bruch's membrane in eye specimens from AMD patients. In addition, AMD patients seem to have increased systemic levels of the inflammatory markers C-reactive protein (CRP) and interleukin-6 (IL-6). Yet, it is debated whether the immune system plays a role in initiating or exacerbating the disease, or if these findings are a response to the retinal damage.

The early stages of AMD are characterized by accumulation of debris (altered proteins and lipids) underneath the RPE. Recent literature suggests that an immune reaction to this debris may promote more tissue damage and/or a neovascular response. Both the innate and the antigen-specific arms of the immune system can cause local damage to RPE cells, Bruch's membrane, and the choriocapillaris, leading to either the atrophic or neovascular forms of AMD.

Histopathology of Drusen

For the last four decades there has been a debate surrounding the mechanism for the formation of drusen. However, whether drusen form from fragments of RPE cells, from abnormal material secreted by dysfunctional RPE cells, or whether some components come from the choriocapillaris, the composition of drusen gives us important information about the pathogenesis of AMD.

During the last decade Hageman, Anderson, Johnson, Penfold, and others have contributed a great deal to our knowledge of drusen composition by extensive histopathological analysis of human AMD specimens obtained within the first few hours of death. They have performed light microscopy, confocal microscopy, electron microscopy, and immunostaining in hundreds of specimens; and have also evaluated the levels of mRNA expression of inflammatory mediators in the RPE and choroid. From these studies they have identified a large number of molecules found in drusen, many of which are in some way related to inflammation:

1. acute-phase reactant proteins such as CRP;
2. inflammatory mediators such as serum amyloid P;
3. potential activators of the complement cascade, including nuclear fragments/nucleic acids, membrane-bound vesicles, mitochondria, modified lipids, cholesterol, and microfibrillar debris;
4. complement components such as C3 and its fragments, C5, and the membrane attack complex (C5b-9); and
5. complement regulatory proteins including vitronectin, clusterin, membrane cofactor protein (CD46), complement receptor 1, and complement factor H (CFH).

Role of Macrophages

Some studies have suggested that macrophages may play a protective role in AMD, while others suggest that they promote disease progression. Some investigators have suggested that macrophages promote CNV formation. They have shown in the mouse laser-injury model of CNV that depletion of macrophages diminishes the size of the CNV lesions. They have also shown that neovascular AMD patients tend to have higher levels of expression of tumor necrosis factor (TNF)-α in their circulating monocytes than controls. TNF-α is considered a marker for monocyte activation. Others propose that macrophages have a role in preventing AMD. Mice deficient in monocyte chemoattractact protein-1 (also known as CCL-2) or its receptor can develop CNV in old age, suggesting that impaired macrophage recruitment in these mice is responsible for decreased clearance of proinflammatory mediators, such as C5 and IgG, from the sub-RPE tissues, resulting in an increased risk for CNV. This idea is very attractive, but other groups have had difficulty reproducing the results. Mouse studies

using the laser model of CNV have shown that IL-10 inhibits recruitment of macrophages into CNV lesions, but this leads to increased CNV size, suggesting that macrophages are antiangiogenic. Additional animal studies propose that senescence may cause a shift in the ocular microenvironment (including higher IL-10 levels) that makes it more proangiogenic; and that microenvironment, in turn, alters the polarization of macrophages toward an M2 phenotype which is unable to regulate angiogenesis. Thus, young macrophages appear to have an antiangiogenic role, while aging M2 macrophages change toward a proangiogenic phenotype. This could explain the different results obtained by different groups using the mouse laser model. Although it is still too early to determine if these conclusions apply to a noninjury model of CNV or to human AMD, the idea that "not all macrophages are made equal" and under different conditions may have opposing roles in AMD is very attractive.

Adaptive Immune System

The potential role of the innate arm of the immune system in AMD is further explored under the topic of genetics. The adaptive arm of the immune system is composed primarily of T cells and B cells. Although T and B cells have been identified in human AMD lesions, it is still not known whether they play causal roles in AMD versus being epiphenomena. Some investigators suggest that these T and B cells may be responding to subretinal neoantigens. Proteome analysis of the Bruch's membrane of AMD patients demonstrates higher levels of lipid–protein adducts derived from oxidative damage when compared to controls. These carboxyethyl pyrrole (CEP)–protein adducts are generated by the cross-linking of oxidized lipids and proteins. It has been proposed that the CEP–protein adducts may serve as neoantigens triggering an antigen-specific immune response in the subretinal/sub-RPE tissues that could promote the development of AMD. Moreover, immunization of mice with CEP-adducted mouse serum albumin led to an immune response and the formation of drusen and GA-like lesions in some animals.

Infectious Agents

Several mechanisms have been proposed by which infectious agents may promote the development of AMD. Molecular mimicry occurs when a microbial antigen resembles a self-antigen (in AMD it could be molecules on RPE cells or Bruch's membrane) so much that the immune system attacks the self-antigen while trying to eradicate the intended microbial antigen. By-stander injury refers to injury to self-tissues caused by the immune system as it tries to attack a microbial organism in close proximity. Finally, the infection can directly injure the host tissues. It is not clear if in AMD any of these mechanisms can be invoked.

In 2005, the Nobel prize in medicine was awarded for the work associating *Helicobacter pylori* with gastritis and peptic ulcer disease. Several epidemiological studies have found that *Chlamydia pneumoniae* (serology) may be associated to atherosclerosis, a disease that has several risk factors in common with AMD. Moreover, recent findings indicate that patients with AMD may be more likely to have higher anti-*C. pneumoniae* antibody levels than matched controls. There was also an association with pathology specimens of surgically excised choroidal neovascular membranes. Two other studies in Japan and Australia confirmed the serological association. Other studies could not reproduce these results, but instead found an association between high anti-CMV antibody levels and neovascular AMD. Critics comment that these are mere statistical associations and not proof of causality. Furthermore, they may be the result of unintentionally biased statistical analyses. Finally, the numbers included in the studies were often low. In the case of *Chlamydia* and atherosclerosis, clinical studies found that antibiotics did not alter the risk for vascular events. This could mean that *Chlamydia* is merely a commensal organism that thrives on atheromatous plaques without causing the disease; or it could mean that *Chlamydia* triggers the disease, but is not needed for disease progression. The same reasoning applies to AMD. One potential hypothesis is that *Chlamydia* or other organisms could cause a chronic low-grade infection at the deep retina/RPE/choriocapillaris level, and that in susceptible individuals (e.g., those with the at-risk variant of complement factor H) this could lead to chronic low-grade inflammation and the formation of drusen or CNV. It is difficult to prove this hypothesis due to the lack of good experimental models. However, we expect further research may shed light on this.

Genetics of AMD and Evidence for a Role of Inflammation in the Pathogenesis of AMD

Mutations may account for up to 70% of the population-attributable risk for AMD. Specific single nucleotide polymorphisms (SNPs) that increase the risk for AMD have been identified in several genetic loci. Two of these loci are particularly interesting since they have been reproduced by different research groups and in different populations. The first locus is in chromosome 1q32 (regulator of complement activation or RCA locus), which includes the gene for complement factor H. Several SNPs that appear to be statistically associated with the development of AMD have been identified within this locus. The most consistent association has been with a polymorphism that causes a substitution of a tyrosine for a histidine at amino acid position 402 in complement factor H (CFH Y402H).

However, several other polymorphisms, including CFH I62V and some intronic SNPs, have also been found to be associated to AMD by different groups. Within the same locus 1q32, a deletion affecting factor-H-related genes (CFHR1 and CFHR3) may decrease the risk of AMD, perhaps by decreasing the competition with factor H for the binding of C3.

The second locus of interest involves a region of chromosome 10q26 containing three genes PLEKHA, LOC387715/ARMS2, and HTRA1. The strongest associations in this locus have been with SNPs in the hypothetical gene LOC387715 and in the promoter region for HTRA1.

A third, and perhaps less common association, involves a locus in chromosome 6p21. Mutations affecting complement factors B and C2 in this region have been shown to alter the risk for AMD.

It is difficult to determine if there is a causal relationship between all these SNPs and AMD phenotypes. The best rationale for causality is for the Y402H mutation. Complement factor H (CFH or Cfh) is a key regulator of the alternative complement pathway. A point mutation that leads to a histidine, instead of a tyrosine at amino acid position 402 of CFH (Y402H), increases the risk of AMD by sevenfold in homozygotes. Moreover, this histidine variant of CFH appears to make AMD patients resistant to therapy with anti-VEGF agents. Despite the eagerness of the pharmaceutical industry to dive into this field, our knowledge of the mechanisms explaining this increase in risk for disease and decrease in susceptibility to therapy is in its infancy. One hypothesis is that normally CRP opsonizes subretinal debris and helps macrophages clear this debris in a noninflammatory fashion. For this to work, CFH has to bind CRP, preventing CRP from fully activating the complement cascade. The at-risk variant of CFH (402H) has a reduced affinity for CRP, which may lead to reduced binding of CFH to CRP in the subretinal debris. Thus, the full complement cascade would be activated by CRP, resulting in a vicious cycle of accumulation of debris and CRP, activation of complement, and tissue damage. In support, one study demonstrated that individuals homozygous for the at-risk variant of CFH have elevated levels of CRP in the choroid. Moreover, 402 YY patients receiving a liver transplant from 402 HH donors quickly developed drusen. Nevertheless, some investigators suggest that the Y402H mutation may not be pathogenic; that it may simply be in linkage disequilibrium with a yet-unidentified pathogenic mutation. It is essential to determine if Y402H has causal relevance in AMD.

It is more difficult to explain causality for the 10q26 SNPs: LOC387715 is still considered a hypothetical gene since the protein it codes for has not been unequivocally identified. HTRA1 is a serine protease and it has been proposed that it may be involved in the facilitation of penetration of Bruch's membrane by neovascular fronds. Unfortunately, many of the identified SNPs are in regions of high linkage disequilibrium. In other words, it may be that the identified SNPs are not directly responsible for the disease, or that they are simply strongly associated with other mutations which are the direct culprits for the pathological events leading to AMD.

A large group of investigators from several institutions have recently published a single report showing an association between a mutation in the gene for toll-like receptor 3 (TLR3) and the development of GA using three separate case-control series. SNP rs3775291 in TLR3 seemed to offer mild-to-moderate protection against GA. It has no effect on drusen or CNV formation. Toll-like receptors are a class of membrane-spanning receptors that recognize structurally conserved molecules derived from microbes and play a critical role in innate immunity. TLR3, in particular, is expressed on dendritic cells and B lymphocytes and recognizes double-stranded RNA (dsRNA, usually from viruses). The hypothesis is that dsRNA from infecting viruses may trigger apoptosis of RPE cells through activation of TLR3. The SNP in question causes a reduction in TLR3-mediated cell death. If this hypothesis is correct, it not only implies a role for infectious agents in inducing AMD, but also raises concern for RPE damage with the new small interfering RNA (siRNA) investigational drugs (which are also small double-stranded RNA molecules). However, an earlier study was not able to find any association between the same SNP in TLR3 and AMD.

Mouse Models of AMD

Several groups have recently demonstrated that, despite the obvious anatomical differences with humans (lack of a macula), mice can develop drusen and CNV similar to those seen in clinical AMD. Some of the most interesting models will be discussed here.

One study examined mice deficient in either chemokine ligand 2 (CCL2) or chemokine receptor 2 (CCR2). The findings were discussed earlier. Investigators at the National Eye Institute have generated mice that are deficient in both chemokine receptors CCL2 and CX3CR1. These mice develop drusen-like and pigmentary changes by 6 weeks of age, and 15% of them develop CNV as early as 12 weeks of age. It should be noted that, at least in CX3CR1-deficient mice (not deficient in CCL2), another group in France has shown that the drusen-like lesions seen clinically are histopathologically different from drusen seen in AMD and consist of lipid-bloated subretinal microglial cells rather than subretinal pigment epithelium deposits. Both CCL2 and CX3CR1 are involved in the recruitment of microglia and monocytes into tissues. Monocytes can then further differentiate into macrophages and dendritic cells. Somewhat counter-intuitively, the CCL2/CX3CR1-deficient mice have increased numbers of macrophages and microglia in the subretinal space and retinal lesions. Some investigators suggest that an alternative pathway for monocyte recruitment involving the upregulation of CCL5 is

responsible for this finding. They also suggest that CX3CR1-deficient microglia may behave abnormally and produce local tissue injury. Furthermore, these mice have increased complement activation and retinal autoantibodies in their retinas. It is still not clear the mechanism by which these mice develop the AMD-like changes and if these mechanisms are relevant to human AMD. An association between two mutations in CX3CR1 and AMD has been reported. However, these mutations have not been identified in genome-wide scans and other studies. Further studies will be required to determine if mutations in CX3CR1 and/or CCL2 are truly involved in the pathogenesis of human AMD. In the meantime, it is clear from these studies that the migration and function of macrophages, microglia, and dendritic cells may lead to features similar to those seen in AMD and may, under certain circumstances or in certain subgroups of patients, have pathophysiologic relevance.

The effect of apolipoprotein (ApoE) variants on AMD pathogenesis has been examined in mice. It was shown that the eyes of aged, targeted replacement mice expressing human apoE4 and maintained on a high-fat and cholesterol diet develop diffuse sub-RPE deposits, drusenoid deposits, thickened Bruch's membrane, and RPE pigmentary abnormalities. Close to 20% of the mice also developed CNV. Multiple genetic studies have given mixed results regarding the clinical relevance of ApoE variants and/or mutations.

Studies in superoxide dismutase 1 (SOD1)-deficient mice show that they develop drusen and CNV at an old age. This suggests that the increased oxidative stress in the retina leads to tissue injury and accumulation of debris. It should be noted that more recent work suggests that the yellow deposits seen clinically in these animals may not be drusen, but collections of lipid-laden macrophages. Moreover, there is no genetic evidence for an association between SOD1 and AMD.

Summary

The pathogenesis of AMD is complex and clearly involves genetic and environmental risk factors. At least three genes have been identified to be strongly correlated to the disease. However, it is likely that many others have an impact in the disease for some subpopulations of patients. A very simplified diagram on the pathogenesis of AMD is included in Figure 1. Note that the potential roles of neither the 10q26 locus and the TLR3 mutation nor the antibodies and T cells have been included.

Based on the genetic, histopathologic, serologic, and animal model data, it is clear that the immune system has a significant role in the development of AMD. However, we are still far from determining the exact mechanisms by which it affects the clinical course of the disease. In fact,

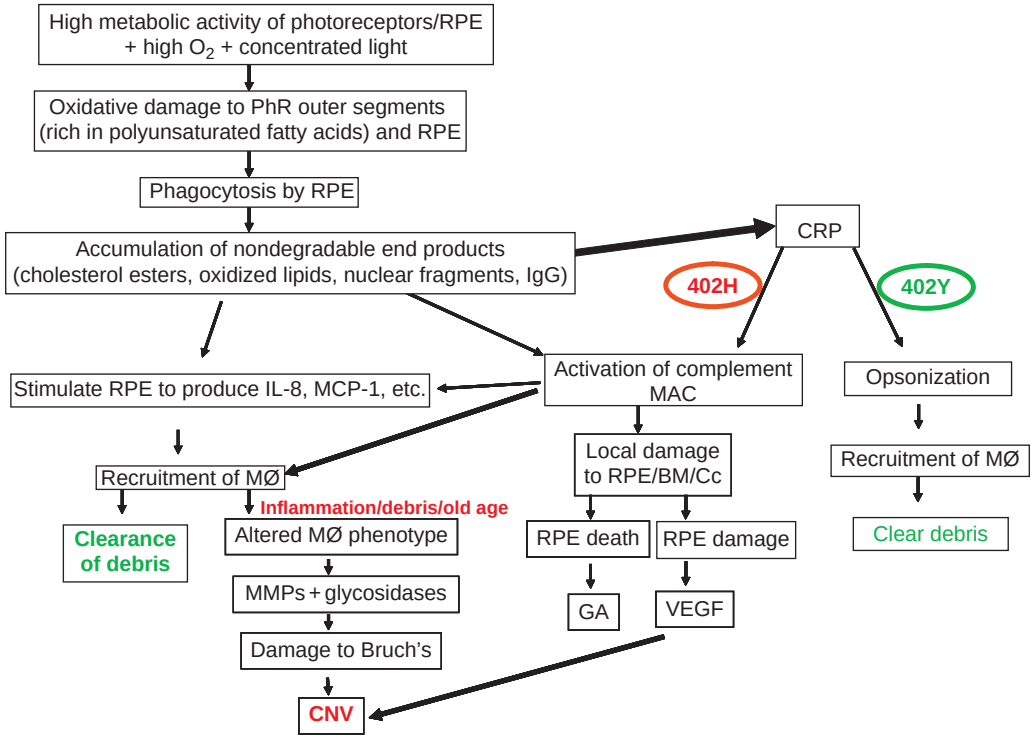

Figure 1 Proposed simplified pathogenesis of AMD. BM, Bruch's membrane; Cc, choriocapillaris; CNV, choroidal neovascularization; CRP, c-reactive protein; GA, geographic atrophy; IgG, immunoglobulin G; IL-8, interleukin 8; MAC, membrane attack complex; MCP-1, monocyte chemoattractant protein 1; MMPs, matrix metalloproteinases; MØ, macrophage; O_2, oxygen; PhR, photoreceptor; RPE, retinal pigment epithelium; VEGF, vascular endothelial growth factor; 402H, histidine-402 variant of complement factor H; 402Y, tyrosine-402 variant of complement factor H.

although the strongest incriminating data available point to the complement system and macrophages, it is not clear if the adaptive immune system (T cells, B cells, and antibodies) is also important.

The pharmaceutical industry, at present, has a great impetus to develop new therapeutic agents for AMD based on controlling inflammation. Several agents that block complement components 3 or 5 or factor B are in preclinical or early clinical trials. Furthermore, the effect of anti-inflammatory agents, in combination with anti-VEGF agents, is being studied. Yet, given our limited knowledge, the approach is far from ideal. Better animal models of AMD (based on genetic and environmental risk factors known to be important in AMD) would help us improve our understanding of the early steps in the pathogenesis of the disease, and perhaps allow us to identify new therapeutic targets and test new drugs.

Glossary

Adaptive immune responses – Immune responses that require priming, participation of T lymphocytes, and are characterized by antigen specificity and memory.
Antigen-presenting cells (APCs) – These cells may either stimulate or inhibit T-cell-mediated immune responses.
Complement regulatory proteins (CRPs) – Cell membrane-bound and secreted molecules that disable the complement cascade and thereby inhibit the efficacy of complement-fixing anti-tumor antibodies.
Human leukocyte antigen (HLA) – Necessary for target cell recognition by (NK) and T cells.
Innate immune response – Immune responses that are T-lymphocyte-independent, lack antigen specificity, and do not express memory. Innate immune elements include granulocytes, macrophages, NK cells (see below), and the complement system. Innate immune elements are the first responders and do not require priming to produce their effects.
Melanoma antigen-encoding gene (MAGE) – Proteins encoded by MAGE are expressed on skin and uveal melanomas and are potential immunogens for eliciting anti-tumor immunity.
Natural killer (NK) cells – Lymphocytes that spontaneously kill tumor cells that do not express human leukocyte antigen (HLA) class I molecules.
Uvea – Ocular tissue composed of the iris, ciliary body, and choroid.
Uveal melanoma – Most common intraocular tumor in adults; originates from neural crest precursors.

Introduction

Different types of tumors may arise in the eye, but the most common primary malignant ocular tumors are retinoblastoma in children and uveal melanoma in adults. While there are many treatments for the intraocular tumors, metastases are more difficult to manage. Cutaneous melanoma has been a target for many types of immunotherapy, and as cutaneous and uveal melanoma share many characteristics, one might expect a similar situation with regard to uveal melanoma. However, with sporadic exceptions, immunotherapy for uveal melanoma metastases has as yet not been successful. Uveal melanoma seems to be able to escape immune responses irrespective of the manner in which the immune system is triggered. While immunotherapy of metastases does not seem to be effective, there are many indications that the innate immune system influences the tumor's behavior. Macrophages are associated with increased malignancy by their mechanism of influencing the development of blood vessels in the tumor. Natural killer (NK) cells may play a role during the migration of metastatic cells through the blood and their residence in the liver. As many uveal melanoma patients die from liver metastases, it is clear that the immune system is not effectively recognizing and eliminating disseminated uveal melanoma cells. Some of the most important mechanisms involved in immune surveillance and the tumor's response against them will be discussed in this article.

Survival

Uveal melanoma is the most frequent intraocular tumor in adults. Death from this tumor usually results from the development of liver metastases. Indeed, approximately 90% of uveal melanoma patients have liver metastases at the time of death. An important characteristic of uveal melanoma is the time between recognition of the primary tumor and the first sign of metastases. Metastases are rarely found when the intraocular tumor is first diagnosed, but up to one-third of patients may develop clinically recognizable metastases during the 3 years thereafter (**Figure 1**). Although there are many effective therapies for managing primary uveal melanomas, there are no therapeutic modalities that have been proven to be effective in the treatment of liver metastases. Indeed, the 5-year survival rate for uveal melanoma patients has not improved in the past 30 years. Potential new approaches include transfer of uveal melanoma-specific T cells and induction of strong T-cell responses by using newly developed vaccines. Uveal melanomas are antigenic, and, in theory, they should be accessible to anti-tumor immune responses. However, the tumors originally reside in the eye, which provides an immunologically privileged environment that inhibits both the induction and expression of many forms of immunity. Both the innate and adaptive

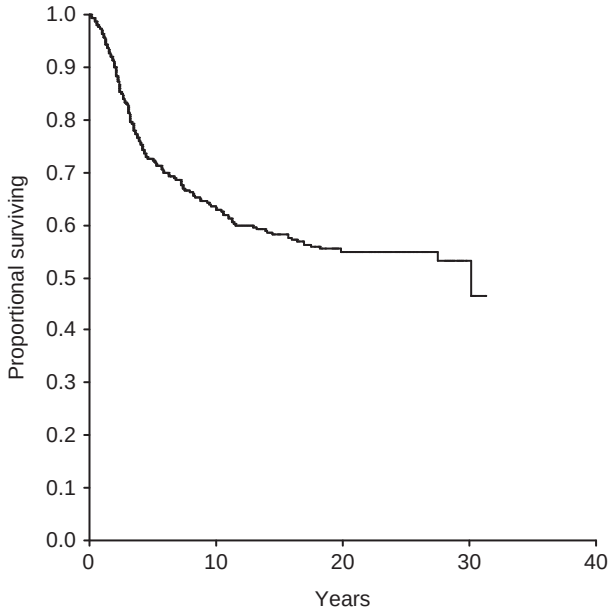

Figure 1 Long-term survival of patients who underwent enucleation for a uveal melanoma.

immune responses are impaired within the eye. Moreover, mounting evidence suggests that uveal melanoma cells have adopted many of the strategies that the eye utilizes to promote immune privilege and disarm destructive immune responses.

Anti-Tumor Immune Responses

T-Cell Immunity

The immune system may function in different locations: in the primary intraocular tumor, during the transportation of tumor cells through the blood, and at the site of the metastases.

With regard to the intraocular tumor, several studies have reported the presence of CD4+ and CD8+ T cells in the tumor, although the degree of T-cell infiltration varies among tumors. At least one out of five uveal melanomas contains significant numbers of infiltrating lymphocytes, which can be analyzed for their cell-surface characteristics. Most infiltrating cells are T cells, with many more CD8+ suppressor/cytotoxic T cells than CD4+ helper T cells. Infiltrating T cells often express human leukocyte antigen DR-1 (HLA-DR), while T helper cells often express receptors for cytokines such as interleukin (IL)-2R, most of the T suppressor/cytotoxic cells do not. This would limit the capacity to stimulate the expansion of cytotoxic T lymphocytes (CTLs) with IL-2. In addition, many tumors contain macrophages. However, there is a paucity of NK cells in primary uveal melanomas. Interestingly, there is evidence that the presence of tumor-infiltrating lymphocytes is associated with a poor prognosis in uveal melanoma, which is the opposite of what has been reported with cutaneous melanoma. It is clear, however, that the presence of tumor-infiltrating macrophages is associated with a poor prognosis both in uveal and cutaneous melanomas.

Antigen Expression

The expression of anti-tumor immunity is affected by the expression of two molecules on the tumor cell membrane: HLA class I molecules and melanoma-specific antigens. HLA class I molecules act as docking stations for the CTLs and also provide the grooves into which tumor-specific peptides are presented for cognate recognition by CTLs. HLA class II molecules can also function as restricting elements that present tumor antigens to CD4+ T cells, which exert their anti-tumor activity by elaborating cytokines such as tumor-necrosis factor alpha (TNF-α), which is toxic to the tumor cells, and other cytokines such as interferon-γ (IFN-γ), which activates elements of the innate immune system (e.g., macrophages and NK cells). Several studies on tumor-containing eyes have analyzed the presence of target molecules on uveal melanoma cells. Immunohistochemical approaches with monoclonal antibodies directed against cutaneous melanoma-associated antigens demonstrated the expression of many immunological epitopes on uveal melanoma cells. Potential T-cell targets that are expressed on uveal melanoma cells include the melanoma-associated antigens S-100 (a protein found in brain cells that cross-reacts with melanoma and melanocytes), HMB45 (which is specific for the melanosomal gp100 protein), tyrosinase, tyrosinase-related protein (Tyrp1), and Melan-A/Mart 1. In addition, MC1R, the receptor for α-melanocyte-stimulating hormone, is present on almost all primary uveal melanomas and all metastases tested so far. Uveal melanoma also expresses melanoma-specific antigens from the melanoma antigen-encoding gene (MAGE) family. These findings indicate that specific T cells should be able to lyse uveal melanoma cells, assuming that the melanoma cells co-express the proper HLA antigens.

Effect of HLA Expression on the Progression of Uveal Melanomas

Different studies have demonstrated that uveal melanoma can express HLA class I and II molecules, but often at low expression levels. In general, HLA expression as detected by monoclonal antibodies is usually high on primary tumors and cell lines, and can be further upregulated by exposure to IFN-γ. In cell lines derived from uveal melanoma, loss of one or both B alleles has been observed; loss of one HLA-A or one HLA-B gene leads to homozygosity for the HLA area on chromosome 6.

HLA-A2 and-A3 are usually highly expressed on histological sections of primary tumors, while the HLA-Bw4 and Bw6 antigens are only weakly expressed. These observations indicate that selective loss or downregulation of HLA class I expression may occur and this may provide a selective advantage to the tumor for avoiding immune-mediated destruction by CTLs. Interestingly, HLA class I antigens are highly expressed on liver metastases, which may be an effective mechanism for evading NK-cell-mediated surveillance in the liver, which contains one of the highest concentrations of NK cells of any organ in the body (see below).

NK Cells

In vitro studies using a battery of human uveal melanoma cell lines have demonstrated that uveal melanomas are vulnerable to NK cell-mediated cytolysis. Studies in mice have shown that metastasis of ocular melanoma cells is inhibited by NK cells, as disruption of NK-cell function in mice produces a sharp increase in the formation of liver metastases. The susceptibility of tumor cells to NK-cell-mediated cytolysis is influenced by the expression of major histocompatibility complex (MHC; HLA in humans and H-2 in mice) class I molecules on the surface of the tumor cells. As discussed earlier, MHC class I molecules serve as docking stations for CTLs and are absolutely necessary for CTL-mediated cytolysis of target cells. However, many tumors downregulate MHC class I molecules to escape cytolysis by tumor-specific CTLs. By contrast, the absence of MHC class I molecules provokes cytolysis by NK cells, which are programmed to kill any cell lacking MHC class I molecules. Thus, the absence of MHC class I molecules would seem to render uveal melanomas vulnerable to NK-cell-mediated destruction. However, the fluids in the eye contain macrophage-migration-inhibitory factor (MIF) and transforming growth factor-β (TGF-β) which profoundly suppress NK-cell-mediated cytolysis. Uveal melanomas most frequently metastasize to the liver, which contains one of the highest concentrations of NK cells of any organ in the body. Thus, uveal melanoma metastases would seemingly be vulnerable to NK-cell-mediated clearance in the liver. However, there is evidence that uveal melanoma cells undergo a selection process that favors the emergence of NK-resistant subpopulations in the liver. Melanoma cells isolated from a primary uveal melanoma and liver metastases in the same patient have revealed that the expression of MHC class I molecules was 10-fold higher in liver metastases compared to the primary tumor. The elevated expression of MHC class I dramatically reduces the vulnerability of the melanoma metastases to NK-cell-mediated clearance in the liver.

That NK cells may play a role during the metastatic spreading itself is supported by retrospective studies on archival specimens from human uveal melanoma patients; tumor sections were examined for the expression of the HLA-A and-B loci using monoclonal antibody HCA2 for HLA-A and HC10 for HLA-B. Of the 30 tumors, only 12 expressed HLA-A and seven HLA-B on more than 25% of their cells. A high expression of HLA-B was associated with the presence of epithelioid cells, which is a bad prognostic sign. Indeed, high HLA class I expression on the primary intraocular tumor was associated with significantly poorer survival. By contrast, uveal melanomas with low HLA class I expression – which are considered good NK-cell targets – were associated with excellent survival. Thus, primary uveal melanomas contain subpopulations of cells that express low amounts of MHC class I and are vulnerable to NK-cell-mediated cytolysis. However, NK cells would not have been able to attack the primary tumor, as soluble factors in the aqueous humor – such as MIF and TGF-β – block NK activity within the eye.

Immune Escape Mechanisms

A similar condition might apply to elements of the adaptive immune system such as CTL. As discussed earlier, many uveal melanomas express melanoma-associated antigens and tumor-specific antigens along with the relevant MHC class I molecules that present these antigens to CTLs; despite this, tumor-infiltrating T cells isolated from these eyes fail to express significant cytolysis of the tumor cells when examined *in vitro*. A variety of factors present in the aqueous humor are known to inhibit T-cell activity. Thus, the function of tumor-infiltrating CTLs might be suppressed in the ocular tumor in the same manner that occurs with tumor-infiltraing NK cells.

As stated above, many uveal melanoma cells express tumor-specific antigens and appropriate MHC class I molecules that should render them vulnerable to immune elimination by CTLs. Likewise, a significant number of uveal melanoma cells are susceptible to NK-cell-mediated cytolysis *in vitro*, yet uveal melanoma metastases that have escaped from the eye will thrive in the liver – which expresses the highest concentration of NK cells of any organ in the body. These two observations suggest that uveal melanoma cells have the capacity to escape immune surveillance by both the adaptive and innate immune systems. A growing body of evidence suggests that uveal melanomas escape immunological attack by adopting some of the same strategies that support immune privilege in the eye.

Indoleamine 2,3 Dioxygenase

T cells require tryptophan for clonal expansion and proliferation, and in the absence of tryptophan, T cells perish. The enzyme indoleamine 2,3-dioxygenase (IDO) catabolizes the degradation of tryptophan, and accordingly, upregulation

of IDO results in rapid depletion of this necessary amino acid. Although tryptophan is not vital for NK-cell survival, IDO inhibits the cytolytic activity of NK cells. Thus, IDO impairs the expression of both the adaptive and innate immune responses. IDO can be upregulated by proinflammatory signals such as IFN-γ. IDO is produced in the eye and is believed to contribute to the immune privilege in the anterior chamber. Uveal melanoma cells do not constitutively produce IDO; however, when exposed to the T-cell cytokine IFN-γ, uveal melanoma cells produce significant quantities of IDO. Thus, uveal melanomas have the capacity to produce an immune privileged environment once they perceive the presence of an immune response (i.e., T-cell- and NK-cell-derived IFN-γ). Whether this is an effective strategy utilized by uveal melanomas to evade T-cell immunity remains to be determined, but is an intriguing possibility.

Programmed Death-1 Ligand

The cells lining the interior of the eye are decorated with a variety of cell membrane-bound molecules that protect the eye from inflammation by inducing apoptosis of infiltrating T cells. Among these cell membrane molecules is programmed death-1 ligand (PD-L1), which is a transmembrane glycoprotein belonging to the B7 family. Its receptor, programmed death-1 (PD-1) is expressed on thymocytes, mature T cells, and myeloid cells, and interaction of PD-L1 with its receptor leads to downregulation of T-cell proliferation and apoptosis. PD-L1/PD-1 interactions are important in regulating T-cell-mediated immune responses and for preserving immune privilege in the eye. Corneal allografts express PD-L1, which is crucial for their survival, as blocking PD-L1/PD-1 interactions culminates in a steep increase in the incidence and tempo of corneal allograft rejection. PD-L1 is also expressed on human uveal melanoma cells and may serve a similar role in the evasion of T-cell attack. Similar to IDO, PD-L1 expression is upregulated by the T-cell and NK-cell cytokine IFN-γ. The induced expression of PD-L1 is believed to contribute to the uveal melanoma cell's capacity to elude attack by T cells and NK cells. When activated T cells are exposed to PD-L1-expressing uveal melanoma cells, they downregulate their production of IFN-γ and TNF-α – two potent cytokines involved in the immune surveillance of many tumors. Thus, T-cell- and NK-cell-derived factors (e.g., IFN-γ) appear to alert uveal melanomas of the presence of activated T cells and NK cells and prompt intraocular tumors to upregulate the expression of immunoevasive molecules such as PD-L1 and IDO.

Complement Regulatory Proteins

The complement system is a complex array of serum proteins with enzyme-like activity, which are activated in a cascade-like fashion resulting in the generation of a membrane-attack complex that perforates bacterial and mammalian cell walls and induces osmotic lysis. Activation of complement also generates a variety of chemoattractants that induce the migration and activation of granulocytes. The complement cascade can be activated by the classical pathway when antibodies bind to their cognate antigens on the surface of bacterial or mammalian cells. Complement can also be activated by bacterial products in the absence of antibodies, which is referred to as the alternative pathway. Since the complement cascade can be activated by specific antibodies or by bacteria, it straddles the adaptive and innate immune systems. The complement membrane-attack complex is an effective mechanism for destroying bacteria and mammalian cells, including some tumor cells. However, complement activation stimulates robust granulocytic inflammation, which could inflict injury to ocular tissues. The eye is protected against the unwitting activation of the complement cascade through its expression of complement regulatory proteins (CRPs), which act as buffers to dampen the deleterious effects of complement activation. CRPs can occur as soluble molecules within the aqueous humor or as cell membrane molecules on the surface of intraocular cells. CRPs restrain the untoward effects of complement and protect the eye from immune-mediated injury. Studies in rats have shown that animals with deleted CRP genes suffer severe spontaneous complement-dependent ocular inflammation. Uveal melanomas express CRPs and have been found to be highly resistant to complement-mediated cytolysis initiated by complement-fixing antibodies. Thus, uveal melanomas have adopted yet one more of the strategies employed by the eye to foster immune privilege and have used it to evade immune destruction.

Resistance to Perforin-Mediated Cytolysis

As mentioned previously, treatment with IFN-γ stimulates expression of HLA class I on uveal melanoma cells. The effect has been determined in several uveal melanoma cell lines, and in all cases, expression of HLA class I was sensitive to upregulation by incubation with IFN-γ. As CTLs lyse tumor cells following recognition of the specific peptide presented by an HLA class I molecule, one might expect that tumor cells would undergo extensive cytolysis after incubation with IFN-γ. However, this does not occur. Uveal melanoma cells exposed to IFN-γ resist CTL-mediated lysis. This protection develops when uveal melanoma cells are incubated with either IFN-γ or TNF-α, both of which upregulate HLA class I expression. CTLs utilize a variety of molecules to kill their target cells. These include Fas ligand (FasL), TNF-related apoptosis-inducing ligand (TRAIL), cytokines such as TNF-α, and the direct deposition of cytolytic granules (i.e., perforin) onto the cell membrane of the target cells. Although uveal

melanoma cells are sensitive to perforin-mediated cytolysis, they become resistant following exposure to IFN-γ. This represents one more example of how uveal melanomas seem to perceive the presence of a potentially injurious immune response and respond by elaborating molecules that disable immune effector mechanisms.

Overcoming the Immune Privilege of Uveal Melanomas

Although uveal melanomas reside within an immunologically privileged site and incorporate a variety of novel mechanisms to create their own independent form of immune privilege, there are promising immunotherapeutic strategies on the horizon. A particularly interesting new approach is to create designer tumor vaccines using engineered HLA class II-matched uveal melanoma cells selected from a bank of uveal melanoma cell lines that express different HLA class II haplotypes, which can be matched with the prospective patient. These HLA class II-matched uveal melanoma vaccines can be engineered to express co-stimulatory molecules so that they act as surrogate APCs to stimulate melanoma-specific, MHC class II-dependent, CD4+ T-cell-mediated immune responses. As HLA class II alleles are not as polymorphic as the MHC class I alleles, a relatively small set of cell lines with the most common HLA class II antigens would be sufficient for use in tailoring vaccines for individual patients. These vaccines can be applied early after identifying patients with a high risk of metastases. The designer vaccine approach, although risky, is worth pursuing considering the conspicuous absence of any proven therapeutic modality for treating uveal melanoma metastases and the stagnation in the 5-year survival rate for uveal melanoma patients.

Conclusion

Although uveal melanomas express many of the relevant target and accessory molecules needed to provoke and succumb to an effective immune response, they also possess an array of molecules that allow them to evade immune effector elements. Many of these molecules are the same ones that endow the eye with immune privilege. These molecules not only protect the primary intraocular tumor from immune attack, but also shield uveal melanoma metastases from the immune effector mechanisms that greet them when they enter the liver. The goal for the tumor immunologist is to gain a better understanding of immune privilege of the eye and its tumors and, in so doing, design immunotherapeutic strategies that abrogate immune privilege and unleash the full potential of the immune system to rid both the eye and the liver of uveal melanoma cells.

Published by Elsevier Ltd.

Glossary

Antibodies (Abs) – Also called immunoglobulins, these protein molecules are produced by differentiated B cells (i.e., plasma cells) and are secreted into the serum. Antibodies bind to antigens and can either neutralize pathogens or activate the complement cascade. The latter process generates membrane-attack complexes that pierce the cell walls and membranes of bacteria leading to bacterial cell death.

Antigens (Ags) – High-molecular-weight proteins that are recognized by the adaptive immune system as foreign and as a result, antigens induce immune responses that culminate in protective immunity or in some cases, autoimmune diseases.

Autoimmune regulator (AIRE) – A gene that causes the expression of a wide selection of organ-specific proteins in the thymus. The expression of organ-specific antigens in the thymus reduces the risk of the unwitting generation of autoimmunity by promoting the deletion of autoreactive T cells by the process of negative selection.

Antigen-presenting cells (APCs) – Dendritic cells, macrophages, and B cells that process antigens and present them to T lymphocytes. This is the first step in the generation of an adaptive immune response.

Complete Freund's adjuvant (CFA) – A mixture of mineral oil, alum, and killed *Mycobacterium*. Antigens mixed with CFA elicit potent adaptive immune responses.

Experimental autoimmune anterior uveitis (EAAU) – An animal model of uveitis of the anterior segment of the eye. Melanin-associated antigens mixed with CFA induce uveitis of the anterior segment in rodents.

Experimental autoimmune uveitis (EAU) – An animal model of posterior segment uveitis is elicited when rodents are immunized with interphotoreceptor-binding peptide (IRBP) or retinal S-antigen (S-Ag) emulsified in CFA. The inflammation is usually progressive and destroys the retina. This model most closely resembles sympathetic ophthalmia.

Experimental melanin-induced uveitis (EMIU) – A model of uveitis that closely resembles EAAU.

Hemagglutinin (HA) – A transgene of this influenza virus antigen, has been expressed in the retinas of experimental mice as a means of developing a novel model of uveitis.

Hen egg lysozyme (HEL) – The transgene of HEL has been expressed in the retinas of experimental mice as a means of developing a novel model of uveitis.

Human lymphocyte antigens (HLAs) – Also called major histocompatibility complex antigens, these class I HLA antigens are expressed on virtually all nucleated cells in the body and are used as platforms to present endogenous antigens to the immune system.

Pertussis toxin (PTX) – This is used to breach the blood–retina barrier and thereby facilitate the full expression of EAU and other autoimmune diseases in rodents.

T cell receptor (TCR) – The heterodimer molecule that is expressed on the surface of T cells and displays exquisite specificity in recognizing a specific antigen. Each TCR binds to a very limited range of antigens. Antigens binding to the TCR in the presence of co-stimulatory molecules expressed on APC activate a signaling cascade that leads to activation and clonal expansion of specific T-cell populations.

Transgenic (Tg) – Introducing a specific gene into a cell or an animal's genome is a means of studying the gene's specific function or the effect of overexpression of a specific gene.

Uveitis: The Disease and Its Experimental Models

The eye is an immunologically privileged organ, which translates to an ability to protect itself from day-to-day inflammatory insults using a variety of passive and active mechanisms. Of the rather short list of organs considered immunologically privileged (eye, brain, ovary, testis, the pregnant uterus and – of all things – the hamster cheek pouch), the eye is arguably the most privileged. Although immune privilege undoubtedly serves to protect the visual axis from damage resulting from overzealous immune responses to random environmental stimuli, the eye is subject to autoimmune uveitis. Autoimmune uveitis,

which has no known infectious etiology, can accompany one of a number of systemic diseases affecting a range of organs, or can be a stand-alone disease in which the eye is the only target. Ankylosing spondylitis, Behçet's disease, systemic sarcoidosis (SS), and Vogt–Koyanagi–Harada disease (VKH) are examples of the former, whereas Fuchs heterochromic cyclitis, birdshot retinochoroidopathy (BR), and sympathetic ophthalmia (SO) are examples of the latter. Autoimmune uveitis can be either anterior (Fuchs heterochromic cyclitis or uveitis accompanying ankylosing spondylitis), or mainly posterior, as in Behçet's disease, VKH, SS, BR, and SO. Due to the ocular anatomy, it is the posterior uveitides that are particularly likely to affect the photoreceptor cells and damage vision. Uveitic diseases of an autoimmune nature have been estimated to cause about 10% of severe visual handicap in the US.

Uveitis patients often exhibit lymphocyte and antibody responses to antigens present in the eye, supporting the autoimmune nature of the disease. Although it is unclear whether these responses are the cause or represent an epiphenomenon resulting from autoimmunization to tissue-breakdown products, they are believed to fuel progression of the disease. The etiologic causes of uveitis are unclear, with the exception of SO, which is precipitated by ocular trauma to one eye that is followed by inflammation in the nontraumatized, or sympathizing, eye. It is thought that antigens (Ags) released from the traumatized eye find their way into the draining lymph node and elicit systemic immunity. An accompanying infection may provide an adjuvant effect. In uveitic disease that cannot be linked to a trauma, it is believed that lymphocytes capable of recognizing retinal Ags are primed in the periphery by a cross-reactive microbial stimulus. Animal models of uveitis based on immunization of laboratory animals with retinal Ags in complete Freund's adjuvant (CFA) seek to duplicate this condition.

The objective limitations and ethical issues inherent in human studies have made animal models of uveitis an invaluable tool for dissecting the basic mechanisms in pathogenesis of the disease. As no animal model can reproduce the full complexity of the human disease, it is necessary to develop and use a variety of models to represent different aspects and diverse clinical/immunological manifestations of uveitis. The longest used and by far the best-explored model is experimental autoimmune uveitis (EAU), which is induced by active immunization with one of a number of retinal Ags in complete Freund's adjuvant. Although EAU can be elicited in a variety of species and with a variety of antigens, the model in rats induced with retinal arrestin (retinal soluble Ag, S-Ag) and the model in mice induced with the interphotoreceptor retinoid-binding protein (IRBP) have gained the widest acceptance. Quantitative histological scores can be assigned with a fair degree of precision based on fundus examination or histopathological appearance (**Figure 1**). The mouse model in particular has been extremely useful

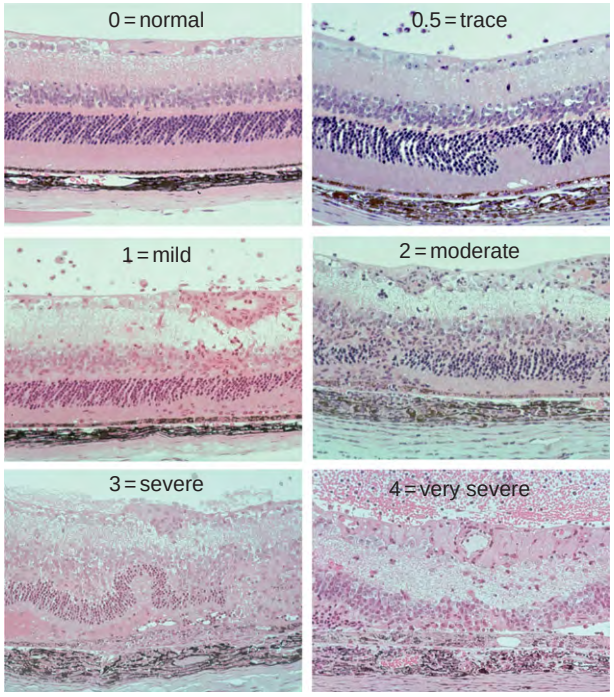

Figure 1 EAU histopathology of eyes collected from B10.RIII mice 21 days after uveitogenic immunization with IRBP, representing a range of disease scores. Eyes were processed and embedded in methacrylate. Sections 4–6 μm in thickness were stained with hematoxylin and eosin and photographed at ×400 magnification. Reprinted from Cortes, L.M., Mattapallil, M.J., Phyllis B. Silver, P.B. (2008). Repertoire analysis and new pathogenic epitopes of IRBP in C57BL/6 (H-2^b) and B10.RIII (H-2^r) mice. *Investigative Ophthalmology and Visual Science* 49: 1946–1956. Note: Clinical scoring by fundus appearance is depicted and described in the reference cited as Xu et al. (2008).

for dissecting basic cellular and molecular mechanisms of the disease. Over the years, the mouse model has seen a proliferation of variants on the EAU theme as to mode of induction and antigenic target, which have allowed investigators to address specific questions (**Table 1**).

Particular models and their attributes are mentioned further on, in conjunction with the immunopathogenic mechanisms to which they pertain, but it is of interest to mention here a model of EAU that develops in HLA class II transgenic (Tg) mice, in which the mouse MHC class II molecules have been replaced with the human counterparts. HLA-DR3 (DRB1*0301), –DR4 (DRB1*0401), –DQ6 (DQB1*0601), or –DQ8 (DQB1*0302). Tg mice present and respond to antigenic epitopes that would be recognized by humans bearing these class II molecules. Unlike the wild-type (WT) parental mice that are resistant to S-Ag induced EAU, the HLA Tg mice develop disease when immunized with S-Ag. Importantly, HLA DR3 mice responded immunologically and developed EAU when immunized with defined S-Ag peptides, among them peptide N (residues LPLLANNRERRGIALDGKIKHE) that is known to elicit lymphocyte responses in uveitis

Table 1 Models of autoimmune uveitis

#	*Type of model*	*Examples of models*	*Comments*
1	Active immunization with an ocular antigen emulsified in complete Freund's adjuvant (CFA)	Experimental autoimmune uveitis (EAU) induced in B10.RIII or C57BL/6 mice with IRBP, or in HLA-Tg mice with S–Ag. Anterior uveitis induced by immunization of rats with melanin components (EAAU; EMIU – see glossary). Other Ags, or their peptide fragments, can be used	Mycobacteria in CFA provide innate danger signals that polarize autoimmune lymphocytes toward the Th1 and Th17 lineages. Pertussis toxin (PTX) as additional adjuvant is needed in less susceptible strains
2	Infusion of Ag-pulsed mature dendritic cells	EAU variant induced in B10.RIII mice by injection of splenic DC elicited with Flt3L, matured *in vitro* and pulsed with IRBP (pp. 161–180)	Requires 2 injections of DC and pertussis toxin. Less severe than #1 and appears mostly dependent on Th1 cells
3	Mice transgenic for a TCR that recognizes a retinal Ag	Spontaneous EAU-like uveitis in IRBP TCR Tg mice	High frequency of TCR Tg cells
4	Tg mice expressing a neo-Ag in the retina bred to mice expressing, or adoptively transferred with, T cells bearing the specific TCR. Conceptually meant to mimic #3.	Uveitis in mice transgenic for hen egg lysozyme (HEL) or betagalactosidase (β-gal) on a retinaspecific promoter. A variant is *in vivo* retrovirally induced expression of influenza hemagglutinin (HA) in the retina and adoptive transfer of activated T cells specific for HA	May be spontaneous in some double-Tg mice. This may at least in part depend on the frequency and affinity of the transgenic TCR
5	Disrupted negative selection of T cells in the thymus	Spontaneous uveitis in AIRE$^{-/-}$ mice directed at IRBP, spontaneous uveitis in nude mice implanted with embryonic rat thymus	Higher frequency and higher affinity of cells bearing TCRs to IRBP

patients. HLA Tg mice may thus help to define the antigenic regions involved in human disease, and thus may be important for devising antigen-specific therapies for human uveitis.

Central Tolerance: Retina-Specific Antigens and the Thymus

As is discussed later, susceptibility to uveitis is affected by the frequency of pathogenic T cells on the one hand, and natural regulatory T cells on the other hand. Both are controlled by the thymic selection process, which leads to establishment of central tolerance. Many tissue-specific antigens, including retinal Ags such as S-Ag, IRBP, and S100, are expressed ectopically in the thymus under control of the transcription factor, autoimmune regulator (AIRE). Other Ags are imported from outside the thymus and presented on bone-marrow-derived Ag-presenting cells. These self-Ags actively select the developing T-cell repertoire by eliminating or anergizing (i.e., rendering unresponsive) T cells with high affinity to self-antigens that could mediate autoimmunity and sparing T cells with low affinity to self, which will mediate host defense. The level of thymic expression of the retina-specific Ags S-Ag and IRBP was shown to be inversely correlated with susceptibility of the particular strain of mice or rats to uveitis induced with these Ags, suggesting that a quantitatively higher expression of these molecules more efficiently deletes autoreactive cells. Qualitative and quantitative changes in the autoreactive repertoire to IRBP have subsequently been demonstrated to occur in IRBP gene knockout (KO) versus WT mice and to be directly related to presence of IRBP in the thymus.

These data raised the notion that precursor frequency of retinal Ag-specific cells is an important factor in setting the threshold of EAU susceptibility. Direct experimental support for this notion comes from observations that gene-manipulated mice that have deficient thymic selection of IRBP-specific cells, and consequently sport an expanded T-cell repertoire to IRBP, are more susceptible to EAU, or even develop spontaneous EAU-like disease. Three such examples can be cited: (1) thymectomized, immunoablated, and bone-marrow-reconstituted WT mice that receive thymi from IRBP-deficient mice (forced to re-select their T-cell repertoire on the IRBP-deficient thymus) respond to IRBP epitopes that are not recognized by WT mice, and are extremely susceptible to EAU induced with IRBP; (2) mice that were made deficient in the AIRE molecule, which controls ectopic expression of tissue Ags in the thymus, develop multiorgan autoimmunity, including antiretinal antibodies, cellular responses to IRBP, and a spontaneous EAU-like uveitis directed at IRBP. Interestingly, although thymic selection to S-Ag and other retinal Ags controlled by AIRE is also compromised, IRBP is the only antigen recognized by these mice as pathogenic; and (3) nude mice grafted with a neonatal thymus develop a spontaneous autoimmune disease that

resembles the AIRE deficiency disease, and exhibit an immune response directed against photoreceptors with specificity to IRBP, but not S-Ag. Data obtained using human thymic tissue from immunologically normal patients undergoing open-heart surgery suggest that thymic control of repertoires specific to retinal Ags may also hold true for humans.

In addition to deleting high-affinity autoreactive T cells, the thymus also positively selects T cells with intermediate affinity that is slightly below the threshold for negative selection. Instead of being deleted, these cells are rendered unresponsive (i.e., anergized) acquire regulatory function, and exit into the periphery as natural regulatory T cells. Studies with IRBP KO mice demonstrated that selection of IRBP-specific natural T-regulatory cells requires endogenous expression of IRBP (see ahead).

Peripheral Tolerance and the Double-Edged Sword of Immune Privilege

The process of negative selection is not 100% efficient, and some autoreactive T cells escape deletion and exit into the periphery. Such escapees are subject to peripheral tolerance, which follows encounter with tissue Ags under non-inflammatory conditions (in the absence of co-stimulation). However, Ags residing in the healthy eye are sequestered behind an efficient blood–retina barrier and are not freely accessible to recirculating lymphocytes. This hinders peripheral tolerance and leaves a population of circulating retina-specific T lymphocytes that are ignorant, but not tolerant, and are able to be triggered by a chance encounter with their nominal or a cross reactive Ag (**Figure 2**).

The notion that retinal Ags are in fact functionally sequestered from the immune system has recently been debated. On the one hand, there is the phenomenon known as anterior-chamber-associated immune deviation (ACAID) in which Ags injected into the anterior chamber of the eye are not ignored, but rather induce a deviant type of immunity that includes a generation of Ag-specific regulatory cells that suppress cell-mediated immune responses. However, one must be careful when extrapolating from these data to Ags residing in the healthy eye, since ACAID by necessity involves perturbation of the ocular integrity. On the other hand, experiments using HEL transgenically expressed in the retina demonstrated

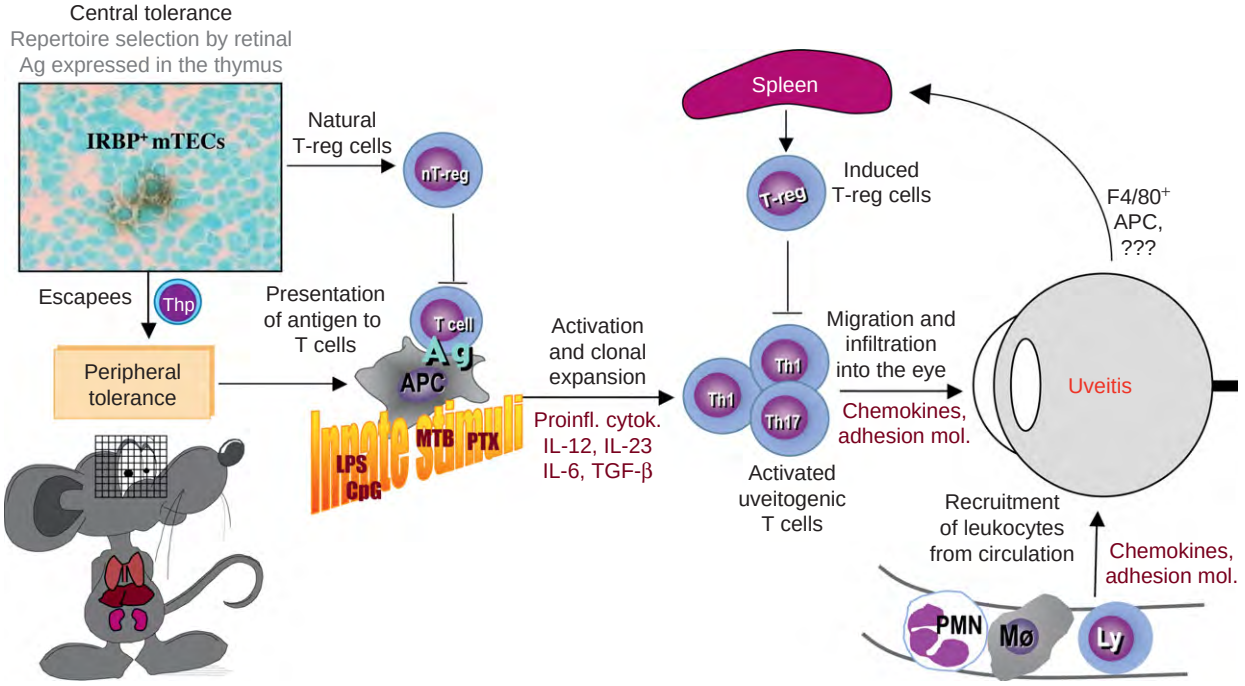

Figure 2 Critical checkpoints in pathogenesis of uveitis, based on data from animal models of EAU. Autoreactive T cells that failed to be deleted in the thymus have limited access to retinal Ags due to their relative sequestration from the immune system, which hinders peripheral tolerance. Despite the presence of natural T regulatory cells, such nontolerant thymic escapees may get primed by exposure to retinal or cross-reactive microbial Ag, and in the appropriate milieu differentiate to Th1 or Th17 effector lymphocytes that reach the eye, recognize their Ag *in situ*, and recruit inflammatory leukocytes from the circulation. T regulatory cells that are induced during and as a result of the disease process ultimately control the pathogenic effector cells and downregulate inflammation. Ag, antigen; APC, Ag-presenting cells; Mol, molecules; Proinfl, proinflammatory; Cytok, cytokines; LPS, lipopolysaccharide (bacterial endotoxin); MTB, mycobacterium tuberculosis; PTX, pertussis toxin; CpG, cytosine and guanidine separated by a phosphate (bacterial DNA motif); mTEC, thymic medullary epithelial cells; T-reg, T regulatory cells; nT-reg, natural T-reg; Th, T helper; Thp, Th precursor. Adapted from Caspi, R. R. (2006). Ocular autoimmunity: The price of privilege? *Immunological Reviews* 213: 23–35.

that peripheral tolerance to Ags expressed in the eye is low compared to Ags residing in nonprivileged tissues such as the pancreas, even though their thymic expression is similar. In keeping with this, forced expression of retinal Ags outside the eye results in enhanced tolerance, and in resistance to uveitis, support the notion that peripheral tolerance to ocular Ags can be improved. Recent data suggest that retinal expression of a novel, nonmammalian transgene (β-galactosidase) may generate some level of peripheral tolerance, but it is too low to alter susceptibility of these mice to EAU induced with β-galactosidase. On the whole, these studies lead to the conclusion that peripheral tolerance to Ags residing in the intact eye, while perhaps not entirely absent, is relatively limited.

Effector T Cells in Uveitis: Activation and Activity

As peripheral tolerance to retinal Ags is inefficient, autoreactive cells persist in the periphery in the nontolerized state. Accidental exposure to a retinal Ag released as a result of trauma or to a microbial agent can activate these naive T cells and induce them to differentiate into mature effector T cells that orchestrate tissue damage by producing proinflammatory cytokines and chemokines. This process is strongly promoted by innate endogenous and exogenous adjuvant co-stimulatory danger signals provided by tissue breakdown and/or microbial products. Strong danger signals also appear to overcome the threshold of resistance afforded by naturally occurring T regulatory cells (nTregs) and under some circumstances may temporarily inactivate them. In keeping with this, immunization of experimental animals for induction of EAU requires delivery of the retinal antigen in CFA, which contains heat-killed mycobacteria. Without them, disease is not induced and the effector T cells differentiate toward a nonpathogenic or a regulatory phenotype.

Activated retina-specific effector T cells are necessary and sufficient to elicit EAU when transferred from diseased donors to healthy recipients. Antibodies in hyperimmune serum by themselves are insufficient to initiate disease. Due to their molecular size, they are unable to penetrate the blood–retinal barrier. However, if the blood–retinal barrier is breached by uveitogenic T cells, serum antibodies enter the eye and result in an exacerbation of EAU scores. A considerable body of evidence has accumulated over the years to support an association between EAU and T helper 1 (Th1) effector T cells, whose hallmark cytokine is interferon-gamma (IFN-γ). However, recent findings in other autoimmune disease models identified a new effector cell phenotype involved in autoimmune inflammation; it was named Th17 after its hallmark cytokine, interleukin-17 (IL-17). Th1 and Th17 cells differentiate from the same naive precursor under different sets of conditions: Th1 cells are induced in the presence of the cytokine IL-12 and express the lineage-specific factor T-bet, whereas TGF-β and IL-6 drive commitment to the Th17 lineage, which is maintained by IL-23, and these cells express the lineage-specific transcription factor RORγt. Findings showing that interference with induction or with function the Th17 lineage abrogates induction of the classical autoimmune disease models such as experimental autoimmune encephalomyelitis (EAE, a model for multiple sclerosis), and collagen-induced arthritis (CIA, a model of rheumatoid arthritis), led investigators to propose that Th17 and not Th1 is the major pathogenic effector in autoimmune inflammation, and that Th1 has a minor role, if any.

Th17 cells indeed appear to have a critical role in EAU induced with IRBP immunization in CFA. In contrast to neutralization of systemic IFN-γ, neutralization of IL-17 prevents and reverses EAU in this model. Furthermore, Th17 cells are able to act as stand-alone effectors in the absence of Th1cells. Not only do IFN-γ KO mice develop severe EAU, but T cells from IFN-γ KO mice polarized toward the Th17 phenotype induce EAU in unimmunized IFN-γ KO recipients which do not have a Th1 response. Conversely, however, IL-17 KO mice develop EAU and polarized Th1 cells induce ocular pathology without participation of host-derived IL-17, showing that Th1 cells can also be stand-alone uveitogenic effectors. Finally, in the recently developed EAU model induced with Ag-pulsed mature dendritic cells (DCs) there seems to be a requirement for a generation of IFN-γ producing effector T cells, as IFN-γ KO mice fail to develop EAU when injected with uveitogenic DC that induce EAU in WT mice. It thus appears that ocular autoimmunity can be driven by either a Th17 or a Th1 effector response. Extrapolating from the CFA–EAU and the DC–EAU models, the effector type that is destined to predominate in a given situation is affected by the conditions of disease induction. Presentation of Ag in the context of mycobacteria (included in CFA) by diverse APC present in the lymph node (LN) appear to promote a dominant Th17 response, whereas Ag presented by DC matured *in vitro* with LPS and anti-CD40 as a single APC type promotes a Th1 response.

It is important to keep in mind that human uveitis is clinically heterogeneous even though the patients may respond to the same retinal Ag(s). Both Th1 and more recently the Th17 response has been associated with uveitic diseases. It is conceivable that the CFA and the DC-induced EAU models, which differ immunologically as well as clinically despite having been induced with the same Ag in genetically identical mice, could shed light on this heterogeneity of human uveitis. The initial eliciting event(s) connected to human uveitis are largely unknown, but if the animal models are in any way representative, the conditions prevailing at the time of Ag exposure could determine the subsequent course of disease.

Regardless of the Th1 or Th17 phenotype, the uveitogenic effector T cells that have been primed in the periphery travel through the circulation and extravasate into tissues, seemingly at random. A number of studies based on tracking the migration of labeled uveitogenic lymphocytes infused into naive recipients revealed that only a very few of the infused cells actually reach the eye, about 150 cells out of 10 million (= 0.0015%). Since half a million uveitogenic T cells are sufficient to cause EAU, this translates to 7–10 cells per retina. Cytokines, chemokines, and other soluble mediators released by these initial infiltrating cells upon recognition of their Ag in the tissue, trigger a complex process of activation of the ocular resident cells and the vascular endothelium, breakdown of the blood–retinal barrier and recruitment of inflammatory leukocytes, including neutrophils, monocytes, and nonspecific T cells, that are the final mediators of tissue damage (**Figure 2**). Each of these cell types apparently provides an essential function, as depletion of any one of them lowers EAU susceptibility.

Th1 and Th17 cells recruit different populations of inflammatory leukocytes by producing different sets of cytokines and eliciting different sets of chemokines. Th17 cells are known to preferentially attract neutrophils, whereas Th1 cells preferentially attract mononuclear cells, and this is in fact reflected in the composition of the inflammatory infiltrate in eyes of mice with EAU induced by adoptive transfer of Th1- or Th17-polarized uveitogenic cell populations, Paradoxically, however, the dominant ocular infiltrate in CFA-induced EAU, which is Th17 dependent, is mainly mononuclear, whereas the infiltrate in the Th1-dependent DC-induced EAU is predominantly polymorphonuclear. This suggests that the intraocular microenvironment is only partly determined by the systemically dominant effector T cell type and underscores the complexity of *in vivo* systems.

Regulatory T Cells and Uveitis

Tregs control induction and progression of immune responses. Two major categories of Tregs have been described: natural and induced. Natural Tregs (nTregs) were initially discovered as a result of the 3-day neonatal thymectomy model, in which mice whose thymus is removed 3 days after birth develop a variety of organ-specific autoimmune diseases, including oophoritis, gastritis, and thyroiditis. It was subsequently found that nTregs are generated in the thymus by positive selection on ectopically expressed self-Ags, in parallel to negative selection of high-affinity autoreactive effector T cells. nTregs are believed to originate from precursor T cells with intermediate affinity T-cell receptors (TCRs), just below the borderline of negative selection. Instead of being deleted, they become anergic and acquire regulatory function. They are typically $CD4^+CD25^+$ and express the Treg-lineage-specific transcription factor FoxP3.

Although spontaneous uveitis has not been reported as one of the autoimmune manifestations in the 3-day thymectomy model, nTregs appear to be important in controlling responses to retinal Ags. Depletion of natural Tregs by treatment with anti-CD25 antibodies (Abs) prior to immunization with a uveitogenic dose of IRBP greatly exacerbates EAU scores and associated immunological responses and permits EAU to develop in normally resistant mouse strains such as BALB/c. This demonstrates the role of nTregs in raising the threshold of susceptibility to EAU. Thymic generation of IRBP-specific nTregs is dependent on endogenous expression of IRBP, as they are absent in $IRBP^{-/-}$ mice.

When regulation by nTregs is insufficient and priming of functional retina-specific effector T cells occurs, exposure to Ag induces Tregs *de novo* from peripheral T cells. The distinction between natural and induced Tregs blurs in immunized animals, as both share FoxP3 expression and surface markers, although some induced Tregs are $CD8^+$. As part of its immune-privileged status, the eye is capable of inducing Tregs through a variety of methods, both local and systemic. Two examples of systemic induction of eye-related Tregs are: (1) the ACAID phenomenon discussed above, which when induced with IRBP can prevent and reverse EAU and (2) postrecovery regulatory T cells, whose induction is dependent on the presence of the eye and does not occur in enucleated animals immunized as for induction of EAU. Although induced Tregs come into play as a result of damage already sustained by the eye, they can limit further development of disease and ameliorate its re-induction.

During EAU, $FoxP3^+$ Tregs accumulate in the eye, reaching 20% of $CD4^+$ T cells in the eye 5 weeks after uveitogenic immunization, and this increase parallels resolution of disease. Data from IRBP TCR Tg mice demonstrate that the fraction of IRBP-specific Tregs (detectable by their specific TCRs) in the $FoxP3^+$ population is enriched in the eye fourfold to fivefold compared to the submandibular (eye draining) and other lymph nodes. It is not known whether this reflects preferential retention, proliferation, or conversion of non-Treg cells to Tregs within the eye; however, the ocular microenvironment has the potential to promote local induction of Tregs. Ocular resident cells including Müller cells and ocular pigmented epithelial cells are inhibitory to T cells. Ocular pigmented epithelia (though not Müller cells) may convert T cells to Tregs upon contact. Furthermore, the ocular fluids contain TGF-β, α-MSH, and other factors that can directly inhibit T-cell activation and function, and/or convert them to regulatory cells. Although these data are quite compelling, they represent mostly *in vitro* observations and it is still unclear how much of a role these phenomena have *in vivo* in controlling uveitis.

Treg defects have been reported in some human autoimmune diseases, such as multiple sclerosis and type-1 diabetes. The importance of Tregs in controlling human uveitic disease is not well understood, but patients with uveitis associated with VKH disease have been noted to have reduced Treg function. In contrast to human uveitis, which tends to be chronic, EAU in rodent models tends to be monophasic. This may conceivably be due to Treg defects in predisposed human patients, which are not found in the common strains of laboratory rodents, in which uveitis must be induced with the aid of strong immunization regimens. This notion is supported by findings showing that weak Treg activity may contribute to recurrent versus monophasic uveitis in the rat EAU model.

Non-Treg Cells in Regulation of Uveitis

To complete the picture, it is important to keep in mind that cells and processes other than the classical natural and induced T regulatory cells may also regulate uveitis. Inhibition of T-cell activation and function by ocular resident cells, at least *in vitro*, has already been mentioned. At the systemic level, non-Treg cells able to produce cytokines also may regulate disease. Natural killer T (NKT) cells rapidly produce cytokines upon engagement of their TCR, including IFN-γ, IL-4, and more recently they were also demonstrated to produce IL-17. Mice immunized for EAU and concurrently treated with the glycolipid α̃GalCer, which is a ligand for the invariant NKT TCR, develop reduced disease scores. Interestingly, among analogs that elicit different amounts of IFN-γ versus IL-4 from NKT cells, the most protective analog was the one that elicited the highest levels of IFN-γ. Protection was associated with reduced adaptive IL-17 and IFN-γ responses to IRBP. Concurrent treatment with a neutralizing IFN-γ Ab reversed protection and restored adaptive IFN-γ and IL-17 responses, demonstrating the role of IFN-γ in this process. This is reminiscent of data showing that injection of IL-12 at the time of immunization had a protective IFN-γ-dependent effect, and was shown to be associated with apoptotic elimination of newly primed effector T cells. Thus, unlike locally produced IFN-γ which enhances pathology by inducing a broad spectrum of proinflammatory mediators, elevated systemic levels of IFN-γ at the time of priming, restrain development of adaptive immunity. Endogenous ligands that bind to the NKT cell invariant TCR might trigger them to regulate EAU. These data help to reconcile the apparent paradox that lack of IFN-γ (through genetic or treatment-induced deficiency) results in higher EAU scores in the IRBP–CFA model.

Immunopathogenesis of HSV Keratitis

K Buela, G Frank, J Knicklebein, and R Hendricks, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA

Glossary

Anterograde axonal transport – Transport through the cytoplasm of axons from the neuron cell body or soma towards the synapse.
Chemokine – A combined form of the words chemotactic (able to attract cells) and cytokines. Chemokines are a family of low-molecular-weight chemotactic cytokines that attract and activate leukocytes at sites of infection and inflammation.
Cytokine – A large and diverse family of intercellular molecular messengers that, like hormones, transmit information from one cell to another. The term is often used to denote polypeptides with immunomodulatory activity.
HSV-1 latency – The retention of a complete viral genome for extended periods without production of infectious virions.
Immunosurveillance – The continuous monitoring function of the immune system whereby it recognizes and reacts against aberrant cells arising within the body.
Regulatory T cells – Specialized subpopulation of T cells that act to suppress activation of the immune system and thereby maintain immune system homeostasis and tolerance to self-antigens.
Retrograde axonal transport – The transport of vesicles from the synaptic region of an axon toward the cell body or soma.
T cells – A population of lymphocytes that derive from bone marrow precursors, mature in the thymus, and play a central role in cell-mediated immunity.
Trigeminal ganglia – The ganglia that house the cell bodies of primary afferent neurons innervating the head and neck.
Virion – A mature infectious virus particle existing outside a cell.

Natural History of Herpes Stromal Keratitis

Although herpes stromal keratitis (HSK) has been studied in a variety of animal models, much of our current knowledge regarding the immunopathogenesis of HSK has derived from murine models due to the plethora of immunologic reagents available to dissect the immune response in mice. Strain differences in susceptibility to HSK have been noted with A/J>Balb/c>C57BL/6. With most strains of HSV-1, corneal infection requires surface abrasion to facilitate entry of the virus into corneal epithelial cells. An epithelial lesion then forms as a result of virus replication in and destruction of epithelial cells. The lesions are transient, resolving by 4 days post infection (dpi), with eradication of replicating HSV-1 by 7–8 dpi. Healing of the lesions is aided by the rapid turnover of corneal epithelial cells.

Eradication of Replicating HSV-1 from the Corneal Epithelium

Viral clearance appears to be largely a function of the innate immune system, consistent with the rapid kinetics of virus elimination. Evidence suggests a role for neutrophils, natural killer (NK) cells, and γδ T cells in the eradication of replicating virus from the cornea. These cells are attracted to and activated within the cornea as a result of the release of cytokines, including cyclooxygenase 2, prostaglandin E2, type 1 interferon, interleukin (IL)-1, IL-6, IL-17, granulocyte macrophage colony stimulating factor (GM-CSF), and tumor necrosis factor (TNF); and chemokines including CXCL10 (IP-10), CXCL9 (MIG), CXCL2 (MIP-2), and CCL3 (MIP-1α). The production of these cytokines and chemokines appears to be initiated by ligation of toll-like receptors (TLRs), especially TLR2 and TLR9, and in response to cytokines including IL-17, IL-6, and interferon-gamma (IFN-γ). The initial neutrophilic infiltrate peaks in HSV-1 infected mouse corneas around 4 dpi, and declines between 6 and 8 dpi, coincident with the peak and decline of viral titers in the mouse cornea.

The adaptive immune system appears to play a less significant role in the initial clearance of HSV-1 from the infected cornea following primary infection. However, it is noteworthy that severe combined immune-deficient (SCID) mice that lack an adaptive immune system do not fully eradicate replicating virus from the cornea. Accordingly, activated CD4 T cells have been detected within the infected cornea by 3 dpi, although their role in inhibiting HSV-1 replication within the cornea has not been established. It is possible, and indeed likely that the failure of SCID mice to eradicate replicating HSV-1 from the cornea during primary infection results from their inability to fully establish and maintain viral latency in the trigeminal

ganglion. Replicating virus in the trigeminal ganglion could then be transported back to and shed into the cornea, perpetuating the corneal infection. The role of T cells in clearing virus from the corneal epithelium following reactivation has not been studied. Antibodies also appear to play an important role in the clearance of HSV-1 from the cornea during both primary and recurrent disease.

HSV-1 Colonization of Sensory Ganglia

During the course of virus replication in epithelia of the cornea, oral, or nasal passages of mice, the virus gains access to the termini of sensory neurons and is transported to neuronal nuclei in trigeminal ganglia. There it replicates briefly and then establishes a latent infection that is characterized by retention of a functional viral genome without production of infectious virions. Evidence suggests that control of acute HSV-1 replication and establishment of latency in trigeminal ganglia is mediated largely by an innate response of macrophages and NK cells mediated by TNFα, IFN-γ, and nitric oxide. However, complete eradication of replicating virus requires reinforcement by $CD8^+$ T cells and γδ T cells. Latently infected neurons within the ophthalmic branch of trigeminal ganglia then serve as a source of virus for recurrent corneal disease. HSV-specific $CD8^+$ T cells then remain in the trigeminal ganglion in close apposition to infected neurons for the life of the mouse. These $CD8^+$ T cells express a persistent activation phenotype and have been shown to inhibit HSV-1 reactivation from latency both *in vivo* and in *ex vivo* ganglionic cultures. A similar association of activated $CD8^+$ T cells with latently infected neurons has also been established in human ganglia. Moreover, psychological stress, which is associated with recurrent herpetic disease in humans, causes a transient compromise of the function of ganglionic $CD8^+$ T cells and HSV-1 reactivation from latency in trigeminal ganglia of mice. These findings suggest that maintenance of HSV-1 latency and prevention of recurrent shedding of virus at mucosal surfaces such as the cornea requires constant immunosurveillance by $CD8^+$ T cells.

Herpes Stromal Keratitis

Following resolution of the epithelial lesion, corneal clarity is reestablished in mice. However, by 7–10 dpi corneal opacity develops accompanied by ingrowth of blood vessels into the normally avascular cornea, and massive leukocytic infiltration. These are manifestations of HSK, which in mice progresses from a non-necrotizing form with little epithelial involvement to severe necrotizing keratitis in which stromal inflammation gives rise to epithelial necrosis. The necrotizing form represents about 7% of human HSK, with 88% exhibiting the non-necrotizing form, and 5% exhibiting a mixture of both forms. It is not clear if the reduced incidence of necrotizing HSK in humans relative to mice is due to medical management of inflammation in human corneas or a reflection of fundamentally different pathogenic mechanisms in most human cases of HSK.

T Cells in HSK

Early studies revealed that HSK failed to develop in athymic nude mice that lacked T cells, but could be reconstituted in these mice by T-cell adoptive transfer. The $CD4^+$ T cell population appears to be the predominant mediator of HSK in most mouse models, with $CD8^+$ T cells tending to reduce disease severity. However, $CD8^+$ T cells can also mediate a milder and more transient form of HSK when mice are deficient in $CD4^+$ T cells or infected with certain strains of HSV-1. Human corneas with HSK contain both $CD4^+$ and $CD8^+$ T cells that are specific for HSV antigens, though the relative contribution of these cells in the progression or resolution of HSK cannot be evaluated. Recently, a population of $CD4^+$ T cells referred to as natural T regulatory cells (nTregs) that co express CD25 and the forkhead/winged-helix transcriptional regulator, FoxP3 were shown to moderate the severity of HSK. The fact that these nTregs maintain the capacity to regulate HSK when expanded *in vitro* and adoptively transferred into infected mice offers a potentially useful therapeutic modality.

Cytokines and Their Role in HSK

Cytokines provide a means of communication among leukocytes and between leukocytes and parenchymal cells at sites of infection and/or antigen deposition. Under optimal conditions cytokines orchestrate an immunoinflammatory response that eliminates a pathogen with minimal damage to host tissue. In HSK resolution of the immunoinflammatory lesions in the cornea is accompanied by scar tissue formation. This trade-off of strength for clarity is unacceptable in a tissue within the visual axis. Moreover, the fact that in both mice and humans HSK can develop in the absence of replicating virus in the cornea renders HSK a purely immunopathological process. Thus, regulating the production and/or function of the cytokines that orchestrate HSK would reduce tissue damage without compromising protection of the host.

Most studies in the murine models have implicated the Th1 cytokines as playing a primary role in the pathogenesis of HSK. The prototypic Th1 cytokine, IFN-γ, aids neutrophil extravasation into the cornea at least in part through upregulation of platelet/endothelial cell adhesion molecule 1 (PECAM-1, CD31) on local vasculature. Th1 cells also produce IL-2 that has been shown to directly or indirectly regulate the migration of neutrophils into the central cornea during HSK. The Th1-associated cytokine

IL-12 also contributes to HSK development, presumably through its capacity to regulate IFN-γ production. The cytokine IL-6 also plays a central role in orchestrating HSK in part through its ability to induce the neutrophil chemokine MIP-2 (CXCL2).

Recently, the functional repertoire of $CD4^+$ T cells was expanded to include Th17 cells. The IL-17 cytokine family represents the signature cytokines of Th17 cells, and is now implicated in a variety of inflammatory processes and autoimmune diseases. IL-17 is produced in both human and mouse corneas during HSK. Both human and mouse keratocytes express receptors for IL-17, and engagement of this receptor induces their production of neutrophil chemotactic factors as well as GM-CSF. The chemotactic factors attract neutrophils into the cornea while GM-CSF activates them and maintains their viability. Recent studies support a role for IL-17 in neutrophilic infiltration during the early stages of HSK. The requirement for IL-17 is transient and presumably superseded by Th1 cytokines as HSK progresses.

Regulating the production or blocking the function of the Th1 and Th17 cytokines offer potential therapeutic benefit in preventing the progression of HSK. In addition, the Th1/Th2/Treg cytokine IL-10 has a proven capacity to ameliorate HSK. The general anti-inflammatory properties include inhibition of the production and function of IFN-γ.

Antigen-Presenting Cells in HSK

Antigen-presenting cell (APC) refers to the ability of certain cells, including macrophages, dendritic cells, and B lymphocytes to take up, process, and present antigenic peptides to naive $CD4^+$ T cells in the context of major histocompatibility complex class II (MHC class II) and co-stimulatory molecules. The once prevalent view that the normal cornea is devoid of these specialized cells has now been dispelled by several recent histological studies of mouse and human corneas. Dendritic cells (DCs) are present in the basal layer of the corneal epithelium and macrophages are present throughout the corneal stroma, with the density of both cell types gradually diminishing from the peripheral to the central cornea.

During HSV-1 infection of the corneal epithelium, the resident DCs are reinforced by immigrants from the limbus. Studies employing ultraviolet irradiation to diminish DCs or cautery to increase their presence in the cornea prior to HSV-1 infection suggested a role for these cells in directly or indirectly inducing a delayed-type hypersensitivity response in lymphoid organs. Since DCs exhibit transient survival following HSV-1 infection, it is likely that either noninfected corneal DCs acquire viral antigens from corneal epithelial cells for direct presentation to T cells in the lymph nodes, or infected corneal DCs travel to the lymph nodes where they are phagocytosed by resident DCs and viral antigens are cross-presented to T cells. The DC depletion studies also suggested an important role for corneal DC in presenting HSV-1 antigens to $CD4^+$ T cells upon infiltration of the infected cornea. This is consistent with the observation that $CD4^+$ T cells induce a second and more profound infiltration of DC into the cornea at the time of onset of HSK. It should be noted, however, that the method of DC depletion employed in these early studies was not specific, and the role of DC and DC subpopulations in the efferent and afferent limbs of the $CD4^+$ T cell response in HSK awaits confirmation in studies employing specific depletion strategies now available.

Although many cell types can be induced to express MHC class II antigens, professional APCs are uniquely able to co-express the co-stimulatory molecules that are required for the activation of naive and, in many cases, effector $CD4^+$ T cells. In a mouse model of HSK, blocking the interaction of the ligands B7-1 (CD86) and B7-2 (CD80) on APCs with the co-stimulatory molecule CD28 on $CD4^+$ T cells locally within the cornea inhibited the HSK progression. In contrast, ligation of the inhibitory receptor program death 1 (PD-1) by its ligand B7-H1 (CD274) appears to inhibit HSK progression, though it is not clear if this effect is exerted in the cornea or lymphoid organs. HSK progression was not influenced by blocking the interaction of the APC activating receptor OX40 by its T-cell ligand OX40L (CD154). These studies suggest that local inhibition of co-stimulatory molecule or augmentation of inhibitory molecule signaling in $CD4^+$ T cells might hold therapeutic potential in the management of HSK.

Chemokine Involvement in HSK

Chemokines are chemotactic cytokines that activate and direct the migration of leukocytes into sites of inflammation. Chemokines not only orchestrate the innate immune response that eradicates replicating HSV-1 from the cornea (see above), but also have a central role in regulating HSK. Defining the role of chemokines in inflammatory processes is complicated by the fact that they are pleiotropic, have overlapping functions, share receptors, and can bind to multiple receptors. Not surprisingly, studies of their involvement in HSK, have in some cases, produced conflicting results. While IP-10 (CXCL10) and MCP-1 (CCL2) appear to be important for directing $CD4^+$ T cells into the cornea, IP-10 might also inhibit neovascularization (see below). The chemokine CCL20, expressed by HSV-1-infected corneal epithelial cells and corneal keratocytes when stimulated by IL-1β and TNFα, appears to be involved in DC infiltration during both epithelial lesions and the secondary infiltration during HSK development. The chemoattractants MIP-2 (CXCL2), MIP-1α (CCL3), and RANTES (CCL5) have all been implicated in guiding neutrophils into the cornea

during HSK. A variety of neutralizing antibodies, and peptide and nonpeptide inhibitors of these chemokines have been developed and might have therapeutic potential in managing HSK, though their successful use will likely be complicated by the redundant nature of the chemokines.

Angiogenesis in HSV-1 Stromal Keratitis

Neovascularization of the normally avascular cornea appears to be a requisite step in the development of severe HSK in mice. Both vascular endothelial growth factor (VEGF) and matrix metalloproteinase (MMP)-9 have an important role in the neovascularization of corneas with HSK. Production of these factors is induced by IL-1, IL-6, and MIP-2. Corneal cell production of soluble VEGF receptors prevents vascularization of the cornea during steady state. Clearly, the capacity of the soluble VEGF receptor to neutralize VEGF and prevent its binding to VEGF receptors on the limbal vascularture is overwhelmed by the amount of VEGF produced in HSV-1 infected corneas. Neovascularization provides enhanced corneal access of blood-borne leukocytes that mediate HSK, and blocking neovascularization effectively prevents HSK progression. Based on the established roles for vascularization and VEGF in mouse models of HSK, and the prominent presence of corneal vessels in necrotizing keratitis in humans, therapeutic approaches geared toward blocking vascularization hold great promise in the management of HSK.

Models of HSK Pathogenesis

Despite extensive advances in our understanding of the pathogenesis of HSK in mice, one of the most basic questions (viz., what stimulates the $CD4^+$ T cells that mediate HSK) remains unanswered. Three models of CD4+ T-cell activation in HSV-1 infected corneas have been advanced and supported by experimental data. These include: (1) bystander activation by the cytokine milieu present in the cornea, (2) autoimmunity to corneal tissue resulting from molecular mimicry by viral proteins, and (3) virus-specific activation.

The concept that bystander activation of $CD4^+$ T cells mediated by the cytokine milieu within the infected cornea is sufficient to induce HSK was proposed based on findings in mice whose T cells all express transgenic T-cell receptors (TCRs) specific for ovalbumin (ova). When the corneas of these mice were infected with HSV-1, they developed HSK that was mediated by ova-specific $CD4^+$ T cells. However, these mice failed to control HSV-1 replication in the cornea, and succumbed to infection early during HSK development. Indeed, when HSV-1 replication was controlled in the corneas of these with kinetics similar to that of immunologically normal mice, the mice failed to develop HSK. Thus, in immunologically normal mice (and presumably people) bystander activation of $CD4^+$ T cells might contribute to, but is not itself sufficient for, the development of HSK.

Other studies incorporating BALB/c mice that are congenic for the IgH locus concluded that HSK develops as a result of an autoaggressive attack of $CD4^+$ T cells on corneal tissue. This autoimmune response was induced by a peptide contained in the viral UL6 protein that mimicked a sequence in a corneal protein and in the Ig heavy chain of one of the congenic strains. The BALB/c strain that expressed the mimicked peptide in its Ig heavy chains did not respond to the peptide due to clonal deletion, and were highly resistant to HSK. In contrast, the congenic strain that failed to express the UL6-mimicked peptide in its Ig heavy chain generated a response to UL6 that cross-reacted with a corneal protein. The authors concluded from these findings that HSK is an autoimmune disease arising from antigenic mimicry by the HSV-1 UL6 protein. Unfortunately, these intriguing findings were not reproduced in subsequent studies by another group, and no UL-6-specific or cornea-specific $CD4^+$ T cells have been isolated from mouse or human corneas with HSK. Thus, the involvement of autoimmunity in HSK remains uncertain.

A third possibility is that reactivity of HSV-specific $CD4^+$ T cells to HSV antigens within the cornea triggers HSK. This hypothesis is consistent with the fact that HSV-1-specific $CD4^+$ T cells have been isolated from both human and murine corneas at varying stages of keratitis. Further support for this concept came from a study in which partial tolerization of $CD4^+$ T cells to HSV-1 antigens was associated with reduced severity of HSK. However, no studies to date have established a clear role for HSV-1-specific $CD4^+$ T cells in directly mediating HSK. Based on the available data, it is likely that the initiation of HSK results from stimulation of HSV-specific $CD4^+$ T cells in the cornea, while bystander activation might contribute to the progression and chronicity of the inflammation.

Epidemiology and Pathogenesis of Human HSK

Clinically, ocular HSV-1 infection remains a significant cause of visual impairment worldwide. In developed nations, there are approximately 8.4–13.2 new ocular HSV-1 infections per 100 000 person-years with an overall incidence, including recurrences, of 20.7–31.5 episodes per 100 000 person-years. Perhaps the most serious manifestation of ocular HSV-1 infection is the potentially blinding HSK, which accounts for only 2% of initial HSV-1 ocular presentations but represents 20–61% of recurrent disease.

Multiple forms of HSK exist and no classification system is universally accepted (here we use a classification system described by Liesegang). HSK commonly presents as a non-necrotizing or immune form, but can also present as the rarer but more serious necrotizing form. Based on limited data, it appears that both the necrotizing and immune presentations of human HSK share the features of neovascularization and leukocytic infiltration seen in the mouse model. Since HSK in the mouse progresses from disease resembling immune HSK to disease resembling necrotizing HSK, it is reasonable to propose that the two forms represent a continuum rather than distinct pathologies. However, there are important differences between the human and mouse HSK, including the fact that HSK rarely leads to corneal perforation in humans, while perforation is a frequent occurrence in the mouse model. Moreover, human HSK is often associated with replicating HSV-1 in the cornea and overlying epithelial lesions, whereas replicating HSV-1 is typically eradicated from the mouse cornea prior to the onset of HSK.

Management of Human HSV Stromal Keratitis and Implications on Pathogenesis

Management of HSK is complicated by the fact that the cells that are responsible for eliminating the virus also contribute to immunopathology in the cornea. Treating the inflammation alone can significantly exacerbate viral replication. In contrast, treating with antivirals alone can lead to uncontrolled inflammatory damage to the cornea. The current standard of care for both non-necrotizing and necrotizing HSV stromal keratitis includes topical corticosteroids and topical antivirals. Corticosteroids are used to diminish the immunopathological component of stromal disease, while the antivirals prevent further viral replication. However, corticosteroids applied to the ocular surface can lead to adverse side effects including development of cataracts or glaucoma. A less well-studied treatment option for patients suffering from HSV stromal keratitis is topical cyclosporin A (CsA) in addition to topical antivirals. Several small noncontrolled trials in humans with HSK suggested that treatment with CsA may be beneficial in cases resistant to corticosteroids. Additionally, studies using murine models of HSK revealed that CsA effectively reduced stromal inflammation and haze in a dose-dependent manner. Similar to corticosteroids, CsA also functions to dampen the immune system. CsA blocks transcriptional activation of CD4+ T-cell pathways necessary for production of inflammatory cytokines, such as IL-2 and IFN-γ. Furthermore, CsA inhibits corneal neovascularization in murine models of HSK.

Successful medical treatment of human HSK has important implications concerning the theories of HSK pathogenesis. CsA functions to inhibit TCR-induced calcineurin signaling that leads to production of inflammatory cytokines, such as IL-2. Therefore, effective treatment of HSK with CsA implicates TCR signaling, favoring $CD4^+$ T-cell activation by viral or autoantigens, but not by cytokines.

Studies in mice emphasize an important role for neovascularization in HSK progression. Mouse studies also implicate VEGF as a critical regulator of vascularization associated with HSK. The current availability of therapeutic agents such as Avastin and Leucentis that inhibit vascularization by blocking VEGF offers the potential for exciting new treatment alternatives.

Glossary

Microfilariae – First stage (L1) larvae of filarial nematodes including *Onchocera volvulus*, the causative agent of river blindness.
TLR (toll-like receptor) – A family of surface and endosomal receptors that are expressed on mammalian cells, including the cornea. These receptors recognize microbial products and transmit cell signals that culminate in the elaboration of chemokines and cytokines.
Wolbachia – Obligate intracellular bacteria that exist as endosymbionts in filarial nematodes including *Onchocerca volvulus*.

Onchocerciasis (river blindness) remains endemic in a number of sub-Saharan African countries and has foci in Yemen and in Latin America. Most recent (2006) estimates indicate that there are 37 million individuals infected with *Onchocerca volvulus*. The life cycle of all filarial nematodes includes transmission through insect vectors, with *Simulium* blackflies transmitting *O. volvulus*. First stage larvae (microfilariae, L1) are ingested during a blood meal and migrate through the insect gut, thorax and into the salivary gland having undergone two molts to the third-stage larvae (L3). Infective L3 enter the mammalian host during a second insect blood meal, where they develop to L4 stage and then adult males and females. Adult male and female worms live for over 10 years in subcutaneous tissues, producing millions of microfilariae over their lifespan. Microfilariae can survive for over 1 year in the skin, and can enter the anterior and porterior segments of the eye. While alive, microfilariae appear to cause minimal damage, and individuals can be very heavily infected; however, when the larvae die either by natural attrition or following chemotherapy, the host immune response causes acute and chronic tissue damage, with severe onchodermatitis in the skin, visual impairment, and blindness. **Figure 1** shows examples of sclerosing keratitis and of cellular infiltration and vascularization in the corneal stroma of an infected individual in west Africa.

The Role of Endosymbiotic *Wolbachia* Bacteria in Onchocerciasis

Intracytoplasmic *Rickettsia*-like bacteria were first described in filarial nematodes in 1977, and later identified as *Wolbachia pipientis*. Although 75% of insect species and a number of crustaceans harbor *Wolbachia* as endosymbionts, filarial nematodes are the only group of parasitic worms that are infected, most likely because they are the only nematode group with an obligate insect host. In filarial nematodes, *Wolbachia* are detected with in cells in the hypodermis and uterus, in immature microfilariae in the uterus, and in mature microfilariae in the skin and cornea. The bacteria are most numerous in the mammalian host compared with the insect stage, and appear to have an essential, though poorly understood, role in nematode embryogenesis. Antibiotic (Doxycycline) treatment of filaria-infected individuals effectively sterilizes the adult females, reducing overall microfilaria numbers in the skin and blocking disease transmission.

Role of *Wolbachia* in Pathogenesis – Evidence from Infected Individuals

The role of *Wolbachia* in the pathogenesis of filarial disease has been implicated from observations made after antifilarial therapy. Elevated *Wolbachia* DNA and even intact *Wolbachia* are detected in the blood, and are associated with the proinflammatory cytokines seen in patients with post-treatment side effects such as fever, edema, and headache. Using quantitative PCR for *Wolbachia* surface protein (WSP) gene, which is present as a single copy per organism, the number of bacteria per worm was found to be similar in all insect stages of *B. malayi*. However, within 7 days in the mammalian host, bacteria numbers increased 600-fold and showed a high ratio of *Wolbachia*/nematode DNA in L4 larvae, indicating rapid bacterial replication within the worms. This *Wolbachia* load is maintained in adult males, but increases in females during embryogenesis. *Wolbachia* are therefore a target for antibiotic treatment, and patients given a course of doxycyline in addition to annual ivermectin treatment have reduced systemic microfilariae, and significantly fewer adult worm number in subcutaneous nodules. *Wolbachia* appear to mediate recruitment of neutrophils, as the number of neutrophils in nodules from doxycycline-treated individuals is greatly reduced compared with untreated individuals. An additional line of evidence for a role for *Wolbachia* in the pathogenesis of onchocerciasis relates to earlier studies showing that two strains of *O. volvulus* that differ in virulence exist in West Africa based on DNA probes using a noncoding repeat sequence, and the strain

Figure 1 Ocular onchocerciasis. (a) Blind individual in endemic region of Cote D'Ivoire, West Africa, 1999, with both corneas opaque as a result of infection with *Onchocerca volvulus* (photograph by Eric Pearlman); (b) sclerosing keratitis, showing central region of corneal opacification and neovascularization (with permission from Dr Hugh Taylor); (c) corneal section showing intact microfilariae (arrow) in the corneal stroma. Blood vessels (V) and cellular infiltrate are also visible (from Armed Forces Institute of Pathology).

shown to cause more severe ocular disease has significantly higher *Wolbachia* loads compared with the second, less virulent strain, indicating a correlation between virulence and *Wolbachia* in ocular onchocerciasis.

Taken together, these findings strongly support the notion of an important role for *Wolbachia* in the proinflammatory response and pathogenesis of onchocerciasis.

The Role of *Wolbachia* in the Pathogenesis of ocular onchocerciasis – Lessons from the Murine Model of *O. volvulus*/*Wolbachia* Keratitis

Microfilariae invade both the anterior and the posterior segments of the eye. In the latter case, they cause uveitis and chorioretinitis, resulting in loss of vision; therefore, although *Onchocerca* keratitis is more frequent and more readily detectable, corneal transplants are not conducted as the patients generally also have posterior segment disease. Because eyes from human cases of onchocerciasis are not available, the host response to *Onchocerca* has been examined in the skin of infected individuals. As such, *Onchocerca* infected individuals show microfilariae in the dermis surrounded by neutrophils, eosinophils, or macrophages. The likely explanation is that neutrophils surround recently dead and degenerating worms in the skin, whereas macrophages and eosinophils migrate to the site at later time points. Our findings in a murine model of *Onchocerca* keratitis shows that neutrophils surround microfilariae in the cornea within 24 h and immunogold labeling of the major *Wolbachia* surface protein shows neutrophils in close proximity to *Wolbachia* (Figure 2). Using this mouse model of *O. volvulus* keratitis in which filaria/*Wolbachia* extracts are injected into the corneal stroma, St. Andre and colleagues demonstrated that endosymbiotic *Wolbachia* bacteria are essential for the pathogenesis of *O. volvulus* keratitis as: (1) *O. volvulus* from individuals depleted of *Wolbachia* by antibiotic treatment do not induce corneal inflammation; (2) related filarial species containing *Wolbachia* induce keratitis in contrast to filarial species lacking *Wolbachia*; and (3) isolated *Wolbachia* induce neutrophil recruitment to the corneal stroma.

Wolbachia and TLRs in the Cornea

TLRs are surface and endosomal receptors that are expressed in the cornea and respond to microbial products such as lipopolysaccharide (TLR4) and lipoproteins (TLR2). TLR2 forms heterodimers with TLR1 or TLR6 to initiate signaling through adaptor molecules and induce nuclear factor kappa B (NFκB) translocation to the nucleus, and results in production of pro-inflammatory and chemotactic cytokines. Our findings using gene knock-out mice clearly demonstrate that either *O. volvulus* extracts

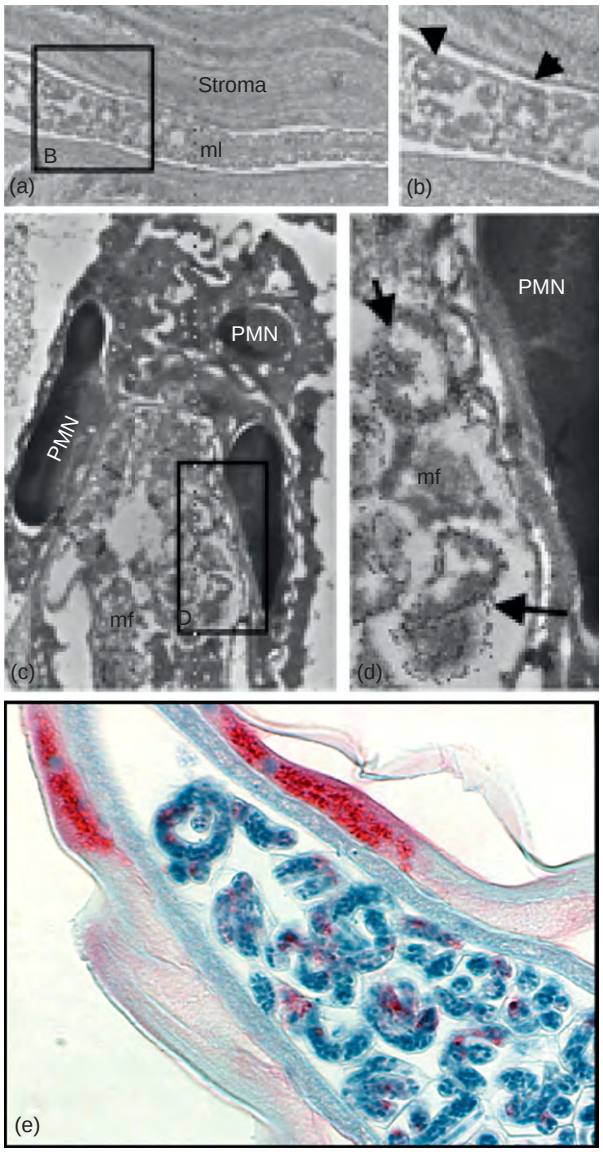

Figure 2 Presence of endosymbiotic *Wolbachia* bacteria in microfilaria and adult female worms. C57BL/6 mice were injected into the corneal stroma with microfilariae, corneas were removed after 4 h or 18 h and thin sections were immunostained with anti-*Wolbachia* Surface Protein (WSP) and visualized with IgG conjugated to 15 nm gold particles. Sections were counterstained with uranyl acetate and lead citrate, and examined by electron microscopy. (a, b) 4 h after injection. WSP was clearly detected inside microfilariae in the corneal stroma (arrows). Mf: microfilariae. (c, d) 18 h after injection microfilariae containing *Wolbachia* were surrounded by neutrophils (PMN). WSP labeled with gold particles (arrows) are present in the microfilariae adjacent to the neutrophils. Magnifications: (a) ×4800; (b) ×8400; (c) ×5300; (d) ×16 000. Reprinted with permission from Gillette-Ferguson, I., Hise, A. G., McGarry, H. F., et al. (2004). *Wolbachia*-induced neutrophil activation in a mouse model of ocular onchocerciasis (river blindness). *Infection and Immunity* 72: 5687. containing *Wolbachia*, or isolated *Wolbachia* bacteria selectively activate TLR2 and TLR6, and adaptor molecules MyD88 and Mal. **Figure 3** shows that corneal inflammation (neutrophil infiltration and increased corneal haze) is entirely dependent on activating TLR2. Moreover, studies using chimeric mice have shown that TLR2 expressed on bone-marrow-derived cells have an important role in provoking corneal inflammation.

Taken together, findings from our group and others indicate that *Wolbachia* induces TLR2 activation in resident macrophages in the corneal stroma, and produce pro-inflammatory cytokines and CXC chemokines, which mediate neutrophil recruitment from peripheral, limbal vessels into the corneal stroma. Neutrophil responses to *Wolbachia* are also dependent on TLR2/MyD88, which mediate cytokine production by these cells, and may contribute to degranulation and secretion of reactive oxygen species and matrix metalloproteinases, resulting in cell death and loss of corneal clarity.

In chronically infected, untreated individuals, there is also an ongoing adaptive immune response, due to repeated invasion of microfilariae into the corneal stroma, and prolonged worm degeneration and release of *Wolbachia*. Infiltrating eosinophils and macrophages also contribute to tissue damage, manifesting as corneal opacification, loss of vision, and blindness. We found that a third role for the TLR2 is filaria/*Wolbachia* activation of dendritic cells and T-cell production of IFN-γ but not IL-4 or IL-5. IFN-γ also has an indirect role in enhancing pro-inflammatory and chemotactic cytokine production, thereby increasing neutrophil recruitment to the corneal stroma (**Figure 4**). Together, these findings demonstrate that TLR2 governs the host response to *Wolbachia* at several levels, including systemic and corneal responses, and may be a target for blocking corneal inflammation.

Identification of a *Wolbachia* TLR2/TLR6 Ligand

The TLR2/TLR6 heterodimer is activated by diacylated lipoproteins. To identify possible *Wolbachia* lipoproteins that activate TLR2/TLR6, Taylor and colleagues searched the lipoprotein databases, and identified *Brugia malayi Wolbachia* peptidoglycan-associated lipoprotein PAL (wBmPAL). Synthetic diacylated wBmPAL was shown to selectively induce IFN-γ production, to induce systemic TNF-α in a murine model of lymphatic filariasis, and to induce corneal inflammation in a TLR2/TLR6–dependent manner. These data indicate that the interaction between these (and likely other) lipoproteins and TLR2/6 in the cornea is essential for the development of *O. volvulus* keratitis.

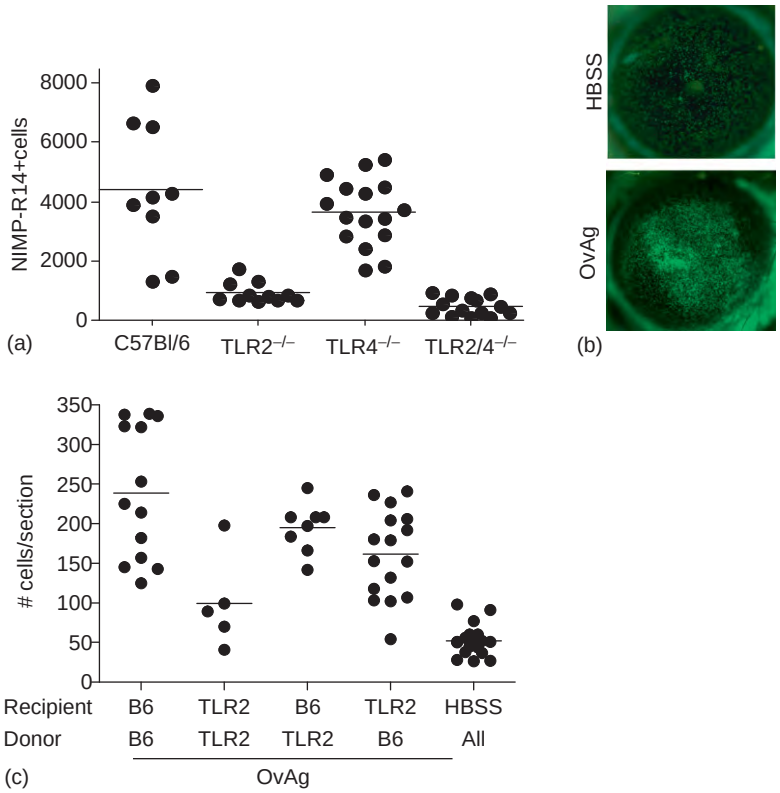

Figure 3 *O. volvulus* /*Wolbachia* keratitis is dependent on TLR2. *O. volvulus* extract containing *Wolbachia* (OvAg) was injected into the corneal stroma of C57BL/6, TLR2$^{-/-}$, TLR4$^{-/-}$ and TLR2/4$^{-/-}$ mice. After 18 h, mice were sacrificed and corneas were examined as described. (a) Single cell suspension was prepared from the corneal stroma, and total neutrophils were detected by flow cytometry using MAb NIMP-R14. (b, c) Bone marrow cells from donor C57BL/6 / eGFP+ and TLR2$^{-/-}$ mice were used to reconstitute sublethally irradiated recipient C57BL/6 or TLR2$^{-/-}$ mice. After 2 weeks, chimeric mice were injected intrastromally with *O. volvulus* extract (OvAg) or saline (HBSS), and 18 h later, 5 μm corneal sections were examined by fluorescence microscopy. Corneal sections were examined for neutrophils by immunohistochemistry. (b) Representative corneas from irradiated C57BL/6 mice reconstituted with C57BL/6 / eGFP+ bone marrow cells. After 2 weeks, mice were either untreated (naive), or examined 24 h after injection with either saline (HBSS) or *O. volvulus* extract (OvAg). (c) Total neutrophils per corneal section. Data points represent individual corneas; these data points are combined from three repeat experiments. Reprinted from Gillette-Ferguson, I., Daehnel, K., Hise, A. G., et al. (2007). Toll-like receptor 2 regulates CXC chemokine production and neutrophil recruitment to the cornea in Onchocerca volvulus/*Wolbachia*-induced keratitis. *Infection and Immunity* 75: 5908–5915.

Conclusion

River blindness appears to be mostly under control due to mass distribution of ivermectin (Mectizan), which kills microfilariae and has led to reduced prevalence of disease. Recent studies targeting *Wolbachia* for antibiotic treatment now demonstrate that doxycycline can also be used to treat infected individuals. This is not only a paradigm shift in treating filarial-infected individuals, but given the risk for ivermectin resistance, also provides a critical second approach to treatment, although this is still at the clinical trial stage. The Bill and Melinda Gates Foundation recently provided funds to develop novel antibiotics as an adjunct treatment for river blindness and lymphatic filariasis, and are described in the anti-*Wolbachia* website. Overall, the increased understanding of the pathogenesis of this disease and targeting *Wolbachia* in particular bring these devastating diseases closer to being controlled.

Acknowledgments

We gratefully acknowledge the contribution of our colleagues in these studies, including Illona Gillette-Ferguson, Amy Hise, Achim Hoerauf and Mark Taylor. This work was supported by NIH grants EY10320 and EY11373, by the Research to Prevent Blindness Foundation and the Ohio Lions Eye Research Foundation.

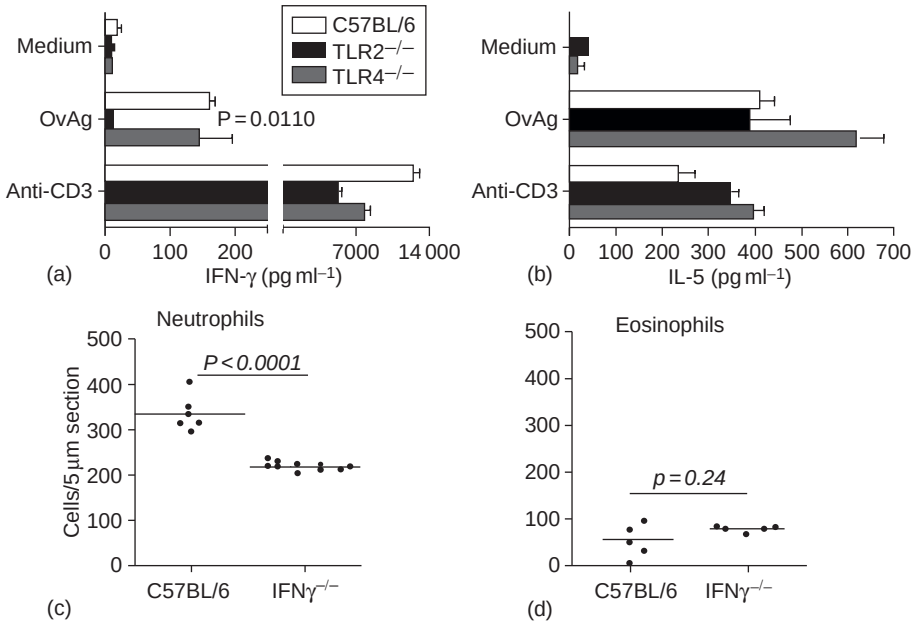

Figure 4 IFN-γ production is dependent on TLR2 and regulates neutrophil recruitment to the corneal stroma. (a, b) Mice were immunized three times with soluble *O. volvulus* extract containing *Wolbachia* (OvAg). After the final immunization, mice were sacrificed and spleens removed for *in vitro* recall response with soluble OvAg. As a positive control, splenocytes were incubated with stimulatory anti-CD3. Cytokine production by splenocytes after 72 h of culture was measured by ELISA. Note TLR2-dependent IFN-γ, but not IL-5 production. (c, d) C57BL/6 and IFNγ$^{-/-}$ mice were immunized 3 times subcutaneously with OvAg, and injected into the corneal stroma with OvAg. After 24 h, 5 μm corneal sections were immunostained for neutrophils or eosinophils, and the number of positive cells in the corneal stroma was assessed by fluorescence microscopy. Each data point represents an individual cornea, and the experiment was repeated 3 times. Note IFN-γ-dependent recruitment of neutrophils, but not eosinophils to the cornea. Immunopathogenesis of Pseudomonas Keratitis

L D Hazlett, Wayne State University School of Medicine, Detroit, MI, USA

Glossary

Akt1 – Also known as Akt or protein kinase B, it is an important molecule in mammalian cellular signaling and inhibits apoptotic processes.
Eicosanoids – Signaling molecules made by oxygenation of 20-carbon essential fatty acids. There are four families of eicosanoids: the prostaglandins, prostacyclins, thromboxanes, and the leukotrienes.
IRF1 (interferon regulatory factor 1) – A member of the interferon regulatory transcription factor family. IRF1 serves as an activator of interferons alpha and beta transcription, and in mouse it has been shown to be required for double-stranded RNA induction of these genes. IRF1 also functions as a transcription activator of genes induced by interferons alpha, beta, and gamma. Further, IRF1 has been shown to play roles in regulating apoptosis and tumor-suppression.
Keratitis – A condition in which the cornea becomes inflamed. The condition is often marked by moderate to intense pain and usually involves impaired eyesight.
LPS (lipopolysaccharide, endotoxin) – Major outer membrane component of Gram-negative bacteria comprising a lipid A core (endotoxin) and polysaccharide of varying length and composition. Toll-like receptor 4 (TLR4) and MD2 (myeloid differentiation 2) bind to the lipid A moiety.
MAPK (mitogen-activated protein kinase) – Serine/threonine-specific protein kinases that respond to extracellular stimuli (mitogens) and regulate various cellular activities, such as gene expression, mitosis, differentiation, and cell survival/apoptosis.
Matrix metalloproteinase-9 (MMP-9) – Gelatinase B, 92 kDa gelatinase, 92 kDa type IV collagenase is a biological enzyme. Proteins of the MMP family are involved in the breakdown of extracellular matrix in normal physiological processes, as well as in disease processes. Most matrix metalloproteinases (MMPs) are secreted as inactive pro-proteins which are activated when cleaved by extracellular proteinases. The enzyme encoded by this gene degrades type IV and V collagens.
NF-κB (nuclear factor-kappa B) – A protein complex that is a transcription factor. NF-κB is found in almost all animal cell types and is involved in cellular responses to stimuli such as stress, cytokines, free radicals, ultraviolet irradiation, and bacterial or viral antigens.
Peroxynitrite – An anion, with the formula $ONOO^-$, it is an unstable valence isomer of nitrate, NO_3^-, which has the same formula but a different structure. Although peroxynitrous acid is highly reactive, its conjugate base, peroxynitrite is stable in basic solution.
SIGIRR (single immunoglobulin interleukin 1 receptor (IL-1R)-related protein) – An inhibitory member of this receptor superfamily. SIGIRR seems to temper cellular activation by IL-1, LPS, and probably other activators of receptors in the TLR–IL-1R superfamily, such that the biological outcome will be the result of a balance between activation by a receptor and dampening by SIGIRR. SIGIRR therefore acts as a brake on the TLR system, which may be essential for regulating the detrimental effects of innate immunity, as occurs in sepsis and chronic inflammation.
siRNA (short interfering RNA or silencing RNA) – A class of 20–25 nucleotide-long double-stranded RNA molecules that play a variety of roles in biology. Most notably, siRNA is involved in the RNA interference pathway, where it interferes with the expression of a specific gene.
T helper (Th) 1 (e.g., predominant IL-12 and interferon gamma production) and Th2 (predominant IL-4, 5, 10, 13) response – Response involving effector T cells that play an important role in establishing and maximizing the capabilities of the immune system.

Introduction

In the United States, microbial keratitis is frequently associated with complications resulting from use of extended wear contact lenses with an incidence of about 30 000 cases annually. The cost of treatment is estimated at between $15 and $30 million, representing a considerable medical and economic impact. Of the bacterial organisms able to induce keratitis, *Pseudomonas aeruginosa* remains an important Gram-negative pathogen. The bacteria is often referred to as opportunistic, as it is capable of inducing keratitis not only in extended wear contact lens users, but

also in more tropical climates, and in patients that are either debilitated or hospitalized. Most of the complications of bacterial keratitis are structural alterations of the cornea, but other sight-threatening problems include development of secondary glaucoma and cataract. These consequences are largely caused by the host's inflammatory response, but the influence of bacterial toxins, exoproducts, and toxicity from antibiotic treatment cannot be overlooked. There is also a recent increase in the incidence of reported antibiotic resistant strains and failure of an initially promising treatment using antimicrobial peptides to manage keratitis, suggesting that better understanding of the pathogenic mechanisms of disease induction by this pathogen will be critical to development of improved therapeutic strategies.

P. aeruginosa, like most other microorganisms, typically requires surface injury to permit corneal invasion. Because it has few nutritional requirements, it can adapt to a variety of ecological conditions and niches, such as preserved ophthalmic solutions and the hospital environment. Pseudomonal and other Gram-negative bacterial infections often present as a rapidly progressing, suppurative stromal infiltrate with a marked mucopurulent exudate. Yellowish coagulative necrosis surrounded by inflammatory epithelial edema is distinctive and stromal ulceration can lead to stromal tissue destruction and vision loss. A ring infiltrate may appear in the surrounding paracentral cornea and hypopyon (a dense inflammatory coagulum) is usually present; in addition, descemetocele (ulcer penetrated through cornea) formation or corneal perforation are not uncommon. Animal models of bacterial keratitis continue to be of value in the study of this disease and are produced by topical bacterial application after abrading the epithelium, by intrastromal inoculation, or by placing a contaminated suture or contact lens on the cornea. These approaches and models have led to increased understanding of the mechanisms of corneal inflammation and innate immunity that are operative in bacterial keratitis.

Bacterial eradication by neutrophils (PMN) involves phagocytosis, lysosomal degranulation and bacterial killing within the acidic lysosomal compartment of the cell. Phagocytosis and intracellular degranulation by PMN also involve oxidative attack, production of toxic oxygen metabolites, triggering of the respiratory burst, biosynthesis of superoxide anions, and other oxidizing agents such as hydrogen peroxide and formation of peroxynitrite. Phagocytic secretion and lysis result in release of extracellular lysosomal enzymes, including, but not limited to, elastase, collagenase and myeloperoxidase (MPO). These enzymes and the oxygen-derived free radicals cause stromal destruction by breaking down collagen, digesting glycosaminoglycans, and disrupting stromal keratocytes. Nitric oxide (NO) also mediates vasodilation and can be important in bacterial killing as well as in bystander tissue damage. These and other substances released from activated PMN and other inflammatory cells (e.g., macrophages, Mϕ) contribute to stromal necrosis and corneal edema during bacterial disease. Bacterial endotoxin and exotoxins also stimulate Mϕ to release biologically active substances including, but not limited to, interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF)-α, cytokines that synergize to elicit inflammatory events. Selected cytokines, certain eicosanoids, and other molecular mediators are also involved in ulceration and angiogenesis during bacterial keratitis.

Maintenance of leukocyte recruitment during inflammation requires intercellular communication between infiltrating leukocytes, the epithelium, neuropeptides such as substance P (SP) and vasoactive intestinal peptide (VIP), vascular endothelium, and resident stromal cells. These events are mediated by generation of early response cytokines (e.g., IL-1), the expression of adhesion molecules such as intercellular adhesion molecule-1, and the production of chemotactic cytokines and chemokines.

PMN, Cytokines, and Chemokines

If leukocytes such as PMN persist within the cornea, destructive pathology ensues, including stromal scarring and perforation, potentially requiring corneal transplantation. PMN infiltration into inflamed tissue is controlled largely by local production of inflammatory mediators. In the mouse, two members of the CXC family of chemokines, MIP-2 (functional homolog of human IL-8) and KC, are potent chemoattractants and activators of PMN. In corneal infections, MIP-2 has been shown to be the major chemokine that attracts PMN into the *P. aeruginosa* infected cornea and persistence of PMN in the cornea of susceptible (cornea perforates) C57BL/6 versus resistant BALB/c (no corneal perforation) mice (Table 1) was found to correlate with higher MIP-2 chemokine levels (both mRNA and protein). IL-1, produced by Mϕ, monocytes, and resident corneal cells also influences PMN infiltration into tissues. When tested, IL-1α and β (mRNA and protein) were elevated in the infected cornea of C57BL/6 over BALB/c mice. Furthermore, after infection, MMP-9 was shown to upregulate chemotactic cytokines/chemokines (IL-1β and MIP-2), contribute to degradation of collagen IV, and overall, enhanced *P. aeruginosa* keratitis. In contrast, neutralization of IL-1β in infected C57BL/6 mice reduced

Table 1 Response to *P. aeruginosa* corneal infection in mice

C57BL/6 (B6)	*BALB/c*
Th1 responder	Th2 responder
Corneal perforation	Corneal healing
IFN-γ, IL-12	IFN-γ, IL-10

disease severity, evidenced by reduction of PMN in cornea (MPO assay), decreased bacterial load, and decreased levels of MIP-2 at both the mRNA and protein levels. The use of caspase 1 (enzyme that processes IL-1β to generate the mature cytokine) inhibitor treatment in C57BL/6 mice confirmed these data, even when inhibitor treatment was initiated 18 h after disease onset. In addition, improvement was augmented when the caspase 1 inhibitor was given after infection together with the antibiotic ciprofloxacin. A live attenuated *P. aeruginosa* vaccine also has been tested and found to elicit outer membrane protein-specific active and passive protection against corneal infection.

T Cells and IL-12

The role of other cells, such as T cells in *P. aeruginosa* corneal infection, was first studied in inbred C57BL/6 wild type and cytotoxic, CD8(+) T deficient, β2 microglobulin knockout mice (on the C57BL/6 background). Corneas of both groups of mice perforated by 7 days post-infection (p.i.) and histopathology was similar, with infiltration of PMN within 24 h p.i. In contrast, corneas of wild-type mice antibody depleted of helper, CD4(+) T cells and infected with *P. aeruginosa* did not perforate at 7 days p.i., versus mice depleted of CD8(+) T cells or treated with an irrelevant antibody. Antibody neutralization of IFN-γ before infecting C57BL/6 mice also prevented corneal perforation and was associated with a lower delayed type hypersensitivity response when compared with C57BL/6 mice similarly treated with an irrelevant antibody. These data support that a CD4(+) T cell T helper type 1 (Th1) dominant response following *P. aeruginosa* infection is associated with genetic susceptibility and corneal perforation in C57BL/6 mice and provided the first evidence that CD4(+) T cells are important in development of severe keratitis and eventual corneal perforation. In addition, use of gene array studies confirmed a Th1 versus Th2 bias of C57BL/6 versus BALB/c mice to infection with *Pseudomonas*. Other studies investigated whether IL-12 (IL-12 p40) was associated with IFN-γ production and the susceptibility response of C57BL/6 mice after *P. aeruginosa* challenge. IL-12 p40 knockout mice (C57BL/6 background) versus wild-type mice were tested to examine disease progression in endogenous absence of the cytokine. When tested, both groups of mice were susceptible to corneal challenge with *P. aeruginosa* and corneal perforation was observed at 5–7 days p.i. Semi-quantitative reverse transcription polymerase chain reaction (RT-PCR) and enzyme-linked immunosorbent assay analyses confirmed that IL-12 p40 message and protein levels were elevated after infection in the wild type over the expected absence of IL-12 p40 in the knockout mouse cornea. Immunostaining for IL-12 in wild-type C57BL/6 mice revealed that stromal PMN were at least one source of the cytokine.

IL-18 and IFN-γ

The role of IL-18 and IFN-γ production in the resistance response of the predominantly Th2 responding BALB/c mouse was also tested. Semi-quantitative RT-PCR detected IFN-γ mRNA expression levels in the cornea of infected mice at 1–7 days p.i. Cytokine levels were significantly upregulated when compared with control, uninfected normal mouse corneas. Using RT-PCR, IL-18 mRNA expression was detected constitutively in the normal, uninfected cornea, but levels were significantly elevated 1–7 days p.i. To test whether IL-18 regulated IFN-γ production, BALB/c mice were injected with an anti-IL-18 monoclonal antibody. Treatment decreased corneal IFN-γ mRNA levels and both bacterial load and disease severity increased when compared to immunoglobulin G injected control mice. Data provided evidence that IL-18 is critical to the resistance response of BALB/c mice by induction of IFN-γ and that IFN-γ is required for bacterial killing/stasis in the cornea. Another separate study showed that the killing effect of IFN-γ was indirect, through regulation of NO levels in the infected cornea.

IFN-γ and SP

Further study of the resistance response in BALB/c mice examined the role of the pro-inflammatory neuropeptide, SP in IFN-γ production. This study provided evidence that natural killer (NK) cells were required to produce IFN-γ; that the cells expressed the neurokinin-1 receptor (NK1R, the major SP receptor); and that they directly and tightly regulated IFN-γ production through SP interaction with this receptor, suggesting a unique link between the nervous system and development of innate immunity in the cornea. On the other hand, a disparate distribution of SP in the infected cornea of susceptible C57BL/6 (higher levels) versus resistant BALB/c (lower levels) mice also has been documented and blocking the interaction of SP with its major receptor (NK1R) in C57BL/6 mice improved disease outcome, supporting a role for SP in development of the susceptible phenotype after *P. aeruginosa* corneal infection. Thus, the amount of SP and its interaction with available NK1R sites after infection contributes either to resistance or susceptibility, and appears an important component of keratitis outcome in these murine models.

Neuropeptides

SP

In this regard, SP involvement in the pathophysiology of inflammatory disease generally has been evidenced by aberrant levels of SP and SP containing nerve fibers,

as well as NK1R, in diseased tissues. SP has been shown to elicit cytokine secretion (IL-2, IL-4, IL-10, and IFN-γ) from mouse T cells. In addition, it was demonstrated that human bronchial epithelial cells produce IL-6, IL-8, and TNF-α after SP treatment. SP-induced cytokine production and secretion by leukocytes, including T cells, Mϕ, and dendritic cells leads to the release of a number of inflammatory mediators such as additional cytokines, oxygen radicals, arachidonic acid derivatives, and histamine, all of which further amplify the inflammatory response.

VIP

Recent studies have also provided ample evidence for another neuropeptide, VIP, functioning as a potent endogenous anti-inflammatory molecule affecting the immune response antithetically when compared to SP. VIP regulates inflammatory mediators via several transduction pathways and transcription factors essential for gene activation, such as nuclear factor-kappa B, interferon regulatory factor-1 (IRF-1), mitogen-activated protein kinase (MAPK), and cAMP response element. VIP downregulates the production of several pro-inflammatory cytokines, including: TNF-α, IL-1, IL-6, IL-12, and IFN-γ, while stimulating production of anti-inflammatory cytokines IL-10, IL-1 receptor (R) antagonist, and TGF-β. Investigation of the effect of VIP in a murine endotoxin challenge model showed that after treatment with VIP, levels of TNF-α and IL-6 in serum and peritoneal fluid were reduced by almost 50%. Regarding the eye, VIP treatment converted the susceptible phenotype (corneal perforation) to resistant (no perforation) in a mouse model of *P. aeruginosa*-induced infection via downregulation of pro-inflammatory mediators, upregulation of anti-inflammatory molecules, and modulation of host inflammatory cell activation. Thus VIP, a 28-amino-acid peptide, delivered by several types of neurons to immune organs and lymphoid tissues in the heart, gastrointestinal tract, lungs, kidney, cornea and skin, is anti-inflammatory. In fact, evidence indicated a differential response to VIP between infected BALB/c (more) and C57BL/6 (less) mice, due to disparate VIPR1 expression by Mϕ (which can be induced in a dose-dependent manner by VIP itself). Mϕ are known to play a key role in regulating/balancing pro- and anti-inflammatory activity in the resistant (BALB/c) and susceptible, C57BL/6 murine models; therefore, evidence that VIP influences the functional behavior of these cells further supports a more salient role for this neuropeptide in regulating the inflammatory response.

TLR

Mouse eye infection models have also been used to study the role of Toll receptors in disease. The Toll family of receptors, conserved throughout evolution from flies to humans, is central in initiating innate immune responses. This family of receptors, composed of trans-membrane molecules, links the extracellular compartment where contact and recognition of microbial pathogens occurs and the intracellular compartment, where signaling cascades leading to cellular responses are initiated. Gene array data showed that the expression of TLRs and related molecules including CD14, soluble IL-1 receptor antagonist, TLR-6, and IL-18R-accessory-protein were significantly elevated in susceptible (C57BL/6) versus resistant (BALB/c) mice following challenge with *P. aeruginosa*. In another model system involving induction of sterile keratitis, when C3H/HeJ (Toll-like receptor 4, TLR4, point mutation) versus control mice were treated with lipopolysaccharide (LPS) from *P. aeruginosa,* a significant increase in stromal thickness and haze was seen in the cornea of TLR4 sufficient control, but not in TLR4 deficient mutant mice. The severity of disease coincided with PMN stromal infiltration, indicating that TLR4 signaling enhances corneal disease. In contrast, in a bacterial keratitis model, TLR4 mRNA expression was markedly increased in the cornea of resistant BALB/c mice after bacterial infection. These data led to testing corneas from TLR4-deficient and wild-type control (BALB/c) mice after challenge with live *P. aeruginosa* to determine the role of TLR4 in bacterial keratitis. Given that TLR4 deficiency was suggested to be protective in sterile keratitis, we might predict that corneas of TLR4-deficient mice would be less susceptible and exhibit a decreased inflammatory response to bacterial infection. In marked contrast, TLR4-deficient versus control mice exhibited significantly increased inflammation and corneal perforation instead of healing after infection. Furthermore, data from clinical score, slit lamp, and histopathology confirmed that TLR4-deficient versus wild-type control mice exhibited significantly increased corneal disease with more opacity and more severe stromal swelling and destruction. In addition, bacterial load (more than 10-fold higher) and PMN recruitment (MPO activity) were markedly upregulated in the infected cornea of TLR4-deficient versus TLR4-sufficient control mice. The data provide strong evidence that TLR4 is required for the resistance response of BALB/c mice to *P. aeruginosa* challenge and, unlike the sterile keratitis model, TLR4 is required for disease resolution in bacterial keratitis.

Overall, it appears conflicting that TLR4 is critical in the pathology of corneal disease in sterile keratitis, while it is protective in bacterial keratitis and required for host resistance. In fact, these data illustrate the characteristic double-edge sword activity of TLR4 activation. On the one hand, in the keratitis model, TLR4 recognized LPS, a component of *P. aeruginosa,* and initiated an innate immune response that was important for bacterial clearance. TLR4 deficiency impaired bacterial clearance, led

to overgrowth of bacteria, an overwhelming PMN infiltrate and excessive pro-inflammatory cytokine production. This in turn contributed to corneal destruction and perforation. In the sterile keratitis model, activation of LPS-TLR4 signaling in TLR4 sufficient mice, lead to pro-inflammatory cytokine production and PMN infiltration, increased stromal thickness and contributed to haze production which increased, albeit transiently, corneal perturbation when compared with TLR4 mutant mice.

Negative regulators of TLR are also of importance and recent evidence showed that one of them, single immunoglobulin IL-1R related molecule is differentially expressed in BALB/c (resistant) versus C57BL/6 (susceptible) mice. This Toll receptor is critical in resistance to *P. aeruginosa* infection in BALB/c mice, functioning to downregulate type 1 immunity and negatively regulating sustained IL-1 and TLR4 signaling. siRNA treatment to knockdown TLR9 was also found to influence the outcome of bacterial keratitis, and lead to reduced inflammation, but with the unwanted effect of decreased bacterial killing.

Apoptosis

Delay in apoptosis in bacterial keratitis, as evidenced by terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) staining, also contributes to corneal perforation in C57BL/6 mice. Consistent with this finding, Bcl-2, an anti-apoptotic gene, was significantly upregulated in C57BL/6 mouse cornea at 18 h p.i., suggesting that the delayed onset of apoptosis in C57BL/6 mouse cornea may be, in part, due to upregulation and signaling of this gene. These data are also consistent with previous studies showing that over-expression of Bcl-2 reduces lymphocyte apoptosis in *P. aeruginosa*-induced pneumonia.

In the process of apoptosis, execution of cells largely depends on proteolytic cleavage and activation of caspase 3. In this regard, BALB/c versus C57BL/6 mouse cornea expressed more intense staining for activated caspase 3 at 1 day p.i. compared to the delayed peak intensity in C57BL/6 mice. The two mouse groups were also disparate for expression of caspase 9, with significantly more mRNA expression in BALB/c over C57BL/6 mice. Although only hypothetical, these data suggest that different pathways of apoptosis may be operative in the infected cornea of the two groups of mice. Our studies, using a combination of TUNEL and immunostaining, as well as PMN depletion, also provided evidence that the corneal apoptotic cells identified in both groups of mice were predominantly PMN and confirmed that apoptosis of these cells is delayed in C57BL/6 mice. We hypothesize that earlier apoptosis of PMN in resistant BALB/c mice is consistent with effective elimination of invading bacteria, while inducing minimal tissue damage due to unresolved and persistent inflammation.

Neuropeptides

The balance between apoptosis and cell survival, as well as the tissue milieu and timing of apoptosis, is critical in immune defense. In this regard, the neuropeptide SP, mentioned above, is a potent anti-apoptotic regulator and can exacerbate inflammation.

SP has been shown to stimulate phosphorylation of the anti-apoptotic molecule Akt in colonic mucosa both *in vivo* and *in vitro*, preventing apoptosis in humans with colitis. In another *in vitro* study, SP induced p53, Bcl-2, and NO expression in peritoneal Mϕ, blocking apoptotic signals. SP delays spontaneous apoptosis of PMN in a dose-dependent fashion by its interaction with the NK1R *in vitro*, and this effect could be inhibited by application of the NK1R antagonist GR82334.

In this regard, C57BL/6 mice treated with another NK1R antagonist, Spantide I, showed significantly improved disease outcome and an earlier onset of apoptosis, similar to the pattern observed in naturally resistant BALB/c mice. Consistent with earlier onset of apoptosis, mRNA expression of caspase 3 was also significantly upregulated earlier in the cornea of Spantide I, versus control treated animals. The data suggest that the protective mechanism of Spantide I treatment in C57BL/6 mice involves induction of earlier PMN apoptosis in the infected cornea, with less bystander tissue damage. Whether in C57BL/6 mice, the effects of Spantide I are directly mediated via the PMN or indirectly through Mϕ regulation of PMN also required resolution. Clodronate depletion of Mϕ with or without Spantide I treatment revealed that in the absence of the Mϕ, apoptosis was reduced/absent in the cornea. To further explore the role of this cell in susceptibility and resistance, Mϕ from both groups of mice (C57BL/6 and BALB/c) were incubated in the presence of SP together with LPS or with LPS alone. Significantly fewer apoptotic cells were detected in cells from C57BL/6 mice in the presence of SP and LPS versus LPS alone, while the same combined treatment (SP and LPS) did not decrease the number of LPS induced apoptotic Mϕ from BALB/c mice. To determine the mechanism for the disparate response to SP treatment between Mϕ from the two mouse groups, expression levels of the NK1R were comparatively tested. Although cells from both groups expressed the receptor, with a slightly weaker signal in BALB/c cells, after LPS stimulation, mRNA expression for the NK1R was only detected in cells from C57BL/6 mice. These data suggest that the possible mechanism for the absence of the anti-apoptotic effects observed in BALB/c Mϕ after SP treatment may involve a low level of NK1R expression on the cells and possible rapid depletion of the receptor upon LPS stimulation. In this regard, VIPR1, the major receptor for the neuropeptide VIP, was also reported to be expressed disparately in Mϕ from C57BL/6 (less) versus BALB/c (more) mice.

Figure 1 *P. aeruginosa* infection in Marmoset monkey model.

Mϕ also may provide distinct activation signals for Th1/Th2 differentiation. In this regard, others have reported that *Leishmania major* infected Mϕ enhanced the proliferation and IL-4 secretion of Th2 T cells, but inhibited the response of Th1 T cells. When testing for this possibility, we detected that Mϕ from C57BL/6 mice expressed significantly more IL-12, while BALB/c Mϕ expressed more IL-10 after LPS stimulation. IL-10 appears protective in the BALB/c infected cornea, as after subconjunctival injection of clodronate-containing liposomes to deplete these cells, higher levels of IFN-γ and lower levels of IL-10 were detected and resistant mice were converted to the susceptible phenotype. It was also reported that VIP treated C57BL/6 mice showed improved disease outcome and increased IL-10 expression after *P. aeruginosa* corneal infection. Furthermore, the data suggest that SP, which acts in an anti-apoptotic manner toward activated C57BL/6 mouse Mϕ, may also enhance an IL-12 driven, Th1 type immune response and thus further contribute to the susceptibility of this mouse strain to *P. aeruginosa* infection.

New Animal Model

Without doubt, experimental animal models of bacterial infection with *P. aeruginosa* have provided us with important insights into mechanisms underlying ocular infection and inflammation and our understanding of the effector and regulatory mechanisms involved in disease continues to grow. However, our understanding and knowledge of the precise mechanisms operative in human cases of keratitis (sterile and infectious) remains much more limited. In this regard, development of a new primate model of keratitis would be a timely and important translational approach to facilitate eventual human application of what has been learned in rodent and other species. The Marmoset monkey, with 98% homology to the human genome, provides such a model. Initial studies have been undertaken in the monkey and show that with scarification of the cornea (similar to that done in the mouse), infection can be initiated and progresses similar to the human pattern. A photograph of the new animal model is provided in Figure 1. This model will allow us to explore treatment paradigms that have been efficacious in the mouse and other rodent species and may more quickly result in clinical trial of successful candidates.

Immunosuppressive and Anti-Inflammatory Molecules that Maintain Immune Privilege of the Eye

A W Taylor, Schepens Eye Research Institute, Boston, MA, USA

Glossary

Adaptive Immunity – The part of the immune system utilizing T cells and B cells that adapt to specifically target, eliminate, and prevent pathogenic infections. Through adaptive immunity, immunological memory is established to further adapt immunity to mount stronger responses each time the pathogen is encountered.

Immune homeostasis – The state of immunity in a stable, unperturbed tissue environment.

Immune privilege – The immune status of the ocular microenvironment that has evolutionally adapted itself to prevent the induction of excess inflammation, thereby protecting its delicate structures from the damages of inflammation. It is also defined as any tissue site, such as the brain and eye, which affords survival of incompatible grafts without immunosuppressive therapy.

Innate immunity – A more primitive defensive mechanism against infecting pathogens. The activation of innate immunity is through pathogen-associated molecules that bind specific recognition receptors on innate immune cells. Innate immunity is associated with phagocytosis, complement activation, and infiltration of neutrophils and macrophages.

Neuropeptides – The low-molecular-weight proteins that are found in, and released from, centrally derived neurons; however, their production is not limited to neurons. They are produced by cells of endocrine glands, immune cells, and cells that make up immune-privileged tissue microenvironments.

Immunosuppression and Anti-Inflammatory Activity in Aqueous Humor

The immune-privileged microenvironment of the eye suppresses the induction of inflammation. One of the most dominant mechanisms of this suppression, by which the immune-privileged eye prevents induction of inflammatory immunity, is the manipulation of the functionality of immune cells that enter the ocular microenvironment. A well-characterized set of neuropeptides that targets specific immune cells and their activities mediates this manipulation. The result of this immunosuppression and immunoregulation is the induction of immune cells that are not only prevented from expressing proinflammatory functionalities, but also regulate other immune cells. The regulatory activity itself is not unique; it occurs at the resolution of immune responses and is part of the mechanisms that prevent the induction of autoimmunity. These are the mechanisms of immune homeostasis that tailor the immune response, and prevent uncontrolled immunity. What is unique is that within the ocular microenvironment these mechanisms are constantly active, and are mediated by constitutively present soluble factors that provide the eye with its unique form of immune homeostasis.

Over the past two decades, we have come to understand that the ocular microenvironment is rich with immunosuppressive molecules that influence the activity of immune cells. Many of these molecules are found in the aqueous humor. The first indication that soluble mediators in the eye manipulate the function of immune cells was the finding that aqueous-humor-treated macrophages process and present antigen in a manner that promotes activation of suppressor T cells. This activity is associated with a phenomenon of systemic antigen-specific immunosuppression induced by placing an antigen into the anterior chamber of the eye. This phenomenon is called anterior-chamber-associated immune deviation (ACAID), which may be responsible for the highly successful acceptance of corneal grafts, and may be important in the survival of ocular stem cell and retinal transplants.

Macrophages and dendritic cells stimulated with bacterial products that activate innate immune-mediated inflammation fail to mediate inflammation when they are treated with aqueous humor. The expected promotion of macrophages and dendritic-cell-antigen-presenting cell functionality to promote proinflammatory T-cell activation are also suppressed by aqueous humor treatment. Moreover, aqueous-humor-treated macrophages and dendritic cells produce anti-inflammatory cytokines, and present antigens in a manner that promotes immune regulation. Therefore, resident ocular macrophages and dendritic cells, while still able to respond to infectious agents and unhealthy cells, are inhibited from mediating an inflammatory response. It is not completely understood how aqueous humor manipulates the functionality of macrophages. It is possible that ocular resident macrophages function perfectly well in

clearing and defending the ocular microenvironment from a pathogen, but cannot recruit other immune cells to help control the infection through inflammation, or to mediate an effective wound response.

T cells treated with aqueous humor are inhibited in proliferation, cytotoxic activity, and production of proinflammatory cytokines. The $CD4^+$ T cells treated with aqueous humor are not only suppressed in their production of the proinflammatory cytokine interferon-gamma (IFN-γ), but they also produce the regulatory cytokine, transforming growth factor-beta (TGF-β). This change in cytokine production is associated with a change in T-cell functionality from inflammatory to regulatory. The resistance of the ocular microenvironment to the activation of inflammation mediated by T cells is seen when T cells that mediate delayed-type hypersensitivity are placed into the anterior chamber of the eye along with antigen and antigen-presenting cells. These T cells normally mediate inflammation if injected into the skin, a conventional immune site, with their antigen and antigen-presenting cells; however, in the anterior chamber, the T cells do not mediate inflammation. In addition, treating the T cells *in vitro* with aqueous humor and then transferring them into the skin fails to produce inflammation. Moreover, aqueous-humor-treated T cells function as regulatory T cells that can suppress the activation of other hypersensitivity-mediating T cells. Therefore, the constitutive immunoregulation and immunosuppressive soluble factors of aqueous humor prevent the activation of inflammatory immunity while turning the immune response onto itself to further regulate the immune response within the immune-privileged ocular microenvironment.

There is an ever-growing list of identified factors in aqueous humor that have the potential to suppresses and regulate immunity (**Table 1**). Neuropeptides form a major group of these factors and most of these factors are found throughout the eye, suggesting that they regulate immunity in all tissue sites of the ocular microenvironment. The factors important for the regulation of T-cell activation and innate immunity in aqueous humor are TGF-β, alpha-melanocyte-stimulating hormone (α-MSH), calcitonin-gene-related peptide (CGRP), somatostatin (SOM), and vasoactive intestinal peptide (VIP) (**Figure 1**). Other factors, such as Fas ligand (FasL), maybe important in eliminating activated T cells within the ocular microenvironment, and factors such as macrophage migration inhibitory factor (MIF), and complement inhibitors are important in the regulation of innate immunity. In addition to neuropeptides, the retina produces thrombospondin-1 (TSP-1), and pigment epithelium-derived factor (PEDF), which influence the activation and regulation of immunity. It is the collective activity of these molecules within an intact blood–ocular barrier that maintain the unique immune homeostasis of the ocular microenvironment, a process called immune privilege.

Table 1 Immunoregulating and immunosuppressive factors of ocular immune privilege

Immune response	*Regulation*	*Factors*
Innate immune-mediated inflammation[a]	Suppression	α-MSH, CGRP, PEDF, MIF, CRP[e]
Adaptive immune-mediated inflammation		
APC[b]	Suppression	α-MSH, CGRP, VIP, TGF-β2
T cell[c]	Suppression	TGF-β2, α-MSH, VIP, SOM, FasL
Regulatory immunity		
ACAIDogenic APC[d]	Induce	TGF-β2, TSP-1
Treg cells	Induce	α-MSH, TGF-β2, SOM

[c]Assayed for antigen-stimulated T-cell production of proinflammatory cytokines, proliferation, cytotoxic activity, and survival.
[d]Assayed in an adoptive transfer of treated APC for induction of immune deviation.
[e]Complement regulatory proteins.

The Immunoregulatory and Immunosuppressive Factors of The Immune-Privileged Eye

Transforming Growth Factor-Beta

TGF-β was the first identified immunosuppressive factor in aqueous humor. While it is common to discuss TGF-β in a generic manner, the most interesting aspect of the TGF-β produced in the eye is that a single isoform, TGF-β2, is the dominant form found in aqueous humor, with very little of the other forms of TGF-β being present in the aqueous humor. The dominant expression of TGF-β2 over the other isoforms of TGF-β is a common feature of neurological tissues. The significance of expressing TGF-β2 over the other isoforms of TGF-β is not known. In addition, TGF-β is normally expressed in a latent form, requiring activation by other enzymes or binding proteins. It is through TGF-β2 that aqueous humor induces ACAID-mediating antigen-presenting cells (APCs). Treating macrophages *in vitro* with TGF-β2 induces the characteristics of the aqueous-humor-induced and the *in-vivo*-induced ACAID APCs. When exposed to TGF-β2, the macrophages increase their expression of the surface marker F4/80, and have reduced expression of co-receptors needed in T-cell activation. The macrophages express anti-inflammatory cytokines of interleukin-10 (IL-10) and activated TGF-β. The activated TGF-β production by the macrophages is probably associated with an

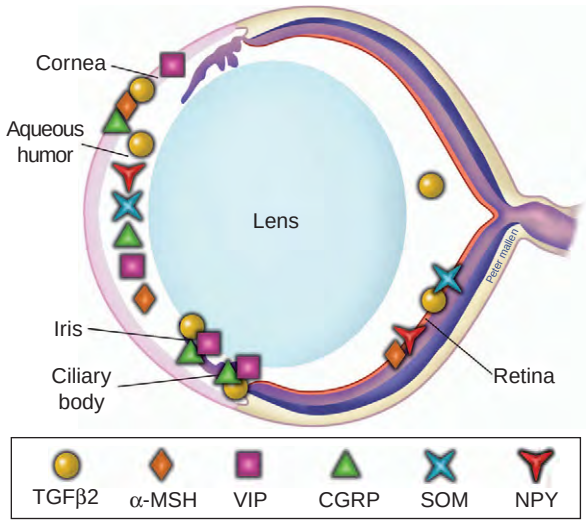

Figure 1 Distribution of soluble immunomodulating proteins in the eye. TGF-β, transforming growth factor-beta; α-MSH, alpha-melanocyte-stimulating hormone; VIP, vasoactive intestinal peptide; CGRP, calcitonin-gene-related peptide; SOM, somatostatin; NPY, neuropeptide Y. Adapted from Taylor, A. W. (2009). Neuropeptides, aqueous humor, and ocular immune privilege. In: Troger, J., Kieselbach, G., and Bechrakis, N. (eds.) *Neuropeptides in the Eye*, pp. 79–91. Research Signpost, Kerala, India.

autocrine pathway involving TSP-1. This induction of ACAID-inducing APCs is not limited to the anterior chamber and aqueous humor. Injecting antigen into the retina induces a similar immune deviation involving TGF-β and TSP-1 as well. While the phenomenon of ACAID is an antigen-specific systemic immunosuppression initiated by ACAIDogenic APCs that migrate to the spleen, it is not clear how these APCs may function within the ocular microenvironment. Macrophages or dendritic cells that take up residence with the ocular microenvironment will likely be exposed to some level of activated TGF-β2, and as a result, they express low levels of molecules that promote T-cell action, and simultaneously produce anti-inflammatory cytokines. There is evidence to support this hypothesis. Expression of antigen-presenting molecules within the ocular microenvironment is rarely detected. However, the expression of anti-inflammatory cytokines, such as IL-10, has not been found in abundance in normal aqueous humor. This suggests that while the presentation of antigen by resident APCs in the eye is impaired by TGF-β, other functionalities induced by TGF-β *in vitro* may not occur within the ocular microenvironment. Some of the suppression of T-cell activation by aqueous humor may involve TGF-β2; however, neutralization of TGF-β2 in aqueous humor does not eliminate all of the T-cell suppression by aqueous humor. Aqueous-humor-treated T cells function as regulatory T cells, which produce TGF-β and suppress the action of other T cells. Therefore, it appears that one of the effects of TGF-β2 in the ocular microenvironment is the suppression of antigen presentation that promotes inflammatory T-cell activation. If there is activation, it results in the generation of immune cells that produce additional TGF-β that further promotes immune privilege.

Alpha-Melanocyte-Stimulating Hormone

The neuropeptide α-MSH is a 13-amino-acid-long neuropeptide that is derived from sequential endoproteolytic cleavage and post-translational modifications of the protein proopiomelanocortin (POMC) hormone. Originally described for its melanin-inducing activity in frogs, α-MSH has a fundamental role in modulating inflammatory responses. Injections of α-MSH suppress systemic inflammatory responses to endotoxin, and proinflammatory cytokines such as IL-1 and tumor necrosis factor (TNF). Its anti-inflammatory activity is greatest on macrophages, dendritic cells, and neutrophils where it can suppress the induction of reactive oxygen intermediates, nitric oxide, proinflammatory cytokine production, and immune cell migration. It also enhances its own receptor expression and production in macrophages, which in turn, promotes an anti-inflammatory autocrine loop. α-MSH also induces IL-10 production by macrophages and dendritic cells. The anti-inflammatory activity of aqueous humor resembles the anti-inflammatory activity of α-MSH. α-MSH is constitutively present in the aqueous humor in pg ml^{-1} amounts that are highly anti-inflammatory. In aqueous humor, α-MSH has two roles: it suppresses proinflammatory cytokine production by endotoxin-stimulated macrophages and it induces regulatory activity in T cells. While α-MSH suppresses proinflammatory cytokine production, it does not affect antigen presentation other than causing the APCs to present antigen in a manner that does not promote inflammatory T-cell activation. α-MSH-treated macrophages that are stimulated with endotoxin have their intracellular signaling pathway from endotoxin-bound receptors blocked by α-MSH treatment. Thus, instead of a classically activated macrophage producing proinflammatory cytokines and anti-microbial molecules, it produces anti-inflammatory cytokines. This suggests that the ocular microenvironment has a pathway to clear microbial molecules or pathogens without inducing an inflammatory response. Whether this is an effective process is yet to be confirmed.

The effect of aqueous humor α-MSH on T cells is profound. It is possible to change an antigen-specific proinflammatory T-cell response to an antigen-specific regulatory T-cell response by treating T cells with aqueous humor or with α-MSH. In this process, TGF-β2 helps in promoting α-MSH induction of regulatory activity in T cells. Flow cytometric analysis of the α-MSH-treated T cells has shown that they express the regulatory T-cell marker CD25 and that this activity is limited to $CD4^+$

T cells. Unlike other types of regulatory T cells, TGF-β is the only cytokine that appears to be produced by these α-MSH-induced regulatory T cells. Such regulatory T cells can be generated *in vitro* and used in adoptive transfer experiments to show that they require antigen specificity to activate their suppressive functionality. When their antigen specificity is for retinal autoantigens, they can be used to suppress autoimmune uveitis, and promote retinal allograft survival. Recently, it has been reported that mice that naturally recovered from autoimmune uveitis produce regulatory $CD4^+$ T cells that are specific for retinal autoantigens. Importantly, such $CD4^+$ T-regulatory cells are not detected in mice that do not require the receptor for α-MSH on their T cells. There are four α-MSH receptors that are differentially expressed on immune cells. For T cells, it is the melanocortin 5 receptor (MC5r) that is required for α-MSH to induce regulatory T-cell activity. Interestingly, the retinas of post-experimental autoimmune uveitis (EAU) mice, which do not express MC5r, are severely damaged with losses in photoreceptors. This severe damage is not seen in normal post-EAU mouse retinas. The retina itself also expresses MC5r, and there is evidence that the melanocortin family of proteins is needed for normal ocular development. This suggests that α-MSH, which is produced by several layers of cells in the retina, is important for healthy retinal development, survival, and immune privilege. It has been proposed that immune privilege is an evolutionary adaptation to protect the eye from inflammation, and α-MSH may be one these adaptations of a molecule originally used for other purposes, but now has the added role of being immunosuppressive and immunoregulatory.

Other Neuropeptides

Three neuropeptides were examined for their presence, and a possible role in aqueous humor immunosuppression because they are found in the neurons that innervate the anterior chamber and some are produced by neural cells of the retina. SOM, CGRP, and VIPs are constitutively present in aqueous humor in ng ml^{-1} amounts, are expressed in the retina, and target different cells of the immune response.

While SOM is found in aqueous humor, its presence was not required for aqueous-humor-mediated immunosuppression. We discovered that SOM induced α-MSH production in T cells that in turn caused the T cells to become regulatory T cells. Therefore, SOM contributes to immune privilege by further promoting production of anti-inflammatory and immunoregulating factors by immune cells. There are some contradictory findings regarding the role of SOM in the retina. A protein produced by a retinal pigment epithelial (RPE) cell called PEDF was found to suppress the induction of inflammatory activity in macrophages. However, this suppression was countered by SOM. Activating macrophages by treatment with RPE-derived factors results in enhanced nitric oxide production, yet the macrophages continue to produce anti-inflammatory cytokines. The meaning for this contradictory finding is not clear. It is possible that macrophages are alternatively activated within the retina and possibly in other tissue sites of the ocular microenvironment.

The role of VIP in immune privilege still remains a bit of a mystery. This neuropeptide is in aqueous humor, and it suppresses the activation and proliferation of T cells; however, it does not induce regulatory T cells. The suppression of T-cell proliferation by VIP is only 50%, and there is some speculation that selected populations of T cells are responsive to VIP. Therefore, it is possible that whole aqueous humor selectively expands a subpopulation of T cells that is not responsive to VIP. Maybe these are the regulatory T cells. VIP receptors are present on macrophages, but there is nothing known about the role of aqueous humor VIP on antigen presentation, and on inflammatory activity of macrophages. One problem is that it is not clear whether VIP exists in the ocular microenvironment as a whole molecule or as immunoreactive functional peptide. It is possible that in aqueous humor, or in other regions of the ocular microenvironment, different types of VIP fragments are present and affect different target cells and have different effects on immunity. Whether it is a whole polypeptide or a fragmented peptide, VIP is a contributing factor to the immunosuppression seen within the immune-privileged eye.

Unlike the other neuropeptides in aqueous humor, GCRP does not target T cells, but instead, influences macrophage activity. Most mature T cells are unresponsive to CGRP. The CGRP in aqueous humor suppresses nitric oxide generation by macrophages that have been stimulated with endotoxin and IFN-γ. Neutralization of CGRP activity in aqueous humor also eliminates aqueous-humor-mediated suppression of nitric oxide production by inflammatory macrophages. The concentration of CGRP in healthy aqueous humor is 20-fold less than its concentration in uveitic aqueous humor. At the higher concentration found in uveitic eyes, CGRP has no effect on inflammatory macrophage function. This suggests that in normal conditions, there is a specifically maintained concentration of CGRP for immunosuppression. Studies on CGRP in aqueous humor have brought to light several issues about the homeostatic environment of the immune-privileged ocular microenvironment. The immune-privileged ocular microenvironment needs to not only maintain a constitutive level of a specific set of factors, but also must maintain them at physiological and functional concentrations.

Other Molecules

There are several publications that individually describe the immunosuppressive activity of proteins that are not

always considered immunosuppressive. Two that have already been discussed above, PEDF acting as an anti-inflammatory cytokine, and TSP-1 being important in TGF-β activation and in the process of ACAID, are usually considered anti-angiogenic factors. Their regulation of angiogenesis may be their main function within the eye, but may have evolved like α-MSH, also to function as an immunoregulatory factor. The inflammatory cytokine, macrophage MIF, was considered an important molecule produced by activated T cells to keep macrophages migrating from sites of inflammation. In the eye it has been found to be constitutively expressed in aqueous humor and has a role in preventing natural killer (NK) cells from killing cells not expressing major histocompatibility complex (MHC) antigens. Transformed and injured cells express altered or reduced MHC class I antigens on their surface, and NK cells see this as signal to kill the cell. Since MHC class I molecules are expressed at low levels within the ocular microenvironment, the presence of MIF protects these cells from NK cell attack. The regulation of NK cells and inflammatory macrophages is part of the ocular microenvironment that controls innate immunity. Another component of innate immunity is the complement cascade pathways that release protein fragments that induce migration and activation of immune cells, vascular leakage, and cellular lysis. There are constitutively expressed inhibitors of complement within the eye. In aqueous humor, there are two inhibitors that prevent activation of the alternative complement pathway. Although complement inhibitors are present in the eye, there is evidence that complement activation maybe occurring at a low level that might be necessary to maintain normal aqueous flow.

Finally, there is the expression of FasL, a membrane-bound immunosuppressive molecule that is expressed by cells throughout the ocular microenvironment. When FasL binds to Fas, a molecule on activated immune cells, it triggers programmed cell death. It has been suggested that it is a major contributor to immune privilege and is necessary for graft survival within the ocular microenvironment. However, its expression has not explained the finding that FasL expression can induce neutrophil activation and destruction of corneal grafts. Recently, there is some evidence that FasL exists as a soluble molecule in aqueous humor, and that soluble FasL may block neutrophil activation, and act as an immunosuppressive molecule. This could mean that the balance between soluble FasL and membrane-bound FasL is what is important for maintaining immune privilege in the eye. In addition, surviving allografts of other tissues when engineered to express FasL promote induction of graft-specific regulatory T cells. While expression of FasL may keep activated immune cells at bay, it could be a selective element within ocular microenvironment promoting activation of regulatory immune cells.

Application of the Lessons of Immune Privilege

The rapidly expanding discoveries of the mechanisms of immune privilege demonstrate that within the ocular microenvironment are active processes for suppressing inflammatory immunity, promulgating alternative activation of immune cells, and mediating regulatory immunity are present. Many of these mechanisms are normally found at various phases of a conventional immune response, especially in the resolution phase, and it appears that the responsiveness of the immune cells to the ocular immunosuppressive and immunoregulating mechanisms is the same whether the cells are taken from the eye or from other tissues. Therefore, it is becoming clear that such mechanisms of ocular immune privilege can be imposed onto immunity to prevent, cure, and establish or reestablish immune tolerance in various hypersensitivity responses, autoimmune diseases, and prevent allograft rejection in tissues other than just the eye. The mechanisms of ACAID and α-MSH-mediated suppression of immunity have been used to demonstrate the potential of applying the lessons of ocular immune privilege as a therapy.

The therapeutic approaches for both mechanisms are direct applications that in some ways are personalized therapies tailored to the disease and the patient. The ACAID therapy involves the use of patient's monocytes, which are treated *ex vivo* with TGF-β and antigen and reinfused into the same patient. The α-MSH therapy involves either injecting the neuropeptide into the tissue site or collecting the patients' own immune cells and treating them *ex vivo* with α-MSH while they are restimulated with autoantigen. The feasibility of these therapeutic approaches has been demonstrated using rodent models of autoimmune diseases, allografts, and hypersensitivity. The therapeutic utilization of the mechanisms of ocular immune privilege is in its infancy, and has a strong potential in being a new direction in immunotherapy.

Conclusion

Starting with the first experimental description of ocular immune privilege by Medawar in the 1940s, the understanding of the mechanisms of immune privilege has grown. Along with this understanding is a change in the concept of immune privilege. At first, immune privilege was viewed as an interesting experimental phenomenon that was explained by the unique anatomical features of the ocular microenvironment, which include the anterior chamber's lack of direct lymphatic drainage and the presence of an ocular–blood barrier. These passive mechanisms suggested that the immune system was ignorant of the presence of antigen within the eye. However, today we

know that the immune system perceives antigen placed into the eye, but it is the active engagement with the ocular microenvironment that regulates and controls immunity within the eye and systemically to the intraocular antigen. This active engagement is mediated by soluble immunoregulatory and immunosuppressive factors and neuropeptides. Our discovery and understanding of the mechanisms of ocular immune privilege will not only lead to potentially new immunotherapeutic approaches, but may also reveal the mechanisms of how the immune system regulates itself.

Inflammation of the Conjunctiva

T Nishida, Yamaguchi University Graduate School of Medicine, Yamaguchi, Japan

Glossary

Cell-adhesion molecule – Cell-adhesion molecules are cell surface proteins, usually glycoproteins, that mediate cell–cell adhesion. They play important roles in the assembly and maintenance of tissues, wound healing, morphogenic cellular movements, cell migration, and metastasis. Intercellular adhesion molecule-1 (ICAM-1) functions in leukocyte adhesion and inflammation. Its expression is induced in various cell types by interferon-γ (IFN-γ), and it mediates interactions with neutrophils in inflamed tissue. Vascular cell-adhesion molecule-1 (VCAM-1) is presented on the surface of various cell types, including endothelial cells, tissue macrophages, fibroblasts, and dendritic cells. Its expression is induced by cytokines, and it plays a key role in the recruitment of eosinophils to sites of inflammation.

Collagenase (microbial) – Microbial collagenase is a metalloproteinase produced by bacteria that degrades helical regions of native collagen to yield small protein fragments. The preferred cleavage site is immediately upstream of the glycine residue in the sequence – proline–X–glycine–proline – where X is any amino acid. Six forms (or two classes) of microbial collagenase have been isolated from *Clostridium histolyticum*; these proteins are immunologically cross-reactive but possess different amino acid sequences and different specificities. Other variants have been isolated from *Bacillus cereus, Empedobacter collagenolyticum, Pseudomonas marinoglutinosa*, and species of *Vibrio* and *Streptomyces*.

Helper T cell – Helper T cells constitute a specific subpopulation of $CD4^+$ T cells that provides help to other cells of the immune system in mounting an immune response either through direct cell–cell interaction or the secretion of cytokines. They are also referred to as effector T cells. Several distinct subtypes of helper T cells, designated Th1, Th2, Th3, and Th17, have been identified.

Matrix metalloproteinase – Matrix metalloproteinases (MMPs) constitute an important family of enzymes that regulate composition of the extracellular matrix. They are synthesized as inactive precursor proteins that consist of propeptide, catalytic, and hemopexin domains; proteolytic removal of the propeptide domain results in MMP activation. MMPs are zinc-dependent endopeptidases that cleave one or several constituents of the extracellular matrix as well as nonmatrix proteins, and they play an important role in cleaving fibrillar collagen types I, II, and III into characteristic three-fourths and one-fourth fragments. Some MMPs are associated with the cell membrane, either through a transmembrane domain or through glycosylphosphatidylinositol anchor; such MMPs may act within the pericellular environment to influence cell migration. MMP-1, MMP-8, and MMP-13 are also known as collagenase 1, collagenase 2 (neutrophil collagenase), and collagenase 3, respectively.

Th1 cytokine – Th1 cytokines include interleukin (IL)-2, IFN-γ, IL-12, and tumor necrosis factor-β. They are secreted by Th1 cells and play an important role in cell-mediated immunity and chronic inflammation. In general, Th1 responses are stimulated by intracellular pathogens, including viruses as well as certain mycobacteria, yeasts, and parasitic protozoans.

Th2 cytokine – Th2 cytokines include IL-4, IL-5, IL-6, IL-10, and IL-13. They are secreted by Th2 cells and play a key role in the initiation of allergic responses. Th2 responses are also elicited by free-living bacteria and other parasites.

Inflammation

Inflammation is a biological response of the living body to injury or other harmful insults including microbial pathogens, allergens, and physical or chemical agents. It serves to protect the body and is the precursor to wound healing. Classical signs and symptoms of inflammation include redness, swelling, heat, pain, and loss of tissue function. Thus, although inflammatory reactions are well regulated to maintain homeostasis of the body and to promote wound repair, they may result in bodily discomfort. In some instances, however, excessive inflammation may result in tissue damage. Classically, inflammation has been considered to begin with a reaction of vascular tissue that renders vessels permeable to blood cells at the site of injury, resulting in the extravasation of such cells. Recent advances in immunology and molecular cell biology have revealed the mechanisms of inflammation at the level of cellular

interactions and molecular networks. Allergens and infection by pathogens are the major pathological triggers for inflammation at the ocular surface.

The Conjunctiva and Cornea

The ocular surface is composed of the cornea, conjunctiva, lacrimal glands, and associated lid structures. Both the conjunctiva and the cornea are derived from the embryonic epidermis, and they are separated from each other by tear fluid. External insults to the ocular surface evoke different types of inflammatory reactions in the conjunctiva and the cornea that are related to the anatomic differences and physiological roles of these two structures as well as to their connection via tear fluid (Figure 1).

The conjunctiva is a semitransparent membrane that covers the surface of the eye from the back surface of the eyelids to the edge of the transparent cornea. It serves as a barrier at the surface of the eyeball and helps to protect against the invasion of biological, chemical, or physical agents without interrupting the free movement of the eyeball. The surface of the conjunctiva is covered by multiple layers of epithelial cells. The conjunctival epithelium is a relatively inefficient barrier, however, with the result that pathogens, allergens, and biologically active substances readily penetrate into the stroma of the conjunctiva. The conjunctival stroma consists of conjunctival fibroblasts, loosely packed collagen fibers, a vascular system, and abundant immune cells. The triggering of an inflammatory reaction by pathogens or allergens results in enlargement of the blood vessels of the conjunctiva and consequent increased blood flow (hyperemia). The associated increase in the permeability of the conjunctival vascular system leads to leakage of liquid components and to the development of conjunctival edema. It also allows the infiltration of blood cells into the conjunctival stroma and the consequent activation of conjunctival fibroblasts.

Like the conjunctiva, the cornea faces the external environment. However, unlike the conjunctiva, the cornea is transparent, and its surface must be maintained smooth for the proper transmission of light into the eye. The anatomic structure of the cornea is relatively simple compared with that of the conjunctiva. Its surface is also covered by multiple layers of epithelial cells, but the corneal epithelium provides a much tighter barrier than does the conjunctival epithelium. In the absence of any loss or dysfunction of its component cells, the corneal epithelium prevents the entry of pathogens and allergens into the corneal stroma. The cornea does not contain a vascular system. Although a small number of immune cells such as Langerhans cells, stromal dendritic cells, and macrophages are present in the cornea, its major cellular components are epithelial cells, stromal keratocytes (corneal fibroblasts), and endothelial cells. Both the conjunctiva and the cornea are innervated by the ophthalmic branch of the trigeminal nerve, but the cornea is the most sensitive tissue at the ocular surface, and indeed maybe in the entire body, as a result of the high density of sensory nerve endings in the corneal epithelium.

Tear Fluid: A Reservoir of Inflammatory Cells and Modulators

Tear fluid functions as a lubricant between the tarsal conjunctiva and the surface of the cornea and serves to

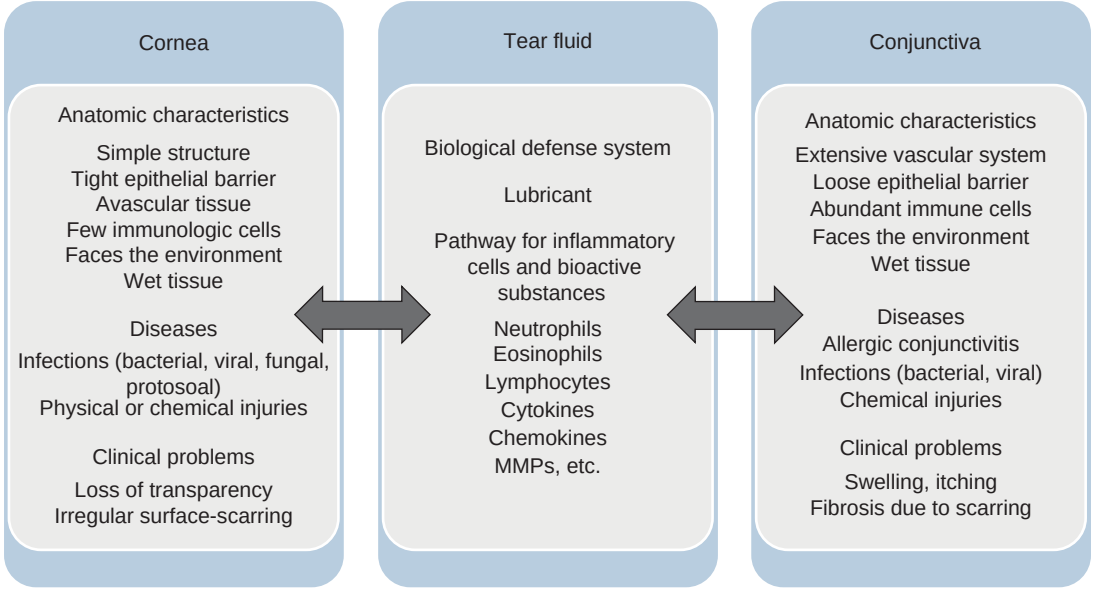

Figure 1 Cornea–tear fluid–conjunctiva axis in ocular surface inflammation. MMP, matrix metalloproteinase.

maintain the ocular surface wet. It is also important for ensuring the generation of a clear image on the retina. Moreover, it contributes to the biological defense system of the ocular surface, containing immunoglobulin, lactoferrin, lysozyme, and other protective proteins. With regard to inflammation at the ocular surface, tear fluid provides a pathway for the movement of inflammatory cells – such as neutrophils, eosinophils, and lymphocytes – between the conjunctiva and the cornea. It also serves as a reservoir of various inflammatory cytokines, chemokines, and growth factors as well as of nutrients and oxygen. Collagen-metabolizing enzymes such as matrix metalloproteinases (MMPs) are present in the tear fluid of individuals with certain ocular inflammatory conditions.

Allergic Reactions in the Conjunctiva

The conjunctiva is a common site for allergic reactions (Figure 2). Clinical characteristics of conjunctival allergic disease include hyperemia, edema, the formation of papillary discharge, the development of corneal epithelial disorders, and, in some patients, corneal ulcer. Hyperemia and edema result from dilation and an increase in the permeability of the vascular system in the conjunctiva. Conjunctival fibroblasts are responsible for the formation of papillae. Mechanical injury caused by papillae as well as the effects of inflammatory cytokines, such as interleukin (IL)-4, IL-13, and tumor necrosis factor-alpha (TNF-α), are responsible for discharge and damage to the corneal epithelium. Disruption of corneal epithelial barrier-function results in the spread of inflammation to the cornea and the development of various types of corneal epithelial disorders. Corneal fibroblasts contribute to the pathology of corneal ulceration. The primary cells that mediate allergic reactions at the ocular surface include mast cells, vascular endothelial cells, eosinophils, T helper 2 (Th2) cells, and conjunctival fibroblasts, with corneal epithelial cells and corneal fibroblasts also contributing in some cases.

Certain allergens that enter tear fluid from the environment are solubilized by the fluid and penetrate through the loose barrier provided by the conjunctival epithelium into the conjunctival stroma. In the stroma, the allergens trigger the secretion of histamine and inflammatory cytokines, such as IL-4, IL-13, TNF-α from mast cells, and IL-3 and IL-5 from Th2 cells. Histamine acts on the vascular endothelium to increase vessel

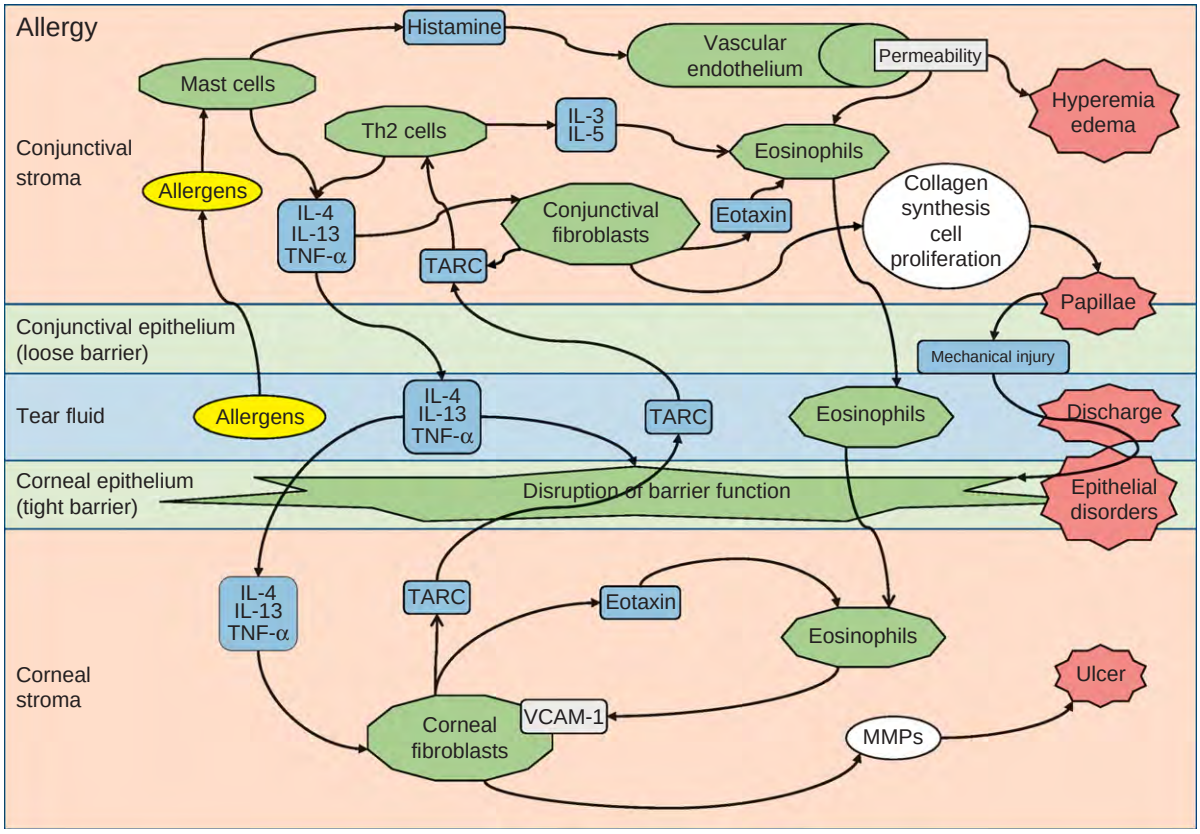

Figure 2 Clinical characteristics of allergic reactions in the conjunctiva and the cornea. IL, interleukin; MMP, matrix metalloproteinase; Th2, T helper 2 cell; TARC, thymus and activation-regulated chemokine; TNF-α, tumor necrosis factor alpha; VCAM, vascular cell-adhesion molecule.

permeability and induce vessel enlargement, resulting in conjunctival hyperemia and edema. IL-4, IL-13, and TNF-α – released by mast cells – activate conjunctival fibroblasts and trigger their secretion of the chemokines eotaxin and thymus and activation-regulated chemokine (TARC). Eotaxin attracts eosinophils to the interstitial space, and the extravasated eosinophils are then activated by IL-3 and IL-5 released by Th2 cells. TARC attracts Th2 cells into the interstitial space, and these cells then serve as an additional source of IL-4, IL-13, and TNF-α. Exposure of conjunctival fibroblasts to IL-4, IL-13, and TNF-α also stimulates the synthesis of collagen and cell proliferation – effects that give rise to the formation of papillae. The protrusive shape of the papillae results in mechanical injury of both conjunctival and corneal epithelia; such injury together with the effects of IL-4, IL-13, and TNF-α that enter tear fluid from the conjunctiva lead to disruption of the barrier function of the corneal epithelium and to discharge. Eosinophils that enter tear fluid from the conjunctiva are then able to penetrate into the corneal stroma. IL-4, IL-13, and TNF-α also enter the corneal stroma from tear fluid and activate corneal fibroblasts to express TARC, eotaxin, and vascular cell-adhesion molecule-1 (VCAM-1) – a cell-adhesion molecule for eosinophils. The activated corneal fibroblasts also produce MMPs, which degrade collagen of the extracellular matrix in the corneal stroma, resulting in corneal ulceration. TARC released from corneal fibroblasts passes through tear fluid into the conjunctival stroma, where it further promotes the secretion of IL-4, IL-13, and TNF-α by Th2 cells in a vicious cycle. This scenario thus reveals that, although immune cells such as mast cells, Th2 cells, and eosinophils play a prominent role in allergic disorders at the ocular surface, resident fibroblasts in both the conjunctiva and cornea also contribute to the inflammatory process.

Infection of the Conjunctiva or Cornea

The clinical characteristics of infection at the ocular surface include swelling, hyperemia at the conjunctiva, discharge, and epithelial defects and ulceration in the cornea. As with allergic reactions, the reactions of the conjunctiva and cornea to infection differ (**Figure 3**). The vascular system of the conjunctiva ensures a robust immune response to infection in this tissue, with conjunctivitis being a relatively mild clinical condition. However, the cornea is avascular and possesses few immune cells, with the result that corneal infection is more serious and may become sight threatening.

If a pathogen survives the biological defense system in tear fluid, it readily penetrates the conjunctival epithelium and triggers the dilation and permeabilization of conjunctival blood vessels, resulting in swelling and hyperemia. Neutrophils and Th1 cells enter the conjunctival stroma from the bloodstream and serve as the second line of defense against pathogens. Both neutrophils and Th1 cells secrete IL-1, with Th1 cells also secreting interferon-γ (IFN-γ). These cells and cytokines may be sufficient to inactivate the pathogen and limit the inflammatory response to the conjunctiva. However, pathogens also act on conjunctival epithelial cells to trigger the secretion of IL-8, IL-6, and TNF-α. These cytokines together with IL-1 and IFN-γ can enter tear fluid and, in the presence of damage to the corneal epithelium, may penetrate into the corneal stroma and activate corneal fibroblasts.

The tight barrier provided by the corneal epithelium normally prevents the entry of pathogens into the cornea. However, corneal epithelial injury can result in pathogen penetration into the corneal stroma. Pathogen-associated various factors such as lipopolysaccharide (LPS) of Gram-negative bacteria and peptidoglycan (PGN) of Gram-positive bacteria are recognized by toll-like receptors (TLRs) on the surface of corneal fibroblasts and trigger the production of IL-8 and the expression of intercellular adhesion molecule-1 (ICAM-1) by these cells. IL-8, IL-6, TNF-α, IFN-γ, and IL-1 that enter the corneal stroma via tear fluid also induce IL-8 production by corneal fibroblasts. IL-8 then attracts neutrophils exuded (extravasated) from conjunctival blood vessels into the corneal stroma, and these cells interact with corneal fibroblasts via ICAM-1. IL-1 released from neutrophils further stimulates corneal fibroblasts.

Corneal infection is associated with the production of two types of collagen-degrading enzymes: collagenase released from the pathogen and MMPs released from corneal fibroblasts. These enzymes destroy stromal collagen, eventually resulting in the development of corneal ulcer. Collagen destruction by MMPs released from activated corneal fibroblasts may continue even if the pathogen has been killed by antimicrobial treatment. Neutrophils were originally thought to destroy stromal collagen, but these cells were subsequently found to promote the production of MMPs by corneal fibroblasts rather than to degrade the collagen themselves. As with ocular allergy, corneal fibroblasts thus play a key role in the progression of the inflammatory response to corneal infection.

Tear Fluid as a Diagnostic Indicator of Inflammation

The measurement of inflammatory cytokines or chemokines and the cellular components of tear fluid provides clinically important information on inflammation at the ocular surface. The presence of eosinophils in tear fluid thus confirms a diagnosis of allergic inflammation,

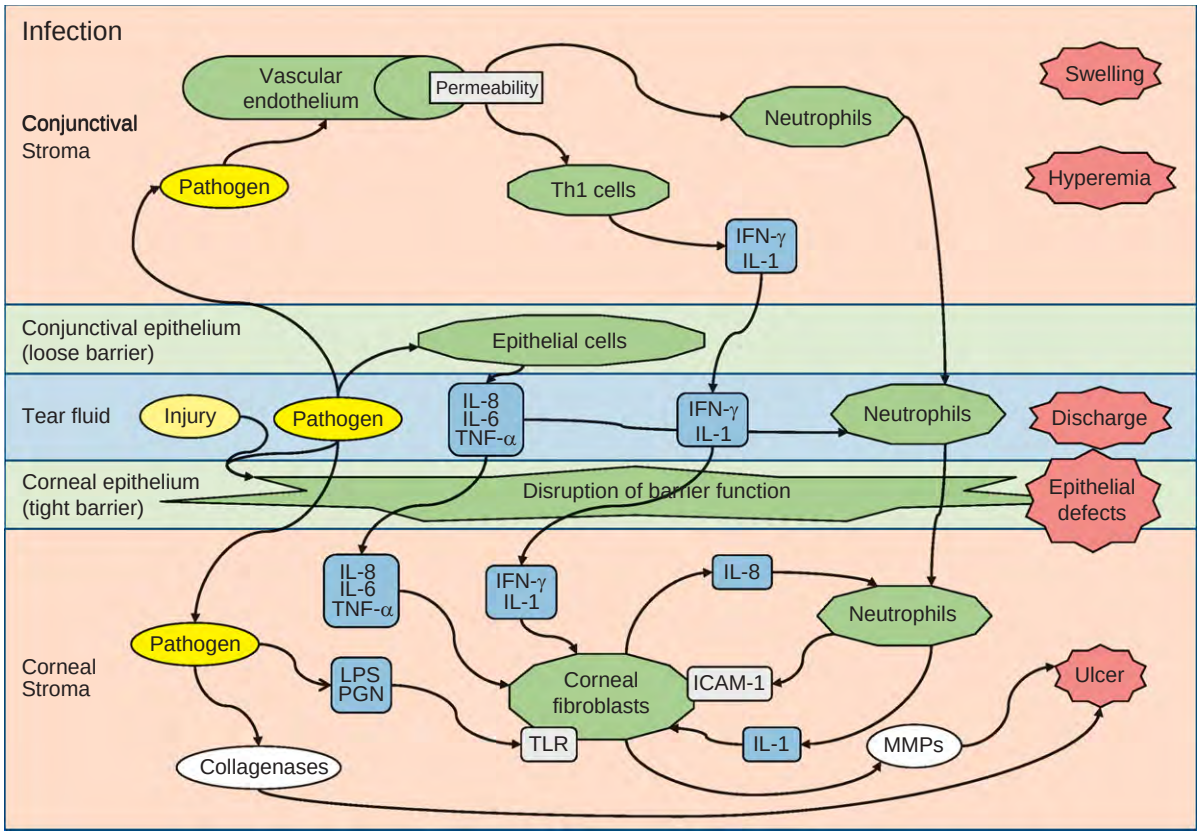

Figure 3 Clinical characteristics of infection in the cornea and conjunctiva. ICAM, intracellular adhesion molecule; IFN-γ, interferon-gamma; IL, interleukin; LPS, lipopolysaccharide; MMP, matrix metalloproteinase; PGN, peptidoglycan; Th2, T helper 2 cell; TARC, thymus and activation-regulated chemokine; TLR, toll-like receptor; TNF-α, tumor necrosis factor alpha.

whereas the presence of neutrophils is indicative of infectious inflammation.

In addition to being of diagnostic value, the condition of the tear fluid can affect the progression of ocular surface inflammation. In individuals with dry eye, for example, the decrease in tear secretion and small volume of tear fluid may result in concentration of inflammatory cells and proteins. The condition of tear fluid should thus be taken into account in the treatment of patients with ocular surface inflammation.

Connection of the Conjunctiva and Cornea via Tear Fluid

The surfaces of both the conjunctiva and the cornea are covered by epithelial cells. However, the biological responses of these two tissues to allergens or to pathogens differ markedly. The conjunctiva has a prominent vascular system and contains abundant immune cells, whereas the cornea is transparent and avascular and contains few immune cells. These anatomic differences between the conjunctiva and cornea are reflected in the types of inflammatory condition that affect them. The conjunctiva is the principal target tissue for allergic reactions at the ocular surface, whereas the cornea is the main target for microbial infection or injury. The vascular system of the conjunctiva serves as a key source of immune cells in each of these conditions. The cornea is also affected by inflammatory reactions that occur in the conjunctiva, with the tear fluid that covers the surface of both the conjunctiva and the cornea serving as a conduit for the exchange of immune cells, cytokines, chemokines, and growth factors.

The concept of inflammation was first described more than 2000 years ago as redness and swelling with heat and pain by Celsus. In the nineteenth century, the concept of loss of tissue function associated with inflammation was recognized. Recent advances in cell and molecular biology have revealed the cytokine and chemokine network that underlies inflammation. However, the availability of effective anti-inflammatory drugs other than steroids remains limited. Nonsteroidal antiallergic drugs have been developed and are effective for the treatment of allergic conjunctivitis. Nonsteroidal anti-inflammatory drugs (NSAIDs) are also effective in ameliorating inflammatory reactions. However, anti-inflammatory agents that halt tissue destruction

are needed. Further characterization of the bidirectional regulation of conjunctival and corneal resident cells via cytokines and chemokines, as well as immune cells, released into tear fluid may provide a basis for the development of new drugs effective for the treatment of inflammation at the ocular surface.

Information Processing in the Retina

F S Werblin, UC Berkeley, Berkeley, CA, USA

Glossary

Directional sensitive ganglion cell – Ganglion cells that are particularly sensitive to movement of an image in a specific direction across the retina.
Local edge detector (LED) – A ganglion cell that appears to be unique in that it is activated by a local edge at the center of its receptive field, and suppressed by edges in the surround.
OFF pathway – Retinal circuitry within the retina responding at the offset of light.
ON pathway – Retinal circuitry within the retina responding at the onset of light.
Starburst amacrine cell – Retinal amacrine cells with a large and symmetrical dendritic arbor that uses both actylcholine and gamma aminobutyric acid. These cells play an important role in directional selectivity.

Introduction

The retina creates a dozen different representations of the visual world, each embodied at a separate sublayer of the inner plexiform layer, and carried by a separate class of ganglion cell. These representations are not just enhanced edges, but are often also complex space–time abstractions of the visual world. The early studies of Barlow; Maturana, Lettvin, McCulloch, and Pitts; and Campbell and Robson suggested that the optic nerve contains information carried by a number of different channels, each formed as a result of sophisticated neural computations. In the frog, for example, the retinal output contains the trigger features that guide the frog's behavior, including detectors for flys, edges, dimming, and contrast. As Barlow points out, the activity of individual neurons is not just a reflection of thought processes, but these activities are also thought processes. Therefore, what are these processes and how are they formed through neural interactions in the retina?

Over the last 40 years, visual neuroscientists have attempted to understand retinal function from a variety of perspectives. What is the nature of the representations of the visual world formed by the retina? Through what neural processes are these representations formed? Answering these questions requires a merging of information from a variety of different disciplines. Retinal anatomists have defined both the morphology and the conductivity between retinal neurons at the light electron microscope levels. Retinal electrophysiologists have defined the response properties of each class of retinal neurons. Retinal circuitry has been analyzed, aided in great measure by pharmacological studies where specific synaptic pathways have been defined for the use of receptor agonists and antagonists. A number of general principles of organization and function have been gleaned from these studies.

For example, as predicted by Horace Barlow and later verified through experiment, most retinal neurons operate in a spikeless mode, whereby membrane potential and synaptic transmission are continuous and graded. Furthermore, under most ambient conditions, most graded-potential retinal neurons operate at or near the midpoint of their response range, capable of signaling both increments and decrements. Embedded in a complex circuitry including feedback, most neurons are constantly active, talking to each other with a continuous stream of activity. The presentation of visual stimuli offsets this ambient state, generating at least a dozen different space–time patterns of neural activity at the retinal output that correspond to, and represent, the visual input.

The Outer Retina, Gain and Level Adjustment

One of the first steps in retinal processing performs the operations that match the response range of retinal neurons to the light input, setting the dynamic range. A significant amount of neural housekeeping is required to maintain the retina in a steady-state condition such that most neurons are operating near their mid-potential range. This set point control is achieved through a series of processes known as adaptation. Adaptation to luminance maintains the photoreceptors at an ambient potential level that varies little with the overall luminance state, over very many orders of magnitude. This is accomplished because cone gain decreases as ambient luminance increases. It is as though the cones put on sunglasses as the brightness of the environment increases. This adaptation is an inherent part of the transduction machinery, mediated at the outer segments of photoreceptors. Much more about the process of adaptation can be found in elsewhere in the encyclopedia.

Bifurcation of the Visual Pathways into ON and OFF streams

The pathway from cones to bipolar cells bifurcates at the bipolar dendrites into the ON and OFF streams of activity. Activity is initiated in OFF bipolars via ionotropic glutamate receptors in the bipolar dendrites; therefore, OFF bipolars polarize in phase with the photoreceptors. Activity is initiated in the ON bipolar dendrites via metabotropic receptors such that ON bipolar cells polarize out of phase with the photoreceptors. Both bipolar types drive ganglion cells via α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA), kainate, and *N*-methyl-D-aspartic acid (NMDA) receptors; therefore, all ganglion cells respond in phase with their bipolar cell inputs. These differential streams are carried to different strata of the inner retina with most of the OFF streams in regions that are distal to the ON streams. These ON and OFF streams are then carried through many synapses in the visual system and can also be measured at the visual cortex. A sketch of the retinal pathways from cones to the ON and OFF bipolars, to the ON and OFF ganglion cells, is shown in Figure 1. More about bipolar cells can be found elsewhere in the encyclopedia.

Horizontal Cell Synaptic Interactions

The pathway from cones to bipolar cells is intersected by horizontal cells. Cones drive the horizontal cells, but horizontal cells are strongly electrically coupled; therefore, the neural image carried by horizontal cells is blurred. The coupled network of horizontal cells feeds forward to bipolar cells via *gamma aminobutyric acid* (GABA)ergic synapse. ON and OFF bipolar cells respond with opposite polarities to light; therefore, horizontal cells must polarize the ON and OFF bipolar cells in opposite directions: GABA depolarizes ON bipolar cells and hyperpolarizes OFF bipolar cells because the chloride concentrations, and therefore the reversal potentials for GABA input, are different in the two bipolar cell types. Horizontal cells also feed back to cones, but the feedback mechanism from horizontal cells to cones remains controversial. Feedback may be mediated by an electrical synaptic feedback, by GABA, or it might be controlled by pH. Experiments in different animals under different conditions have led to these diverse theories. The circuitry is shown in Figure 2, added to the ON–OFF streams shown above. The role of GABA in horizontal cells is described elsewhere in the encyclopedia.

Horizontal Cells and Local Gain Control

Feedback from horizontal cells to cones provides a form of local adaptation or gain control so that local bright spots do not saturate neural activity the way they might in a conventional camera where the level of light arriving at the sensor is controlled by aperture size. Local gain control is achieved by the electrical coupled horizontal cells network whose blurred image is subtracted from the sharper image carried by the cones and bipolar cells. This subtraction normalizes activity across the retina with respect to the blurred activity of horizontal cells. The subtraction has two major results: the neural representation of edges is

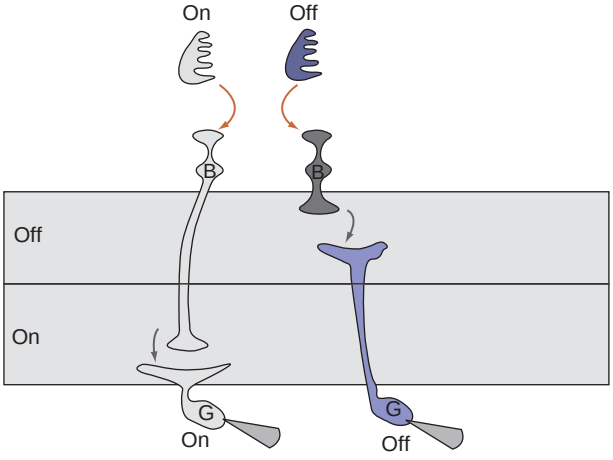

Figure 1 General glutamatergic pathways in the retina from photoreceptors (top) to bipolar cells (B) to ganglion cells. ON and OFF pathways are initiated at the dendrites of the bipolar cells (B, orange arrows). ON and OFF ganglion cells (G) are driven by their respective ON and OFF bipolar cells (black arrows). OFF activity is located in the distal half of the outer plexiform layer, while ON activity is located in the proximal half.

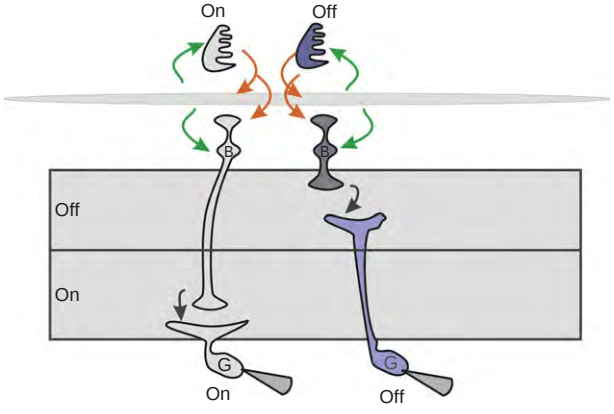

Figure 2 Horizontal cell feedback and feedforward added to the circuitry. Orange arrows represent glutamate pathways from cones to ON and OFF bipolar cells and to horizontal cells. Green arrows represent inhibitory pathways that mediate the horizontal-mediated antagonistic surround. The synaptic mechanism underlying this feedback pathway is still not fully understood. This feedback pathway is also implicated in local gain control. GABA is also thought to be fed forward to both bipolar cell types.

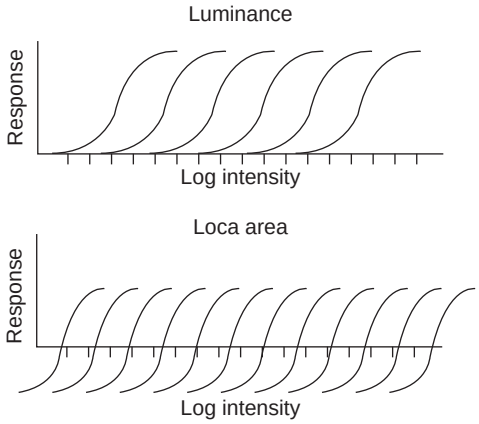

Figure 3 Luminance and local gain changes. Upper traces: gain changes at the photoreceptors shift the intensity–response curves along the log intensity axis; as ambient illumination increases, the transduction gain is reduced. Lower traces: local adaptation mediated by horizontal cell feedback subtracts the luminance level from the cone-to-bipolar signal, leaving mainly the contrast signal.

sharpened by the subtraction, resulting in the presence of Mach bands. Put differently, broadly distributed luminance changes are lost, subtracted from the cone to bipolar patterns by the blurred horizontal cell image. The neural image that remains after this subtraction is primarily related to local contrast. It is the local contrast image that is then brought to the inner retina at the synaptic terminals of the ON and OFF bipolar cells. A family of adaption curves is shown in Figure 3.

Interactions at the Inner Retina: Contrast Gain

The local gain-controlled neural image, brought to the inner retina, is subject to an additional adjustment by contrast gain control, that constrains signal magnitude so that postsynaptic neurons operate within their dynamic range. Contrast gain control is mediated by at least two mechanisms. Amacrine cell feedback to bipolar cells is thought to contribute to contrast gain control. In addition, a more significant mechanism, still not well understood, but likely located at the bipolar cell terminals, has been shown to increase contrast gain at low temporal contrast and to decrease gain at high temporal contrast. Contrast gain control is described elsewhere in the encyclopedia.

To summarize, there are three main gain control systems in the retina: luminance gain at the outer segments, local luminance gain at the horizontal cell system, and contrast gain control. These systems, taken together, allow the retina to detect dim objects at low contrast or bright objects at high contrast, with all neurons operating near their optimal gain and never saturating.

General Organizational Principles

Lateral Interactions are Concatenated

The results of an interaction that takes place early in visual processing are carried through and appear at later stages of processing. As an example, antagonistic lateral interactions at the outer retina, mediated by horizontal cell feedback and feedforward, form an initial antagonistic center-surround receptive field interaction. These concentric fields are first formed at the cone terminals, mediated by feedback from horizontal cells; however, this activity is read out by both the ON and OFF bipolar cell types. Therefore, bipolars, similar to cones, show concentric antagonistic receptive fields. Part of the antagonistic surround measured at ganglion cells derives from the interactions between cones and horizontal cells at the outer retina and carried to the ganglion cells via the bipolar cells. Additional antagonistic components are added through interactions at the inner retina, mediated by amacrine cells, and then measured in ganglion cells. Therefore, ganglion cells carry the results of lateral antagonism at the outer retina superimposed upon additional forms of lateral interaction formed at the inner retina. Ganglion cells can contain as many as five different lateral antagonistic components.

Mutual Antagonism is a Form of Amplification

Once again, lateral antagonism at the outer retina serves as an example of mutual antagonism because adjacent retinal regions, via horizontal cells antagonize, are mutually antagonistic. This mutual antagonism amplifies and generates the familiar Mach bands which enhance the neural image of edges in the visual world. As described later, the mutual antagonism between motion-detecting starburst amacrine cells amplifies directional differences. There are many other forms of mutual antagonism in the retina operating in different domains, and each of these serves to amplify the quality represented in that domain.

Redundant Feedforward and Feedback Interactions

As shown above, the lateral antagonistic signal that is fed back to cones is also fed forward to both ON and OFF bipolar cells. In many cases of retinal interaction, the GABAergic signal that is fed back to bipolar cells by amacrine cells is also fed forward to ganglion cells as shown in Figure 4.

Interaction between the Two Complementary Visual Streams in the Visual System

The ON and OFF pathways do not remain independent, but interact at every neural level in the retina and continue to interact at each of the higher visual centers. This interaction between the ON and OFF pathways, called

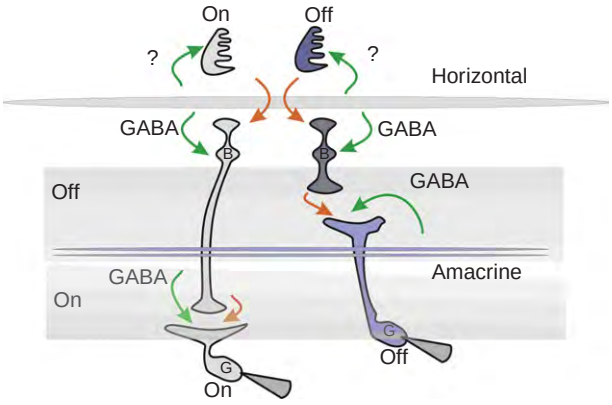

Figure 4 GABAergic amacrine cell feedback and feedforward can provide an additional lateral antagonistic interaction, generating an additional receptive field surround superimposed upon the feedback and feed-forward interactions mediated by horizontal cells at the outer retina.

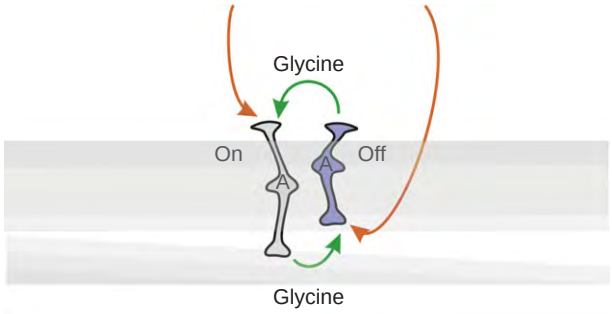

Figure 5 Crossover circuitry isolated. The ON system inhibits the OFF system, and the OFF system inhibits the ON system by way of glycinergic amacrine cells that span the ON–OFF sublaminae. This interaction compensates for the nonlinearities introduced by synaptic transmission. The interaction is found in most bipolar, amacrine, and ganglion cells.

crossover inhibition, is mediated by glycinergic amacrine cells, and serves to relinearize signals that have been distorted by nonlinear transmission at synapses. It is necessary to provide this circuitry compensation at each stage of processing to maintain a linear signal stream because if a nonlinear signal is filtered, linearity can never be reconstructed. In the transistor world, analog signal processing design requires interactions between the equivalent of ON and OFF circuitry to compensate for the rectifying nonlinearities inherent in transistors.

The circuitry underlying crossover inhibition involves ON amacrine cells feeding the OFF pathway, and OFF amacrine cells feeding the ON pathway. The circuit module representing this crossover activity is shown in Figure 5.

The crossover circuitry is superimposed upon and intersects the glutamate pathways and the GABAergic inhibitory pathways. The overall circuitry is summarized in Figure 6. More on amacrine cells can be found in elsewhere in the encyclopedia.

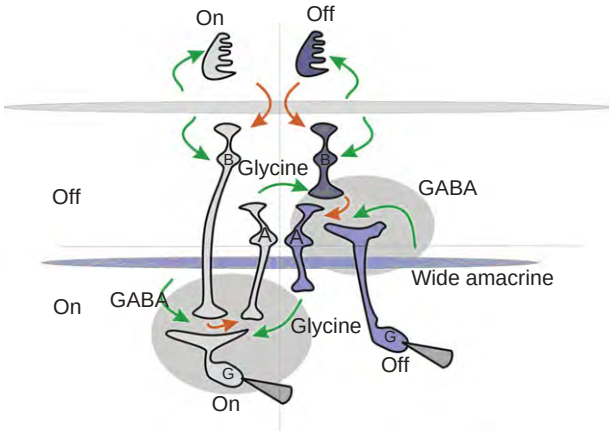

Figure 6 Generalized retinal circuit including horizontal cells, lateral amacrine cells, and vertical amacrine cells. This general circuit includes feedback and feed-forward horizontal cell interactions, feed-forward and feedback GABAergic amacrine cell interactions, and ON to OFF as well as OFF to ON crossover circuitry. Each of these five interactions can generate a different antagonistic receptive field surround for ganglion cells.

This is a summary of a basic retinal design. It accounts for most of the general activity measured in bipolar, amacrine, and ganglion cells. In almost all cases, the inhibition carried by the vertical amacrine cell elements is mediated by glycine, while inhibition carried by the laterally oriented amacrine cells is mediated by GABA. These general circuitry rules underlie a more specific circuitry that generates the physiological behavior of each ganglion cell type. This additional circuitry has been described for a few ganglion cells. In each case, special variations to the basic circuitry endows these cell types with their specific characteristics. More on neurotransmitters and receptors can be found elsewhere in the encyclopedia.

Inner Retinal Processing: Circuitry for Feature Extraction

Having solved both the housekeeping problems related to adaptation to luminance contrast and the nonlinearity problem introduced by synaptic transmission through appropriate crossover circuitry, the stage is set for the real work of the retina, which is creating the appropriate representations of the visual world. Most of the interesting interactions take place at the inner plexiform layer that is itself a multilayered and exquisitely organized structure. There appear to be about 10 strata in every retina species that has been studied. The strata are defined by the 10 levels at which the dendrites of different ganglion cell types ramify. Remarkably, there also appear to be about 10 different types of bipolar cells, and the axon terminals of each of these bipolar cell types also terminate roughly in the same 10 strata as a ganglion cell dendrites. To a first rough approximation, it appears that each

ganglion cell type receives input from a separate bipolar cell type as shown in Figure 7. However, a close look at the bipolar terminals shows that they are often more diffusely distributed, and there are ganglion cells with multistratified dendritic arborizations. Physiologically, the connections must be more diffuse because most ganglion cells ramify in either the ON or the OFF sublamina; however, most ganglion cells appear to receive both ON and OFF inputs (although activity tends to be dominated by either ON or OFF excitation).

Although the excitatory pathway from photoreceptors to bipolars to ganglion cells appears to be relatively straightforward, there exists a bewildering array of amacrine cells that generate a variety of interactions at the inner plexiform layer. Amacrine cells come in many diverse morphologies, and there appear to be approximately 30 different types. Functional properties of these amacrine cells can be thought of at three different levels of refinement: (1) there are two major morphological classes of amacrine cells identified by their vertical versus lateral orientation in the retina, (2) there are circuitries involving amacrine cells that mediate specific functions, and (3) there are amacrine cells that possess unique physiological properties. Each level of functionality is described below.

Amacrine Cell Morphological Types

The majority of amacrine cells falls into one of two general classes. One consists of narrowly ramifying vertically oriented amacrine cells that span the ON and OFF sublamina. This class contains and releases glycine as its inhibitory transmitter. These amacrine cells appear to be strategically located to carry information from the ON to the OFF and the OFF to be ON sublamina, and are probably the key players in mediating crossover inhibition described earlier. The other major class of amacrine cell consists of widely ramifying, but monostratified, amacrine cells, each stratifying in a separate sublamina. These amacrine cells contain and release GABA as their inhibitory transmitter and may be responsible for various forms of lateral inhibition mediated at the inner retina. In some cases, this lateral inhibition is mutual and when this is the case, it serves as an amplifier of the visual quality carried by that specific form of inhibition.

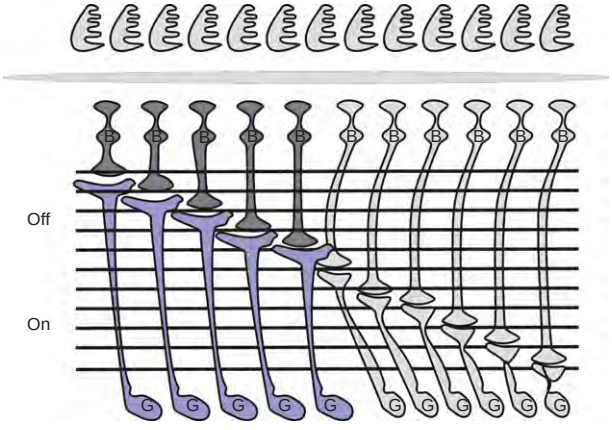

Figure 7 Schematic of the layering of the inner plexiform layer (IPL). Each of the 10 bipolar cell types sends its axon terminal to a distinct region of the IPL, approximately a single substratum of the IPL. Each of the ganglion cell types sends its dendrites to a distinct substratum. Roughly speaking, each bipolar cell type is associated with a unique ganglion cell type. This description is only approximate. In fact, some ganglion cell dendritic fields are bistratified, such as the direction selective (DS) cells, and the axon terminals of some bipolar cells are more diffuse.

Specific Ganglion Cell Circuitries

Directional selectivity

There are a few amacrine cells that have now been identified with very specific personalities. For example, starburst amacrine cells, named for the characteristic starburst pattern of their processes, span about 200 μm. Starburst cells contain and release both GABA and acetylcholine. They are the key elements in the organization of directional selectivity in the retina. A large population of starburst amacrine cells is associated with each directionally selective (DS) ganglion cell, and neighboring DS ganglion cells likely share many starburst amacrine cells. Starburst cells are inherently DS, generating more release for centrifugal movement. One likely mechanism involves calcium-initiated calcium release, but this remains an area of intense exploration. Release occurs along the outer one-third of the starburst processes. These processes not only release GABA, but are also GABA sensitive. This creates a mutual inhibition between starburst cells that acts to amplify directional motion sensitivity as shown in Figure 8. Starburst cells inhibit the DS cells asymmetrically, with stronger inhibition arriving from the null side than from the preferred side. These three mechanisms, inherent directional selectivity in the starburst cells themselves, mutual antagonistic interaction between neighboring starburst cells, and asymmetrical inhibition acting both pre- and postsynaptically at the ganglion and bipolar cells endow the DS cell with some of its directional properties as shown in Figure 9. More on DS circuitry can be found elsewhere in the encyclopedia.

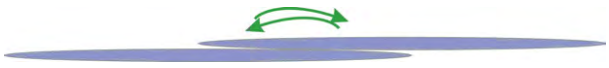

Figure 8 Mutual inhibition between starburst amacrine cells amplifies the directional properties of the starburst network. Here, two starburst amacrine cells, themselves directionally selective, are mutually inhibitory (green arrows). In the circuit of this figure, the right starburst cell supplies inhibition to the ganglion cell for movement in the null direction from right to left. The right starburst cell is turned off by the left starburst cell for movement from left to right.

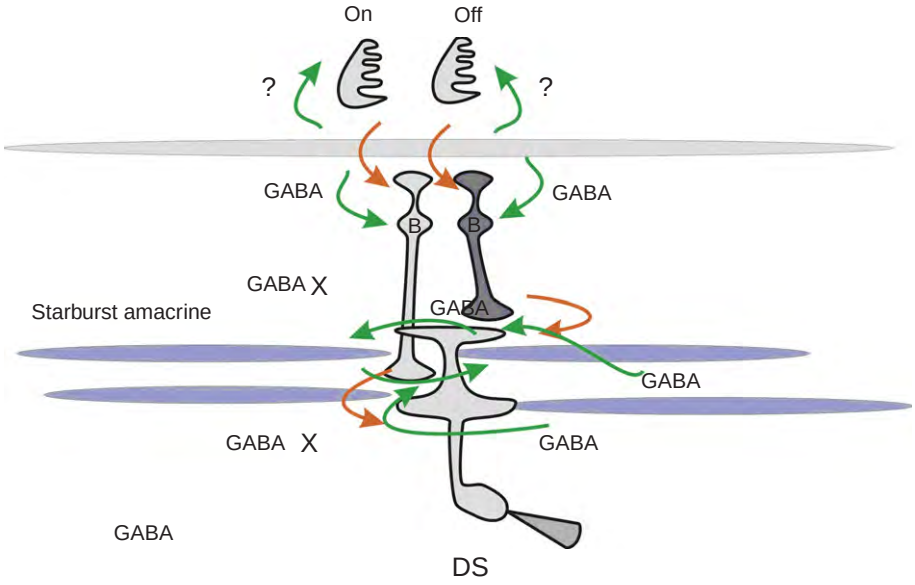

Figure 9 Pathways underlying the behavior of the directionally selective (DS) ganglion cell. Starburst amacrine cells (light blue), themselves directionally selective, are mutually inhibitory. They inhibit by feeding back to bipolar cells and forward to ganglion cells. Both feedback and feed-forward inhibition are asymmetric: they are stronger on the null side than on the preferred side, thereby endowing the DS ganglion cell with directional properties.

The circuitry puzzle regarding the DS cells is far from solved; however, the general organizational rules listed above still apply. The lateral inhibitory interneuron is GABAergic, following the GABA rule for laterally oriented cells.

Functions of AII Amacrine Cells

AII amacrine cells serve a very specific function to transcribe signals in the rod bipolar cells to both the ON and OFF cone pathways. The circuitry underlying this function is now well defined. AII amacrine cells are driven by rod bipolar cells that respond at ON. The AIIs are electrically coupled to cone bipolars, and make glycinergic synaptic contact with the OFF pathway. Recently, the AII amacrine cells have been shown to serve other functions. For example, the AII amacrine cells appear to be the key elements in providing glycinergic inhibition to the so-called looming detectors and in alpha cells, both described elsewhere in the encyclopedia (Figure 10).

There are numerous other examples of special purpose circuitry that utilize laterally oriented amacrine cell interneurons. The polyaxonal amacrine cells are thought to mediate saccadic suppression. In other cases, the same cell type has been implicated in mediating object motion sensitivity. It is likely that other amacrine cell types also serve specific functions, but their properties have not yet been identified.

At about the time that Levick was characterizing the DS ganglion cell, he also described another ganglion cell

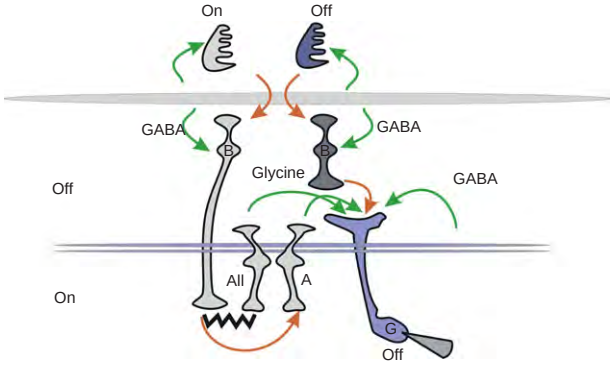

Figure 10 Pathways underlying the behavior of the alpha cell/looming detector. This ganglion cell appears to respond to a dark target at its receptive field center that increases in size, much like an approaching predator. It appears to receive glycinergic inhibition from two types of local amacrine cells: input from an AII amacrine cell that is electrically coupled to ON bipolar cells, and input from another amacrine cell class that receives excitatory glutamate input from ON bipolar cells.

that he termed the local edge detector (LED). This cell appears to be unique in that it was activated by a local edge at the center of its receptive field, and that activity was suppressed by edges in the surround. Van Wyk, Taylor, and Vaney have recently gone on to characterize some of the special temporal properties of this neuron. It receives excitation and also glycinergic inhibition at both ON and OFF, and is inhibited by edge stimuli presented at the surround via a GABAergic lateral pathway. Both inhibitory components follow the general rule of vertical glycinergic and lateral GABAergic activity as

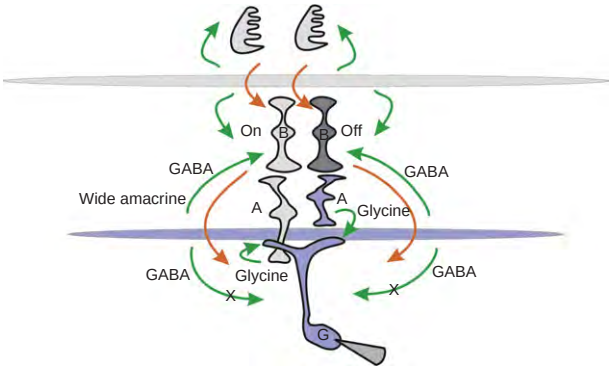

Figure 11 Pathways underlying the response properties of the local edge detector. This cell responds to subreceptive field detail at its receptive field center, most likely from the bipolar cells that drive it. It also receives local ON and OFF inhibition that is glycinergic (green arrows), as well as broad-field inhibition (green arrows) that is GABAergic and also responsive to fine detail. In this cell type, GABA is only fed back, not fed forward.

shown in Figure 11. The role of this neuron in the overall scheme of vision remains obscure, but it is likely involved in high-resolution, slow temporal response activity.

Glossary

Buffer – A device that collects signals from a source and distributes them to targets without taxing the limited capacity of the source.
Dendrodendritic synapses – Unique synaptic motifs where both pre- and postsynaptic assemblies coexist on the same neuronal dendrite rather than segregating into dendrites and axons, respectively; they are the fundamental modes for biological feedback in sensory pathways.
Directional selectivity – The ability of a neuron to preferentially spike in response to stimuli originating from a given visual quadrant, but not others.
Feedback – The use of a portion of an output signal as an additional upstream input to modify the amplification in a network. Negative feedback reduces the gain and noise and improves the frequency response (spatial, temporal, or spectral). Positive feedback can be used to further tune the frequency response or generate resonance.
Feed forward – The use of a portion of an output signal as an additional parallel input to a downstream target. Negative feed forward selectively improves the frequency response (spatial, temporal, or spectral), but has little benefit on system noise or stability. Positive feed forward can be used to further amplify the effect of a signal.
Gain – The ratio of output and input amplitudes for a system, typically specified logarithmically as decibels of power [10 log (Pout/Pin)] or squared voltage [20 log (V^2out/V^2in)].
Nested feedback – The use of a portion of the feedback signal on the feedback process itself, allowing the effect of feedback to be more precisely tuned.
Sign-conserving synapses – Postsynaptic events mediated by receptors whose activation generates the same polarity of signal as the presynaptic terminal, that is, typically, a-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid, *N*-methyl D-aspartate, and nicotinic acetylcholine receptors.
Sign-inverting synapses – Postsynaptic events mediated by receptors whose activation generates the opposite polarity of signal as the presynaptic terminal, that is, typically, gamma aminobutyric acid and glycine.
Transfer function – The output of a given cell or device relative to its input, usually expressed as gain versus temporal or spatial frequency.

Amacrine Cells

Amacrine cells (ACs) and axonal cells (AxCs) are multipolar neurons that shape the ganglion cell (GC) function. While two to four classes of horizontal cells (HCs) provide lateral signal processing in the outer plexiform layer, ACs and AxCs are the most diverse neuronal group of any brain region, with over 30 classes in mammals and even more in highly visual nonmammalians, such as cyprinid fishes, where over 70 AC classes have been documented.

AC Classification, Form, and Patterns

The neural retina is composed of three superclasses of cells: (1) sensory neuroepithelial cells (photoreceptors and bipolar cells (BCs)); (2) multipolar neurons (ACs, AxCs, and GCs); and (3) gliaform neurons (HCs). Retinal multipolar neurons are further divisible into projection neurons (GCs and AxCs) and *bona fide* local circuit neurons, the ACs. This is an important distinction. The definition of the term amacrine refers to lacking an axon and ACs are neurons that mix presynaptic and postsynaptic specializations on their dendrites. These dendrodendritic specializations make them homologous to the anaxonic granule cells (GrCs) of the olfactory bulb (**Figure 1**). Both ACs and GrCs are inhibitory neurons that provide in-channel and cross-channel feedback. Conversely, GCs are classical projection neurons with exclusively postsynaptic retinal dendrites and presynaptic axon terminal ramifications in the central nervous system (CNS). The AxC group is a collection of diverse, nonamacrine retinal neurons that are similar to GCs in having distinct dendritic arbors and one or more long intraretinal axons. The AxC group includes polyaxonal cells in mammals and avians, certain dopaminergic neurons, and interplexiform cells. Interestingly, topologically similar AxCs in the olfactory bulb are the periglomerular cells and some of them are also dopaminergic.

Different kinds of ACs form two large superclasses with shared features: lateral and vertical ACs. Lateral ACs are precisely stratified in a single or a few layers of

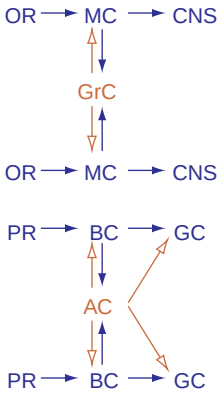

Figure 1 Signal processing in the olfactory bulb (top) and retina (bottom). Glutamatergic sensory neurons such as olfactory receptors (OR) and photoreceptors (PR) directly drive glutamatergic target neurons in the afferent chain, that is, olfactory mitral cells (MC) and retinal bipolar cells (BC), respectively. MCs and BCs then target the next glutamatergic elements as well as sets of inhibitory GABAergic local circuit neurons: olfactory granule cells (GrC) and retinal amacrine cells (AC). Both these neurons provide local inhibitory feedback onto their source neurons. ACs also provide inhibitory feed forward onto ganglion cells (GC) in the chain. Blue elements are glutamatergic. Red elements are GABAergic.

the inner plexiform layer, and spread their dendrites laterally either in a narrow to wide span as needed for their function; most of them release γ aminobutyrate (γ ACs). Vertical ACs distribute their dendrites across several levels of the inner plexiform layer, mostly in narrow and medium spans; most of them are glycinergic (gly ACs). **Figure 2** illustrates three very different structural patterns of vertebrate ACs. Radiate γ ACs (**Figure 2(a)**) are cone BC-driven pyriform cells with a single, thick proximal dendrite that descends to a given level of the inner plexiform layer and then generates nearly 50 dendrites that each radiates unbranched through the retina at one level for up to 0.5 mm. It exists in both on and off varieties, each branching extensively in a narrow band of the inner plexiform layer as a sparse field of processes. Similar cells are present in most vertebrates, but are incompletely studied. Another lateral cell is the widely studied starburst γ AC (**Figures 2(a)** and **2(b)**). It exists in both on and off varieties, each branching extensively in a narrow band of the inner plexiform layer as a dense field of processes. In nonmammalians with thick inner plexiform layers, it is a pyriform cell; however, in most mammals, it is a multipolar cell. Mammalian rod gly ACs exemplify the vertical phenotype (**Figures 2(a)–2(c)**), with deeply branching arboreal dendrites that collect signals from rod BCs in the proximal inner plexiform layer, mid-inner plexiform layer gap junctions with on-cone BCs, and both inputs and outputs onto off BCs from lobular dendrites in the distal inner plexiform layer. As these cells illustrate, the inner plexiform layer is laminated according to cone BC type (**Figure 2(c)**), with off cells terminating in the distal

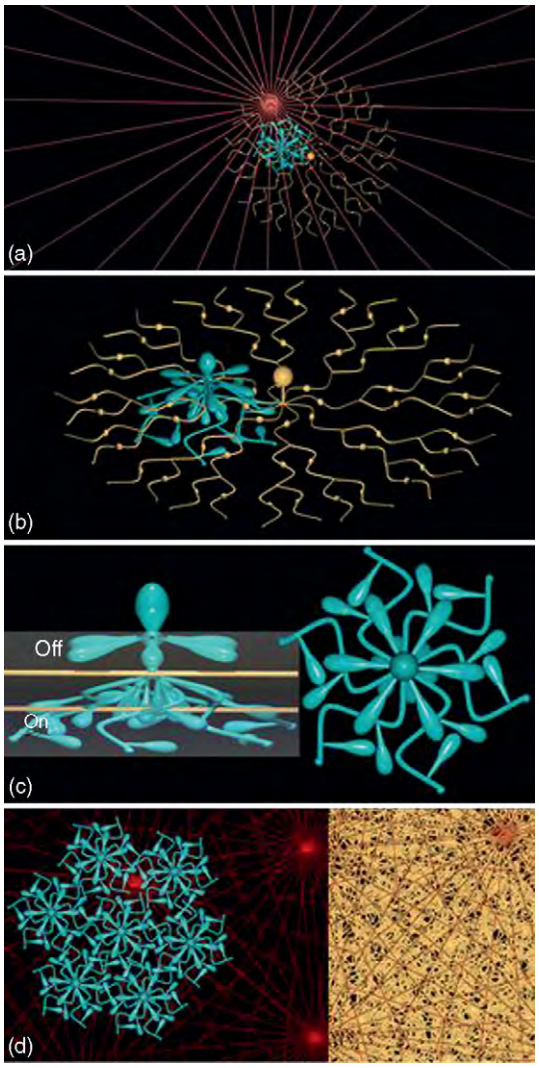

Figure 2 Schematic shapes and patterns of three canonical varieties of retinal ACs. (a) Top view of two lateral ACs and one vertical AC. Red: an off radiate γ AC from goldfish retina, with a wide-field, monostratified nonbranching dendritic arbor over 0.5 mm in diameter. These cells appear to be present in all vertebrates. Yellow: a goldfish off-starburst γ AC with a medium, monostratified, bifurcating, wavy arbor approximately 0.2 mm in diameter. Starburst cells are found in all vertebrates. In species with thick inner plexiform layers, they are pyriform with a single proximal dendrite; in those with thin inner plexiform layers (mammals), they are multipolar. Cyan: a mammalian vertical gly AC with a small, multistratified arbor nearly 0.05 mm in diameter. (b) Oblique view of the starburst γ AC and gly rod ACs showing that the starburst cell captures more synaptic space, but is laminated between the distal and proximal dendrites of the gly rod AC. (c) Vertical and top views of the gly rod AC. Immediately beneath the soma are several large lobular dendrites that contact off BCs. Deep in the inner plexiform layer are arboreal dendrites that capture rod BC inputs at their tips and, as they ascend through the inner plexiform layer, make gap junctions with cone BCs. The inner plexiform layer is divided into on and off layers exemplified by the yellow starburst AC dendritic bands. (d) Coverage patterns of ACs. The red radiate γ ACs are sparse and have coverage factors (CF) of approximately 4–6. The yellow starburst ACs are more frequent and have CF >100 and capture a great fraction of the synaptic space in a thin stratum of the inner plexiform layer. The cyan rod gly ACs are densely packed but have CF ≈ 1.

part and on cells in the proximal part. The AC processes fill the inner plexiform layer from the AC layer to the GC layer. The on- and off-starburst ACs indicate the positions of two fine on- and off-sublayers and exemplify the lateral motif of a large cohort of γ ACs. The gly rod ACs exemplify the vertical motif, bridging both on and off layers and transporting scotopic information in the on → off direction.

AC branching is quantified in many ways. The fractal box dimension (D) summarizes how effectively a dendritic pattern captures the synaptic space in a plane. $D = 1$ for a line and $D = 2$ for a complete plane. For radiate cells, $D \approx 1.2$ (low capture efficiency), while it approaches 1.5 for starburst cells (very high capture efficiency). In biological terms, radiate cells rigidly cover space, but not synapses, and contact inputs stochastically as they traverse wide swaths of the image. Conversely, starburst cells aggressively capture many synapses, rather than space, with curving dendrites. Thus, these cells will have very different signal-processing functions. Most ACs are distributed in coverings, which is one of the three types of two-dimensional (2D) cell patterns. The other two are packings (photoreceptors) and tilings (GCs). Patterns are partly defined by the extent of overlap that exists between members of a cell group (the coverage factor, CF) and how evenly the geometric centers of the cell fields are distributed over space (the conformity ratio, CR). Packings such as blue cones have CF < 1 and CRs ≈ 3 (weakly orderly) in mammals to >15 (crystalline) in fishes. GCs tile, with CFs ≈ 1 and CRs ≈ 3. Coverings shown by ACs have CF >1–100, indicating that for some ACs, dendritic fields of over 100 cells overlap a single point in the image plane, implying an intense synaptic control of signaling in that zone. Most CRs for ACs range from 1 to 4 in mammals. Using our examples from above (**Figure 2(d)**), radiate cells have CF $\approx$ 4–6 (center-to-center spacing) and form a sparse, but orderly, synaptic mesh over the retina. Starburst cells have CF ≈ 60 or more and densely pack the synaptic space. Narrow-field glycinergic ACs have CF ≈ 1 and act as nonspatial intercalary amplifiers or cross-channel controllers (discussed below).

AC Synapses and Neurochemistry

Almost all ACs are driven by BCs at ribbon synapses, decoding that glutamatergic input with a-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors. ACs driven by rod BCs almost exclusively use AMPA-receptor-mediated currents, while most of those driven by cone BCs amplify and sustain the initial AMPA-driven currents with *N*-methyl D-aspartate (NMDA) receptors. Most native AMPA receptors are heteromers (some homomers may exist) of two or more of four known glutamate receptor (GluR) subunits: GluR1, GluR2, GluR3, and GluR4. There is no required stoichiometry; however, receptors with a mixture of GluR2 and GluR3 subunits are common in the brain and retina. There are post-translational modifications that change receptor conductances, kinetics, and glutamate sensitivity. The most important of these is the *gluR2* messenger ribonucleic acid (mRNA) pre-editing of a codon that converts a pore-lining neutral Q residue to a cationic R residue. Almost all mature GluR2 subunits are edited.The expressing of a GluR2 subunit has four important actions regardless of its partners: (1) it nearly abolishes the AMPA receptor Ca^{2+} permeability; (2) it decreases the channel conductance twofold or more; (3) it linearizes the I–V relation; and (4) it eliminates the GluR1 subunit phosphorylation-dependent increases in receptor conductance. Thus, ACs can express a range of sensitivities to glutamate. The most glutamate-sensitive neuron in the retina is the starburst AC population. Similarly, ACs express different levels and kinds of NMDA receptors, resulting in a broad spectrum of response attributes.

The outputs of ACs are conventional synapses targeting BCs, ACs, and GCs. Thus, ACs are positioned to powerfully shape all signal flow through the retina. However, there is a key difference in the high tonic vesicle fusion rate synapses of photoreceptor and BC ribbon synapses and the transient vesicle fusion of ACs. As a result, ACs act as temporal filters and signal through bursts of apparently precisely timed inhibitory transmitters. The presynaptic vesicle pools of ACs are generally very small, with tens to hundreds of vesicles, rather than the pools of thousands harbored by BCs. Thus, the actions of ACs are both swift and subtle. This is unlike the strong tonic influence of HCs as shown below.

Of the approximately 30 classes of ACs described for mammals, half to two-thirds of the classes are GABAergic and release GABA via small to large patches of vesicles at conventional synapses. Most of the remaining cells are narrow-field glycinergic cells. These two fast classical inhibitory transmitters act largely by opening anion-permeant channels that, in most cases, generate hyperpolarizing inward chloride currents. The purpose of the two kinds of anion channel transmitters is additivity: they do not occlude each other's receptors either by desensitization or by subadditivity, as in the cases of side-by-side GABA receptor patches.

The targets of GABAergic ACs decode GABA signals with either ionotropic GABAA or GABAC receptors (which modulate anion conductances) or metabotropic GABAB receptors that modulate K^+ conductances, or the operating range of voltage-gated Ca^{2+} channels. The difference between GABAA and GABAC receptors is similar to the difference between fast AMPA receptors and slower, more sustained NMDA receptors. GABAA receptors are heteromeric pentamers of GABA receptor subunits. Though they can have large anion conductances, they tend to desensitize quickly and act transiently. GCs and ACs predominantly express GABAA receptors. Ionotropic

GABAC receptors are homomeric assemblies of ρ subunits and are, arguably, a subset of the GABAA receptor group. When activated by GABA, GABAC receptor conductances are smaller, but more sustained, and they are more GABA sensitive. These receptors are primarily expressed by BCs. Since both ionotropic GABA and glycine receptor types activate chloride conductances, their efficacies can vary with the membrane potential of the target cell and the chloride gradient. Another mechanism that mediates the inhibition is shunting inhibition, where large conductance increases diminish the space and time constants of small dendrites. This inhibition is independent of the postsynaptic voltage and the chloride gradient and is most effective on small processes far from the major dendrites of a cell.

GABAB receptors are also highly effective regardless of membrane potential. They are guanine nucleotide binding protein coupled receptors (GPCRs) that either increase the voltage threshold of synaptic Ca^{2+} channels or the conductance of K^+ channels, strongly hyperpolarizing the cells (both slowing synaptic release). The former effect seems more prominent on BC axon terminals and the latter in GC dendrites or somas. Each mechanism can inhibit synaptic signaling in target processes with different timing and efficacy. However, the synaptic gain of such signaling is generally low and is often lesser than 1. Thus, individual GABAergic or glycinergic synapses are rather weak, and stimulus-dependent synchronicity is required for strong effects.

Several additional neuroactive signals associated with GABAergic ACs are co-transmitters: acetylcholine (ACh), certain catecholes, serotonin in nonmammalians, several peptides, and nitric oxide (NO). The differential regulation (if any) of GABA and ACh, catecholamine, serotonin, or peptide release is poorly understood. Glutamate may also be an excitatory AC co-transmitter for glycinergic ACs that express vGlut3, a vesicular glutamate transporter. Further, the roles of peptides and monoamines in information processing *per se* are also not completely clear, though some data suggest that peptides such as somatostatin may improve signal-to-noise ratios through an unknown mechanism.

ACs and Signal-Processing Fundamentals

ACs are components of small network submotifs (stereotyped aggregates of cell processes and synapses) that carry out analog signal-processing operations, including filtering (spatial, temporal, and spectral), gain control, signal–noise separation, signal buffering, and feature definition. Feedback is an essential control process in all amplification systems. Sign-inverting feedback (**Figure 3(a)**) is the primary mechanism by which most of these operations are effected in biology and electronics, and its essential nature is the addition of a scaled, inverted copy of the output of an amplification stage back to that stage. Every system has an input–output response R that, for simple time-invariant linear systems, can be expressed as a transfer function of stimulus frequency $G(s)$, where G is the system gain and s is frequency. This is often referred to as the open-loop gain and has a shape similar to that in **Figure 3**. As inputs become faster (higher frequency), the gain begins to fall off. In a moving transient world, we would prefer to have the best gain at a higher frequency and negative feedback as the mechanism. The electronic negative-feedback amplifier was invented by Harold Stephen Black of Bell Laboratories in 1927, and the biological one by evolution some 3 billion years BP. By providing an inverted signal with transfer function $H(s)$ to the input, R changes from $G(s)$ to $G(s)/[G(s)H(s)+1]$. For $H(s) \geq 1$, the shape of the response function changes based on the shape of $H(s)$. If $H(s)$ is a slow, tonic response, then by depressing slow frequencies more than fast ones, R feedback has an improved frequency response. Similarly, feedback can reduce noise. Negative feedforward is also common biologically and can be even more potent in shaping outputs than feedback, although it is not as effective for frequency response or noise control.

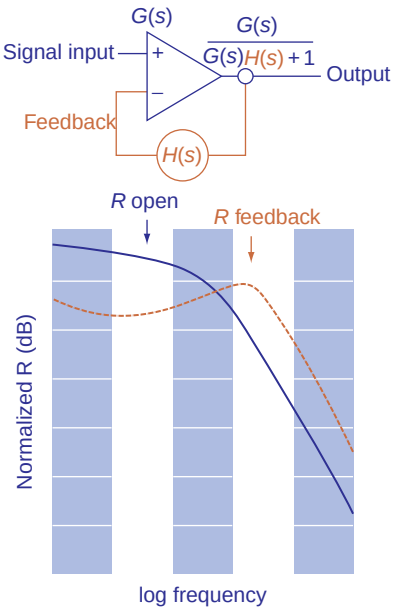

Figure 3 The basic principles of feedback. Top: an operational amplifier feedback circuit with an open loop sign-conserving transfer function $G(s)$ and part of the output fed back to the sign-inverting input, the transfer function $H(s)$, and net output transfer of $G(s)/[G(s)H(s)+1]$. Bottom: the effect of feedback on a given amplifier's performance. With no feedback, the response R as a function of frequency slowly rolls off. With feedback, the normalized peak response is at a higher frequency.

We can consider the retina as having only two amplification stages: (1) photoreceptors → BCs and (2) BCs → GCs (**Figure 4**). Every stage of feed-forward gain also requires feedback or feed-forward control, whether made of silicon or cells. In the retina, an amplification stage is a

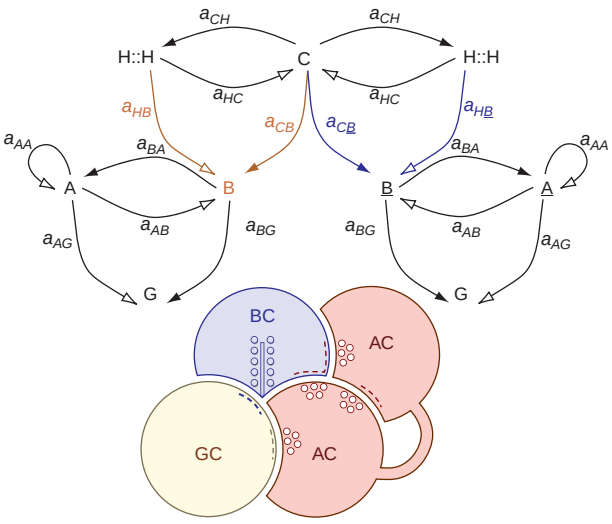

Figure 4 The basic connectivity of ACs. Top: the stages of amplification in the retina flowing from cones (C) to BCs (B) to GCs (G). Cones provide lateral excitatory signals to coupled sheets of HCs (H::H) which, in turn, provide lateral feedback to cones and lateral feed forward to BCs. Cone signals bifurcate, generating sign-conserving responses in off BCs (B) and sign-inverting responses in on BCs (B̲). Similarly, any feed-forward HC signals must also bifurcate to generate sign-inverting signals in off BCs and anomalous sign-conserving signals in on BCs. BC signals bifurcate and drive both ACs and GCs with sign-conserving mechanisms. ACs have the most complex topology, with feedback signals to BCs, feed-forward signals to GCs, and nested feed-forward/feedback by re-entrant loops. Every pairwise signal transfer has a transfer function, for example, B → A has transfer a_{BA}. Bottom: the topology of AC signaling at the BC → GC synapse. BCs provide a fast glutamatergic ribbon synapse input to ACs and GCs via AMPA receptors (blue dashes). ACs provide small conventional synapse GABA inhibition at predominantly ionotropic GABA receptors (red dashes) on ACs, BCs, and GCs.

small collection of properly connected excitatory and inhibitory synapses. Each synapse is itself a bicellular amplifier that encodes a presynaptic input voltage as a time-varying neurochemical signal, and postsynaptically decodes it as a direct current via ionotropic receptors or an indirect current or response modulation (e.g., intracellular Ca^{2+} release), typically through G-protein-coupled receptors (GPCRs). Excitatory synapses typically have amplifications or gains >>1, while inhibitory synapses typically have gains <1. ACs are the key feedback and feed-forward devices of the inner plexiform layer and their spatial distributions shape the nature of their interactions with BCs and GCs.

In detail, there are three primary submotifs that can strongly shape how ACs are involved in signal processing (Figure 4). The first is the classical reciprocal feedback synapse BCΔAC, wherein a signal from a BC ribbon onto an AC process is directly antagonized by an AC, typically a γ AC. This signaling pathway increases the frequency response and stabilizes the gain of the BC itself. The second is the parallel classical feed-forward synapse chains BC1 G and BC1 AC G where the AC synapse antagonizes the BC excitation directly in the GC. However, as any BC noise has already been amplified by the BC1 G synapse, feed forward is ineffective in improving the signal-to-noise ratio. However, it is very effective in generating stimulus-specific lateral signals in GCs. The third submotif is the AC AC synapse. While extremely common, the kind of signal processing associated with this submotif is poorly understood. In its most concrete form, homotypic or even autotypic AC synapses appear to be a fundamental attribute of the reciprocal feedback system by adding a loop known as nested feedback: BC□AC□. This process is reminiscent of nested transconductance amplifiers where stages of looped self-inverting signals are used to tune up the amplifier, endowing it with better, high-frequency performance and giving it a wider bandwidth. Nested AC feedback may do the same.

Examples of AC Networks

There are almost no AC systems whose complete range of functions is completely understood, largely owing to their diversity and the difficulty of obtaining large physiological samples. Four generic mammalian AC networks and signal processing functions that are of particular interest are outlined here.

γ ACs of the Rod Pathway

γ ACs of the rod pathway mediate temporal processing, gain control, and noise suppression. Extensive anatomy, ultrastructure, physiology, and pharmacology reveal the serotonin-accumulating (S1/S2) γ ACs of the mammalian retina to be archetypal in-channel feedback devices. The mammalian rod pathway is unique among vertebrates (as far as is known) in using two cycles through BC amplification (Figure 5). All the outputs of the rod BC target ACs of two major classes: γ ACs that engage in feedback and gly ACs that engage in re-entrant feed forward to pass rod signals through the cone on and off channels. Every BC displays γ feedback synapses, which suggests that the narrowly stratified medium-to-wide field γ AC is a standard motif component. Rod BCs display clear GABAC-mediated inhibition and the S1/S2 γ ACs that provide feedback are strongly AMPA driven, on-center ACs. This simple feedback circuit will provide the BC with better temporal response, as scotopic light gets brighter, and improve signal-to-noise performance. Though the mammalian retina contains no serotonin, it is likely that the indoleamine-transporting S1/S2 cells are descendants of the nonmammalian serotoninergic/γ (S γ AC) system, which forms feedback synapses with both off and on mixed rod-cone BCs. The disappearance of serotonin signaling is clearly a recent evolutionary event, but the

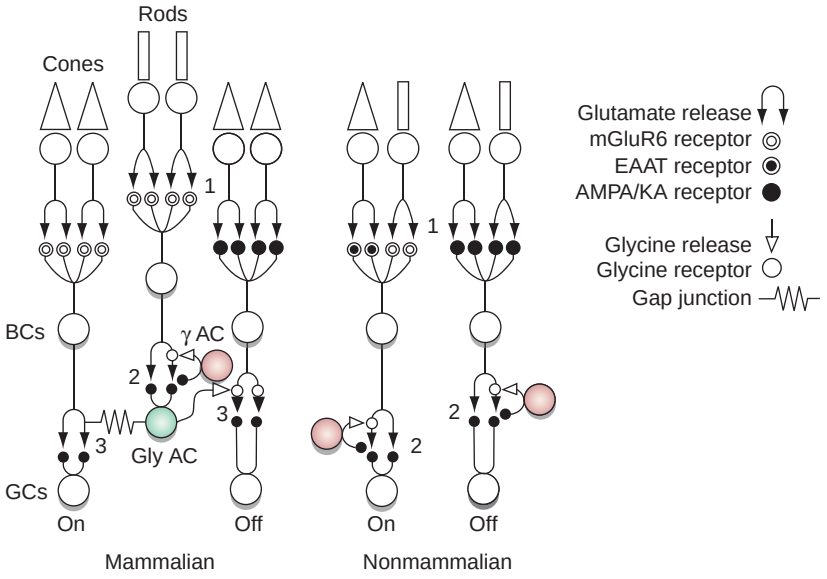

Figure 5 A comparison of rod and cone convergence onto GCs in mammalian and nonmammalian retinas. Nonmammalians use conventional mixed rod-cone BCs with direct input onto GCs and classical GABAergic feedback. Mammals predominantly exploit a rod BC that drives an intermediate stage of gain via the gly rod AC, which re-enters the cone pathways at the inner plexiform layer. The gly rod AC rives the off-BC pathway with sign-inverting glycine receptors and the on-BC pathway with gap junctions. Similar to nonmammalians, the γ rod AC provides BC feedback.

association of this simple BCΔAC network with rod BC pathways is clearly ancient.

Gly ACs of the Rod Pathway

Gly ACs of the rod pathway mediate cross-channel feed-forward buffering. In electronics, a buffer is an element interposed between two device stages to provide improved transfer. Buffers are often used to fan out input signals to several different outputs while isolating the input stage from the output loads. The gly rod AC represents an evolutionary buffer to further amplify the rod signal and distribute it in a low-noise manner. All vertebrates send rod signals to the CNS via GCs that also carry cone signals. There is no private rod pathway to the brain, though almost all species have private pure cone photopic channels (e.g., the primate foveal midget pathway). Nonmammalians combine the rod and cone pathways at the first synapse in the outer plexiform layer by converging on mixed rod-cone BCs. This chain involves two high-gain ribbon synapses: rod → mixed BC → GC. Mammalians combine rod and cone pathways by fanning out from a pure rod BC pathway back into cone pathways via two scotopic motifs in the inner plexiform layer:

1. rod → rod BC → gly rod AC :: ON cone BC → GC and
2. rod → rod BC → gly rod AC → OFF cone BC → GC.

This circuit is more complex as there are two photopic motifs:

1. cone → OFF cone BC → gly rod AC and
2. cone → ON cone BC :: gly rod AC.

There are also γ AC → gly AC inputs of unknown provenance. Physiologically, dark-adapted rod ACs have strong transient AMPA-like depolarizations, while light-adapted cells have more sustained, small depolarizations. In what manner all of the inputs are regulated remains unknown.

Small γ ACs of the Primate Midget BC → GC Pathway

These cells may mediate the red–green (R–G) color opponent pathway. These ACs receive direct input from midget BCs of either the on or off pathways and provide reciprocal feedback as well as feed forward to a small patch of midget GC dendrites. Midget GCs apparently connect almost exclusively to cones that express the long-wave system (LWS) pigment gene: either LWS VP 560 nm (R) or LWS VP 530 nm (G) cones. By extension, midget BCs exist as R and G forms. Ultrastructural data suggest that each AC collects signals from several midget BCs and is presynaptic to each. This suggests that there is no R–G chromatic selectivity in the AC surround and that a midget-pathway AC has no mechanism to sort BC chromatic type. This sets the stage for one of the longest running controversies in primate vision. Are midget CG receptive fields truly center/surround (C/S) pure opponent [+R/–G, –R/+G, +G/–R, and –G/+R] or are they a collection of cells with a weighted distribution of

surrounds that range from predominantly R or G or a mixture of R+G or yellow (Y) signals? A purely theoretical model has been proffered that involves glyc ACs as nulling tools to remove the inappropriate signal, making the surround appear pure. In any case, the appearance of small, spectrally pure antagonistic surrounds is inconsistent with large yellow-dominated HC surrounds observed in blue on-center GCs. How that signal disappears from R and G cone BCs remains a mystery in the face of strong evidence of coneΔHC feedback.

γ ACs of the Directionally Selective GC pathway

γ ACs mediate feature detection in the directionally selective (DS) GC pathway. The best-known feature detection event in the retina is the dependence of mammalian DS GC signaling on ionotropic GABA receptors. DS GCs exist in both on and on–off varieties; however, the qualitative feature of their signaling is similar. DS GCs have two response modes: (1) when a stimulus spot approaches the cell from the excitatory side, the cell fires, excited by both cone BC glutamate release activating AMPA receptors and starburst AC ACh activating nicotinic ACh receptors. Similar to the rod gly AC, starburst ACs provide the afferent flow with another burst of gain: cone → cone BC → starburst AC → GC. As starburst ACs are one of the most glutamate-sensitive cells in the retina, this makes DS cells exceptionally responsive. (2) When a stimulus spot approaches the cell from the null side, firing is inhibited by a GABAergic mechanism, possibly a γ AC or AxC (see below) with an eccentric output field so that it receives excitation long before the DS GC does. The blockade of ionotropic GABAA receptors converts the DS GC into a highly excitable cell with no directional bias. It has been found that starburst ACs themselves have a directional bias in that stimuli starting at the tips of the dendrites tend to hyperpolarize and those starting dead center and moving away tend to depolarize; in addition, some authors argue that this is sufficient to build a DS network. However, given the CF of the starburst ACs (>100) compared to that of the DS GCs (≈1), the geometric requirements for this seem difficult to achieve. It is possible, even probable, that an additional γ AC or AxC is involved, as shown in **Figure 6**.

Axonal Cells

A subset of retinal neurons are the axonal or polyaxonal cells, which includes one of the dopaminergic neurons of the mammalian retina. Many are clearly GABAergic, while others, such as the dopaminergic neuron, may be dual glutamate/dopamine neurons. The essential feature of AxCs is the axon: a long–range output device that enables these neurons to send signals to regions substantially displaced from the soma and dendritic arbor. AxCs (including dopamine neurons) show either on or on–off responses. In nonmammalian retinas, object motion-selective (OMS) cells achieve their feature detection via polyaxonal γ AxCs. This raises the question of whether the mammalian DS GC uses the same strategy.

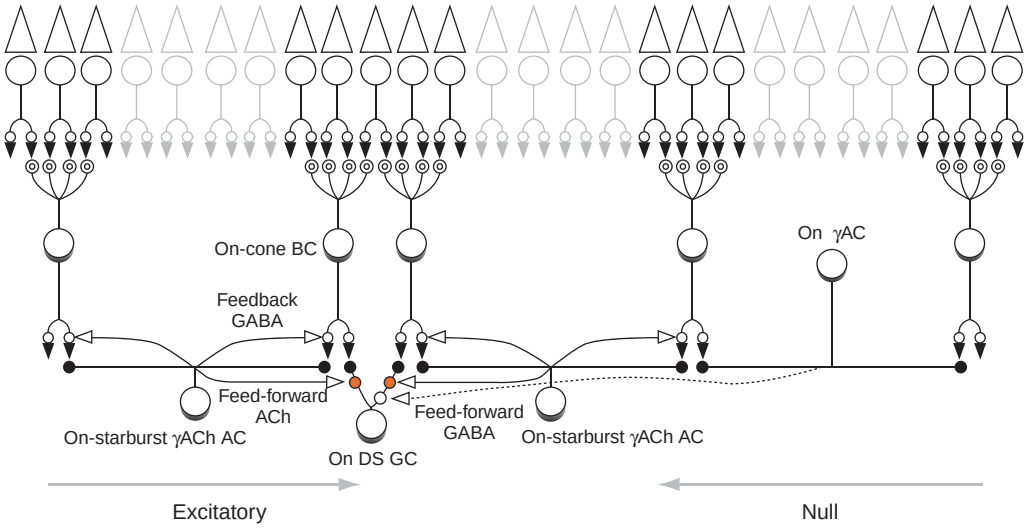

Figure 6 One topology for the generic on directionally selective (DS) pathway. The on DS GC receives glutamatergic excitation directly from on-cone BCs (black arrows and dots) and cholinergic feed-forward excitation (red dots) from local patches of starburst ACs. The starburst ACs also provide GABAergic feedback to BCs (open arrows and dots). While some argue that the starburst alone can generate directional surrounds for DS GCs, the symmetry of starburst AC fields makes this a challenging model. Similar to object motion sensitive (OMS) GCs, it is also possible that a γ polyaxonal AxC provides asymmetric inhibition for targets approaching from the null direction.

ACs and Disease

Over the past 5 years, it has become evident that, similar to the CNS, the retina undergoes extensive remodeling in response to sensory deafferentation effected by retinal degenerations, especially the retinitis pigmentosas. ACs are especially active components of remodeling, often sprouting new dendrites and participating in anomalous synaptic structures known as microneuromas. In addition, similar to other retinal neurons, they can be induced to relocate to ectopic somatic clusters loci (either to the distal retinal margin or GC layer) via anomalous migration columns. The most resilient cells of all, they are the last to die as the retina is slowly depleted of neurons. In fact, ACs may be a key component of neural survival in the remnant retina by providing a periodic source of neural activity in the absence of photoreceptors.

Information Processing: Bipolar Cells

S M Wu, Baylor College of Medicine, Houston, TX, USA

Glossary

Center-surround antagonistic receptive field (CSARF) – A receptive field of a visual neuron whose light response to light falling on the center region is of the opposite polarity (or spike increment/decrement) to the response to light falling on the surrounding regions of the cell's receptive field.

Depolarizing (ON-center) bipolar cell (DBC) – A bipolar cell exhibiting a depolarizing voltage response to light falling on the center region of its receptive field and a hyperpolarizing voltage response to light on its receptive field surround region.

Distal and proximal retina – In a retinal cross section, the distal retina refers to the photoreceptor side of the retina and the proximal retina refers to the ganglion cell side.

Feedback synapse – A synapse made from a higher-order neuron to a lower-order neuron, such as synapses made from horizontal cells to cones and from amacrine cells to bipolar cell axon terminals.

Hyperpolarizing (OFF-center) bipolar cell (HBC) – A bipolar cell exhibiting a hyperpolarizing voltage response to light falling on the center region of its receptive field and a depolarizing voltage response to light on its receptive field surround region.

Metabotropic glutamate receptor 6 (mGluR6) – A metabotropic glutamate receptor coupled with a second-messenger cascade found in DBC dendrites. It results in closure of cation channels in DBCs when bound with glutamate or its agonist L-2-amino-4-phosphonobutyrate (LAP4).

Rod bipolar cell – A bipolar cell whose light-evoked cation current is mediated primarily by rod synaptic inputs. In mammals, only rod DBCs have been identified.

Bipolar cells (BCs) are second-order neurons in the retina whose somas are located in the distal half of the inner nuclear layer (INL) (except for the displaced BCs found in some species whose somas are located in the outer nuclear layer (ONL)). BC dendrites branch in the outer plexiform layer (OPL) and make synaptic contacts with rod spherules, cone pedicles, and horizontal cell (HC) dendrites. Each BC bears an axon projecting to the inner plexiform layer (IPL) with terminals ramifying in different patterns at different sublaminae of the IPL. Based on their rod/cone contacts and axon terminal ramification patterns, BCs have been classified morphologically into several types. In mammals, one type of rod BC and 9 to 10 types of cone BCs have been identified (**Figure 1**). In fish, small BCs make synaptic contacts exclusively with cones and large BCs make contacts with both rods and cones, and in turtle, 11 morphological types of BCs have been found, with some contacting only cones and others contacting only rods. BCs in amphibian retinas contact both rods and cones, but some are clearly rod dominated where others are cone dominated.

BCs are the first neurons along the visual pathway that exhibit the center-surround antagonistic receptive field (CSARF) organization, the basic code for spatial information processing in the visual system. Light falling directly on the BC receptive field center region elicits voltage responses of the opposite polarity to the responses elicited by light falling on the surrounding regions of the BC's receptive field. BCs may be ON center with OFF surrounds (named ON-center BCs or depolarizing BCs (DBCs)), or OFF center with ON surrounds (named OFF-center BCs or hyperpolarizing BCs (HBCs)). The center input of BCs is mediated by rod and cone photoreceptors, which make chemical synapses on BC dendrites. BC receptive field centers are often found to be larger than their dendritic fields, suggesting that these cells may be electrically coupled. The surround input to BCs is mediated by interneurons that carry signals laterally from the surround region to the central region of the BCs' receptive field. These interneurons include HCs in the outer retina and amacrine cells (ACs) in the inner retina. HCs mediate BC surround responses through HC–cone–BC feedback synaptic pathways and/or HC–BC feed-forward (electrical or chemical) synapses, whereas ACs mediate BC surrounds through chemical synapses made on BC axon terminals in the IPL.

By using the whole-cell or microelectrode recording techniques in conjunction with fluorescent dye filling method, it has been shown that light response characteristics of various types of BCs are closely correlated with their axon terminal morphology. For example, it has been found in many species that axon terminals of DBCs ramify in the proximal half (sublamina B) of the IPL, whereas those of the HBCs ramify in the distal half (sublamina A) of the IPL. Axon terminals of rod BCs in mammalian retinas end near the proximal margin of the IPL, and axon terminals of cone BCs ramify in more central regions of the IPL. This agrees with the patterns of BC axon terminal stratification

in the salamander: axon terminals of rod-dominated BCs ramify at the two margins of the IPL, whereas those of cone-dominated BCs ramify at central regions of the IPL. Additionally, despite the anatomical finding that mammalian rod and cone BCs make segregated synaptic contacts with rods and cones, it has been recently shown that some mammalian BCs exhibit mixed rod/cone responses similar to most BCs in lower vertebrates. Furthermore, although rod HBCs were not identified by earlier mammalian anatomical studies, recent physiological evidence suggests that they may exist at least in some mammals.

Based on studies of BC physiological properties in various species, it is reasonable to propose that vertebrate retinas have six major functional types of BCs: the rod (or rod dominated), cone (or cone dominated), and mixed (rod/cone) depolarizing and hyperpolarizing BCs (DBC_R, DBC_C, DBC_M, HBC_R, HBC_C, and HBC_M). Each carries a characteristic set of light response attributes and projects them to the inner retina through axons that terminate at segregated regions (strata) of the IPL. Such stratum-by-stratum projection of light response attributes is exemplified by a large-scale voltage-clamp study of the salamander BC responses and morphology. This study reveals several rules for the function–morphology relationships of retinal BCs: (1) Cells with axon terminals in strata 1–5 (sublamina A) are HBCs (with outward light-evoked cation currents (ΔI_C)) and those in strata 6–10 (sublamina B) are DBCs (with inward ΔI_C). This agrees with the sublamina A/B rule observed in many vertebrate species (see, e.g., **Figure 1**, in which the IPL is divided into five sublaminae instead of 10). (2) Cells with axon terminals in strata 1, 2, and 10 are rod dominated, those in strata 4–8 are cone dominated, and

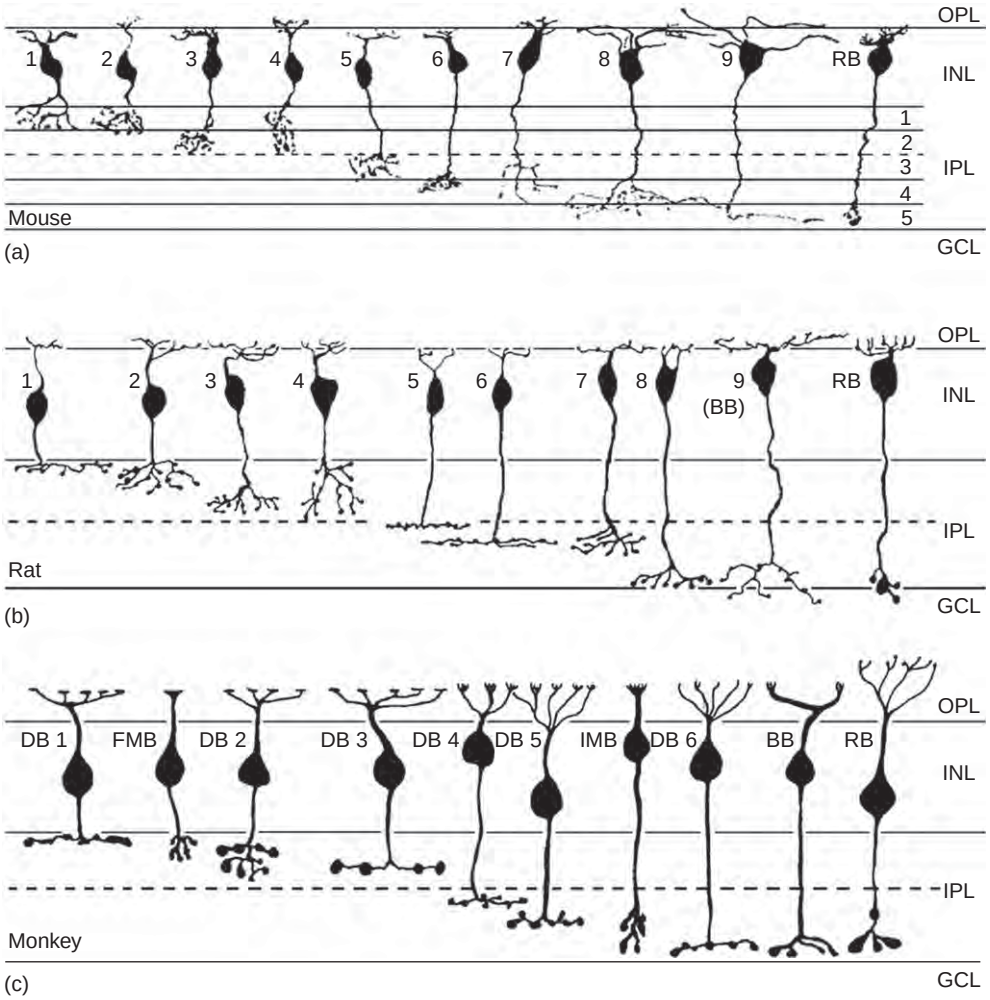

Figure 1 Schematic diagram of various types of bipolar cells in the mouse (a), rat (b), and monkey (c) retinas. Bipolar-cell images are derived from confocal images (a) or drawings (b) of Lucifer yellow/neurobiotin-injected cells, or drawings of Golgi-stained retinas (c). Inner plexiform layer (IPL) in this figure is divided into five sublaminae and IPL in the salamander retina (**Figures 2** and **3**) is divided into 10 sublaminae. OPL, outer plexiform layer; INL, inner nuclear layer; GCL, ganglion cell layer. From Ghosh, K. K., Bujan, S., Haverkamp, S., Feigenspan, A., and Wassle, H. (2004). Types of bipolar cells in the mouse retina. ***Journal of Comparative Neurology* 469: 70–82.**

those in strata 3 and 9 exhibit mixed rod/cone dominance. (3) Light-evoked ΔI_C at light onset in rod-dominated HBCs and DBCs are sustained, that of the cone-dominated HBCs exhibit a smaller sustained outward current followed by a transient inward current at the light offset, and that of the cone-dominated DBCs exhibit a sustained inward current followed by a small transient off outward current. (4) ΔI_{Cl} (light-evoked chloride currents) in rod-dominated BCs are sustained ON currents, whereas those in cone-dominated BCs are transient ON–OFF currents. ΔI_{Cl} in all BCs are outward, and thus they are synergistic to ΔI_C in HBCs and antagonistic to ΔI_C in DBCs. (5) BCs with axon terminals stratified in multiple strata exhibit *combined* light response properties of the narrowly monostratified cells in the same strata. (6) BCs with pyramidally branching or globular axons exhibit light response properties very similar to those of narrowly monostratified cells whose axon terminals stratified in the same stratum as the axon terminal endings of the pyramidally branching or globular cells.

In addition to projecting signals to various strata of the IPL, where ACs and ganglion cells (GCs) gather their inputs, BCs with various light response attributes have different CSARF organizations. **Figure 2** shows the morphology, patterns of dye coupling, light responses, CSARF properties, and membrane resistance changes associated with the center and surround voltage responses of the six functional types of BCs (HBC_R, HBC_M, HBC_C, DBC_C, DBC_M, and DBC_R) in the tiger salamander retina. These results suggest that the center and surround responses of various types of BCs in the retina are mediated by heterogeneous synaptic circuitry. The BC receptive field center diameters (RFCDs) vary with the relative rod/cone input: RFCD is larger in DBCs with stronger cone input, and it is larger in HBCs with stronger rod input. RFCD also correlates with the degree of dye coupling: BCs with larger RFCD are more strongly dye coupled with neighboring cells of the same type, suggesting that BC–BC coupling significantly contributes to the BC receptive field center.

BC center inputs are mediated by glutamatergic synapses. In darkness, glutamate is released from rod and cone photoreceptors, and it closes cation channels in DBCs and opens cation channels in HBCs. Postsynaptic responses of DBCs are mediated by metabotropic (metabotropic glutamate receptor 6 (mGluR6), L-2-amino-4-phosphonobutyrate (L-AP4)-sensitive) receptors coupled with a second-messenger cascade. In fish, the cone-to-DBC synaptic signal is mediated by a glutamate-activated chloride current that is suppressed by light and thus results in a membrane depolarization. Postsynaptic responses of HBCs are mediated by ionotropic receptors, and recent studies have shown that different subtypes of ionotropic glutamate receptors may be used by different types of HBCs in mediating rod/cone and transient/sustained signals.

Membrane resistance measurements in **Figure 2(e)** demonstrate that the center responses of all HBCs are associated with a resistance increase and the center responses of all DBCs are accompanied with a resistance decrease. This is consistent with the notion that glutamate released from rods and cones in darkness opens α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA)/kainate receptor-mediated cation channels in HBCs and closes mGluR6-receptor-mediated cation channels in DBCs. Center light stimuli hyperpolarize rods and cones, suppress glutamate release, and result in a resistance increase (close ion channels) in HBCs and a resistance decrease (open ion channels) in DBCs.

Figure 3 is a schematic representation of the possible and unlikely synaptic pathways underlying surround inputs of various types of BCs, based on the surround response polarity and accompanying resistance changes shown in **Figure 2**. These results suggest that the HC–cone–BC feedback synapses may contribute to the surround responses of all six types of BCs. The negative HC–cone feedback synapses (pathway I) partially turn off the center responses by depolarizing the cones, as the membrane resistance changes associated with surround responses of all BCs are opposite to the resistance changes associated with center responses (**Figure 2(e)**).

Although all BCs share a common surround response pathway (the HC–cone–BC feedback pathway), various types of BCs use different HC and AC synaptic inputs to mediate their surround responses. It is unlikely, for example, that HBC surround responses are directly mediated by chemical synaptic inputs from hyperpolarizing lateral neurons, such as HCs and AC_{OFF}s, because of resistance change mismatch, and thus HBCs may only receive surround inputs from HC–cone–HBC and AC_{ON}–HBC synapses. On the other hand, resistance analysis suggests that DBC surround responses can be mediated by HC–cone–DBC, HC–DBC and AC_{OFF}–DBC chemical synapses, but not the AC_{ON}–DBC synapses. Moreover, dye coupling (**Figure 2(a)**) results indicate that DBC_Cs receive additional surround inputs from wide-field HCs through electrical synapses. Despite the heterogeneity, it is interesting to point out that an ON/OFF crossover inhibition rule applies here: cells with OFF (hyperpolarizing) responses (HCs and AC_{OFF}s) mediate surround inhibitory inputs to ON cells (DBCs); and cells with ON (depolarizing) responses (AC_{ON}s) mediate surround inhibitory inputs to OFF cells (HBCs). ON/OFF crossover inhibition from ACs to GCs have been reported in the salamander and mammalian retinas, and the data shown in **Figures 2** and **3** suggest that it may be a general rule for lateral inhibition in the visual system.

HCs mediate BC surround responses through the feedback synaptic pathway (HC→cone→BC) and/or the feed-forward synapses (HC→BC). Three synaptic mechanisms have been proposed for the HC feedback actions on cones. The first is that HCs release an inhibitory neurotransmitter (gamma aminobutyric acid (GABA) in several

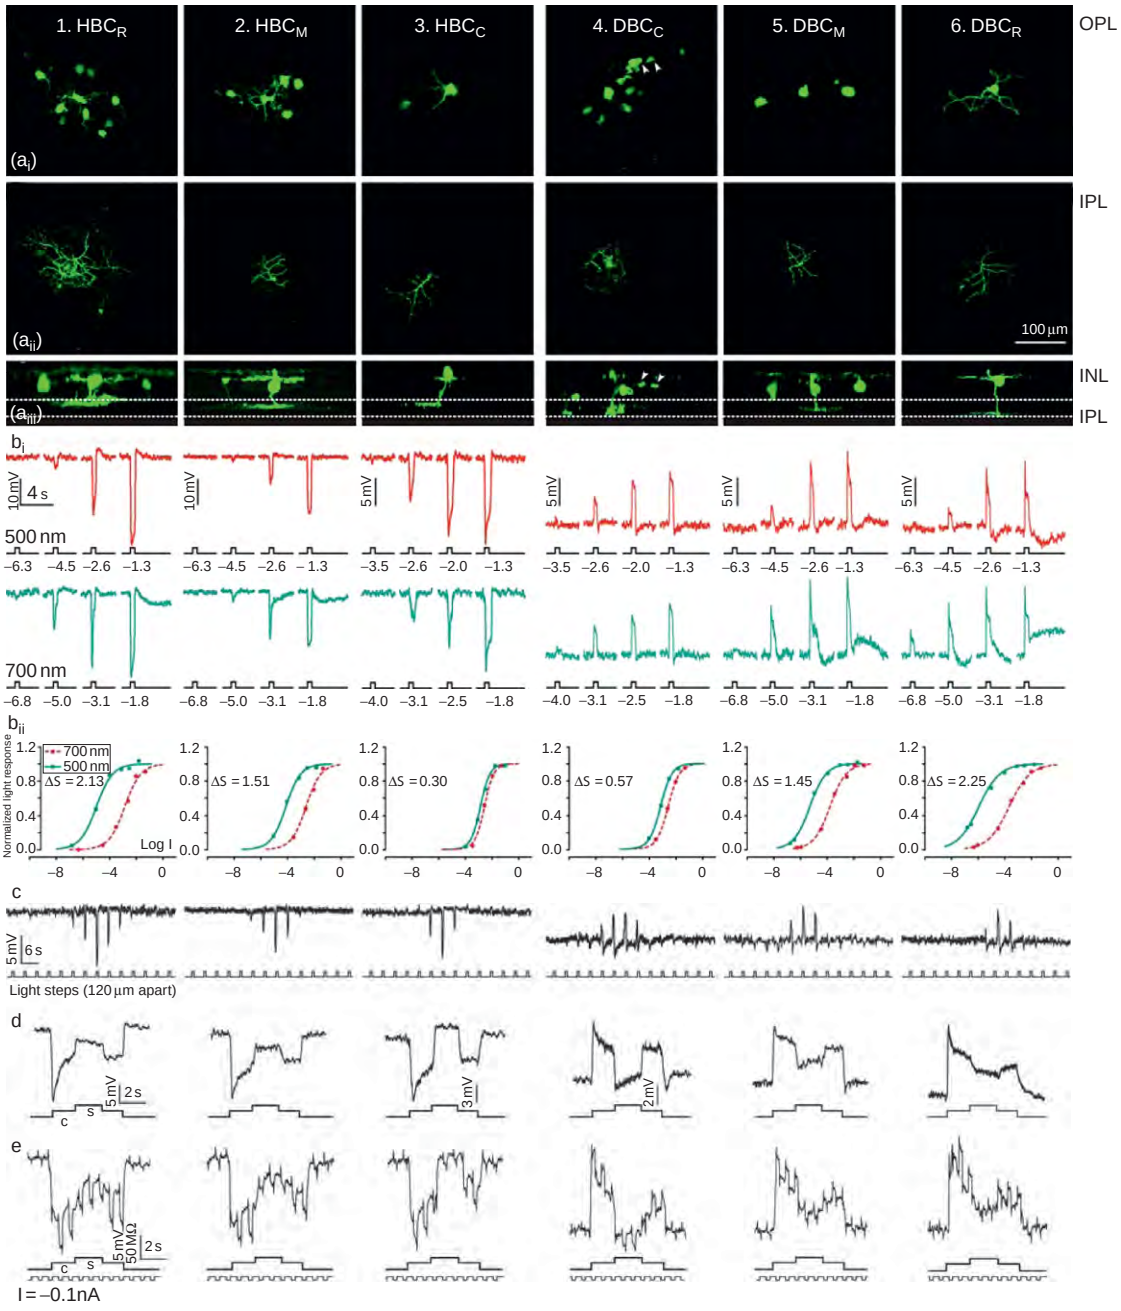

Figure 2 Morphology, light responses, and receptive fields of six types of bipolar cells in the tiger salamander retina. (a) Fluorescent micrographs of a neurobiotin-filled HBC_R (column 1), an HBC_M (column 2), HBC_C (column 3), a DBC_C (column 4), a DBC_M (column 5), and a DBC_R (column 6) viewed with a confocal microscope at the outer INL/OPL level (a_i), the IPL level (a_{ii}), and with *z*-axis rotation (a_{iii}). Scale bar = 100 µm. (b_i) BC voltage responses to 500 nm and 700 nm light steps of various intensities. (b_{ii}) Response-intensity (V-Log I) curves of the responses to 500-nm and 700-nm lights. ΔS (spectral difference, defined as $S_{700} - S_{500}$, where S_{700} and S_{500} are intensities of 700-nm and 500-nm light-eliciting responses of the same amplitude) of the six BCs are: 2.13, 1.51, 0.30, 0.57, 1.45, and 2.25. Since ΔS for the rods is about 3.4 and that for the cones is about 0.1 in the salamander retina, BCs with $\Delta S > 2.0$ are rod-dominated BCs, BCs with $\Delta S < 1.0$ are cone-dominated BCs, and BCs with $1.0 < \Delta S < 2.0$ are mixed rod/cone BCs. (c) Measurements of BC receptive field center diameters (RFCDs) by recording voltage responses to a 100-µm-wide light bar moving stepwise (with 120-µm step increments) across the receptive field. (d) Voltage responses of the six types of BCs elicited by a center light spot (300 µm) and a surround light annulus (700 µm, inner diameter; 2000 µm, outer diameter). The surround light annulus was of the same intensity (700 nm, –2) for all six cells, whereas the intensity of the center light spot was adjusted so that it allowed the annulus to produce the maximum response. (e) Voltage responses of the six types of BCs elicited by a center light spot and a surround light annulus (same as in (d)), and by a train of –0.1-nA/200-ms current pulses passed into the cell by the recording microelectrode through a bridge circuit. species) in darkness that opens chloride channels in cones, and surround light hyperpolarizes the HCs, suppresses feedback transmitter release, depolarizes the cones, depolarizes the HBCs, and hyperpolarizes the DBCs. The second mechanism is that surround light hyperpolarizes HCs, resulting in an outward current through hemichannels in their dendrites near the cones, charging the cone membrane and modulating calcium currents in cones, increasing their calcium-dependent glutamate release which depolarizes the HBCs and hyperpolarizes the DBCs. The third mechanism is that surround-induced HC hyperpolarization elevates the pH in the HC–cone synaptic cleft, leading to an increase of calcium current in cones and a higher rate of glutamate release which depolarizes the HBCs and hyperpolarizes the DBCs. It is possible that different species under different conditions favor different feedback synaptic mechanisms, and/or different types of HC–cone synapses in the same animal may use one or more of

these three HC–cone feedback mechanisms. This idea is supported by a recent study demonstrating that the responses of salamander GCs to dim surround stimuli are sensitive to GABA blockers and those to bright surround stimuli are sensitive to carbenoxolone, a gap-junction/hemichannel blocker.

The HC–BC feed-forward pathway requires a sign-preserving HC–DBC synapse and a sign-inverting HC–HBC synapse. Studies from salamander retina suggest that HC→DBC feed-forward synapses may be functional. However, application of GABA on BC dendrites in Co^{2+} Ringer's does not elicit any response, indicating that if feed-forward synapses are chemical, the neurotransmitter is not GABA. Histochemical evidence suggests that only about 50–60% of the HCs in the salamander retina are GABAergic, and the identity of neurotransmitter(s) in the rest of the HCs is unknown (but unlikely to be glycine). As illustrated in the salamander (**Figure 2(a)**) and the rabbit retinas, subpopulations of BCs are dye coupled with HCs, raising the possibility that HC–BC electrical coupling may be involved in mediating the HC–BC feed-forward synapses for DBC surround responses.

The AC–BC contribution to BC surround responses are mediated by GABAergic or glycinergic synapses. GABA receptors on ACs and GCs are largely $GABA_A$, and those on BC axon terminals are largely $GABA_C$. Glycine receptors have been localized in ACs, GCs, BC dendrites, and BC axon terminals. These receptors localized in the IPL are postsynaptic to glycinergic ACs, while those in the OPL are postsynaptic to glycinergic interplexiform cells. In the *Xenopus* retina, GABA suppresses the surround responses of the DBCs, but only slightly reduces the surround of the HBCs, and glycine suppresses the surround responses of both DBCs and HBCs. In the tiger salamander, one study shows that GABA reduces the surround responses of a subpopulation of HBCs, but another report reveals that application of picrotoxin and strychnine does not affect the surround responses of either DBCs or HBCs. Recent studies in the primate retina indicate that the HC feedback signal to cones as well as to the surround responses of GCs are not sensitive to GABAergic or glycinergic agents, but sensitive to carbenoxolone, suggesting that the surround responses in GCs are mainly mediated by HC actions on BCs in the outer retina, not by GABAergic or glycinergic AC actions in the inner retina. The reasons for these different GABA/glycine actions on surround responses are unclear. As illustrated in **Figures 2** and **3**, surround responses of different functional types of BCs in the salamander retina are mediated by different combinations of synaptic circuitries: HC→cone (GABA/hemichannel/proton) →BC, HC→BC (chemical/gap junction) and AC→BC (GABA/glycine). It is conceivable that the surround responses of different BCs/GCs from different animals under different conditions are mediated by different combinations of surround synaptic pathways, and thus they are sensitive to different synaptic blockers. The wide variation of synaptic circuitries underlying surround responses of various functional types of BCs allows for flexibility in function-specific modulation of BC/GC receptive fields. Hence different features of spatial and contrast information, such as rod/cone and ON/OFF signals, can be differentially modulated by different lighting and adaptation conditions.

Information Processing: Contrast Sensitivity

M B Manookin and J B Demb, University of Michigan, Ann Arbor, MI, USA

Glossary

Adaptation – The change in response properties of a neuron, which enhance the ability to encode the immediate environment.
Contrast – The percent deviation in light intensity from the mean intensity (as defined over some period of time and region of visual angle).
Filter – The concept of a neuron's receptive field as a tuning function that is matched to certain spatial or temporal frequencies.
Receptive field – The area of space and period of recent time over which changes in light input can modulate the response of a neuron.
Threshold – The lowest contrast level of a spatiotemporal pattern where a neuron can respond to the stimulus reliably (physiology) or where an observer can perceive the stimulus reliably (psychophysics).

Contrast Processing and Adaptation

Humans can see and behave across a wide range of lighting conditions. For example, one can navigate through the woods on a starry night, where each rod photoreceptor absorbs a photon only about once per minute; and yet one can also navigate across the beach on a cloudless day, where cone photoreceptors absorb thousands of photons per second. The mean luminance between these extreme examples can differ by ~100-million-fold. This wide range of intensities poses a computational problem for the retina, because a ganglion cell can fire only about 20 action potentials (spikes) in the ~100 ms integration time of a postsynaptic neuron. Thus, the ganglion cell must continually adjust its sensitivity so that the wide range of light levels (~8 log units) can be encoded with the narrow range of output signals (~1–2 log units).

To deal with the mismatch between input and output, the retina adjusts its sensitivity depending on the mean intensity, through mechanisms of light adaptation. These mechanisms are varied, and they include: the switch between rod photoreceptors (for night vision) and cone photoreceptors (for day vision); intrinsic properties of each receptor type that alter sensitivity depending on mean intensity; and postreceptoral mechanisms within the retinal circuitry. The apparent purpose of light adaptation is to adjust the ganglion cell's response to report, not the absolute intensity, but rather the contrast, or the percentage deviations from the mean intensity.

The contrast of a visual stimulus is a more robust property than the absolute intensity. To illustrate this point, consider a simple example, where an observer gazes at a bird on a background of leaves. Assume that the bird reflects 50% more light toward the observer's eye compared to the leaves (and ignore color in this example). Now imagine that the light reflected to the eye is reduced either by the observer's action (i.e., putting on a pair of sun glasses) or by a change in the light source reflecting off the objects (i.e., a cloud passes overhead, obscuring the sunlight). In either case, the light reflected into the eye is reduced 10-fold or more. However the relative reflectance is unchanged: the bird still reflects 50% more light than the leaves. Hence, it follows that the retina (and most of the visual system) is designed to encode contrast or the relative reflectance of objects within the same scene: the relative reflectance of objects represents a stable property of natural scenes, whereas absolute reflectance does not. Physiological measurements of retinal ganglion cells confirm this idea, showing that responses to a given contrast level are relatively constant over several orders of mean light level.

The Spatial Receptive Field

A ganglion cell calculates contrast over a specific retinal region known as its spatial receptive field. There are approximately 20 different types of ganglion cells whose axons form the optic nerve. These types encode different aspects of visual information, and some are highly selective for features such as wavelength of light or the direction of moving objects. Here, the focus is on the several types of ganglion cell that have a relatively conventional receptive field that can be described with an excitatory center region and an inhibitory surround region.

A ganglion cell's excitatory center corresponds to the retinal region aligned with its dendritic tree. Thus, the photoreceptors within the span of the ganglion cell's dendritic tree would all contribute to driving the excitatory center region. These photoreceptors synapse onto both ON- and OFF-types of bipolar cell, which express distinct glutamate receptors at their dendrites (metabotropic or

ionotropic, respectively) and therefore have opposite responses to light: ON-type cells are excited by light increments, whereas OFF-type cells are excited by light decrements. Most ganglion cell types collect synapses from either ON-type bipolar cells or OFF-type bipolar cells and then inherit the ON- or OFF-center property from these presynaptic bipolar cells.

A ganglion cell's inhibitory surround corresponds to the retinal region that extends beyond the dendritic tree. Thus, an OFF-center cell that is excited by light decrements over the tree is inhibited by light decrements over the surround region, beyond the tree. The center and surround combine to report the relative contrast over space. The center is commonly stronger than the surround, so that a large object covering both the center and surround will drive a center response (e.g., a large bright object will provide some excitation to an ON-center cell). For some cell types (e.g., the X/beta-type ganglion cell of the cat or the midget/parvocellular-projecting ganglion cell of the monkey), the center and surround combine in an approximately linear fashion. Thus, the response to center plus surround stimulation can be predicted reasonably well by summing the separate responses to center and surround measured individually. For other cell types (e.g., the Y/alpha-type of the cat) there is a nonlinear combination of center and surround regions. For these nonlinear receptive fields, the presynaptic bipolar cells may be described by relatively linear receptive fields; the major nonlinearity of the ganglion cell receptive field may arise at the level of the synaptic output of the bipolar cells as they converge onto the ganglion cell. In general, a ganglion cell's excitatory center is driven by the presynaptic bipolar cells, whereas the surround arises at two levels: the horizontal cells in the outer retina and the amacrine cells in the inner retina.

The Temporal Receptive Field

In addition to the two-dimensional spatial component, a ganglion cell's receptive field also has a temporal component. In many cases, ganglion cell responses can be described with a temporal filter that represents the best stimulus for driving a response. Thus, if the time course of the stimulus contrast over the past ~250 ms matches the filter, the response will be maximal. Ganglion cell firing rates can increase above the baseline rate much more than they can decrease below the baseline rate. In extreme cases, some ganglion cell types have essentially no background rate. Thus, a substantial nonlinearity in the ganglion cell's response is the threshold for firing action potentials (also known as rectification). The temporal filter concept must thus be combined with the concept of an output nonlinearity to predict a cell's response to a contrast modulation presented over time (**Figure 1**). A common method for modeling such responses is the linear–nonlinear model. The temporal filter can be measured by presenting a randomly flickering stimulus (commonly called white noise). For example, a spot over the receptive field center could have its intensity modulated over time. The response in the ganglion cell's firing rate could then be correlated with the stimulus to generate the filter. A separate step is used to relate the filtered output (a linear prediction of the temporal response) to

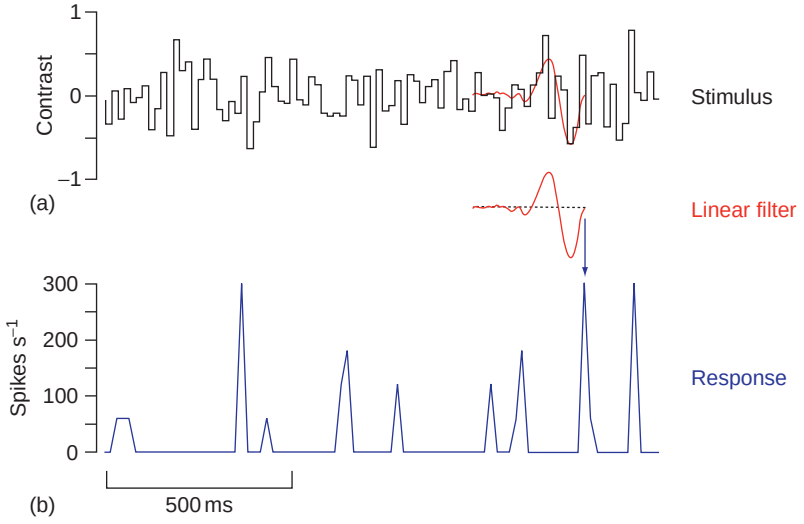

Figure 1 The retina temporally filters visual input. A temporal white-noise stimulus and firing rate response can be correlated to generate the linear filter. The filter represents a model of the temporal receptive field of the ganglion cell. The initial downward deflection (going backwards in time) indicates that the cell is an OFF-center type. The filter (red) is superimposed on the stimulus at a time when the stimulus closely matches the filter and the response output is large.

the actual firing rate; this step represents the nonlinearity associated with firing action potentials and typically includes a threshold for firing and also a point at which the firing rate saturates.

Receptive Field Properties Explain Contrast Sensitivity Functions

For cell types with linear receptive fields, the contrast sensitivity function can be explained by the receptive field properties described over space or time. For example, Figure 2(a) shows a temporal filter and its relationship to sinusoidal modulation of luminance of different temporal frequencies. The biphasic filter is best matched to the 6-Hz frequency and would thus predict a strong response to this frequency. At the lower frequency (1 Hz), the two phases of the filter are stimulated simultaneously and would therefore cancel to some extent; at the high frequency (12 Hz), the two phases of the filter are not stimulated strongly by the modulations and would thus, likewise, yield suboptimal responses. The response as a function of temporal frequency is plotted as the solid line in Figure 2(b). This line represents the cell's temporal tuning function (or temporal contrast sensitivity function).

The same concept of filtering can be applied to the spatial domain (Figure 2(c2) shows a one-dimensional cut through a circular center–surround receptive field). In this case, sinusoidal modulation of light (over space; described in cycles per degree of visual angle) is presented to a center–surround receptive field. The center–surround filter best matches the 8 cycles deg^{-1} stimulus, whereas lower or higher frequencies are suboptimal. The tuning function (solid line in Figure 2(c3)) describes the spatial contrast sensitivity function.

Temporal and spatial contrast sensitivity functions can also be used to describe threshold measurements in human psychophysical experiments. In this case, the spatial or temporal filter is that of the entire visual system. A human is presented with brief stimuli of various spatial or temporal frequency contrast modulation and a threshold is determined (i.e., the lowest contrast at which the pattern can be reliably discriminated from the mean luminance). The perceptual contrast sensitivity function resembles the sensitivity functions of individual ganglion cells, at least superficially. It is difficult to determine how perceptual and neural sensitivity functions are related to one another, because perception depends on the output of many different types of ganglion cell as well as further processing at later stages in the brain.

Disrupting Specific Retinal Pathways Alters Perceptual Contrast Sensitivity in Selective Ways

The retinal ganglion cell axons exit the eye and travel to several different nuclei in the brain, including targets in the brainstem, midbrain, and thalamus. The pathway for

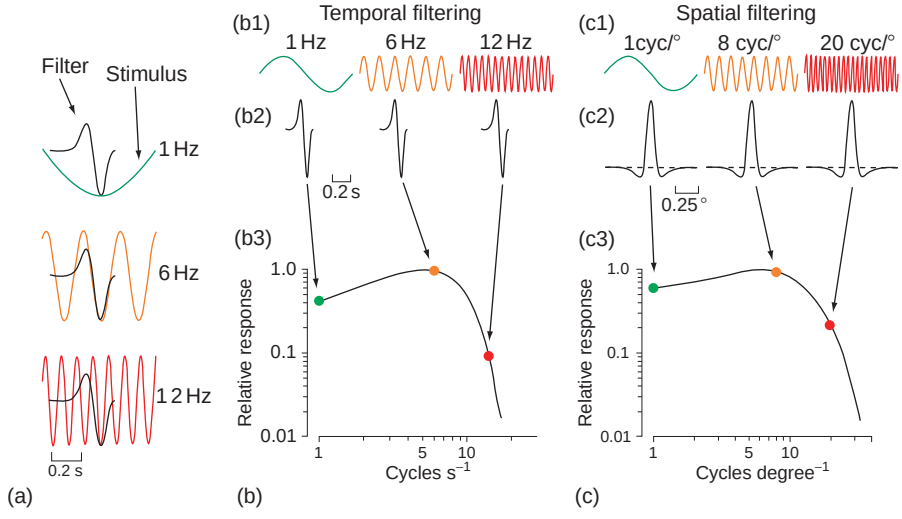

Figure 2 Spatial and temporal filtering explains the contrast sensitivity function.
(a) A temporal filter is shown with stimuli of three frequencies. The 6-Hz stimulus provides the best match to the filter.
(b) Temporal contrast sensitivity function. (b1) Three temporal frequencies (sine waves).
(b2) The filter is best matched to the 6-Hz sine wave. (b3) The sensitivity function represents the filter's normalized response to each frequency.
(c) Spatial contrast sensitivity function. (c1–c3) Same as for part (B) but for spatial frequency stimuli and the spatial filter. The filter shown is a one-dimensional cut through a circular center–surround receptive field.

conscious vision is believed to arise from the retinal projection to the thalamus, where relay cells then project retinal signals to the visual cortex. About a dozen or more different types of ganglion cell project to the lateral geniculate nucleus of the thalamus (LGN); and LGN relay cells provide a major input to primary visual cortex.

In primates, the LGN is organized into six prominent layers. The top four parvocellular (P) layers contain small cell bodies (ON and OFF midget/P cells), whereas the bottom two magnocellular (M) layers contain large cell bodies (ON and OFF parasol/M cells). Both P and M layers are separated by the eye where the ganglion cells originate; thus there are two P layers and one M layer that each receives input from the contralateral eye, whereas the other layers each receives input from the ipsilateral eye. The ON and OFF M and P cells thus account for four of the ~13 types that project to the LGN. The other nine ganglion cell types apparently project to relay cells that either reside in the layers between the M and P layers (the intercalated layers) or intermingle with the M and P cell bodies. These pathways are referred to collectively as koniocellular (K) cells.

To understand the role of the different ganglion cell types in perceptual contrast sensitivity, the M or P layers of the LGN were lesioned. We now understand that these lesion experiments were not entirely selective; the lesions to the P layers, for example, must have also affected some of the other (less numerous) K pathway ganglion cell types that project to the dorsal region of the LGN. Nevertheless, the M and P cells are the most numerous cell types that project to the LGN, and lesions to either the M or P layers yielded distinct deficits on contrast sensitivity measurements. Thus, these deficits are probably explained in large part by the lesions of either M or P cell types.

Lesions to the M layers reduced the monkey's sensitivity for high temporal frequency and low spatial frequency stimuli, whereas lesions to the P layers reduced sensitivity for low-temporal-frequency and high-spatial-frequency stimuli. Thus, the different ends of the monkey's contrast sensitivity function depended most heavily on distinct ganglion cell classes in the retina. There are two clear conclusions from these studies: there was no single cell type that could explain perceptual sensitivity for all possible patterns; and specific spatial or temporal domains of perceptual sensitivity depended most heavily on particular cell types.

Physical Limits to Contrast Sensitivity

Under optimal conditions, humans can detect small spots with contrasts of 1–3%. The most sensitive ganglion cell types can also detect small spots with contrasts of 1–3%. Thus, there may be certain conditions where perceptual thresholds are driven by a small number of ganglion cells and there may be relatively little information lost between the retina and the brain. However, there is a loss between the contrast threshold that could (theoretically) be computed at the level of photon absorptions by the photoreceptors and the threshold measured in the ganglion cell. Recent computational analysis suggests that, under certain conditions, this loss may be a factor of ~10–20.

The ability to detect contrast depends on the statistics of photon arrival and the statistical properties of various cellular processes. Photon arrival follows Poisson statistics, where the mean and the variance are equal. For example, consider a case where a ganglion cell integrates signals over 20 photoreceptors across the retina and over a 100-ms integration time and where the mean rate of photoisomerizations (i.e., absorbed photons) is 50 isomerizations (R^*) per photoreceptor per second (i.e., 5 R^*/photoreceptor/integration time). In this case, the mean R^* rate over the spatial/temporal integration ($20 \times 100 \times 5$) is 10 000 and the variance (across multiple trials) would be the same. Thus, the SD (or noise level) would be the square root or 100 R^*. The signal-to-noise ratio (mean/SD per integration time) would then be $10\,000/100 = 100$. Therefore, the cell in question would have difficulty detecting a difference of less than 1/100 (i.e., SD/mean) or 1% deviation from the mean level (i.e., 1% contrast). The contrast threshold would be worse (i.e., higher) when the mean luminance is lower, the number of integrated photoreceptors is fewer or the temporal integration time decreases.

Similar limitations on contrast sensitivity must arise within the neural circuit of the retina. For example, the release of neurotransmitter at retinal synapses probably obeys Poisson statistics similar to the case of photon arrival. Thus, the ability of the synapses to transfer information at low contrast depends on the release rates at these synapses and the number of synapses that are integrated by a given neuron. For example, the threshold of a cell would be best (i.e., lowest) in the presence of high release rates and a large number of integrated synapses (i.e., high degree of synaptic convergence within the circuitry). Thus, several physiological factors will place neural limits on the contrast threshold of retinal ganglion cells.

Information Processing: Direction Sensitivity

Z J Zhou and S Lee, Yale University School of Medicine, New Haven, CT, USA

Glossary

Accessory optic nuclei – A series of small nuclei in the rostral midbrain, near where the optic tract enters the lateral geniculate nucleus. They receive inputs from motion-sensitive ganglion cells and project to the vestibular nuclei, triggering optokinetic movements in response to movement of the visual world across the retina. This system is very important for animals without foveae, but is poorly developed in humans.

Optokinetic nystagmus – The repeated reflexive responses of the eyes to ongoing large-scale movements of the visual scene.

Patch-clamp recording – A sensitive electrophysiological recording technique that permits the measurement of ionic currents flowing through individual ion channels. It uses a glass micropipette that has an open-tip diameter of about 1 μm. The micropipette tip is sealed onto the cell surface, enclosing a membrane surface area or patch that often contains only a few ion channels. Several variations of this technique are commonly applied.

Spatially offset inhibition – An inhibitory synaptic input from the receptive field surround that is asymmetrically offset to one direction.

Two-flash apparent motion stimulation – A visual stimulation paradigm, in which two nearby spots of light are flashed in rapid succession to simulate the motion of a light spot.

Detecting the direction of image movement is an essential task of the visual system. Neurons in many parts of the visual system show directional sensitivity to image motion. The initial computation of movement direction is accomplished in the retina. In the early 1960s, Barlow and co-workers discovered that a subset of output neurons in the rabbit retina responds vigorously to an image moving across its receptive fields in a particular (preferred) direction, but gives little or no response to the same image moving in the opposite (null) direction (Figure 1). These retinal neurons, termed direction-selective ganglion cells (DSGCs), display a directional preference that is independent of the nature of the image, such as contrast, size, and complexity. They are specialized in processing visual information regarding motion and motion direction.

Physiological Functions of DSGCs

In rabbit, a species for which retinal direction selectivity is best characterized, two types of DSGCs have been found: the ON type, which responds to the onset of a small spot of light flashed in the center of the cell's receptive field, and the ON–OFF type, which responds to both the onset and the offset of such a flash. ON DSGCs project their axons to the accessory optic system. They are believed to be involved in the feedback mechanism that stabilizes a moving image on the retina, for example, during the smooth tracking movements of the eyes. These cells respond best to slow image movements ($\sim 0.3^\circ\ s^{-1}$) and contribute significantly to the control of optokinetic nystagmus over the range of stimulus velocities that produce the most complete minimization of image motion on the retina. ON DSGCs are divided into three subtypes, distinguished by their preferred directions pointed roughly toward the anterior, superior, and inferior retina, respectively. Each of these three preferred directions is thought to correspond to a component of the head rotation that activates one of the three pairs of semicircular canals in the inner ears, suggesting that these cells may also detect the slippage of a visual image on the retina during head rotation and provide an error signal that tells the visual servo-system to compensate the difference between head rotation and eye rotation.

ON–OFF DSGCs, on the other hand, project to the superior colliculus and the lateral geniculate nucleus. They are further categorized into four subtypes, characterized by their preferred directions which, respectively, point roughly toward the four cardinal directions in the retina: superior, inferior, anterior, and posterior. It has been suggested that these four directions may correspond to the directions in which the eye is rotated by the four extraocular rectus muscles, indicating that ON–OFF DSGCs are also involved in the feedback mechanism that controls eye movement. However, unlike the ON type, ON–OFF DSGCs give largest responses to fast movements ($\sim 10^\circ\ s^{-1}$ or faster) and respond poorly to slow movements. Their contribution to image stabilization during the slow phase of optokinetic nystagmus may be significant only at stimulus velocities exceeding $\sim 3^\circ\ s^{-1}$. The fact that ON–OFF DSGCs project to the lateral geniculate nucleus in addition to the superior colliculus suggests that these cells may also process directional information of object movement for visual perception. However, the exact physiological functions of ON–OFF DSGCs remain to be understood.

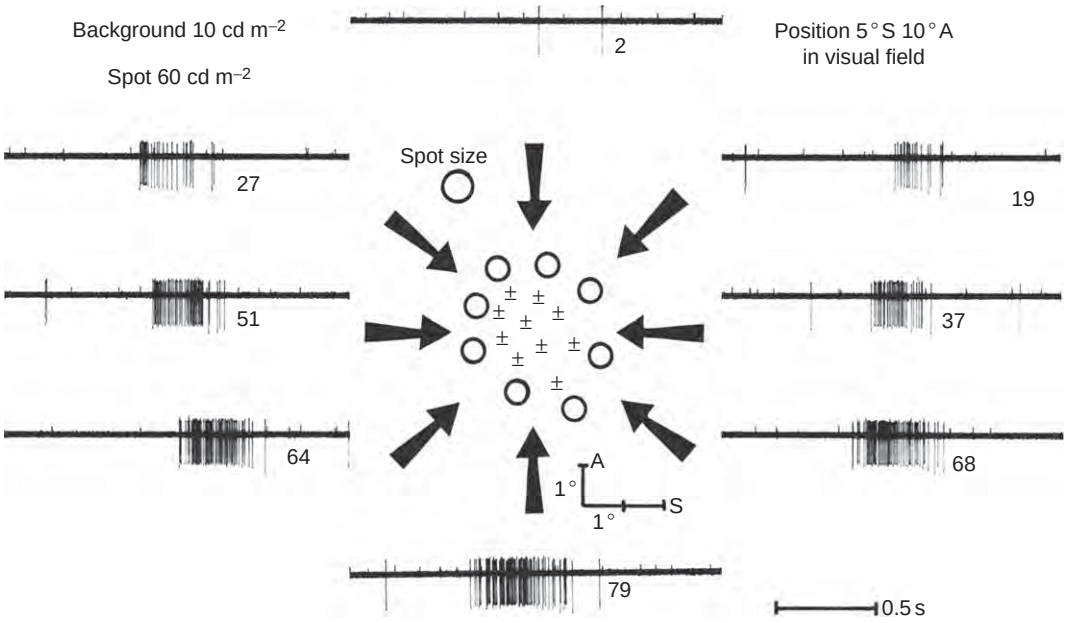

Figure 1 Responses of a directionally selective ganglion cell (recorded from its axon) to stimulus motion in different directions. Map of receptive field in center. Traces show responses (spikes) elicited by the movement of a spot of light across the receptive field in the direction of adjacent arrow. This cell shows a preferred direction pointing upward. Anterior (A) and superior (S) meridians in the visual field are shown together with 1° calibration marks. The number of spikes is shown immediately after each response. Conventions are as follows: ±, response to stationary spot at both ON and OFF; O, no response; there are no responses outside the ring of Os. Adapted from Barlow, H. B., Hill, R. M., and Levick, W. R. (1964). Retinal ganglion cells responding selectively to direction and speed of image motion in the rabbit. *Journal of Physiology* 173: 377–407.

Synaptic Circuitry of DSGCs

As direction selectivity in the retina represents a fundamental form of information processing, it has been regarded as a model system for understanding neuronal computation in the brain. In their 1965 work, Barlow and Levick first suggested that the direction selectivity of ganglion cells is built from sequence-discriminating subunits. The primary mechanism for this discrimination was thought to result from a spatially offset lateral inhibition, which vetoes responses to sequences corresponding to stimulus movement in the null direction. Pharmacological experiments by Daw and colleagues subsequently found that gamma aminobutyric acid (GABA) receptor antagonists block direction selectivity by bringing out strong responses of DSGCs to stimulus movement in the null direction, suggesting that the spatially offset inhibition is mediated by GABA. Direct measurement of the inhibitory inputs to ON–OFF DSGCs became possible in the early 2000s, when whole-cell patch-clamp recordings were made successfully from these cells in the whole-mount rabbit retina by several labs. Fried and co-workers showed that the inhibitory input to ON–OFF DSGCs is larger during stimulus movement in the null direction than that in the preferred direction, and that the inhibitory input arrives ahead of the excitatory input when the stimulus moves in the null, but not in the preferred direction. The spatial extent of the inhibitory input measured by whole-cell patch clamp is offset from the ON–OFF DSGC dendritic field toward the null direction. The excitatory current input to an ON–OFF DSGC is also directionally asymmetric: larger for preferred direction movement than for null direction movement. Similar results were also obtained from ON DSGCs in the mouse retina. These findings establish that the synaptic inputs to a DSGC are already directionally asymmetric.

An important clue to the origin of major synaptic inputs to DSGCs comes from the anatomical structure of these cells. DSGCs have a distinctive morphology, characterized by the looping dendritic branches (**Figure 2**). The dendritic stratification pattern of DSGCs follows the general rule of segregation between the ON and OFF channels in the inner plexiform layer (IPL) of the retina. Thus, ON DSGCs arborize only in the proximal half (ON sublamina) of the IPL, whereas ON–OFF DSGCs arborize in both the proximal and the distal half (OFF sublamina). Both the ON and OFF arborizations stratify narrowly in the IPL, juxtaposing the two narrow cholinergic strata, suggesting that DSGCs receive synaptic inputs from the relatively small number of bipolar and amacrine cell subtypes that terminate specifically in these strata. In particular, cholinergic amacrine cells, which are the only cholinergic cells in the mammalian retina, are expected to provide a significant amount of lateral input

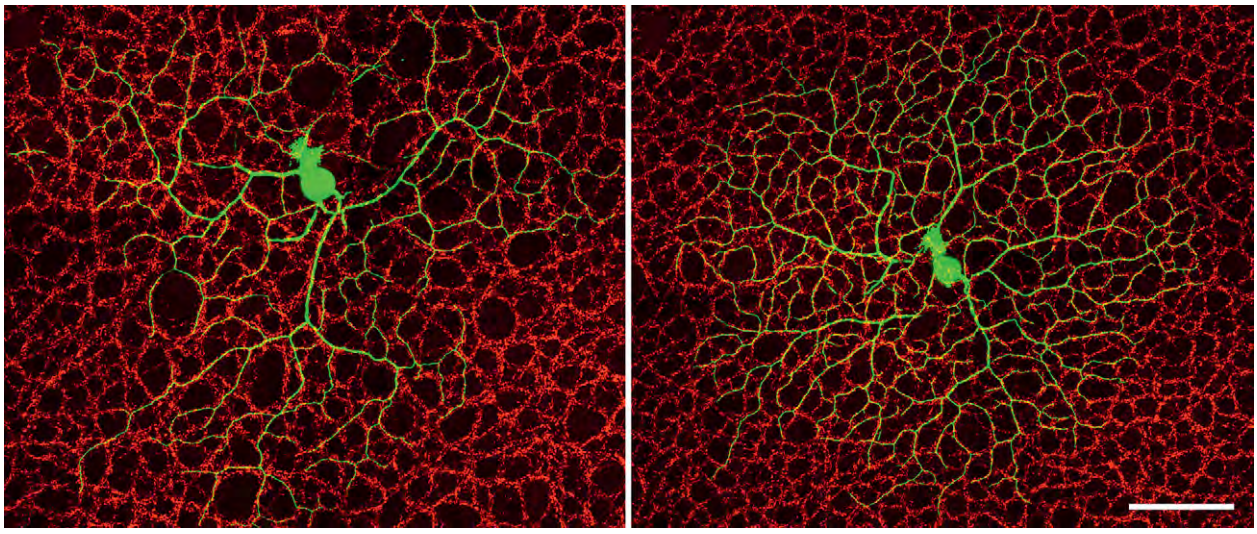

Figure 2 Dendritic morphology of ON–OFF direction-selective ganglion cell. Confocal micrographs of an intracellularly injected ON–OFF DSGC in the whole-mount rabbit retina, showing bistratified dendritic arbors in the ON (left panel) and OFF (right panel) sublamina of the inner plexiform layer. The characteristic looping dendrites co-stratify extensively with the cholinergic plexus (labeled with choline acetyltransferase in red). Scale bar = 100 μm. Figure 3 Dendritic morphology of starburst amacrine cell. Fluorescence micrograph of a SAC, with its soma located in the ganglion cell layer in a postnatal day 18 retina of a rabbit. The cell has a radially symmetric dendritic tree and a polar asymmetric synaptic structure. The input synapses from bipolar cell are distributed over the whole dendritic tree, but the output synapses are localized in the distal varicose zone, where synaptic vesicles are concentrated. Unpublished micrograph provided by Lee S and Zhou ZJ.

to DSGCs. Cholinergic amacrine cells are also known as starburst amacrine cells (SACs; Figure 3). They exist as two mirror-symmetric populations across the IPL. They have four to five primary dendrites, each branching out regularly into secondary and tertiary processes, with numerous varicosities imbedded in the distal dendritic zone. The dendritic tree of a SAC emanates from the soma with a nearly perfect radial symmetry, rendering the cell a starburst appearance and hence its popular name. The processes of neighboring SACs overlap significantly and form honeycomb-shaped plexuses which co-fasciculate extensively with the looping dendrites of DSGCs, suggesting intimate synaptic interactions between the two cell types. Indeed, direct synapses from SACs to ON–OFF DSGCs have been observed at the electron microscopic level.

The neurochemical significance of the synapses between SACs and DSGCs became apparent when SACs were found to synthesize and release both acetylcholine (ACh) and GABA, a property that also rendered SACs the first known exception to Dale's principle of one neuron releases one fast neurotransmitter. The GABAergic nature of cholinergic amacrine cells suggests that these cells may provide the crucial, spatially offset GABAergic inhibition to DSGCs, an idea that has been tested and debated extensively in the literature. The co-release of ACh and GABA by SACs also raises the possibility that these two neurotransmitters may be used by SACs in a complimentary manner to enhance the sensitivity of DGSCs to motion and motion direction.

The first functional evidence for a key role of SACs in direction selectivity came from the finding that ablation of SACs by immunotoxins and neurotoxins results in an apparent elimination of the directional discrimination of DSGCs in the mouse retina, as well as a loss of optokinetic nystagmus. This finding demonstrates a critical

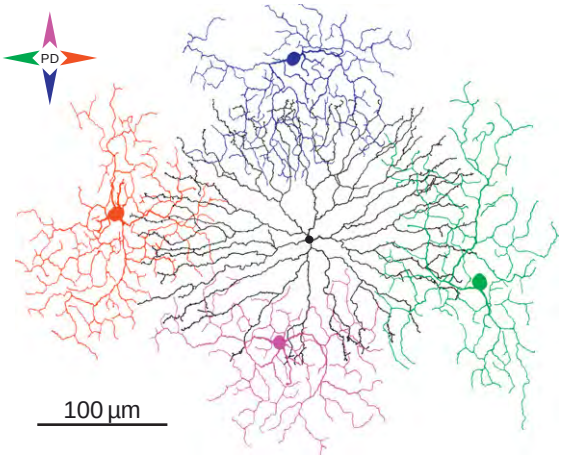

Figure 4 Synaptic circuit of ON–OFF direction selective ganglion cells. ON–OFF DSGCs receive GABAergic inhibitory inputs only from starburst amacrine cell dendrites that point in the null direction, but not in the preferred direction. A single SAC (shown in black) can provide null-direction inhibition to all four subtypes of ON–OFF DSGCs with preferred directions along four orthogonal directions (shown in different colors). For simplicity, only the circuitry in the ON sublamina is shown. Adapted from Taylor, W. R. and Vaney, D. I. (2003). New directions in retinal research. *Trends in Neurosciences* 26(7): 379–385.

link not only between SACs and direction selectivity, but also between direction selectivity and optokinetic nystagmus. Dual patch-clamp recordings from SAC–DSGC pairs in the rabbit retina subsequently demonstrated that DSGCs receive direct GABAergic synaptic inputs from SACs, and that such inputs come only from SACs located on the null side, but not the preferred side of the DSGC. This result establishes that SACs exert a spatially offset GABAergic inhibition on DSGCs through directionally asymmetric hardwiring between SACs and DSGCs, a landmark finding that forms the basis of the current model of the synaptic circuitry of DSGCs (**Figure 4**).

Direction-Selective Responses in SAC Processes

For the asymmetric wiring model of direction selectivity shown in **Figure 4** to work, the release of GABA from each branch of a SAC must also be directionally selective: larger during a null-direction movement and smaller during a preferred-direction movement. Otherwise, the SAC dendrites that synapse on a DSGC from the null direction would still inhibit the DSGC when an image moves to the DSGC receptive center along the preferred direction, even though such an inhibitory input may not precede the glutamatergic excitatory input from bipolar cells. Experiments using apparent motion stimulation also show that the GABAergic input to a DSGC (from SACs on the null side) is strongly suppressed by two-spot flashes that simulate a preferred-direction movement, indicating that GABA release from SAC dendrites is directionally selective. This result suggests that a critical component of the direction-selective mechanism must reside upstream from DSGCs and in SACs.

How does a morphologically symmetric cell like the starburst produce the functional asymmetry required for direction-selective GABA release? A close anatomical examination of the SAC tells us that, despite the striking radial symmetry in the dendritic tree, the synaptic structure of the cell has a profound polar asymmetry. Input synapses on starburst dendrites distribute more or less uniformly along the entire dendritic length, whereas output synapses are localized in the distal varicose zones, where synaptic vesicles are concentrated (**Figure 3**). The distal varicose zones are believed to be electrotonically semi-isolated, due to the thin diameter of the dendrites and a heavy expression of K_{V3} voltage-gated potassium channels on the proximal dendrites. This polar asymmetry in input–output relation, combined with the short electrotonic length of the dendrites, would enable the distal dendrites of a SAC to process directional signals independently, with a preference to centrifugal stimulus movement, as predicted by computational models. In an elegant two-photon Ca^{2+}-imaging experiment, Euler and co-workers showed that distal starburst dendrites respond to spot illumination with intracellular Ca^{2+} transients that are restricted to distal dendrites. Importantly, these local Ca^{2+} responses tended to be directionally selective: stronger for centrifugal than for centripetal stimulus movement.

Two-flash apparent motion experiments further show that the direction selectivity in distal starburst dendrites involves both centrifugal excitation and centripetal inhibition. The underlying mechanism may involve both cell-autonomous properties and synaptic interactions at SAC dendrites. Cell-autonomous properties, such as nonlinear interactions between the activation of voltage-gated calcium channels and a gradient in membrane potential along the SAC dendrites, may contribute to an enhanced response of the distal dendrites to centrifugal image movement. On the other hand, synaptic interactions, particularly GABAergic inhibition from the receptive field surround, play a key role in centripetal inhibition. Dual patch-clamp recording experiments found that neighboring SACs inhibit each other through reciprocal GABAergic synapses. Zhou and Lee proposed that the synaptic mechanism for direction-selective release of GABA in distal starburst dendrites is built primarily from a classic center-surround receptive field structure. Synaptic inputs to the receptive field center are dominated by the glutamatergic input from bipolar cells, whereas synaptic inputs from the receptive field surround are dominated by the direct GABAergic input from neighboring SACs. Such a concentric receptive field structure would normally be directionally symmetric for a neuron that makes an integrative

output decision at the soma or axon hillock. However, since the output decisions of a SAC are made independently in individual distal dendrites, such a concentric center-surround receptive field structure would produce a profound directional asymmetry at distal dendrites, where synaptic inputs received during centrifugal stimulus movement are dominated by excitation, but synaptic inputs received during centripetal stimulus movement are dominated by inhibition. This synaptic mechanism, together with an intrinsic mechanism that promotes centrifugal facilitation, would produce robust direction-selective GABA release from SACs.

Integration of Multiple Cooperative Mechanisms for Direction Selectivity

The direction-selective circuit so far identified consists primarily of DSGCs, SACs, and subsets of bipolar cells, although other amacrine cell types may also participate in the regulation of DSGC receptive fields. Distinct mechanisms of direction selectivity work in concert at three different levels. First, at the DSGC level, direction selectivity is shaped largely by a spatially offset inhibition from SACs, whose distal dendrites release GABA in a direction-selective manner and make GABAergic synapses onto DSGCs asymmetrically from the null direction only. Direction selectivity of DSGCs is also enhanced by the directionally asymmetric excitatory inputs, which may contain both glutamatergic and cholinergic components. In addition, a postsynaptic mechanism, involving local signal computation and spike generation in DSGC dendrites, may further sharpen direction selectivity. Second, at the SAC level, direction selectivity is formed in the distal starburst dendrites by a profound polar asymmetry between centrifugal excitation and centripetal inhibition. GABAergic inhibition, mediated largely by reciprocal inhibition between SACs, plays a key role in suppressing SAC responses to centripetal stimulus motion. However, the nature of lateral synaptic interaction during centrifugal motion is currently unclear. A model based on differential expression of two different chloride transporters proposes that the excitability of GABAergic input changes as the image moves centrifugally or centripetally along a SAC dendrite. Further experiments are required to test directly the predictions of this model. In addition to synaptic interactions, intrinsic cellular properties also play an important role in shaping direction selectivity in SAC dendrites, predominantly by contributing to centrifugal facilitation. Third, at the bipolar cell level, a direction-selective release of glutamate is strongly implicated by the finding of asymmetric excitatory inputs to DSGCs, but the underlying mechanism remains a major missing piece of the puzzle. A key issue is whether local terminals of a bipolar cell axon can function independently and make selective synapses with the dendrites of specific subtypes of DSGCs. An intriguing possibility in this regard is that SACs asymmetrically inhibit specific bipolar cell output synapses, which in turn synapse selectively on DSGCs in a spatially asymmetric manner.

While the critical GABAergic contribution of SACs to direction selectivity is well accepted, the cholinergic role of SACs remains elusive. Various models of cholinergic contributions to direction selectivity and motion sensitivity have been proposed over the years. However, the basic mode of nicotinic cholinergic action in the retina still remains obscure: Does ACh mediate fast neurotransmission at precise synaptic sites between SACs and DSGCs, or does it play a diffuse, paracrine role in modulating the activity of many ganglion cell types? More detailed experimental results are needed before it can be concluded as to how the release of ACh from SACs may enhance the sensitivity of DSGCs to image movement, whether cholinergic interactions enhance direction selectivity, how cholinergic synapses form a neural circuit, and how the cholinergic and GABAergic circuits of SACs interact with each other. Investigations into some of these questions are currently underway and may uncover additional levels of cooperation among synaptic mechanisms of motion and direction selectivity in the near future.

Concluding Remarks

Direction selectivity is a basic form of information processing produced by a relatively simple neuronal circuit in the inner retina. In order for this circuit to accomplish the robust computation required for detecting motion direction, multiple levels of cooperative mechanisms are integrated at each synapse. Such synaptic integration may represent an important feature of network computation in the central nervous system. From an anatomical point of view, the direction-selective circuit in the retina reveals a level of selectivity and precision in network organization that was previously unappreciated in most other parts of the central nervous system. Understanding the developmental mechanisms that control the establishment of the direction-selective circuit in the retina remains a challenging task of future investigation and will shed important light on the development of neuronal circuits in general.

Information Processing: Ganglion Cells

T A Münch, University of Tübingen, Tübingen, Germany

Glossary

Excitation – The synaptic input to a cell that serves to depolarize and activate it.
Inhibition – The synaptic input to a cell that serves to hyperpolarize and suppress it.
Receptive field – For retinal cells, this refers to a region in the visual environment in which the presence of a visual stimulus will influence the activity of the neuron.

The eye is often compared to a camera, in which the retina plays the role of the film. However, this analogy does not do justice to the remarkable image- and information-processing capabilities of the retina. The roles that horizontal cells, bipolar cells, and amacrine cells play in the information processing in the retina have been discussed elsewhere in the encyclopedia. All their activity merges into the output cells of the retina, the ganglion cells. These cells form a sort of bottleneck through which all the information has to pass, which is destined to reach higher visual centers in the brain.

Ganglion Cell Types

The signals leaving the retina are transmitted by several channels, each channel carrying information about different features of the visual world. Each channel is embodied by a certain type of ganglion cell. It is still controversial how many different types of ganglion cells exist, but 20 should be a reasonable upper limit. Two ganglion cells are considered to belong to the same type if they share a defined set of properties, including morphological, physiological, and genetic properties. However, it is not trivial to define what such characterizing properties should be. Too fine a distinction would artificially separate ganglion cells into different types, even though they might belong to the same type, while a course classification will not do justice to the rich diversity of image-processing capabilities of the retina. For the purpose of this article, the term ganglion cell type will be loosely and pragmatically defined as the population of ganglion cells extracting the same features from the visual world and therefore performing the same function. Later in this article, we describe some specific examples of ganglion cell types and the visual features that activate them. First, however, we discuss some general principles of ganglion cell processing.

Principles of Ganglion Cell Processing

Neural activity in the retina is unusual in the central nervous system as most retinal neurons are analog: they do not fire action potentials; instead, transmitter release is a continuous function of membrane voltage. Ganglion cells are different; they use action potentials to transmit their signals along their axons which form the optic nerve. These cells integrate excitatory input from bipolar cells and inhibitory input from amacrine cells. It is the precise temporal and spatial integration of these inputs that leads to the final spiking output of the ganglion cells. It will become clear from the examples below that it is the inhibitory activity of the amacrine cells that creates most of the specificity in ganglion cell responses. Bipolar cells serve to set up a range of permissive stimuli, that is, the set of stimuli that a ganglion cell could, in principle, respond to. This stimulus space is then strongly restricted by the activity of the inhibitory amacrine cells, resulting in the specific responses of ganglion cell types.

Temporal Processing

Ganglion cells show diverse responses to step changes of light (**Figure 1(a)**). Generally, responses can be divided into ON (activated by increases of light intensity), OFF (activated by decreases of light intensity), and ON–OFF (activated by both increases and decreases of light intensity). The ganglion cells expressing these responses are accordingly termed ON cells, OFF cells, and ON–OFF cells. Within each of these classes, one can find cell types with transient or sustained responses. In addition, different cells have different latencies from stimulus onset until the time of the first spike. For some cell types, Gollisch and Meister demonstrated that the relative spike latency can code for the stimulus intensity (**Figure 1(b)**).

The different temporal response characteristics of ganglion cells are correlated with the level of stratification of ganglion cell dendrites. The dendrites of ON ganglion cells stratify in the inner half of the inner plexiform layer (sublamina b, close to the cell bodies of the ganglion cells), while the dendrites of the OFF ganglion cells stratify in outer half (sublamina a, toward the bipolar cells). The transient cells tend to stratify toward the center of the inner plexiform layer (IPL), while the sustained cells send their dendrites to the two borders of the IPL.

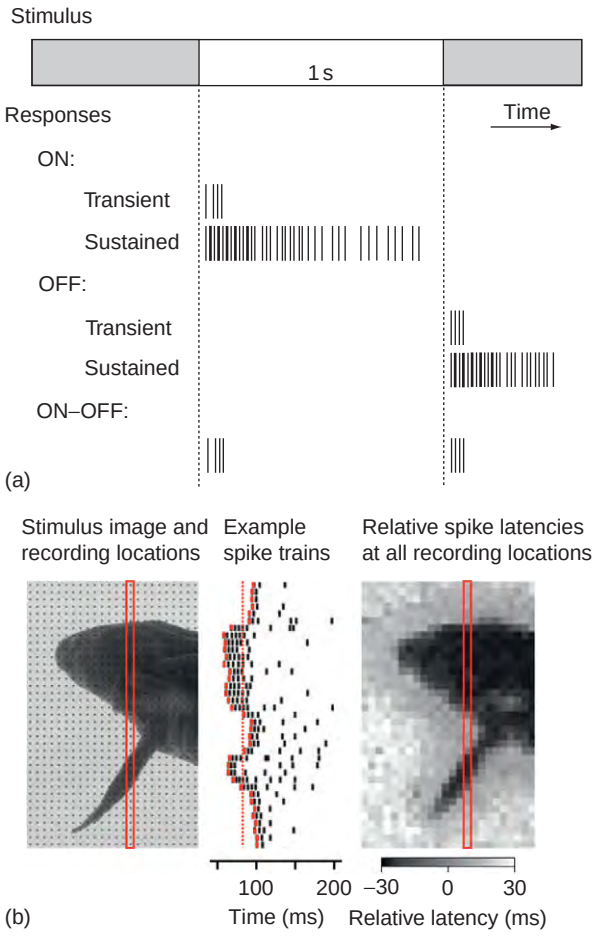

Figure 1 Temporal response characteristics of ganglion cells. (a) Different types of ganglion cells respond differently to the onset of a bright stimulus in the receptive field. ON cells respond at the onset of the stimulus; OFF cells respond at the offset; and ON–OFF cells respond at the both the on- and offset. Within these cell classes, one can find transient and sustained types of responses. (b) The latency of responses of some cell types indicates the intensity of the stimulus. Left: The stimulus image was presented to the retina multiple times at different locations, so that the recorded ganglion cell was located at the positions indicated by the dots. Middle: Spiking responses for the column of recording locations indicated by the red rectangle in the left panel. The first spike after stimulus onset is marked in red. The average time-to-first-spike is indicated by the dotted red line, and serves as time point 0 in the right panel. Right: Relative spike latency for each recording location coded as a grayscale value. Adapted from Gollisch and Meister (2007).

Spatial Processing

Center-Surround Receptive Fields

Many ganglion cell types express antagonistic center-surround receptive fields, first described by Kuffler in 1953. The terms ON and OFF cells defined in the previous paragraph are a shorthand for ON center cell and OFF center cell, describing the response characteristics of the cells when they are stimulated in their receptive field center. When a stimulus spot falls in the surround region, an ON center cell might respond when a bright spot is removed, that is, with an OFF-type response (point 2 below). In his 2001 work, Ralph Nelson summarized the effects that the surround can have on ganglion cell responses. Point 4 of the list given below is equivalent to a size tuning of the response, that is, responses to larger spots can be weaker than responses to smaller spots.

1. Change from sustained to transient center response as stimuli are displaced from center.
2. Responses evoked to opposite stimulus phase with surround stimulation.
3. Active inhibition of the center response with surround stimulation.
4. A maximal response can be evoked only with an optimally sized spot.

Center-surround receptive fields can be successfully modeled as difference of Gaussians, describing two overlaying concentric receptive fields with opposite effects on the cell (**Figure 2**). For small stimuli, the effect of the strong center receptive field prevails. For larger stimuli, the weaker surround begins to show its effect due to its larger radius. Physically, center responses originate from the excitatory input of bipolar cells to the ganglion cell dendrites. Usually, the size of the receptive field center of a ganglion matches the size of its dendritic field quite well. Surround properties originate from the activity of laterally oriented inhibitory interneurons in the retina, namely horizontal cells and amacrine cells. The activity of these cells contributes to the surround at three levels. They suppress the activities of bipolar cells either in the outer retina (horizontal cells) or inner retina (amacrine cells). Amacrine cells also give direct input to ganglion cells, contributing to the inhibitory surround at a third level of interaction.

Tiling

One of the properties characterizing a ganglion cell type is that its members tile the retina. This means that, as a population, the ganglion cells of any type carry information about the whole scene; a single ganglion cell is contributing one pixel. Ganglion cells with small receptive fields (e.g., midget ganglion cells) can convey spatial details of the visual scene (**Figure 3(a)**, left column), while a ganglion cell with a large receptive field (e.g., parasol ganglion cells) will not be able to convey much detailed spatial information (**Figure 1(a)**, right column) – the cell's activity will signal that it was triggered from somewhere within its receptive field, but it is not possible to pinpoint the exact spatial location just from the activity of a single cell, or from the activity of the cell population. The situation is better when the ganglion cells of a type overlap (**Figure 3(b)**), a situation which is frequently

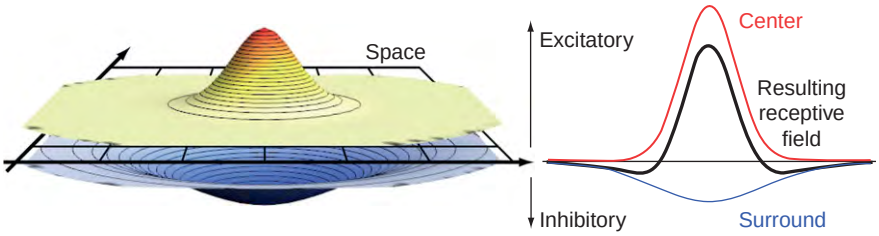

Figure 2 Difference of Gaussian model of center-surround receptive fields. According to this model, the receptive field of a ganglion cell consists of two bell-shaped components, a smaller excitatory component (center), and a larger inhibitory component (surround). The resulting overall receptive field has the shape of a Mexican hat (black curve, right).

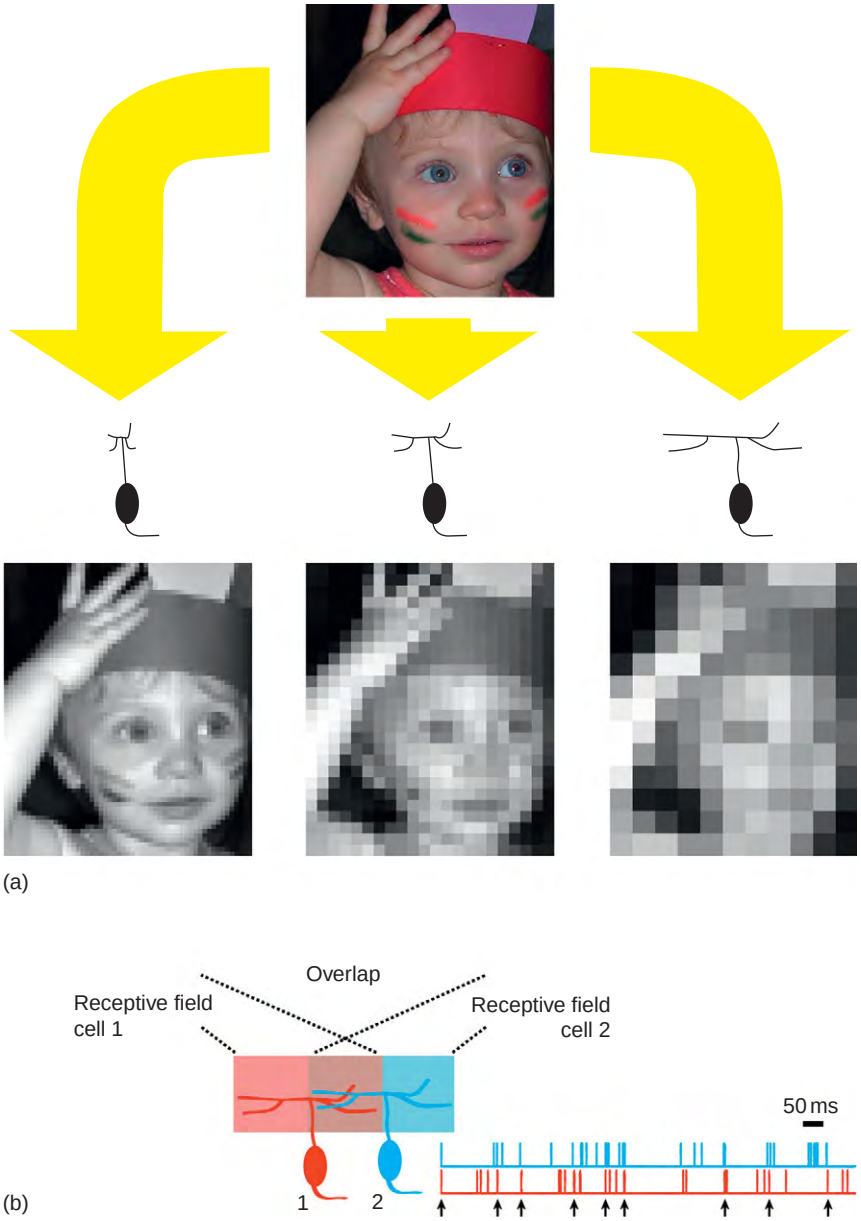

Figure 3 Spatial processing by ganglion cells. (b) Ganglion cells of the same type usually tile the retina so that each region in the visual environment is seen by at least one member of each type. One cell contributes one pixel of the image transmitted to the brain. Ganglion cells with small receptive and dendritic fields convey more detailed spatial information than larger cells. (b) Neighboring ganglion cells often fire action potentials synchronously. One possible mechanism is shared synaptic input. Then, the presence of synchronous spikes is an indication of the presence of an image feature in the region of overlap between two cells, which can increase the spatial resolution of a ganglion cell type. Spike trains adapted from Shlens, J., Rieke, F., and Chichilnisky, E. (2008). Synchronized firing in the retina. *Current Opinion in Neurobiology* 18: 396–402.

encountered (e.g., alpha ganglion cells). When a stimulus feature occurs in the region of overlap between neighboring cells, one can often observe a strongly increased probability of synchronous action potentials of the two cells. In many cells, the main reason for the synchronization is shared synaptic input. Consequently, if the two cells are triggered simultaneously by two separate stimuli occurring in the two nonoverlapping regions of their receptive fields, the firing is not synchronized. The precise relative timing of action potentials can therefore contribute to the spatial information conveyed by the ganglion cell population. More details on modes and mechanisms of synchronous firing in the retina can be found in the 2008 review by Shlens and co-workers.

Stimulus Features that Trigger Ganglion Cell Activity

As mentioned above, any ganglion cell type can be considered as a channel that conveys information about a certain image feature to higher visual centers of the brain. The activity of such a ganglion cell means that (one of) the trigger feature(s) has been present in the visual stimulus in the receptive field of the cell. What are the features that trigger ganglion cell activity?

Ganglion Cells as Spatiotemporal Filters

One way of looking at the processing of visual stimuli by ganglion cells is to interpret them as a bank of spatiotemporal filters (**Figure 4**). Each ganglion cell has certain frequency response characteristics in both space and time. For example, the size of the receptive field together with the surround properties may determine the spatial frequency to which a cell is tuned (small receptive field = high spatial-frequency response). The temporal frequency response is determined not only by cell-autonomous properties of the ganglion cells, but also by the properties of the presynaptic neurons. For example, if the presynaptic neurons are not able to follow a fast-flickering stimulus, neither will be the ganglion cell that is activated by those neurons. Interestingly, ganglion cells with a high spatial-frequency response tend to have a low temporal-frequency response and vice versa. In other words, ganglion cells tend to carry detailed information about space or time, but not both. In general, however, ganglion cells fill up the frequency range in space and time which is occupied by natural stimuli.

Ganglion Cells as Specific Feature Detectors

The following discussion is limited to one important category of visual events in the environment, namely

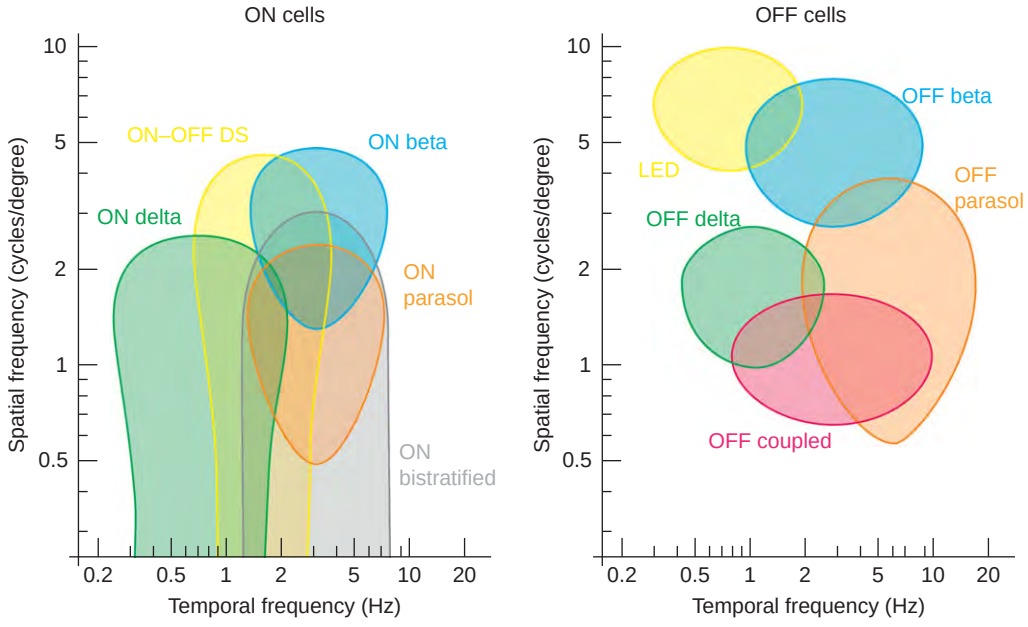

Figure 4 Ganglion cells as spatiotemporal filters. Range of frequencies in space and time over which each ganglion cell type in the rabbit retina responds. The colored blobs represent the full range of responses for each ganglion cell type when measured with a flashed square of light, 600 um on a side. Data have been generated by analyzing the response characteristics in space and time by Al Molnar and Frank Werblin based on data from Roska, B., Molnar, A., and Werblin, F. S. (2006). Parallel processing in retinal ganglion cells: How integration of space–time patterns of excitation and inhibition form the spiking output. *Journal of Neurophysiology* 95: 3810–3822; and Roska, B. and Werblin, F. (2003). Rapid global shifts in natural scenes block spiking in specific ganglion cell types. *Nature Neuroscience* 6: 600–608. Figure courtesy of Frank Werblin.

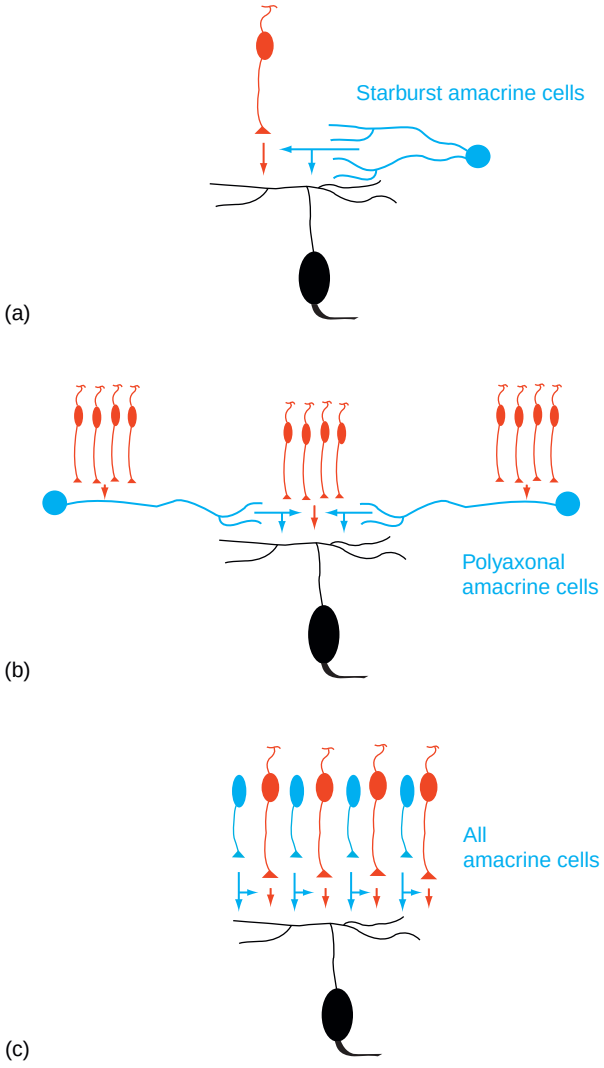

Figure 5 Circuits of movement-encoding ganglion cells. These cells employ common computational principles. The inhibitory circuitry is wired such that unwanted responses are canceled. The targets of the inhibitory input are the dendrites of the ganglion cells and the terminals of the excitatory bipolar cells. The specific wiring diagram is different for each cell type to achieve the desired computation. (a) The inhibitory circuit of direction-selective (DS) ganglion cells is spatially directed and asymmetric. Inhibition is supplied by starburst amacrine cell processes that point in the null direction of the targeted DS cell. The spatial asymmetry creates a temporal difference in the synaptic inputs; inhibition arrives before a suppressed excitatory input for movement in the null direction. (b) Object-motion-sensitive (OMS) cells get long-range inhibitory input from polyaxonal amacrine cells. The OMS cell and the polyaxonal cells get activated by strongly rectifying bipolar cells with similar properties, reporting about the presence of movement. Different trajectories of movement create different temporal sequences of activity, and same trajectories create similar sequences. When an OMS cell sees the same trajectory as a majority of polyaxonal cells, its responses are canceled by the correlated inhibitory activity. When the OMS cell sees a different trajectory, for example, because an object moves within its receptive field relative to the background, it is allowed to respond. Polyaxonal cells have active properties so that the inhibition arrives sufficiently fast at the OMS cell. (c) Approach-sensitive cells receive inhibitory input from AII amacrine cells, which are ON cells. They receive excitatory input from OFF bipolar cells. When dark and bright borders move concurrently within the receptive field, the inhibitory activity elicited by the bright borders cancels the excitatory activity elicited by the dark borders. This situation is encountered by laterally moving small objects or by image drift of a sufficiently detailed scene over the retina. An approaching dark object is expanding in size and has no bright moving image borders, allowing the cell to respond. AII cells get activated through electrical synapses with ON bipolar cells, so that the inhibition arrives sufficiently fast at the approach-sensitive ganglion cell.

that of object motion. Evolution appears to have dedicated a significant amount of retinal hardware to the detection and decoding of moving stimuli. There are at least eight types of direction-selective (DS) ganglion cells (four ON–OFF DS cells, three ON DS cells, and one OFF DS cell) that encode information about the direction of object motion or image drift over the retina. In addition, several ganglion cell types seem to be specialized to recognize the movement of an object relative to global background motion (object-motion-sensitive (OMS) ganglion cells). Recently, a ganglion cell type has been described, which is sensitive to yet another important aspect of object motion, namely when an object is approaching the animal. In the remainder of this article, these different types of motion-sensitive ganglion cells are discussed in greater detail, with emphasis on the underlying mechanism of their response specificity. The basic principle is always the same: responses to unwanted visual stimuli are suppressed by specific inhibitory circuitry (Figure 5).

Direction-selective (DS) ganglion cells

The defining property of DS ganglion cells is that they respond well to a moving object when it moves in a so-called preferred direction. However, when the same object moves in the opposite so-called null direction, they remain silent. The best characterized are the ON–OFF DS cells. Their dendrites are bi-stratified in the ON and OFF sublaminae of the IPL, and the cells respond to both bright and dark objects. The neural circuitry computing the DS responses are present in both the ON and OFF systems, and seem to compute direction selectivity independently from each other. The importance of the inhibitory system can be appreciated by applying blockers of the inhibitory neurotransmitter gamma aminobutyric acid (GABA) to the retina. This results in equal responses to movement in all directions: responses to null-direction movement are uncovered, while responses to preferred-direction movement are hardly changed at all. The directionality of DS ganglion cell behavior is therefore obtained by actively suppressing responses to null-direction movement.

The interneuron responsible for this suppression of null responses is the starburst amacrine cell. Starburst cells have peculiar properties that make them particularly suited for this task. For example, they have an asymmetric spatial distribution of incoming and outgoing synapses along their dendritic processes, which enables them to act at a distance: activation anywhere within the dendritic field can lead to release at the distal tips. In addition, their responses express DS properties themselves. Details of these are discussed elsewhere in the encyclopedia. The most important property responsible for the directional behavior of DS cells, however, is the geometrically specific connectivity between starburst cells and DS ganglion cells, and therefore a circuit property of the retina rather than a cell-autonomous property of either the DS cells or the starburst cells themselves. The geometry of the connectivity is such that only starburst cells located on the null side of the DS cell dendritic field inhibit the DS cell. As a consequence, a stimulus moving in the null direction will first encounter and activate this field of inhibitory starburst cells, which can then perform their action at a distance and inhibit the DS cell before the stimulus also enters the excitatory receptive field of the DS cell. This geometrically asymmetric connectivity can also be observed with static receptive field measurements: The inhibitory receptive field of DS cells is offset to the null side with respect to the excitatory receptive field, which matches the dendritic field quite well. DS cells are, therefore, an example of a cell type that does not have a classical center-surround receptive field.

Inhibitory activity acts at three levels in the DS circuitry to make the DS responses more robust. One level, already mentioned in the previous paragraph, is the geometrically asymmetric inhibition of DS ganglion cells by starburst amacrine cells. Geometric asymmetry is translated by a moving stimulus into a timing difference: during null movement, inhibition will reach the DS cell before excitation; however, during preferred movement, this will not be the case. A second level of inhibition targets the terminals of bipolar cells, and shows the same geometric properties as the inhibition of the DS cell dendrites. The properties of this presynaptic inhibition are consistent with the hypothesis that the same starburst cells that inhibit the DS cell also inhibit the presynaptic bipolar cells that make input to that DS cell. As a consequence, the excitatory input delivered by these bipolar cells is direction-selective because excitation during null-direction movement is strongly reduced. A third level of inhibition relates to the inhibitory input itself. During preferred-direction movement, the inhibitory input to DS cells is suppressed, as a consequence of the above-mentioned directional properties of starburst cell dendritic properties. These directional properties may be brought about, at least partly, by mutually inhibitory interactions between starburst cells.

In summary, because of inhibitory activity at many levels, DS ganglion cells receive directionally asymmetric synaptic inputs: during null-direction movement, they receive early-and-strong inhibitory input together with late-and-weak excitatory input; and during preferred-direction movement, they receive early-and-strong excitatory input with late-and-weak inhibitory input. Internal nonlinear properties of the DS cell itself emphasize the directional differences of the synaptic inputs: it appears that the DS cell contains local dendritic nonlinear properties. Calcium-driven spikes are generated locally in the dendrites when some threshold is crossed. These spikelets travel to the soma where they trigger standard sodium spikes.

Object motion sensitive (OMS) ganglion cells

The visual system constantly has to deal with global image jitter caused by eye, head, and observer movements. It poses a considerable challenge to neglect this global image movement and extract the more relevant movement of objects embedded in this scene. In other words, a ganglion cell with such properties would be active if an object moves within its receptive field (relative to the background), but it would be silent if there is only background movement within the receptive field, even if the local image trajectory is identical in both cases. Markus Meister and colleagues termed such ganglion cells as Object Motion Sensitive (OMS). The responsiveness of such a cell does not depend solely on the local image properties, but on a comparison of local and global properties. The next few paragraphs describe the computational principle of object motion detection.

The excitatory receptive field of OMS ganglion cells consists of small subunits, namely bipolar cells. Each of these subunits is strongly rectifying. This means that each subunit only gives input to the OMS cell if it is strongly activated. This results in relatively sparse excitatory input to the OMS cell.

Inhibitory input is provided by a class of amacrine cells called polyaxonal. Polyaxonal amacrine cells have a relatively small receptive field comparable in size to the OMS ganglion cell, but they have several axonal processes with active properties spreading across a considerable fraction of the whole retina. As a result, an OMS cell can receive inhibitory input from a polyaxonal amacrine cell that looks at a completely different area of the visual scene. Importantly, polyaxonal amacrine cells are electrically coupled with each other, so that they function as a coherent network through which activity can spread. Even though the axonal processes of a single polyaxonal cell are quite sparse, the network of these cells creates a dense mesh of axons. Polyaxonal cells receive similar excitatory input as OMS cells, namely temporally sparse input provided by strongly rectifying bipolar cells. These cells

have a relatively high threshold, so that the polyaxonal network gets activated only if it receives near-simultaneous excitatory input from a large fraction of the visual scene. This condition is met during global image motion, because many of the subunits providing excitatory input to polyaxonal amacrine cells are activated simultaneously. Because of the coupling, all polyaxonal amacrine cells, as a network, fire a burst of action potentials. In time, this results in a relatively sparse sequence of activity in polyaxonal amacrine cells, and consequently in a sparse sequence of inhibitory events in OMS ganglion cells.

An OMS cell therefore receives sequences of excitatory and inhibitory inputs that are temporarily sparse. If there is an object in the receptive field of an OMS cell that moves uncorrelated relative to the global (background) movement, the temporal sequence of the sparse excitatory (local) and sparse inhibitory (global) events will also be uncorrelated. Therefore, the inhibitory events cannot cancel the excitatory events, and the OMS cell will be active. On the other hand, an OMS cell sitting in the background region of the image will receive correlated excitatory and inhibitory inputs, the inhibitory events suppress the excitatory events, and the cell remains silent. In fact, inhibitory input arrives at the OMS cell about 25 ms before the excitatory input, at least in salamander retina, presumably because of the fast active properties of polyaxonal amacrine cells. An OMS cell can, therefore, effectively report the existence of an object moving relative to background.

Recently, in 2008, Baccus and co-workers expanded on their original findings and reported that the main target of the inhibitory input by polyaxonal amacrine cells is not the OMS ganglion cell itself, but the bipolar cell terminals which provide input to the OMS cell.

Saccadic suppression

Roska and Werblin showed that in rabbit retina some ganglion cells are suppressed during saccades, sudden eye movements that serve to shift gaze direction. They suggest that this is due to the inhibitory activity of polyaxonal amacrine cells. This resets the activity of ganglion cells for each visual episode in-between saccades. It is possible that saccadic suppression is a consequence of the same circuitry and mechanism described for OMS ganglion cells in the paragraph above. Roska and Werblin provided a detailed list of ganglion cell types which receive saccadic suppression in rabbit retina, while Meister and colleagues have remained vague about the cell types in rabbit retina, which have the OMS property.

Approach-sensitive ganglion cells

The detection of approaching or looming optical stimuli is important for survival. Such stimuli trigger robust behavioral avoidance responses in basically all animals tested, from insects to humans. Babies as young as 2 weeks react with widening of the eyes, turning of the head, lifting of the arms, and crying when they view a symmetrically expanding shadow on a screen directly in front of them. This suggests that hard-wired neural circuitry exists to detect such looming stimuli and to trigger these protective motor responses. Recently, we described a ganglion cell in the retina that is sensitive to dark approaching visual stimuli, such as widening shadows. Similar to the other cells described earlier, the function of these cells can only be appreciated when one considers the space of null stimuli, that is, the range of stimuli to which the cell does not respond because of active suppression by inhibitory circuitry. In the case of the approach-sensitive ganglion cells, these null stimuli comprise lateral movement of a small object within the receptive field, or lateral drift of the visual scene. In the case of a small, dark, moving object, for example, a hawk flying in sky, the cell will respond when the object is approaching the observer, but it will be suppressed when the object is moving on a lateral trajectory. Lateral drift of a visual scene is encountered during observer head or eye movements, similar to the OMS cells described in the above paragraph, but the mechanism for response suppression is substantially different.

The receptive field of approach-sensitive cells is comprised of small subunits for both the excitatory and inhibitory inputs. The excitatory input is mediated by transient OFF bipolar cells. Whenever a dark stimulus border is moving into a new subunit (i.e., into the receptive field of another bipolar cell), the approach-sensitive ganglion cell receives another episode of excitatory input, resulting in spiking output. This is true for any moving dark border within the receptive field of the ganglion cell, unless these events are canceled by simultaneously moving bright stimulus borders within the receptive field, as it would be encountered by the trailing edge of a laterally moving small dark object, but not by an approaching dark object, which does not create any trailing edges. The reason for the suppression by moving bright image borders is the structure of the inhibitory receptive field: it also consists of small subunits, but of the opposite polarity; the inhibitory input is mediated by ON amacrine cells with a small receptive field. The suppression of null responses is therefore computed on a local scale within the receptive field of ganglion cell.

The most interesting aspect of the approach-sensitive circuitry is the identity of the inhibitory amacrine cell and the specific synaptic connectivity employed. The amacrine cell responsible for the inhibition of the approach-sensitive ganglion cell is the well known AII (pronounced A-two) amacrine cell. AII amacrine cells are a main conduit for visual signals during nighttime vision. They are activated by rod bipolar cells through a glutamatergic chemical synapse, and then pass the signals on to both ON and OFF cone pathways. OFF pathways are activated through a glycinergic chemical synapse. The targets of

these synaptic connections are both the terminals of OFF cone bipolar cells, and the dendrites of OFF ganglion cells. ON pathways are activated through electrical synapses (gap junctions) between the AII cells and the terminals of ON cone bipolar cells. During daytime vision, rods are saturated, and rod bipolar cells are not active. Under these conditions, AII cells are activated mostly by ON cone bipolar cells by virtue of the electrical synapse between these cells. Once activated, AII cells can release glycine and inhibit their targets in the OFF pathway. One such target is the approach-sensitive ganglion cell, and the bipolar cells that activate it.

This pathway for the inhibitory input of the approach-sensitive ganglion cell has properties ideally suited for the approach-sensitive computation. AII cells are small, with a receptive field not larger than that of bipolar cells. Therefore, the excitatory and inhibitory subunits are of compatible size. Another important aspect is the dynamics of the inhibition. As explained above, null stimuli for the approach-sensitive cell are those that have concurrently moving dark and bright borders. The inhibitory input, activated by the bright borders, suppresses responses that would be elicited by the dark borders. This requires the inhibition to arrive at its target fast enough, so that no excitatory signal slips through, similar to the fast inhibitory input arriving at DS cells and at OMS cells. In the case of the AII cells, the speed of inhibition seems to be ensured by the electrical synapse in the pathway. The electrical synapse effectively reduces the number of chemical synapses in the inhibitory pathway to the same number as those in the excitatory pathway.

Glossary

Ephaptic transmission – A nonsynaptic electrical interaction mediating cellular communication. Closely apposed neural elements may share signals through an extracellular voltage change caused by the flow of current in a confined, resistive interstitial space between neurons. Changes of extracellular ion concentrations, such as high potassium levels caused by potassium extrusion from an active, depolarized neuron, also affect close-neighboring neurons.

Gain control – The gain or amplification of a graded potential synapse, such as that between photoreceptors and second-order neurons in the retina, is defined as the postsynaptic amplitude divided by presynaptic amplitude. To optimize signal-to-noise ratios, synaptic strength may be controlled by reciprocal signals that increase synaptic gain when signals are small, and reduce the gain when signals are large and saturating.

Gap junctions – The specialized electrical junctions between cells consisting of two connexons, each termed a hemichannel and made up of connexin proteins, which together form an intercellular pore. These mediate rapid electrical events between cells, allow diffusion of ions and small proteins, and are regulated by neuromodulators, including dopamine, nitric oxide, and retinoic acid, in the retina.

Photoreceptor synaptic triad – The synaptic arrangement consisting of two lateral horizontal cell endings or terminals and an ON bipolar cell dendrite that invaginate into a photoreceptor terminal.

Protons – The free hydrogen ions, as H^+ or hydronium ions (H_3O^+), in solution, usually bound (buffered) by other molecular constituents.

Receptive fields – The receptive fields of neurons in the visual system are the regions of retinal surface, receiving an optical projection of visual space, for which light stimulation causes a response in the cell. The classic center-surround antagonistic receptive field typically has a circular center and, forming a ring around the center, an annular surround. The sign of the cell's response to light in the center is the opposite of that in the surround. This receptive-field organization underlies edge detection by enhancing contrast between regions of varying brightness and/or color.

Roll back – A modest, slowly depolarizing trajectory seen in the horizontal cell voltage waveform, counteracting the rapid hyperpolarization of 30–50 mV during the response to a light stimulus. The roll back, whose amplitude is dependent on the intensity and diameter of the stimulus, is considered to be due to inhibitory feedback from horizontal cells to photoreceptors.

Introduction

Visual information is conveyed through the retina from photoreceptors via bipolar cells to ganglion cells, and the signal is modulated by inhibitory lateral interactions provided by horizontal cells in the outer plexiform layer and amacrine cells in the inner plexiform layer. Retinal neurons are characterized by having an antagonistic, concentric center-surround receptive-field organization.

Horizontal cells play a critical role in generating the inhibitory receptive-field surround of cone photoreceptors and bipolar cells in both mammalian and nonmammalian retinas. These cells are characterized by a broad, lateral spread of their processes as well as homologous coupling through gap junctions to other horizontal cells. In mammalian retinas, both A-type and B-type horizontal cells receive input from cone photoreceptors at their dendritic tips, and rod photoreceptors at their axon terminals. Horizontal cells transmit spatially broad visual signals back to photoreceptors and bipolar cells, to generate receptive-field surrounds (**Figure 1**). The antagonistic, center-surround receptive-field spatial organization contributes to visual processing that highlights changes in luminance and contrast to improve visual acuity. Horizontal cells also participate in setting the gain of the photoreceptor synapse through inhibitory feedback of information about local illumination levels, and in lower vertebrates, color-opponent receptive fields are generated through color-specific, antagonistic receptive-field surrounds.

Synaptic Interactions and Gap-Junction Coupling of Horizontal Cell Subclasses

There are two physiological classes of horizontal cells, which code for luminosity and chromaticity, in the vertebrate retina. The luminosity (L-type, or H1) horizontal cell responds to the whole range of visible light with a graded hyperpolarization, due to receiving inputs from all types of cone photoreceptors. The chromaticity (C-type, or H2, H3) horizontal cells respond to certain wavelengths of light with a hyperpolarization and a depolarization to others, in a biphasic or triphasic manner, due to selective connectivity with and feedback onto different spectral subtypes of cone photoreceptors. In this manner, the C-type horizontal cells begin the process of encoding color opponency. In addition, there are also horizontal cells that synapse selectively with rod photoreceptors in some species, including teleosts; however, most lower vertebrates exhibit mixed rod and cone inputs into horizontal cells. Mammals appear to have only the L-type horizontal cells, and these do not exhibit color-opponent properties.

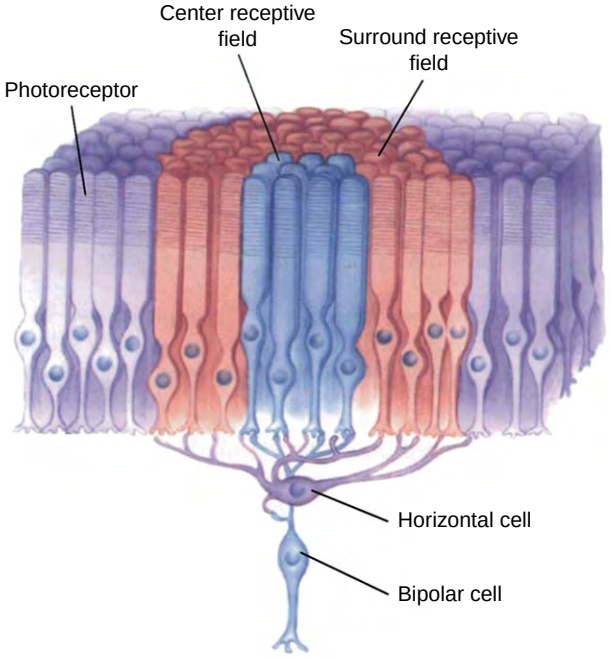

Figure 1 Formation of bipolar cell center-surround antagonistic receptive fields by integration of direct photoreceptor inputs at center of receptive field (shown in blue) and surround photoreceptor inputs (shown in red) carried through a large receptive-field horizontal cell. Horizontal cells are normally homologously coupled, except under the condition of extreme light adaptation. The horizontal cell signal is conducted to the bipolar cell through inhibitory feedback at the photoreceptor terminals and through direct feed-forward signaling to the bipolar cell. Reproduced from figure 9.22 of Bear, M. F., Connors, B. W., and Paradiso, M. A. (eds.) (2007). *Neuroscience: Exploring the Brain*, 3rd edn. Philadelphia, PA: Lippincott Williams & Wilkins.

In general, in mammals, A- and B-type horizontal cell dendrites form synapses with cone photoreceptors, whereas the axon terminal system of the B-type forms synapses with rod photoreceptors. Due to the high electrical resistance in the long axon connecting the axon terminals to the somatodendritic region, the two compartments of the B-type horizontal cell are thought to act as functionally independent units. Horizontal cells receive excitatory glutamatergic input from the photoreceptors and feedback onto the cone and rod terminals, presumably at the horizontal cell endings within the photoreceptor terminals. In darkness, photoreceptors release transmitter; thus, the membrane potential of horizontal cells is relatively depolarized. In response to light, all horizontal cells studied exhibit slow, graded hyperpolarizing potential changes due to the reduction in transmitter release from photoreceptors. These slow potentials were originally called S-potentials (in honor of Gunnar Svaetichin, who initially described them in 1953). With the advent of intracellular dyes, it was shown that S-potentials arose from horizontal cells in the outer retina.

A slow-adapting depolarization is seen in the horizontal cell voltage waveform, immediately following the hyperpolarization seen during the response to a light stimulus (**Figure 2**). This so-called roll back, whose amplitude is dependent on the diameter of the stimulus, as well as on the intensity and duration of the stimulus, is considered to be due to inhibitory feedback from horizontal cells to photoreceptors.

A key feature of horizontal cells is that they form a syncytium through gap-junction coupling between homologous horizontal cell subtypes, such that the networks of A-type horizontal cells are distinct from those formed by the B-type horizontal cells. As a result, the receptive fields of horizontal cells are considerably larger than the spread

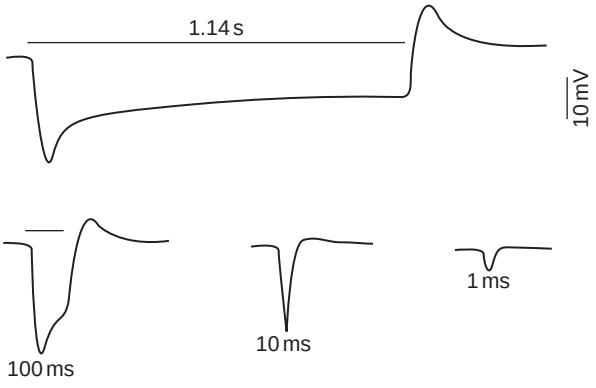

Figure 2 The S-potential in early recordings from the retina of cat, showing horizontal cell responses to bright light stimuli of various durations (1.14 sec, 100, 10, and 1 ms). Vertical bar on right corresponds to 10 mV. Reproduced from figure 8 of Brown, K. T. and Wiesel, T. N. (1959). of their dendritic arborization. Furthermore, the number of coupled cells varies depending on the state of light adaptation of the retina. It is now known that several neuromodulators, including dopamine, nitric oxide, and retinoic acid, act through various signaling systems and distinct retinal circuitry to regulate properties of gap junctions within the coupled network of horizontal cells.

Ionic Conductances of Horizontal Cells and the Response to Light

The ionic conductances that shape the graded potentials of horizontal cells are attributable to the postsynaptic α-amino-3-hydroxyl-5-methyl-4-isoxazole-propionate (AMPA; GluR1, GluR2/3, and GluR4) and kainate (KA2, GluR6) ionotropic glutamate receptors that mediate photoreceptor input and an ensemble of voltage-gated ion channels, ion transport mechanisms, and voltage-insensitive ion channels. **Figure 3** shows a voltage-clamp recording from an isolated goldfish horizontal cell that illustrates several of the voltage-sensitive ion channel currents. In total, there are at least three types of voltage-gated K^+ channels (inward rectifier, delayed rectifier, and transient A-type), two types of voltage-gated Ca^{2+} channels (L- and N-type) and tetrodotoxin (TTX)-sensitive Na^+ channels. Horizontal cells also express hemichannels (formed from a variety of connexins in a species-dependent manner), amiloride-sensitive Na^+/H^+ channels (ENaCs), acid-sensitive Na^+/proton channels (ASICs), as well as a range of electrogenic exchangers for Na^+, Ca^{2+}, Cl^-, K^+, and HCO_3^- (Na^+/Ca^{2+}, $Na^+/Ca^{2+}/K^+$, $Na^+/K^+/2Cl^-$, and AE3) and pumps (Na^+/K^+- and Ca^{2+}-adenosine triphosphate (ATP)ases, H^+-pumping plasma membrane V-ATPases) for maintaining ionic gradients. Finally, inositol 1,4,5-trisphosphate-sensitive and caffeine-sensitive intracellular Ca^{2+} stores contribute to calcium signaling and may influence synaptic transmission.

In the dark, horizontal cell membrane potential is driven by input from photoreceptors releasing L-glutamate acting at AMPA and kainate receptors to depolarize cells to a level near −20 mV (**Figure 4**). The balance of excitatory synaptic input and activation of delayed rectifier K^+ channels set this membrane potential. Reduction of glutamatergic input from photoreceptors by light terminates the depolarizing influence, and the membrane hyperpolarizes toward the potassium equilibrium potential (E_K) where inward rectifier K^+ channels (K_{IR}) activate and dominate the membrane potential. In fact, horizontal cell K_{IR} channels strongly clamp these cells at a potential near −70 mV in the absence of glutamate. The dihydropyridine-sensitive, L-type ($Ca_V1.2$ and 1.3, α1C and D) and N-type Ca^{2+} channels, which normally activate above −50 mV, may mediate vesicular fusion, and produce Ca^{2+} fluxes that activate Ca^{2+}-dependent enzymes, and trigger release of Ca^{2+} from internal stores. Na^+ channels are thought to have roles in accelerating the depolarizing phase of the horizontal cell response at the termination of a light step, and, in coordination with the A-type K^+ channels, participate in oscillatory potential production. Some of these channels are also modulated by neurotransmitters: inward

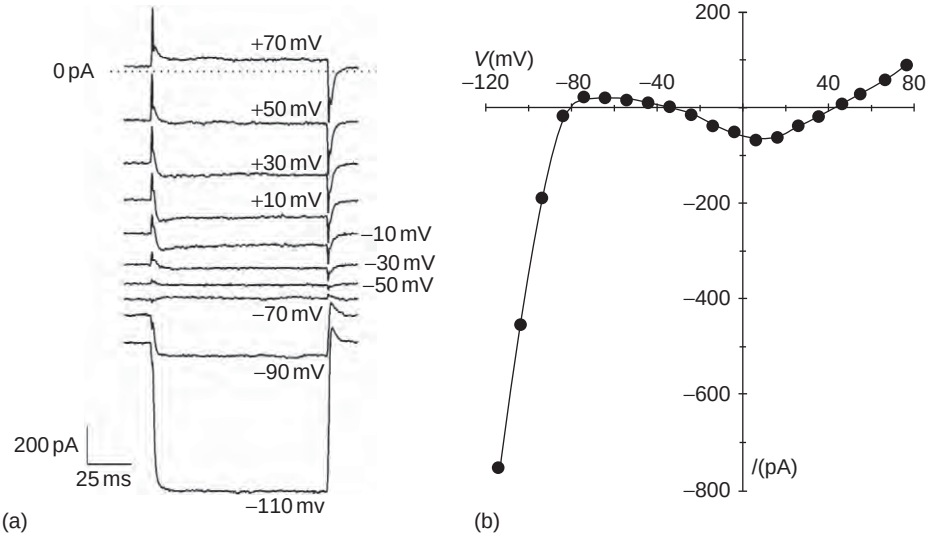

Figure 3 Current–voltage relation of isolated goldfish horizontal cell, recorded from a holding potential of –40 mV with steps in (a) to show temporal characteristics of the response and in (b) a depolarizing ramp voltage clamp protocol. The characteristic N-shape of the *I–V* relation illustrates the prominent inwardly rectifying current carried by K^+ at potentials more negative than –80 mV, an extended negative slope region due to L-type Ca^{2+} channels positive to –40 mV, and modest outward rectification positive to +40 attributable to delayed rectifier K^+ channels and hemichannels. Proton modulation of ion channels in isolated horizontal cells of the goldfish retina. *Journal of Physiology (London)* 581(Pt 2): 529–541, with permission from Wiley-Blackwell.

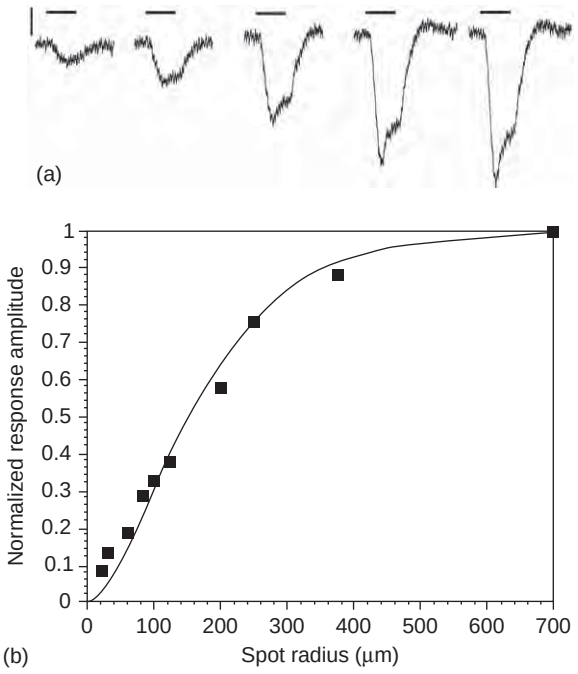

Figure 4 Responses of a mouse horizontal cell to (a) light spots of increasing radius (40, 90, 200, 375, and 700 μm) and constant intensity (log $I/I_0 = -2.1$) lasting 250 ms (horizontal bars). Note the prominent roll back of the hyperpolarization response with the largest spot stimulations, reflecting the engagement of the surround response. Vertical scale bar is 2 mV. (b) Plot of normalized response amplitudes against spot radius. Reproduced from figure 4 of Shelley, J., Dedek, K., Schubert, T., et al. (2006). Horizontal cell receptive fields are reduced in connexin57-deficient mice. *European Journal of Neuroscience* 23(12): 3176–3186, with permission from Wiley-Blackwell.

rectifier K^+ channels and L-type Ca^{2+} channels are suppressed by L-glutamate, and the L-type Ca^{2+} channels are modulated by dopamine in cone-driven horizontal cells.

Cellular Mechanisms of Horizontal Cell Neurotransmission

Lateral inhibition in the outer retina generates receptive-field surrounds of retinal neurons at photoreceptor terminals and at bipolar cell dendrites. In other words, the photoreceptor response can be modulated by light falling on neighboring photoreceptors through horizontal cell feedback. As the diameter of a spot of light increases and the horizontal cell feedback network is engaged, the hyperpolarizing membrane potential response of photoreceptors and horizontal cells exhibit a slow depolarizing sag or roll back in the membrane potential, which is attributed partly to this feedback (**Figure 4**). Although it is generally accepted that horizontal cells provide inhibitory feedback onto photoreceptor terminals, the synaptic and cellular mechanisms underlying this process are poorly understood. There are several proposed mechanisms of synaptic transmission, involving gamma aminobutyric acid (GABA), protons, and an ephaptic mechanism through hemichannels, at the tips of horizontal cells. Discrepancy between findings from different groups may reflect technical issues and different biological strategies used by mammalian versus nonmammalian species, and perhaps even different synaptic mechanisms used by the different horizontal cell subtypes. Furthermore, it is also possible that different cellular mechanisms encode different aspects of visual information or may be used under different light conditions. However, it seems clear that the principal effect of horizontal cell feedback onto cone and rod photoreceptor terminals involves the modulation of their voltage-gated L-type Ca^{2+} channels.

Horizontal Cell Feedback and Feed-Forward

The inhibitory transmitter GABA has been proposed as the horizontal cell neurotransmitter, and the release of GABA is thought to occur through the voltage-modulated action of a plasma membrane GABA transporter (GAT) in nonmammalian retinas and by regulated vesicular release in mammalian retinas, as mammalian horizontal cells do not express GATs. An ephaptic model of feedback onto cone terminals was originally conceived by Byzov and colleagues, and later elaborated to involve hemichannels as current sinks. More recently, evidence has accumulated for protons as a key messenger. In any case, since the ON and OFF bipolar cells depolarize or hyperpolarize, respectively, in response to light-mediated reductions in glutamate release from photoreceptors, it seems simplest that for surround antagonism to affect the two types of bipolar cell responses in a coherent manner, the modulatory effect would be integrated at the presynaptic photoreceptor terminal by a feedback mechanism. To invoke feed-forward surround inhibition requires the horizontal cell transmitter to affect the postsynaptic ON and OFF bipolar cells through mechanisms of opposite polarity.

Several convergent findings indicate that GABA is a mammalian horizontal cell transmitter. One or both of the L-glutamate decarboxylase (GAD) isoforms are found in horizontal cells at the messenger RNA (mRNA) and protein levels. Many, but not all, studies have shown GABA immunoreactivity in horizontal cells of guinea pig, cat, rabbit, and primate retina. In contrast, there are studies reporting low or nondetectable levels of GAD_{67} or GABA immunoreactivity in horizontal cells of the adult mouse and rat retina, whereas GAD immunostaining is present at high levels in horizontal cells of the developing and juvenile mouse retina. The detection of GAD or GABA in the adult retina is influenced by several factors, including differential expression of GAD isoforms and levels of GAD and GABA in horizontal cells, as well as technical issues related to fixation protocols and antibody

specificity. The presence of vesicular GABA transporter (VGAT) immunoreactivity in horizontal cells is consistent with a transmitter role for GABA in mammals, as VGAT mediates the accumulation of GABA into synaptic vesicles. The highest level of VGAT immunostaining is in horizontal cell processes underneath the photoreceptor terminals, and in the dendritic and axonal endings within the synaptic triad.

Feed-Forward onto Bipolar Cell Dendrites

Bipolar cells possess antagonistic receptive-field surrounds, which may be to some extent mediated by horizontal-cell feed-forward transmission onto bipolar cells. At the ultrastructural level, synapses between horizontal cell processes and bipolar cell dendrites have been reported. $GABA_A$ and $GABA_C$ receptor immunoreactivity is localized to bipolar cell dendrites adjacent to horizontal cell processes. In perforated-patch recordings, GABA elicits depolarizing inward currents when applied to dendrites of mouse rod bipolar cells and hyperpolarizing currents when applied to OFF-type cone bipolar cells, consistent with a GABAergic feed-forward input from horizontal cells in the creation of receptive-field surrounds. The inhibitory and excitatory actions of GABA at ON- and OFF-bipolar cell dendrites may be accounted for by the different Cl^- concentrations in bipolar cell dendrites maintained by chloride co-transporters. NKCC (Na-K-2Cl transporter), which accumulates Cl^- intracellularly, has been immunolocalized to dendrites of ON bipolar cells, whereas, KCC2, which extrudes Cl^-, has been localized to those of OFF bipolar cells. The localization of these chloride transporters would predict that chloride equilibrium potential (E_{Cl}) would be positive to the membrane potential (V_m) in the former situation, and E_{Cl} would be negative to V_m in the latter.

While horizontal cell inputs to bipolar cells could be demonstrated by direct current injection into or light stimulation of horizontal cells, it has been more difficult to sort out the contributions of the indirect pathway of horizontal cell to cone photoreceptor to ON bipolar cell from the direct horizontal cell to bipolar cell dendrite pathway. In experiments where L-2-amino-4-phosphonobytyric acid (L-AP4) was used to block photoreceptor input to ON bipolar cells, and by extension the indirect pathway, light stimulation produced a hyperpolarization response in these bipolar cells. From the relative magnitudes of the surround responses with and without L-AP4, about a quarter to a third of the surround response came through the feed-forward horizontal cell to bipolar cell synapse; the majority arose through the feedback to the cone photoreceptor terminals. Low cobalt concentrations (<500 μM) selectively block surround-evoked depolarization of cones (and receptive fields of downstream neurons), without affecting transmission from cones to horizontal cells. It has been proposed that low concentrations of cobalt may act by blocking GABA-induced current in turtle cones, but hemichannels and proton-permeable ENaCs have also been reported to be sensitive to low concentrations of cobalt. Finally, there is anatomical evidence from rabbit retina as well as electrophysiological and tracer evidence from salamander that indicate gap-junction coupling between horizontal cells and cone ON-type bipolar cells.

Feedback onto Photoreceptor Terminals

In turtle and salamander retina, there are extensive data supporting the GABA-mediated inhibitory feedback from horizontal cells to cones. A clear, nonzero reversal potential of this feedback synapse onto cones suggests that the underlying synaptic mechanism is likely chemical, rather than electrical. Moreover, bathing the retina in GABA blocks the feedback response of cone photoreceptors, as would be expected if a decrease in GABA release signals the horizontal cell feedback. In turtle cones, the effect of GABA was hyperpolarizing upon break-in in ruptured patch recordings, suggesting that the reversal potential for chloride in cones was negative to the resting membrane potential. The surround response would reflect a diminution of this hyperpolarizing current. However, the currents evoked by GABA in turtle cones in whole retina preparations were too small to account for feedback, unless enhanced by modulators of $GABA_A$ receptors (e.g., pentobarbital), suggesting that the contribution of the GABA-induced current to surround formation was minor. In salamander cones, the reversal potential for chloride in cones is close to the dark resting potential, suggesting GABAergic disinhibition near the dark potential should produce little membrane-potential change. This result is inconsistent with the postulated role for GABA in generating the feedback depolarization and supports other studies using GABA receptor antagonists, suggesting that GABA does not have a role in horizontal cell to cone photoreceptor feedback.

In contrast, the localization of GABA receptors to photoreceptor terminals is consistent with a feedback role for GABA. Morphological and molecular support for a feedback role includes the expression of $GABA_A$ receptor subunit messenger RNA (mRNA) by photoreceptors detected by *in situ* hybridization immunohistochemistry and single-cell RT-PCR. In addition, cone terminals of pig, mouse, and rat show $GABA_C$ receptor (ρ subunit) immunoreactivity. Similar to the GABA-induced currents in turtle cone pedicles, recordings from mouse and pig cones show the presence of functional $GABA_A$ and $GABA_C$ receptors, whereas rods in porcine and turtle retina exhibit little sensitivity to GABA. In addition to ionotropic GABA receptors, metabotropic $GABA_B$ receptors are expressed on horizontal cell processes, suggesting that GABA may also act presynaptically on horizontal cells. Finally, it is also likely that GABA

acts on autoreceptors on horizontal cells as well as on neighboring horizontal cells, where it would likely be depolarizing as E_{Cl} is above V_m; this would provide positive feedback. Overall, these studies indicate multiple targets for GABA in the outer plexiform layer, which could mediate complex actions of GABA in the outer retina.

There are also findings that argue against the role of GABA in mediating horizontal cell feedback onto cones. Principally, GABA agonists and antagonists do not always appear to affect surround-evoked depolarization of cones. However, the presence of GABA receptors on horizontal cells, bipolar cells, as well as on cone photoreceptors complicates the interpretation of experiments using GABA antagonists. Furthermore, it is clear that small changes in the Ca^{2+} currents produced by feedback are not reflected in large changes in the membrane potential of the photoreceptor.

Ephaptic Transmission between Horizontal Cells and Photoreceptor Terminals

An ephaptic effect has also been hypothesized to underlie the feedback signal from horizontal cells to rod and cone photoreceptors. Originally, this electrical feedback mechanism was proposed to involve only glutamate-gated channels in the tips of horizontal cell processes that invaginate cone synaptic terminals. More recently, evidence for hemichannels at the tips of horizontal cell processes added this conductance mechanism as an additional current sink in the horizontal cell dendrites. Current flowing through the bulk resistance of the interstitial space and into hemichannels and glutamate receptor ion channels is proposed to produce a voltage drop in the synaptic cleft. This extracellular negative potential, in effect, shifts the activation of presynaptic Ca^{2+} channels in the positive direction, reducing the amount of glutamate released by the photoreceptor synapse.

The amplitude of the extracellular voltage drop is a critical function of the current density and the interstitial resistivity, and there is no consensus yet that the amplitude is sufficient to carry the 5–10-mV feedback signals that presynaptic Ca^{2+} channels apparently sense. Furthermore, the time course of an ephaptic response should be nearly instantaneous since it is electrical in nature, but it is well known that there is a slow time course of the roll back of the horizontal cell light response (**Figure 2**). The more rapid depolarization of the photoreceptor (or OFF bipolar cell) in response to strong surround inhibition seems better suited kinetically to the ephaptic effect. Carbenoxolone-induced block of hemichannels has been cited as evidence for ephaptic transmission. However this drug also blocks Ca^{2+} currents in photoreceptors at concentrations used to block ephaptic transmission.

Proton Mediation of Horizontal Cell Feedback

Recent work in turtle, salamander, ground squirrel, primate, zebra fish, and goldfish retina indicates that modulation of the extracellular pH in the synaptic cleft between horizontal cells and photoreceptors may be used to signal feedback to photoreceptors. Evidence that protons modulate voltage-gated Ca^{2+} channels at photoreceptor terminals, carrying the feedback signal, is substantial. The principal evidence is that 1–20-mM HEPES and other pH buffers reversibly block feedback onto photoreceptors by eliminating the shift in activation of the photoreceptor Ca^{2+} channel current. The exact cellular mechanism that controls the pH of the synaptic cleft between photoreceptors and horizontal cells remains undefined, but horizontal cell plasma membrane V-ATPases, ENaCs, ASICs, and hemichannels are possible membrane mechanisms by which horizontal membrane potential could alter cleft pH. Depolarized horizontal cells would produce or contribute to cleft acidification by extruding protons and/or by not taking them up, while hyperpolarized horizontal cells would facilitate cleft alkalinization by not releasing protons and/or by taking them up. The sensitivity of presynaptic Ca^{2+} channels to alterations in extracellular pH suggest that cleft pH is modulated between ~pH 7.0, during the peak of inhibitory feedback signaling, and ~pH 7.8, during maximal horizontal cell hyperpolarization and the absence of presynaptic inhibition. Physiological measurements and estimates of cleft pH changes support the possibility that pH changes of this magnitude occur.

Functional Roles of Horizontal Cells

The proposed functional roles of mammalian horizontal cells are derived from the notion that these cells provide inhibitory feedback onto photoreceptors. This idea is based largely on investigations of nonmammalian model systems that show: (1) a global contribution to retinal adaptation to different mean levels of illumination; (2) a local contribution to spatial processing and contrast enhancement by a spectrally broadband, but spatially restricted feedback to create the antagonistic receptive-field surrounds of photoreceptors, bipolar cells, and ganglion cells; and (3) a local contribution to chromatic processing by a chromatically selective feedback to create color-opponent receptive fields of cones, bipolar cells, and ganglion cells.

Retinal Adaptation

The syncytium of horizontal cells formed through electrical coupling of homologous cells shows characteristic changes with different states of light adaptation. Dark adaptation reduces coupling (from space constant determinations, tracer coupling), smaller receptive-field sizes

(surround-to-center ratio), and decreased sensitivity of horizontal cells. The decreased electrical coupling would also increase input resistance of the cell, resulting in larger voltage changes to a given light stimulus. Several modulators of horizontal-cell gap-junctional coupling have been identified, including dopamine, nitric oxide, and retinoic acid, which appear to mediate the effects of adaptation.

The dopaminergic modulation of horizontal-cell gap-junction conductivity has been reported for both nonmammalian and mammalian retinas. During light stimulation, the levels of dopamine rise in the retina and, through activation of D1 dopamine receptors on horizontal cells in a cyclic adenosine monophosphate (cAMP)-dependent manner, the duration and frequency of gap-junction openings are reduced. This results in the uncoupling of horizontal cells, such that responses of a smaller pool of photoreceptors and, thus, input from a smaller visual area, influence the horizontal cell response, reflected in the reduced surround-to-center (annulus-to-spot) ratios. Findings in rabbit retina indicate that the network of coupled horizontal cells is greatest in dim, scotopic conditions (dim ambient light) and less extensive in darkness and in photopic conditions, that is, the degree of coupling reflects the adaptational state of the retina (**Figure 5**). The retinal circuit underlying the modulation of dopamine release appears to involve a pathway from photoreceptors to ON bipolar cells to dopaminergic amacrine cells to horizontal cells. In addition to differing adaptational states, retinal levels of dopamine vary with a circadian rhythm.

Similar to dopamine, nitric oxide appears to uncouple horizontal cells, modulating the electrical coupling through activation of soluble guanylate cyclase and a cyclic guanosine monophosphate (cGMP)-dependent cascade in horizontal cells. Interestingly, in rabbit retina, nitric oxide also appeared to increase the sensitivity of horizontal cells to light through possibly an indirect action on photoreceptor transduction or at the photoreceptor-horizontal cell synapse, in addition to the increased input resistance resulting from the reduced cellular coupling. This may occur to some extent through the modulation of the ionotropic glutamate receptors found on horizontal cells. It has been speculated that increased nitric oxide production by horizontal cells under dark-adapted conditions and by amacrine cells under light-adapted conditions may account for the biphasic modulation of horizontal cell coupling with adaptational state.

Illumination increases the levels of all *trans*-retinoic acid (at-RA), which is a byproduct of the phototransduction cycle, and thereby correlates with the amount of light illumination. at-RA can uncouple horizontal cells in mouse, rabbit, and carp in a stereospecific manner and can do so in the presence of D1 dopamine receptor antagonist, indicating that it is not acting through modulation of the dopaminergic pathway. In the presence of at-RA, the receptive-field sizes of horizontal cells, as measured by annulus-to-spot ratios, were reduced. In addition to its effects on spatial response characteristics of horizontal cells, at-RA application in dark-adapted retinas could induce effects resembling light adaptation, such as reduced light responsiveness, changes in chromatic properties of H2 horizontal cells in teleosts, decreased gap-junctional permeability, as well as spinule formation in fish horizontal cells.

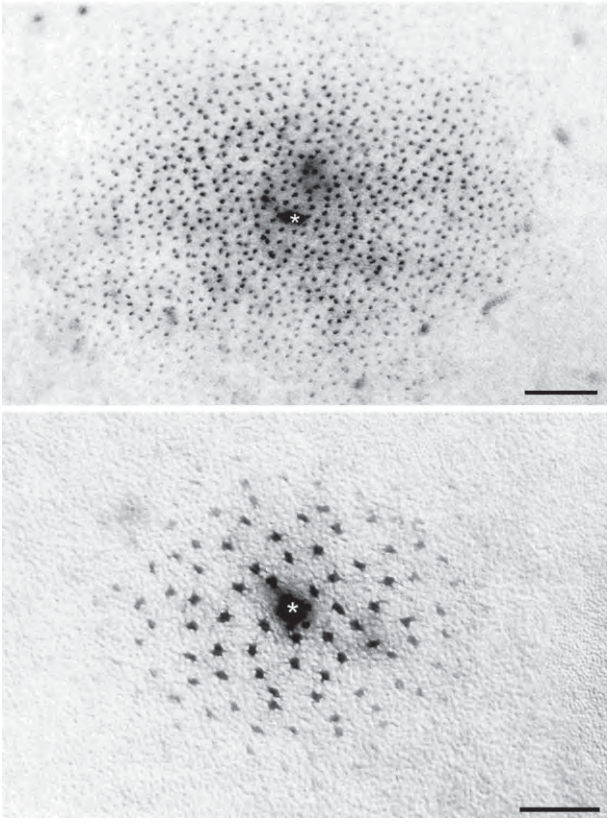

Figure 5 Regulation of horizontal cell tracer coupling by exposure of rabbit retina to different light intensities. (Top) Exposure to dim light intensity (log –6.0) produced coupling of over 1200 cells. (Bottom) Exposure to bright light intensity (log –1.0) produced coupling of 124 cells. Scale = 100 μm in top panel, 50 μm in bottom panel. Adapted from figures 7 and 8 of Xin, D. and Bloomfield, S. A. (1999). Dark- and light-induced changes in coupling between horizontal cells in mammalian retina. *Journal of Comparative Neurology* 405: 75–87.

Gain Control of Synapses in the Outer Retina

The gain of the graded potential synapses between photoreceptors and horizontal cells is defined as the postsynaptic amplitude divided by presynaptic amplitude. High-gain synapses in an open-loop system (e.g., no inhibitory feedback) are inherently unstable, tending to saturate their

postsynaptic targets. To maintain stability and to optimize signal-to-noise ratios, synaptic gain is controlled by reciprocal feedback signals so that gain is high and stable when signals are small, and gain is reduced when signals are large and potentially saturating. Having each photoreceptor synapse under closed-loop inhibitory feedback control imparts gain control to the system.

The ability of the horizontal cell network to adjust to different states of light adaptation permits in part the retina to operate optimally over 10 orders of magnitude of light intensities. The input-output relations of photoreceptor to second-order neurons are modulated by light and dark adaptation. For example, dim background illumination can increase the voltage gain of the rod output synapse by increasing the conductance of horizontal cell kainate receptors through a dopaminergic signaling pathway and enhancing rod Ca^{2+} channel activation. Tonic activation of the feedback synapse by the steady illumination of receptive-field surrounds shifts (or resets) the operating range of bipolar cells to the right along the intensity axis, such that a brighter light is now necessary to elicit a given response.

Spatial and Temporal Processing

The antagonistic center-surround receptive-field organization underlies our ability to detect edges, enhancing contrast between regions of varying brightness and color, and it is ultimately responsible for visual acuity. Baylor and colleagues demonstrated that the turtle cone photoreceptor light response was modulated by light intensity as well as by the pattern of light stimulation, where cone response to center illumination was modified by the stimulation of the surround. Moreover, hyperpolarization of horizontal cells could produce a depolarization in nearby cones. These data indicated that horizontal cells participate in generating antagonistic receptive-field surrounds of cone photoreceptors. The two morphological types of horizontal cells exhibit different spatial summation properties, owing to differing dendritic field sizes and degree of electrical coupling. The reduction of horizontal cell receptive-field sizes in darkness due to uncoupling would further improve spatial contrast ability. Because of their large dendritic fields and electrical coupling, in general, horizontal cells integrate light stimuli over a large area and thus respond well to large light stimuli (i.e., low spatial frequency), whereas small spot stimuli (i.e., high spatial frequency) evoke small responses. The knockout of connexin 57 (Cx57), a gap-junction protein specific to horizontal cells, in mice reduced the receptive-field sizes of horizontal cells, but did not eliminate the rollback in the horizontal cell light response, reflective of negative feedback to cones (**Figure 4**). The knockout diminished the tracer coupling of horizontal cells by 99%, which indicates that Cx57 is the principal connexin in horizontal cells. Furthermore, the regulation of coupling by dopamine was lost, suggesting that gap junctions formed by Cx57 are the targets of this modulation.

In fish, D1 antagonists blocked the uncoupling of horizontal cells produced by flickering light, but not the uncoupling resulting from steady ambient light, suggesting that the temporal characteristics of the light stimulation may affect the pathway activated.

Chromatic Processing

The Stell model emerged from anatomical analysis of the connectivity of color-sensitive cones and three types of cone-driven horizontal cells in fish retina (**Figure 6**). The model accounted for findings that monophasic horizontal cells (H1) hyperpolarize irrespective of wavelength, but peak in the red or long wavelengths, biphasic horizontal cells (H2) hyperpolarize at short and medium wavelengths and depolarize at long wavelengths, and triphasic horizontal cells (H3) hyperpolarize at short and long wavelengths, while depolarizing at medium wavelengths. Hence, monophasic H1 cells signal luminance, whereas the other two types provide color-opponent signals. In the

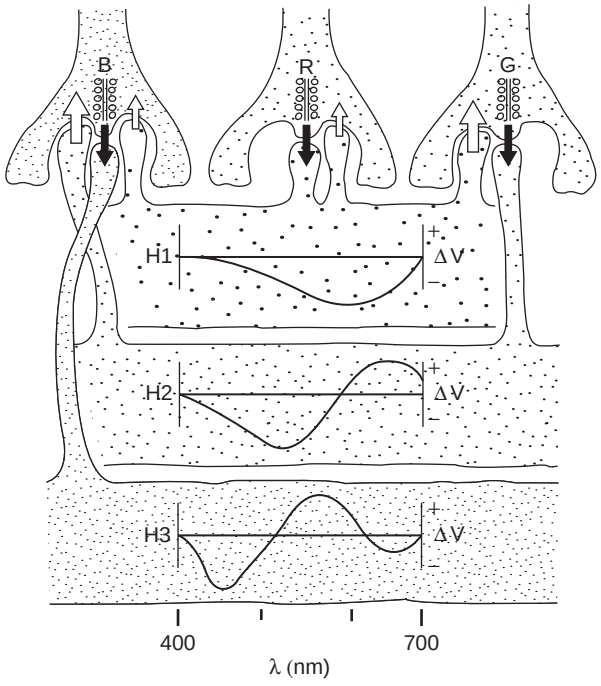

Figure 6 The Stell model of chromatic interactions in the goldfish retina. Cone types are labeled R, G, and B. The H1, H2, and H3 horizontal cells generate monophasic, biphasic, and triphasic spectral response functions by the pathways shown. Synaptic pathways from cones to horizontal cells are shown with filled arrows while feedback pathways are shown in open arrows. Reproduced from figure 2 of Stell, W. K., Lightfoot, D. O., Wheeler, T. G., and Leeper, H. F. (1975). Goldfish retina: Functional polarization of cone horizontal cell dendrites and synapses. *Science* 190(4218): 989–990. Reprinted with permission from AAAS.

case of the H2 red/green biphasic C-type cells, the depolarizing responses to long wavelengths appear to arise from feedback from red-sensitive L-type horizontal cells to green cones, which then synapse onto H2 cells, and, similarly, the depolarizations in the H3 come about through H2 feedback to short wavelength or blue cones, which then drive the H3 cells. Mammalian retinas do not appear to have color-opponent horizontal cells.

Conclusions

The visual system operates over a large range of stimulus intensities. That animals can see in the dark of a moonless night and in near-blinding sun-drenched scenes is a remarkable feat achieved by exploiting the dynamic range of numerous cascaded stages. Several adaptation stages have been described in rods and cones, beginning in the light-transducing outer segments. Modulation of the rod and cone output synapses is another critically important stage, and here adaptation results in large part from horizontal cell feedback and feed-forward, and may alter the form of some receptive fields. Many of the anatomical and biophysical features of the photoreceptor triad synapse are known in great detail, and regulation of the synapse by integrative feedback from horizontal cells is one area of critical importance in retinal neurobiology. Future studies will aid us in understanding the complex analysis of information in the visual system, and, in particular, how the visual system has evolved algorithms that optimize acuity under changing levels of ambient illumination.

Information Processing: Retinal Adaptation

K R Alexander, University of Illinois at Chicago, Chicago, IL, USA

Glossary

Contrast – Magnitude of luminance variation with respect to mean luminance, defined as Weber contrast (C_w) for discrete stimuli: $C_W = (I_T - I_B)/I_B$, where I_T and I_B refer to the retinal illuminance of a test probe and background, respectively; or as Michelson contrast (C_M) for periodic stimuli: $C_M = (I_{max} - I_{min})/(I_{max} + I_{min})$, where I_{max} is the maximum retinal illuminance and I_{min} is the minimum retinal illuminance.

Gain – Change in the neural response produced by either a change in luminance or a change in contrast over the range for which the stimulus–response function is reasonably linear, specified in units such as impulses per quantum or impulses per percent contrast.

Luminance – Amount of light given off by an extended source, either emitted or reflected, and usually specified in candelas per square meter (cd m^{-2}), although many alternative units exist, including apostilbs (asb), foot-lamberts (ftL), millilamberts (mL), and nits.

Retinal illuminance – Luminance in cd m^{-2} multiplied by pupil area in square millimeters (mm^2) and specified in trolands (td).

Threshold – In psychophysics, the light level that marks the transition from invisibility to visibility, defined as either the absolute threshold ("yes, I see it") or the difference threshold ("yes, it is different"); in electrophysiology, the light level that elicits a criterion neural response amplitude or a criterion change in response amplitude.

The eye can potentially be exposed to an enormous range of light intensities, ranging from a few photons per second under extremely dim lighting conditions to light levels that can be more than 10-billion-fold higher (i.e., a factor of 10^{10} or 10 log units). Furthermore, there may be rapid temporal fluctuations in the light level due to eye movements. In addition, there can be marked changes in the chromatic properties of the visual environment, such as when viewing objects in incandescent room illumination versus outdoors at noon on a sunny day. Remarkably, the visual system is able to cope with the large range of illumination conditions through complex neural mechanisms that are collectively termed adaptation.

It should be noted, however, that there are actually a number of different uses of the term adaptation, ranging from an adjustment to the overall light level to more complex forms, such as spatial frequency adaptation, motion adaptation, and adaptation to artificially induced retinal image distortion or rotation. The emphasis of this article is on adaptation that is presumed to occur within the retina. How do we know which processes are retinal and which involve higher levels of the visual system? One method is to identify neurons within the retina that exhibit the physiological characteristics of the type of adaptation under investigation. This can be determined by recording from single neurons within the retina, by recording simultaneously from groups of neurons using a multi-electrode array, or by recording the electroretinogram (ERG), which is the massed electrical response of the retina. Further insight into the sites and mechanisms of adaptation can be gained through the study of transgenic animals that have a mutation in, or knockout of, putative components of the adaptation process, or of humans who have spontaneously occurring mutations in these components.

A complementary, behavioral method for investigating the site of adaptation is to employ dichoptic stimulation. In this technique, an adapting stimulus is presented to one eye and a test stimulus is presented to the other eye. The goal is to determine whether adaptation of the contralateral eye affects performance for targets presented to the tested eye. The first site at which there is a combination of information from the two eyes occurs at a cortical level. Therefore, if there is interocular transfer of the adaptation, then it is presumed that the primary site of the adaptation is cortical. On the other hand, if there is no evidence of interocular transfer, then the adaptation is presumed to occur at the retinal level.

Based on such considerations, the forms of adaptation that are thought to be predominantly or exclusively retinal in origin are: (1) light adaptation, which refers to the adjustment of the visual system to changes in the overall or mean illumination level; (2) contrast adaptation, which refers to the ability of the visual system to adjust to the variance of the illumination rather than to its mean; (3) chromatic adaptation, which refers to an adjustment to the spectral composition of light; and (4) dark adaptation, which refers to the time-dependent recovery of visual sensitivity in the dark following exposure to light. These forms of adaptation are the subject of this article, although the emphasis is on light adaptation.

In addition to adaptation, though, there are additional strategies that are employed by the visual system to cope with the broad range of illumination levels encountered by the visual system. One strategy is a change in pupil size, which is a mechanical way in which the visual system can partially adjust to varying light levels. As the overall light level increases, the pupil area decreases, which in turn decreases the retinal illuminance. However, the maximum change in pupil area is essentially 16-fold (i.e., a change in diameter from 2 to 8 mm); therefore a change in pupil size can compensate for only a small portion of the potential illumination range. Furthermore, owing to the directional sensitivity of the cone photoreceptors (the Stiles–Crawford effect), light entering the edge of the pupil is a less efficient stimulus for the cone system than light entering the pupil center. Therefore, the effective increase in retinal illuminance with increasing pupil size is actually less than would be predicted based on pupil area.

Another strategy used by the visual system to cope with the large range of environmental light levels is to split the load between the rod and cone systems. The rod system, which is extremely sensitive, covers the lower 3 log units of stimulation, termed the scotopic range. The cone system handles the highest 6 log units, termed the photopic range. Between these two ranges is the mesopic range, within which visual sensitivity can be rod-mediated or cone-mediated, depending on such factors as target wavelength, duration, size, and retinal eccentricity. Thus, the duplex nature of the retina provides a partial solution to the problem of dealing with the wide range of light levels impinging on the retina. However, adaptive processes within the rod and cone systems are also necessary in order to provide useful vision under all illumination conditions.

Light Adaptation

Light adaptation typically refers to the adjustment of the visual system to the overall illumination level. This adjustment allows for an amplification of neural signals relative to noise at low light levels, and prevents or minimizes saturation of the neural response at high light levels. Light adaptation also changes the way in which spatial and temporal information is processed. For example, spatial resolution is typically better at high illumination levels.

Characteristics of Light Adaptation

The typical light adaptation paradigm consists of the presentation of a brief test probe of retinal illuminance I_T against an adapting field of retinal illuminance I_B. The dependent variable is the increment threshold ΔI, defined as:

$$\Delta I = (I_T - I_B) \quad [1]$$

which is usually measured at different values of I_B. The typical threshold versus retinal illuminance or tvi function is illustrated in **Figure 1**. The data points in this figure represent psychophysical increment thresholds for a small achromatic test probe presented foveally against a large achromatic adapting field. The curve represents the log form of the equation:

$$\Delta I = K(I_B + I_0)^n \quad [2]$$

where K and I_0 are fit parameters that represent the absolute threshold and the inflection point of the function, respectively, on log–log coordinates and n determines the slope of the function at high retinal illuminances.

At low adapting levels, the increment threshold is relatively independent of the retinal illuminance of the adapting field. Under these conditions, it is generally assumed that the threshold is governed by the internal noise within the visual system, also termed dark light or eigengrau. As the retinal illuminance of the adapting field increases, the increment threshold begins to rise as the internal noise becomes overwhelmed by the neural response to the adapting field. At high retinal illuminances, the increment threshold is proportional to the adapting field retinal illuminance, such that:

$$\Delta I / I_B = K \quad [3]$$

This relationship is referred to as the Weber–Fechner relationship or Weber's law. On a log–log plot, Weber's law has a slope of 1. An important implication of Weber's

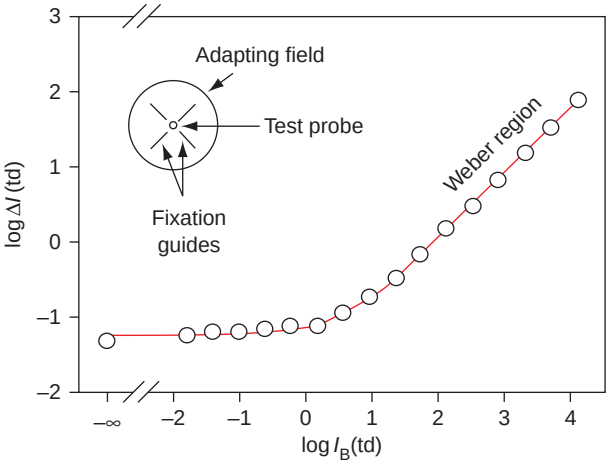

Figure 1 Increment threshold (circles) as a function of adapting field retinal illuminance for a foveally presented brief achromatic test probe in the center of an achromatic adapting field, as depicted in the inset. The curve represents the least-squares best fit of eqn [1].

law is that the visual system is organized to signal contrast rather than absolute luminance. In other words, because $\Delta I/I_B$ is constant within the Weber region, Weber contrast is also constant, regardless of the adapting level.

The data of Figure 1 represent a tvi function for the foveal cone system, but an increment threshold function can also be obtained for the rod system if a short-wavelength test probe, to which the rods are sensitive, is presented in the visual field periphery against a long-wavelength adapting field that desensitizes the cone system. A schematic of a rod increment threshold function is shown in Figure 2. As is the case for the cone system, there is a range of low retinal illuminances over which the rod threshold remains constant. This is followed by a region over which the rod threshold is proportional to the square root of the retinal illuminance (the Rose–deVries region), and then there is a transition to Weber-law behavior. However, a primary difference between the rod and cone increment threshold functions is that the rod function shows saturation, or an upward turn at high retinal illuminances that is steeper than Weber's law. For adapting field retinal illuminances above rod saturation, the cone system mediates detection of the test probe.

Saturation can be observed in individual rod photoreceptors, in the sense that there can be a complete shutdown of the rod circulating current resulting from light exposure. However, there is considerable evidence that psychophysical rod saturation does not represent saturation at the level of the rod photoreceptors, but rather is a property of the pathway through which the rod signals travel. For example, the value of I_B at which the onset of psychophysical rod saturation occurs depends on whether the adapting field is steady or flashed, on the size of the test probe and the wavelength of the adapting field, and on the level of cone stimulation, all of which indicate that postreceptoral factors are involved.

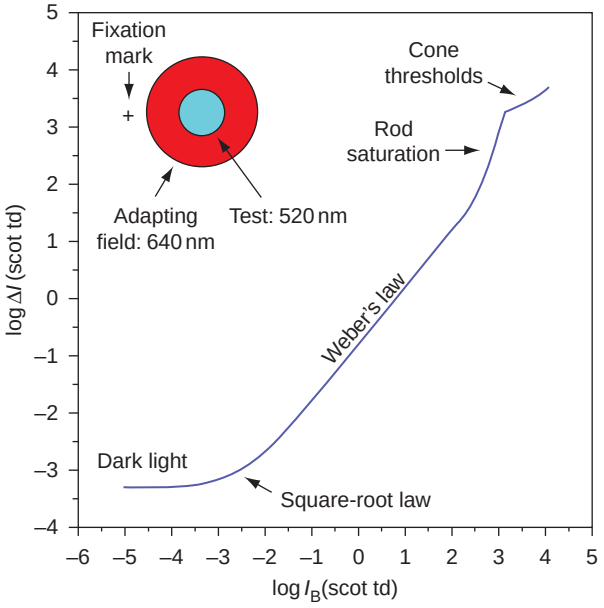

Figure 2 Schematic increment threshold function obtained under rod-isolating conditions. The inset depicts the stimulus configuration, which consists of a large short-wavelength (blue) test probe presented in the visual field periphery against a larger long-wavelength (red) adapting field.

The tvi function of the cone system typically does not show saturation, owing to photopigment bleaching. When cone photopigment molecules become bleached as a result of light exposure, there is less total photopigment within a cone photoreceptor that is available to capture photons. As a result, a proportionally greater level of stimulation is needed to produce the same neural response. At equilibrium, the relationship between p, the fraction of unbleached cone photopigment, and retinal illuminance I in td is:

$$1 - p = I/(I + I_0) \quad [4]$$

where I_0 is the half-bleaching constant of 4.3 log td. The effect of cone photopigment bleaching on vision has been likened to wearing sunglasses, which reduce the retinal illumination by a scaling factor. Photopigment bleaching is a way of avoiding saturation within the cone system but it is not a factor within the rod system, because the rod photoreceptors are saturated by illumination levels that bleach only a few percent of the rhodopsin molecules within an outer segment.

However, saturation within the cone system can be demonstrated if a probe-flash paradigm is used. In this paradigm, the test probe is presented simultaneously with a briefly flashed adapting field. A typical finding is that the threshold rises rapidly with increasing retinal illuminance of the flashed adapting field, such that at high retinal illuminances, the test probe itself is invisible and its presence can only be detected by virtue of an afterimage.

The probe-flash paradigm is a variant of Crawford masking or early light adaptation, in which the increment threshold for a test probe is measured with respect to the time of onset of a transient rather than a steady-state adapting field. Typically, the threshold begins to rise when the test probe is presented slightly before the masking flash. This curious result has been attributed to the differential latencies of the neural responses to the weak test probe and the stronger masking flash. The threshold is highest when the test probe and masking flash have simultaneous onsets. If the test probe is presented during the middle of a long-duration masking flash, then the threshold corresponds approximately to the steady-state level.

Traditionally, studies of light adaptation have used aperiodic test stimuli, such as the light pulses described above. However, there has been another experimental approach to light adaptation that has used periodic test stimuli, such as one whose retinal illuminance varies sinusoidally over time. In this approach, the dependent variable is contrast sensitivity, defined as the reciprocal of

the threshold contrast in Michelson units. A typical finding is that, at low temporal frequencies, contrast sensitivity is invariant with respect to mean retinal illuminance, which corresponds to Weber-law behavior. At high temporal frequencies, however, contrast sensitivity changes with mean retinal illuminance, such that the amplitude of the flicker rather than its contrast determines sensitivity. This finding indicates that there is a high-frequency linearity that discounts the mean retinal illuminance. In addition, the shape of the temporal contrast sensitivity function changes with adaptation level, becoming more band-pass at high retinal illuminances, so that sensitivity to intermediate frequencies becomes enhanced. This shape change has been attributed to a contrast gain-control mechanism.

The explanation for the high-frequency linearity, which is seen both psychophysically and in electrophysiological recordings, remains unclear, although several quantitative models have been proposed to account for it. In fact, a major theoretical challenge has been to develop a computational model that can encompass the adaptational features of data obtained with both periodic and aperiodic stimuli. To date, this attempt has not been entirely successful.

Mechanisms and Sites of Light Adaptation

As illustrated in **Figures 1** and **2**, the rod and cone systems can respond over a considerable range of retinal illuminances. However, individual neurons within the retina can only respond over an approximately 400-fold range of illumination levels. The typical response R of a retinal neuron as a function of retinal illuminance I is illustrated as the solid curve in **Figure 3**. This curve represents a plot of the Naka-Rushton equation:

$$R/R_{\max} = I^n/(I^n + I_s^n) \qquad [5]$$

where $R_{\max}$ is the maximum neural response, I_s is the retinal illuminance that produces $R_{\max}/2$, and n governs the steepness of the function, although n is usually set to 1. This response function is S-shaped when plotted on semi-log coordinates, as in **Figure 3**. A major characteristic of the neural response function is that it shows saturation at high illuminance levels. The response function is considered to represent a static nonlinearity, or one which acts instantaneously with no change over time.

If a retinal neuron only operated according to the solid curve in **Figure 3**, then the presence of an adapting field would lead to response compression. For example, the adapting field indicated by the vertical line in **Figure 3** would produce a neural response that is toward the top of the response range, as indicated by the solid horizontal line. This would then leave little room for an additional response to an increment of light. In fact, if the retinal illuminance of the adapting field were high enough, additional increments of light would be invisible due to response saturation.

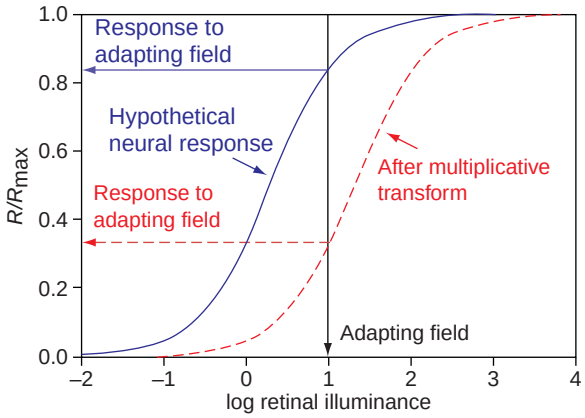

Figure 3 Normalized response amplitude vs. log retinal illuminance for a hypothetical retinal neuron before (solid curve) and after (dashed curve) a multiplicative transform. The vertical line with arrowhead indicates an arbitrary adapting field retinal illuminance, and the horizontal lines represent the hypothetical neural responses to the adapting field, based on the respective illuminance-response functions.

One way in which a neuron can avoid saturation is by shifting its operating range in proportion to the mean level of illumination. This shift of the response function is termed multiplicative adaptation and is illustrated in **Figure 3** as the dashed curve. Multiplicative adaptation is also known as von Kries adaptation, dark glasses adaptation, and automatic gain control. After a multiplicative transform, the same adapting field retinal illuminance produces a smaller neural response, as indicated by the horizontal dashed line in **Figure 3**. This allows for the detection of light increments that would otherwise be invisible without the multiplicative response scaling. Multiplicative adaptation tends to be relatively fast acting, with a time constant on the order of a few tens of milliseconds, and is thought to be the result of a neural feedback circuit.

A second way in which a neuron can avoid saturation is through subtractive adaptation. This form of adaptation subtracts out the neural response to an adapting field, thus bringing the response down out of the saturating range, without affecting the response to a brief test probe. There are both fast and slow forms of subtractive adaptation, although both are typically much slower than multiplicative adaptation, with time constants on the order of seconds to tens of seconds. Fast subtractive adaptation is presumed to represent center-surround antagonism within neuronal receptive fields. Slow subtractive adaptation may be due to a change in the membrane hyperpolarization of retinal neurons.

The rod system is desensitized by dim backgrounds that produce a quantal absorption in only a very few rod photoreceptors. This observation has led to the concept of a rod adaptation pool, according to which signals from

multiple rod photoreceptors are combined in controlling light adaptation. Pooling allows a retinal ganglion cell to respond to light when only a tiny fraction of the rods absorb photons, but it also increases the likelihood of neuronal saturation. Neural pooling can also be a factor with respect to light adaptation within the cone system. Signals from cone photoreceptors are processed by two major parallel pathways: magnocellular (M) and parvocellular (P), which are first organized at the retinal level and extend to the visual cortex. M retinal ganglion cells have a high contrast gain and saturate at relatively low levels of contrast. P ganglion cells have a low contrast gain and a more linear contrast-response function. There is generally a greater degree of spatial integration or pooling within M cells, due to their relatively larger receptive fields. Therefore, M cells are typically more light adapted by a given adapting field than are P cells.

The retinal site or sites of the various neural processes underlying light adaptation remain to be fully explicated. However, the following general conclusions can be drawn. With respect to the cone system, the site of adaptation appears to shift depending on the illumination level. At lower retinal illuminances, adaptation is dominated by postreceptoral processes, sometimes referred to as network adaptation. There is recent evidence that postreceptoral adaptation within the cone system occurs at the synapse between bipolar cells and ganglion cells. At higher retinal illuminances, adaptation occurs primarily within the cone photoreceptors themselves. Rod photoreceptors in the mammalian retina can show adaptation, in that there are changes in sensitivity and response kinetics as a function of illumination level. However, much of the light adaptation within the rod system appears to be postreceptoral in origin, occurring at the synapse between rod bipolar cells and AII amacrine cells.

A potentially powerful way to investigate the relationship between the phenomenology of light adaptation and retinal physiology is to study humans who have genetic mutations that can affect putative components of the adaptational process. An example is a visual condition termed bradyopsia (slow vision) that has been identified recently. Individuals with bradyopsia have mutations in the guanosine triphosphatase-activating protein RGS9 or its anchor protein R9AP, which impedes deactivation of the phototransduction cascade. Bradyopsia is characterized by a slow recovery of sensitivity following a sudden change in illumination and also a loss of motion sensitivity, particularly at low contrasts.

Contrast Adaptation

Contrast adaptation refers to an adjustment to the variance or contrast of the illumination, rather than to its mean level. There are two types of contrast adaptation: spatial and temporal. Spatial contrast adaptation is selective for stimulus spatial frequency and orientation and is therefore predominantly cortical in origin. Temporal contrast adaptation, on the other hand, is observed in recordings from retinal ganglion cells in response to spatially uniform fields of light. Examples of stimuli used to study contrast adaptation are illustrated in **Figure 4**. Both involve the temporal modulation of a uniform field of light. One type of stimulus (**Figure 4**, top) is contrast-modulated sinusoidal flicker, whose mean luminance and temporal frequency remain constant but whose contrast is changed abruptly. The second (**Figure 4**, bottom) is contrast-modulated white noise.

Following a transition from a low-contrast to a high-contrast stimulus, there is an essentially instantaneous change in the gain and temporal response of retinal ganglion cells. This is followed by a slow change in the firing rate that may take several seconds to complete. There are similar fast and slow changes following a transition from a high-contrast to a low-contrast stimulus, including a temporary decrease in the maintained discharge rate, but these changes are typically more sluggish than for a transition to high contrast. Fast contrast adaptation represents the action of a gain-control mechanism, whereas slow contrast adaptation appears to involve membrane hyperpolarization. Temporal contrast adaptation may form the neural substrate for psychophysical flicker adaptation, in which exposure to high-contrast flicker reduces sensitivity for a subsequently viewed low-contrast flickering test stimulus.

Temporal contrast adaptation has been shown to occur at multiple sites within the retina, beginning in bipolar cells and including processes intrinsic to ganglion cells.

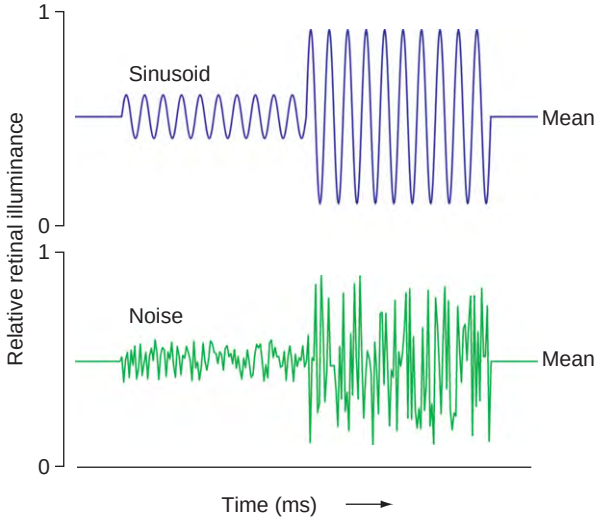

Figure 4 Examples of contrast-modulated stimuli used to study contrast adaptation. The top waveform is a contrast-modulated sinusoid; the bottom waveform represents contrast-modulated noise.

Temporal contrast adaptation is observed in M but not in P ganglion cells, owing in part to the faster temporal response and greater spatial pooling of M cells. Contrast adaptation and mean-luminance adaptation share certain similarities, but whether these forms of adaptation represent a common mechanism or distinct mechanisms remains to be determined.

Chromatic Adaptation

Chromatic adaptation refers to the effect of spectrally selective adapting fields on the detection and appearance of test stimuli of various wavelengths. When chromatic test probes and adapting fields are used to study light adaptation, the increment threshold function of the foveal cone system typically consists of more than one component, as illustrated in **Figure 5**. With the combination of test and adapting field wavelengths shown in **Figure 5**, the test probe is initially detected by a middle-wavelength-sensitive mechanism that becomes progressively more desensitized by the middle-wavelength adapting field. At high retinal illuminances, a short-wavelength-sensitive cone mechanism governs detection.

A change in test wavelength displaces a given tvi function vertically, and a change in adapting field wavelength displaces the tvi function horizontally. Initially, it was thought that the spectral sensitivities of the short-wavelength (S), middle-wavelength (M), and long-wavelength (L) cone photopigments could be derived by evaluating the relative displacements of the tvi functions as the test wavelength and adapting field wavelength were varied. This approach was used by W. S. Stiles to define what are known as π mechanisms. However, instead of identifying three π mechanisms corresponding to the three cone types, seven π mechanisms were derived from this method. The field sensitivities of three of the seven (π_1, π_4, and π_5) correspond approximately to the spectral sensitivities of the S, M, and L cones, respectively. Nevertheless, the shapes of the π_4 and π_5 mechanisms are broader than would be expected from the known spectra of the cone photopigments, and there are other failures of the π mechanisms to correspond to properties predicted by adaptation of the cone photoreceptors.

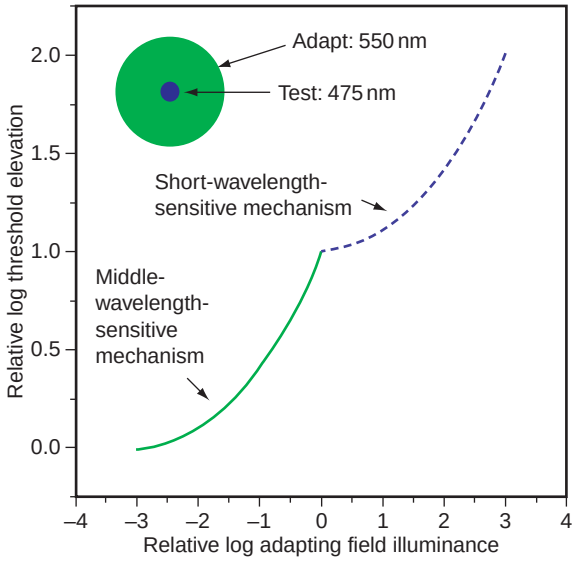

Figure 5 Schematic tvi functions for a 475-nm test probe (blue) presented foveally against a 550-nm adapting field (green), plotted in relative units. The curves represent plots of the tvi template of Stiles, and the lower (green) and upper (blue) branches represent detection by middle-wavelength-sensitive and short-wavelength-sensitive cone mechanisms, respectively.

Partly to account for the mismatch between the properties of the π mechanisms and the cone spectral sensitivities, two-stage models of chromatic adaptation have been developed. The first stage consists of receptor adaptation, and the second stage combines signals from the S, M, and L cones in an opponent manner. The site of the opponent interactions among signals from different cone types has not yet been identified definitively. Candidates include horizontal cells (although these are not typically spectrally opponent), amacrine cells, and possibly gap-junctional connections between photoreceptors.

Chromatic adaptation also refers to a change in the color appearance of a test light as a result of a change in adapting field chromaticity. For example, a monochromatic light that appears yellow in isolation will appear greenish when superimposed on a long-wavelength adapting field. This change in color appearance has been attributed to a relative desensitization of the L-cone photoreceptors through von Kries or multiplicative adaptation. However, there are instances in which photoreceptor desensitization alone cannot account for the changes in color appearance, such as when the level of retinal illuminance is changed, or when a monochromatic light becomes desaturated during extended viewing. These changes in color appearance are presumably due to second-site adaptation in addition to cone photoreceptor adaptation. Two-stage models are also presumed to account for color constancy, in which colored surfaces maintain their appearance despite substantial changes in the spectral content of the illumination, such as the change from sunlight to incandescent lighting.

Dark Adaptation

Following the exposure of the eye to an adapting field that bleaches a significant fraction of photopigment, there is a systematic recovery of visual sensitivity that is referred to as dark adaptation. Whereas light adaptation occurs relatively quickly, dark adaptation can require a substantial period of time, on the order of tens of minutes. Strictly speaking, the term dark adaptation refers to the recovery of sensitivity to a briefly flashed test probe presented in complete darkness following the offset of a bleaching

light. However, there are also variants of bleaching recovery in which the eye is not kept in darkness. These include the photostress recovery test, which measures the recovery of visual acuity following exposure to light from an ophthalmic instrument.

Characteristics of Dark Adaptation

The typical time course of dark adaptation following a bleach is illustrated in Figure 6. The data points in this figure represent thresholds for a test probe of 500 nm, a wavelength to which rod and cone systems are both sensitive. The test probe was presented at a retinal eccentricity of 20°, a retinal locus that contains both rod and cone photoreceptors. Thresholds are plotted relative to a baseline threshold that was measured in the fully dark-adapted state prior to a bleach. The recovery of sensitivity follows a two-branched course, each part of which is reasonably well fit by an exponential function. Immediately following the offset of the bleaching light, the recovery of sensitivity occurs relatively rapidly, and then sensitivity reaches a plateau region. This initial portion represents the recovery of cone system sensitivity. There is then a second region of rapid recovery followed by a slower phase, such that full recovery from a substantial bleach can take 45–50 min. This second region represents the return of rod system sensitivity. The transition point from cone-mediated to rod-mediated thresholds is termed the rod–cone break.

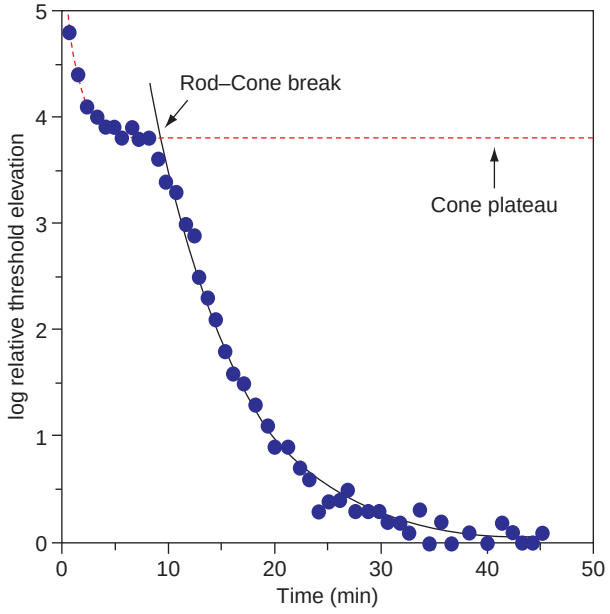

Figure 6 Recovery of visual sensitivity following exposure to a bleaching light, measured with a test probe of 500 nm presented to the peripheral retina in the dark. Thresholds are plotted with respect to the prebleach dark-adapted threshold. The dashed and solid curves are exponential functions fit to the cone-mediated (upper) and rod-mediated (lower) portions of the dark adaptation data, respectively.

Although the rod portion of the dark adaptation function in Figure 6 has been fit with an exponential function, it is more accurately represented by several regions with linear slopes on log-linear coordinates, with each region representing a different physiological process.

The relative vertical placements of the rod and cone dark adaptation curves and the time course of the recovery of sensitivity depend on a number of factors, including the retinal location of testing, the wavelength of the test probe, and the retinal illuminance of the bleaching light. For example, dark adaptation testing at the rod-free fovea reflects only the cone portion of the curve. Long-wavelength test probes, to which the rod system is relatively insensitive, typically produce a less-pronounced and delayed rod–cone break. Weak bleaching lights produce a faster time course of recovery than strong bleaches.

The psychophysical threshold not only is elevated following the offset of a bleaching light, but it is also elevated by the presence of an adapting field. This correspondence has led to the concept of the equivalent background, which holds that the aftereffect of a bleach is equivalent to the presence of a background of real light. This equivalent background, which is sometimes termed dark light, is generally not visible because it is stabilized on the retina. However, it can sometimes be observed in the form of an afterimage. Real light and dark light may have similar properties under some test conditions, but they are not always identical.

Although dark adaptation typically follows the time course illustrated in Figure 6, it is not always the case that sensitivity improves following the offset of a bleaching light. Under certain conditions, sensitivity actually decreases as dark adaptation progresses. One example occurs when the task is to determine the hue threshold or Lie specific threshold, which refers to the retinal illuminance of a test probe at which it appears to have a color. The hue threshold begins to rise at the time of the rod–cone break, rather than remaining constant once the cones have recovered. This rise in the threshold for hue has been attributed to an influence of the recovering rod system on color appearance.

A second example occurs when the task is to determine whether a rapidly flickering test stimulus, presented at a frequency above the rod temporal resolution limit, appears to flicker. The threshold for flicker detection does not remain constant once the cone system has recovered, but instead rises as the rods recover their sensitivity. The rise in the flicker threshold has been attributed to a suppressive effect of the dark-adapting rod system that surrounds the test stimulus on the temporal sensitivity of the cone system.

A threshold elevation during dark adaptation also occurs when the task is to detect a short-wavelength test probe following the offset of a long-wavelength adapting field. In this case, there is a substantial threshold elevation immediately following the adapting field offset, which is

followed by a gradual decrease in threshold. The brief threshold increase, termed transient tritanopia, is thought to represent a change in sensitivity within a postreceptoral opponent color mechanism. Transient tritanopia can also be observed in the ERG, indicating that it is retinal in origin.

Mechanisms of Dark Adaptation

The recovery of sensitivity in the dark, following light exposure, depends ultimately on the regeneration of bleached photopigment. For example, individuals with vitamin A deficiency, which limits the regeneration of rod photopigment, typically have a prolonged time course of rod dark adaptation, and rod thresholds may never reach a normal level. Yet, the recovery of rod sensitivity depends on more than the regeneration of a light absorber. This is demonstrated by the fact that rod thresholds remain elevated by 2 to 4 log units at a time when 90% of rhodopsin has been regenerated following a bleach. It is likely that the presence of various bleaching intermediates, such as metarhodopsin products and free opsin, contribute to the rod threshold elevation during dark adaptation.

In addition to physiological processes occurring within photoreceptors, it is apparent that postreceptoral factors are involved in the recovery of sensitivity during dark adaptation. For example, a change in the size of the test probe can influence the shape of the dark-adaptation curve, although test probe size should have no influence on the rate of photopigment regeneration. Furthermore, dim lights that bleach a trivial amount of photopigment and that have no effect on the receptor potential or on horizontal cell responses in the skate retina, nevertheless, result in an elevation of ERG b-wave and ganglion cell thresholds that requires several minutes to recover. Thus, dark adaptation appears to involve mechanisms at multiple levels within the retina.

Human gene mutations are continuing to provide important insights into the physiological processes underlying dark adaptation. For example, mutations in either the rhodopsin kinase gene or the arrestin gene produce Oguchi disease, in which there is a prolonged recovery of rod sensitivity following light exposure that is thought to be due to impaired deactivation of rhodopsin. Mutations in the RDH5 gene, which encodes the enzyme 11-*cis* retinol dehydrogenase, result in fundus albipunctatus, which is characterized by extremely prolonged rod dark adaptation, presumably due to an impairment in the conversion of 11-*cis* retinol to 11-*cis* retinal.

Conclusion

Retinal adaptation refers to diverse visual phenomena and neural processes, all of which represent the adjustment of the visual system to the prevailing conditions of light stimulation. Through the use of psychophysical and electrophysiological techniques, great progress has been made in understanding the fundamental mechanisms underlying retinal adaptation, but many of the details have yet to be clarified. Studies of transgenic animal models and of naturally occurring human mutations, in which there are alterations in the putative components of adaptation, show great promise in furthering our knowledge of this fundamental visual process.

Inherited Optic Neuropathies

A A Sadun and C F Chicani, University of Southern California-Keck School of Medicine, Los Angeles, CA, USA

Glossary

Cecocentral scotoma – Visual field defect involving the optic disk area (blind spot) and papillomacular bundle (PMB) fibers.
Cybrid cells – These are a eukaryotic cell line produced by the fusion of a whole cell with a cytoplasmic mitochondria.
Donder's curve – An expected reduction of lenticular accommodation as a function of age.
Dyschromatopsia – A partial or complete loss of color vision.
Genetic penetrance – The degree to which individuals express a genetically determined condition.
Papillomacular fibers – Axons from the smaller retinal ganglion cells that carry the information from the macula.
Searching nystagmus – A condition where both eyes occasionally make a wide, comparatively slow, sweeping movement caused by poor vision.
Tapetoretinal – The region of the photoreceptors and retinal pigment epithelium in the retina.

Inherited optic neuropathies fall under the rubric of metabolic optic neuropathies. Metabolic optic neuropathies share many pathophysiologic and clinical characteristics. Most metabolic optic neuropathies involve derangements that affect mitochondria and oxidative phosphorylation. Acquired metabolic optic neuropathies are further divided into those of toxic and those of nutritional deficiency states. For example, both ethambutol toxicity and vitamin B12 deficiency produce bilateral symmetrical optic neuropathies that are very similar to inherited optic neuropathies.

This article discusses hereditary optic nerve diseases that affect the optic nerve in isolation. Common hereditary optic neuropathies include Leber's hereditary optic neuropathy (LHON), dominant optic atrophy (DOA), and congenital recessive optic atrophy (ROA). Like most acquired optic neuropathies, inherited optic neuropathies involve mitochondrial function. In all cases, mitochondria are impaired either by mutations of their own DNA (mtDNA), or mutations of nuclear DNA involved in the transcription of mitochondrial proteins or substrates for mitochondrial biochemistry. All three have a similar presentation inherited mitochondria optic neuropathy. This makes the diagnosis both challenging and, at the same time, the clinical evaluation similar. The presentation is usually that of bilateral symmetric visual loss with dyschromatopsia, and central or cecocentral visual field defects, which involves the optic disk and papillomacular fibers. This archetypical set of clinical signs reflects the fact that in metabolic optic neuropathies there is a strong predilection for the papillomacular bundle (PMB). The distinctions between acquired and inherited optic neuropathies usually come down to issues of personal history, such as toxic exposure, decreased vitamin intake or malabsorption, and, especially for inherited optic neuropathies, family history. However, because of variable penetrance, the family history in inherited optic neuropathies may not be always positive. Prompt recognition of the characteristic elements from history and physical examinations often precludes unnecessary patient laboratory evaluation.

Leber's Hereditary Optic Neuropathy

LHON was first described in 1871 by Theodore Leber. Later von Hippel, Gowers, and Collins refined our understanding and introduced the term hereditary optic atrophy. As recently as the 1980s, LHON was considered to be a non-Mendelian inherited genetic disorder, since there was no male-to-male transmission. In 1988, Douglas Wallace demonstrated LHON as the first maternally inherited disease to be associated with point mutations in mitochondrial DNA, and it is now considered the most prevalent mitochondrial disorder.

LHON typically manifests as a subacute central loss of vision that predominantly affects young adult males. Age of onset is usually between 15 and 35 years; however, it has been reported to occur as young as 2 and as old as 80 years of age. Almost invariably the second eye is affected, within weeks to months. LHON is usually due to one of three pathogenic mitochondrial DNA (mtDNA) point mutations. These mutations affect nucleotide positions 11778, 3460, and 14484, respectively, in the ND4, ND1, and ND6 subunit genes of complex I which is integral for oxidative phosphorylation in mitochondria. These three primary mutations are responsible for about 95% of LHON cases; other rarer mutations continue to be described. In some pedigrees of LHON, associated systemic features have been reported; these include cardiac abnormalities such as pre-excitation syndromes and

hypertrophic cardiomyopathy, reflex and sensory changes, Charcot-Marie-Tooth disease, and skeletal disorders. It is hypothesized that the respiratory chain dysfunction leads to energy depletion and reactive oxygen species (ROS) accumulation which in turn produce axoplasmic stasis and swelling, thereby blocking ganglion cell function and causing loss of vision. In some patients, this loss of function is reversible in a substantial number of ganglion cells, but in others, a cell-death pathway, probably apoptotic, is activated with subsequent extensive degeneration of the retinal ganglion cell layer and optic nerve. The retinal ganglion cell degeneration and axonal loss occur predominantly in the PMB of the optic nerve.

Biochemical and cellular studies in LHON point to a partial defect of respiratory chain function that may generate either an ATP synthesis defect and/or a chronic increase of oxidative stress through the accumulation of ROS. Histological evidence of myelin pathology in LHON also suggests a role for oxidative stress, possibly affecting oligodendrocytes of the optic nerves. In cell culture studies, LHON cybrid cells, constructed from the merging of heteroplasmic cytoplasm of a cell which had its nucleus removed and the cytoplasm from a second normal cell that had all its mitochondria removed, are forced by the reduced rate of glycolytic flux to utilize oxidative metabolism by a shift from glucose to galactose in the media. This causes these cells to be sensitized to a mitochondrial-mediated apoptosis. It has also been proposed that in cells carrying LHON mutations, there is a decrease in antioxidant defenses. Recent evidence shows that mitochondrial distribution reflects the different energy requirements of the unmyelinated prelaminar axons in comparison to the myelinated retrolaminar axons.

In LHON, the pathologic mutation may be either homoplasmic (involving all the mitochondria) or heteroplasmic (involving only a fraction of the mitochondria). Most heteroplasmic pedigrees have much lower penetrance but surprisingly, the disease is not milder in form. Even with homoplasmic families, penetrance is highly variable. The rate of penetrance varies with the mutation and pedigree, although it is always greater in males. Hence, in a typical family with 11778 mtDNA, 8–10% of the women and 40–50% of the men may suffer devastating and sudden visual loss in young adulthood. This marked incomplete penetrance and gender bias imply that additional mitochondrial and/or nuclear genetic or epigenetic factors must be modulating the phenotypic expression of LHON. It is also likely that environmental factors contribute to the onset of visual failure. For example, there is increasing evidence that tobacco and alcohol consumption plays a role. There is an active search for nuclear genes that might modify the penetrance.

In LHON, fundus changes, such as microangiopathy and nerve fiber layer swelling, have been described to immediately precede or accompany the onset of visual loss (**Figure 1**). This process, although usually bilateral, occurs asynchronously over the course of several weeks to months and eventually evolves to severe optic atrophy and irreversible impairment of vision. The smaller caliber fibers of the PMB are selectively lost at a very early stage of the pathological process, which eventually extends to most of the rest of the nerve leading to optic atrophy.

The acute stage of LHON usually lasts a few weeks. The affected eye characteristically demonstrates an early dropout of the PMB; an edematous appearance of the rest of the nerve fiber layer, especially in the arcuate bundles; and enlarged or telangiectatic and tortuous peripapillary vessels (microangiopathy). There is absence of leakage from the optic disk or peripapillary region on fluorescein angiography These main features are seen on fundus examination, just before or subsequent to the onset of visual loss. In optical coherence tomography (OCT), LHON-affected patients showed extensive thinning of the retinal nerve fiber layer (RNFL), as would be expected in cases of optic atrophy. LHON carriers sometimes show significant RNFL thickening of the arcuate

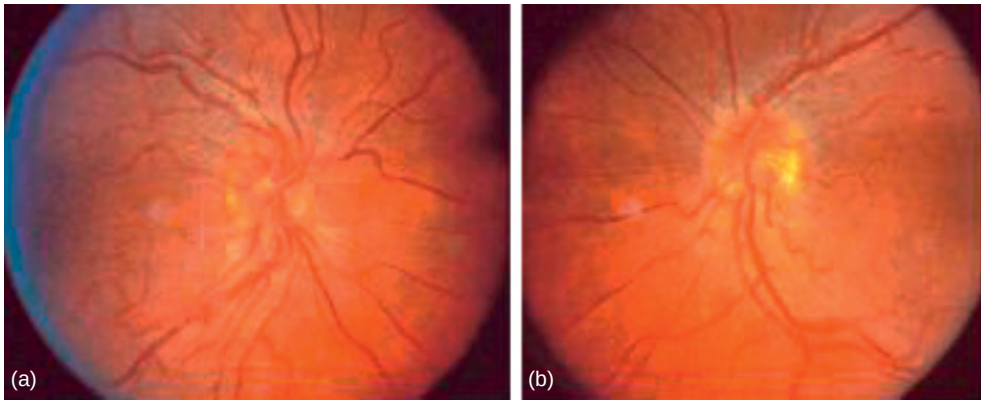

Figure 1 Right (a) and left (b) eyes of a patient with acute phase Leber's hereditary optic neuropathy (LHON). Fundus photographs of both eyes demonstrate hyperemic optic nerve heads, with dilated tortuous vessels, indistinct optic disk margins and swollen retinal nerve fiber layers (pseudoedema of the optic disk). Note also the telangectatic vessels.

bundles, in correlation with similar changes noted by funduscopy or the GDx nerve fiber analyzer, usually in the temporal sector, suggesting that the inferior temporal portion is affected first; this could be a subclinical sign. Several authors have described subclinical changes in the examination of asymptomatic carriers such as subtle optic disk findings, mild dyschromatopsia, OCT, and alterations in electrophysiology suggesting that LHON has some subtle chronic aspects.

In LHON-affected patients, the clinical examination reveals decreased visual acuity, dyschromatopsia, and cecocentral scotoma on visual field examination. There are a few reports of spontaneous recovery, especially with the 14484/ND6 mutation (up to 60% of cases) and in younger patients. Visual recovery may occur in one or both eyes and may happen as late as 10 years after the onset of visual loss. However, most often in LHON-affected individuals, the visual loss progresses and stabilizes within a year, with temporal optic atrophy.

There is currently no clinical evidence for an efficacious treatment to reverse vision loss in LHON. Theoretical considerations have led to the use of several agents involved with mitochondrial energy production and with anti-oxidant capabilities such as coenzyme Q10, succinate, L-carnitine, and vitamins K1, K3, C, B12, folate, and thiamine. Coenzyme Q10 is less likely to offer benefit since it is not transported to the mitochondria in sufficient concentration. A similar agent, Idebenone, has better drug delivery characteristics, and there have been a few encouraging reports and a prospective clinical trial with Idebenone in LHON. Case reports of successful recovery in LHON have to be considered in the light of spontaneous recovery. It remains unlikely that any of these agents alone or in combination will prove consistently useful in the treatment of acute visual loss in LHON or in the prophylactic therapy in asymptomatic family members at risk.

However, it is prudent to recommend the avoidance of agents that might induce oxidative stress or impair mitochondrial energy production. Most specifically, it is imperative to avoid exposure to smoke and alcohol as these environmental factors can trigger the loss of vision in susceptible individuals.

Dominant Optic Atrophy (DOA)

DOA, or Kjer's optic neuropathy, is one of the most common forms of hereditary optic atrophies, with estimated disease prevalence in the range of 1:10 000–1:50 000. Presentation usually occurs at latency age (7–10 years old). It often presents with imperceptible onset, a slowly progressive course, and leads to mild to moderate visual impairment (20/40–20/400). Insofar as onset is insidious and progression is slow, the young patient is often unaware of the visual loss. This usually comes to the parent's attention after a school-based visual screening.

The inheritance of DOA is autosomal dominant. Despite the variability in expression, the penetrance is actually very high. However, the vision impairment is often very mild; hence, the apparent absence of family history may not be accurate. We recommend the direct examination of the parents. DOA presents as mild, bilateral, sometimes asymmetric loss of visual acuity. On examination, there is a central, paracentral, or cecocentral visual field deficit; temporal optic disk pallor, often with a wedge shaped area of temporal excavation (**Figure 2**). There is mild generalized dyschromatopsia. In general, visual prognosis is good. However, patients with DOA often re-present around the age of 35 complaining of further visual loss. In fact, this represents premature presbyopia brought about by their lifelong habit of holding reading material much closer to their faces. Therefore, Donder's curve should not be applied to DOA patients. Instead, they should be offered plus lenses at about age 35 and graduated up to about plus 3.50 by age 50 to compensate for their closer near point.

In the year 2000 came the remarkable news that the genetic cause of dominant optic neuropathy had been identified. The gene OPA1 was, of course, nuclear and located on chromosome 3. However, the OPA1 protein encoded is imported to the mitochondria and serves structural roles in mitochondrial fission, fusion, and transport. Hence, though the genetics are somatic, the problem, like LHON, is in the mitochondria. Subsequently, other DOA genes have been found, as variations on the same theme. In addition to OPA1, there are OPA4 and other OPAs, which have been mapped to the 3q and 18q regions, respectively. All these genes are responsible for mitochondrial structural proteins.

Histological examination exhibited diffuse atrophy of the retinal ganglion cell layer, which is associated with atrophy and loss of myelin within the optic nerves. As in LHON, the retinal ganglion cells and axons lost are predominantly those of the PMB. However, the extent of axonal loss is significantly less in DOA.

In DOA, there is also an increased occurrence of associated sensorineural hearing loss so these patients should be advised to undergo audiology investigation. As in LHON, many agents have been tried as possible treatment options, and none were found to be effective. It remains unclear as to the role of environmental factors. These patients should be offered genetic counseling.

Recessive Optic Atrophy

This autosomal recessive somatic condition is the most uncommon form of inherited optic nerve disease.

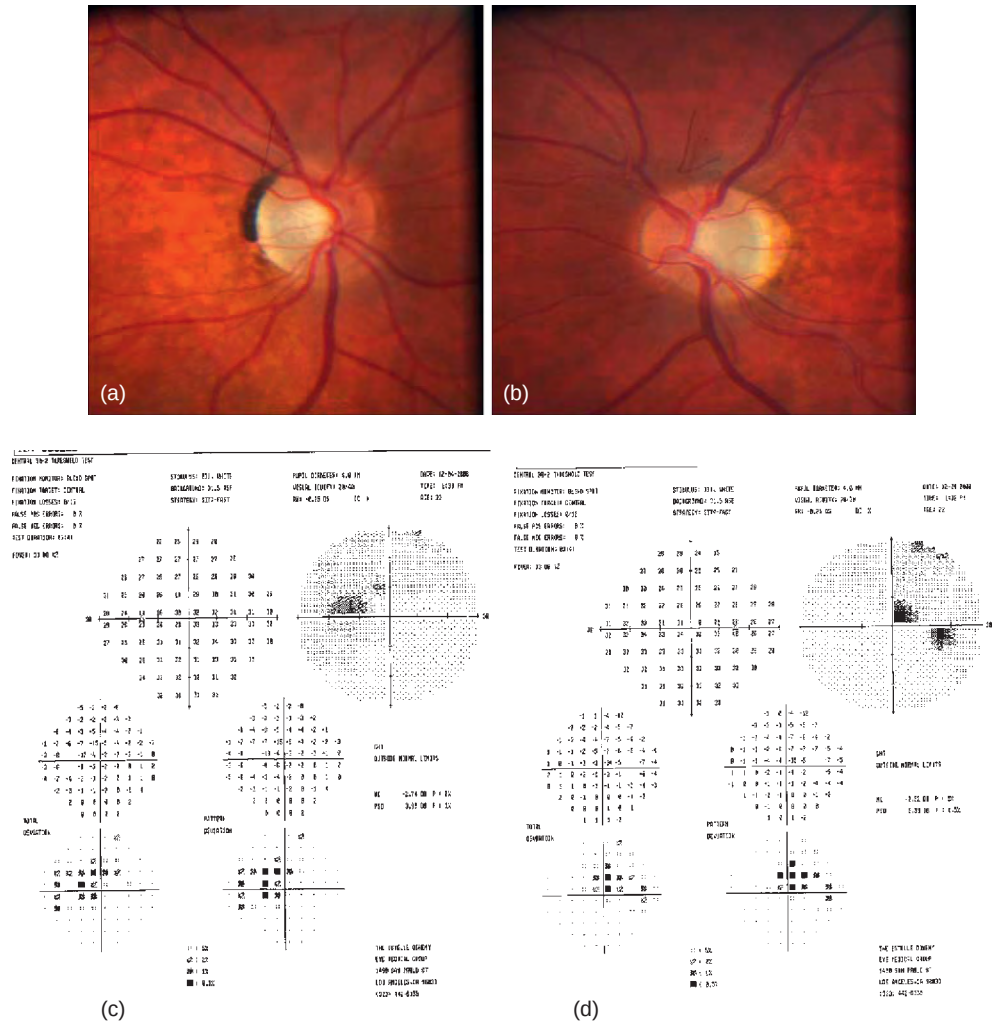

Figure 2 Right (a) and left (b) eyes in a patient with dominant optic atrophy (DOA): Fundus photographs show the characteristic wedge-shaped optic atrophy seen on the temporal side of both optic disks. 2(c) (Left) and 2(d) (Right): DOA. Humphrey Visual Fields demonstrate bilateral cecocentral visual field defects. Patient photographs are through the courtesies of Peter Quiros, MD.

Unlike LHON and DOA, ROA is usually discovered in the first 3–4 years of life. It often presents as severe visual impairment, frequently associated with searching nystagmus. Visual acuity ranges between no light perception (NLP) to 20/400. There is diffuse optic disk atrophy, sometimes with attenuation of the retinal arterioles, similar to that seen in tapetoretinal degenerations. Hence, the differential diagnosis of ROA is not so much a comparison to the other hereditary optic neuropathies as it is a comparison to retinal dystrophies. Electrophysiology using eletroretinography plays an important role in differentiating ROA from tapetoretinal degeneration, retinitis pigmentosa, or Leber's congenital amaurosis, this is normal in ROA and severely impaired in the retinal degenerations.

The gene/chromosome for ROA remains to be identified. Not surprising for an autosomal recessive condition, there are several reports of consanguinity related to ROA.

Other Inherited Conditions with Optic Atrophy

There are several well-characterized syndromes that also include optic atrophy. Wolfram's syndrome which is characterized by diabetes insipidus, diabetes mellitus, optic atrophy, and deafness is linked to the WFS1 gene located on chromosome 4p. Patients with Behr's syndrome, which consists of progressive encephalopathy, mental retardation, ataxia, nystagmus, and pes cavus, may also have optic atrophy. It is linked to the OPA3 gene located on chromosome 19q. Friederich's ataxia often includes vision loss and optic atrophy.

Conclusion

All of the inherited optic neuropathies serve to remind us that the optic nerve is highly dependent on mitochondrial

function. Indeed, acquired optic neuropathies that affect mitochondrial metabolism are often in the differential diagnosis of genetic optic neuropathies. The genetics of LHON involve a mutation of mitochondrial DNA resulting in impairments of complex I, which in turn leads to decreased ATP production and increased ROS. This is in contradistinction to DOA in which the genetics involve nuclear DNA. However, despite the fact that these mutations are somatic, the OPA genes control structural mitochondrial proteins that also limit mitochondrial functions such that the final consequences are similar: decreased ATP production and increased ROS. Hence, inherited optic neuropathies and metabolic optic neuropathies, whether toxic or nutritional, all share the common pathophysiology of producing mitochondrial dysfunction and subsequent retinal ganglion cell loss. Not surprisingly, all mitochondrial optic neuropathies share a similar clinical presentation. If a treatment proves to be effective in one, it is likely to be of benefit in the other mitochondrial optic neuropathies.

Exciting new treatment options with agents that modulate mitochondrial function that have anti-apoptotic effects or are helpful for neuronal survival, are currently being studied. Inherited optic neuropathies may serve as the ideal model with which to test these purportive neuroprotective agents.

Injury and Repair Responses: Retinal Detachment

S K Fisher and G P Lewis, University of California, Santa Barbara, Santa Barbara, CA, USA

Glossary

Glial scar – The proliferation and growth of glial cells (astrocytes and oligodendrocytes in the brain and spinal cord) in response to a physical wound to the central nervous system.
Immunocytochemistry – A laboratory technique that uses antibodies (the primary antibody) targeted to specific peptides or proteins (antigens) in the cell. The primary antibody is made to recognize its specific protein by the immune system of a specific species (i.e., it may be a rabbit immunoglobulin G (IgG) antibody). In addition, it can be bound to an antibody made in a second species (i.e., goat anti-IgG) that is bound with some detectable marker, often a fluorescent dye. Using appropriate imaging techniques, the localization can be subcellular.
Laser scanning confocal microscope – An optical imaging technique used to increase contrast and/or resolution by eliminating out-of-focus planes within a tissue section by using a spatial pinhole. Optical image plane thickness can be selected (usually 0.5–1.0 μm) and images from several optical sections collapsed together, played as a movie loop, or used to reconstruct objects in three dimensions. In biological research, this technique is most commonly used with immunocytochemistry with fluorescent dyes.
Pneumatic retinopexy – A method for repairing a retinal detachment by the injection of expanding gasses (usually sulfur hexafluoride (SF_6) or perfluoropropane (C_3F_8)) into the vitreous cavity.
Retinal detachment – A site-threatening condition that results from the physical separation of two cellular layers of the retina, the retinal pigmented epithelium and the neural retina.
Rhegmatogenous retinal detachment – A specific type of retinal detachment in which the neural retina is torn, allowing fluid from the vitreous to separate the two layers. This type is the most common form of retinal detachment.
Scleral buckle – A surgical method for repairing a retinal detachment by placing a band or bands of material (now usually silicone rubber and/or silicone sponges in a variety of configurations) to encircle the globe and to indent the wall of the eye in the region of the detachment. A scleral buckle is used in conjunction with cyrotherapy or laser treatment to seal the retinal break.
Serous retinal detachment – A retinal detachment that occurs when fluid accumulates between the neural retina and retinal pigmented epithelium, but without a tear in the retina.

Injury to the Retina

Introduction

Retinal glial cells

Damage to the retina, whether a result of physical injury, disease, or a genetic condition, produces similar cellular responses on the part of glial cells. Glial cells are non-neuronal, supportive cells found in all parts of the central nervous system (CNS). In the brain and spinal cord, where they also play an important role in injury, there are two types of true glia: oligodendrocytes and astrocytes. Oligodendrocytes are found in the optic nerve, but not in the retina itself. Astrocytes, similar to those in the brain and spinal cord, are star-shaped cells limited to the bundles of axons that run across the surface of the retina and exit the eye as the optic nerve. The glial cell with the most prominent role in the retina's response to injury is a highly modified, structurally complex radial astrocyte referred to as the Müller cell (first described in the mid-nineteenth century by the German anatomist Heinrich Müller). This cell spans the entire width of the neural retina (**Figure 1**), and, in many ways, its reaction to injury mirrors that of astrocytes. Microglia comprise another cell type important in the retina's response to injury. However, these are not true glia since they are derived from blood-borne marcrophages and have a different developmental lineage than that of astrocytes and Müller cells.

Retinal injury and retinal detachment: A close relationship

Physical injury to the retina can occur in many ways, from a penetrating wound to a spontaneous tearing of the retina in highly myopic individuals. Anytime the retina is physically damaged, there is great risk that the neural retina will separate from the underlying retinal pigmented epithelium (RPE in **Figure 1**) in a condition known as a rhegmatogenous retinal detachment (RD; **Figure 2**; the prefix rhegma is derived from the Greek word meaning a

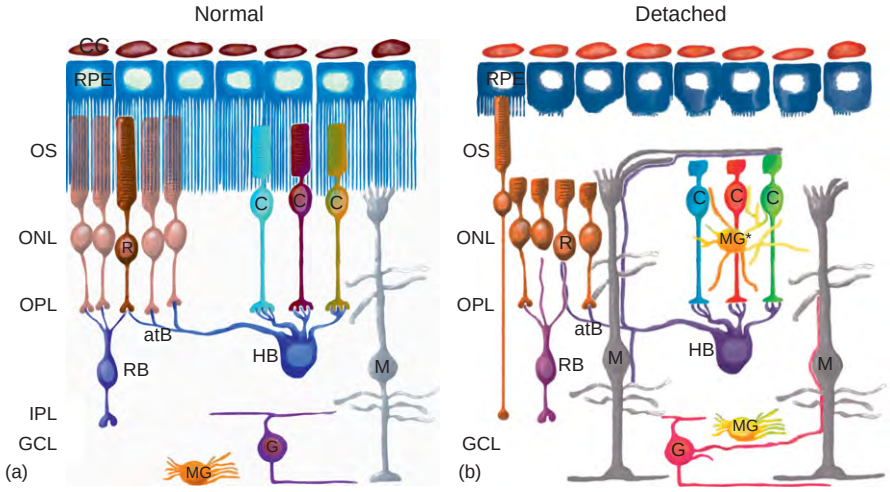

Figure 1 Diagrammatic representation of major cell types in which important reactions to injury of the retina by retinal detachment have been identified. (a) Normal retina and (b) representative changes after detachment. The rod photoreceptor on the left in (b) (gold cell) represents a characteristic response that occurs in some rods after reattachment; that is, they regenerate an axon that grows beyond its normal target, the OPL. CC, choriocapillaris, the main vasculature supply for the RPE and photoreceptor cells; RPE, retinal pigmented epithelium; R and C, rod and cone photoreceptors; OS, outer segments; ONL, outer nuclear layer (cell bodies of rods and cones); OPL, outer plexiform layer (region where photoreceptors synapse with second-order neurons); HB, a subclass of horizontal cells; atB, the axon of the B type horizontal cell; RB, rod bipolar cell; M, Müller's cell (the radial glial cell of the retina); IPL, inner plexiform layer (region where second-order neurons synapse with third-order neurons); GCL, ganglion cell layer, the third-order and output neurons of the retina; MG, microglia; MG*, activated microglia.

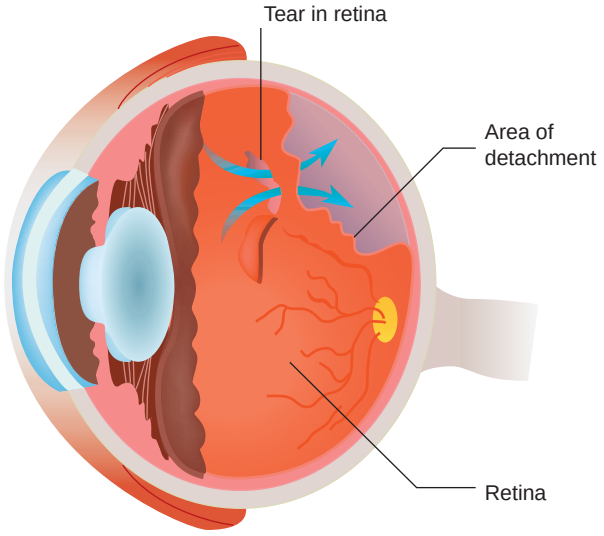

Figure 2 A rhegmatogenous retinal detachment forms when a hole or tear occurs across the neural retina, allowing fluid to flow from the vitreous and separate the neural retina from the retinal pigmented epithelium.

break in continuity). This condition occurs with a prevalence estimated at 1:10 000 in the United States and is usually treated by a retinal surgeon who repairs the retinal tear and reapposes the two layers of tissue. Thus, studying RD is, in essence, a study of retinal injury, and used to demonstrate the variety of cellular responses that can occur in many different insults or injuries to the retina.

What is an RD?

An RD refers to a separation between the neural retina and the RPE. As discussed above, rhegmatogenous detachment (hereafter, simply detachment or RD) involves a specific injury to the retinal tissue. An important physiologicalra mification of such a detachment is an increase in the physical distance between the photoreceptor cells and their blood supply, a highly branched capillary network (the choroicapillaris, which lies behind the RPE; see Figure 1). The choriocapillaris provides nearly all of the oxygen and nutrients to photoreceptors and also carries away metabolic waste products from these extraordinarily active cells. A decrease in oxygen availability across the expanded extracellular space may be a critical step in the rapid degeneration of photoreceptor outer segments that occurs after detachment (Figure 1). A certain number of these photoreceptors are destined to die by apoptosis, in most species reaching a peak about 3 days after detachment and declining thereafter to a low, but steady level. Indeed, some studies in animal models have demonstrated that placing animals in an environment of 70% oxygen has the capacity to stop many of the degenerative effects of detachment including photoreceptor cell death. Detachment also creates a foreign environment for the photoreceptor outer segments as components from the vitreous wash through the tear and into that space. Indeed, it is this movement of fluid through the tear and under the retina that is generally assumed to create and maintain a detachment. Another type of RD is known as a serous

detachment and involves the accumulation of fluid within the same space, but without a retinal tear. Its symptoms and treatment are very different.

Symptoms and signs of RD in people

All detachments are accompanied by some loss of visual function, but this will vary depending upon the size and retinal location, making it difficult to ascribe one set of symptoms to the condition. Diagnosing RD is complex, with many qualifications. Abnormal vision is the only reliable symptom of RD; however, the types of abnormal vision are large and varied: light flashes, floaters, changes in the peripheral visual field, decreased acuity, defective color vision, distorted vision (metamorphopsia), or even unilateral double vision (diplopia). The detachment of the fovea always involves a loss of central visual acuity.

Brief history

Greg Joseph Beer provided the earliest systematic description of RD in the early eighteenth century. After Hermann von Helmholtz recognized the clinical significance of the ophthalmoscope in *c.* 1850, detailed descriptions of detachments and accompanying retinal breaks or tears proliferated rapidly. The first treatment of rhegmatogenous detachment by sealing the retinal break with a red-hot probe occurred in 1889, and was revived as a standard treatment by Jules Gonin in the early 1920s. Gonin devoted much of his research career to studying the relationship between retinal tears and detachment and also was the first to suggest a relationship between detachment duration and successful visual recovery. His technique is credited with moving an inevitably blinding retinal injury into a treatable one. The next major advance occurred 70 years later when Ernst Custodis described the scleral buckle, a band or bands of material (now usually silicone rubber and/or silicone sponges) surgically placed to encircle and indent the wall of the eye in the region of the detachment, thus reapposing the RPE and neural retina. A scleral buckle is used in conjunction with cyrotherapy or laser treatment to seal the retinal break, probably by creating a localized glial scar. In the early 1970s, pneumatic retinopexy, or injection of an expanding gas bubble (sulfur hexafluoride or perfluoropropane), into the vitreous cavity to reappose the retina and RPE became widely used. There is still much ongoing discussion on the use of scleral buckling, primary vitrectomy, and pneumatic retinopexy to treat RD.

Cellular Responses of the Retina to Injury

General Events

Overall, the retina may be described as including two major cellular layers, the RPE and the intimately apposed neural retina. The neural retina is highly organized, consisting of three cellular layers and two synaptic layers (**Figure 1**). Since it is so highly structured, changes in its normal architecture are readily noted by conventional histology and light microscopy as shown in **Figure 3**.

In the 1960s through the 1980s, investigators used combinations of light and electron microscopy to reveal cellular and subcellular structural changes induced by detachment in photoreceptors including outer segment degeneration, loss of mitochondria, and the general disorganization of organelles involved in protein synthesis. It was also recognized in these early structural studies that Müller's cells underwent vast changes in structure (hypertrophy) with growth out of the retina and into the subretinal space (**Figure 3(b)**). In recent years, it has been recognized that cellular effects of detachment occur well beyond the site of separation of the RPE and neural retina. Almost all of the cellular changes have been validated in tissue samples taken from human detachments including the capacity of photoreceptors to regenerate outer segments after surgical reattachment. When immunocytochemistry became a routine laboratory procedure in the late 1980s, and laser scanning confocal imaging allowed the efficient collection of high-resolution immunofluorescence images by light microscopy, it became apparent that cellular responses to detachment were far more complex than the degeneration of photoreceptor outer segments and the hypertrophy of Müller's cells. It first became clear in these animal studies that a number of photoreceptors actually die (see **Figure 3**).

As Müller's cells are the primary players in the retina's gliotic response to injury, they are discussed first and in most detail. In animal models, these range from molecular changes that occur within minutes to hours (e.g., phosphorylation of the fibroblast growth factor receptor 1, and the extracellular signal-regulated kinase, with later synthesis of the AP1 family transcriptional activators cFos and cJun in Müller's cells), cellular changes recognizable within hours (photoreceptor outer segment degeneration) to cellular events that begin in days and can extend for weeks or months (e.g., Müller cell reactivity, rod cell death, glial scar formation, and neuronal remodeling). The cellular level events are summarized in **Figure 4**.

Müller's cells

Except for the death of photoreceptors, the reactivity of Müller's cells may be one of the most important consequences of injury to the retina. The cell body of the Müller cell lies among the interneurons of the inner nuclear layer and extends main stalks in both directions (M in **Figure 1**). The inner stalk expands along the vitreal border of the retina to form a so-called endfoot. Müller's cells are arrayed across the retina to assure that adjacent endfeet form a continuous layer on the vitreal surface (the green cells in **Figure 5(c)** are good examples). They are not, however, linked by tight junctions and, hence,

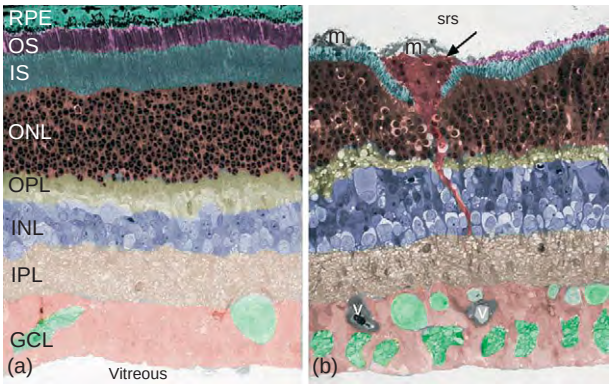

Figure 3 (a) Light micrographs of a normal mammalian retina and (b) micrograph showing the overall disorganization of the retina with a characteristic glial scar in the subretinal space (arrow in (b), dark red) after a retinal detachment. The retinal layers were colored to allow for easier comparison between the two images. The retinal pigmented epithelium (RPE, light green in A) that is anatomically tightly apposed to the photoreceptor outer segments (OS, light purple) in normal retina becomes several hundred micrometers removed from the neural retina after detachment and does not appear in (b). There is a dramatic degeneration of light-sensitive rod and cone outer segments (OS, light purple) and inner segments (IS, light gray) in the detached retina. The latter are responsible for most of the energy production and protein synthesis in normal photoreceptors. The outer nuclear layer (ONL, dark brown) which contains the cell bodies and nuclei of the photoreceptors is greatly thinned in the detached retina as a result of the loss of cells by apoptotic cell death. Notice that many of the photoreceptor cell bodies in (b) appear swollen with clear cytoplasm surrounding highly condensed nuclei, indicative the fact that they are in the process of undergoing apoptosis. The outer plexiform layer (OPL, light green) is greatly thinned in the detached retina by the loss of rod photoreceptor terminals and probably dendrites of second-order neurons whose cell bodies reside in the inner nuclear layer (INL, blue). The INL appears thickened in the detached retina due to the significant swelling of the cells and also due to the hypertrophy and migration of Müller's cells within the layer (see text). Although we know there are subtle changes in the inner plexiform layer (IPL, light brown) after detachment, these are difficult to discern by light microscopy. The endfeet of Müller's cells (pink) form a continuous layer along the vitreous cavity of the retina (vitreous) and assume a somewhat thickened and contorted appearance as they expand after detachment (this effect is more obvious when the Müller cells are specifically stained by immunolabeling as in **Figures 5** and **6**). The cells of the ganglion cell layer (GCL, green) and their axons (green) appear little affected in this thin histological section, but immunolabeling studies show that they undergo significant remodeling through the sprouting of neurites (see **Figure 8(b)**). Müller's cells expanding beyond the boundaries of the retina form a layer of scar tissue on the photoreceptor surface (arrow, dark red), in the subretinal space (srs). The dark round structures embedded in the subretinal scar represent nuclei of Müller's cells that migrate through their processes into the scar as well as some photoreceptor cell bodies that migrate from the ONL to appear among the scar tissue. These subretinal scars can block the regeneration of outer segments after surgical reattachment, and they can also contract, wrinkling and redetaching the retina after reattachment. Two macrophage cells (m) appear in the subretinal space in (b). These cells engulf debris from degenerating outer segments. Two retinal blood vessels (v) appear among the Müller cell endfeet in (b).

extracellular molecules can flow freely between them. Some branching of the main stalk occurs in all retinal layers, but reaches its greatest complexity as the individual cells interweave between all photoreceptor cell bodies so that each is separated from the next by a thin layer of Müller cell cytoplasm. The Müller cell ends as a tuft of microvilli at the level of the photoreceptor inner segments. Thus, this cell is ideally situated to sample the internal environment of the retina, the vitreous, and the space between photoreceptors and RPE. Adhering junctions between adjacent Müller's cells and photoreceptors form a continuous, recognizable layer known as the outer limiting membrane.

Functionally, Müller's cells are responsible for much of the homeostasis of the neural retina. They are known to actively recycle glutamate released as a neurotransmitter by retinal neurons through uptake and conversion to glutamine. Potassium balance, water regulation, and pH balance are all thought to depend strongly on Müller's cells. There is even some evidence that they may act as light pipes – optically funneling light through the retinal layers to the outer segments. While much of the focus of this article is on the formation of glial scars by Müller's cells as part of the injury response, there is also significant experimental evidence that activated Müller's cells can play a neuroprotective role in retinal injuries resulting from excitotoxicity generated by the excess release of the neurotransmitter glutamate.

Müller's cells and RD: Glial scarring

Following RD, there are rapid changes in molecular events in Müller's cells as discussed above. This fairly quickly translates into two major events: proliferation of the cells and hypertrophy or excessive growth. Both are poorly understood, but the latter is known to have important ramifications. If a retina is labeled with markers for DNA synthesis (tritiated-thymidine, bromodeoxyuridine, or antibodies to cell-cycle-specific proteins such as Ki-67), many cell types can be shown to divide, with Müller's cells and microglia being among the most prominent (**Figure 5**).

This newly activated cell division appears to peak 3–4 days after detachment in the feline and rabbit retina, but continues at low levels thereafter as long as the retina is detached. The fate of the daughter cells produced by dividing Müller's cells is still controversial, although, in species such a chick or teleost fish, they appear to regress to an earlier pluripotent stage where they can regenerate retinal neurons. There is scant evidence that this occurs in mammals. Details of how these morphologically complex cells divide or exactly what cell types they produce in the mammalian retina are unknown. One intriguing scenario is that after nuclear division, a daughter nucleus migrates into the outer retina and then buds off a daughter cell. If this is true, the proliferating Müller's cells may indeed

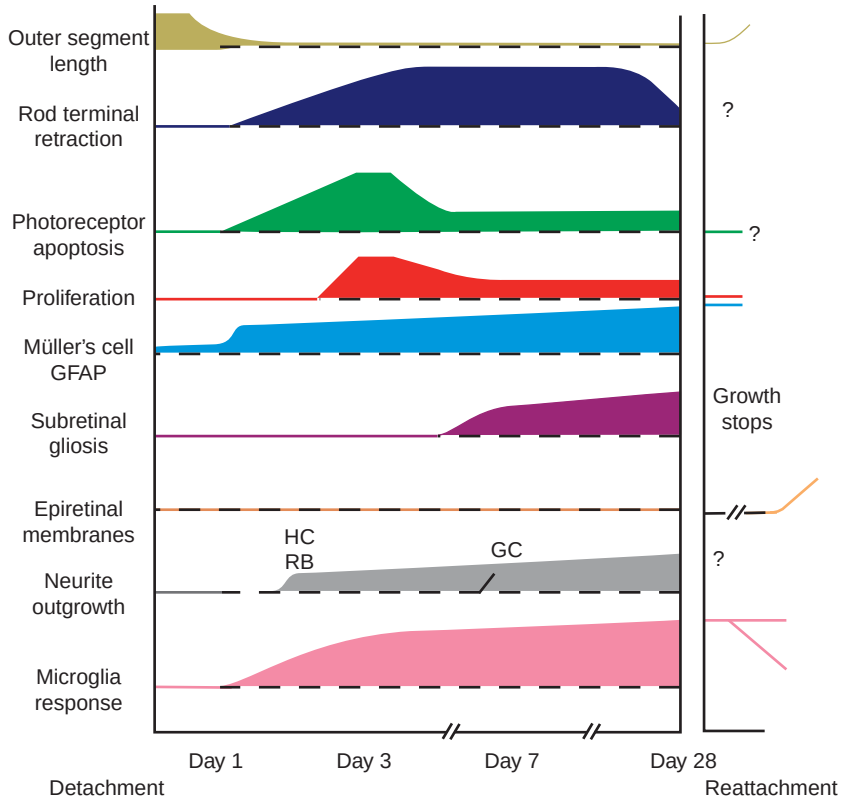

Figure 4 A diagram representing cellular events that occur after retinal detachment. The purpose is to show how the various events are temporally related. For example, outer segments degenerate very quickly with rod terminal retraction and photoreceptor apoptosis starting around the end of the first day of detachment. Epiretinal membranes do not form in the detached retina, but begin forming when the retina is reattached. Their time of formation is highly variable, but can range from weeks to months. Rod terminal retraction and apoptosis are stopped by reattachment, but the timing is unknown. Indeed, following reattachment, rod axons regrow into the outer plexiform layer. Müller cell proliferation is stopped by reattachment, but glial fibrillary acidic protein (GFAP) expression can remain elevated for an unknown period of time. Neurite sprouting occurs from horizontal and rod bipolar cells (HC, RB) before it does from ganglion cells (GC). The microglial response is variable after reattachment, remaining high in areas of poor regeneration, but returning to normal in areas of good regeneration.

be producing a small population of pluripotent cells that have remained unidentified in mammals. The proliferation of glial cells is common to virtually all types of CNS injuries.

Structural remodeling of Müller's cells can be observed as early as 1 day after detachment by the hypertrophy of their main trunk and lateral branches within the retina. At this time, they also decrease their expression of the proteins glutamine synthetase, carbonic anhydrase II, and cellular retinaldehyde-binding protein, and dramatically increase their expression of two intermediate filament proteins, glial fibrillary acidic protein (GFAP) and vimentin (**Figures 6(a)–6(d)**). The increased expression of these two proteins is especially useful as hallmarks of the retina's reaction to injury. Indeed, their tissue expression profile varies by species, but an increased expression of GFAP is widely used as an indicator of retinal stress or injury. In the normal feline retina, both of these proteins are mainly restricted to the endfoot of the Müller cell (**Figures 6(a)** and **6(b)**). There are interesting species differences in the expression of these molecules. In rabbit, ground squirrel, rat, and mouse retinas, vimentin is expressed from the endfoot into the layer of photoreceptors, whereas GFAP is limited to the endfoot or virtually undetectable by immunocytochemistry. GFAP does, in all of these species, occur abundantly in astrocytes while vimentin does not. Following detachment or injury, the proteins rapidly increase their expression so that within a few days, they fill the entire cytoplasm of the cell (**Figures 6(c)** and **6(d)**; see also **Figure 5**). The interesting exception occurs in the cone-dominant ground squirrel retina which increases its expression of vimentin, but not GFAP, and does not show the Müller cell hypertrophy characteristic of the all other species studied. In feline retina, the balance of expression of GFAP and vimentin within individual Müller's cells shifts fairly rapidly over the first few days of detachment. Within a day or so, there is a shift so that GFAP expression in the endfoot increases rapidly as it acquires a more elongated and branched appearance. This is one of the earliest recognizable stages of the hypertrophic growth of these cells after

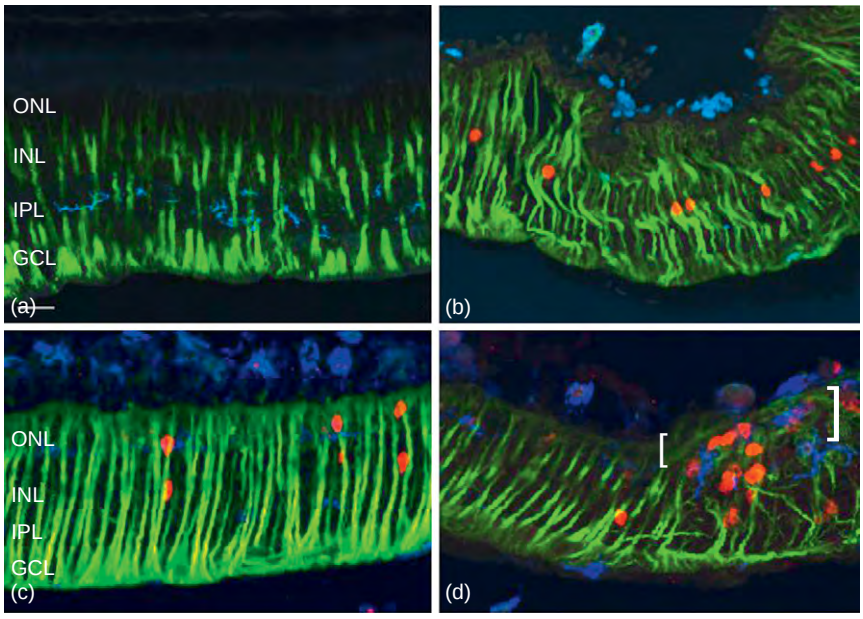

Figure 5 A series of immunofluoresence images acquired by laser scanning confocal microscopy, illustrating the proliferative response of Müller's cells in reaction to retinal detachment and their participation in glial scar formation. The red-colored portions indicate the signal from immunolabeled bromodeoxyuridine, a nucleotide that can become incorporated into DNA as cells undergo DNA synthesis in preparation for division. Green labeling is a marker for Müller's cells and blue a marker for microglia and macrophages. Panel (a) is an image from normal retina. Notice that there are no red cells because neurons and Müller's cells of the adult mammalian retina are postmitotic. In (b)–(d), the bromodexoyuridine-labeled nuclei are associated with Müller's cells. In (b), these occur at the normal location of Müller cell nuclei in the inner nuclear layer (INL), while 24 h later (c), many of them have migrated into the outer nuclear layer (ONL). At a later time point, Müller's cells begin to to form a characteristic glial scar (brackets in (d)) on the photoreceptor layer and many of the bromodeoxyuridine-labeled Müller's cells reside within the glial scar, suggesting a link between Müller cell proliferation and glial scar formation. Notice that many of the microglial cells (blue) occur within the glial scar as well. IPL, inner plexiform layer; GCL, ganglion cell layer. Scale bar = 20 μm.

injury of the retina (**Figures 6(c)** and **6(d)**). By 3 days, GFAP expression increases throughout the cell and the cell shows expansive growth of its processes within the retina, in later stages forming large columns of cytoplasm across the retina and filling space left by dying photoreceptors. An important subpopulation of Müller's cells will eventually grow into the space between the retina and RPE to form glial scars over the photoreceptor surface (**Figures 6(e)** and **6(f)**). Interestingly, these cells will quickly begin heavy expression of vimentin in their outer half. The extension of Müller's cells into the subretinal space is part of a reaction comparable to glial scarring in the brain and spinal cord where the scars block axon growth. Here, they effectively block outer segment regeneration after reattachment. The growth of Müller's cells into this space does not appear to be random, but, in feline retina, spatially associated with the presence of cone photoreceptors (inset to **Figure 6(d)**), suggesting some attraction between cones and the vimentin-rich Müller's cells. There is no molecular mechanism known to underlie this process. Once growth into the subretinal space is initiated, it continues at a rapid pace so that a Müller cell scar can rapidly expand broadly over the photoreceptor surface of the retina (**Figures 6(e)** and **6(f)**). Besides inhibiting outer segment regeneration, these scars also appear permissive for the growth of neurites out of the retina (see below).

Retinal reattachment appears to greatly slow much of the intraretinal hypertrophy of the Müller cells as well as their growth into the subretinal space. It does not, however, completely halt their reactivity since cell division can still occur at low levels. In addition, reattachment appears to stimulate a redirection in the growth of Müller's cells from the subretinal space toward the vitreal surface of the retina where they break through the vitreoretinal interface to form glial scars on this surface of the retina. Curiously, the Müller cell processes that expand into the vitreous predominately express GFAP instead of vimentin. Their growth into the vitreous may mark the beginning for a devastating disease called proliferative vitreoretinopathy (PVR). The Müller cells can form long fibers on the retinal surface and become populated with a variety of other cell types, including RPE and immune cells. There are no pharmacological treatments to date that will inhibit this disease from occurring or reverse its progression. It continues to occur in a small percentage of successful reattachment surgeries. The cellular strands can become contractile, causing a secondary tractional detachment (essentially a rhegmatogenous

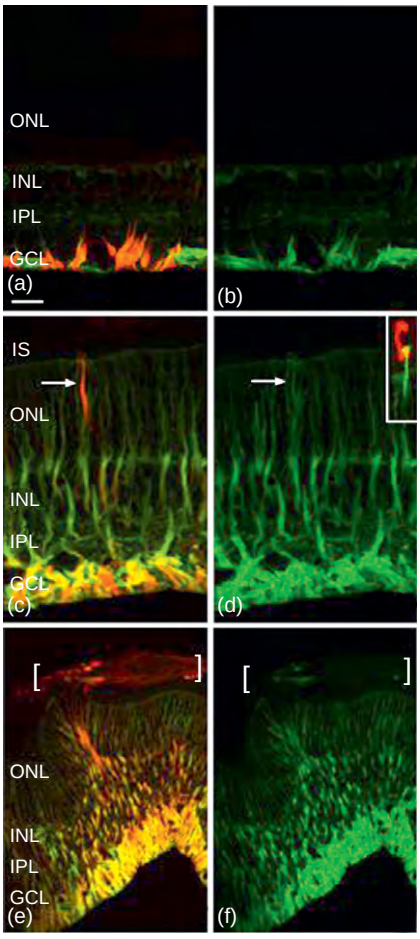

Figure 6 A series of immunofluoresence images acquired by laser scanning confocal microscopy, illustrating the upregulation of the intermediate filament proteins vimentin (red) and GFAP (green) that occurs as Müller's cells react to injury. Panels (a), (c), and (e) show the fluorescent signals from both (when the signals overlap, yellow results). Panels (b)–(e) show only the signal from GFAP. Panels (a) and (b) are images from a normal retina. The retinal astrocytes reside among the ganglion cells with their axons containing GFAP, while the endfeet of the Müller's cells (where these cells terminate on the vitreal border of the retina as shown in **Figure 1**) have a mixture of the two proteins (with vimentin being at a higher level of expression than GFAP). Panels (c)–(f) show the very large uprergulation of both of these molecules as the Müller's cells react to injury. Panels (c) and (d) show that although both increase their expression in Müller's cells after 3 days of detachment, the largest overall increase is associated with GFAP. However, one Müller's cell predominately shows vimentin expressed at its apex (arrow), and this cell is just beginning to grow out of the retina to form a glial scar in the subretinal space (the space created between the neural retina and RPE by the detachment). Panels (e) and (f) show further upregulation of both at 7 days of detachment and also a large subretinal glial scar (brackets) in which the Müller's cell processes predominately express vimentin. The inset to panel (d) shows a characteristic phenomenon where Müller's cell processes (yellow/green) grow out of the retina at the location of cone photoreceptors (red). ONL, outer nuclear layer; IS, photoreceptor inner segment layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. Scale bar = 20 μm.

detachment caused by the contractional force generated by this strand of fibrous-like scar tissue). Similar to their counterparts in the subretinal space, these epiretinal membranes can act as substrates for the growth of ganglion cell neurites (discussed below) out of the retina. From these examples, it is clear that Müller's cells are highly involved in the reaction of the retina to detachment. There is evidence in mice which are genetically modified so that they do not express vimentin and GFAP that subretinal scars do not form. There is also some experimental evidence that certain inhibitors of cellular proliferation may help prevent the formation of glial scars. There are currently no drugs that target the former, although inhibiting proliferation of cells with antiproliferative drugs after retinal injury is an area of active investigation.

Injury and Other Cell Types

Photoreceptors

Besides undergoing degeneration of their light-sensitive outer segment, photoreceptors undergo a number of other changes when the retina is detached, or when they lie in the immediate vicinity of retinal injury. Within a day after detachment, they undergo changes in the way they express proteins; the light-sensitive protein, opsin, normally localized in the membranes of the outer segment soon becomes distributed throughout the plasma membrane of the cell (red staining, right side of **Figure 7(a)**), essentially outlining the whole cell. This may occur because the cell cannot construct an outer segment as part of its ongoing membrane renewal process; however, since the cell does continue to synthesize opsin, the protein is then aberrantly inserted into the plasma membrane. Some proteins (e.g., peripherin/rds) remain inside transport vesicles that accumulate within the cytoplasm. Rods and cones appear to differ in this respect inasmuch as cones may actually downregulate much of their protein synthetic machinery, perhaps giving these critical cells a better chance of survival in a stressful environment.

Rod photoreceptors have short axons that retract after detachment, pulling their synaptic terminal back toward the cell body. This can be seen as a loss of synaptic terminals in the outer plexiform layer and the appearance of these terminals among the cell bodies of photoreceptors (**Figures 7(c)** and **7(d)**). Cone photoreceptor axons do not appear to retract, but there are numerous structural modifications in their synapses (**Figures 7(e)** and **7(f)**). Given the complexity of photoreceptor synapses, it seems reasonable to expect that these structural changes effect communication to second-order neurons. Importantly, rod axons appear to regrow back toward their normal location after reattachment; some even overshoot their target and grow into the inner retina (**Figure 7(b)**),

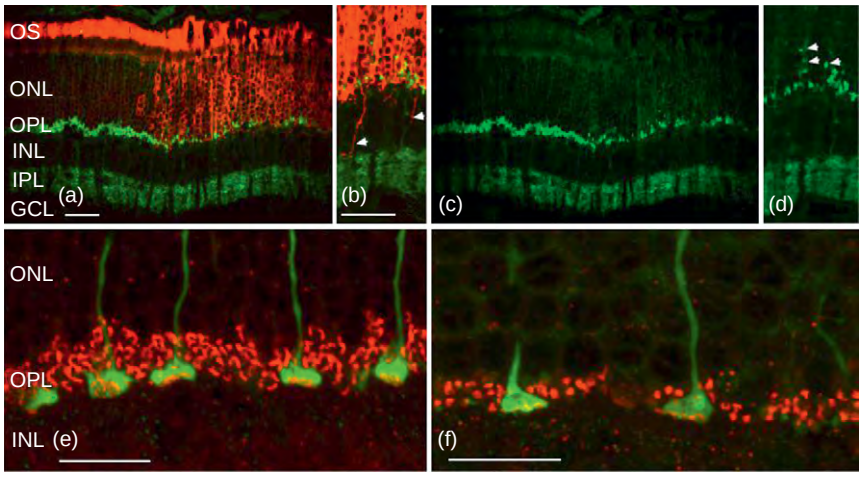

Figure 7 A series of immunofluoresence images acquired by laser scanning confocal microscopy, illustrating various responses of photoreceptor cells caused by detachment. In panels (a)–(d), the retina has actually been surgically reattached, but shows characteristics of both normal morphology and that after detachment. In panels (a) and (b), the retinal sections were labeled with antibodies to the rod photopigment, rhodopsin (red), and a synaptic vesicle protein, synaptophysin (green). Panels (c) and (d) show labeling with synaptophysin alone. In panel (a), the layer of rod outer segments (OS) is uniform in the nondegenerate area to the left, but highly disrupted in the degenerate area to the right. Characteristically, as the OS structure is disrupted by injury, the rhodopsin molecules become distributed throughout the plasma membrane of the rod photoreceptors instead of being restricted to the outer segment, hence the heavy red labeling in the ONL in panels (a) and (b). Also shown in panel (b) is the characteristic overgrowth of some axons (arrowheads) that occur in some rods after reattachment (also see **Figure 1**). The fate of these overgrown axons is unknown. The green labeling compares the organization of the photoreceptor synaptic terminals in areas that are normal (to the left in (a) and (c)) to the organization in areas of photoreceptor degeneration (to the right in (a) and (c)). Notice the sparseness of terminals in areas of degeneration. This is caused largely by the withdrawal of rod axons and the retraction of the terminals into the layer of photoreceptor nuclei (ONL, arrowheads in (d)). Axonal retraction appears to be a common response of rod photoreceptors to retinal injury but the same is not true of cones. Figures (e) and (f)show the responses of cone photoreceptors (green) as well as an organelle characteristic of all photoreceptor synapses, the synaptic ribbon (red). In the normal retina, the cone synaptic terminals are very large by comparison to those of rods and contain many of the synaptic ribbons (red/yellow areas within the green terminals). Rod terminals, on the other hand (unstained in these images), contain only one or two of the crescent-shaped synaptic ribbons. As rod and cone photoreceptors degenerate, cone axons (green) do not withdraw as do those of rods, but the cone synaptic terminals assume a flattened appearance and lose the characteristic synaptic morphology of normal terminals. Notice that the rod synaptic ribbons are transformed from a crescent shape in (e) to a small clumped appearance in (f). There are also many fewer of the rod terminal ribbons in (f) due to the loss of rod synaptic terminals from their normal location in the OPL. OS, layer of photoreceptor outer segments; ONL, outer nuclear layer; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. Scale bar = 20 μm.

a phenomenon that also occurs in retinal development. There is almost nothing known about the recovery of connections to second-order neurons, but the repopulation of the outer plexiform layer with rod terminals appears imperfect after a month of reattachment. It may be the reformation of synaptic connections that partially accounts for the prolonged period of visual recovery that can occur after reattachment, rather than simply a defect in the recovery of outer segments, since the latter are known to have a remarkable capacity to regenerate and recovery quickly, usually within a few weeks of reattachment.

Second- and Third-Order Neurons

The interneurons of the inner retina and the ganglion cells undergo remarkable structural remodeling as the photoreceptors undergo degenerative changes. Rod bipolar cells and horizontal cells show rapid neurite sprouting with fine thread-like processes extending deep into the outer nuclear layer, usually terminating near withdrawn rod terminals (**Figure 8(a)**). However, many neurites from horizontal cells grow across the retina, following intermediate filament-filled Müller cell processes into the subretinal space (**Figure 8(b)**). Postsynaptic processes are probably pruned from both of these cell types as well. A subpopulation of ganglion cells, those with the largest cell bodies, undergoes changes that mirror the responses of horizontal cells. They upregulate the expression of at least two proteins, GAP 43 and neurofilament protein, both of which are expressed at low levels in adult ganglion cell bodies and dendrites (**Figure 8(b)**). The same cells also sprout neurites that can become extensive and grow into the vitreous or across the retina and into the subretinal space, always following gliotic Müller cell scars.

Thus, the detachment of the neural retina from the RPE initiates a series of events in neurons not just among photoreceptors, but also throughout the retina. Ensuing

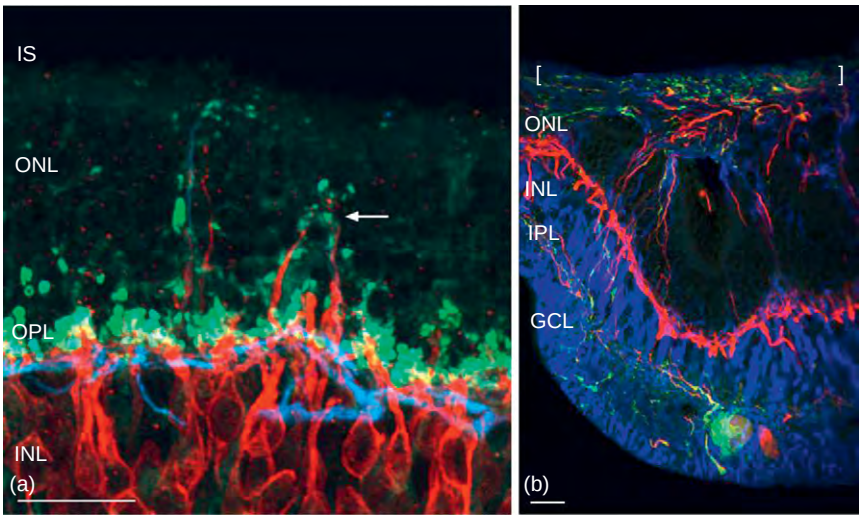

Figure 8 A series of immunofluoresence images acquired by laser scanning confocal microscopy, illustrating the remodeling response of second- and third-order neurons to retinal injury and the relationship of that reaction to glial scars formed by Müller's cells in the subretinal space. (a) All rod bipolar cells (red) label with an antibody to protein kinase C. Synaptic terminals of the photoreceptors (green) are labeled by an antibody to the synaptic vesicle protein synaptophysin. Notice that many of the synaptic terminals have withdrawn into the outer nuclear layer (ONL) as part of the injury response (white arrow). The dendrites of rod bipolar cells normally terminate only among the layer of rod terminals in the outer plexiform layer (OPL), but, in the detached retina, these cells extend neurites deep into the ONL with many of them terminating close to the withdrawn rod terminals. Electron microscopic studies show that these usually do not terminate close enough to the rod terminal to participate in the normal transmission of signals from the rod cells. (b) Horizontal cells and ganglion cells can show extreme remodeling in response to many retinal degenerations including retinal detachment. This image shows processes from horizontal cells (red) and ganglion cells (green) extending across the retina and into a glial scar formed by Müller cell processes in the subretinal space (white brackets). In a normal retina, the horizontal cell postsynaptic processes would terminate among the layer of photoreceptor synaptic terminal in the OPL, and ganglion cell processes would terminate in the IPL where they are postsynaptic to bipolar and amacrine cells. Müller's cells and their processes forming the subretinal scar are labeled with an antibody to GFAP (blue). Scale bar = 20 μm.

changes in synaptic circuitry could have a profound effect on retinal function and there is evidence that the activity of ganglion cells is abnormal in the detached feline retina. The reorganization of synaptic circuitry after reattachment may underlie the long-term changes in vision that are known to occur in many reattachment patients.

Microglia and the Immune Response

Microglial cells are immune cells that normally reside in the inner retina. Almost any injury to the retina will activate these cells, meaning that they begin to proliferate and migrate from their normal location in the inner retina into the photoreceptor layer where they scavenge dead or dying cells (**Figure 9**).

Microglia may cause or prevent photoreceptor cell death by modulating the release of trophic factors from Müller's cells. Macrophages from the circulation enter the subretinal space where they also scavenge debris from degenerated outer segments. Microarray analysis of messenger ribonucleic acid (mRNA) in a number of species has now identified significant changes in the expression levels of many genes involved in the immune and inflammatory responses, with most of these genes being up regulated. In the reattached retina, the presence of microglia correlates strongly with the degree of photoreceptor recovery; areas showing less outer segment recovery have a greater population of microglia distributed among the photoreceptor cells (**Figure 9(c)**). The role of the immune system and the inflammatory response following detachment and retinal injury is only beginning to be appreciated. It is quite clear from cellular localization studies that both macrophages and microglia can populate glial scars formed on either surface of the retina. What role they play there is unknown.

Retinal Pigmented Epithelial cells

Retinal pigmented epithelial cells react to detachment by retracting their highly specialized apical microvillii – actin-filled processes that normally drape the outer segments (**Figure 1**). The cells do, however, retain a fringe of conventional microvilli much like those that appear on cultured RPE cells and these microvilli then have the capability of regenerating after reattachment. RPE cells can also proliferate after injury to the retina and then migrate from their monolayer to form complex assemblies of cells in the expanded subretinal space. This is an important response to injury because these cells are structurally and physiologically polarized so that their apical

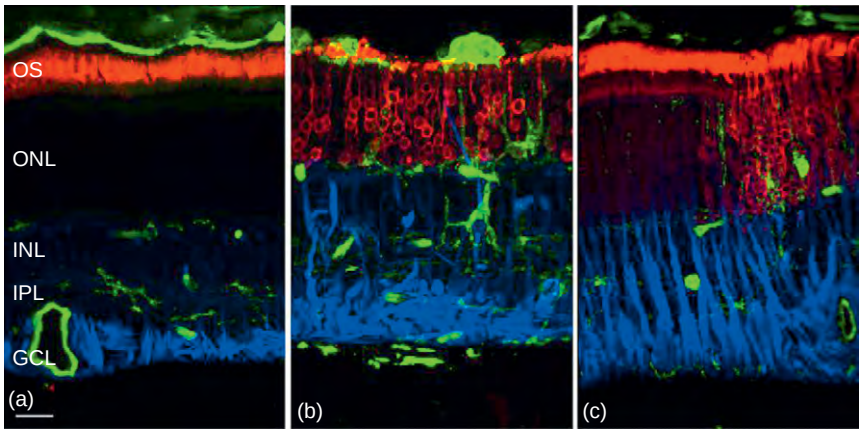

Figure 9 A series of immunofluoresence images acquired by laser scanning confocal microscopy, illustrating the microglial and macrophage component of the response to retinal detachment. Microglia and macrophages (green) are labeled by a lectin molecule that binds to sugar groups on protein molecules. Notice that this lectin also binds to blood vessels that are represented by the large choroidal vessels above the OS and a large inner retinal vessel bridging the GCL/IPL layers in panel (a). Rod photoreceptors (red) are labeled with an antibody to the protein rod opsin, and Müller's cells by an antibody to GFAP (blue). Rod opsin is restricted to the layer of outer segments (OS) and GFAP to the Müller cell endfeet and astrocytes, both in the ganglion cell layer (GCL). The microglia are the green spindly cells within the INL. (b) In a detached retina, the OS are highly degenerated; rod opsin labeling now extends throughout the rod cell plasma membrane and the Müller cells have upregulated the expression of GFAP. Lectin-labeled microglia are now found in the outer retina, and macrophages are present on top of the degenerated outer segments. (c) An example of a retina that has been reattached but shows patchy areas of good and poor outer segment regeneration. In the area of good outer segment regeneration (to the right), opsin is once again restricted to the layer of outer segments and microglia are no longer found in the outer retina. In the area of poor outer segment regeneration, opsin is found distributed throughout the plasma membrane of the rod cells and microglia still reside in the outer retina. Notice that even though this retina was reattached for 28 days after a 3-day period of detachment, there is still a large amount of GFAP in the Müller cells. Scale bar = 20 μm.

and basal surfaces physiologically differ. If a new layer of RPE cells is generated in response to detachment and their basal surface faces the retina, no outer segment regeneration will occur. These cells also have the remarkable ability to migrate across the neural retina and integrate into epiretinal membranes (referred to above as glial scars) that contribute to the disease PVR. Indeed, because of the presence of melanin pigment granules, RPE cells within these membranes are highly visible and, for many years, PVR was thought to be a disease of RPE cell origin. This is still a point of controversy, but it seems clear that RPE cells can be involved along with glia and immune response cells.

Summary

Rhegmatogenous RD is a form of retinal injury that produces cellular responses common to many other injuries. Detachment as well as other physical injuries to the retina can result in long-lasting visual deficits. New information at the cellular and molecular level may lead to an understanding of why successful anatomical reattachment can still leave a patient with imperfect vision or the mechanisms by which some repairs fail. Müller's cells of the retina respond similarly to astrocytes in the brain and spinal cord and there is still much to learn about the role of these enigmatic cells in the retina's responses to injury and its ability to recover.

Injury and Repair: Light Damage

N A Mandal, R E Anderson, and J D Ash, University of Oklahoma Health Sciences Center, Oklahoma City, OK, USA

Glossary

Acute light damage – Single exposure of intense light (1000–13 000 lux) for a brief period (20 min–24 h), which causes photoreceptor cell death, mainly in the central retina.

Apoptosis – A form of programmed cell death in multicellular organisms, which involves a series of biochemical events leading to a characteristic cell morphology and death. Death and the disposal of cellular debris do not damage the neighboring cells. Light-induced photoreceptor cell death occurs by apoptosis.

Chronic light damage – Exposure to sublethal doses of light (200–800 lux) in a cyclic manner (day–night) for a longer period of time (7–12 weeks). This causes overall thinning of the photoreceptor layer in the entire retina.

Inflammation – The complex biological response of vascular tissues to harmful stimuli such as pathogens, damaged cells, or irritants. It is a protective response by the organism to remove the injurious stimuli as well as initiate the healing process for the tissue.

Photoisomerization – The event in which a light-sensitive molecule absorbs a photon of light energy and undergoes a chemical change. In the current context, the 11-*cis*-retinal chromophore of rhodopsin is isomerized to all-*trans*-retinal, leading to activation of rhodopsin (R*) and initiation of the visual process.

Photostasis – Retinal adaptive response to different levels of cyclic illuminances. In bright cyclic light, rod outer segment (ROS) length is shortened, concentration of rhodopsin per unit of ROS is decreased, and ROS membranes become disorganized, compared to animals raised in dim cyclic light. This remarkable plasticity allows the retina of animals raised in dim and bright cyclic light to catch an equivalent number of photons each day.

Introduction

In 1966, Werner Noell discovered that the exposure of albino rats to bright visible light led to a rapid, specific, and irreversible loss of rod photoreceptor cells. Over the next four decades, this light-damage model has been used extensively to study mechanisms of retinal cell death and to test the efficacy of a variety of putative neuroprotective compounds. In his pioneering work, Noell discovered that photo-bleaching of rhodopsin was absolutely essential for light damage; rats raised on vitamin-A-deficient diets were not sensitive to light damage and the susceptibility to light damage followed the absorption spectrum of the visual pigment rhodopsin. Although the mechanism for initiation of the cell death signal in light damage is not known, recent studies have shown that while activation of rhodopsin is required, the visual transduction pathway downstream is not. Several outstanding reviews have been written on various aspects of light damage and therapeutic interventions. This article focuses on recent advances in identifying potential molecular mechanisms of cell injury and death, as well as the discovery of two independent mechanisms of endogenous self protection which are activated by light and stress in retinal photoreceptors.

There are several major advantages in using light damage to study retinal degeneration. Most inherited retinal degenerations occur over a long period of time with only a few photoreceptors dying each day. This makes it extremely difficult to biochemically study mechanisms of cell death or to study the effectiveness of therapeutic interventions. Light damage, on the other hand, has the advantage to more or less induce cell death in whole populations of photoreceptors at once. In addition, light damage can be tuned in terms of severity by varying the intensity of the light and duration of exposure. Hence, the intensity and duration required to cause a certain level of damage are correlated and a longer exposure can substitute for a higher intensity.

Over the years, two models of light damage have emerged: acute (short bright exposure) and chronic (less bright cyclic exposure). Both lead to retinal degeneration, but have quite different phenotypes. In the acute model, animals placed in light intensities ranging from 1000 to 13 000 lux in a time frame of 20 min to 24 h undergo a rapid and specific loss of rod photoreceptors. An example of acute light damage in a Sprague Dawley (SD) rat is shown in **Figure 1**. There is a clear demarcation of photoreceptor cell death, with normal-appearing retina (yellow arrow) adjacent to an area of moderate-to-massive cell death (white arrows). It is interesting that the subretinal space underlying the normal retina (yellow arrow) has been infiltrated with immune cells, suggesting that an inflammatory process is occurring prior to photoreceptor cell death. The role of inflammation in light damage is

discussed subsequently in this article. A so-called spider graph of the thickness of the outer nuclear layer (ONL, rod nuclei) measured at defined distances from the optic nerve head to the inferior and superior ora serrata along the vertical meridian clearly demonstrates the specific loss of photoreceptor cells in the central superior region of the retina (Figure 2). The chronic light damage model involves raising albino rodents in sublethal levels of cyclic light (200–800 lux, depending upon the strain). Retinas of SD rats raised from birth to 7 weeks of age in 700-lux cyclic light show remarkably normal retinal morphology except for a thinning of the ONL (Figure 3). The loss of photoreceptor cells is quite different from that which occurs in acute light damage, showing no regional differences (Figure 4). An interesting feature of the chronic light damage model is that, although the retina slowly loses photoreceptors, it is protected against the massive loss that occurs when these animals are placed in acute bright light. This point is discussed in detail later on in this article. These two models thus provide a means of testing putative neuroprotective compounds in two experimental paradigms. They are also useful to identify the molecular mechanisms that are responsible for light-induced damage, although the initial sequence of events leading to apoptosis may differ significantly from one protocol to another.

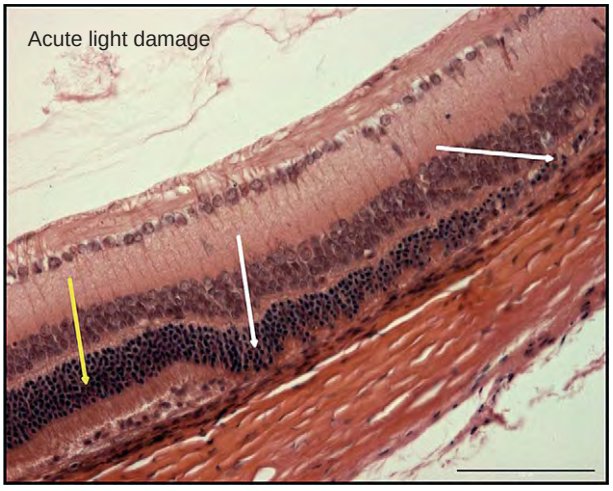

Figure 1 Sprague-Dawley rats were born and raised in 5 lux cyclic light. At 6–7 weeks of age, they were exposed to 2700-lux light for 6 h, after which they were returned to their cyclic light environment for 7 days. The white arrows point to areas of moderate to severe degeneration adjacent to an area of normal retina (yellow arrow).

Role of Rhodopsin Activation in Light Damage

While the precise mechanisms for cell damage are not fully understood, several genes have been identified that regulate photoreceptor sensitivity to light damage. When first identified, the action spectrum of light damage overlapped with the absorption spectrum of rhodopsin, suggesting a role for photoisomerization and phototransduction in cell injury. Indeed, a single, strong rhodopsin bleaching event is sufficient to induce light damage. The role of photoisomerization of 11-*cis*-retinal and rhodopsin activation as a requirement for light damage has been demonstrated pharmacologically and genetically. Pharmacological inhibition of rhodopsin regeneration with either the anesthetic halothane or by retinoic acid analogs, isotretinoin or 13-*cis*-retinoic acid, renders retinal photoreceptors less susceptible to light damage. Therefore, the severity of damage depends on the regeneration of rhodopsin during light exposure.

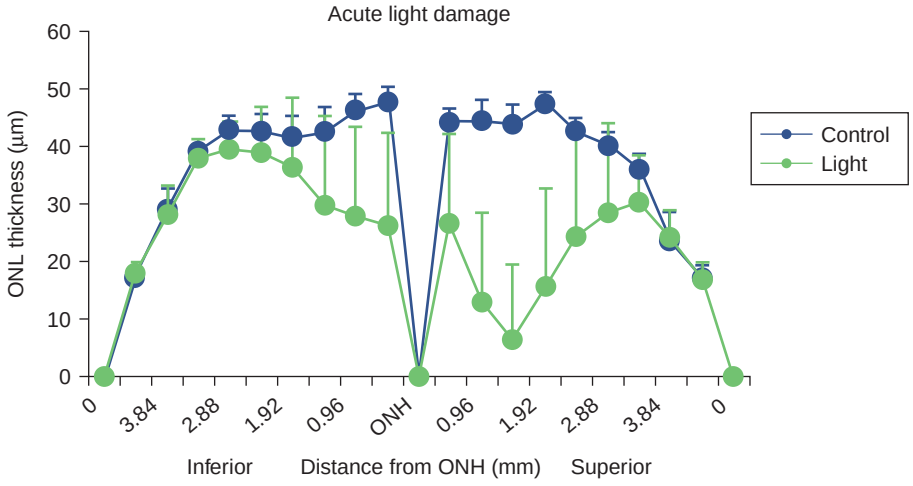

Figure 2 Sprague-Dawley rats were born and raised in 5-lux cyclic light. At 7 weeks of age, they were exposed to 2700-lux light for 6 h, after which they were returned to their cyclic light environment for 7 days. Plotted is the thickness of the outer nuclear layer (ONL) against distance from the optic nerve head (ONH) along the vertical meridian.

This sensitivity may be affected by polymorphisms or disease-causing mutations in opsin. The P23H opsin mutation is known to cause retinitis pigmentosa (RP) in humans. Work by Muna Naash and Daniel Organisciak, using transgenic mice or rats expressing human rod opsin with the P23H mutation, has shown that photoreceptors from these animals degenerate faster in bright cyclic light. Several recent studies have shown that mice with mutations in opsin, and phototransduction termination proteins arrestin and rhodopsin kinase are more sensitive to light damage. These results suggest that a prolonged R* or activated rhodopsin state is responsible for sensitivity to light damage. In more recent years, the Zurich group of Charlotte Reme, Andreas Wenzel, and Christian Grimm confirmed the necessity for rhodopsin photobleaching by demonstrating that mice lacking the RPE65 gene, which encodes a protein necessary for photoisomerization of all-*trans*-retinyl esters, were protected from light-induced cell death. The same group has also shown that a slow rate of rhodopsin regeneration due to an L450M variation in the RPE65 protein also renders mice less susceptible to light damage. However, while activation of rhodopsin is required for acute light damage, activation of phototransduction through guanine nucleotide-binding protein α_t ($G\alpha_t$ or transducin) is not. This was demonstrated in an elegant study by Wenshan Hao using combinations of rhodopsin kinase, arrestin, and transducin knockout mice. The study clearly suggests that a transducin-independent but, rhodopsin-dependent, signaling is required for acute light damage.

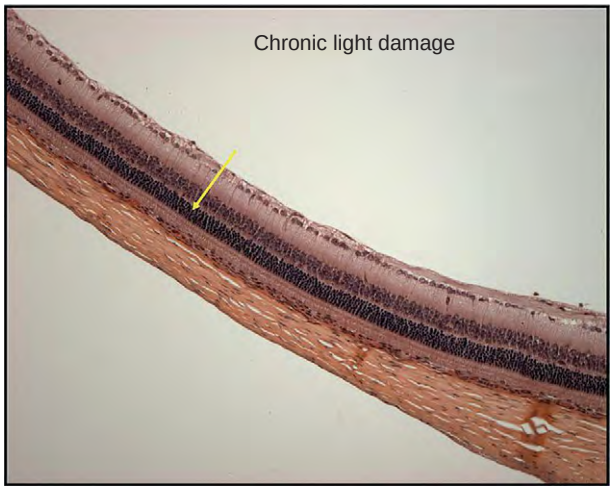

Figure 3 Sprague-Dawley rats were born and raised under 700-lux cyclic light until they were 7 weeks old. The retinas appear normal except for the thinning of the outer nuclear layer (ONL; yellow arrow). ONH, optic nerve head.

Mechanisms of Photic Injury: From Gene Expression to the Molecular Pathway

Gene expression analyses by DNA microarray studies have uncovered several possible molecular mechanisms of cell death in light damage. Our primary focus has been acute light damage (2700–3000 lux for 6 h) in albino mice or rats. This exposure paradigm induces oxidative stress that is sufficient to cause loss (>80%) of the photoreceptor cells in the central retina with no recoverable electroretinogram (ERG). However, cell death does not occur immediately following light exposure. It should be noted that by isolating RNA immediately after light exposure one can assess the stress response of photoreceptors before the onset of cell loss and detectable apoptotic cells in the retina. Therefore, by determining this early response one can decipher the molecular pathways that might regulate light-induced cell death. Retinas harvested

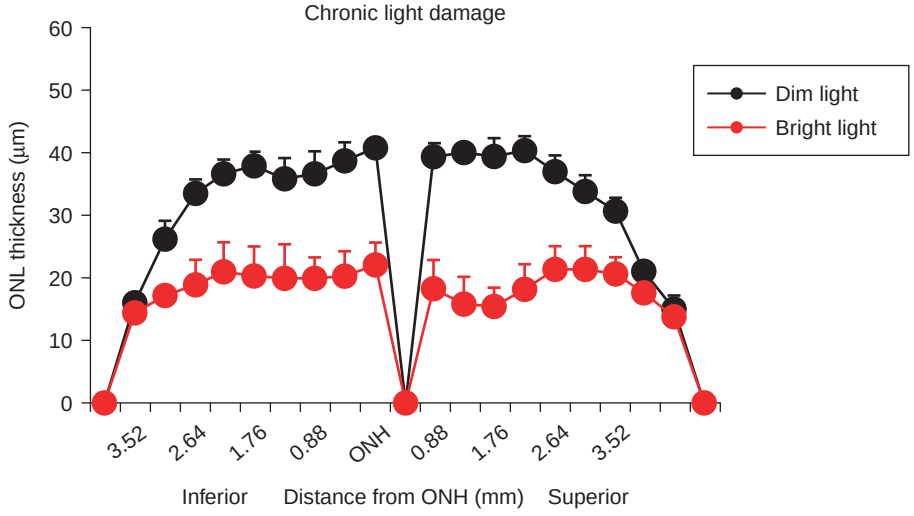

Figure 4 Sprague-Dawley rats were born and raised under 5 lux or 700 lux cyclic light until they were 7 weeks old. Plotted is the thickness of the outer nuclear layer (ONL) against distance from the optic nerve head along the vertical meridian.

immediately after the light exposure were used to generate complementary DNA (cDNA) to expressed messenger RNA (mRNA). The expression of the genes is studied by high-throughput DNA microarray analysis followed by quantitative (real-time) RT-PCR methods (RT-PCR, reverse transcriptase-polymerase chain reaction).

Apoptosis Genes

It has been well documented that apoptosis is the mechanism of photoreceptor cell death in light damage. Light damage induces expression of members of the activator protein 1 (AP-1) transcription factor family: *c-fos*, *FosL1* (*fra-1*), *junB*, and *c-Jun*. The dimeric AP-1 transcription factor is formed by either *c-fos* or *fra-1* binding to Jun proteins. The bright-light-induced apoptosis in retina is dependent upon activation of *c-fos*, and this *c-fos* upregulation plays a critical proapoptotic role, as evidenced from *c-fos* knockout mice, which showed marked resistance to light damage. Further, activation of the glucocorticoid receptor, which inhibits AP-1, also protects against light damage.

There are indications of involvement of other apoptosis genes in light damage. We have observed marked upregulation in the expression of tumor necrosis factor (TNF) receptor superfamily, member 1A (*Tnfrsf1a*), growth arrest and DNA-damage-inducible, beta (*Gadd45b*), and pleckstrin homology-like domain, family A, member 1 (*Phlda1*) genes. The protein encoded by *Tnfrsf1a* is one of the major receptors for the TNF-alpha (TNFα). This receptor can activate nuclear factor kappa-light-chain-enhancer of activated B cells (NFκB), mediate apoptosis, and function as a regulator of inflammation. In addition, the anti-apoptotic protein BCL2-associated athanogene 4 (BAG4/SODD) and adaptor proteins TRADD and TRAF2 have been shown to interact with this receptor. GADD45b can respond to environmental stresses by mediating activation of the p38/JNK pathway, which is involved in the regulation of growth and apoptosis. *Phlda1* encodes an evolutionarily conserved proline–histidine-rich nuclear protein, which may play an important role in the anti-apoptotic effects of insulin-like growth factor-1. In summary, we observed a significant upregulation of many proapoptotic genes, which are mainly involved in the AP-1-mediated apoptotic pathway and did not detect any changes in the caspase-related genes in the initial phase of degeneration.

Role of Oxidant Stress in Light Damage

Oxidant stress has long been implicated in the pathogenesis of light damage. Intense light involves the generation of oxidants in the photoreceptors and the accumulation of oxidatively modified lipids, nucleic acids, and proteins. Oxidant stress is further supported by several reports describing protection from light damage induced by a variety of antioxidants, including ascorbate, dimethylthiourea, thioredoxin, and NG-nitro-L-arginine-methyl ester (L-NAME). We observed that pretreatment with the free radical trap phenyl-*N*-*tert*-butylnitrone (PBN) completely abrogates light-induced degeneration of the retina. The PBN protection not only involves the stabilization of the free radicals, but also suppresses the expression of many proinflammatory and apoptotic genes. Gene expression analysis has shown that light damage upregulates the expression of antioxidant genes heme oxygenase 1 (*Ho-1*), superoxide dismutase (*Sod*), thioredoxin, glutathione peroxidase, ceruloplasmin (*Cp*), and metallothioneins (*Mt*)-1 and-2. Mice expressing mutant SOD1 are highly susceptible to light damage and have accelerated age-dependent degeneration of the retina. CP is a ferroxidase that functions as an antioxidant by oxidizing iron from its ferrous to ferric form. Iron-derived hydroxyl radicals produced by the Fenton reaction may be important mediators of retinal photic injury as systemic administration of the iron chelating reagent desferrioxamine attenuates light-induced damage in rat retinas. Metallothioneins (MTs), another group of antioxidants, are copper- and zinc-binding proteins which can quench superoxide and hydroxyl radicals. Expression of oxidant defense genes further supports the hypothesis that light-induced retinal degeneration involves oxidative stress.

Role of Inflammation in Light Damage

We have noticed recurrent appearance of a host of inflammatory genes in the group of upregulated genes in many light-damage studies. In fact, invading immune cells are often observed in the retina near dying photoreceptors. These can be seen under the relatively normal photoreceptors (yellow arrow, **Figure 1**) adjacent to the injured photoreceptors (white arrows, **Figure 1**). While the connection between inflammation and light damage is not well known, two recent studies have suggested there is a strong link. Work from Barbel Rohrer has shown that genes related to complement activation are upregulated in response to light stress and that elimination of complement factor D reduces susceptibility to light damage. Work from Ying-qin Ni has shown that light stress leads to the upregulation of interlukin 1β (IL-β) and activation of resident microglia. Significantly, the study found that inhibiting microglia activation with naloxone protected photoreceptors from subsequent light damage. These studies suggest that an inflammatory response plays an active role in promoting photoreceptor death in light damage. Inflammation is also becoming recognized as a key factor in many retinopathies, including the epidemic forms of diabetic retinopathies and age-related macular degeneration (AMD). Therefore, a thorough investigation into the inflammatory process in the retina is essential for an understanding of the mechanism of light damage as well as other forms of retinal degeneration.

Light damage rodent models are slowly being recognized as models for retinal inflammation and are suitable models for human AMD. Here we summarize our observation of inflammatory gene expression changes. Photic injury upregulates the expression of many chemokine genes, Ccls (*Ccl2*, *Ccl3*, *Ccl4*, and *Ccl7*) and Cxcls (*Cxcl1*, *Cxcl11*, *Cxcl10*, and *Cxcl9*). Chemokines are a group of small (8–14 kDa), mostly basic, structurally related molecules that regulate cell trafficking of various types of leukocytes through interactions with a subset of guanine nucleotide-binding protein (G-protein-coupled) receptors. These molecules are divided into two major subfamilies, CXC and CC, based on the arrangement of the first two of four conserved cysteine residues; the two cysteines are separated by a single amino acid in CXC chemokines and are adjacent in CC chemokines. Chemokines also play fundamental roles in the development, homeostasis, and function of the immune system, and they have effects on cells of the central nervous system as well as on endothelial cells involved in angiogenesis or angiostasis. *Ccl2* or monocyte chemoattractant protein-1 (*Mcp-1*) upregulation is very robust and very early in the process of acute light damage. They may signal injury and recruit choroidal macrophages to scavenge retinal debris. Homozygous deletion of Ccl2 resulted in a mouse phenotype reported to be similar to human AMD. CCL3, also known as macrophage inflammatory protein-1, or monokine, is involved in the acute inflammatory state in the recruitment and activation of polymorphonuclear leukocytes. CCL4, a cytokine that is upregulated during the inflammatory response, is involved in the recruitment of neutrophils. CCL7 or monocyte chemotactic protein 3, a secreted chemokine, attracts macrophages during inflammation and metastasis. In addition, CXCL10 binds to its receptor CXCR3 and results in pleiotropic effects, including stimulation of monocytes, migration of natural killer and T-cells, and modulation of adhesion molecule expression. Upregulation of CXCL11 indicates probable activation of interferon gamma, which is a potent inducer of CXCL11 transcription.

Besides chemokines, we found significant upregulation of genes, which are either members of classic inflammatory proteins or involved in regulation of cellular inflammation. Expression of intercellular adhesion molecule 1 (*Icam1*), CCAAT/enhancer-binding protein (*Cebpb*/C/EBP, beta), cytokine-cardiotrophin-like cytokine factor 1 (*Clcf1*), lipopolysaccharide-induced TNF factor (*Litaf*), cyclooxygenase 2 (*Cox2*), ring finger protein 125 (*Rnf125*), and *Cd44* genes were significantly upregulated in acute light stress. The protein encoded by the *Cebpb* gene is a basic-leucine zipper (bZIP) transcription factor, which can bind as a homodimer to certain DNA regulatory regions of genes involved in immune and inflammatory responses and has been shown to bind to the IL-1 response element in the IL-6 gene, as well as to regulatory regions of several acute-phase and cytokine genes. The CLCF1 protein belongs to the IL-6 family of cytokines, which are involved in cell signaling through phosphorylation of gp130. Lipopolysaccharide is a potent stimulator of monocytes and macrophages, causing secretion of TNFα and other inflammatory mediators. COX2 is the key enzyme in prostaglandin biosynthesis and acts both as a dioxygenase and as a peroxidase and is involved in inflammation and mitogenesis. The *Rfn125* gene encodes a novel E3 ubiquitin ligase that contains an N-terminal RING finger domain, which may function as a positive regulator in the T-cell receptor signaling pathway. This is a small list of the inflammatory genes (~30% of all the upregulated genes) that are induced in acute light damage and clearly indicates a role in the pathogenesis of light damage.

Tissue Remodeling

Inflammatory signaling events are usually followed by tissue remodeling for the invasion of the macrophages and other cells, which then leads to the process of advanced cell death and removal of debris. We observed significant upregulation of matrix metallopeptidase 3 (*Mmp3*), tissue inhibitor of metallopeptidase 1 (*Timp1*), growth differentiation factor 15 (*Gdf15*), and plasminogen activator, tissue (*Plat*) genes. MMP3 is an endopeptidase that degrades extracellular matrix proteins and TIMP1 acts as an inhibitor of metalloprotease activity; PLAT is an enzyme that also plays a role in cell migration and tissue remodeling.

Transcription Factors

Many of the genes described under apoptosis, oxidative stress, and inflammation are transcription factors. However, there are other transcription factors upregulated in retinal light damage, which are involved in neuronal injury and various processes in cell death and survival. These include early growth response 1 (*Egr1*), zinc finger protein 36 (*Zif36*), activating transcription factor 3 (*Atf3*), and stress-signal transducer and activator of transcription 3 (*Stat3*).

Identification of Two Nonredundant Mechanisms of Endogenous Protection of Photoreceptors

Several recent studies have been designed to reveal pathways that protect photoreceptors from light damage. These studies have identified two independent protective pathways. One pathway is rapidly activated by phosphorylation

following light stimulation, while the second pathway requires induction of new gene expression in response to chronic light stress.

Rhodopsin-Activated Endogenous Protection

Work from Raju Rajala has demonstrated that rhodopsin activation by light results in ligand-independent activation of the insulin receptor, which leads to activation of downstream signaling including increased PI3K and Akt kinase activity in photoreceptors. This activation was subsequently shown to be transducin independent. Genetic inactivation of the insulin receptor, insulin receptor substrate 2 (IRS2), AKT2, or BCL-XL have all led to increased photoreceptor susceptibility to acute light damage. These studies suggest that rhodopsin signaling, independent of transducin, is responsible for the activation of a defense mechanism through the insulin receptor and AKT2. Insulin receptor regulation of AKT2 is an ideal protective pathway for acute changes in light intensity since the entire pathway can be activated quickly through a series of phosphorylation events and does not require new gene expression. However, the AKT2 defense mechanism is overwhelmed as the duration of light exposure or intensity of light begins to induce cell death. It seems that the retina requires a secondary system of protection from chronic stresses such as prolonged bright light exposure and inherited genetic mutations.

Identification of Mechanisms for Chronic Light Stress-Induced Endogenous Protection

Noell's observation that animals raised in bright cyclic light were less susceptible to a subsequent light challenge than those raised in dim cyclic light or darkness inspired the discovery by John Penn and Ted Williams in the 1980s that albino rats born and raised in bright (but sublethal) cyclic light were protected from acute light damage. They discovered an enormous plasticity of the retina. Animals raised in dim cyclic light enhanced their chances of photon capture by lengthening their outer segments and increasing the packing density of rhodopsin in rod outer segment disk membranes. On the other hand, animals raised in relatively bright cyclic light reduced the length of outer segments, which also became somewhat disorganized, and decreased the packing density of rhodopsin in the disk membrane. The net result was to reduce the efficiency of photon capture by rhodopsin. Penn and Williams coined the term photostasis to describe the phenomenon of biochemical and morphological adaptation of the retina to modify efficiency of photon capture in animals exposed to different levels of cyclic light. It was suggested that these changes allowed photoreceptors to capture an equivalent number of photons each day regardless of their light environment. The morphological changes associated with bright cyclic rearing were also accompanied by biochemical changes described by Penn and Anderson that included increased activity of glutathione enzymes (peroxidase, S-transferase, and reductase), elevation of retinal vitamins E and C, and decreased levels of polyunsaturated fatty acids (substrates for lipid peroxidation). These studies suggest that in response to chronic light stress, photoreceptors undergo photostasis to reduce activation of rhodopsin and induce an antioxidant defense. Similar findings have been shown in both mice and rats. Importantly, these stress-induced molecular and morphological adaptations were shown to protect photoreceptors almost completely from acute light damage.

The mechanism by which retinas of rodents raised in bright cyclic light are protected from acute light damage is an important area of research and significant progress has been made toward identifying the factors and receptors that are required, as well as identifying their relevant signal transduction pathways. Since the insulin receptor/PI3K/Akt2 pathway is involved in providing protection from acute light damage, this pathway was considered a likely candidate for chronic light stress-induced protection. However, recent findings suggest that chronic light stress-induced protection is independent of this pathway. Unlike the insulin receptor and AKT2-dependent protection, induced protection requires several days of preconditioning, suggesting that new gene expression is required. This indirectly suggests a different mechanism. In support of this, we have shown that induced protection is independent of AKT phosphorylation, and we have shown that *Akt2* knock-out mice have induced protection that is identical to wild-type mice. The insulin receptor and AKT2 appear to function as a rapid response to an acute injury, but is not necessary or perhaps is unable to protect from chronic injury. These studies demonstrate that there are two mechanisms of endogenous protection, one for acute injury that utilizes the insulin receptor and AKT2, and one for induced protection from chronic injury.

Role of Leukemia Inhibitory Factor

Several groups, including Steinberg, LaVail, Wen, and Stone, have shown that light preconditioning in rats induces the expression of several factors including basic fibroblast growth factor (FGF) (FGF2) and ciliary neurotrophic factor (CNTF). More recently in mice, the Grimm and Ash laboratories have shown that preconditioning induces the expression of leukemia inhibitory factor (LIF), cardiotrophin-like ligand (CLC), onchostatin M (OSM), FGF2, endothelin 2 (End2), and brain-derived neurotrophic factor (BDNF). While many factors are upregulated, it was not known which were responsible for induced protection. Early work from Steinberg and LaVail demonstrated that the intravitreal injection of FGF2, CNTF, LIF, or BDNF resulted in substantial

protection of rat photoreceptors from a subsequent acute light damage independent of preconditioning. Additional work from Wen and Ash has similarly found that injection of LIF, CNTF, or BDNF protects mouse photoreceptors from a subsequent acute light damage. Of these, LIF and CNTF have tremendous therapeutic potential, given their ability to protect photoreceptors not only from acute light damage but also from inherited retinal degenerations.

Studies using intravitreal injections have demonstrated that multiple factors can induce protection, but did not demonstrate which factors were required for chronic light stress-induced protection. We have recently shown that LIF, CNTF, or CLC are the most likely candidates. This was demonstrated using an antagonist (LIF05) to the LIF receptor (LIFR), which blocks the activity of LIF, CNTF, and CLC. Intravitreal injection of LIF05 during light stress preconditioning greatly diminishes stress-induced protection from acute light damage. We also used conditional knock-out mice for the gp130 receptor and found that mice lacking gp130 expression in retinal photoreceptors also lose chronic light stress-induced protection. These recent studies demonstrate that the LIFR and gp130 expression in photoreceptors is essential for stress-induced protection and that the likely ligands are LIF, CLC, or CNTF, since these upregulated cytokines all utilize the LIFR and gp130. Our studies suggest that LIF may be the more important ligand since its expression is induced more than 100-fold following chronic light stress-induced preconditioning.

As described above, stress-induced protection was accompanied by upregulation of oxidant defense enzymes as well as photostasis. More recently, we have injected different doses of LIF into the vitreous of mice to determine whether LIF could induce both events. We found that at lower doses, LIF could induce protection from light damage without reducing photoreceptor sensitivity to light flashes. At higher concentrations, LIF not only induced protection, but also induced photostasis through decreased mRNA and protein expression of opsin, transducin (α and β subunits), and cyclic guanosine monophosphate (GMP) phosphodiesterase (PDE6A and PDE6B). Because of decreased expression of genes required for phototransduction, photoreceptors exhibited reduced efficiency in photon capture. These results demonstrate that LIF is upregulated by chronic bright-light stress and its induced expression is necessary for protection. LIF also has the ability to upregulate both photostasis and oxidant defense mechanisms. These studies clearly establish that in mice, LIF receptor, gp130, and perhaps LIF are essential players in chronic light stress-induced endogenous protection from acute light damage.

Many questions remain to be answered. In particular: Is LIF the essential factor? Which cells induce expression of LIF? Which signal transduction pathways are required for protection? What changes in gene expression are required for protection? In a series of studies, we have shown that intravitreal injection of LIF results in activation of ERK1/2 and STAT3. The pattern of activation changes over time. Within the first 30 min of injection, both phosphorylated ERK1/2 and STAT3 were detected only in Müller's cells and some ganglion cells. Within 4 h, however, all retinal cells were positive for STAT3, while ERK1/2 activation returned to basal levels. Detectable phosphorylated STAT3 remained up to 6 days following a single injection of LIF. Since phosphorylated STAT3 is a transcription factor, these results suggested that LIF could induce gene expression changes in all retinal cells including Müller's cells and photoreceptors.

Concluding Remarks

Light-damage models have led to major advances in our molecular understanding of retinal degeneration through oxidative injury mechanisms and, in the future, light-damage studies will be used to advance our understanding of injury induced by inflammation. Light-damage models have also led to the discovery of two independent mechanisms of endogenous neuroprotection, as well as to the discovery of promising new therapies to prevent or delay inherited retinal degenerations. Indeed, phase I clinical trials using encapsulated cells expressing CNTF have been completed with promising early results, and the study has since progressed into phase II trials. The protective effect of CNTF was initially described in the retina using the light-damage model. This alone should clearly establish the relevance for using light damage to identify potential therapeutic agents. By further defining the mechanisms of cell injury or protection, light-damage studies will likely lead to the development of new and more specific therapies.

Injury and Repair: Neovascularization

M E Kleinman and J Ambati, University of Kentucky, Lexington, KY, USA

Glossary

Complement – A complex molecular cascade that directly removes pathogens and activates the host immune system.
Cytokines – The secreted proteins that mediate cellular communication through a specific set of cell-surface receptors.
Extracellular matrix – The extracellular material that supports cell structure and intercellular communication.
Laser-induced injury – A reproducible model of tissue injury with the application of a high-energy laser photocoagulation to the fundus.
Neovascularization – The formation of new blood vessels.
Vascular endothelial growth factor – A potent cytokine that is critical for the process of neovascularization.

Introduction

The retina is a highly organized multicellular system designed to efficiently convert light into electrical signals which can then be transmitted to the brain for cortical integration and, ultimately, visual perception. In an acute setting of retinal injury, the cellular components of the neural retina, retinal pigment epithelium (RPE), and choroid get activated in order to contain the wound, destroy any invading pathogens, and initiate the repair process. As a result of the subsequent proinflammatory surge, blood vessels invade the wound bed to revascularize injured and hypoxic tissue and provide a new source of nutrients to the remodeling tissues. Typically, as in several other peripheral tissues in the human body, such as skin, this vascular growth allows for tissue healing and scar remodeling; however, in the delicate architecture of the retina, these abnormal vessels grow in an unregulated fashion and are susceptible to leakage and rupture. These traits are hardly suitable for the retina's highly specialized function of vision and often lead to neovascularization (NV) as a cause of blindness in the context of retinal disease and injury. NV also contributes to other cellular responses in the injured retina, including gliosis and fibrosis. Through clinical observations and scientific investigation, critical insights into the biology of NV in injury and repair in the retina, RPE, and choroid have modernized our current understanding of the cellular and molecular pathways that drive this pathological process.

Mechanisms of Injury

Retinal, RPE, and choroidal injury may be caused by a plethora of mechanical, cellular, physiologic, photochemical, and iatrogenic processes that are addressed in detail in other sections. Each of these instigating factors, either individually or in concert with one another, is capable of setting off the intricate cascade of factors leading to subretinal NV. A list of some of the common causes of injury-induced NV is provided next.

1. *Mechanical trauma.* Blunt trauma to the eye disorganizes the retinal architecture to varying degrees with displacement of reactive glial cells and RPE to the vitreo-retinal interface. These cells can form a fibrotic scar at the surface of the internal-limiting membrane (ILM), in the case of epiretinal membrane, and even grow into the vitreous as in the case of proliferative vitreo-retinopathy. More ominous is the presence of a choroidal rupture, a finding that is very likely to induce neovascular invasion of the retina through fractures in Bruch's membrane. Over time, these lesions eventually involute but do leave behind a residual fibrotic scar that significantly decreases visual acuity in the area.
2. *Age-related macular degeneration.* One of the most common forms of retinal injury is due to a combination of inflammation, oxidative stress, and photochemical damage secondary to age-related macular degeneration (AMD), a disease which accounts for the epidemic loss of vision in people over 60 years of age in the developed world. Between 10% and 20% of people with AMD will progress to the neovascular or wet form, which is responsible for about 90% of vision loss in patients with AMD. Recent evidence suggests that the gradual accumulation of inflammatory debris in drusen beneath the RPE and within the choroid ultimately leads to the production of proangiogenic cytokines and retinal invasion by abnormal and leaky vasculature. Some of these inflammatory components are comprised of photochemically altered proteins that are linked to intermediate or terminal products of the vitamin-A cycle or lipid-breakdown products released

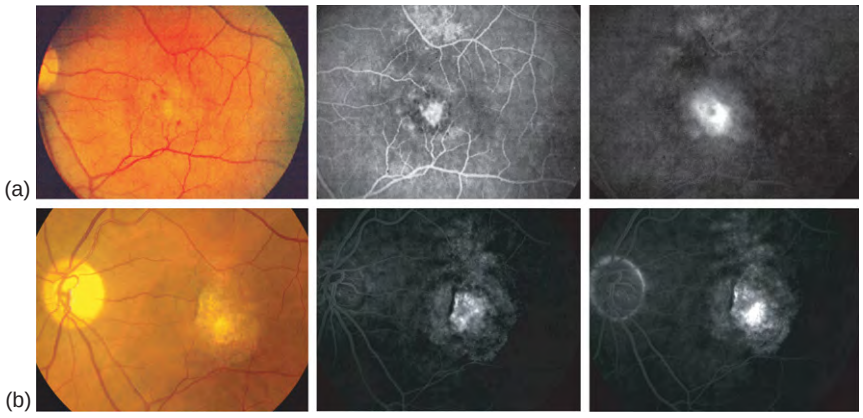

Figure 1 Retinal injury progression through inflammation, neovascularization, and fibrosis. (a) Left to right sequence of images representing CNV (far left, color fundus photography) after an inciting inflammatory event leading to leaky vasculature in the macula as evident on fluorescein angiography (middle, 45-s time point, far right, 10-min time point); (b) The same patient several years later showing subretinal fibrosis (far left) with fluorescein staining scar and RPE dropout (same sequence as above).

by dying photoreceptors and RPE. Neovascular AMD occurs either below the RPE in its occult form or invades the neural retinal in its classic form. Choroidal NV (CNV) can wreak havoc through leakage into the intraretinal or vitreous spaces which acutely decreases visual acuity (Figure 1). Overtime, these NV membranes remodel into fibrotic scars that may still harbor abnormal vasculature and become sites of active NV recurrence.

3. *Diabetic retinopathy.* Diabetic retinopathy (DR) remains the primary cause of vision loss in patients aged less than 65 years. Hyperglycemia induces multiple microvascular abnormalities in the retina, eventually leading to retinal NV.
4. *Vaso-occlusive disease.* The retina receives dual blood supply with the central retinal artery feeding the inner layers and the choroidal vasculature feeding the outer layers, including the highly metabolic photoreceptor segments. Numerous pathologic processes can choke the retinal circulation, including atherosclerosis, vasculitis, thrombosis, and emboli. Retinal venous outflow is through the central retinal vein which is also at risk for collapse, stasis, or thrombosis. Choroidal venous flow exits through the vortex veins where thrombus may also form, albeit in a less-dramatic presentation than the central retinal vein occlusion. Another vascular disease that can trigger massive retinal ischemic injury is giant-cell arteritis, an inflammatory disorder that can occlude the central retinal artery. Ischemic damage to the retina is irreversible approximately 90–100 min after initial insult and can result in a widespread neovascular response in the retina, iris, and angle. These sequelae are the leading causes of enucleation after such catastrophic vascular events in the eye.
5. *Choroidal disease.* Histoplasma capsulatum is a fungal organism endemic to the Ohio and Mississippi river valleys that infects the choroidal tissue and causes localized areas of subretinal NV, which eventually scar over with RPE and glial cells. The organism is rarely isolated; however, patients often show a positive skin-allergy test thus earning this condition the title of presumed ocular histoplasmosis (POHS). Choroidopathies are a group of rare disorders that affect the tissues around the RPE due to either immune dysregulation or infectious disease, most often associated with nematode invasion. Although it is difficult to discern among the different forms of choroidopathy, several of them may lead to the formation of CNV. Multifocal choroiditis (MFC), multiple evanescent white-dot syndrome (MEWDS), bird-shot choroidopathy, serpiginous choroidopathy, and diffuse unilateral subacute neuroretinitis (DUSN) have all been associated with NV, hypothesized to be secondary to inflammation or immune dysregulation.
6. *Cryogenic injury.* Cryotherapy is a widely used treatment modality in vitreoretinal surgery to seal peripheral retinal tears in order to prevent rhegmatogenous retinal detachments. It is also used in combination with scleral buckling to destroy large areas of ischemic retina in order to prevent further NV. In some instances, cryotherapy itself can lead to subretinal NV.
7. *Laser-induced injury.* The use of laser photocoagulation for targeted retinal injury in the treatment of extrafoveal NV and proliferative DR has been widely used with success for several decades. In the treatment of CNV, focal laser injury is able to inhibit growth and decrease leakage from abnormal microvasculature. With panretinal photocoagulation, laser is used to ablate large swaths of the peripheral retina in DR that would otherwise be ischemic, producing proangiogenic factors. It is through the destruction of this pathologic tissue, that NV is spared in the precious visual real estate in the macula. Laser-injured tissues will commonly

remodel into small areas of RPE hyperpigmentation with fibrosis and only go on to develop CNV when high-energy laser photocoagulation is able to break through Bruch's membrane. It is critical to note that laser-induced injury which fractures Bruch's membrane serves as a very well-described animal model of CNV in many different laboratory animals, which is addressed in the following section.

Animal Models of NV after Laser-Induced Injury

In order to study the natural history of injury-induced NV *in vivo,* several experimental models have been developed to mimic the disease process which occurs in humans. Over 25 years ago, Stephen Ryan described a laser-induced injury model of subretinal NV in rhesus monkeys. The same technology has since been used to develop similar models in a variety of research animals, including the mouse. In this model, laser photocoagulation is used to fracture Bruch's membrane, which results in the formation of CNV (**Figure 2**). The laser-induced model captures many of the important features of the human condition including: migration of choroidal endothelial cells into the subretinal space via defects in Bruch's membrane (**Figure 3**), accumulation of subretinal fluid, congregation of leukocytes adjacent to neovascular tufts, gliosis (**Figure 4**), leakage of fluorescein from immature new vessels into the subretinal space, and increased expression of angiogenic growth factors and their receptors in cells and ocular tissues. The cellular and molecular details of retinal injury and repair are discussed below.

Acute Responses to Retinal Injury

Blood–Retina Barrier Breakdown

In a normal uninjured retina, the blood–retina barrier (BRB), comprised of RPE and retinal endothelial cell tight junctions, serves to prevent the influx of circulating proinflammatory cells and proteins where their presence and actions would compromise vision; however, in animal models of high-energy laser injury, there is an immediate disruption in the neural retinal, RPE tight junctions, and Bruch's membrane, leading to BRB breakdown.

Acute Release of Cytokines

With laser injury, thousands of retinal and RPE cells suffer instantaneous thermal damage or death and disperse their intracellular contents into the interstitium. Many pro- and antiangiogenic cytokines which are harbored in cytoplasmic granules are immediately released

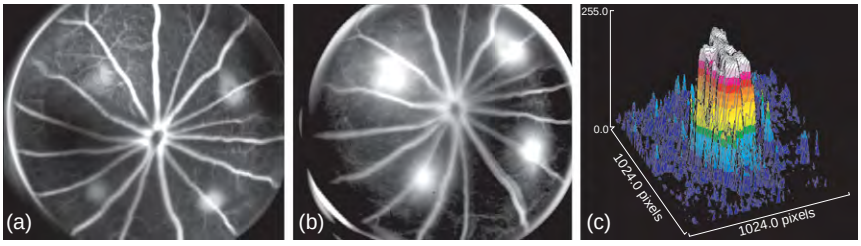

Figure 2 The mouse model of retina injury with laser photocoagulation. (a) An early time-point fundus fluorescein angiogram 7 days after laser injury of the retina, RPE, and Bruch's membrane showing hyperfluorescent hot spots. (b) Later time-point fluorescein angiogram of the same mouse eye exhibiting significant vascular leakage similar to the human form of CNV. (c) Vascular volumetrics and surface mapping reveal the size and shape of the CNV lesion in an important animal model that allows for scientific exploration into the molecular mediators of this process.

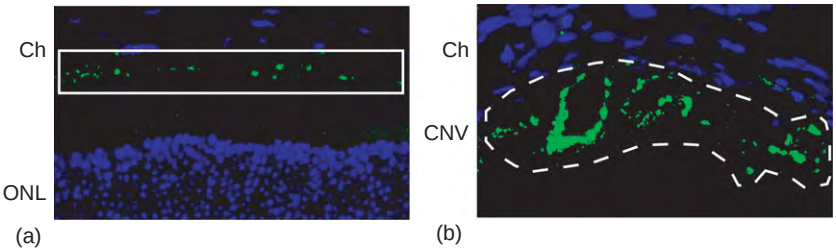

Figure 3 Choroidal vasculature before and after laser injury. (a) In the normal eye, the choroidal vasculature is organized into an extensive capillary network, the choriocapillaris, which exists in a single tissue plane below Bruch's membrane (white box encloses normal mouse choriocapillaris with vasculature appearing green). (b) After laser injury, the vasculature invades the retina where it grows into leaky neovascular membranes (dashed-line marks area of CNV formation 7 days after laser injury of the fundus).

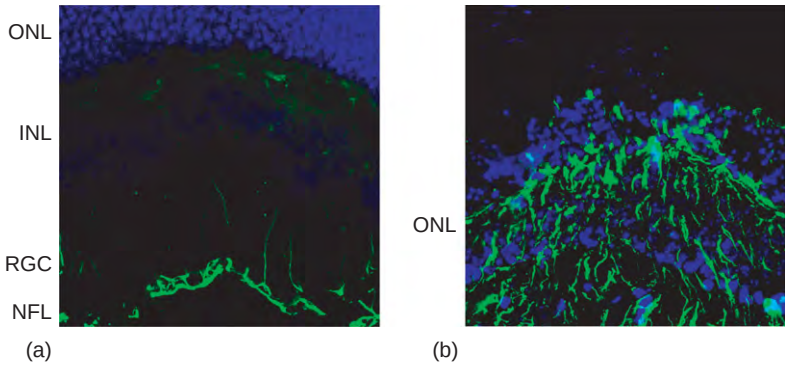

Figure 4 The participation of neural-retina derived cells to CNV pathogenesis. (a) Glial cells (retinal astrocytes shown here with glial-fibrillary acid protein (GFAP)) in green are located in well-demarcated areas of the un-injured neural retina. (b) Upon injury, glial cells migrate to areas of wound healing and proliferate along with endothelial cells while providing both structural and growth-factor support.

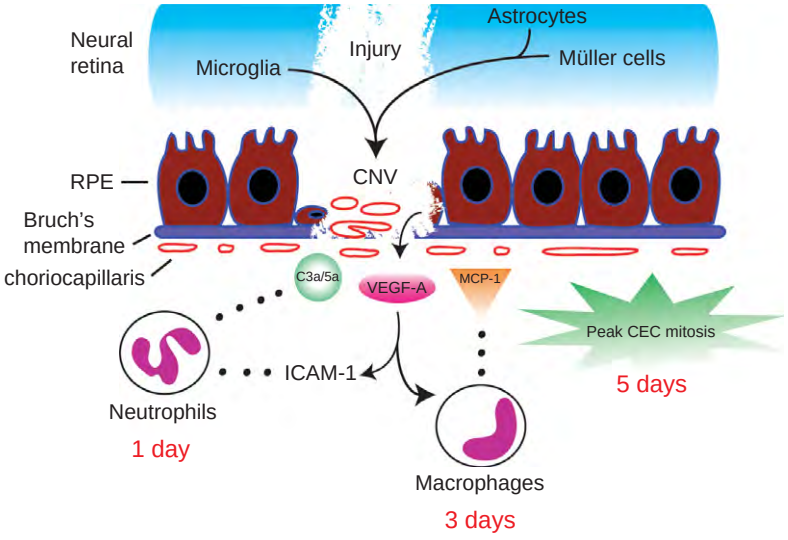

Figure 5 Critical mediators in CNV formation after acute and chronic injury. The initiating step of CNV is often an injury or disease process that induces local inflammation in the retina, RPE, and choroid. Locally produced leukocyte chemoattractants and provascular growth factors are secreted in the wound bed resulting in peak neutrophil infiltration at 1 day, maximal macrophage influx at 3 days, and a spike in choroidal endothelial cell proliferation at 5 days.

inducing the influx of circulating leukocytes into the retinal tissues (Figure 5). There is a paucity of evidence on which resident cells are the sources of these cytokines. RPE cells constitutively produce a wide array of cytokines that are usually secreted in a polarized fashion either toward choriocapillaris or the photoreceptor layer to maintain their relative functions. For example, pigment-epithelium-derived factor (PEDF), a potent antiangiogenic mediator, is secreted from the apical RPE surface toward the photoreceptor layer, while vascular endothelial growth factor-A (VEGF-A), a predominant proangiogenic cytokine, is secreted from the basal RPE toward the choriocapillaris. With injury, this directionality is lost allowing for the disinhibition of angiogenesis in normally avascular tissue planes.

VEGF-A belongs to the highly conserved platelet-derived growth factor (PDGF) family along with several other related proteins that constitute the VEGF subfamily, including placental growth factor (PlGF), VEGF-B, VEGF-C, and VEGF-D. For nomenclature purposes, the original VEGF protein was designated VEGF-A. Multiple isoforms of VEGF-A exist due to alternative splicing of the *Vegfa* gene; however, the 165-amino-acid variant in humans ($VEGF\text{-}A_{165}$) is the most potent and prevalent among the major isoforms expressed during pathologic NV. Many other important components within the VEGF family contribute to injury-related NV. Several genes important in VEGF regulation and activation, such as the coreceptors neuropilin-1 and-2 as well as PlGF, are

acutely upregulated in the setting of laser injury and in some forms of human subretinal NV.

An acute elevation of VEGF-A released from various resident cells types, including RPE, microglia, Müller cells, and retinal astrocytes, transiently induces vascular permeability and upregulates endothelial cell expression of intercellular adhesion molecule (ICAM)-1. In response, there is a marked leukocytosis of injured tissues within 24 h. Resident cells also spew monocyte-chemoattractant protein (MCP)-1 into the wound matrix which acts as a homing device for circulating monocytes expressing its cognate receptor (CCR2). Interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α), and interleukin-6 (IL-6), all potent cytokines that sequester a wide range of inflammatory cells and induce their proliferation, are increased within 24 h of injury. IL-6 is instrumental in promoting continued expression of VEGF-A, ICAM-1, and MCP-1, which regulate the specific sequence of leukocyte chemotaxis that occurs over the initial 72 h after injury.

Injury-Induced Complement Activation

Complement factors are also a major participant in the robust and rapid retinal tissue response to injury. The complement pathways are comprised of multiple, complex, domino-like cascades engineered to generate massive pro-inflammatory induction through cytokine expression and leukocyte invasion in addition to promoting the self-assembly of molecular components that are capable of directly lysing bacteria and virus-infected cells. The two main active byproducts of complement activation, C3a and C5a, are predominantly responsible for the anaphylactic response. After laser injury, C3a and C5a levels are selectively and swiftly increased in the RPE and choroid within 4 h after photocoagulation with peak concentrations at 12 h. With blockade of C3a and C5a, as in mice that are deficient in C3a or C5a receptors, VEGF-A production is downregulated which may also inhibit leukocyte trafficking. Functional blockade of complement activation may be a valuable preventative therapy to arrest NV progression in patients with retinal disease and injury.

Other Angiogenic Mediators in the Retinal Response to Injury

Several other molecular factors have been implicated in the development of injury-induced NV through descriptive expression analyses in human specimens, including transforming growth factor-beta 1(TGF-β1), PDGF, fibroblast growth factor-2 (FGF-2), insulin-like growth factor-1 (IGF-1), and estrogen. Hepatocyte growth factor (HGF) is produced by RPE, upregulated as early as 6 h after laser injury, and hypothesized to mediate RPE proliferation during tissue repair.

Endogenous antiangiogenic molecules have also been identified such as PEDF and thrombospondin-1 that are decreased in CNV lesions and are capable of regulating NV responses in animal studies. These factors provide yet another level of control in this increasingly complex system of vascular regulation.

Modulation of the Extracellular Matrix

The biologic activities of VEGF-A and other cytokines, which acutely increased after injury, are influenced by the myriad of interactions between cells and the extracellular matrix (ECM). ECM proteins transmit cell–ECM communication and modulate tissue-remodeling events including NV. CNV membranes contain an abundance of ECM proteins similar to those found in granulation tissue during epithelial wound healing. Fibrin, fibronectin, and integrin receptors, all of which are important in ECM-guided angiogenesis, are present in surgically excised CNV membranes. The pathogenesis of injury-induced NV requires invasion of pre-existing ECM and the formation of new vascular conduits (**Figure 6**). Matrix metalloproteinases (MMP-2 and 9), which are capable of ECM dissolution, are upregulated in the acute-phase response. Tissue inhibitors of MMPs (TIMPs), which prevent excessive degradation of ECM by MMPs, are also expressed in CNV membranes thus offering a novel therapeutic target. Another proteinase mechanism, known to be involved in CNV progression, is the urokinase plasminogen activator pathway which is also being evaluated as an alternative treatment modality for pathologic NV.

More recently characterized ECM proteins may also be involved in VEGF-A signaling and NV response after injury. The matricellular protein SPARC (secreted protein, acidic, and rich in cysteine) is involved in tissue remodeling, cellular migration, and angiogenesis through its interaction with VEGF-A. After injury, SPARC expression is acutely decreased thus allowing VEGF-A to activate VEGFR-2 inducing endothelial cell proliferation and migration. In a paradoxical molecular mechanism, intravitreous administration of VEGF-A is able to suppress CNV when delivered after laser injury, whereas VEGF-A treatment prior to laser injury expectedly augments pro-angiogenic tissue response. These data may help improve our understanding of VEGF-A duality in NV induction and enhance the timing of administration of our targeted therapeutics to suppress this unwanted growth.

Cellular Response in Injury-Induced NV

Similar to epithelial wound healing, retinal injury is succeeded by an orchestrated arrival of various inflammatory cell types, a process that is determined by the acute response to injury discussed above. From other

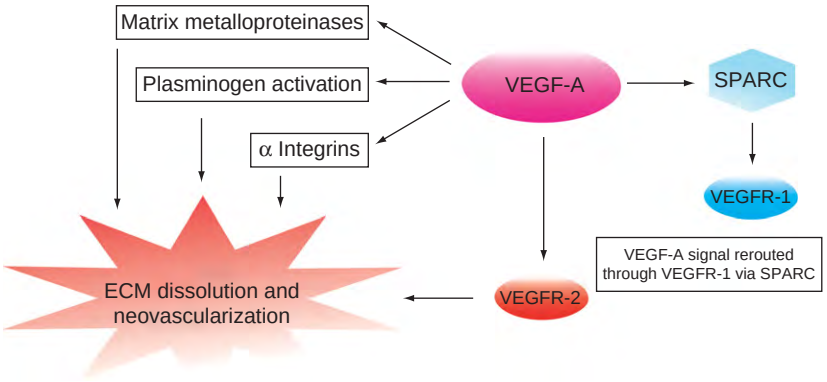

Figure 6 Modulation of the ECM with injury and VEGF-A upregulation. VEGF-A is a major factor in the pathogenesis of CNV through its direct effects on endothelial cell proliferation and modulation of the extracellular matrix. Integrins, plasminogen factors, and MMPs are all upregulated in response to VEGF-A contributing to ECM degradation that promotes neovascular invasion. VEGF-A is also able to curb the endothelial cell responses through its interaction with SPARC which reroutes signal transduction away from the proangiogenic pathways of VEGFR-2 to the nonproliferative cellular pathways of VEGFR-1.

wound-healing studies, it is known that inflammatory cell recruitment is directed by the expression of cytokines such as MCP-1, GROα (also known as CXCL1), and macrophage inflammatory protein-1α and-2 (MIP-1α, MIP-2). Many of these counterparts have been shown to be involved in NV progression in retinal injury.

Neutrophils

With breakdown of the BRB and acute VEGF-A-driven expression of ICAM-1 on the retinal and choroidal endothelia, there is an immediate and rampant neutrophil extravasation into the injured tissues which is maximal at 24 h. In addition to C5a, acute elevations in IL-1β and TNF-α may upregulate interleukin-8 (IL-8) which also acts as a potent neutrophil chemoattractant. These cells serve as a potent proinflammatory stimulus by secreting more VEGF-A along with numerous proangiogenic cytokines into the wound. Moreover, neutrophils are capable of engulfing invading pathogens and destroying them through the release of hypochlorous acid. Without neutrophil participation in wound healing, there is only a partial abrogation of the NV response to laser injury.

Macrophages

The next major influx of circulating proinflammatory leukocytes is the macrophage, which is driven by the enhanced expression of MCP-1 that peaks at 2 days after injury. These professional inflammatory cells home to sites of increased MCP-1 gradients through the expression of its cognate receptor, CCR2. This signaling axis is responsible for maximal macrophage infiltration into the choroid at 3 days post injury. Macrophages are able to respond to the proinflammatory milieu of vascular growth factors and secrete even more VEGF-A in order to aid revascularization and tissue repair. After the arrival of macrophages, endothelial cells continue to increase their mitotic activity with peak proliferation at 5 days post injury. Approximately 1 week after injury, organized subretinal NV membranes are formed, which can be visualized *in vivo* with fluorescein angiography. Without macrophage influx, the ability of laser-injured areas to fully develop CNV is completely eliminated signifying the critical importance of this infiltrating cell in injury-induced NV.

Progenitor/Stem Cells

Pluripotent stem/progenitor cells are also recruited to sites of NV during injury and repair and incorporate into pathologic vasculature. Animal studies have now demonstrated that interfering with stem/progenitor cell homing to the sites of CNV through the modulation of the hypoxia responsive cytokine stromal-derived factor (SDF)-1α and its receptor, CXCR4, inhibits neovascular growth, a finding that offers another potential treatment for the human condition.

Other Infiltrating Cell Types

Although mast cells and eosinophils are able to generate significant proinflammatory stimuli, their contribution to injury-induced NV in the retina is believed to be negligible. B- and T-lymphocytes as well as natural killer cells are also able to infiltrate retina injuries, yet their particular effects and contribution to NV are still unclear but likely to be negligible.

Resident Tissue Cells

Among the resident cells of the retinal, RPE, and choroidal tissues that are involved in injury-induced NV, the

effects of RPE cells, microglia, retinal astrocytes, and Müller cells are the most evident.

Microglia

Microglial cells are tissue macrophages dispersed throughout the normal retina, choroid, and central nervous system. Their primary functions are to respond to the local invasion of pathogens through activation of the innate immune system, promotion of inflammation, and phagocytosis of bacteria and virus-laden cells. Microglia express a unique set of surface markers, as well as the chemokine receptor CX3CR1 which binds to fractalkine (or CX3CL1), a cytokine that is secreted preferentially by inflamed retinal and endothelial cells. CX3CR1 is present on a number of differentiated cell types derived from myeloid progenitor cells, such as dendritic cells, infiltrating macrophages, neutrophils, and some endothelial cells, thus providing another signaling axis for the infiltration of professional inflammatory cells after laser injury.

As part of their immune-surveillance capabilities, microglia express a series of innate immune receptors, called toll-like receptors (TLRs), that recognize pathogen-associated molecular patterns and respond by alarming other immune system components, mediating cellular infiltration, and selectively inducing apoptosis to prevent infectious spread. Several TLRs, including TLR 2–9, all of which are expressed on microglia, are likely to be involved in modulating angiogenesis in the setting of injury, thus creating a significant link between the innate immune response and NV. This immunovascular phenomenon is an area of great interest at this time given the strong evidence that several neovascular-related diseases, including AMD, may be driven by immune-system activation.

VEGF-A, once thought to be a pure vascular mediator, has been discovered to impart significant cellular effects on neural cells including microglia. Similar to blood-derived macrophages, microglia express VEGF receptor-1 (VEGFR-1) enabling their migration toward areas of VEGF-A production. With injury, microglia switch from their quiescent state to become activated, demonstrated by increased cytokine secretion, immune receptor expression, and proliferation.

Retinal astrocytes

Activated microglia may also initiate the reparative process by inducing the chemotaxis and proliferation of retinal astrocytes through TGF-β1, IL-1β, and TNF-α. Unlike microglia, astrocytes may be far more robust in the promotion of immune-mediated inflammation and contribution to glial scarification after retinal injury.

Müller cells

Müller cells are specialized glia that provide structural and trophic support, among numerous other functions, in the retina. In the setting of injury, Müller cells are able to proliferate and dedifferentiate into progenitor-like cells thus providing a potential source for retinal regeneration. Whereas some vertebrates (avian, amphibian, and fish) have been found to demonstrate such reparative potential, there is still controversial evidence on whether Müller cells of the mammalian retina are capable of this phenomenon.

Cellular Responses to VEGF-A Receptor Binding

VEGF-A is a multifaceted cytokine that influences multiple endothelial cell pathways promoting growth, survival, and vascular permeability. Its signal transduction is mediated primarily through two receptor tyrosine kinases, VEGFR-1 and VEGFR-2; however, the latter is implicated as the principal proangiogenic transducer. Both VEGFR-1 and R-2 are expressed in normal human eyes and surgically excised CNV membranes. There is a continuing controversy on the role of VEGFR-1 as a decoy receptor designed to sequester free VEGF-A and prevent excessive VEGFR-2 activation. In multiple models of injury-induced NV, VEGFR-1 has been shown to function bilaterally as both a pro- and antivascular mediator. Importantly, it does not appear that VEGFR-1 does this by simply serving as a decoy, as VEGFR-1 can repress VEGFR-2 mediated endothelial cell proliferation through active signaling after retinal injury. Thus, VEGF-A may possess the ability to function dichotomously in both pro- and anti-angiogenic capacities.

Conclusion

NV in the context of injury and repair is designed to aid the healing process, but, in the fragile and transparent cellular layers of the retina, it wreaks havoc on neural function and visual acuity. Several decades of dedicated molecular science and centuries of clinical observations have yielded an exhaustive foundation of knowledge that has significantly improved our understanding of injury-induced blood vessel growth. These mechanisms are currently being elucidated with such resolution and speed that a detailed molecular map of this disease process may be within our reach in the near future. More importantly, the work has been a tremendous benefit to society, as several targeted therapeutics are now available to the millions of people around the world suffering from neovascular diseases. It is our hope that scientific investigation of the unique biologic responses to retinal injury will continue to reveal critical facets in vasomolecular medicine both in the eye and elsewhere that will aid in the design of advanced therapeutics.

Injury and Repair: Prostheses

G J Chader, A Horsager, J Weiland, and M S Humayun*, USC School of Medicine, Los Angeles, CA, USA

Glossary

Age-related macular degeneration (AMD) – Retinal degeneration, primarily in the macula that is prevalent in the aging population.
Bare light perception (BLP) – A high level of visual loss but retaining light perception.
Lateral geniculate nucleus (LGN) – One of the central visual areas within the central nervous system.
No light perception (NLP) – A complete lack of visual sensation.
Phosphene – A phenomenon characterized by the experience of seeing light without light entering the eye.
Retinal degenerative diseases (RDDs) – A general term referring to many different types of diseases in which photoreception is lost mainly due to photoreceptor degeneration.
Retinotopy – The spatial organization of the neuronal responses to visual stimuli.
Retinitis pigmentosa (RP) – Retinal degeneration, primarily affecting rod photoreceptor cells starting in the retinal periphery.

Rationale for a Prosthetic Device

The idea of stimulating a portion of the central nervous system (CNS) to elicit formed vision is not new. The need to do this is particularly evident in the case of retinal degenerative diseases (RDDs) in which the retinal photoreceptor cells degenerate and die. The RDD family of diseases has two main branches: retinitis pigmentosa (RP) and macular degeneration (MD). RP primarily affects rod photoreceptor cells, leading initially to loss of dim-light and peripheral vision. It usually is early onset, leaving otherwise normal subjects blind or with severely affected vision for life. RP is thought of as a rare disease with a prevalence of approximately 1:3400 around the world. The MD branch primarily affects cone photoreceptors, degrading central and sharp vision. The most common form of MD, age-related macular degeneration (AMD), strikes later in life (usually >60 years of age), but affects millions around the world. In these diseases, although photoreceptors cells degenerate and ultimately can be lost, other layers of the retina are not as severely affected and remain relatively intact for some time thereafter. Thus, there is a window of opportunity for replacing photoreceptor function with a prosthetic device that will capture visual images, electronically transfer these to remaining secondary neurons of the retina, with subsequent passage to the brain. However, much of the visual processing takes place in the brain so it may be possible to bypass the eye completely with a visual image transmitted directly to vision-processing areas of the brain such as the visual cortex. Both of these approaches have been studied for decades now with the ultimate goal of sight restoration not only in cases of RDD but even when the entire eye has been lost. In fact, each separate anatomical portion of the visual system, such as the retina, the optic nerve, the lateral geniculate nucleus (LGN) of the thalamus, and the primary visual cortex (V1), has been used as a target in attempts at producing visual images.

Brain Prosthetic Devices

In 1962, Brindley found that application of stimulating pulse trains to his own eye with a corneal electrode interfered with visual light stimulation. This established at least the possibility of direct electrical stimulation of the retina. In 1968, Brindley and Lewin first reported on the use of platinum disk electrodes to stimulate the occipital pole of a subject and elicit independent visual percepts. Dr. William Dobelle followed, starting in about 1974, implanting blind subjects with electrodes mainly over the surface of the visual cortex and evaluating phosphene maps, which represent vision without light actually entering the eye. Although neither the pioneering studies of Brindley nor Dobelle were able to yield a useful, commercial visual prosthetic device, they did establish that phosphenes could be evoked by current pulses from an electrode array and that smaller stimulating electrodes would probably be needed to allow for more focal stimulation of cortex neurons. This led to the fabrication of novel, small, high-density arrays made of biocompatible silicon capable of penetrating the cortex (e.g., the work by Wise et al.). About this time, the National Institutes of Health actively developed a group dedicated to stimulating the primary visual cortex (area VI) using fine-wire electrodes in the hope of sight restoration in blind subjects. Since then, a number of groups (Normann et al. Hambrecht et al., Troyk et al., etc.) have continued to develop a cortical prosthesis. In most of this work, a video

camera is used to capture a visual image, which, through a processor, delivers electrical signals to intracortical electrodes that finally deliver the image to the appropriate brain area(s). To date, this body of work has established that electrical stimulation of the visual cortex can produce phosphenes and that penetrating electrodes allow for the use of low, relatively safe levels of stimulation. The LGN can also be electrically stimulated to produce visual percepts. For example, Pezaris and Reed in 2007 demonstrated that either electrical or visual stimulation of specific receptive fields of the LGN results in highly localized and repeatable eye movements in a nonhuman primate.

Unfortunately, the field of electrical stimulation of brain areas to produce formed vision has only slowly advanced in the last few years. There are currently only a few investigators doing basic research in the area, perhaps because of difficulties in continuing human testing and moving to *bona fide* clinical trials. In contrast, work on retinal prosthetic devices has proceeded briskly, with many groups around the world applying unique concepts and designs in human testing.

Retinal Prosthetic Devices

As the optic nerve is a bundle of ganglion cell axons, it rightfully can be considered as an extension of the neural retina. Optic nerve stimulation became feasible after the development of cuff electrodes for nerve fiber recordings by Hoffer and collaborators in the 1980s. Since then, several groups have demonstrated that such electrodes are effective in generating visual percepts in the blind. A problem with this approach though is that the optic nerve does not maintain spatial organization (retinotopy), making spatial mapping of the stimulus difficult. In the 1950s, a US patent was issued describing the insertion of a light-sensitive selenium cell behind the retina and the subsequent transient restoration of light perception. It was not until the 1990s though that the investigators demonstrated that there were enough inner neurons remaining in the retina of RP patients to warrant prosthesis implantation. Work by Milam, Humayun, and co-workers, for example, reported that about 30% of the ganglion cells remained in advanced RP retinas and an even larger proportion of cells in the inner nuclear layer. Similar studies on eyes procured from AMD patients revealed that both the ganglion cell layer and the inner nuclear layer were relatively well preserved. Thus, in both diseases, enough cells remain such that they can act as a platform for the array and could perhaps adequately transmit an electronic stimulus to the brain. In 1993, the first report was presented by Humayun and colleagues that direct electrical stimulation of the retinal surface could produce visual percepts in a blind human subject. In this case, a man with advanced RP, essentially no light perception (NLP), was able to perceive a spot of light with the temporary electrical stimulation. At that time, many other groups were working in parallel to develop other versions of the retinal prosthetic device – some intraocular, some extraocular.

All these approaches have different pros and cons, both with respect to efficacy and safety. For example, in the extraocular approach, one major hurdle is the relatively large distance between the electrodes and the retina. Chowdhury and co-workers though have presented evidence in an animal model that electrodes placed on the exterior surface of the eye can, in fact, stimulate the retina, evoking responses from the visual cortex. Tano and co-workers have shown that suprachoroidal–transretinal stimulation (with the anode in the fenestrated sclera and the cathode in the vitreous) is able to elicit excitatory electrical potentials (EEPs) from the visual cortex. Within the eye, electronic arrays have been implanted either in the subretinal or epiretinal positions. Subretinal positioning, as used by Zrenner et al., Rizzo and Wyatt, Chow et al., etc., is logical since the array is in the natural position of the lost photoreceptors. This juxtapositioning of the array to the bipolar cells could theoretically maximize the computational processing of the retinal circuitry but could be made difficult or impossible by lack of fidelity of the bipolar–ganglion cell synapse. There is also growing evidence for a substantial gliotic wall in the RDD subretinal space that could effectively limit the signaling from the subretinal implant to the overlying neurons. As shown by Marc in cases of severe RDD, the outer retina (bipolar, horizontal, and, to some extent, amacrine cells) undergoes marked reorganization, altering the synapses, and hence making the approach of stimulating bipolar cells more challenging. In addition, surgical placement of the array in the subretinal space is technically more difficult than placement on the vitreal surface. In epiretinal placement, that is, on the vitreal side, surgery is easier as well as access of the array to other components of the device. In patients, it is not known in either the epiretinal or subretinal situations which cell type or types are stimulated and react to the electrical signal. The epiretinal approach, because it is closer to the ganglion cells, has the theoretical advantage of stimulating this layer with lower currents. This is a distinct advantage since this layer does not undergo as significant a reorganization process in end-stage RDD.

Along with position on the retina, power output is an important consideration. Too little and the device might not be effective; too much could induce pathological changes in addition to an already compromised retina. A possible example of the dangers of too small of a power output is the case of the artificial silicon retina (ASR). In this case, Chow and co-workers used passive photosensitive diode arrays powered by only ambient light within the eye. Specifically, the 2-mm diameter ASR contained 5000 microelectrode-tipped microphotodiodes for light-energy processing with no external power supply. In spite of initial positive reports

from a clinical trial that the ASR could improve vision in a number of implanted RP patients, it was subsequently found by Chow, Pardue, and co-workers that the device itself was ineffective and that the improvement in vision probably resulted from a more generalized neurotrophic effect (i.e., release of neuron-survival factors) due to implantation of the device – active or nonactive. Failure of the ASR led others, such as Zrenner et al. and Palanker et al., to use microelectronics to power subretinal devices. In comparison, the epiretinal devices include radio-frequency (RF) power transmission for wireless operation of the implants.

Clinical Trials

The main clinical indication and usefulness of retinal prosthetic devices as discussed above will be to patients with inherited photoreceptor degenerations such as RP and, ultimately, AMD. Although other forms of therapy are now being considered for these diseases, the electronic prosthetic device should be useful in situations where other proposed therapies are not applicable. Current studies on gene therapy, for example, in specific types of RP such as Leber's congenital amaurosis, seem to be successful, but gene replacement therapy will only be useful if the specific gene mutation is known, and if a sufficient number of viable photoreceptor cells are present to allow for a visual response after therapy. Similarly, pharmaceutical therapy, that is, the use of neurotrophic agents and nutritional therapy, for example, the use of antioxidants, will only be possible if photoreceptors are yet present. In the case where few or no photoreceptors remain, photoreceptor cell transplantation or stem cell transplantation could certainly replenish the photoreceptor layer. However, studies on direct photoreceptor transplantation have yet to show significant functional efficacy and studies on stem cell development into mature photoreceptor neurons have yet to demonstrate safety and efficacy. Thus, to many RDD patients, particularly those with severe or advanced photoreceptor degeneration, the retinal electronic prosthesis could be the best hope for sight restoration.

Many groups around the world are working on prosthetic devices – including Japan, Belgium, Korea, Australia, China, Germany, and the USA – too many to cover in any detail in the current article. Only a few groups of the many excellent approaches have progressed to the stage of intensive human testing. To do this, most of the basic science groups have become associated with companies who provide critical functions such as manufacturing and quality control as well as regulatory expertise. The Zrenner group, for example, works with Retina Implant AG, a second group with Intelligent Medical Implants GmbH (IMI), and a third with Epi-Ret GmbH. In the USA, the Humayun consortium has worked with the company, Second Sight Medical Products Inc. (SSMP), to establish a Food and Drug Administration (FDA)-approved clinical trial with retinal arrays chronically implanted in RP patients.

In the subretinal approach taken by Zrenner and Retina Implant AG, an external energy source is used along with a microphotodiode array (about 3 mm in diameter containing 1600 microphotodiodes) that is implanted in the subretinal space. Experiments on animal models of inherited retinal degeneration have shown that ganglion cells are indeed stimulated by this device. Cortical evoked potentials could also be recorded in some of the animal experiments. Based on these positive preclinical findings, Retinal Implants AG has proceeded to human testing, first studying the short-term effects of the implant in RP patients. More recently, a prospective, open pilot clinical trial has been initiated with the subretinal implant and functional placebo controls. Eligible participants must have inherited retinal degeneration, be blind in at least one eye, or have visual function not compatible with navigation and orientation. The primary outcome is a measure of activities of daily living and orientation as well as safety. Latest information indicates that Retina Implants AG has implanted eight subjects for 4 weeks to date in their trial (clinicaltrials.gov identifier: NCT00515814). IMI GmbH has reported on four subjects with an epiretinal array of 49 electrodes designed to be functional for 18 months (clinicaltrials.gov identifier: NCT00427180). A 25-electrode array, EPI RET3, was implanted for 4 weeks in six subjects (clinical trial identifier: DE/CA21/A07). Finally, SSMP has conducted a long-term trial with a 16-electrode array (clinicaltrials.gov identifier: NCT00279500) and a more recent study with a 60-electrode array (clinicaltrials.gov identifier: NCT000407602).

Due to space limitations, this article will mainly focus on the SSMP effort and its clinical trial as an example of progress with retinal prosthetic devices. In addition, many of the early results from the SSMP trial have been reported and are clearly documented in the scientific literature. Finally, testing of the SSMP device has been continuous since 2002 in specific patients who have not only had regular laboratory testing but also have been able to use the device at home for direct assessment of quality-of-life (QOL) improvements. The approach taken by Humayun and co-workers has been epiretinal with the electrode array tacked on to the vitreal surface of the retina. Work initially started with studies on animal models of inherited retinal degeneration. These studies demonstrated no major problems in terms of inflammation, neovascularization, or encapsulation of the device. These positive safety studies allowed for short-term human testing where electrodes were temporarily juxtaposed to the retina of subjects with advanced RP and activated to ascertain if phosphenes were elicited. Results were positive in that appropriate phosphene signals were reported by the subjects. Since safety was also apparent in these acute studies, more

chronic implantation in the formal setting of a feasibility clinical trial was allowed by the FDA in 2002. The first-generation device used in the trial was called the Argus I; it had 16 electrodes affixed to the retina. Patients who had outer retinal degenerative diseases with a preoperative vision of bare light perception or worse and a nonrecordable electroretinogram (ERG) were chosen. The entire device is complex, with many interacting components that are the result of new technology modified from the cochlear implant. Functionally, the device has an external system that includes a tiny, lightweight video camera housed in the subject's glasses. This allows for image capture and initial processing. Image and power data are sent to the array using RF wireless transfer through a transmitter coil. The microelectronic implant is under the skin on the temporal bone behind the ear. A cable is threaded under the skin toward the orbit and around the eye under the rectus muscles. Once entering the eye through a sclerotomy, it is connected to the array, which is tacked to the retinal surface. The Argus 1 array has 16 platinum electrodes in a 4×4 arrangement within a silicone platform. The array is implanted in the macular region and is approximately 2.0×2.9 mm. It subtends an approximate 10° of visual angle with 14° on the diagonal.

Starting in 2002, six subjects were implanted with the Argus 1 device in the SSMP-sponsored feasibility clinical trial. The results were promising, in that safety was observed both for the subject and the device. No device failures were encountered, and no significant sequelae of the implantation were observed in the subjects. Because the device can be independently monitored and controlled (i.e., through the head-worn video camera or by custom software on a laptop computer), testing continues to date. Valuable longitudinal data have been obtained from this initial study. For example, although not surprising, it was found that the impedance and threshold values were inversely proportional to the distance of the electrode array from the retinal surface and that most of the electrodes had stimulatory thresholds below the safe charge injection limit. Importantly, subjects could spatially resolve the individual electrodes within the array with good resolution of the perceived locations of the elicited phosphenes, good two-point resolution, and good perception of motion direction. There was also a good correlation between percept brightness and stimulation level, demonstrating the ability of the implanted subjects to differentiate between different levels of illumination. Cortical responses were also evoked by the device. The electrically evoked responses (EERs) from the visual cortex are a primary measure of the possibility of functional vision. Most encouragingly, testing for object recognition showed that subjects with the use of the implant could differentiate between a cup, knife, and saucer. In mobility testing, patients could follow a line on the floor and identify and walk toward test doors. In the object recognition test, repeated testing gave scores significantly above chance, statistically at $P < 0.001$. Investigators at SSMP have also just concluded the first detailed study of spatial vision in an Argus I-implant patient definitively showing patterned visual perception with logMAR = 2.21, which is well matched to the sampling limit determined by the spacing of the electrodes. This provides strong evidence that it is possible for the brain to use the special information provided by individual electrodes. However, further testing is ongoing to understand the level of visual acuity obtainable with arrays that have more numerous or more closely spaced electrodes.

Testing of these subjects remains ongoing to determine if their QOL is enhanced, especially since they are able to use the devices at home while not under direct supervision. As might be expected though, differences between the performances of different subjects were observed. This could be based on differences in disease type and on the stage, that is, severity, of the degeneration in the individuals. Factors such as the site of implantation of the array and its proximity to the retinal surface must also be considered. All in all though, it is perhaps surprising that any functional efficacy is observed using the 16-pixel array. Theoretically, with such a simple array, only areas of light/dark should be discerned by the subjects, perhaps modified by shades of gray. That simple objects and letters can be identified though and mobility enhanced perhaps indicates that the brain can indeed make sense out of primitive signals and that, through a patient learning process, useful vision can indeed be restored.

Based on the positive results from both safety and efficacy in the feasibility portion of the trial, SSMP has initiated an international feasibility trial using a second-generation device, the Argus II. This new device has several improved designs, notably, an increased electrode count with up to 60+ electrodes on the retinal array. It also is much smaller than the first-generation device, allowing for an easier and shorter surgery procedure. Finally, as with the Argus I, the Argus II is designed to last the lifetime of the patient. Only severely affected RP patients are chosen to participate, with visual acuity and safety as the primary outcome measures. Secondary outcomes are improvements in orientation and mobility, activities of daily living, and general QOL. Early indications are that the Argus II device is safe (both to subject and device), although this certainly can only be properly assessed over a longer time period. Similarly, early data indicate that there is enhanced efficacy (i.e., improved vision). As alluded to above for the Argus I though, this does not come immediately and is a learning process over a period of months.

Challenges

Although the data presented above are encouraging, significant challenges yet remain in perfecting a prosthetic

device that will restore a high level of functional vision, be it epiretinal, subretinal, or one of the other approaches. For example, it will be important to determine the actual mechanism of action of the array, in particular, which populations of neurons are stimulated. In this way, the efficacy and efficiency of the device might be enhanced, irrespective of future design improvements. Another important area of future investigation must be directed at gaining a better understanding of the different pathologies and how the usefulness of the device is affected by the state of each individual retina. Although significant numbers on inner retinal neurons remain alive in cases of advanced retinal degeneration, neural remodeling takes place such that morphology is altered and synaptic contacts rearranged. Investigators such as Milam, Marc, and Strattoi have presented compelling evidence that inappropriate neurite sprouting takes place in remaining rod, horizontal, and amacrine cells, with abnormal contacts with both neuronal and glial (Müeller) cells. These changes, along with the appearance of a dense fibrotic layer in the subretinal space, could severely affect proper inner retinal cell processing and signal transmission down the optic nerve. The effects of electrical stimulation on the normal retina have been well studied, but the effects on retinas affected with an inherited retinal degeneration are just beginning to be examined. These effects will have to be better defined in different genetic forms of RD and at different stages of disease such that the electrical properties of the device can be tuned and adjusted to individual situations. Similarly, the state of central connections could be a problem, particularly in patients with long-term degeneration (i.e., no or bare light perception) and with patients with very-early-onset degeneration such as Leber's congenital amaurosis in which central connections may not even have been initially formed. All of these factors will vary considerably from subject to subject and will have to be individually assessed in each case. That a level of functional vision has been restored though in a number of older human subjects with severe retinal degeneration indicates that, at least in many cases, enough functional inner retinal neurons and their synaptic connections do remain, and the visual cortex remains functional enough to process the electrically derived information into discernable forms.

Issues of safety also remain, particularly with regard to long-term implants. There is yet the possibility of low-level but cumulative damage from both electrical and mechanical effects of array implantation. Too high an electrical input could not only grossly burn the retina but, more subtly, also induce an altered state of conductivity and responsiveness within the remaining retinal cells. In addition, as preclinical and clinical studies continue, the properties of the implant itself may need to be modified as to materials, size, and shape. On the positive side, implantation of the Argus I began in 2002 with testing continuing to date, giving several years of evidence for not only patient and device safety but also continuation of efficacy.

Future Prospects

From an engineering standpoint, one of the greatest challenges but most exciting prospects for the future is in the enhancement of vision through improved and more sophisticated electronics, for example, an increased number of electrodes impinging on the retina. Theoretically, an electrode count of 1000+ should allow for face recognition and reading ability, leading to a marked improvement in QOL and mainstreaming of patients back into society. With this type of improved function, retinal electronic prosthetic devices should thus be helpful not only to the relatively limited number of patients with RP but also to the millions with AMD.

There are several other obvious but diverse factors that can be studied that should lead to improved action of a retinal prosthesis. One of these would be to assure close and uniform proximity of the array to the retinal surface in the specific cases of epiretinal and subretinal implantation. A bioadhesive glue that is biocompatible and reversible would be useful in this regard, particularly in an epiretinal device. Another area of improvement could be the use of an intraocular rather than extraocular camera. This would allow for more natural object tracking, as the eye rather than the head moves. A third area of interest would be to increase the relatively narrow visual field of the implants currently under study such that peripheral vision is restored. Finally, could it be possible to restore color vision? The implant subjects to date do describe different colors, including blue, yellow, orange, and green. Although not important to most of the visual tasks we perform, colors do abundantly increase our appreciation of our environment and certainly increase QOL.

Injury and Repair: Retinal Remodeling

R E Marc, University of Utah, Salt Lake City, UT, USA

Glossary

Glial seal – A compaction of the distal microvillar processes of mature Müller cells and their stabilization by intermediate junction to form a barrier to diffusion and cellular movement.
Microneuromas – New, anomalous complexes of synapses by mature neurons.
Migration – The ability of a cell to relocate to a new position in a tissue. It is often thought that mature neurons cannot migrate without de-differentiating, but mature retinal neurons can migrate both intra- and extraretinally without losing their characteristic molecular profiles.
Neuritogenesis – The activation of new dendrites and axons from neurons; typically associated with developing cells, it is vigorously demonstrated by mature neurons in remodeling retinas.
Reprogramming – A major change in the gene expression profile of a cell, typically the expression of genes not characteristic of homeostasis.
Self-signaling – The ability of retinal networks to generate their own excitatory activity in the absence of a photoreceptor drive.

Overview

Retinal remodeling is a collection of molecular and cellular revisions triggered by primary inherited degenerative diseases such as retinitis pigmentosa (RP), Usher syndrome; secondary degenerative diseases with mixed environmental/genetic risks, such as age-related macular degeneration (AMD); and acquired retinal defects such as prolonged retinal detachment and light-induced retinal damage. These revisions include anomalous neuronal rewiring (targeting canonically inappropriate cells) and reprogramming (expressing canonically inappropriate genes or repressing characteristic genes); *de novo* neuritogenesis and synaptogenesis; spontaneous and corruptive self-signaling; bipolar cell (BC) dendrite truncation; supernumerary axon generation; neuronal migration along hypertrophic Müller cell (MC) columns; neuronal death; altered glial molecular profiles; vascular remodeling; and retinal pigmented epithelium (RPE) invasion, vascular occlusion, and hyperpigmentation. Some revisions (e.g., reprogramming) begin as soon as photoreceptor stress is initiated, while others (e.g., synaptogenesis) are manifest only after complete local photoreceptor loss. Importantly, the local survival of even heavily altered cones can prevent much late-stage remodeling, apparently by stabilizing the dendritic compartment of BCs. Remodeling impacts the timing and potential outcomes of gene therapy, survival factor treatments, stem or progenitor cell implantation, retinal transplantation, and bionic implants.

It was not until the detailed imaging studies of Ann Milam (University of Pennsylvania) in the mid-1990s that the nature and scope of remodeling in human RP became evident. More recently, Enrica Strettoi (Centre National de la Recherche Scientifique, Pisa, Italy) and Bryan W. Jones (University of Utah) independently demonstrated that remodeling was also characteristic of animal models of human inherited retinal degenerations. Though remodeling was not initially given much credence despite strong homology to central nervous system (CNS) degenerative disorders, it is now gaining understanding as a serious denouement of retinal disease.

Progression

Remodeling kinetics are largely independent of the source of photoreceptor deafferentation and occur in distinct phases (**Figure 1**). In phase 1, neuronal and glial cells react to photoreceptor stress signals prior to photoreceptor death. In phase 2, neurons, glia, and microglia interact in the processes of photoreceptor death, outer nuclear layer (ONL) decimation, and formation of the glial seal, encapsulating the remnant retina. In phase 3, neural cells respond to deafferentation and non-neural cells form new cytoarchitectures in the remnant retina. The speed of these phases depends on the nature of the degeneration (**Figure 2**). Aggressive primary rod, cone–rod, or cone dystrophies, as well as RPE phagocytosis defects can rapidly transit phases 1 and 2 to extensive phase 3 remodeling. Slower photoreceptor degenerations (e.g., autosomal-dominant RP (adRP) models of rhodopsin mutations) can lead to extended periods of cone survival, delaying the onset of phase 3. In rodent models, the faster overall kinetics are partly due to the small eye and the likely constancy of cell–cell interaction areas. Greater loss of peripheral retina is tolerated in humans as long as the macula is spared.

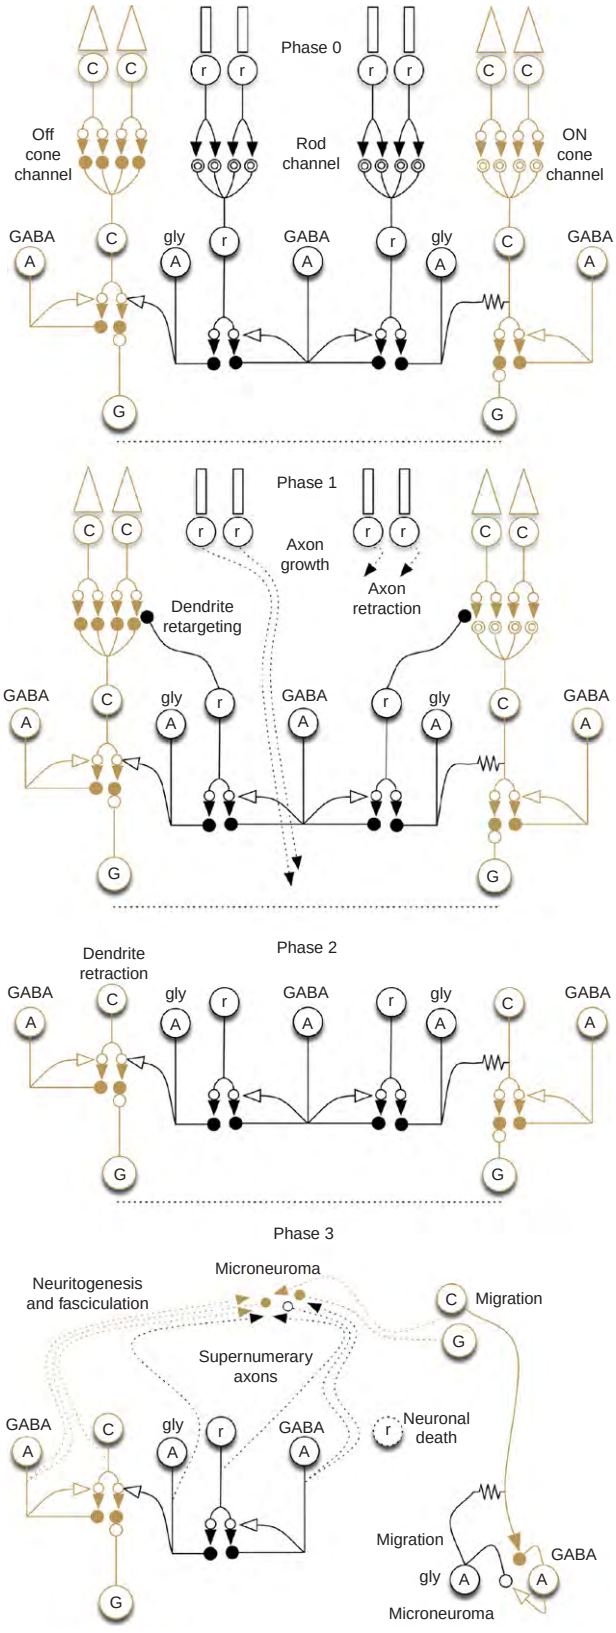

Figure 1 Remodeling phases in the mammalian retina. Phase 0 is the normal retina prior to the onset of acquired or inherited defect stress. The mammalian retina uses separate cone (C) and rod (r) channels prior to converging on retinal GCs (G).

Phase 1

The first evidence that remodeling precedes photoreceptor death was the demonstration that human rods harboring a rhodopsin defect were able to form new fascicles of axons, bypass their normal BC targets, and project into the ganglion cell (GC) layer prior to apoptotic stress and death. Some rodent model degenerations show the same ability. Furthermore, rodents with autosomal-recessive RP, such as the phosphodiesterase B 6 (*Pdeb6*^{rd1}) mouse (the rd1 mouse), show truncated BC dendritic arbors and horizontal cell (HC) axonal fields long before photoreceptor death. MC stress signals and protective alterations in neuronal glutamate receptor expression in light-induced retinal degeneration (LIRD) albino rodents are activated within hours of light-stress onset and long before photoreceptor death.

Phase 2

The degenerations transition to extensive cell-autonomous and/or bystander photoreceptor death. The ONL is dismantled with the involvement of activated microglia and hypertrophic MCs. The details are poorly understood and may vary according to gene defect. For example, dominant mutations that impair rhodopsin trafficking may activate endoplasmic reticulum (ER) stress in several ways such as anomalous protein multimerization, inhibition of proteasome cycling, and activation of the unfolded protein response. This results in a slow dismantling of the ONL by sporadic apoptosis. Conversely, mutations of transduction pathways that trigger calcium-dependent apoptosis are faster and more coherent. In either case, photoreceptor apoptosis and migroglial-initiated bystander cytolysis may create debris zones that must be cleared. The mechanisms of such clearance are unknown. Phase 2 ends with the entombment of the remnant neural retina by a thick seal of distal MC processes similar to the normal outer limiting membrane, with extensive intermediate junctions between the processes. Though often termed a glial scar, there is no evidence that the seal involves astrocyte proliferation as in

Cone BCs receive cone input with either ionotropic sign-conserving glutamate receptors (solid circle) or metabotropic sign-inverting glutamate receptors (double circle), and drive ACs (A) and GCs which decode signals with sign-conserving glutamate receptors. Rod BCs receive rod input with metabotropic sign-inverting glutamate receptors and then drive glycinergic rod ACs, which fan their signals out to ON cone channels through gap junctions (resistor symbol) and OFF cone channels through glycine release decoded by inhibitory receptors (open circles). In phase 1, rod photoreceptors reprogram to either bypass rod BCs with new axons or retract their synapses. Rod BCs both retract dendrites and retarget some to adjacent cone pedicles. In phase 2, photoreceptors are lost and all BCs lose their dendrites. In phase 3, extensive rewiring, neuritogenesis, microneuroma formation, cell migration, and neuronal death occur.

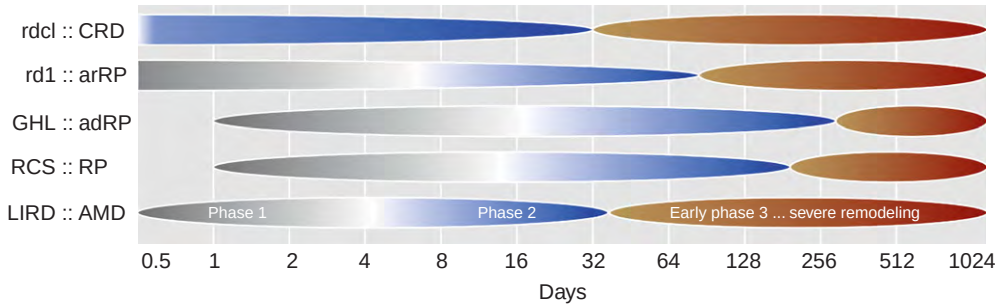

Figure 2 Different forms of retinal degeneration express different kinetics. The abscissa is exponential in time in either postnatal or postlight exposure days. Light-induced retinal degeneration (LIRD) is fast with phase 1 stress appearing almost immediately and phase 2 photoreceptor death extending for a couple of weeks before patches of phase 3 remodeling begin. In the the Royal College of Surgeons (RCS) rat, photoreceptor debris build up in the subretinal space causes stress, but photoreceptor death is not complete for 3 months or more, after which extensive remodeling occurs. The triple mutation valine 20 → glycine, proline 23 → histidine, proline 27 → leucine GHL mouse model of autosomal-dominant RP (adRP) does not begin to show photoreceptor stress until opsin synthesis begins and slowly traverses phase 2 for nearly a year before phase 3 remodeling begins. In contrast, the rd1 model of autosomal-recessive RP (arRP) is already stressed at birth with phase 2 photoreceptor death reaching completion close to 90 days. Similarly the rodless–coneless (rdcl) mouse is a model of cone–rod dystrophy (CRD) and cell death actually begins prenatally. This model spends most of its life in phase 3.

CNS glial scars. There are occasional breaks in the seal that are associated with phase 3 RPE and choroidal vascular invasion of the neural retina and neuronal escape into the choroid.

Phase 2+

In some degenerations, the death of rods is slow and seems to trigger variable bystander killing, leaving clusters of deconstructed cones with apparently functional synaptic contacts. This results in patches of retina suspended in late phase 2 (phase 2+) in a sea of phase 3 retina. The extent to which these preserve vision is unknown, but they definitely provide evidence that even marginal rescue of cones is a critical step if late-phase therapies are to be viable.

Phase 3

After loss of all photoreceptors, the stability of neuronal connectivity in the retina becomes progressively compromised through at least nine distinct processes (see below) including molecular reprogramming, individual cell rewiring, large-scale neuritogenesis, synaptogenesis and microneuroma formation, spontaneous self-signaling, neuronal migration to ectopic foci, progressive neuronal death, MC remodeling and altered gene expression, as well as RPE and vascular remodeling and migration. In severe degenerations, including human late-stage RP and geographic atrophy, the revision of the retina can be so severe that no visual function could ever be restored. In other cases, the neural retina survives but is likely to be so altered that upstream strategies such as subretinal implants, stem/progenitor cell transplants, or even fetal retinal transplants will likely not successfully deliver form vision. Further, there is increasing evidence that bionic implants and transplants do not stabilize phase 3 remodeling and may accelerate it.

Remodeling Events

Reprogramming

Reprogramming is a shift, possibly reversible, in the gene expression of cells to anomalous molecular and anatomic states. This is best known for MCs in retinal stress where intermediate filament expression is elevated and is also becoming evident for retinal neurons, especially in terms of glutamate receptor expression. Receptor reprogramming can begin in phase 1–2 when rods lose the ability to directly signal rod BCs. In the *Pde6b*^{rd1} mouse, the expression, localization, and function of the metabotropic glutamate receptor 6 (mGluR6) essential for proper ON pathway encoding decrease. In both mouse and human RP models, rod ON BCs appear to transiently upregulate expression of ionotropic glutamate receptors (iGluRs). In the LIRD mouse model, rapid upregulation of protective GluR2 subunits occurs within 24 h after initiation of photoreceptor stress. There is also evidence of gamma-aminobutyric acid (GABA) receptor redistribution in ON BCs of the *Pdeb6*^{rd1} mouse. Further, the expression of dendrites in all BCs appears to be completely suppressed after rod and cone loss, and supernumerary axons are formed. While the mechanisms initiating these changes are not yet known, they demonstrate that mature retinal neurons can change their architectures and receptor expressions, while glia can change their architectures and metabolic profiles. More reprogramming events are certain to be found.

Rewiring

Rewiring is the switching of dendritic or axonal targeting. The first known instance of this was the escape of rod synaptic terminals from BC dendrites to form long axonal fascicles (Figure 1), but with no established targets; cones behave similarly in some cases. In other forms of retinal degeneration, photoreceptors retract their synaptic terminals, which may be associated with alterations in the balance of cAMP/cGMP production (Camp, cyclic adenosine and guanosine monophosphate; cGMP, guanosine monophosphate). The numerous reports of BC sprouting in many model degenerations as well as aging mice likely reflect the simple extension of the dendrites still attached to retracting rod synaptic terminals and not true plasticity. More concretely, BCs bereft of rod input transiently retarget dendrites to cone terminals and, though they do not make structurally appropriate ribbon-associated synapses, they do express anomalous iGluRs. This is consistent with the disappearance of the electroretinogram b-wave, despite the fact that no rod BCs die early in phase 2, and with observations that ON center GC responses disappear long before those of OFF center GCs.

Neuritogenesis

Neuritogenesis is the large-scale evolution of new processes by amacrine cells (ACs), BCs, and GCs in phase 3. The mechanism of activation is unknown, but it encompasses all cell classes, suggesting a global signaling process and a pan-neural response. Many new fascicles course just distal to the glial seal and contain mixed neurites in patterns never observed in the normal retina. In other regions, especially near invading RPE processes, large tracts of tiny new neurites with only one or two microtubules form homogeneous fascicles. The tracts can traverse several hundred microns, suggesting significant alteration in the spatial patterning of circuits.

Synaptogenesis and Microneuromas

A logical extension of neuritogenesis is synaptogenesis. The extent to which new synapses are made in the inner plexiform layer (IPL) of phase 3 remodeling retina is not clear, but in regions of the MC's hypertrophy, surrounding migration columns (see below), in the GC layer, and especially in the remnant distal retina, numerous new AC, BC, and GC connections are made. The most distinctive zones are microneuromas, which range from 10 to 100 ìm in width and contain abundant conventional and ribbon synapses. The mechanisms that stimulate new synapse formation are also unknown but seem closely associated with RPE processes. As RPE cells are known to release several growth factors, it is plausible that they are the activators of synaptogenesis. The wiring within microneuromas seems chaotic and, by serial section reconstruction and modeling, such networks appear to be resonant, which is incompatible with visual processing.

Self-Signaling

A number of observations suggest that retinal degenerations lead to spontaneous self-signaling in phase 3 retina. Photopsias (scintillating illusions common in RP) are initiated in the retina and the generator mechanisms can remain quiescent for decades in the absence of vision, only to be reactivated by experimental transocular currents. Spontaneous, erratic retinal waves of depolarization occur in rodent models of RP after light-driven responses are lost. Physiological measures show that rodent ACs and GCs are glutamate-activated in phase 3. GC activation in the phase 3 *Pdeb6*^{rd1} mouse is clearly glutamatergic and not intrinsic. This means that BCs must be voltage modulated in some way. However, most remodeled BCs lack functional glutamate receptors and they must be depolarized by another mechanism. One plausible mechanism is periodic AC membrane potential fluctuations, leading to the modulation of BC anion currents and modulation in BC glutamate release. Some isolated ACs have shown endogenous oscillations in K^+ channel conductance, alternately hyperpolarizing and depolarizing them, presumably modulating GABA (or glycine) release. The isolation of ACs from the normal visual drive in retinal degenerations may unmask this intrinsic capacity. Once self-signaling is initiated, resonant networks created by rewiring or microneuroma formation can rapidly generate periodic activity. Such networks may be inimical to restoration.

Migration

Neuronal migration is a large-scale remodeling event. In most instances, migration is closely associated with both hypertrophy of MCs and anomalous vascular tangles (see below). All forms of cell mixing occur: collections of ACs and BCs can become displaced to the GC layer. Conversely, ACs and even GCs can migrate to the distal margin of the remnant retina. One fundamental question is whether these cells remain functional. Ultrastructurally, cells in migration columns such as GCs seem to have processes extending both distally and proximally much like neuroepithelial cells in development. However, after migration, the original orthotopic processes seem to be retracted. Migrated cells seem heavily connected to microneuromas. A more serious form of migration (emigration) occurs when RPE cells and the basement membrane are focally ablated and the distal seal can surge into the choroid. Large tracts of MCs and neurons can emigrate, decimating the remaining neural structures. This is especially evident in LIRD and suggests that it may play a role in loss of vision in severe nonvascular forms of AMD such as geographic atrophy.

Cell Death

There is little evidence of glial death in remodeling, but the proportions and numbers of survivor neurons change significantly. BCs form the largest cohort of neurons (other than photoreceptors) in normal retina; however, ACs always predominate in phase 3, suggesting that BC death is far more common than AC or GC death. This may be due to the fact that BCs are the only retinal cells that lose all of their glutamatergic input. Neurons require a basal level of Ca influx to maintain homeostatic gene expression and, through self-signaling, ACs and GCs clearly possess the critical glutamatergic input required to provide both transmitter-gated Ca flux and voltage-gated Ca-channel activation; BCs clearly lack that input. As subjects age, ACs and GCs also decrease in number. In any event, the loss of neurons has strong implications for all therapeutic interventions, including epiretinal implants.

MC Remodeling

MCs make up nearly 50% of the mass of the peripheral primate retina and are one of the major drivers of remodeling. While there has been little analysis of phase 1 MC function in inherited retinal degenerations, there is abundant evidence that they respond to rapid, coherent photoreceptor stress initiated by LIRD within hours by increasing intermediate filament expression, displaying distal process hypertrophy in the ONL, and increasing arginine expression (a marker of increased protein synthesis). In phase 2, MCs play a lead role in forming a seal between the remnant RPE and/or choroid. The transport characteristics of that seal are unknown, but its formation is paralleled by a massive increase in MC glutamine levels. MCs normally export glutamine from MCs to surrounding neurons. This transport is voltage sensitive and, similar to many Na-coupled transporters, allows increasing export with depolarization. Depolarization of MCs is closely coupled to light-activated events, and the loss of photoreceptors may play some role in progressive hyperpolarization of MCs and retention of gluamine. However, as the increase in MC glutamine is temporally linked to the formation of the distal seal, the mechanism of glutamine retention appears more complex than just constraining the MC voltage.

RPE Remodeling

In classical RP, invading RPE cells are one of the hallmarks of advanced disease. After formation of the MC seal, certain RPE cells and, sometimes, choriocapillaris endothelia are able to penetrate into the neural retina, forming large complexes of hypertrophic MCs, RPE with altered melanosomes encapsulating invading and remnant retinal capillaries, clusters of new neurites, and columns of migrating neurons. RPE cells seem to be the foci of large-scale morphologic derangements in the survivor retina, but whether they are initiators or responders is not clear. The RPE remains partially intact for long periods in many retinal degenerations, including the Royal College of Surgeons (RCS) rat defect; however, the RPE layer can become broken by patches of invading RPE cells and apical processes. In the RCS rat, apical RPE processes can extend to the GC layer.

Vascular Remodeling

New capillaries invade the neural retina in phase 3, emanating from both vitreal and choroidal sources. Little is known of the fundamental transport properties of these new vessels (e.g., whether they are fenestrated or not), but both molecular and genetic profiling show that neural retina in RP is metabolically deprived. New imaging data as well as electron microscopy suggest that the new vessels are too attenuated and too heavily invested by hypertrophic MCs and RPE to allow proper perfusion of the retina. These anomalous foci may trigger neuronal migration. The stimuli for vascular remodeling remain unknown, but VEGF secretion by invading RPE cells is one plausible source.

Impact of Remodeling on Therapeutics

The potential reversibility of remodeling events varies. For example, phase 1 and 2 changes in reprogramming of gene expression and neurite switching are reminiscent of normal plastic behavior and might respond to the appropriate therapeutic signals. However, phase 3 changes such as rewiring, neuritogenesis, and microneuroma formation, migration, and neuronal cell death are not reversible by any known means. Intermediate phenomena such as MC, RPE, and vascular remodeling are similarly challenging. Human RP patients show the full spectrum of remodeling defects; therefore, most therapies are impacted by a narrowing therapeutic window.

Primary Gene Therapy

All prospective primary gene therapies (those targeting known gene defects) depend on photoreceptor survival. However, it is clear that photoreceptor deconstruction starts long before photoreceptor death. The recent successes with gene therapy for replacing the deficient isomerase (RPE65) in that variant of Leber's congenital amaurosis (LCA) is not likely relevant to primary rod or cone gene defects, nor to defects associated with the accumulation of genotoxic and cytotoxic debris in the

subretinal space such as those due to defects in RPE mer tyrosine kinase (MERTK). In human rod dystrophies, it is clear that mutations impacting rhodopsin trafficking also lead to changes in the inner segment function and photoreceptor architecture. Rod photoreceptor rewiring in human RP is unlikely to be reversible regardless of the success in replacing defective phototransduction genes. So far, gene therapy successes in animal models are largely restricted to prenatal or early postnatal genetic interventions. With the exception of soft diseases such as LCA and stationary night blindness that do not trigger photoreceptor deconstruction, most retinal degenerations clearly have only a tiny window for gene therapy. Primary gene therapies are currently restricted to phase 1.

Survival Factor Therapy

One strategy to retard retinal degeneration involves the use of survival factors such as neurotrophins (e.g., ciliary neurotrophic factor, CNTF) that slow photoreceptor apoptosis. These strategies were validated for slower models of adRP (the rat P23H and S344ter rhodopsin transgenic models). Some argue that the structural preservation afforded by CNTF in these models does not reflect a parallel functional rescue. There is evidence that early postnatal CNTF infusion in other rodent models of RP negatively alters photoreceptor gene expression profiles, activates MC stress signaling, and alters inner retinal organization. Simple survival factor therapy without a known cellular and molecular target is not likely to generalize well across human RP types. At present, survival factors offer little prospect of reversing or retarding remodeling. Survival factor therapies are restricted to phase 1 and early phase 2.

Stem/Neuroprogenitor Cell Therapy

Several groups have shown that isolated stem/ progenitor cells, particularly murine postnatal day 5 rod neuroprogenitor cells, have the potential to intercalate in the ONL and, possibly, repopulate the retina. The efficiency of such intercalation is low and it is not likely that these cells will survive in phase 3 retinas. Penetration of the MC seal is unlikely and several groups have failed to obtain significant numbers of exogenous photoreceptors to extend synapses through it. Direct injection into the retina is likely to activate microglial killing and, in any event, isolates any surviving photoreceptors from the remnant RPE. For photoreceptor progenitor cells to be successful in rescuing vision, they must also lead to cone survival and reconnect with existing neurons before morphologic remodeling begins. This excludes most current RP patients. Stem/neuroprogenitor cell therapies are currently restricted to phase 1 and early phase 2.

Retinal Transplantation

The team of Seiler and Aramant pioneered the effort to insert sheets of fetal retina into the subretinal space of degenerating retina. They have successfully demonstrated long-term photoreceptor survival and some visual driving in rats. Remodeling remains a major barrier in several ways. The extent of transplant-to-host neurite intermingling is small, and the glial seal predominates. Further, the transplanted retina begins to remodel and appears even more susceptible to alteration than the host. This suggests that remodeling signals emanate from the survivor retina. Certainly, after phase 3 BC dendrite truncation in the host retina, a semi-intact fetal retina cannot recapitulate normal circuitry by tandem connections. It is likely that most transplant-to-host connectivity is AC → AC driven and probably functionally random. Even so, such networks can generate light-driven behavior. Though lacking the spatiotemporal precision normal GCs, transplants have the potential for much higher sensitivity, range, and resolution than bionic mechanisms. Retinal transplantation therapies are largely restricted to phases 1–2, but may function if the connection can traverse the glial seal in phase 3 retinas.

Secondary Gene Therapies: Photosensitive Proteins

A recent development of import is the ability to induce expression of photosensitive proteins in survivor neurons by viral or molecular transfection, generating light responses directly in neurons. Several groups have shown that it is possible to express channelrhodopsin 2 (ChR2) in retinal BCs, and elicit ChR2-BC-driven photoresponses in GCs and light–dark preferences in behavioral search. This is an important advance and represents the potential to convert blind retinas into navigational systems without surgical intervention and ancillary equipment. The challenge is to demonstrate that this is possible in phase 3 profoundly blind patients, as they are the most obvious candidates for therapy. This technique has, once again, only been established in phase 2 or earlier models. Further, as with transplantation, there is no evidence that such secondary therapies will be resistant to remodeling, prevent cell death, or overcome signal corruption. A significant amount of basic research remains to be done but, despite promise, secondary gene therapies still seem limited to phases 1–2, although they may function in phase 3, even if randomly targeted.

Bionic Implants

The most successful schemes to restore vision to the profoundly blind from aggressive phase 3 retinal degenerations are epiretinal bionic implants. Surgically placed near the

GC layer, epiretinal implants provide direct current stimulation of retinal GCs or nearby circuitry to activate patches of visual sensation. The argument that such stimulation conflates ON and OFF responses seems irrelevant as several implanted patients can now successfully navigate with such devices. It is clear that the severe remodeling, especially neuronal death, limits candidacy. All implants, whether they are epiretinal, intraretinal, or subretinal, seem to induce further glial and neuronal remodeling. Severe remodeling, BC death, and microneuroma formation will more severely impact subretinal models.

The Importance of Cone Rescue

In every model, the survival of cones seems to delay the onset of phase 3, holding the retina in a phase 2+ state indefinitely. The effect is local and small patches of cones preserve connected BC dendrite structure even when surrounding BCs have lost all dendrites and glutamate receptors. The preservation persists even when cones are severely deconstructed, lacking outer segments and visual pigment expression, and significantly reduced in size. This suggests that cone contact alone, perhaps through synaptic integrins, may be sufficient to preserve BC function. Expression array studies suggest that cone deconstruction may be accelerated by metabolic deprivation. While preserving cones will not rescue vision, it will permit holding the survivor retina in suspended animation, making an array of interventions such as stem/progenitor cell transplantation, fetal retinal sheet transplantation, and secondary gene therapy viable for adults suffering from advanced retinal degenerations. Revisiting survival factor research with a focus on cones may be the critical advance needed for all intervention methods.

Glossary

Choriocapillaris – Vascular layer of the eye, located between the sclera and Bruch's membrane.
Ganglioside – A component of the cell membrane involved in signal transduction.
Neuroprotection – Halting apoptotic cell death of neurons through delivery of diffusible growth factors.
Proteoglycans – A unique class of heavily glycosylated glycoproteins.
Tetraspanins – A family of membrane proteins with four transmembrane domains.

Introduction

The use of surgical procedures for the treatment of blinding conditions has a long history, most notably for cataract. In the modern era, refinements in ophthalmologic techniques and pharmacology have greatly expanded the range of available interventions for a host of ocular conditions. Nevertheless, conditions involving the loss of nonregenerating cell types remain a persistent therapeutic challenge. In the case of diseases involving the loss of corneal endothelial cells, tissue transplantation has proven successful, even though the limited availability of donor corneas restricts the use of this approach.

More problematic are diseases involving the loss of retinal neurons and retinal pigment epithelial (RPE) cells where few, if any, options are currently available to the treating clinician. As a group, diseases of this type are common and examples include age-related macular degeneration, retinal detachment, retinitis pigmentosa, as well as various forms of optic neuropathy, including glaucoma. In addition, common retinal vascular diseases such as diabetic retinopathy and vascular occlusive disease frequently involve retinal cell loss. Given the prevalence of visual disability resulting from these conditions, novel methods of both preserving and replacing retinal neurons are sorely needed.

Early Transplant Work

Over the last several decades, experimental work in rodents has made considerable progress in neuroprotection as well as cell and tissue transplantation in the setting of retinal cell loss. Seminal work by LaVail and Steinberg demonstrated the power of growth factor-mediated neuroprotection for retinal degeneration, both hereditary and acquired. Work by Lund's group showed that transplanted retinal tissue can, to a certain extent, engraft and integrate with the recipient visual system. Work by the Turner and Gouras laboratories showed that RPE transplantation can confer survival benefits to host photoreceptors following placement in the subretinal space. This last observation was made in dystrophic Royal College of Surgeons (RCS) rats and was subsequently extended to a variety of manipulations in this model. Taken together, these early studies provided compelling evidence of efficacy in mammals.

Despite the above advances, however, significant limitations remained, thereby encumbering further development of these otherwise promising strategies. In the case of neuroprotection, a major challenge has been to find a method of sustained intraocular delivery that is not neutralized due to the rapid degradation of peptide growth factors by endogenous proteases. For neural transplantation, a perplexing challenge has been to find a method of promoting regeneration across injury-induced gliotic barriers. Furthermore, RPE cell transplantation was challenged by the apparent reluctance of grafted cells to reconstitute an orthotopic epithelial monolayer on Bruch's membrane. In all these cases, a compounding impediment to translation of these strategies was posed by the limited ability of the rodent eye to model an approach with tangible clinical relevance.

Within the past 10 years, new breakthroughs pertaining to the above challenges have emerged from the nascent field of stem cell transplantation, as will be discussed presently.

Neural Progenitor Cells

The first report of successful transplantation of stem-like cells to the retina was from Masayo Takahashi, then working in the laboratory of Fred Gage. The cells used were adult hippocampal progenitor cells (AHPCs), a clonally selected line of highly mitotic cells cultured from the brain of mature rats and genetically altered to express green fluorescent protein (GFP) as a reporter gene. This study showed a remarkable degree of apparently seamless integration of donor AHPCs into the immature retina of normal recipients. Although the cells fell short in terms of marker expression, their morphology, placement, and orientation were strikingly similar to resident retinal cell types.

In addition to working with Gage, we showed that AHPCs can also integrate into the diseased or injured retina of mature rats and that at least a degree of phenotypic marker expression was achievable, thereby underscoring the potential of using stem cells for cell replacement in the setting of common retinal disorders.

Together, these two studies with AHPCs stimulated considerable interest in stem cell research within the scientific community, particularly with respect to retinal applications. Initial work on cultured cells continued to focus on AHPCs as the first cell type with a demonstrated ability to integrate into the cytoarchitecture of the neural retina. These cells were shown to exhibit a number of nonimmunogenic properties and to express a number of important cytokines, as did similar brain-derived cells of human origin. Neural progenitor cells from the brains of human and GFP-mouse brain were compared in terms of surface marker expression. It was found that cultured neural progenitor populations consistently express 3-fucosyl-*N*-acetyl-lactosamine (CD15), GD(2) ganglioside, and the tetraspanin proteins CD9 and CD81 across species, whereas major histocompatibility complex (MHC) expression is more variable, specifically for class I antigens. Transplantation of the mouse cells showed that they exhibited characteristics of an immune-privileged cell type. Similar cells were later derived from the brain of the pig and cat.

Retinal Progenitor Cells

A significant limitation that emerged from the work with brain-derived progenitors was the difficulty in obtaining photoreceptor marker expression from these cells following engraftment in the retina. While it has been shown that recoverin expression can be induced under exceptional circumstances, it remained to be seen whether a stem-like cell could generate cells with outer segments that co-express multiple appropriate markers such as recoverin and rhodopsin. It was this challenge that led us to explore the possibility of deriving transplantable progenitor cell cultures from the mammalian neural retina.

Starting with newborn GFP-transgenic mice, we were able to grow cells from dissociated retinal tissue in the presence of mitogenic stimulation from epidermal growth factor (EGF). These cells were capable of expressing rhodopsin, either in culture under differentiation conditions or following engraftment in the host retina. We have obtained similar findings in work with porcine and human donor tissue of fetal origin. Following differentiation, either *in vitro* or *in vivo*, these cells have been shown to be capable of co-expressing rhodopsin and recoverin, consistent with rod photoreceptor phenotype. Retinal progenitor cells (RPCs) therefore represent a stem-like cell type that provides a potential source of new photoreceptors for retinal repair in the setting of various forms of diseases and injuries.

As mentioned above, transplantation of mature RPE cells for cell replacement has been hampered by the apparent inability of these cells to recreate an epithelial sheet and adhere to Bruch's membrane. In contrast, retinal and various types of neural progenitor cells have also shown an ability to integrate into the RPE monolayer, although it is not yet known if such cells can replace native RPE cells at the functional level. Recent work with pluripotent stem cells suggests that these represent a source for new retinal cells with functional properties.

Induced Pluripotent Stem Cells

A new development in stem cell biology that has changed the way we think about commitment and differentiation is a process known as direct reprogramming (**Figure 1**). Yamanaka and colleagues were the first to demonstrate this technique, in which somatic cells are reprogrammed to become pluripotent stem cells through the addition of several stemness transcription factors. They began with a type of skin cell known as a fibroblast, and inserted four transcription factors (Oct3/4, Klf4, Sox2, and c-Myc) using retroviruses. A subpopulation of the fibroblasts began expressing other markers of embryonic stem (ES) cells, such as nanog, and formed teratomas when transplanted into immunocompromised mice. Careful evaluation of the resulting cells revealed that they indeed had all the properties of ES cells, and have been termed induced pluripotent stem (iPS) cells.

There are several important ramifications of this work. First, this technology offers the promise of creating patient-specific stem cells. One could harvest skin cells from a donor, turn these cells into iPS cells, and subsequently differentiate this population into the cells of interest, which would then be transplanted back into the donor. Importantly, this would obviate the need for chronic immunosuppression and eliminate the risk of immunorejection of the grafted cells. Many of the ethical issues associated with ES cells would also be circumvented by using this technique, although as with most such developments, new and unexpected ethical questions arise. Thus far, no one has created a viable embryo through this technology, and indeed there are many biological hurdles standing in the way of this. However, as the theoretical possibility of using iPS cells for reproductive cloning exists, this work raises novel moral issues.

A number of technical barriers must be overcome before iPS cells can be useful for the treatment of disease. Foremost among these is the use of oncogenes (cancer-associated transcription factors) to reprogram fibroblasts. These genes often lead to tumorogenesis, and indeed scientists have seen cancerous growths from the

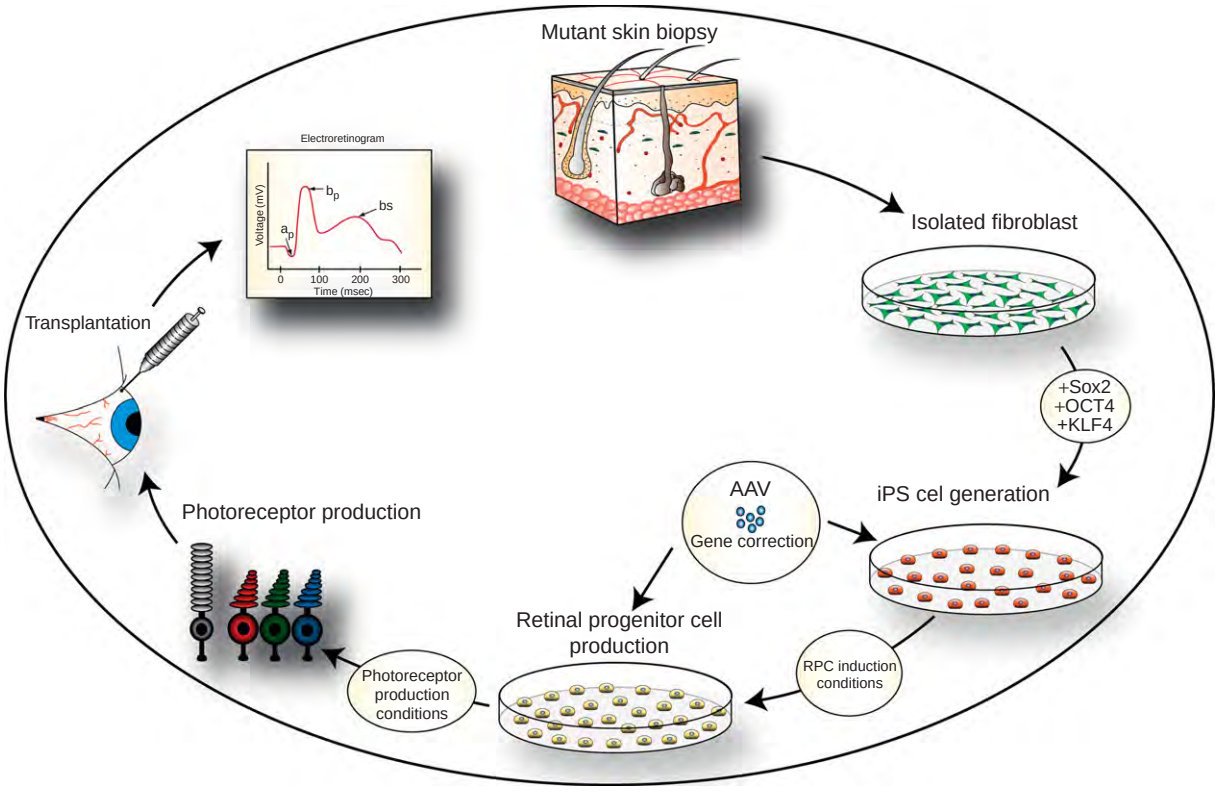

Figure 1 Schematic diagram illustrating the steps toward differentiation of reprogrammed fibroblasts into retinal neurons.

transplanted progeny of iPS cells. In addition, the use of retroviruses to deliver the four factors to the nuclei of the fibroblasts must be replaced by other means before using these cells in the clinic. It is worth noting, however, that in the months that followed the first publication of this technique, a flurry of scientific papers were published in which only two or three of the reprogramming factors were needed, and vectors other than retroviruses were used for gene insertion. This field is developing extremely rapidly, and it is likely only a matter of time until these methodological obstacles are overcome.

Stem Cells for Neuroprotection

In addition to cell replacement, stem-like cells have potential use in retinal neuroprotective strategies. We reported evidence that murine RPCs confer survival benefits to dysfunctional rods following transplantation to the retina of rhodopsin double knock-out mice. This result indicated that RPCs, or their more differentiated progeny, possess an inherent neuroprotective influence that is revealed in this setting. Interestingly, a similar finding was obtained in retinal dystrophic mice in work with a very different type of stem cell derived from the bone marrow.

Elucidating the mechanisms underlying such effects remains a subject of active interest; however, an alternative method for inducing neuroprotection via stem cells is to modify them genetically so as to over-express the therapeutic gene of interest. Gamm and colleagues have shown that brain-derived progenitor cells modified to ever express a GDNF transgene were capable of rescuing photoreceptor cells in the RCS rat following transplantation.

Retinal Transplantation

As suggested above, to achieve functional repair in patients afflicted with retinal degenerative disorders, there is an urgent need to reconstruct, via cellular replacement, the damaged or lost layers of the retina. During the past 30 years attempts have been made in order to achieve retinal regeneration via transplantation of developing donor material. Although significant progress and invaluable information have been acquired, visual restoration using this technique has not been achieved. For instance, although embryonic rat retina was shown to survive without immune rejection, develop normally, and continue to respond to light for up to 3 months post-transplantation, extensive host–donor integration was not identified. Similarly, comparable experiments performed in pig models of retinal dystrophy showed that although healthy retinal tissue from fetal donors survived and maintained proper laminar structure and cellular

organization for up 6 months post-transplantation, this tissue did not integrate with the host retina, and as such, did not aid in visual restoration. These findings collectively suggest that the eye is an amenable site for transplantation; however, the proper donor material or extracellular conditions have yet to be met.

Transplantation Strategies

Stem/progenitor cell transplantation as a means of inducing tissue reconstruction and functional regeneration has garnered extensive interest in the field of regenerative medicine. Unlike the solid tissue transplants mentioned above, stem cells have the ability to integrate within host tissue and develop into retinal specific cell types. For instance, in 2004, we were able to show that a subset of grafted RPCs gave rise to mature retinal ganglion and photoreceptor cells following transplantation. Since then, numerous studies reporting varying degrees of success have utilized an assortment of different cell types, including the fate-restricted photoreceptor precursor and the pluripotent ES cell. Regardless of the cell type used, efficient delivery methods are required. Traditionally, the two transplantation techniques most extensively utilized for cell delivery were vitreal cavity and subretinal space injections. Regardless of species, vitreal cavity injections generally involve insertion of a needle through the pars plana into the vitreal space, where in the case of mice, approximately 1 µl of cell suspension as a bolus is injected (**Figure 2(a)**). The subretinal space, unlike the vitreous, is actually a pseudo-space that is created upon detachment of the retina from the underlying RPE layer. Cellular injections into this space are performed by one of the two techniques. The first, which is very similar to that carried out during vitreal injections, involves entering the eye through the pars plana and inserting a needle beneath the retina via a precut hole, or retinotomy. Through this hole, fluid, most often saline, is injected, creating a retinal detachment and bleb into which the cell of choice can be delivered (**Figure 2(b)**). This approach generally requires a larger vitreal space in which to work and is often performed in larger models of retinal disease, such as the pig and human. The second technique, which is more often employed in smaller organisms such as rodents, is performed by making an incision through the sclera (sclerotomy), choriocapillaris, Bruch's membrane, and overlying RPE, through which a needle is inserted and saline is injected. This again creates a retinal detachment/bleb into which cells can be delivered (**Figure 2(c)**). The reasons for choosing one approach over the other are vast and may range from personal preference to surgical competence. However, more practical reasons for choosing vitreal or subretinal approaches for stem cell transplantation exist, including the type of injury and cell/retinal layer being targeted. For instance, subretinal transplantation would be more beneficial for targeting the retinal photoreceptor layer in retinal degenerative diseases such as retinitis pigmentosa (RP) and age-related macular degeneration (AMD), while vitreal transplantation would be more beneficial for targeting the inner nerve fiber layer in diseases such as glaucoma and various other optic neuropathies. Tailoring the transplantation approach to the specific disease at hand allows for larger numbers of cells to be provided to the area required. For instance, performing vitreous cavity injections of retinal stem cells as a treatment regime for photoreceptor cell replacement requires that the cells migrate through the entire thickness of the remaining retina before arriving at the desired location. With an increased distance for cellular migration, there is a greater chance that cells will take up residence in unwanted retinal layers, thus decreasing the chance that they will actually reach the appropriate target.

Polymer Substrates

Despite choosing the correct transplantation technique, the use of bolus cell injection as a delivery method is actually quite inefficient and typically results in massive cellular efflux, low cellular survival, and poor integration. For example, it has previously been suggested that as little as 0.1% of transplanted retinal stem cells actually survive for an extended period of time following traditional bolus injection. Issues such as these, which hinder functional regeneration, are largely accounted for by the lack of cellular support and trauma associated with the injection processes. For instance, in a recent publication we were able to show that the shearing forces placed on retinal stem cells by passing them through the typical glass injection needle resulted in nearly 60% cell death at 3 days post-passage. When the glass injection needle was replaced with a large bore pipette, cell death was reduced to less than 2%. However, even if a large bore pipette could be used during the transplantation process, the fact remains that a large portion of the cells injected would still be lost to efflux via the implantation port. This is especially true when attempting to place cells into the subretinal space through an opening in either the retina or sclera. One approach that we have developed in an attempt to circumvent these issues is to apply tissue-engineering techniques focused on the use of biodegradable polymer scaffolds as cell delivery vehicles. In one study we were able to show that the transplantation of retinal stem cells on a biocompatible poly(lactic-*co*-glycolic acid) (PLGA) polymer resulted in greatly reduced cell death and prevented leakage and migration of retinal stem cells away from the transplantation site. This resulted in significantly improved cellular integration when compared to bolus cell injections.

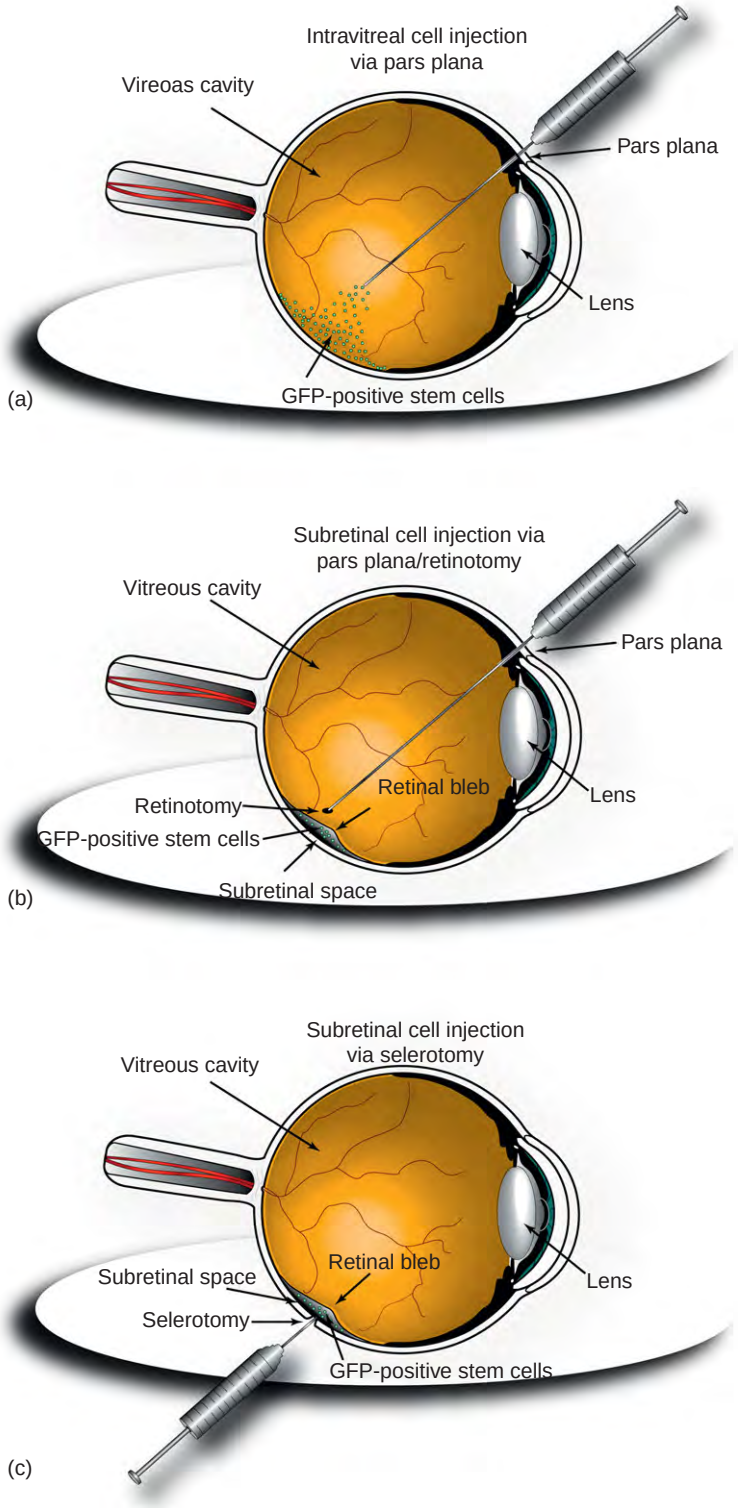

Figure 2 Schematic diagram illustrating three transplantation techniques.

Inhibitory Barriers

Although we have developed an efficient means of cell delivery, in order to achieve functional regeneration via retinal reconstruction/repopulation, a further increase in cellular integration and axonal extension/synapse formation is required. As suggested above, a major contributor to the lack of functional regeneration in the face of efficient

cell delivery is the presence of an inhibitory extracellular environment. Unlike the peripheral nervous system (PNS), the central nervous system (CNS) is stricken with an abundance of myelin-associated extracellular matrix (ECM) proteins, namely MAG, Nogo, and Omgp, which are well known for their ability to inhibit process extension and functional regeneration. The optic nerve, like other CNS locations, is laden with these inhibitory proteins, and as such, their chemical and/or enzymatic neutralization has been shown to significantly enhance retinal ganglion cell axon extension and optic nerve regeneration. Thus, in order for stem cell therapies to be used as an effective treatment for diseases such as glaucoma, which affect the retinal ganglion cell layer and optic nerve, inhibition of these proteins will ultimately be required.

Unlike the optic nerve, the retina is void of myelin, oligodendrocytes, and their associated inhibitory ECM molecules. Thus, these factors are not a concern when attempting to stimulate regeneration in retinal degenerative diseases such as RP and AMD, both of which predominantly affect the retinal outer nuclear layer. Why then are attempts at stimulating retinal regeneration via stem cell transplantation still largely unsuccessful? The lack of functional integration following transplantation is in large part due to the presence of an inhibitory injury induced glial scar that forms during reactive gliosis. In the retina, reactive gliosis is predominantly characterized by Müller glial activation, as indicated by upregulation of intermediate filament proteins such as glial fibrillary acidic protein (GFAP) (**Figure 3(a)**, red) and the projection of processes from their original location (forming the outer limiting membrane) into the subretinal space. Here, these processes proceed to form a dense fibrotic barrier that contains a variety of growth inhibitory ECM/adhesion molecules, which include the chondritin sulfate proteoglycan (CSPG) Neurocan (**Figure 3(a)**, blue) and the hyaluronan-binding glycoprotein CD44 (**Figure 3(b)**, red). Both Neurocan and CD44 have previously been shown to function as chemical inhibitors to axon growth and cellular migration, thus preventing regeneration and functional synapse formation. A variety of approaches have been taken in an attempt to remove these inhibitory ECM molecules, including enzymatic degradation of the proteins themselves. One such enzyme that we have utilized for this purpose is the matrix metalloproteinase 2 (MMP2). MMPs are well known for their ability to degrade a variety of ECM and cell adhesion molecules, including CD44, the CSPGs, and the aforementioned myelin-associated inhibitors. MMP2, in particular, has been shown to cleave both CD44 and Neurocan, thus releasing their negative hold on axonal extension and cellular migration. In a recent study, we discovered that endogenous MMP2 induction resulted in glial barrier-associated CD44 and Neurocan degradation at the outer limits of heavily scarred degenerating retinas, subsequently stimulating integration and synapse formation between the host and healthy transplanted tissue grafts. Conversely, chemical and/or genetic inhibition/removal of MMP2 was shown to completely abolish stem cell migration and retinal repopulation. In light of these findings, we have developed a biodegradable PLGA polymer scaffold that, as in previous permutations, is capable of efficient cell delivery and also possesses the ability to provide a sustained controlled release of active MMP2 following degradation (MMP2-PLGA). Subretinal transplantation of this polymer in conjunction with retinal stem cells as a composite graft has resulted in efficient glial barrier degradation and enhanced stem cell integration. This new polymer scaffold will undoubtedly act as an invaluable transplantation tool

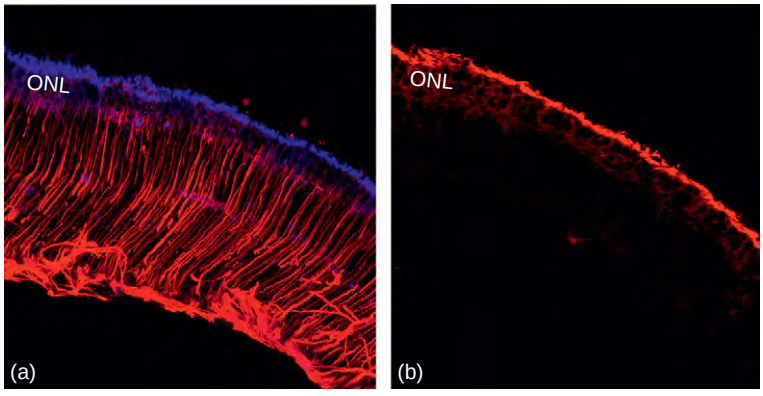

Figure 3 Injury-induced Müller cell activation stimulates inhibitory ECM molecule deposition and glial barrier formation. Eyes from adult retinal degenerative mice (Rho–/–) were enucleated, fixed, cryoprotected, sectioned, and immunostained for GFAP, CD44, and Neurocan. (a) Representative micrograph illustrating CD44 (blue) and GFAP (red) expression in the adult degenerative Rho–/– mouse retina. Activated Müller cells extend processes through the degenerating photoreceptor layer (ONL) into the subretinal space and deposit CD44 at the outer limits of the retina. (b) Representative micrograph illustrating neurocan (red) expression in the adult Rho–/– mouse retina. Inhibitory glial barrier-associated proteins, CD44 and Neurocan, deposited at the outer limits of the degenerating retina. Inhibitory CD44 and Neurocan molecules are intertwined within the degenerating photoreceptor layer, preventing cellular/axonal integration following subretinal transplantation.

for targeted repopulation of the retinal and restoration of vision.

Conclusions

Regardless of the source of the transplanted material, retinal transplants aim to rescue or replace injured photoreceptors. It is likely that each of these objectives will require different cell types as donor tissue. For example, rescue of diseased rods may be accomplished by delivering nonengrafting mesenchymal stem cells, or perhaps with engrafting neural stem cells. In these cases, rescue would be achieved by the delivery of growth factors such as glial cell-derived neurotrophic factor (GDNF) or brain-derived neurotrophic factor (BDNF) in a nonspecific fashion, possibly to cells other than photoreceptors (e.g., Müller glia). Engraftment and long-termed survival is a requirement if rescue of the diseased photoreceptors is to be prolonged. In contrast, repair through reconstruction involves a more complicated and indeed more difficult set of concerns. Cell replacement not only requires engraftment and long-termed survival, but also necessitates differentiation.

A cell type that can differentiate into fully mature, functional photoreceptors narrows the field of players somewhat. While a hematopoetic or stromal stem cell may by somewhat ill-suited to such a task, retinal stem cells or ES cells may be ideal candidates.

Innate Immune System and the Eye

M S Gregory, Schepens Eye Research Institute, Harvard Medical School, Boston, MA, USA

Glossary

Endocytosis – The process by which cells absorb molecules, such as proteins, from outside the cell by engulfing them with their cell membrane to form an endosome.
Endophthalmitis – An infection of the posterior of the eye.
Opsinization – The process by which a pathogen or infected cell is marked for destruction by a phagocyte.
Phagocytosis – The engulfment of solid particles, such as bacteria, by the cell membrane to form an internal phagosome.

Introduction

Innate immunity comprises a large number of molecules and cells that recognize and respond rapidly to pathogens, providing immediate defense against infection. However, innate immunity also carries with it the potential of highly destructive inflammation that presents an important dilemma for the eye. Inflammation is necessary for successfully eradicating pathogens. An ideal response would eliminate the microorganisms before they are able to directly damage any ocular tissues. The innate immunity would be limited and produce little or no damage to the surrounding normal tissues. However, some types of ocular infections trigger inflammation that is either (1) insufficient to clear the microorganisms, resulting in direct destruction of ocular tissue by the pathogen, or (2) excessive inflammation that clears the microorganisms, but destroys a significant amount of normal tissue. Either of these two scenarios is undesirable and can lead to significant loss of vision. Therefore, a delicate balance must be achieved between the amount of inflammation required for pathogen clearance and the amount of nonspecific tissue damage.

The innate immune system of the eye is similar to other mucosal surfaces. The first tier is passive consisting of several anatomic, physical, and chemical barriers that work together to prevent infection without inducing inflammation. The second tier is active consisting of cellular and secretory components that together cause acute inflammation aimed at eradicating the pathogen. The delicate tissues of the eye that make up the visual axis (cornea, lens, and retina) have a very low tolerance for inflammation, as a very small amount of damage can produce a significant loss of vision. The two-tiered system helps to prevent unnecessary inflammation and the active mechanisms of innate immunity are only turned on once the passive barriers have been breached. Both the passive and active arms of ocular innate immunity are the focus of this article.

Passive Innate Defense System

Anatomic and Physical Barriers

Several anatomic and physical barriers protect the anterior and posterior of the eye from invading pathogens (Figure 1). The active arm of innate immunity is only triggered when pathogens breach these barriers. The cornea is exposed to the external environment, making the anterior segment highly vulnerable to potential pathogen invasion. Therefore, the anterior segment possesses a multilayer barrier system that includes: eyelids and eyelashes, tear film, and the corneal epithelium. By contrast, the posterior segment is not exposed to the external environment, and is therefore less vulnerable to infection. The critical barriers of the posterior segment include (1) the retinal pigment epithelium (RPE), which lies between the blood-rich choroid and the neural retina, and (2) the posterior lens capsule that forms the barrier between the anterior and posterior segments. Each component of the passive innate defense system is described briefly below.

Eyelids and eyelashes

The outermost barrier of the ocular surface consists of the eyelids and eyelashes. The eyelashes protect the ocular surface from dust and foreign debris. The regular blinking action of the eyelids moves the tears across the ocular surface, washing away potentially colonizing or infecting organisms.

Tear film

Tears form the second barrier, lubricating and protecting the ocular surface. Tears also posses a potent defense system that limits the growth, colonization, and survival of microorganisms. The tear film consists of three layers: the outermost lipid layer, an aqueous layer, and the inner mucus layer (Figure 2). The lipid layer lubricates the eyelid and slows evaporation of the aqueous tear film layer. The aqueous layer forms the major component of the tear film and contains numerous antimicrobial

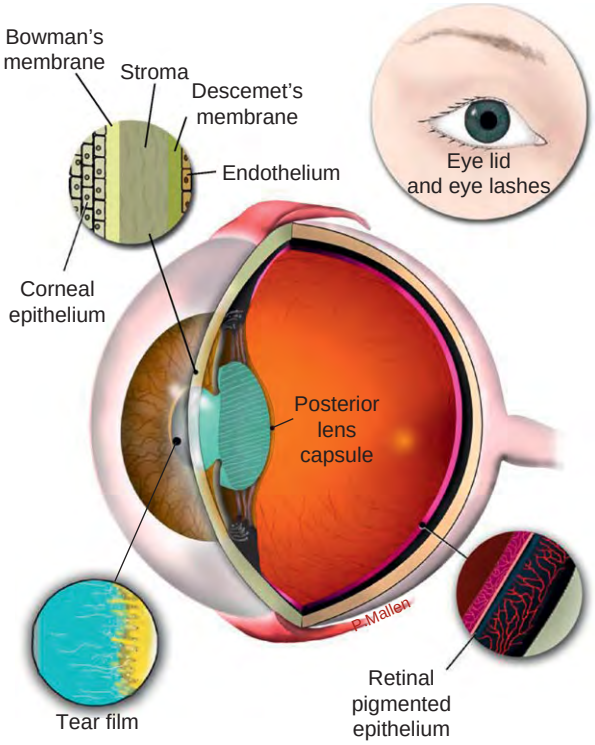

Figure 1 Anatomic and physical barriers of the eye. The eyelid, eye lashes, tear film, and corneal epithelium serve as barriers of the anterior segment of the eye. The posterior lens capsule and RPE serve as barriers of the posterior segment of the eye.

proteins including: lysozyme, lactoferrin, defensins, secretory IgA (sIgA), and complement. Many of these antimicrobial proteins are constitutively expressed and provide early, broad-spectrum protection against invading pathogens and also prevent the overgrowth of commensal bacteria. The innermost mucus layer of the tear film is made up of secreted and membrane-bound mucins that protect the epithelium from debris, pathogens, and desiccation. Mucins are high-molecular weight glycoproteins characterized by extensive *O*-glycosylation. Membrane-bound mucins expressed by the ocular surface epithelia include MUC1, MUC4, and MUC16. Secreted mucins are also found in the mucus layer and include MUC2, MUC5AC, and MUC19. The membrane-bound mucins anchor the ocular tear film to the corneal epithelium and are thought to act as a physical barrier against pathogen penetrance. Secreted mucins bind to pathogens in the tear film, facilitating their clearance from the ocular surface. Under normal conditions, mucin production and secretion by goblet cells and corneal epithelial cells are constitutive. However, mucin production can also be induced via Toll-like receptors (TLRs) expressed on the surface of corneal epithelial cells. Moreover, inflammatory cytokines, such as IL-1β, IL-6, and TNFα, have also been shown to induce mucin production and secretion. Together, these data reveal that constitutively expressed mucins make up a critical component of the passive defense system, while at the same time, upregulation of mucin production and secretion can also be a product of the active arm of innate immunity in the eye.

Corneal epithelium

The final barrier of the ocular surface consists of nonkeratinized stratified epithelial cells bound together by tight junctions. The corneal epithelium acts as a physical barrier to invasion of microorganisms due to the presence of epithelial intercellular tight junctions and the rapid renewal of epithelial cells with frequent shedding of the superficial layers of potentially infected epithelium. As mentioned in the previous section, the epithelium also expresses membrane-bound mucins that inhibit bacterial binding to the epithelial surface and produce several of the antimicrobial factors that are present in the ocular tear film.

Posterior lens capsule

The posterior lens capsule forms a physical barrier between the anterior and posterior segments of the eye after extracapsular cataract surgery and prevents the spread of microorganisms from the anterior chamber into the posterior chamber in the postsurgical eye. The best example of this is the fact that an intact posterior lens capsule is critical in preventing endophthalmitis following cataract surgery. Contamination of the aqueous humor can occur during cataract surgery. However, the pathogens are quickly cleared and endophthalmitis does not develop. By contrast, when the posterior capsule is breached, the rate of endophthalmitis increases significantly. This supports the finding that the anterior segment is much more efficient at clearing bacteria as compared to the posterior segment. Studies suggest the difference in ability to clear pathogens in the anterior versus posterior of the eye may be linked to expression of antimicrobial peptides. One major difference is that the AH is continuously secreted and drained, whereas the vitreous humor is not. The vitreous also offers greater opportunity for microbes to bind its fibrils. However, the exact molecular mechanisms involved remain unclear.

Retinal pigment epithelium

The RPE consists of a single layer of cells joined by tight junctions that lie between the photoreceptors of the neural retina and the blood-rich choroid. The RPE serves multiple functions aimed at protecting and maintaining the health of the neural retina. RPE cells (1) phagocytose shed disks from the photoreceptor outer segments and recycle their components; (2) transport nutrients from the choroid to the retina; (3) absorb light; (4) provide adhesive properties for the retina; and (5) serve as a rich source of cytokines, chemokines, and growth factors. More recently, RPE have also been linked to immunity and have been

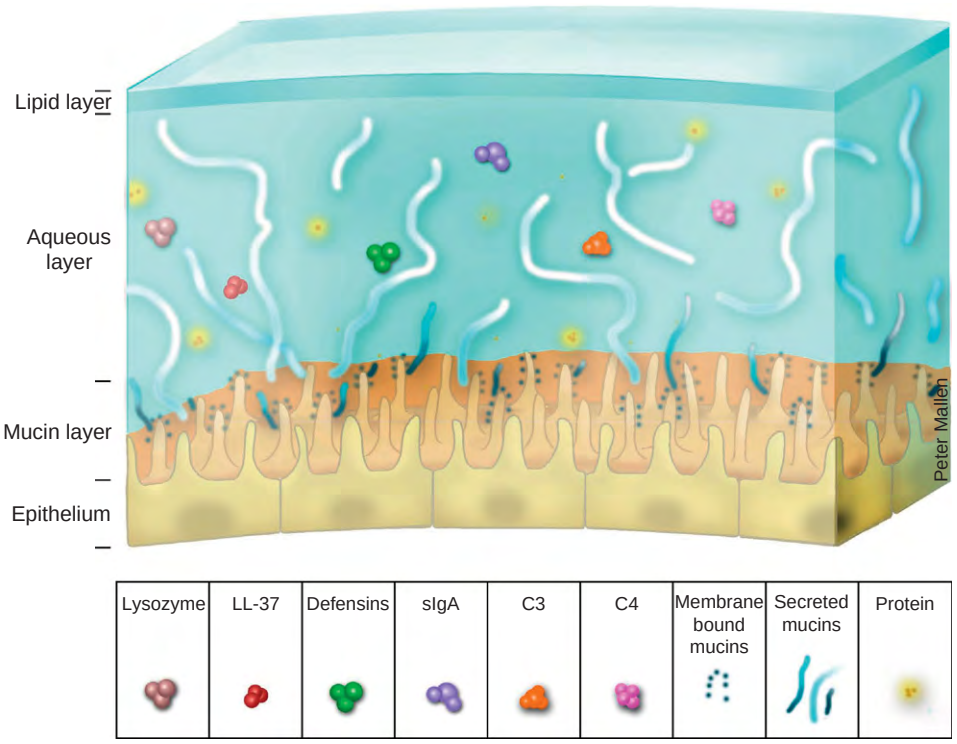

Figure 2 Ocular tear film. The ocular tear film is composed of three layers: the outermost lipid layer, the aqueous layer, and the innermost mucus or mucin layer. The lipid layer lubricates the eyelid and slows evaporation of the aqueous tear film layer. The aqueous layer forms the major component of the tear film and contains numerous antimicrobial proteins including: lysozyme, cathelicidin (LL-37), defensins, secretary IgA (sIgA), and complement components (C3 and C4). The mucin layer acts as a physical barrier against pathogen invasion and consists of both membrane bound and secreted mucins.

shown to behave as antigen-presenting cells that phagocytose pathogens, produce cytokines, and present pathogen-derived peptides to sensitized T cells. Therefore, while RPE acts as a physical barrier to the posterior segment, it is also important in shaping and regulating the adaptive immune response once this barrier has been breached.

Chemical Barriers

In addition to the anatomic and physical barriers designed to block invasive pathogens, there are also a number of soluble factors that inhibit bacterial growth, adherence, and survival. Several of these factors are constitutively expressed at low levels, providing a baseline of protection from foreign pathogens. However, many of these factors can also be upregulated in response to pathogens and inflammation; thus, these become an important product of the active arm of innate immunity. Some of the more important factors are discussed in more detail below.

Lysozyme

Lysozyme is bacteriacidal and makes up 20–40% of the total tear protein. Lysozyme kills bacteria by (1) binding to and creating pores in the bacterial cell wall, or (2) dissolving bacterial membranes by enzymatic digestion.

Secretory phospholipase A_2

Secretory phospholipase A_2 exhibits potent antibacterial activity against Gram-positive bacteria. Similar to lysozyme, secretory phospholipase A_2 dissolves bacterial membranes by hydrolyzing the principal phospholipid, phosphatidylglycerol.

Cathelicidin (LL-37)

LL-37 is a small cationic peptide with potent antimicrobial activity against Gram-positive and Gram-negative bacteria as well some viruses. The precise mechanism of action is incompletely understood, but it is widely believed that the antimicrobial activity is due to disruption of the microbial membrane or viral envelope.

Defensins

Beta defensins are expressed in epithelial cells that line mucosal surfaces such as the cornea. Similar to LL-37, defensins have a broad spectrum of antimicrobial activity and are effective against: Gram-positive and Gram-negative bacteria, fungi, and enveloped viruses. In addition to their antimicrobial activities, defensins modulate a variety of cellular activities including immune cell chemotaxis, epithelial proliferation, cytokine secretion, and stimulation of histamine release from mast cells. Human

corneal epithelial cells constitutively express human beta defensin-1 (hBD-1) and hBD-3. By contrast, hBD-2 is induced in response to corneal injury, infection, or inflammation, and is approximately 10-fold more potent than hBD-1 with an even wider antibacterial spectrum. Therefore, while hBD1 and hBD-3 provide a baseline defense to protect the cornea from infection, upon injury or microbial invasion, hBD-2 is upregulated and displays increased antimicrobial activity.

Lactoferrin

Lactoferrin is bacteriostatic and binds to and depletes iron from the tear film, which is required for microbial metabolism and growth. Lactoferrin is also bactericidal and permeabilizes membranes of Gram-positive and Gram-negative bacteria. Additional functions of lactoferrin have also been described: (1) inhibits biofilm development, (2) inhibits bacterial adhesion to host cells, (3) inhibits intracellular invasion, (4) amplifies apoptotic signals in infected cells, and (5) enhances bactericidal activity of neutrophils.

Lipocalin-A

Lipocalin A prevents bacteria from obtaining iron, an essential nutrient for microorganism survival. However, unlike lactoferrin, lipocalin-A does not bind iron directly. Lipocalin-A inhibits the iron acquisition system of microbes by binding to and blocking microbial sidephores used to transport iron into bacteria.

Secretory IgA

sIgA protects the ocular surface against colonization and possible invasion by pathogenic microorganisms by binding to bacteria and facilitating clearance. In addition, sIgA can opsonize bacteria for phagocytosis.

Complement

Complement components (such as C3 and C4) are constitutively expressed in the tear film and are involved in phagocytic chemotaxis, opsonization, and lysis of bacteria. The eye is unusual in that there is a constitutive low level of activated complement that is present even in uninfected normal eyes. It is believed that this low level of activated complement provides innate immune surveillance of microbes and allows for a rapid activation of the full complement cascade upon pathogen invasion.

Active Innate Defense System

Pattern Recognition Receptors

Innate immunity develops rapidly and is described historically as nonspecific, while adaptive immunity develops slowly and is antigen-specific. However, the discovery of pattern recognition receptors (PRRs) that detect unique pathogen-associated molecular patterns revealed a level of specificity in innate immunity that not only allows discrimination between self and non-self, but also allows the development of innate immunity tailored to specific pathogens, such as bacteria, viruses, and fungi.

There are two classes of PRRs: (1) TLRs and (2) nucleotide-binding oligomerization domain (NOD)-like receptors (NLRs) (**Table 1**). TLRs are expressed on the cell surface and detect pathogens at the cell membrane. TLRs are also expressed within endosomes and detect pathogens that have been endocytosed. By contrast, NLRs are expressed within in the cytoplasm and detect the presence of microbial molecules inside the host cell. These two classes of PRRs are discussed in detail below.

Toll-like receptors

TLRs are type 1 transmembrane proteins with an extracellular domain for ligand binding composed of leucine rich repeats and a cytoplasmic domain for intracellular signaling which is known as the Toll/IL-1 receptor (TIR) domain. TLRs recognize bacteria, viruses, fungi, protozoa, and endogenous ligands, such as heat shock proteins and fibrinogen. Triggering of the TLR leads to activation of the transcription factor, nuclear factor-kappa B (NF-κB), and the expression of pro-inflammatory molecules, such as TNF-α, IL-1, and IL-2. To date, 10 human TLRs have been identified and each TLR has a unique ligand specificity (**Table 1**). TLRs were first identified on innate immune cells: neutrophils, macrophages, monocytes, and dendritic cells. More recently, TLRs were also identified on epithelial cells that lie at the host/environment interface: skin, gastrointestinal tract, respiratory tract, and urogenital tract. Furthermore, several TLRs have been identified on ocular tissue in both the anterior and posterior segment of the eye, including cornea, iris, ciliary body, choroid, and RPE.

Similar to other barrier epithelium, several TLRs have been identified on the RPE and corneal epithelial cells and are vital for sensing microbes and triggering a rapid response to eliminate the pathogen. The study of TLRs in ocular immunity is still relatively new and debate remains over which TLRs are expressed in the eye and whether TLRs are expressed on the cell surface or within endosomes. However, it is clear that TLRs are required for initiation of innate immunity in the eye. This is supported by studies using TLR knockout mice that demonstrate a significant decrease in inflammation characterized by decreased neutrophil infiltration and increased susceptibility to infection in the absence of TLRs.

NOD-like receptors

The NLRs comprise a large family of cytoplasmic PRRs that recognize bacteria and endogenous danger signals such as uric acid (**Table 1**). All members of the NLR family share a conserved NOD. However, the NLR family

Table 1 TLR and NLR expression within the eye

	Ligand	*Location in the eye*
TLR1	Triacyl lipopeptides	Cornea, conjunctiva, RPE[a]
TLR2	Glycolipds, lipopeptides, lipoproteins, PGN, LTA, HSP70, zymosan	Cornea, onjunctiva, RPE
TLR3	dsRNA (viruses)	Cornea, conjunctiva, RPE
TLR4	Lipid A (Gram-negative bateria), LPS, bacterial HSP60, RSV coat protein	Cornea, conjunctiva, iris, ciliary body, choroid, whole retina, RPE
TLR5	Flagellin	Cornea, RPE
TLR6	Diacyl lipopeptides	Conjunctiva, RPE
TLR7	ssRNA (viruses)	Cornea, conjunctiva, RPE
TLR8	ssRNA (virsues)	None detected
TLR9	Unmethylated CpG motifs of bacterial DNA, dsDNA (viruses and bacteria)	Cornea, conjunctiva, RPE
TLR10	N/d	Cornea, conjunctiva, RPE
TLR11	profillin	N/d
NOD1	iE-DAP	Anterior and posterior portions of the eye,[b] HCE-T and HCE[c]
NOD2	MDP	Anterior portion, HCE-T and HCE
NALP1	Cell rupture	HCE-T and HCE
NALP2	N/d	HCE-T and HCE
NALP3	Bacterial RNA, toxins and ATP, uric acid	HCE-T and HCE
NALP10	N/d	HCE-T

[a]RPE: primary cultures of human retinal pigment epithelial cells.
[b]Anterior portion contains corneal tissues; posterior portion contains all other ocular tissues.
[c]HCE-T, SV-40 immortalized human corneal epithelial cell line; HCE, human primary corneal epithelial cells.
TLR, Toll-like receptor; NLR, NOD-like receptors (caspase recruitment domain-containing NODs and pyrin domain-containing NALPs); PGN, peptidoglycan; LTA, lipoteichoic acid; iE-DAP, γ-D-glutamyl-meso-diaminopimelic acid; RSV, respiratory syncytial virus; MDP, muramyl-dipeptide; N/d, not determined.

can be subdivided into three groups based upon their N-terminal domains: caspase recruitment domain (NODs), pyrin domain (NALPs), or baculovirus inhibitor repeat (neuronal apoptosis inhibitor proteins, NAIPs). At present, the human NLR family comprises of 23 proteins, while at least 34 NLR genes have been identified in mice. NALPs are unique in that upon binding to their ligand, NALPs form a complex termed the inflammasome resulting in caspase-1 activation and the release of active IL-1β. Recently, NALP1, 3, and 10 were identified in corneal epithelial cells, but their potential function in regulating ocular innate immunity has not been determined. NAIPs inhibit caspase effectors and are mainly expressed in neurons where their primary role is to protect against apoptosis. NAIPs have not yet been found in ocular tissues. NODs are the most extensively studied members of the NLR family and are expressed in ocular tissue.

Both NOD1 and NOD2 are constitutively expressed within the eye; NOD1 in the anterior and posterior segments of the eye and NOD2 only in the anterior segment. However, which specific tissues express NODs is unknown. NOD1 and NOD2 recognize specific subcomponents of bacterial peptidoglycan. NOD1 recognizes D-γ-glutamyl-meso-diaminopimelic acid, while NOD2 recognizes muramyl dipeptide. Recently, a mutation in NOD2 was linked to the development of uveitis in patients with Blau syndrome, suggesting that cytoplasmic NODs may be important in ocular inflammation. While the importance of NOD receptors in innate immunity and the pathogenesis of inflammatory disease are recognized outside the eye, the study of NODs within the eye is at an early stage. A complete understanding of ocular host defense will require a better understanding of where NODs and other NLRs are expressed and how they regulate innate immunity within the eye.

Complement

Similar to PRRs, the complement system acts as an innate immune surveillance system, detecting the first signs of pathogen invasion. The complement system was first identified as a biochemical cascade of serum proteins that help or complement antibodies to clear pathogens and mark them for opsinization by phagocytes. It is now known, however, that the complement system can also be activated directly by microbial products via the alternative pathway. Several studies demonstrate that complement is constitutively active at low levels in the eye. This is thought to be a primary defense mechanism of the eye against pathogenic infection. Upon pathogen invasion the complement system is further activated to clear the infection through (1) generation of inflammatory factors (C3 and C5a), (2) chemotaxis of phagocytes (C3 and C5a), (3) opsonization of Ab-coated cells (C3b), and (4) lysis of bacteria and virus-infected cells (C8 and C9).

Cytokines, Chemokines, and Effector Cells

Once pathogens breach the passive barriers of the eye and trigger the PRRs or the complement system, the primary function of innate immunity is to eliminate the invading pathogen as quickly as possible. To achieve this innate immunity must: (1) trigger an immediate immune response, (2) amplify the response, (3) clear the pathogens, and (4) activate the adaptive system if the pathogen cannot be cleared quickly. Cytokines, chemokines, and adhesion molecules play critical roles in regulating each of these stages.

Initiation and amplification

PRRs (TLRs and NLRs) recognize microbial products in the earliest phase of host defense and activate many immune and inflammatory genes, the products of which are important in initiating and amplifying antimicrobial immunity. Triggering TLRs on either the corneal epithelium or the RPE leads to activation of NF-κB via the (1) MyD88-dependent or (2) MyD88-independent pathway. The MyD88-dependent pathway is utilized via most TLRs (TLR1, 2, 4, 5, 6, 7, 8, and 9) and leads to the production of proinflammatory cytokines and chemokines (IL-6, IL-8, IL-18, MIP-1, and TNF-α). By contrast, only TLR3 and TLR4 utilize the MyD88-independent pathway and leads to the production of IFN-α and IFN-β. Recruitment of neutrophils into inflamed tissues is controlled predominantly by two chemokines (MIP-2 (= IL-8 in humans) and KC). In *Pseudomonas aeruginosa*-induced corneal keratitis, elevated MIP-2 and KC correspond with increased infiltration of neutrophils. In the posterior segment, elevated TNF-α, IL-1β, and CINC (rat homolog of IL-8) contribute to the breakdown of the blood–retinal barrier and the recruitment of neutrophils in response to *Staphylococcus aureus*. The adhesion molecules ICAM-1 and E-selectin are also upregulated early in iris, ciliary body, and retinal vessels, serving to enhance the infiltration of neutrophils to the site of infection.

Clearing the pathogen

In response to inflammatory cytokines and chemokines, neutrophils and macrophages are recruited to the site of infection. Bacterial clearance by neutrophils is accomplished by (1) phagocytosis, (2) generation of reactive oxygen species, and (3) the release of granule-associated enzymes: cathepsin G, myeloperoxidase, lactoferrin, and elastase. While the recruitment of neutrophils to the site of infection is essential for clearance of the pathogen, the persistence of neutrophils and the prolonged release of inflammatory mediators is also associated with nonspecific host tissue damage. Similar to neutrophils, macrophages also phagocytose and directly kill microbes as part of innate immunity. However, macrophages are also antigen-presenting cells, and as such participate in the development of the adaptive immune response. The natural killer (NK) cell is another important innate effector cell in host defense against viral infections of the cornea such as herpes simplex virus type-1. NK cells respond in an antigen-independent manner and kill virus-infected host cells through the release of perforin and granzymes or through binding of the death receptors Fas and TRAIL-R on the target cell. If innate effector cells fail to clear the infection, adaptive immunity will take over and finish eradicating the pathogen. However, if the infection is successfully cleared, the final and most important step of innate immunity is preventing nonspecific host tissue damage. This is accomplished in the eye through several mechanisms that together make up innate immune privilege.

Innate Immune Privilege

The primary role of innate immunity is to rapidly eradicate invading pathogens through the induction of inflammation. As a general rule, the level of inflammation is proportional to the size and virulence of the infection. Small, nonvirulent infections are cleared by mild inflammation, while larger, more virulent infections induce intense inflammation. The potential danger of inflammation occurs when intense and/or prolonged inflammation threatens the surrounding normal tissue, resulting in nonspecific tissue damage and scarring. The potential danger of inflammation in the eye is magnified by the presence of irreplaceable and highly sensitive ocular tissues. Therefore, it is not surprising that immune privilege in the eye has multiple mechanisms to control innate immunity and limit nonspecific tissue damage. The aqueous humor contains multiple factors that directly inhibit innate immunity including: (1) TGF-β, soluble Fas ligand, and alpha-melanocyte stimulating hormone (inhibit neutrophil activation); (2) macrophage migration inhibitory factor (inhibits NK cell-dependent lysis of target cells); (3) calcitonin gene-related peptide (inhibits nitric oxide release from activated macrophages); and (4) complement regulatory factors: CD46, CD55, CD59, and Crry (inhibit complement activation). These factors work together to limit the damaging consequences of inflammation and to preserve the visual axis. Unfortunately, while these mechanisms evolved to limit local tissue destruction and preserve the visual axis, they may leave the eye more vulnerable to organisms whose virulence often requires a robust inflammatory response for eradication. Therefore, a delicate balance must be made between the amount of inflammation needed for eradicating the pathogen and the amount of nonspecific tissue damage.

Link between Innate and Adaptive Immunity

Innate and adaptive immunity have long been discussed as separate arms of the immune system. However, it is

increasingly clear that they are indeed not separate but highly integrated. Several studies, both outside and inside the eye, identified the dendritic cell as a central link between innate and adaptive immunity. Immature dendritic cells reside in peripheral tissues and through triggering of TLRs, participate in the primary immune response against microbial infections. Immature dendritic cells encounter invading pathogens, capture bacterial antigens, and migrate to the draining lymph node. Once in the lymph node, only mature dendritic cells can efficiently prime naïve T cells and initiate adaptive immunity. Studies using TLR and MYD88 deficient mice, reveal that TLR signaling is required for bacteria-induced maturation of dendritic cells and induction of adaptive immunity. Therefore, TLRs on dendritic cells are essential for (1) sensing the microbe and initiating the immediate innate immune response, as well as (2) inducing the development of an adaptive immune response. While dendritic cells have been identified in the cornea and retina, additional studies are needed to completely understand their function in linking innate and adaptive immunity within the eye.

Conclusion

Innate immunity is a critical first line of defense against ocular infections. However, the regulation of innate immunity within the eye is just beginning to be unraveled. The identification of TLRs and NLRs has provided new insights into the mechanisms of host defense and the pathogenesis of inflammatory diseases. A better understanding of how microbial agents and endogenous host factors interact with TLRs and NLRs in the eye will be critical in advancing our knowledge of the pathogenesis of infectious and noninfectious eye diseases. Moreover, a better understanding of these mechanisms will lead to the identification of new therapeutic targets for treating and preventing sight-threatening infections.

Innate Immunity and Angiogenesis

S Frantz, Medizinische Universitaetsklinik, Wuerzburg, Germany
K A Vincent and R A Kelly, Genzyme Corporation, Framingham, MA, USA

Glossary

Angiogenesis – The definition of angiogenesis – also termed neovascularization – in the context of this article refers to new blood vessel formation and growth following development. The process of angiogenesis is highly sensitive to hypoxia (i.e., a low cellular oxygen content within cells), which is sensed by a family of transcription factors or master switch proteins present in all nucleated cells, termed hypoxia inducible factors (HIFs). These in turn trigger the transcription, synthesis, and release of cascades of pro-angiogenic cytokines, including, among others, vascular endothelial growth factors (VEGFs), hepatocyte growth factor (HGF), and inflammation-related cytokines such as tumor necrosis factor alpha TNF-α.

Hemostasis – Limitation of blood loss following injury due to localized vasoconstriction, pressure applied to the bleeding site, or by mechanical means (e.g., sutures).

HGF – Hepatocyte growth factor (HGF), in addition to its role in hepatic (liver) development, also plays a key role in the growth and remodeling of blood vessels in response to tissue hypoxia as well as triggering release of inflammatory signals that can accelerate and stabilize nascent (i.e., new) arterioles.

Innate immunity – Innate immunity, also termed nonadaptive or natural immunity, is the evolutionarily ancient, germ-line encoded, hardwired components of the immune system, which trigger rapid, albeit relatively nonselective, recognition and subsequent destruction and removal of possible pathogens.
A large and growing number of pathogen-associated molecular patterns (PAMPs) have been identified to date, that are characterized by specific molecular motifs on a wide variety of potentially infectious organisms. These highly conserved molecular motifs are, in turn, recognized or sensed by specific molecular motifs termed pattern recognition receptors (PRRs), which can trigger an initial, rapid innate immune response. Importantly, long-term suppression of specific pathogens in vertebrates requires recognition by, and subsequent activation of, an appropriate innate immune response. Thus, the initial innate, and subsequently acquired, pathogen-specific immune responses are typically both necessary for long-term pathogen suppression.

iNOS (inducible nitric oxide synthase (iNOS)) – It is an enzyme associated with innate immunity as activation of this enzyme can trigger release of relatively large amounts of oxygen radicals that limited pathogen growth. iNOS activation also causes vasodilation which facilitates increased blood flow to regions of injury or infection, as well as producing oxygen radicals that suppress pathogen growth.

PAMPs (pathogen-related molecular pattern ligands) and PRRs (pattern recognition receptors) – These refer to specific, phenotypically stable, molecular motifs, or patterns that are characteristic of infectious organisms but not normal host tissue or cells.

Selection pressure – During evolution, changes in the environment over time, which may affect access to supplies of energy, water, and other essentials, generate a selection pressure in which those organisms whose genetic make-up provides an survival advantage in the current environment may thrive, while those whose genetic background is not as favorable for survival will be at a disadvantage. This concept applies to vertebrates as much as to viral or bacterial evolution.

siRNAs (small interfering RNAs) – siRNA disruptions occur naturally and play an important role in the regulation of the expression and/or degradation of RNA transcripts, which affects the synthesis and/or degradation of multiple proteins. Artificial siRNA constructs are now being widely used as highly specific reagents to selectively increase or suppress transcription of selected gene. Mutiple clinical trials using these novel reagents are now in progress.

Toll-like receptors (TLRs) – TLRs, originally identified in the fruit fly *Drosophila*, are families of trans-membrane proteins that were among the first innate immunity signaling proteins to be identified that provided a contextual, danger signal in the presence of potential pathogens. Different classes of TLRs recognize distinct molecular motifs termed pathogen-associated molecular patterns (PAMPs) on pathogenic organisms. The innate immune system is germ-line encoded in the fly as well as

vertebrates, although the fly has no capacity for a specific adaptive immune response, that is, a more rapid, extensive, and importantly specific immune response following on a repeat challenge to the same pathogen.

Transcription – Transcription refers to the generation of messenger RNA (mRNA) sequence from a DNA sequence template. This is followed by translation of the mRNA sequence into an appropriate sequence of amino acids (i.e., a protein sequence).Vascular endothelial growth factors (VEGFs) – They are families of intercellular signaling proteins or cytokines that are principally involved in regulating blood vessel formation (angiogenesis) and the subsequent growth and remodeling of smaller vessels into larger vessels termed or arterioles, which is termed arteriogenesis.

Inflammation is a coordinated response triggered by either infection or tissue injury, the primary goals of which are the containment and, eventually, removal of pathogens followed by cellular repair and restoration of tissue homeostasis. In general, immunity to infection in vertebrates is mediated by two distinct, but complementary forms of immune response pathways: germ-line encoded innate immunity and acquired immune responses. Acquired (i.e., specific, targeted, and adaptive) immunity recognizes molecular motifs on pathogens by a trial and error process based on successive random gene rearrangement, followed by identification and rapid amplification of antigen receptors on B and T lymphocytes that are highly specific for epitopes on pathogens.

In contrast, the components of innate immunity (i.e., nonadaptive, or natural immunity) are expressed constitutively, act immediately, and are not dependent upon prior exposure to a specific pathogen. The innate immune system recognizes invariant molecular patterns shared by groups of potentially pathogenic microorganisms but not by host tissues, such as bacterial lipopolysaccharides (LPSs, also termed endotoxin), viral double-stranded RNA, or yeast cell wall mannans among others. These pathogen-associated molecular patterns or PAMPs are typically highly conserved since they are essential for the structural integrity and survival of their respective families of microbes. The innate immunity receptors for these largely invariant motifs on potential pathogens are germ-line-encoded, either soluble or cell-associated proteins, that exhibit a broad range of specificities to highly conserved structural motifs on specific families of pathogens (note that the nomenclature for some specific components of innate immunity has not yet been standardized; in this article, we will utilize principally the definitions as originally coined by Medzhitov and Janeway). Unlike the acquired or adaptive arm of the immune system, which gained the ability to evolve highly specific approaches to target pathogens, as noted above, the innate immune response is not a single entity, but rather a collection of relatively independent subsystems or modules. Importantly, selected components of innate immunity signaling also provide a contextual signal, that is, the recognition of highly conserved molecular motifs on potential pathogens.

The innate immune response is obviously imperfect and/or insufficient, however, in that serious infections sometimes do occur, while inappropriate activation or delayed downregulation of an immune response may sometimes injure the host, as in the case of autoimmunity, for example. Only metazoans (vertebrates) have evolved alternative strategies for dealing with repeated pathogen recognition and elimination, including the capacity to mount a more rapid, robust, and, importantly, specific response upon repeat exposure to a pathogenic organism.

Recent work suggests that specific protein sequences or epitopes related to certain products of tissue injury can be detected by innate immunity pattern recognition receptors or PRR's. Coined the Danger hypothesis, this postulate suggests that the appearance of epitopes characteristic of damaged or necrotic tissue, even in the absence of any evidence of an infection, will be recognized by components of the innate immune system. In support of this hypothesis, resting dendritic cells can be activated by damaged cells or necrotic debris, but not by healthy cells, or cells undergoing programmed cell death (i.e., apoptosis).

A review of recent data details a number of aspects of the evolutionary selection pressure that have resulted in strategies that vertebrates have evolved for the control of infection and wound repair. Despite the obvious differences between tissue destruction due to trauma compared to an infectious origin, for example, there are a number of responses to both forms of injury that have many common features. First, there is a high likelihood that some degree of infection will eventually accompany significant amount of tissue injury. Second, mechanisms that are important for pathogen recognition and removal are also necessary for wound repair and healing. For example, macrophages are necessary to both clear cellular debris and initiate tissue remodeling after injury, besides assisting in the suppression of pathogen growth.

Innate Immunity and Wound Healing

Following hemostasis, angiogenesis in injured tissue – an essential component in the process of wound healing – is dependent on the activation of different parts of the innate immune system, including inflammatory cytokines, toll-like receptors (TLRs), the receptor for advanced glycosylation end products (RAGEs), as well as transcription factors such as hypoxia inducible factor 1 alpha

(HIF-1α). The involvement of these essential elements links innate immunity and angiogenesis in the process of wound healing. Innate immunity cytokines – a generic term denoting relatively short, soluble extacellularc signaling proteins, such as angiopoietins, transforming growth factor beta (TGFβ), or members of the several VEGF families and their respective sub-isoforms – are essential for both angiogenesis (i.e., the process of endothelial cell division and sprouting) and arteriogenesis (i.e., the recruitment of pericytes and vascular smooth muscle cells), with subsequent circumferential growth of smaller vessels into arterioles. Inflammatory cytokines, such as tumor necrosis factor alpha (TNFα) and interleukins among others, released by neighboring cells (e.g., macrophages) also contribute to accelerated arteriolar growth, suppression of infection, and preservation of local tissue architecture. However, rapid pathogen growth and/or unrestrained release of inflammatory pro-angiogenic cytokines may also result in excessive tissue fibrosis (scarring), particularly if the initial inflammatory stimulus is not appropriately suppressed as infectious organisms are cleared. Ideally, damaged or infected cells would be phagocytosed (i.e., internalized by neighboring tissue macrophages), triggering only an appropriate degree of inflammation, which would subsequently suppressed as the infection is cleared.

The process of removal of cells with minimal inflammatory reaction is termed programmed cell death or apoptosis. Apoptosis is characterized in part by active suppression of inflammatory cytokine production by specialized scavenger cells (i.e., macrophage-derived, so-called professional phagocytes). In contrast, cells undergoing necrotic cell death induced by, among other causes, tissue trauma, infection, or profound hypoxia and acidosis contribute to a decline in both plasma and mitochondrial membrane potentials, ionic gradients that are essential to maintain cellular homeostasis. Typically, this results in rapid death of numerous cell types and the release of intracellular contents, which in turn triggers the synthesis and release of pro-inflammatory cytokines.

TLRs and Angiogenesis

Cells dying via necrosis also typically induce activation of innate immunity PRRs such as toll-like receptor-2 (TLR-2), which, when activated, initiate transcriptional responses that are qualitatively different from that induced by, for example, LPS binding to its innate immunity receptor, TLR-4. Activation of either signaling pathway leads to a series of distinct but complimentary pro-inflammatory downstream signaling cascades, many of which require activation of nuclear factor kappa B (NFκB)-dependent signaling pathways, which also facilitate both angiogenesis and arteriogenesis (see **Figure 1**).
